HISTORICAL REVIEW

Rodrigues, in 1843, may have published the first case of traumatic posterior dislocation of the sternoclavicular joint in the literature, "a case of dislocation inward of the internal extremity of the clavicle."[180] The patient's left shoulder was against a wall when the right side of the chest and thorax

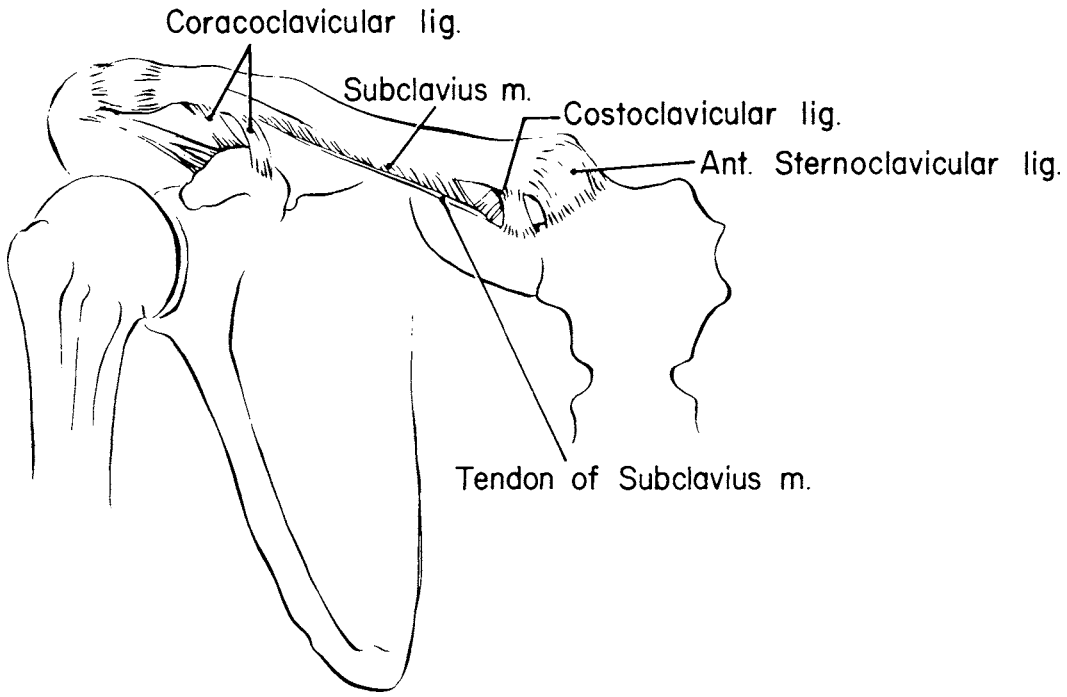

Figure 33-1 Normal anatomy around the sternoclavicular and acromioclavicular joints. Note that the tendon of the subclavius muscle arises in the vicinity of the costoclavicular ligament from the first rib and has a long tendon structure.

were compressed and rolled forward almost to the midline by a cart. Immediately, the patient experienced shortness of breath, which persisted for 3 weeks. When first seen by the physician, he appeared to be suffocating and his face was blue. The left shoulder was swollen and painful, and there was "a depression on the left side of the superior extremity of the sternum." Pressure on the depression greatly increased the sensation of suffocation. Rodrigues observed that when the outer end of the shoulder was displaced backward, the inner end of the clavicle was displaced forward, which relieved the asphyxia. Therefore, treatment consisted of binding the left shoulder backward with a cushion between the two scapulas, but only after the patient had been bled twice within the first 24 hours. Rodrigues may have seen other cases of posterior dislocation, since he stated that the patient "retained a slight depression of the internal extremity of the clavicle; such, however, is the ordinary fate of the patients who present this form of dislocation."

In the late 19th century, a number of articles appeared from England, Germany, and France; it was not until the 1930s that articles by Duggan,[51] Howard and Shafer,[90] and Lowman[131] appeared in the American literature.

SURGICAL ANATOMY AND BIOMECHANICS

The sternoclavicular joint is a diarthrodial joint and is the only true articulation between the clavicle of the upper extremity and the axial skeleton (Fig. 33-1). The articular surface of the clavicle is much larger than that of the sternum, and both are covered with fibrocartilage. The enlarged bulbous medial end of the clavicle is concave front to back and convex vertically, and therefore creates a saddle-type joint with the clavicular notch of the sternum.[6059] The clavicular notch of the sternum is curved, and the joint surfaces are not congruent. Cave[32] has demonstrated that in 2.5% of patients, there is a small facet on the inferior aspect of the medial clavicle that articulates with the superior aspect of the first rib at its synchondral junction with the sternum.

Because less than half of the medial clavicle articulates with the upper angle of the sternum, the sternoclavicular joint has the distinction of having the least amount of bony stability of the major joints of the body. As Grant[81] noted, "The two (make) an ill fit." If a finger is placed in the superior sternal notch, with motion of the upper extremity one can feel that a large part of the medial clavicle is completely above the articulation with the sternum.

LIGAMENTS OF THE STERNOCLAVICULAR JOINT

There is so much joint incongruity that the integrity has to come from its surrounding ligaments: the intraarticular disk ligament, extraarticular costoclavicular ligament (rhomboid ligament), capsular ligaments, and interclavicular ligament.

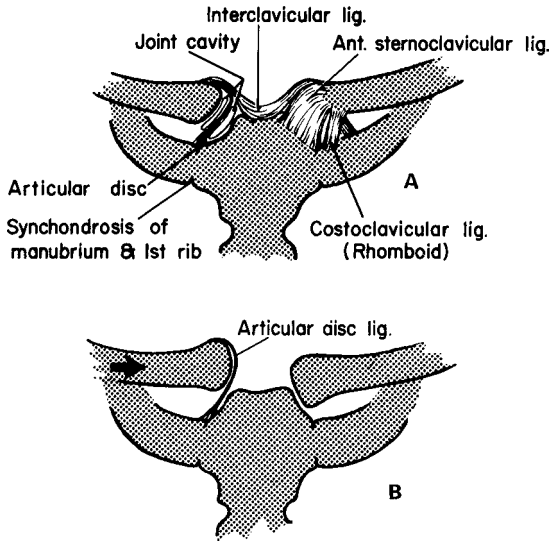

Figure 33-2 **(A)** Normal anatomy around the sternoclavicular joint. Note that the articular disk ligament divides the sternoclavicular joint cavity into two separate spaces and inserts onto the superior and posterior aspects of the medial clavicle. **(B)** The articular disk ligament acts as a checkrein for a medial displacement of the proximal clavicle. (Reprinted with permission from Rockwood CA, Matsen F III, eds. *The shoulder.* Philadelphia: WB Saunders, 1990: Fig. 13-2.)

Intraarticular Disk Ligament

The intraarticular disk ligament is a very dense, fibrous structure that arises from the synchondral junction of the first rib to the sternum and passes through the sternoclavicular joint, which divides the joint into two separate joint spaces (Fig. 33-2).[7,59,60] The upper attachment is on the superior and posterior aspects of the medial clavicle. DePalma[47] has shown that the disk is perforated only rarely; the perforation allows a free communication between the two joint compartments. Anteriorly and posteriorly, the disk blends into the fibers of the capsular ligaments. The disk acts as a checkrein against medial displacement of the inner clavicle (see Fig. 33-2).

Costoclavicular Ligament

The costoclavicular (CC) ligament, also called the rhomboid ligament, is short and strong and consists of an anterior and a posterior fasciculus (Fig. 33-3).[11,32,60] Cave[32] reported that the average length is 1.3 cm, the maximum width 1.9 cm, and the average thickness 1.3 cm. Bearn[11] has shown that there is always a bursa between the two components of the ligament. Because of the two different parts of the ligament, it has a twisted appearance. The costoclavicular ligament attaches below to the upper surface of the first rib and at the adjacent part of the synchondral junction with the sternum, and above to the margins of the impression on the inferior surface of the medial end of the clavicle, sometimes known as the rhomboid fossa. Cave[32] has shown, from a study of 153 clavicles, that the attachment of the costoclavicular ligament to the clavicle can be any of three types: a depression, the rhomboid fossa (30%); flat (60%); or an elevation (10%).

The fibers of the anterior fasciculus arise from the anteromedial surface of the first rib and are directed upward and laterally. The fibers of the posterior fasciculus are shorter and arise lateral to the anterior fibers on the rib and are directed upward and medially. The fibers of the anterior and posterior components cross and allow for stability of the joint during rotation and elevation of the clavicle. The two-part configuration of the costoclavicular ligament is similar to the coracoclavicular ligament on the outer end of the clavicle.

Bearn[11] has shown experimentally that the anterior fibers resist excessive upward rotation of the clavicle and that the posterior fibers resist excessive downward rotation. Clinically, the cruciate nature of the costoclavicular ligament

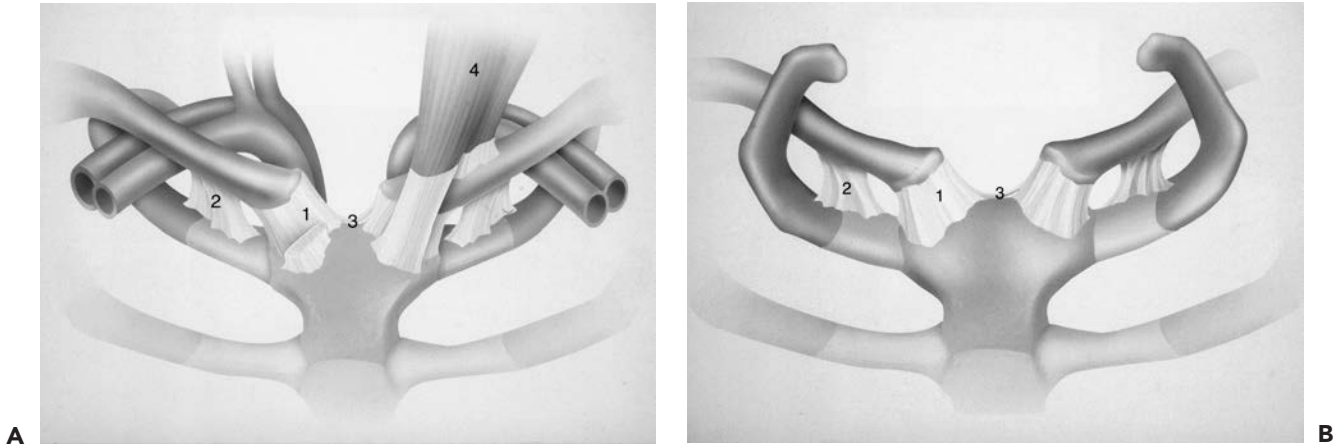

Figure 33-3 **(A)** Anterior view of SC joints. 1 = Anterior capsular ligament, 2 = Costoclavicular ligament, 3 = Interclavicular ligament, 4 = Sternocleidomastoid muscle. **(B)** Posterior view of SC joint. 1 = Posterior capsular ligament, 2 = Costoclavicular ligament, 3 = Interclavicular ligament. Ligamentous restraints to anterior and posterior translation of the sternoclavicular joint. *J Shoulder Elbow Surg* 2002;11(1):43–47.)

provides a point about which the clavicle can rotate when the shoulder is brought through full range of motion.

Interclavicular Ligament

The interclavicular ligament connects the superomedial aspects of each clavicle with the capsular ligaments and the upper sternum (see Fig. 33-3). According to Grant,[8] this band may be comparable with the wishbone of birds. This ligament helps the capsular ligaments to produce "shoulder poise," that is, to hold up the shoulder. This can be tested by putting a finger in the superior sternal notch; with elevation of the arm, the ligament is quite lax, but as soon as both arms hang at the sides, the ligament becomes tight.

Capsular Ligaments

The capsular ligaments cover the anterior and posterior aspects of the joint and represent thickenings of the joint capsule (see Fig. 33-3). The posterior capsular ligament is heavier and stronger than the anterior portion.

According to the original work of Bearn,[11] these may be the strongest ligaments of the sternoclavicular joint, and it is the first line of defense against the upward displacement of the inner clavicle caused by a downward force on the distal end of the shoulder. The clavicular attachment of the ligament is primarily onto the epiphysis of the medial clavicle, with some secondary blending of the fibers into the metaphysis. The senior author has demonstrated this, as have Poland,[162] Denham and Dingley,[45] and Brooks and Henning.[22]

Although some investigators report that the intraarticular disk ligament greatly assists the costoclavicular ligament in preventing upward displacement of the medial clavicle, Bearn[11] has shown that the capsular ligament is the most important structure in preventing upward displacement of the medial clavicle. In experimental postmortem studies, he evaluated the strength and the role of each of the ligaments at the sternoclavicular joint to see which one would prevent a downward displacement of the outer clavicle. He attributed the lateral "poise of the shoulder" (i.e., the force that holds the shoulder up) to a locking mechanism of the ligaments of the sternoclavicular joint (Fig. 33-4). To accomplish his experiments, Bearn dissected all the muscles attaching onto the clavicle, the sternum, and the first rib and left all the ligaments attached. He secured the sternum to a block in a vise. He then loaded the outer end of the clavicle with 10 to 20 lb of weight and cut the ligaments of the sternoclavicular joint, one at a time and in various combinations, to determine each ligament's effect on maintaining the clavicle poise or, thinking of it in another way, which ligament would rupture first when a force was applied to the outer end of the clavicle.

He determined, after cutting the costoclavicular, intraarticular disk, and interclavicular ligaments, that they had no effect on clavicle poise. However, the division of the capsular ligaments alone resulted in a downward depression on the distal end of the clavicle. He also noted that the intraarticular disk ligament tore under 5 lb of weight, once the capsular ligament had been cut. These data demonstrate the importance of the capsular ligaments in maintaining the poise of the clavicle.

Although poise is important, clinically, dislocations of the sternoclavicular joint are seen in the anterior or posterior direction. Therefore, a more recent study by Spencer et al. evaluated the restraints to anterior and posterior translation of the sternoclavicular joint.[203] Thirty-two cadaveric specimens were dissected leaving the ligamentous structures intact. The sternum was mounted in a supine position on a biaxial rotation table while the clavicle was translated anteriorly and posteriorly by the servohydraulic testing system. Serial ligament sectioning of the interclavicular ligament, costoclavicular ligament, and the anterior and posterior capsular ligaments was performed. It was found that the primary restraint to posterior translation was the posterior capsular ligament (Fig. 33-5). The primary restraint to anterior translation was also the posterior capsular ligament, with the anterior capsular ligament providing an important secondary stabilizer (Fig. 33-6). The interclavicular ligament and costoclavicular ligament provided very little stability to the joint. This emphasizes the importance of the posterior capsule, which is twice as thick as its anterior counterpart. This physiologically makes sense in that posterior displacement of the medial end of the clavicle can impinge upon and damage the important neurovascular structures and trachea.

Range of Motion of the Sternoclavicular Joint

The sternoclavicular joint is freely movable and functions almost like a ball-and-socket joint, in that the joint has motion in almost all planes, including rotation.[95,132,230] Inman et al. observed that within the first 90 degrees of arm elevation, the clavicle would elevate 4 degrees per 10 degrees of arm elevation. After 90 degrees of arm elevation there was negligible motion of the clavicle.[95] The clavicle, and therefore the sternoclavicular joint, in normal shoulder motion is capable of 30 to 35 degrees of upward elevation, 35 degrees of combined forward and backward movement, and 45 to 50 degrees of rotation around its long axis (Fig. 33-7). It is most likely the most frequently moved joint of the long bones in the body, because almost any motion of the upper extremity is transferred proximally to the sternoclavicular joint.

Epiphysis of the Medial Clavicle

Although the clavicle is the first long bone of the body to ossify (fifth intrauterine week), the epiphysis at the medial end of the clavicle is the last of the long bones in the body to appear and the last epiphysis to close (Fig. 33-8). The medial clavicular epiphysis does not ossify until the 18th

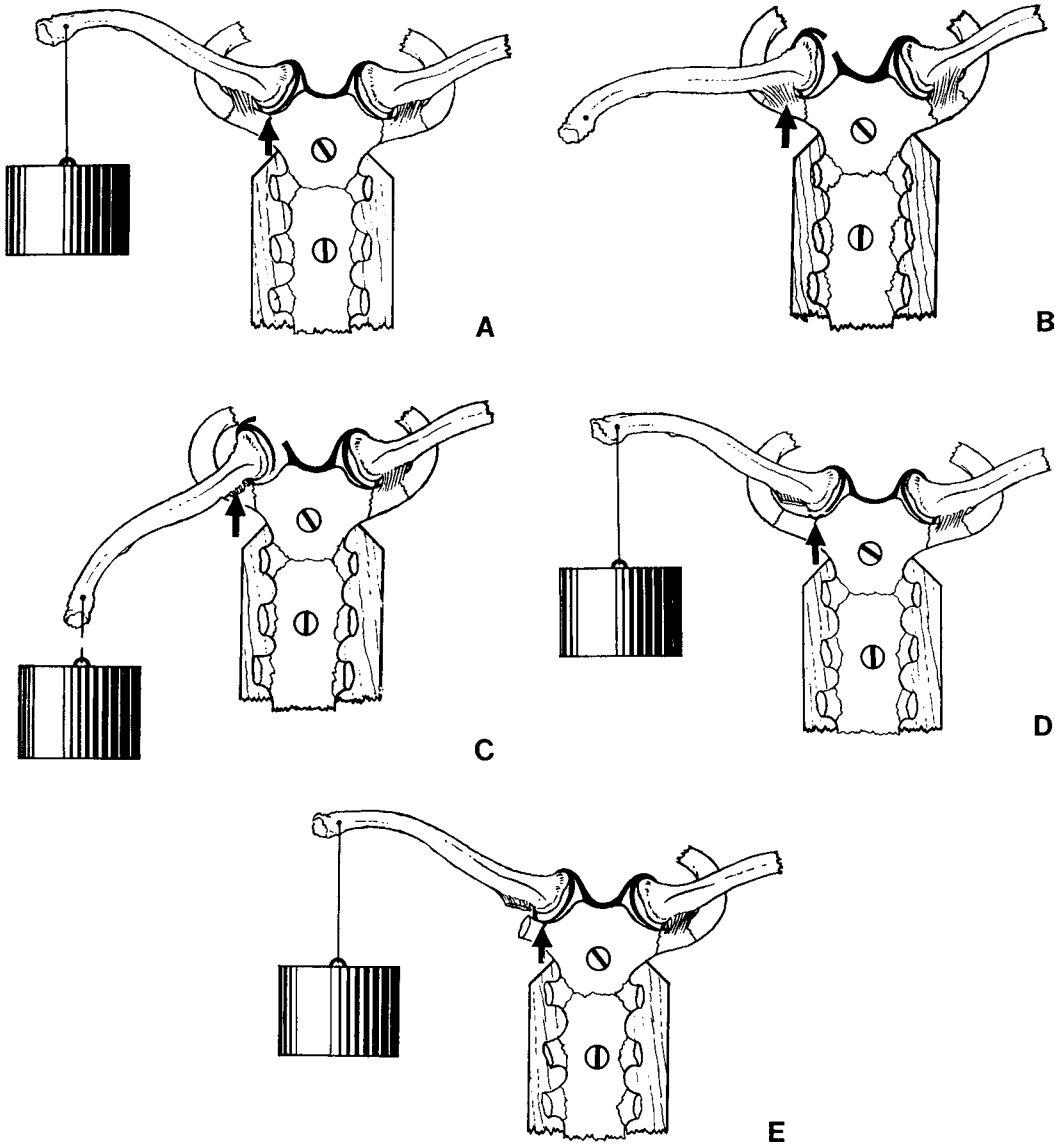

Figure 33-4 The importance of the various ligaments around the sternoclavicular joint in maintaining normal shoulder poise. **(A)** The lateral end of the clavicle is maintained in an elevated position through the sternoclavicular ligaments. The arrow indicates the fulcrum. **(B)** When the capsule is divided completely, the lateral end of the clavicle descends under its own weight without any loading. The clavicle will seem to be supported by the intraarticular disk ligament. **(C)** After division of the capsular ligament, it was determined that a weight of less than 5 lb was enough to tear the intraarticular disk ligament from its attachment on the costal cartilage junction of the first rib. The fulcrum was transferred laterally, so that the medial end of the clavicle hinged over the first rib in the vicinity of the costoclavicular ligament. **(D)** After division of the costoclavicular ligament and the intraarticular disk ligament, the lateral end of the clavicle could not be depressed as long as the capsular ligament was intact. **(E)** After resection of the medial first costal cartilage, along with the costoclavicular ligament, there was no effect on the poise of the lateral end of the clavicle, as long as the capsular ligament was intact. (Reprinted with permission from Bearn JG. Direct observation on the function of the capsule of the sternoclavicular joint in clavicular support. *J Anat* 1967;101:159–170.)

to 20th year of life, and it fuses with the shaft of the clavicle around the 23rd to 25th year.[81,124,128,162,219] Webb and Suchey,[219] in an extensive study of the physis of the medial clavicle in 605 males and 254 females at autopsy, reported that complete unions may not be present until 31 years of age. This knowledge of the epiphysis is important, because it is believed that many so-called sternoclavicular dislocations are actually fractures through the physeal plate.[22,45,68,93,124,,128,133,162,192,226,229]

Applied Surgical Anatomy

The surgeon who is planning an operative procedure on or near the sternoclavicular joint should be completely

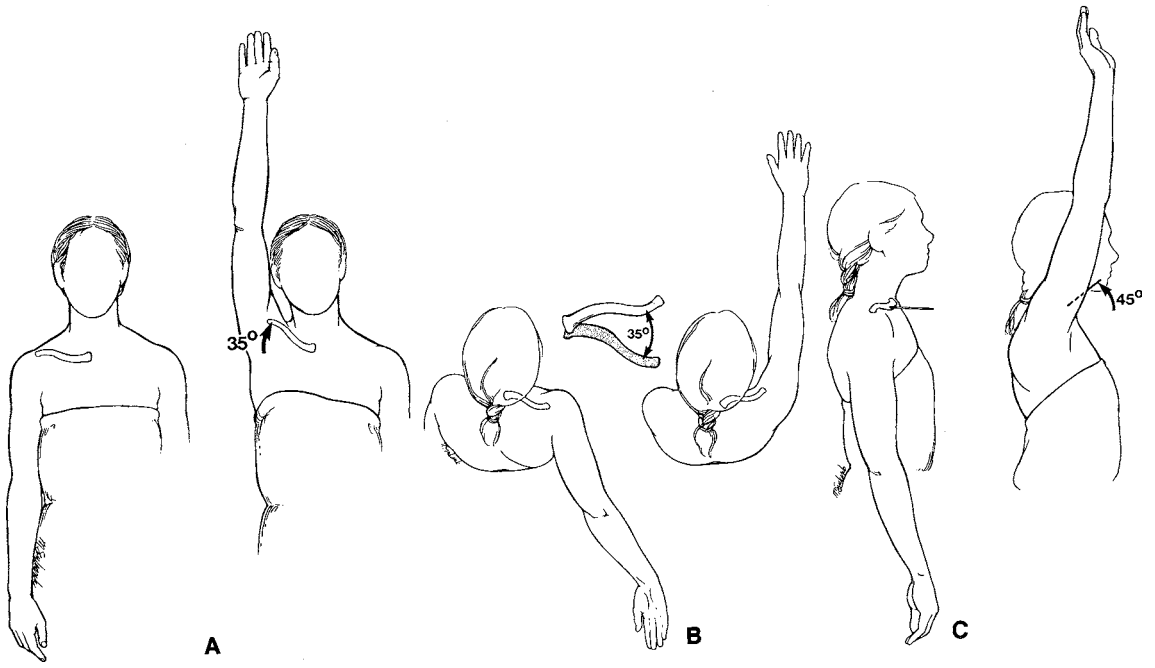

Figure 33-7 Motions of the clavicle and the sternoclavicular joint. **(A)** With full overhead elevation, the clavicle rises 35 degrees. **(B)** With adduction and extension, the clavicle displaces anteriorly and posteriorly 35 degrees. **(C)** The clavicle rotates on its long axis 45 degrees as the arm is elevated to the full overhead position.

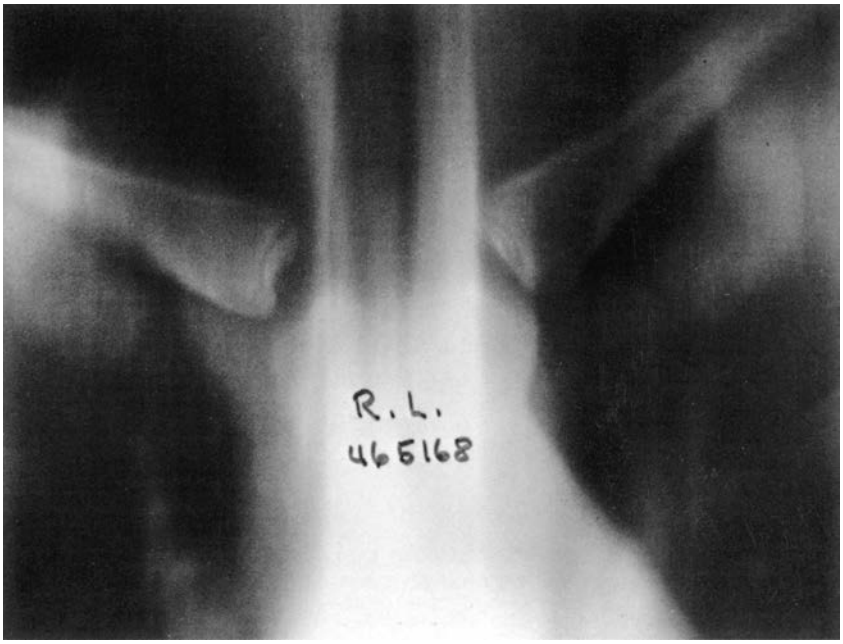

Figure 33-8 Tomogram demonstrating the thin, wafer-like disk of the epiphysis of the medial clavicle.

knowledgeable about the vast array of anatomic structures immediately posterior to the sternoclavicular joint.[168] There is a "curtain" of muscles—the sternohyoid, sternothyroid, and scaleni—posterior to the sternoclavicular joint and the inner third of the clavicle, and this curtain blocks the view of the vital structures. Some of these vital structures include the innominate artery, innominate vein, vagus nerve, phrenic nerve, internal jugular vein, trachea, and esophagus (Fig. 33-9). If one is considering stabilizing the sternoclavicular joint, knowledge of the anatomy is crucial, and we usually have a thoracic or vascular surgeon on standby to help treat an unintended injury of these structures on an emergent basis.

Another structure to be aware of is the anterior jugular vein, which is located between the clavicle and the curtain of muscles. The anatomy books state that it can be quite variable in size; we have seen it as large as 1.5 cm in diameter. This vein has no valves, and when it is nicked, it looks like someone has opened up the flood gates.

ATRAUMATIC CONDITIONS OF THE STERNOCLAVICULAR JOINT

There are several atraumatic conditions that affect the sternoclavicular (SC) joint. Although most are treated nonoperatively, they should not be overlooked. These include osteoarthritis, inflammatory arthritides, sternocostoclavicular hyperostosis (SCCH), osteitis condensans, Friedrich's disease, infections, and spontaneous subluxations or dislocations. Table 33-1 provides a list of these conditions. The following section will explore the pathophysiology, diagnosis, and treatment. Spontaneous subluxations and dislocations will be discussed separately.

Sternocostoclavicular Hyperostosis

Sternocostoclavicular hyperostosis is characterized by bone overgrowth and soft tissue ossification of the medial clavicle, upper ribs, and sternum. According to most investigators,[55,66,71,77,79,85,91,96,99,166,186,195,199,205,209] sternocostoclavicular hyperostosis was first described by Sonozaki et al. in 1974.[199] It is also known as intersternocostoclavicular ossification, pustulotic arthrosteitis, and juxtasternal arthrosteitis.

This condition, usually bilateral, affects adults of both sexes between 30 and 60 years of age. Unilateral cases have been reported and could represent various stages of the disease. It has been reported in patients as young as 11 years of age to as old as 88 years.[186199] Although many cases are reported from Japan, it is recognized worldwide. Saghafi et al. reviewed 251 cases and found that 139 cases were Japanese and 114 were Caucasian.[186]

SCCH is characterized by ossification of the SC joint and medial ribs and sternum and can be associated with aseptic pustular lesions on the palms and soles. The process begins at the junction of the medial clavicle, the first rib, and the sternum as an ossification in the ligaments (primarily the costoclavicular ligament) and later involves the bones. Because the primary lesion is not hyperostosis of the bones but rather new bone formation in the periarticular tissue, it should be classified as an enthesopathy.[71] Fritz et al. emphasized that the osseous hypertrophy caused by periosteal new bone formation occurs in the entire circumference of the clavicle before ossification of

CONDITIONS AND CHARACTERISTICS

Condition	Radiographic Findings	Physical Findings	Treatment
Sternocostoclavicular hyperostosis	Ranges from localized ossification of costoclavicular ligaments to frank bone formation between clavicle, sternum, and upper ribs	Restricted shoulder motion, aseptic pustular lesions of palms and soles in 10%–30% of patients	Most patients respond to NSAIDs, heat, and activity modification; patients with severe pain and severely restricted motion due to complete fusion of clavicle, sternum, and first rib may benefit from surgical excision of hypertrophic bone
Osteitis condensans	Sclerosis and slight enlargement of medial third of clavicle	Swelling and tenderness of sternoclavicular joint	Most patients respond to NSAIDs, heat, and activity modification; excisional arthroplasty of medial end of clavicle in refractory cases
Aseptic necrosis (Friedrich's disease)	Irregularity of sternoclavicular joint with bony destruction of medial end of clavicle	Swelling and tenderness of sternoclavicular joint	Most patients respond to NSAIDs, heat, and activity modification; excisional orthroplasty of medial end of clavicle in refractory cases
Tietze's syndrome	Radiographic studies are of little diagnostic use	Tenderness most commonly noted at costosternal junction of second rib; mild swelling common	Most patients respond to NSAIDs, heat, and activity modification
Osteoarthritis	Subtle erosions and cystic changes particularly involving inferior aspect of medial end of clavicle	Mild swelling and tenderness usually involving sternoclavicular joint of dominant extremity	Most patients respond to NSAIDs, heat, and activity modification
Spontaneous subluxation	Subluxation (anterosuperior) when arm is placed in overhead position	Palpable and visual anterosuperior subluxation of medial end of clavicle with overhead elevation of arm	Self-limiting condition; operative procedures to stabilize sternoclavicular joint are generally unsuccessful
Infection	Soft tissue swelling with erosion of medial end of clavicle	Localized erythema, swelling, warmth, and tenderness to palpation	Irrigation and débridement of sternoclavicular joint with excision of involved portion of medial end of clavicle

NSAIDs = nonsteroidal antiinflammatory drugs.

the CC ligament, suggesting primary marrow pathology.[71] Lagier and colleagues published an excellent review of the x-ray findings and pathology from an autopsy specimen.[120] In some cases, the hyperostosis is extensive and forms a solid block of bone of the sternum, ribs, and clavicle. As might be expected with the fusion of the sternoclavicular joint, shoulder motion is severely restricted. Dohler[50] reported that as a result of the fusion of the sternoclavicular joint, his patient developed compensatory dislocation of the acromioclavicular joint. Patients may have peripheral arthritis. Subperiosteal bone changes have been noted in x-ray films of other bones (i.e., humerus, pelvis, tibia, ribs, and vertebral bodies).

The condition has been graded into three stages by Sonozaki et al.[199] Stage I is mild ossification in the area of the costoclavicular ligament; stage II is characterized by ossification beyond the CC ligament and an ossific mass between the clavicle and the first rib; and in stage III, a bone mass exists between the clavicle, sternum, and first rib. Fritz et al. have described a modification to this classification to include extrasternal manifestations.[71] The subscript "E" denotes extrasternal manifestations while the subscript "R" denotes involvement beyond the first rib. In the early stages a computed tomography (CT) scan will reveal ossification in the cartilaginous portions of the SC joint and first rib. The SC joint itself is well preserved even in the later stages.[195] A bone scan will reveal increased uptake even if the radiographic appearance is normal.[195]

Clinically, patients present with intermittent pain and swelling in and about the SC joints. There is usually localized warmth and swelling. The pain may radiate to the shoulder or arm. Some patients present with an asymptomatic mass.[66] Loss of motion of the shoulder may ensue if the disease progresses to complete ankylosis of the SC joint.[50]

The most consistent laboratory finding is an elevated sedimentation rate, which may increase with progression of the disease. In some cases C-reactive protein and α-1 globulin levels are elevated. Although there is a strong association with seronegative spondyloarthropathies, most patients had a negative HLA-B27.[103] Alkaline phosphatase may be elevated in some.

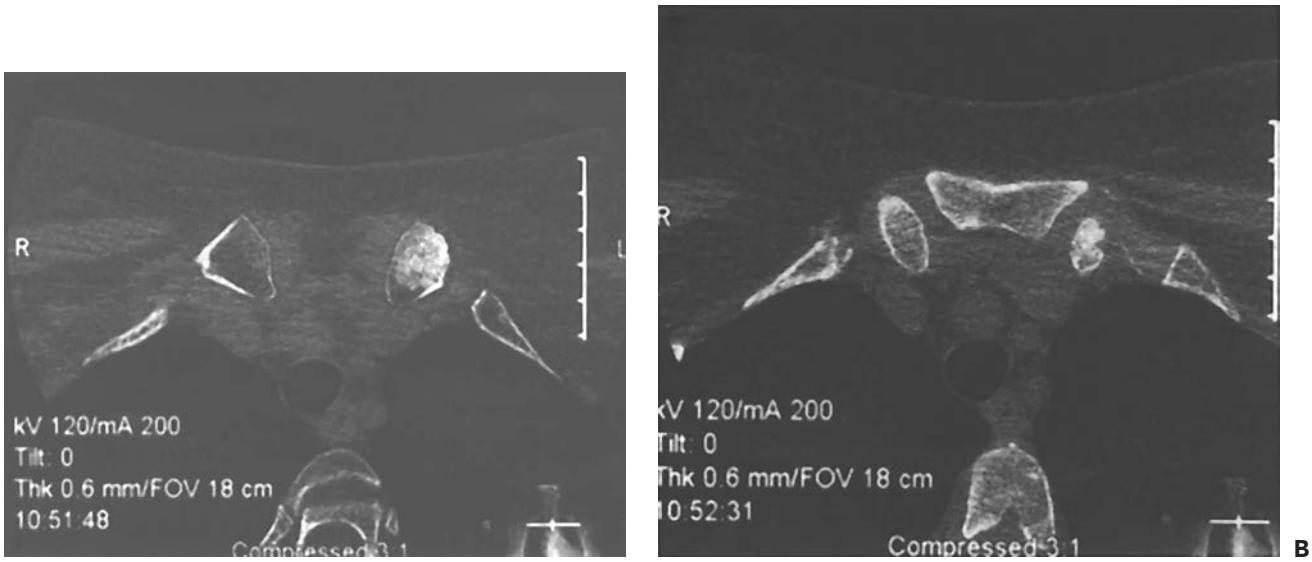
Bone marrow biopsy has demonstrated chronic inflammation with lymphocytes, plasma cells, and macrophagic histiocytes. Other biopsy specimens have revealed bone remodeling and thickening of the trabeculae of the cancellous bone and osteoid formation. Analysis of the periosteum also demonstrates fibroblastic scar remodeling and chronic inflammatory cells. Most culture results are negative, but Edlund et al. did report a positive culture for propionibacterium acne.[55] This is interesting as there is a strong association with pustulosis palmaris et plantaris (PPP), which is a dermatologic condition characterized by aseptic pustular lesions on the palms and soles. In fact, a review of the literature found a 10% to 30% association between the two conditions.[55,71,91,99] Other dermatologic conditions have also been reported in conjunction with SCCH and include acne conglobata, acne fulminans, pustulotic psoriasis, hidradenitis suppurativa, and dissecting cellulites of the scalp.[153] In the dermatologic literature the acronym SAPHO has been applied, which includes the constellation of symptoms of *s*ynovitis, *a*cne, *p*ustulosis, *h*yperostosis, and *o*steitis.

Management of SCCH is usually nonoperative with control of the symptoms with nonsteroidal antiinflammatory drugs. Other options have included radiation, corticosteroids, antibiotics, and surgical excision. None of these options has seemed to affect the natural history of the disease. Surgical excision is usually reserved for those patients with complete ankylosis and loss of shoulder motion.[55,199]

Condensing Osteitis

Brower and associates first described in detail the rare condition known as condensing osteitis of the medial clavicle in two patients in 1974.[23] Although a rare condition, several other authors have described this condition.[14,37,52,69,92,101,116,149,155] It usually occurs unilaterally in women of late child-bearing age and may occur secondary to chronic stress on the joint. No bilateral cases have been reported. The joint is swollen and tender, and radionuclide studies show an increased uptake of the isotope. The pain may be intermittent and worsened with heavy or repetitive lifting. Radiation to the axilla or shoulder is not uncommon. Routine laboratory studies are inconsistent but may reveal an elevated sedimentation rate, but the white blood cell count is usually normal. X-ray films show sclerosis and slight expansion of the medial third of the clavicle. The inferior portion of the sternal end of the clavicle shows sclerotic changes. Some osteophytes may be present, but the SC joint space is preserved. The changes of the medial clavicle are best detected via CT, which reveals sclerosis of the marrow space and enlargement of the medial end of the clavicle[116](Fig. 33-10). The differential diagnosis includes Paget's disease, sternoclavicular hyperostosis, Friedrich's avascular necrosis of the medial clavicle epiphysis, infection, Tietze's syndrome, and osteoarthritis. More recently, Vierboom and associates have described the use of magnetic resonance imaging (MRI) as an adjunctive method for diagnosing this entity.[215]Typically the MRI will reveal low-signal intensity on both T1- and T2-weighted images.

Jones et al. have called into question the actual existence of condensing osteitis of the clavicle based on histologic and serologic data.[101] They reported three cases in children with similar radiographic findings, but incisional biopsies revealed a mixed inflammatory process (neutrophils and lymphocytes) and new bone formation (woven and lamellar)



A B

Figure 33-10 Computed tomography (CT) findings for a 32-year-old woman with dull aching in her left medial clavicle for 18 months. There was no history of trauma. **(A)** CT scan of both medial clavicles reveals dense ossification of the left medial clavicle. **(B)** There is no involvement of the SC joint space. (From Hiramuro-Shoji F, Wirth MA, Rockwood CA Jr. Atraumatic conditions of the sternoclavicular joint. *J Shoulder Elbow Surg* 2003;12(1):79–88, with permission.)

covered by large osteoblasts. Although the cultures and stains were all negative, two had elevated anti-α hemolysin titers, raising the question of staphylococcal infectious cause. In addition, Appell et al. reported seven cases of condensing osteitis in children, four of whom responded to antibiotics.[3] Kruger et al. reported three cases of middle-aged females with similar radiographic findings with incisional biopsies revealing reactive sclerosis, but no mention was made regarding an inflammatory cellular infiltrate.[116] It might be that these cases represent different pathologic processes and may be separate entities entirely. It is interesting that condensing osteitis of the ilium and pubis also occur in women of child-bearing age and have similar radiographic appearance, but no definite associations have been made.[141,172]

Treatment has included antiinflammatory medications, radiation, antibiotics, and surgical excision.[11,23,37,63,116] Varying results have been reported, with complete clinical and radiographic remission reported with antiinflammatory medications.[14] Excisional biopsy is reserved for refractory cases.[23]

Friedrich's Disease

Avascular necrosis of the medial end of the clavicle has been termed Friedrich's disease owing to its original description in 1924 by Friedrich.[70] Its original description included two cases and highlighted the similarities between this condition and other osteonecrotic lesions such as Perthes' disease, Köhler's disease, Kienböck's disease, and Preiser's disease.

It is a rare condition presenting with pain and swelling over the medial end of the clavicle. It usually has an insidious onset and seems to be more common in females. Age of onset has varied from skeletally immature patients to a 58-year-old male.[36,107,127,194] It is usually unilateral but one bilateral case has been reported in a female, but the presentations were 2 years apart.[127]

Radiographs and tomograms reveal irregularity at the medial end of the clavicle with bony destruction. Bone scan usually reveals increased uptake.[194] The sedimentation rate may be slightly elevated, but other laboratory studies including aspirations have been negative, differentiating it from other osteolytic lesions such as infection.[127] Incisional biopsies reveal necrotic bone with empty lacunae.[127]

Most patients will improve within several months with nonoperative treatment with antiinflammatory medications. Although some have been treated successfully with curettage, this was felt to be unnecessary, and simple observation is advocated.[127] Resection arthroplasty has been reported successfully in one case, but it should be reserved for refractory cases.[129]

Infection

Sternoclavicular joint infections account for 1% of all joint infections in the general population but 17% of those found in IV drug abusers.[41,75,181,221] Ross and Shamsuddin[181] reviewed 180 cases of sternoclavicular joint infections and found that predisposing factors included IV drug abuse in 21%, distant infection in 15%, diabetes in 13%, trauma in 12%, and central line placement/infection in 9%. Interestingly, 23% were in otherwise healthy adults, which has been found in other studies as well.[8,17,84] This highlights the importance of a heightened clinical suspicion, even in those patients without a known risk factor. Immunosuppression secondary to concomitant diseases such as cancer, inflammatory arthritides, or HIV or secondary to steroid use are also known risk factors for infection.[181]

The most common isolated organism is *Staphylococcus aureus* even in IV drug abusers.[8,26,30,163,181,197] There are many case reports of isolated infections of the sternoclavicular joint that have been caused by a variety of other microorganisms, including *Escherichia coli*,[44] *Citrobacter diversus*,[72] *Pasteurella multocida*,[34] *Streptococcus pyogenes*,[143] *Pseudomonas aeruginosa*,[108] *Brucella species*,[13] *Neisseria gonorrhoeae*,[142] *Bacteroides*,[169] *Fusiformbacterium*,[122] *Candida albicans*,[54] *Haemophilus influenza*,[115] and Group B streptococcal species.[31] Blankstein and associates reported a septic sternoclavicular joint that cultured *S. aureus* secondary to bacteremia infection from a paronychia of the finger.[17] Richter and associates reported on nine patients with infection of the sternoclavicular joint secondary to tuberculosis.[175] The average time from onset of the disease until diagnosis was 1.4 years. Higoumenakis reported that unilateral enlargement of the sternoclavicular joint is a diagnostic sign of congenital syphilis.[87] The enlargement of the sternoclavicular joint can be mistaken for an anterior dislocation. He reported the sign to be positive in 170 of 197 cases of congenital syphilis. Others have reported on the same condition.[15,49,193] The enlargement is a hyperostosis of the medial clavicle, occurring in the sternoclavicular joint of the dominant extremity, which reaches its permanent stage and size at puberty. The theory of why it affects the sternoclavicular joint relates it to spirochete invasion of the sternal end of the clavicle at the time of early ossification.

Patients most commonly present with pain and swelling localized to the SC joint. In a review by Ross et al., 78% presented with chest pain and 24% with shoulder pain, emphasizing that the pain can radiate. Fever was also common, with 62% having concomitant bacteremia.[181]

A high index of suspicion should be maintained as complications are high, with osteomyelitis occurring in 55%, abscess formation in at least 20%, mediastinitis in 13%, and pleural effusion.[30,181,190,198,213,221] Plain radiographs are helpful but do not exclude the diagnosis, as 80% were read as normal in one series.[26] A CT scan or MRI is mandatory to evaluate the joint and surrounding bones and retrosternal area. The CT scan will reveal bony destruction and, frequently, gas or abscess formation (Figs. 33-11 and 33-12).

Treatment has varied from parenteral use of antibiotics to aggressive en bloc resection of the SC joint with or

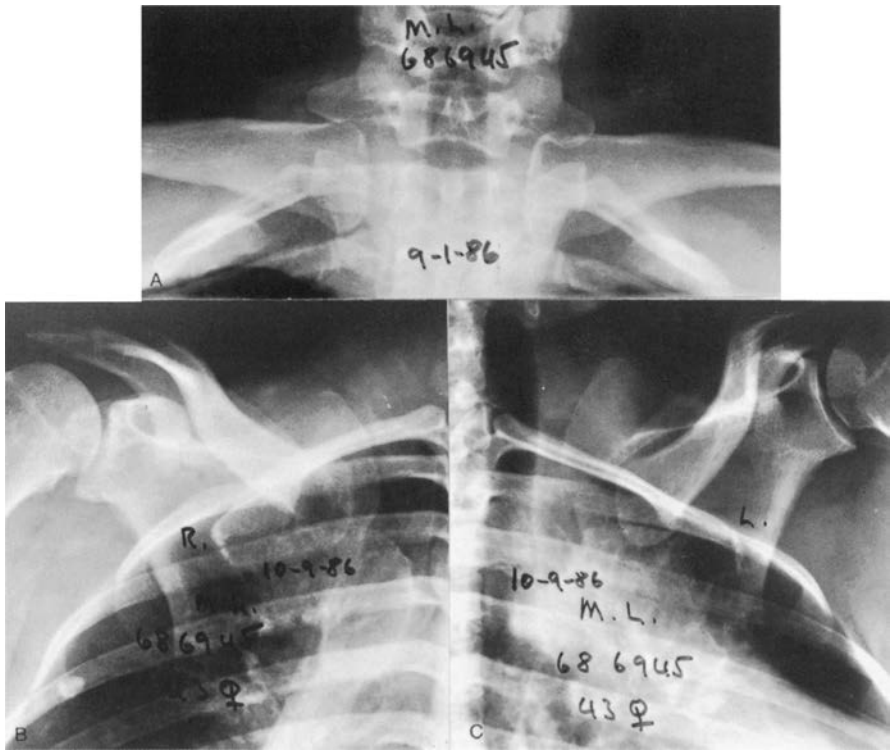


Figure 33-11 Infection in the right sternoclavicular joint. **(A)** On the initial x-ray, there is little difference between the right and left medial clavicles, as seen on the 30-degree cephalic tilt view. **(B,C)** Thirty-eight days later, the medial end of the right clavicle is seen to be dissolving, compared with the medial end of the left clavicle. The patient had a *Staphylococcus aureus* infection in the right sternoclavicular joint, which was managed by open débridement. (Reprinted with permission from Rockwood CA, Matsen F III, eds. *The shoulder.* Philadelphia: WB Saunders, 1990:Fig. 13-14.)

without pectoralis flap augmentation. More aggressive surgical treatment has recently been advocated due to failures of simple débridement.[2630] The relatively small joint capsule of the SC joint allows for minimal distention of purulent fluid and rapid extension beyond the joint. If the infection is isolated to the SC joint without any bony destruction, then simple irrigation and débridement may be performed with good results. The results do seem better if a delayed closure is performed or the wound is allowed to heal by secondary intention.[8,26] If there is bony involvement, then more aggressive treatment is advocated. Song et al. reported recurrence of infection in five of six patients treated with irrigation and débridement alone. These were then revised to en bloc resection of the SC joint and portion of the first rib with pectoralis major advancement, with a cure in these cases.[197] Burkhart et al. reviewed 26 patients, two-thirds of whom required en bloc resection. Fifteen percent had a previous irrigation and débridement. A pectoralis major muscle advancement into the defect based on the thoracoacromial pedicle was performed in 55% with excellent results.[26] Carlos et al. also advocated aggressive treatment if the infection had spread beyond the SC joint.[30] The primary author currently performs these procedures in conjunction with a thoracic surgeon and prescribes 6 weeks of postoperative antibiotics.

In summary, there should be a high index of clinical suspicion for an SC joint infection if a patient presents with pain and swelling, even if there are no other risk factors. Routine serologic examination should be performed including blood cultures. A CT scan or MRI will help determine if there is extension beyond the SC joint, and if present, more aggressive surgical treatment is recommended.

Osteoarthritis

Osteoarthritis is characterized by narrowing of the joint space, osteophytes, subchondral sclerosis, and cysts on both sides of the joint.[112,114,123] Because most of the wear occurs in the inferior part of the head of the medial clavicle, most of the degenerative changes occur in that region. The sometimes discrete degenerative changes are best seen on tomograms and CT scans.[112,114] (Figs. 33-13, 33-14, and 33-15) Kier and associates correlated the x-ray films and the pathologic specimens of patients with osteoarthritis of the sternoclavicular joint.[112] They noted increasing frequency of degenerative changes with age, with 90% to 100% of specimens over the age of 70 having significant degenerative changes. Sternoclavicular joint arthritis and hypertrophy can develop following radical neck surgery, particularly when the spinal accessory nerve is sacrificed, and the incidence is reported to be as high as 54%.[78,160,208] The reason for the arthritis is the downward and forward droop of the shoulder, which puts extra stress on the sternoclavicular joint. The senior author observed one patient who had such stress on the sternoclavicular joint following a radical neck and spinal accessory nerve sacrifice that he developed a posterior dislocation of the sternoclavicular joint. The posterior displacement was so severe that the medial end of the clavicle compressed his trachea and esophagus.

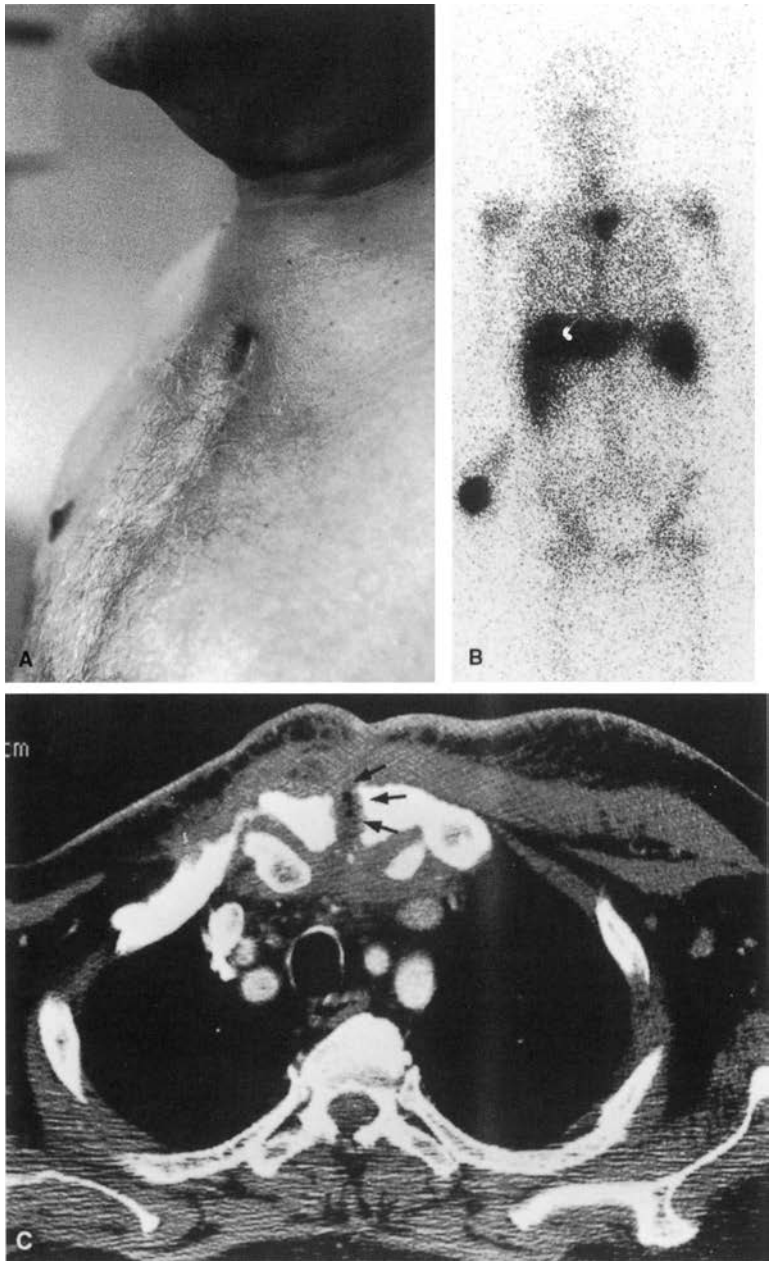

Figure 33-12 **(A)** This patient had long-standing insulin-dependent diabetes and had had a coronary artery bypass procedure that was complicated by a postoperative wound infection. **(B)** Indium-enhanced white blood cell scan consistent with infection in the region of the left sternoclavicular joint. **(C)** Computed tomography scan revealing significant soft tissue swelling, interspersed locules of air within the sternal osteotomy site, and focal irregularity of the posterior aspect of the sternum consistent with an infectious process. (From Wirth MA, Rockwood CA. Injuries to the sternoclavicular joint. In: Rockwood CA, Green DP, Bucholz RW, Hechman JD, eds. *Fractures in adults.* Philadelphia: JB Lippincott, 1996.)

Bremner and Bonnin have both reported on "postmenopausal arthritis," so named because it is most often seen in postmenopausal women.[18,20] Sadr and Swann reported on 22 patients with this problem who were seen in a 5-year study; 20 of the cases were in women, and the majority involved the sternoclavicular joint of the dominant arm.[185] Nonoperative treatment was recommended. The condition is the result of normal degeneration of a frequently moved joint. It is almost without symptoms; a lump develops at the sternoclavicular joint, which occasionally is accompanied by a vague ache (Fig. 33-16). There is no previous history of injury or disease. X-ray studies show sclerosis and enlargement of the medial end of the clavicle, reactive sclerosis of the sternum, and subluxation of the joint. The pathologic changes are those of degenerative arthritis.

In general, standard osteoarthritis and postmenopausal arthritis are managed nonoperatively with nonsteroidal antiinflammatory drugs and activity modification. If that fails, then operative intervention can be considered. Several authors have reported on isolated resection of the medical end of the clavicle with good results.[20,161,177] It is important to note that if there is concomitant instability of the sternoclavicular joint, then a resection arthroplasty will not yield a good result. Rockwood and associates reported on a series of 23 patients who had undergone a resection of the medial end of the clavicle.[177] The patients were divided into two groups: group I, who underwent resection

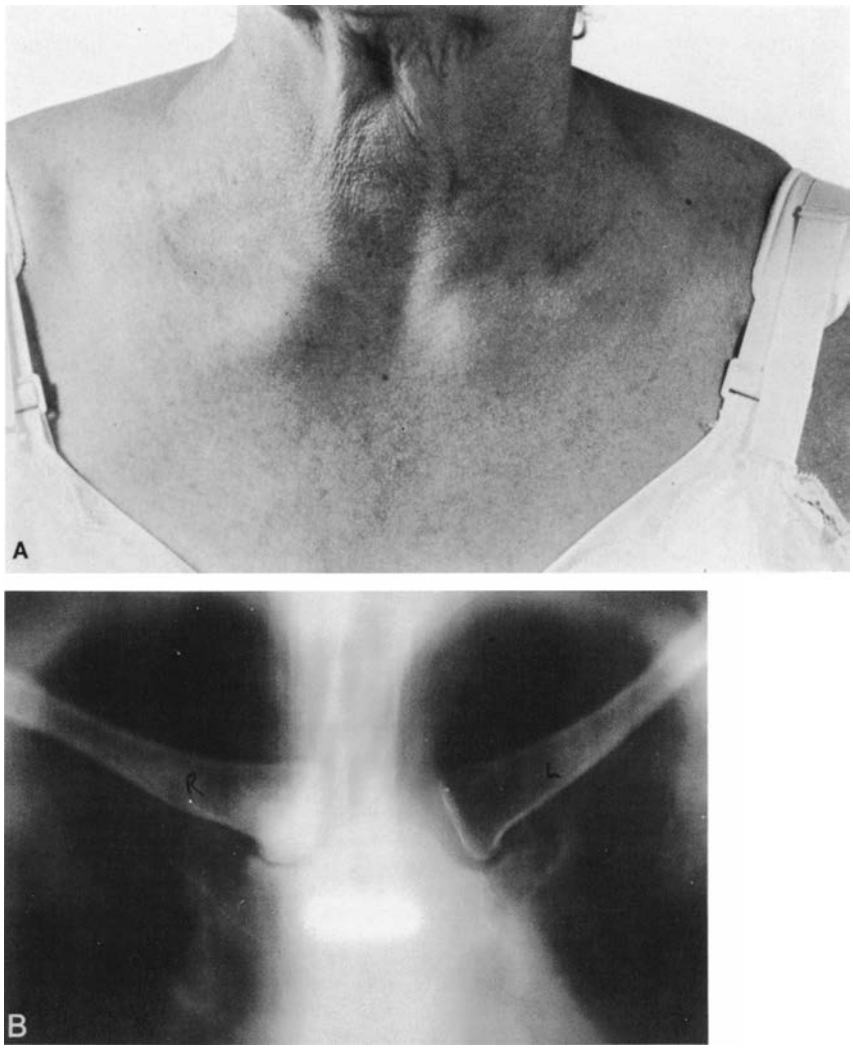

Figure 33-16 **(A)** Bilateral anterior swelling of the sternoclavicular joints in a 67-year-old woman. The right medial clavicle was more prominent because she was right-handed. **(B)** The tomogram demonstrates sclerosis and degenerative changes in the right sternoclavicular joint consistent with ordinary degenerative arthritis. (**B** reprinted with permission from Rockwood CA, Matsen F III, eds. *The shoulder.* Philadelphia: WB Saunders, 1990:Fig. 13-13b.)

of the medial end of the clavicle with maintenance or reconstruction of the costoclavicular ligament; and group II, who had a resection without maintaining or reconstructing the costoclavicular ligament. The outcome in all but one of the seven patients in group II was poor, with persistence or worsening of preoperative symptoms. The only patient of this group with a successful result experienced a posterior epiphyseal separation, in which the costoclavicular ligament remained attached to the periosteum, thus preventing instability. All of the eight patients in group I, who underwent primary surgical resection of the medial end of the clavicle with maintenance of the costoclavicular ligaments, had an excellent result. When the operation was performed as a revision of a previous procedure with reconstruction of the costoclavicular ligaments, the results were less successful, but only one patient of seven was not satisfied with the outcome of treatment.

When operating on the sternoclavicular joint, care must be taken to evaluate the residual stability of the medial clavicle. It is the same analogy as used when resecting the distal clavicle for an old acromioclavicular joint problem. If the coracoclavicular ligaments are intact, an excision of the distal clavicle can be performed (Fig. 33–17). If the coracoclavicular ligaments are insufficient, then in addition to excision of the distal clavicle, one must reconstruct the coracoclavicular ligaments or the capsular ligaments. Stabilization techniques are described in the trauma section of this chapter. If too much clavicle is resected, or if the clavicle is not stabilized, an increase in symptoms can occur (Fig. 33-18). The technique for resection of the medical end of the clavicle involves only resecting enough bone so that there is about 1 cm of space between the medial end of the clavicle and the sternum. The resection should never be carried more lateral than the costoclavicular ligament or the insertions of the sternoclavicular ligament/joint capsules.[16] The anterior sternoclavicular ligament/joint capsule should be repaired over the resection site. Postoperative therapy parallels that of a resection of the lateral end of the clavicle.

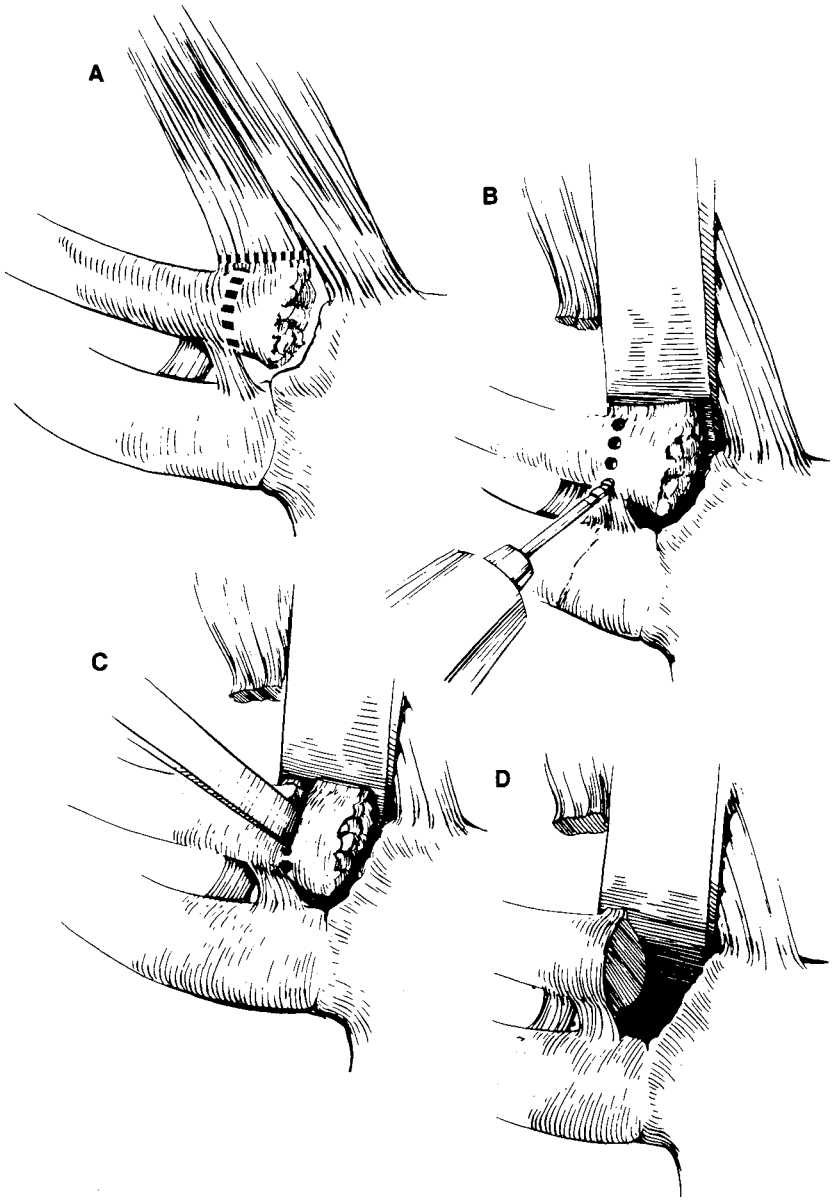

Figure 33-17 Technique for resecting the medial clavicle for degenerative arthritis. **(A)** Care must be taken to remove only that part of the clavicle medial to the costoclavicular (rhomboid) ligaments. There must be adequate protection for the vital structures that lie posterior to the medial end of the clavicle. **(B,C)** An air drill with a side-cutting burr can be used to perform the osteotomy. **(D)** When the fragment of bone has been removed, the dorsal and anterior borders of the clavicle should be smoothed, to give a better cosmetic appearance.

Tietze's Syndrome

Tietze first described the condition in 1921; it is also known as costosternal syndrome, parasternal chondrodynia, costochondritis, and thoracochondralgia.[211] Tietze's syndrome is a benign, self-limiting condition characterized by tender swelling in the region of the anterior chest wall without any other clear evidence that could establish another definite diagnosis.[126,211] Thus, it is often a diagnosis of exclusion.

Although the reported incidence has diminished over time, Jurik and Graudal reviewed the literature in 1988 and found 346 cases.[104] The exact incidence is unknown, but in a group of 320 patients evaluated for chest pain, 10% were found to have Teitze's syndrome.[222]

Patients present with pain in the anterior chest wall with fusiform swelling of the involved costal cartilage. The pain may radiate to the shoulder or arm and is frequently aggravated by coughing or sneezing. The most commonly involved area is the costosternal junction of the second rib. There is usually localized tenderness and warmth, but erythema is usually absent.

Chest radiographs are usually normal, but a bone scan will usually reveal increased uptake in the area. Yang et al. described the use of pinhole skeletal scintigraphy with the appearance of a club-like "C" or an inverted "C" at the affected cartilage.[227] A CT scan frequently reveals enlargement of the cartilage at the sternal junction, but biopsies demonstrate normal cartilage.[21,53]

Clearly the most important aspect of the condition is ruling out a primary cardiac or pulmonary cause necessitating referral to medical specialists. Once that is confirmed, the patient should be reassured that this is a

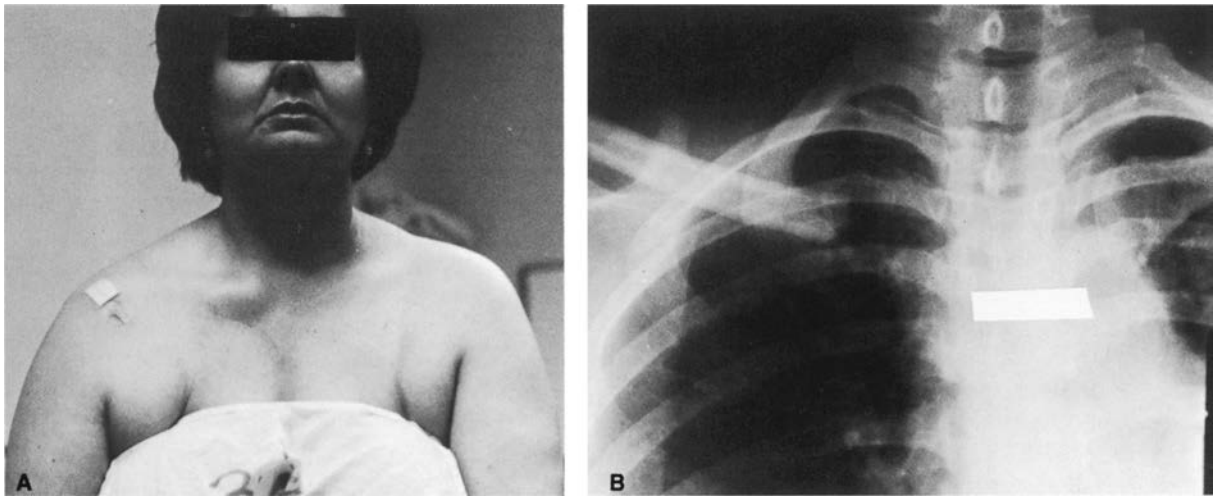

Figure 33-18 **(A)** This postmenopausal, right-handed woman had resection of the right medial clavicle, because of preoperative diagnosis of "possible tumor." The postoperative microscopic diagnosis was degenerative arthritis of the right medial clavicle. After surgery, the patient complained of pain and discomfort, marked prominence, and gross instability of the right medial clavicle. **(B)** An x-ray confirmed that the excision of the medial clavicle extended lateral to the costoclavicular ligaments; hence, the patient had an unstable medial clavicle.

benign condition that is often characterized by relapsing and remitting symptoms. The discomfort is managed nonoperatively with nonsteroidal antiinflammatory drugs and judicious use of corticosteroid injections.

Other Arthropathies

Many other arthropathies and maladies affecting the sternoclavicular joint have been reported. The sternoclavicular joint can be involved with systemic autoimmune arthropathies such as rheumatoid arthritis, psoriatic arthritis, ankylosing spondyloarthritis, gout, and polymyalgia rheumatica.[2,148,173,174,188,206] Hypertrophy after radial neck dissection has also been reported and might be due to increased stress across the joint with trapezial dysfunction.[78,160,208] Neuropathic changes in the sternoclavicular joint have also been noted with a syringomyelia.[35] Synovial osteochondromatosis has also been reported by Vrdojak and Irha.[216] Cameron et al. reported hemodialysis-related amyloid deposition in the sternoclavicular joint.[29] The sternomanubrial joint may also be affected by psoriatic arthritis, and fusion of this joint can be performed when it is refractory to conservative management.

RADIOGRAPHIC FINDINGS

Anteroposterior Views

The older literature reflects that routine x-rays of the sternoclavicular joint, regardless of the special views, are difficult to interpret. Special oblique views of the chest have been recommended, but because of the distortion of one clavicle over the other, interpretation is difficult (Fig. 33-19). The older literature also suggests that the diagnosis of dislocation of the sternoclavicular joint is best made from a clinical examination, not from the x-rays. However, it does indicate that tomography offers more detailed information, often showing small fractures in the vicinity of the sternoclavicular joint. Occasionally, the routine anteroposterior or posteroanterior x-rays of the chest or sternoclavicular joint suggest that something is wrong with one of the clavicles, because it appears to be displaced as compared with the normal side (Figs. 33-20 and 33-21). It would be ideal to take a view at right angles to the anteroposterior plane, but because of our anatomy, it is impossible to obtain a true 90-degree cephalic-to-caudal lateral view. Lateral x-rays of the chest are at right angles to the anteroposterior plane, but they cannot be interpreted because of the density of the chest and the overlap of the medial clavicles with the first rib and the sternum.

Regardless of a clinical impression that suggests an anterior dislocation, x-rays must be obtained to confirm one's suspicions.

Special Projected Views

Kattan[105] has recommended a special projection, as have Ritvo,[176] Fery and Leonard,[64] Tricoire and coworkers.[212] Kurzbauer has recommended special lateral projections.[119] Hobbs, in 1968, recommended a view that comes close to being a 90-degree cephalocaudal lateral view of the sternoclavicular joints.[88] In the same year, Heinig recommended an x-ray projection of the sternoclavicular joint that resembles a "swimmer's view" of the cervical spine.[86]

A B

Figure 33-19 Routine radiographs of the sternoclavicular joint are difficult to interpret, even with a classic posterior dislocation of the joint.

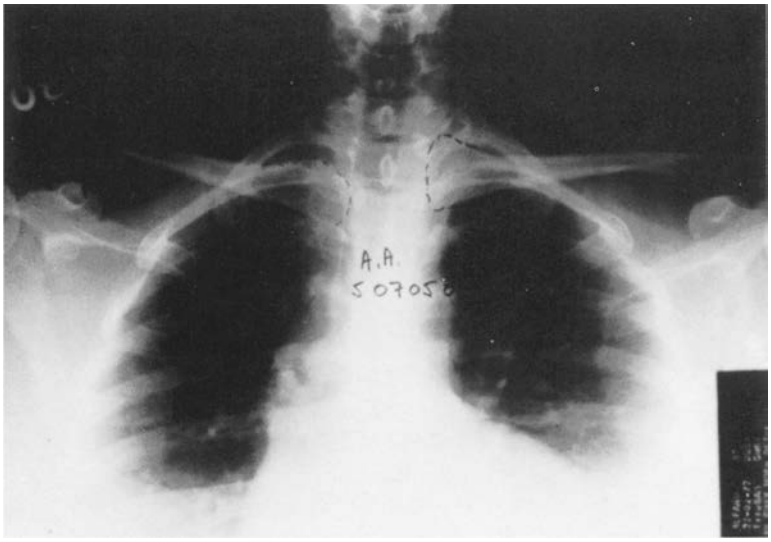

Figure 33-20 Anteroposterior x-ray of the sternoclavicular joints with anterosuperior displacement of the left medial clavicle. The displacement is quite noticeable when the clavicles are outlined.

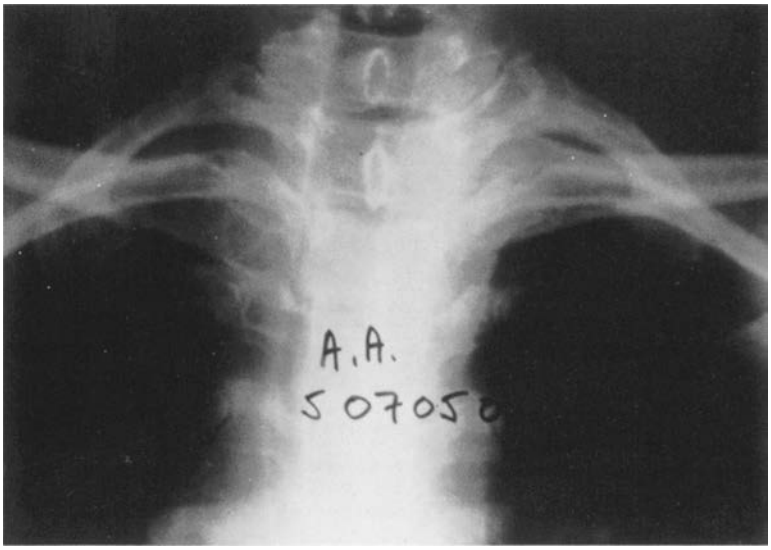

Figure 33-21 Anteroposterior x-ray of the sternoclavicular joints with anterosuperior displacement of the left medial clavicle. The displacement is not as noticeable when the clavicles are not outlined.

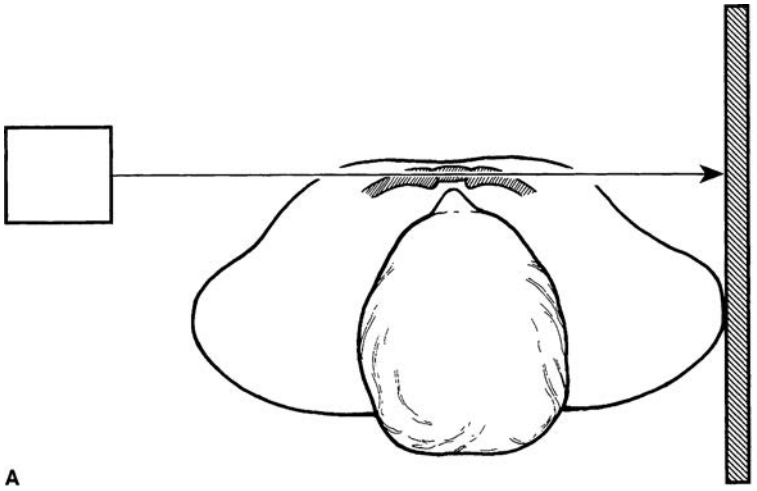

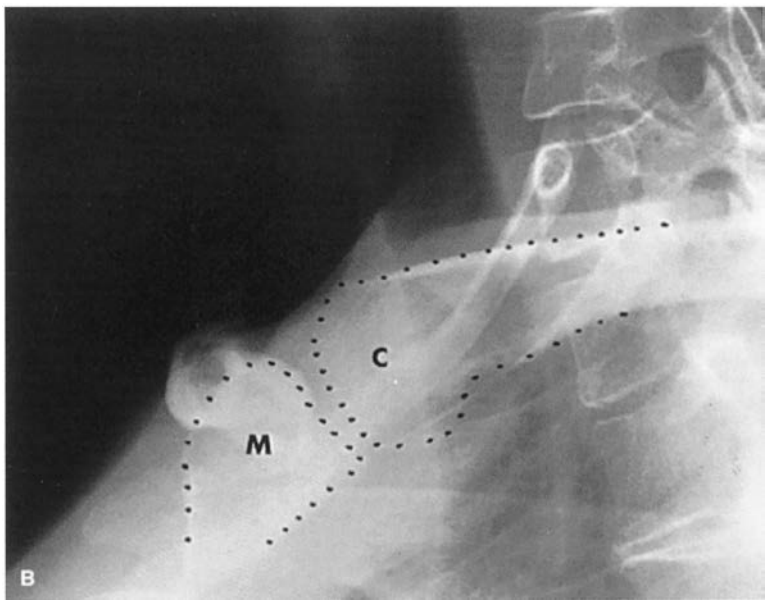

Figure 33-22 **(A)** Positioning of the patient for x-ray evaluation of the sternoclavicular joint, as described by Heinig. **(B)** Heinig view demonstrating a normal relationship between the medial end of the clavicle (*C*) and the manubrium (*M*). (From Wirth MA, Rockwood CA. Injuries to the sternoclavicular joint. In: Rockwood CA, Green DP, Bucholz RW, Hechman JD, eds. *Fractures in adults*. Philadelphia: JB Lippincott, 1996.)

Heinig View

With the patient in a supine position, the x-ray tube is placed approximately 30 in. from the involved sternoclavicular joint, and the central ray is directed tangential to the joint and parallel to the opposite clavicle. The cassette is placed against the opposite shoulder and centered on the manubrium (Fig. 33-22).

Hobbs View

In the Hobbs view, the patient is seated at the x-ray table, high enough to lean forward over the table. The cassette is on the table, and the lower anterior rib cage is against the cassette (Fig. 33-23). The patient leans forward, so that the nape of his or her flexed neck is almost parallel to the table. The flexed elbows straddle the cassette and support the head and neck. The x-ray source is above the nape of the neck, and the beam passes through the cervical spine to project the sternoclavicular joints onto the cassette.

Serendipity View

The serendipity view is rightfully named because that is the way it developed. The senior author, accidentally, noted that the next best thing to having a true cephalocaudal lateral view of the sternoclavicular joint is a 40-degree cephalic tilt view. The patient is positioned on his or her back squarely and in the center of the x-ray table. The tube is tilted at a 40-degree angle off the vertical and is centered directly on the sternum (Fig. 33-24). A nongrid 11 $\times$ 14-in. cassette is placed squarely on the table and under the patient's upper shoulders and neck, so that the beam aimed at the sternum will project both clavicles onto the

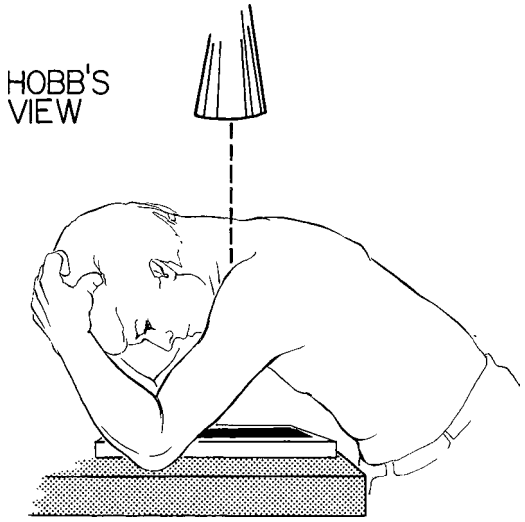

Figure 33-23 Positioning of the patient for x-ray evaluation of the sternoclavicular joint, as recommended by Hobbs. (Redrawn with permission from Hobbs DW. The sternoclavicular joint: a new axial radiographic view. *Radiology* 1968;90:801.)

film. The tube is adjusted so that the medial half of both clavicles is projected onto the film. It is important to note that the cassette should be placed squarely on the x-ray table (i.e., not angulated or rotated) and that the patient should be positioned squarely on top of the cassette.

For children, the distance from the tube to the cassette is 45 in.; for adults, whose anteroposterior chest diameter is greater, the distance should be 60 in. The technical setting of the machine is essentially the same as for a posteroanterior view of the chest.

To understand this view, imagine that your eyes are at the level of the patient's knees and you are looking up toward his or her clavicles at a 40-degree angle. If the right sternoclavicular joint is dislocated anteriorly, the right clavicle will appear to be displaced more anteriorly or riding higher on an imaginary horizontal line when compared with the normal left clavicle (Fig. 33-25). The reverse is true if the left sternoclavicular joint is dislocated posteriorly (i.e., the left clavicle displaced inferiorly or riding lower on an imaginary horizontal plane than the normal right clavicle) (see Fig. 33-27). The idea, then, is to take a 40-degree cephalic tilt x-ray showing both medial clavicles and compare the injured clavicle with the normal clavicle (Fig. 33-26).

Special Techniques

Tomograms

Tomograms can be very helpful in distinguishing between a sternoclavicular dislocation and a fracture of the medial clavicle. They are also helpful in questionable anterior and posterior injuries of the sternoclavicular joint—to distinguish fractures from dislocations and to evaluate arthritic changes (Fig. 33-27). Tomograms have essentially been supplanted by computed tomography and are mentioned for completeness sake.

CT Scans

Without question, the CT scan is the best technique to study problems of the sternoclavicular joint (Fig. 33-28). It clearly distinguishes injuries of the joint from fractures of the medial clavicle and defines minor subluxations of the joint. The orthopedist must remember to ask for CT scans of both sternoclavicular joints and the medial half

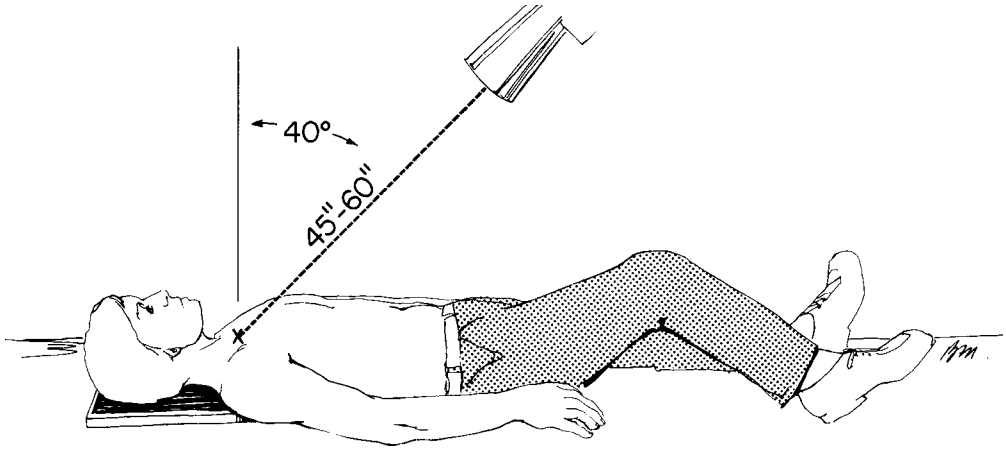

Figure 33-24 Positioning of the patient to take the serendipity view of the sternoclavicular joints. The x-ray tube is tilted 40 degrees from the vertical position and aimed directly at the manubrium. The nongrid cassette should be large enough to receive the projected images of the medial halves of both clavicles. In children, the tube distance from the patient should be 45 in.; in thicker-chested adults, the distance should be 60 in.

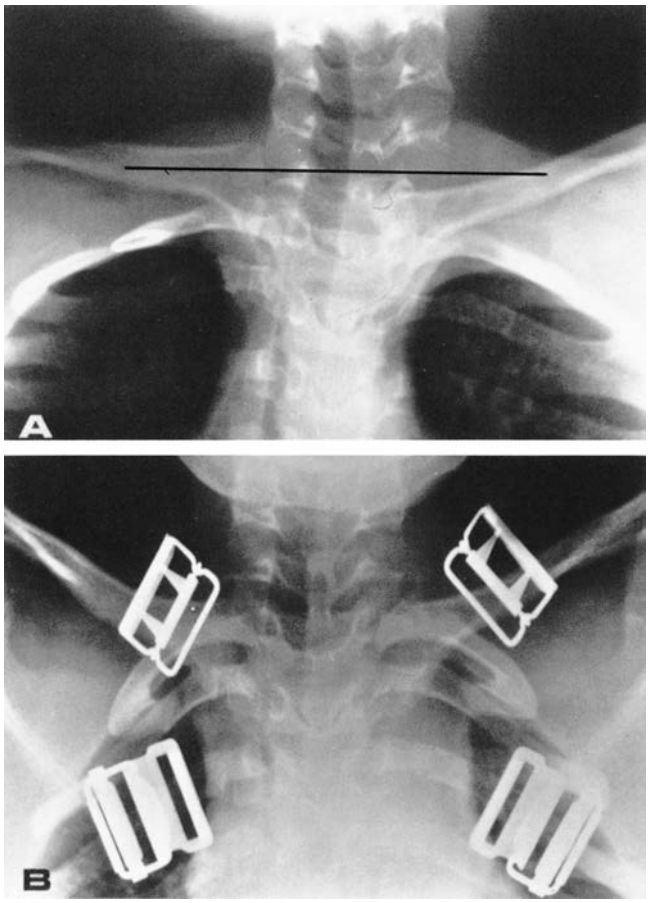

Figure 33-25 **(A)** Posterior dislocation of the left sternoclavicular joint as seen on a 40-degree caphalic tilt x-ray film of a 12-year-old boy. The left clavicle is displaced inferiorly to a line drawn through the normal right clavicle. **(B)** After closed reduction, the medial ends of both clavicles are in the same horizontal position. The buckles are part of the figure-of-eight clavicular harness used to hold the shoulders back after reduction.

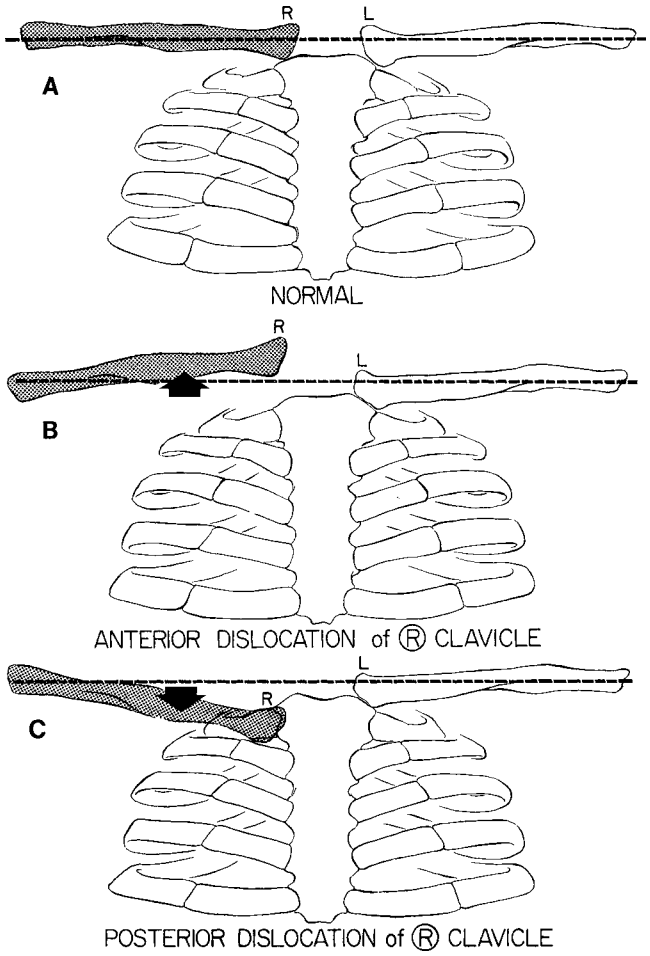

Figure 33-26 Interpretation of the cephalic tilt x-ray films of the sternoclavicular joints. **(A)** In the normal person, both clavicles appear on the same imaginary line drawn horizontally across the film. **(B)** In a patient with anterior dislocation of the right sternoclavicular joint, the medial half of the right clavicle is projected above the imaginary line drawn through the level of the normal left clavicle. **(C)** If the patient has a posterior dislocation of the right sternoclavicular joint, the medial half of the right clavicle is displaced below the imaginary line drawn through the normal left clavicle.

of both clavicles, so that the injured side can be compared with the normal side. The patient should lie flat in the supine position. If one requests a study of the right sternoclavicular joint, the x-ray technician may rotate the patient to the affected side and provide views of only the one joint.

STERNOCLAVICULAR SUBLUXATIONS AND DISLOCATIONS

The section will review traumatic, atraumatic, and developmental subluxations and dislocations of the sternoclavicular joint. The direction of subluxation or dislocation is based on the location of the medial end of the clavicle with respect to the sternum. Although subluxations and dislocations can have an inferior or superior component, the majority of the displacement occurs in an anterior or posterior direction. By convention, they are therefore termed anterior or posterior.

Sternoclavicular injuries are rare, and many of the authors apologize for reporting only three or four cases. Attesting to this rarity is the fact that some orthopedists have never treated or seen a dislocation of the sternoclavicular joint.

The incidence of sternoclavicular dislocation, based on the series of 1,603 injuries of the shoulder girdle reported by Cave and associates, is 3%.[33] (Specific incidences in the study were glenohumeral dislocations, 85%; acromioclavicular, 12%; and sternoclavicular, 3%). In the series by Cave and in our experience, dislocation of the sternoclavicular joint is not as rare as posterior dislocation of the glenohumeral joint.

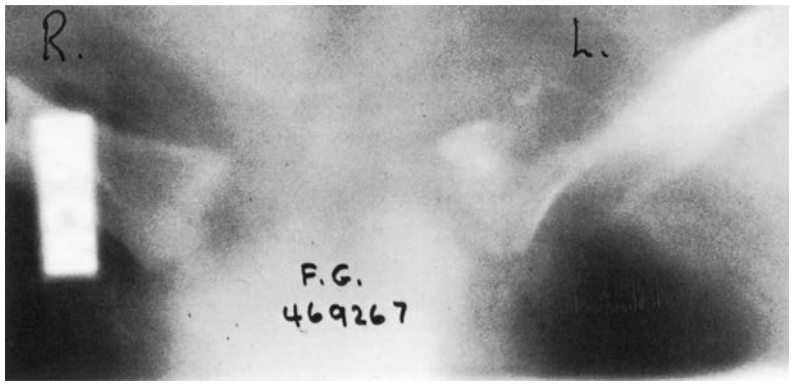

Figure 33-27 Tomogram demonstrating a fracture of the left medial clavicle. The clinical diagnosis before radiography was an anterior dislocation of the left sternoclavicular joint.

Figure 33-28 Computed tomography scans of the sternoclavicular joint, demonstrating various types of injuries. **(A)** Posterior dislocation of the left clavicle compressing the great vessels and producing swelling of the left arm. **(B)** Fracture of the medial clavicle that does not involve that articular surface. **(C)** Fragment of bone displaced posteriorly into the great vessel. **(D)** Fracture of the medial clavicle into the sternoclavicular joint. Figure 33-29 Spontaneous anterior subluxation of the sternoclavicular joint. **(A)** With the arms in the overhead position, the medial end of the right clavicle spontaneously subluxates anteriorly without any trauma. **(B)** When the arm is lowered to the side, the medial end of the clavicle spontaneously reduces. Usually this is not associated with significant discomfort. (Reprinted with permission from Rockwood CA, Matsen F III, eds. *The shoulder.* Philadelphia: WB Saunders, 1990:Fig. 13-10.)

Congenital or Developmental Subluxation or Dislocation

Newlin reported a 25-year-old man who had bilateral congenital posterior dislocation of the medial ends of the clavicle that simulated an intrathoracic mass.[146] Guerin first reported congenital luxations of the sternoclavicular joint in 1841.[82] Nakazato et al. reported on a newborn with a concomitant clavicle fracture and posterior dislocation.[144] Congenital defects with loss of bone substance on either side of the joint can predispose the patient to subluxation or dislocation. Cooper et al. described a patient with scoliosis so severe that the shoulder was displaced forward enough to posteriorly dislocate the clavicle behind the sternum.[38]

Atraumatic or Spontaneous Subluxations and Dislocations

As with classification of glenohumeral joint instability, the importance of distinguishing between traumatic and atraumatic instability of the sternoclavicular joint must be recognized if complications are to be avoided. The vast majority of spontaneous or atraumatic dislocations are anterior, with only a few cases reported in the literature of atraumatic posterior dislocations.

Anterior

Rowe described several patients who had undergone one or more unsuccessful attempts to stabilize the sternoclavicular joint.[182] In all cases, the patient was able to voluntarily dislocate the clavicle after surgery. In addition, he has described several young patients who were able to "flip the clavicle out and back in" without elevation of the arms.

In our experience, spontaneous subluxations and dislocations of the sternoclavicular joint are seen most often in patients under 20 years of age, and more often in females. Sadr and Swann reported on 22 patients with atraumatic anterior dislocations.[185] The majority of patients were middle-aged females presenting with a "lump" in the anterior portion of the neck. In no case was the correct diagnosis made by the referring physician.

Without significant trauma, one or both of the medial clavicles spontaneously displace anteriorly during abduction or flexion to the overhead position (Fig. 33-29). The clavicle reduces when the arm is returned to the side. Patients seem to have only one symptom: The medial end of the clavicle subluxates or dislocates anteriorly when they raise their arms over their head. This occurs spontaneously and without any significant trauma. Many of these patients have the characteristic finding of generalized ligamentous laxity (i.e., hyperextension of the elbows, knees, and fingers, as well as hypermobility of the glenohumeral joints) (Fig. 33-30). This problem might be considered voluntary or involuntary, because it occurs whenever the patient raises the arms to the overhead position. Some patients seen for another shoulder problem are completely unaware that with the overhead motion the medial end of the clavicle subluxates or dislocates.

In the review by Rockwood and Odor of 37 patients with spontaneous atraumatic subluxation, 29 were managed without surgery and eight were treated (elsewhere) with surgical reconstruction.[178] With an average follow-up of more than 8 years, all 29 nonoperated patients were doing just fine without limitations of activity or lifestyle. The eight patients treated with surgery had increased pain, limitation of activity, alteration of lifestyle, persistent instability, and significant scars. In many instances, before reconstruction or resection, these patients had minimal discomfort and excellent range of motion and only complained of a

Figure 33-30 This patient has developed spontaneous subluxation of her sternoclavicular joints. She also has generalized ligamentous laxity of the wrists, fingers, and elbows.

"bump" that slipped in and out of place with certain motions. Postoperatively, these patients still had the bump, along with scars and painful range of motion (Fig. 33-31). Twenty-two patients with atraumatic anterior dislocations were treated nonoperatively by Sadr and Sawnn with resolution of their symptoms.[185] They emphasized the importance of reassuring the patient that this is a benign condition and did not advocate surgery.

Only occasionally does the patient with atraumatic anterior displacement complain of pain during the displacement. Because it is difficult to stabilize the joint and prevent the subluxation or dislocation and end up with a pain-free range of motion, we manage the problem with skillful neglect. The anatomy of the problem is explained to the patient and the family. We explain further that surgery is of little benefit, that they should discontinue the voluntary aspect of the dislocation, and that in time either the symptoms will disappear or they will completely forget that the dislocation is a problem.

Posterior

There are only three radiographically documented atraumatic posterior dislocations of the sternoclavicular joint in the literature.[109,138,139] In the 1800s and early 1900s, three others were described but there was no radiographic confirmation. In 1824, Cooper described a posterior dislocation that occurred spontaneously in a patient with severe scoliosis.[39] In 1911, Preiser reported on a young girl with an atraumatic dislocation.[165] In 1903, Katzenstein described a manual laborer with a slow spontaneous posterior dislocation.[106]

More recently Martin et al. described a spontaneous posterior dislocation in a 50-year-old female.[138] The patient presented with pain and dysphagia, and a posterior dislocation was confirmed with a CT scan. A closed reduction was attempted 5 days after presentation. Although a palpable "clunk" was felt, a postreduction CT scan revealed a persistent posterior dislocation. The joint was left dislocated and she was managed nonoperatively with resolution of her symptoms within a year. Martinez et al. described a 19-year-old female with a radiographically confirmed atraumatic posterior dislocation treated successfully with operative stabilization.[139] Finally, Kayias et al. reported on a 30-year-old male with a radiographically confirmed posterior dislocation treated successfully 10 days out with a closed reduction.[109]

Traumatic Injuries of the Sternoclavicular Joint

Traumatic injuries of the sternoclavicular joint are rare. Undoubtedly, anterior dislocations of the sternoclavicular joint are much more common than the posterior type. It is a diagnosis that can be easily overlooked, especially when the dislocation is in the posterior direction.[40,113,210,224,225] However, the ratio of anterior to posterior dislocations is only rarely reported. Theoretically, one could survey the literature and develop the ratio of anterior to posterior dislocations, but most of the published material on sternoclavicular dislocations is on the rare posterior dislocation. Of the references listed at the end of this chapter that address injuries of the sternoclavicular joint, more than 60% discuss only posterior dislocations and their various complications. The largest series from a single institution is reported by Nettles and Linscheid, who studied 60 patients with sternoclavicular dislocations (57 anterior and three posterior).[145] This gives a ratio of anterior dislocations to posterior dislocations of the sternoclavicular joint of approximately 20:1. Waskowitz reviewed 18 cases of sternoclavicular dislocations, none of which was posterior.[217] However, in our series of 185 traumatic sternoclavicular injuries, there have been 135 patients with anterior dislocation and 50 patients with posterior dislocation.

In 1896, Hotchkiss reported a bilateral traumatic dislocation of the sternoclavicular joint.[89] A 28-year-old man was run over by a cart and suffered an anterior dislocation of the right shoulder and a posterior dislocation of the left one. The senior author has treated four cases of bilateral sternoclavicular dislocation.

To our knowledge, the first reported case of dislocation of both ends of the clavicle was mentioned by Porral in

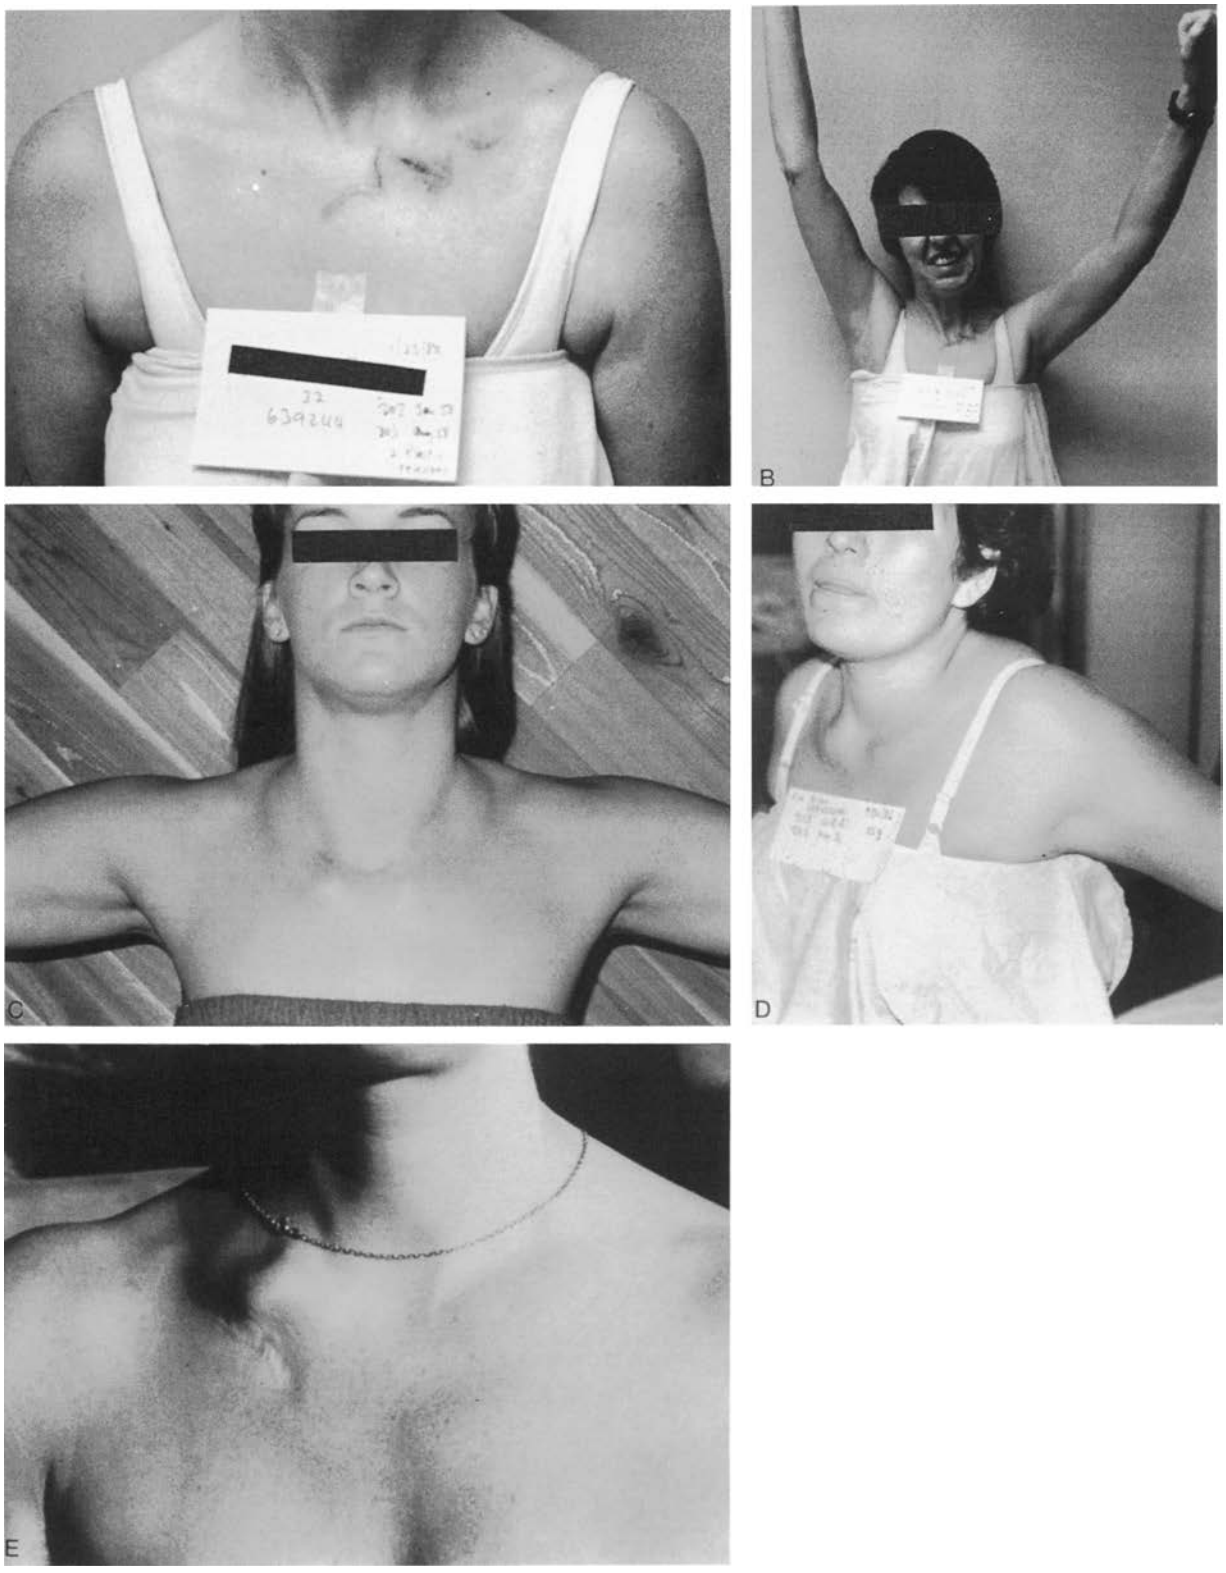

Figure 33-31 Patients treated with surgery for spontaneous, atraumatic subluxation of the sternoclavicular joint had increased pain, limitation of activity, alteration of lifestyle, persistent instability of the joint, and a significant scar. **(A,B)** Not only was the cosmetic scarring a problem, but motion and pain were worse than before the reconstruction. **(C,D)** Despite surgical reconstruction, both patients shown here had persistent subluxation and pain. **(E)** This patient had bilateral spontaneous, atraumatic subluxation of the sternoclavicular joints. Following reconstruction, the right shoulder continued to subluxate, was painful, and significantly altered the patient's lifestyle. The left shoulder had minimal subluxations and was essentially asymptomatic. (Reprinted with permission from Rockwood CA, Matsen F III, eds. *The shoulder.* Philadelphia: WB Saunders, 1990:Fig. 13-30.)

1831.[164] In 1923, Beckman reported a single case and reviewed the literature on 15 cases that had been previously reported.[12] With the exception of this patient, all patients had been treated nonoperatively with acceptable function. In one patient, a brachial plexus neuropathy developed and was treated by excision of a portion of the clavicle. Until recently, to our knowledge, only four additional cases have been reported.[97,167] In 1990, Rockwood and associates reported on six patients who had a dislocation of both ends of the clavicle (an anterior dislocation of the sternoclavicular joint).[179] Two patients who had fewer demands on the shoulder did well with only minor symptoms after nonoperative management. The other four patients had persistent symptoms that were localized to the acromioclavicular joint. Each of these patients had a reconstruction of the acromioclavicular joint that resulted in a painless, full range of motion and a return to normal activity.

Mechanism of Injury

Because the sternoclavicular joint is subject to practically every motion of the upper extremity, and because the joint is so small and incongruous, one would think that it would be the most commonly dislocated joint in the body. However, the ligamentous supporting structure is so strong and so well designed that it is, in fact, one of the least commonly dislocated joints in the body. A traumatic dislocation of the sternoclavicular joint usually occurs only after tremendous forces, either direct or indirect, have been applied to the shoulder.

Direct Force

When a force is applied directly to the anteromedial aspect of the clavicle, the clavicle is pushed posteriorly behind the sternum and into the mediastinum (Fig. 33-32). This may occur in a variety of ways: One athlete jumps on another athlete lying on his back, and the knee of the jumper lands directly on the medial end of the clavicle; a kick is delivered to the front of the medial clavicle; a person is run over by a vehicle; or a person is pinned between a vehicle and a wall (Fig. 33-33). Because of our anatomy, it would be most unusual for a direct force to produce an anterior sternoclavicular dislocation.

Indirect Force

A force can be applied indirectly to the sternoclavicular joint from the anterolateral or posterolateral aspects of the shoulder. This is the most common mechanism of injury to the sternoclavicular joint. Mehta and coworkers reported that three of four posterior sternoclavicular dislocations were produced by indirect force, and Heinig reported that indirect force was responsible for eight of nine cases of

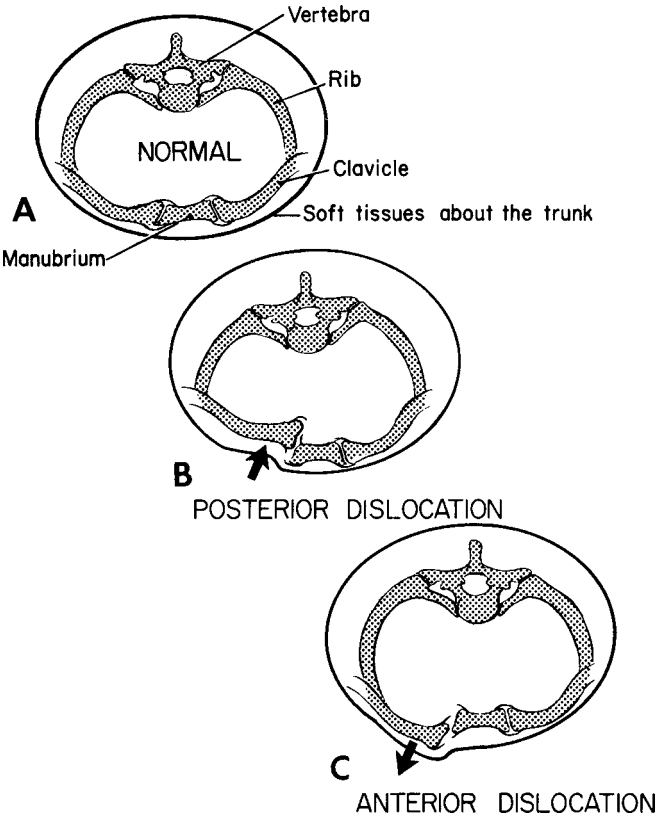

Figure 33-32 Cross-sections through the thorax at the level of the sternoclavicular joint. **(A)** Normal anatomic relationships. **(B)** Posterior dislocation of the sternoclavicular joint. **(C)** Anterior dislocation of the sternoclavicular joint.

posterior sternoclavicular dislocations.[86141] It was the most common mechanism of injury in our series of 185 patients. If the shoulder is compressed and rolled forward, an ipsilateral posterior dislocation results; if the shoulder is compressed and rolled backward, an ipsilateral anterior dislocation results (Fig. 33-34). One of the most common causes we have seen is a pile-on in a football game. In this instance, a player falls on the ground, landing on the lateral shoulder; before he can get out of the way, several players pile on top of his opposite shoulder, which applies significant compressive force on the clavicle down toward the sternum. If, during the compression, the shoulder is rolled forward, the force directed down the clavicle produces a posterior dislocation of the sternoclavicular joint. If the shoulder is compressed and rolled backward, the force directed down the clavicle produces an anterior dislocation of the sternoclavicular joint. Other types of indirect forces that can produce sternoclavicular dislocation are a cave-in on a ditch-digger with lateral compression of the shoulders by the falling dirt; lateral compressive forces on the shoulder when a person is pinned between a vehicle and a wall; and a person's falling on the outstretched abducted arm, which drives the shoulder medially in the same manner as a lateral compression on the shoulder.

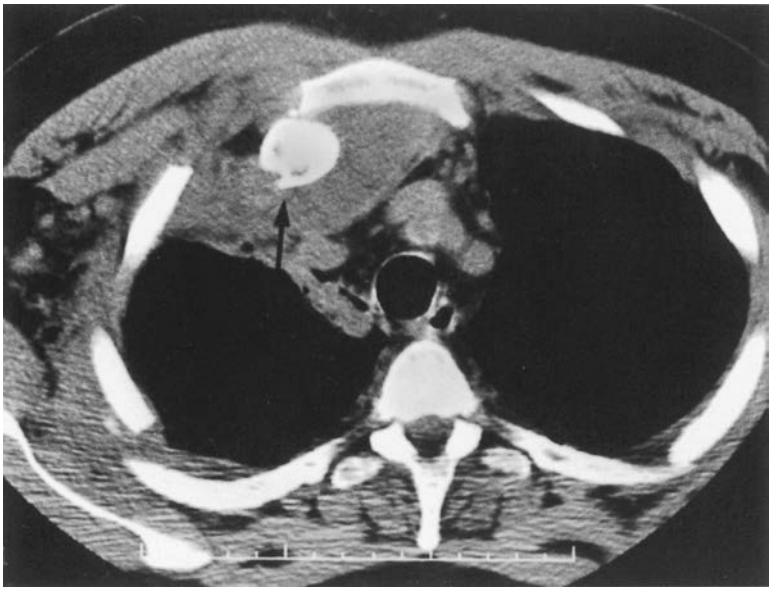

Figure 33-33 Computed axial tomogram of a posterior sternoclavicular joint dislocation that occurred when the driver's chest impacted the steering wheel during a motor vehicle accident. The vehicle was totaled, and the steering wheel was fractured from the driving column. (From Wirth MA, Rockwood CA. Injuries to the sternoclavicular joint. In: Rockwood CA, Green DP, Bucholz RW, Hechman JD, eds. *Fractures in adults*. Philadelphia: JB Lippincott, 1996.)

Most Common Causes of Injury

The most common cause of dislocation of the sternoclavicular joint is vehicular accidents; the second is an injury sustained during participation in sports.[4,137,157,158] Omer reviewed patients from 14 military hospitals and found 82 cases of sternoclavicular dislocations with 80% of these occurring secondary to motor vehicle accidents.

Probably the youngest patient to have a traumatic sternoclavicular dislocation was reported by Wheeler and associates.[220] They described an anterior dislocation in a 7-month-old infant. The injury occurred when she was lying on her left side and her older brother accidentally fell on her, compressing her shoulders together. The closed reduction was unstable, and the child was immobilized in a figure-eight bandage for 5 weeks. At 10 weeks she had full range of motion, and there was no evidence of instability. The senior author has seen an anterior injury in a 3-year-old that occurred as a result of an automobile accident (Fig. 33-35).

Sprains

Acute sprains to the sternoclavicular joint can be classified as mild, moderate, or severe. In a mild sprain, all the ligaments are intact and the joint is stable. In a moderate sprain, there is subluxation of the sternoclavicular joint. The capsular, intraarticular disk, and costoclavicular ligaments may be partially disrupted. The subluxation may be anterior or posterior. In a severe sprain or frank dislocation,

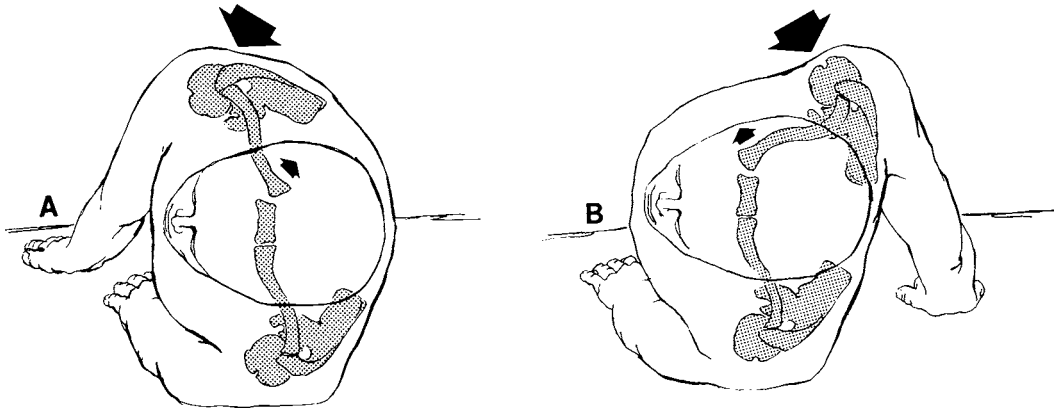

Figure 33-34 Mechanisms that produce anterior or posterior dislocations of the sternoclavicular joint. **(A)** If the patient is lying on the ground and a compression force is applied to the posterolateral aspect of the shoulder, the medial end of the clavicle will be displaced posteriorly. **(B)** When the lateral compression force is directed from the anterior position, the medial end of the clavicle is dislocated anteriorly.

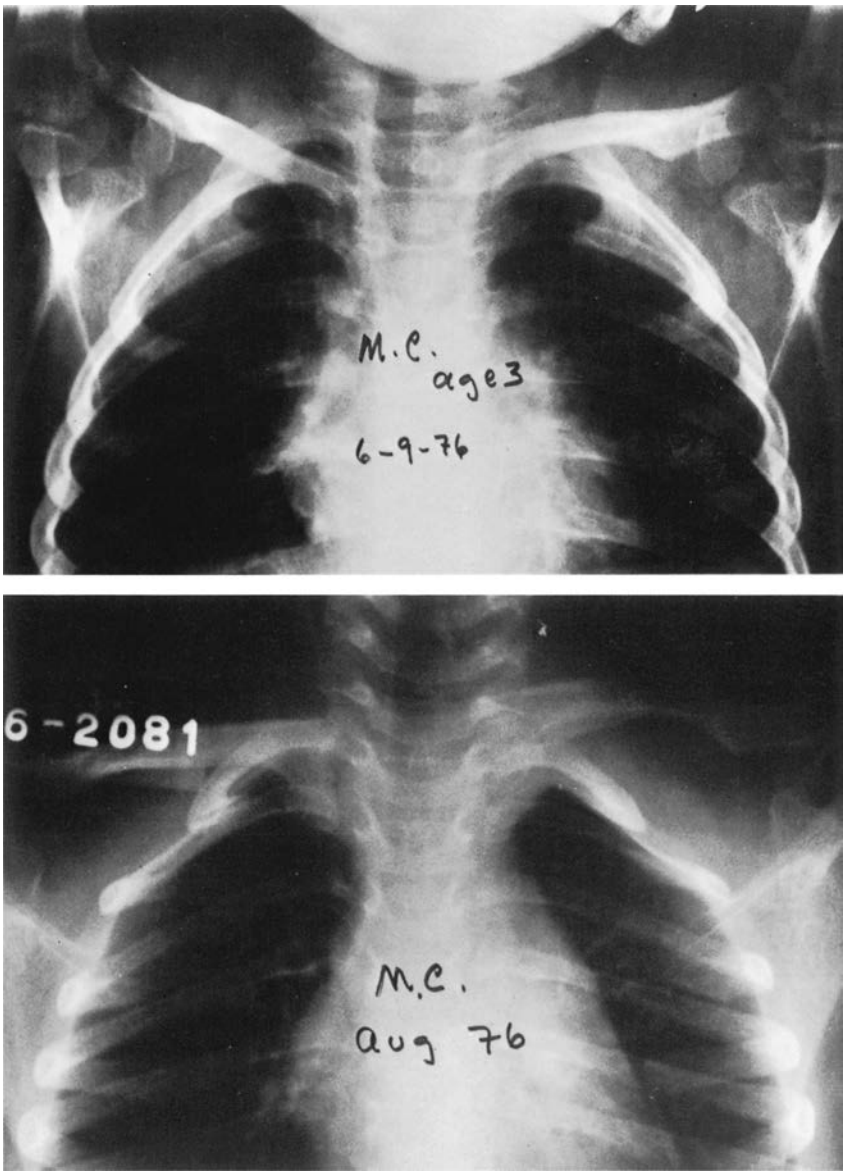

Figure 33-35 X-rays of a 3-year-old child with traumatic anterior dislocation of the left sternoclavicular joint. The chest film demonstrates that the left clavicle is superior to the right, suggesting an anterior displacement of the left medial clavicle.

there is complete disruption of the sternoclavicular ligaments, and the dislocation may be anterior or posterior.

Mild Sprain

In a mild sprain, the ligaments of the joint are intact. The patient complains of a mild to moderate amount of pain, particularly with movement of the upper extremity. The joint may be slightly swollen and tender to palpation, but instability is not noted. The mildly sprained sternoclavicular joint is stable but painful. Application of ice for the first 12 to 24 hours, followed by heat, is helpful. The upper extremity should be immobilized in a sling for 3 to 4 days; then, gradually the patient can regain use of the arm in everyday activities. The senior author undertook a fascinating case of a young woman who, after childbirth, developed aching pain in both sternoclavicular joints. Her bra size, over a period of 4 weeks, had jumped from a 36B to a 38EE. The increase in weight depressed both shoulders and produced pain while upright in both sternoclavicular joints. The discomfort was completely relieved by pushing both elbows up, thus elevating the distal clavicles, which in turn took the strain off her sternoclavicular joints. She was requested to consult her gynecologist and surgeon to determine the quickest way to reduce the size of her breasts.

Moderate Sprain (Subluxation)

A moderate sprain results in a subluxation of the sternoclavicular joint. The ligaments are either partially disrupted or severely stretched. Swelling is noted and pain is marked, particularly with any movement of the arm. Anterior or posterior subluxation may be obvious to the examiner

when the injured joint is compared with the normal sternoclavicular joint. For subluxation of the sternoclavicular joint, application of ice is recommended for the first 12 hours, followed by heat for the next 24 to 48 hours. The joint may be subluxed anteriorly or posteriorly, which may be reduced by drawing the shoulders backward as if reducing and holding a fracture of the clavicle. A clavicle strap can be used to hold up the shoulder and to prevent motion of the arm. The patient should be protected from further injury for 4 to 6 weeks. De Palma[46] has suggested a plaster figure-eight dressing, and McLaughlin[140] has recommended the same type of treatment that would be used for fracture of the clavicle, with the addition of a sling to support the arm. We often use a soft, padded figure-eight clavicle strap to gently hold the shoulders back to allow the sternoclavicular joint to rest. The harness can be removed after a week or so; then the arm is placed in a sling for about another week, or the patient is allowed to return gradually to everyday activities.

Dislocations

The patient with a sternoclavicular dislocation has severe pain that is increased with any movement of the arm, particularly when the shoulders are pressed together by a lateral force. The patient usually supports the injured arm across the trunk with the normal arm. The affected shoulder appears to be shortened and thrust forward when compared with the normal shoulder. The head may be tilted toward the side of the dislocated joint. The discomfort increases when the patient is placed in the supine position, at which time it will be noted that the involved shoulder will not lie back flat on the table.

Anterior Dislocation

With an anterior dislocation, the medial end of the clavicle is visibly prominent anterior to the sternum (Fig. 33-36) and can be palpated anterior to the sternum. It may be fixed anteriorly or may be quite mobile.

There still is some controversy regarding the treatment of acute or chronic anterior dislocation of the sternoclavicular joint. In 1990, de Jong and Sukul reported long-term follow-up results in 10 patients with traumatic anterior sternoclavicular dislocations.[43] All patients were treated nonoperatively with analgesics and immobilization. The results of treatment were good in seven patients, fair in two patients, and poor in one patient at an average follow-up of 5 years. Nettels and Linscheid reported on 14 patients with an anterior dislocation who were treated with a closed reduction.[145] Eleven had no recurrence or pain. Other reports also support nonoperative treatment for anterior dislocations.[189] Some have advocated various forms of operative stabilization for those patients that remain symptomatic.[19,62]

Method of Closed Reduction. Closed reduction of the sternoclavicular joint may be accomplished with local or general anesthesia or, in stoic patients, without anesthesia. Most investigators recommend the use of narcotics or muscle relaxants. The patient is placed supine on the table, lying on a 3- to 4-in. thick pad between the shoulders. In this position, the clavicle may reduce with direct gentle pressure over the anteriorly displaced clavicle. However, when the pressure is released, the clavicle might redislocate. Sometimes, the physician will need to push both shoulders back onto the table while an assistant applies pressure to the anteriorly displaced clavicle. Laidlaw treated an interesting case of a patient who had a dislocated clavicle. The sternoclavicular joint was dislocated anteriorly and was mildly symptomatic.[121] The acromioclavicular joint was most symptomatic and was treated by excision of the distal clavicle. Surprisingly, the anteriorly dislocated sternoclavicular joint reduced and became pain free. Although some if not many patients will redislocate anteriorly, we still believe an attempt at a closed reduction is warranted.

Postreduction Care. If, with the shoulders held back, the sternoclavicular joint remains reduced, the shoulders can be stabilized with a soft figure-eight dressing, a commercial clavicle strap harness, or a plaster figure-eight cast. Some investigators recommend a bulky pressure pad over the anteromedial clavicle that is held in place with elastic

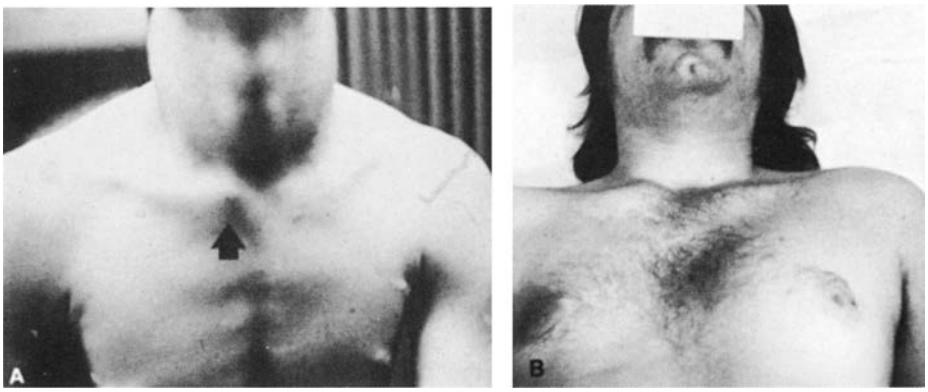

Figure 33-36 **(A)** An anterior dislocation of the right sternoclavicular joint is clinically evident *(arrow)*. **(B)** When the clavicles are viewed from around the level of the patient's knees, it is apparent that the right clavicle is dislocated anteriorly.

tape. A sling might be used, because it holds up the shoulder and prevents motion of the arm. Immobilization should be maintained for at least 6 weeks, and then the arm should be protected for another 2 weeks before strenuous activities are undertaken. If the sternoclavicular joint redislocates when the reduction pressure is released, a figure-eight dressing or a sling can be used until the patient's symptoms subside.

Although some investigators have recommended operative repair of anterior dislocations of the sternoclavicular joint, we believe that operative stabilization should be used with great caution as most patients will do well with nonoperative treatment even if the joint remains dislocated. The technique of operative stabilization for anterior dislocations is the same as those for posterior dislocations and is described later in that section. In most cases of an anterior dislocation the risks of surgery outweigh the potential benefits. Certainly in children, in whom many if not most of the injuries are physeal fractures, a nonoperative approach should be strongly considered.

Physeal Injuries

As described earlier in this chapter, the epiphysis on the medial end of the clavicle is the last epiphysis in the body to appear on x-ray and the last one to close. The epiphysis on the medial end of the clavicle does not appear on x-rays until about the 18th year of life and does not unite with the clavicle until the 23rd to 25th year.

This is important to remember, because many so-called dislocations of the sternoclavicular joint are not dislocations but physeal injuries.[22,45,68,93,124,128,162,192,226,229] Most of the anterior injuries that we have treated in patients up to 25 years of age are not dislocations of the sternoclavicular joint but type I or II physeal injuries, which heal and remodel without operative treatment. In time, the remodeling process eliminates any bone deformity or displacement.

Even though most of the posterior dislocations in this age group also represent physeal injuries, a reduction should be attempted. This is to prevent the potential complications of an unreduced posterior dislocation such as compression of the posterior neurovascular structures, trachea, and esophagus. If the posterior dislocation cannot be reduced closed and the patient is having no significant symptoms, the displacement can be observed while remodeling occurs.

Zaslav and associates have reported successful treatment of a posteriorly displaced medial clavicle physeal injury in an adolescent athlete with CT documentation of remodeling, most probable within an intact periosteal tube.[229] Because of its high osteogenic potential, spontaneous healing and remodeling to the preinjury "reduced" position can occur within this periosteal conduit. Similarly, Hsu and associates reported successful treatment of a posterior epiphyseal fracture dislocation of the medial end of the clavicle in a 15-year-old patient.[93]

If the posterior displacement is symptomatic and cannot be reduced closed, the displacement must be reduced during surgery (Fig. 33-37). At the time of surgery, the unossified or ossified epiphyseal disk, depending on the age of the patient, stays with the sternum. Anatomically, the epiphysis is lateral to the articular disk ligament, and it is held in place by the capsular ligament and can be mistaken for the intraarticular disk ligament.

For posteriorly displaced clavicles, the periosteal sleeve is usually still intact anteriorly. A Darrach retractor can be placed in the physeal fracture site and can be used as a "shoe horn" to reduce the clavicle back into the physis. After reduction the clavicle and physis are usually inherently stable and the periosteum is simply closed. After

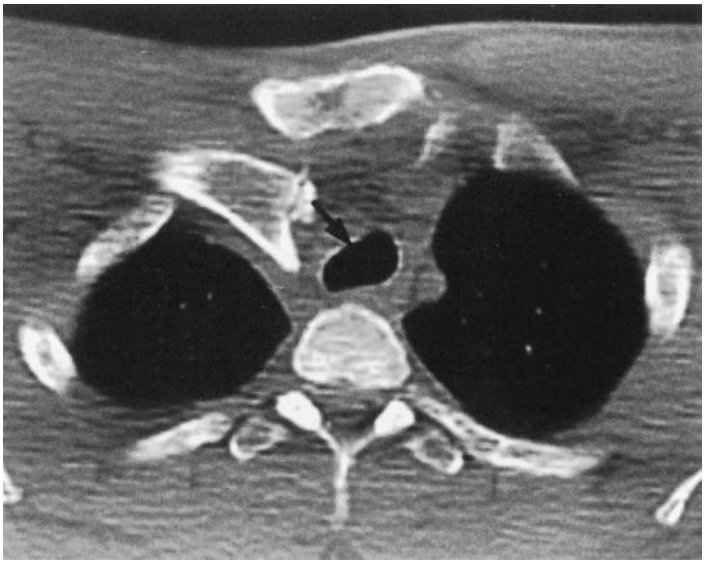

Figure 33-37 Computed tomography scan of a 19-year-old patient who was involved in a motor vehicle accident and presented with complaints of chest pain and a "choking" sensation that was exacerbated by lying supine. Note the physeal injury of the medial clavicle and compression of the trachea (*arrow*). (From Wirth MA, Rockwood CA. Injuries to the sternoclavicular joint. In: Rockwood CA, Green DP, Bucholz RW, Hechman JD, eds. *Fractures in adults.* Philadelphia: JB Lippincott, 1996.)

reduction, the shoulders are held back with a figure-eight strap or dressing for 3 to 4 weeks. Gentle active assisted range-of-motion exercises are initiated with full active motion started at 6 weeks. It is important to remember that open reduction of the physeal injury is seldom indicated, except for an irreducible posterior displacement in a patient with significant symptoms of compression of the vital structures in the mediastinum.

Posterior Dislocation

The patient with a posterior dislocation has more pain than does a patient with an anterior dislocation. The anterosuperior fullness of the chest produced by the clavicle is less prominent and visible when compared with the normal side. The usually palpable medial end of the clavicle is displaced posteriorly. The corner of the sternum is easily palpated as compared with the normal sternoclavicular joint. Venous congestion may be present in the neck or in the upper extremity. Breathing difficulties, shortness of breath, or a choking sensation may be noted.[133] Circulation to the ipsilateral arm may be decreased. The patient may complain of difficulty in swallowing or a tight feeling in the throat, or may be in a state of complete shock or possibly have a pneumothorax.

We have seen a number of patients who clinically appeared to have an anterior dislocation of the sternoclavicular joint but on x-ray studies were shown to have complete posterior dislocation. The point is that one cannot always rely on the clinical findings of observing and palpating the joint to make a distinction between anterior and posterior dislocations. This emphasizes the need for more detailed radiographic studies such as a CT scan. It has been noted by several authors that this is a diagnosis that can be easily missed, and there should be a heightened clinical suspicion for any patient with the above clinical symptoms.[40,48,113,210,224,225] Multiple authors have also described devastating complications with posterior dislocations. Venous compression of the brachiocephalic and subclavian veins has been reported.[56,58,154,200] Arterial compression has also been described.[9074147] Wasylenko and Busse reported a case of a tracheoesophageal fistula that occurred secondary to a chronic posterior dislocation.[218] Other authors have described thoracic outlet syndrome in conjunction with posterior dislocations.[73,98]

A careful examination of the patient is extremely important. Clearly complications are common with posterior dislocation of the sternoclavicular joint, and the patient should receive prompt attention. A careful history and physical examination should be undertaken to rule out damage to the pulmonary and vascular systems. The sternoclavicular joint must be carefully evaluated by all available x-ray techniques and computed tomography, including, when indicated, combined aortogram–CT scan for potential vascular injuries (Figs. 33-38 and 33-39). If specific

Note the large neck of the pseudoaneurysm, which measured approximately 1 cm in diameter (*arrow*). (From Wirth MA, Rockwood CA. Injuries to the sternoclavicular joint. In: Rockwood CA, Green DP, Bucholz RW, Hechman JD, eds. *Fractures in adults.* Philadelphia: JB Lippincott, 1996.)

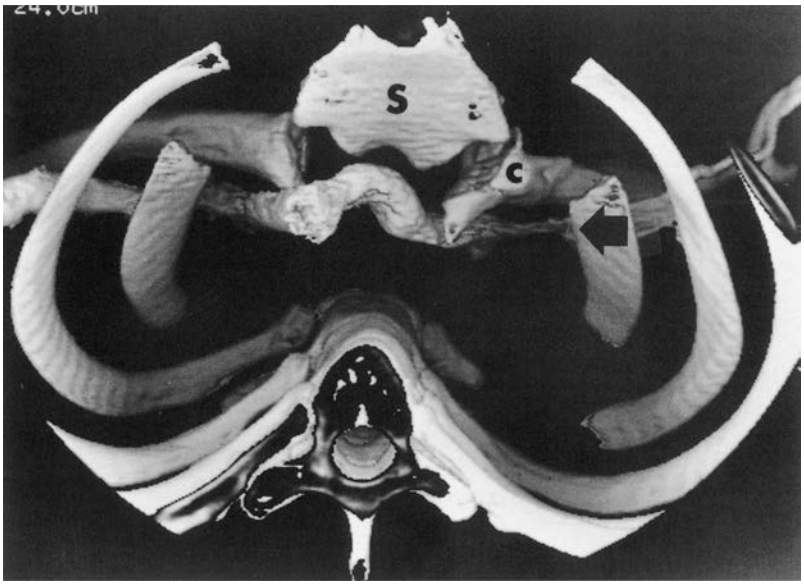

Figure 33-39 Contrast material–enhanced computed tomography scan of 16-year-old boy who presented with left arm swelling and cyanosis 14 months after a wrestling injury. A stenotic lesion of the subclavian vein can be seen adjacent to a posteriorly displaced physeal fracture of the medial clavicle (*arrow*). Note the relationship between the posteriorly displaced clavicle (*C*) and sternum (*S*). (Reprinted with permission from Wirth MA, Rockwood CA. Acute and chronic traumatic injuries of the sternoclavicular joint. *J Am Acad Orthop Surg* 1996;4:268–278.)

complications are noted, appropriate consultants should be called in before reduction is performed. Worman and Leagus reported a posterior dislocation of the sternoclavicular joint, in which it was noted at surgery that the displaced clavicle had put a hole into the right pulmonary artery.[223] The clavicle had prevented exsanguination, because the vessel was still impaled by the clavicle. Had a closed reduction been performed in the emergency department, the result could have been disastrous. Cooper and coworkers reported a posterior sternoclavicular dislocation that transected the internal mammary artery and lacerated the brachiocephalic vein.[38] The vascular injuries were associated with fractures of the anterior ends of the first to third ribs and marked posterior instability of the medial end of the clavicle. The brachiocephalic vein was repaired, but the posteriorly displaced medical clavicle impinged on the suture line. To maintain reduction of the sternoclavicular joint, a novel method of stabilization was employed using an external fixator.

From a review of the earlier literature, it would appear that the treatment of choice for posterior sternoclavicular dislocation was by operative procedures. However, since the 1950s, the treatment of choice has been closed reduction.[25,63,86,228] Some investigators, who had previously performed open reductions, reported that they were amazed at how easily the dislocation reduced under direct vision, and thereafter they used closed reductions with complete success. Many different techniques have been described for closed reduction of a posterior dislocation of the sternoclavicular joint. General anesthesia is usually required for reduction of a posterior dislocation of the sternoclavicular joint, because the patient has so much pain and has muscle spasms. However, for the stoic patient, some investigators have performed the reduction under intravenous narcotics and muscle relaxants. Heinig has successfully used local anesthesia in a posterior dislocation reduction.[86]

Abduction Traction Technique. For the abduction traction technique, the patient is placed on his or her back, with the dislocated shoulder near the edge of the table. A 3- to 4-in.–thick sandbag is placed between the shoulders (Fig. 33-40). Lateral traction is applied to the abducted arm, which is then gradually brought back into extension. This may be all that is necessary to accomplish the reduction. The clavicle usually reduces with an audible snap or pop, and it is almost always stable. Too much extension can bind the anterior surface of the dislocated medial clavicle on the back of the manubrium. Occasionally, it may be necessary to grasp the medial clavicle with one's fingers to dislodge it from behind the sternum. If this fails, the skin is prepared, and a sterile towel clip is used to grasp the medial clavicle to apply lateral and anterior traction (Fig. 33-41).[63,187,228] This has been the most effective technique in our experience.

Adduction Traction Technique. In this technique, the patient is supine on the table with a 3- to 4-in. bolster between the shoulders. Traction is then applied to the arm in adduction, while a downward pressure is exerted on the shoulders. The clavicle is levered over the first rib into its normal position. Buckerfield and Castle reported that this technique has succeeded when the abduction traction technique has failed.[25]

Other Techniques. Heinig and Elting have reported that they accomplished reduction by placing the patient supine

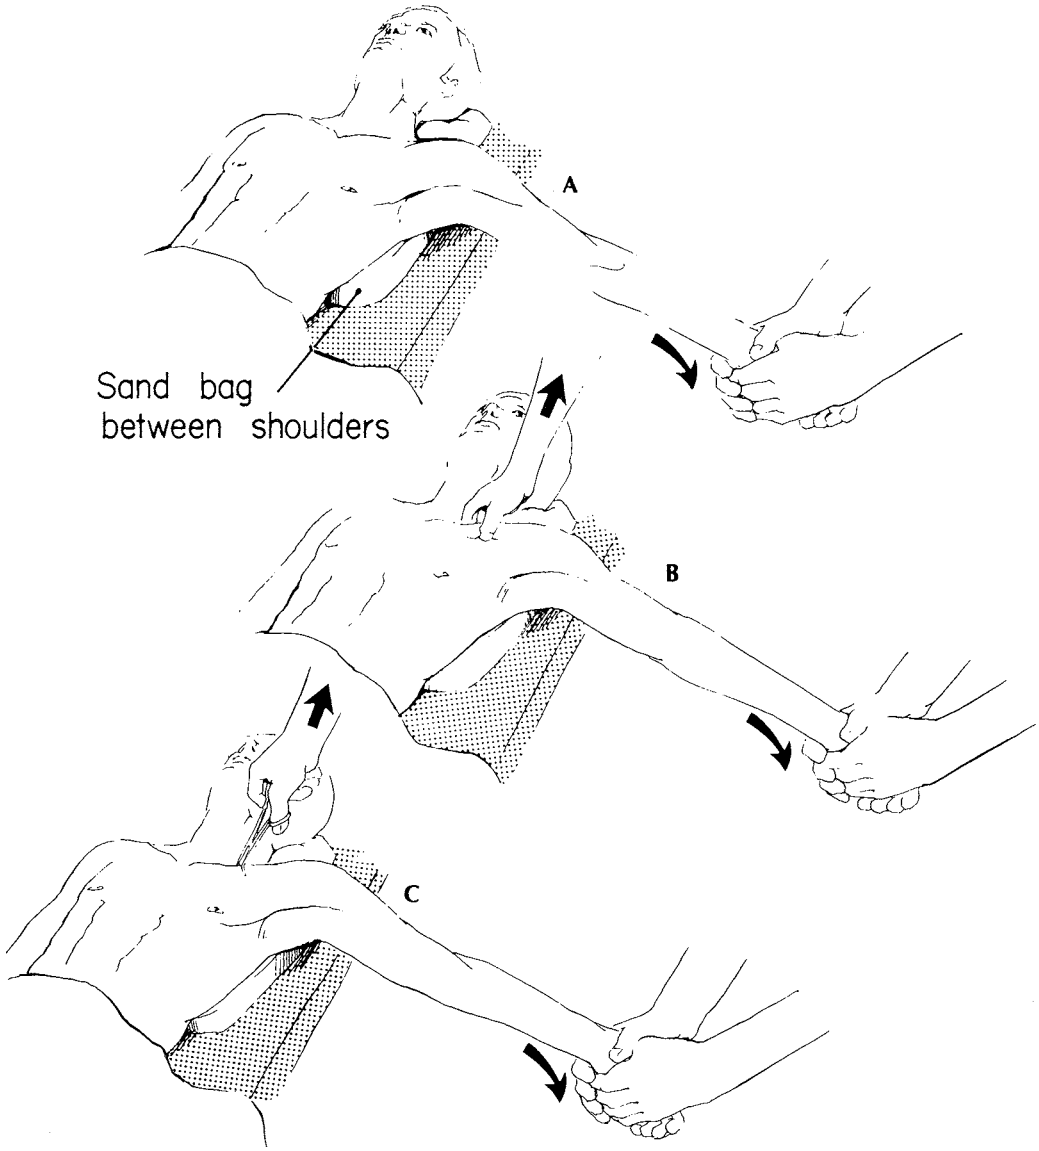

Figure 33-40 Technique for closed reduction of the sternoclavicular joint. **(A)** The patient is positioned supine with a sandbag placed between the two shoulders. Traction is then applied to the arm against countertraction in an abducted and slightly extended position. In anterior dislocations, direct pressure over the medial end of the clavicle may reduce the joint. **(B)** In posterior dislocations, in addition to the traction, it may be necessary to manipulate the medial end of the clavicle with the fingers to dislodge the clavicle from behind the manubrium. **(C)** In stubborn posterior dislocations, it may be necessary to sterilely prepare the medial end of the clavicle and use a towel clip to grasp around the medial clavicle to lift it back into position.

on the table with three of four folded towels between the two shoulders.[57,86] Forward pressure was then applied on both shoulders, which accomplished the reduction. Other investigators have put a knee between the shoulders of the seated patient and, by pulling back on both shoulders, have accomplished a reduction. Stein used skin traction on the abducted and extended arm to accomplish the reduction gently and gradually.[204] Many investigators have reported that closed reduction usually cannot be accomplished after 48 hours. However, others have reported closed reductions as late as 4 and 5 days after the injury.[25]

Postreduction Care. Unlike anterior dislocations, most posterior dislocations are stable after reduction. After reduction, to allow ligament healing, the shoulders should be held back for 4 to 6 weeks with a figure-eight dressing or one of the commercially available figure-eight straps used to treat fractures of the clavicle. Active assisted range-of-motion

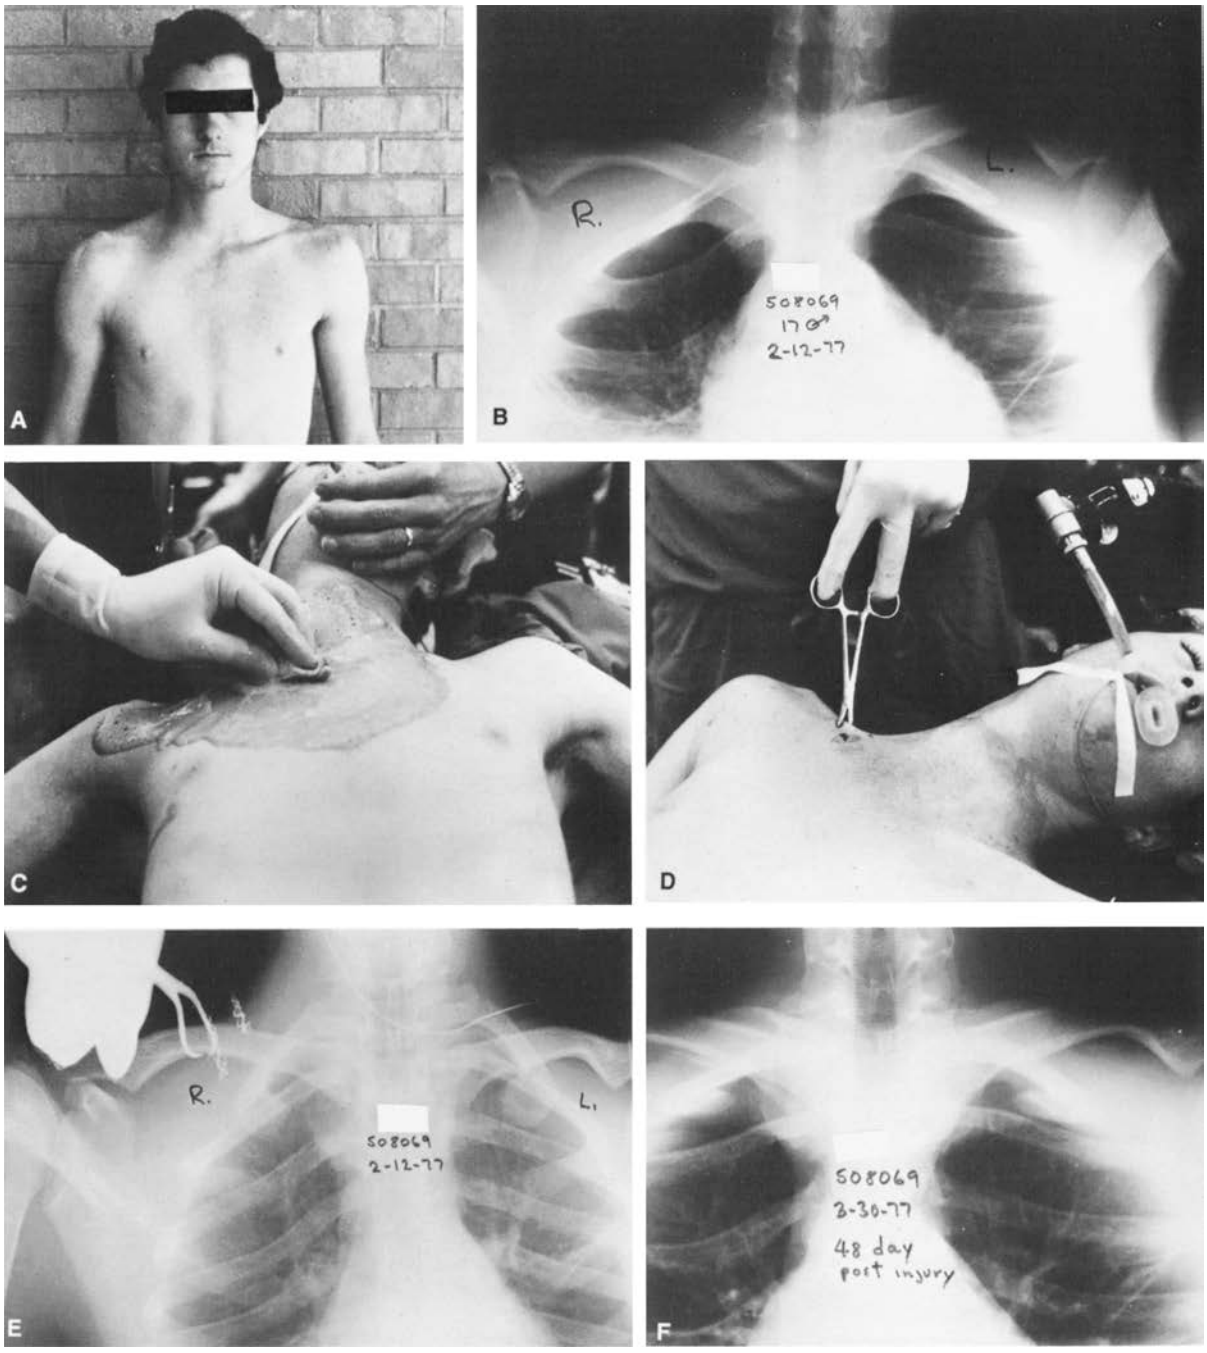

Figure 33-41 Posterior dislocation of the right sternoclavicular joint. **(A)** A 16-year-old boy has a 48-hour-old posterior displacement of the right medial clavicle that occurred from direct trauma to the anterior right clavicle. He noted immediate onset of difficulty in swallowing and some hoarseness in his voice. **(B)** A 40-degree cephalic tilt x-ray film confirmed the posterior displacement of the right medial clavicle, as compared with the left clavicle. Because of the patient's age, this was considered most likely to be a physeal injury of the right medial clavicle. **(C)** Because the injury was 48 hours old, we were unable to reduce the dislocation with simple traction on the arm. The right shoulder was surgically cleansed, so that a sterile towel clip could be used. **(D)** With the towel clip securely around the clavicle and with continued lateral traction, a visible and audible reduction occurred. **(E)** Postreduction x-rays showed that the medial clavicle had been restored to its normal position. The reduction was quite stable, and the patient's shoulders were held back with a figure-eight strap. **(F)** The right clavicle has remained reduced. Note the periosteal new bone formation along the superior and inferior borders of the right clavicle. This is the result of a physeal injury, whereby the epiphysis remains adjacent to the manubrium while the clavicle is displaced out of a split in the periosteal tube.

exercises are initiated at 4 weeks and full active motion by 8 weeks. Full return to sport and activities should be anticipated by 12 weeks.

Recurrent or Unreduced Dislocation

Should closed maneuvers fail in the adult, an operative procedure should be performed, because most adult patients cannot tolerate posterior displacement of the clavicle into the mediastinum. Fig. 33-42 outlines a treatment algorithm for anterior and posterior dislocations. Multiple authors have reported complications following unreduced posterior dislocations.[56,74,102,147,154,200] Gangahar and Flogaites reported a case of late thoracic outlet syndrome following an unreduced posterior dislocation, and Howard and Shafer reported late and significant vascular problems.[73,90] Tircoire and colleagues reported a case of respiratory compromise and dyspnea on exertion in a 65-year-old patient with a posterior sternoclavicular dislocation of 3 months' duration.[212] Rayan reported a thoracic outlet syndrome and brachial plexopathy caused by a chronic posterior sternoclavicular dislocation of 4 years' duration.[170] The injury was presumably missed, due to an associated dislocation of the glenohumeral joint. The patient experienced paresthesias and decreased sensation, and at one time she unknowingly burned her medial forearm with a hot iron. One year following medial clavicle excision and stabilization of the remaining clavicle to the first rib, she was asymptomatic except for mild discomfort related to the glenohumeral joint.

Several of our patients have had unusual complications from traumatic injuries to the sternoclavicular joint. One patient, as the result of a posterior dislocation and rupture of the trachea, developed massive subcutaneous emphysema (Fig. 33-43). Another patient had an anterior dislocation on the right and a posterior dislocation on the left. When first seen, his blood pressure was very low. Following reduction of the posterior dislocation, his blood pressure, as recorded on his monitor, instantly returned to normal (Fig. 33-44). It was theorized that the posteriorly displaced clavicle was irritating some of the vital structures of the mediastinum. The senior author was asked to evaluate a patient who, following a significant injury, complained of swelling and bluish coloration of his left arm after any type of physical activity. He did not have many local sternoclavicular joint symptoms, but by physical examination the left clavicle was displaced posteriorly. CT demonstrated a major posterior displacement of the left clavicle (Fig. 33-45). Because of the marked displacement and the vascular compromise, arteriography combined with CT was performed, which did not reveal any vascular leak. With the help of the chest surgeon, the clavicle was removed from the mediastinum, the medial 1.5 in. were removed, and the shaft was stabilized to the first rib. The greatest displacement we have seen was in a patient with a posteroinferior dislocation of the medial clavicle down into an intrathoracic position.

Worman and Leagus, in an excellent review of the complications associated with posterior dislocations of the sternoclavicular joint, reported that 16 of 60 patients had suffered complications of the trachea, esophagus, or great vessels.[223] We should point out that even though the incidence of complications was 25%, only four deaths have been reported as a result of this injury. Clearly, significant complications can occur with acute and chronic posterior dislocations of the clavicle; therefore, every attempt should be made to reduce a posterior dislocation in the skeletally mature patient.

Surgical Management. Occasionally, following conservative treatment of a subluxation of the sternoclavicular joint, the pain lingers and the symptoms of popping and grating persist. This may require joint exploration. Bateman has commented on the possibility of finding a tear of the intraarticular disk, which should be excised.[10] Duggan reported a case in which, several weeks after an injury to the sternoclavicular joint, the patient still had popping in the joint.[51] Through a small incision, Duggan exposed the capsule and out through the capsule popped the intraarticular disk, which looked like "an avulsed fingernail." Following repair of the capsule, the patient had no more symptoms. The operative procedure should be performed in a manner that disturbs as few of the anterior ligament structures as possible.

For posterior dislocations that fail closed reduction, open reduction is indicated. This should be performed with a thoracic surgeon in the room or on standby notification. The patient lies supine on the table, and the three to four towels or sandbag should be left between the scapulas. The thorax from the superior extent of the neck to the xiphoid process should be prepped on both sides of the sternum. This allows for sterile exposure of the major vessels of the neck and sternotomy to be performed. The upper extremity should be draped free, so that lateral traction can be applied during the open reduction. An anterior incision is used that parallels the superior border of the medial 3 to 4 in. of the clavicle and then extends downward over the sternum just medial to the involved sternoclavicular joint (Fig. 33-46). The trick is to remove sufficient soft tissues to expose the joint but to leave the anterior capsular ligament intact. The reduction usually can be accomplished with traction and countertraction while lifting up anteriorly with a clamp around the medial clavicle. Along with traction and countertraction, it may be necessary to use an elevator to pry the clavicle back to its articulation with the sternum. When the reduction has been obtained, and with the shoulders held back, the reduction and stability should be assessed. If the joint is stable, then it can be managed postoperatively like a closed reduction. If the clavicle is unstable, we recommend reconstruction. The various reconstruction techniques are described below.

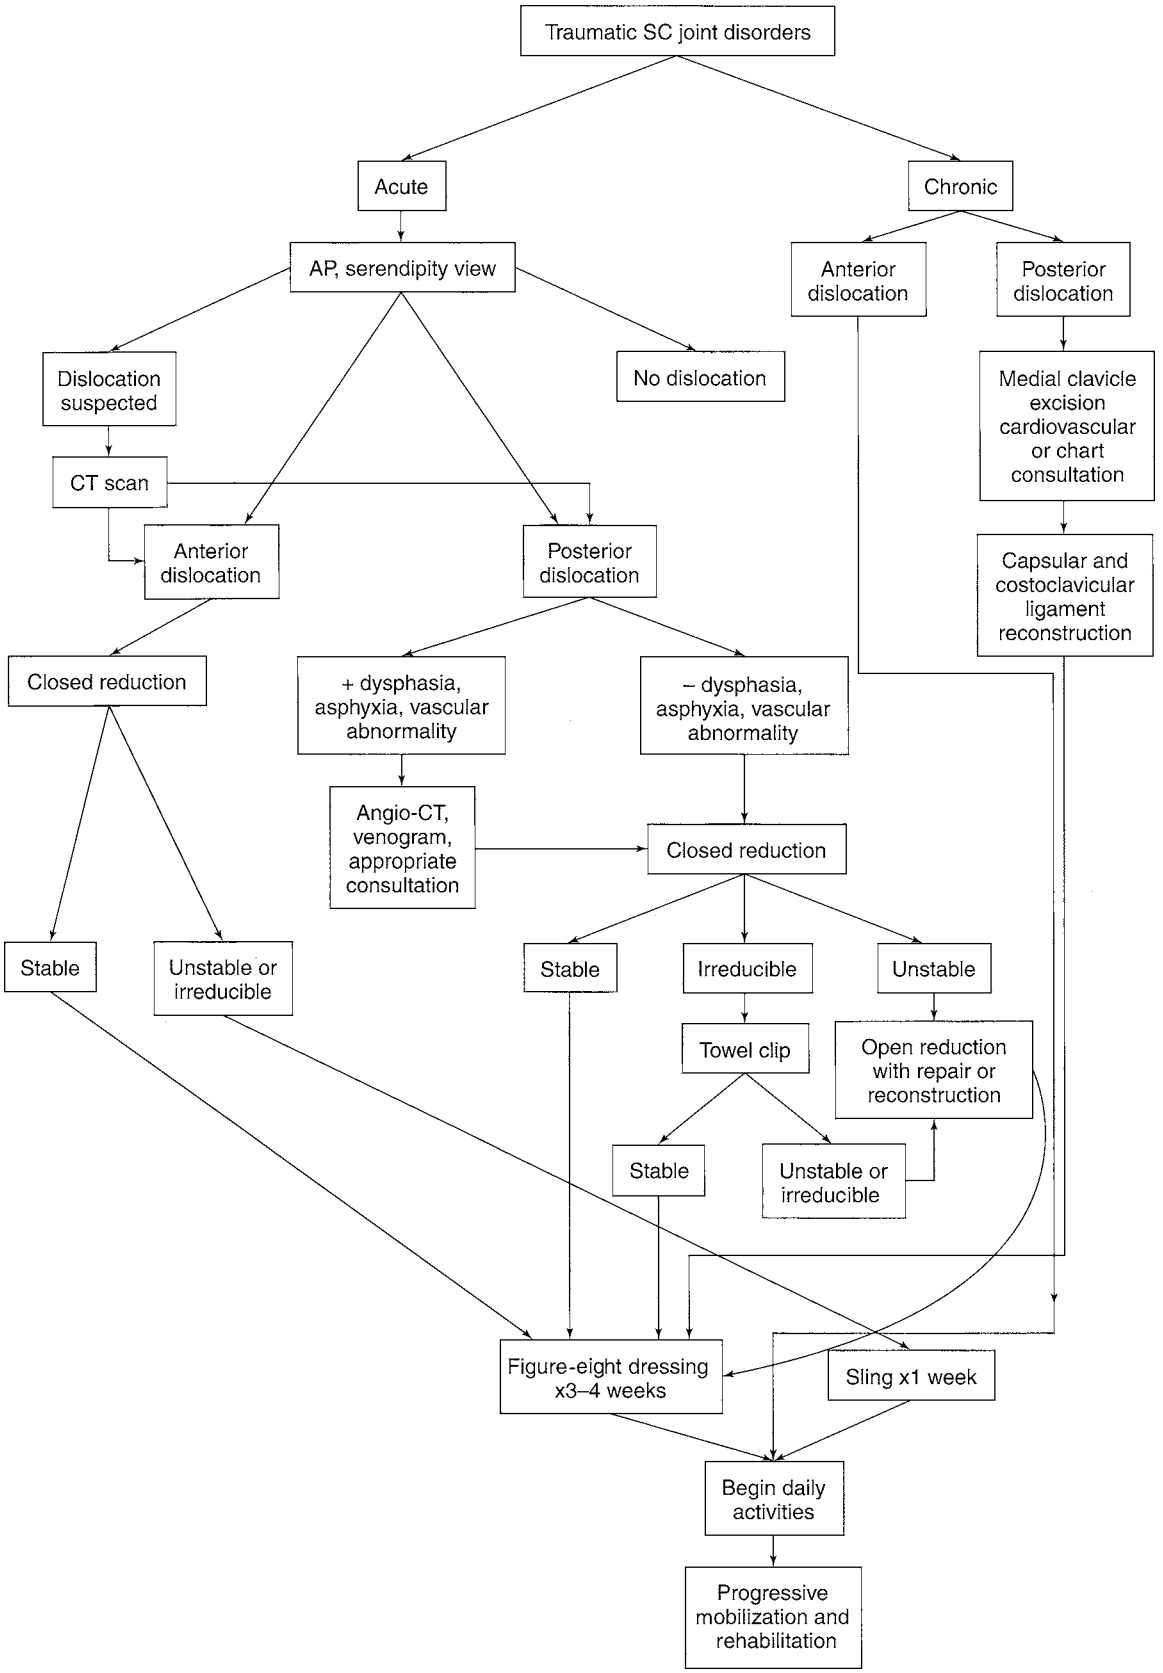

Figure 33-42 Treatment algorithm for traumatic sternoclavicular joint disorders. AP = anteroposterior; CT = computed tomography; SC = sternoclavicular.

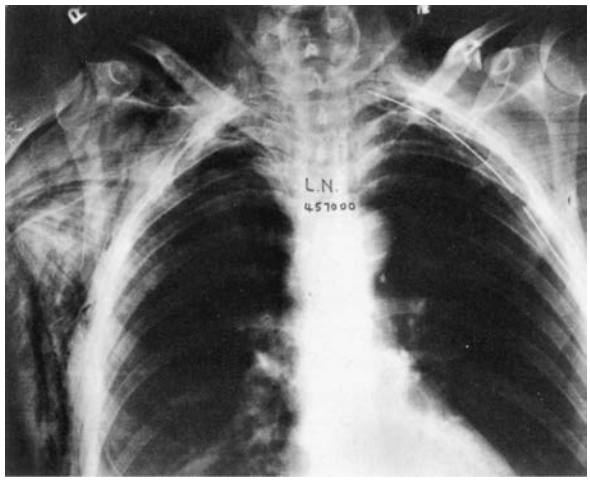

Figure 33-43 Complications of sternoclavicular dislocation. As a result of posterior dislocation of the sternoclavicular joint, the patient had a lacerated trachea and developed massive subcutaneous emphysema.

If degenerative changes become severe in the sternoclavicular joint, excision of the medial end of the clavicle may be required. This is done in a fashion as described for arthritis of the sternoclavicular joint. Again, it should be emphasized that this is analogous to a resection of the lateral end of the clavicle. If there is residual instability with arthritic changes, not only should the medial end of the clavicle be resected, but the joint should also be stabilized as well. Simple resection of the medial end of the clavicle when there is residual instability can result in continued symptoms.

Some of the literature from the 1960s and 1970s recommended stabilization of the sternoclavicular joint with pins. Elting used Kirschner wires to stabilize the joint and supplemented ligament repairs with a short-toe extensor tendon.[57] Denham and Dingley and Brooks and Henning used Kirschner wires.[4522] DePalma recommended repair of the ligaments and stabilized the sternoclavicular joint with one or two Steinmann pins.[46]

Habernek and Hertz; Nutz; Pfister and Weller; Kennedy and Mawhinney; Tagliabue and Riva; Bankart; and Stein avoided the use of pins across the sternoclavicular joint and used loops of various types of suture wires across the joint.[20,46,83,110,151,159,207] Burri and Neugebauer recommended the use of a figure-eight loop of carbon fiber.[27] Maguire; Booth and Roper; Barth and Hagen; and Lunseth and associates reconstructed the sternoclavicular joint using local tendons of the sternocleidomastoid, subclavius, or pectoralis major tendons for repair.[9,19,134,136] Franck et al. reported on the use of a special plate to stabilize the joint.[67] The complications of fixation of the sternoclavicular joint with Kirschner wires or Steinmann pins are horrendous and are discussed in the section on complications.

In 1982, Pfister and Weller recommended open reduction and repair of the ligaments over nonoperative treatment.[159] In symptomatic chronic dislocation or nontraumatic cases, they recommended the use of autogenous grafts between the sternum and the first rib without placing Kirschner wires across the sternoclavicular joint. In 1988, Fery and Sommelet reported 49 cases of dislocations of the sternoclavicular joint.[65] These patients, with an average follow-up of more than 6 years, had 42% excellent results among the operative cases. Of those patients who were treated with closed reduction, 58% were satisfied. Ferrandez and colleagues reported 18 subluxations and dislocations of the sternoclavicular joint.[62] Seven had moderate sprains and 11 had dislocations. Of the three patients with posterior dislocation, all had symptoms of dysphagia. All of the subluxations were treated nonoperatively with excellent results. The remaining 10 patients with dislocations were treated with surgery (i.e., open reduction with suture of the ligaments and Kirschner wires between the clavicle and the sternum). The wires were removed 3 to 4 weeks

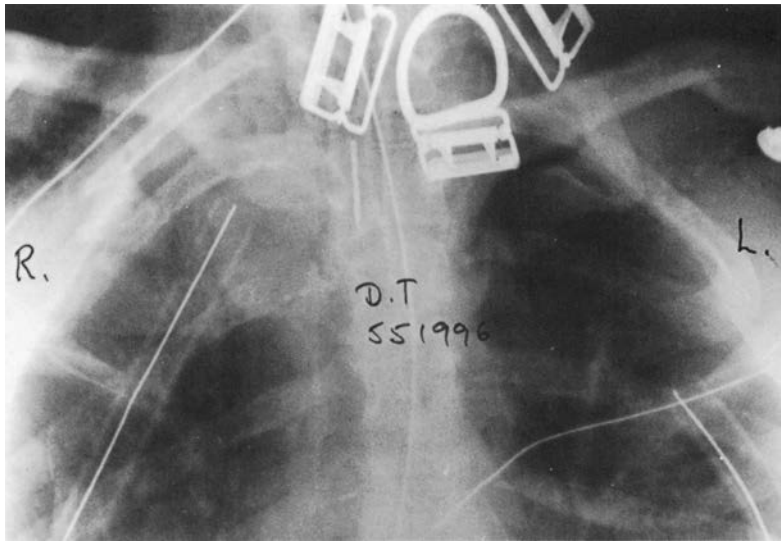

Figure 33-44 Complications of sternoclavicular joint dislocation. This patient had an anterior dislocation on the right and a posterior dislocation on the left. As a result of the posterior dislocation, he had sufficient pressure on the mediastinal structures to cause significant hypotension. When the posterior dislocation was reduced, the blood pressure on the continuous monitor promptly returned to normal.

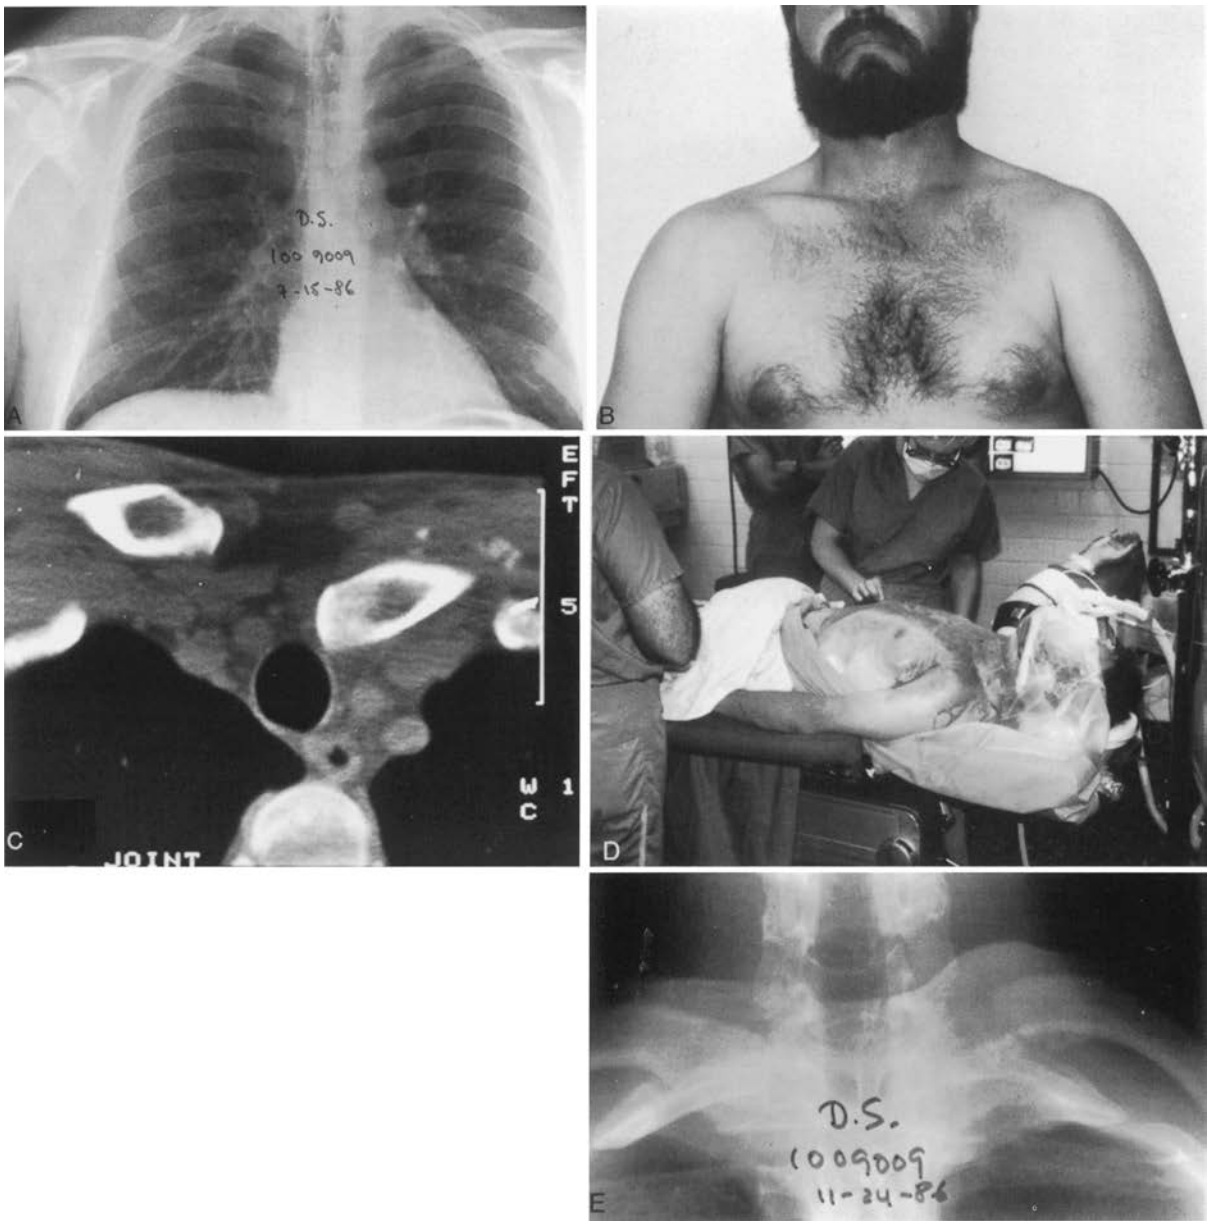

Figure 33-45 Open reduction of a posterior dislocation of the left sternoclavicular joint causing compression of the great vessels in the mediastinum and resultant swelling in the patient's left arm. **(A)** Chest film does not suggest any serious problem with the left medial clavicle. **(B)** Clinically, the medial end of the left clavicle was depressed, as compared with the right. **(C)** The computed tomography scan reveals posterior displacement of the medial clavicle back into the mediastinum, compressing the great vessels and slightly displacing the trachea. **(D)** The patient was carefully prepared for a surgical repair, in cooperation with a cardiovascular surgeon. The patient was prepared from the base of his neck down to the umbilicus, so that we could manage any type of vascular problem or complication. Open reduction was accomplished without any vascular incident. The medial end of the clavicle was totally unstable, so the medial 2 cm was resected and the remaining clavicle stabilized to the first rib. **(E)** Four months after surgery, the slight anterior displacement of the clavicle was essentially asymptomatic and the remaining clavicle was stable. (Reprinted with permission from Rockwood CA, Matsen F III, eds. *The shoulder.* Philadelphia: WB Saunders, 1990:Fig. 13-25.)

after surgery. At 1 to 4 years' follow-up, most of the operative cases had a slight deformity. In two patients, migration of the Kirschner wires was noted but was without clinical significance. Eskola and associates strongly urged operative repair of dislocations of the sternoclavicular joint.[59,60] In 1989, they reported on 12 patients treated for painful sternoclavicular joints. The average time from injury was 1.5 years, and the average follow-up after surgery was 4.7 years. In five patients, the sternoclavicular joint was stabilized with a tendon graft from either the palmaris tendon or the

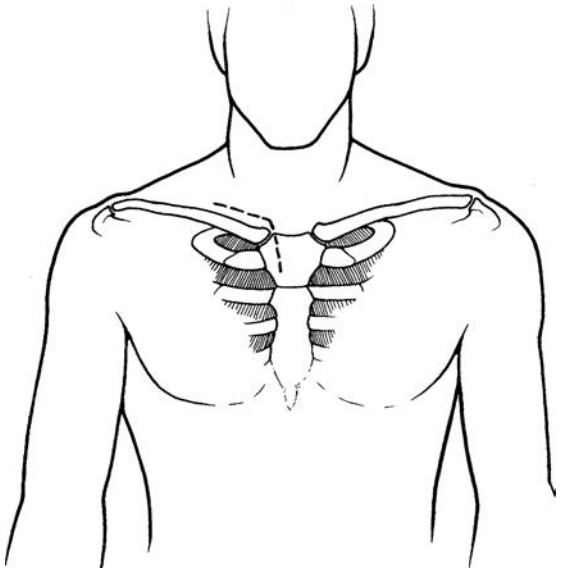

Figure 33-46 Proposed skin incision for open reduction of a posterior sternoclavicular dislocation.

plantaris tendon between the first rib and the clavicle; in four patients, the medial 2.5 cm of the clavicle was resected without any type of stabilization; in three patients, the clavicle was fixed to the first rib with a fascia lata graft. They had four fair results and four poor results in those patients who underwent only resection of the medial clavicle. There was little discussion of the preoperative symptoms, work habits, range of motion, or degree of joint reduction following the surgery. In 1990, Tricoire and colleagues reported six retrosternal dislocations of the medial end of the clavicle.[212] They recommended reduction of these injuries secondary to the possible complications arising from protrusion of the clavicle into the thorax. Sternoclavicular capsulorrhaphy was performed in two patients and a subclavius tenodesis was used in the remaining four patients. All joints were temporarily stabilized with sternoclavicular pins for 6 weeks. Results were satisfactory in all cases at a mean follow-up of 27 months. These case series emphasize the importance of stabilization of the medial end of the clavicle as opposed to simple resection in the case of instability.

Surgical Reconstructions of the Sternoclavicular Joint

There are several surgical procedures to restore stability to the medial end of the clavicle. These can be categorized by the structure or structures that they are attempting to reconstruct. There are three basic styles that have been described. There are those that reconstruct the costoclavicular ligament, those that reconstruct the intraarticular disk ligament, and those that reconstruct the capsular ligaments. Most procedures attempt to reconstruct the costoclavicular ligament with either a local tendon graft or autograft or synthetic material. These include the Burrows reconstruction, which utilizes the subclavius tendon, as well as other fascial loops of autogenous tissue such as fascia lata, which are woven between the first rib and clavicle.[28,59,134,111,171,201] Booth and Roper described a method of using a strip of the sternocleidomastoid tendon looped under the first rib and then secured back to the clavicle.[19] The second method of stabilization reconstructs the intraarticular disk ligament much like a Weaver Dunn reconstruction on the lateral end of the clavicle.[177] A conceptionally similar operation described by Lowman used a loop of fascia in and through the sternoclavicular joint, so that it acts like the ligamentum teres in the hip.[131] The third method of stabilization secures the clavicle to the sternum to reconstruct the capsular ligaments.[6,139,202]

With so many methods to stabilize the sternoclavicular joint, it is difficult to determine the best method. There is not only a lack of agreement on which ligament or ligaments to reconstruct, but also a lack of agreement on how to best reconstruct these structures. This is secondary to the fact that dislocations of the sternoclavicular joint are relatively rare injuries and surgical indications for reconstruction are even rarer. This makes clinical studies to compare one technique with another almost impossible. Thus far, several authors have reported small case series, each with a different technique, but basing reconstruction techniques on these data is almost anecdotal. This emphasizes the need to base reconstruction techniques on biomechanical data elucidating the most important structures to anterior and posterior instability. A biomechanical study by Spencer et al. found that the posterior capsular ligament was the most important structure for anterior and posterior stability, with the anterior capsular ligament serving as an important secondary stabilizer for anterior stability.[203] Therefore, reconstructing these structures would be a logical step.

A separate biomechanical study by Spencer and Kuhn evaluated the stability of the two most common methods of sternoclavicular reconstruction and a novel method that reconstructed the anterior and posterior capsular ligaments.[202] The methods of reconstruction that were compared represented one from each of the three styles described above. The first was the method described by Burrows in which the subclavius tendon is passed through a bone tunnel in the clavicle and sutured back to itself to reconstruct the costoclavicular ligament (Fig. 33-47).[28] The second was a method popularized by the senior author in which the medial end of the clavicle is resected and the intraarticular disk ligament is transferred into the medullary canal (Fig. 33-48).[177] This is similar to a Weaver Dunn reconstruction of the lateral end of the clavicle where the coracoacromial ligament is transferred into the medullary canal of the lateral end of the clavicle. The third method was a novel reconstruction of the anterior and posterior capsular ligaments with a semitendinosis autograft (Fig. 33-49).[202] The semitendinosis is passed in a figure-eight fashion through drill holes in the clavicle and

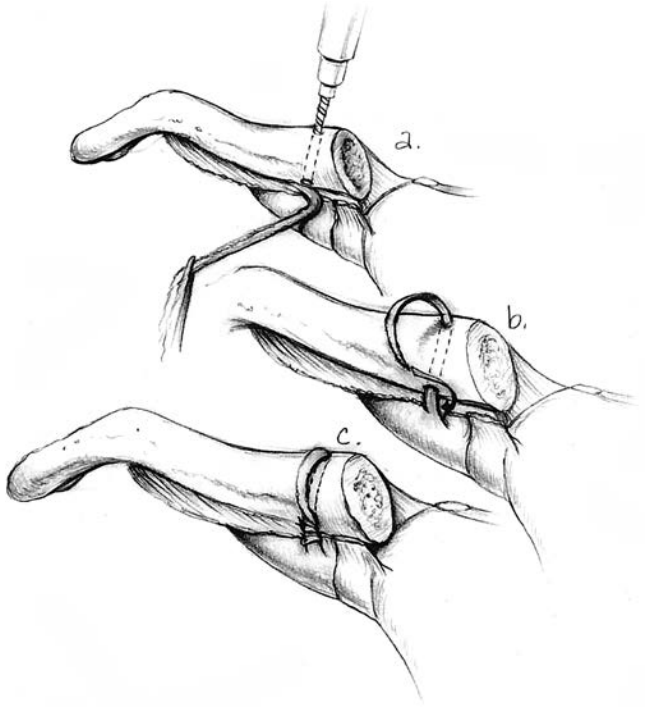

Figure 33-47 Subclavius tendon reconstruction as described by Burrows. **(A)** The subclavius tendon is dissected free, with the sternal attachment left intact, and a drill hole is made in the anterior cortex of the medial part of the clavicle. **(B)** The tendon is routed through the drill hole from inferior to superior. **(C)** The subclavius tendon is sutured to itself. (From Spencer EE Jr, Kuhn JE. Biomechanical analysis of reconstructions for sternoclavicular joint instability. *J Bone Joint Surg Am* 2004;86-A(1):98–105.)

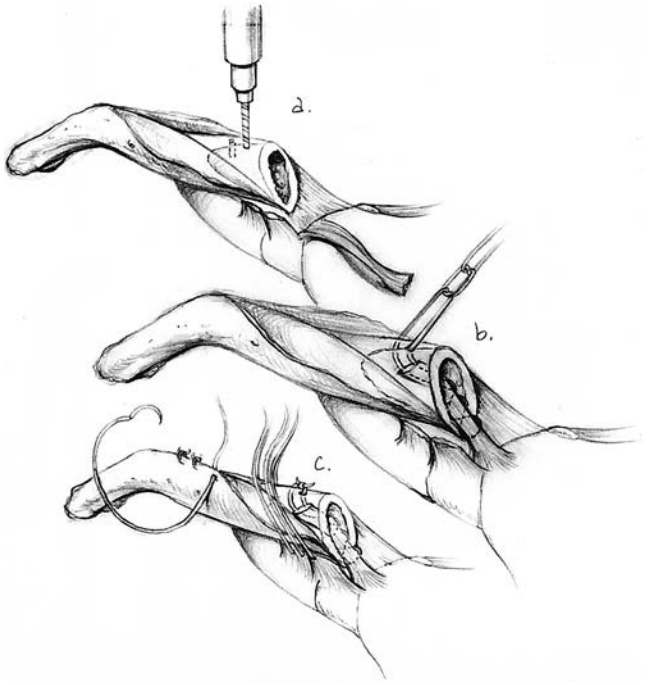

Figure 33-48 Intramedullary ligament reconstruction as described by Rockwood et al. **(A)** The medial head of the clavicle is resected, and the intraarticular ligament and disc are isolated. Two small drill holes are made in the superior surface of the clavicle. **(B)** Sutures are woven into the intraarticular ligament and disk, passed into the medullary canal and then through the drill holes on the superior surface of the clavicle, and secured. **(C)** The soft tissues are sutured to the costoclavicular ligament. (From Spencer EE Jr, Kuhn JE. Biomechanical analysis of reconstructions for sternoclavicular joint instability. *J Bone Joint Surg Am* 2004;86-A(1):98–105.)

manubrium and tied back on itself on the anterior aspect of the joint. The load to failure was almost three times greater for the semitendinosis figure-eight reconstruction in both the anterior and posterior directions.

Description of Techniques

Subclavius Tendon

Burrows recommended that the subclavius tendon be used to reconstruct a new costoclavicular ligament.[28] The origin of the subclavius muscle is from the first rib just 6 mm lateral and 1.3 mm anterior to the attachment of the costoclavicular ligament. The insertion of the tendon is to the inferior surface of the junction of the middle third with the outer third of the clavicle, and the muscle fibers arising from the tendon insert into the inferior surface of the middle third of the clavicle. The muscle fibers coming off the tendon look like feathers on a bird's wing. Burrows detaches the muscle fiber from the tendon, does not disturb the origin of the tendon, and then passes the tendon through drill holes in the anterior proximal clavicle.

In comparing his operation with the use of free strips of fascia, Burrows said that it is "safer and easier to pick up a mooring than to drop anchor; the obvious mooring is the tendon of the subclavius, separated from its muscle fiber and suitably realigned." Lunseth and associates have reported a modified Burrows procedure with the additional use of a threaded Steinmann pin across the joint.[134]

Intraarticular Ligament Transfer

The medial clavicle is exposed by careful subperiosteal dissection (Fig. 33-50). When possible, any remnant of the capsular or intraarticular disk ligaments should be identified and preserved, because these structures can be used to stabilize the medial clavicle. Ordinarily, the intraarticular disc ligament is a very dense, fibrous structure that arises from the synchondral junction of the first rib to the sternum and passes through the sternoclavicular joint, dividing the joint into two separate spaces. The capsular ligament covers the anterosuperior and posterior aspects of the joint and represents thickenings of the joint capsule. This ligament is primarily attached to the epiphysis of the medial clavicle and is usually avulsed from this structure with posterior sternoclavicular dislocation. Similarly, the intraarticular disk ligament usually is intact where it arises from the synchondral junction of the first

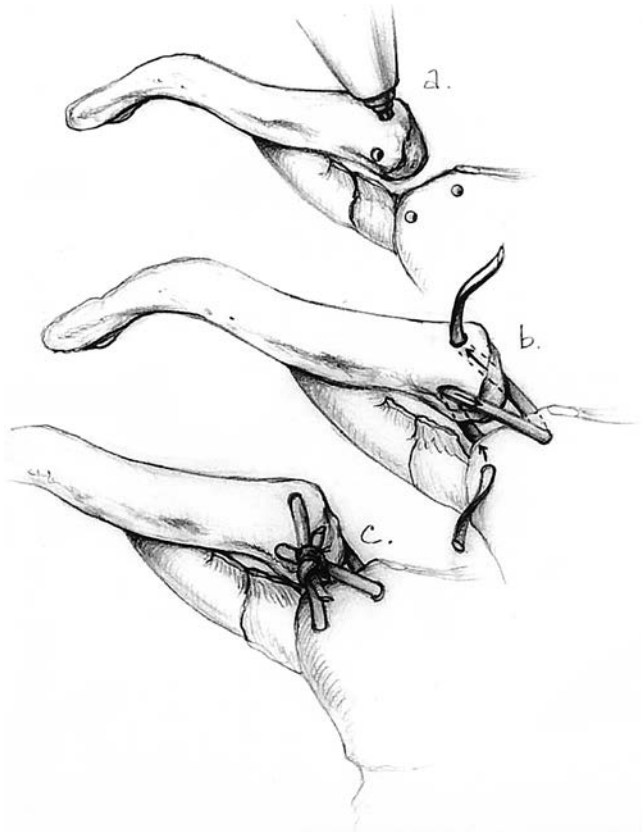

Figure 33-49 Semitendinosus figure-eight reconstruction. **(A)** Drill holes are passed from anterior to posterior through the medial part of the clavicle and the manubrium. **(B)** A free semitendinosus tendon graft is woven through drill holes such that the tendon strands are parallel to each other posterior to the joint and cross each other anterior to the joint. **(C)** The tendon is tied in a square knot and is secured with suture. (From Spencer EE Jr, Kuhn JE. Biomechanical analysis of reconstructions for sternoclavicular joint instability. *J Bone Joint Surg Am* 2004;86-A(1):98–105.)

rib and sternum and is avulsed from its attachment site on the medial clavicle.

If the sternal attachment site of these structures is intact, a nonabsorbable No. 1 cottony Dacron suture is woven back and forth through the ligament, so that the ends of the suture exit through the avulsed free end of the tissue. The medial end of the clavicle is resected, with care taken to protect the underlying structures and to not damage the costoclavicular (rhomboid) ligament or the vascular structures that are located posterior to the medial clavicle and sternoclavicular joint. These vital structures are protected by passing a curved Crego or ribbon retractor around the posterior aspect of the medial clavicle, which isolates them from the operative field during the bony resection. Excision of the medial clavicle is facilitated by creating drill holes through both cortices of the clavicle at the intended site of clavicular osteotomy. Following this step, an air drill with a side-cutting burr or an osteotome is used to complete the osteotomy. The anterior and superior corners of the clavicle are beveled with an air burr for cosmetic purposes.

The medullary canal of the medial clavicle is drilled out and curetted to receive the transferred intraarticular disk ligament (see Fig. 33-48). Two small drill holes are then placed in the superior cortex of the medial clavicle, approximately 1 cm lateral to the site of resection. These holes communicate with the medullary canal and will be used to secure the suture in the transferred ligament. The free ends of the suture are passed into the medullary canal of the medial clavicle and out the two small drill holes in the superior cortex of the clavicle. While the clavicle is held in a reduced anteroposterior position in relationship to the first rib and sternum, the sutures are used to pull the ligament tightly into the medullary canal of the clavicle. The suture is tied, thus securing the transferred ligament into the clavicle. The stabilization procedure is completed by passing several 1-mm cottony Dacron sutures around the medial end of the remaining clavicle and securing the periosteal sleeve of the clavicle to the costoclavicular ligament. Postoperatively, the patient should be wrapped with the shoulders back in a figure-eight dressing for 4 to 6 weeks to allow for healing of the soft tissues. We do not recommend the use of Kirschner wires, Steinmann pins, or any other type of metallic pins to stabilize the sternoclavicular joint. The complications are horrendous, as will be discussed in the section on complications.

Semitendinosus Figure-Eight Reconstruction

The approach is similar to the other methods. A subperiosteal dissection is used to expose the clavicle. Any remaining tissue should be preserved. If there are degenerative changes within the joint, then the medial 1 cm can be resected. Subperiosteal dissection allows a malleable retractor to be placed behind the clavicle and manubrium to protect the posterior structures. A portion of the insertion of the sternocleidomastoid tendon will need to be reflected superiorly to expose the anterior aspect of the manubrium. Drill holes are then placed in an anterior-to-posterior fashion. Two holes are drilled in the clavicle and two in the manubrium. A bone bridge of at least 1 cm should be maintained. We start with a 2.5-mm drill bit and then move up to a 4-mm drill bit. Four millimeters is usually required to pass the semitendinosus graft. The edges of the holes are beveled and the tendon is passed with a Hewson suture passer. The graft is positioned such that limbs are parallel posteriorly. The anterior limbs are crossed and tied in a square knot while the joint is held in a reduced position (see Fig. 33-49). A braided nonabsorbable suture is passed through the knot to secure the fixation. The excess tendon tissue is then placed within the joint as a small anchovy. Any remaining capsular tissue is reapproximated. The patient is placed in a sling for 6 weeks. Gentle active assisted range-of-motion exercises in the supine position are started at 6 weeks. Active motion is started at 10 to 12 weeks. Strengthening exercises can be initiated thereafter. There are no clinical case series reported yet, but

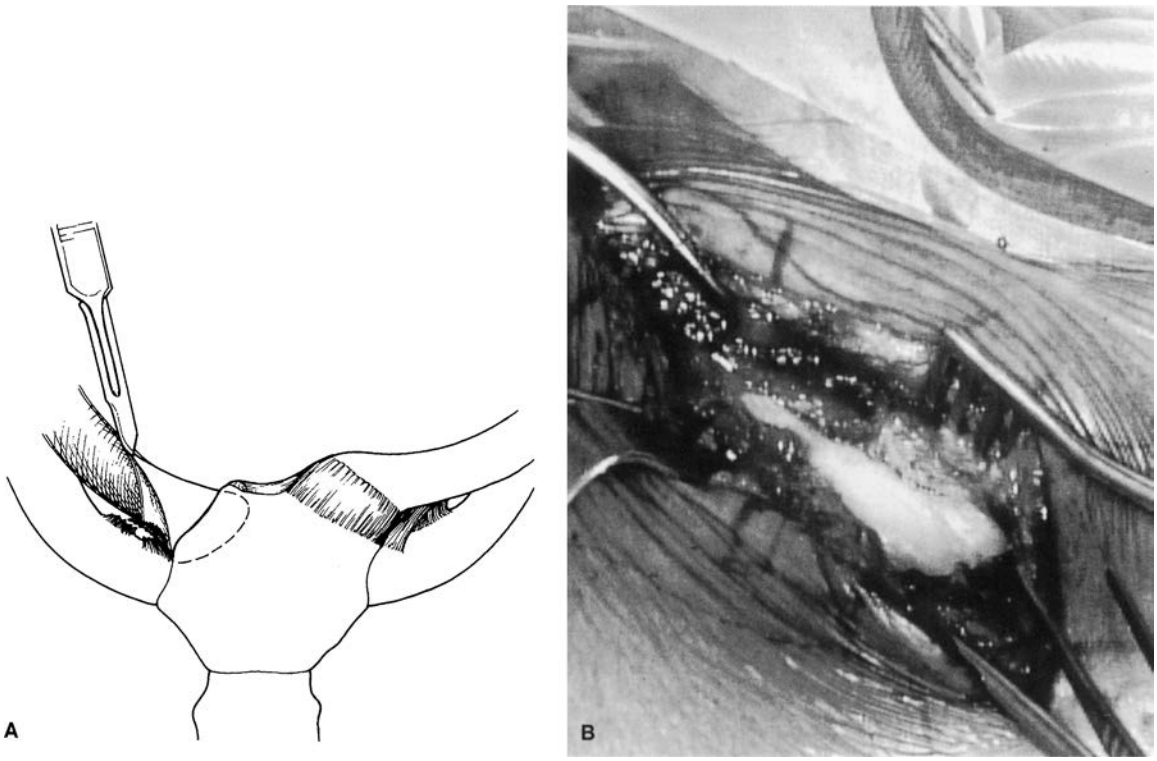

Figure 33-50 Artist's depiction **(A)** and intraoperative photo **(B)** demonstrating subperiosteal exposure of the medial clavicle. Note the posteriorly displaced medial end of the clavicle. (From Wirth MA, Rockwood CA. Injuries to the sternoclavicular joint. In: Rockwood CA, Green DP, Bucholz RW, Hechman JD, eds. *Fractures in adults.* Philadelphia: JB Lippincott, 1996.)

the primary author as well as others have reported good results with this technique.[94117] At the time of the writing of this chapter a clinical study was ongoing.

Complications

Through 1992, seven deaths and three near deaths from complications of transfixing the sternoclavicular joint with Kirschner wires or Steinmann pins were reported.[42,61,62,118,135,184,196,214] The pins, either intact or broken, migrated into the heart, pulmonary artery, innominate artery, or aorta. Tremendous leverage force is applied to pins that cross the sternoclavicular joint, and fatigue breakage of the pins is common. To our knowledge, there were no deaths reported that occurred as a result of migrating pins from the sternoclavicular joint, until the report in 1984 by Gerlach and associates from West Germany.[76] They reported two deaths from migrating nails that caused cardiac tamponade. The physicians were charged with manslaughter by negligence. We do not recommend the use of any transfixing pins—large or small, smooth or threaded, bent or straight—across the sternoclavicular joint.

Brown has reported three complications in 10 operative cases: two from broken pins that had to be removed from a window in the sternum, and one a near death, in which the pin penetrated the back of the sternum and entered the right pulmonary artery.[24] Nordback and Markkula removed a pin that migrated completely inside the aorta.[150] Jelesijevic and associates; Pate and Wilhite; and Rubenstein and colleagues reported cases where the pin migrated into the heart.[100,156,183] Leonard and Giffors and Liu and coworkers reported migration to the pulmonary artery.[125,130] Sethi and Scott reported migration of the pin to lacerate the subclavian artery.[191] Ferrandez and associates described two cases of Kirschner wire migration into the mediastinum.[61] Nettles and Linscheid as well as Salvatore reported migration of pins into the aorta and resultant death.[145,187] Grabski reported migration of the pin to the opposite breast in a 37-year-old woman.[80] In addition, the senior author has personally treated patients in whom the pin has migrated into the chest and up into the base of the neck.

Omer,[86] in a review of 14 military hospitals, reported 15 patients who had elective surgery for reduction and reconstruction of the sternoclavicular joint.[152] Eight patients were followed by the same house staff for more than 6 months with the following complications: of the five patients who had internal fixation with metal, two developed osteomyelitis, two had fracture of the pin with recurrent dislocation, and one had migration of the pin into the mediastinum with recurrent dislocation. Of the three patients who had soft tissue reconstructions, two developed recurrent dislocation (one with drainage) and the third developed arthritis and extremity weakness and

was discharged from military service. Omer commented on this series of complications: "It would seem that complications are common in this rare surgical problem." To Omer's comment we can only add, "Amen."

CONCLUSIONS 1083

INTRODUCTION

The scapulothoracic articulation is a critical component of shoulder function, yet this region, and the disorders that affect it, have received far less attention in the medical literature than the glenohumeral joint. Disorders of the scapulothoracic articulation are frequently misunderstood and misdiagnosed. An appreciation of the anatomy of this region helps in understanding the pathologic conditions that may affect the scapulothoracic articulation.

Surgical Anatomy and Biomechanics of the Normal Scapulothoracic Articulation

The scapula is a thin bone that serves as a site of muscle attachment for the upper extremity and the thorax. Seventeen muscles have their origin or insertion on the scapula (Table 34-1, Fig. 34-1), making it the essential link for coordinated upper-extremity activity. These muscles can be divided into three major groups.

The scapulothoracic muscles coordinate scapulothoracic motion and include the rhomboideus major and minor, the levator scapulae, the serratus anterior, the trapezius, the omohyoid, and the pectoralis minor. Disorders of these muscles may manifest as scapular winging, or scapulothoracic dyskinesia. The rotator cuff muscles control activities of the glenohumeral articulation and include the supraspinatus, infraspinatus, subscapularis, and teres minor. Disorders of these muscles are common and are covered in other sections of this text. The scapulohumeral muscles provide power to the humerus and include the deltoid, the long head of the biceps, the short head of the biceps, the coracobrachialis, the long head of the triceps, and the teres major. Motion of the upper extremity occurs as a result of the coordinated activity of all of these muscles.

TABLE 34-1
MUSCULAR ATTACHMENTS TO THE SCAPULA

Scapulohumeral Muscles
Long head of biceps
Short head of biceps
Deltoid
Coracobrachialis
Teres major
Long head of triceps

Scapulothoracic Muscles
Levator scapulae
Omohyoid
Rhomboid major
Rhomboid minor
Serratus anterior
Trapezius
Pectoralis minor

Rotator Cuff Muscles
Supraspinatus
Infraspinatus
Subscapularis
Teres Minor

Seventeen muscles attach the scapula to the neck, thorax, and humerus, making it the control tower for coordinated upper-extremity activity. Fig. 34-1 displays the location of the attachments of the various muscles.

While at rest, the scapula is anteriorly rotated relative to the trunk approximately 30 degrees.[101,169] The medial border of the scapula is also rotated with the inferior pole diverging away from the spine approximately 3 degrees. The scapula is also tilted forward about 20 degrees in the sagittal plane when viewed from the side[101] (Fig. 34-2). It is thought by some that deviations in this normal alignment may contribute to glenohumeral instability.[181]

Almost every functional upper-extremity movement has components of scapulothoracic and glenohumeral motion. Arm elevation has been studied extensively with efforts directed toward determining the relative contributions of scapulothoracic and scapulohumeral motion with varied and conflicting results. In general, in the first 30 degrees of elevation, the majority of motion occurs at the glenohumeral joint, although this varies between individuals.[8,39,53,185] The next 60 degrees of elevation is accomplished by equal parts of scapulothoracic and glenohumeral motion. The overall effort to obtain 90 degrees of elevation requires approximately a 2:1 ratio of glenohumeral-to-scapulothoracic motion. During arm elevation in the scapular plane, the instant center of rotation of the scapula moves, such that from 0 to 30 degrees the scapula rotates about its midportion and from 60 degrees or more, the rotation occurs near the glenoid, resulting in a medial and upward displacement of the inferior pole of the scapula. In addition, with arm elevation, the coracoid moves superiorly, and the acromion moves superiorly and posteriorly to open the impingement zone (Fig. 34-3).

Muscle Function about the Scapula

Cranial elevation of the scapula is accomplished by activating the upper portion of the trapezius as it inserts into the lateral spine of the scapula, acromion, and distal clavicle. This is countered by the effects of gravity and by the latissimus dorsi, which acts as the primary scapular depressor with the lower portion of the serratus anterior, the pectoralis minor, and the lower portion of the trapezius contributing.

Rotation of the scapula upward is initiated by the middle portion of the trapezius, which stabilizes the scapula by inserting on the medial border of the scapular spine. At

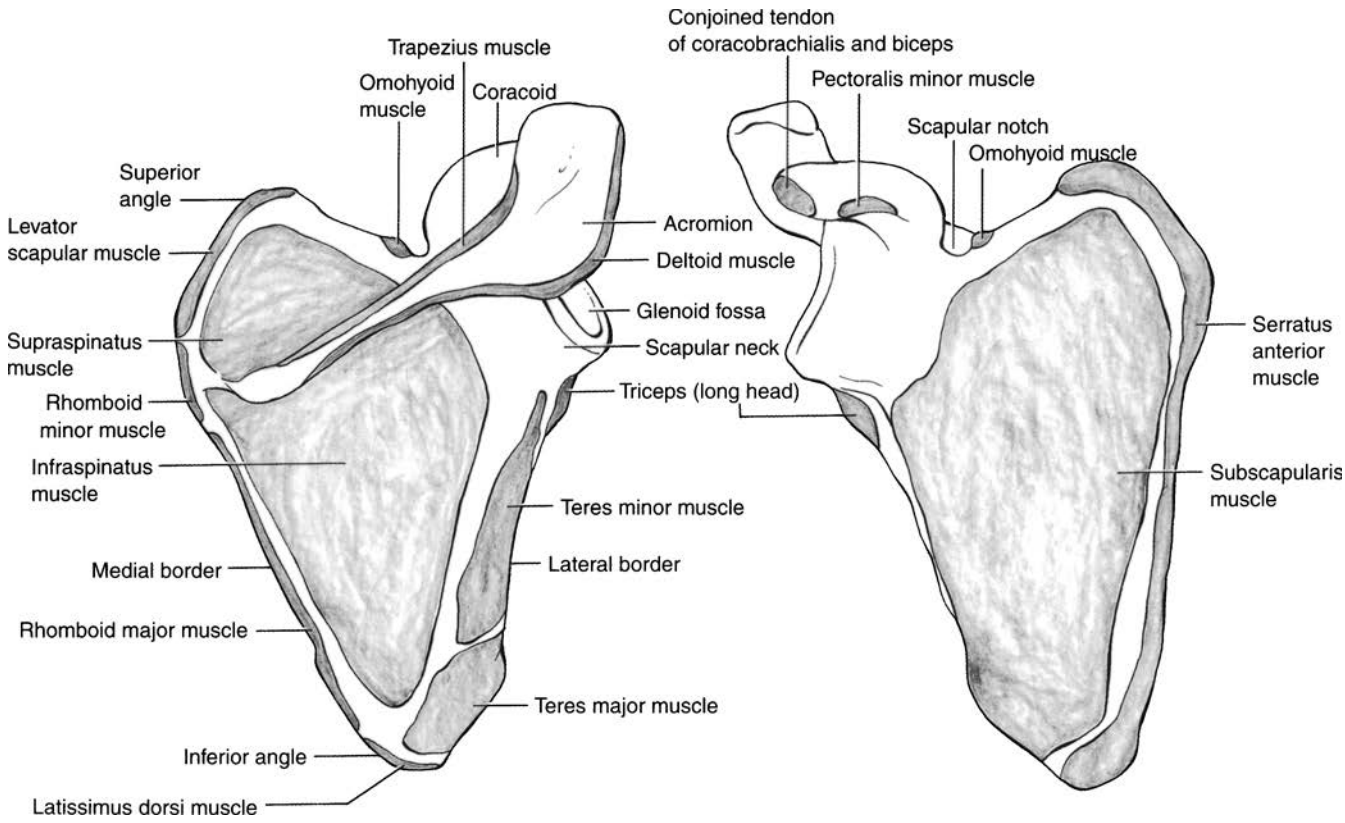

Figure 34-1 Origins and insertions of the muscles of the scapula. Anterior and posterior views of the scapula demonstrate the multiple attachment sites for muscles of the scapula, making the scapula the center for coordinated upper extremity motion.

approximately 45 degrees of scapular abduction, the serratus anterior acts to pull the inferior angle of the scapula laterally. The upper portion of the trapezius elevates the lateral angle of the scapula, while the lower portion of the trapezius pulls down on the scapula through its insertion on the medialmost portion of the scapular spine, inducing upward rotation (Fig. 34-4).

The downward rotators of the scapula include the rhomboideus major and minor and the levator scapulae, which elevate the medial border of the scapula while the pectorals minor, lower portion on the pectoralis major, and the latissimus dorsi depress the lateral portion of the scapula (Fig. 34-5).

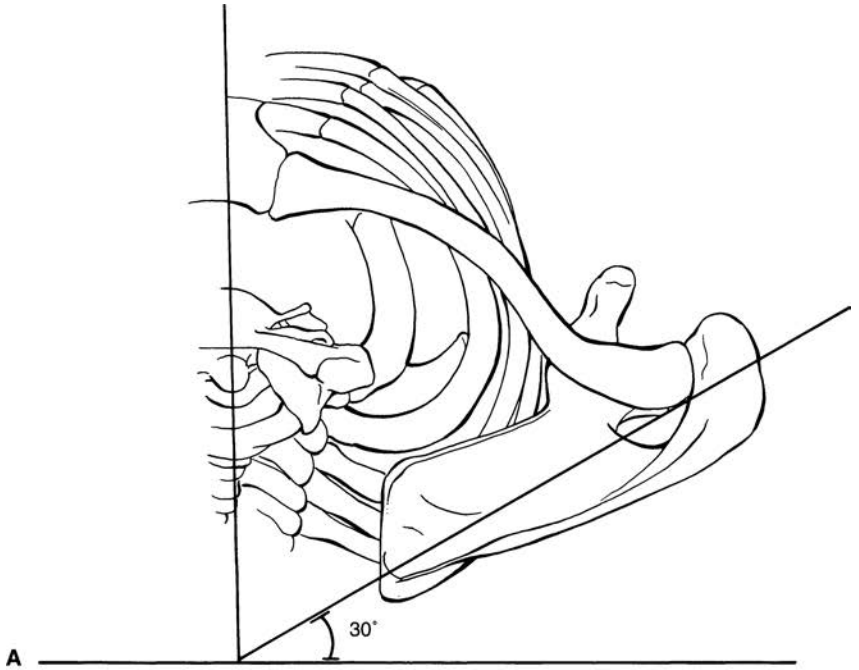
Protraction of the scapula is accomplished by the serratus anterior and pectoralis minor and major as these muscles move the scapula lateral and forward. Retraction of the scapula relies on the middle trapezius and rhomboideus major and minor (Fig. 34-6).

During high-intensity shoulder activities, such as throwing, the trapezius and rhomboideus major and minor have high electromyographic activity during the windup and cocking phases to maximally retract and stabilize the scapula. For acceleration and follow-through the scapula is protracted with serratus anterior and pectoralis minor and major. This is thought to allow the scapula to follow the humeral head, maintaining glenohumeral stability, and help dissipate the tremendous forces generated during the cocking and acceleration phases of throwing.[55,90]

Bursae About the Scapula

Scapulothoracic bursae allow for smooth, gliding scapulothoracic motion. Two major or anatomic bursae and four minor or adventitial bursae have been described for the scapulothoracic articulation (Table 34-2, Fig. 34-7). The first major bursa is found in the space between the serratus anterior muscle and the chest wall. The second major bursa is located between the subscapularis and the serratus anterior muscles.[23,95] These bursae are easily and reproducibly found.[95]

Clinical scapulothoracic bursitis seems to affect two areas of the scapulothoracic articulation, the superomedial angle and the inferior angle of the scapula. When symptomatic, these areas tend to develop inflamed bursae; however, these bursae are not reliably found, and



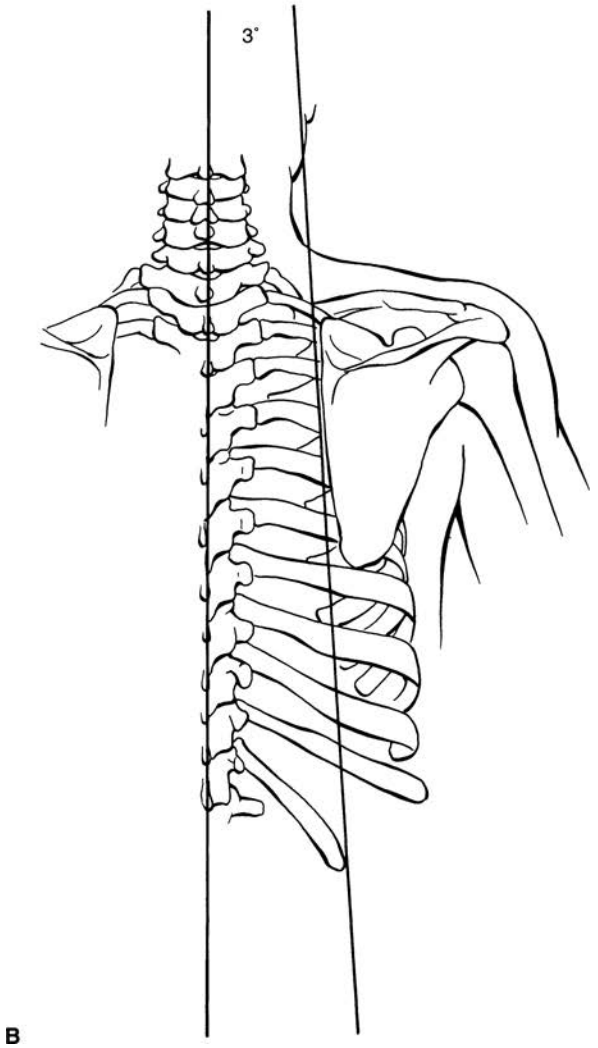


Figure 34-2 Normal resting position of the scapula on the thorax. The resting scapula is 30 degrees anterior to the coronal plane, with the medial border rotated 3 degrees from the spine.

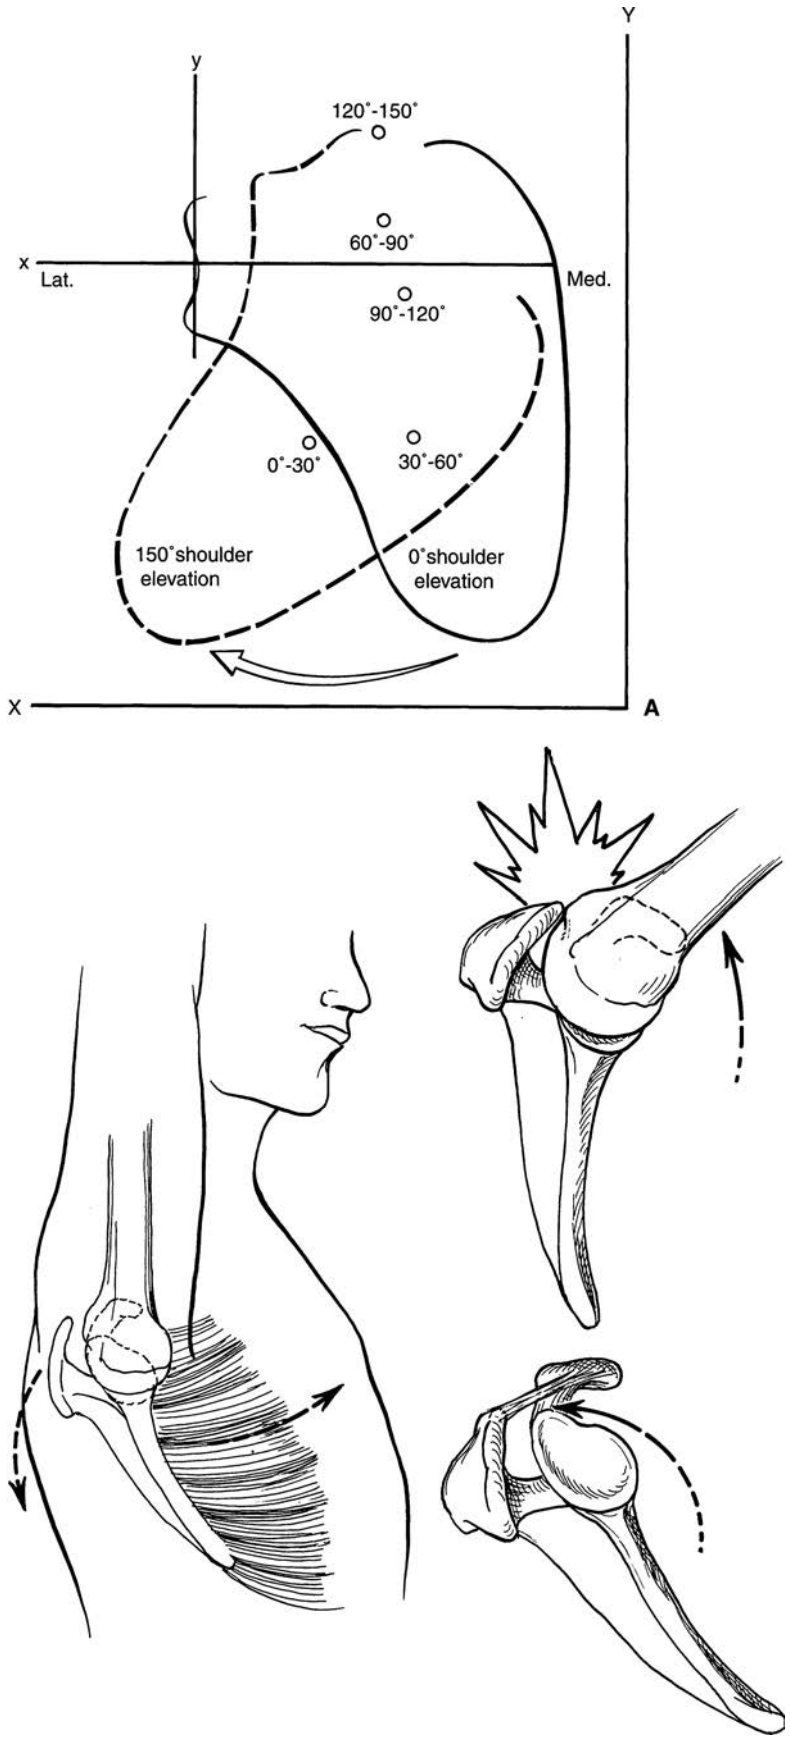

Figure 34-3 Changes in the center of rotation of the scapula with arm elevation. **(A)** demonstrates that the center of rotation moves superiorly during arm elevation, resulting in upward and medial displacement of the glenoid face, with lateral displacement of the inferior angle. (Reprinted with permission from Poppen NK, Walker PS. Normal and abnormal motion of the shoulder. *J Bone Joint Surg Am* 1976;58A:195–201.) **(B)** demonstrates that the scapula rotates with arm elevation clearing the acromion away from the impingement zone. (Reprinted with permission from Kuhn JE, Hawkins RJ. Evaluation and treatment of scapular disorders. In: Warner JP, Iannotti JP, Gerber C, eds. *Complex and revision problems in shoulder surgery.* Philadelphia: Lippincott-Raven Publishers, 1997:357–375.)

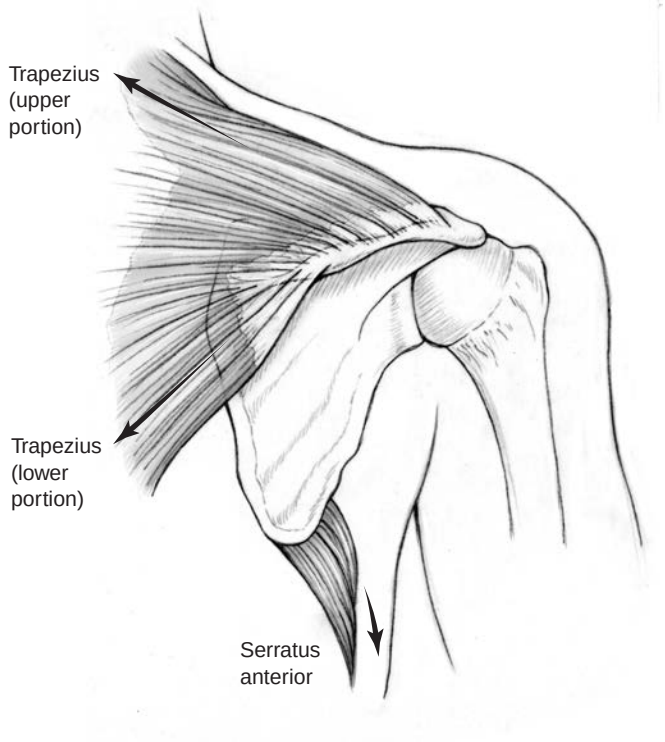

Figure 34-4 Upward rotation of the scapula. As the middle trapezius stabilizes the scapula, the serratus pulls the inferior angle and the upper trapezius elevates the lateral angle.

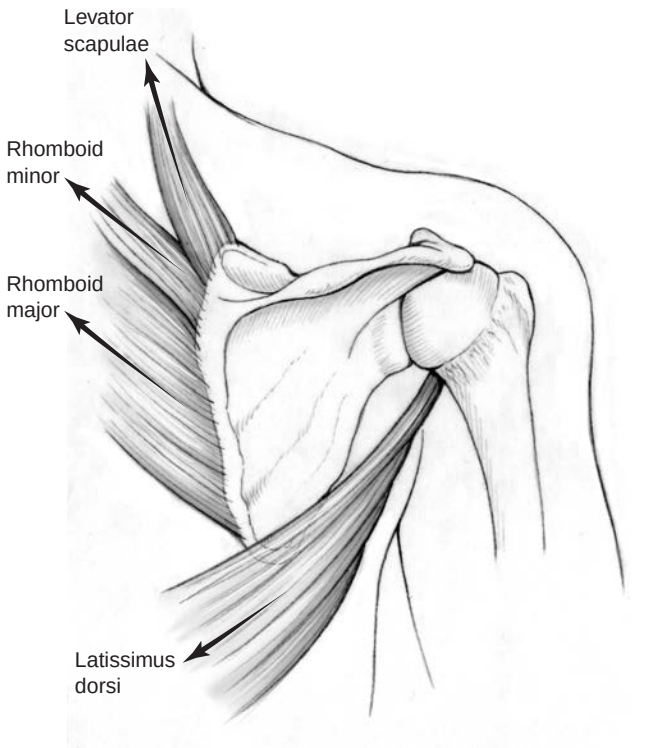

Figure 34-5 Downward rotation of the scapula. The rhomboidei and levator scapulae elevate the medial border of the scapula while the pectoralis minor, lower pectoralis major, and latissimus dorsi depress the lateral portion of the scapula.

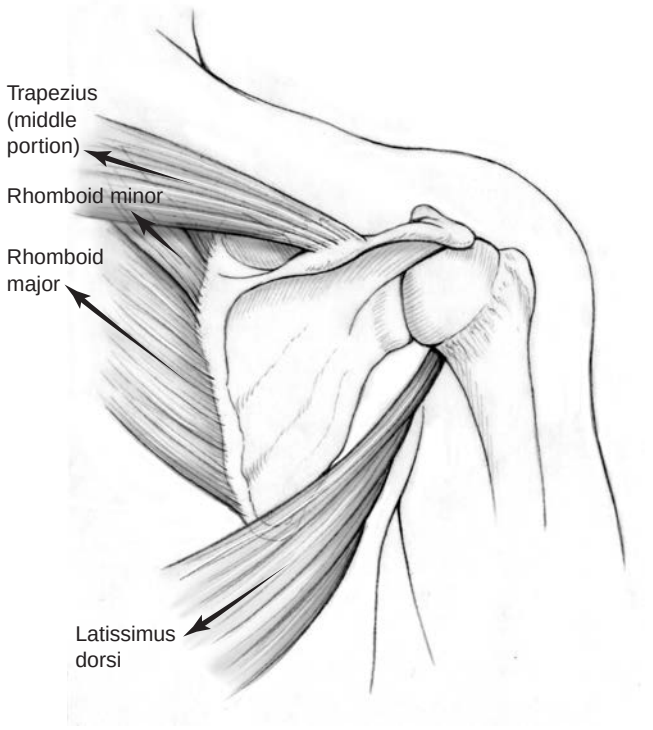

Figure 34-6 Retraction of the scapula. The middle portion of the trapezius and the rhomboidei serve to counter the effect of the serratus and pectoralis and retract the scapula toward the spine.

TABLE 34-2
BURSAE OF THE SCAPULA

Infraserratus bursae—between serratus anterior and chest wall

Supraserratus bursae—between subscapularis and serratus anterior

INFERIOR ANGLE OF THE SCAPULA

Infraserratus bursae—between serratus anterior and chest wall

SPINE OF SCAPULA

Trapezoid bursae—between medial spine of scapula and trapezius

The scapulothoracic articulation is associated with a number of bursae, many of which can become pathologic, causing symptomatic scapulothoracic bursitis. (Reprinted with permission from Kuhn JE, Hawkins RJ. Evaluation and treatment of scapular disorders. In: Warner JP, Iannotti JP, Gerber C, eds. *Complex and revision problems in shoulder surgery.* Philadelphia: Lippincott-Raven Publishers, 1997:357–375.)

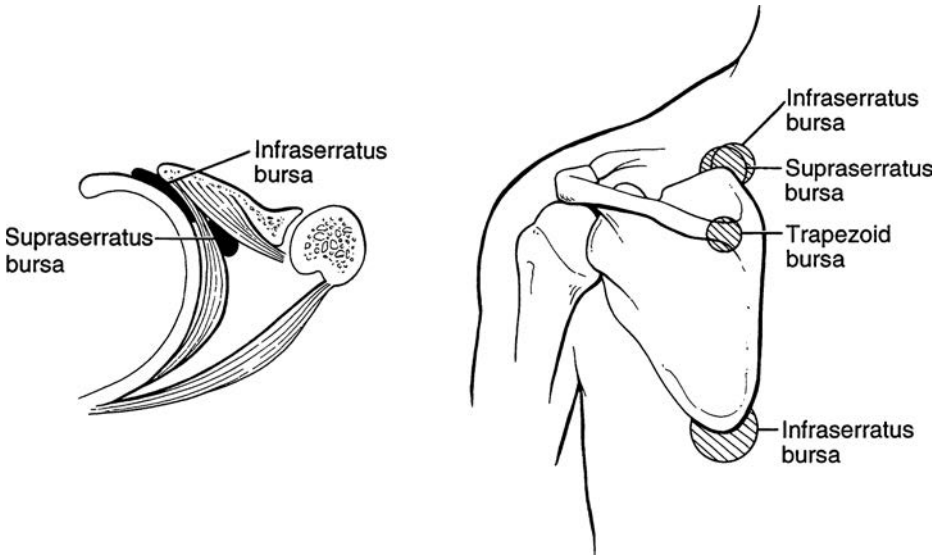

Figure 34-7 Bursae of the scapula. The location of both anatomic (black) and adventitial (hatched) bursae are displayed. (Reprinted with permission from Kuhn JE, Hawkins RJ. Evaluation and treatment of scapular disorders. In: Warner JP, Iannotti JP, Gerber C, eds. *Complex and revision problems in shoulder surgery.* Philadelphia: Lippincott-Raven Publishers, 1997:357–375.)

in fact may be adventitious.[24,95,136] With regard to the inferior angle of the scapula, most authors agree that the affected bursa lies between the serratus anterior muscle and the chest wall.[25,121,162] This bursa has been given many names including the infraserratus bursa[25] and the bursa mucosa serrata.[162,182] The second site of pathology lies at the superomedial angle of the scapula. Here Codman[25] believed this bursa is also an infraserratus bursa, lying between the upper and anterior portion of the scapula and the back of the first three ribs. Von Gruber,[182] on the other hand, identified a bursa in this region between the subscapularis and the serratus anticus muscles, which he called the bursa mucosa angulae superioris scapulae.

A third minor or adventitial bursa, which Codman believed was the site of painful crepitus in scapulothoracic crepitus, was called the trapezoid bursa and is found over the triangular surface at the medial base of the spine of the scapula under the trapezius muscle.[20] Some believe that these minor bursae are adventitial and develop in response to abnormal pathomechanics of the scapulothoracic articulation.[24,95,136] It would not be surprising, then, to find these bursae inconsistently or in different soft tissue planes.

WINGING OF THE SCAPULA

Scapular winging is one of the most common abnormalities of the scapulothoracic articulation and results from a variety of causes. Winging may be described as primary, secondary, or voluntary (Table 34-3). Primary scapular winging results from identifiable anatomic disorders that directly affect the scapulothoracic articulation. Secondary scapular winging usually is associated with some form of glenohumeral pathology. This type of winging will resolve as the glenohumeral pathology is addressed. Voluntary winging, which is quite rare, may have an underlying psychologic cause.

Primary Scapular Winging—Neurologic Disorders

The more common causes of primary scapular winging are attributable to neurologic disorders and include damage to the spinal accessory nerve causing trapezius palsy, damage

III. Voluntary scapular winging

Primary scapular winging results from anatomic disorders of the scapulothoracic articulation. Secondary scapular winging results from glenohumeral or subacromial pathology. Voluntary scapular winging is not pathologic and may have psychologic overtones. (Reprinted with permission from Kuhn JE, Hawkins RJ. Evaluation and treatment of scapular disorders. In: Warner JP, Iannotti JP, Gerber C, eds. *Complex and revision problems in shoulder surgery.* Philadelphia: Lippincott-Raven Publishers, 1997:357–375.)

to the long thoracic nerve causing serratus anterior palsy, and damage to the fifth cervical nerve root causing rhomboideus palsy. Primary scapular winging may also be bony in origin or may be due to scapulothoracic bursitis or disorders in periscapular musculature.

Spinal Accessory Nerve Palsy and Trapezius Winging

The spinal accessory nerve is the only nerve supplying the vast trapezius muscle.[75,147,174] The spinal accessory nerve is superficial, lying in the subcutaneous tissue on the floor of the posterior cervical triangle. Its superficial location makes it susceptible to injury[85,86] (Fig. 34-8). Injury to this nerve causes significant deformity as well as painfully disabling alterations in scapulothoracic function.[35,42,74,85,86,100,131,174,195–197] This nerve can be injured in a variety of ways including blunt trauma,[11,73,197] stretching of the nerve,[197] and penetrating trauma, which includes surgical biopsy of lymph nodes in the posterior cervical triangle[42,131,196,197] and radical neck dissection.[14,147,164]

Signs and Symptoms

Patients will attempt to compensate for a palsy of the trapezius by straining other muscles of the shoulder girdle including the levator scapulae and the rhomboid muscles. This strain may lead to pain and muscle spasm, which can be disabling.[11] Patients can also develop pain from adhesive capsulitis, shoulder subacromial impingement, and radiculitis from traction on the brachial plexus as the shoulder girdle droops.

Upon examination, patients will have difficulty when attempting to shrug their shoulder, and will have weakness in forward elevation and abduction of the arm. The patient will assume a position with the shoulder depressed and the scapula translated laterally with the inferior angle rotated laterally (Fig. 34-9).

Diagnosis and Imaging

The diagnosis is confirmed by electromyography. It is important to specify an examination of the trapezius and spinal accessory nerve on the requisition, as these areas may not be routinely evaluated in a diagnostic evaluation of the shoulder. Serial electromyography at 3-month intervals may be helpful to document the potential for recovery, which may take many months.

Natural History

In the majority of patients, spinal accessory nerve injuries are iatrogenic and are a complication of neck surgery, either radical dissections or lymph node biopsy. In these patients the nerve may be injured as a result of vigorous retraction, but in many patients the nerve is cut or resected. Patients develop symptoms quickly and note a perceived weakness in the shoulder and a feeling of discomfort sitting against the back of a chair. Clearly a transected nerve

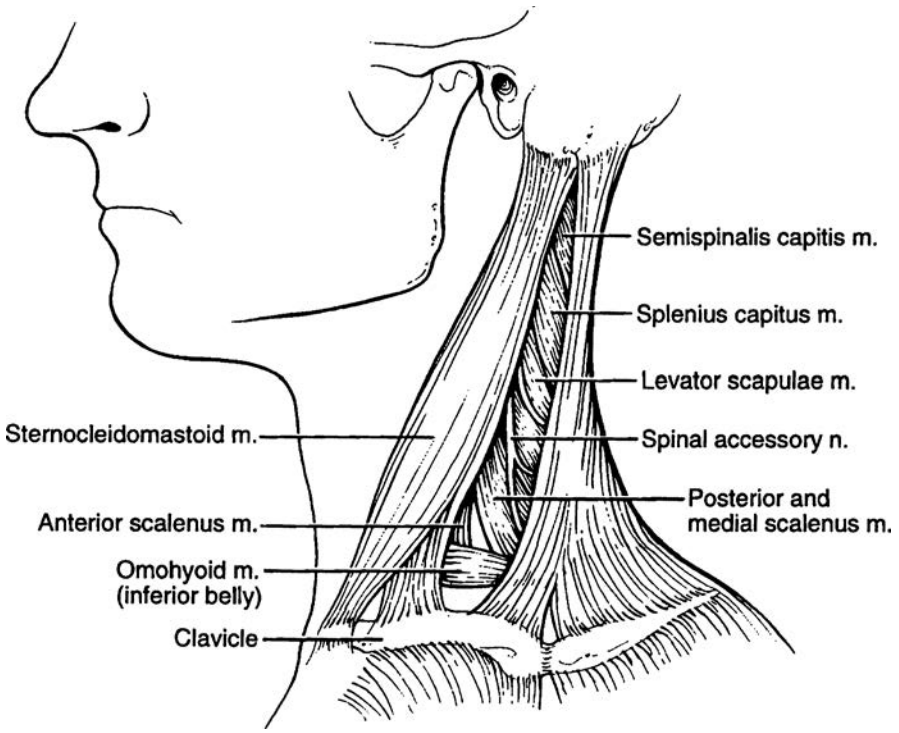

Figure 34-8 Location of the spinal accessory nerve. Its location in the posterior cervical triangle makes it susceptible to injury during surgical procedures in this area.

has no potential for recovery. Nevertheless, it is possible the nerve injury occurred as a result of vigorous retraction and may recover. In all patients serial electromyography will be helpful in assessing the potential for recovery.

Treatment Options

Treatment considerations for patients with trapezius winging depend on the duration and severity of symptoms (Fig. 34-10). The initial treatment is nonoperative. The arm can be placed in a sling to rest the other periscapular muscles. Physical therapy is helpful to maintain glenohumeral motion, preventing stiffness.[137] In cases due to blunt trauma, serial electromyographic analysis should be performed at 4- to 6-week intervals to follow the returning function of the nerve. In cases due to penetrating trauma or when there is no evidence of nerve function on electromyographic analysis, neurolysis and/or nerve grafting can be performed.[1,42,64,130,195] The results of these procedures have been variable; however, the success rate seems to be improved if the neurolysis is performed before 6 months.[11]

Surgical Techniques

Patients who have had symptoms in excess of 1 year are unlikely to benefit from continued nonoperative treatment,[131,174] and surgery can be offered. Historically, a variety of procedures have been described for the treatment of trapezius winging.[35,68,76, 89] These can be divided into static stabilization, including scapulothoracic fusion[68] and any of the many described operations that tether the scapula to the thoracic spine,[35,89] or dynamic stabilization, which involves muscle transfers.[76]

The Dewar-Harris procedure[35] was once a popular operation for trapezius paralysis.[34,104,129,139] In this procedure the medial border of the scapula is stabilized by securing it to the T1 and T2 spinous processes with fascia lata strips, which attempt to compensate for the middle and lower thirds of the trapezius. In addition, the levator scapulae muscle is transferred laterally to the spine of the scapula to compensate for the upper third of the trapezius (Fig. 34-11). Following surgery, the arm is placed in a shoulder spica cast in 45 to 50 degrees of abduction for 6 to 8 weeks. Other operations have been described for trapezius winging that also employ fascial slings, all with the principle effect to compensate for the three portions of the trapezius.[36,40,70,89]

Of historical interest, a partial fusion for trapezius winging has been described by Spira.[165] In this technique, a hole is made in the inferior angle of the scapula. The sixth rib is cut, passed through the hole, and then reapproximated (Fig. 34-12). Complete scapulothoracic fusions can also be performed.[68] However, these are generally reserved for patients with generalized shoulder girdle weakness. Because scapulothoracic fusions limit motion significantly, and because fascial sling suspensions tend to fail, causing a recurrence of winging in 2 to 3 years,[11,76] dynamic muscle transfers have become the procedure of choice for persistent trapezius winging.[11,27,44,98–100,115]

In the Eden-Lange procedure,[44,98,99] the levator scapula, rhomboideus minor, and rhomboideus major muscles are transferred laterally (Fig. 34-13). The levator scapula substitutes for the upper third of the trapezius, the rhomboid major substitutes for the middle third of the trapezius, and the rhomboid minor substitutes for the lower third of the trapezius. By moving these muscle insertions laterally, their

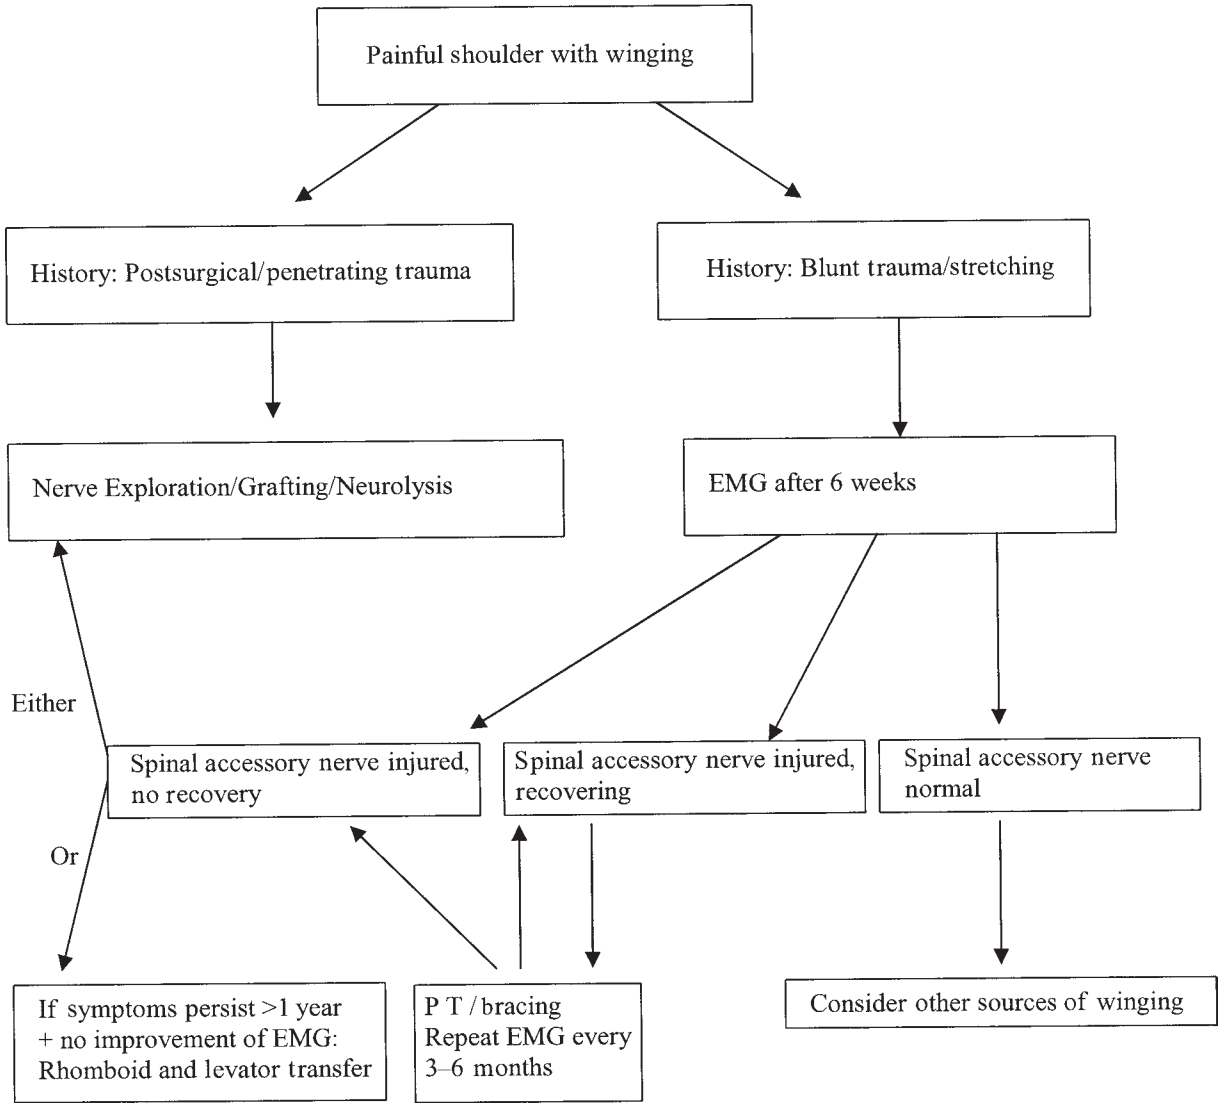

Figure 34-10 Algorithm for treatment of trapezius palsy. EMG, electromyography; PT, physical therapy.

mechanical advantage is improved and winging is eliminated. The surgical technique involves two incisions. The first is along the medial scapular border, and the second is over the spine of the scapula. The levator scapula, rhomboideus minor, and rhomboideus major are detached from the medial scapula taking a small portion of insertional bone. The rhomboideus muscles are advanced laterally under the infraspinatus and are secured with suture, which is passed through drill holes placed 5 cm lateral to the medial border of the scapula. The levator scapula is passed subcutaneously to the second incision and is sutured to the scapular spine through drill holes (see Fig. 34-13).

Postoperative Considerations

Patients are kept in an abduction cast or foam abduction pillow for 4 to 6 weeks and then passive and active range of motion is begun. Resisted exercises should begin after approximately 10 to 12 weeks. Full return to activities as tolerated usually occurs 4 to 6 months after surgery.

Results of Treatment

Bigliani et al. recently reported their results using this procedure on 23 patients with trapezius scapular winging and had 87% excellent and good results.[11] Significant improvement in pain was seen in 91% of these patients and 87% had significant improvement in function.[11]

Complications

Reported complications are rare. Failure occurs in approximately 15% of patients who have poor function, possibly related to poor healing or continued weakness of the trans-

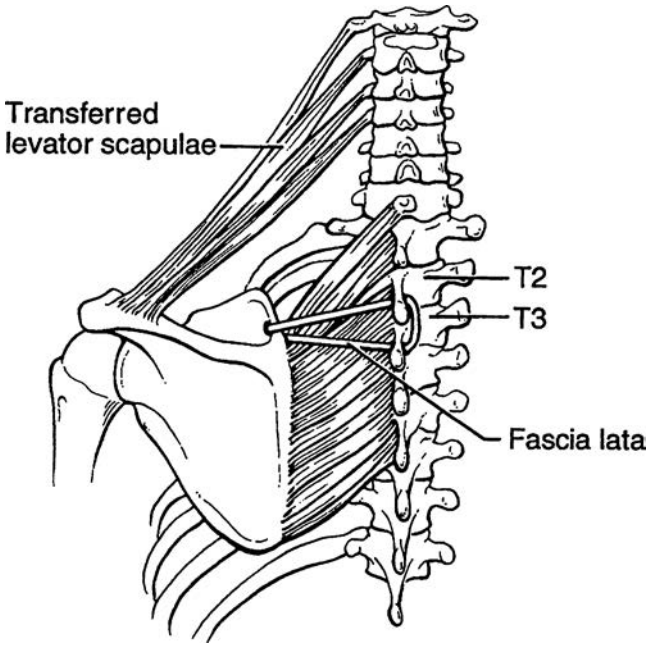

Figure 34-11 Dewar-Harris operation for trapezius palsy. This procedure combines the use of fascial slings to compensate for the middle and lower trapezius, and transfer of the levator scapulae to compensate for the upper trapezius.

ferred muscles. Scapulothoracic crepitus and bursitis may develop after this surgery as well.

Long Thoracic Nerve Injury and Serratus Anterior Palsy

Palsy of the serratus anterior muscle can also cause painful, disabling winging. The long thoracic nerve, which powers

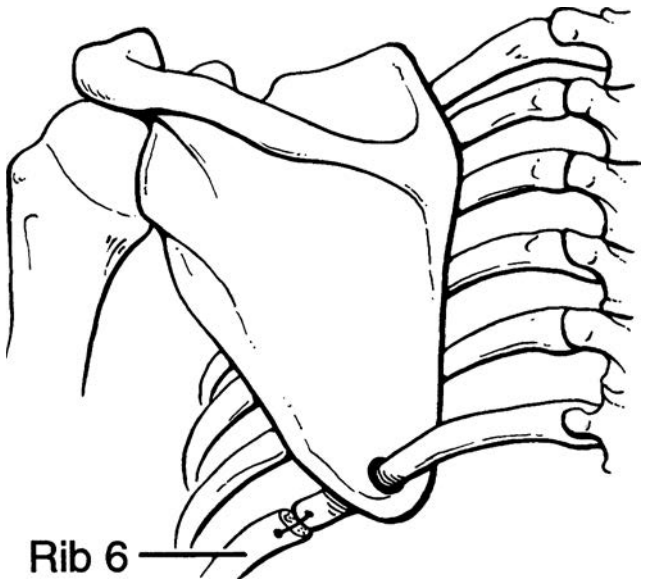

Figure 34-12 Spira's partial fusion for trapezius palsy. In this procedure a hole is made in the inferior angle of the scapula, and the sixth rib is passed through the scapula, stabilizing it.

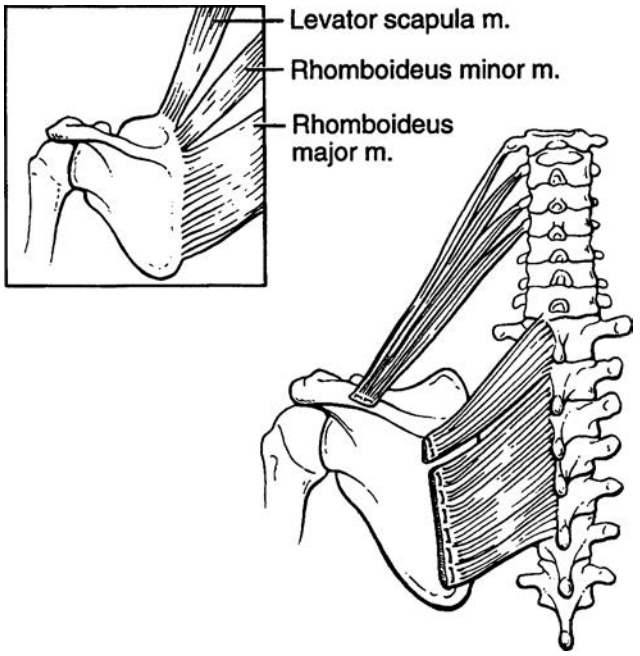

Figure 34-13 Eden-Lange procedure for trapezius palsy. In this procedure, the levator scapula is transferred laterally to function as the upper trapezius, while advancement of the rhomboid major and minor compensate for the loss of the middle and lower trapezius.

the serratus anterior muscle, originates from the ventral rami of the C5, C6, and C7 cervical nerves and travels beneath the brachial plexus and clavicle and over the first rib. It then travels superficially along the lateral aspect of the chest wall, which makes the nerve susceptible to injury (Fig. 34-14). Recently, a fascial band from the inferior aspect of the brachial plexus superior to the middle scalene muscle and inserting on the first rib was found to possibly be a source of nerve compression as the nerve has been shown to "bowstring" across this band with abduction and external rotation.[72]

Signs and Symptoms

Blunt trauma or stretching of this nerve is particularly common in athletics and has been observed in tennis players, golfers, swimmers, gymnasts, soccer players, bowlers, weight lifters, ice hockey players, wrestlers, archers, basketball players, and football players.[48,60,102,179] Repetitive industrial use of the shoulder has also been implicated as a cause of serratus paralysis.[132,163] Penetrating trauma will rarely cause injury to this nerve, yet surgical procedures such as radical mastectomy, first rib resection, and transaxillary sympathectomy have all been identified as potential sources of injury to the long thoracic nerve.[102] This nerve can also be affected by nontraumatic events, including positioning during anesthesia,[132,163] the sequelae of viral illness[45,143] and inoculations,[6] and neuritis affecting the brachial plexus or long thoracic nerve

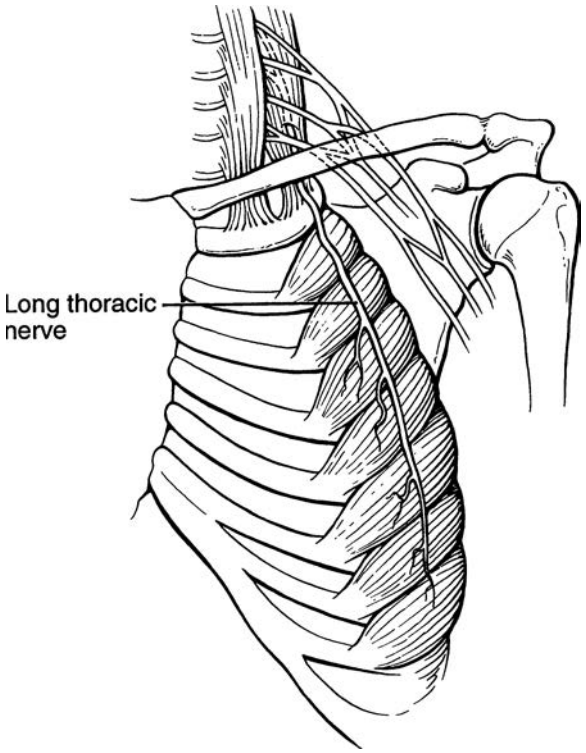

Figure 34-14 Location of the long thoracic nerve. Its superficial location along the chest wall makes it susceptible to injury. (Reprinted with permission from Kuhn JE, Hawkins RJ. alone.[78,79,134] Prolonged bed rest has also been reported to trigger a dysfunction of the long thoracic nerve, particularly if the arm is abducted, for example, propping up the head to read.[104,132,140,142] Interestingly, because the long thoracic nerve has a significant C7 component, patients with a C7 radiculopathy may also present with serratus anterior weakness and scapular winging.[110]

Patients with serratus anterior palsies will complain of pain as the other periscapular muscles try to compensate. More severe pain may indicate an acute brachial plexus neuritis[137] or Parsonage-Turner syndrome, which may affect the long thoracic nerve alone.[134] With an injury to the long thoracic nerve and dysfunction of the serratus anterior muscle, the scapula assumes a position of superior elevation and medial translation, and the inferior pole is rotated medially (see Fig. 34-9). The patient will have difficulty with arm elevation above 120 degrees, which will magnify the degree of winging.[51,84] Pain may be increased with this maneuver and when the head is tilted toward the contralateral side.[137]

Diagnosis and Imaging

Electromyography is recommended to confirm the diagnosis and follow the recovery of the injured long thoracic nerve. When requesting an electromyographic analysis, it is important to specify an evaluation of the long thoracic nerve and serratus anterior muscle. Because the majority of long thoracic nerve palsies will recover spontaneously, regular electromyographic examinations at 1- to 3-month intervals have been recommended to follow nerve recovery.[80,104]

Natural History

Most injuries to the long thoracic nerve are neurapraxic injuries from stretching the nerve. Patients may be able to identify the source of the injury, but frequently the winging is noted without a profound injury. The patient loses arm function, feels like the shoulder is weak, and has pain. These injuries typically do recover, although slowly. Most long thoracic nerve injuries recover spontaneously within 1 year,[9,41,47,51,52,59,60,66,78,81,84,104,132,140,142] although maximal recovery may take up to 2 years.[51,57,103]

Treatment Options

Treatment options are offered as an algorithm in Fig. 34-15. Nonoperative treatment should be implemented immediately upon diagnosis and should include range-of-motion exercises to prevent glenohumeral stiffness. Many types of braces and orthotics have been developed, but their use is controversial.[80,116] In general, these braces attempt to hold the scapula against the chest wall, and may have some role if their cumbersome nature is overshadowed by their symptom relief.[52,84,104,192] Some have recommended bracing to limit continued traction on the nerve in hopes of accelerating nerve regeneration.

Surgical Techniques

There are little data in the literature regarding the results of neurolysis, nerve grafting, or repair of an injured long thoracic nerve.[163] Nevertheless, penetrating injuries should undergo nerve exploration and early repair. Neurorrhaphy may be indicated in circumstances when the lesion can be localized.[104] As mentioned above, the lesion is frequently supraclavicular and neurolysis in this region has been performed in a few patients with good success.[38] Many patients with persistent impairment of the serratus anterior are able to compensate and would not elect to have a surgical reconstruction.[104] In patients with symptomatic serratus winging that persists for more than 1 year, surgical intervention may alleviate pain and improve function. Historically, the operations for serratus paralysis can be classified into three types: scapulothoracic fusions[68]; fascial sling suspensions[36,176,189]; and muscle transfers that have utilized pectoralis minor,[22,79,144] pectoralis major,[155] the sternocostal head of pectoralis major,[42,177] the clavicular head of pectoralis major,[43] teres major,[65] the rhomboideus muscles,[71] and combinations.[167,198]

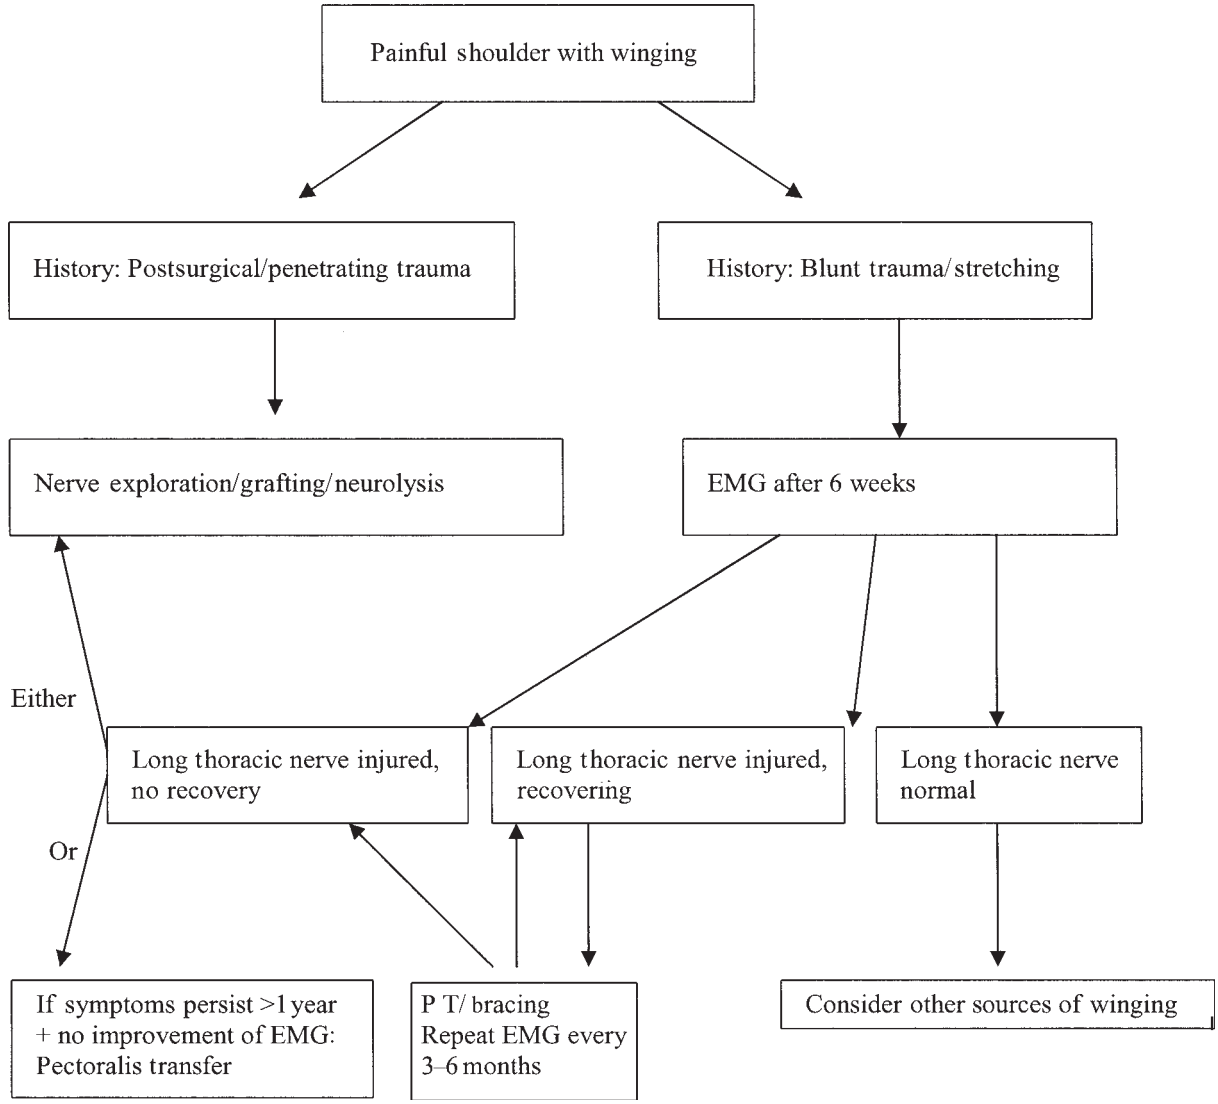

Figure 34-15 Algorithm for treatment of serratus palsy. EMG, electromyography; PT, physical therapy.

Scapulothoracic fusions as a first operation for serratus winging have been discouraged by some,[12,78] primarily for their inherent loss of motion. Pain relief, however, is a reasonable expectation.[68] Complications of scapulothoracic fusions are many and include nonunions and pneumothorax.[68] For these reasons, and because of the limited expectations with regard to motion, scapulothoracic fusions have been generally reserved for salvage operations after failure of other techniques, or for patients with paralysis of other shoulder girdle muscles in addition to the serratus anterior.[80] Another possible indication for primary scapulothoracic fusion for serratus winging is in the laborer who places heavy demand on the shoulder.[103]

Fascial sling suspensions have had their proponents as well.[5,34,36,176,189] However, significant concern exists with regard to fascial sling failure and recurrence of winging.[76] For these reasons, muscle transfers for dynamic scapular stabilization have gained wide acceptance. Although a variety of muscle transfers have been described, transferring the sternocostal head of the pectoralis major with a fascia lata graft extension[112] has become the most popular[47,56,59,80,104,116,129,135,141,171] (Fig. 34-16).

In this technique,[59,112,116,138] the patient is placed in the lateral decubitus position using a bean bag and the involved arm and forequarter are prepared and draped. An incision is made crossing the axilla from the pectoralis major muscle anteriorly to the inferior tip of the scapula. Alternatively, two incisions can be used, with the pectoralis tendon and graft tunneled along the chest wall subcutaneously. The sternocostal head of the pectoralis major is released from its insertion on the bicipital groove of the humerus. A graft of fascia lata measuring 7″ × 2″ is harvested from the ipsilateral

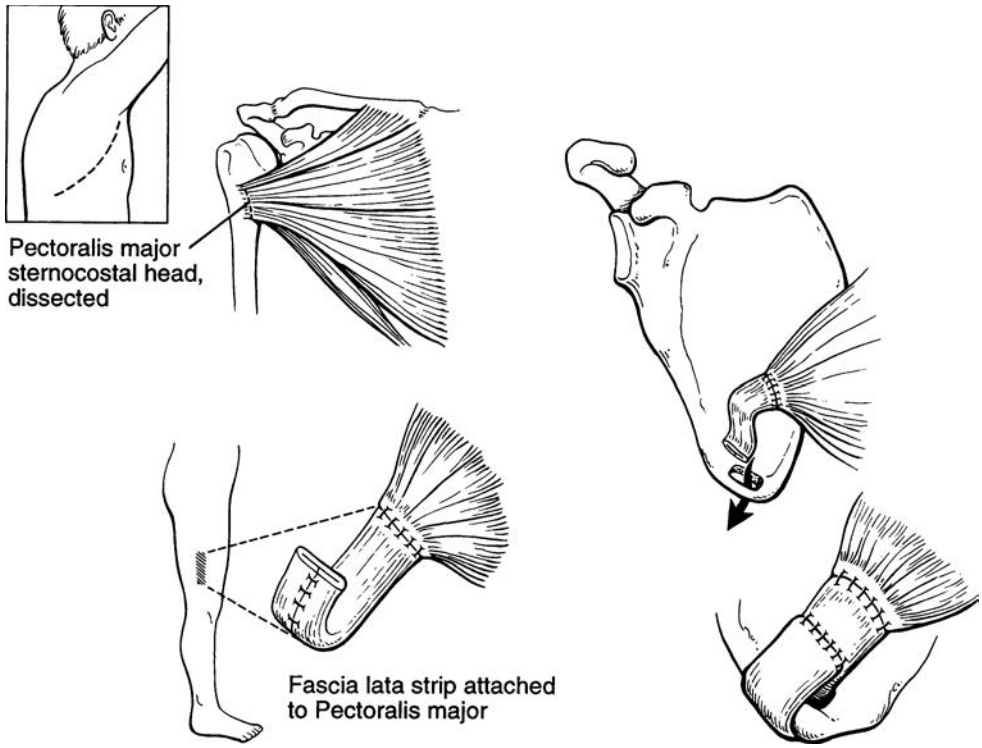

Figure 34-16 Pectoralis major transfer for scapular winging. As described by Marmor and Bechtol,[103] the sternocostal head of the pectoralis major is sutured to a tubularized fascia lata graft and woven through a foramen made in the inferior angle of the scapula. (Reprinted with permission from Kuhn JE, Hawkins RJ. Evaluation and treatment of scapular disorders. In: Warner JP, Iannotti JP, Gerber C, eds. *Complex and revision problems in shoulder surgery.* Philadelphia: Lippincott-Raven Publishers, 1997:357–375.)

leg and sutured into a tube, 7″ long. Alternatively, hamstring tendon may be used. This graft is then sutured to the distal portion of the freed pectoralis tendon. After the inferior border of the scapula has been exposed, a foramen is made in the inferior angle. The graft is inserted through this defect and sutured to itself under moderate tension. It is important to position the graft such that the end of the pectoralis tendon meets the scapula, and the fascia lata graft is used as augmentation. To prevent stretching of the transferred tendon, it has been recommended to have the pectoralis tendon reach the scapula, using augmentation only when necessary.[141] The wounds are closed in layers.

Postoperative Considerations

Postoperatively the arm is placed in a sling or abduction pillow for comfort. Early passive motion is started immediately. Active motion is begun at 6 weeks and strengthening at 12 weeks. Overaggressive therapy may stretch the graft and should be avoided. A scapulothoracic brace may be worn to prevent winging during healing.

Results of Treatment

Although there are few large series in the literature, results using this technique have been encouraging, with 70% to 91% success rates as determined by normal shoulder motion and a significant reduction in pain and winging.[59,80,102,171]

Complications

Surgical complications of this procedure are few but include pneumothorax, and postoperative chest radiographs should always be taken. Late complications include fracture of the inferior border of the scapula or failure of the graft, both of which will manifest as a recurrence of winging.[138] Management of severe complications can be treated with a scapulothoracic fusion.

Rhomboideus Major and Minor Palsy

Weakness of the rhomboid major and rhomboid minor muscles is a rarely identified cause of scapular winging. These muscles receive innervation from the dorsal scapular nerve, which takes its origin from the C5 nerve root. The dorsal scapular nerve passes deep to or through the levator scapulae on its way to the rhomboids. Scapulothoracic winging may result from a C5 radiculopathy or an injury to the dorsal scapular nerve.[152]

Signs and Symptoms

Patients with rhomboid weakness may complain of pain along the medial border of the scapula. The winging produced by rhomboideus palsy at rest is usually minimal, but may appear similar to trapezius winging with the shoulder slightly depressed, the scapula laterally translated, and the inferior angle rotated laterally. In addition, atrophy along the medial border of the scapula may be evident. During arm elevation the inferior angle of the scapula is pulled laterally and downward by the unopposed serratus anterior muscle.[34] With rhomboid weakness, the winging is accentuated by slowly lowering the arm from the forward-elevated position, during which time the inferior angle of the scapula is pulled laterally and dorsally.[152] Patients will have difficulty pushing the elbows backwards against resistance with the hands on the hips.[67]

Diagnosis and Imaging

Electromyography and nerve conduction studies will help differentiate this type of winging from winging caused by other neurologic injury.

Natural History

Unlike other forms of neurapraxic winging, rhomboid winging is not likely going to improve spontaneously. However, the winging is generally not as severe as other forms of winging and may be less symptomatic.

Treatment Options

A treatment algorithm for rhomboid winging is offered in Fig. 34-17. In patients with C5 radiculopathies, addressing

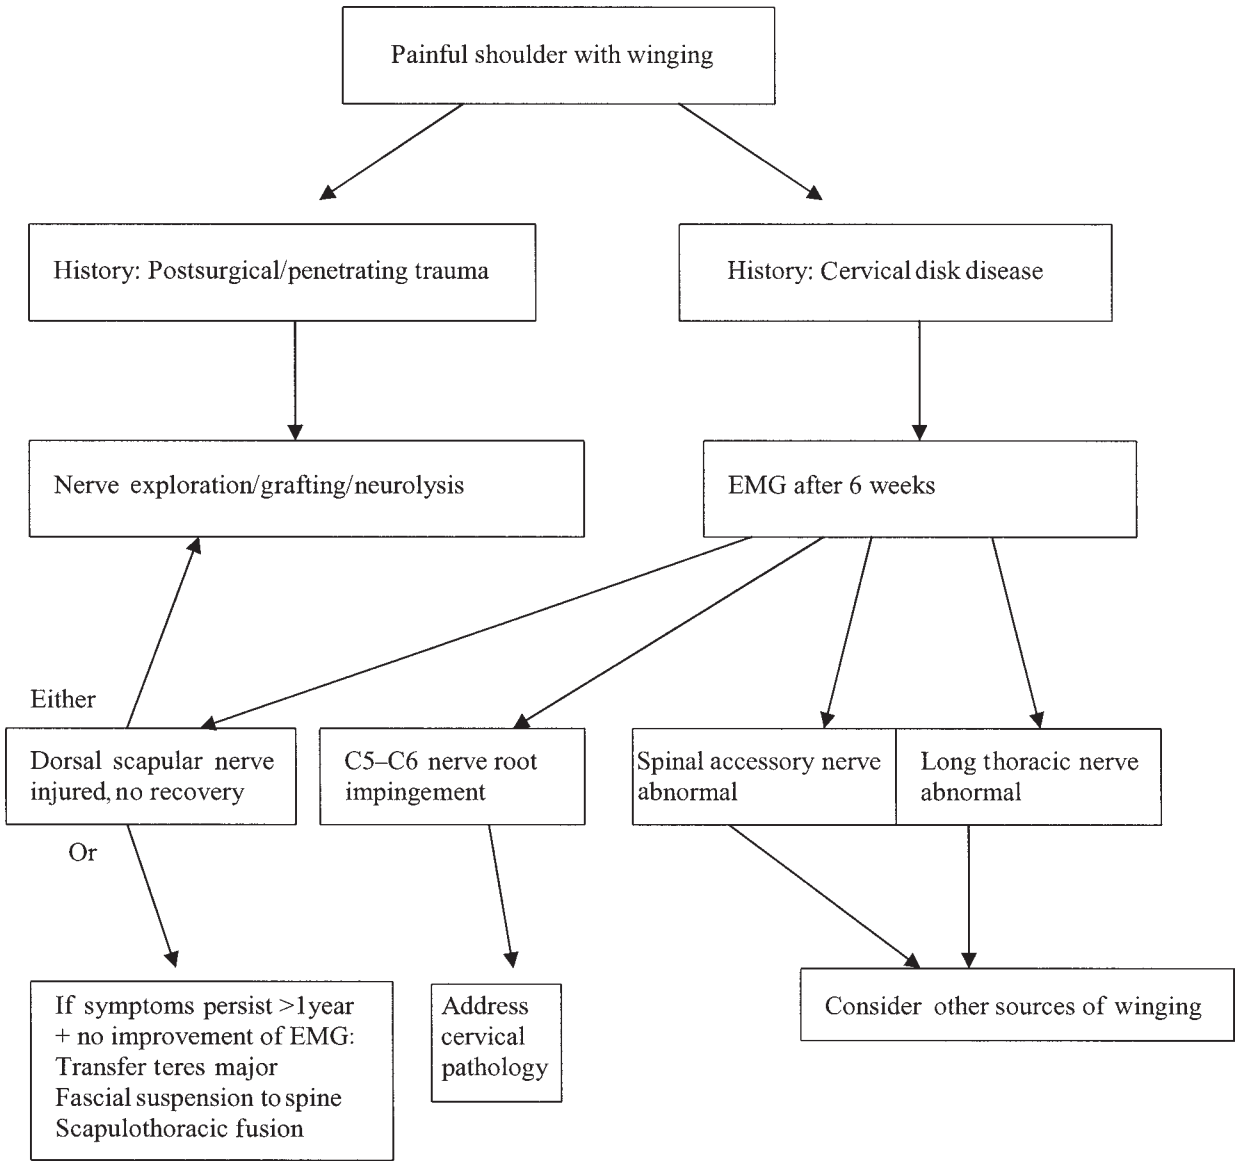

Figure 34-17 Algorithm for treatment of rhomboid palsy. EMG, electromyography.

the source of the radiculopathy may provide some benefit. In general, the treatment of rhomboideus winging consists of trapezius strengthening exercises.

Surgical Techniques

The patient who has significant symptoms and fails nonoperative treatment may be helped by a fascial sling operation as described by Dickson.[34,36] In this operation two fascia lata grafts are tubularized and used to connect the lower vertebral border of the scapula to the spinal muscles and the inferior angle of the scapula to the fibers of the latissimus dorsi. Alternatively, hamstring tendons may be used. This procedure is thought to be useful in stabilizing the scapula and partially arresting the high thoracic scoliosis that may occur with rhomboid and levator scapulae paralysis.[34] There is some concern that fascial sling suspensions may elongate and fail in time.[76] Alternatively, creative muscle transfers may be entertained, such as a transfer of the teres major where the insertion is taken from the humerus, the muscle is flipped on itself, and the insertion is secured to the spinous processes. Finally scapulothoracic fusion may be considered as well.

Postoperative Considerations

The postoperative management of these patients may be difficult. For surgeries designed to stabilize the scapula, either fascial slings or fusions, limiting scapular motion for 8 to 12 weeks is ideal. This can be done with the help of an abduction pillow and/or a scapular brace.

Results of Treatment

There are very few series in the literature to gauge the results of treatment for this type of winging.

Complications

Any surgery around the scapulothoracic articulation, in particular scapulothoracic fusions, is at risk for the development of pneumothoraces. Fascial sling suspensions have been described as having a risk of late failure, after which a fusion may be warranted.

Primary Scapular Winging—Muscle Disorders

Muscle abnormalities that cause winging have included traumatic ruptures and congenital absence of periscapular muscles. In the cases of serratus anterior muscle avulsion, significant trauma has occurred that pulls the muscle insertion from the medial border of the scapula.[50,69,119,132,187] Fiddian and King reported a case of serratus anterior division during thoracotomy, which was a source of symptomatic winging.[48] In these cases, nerve conduction studies are likely to be normal and computed tomography (CT) or magnetic resonance imaging (MRI) should be considered to assist in the diagnosis. Surgical reattachment is recommended in all patients and excellent results can be expected.[50,69,132,187] Advanced age with systemic disease may, however, be a contraindication to surgery.[119] Congenital absence of the serratus anterior,[26,106] the trapezius,[77,88,157,158] and the rhomboideus major and trapezius muscles[159] have all been reported. Patients with these congenital anomalies, however, seem to function very well without treatment.[193]

Fascioscapulohumeral Dystrophy

Fascioscapulohumeral dystrophy is a genetic neuromuscular dystrophy[46] characterized by deletion of the subtelomeric region of chromosome 4q35 and affects the muscles of the face, shoulder girdle, and upper limbs, producing a profound scapular winging of a muscular origin.[83,146]

Signs and Symptoms

A notable feature of fascioscapulohumeral muscular dystrophy is substantial weakness of the shoulder girdle muscles, scapulothoracic instability, and impairment of shoulder flexion and abduction[61]; however, the deltoid seems to be spared. As the scapular stabilizing muscles are affected, patients with this disorder have difficulty with abduction and forward elevation.[61] However, if stability of the scapulothoracic articulation is achieved, the deltoid is able to elevate the arm and improve function.

Diagnosis and Imaging

The diagnosis is clinical and is made with genetic testing.

Natural History

This disorder typically presents in the second decade of life and has a slow progression.[17] However, dysfunction of the upper extremities makes employment and activities of daily living difficult.[188]

Treatment Options

Because this disorder is characterized by multiple muscle involvement, muscle transfers are generally not available, and this form of muscle-origin scapular winging is treated best with a scapulothoracic fusion.[10,18,30,82,89,105]

Surgical Techniques

When performing surgery, it is advisable to use a double lumen endotracheal tube to allow for selective deflation of the ipsilateral lung during wire placement around the ribs.

The patient is positioned prone. The entire arm, scapula thorax, and ipsilateral posterior iliac crest are prepared and draped in the operating field.

An incision is made along the medial border of the scapula from just superior to the scapular spine to the inferior angle. The trapezius muscle is dissected from the spine of the scapula and retracted medially. The rhomboid muscles are dissected from the medial scapula with care to protect the fascial insertional tissue for later reattachment. The medial scapula border can then be retracted laterally and posteriorly to gain access to the posterior thorax.

The subscapularis origin is dissected from the undersurface of the medial border of the scapula approximately one-third of the width of the scapula. The ventral surface of the scapula bone is decorticated with a burr. This should be a minimal decortication to prevent weakening of the scapula and potential later fracture.

At this point the scapula is reduced to the rib cage in the position of interest. For facioscapulohumeral dystrophy, the inferior angle of the scapula should lie over the seventh rib. The vertebral side of the spine of the scapula should lie between the third and fourth rib and should be angled 15 to 20 degrees from the midline.[109] The vertebral border should rest 5 to 7 cm from the spinous processes.[30] This position is thought to prevent neurovascular complications. For other conditions the position may be altered. For example, for problems with associated glenohumeral joint instability, a position of increased angulation of 35 to 40 degrees has been recommended.[97] At this point the ribs corresponding to the decorticated ventral surface of the scapula are identified (typically ribs three to six). The scapula is retracted again, and the ribs are prepared by incising the periosteum and then decorticating lightly with a burr. It is important to remove all soft tissue between the ribs and scapula to allow for bony fusion.

The involved lung is deflated, and cerclage wires (1.5 mm) are passed around the ribs using periosteal dissectors. The location of the wires should correspond to the medial border of the scapula. At this point a one-third semitubular, five- or six-hole, large fragment plate is aligned with the medial border of the scapula on the dorsal side. A 3-mm burr is used to make holes through the scapula at the medial border and the wires are passed through the scapula and through the holes on the plate.

Cancellous bone harvested from the posterior iliac crest is used between the ribs and the scapula, and the wires are then tightened over the plate, compressing the scapula to the ribs. The lung is reinflated, and irrigation is used to search for a pneumothorax. Pneumothorax is very common and a chest tube is placed at this time. The chest tube is also placed to drain any reactive pleural effusion or blood.

Closure is performed in layers. First the rhomboids are reattached to the medial border of the scapula, and then the trapezius may be reattached to the spine. The subcutaneous tissue and skin are closed routinely.

Postoperative Considerations

The patient is placed in a gunslinger-type brace and admitted for observation. A chest radiograph is obtained to evaluate pneumothorax or hemothorax. The chest tube is typically removed after 1 to 2 days.

Patients are discharged with the gunslinger brace. Immobilization is used for 12 weeks. At 12 weeks, physical therapy can begin starting with gentle passive range of motion, emphasizing forward elevation and external rotation. At 16 weeks patients can progress to active range of motion. Strengthening should begin at approximately 18 to 20 weeks after surgery.

Outcomes of Treatment

Humeral function after applying manual compression of the scapula on the chest wall can be useful to predict a successful surgical outcome.[184] Most authors report successful outcomes of long duration[30] with shoulder flexion increasing at least 33 to 56 degrees and abduction increasing at least 25 to 44 degrees.[2,105,178] Although some have performed surgery on both scapulae at the same time,[94] the length of the surgery, the substantial postoperative pain, and the lengthy period of immobilization usually direct the surgeon and patient to having one side fused first and the second side fused at a later date.

Complications

Reported complications include brachial plexopathy,[191] vascular compromise,[109] pleuritic chest pain, pneumothorax, rib stress fractures, and irritation from surgical hardware.[184] Pseudarthrosis is a common complication occurring in approximately 25% of cases.[97]

Primary Scapular Winging—Bony Abnormalities

Bone abnormalities that may present as scapular winging include osteochondromas, the most common tumor of the scapula, which can be a cause of "pseudowinging"[28,32,48,108,135] (Fig. 34-18). Rib osteochondromas may also cause scapular winging.[48] Malunions of fractures of the scapula and clavicle have also been implicated as a source of primary winging of the scapula.[48,118] Because the muscle function would not be expected to be impaired, these patients may not be symptomatic.

Signs and Symptoms

This type of scapular winging is structural and may be associated with scapular crepitus. Patients will have static scapular winging, which may not change with varying the position of the arm.

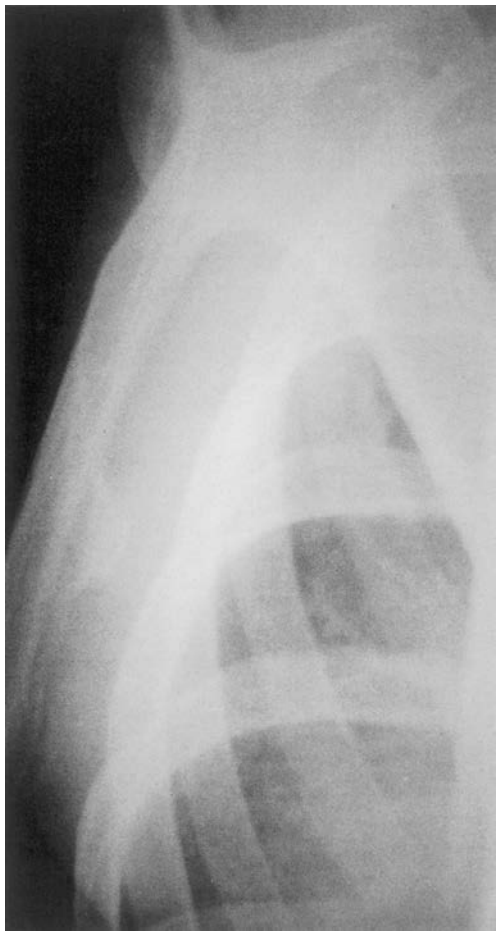

Figure 34-18 Radiograph of a scapular osteochondroma causing scapular winging and crepitus. The patient's symptoms resolved completely with resection of the osteochondroma. (Reprinted with permission from Kuhn JE, Hawkins RJ. Evaluation and treatment of scapular disorders. In: Warner JP, Iannotti JP, Gerber C, eds. *Complex and revision problems in shoulder surgery.* Philadelphia: Lippincott-Raven Publishers, 1997:357–375.)

Diagnosis and Imaging

In this instance, electromyography studies will be normal, and the osteochondroma is identified by radiographs tangential to the plane of the scapula, or computed tomography.

Treatment Options

Winging and scapulothoracic crepitus are alleviated with resection of the bony pathology.

Complications

Few complications of resection of bony pathology of the scapula have been reported.

Primary Scapular Winging—Bursal Disorders

The articulation between the scapula and the thorax has bursae, that, in rare circumstances, may become inflamed. This is one source of scapular crepitance and pain. Winging has been identified in 50% of patients with a snapping scapula and no bony abnormalities.[136] This is presumably related to the subscapular bursitis, and with treatment of the bursitis, either by nonoperative means or surgical bursectomy, the winging resolves.

Secondary Scapular Winging

Secondary scapular winging originates from disorders of the glenohumeral joint, which produce abnormal scapulothoracic dynamics (Fig. 34-19). This phenomenon has not been thoroughly investigated in the literature. A thorough evaluation of the patient with secondary scapular winging usually, but not always, identifies the source of the glenohumeral pathology.[170] The physical examination of every patient with a shoulder condition should include looking for secondary scapular winging at rest with dynamic forward elevation and with resisted forward elevation. A characteristic of secondary scapular winging is a normal electromyographic examination of the long thoracic nerve and serratus anterior, the spinal accessory nerve and trapezius, and the dorsal scapular nerve and rhomboids.

Contractural winging[4] is one example in which contractures about the glenohumeral joint can produce secondary scapular winging. Patients with upper root brachial plexus injuries develop contractures due to unbalanced muscle forces with the humerus abducted and internally rotated relative to the scapula. When the arm is forcibly adducted to the chest wall and externally rotated, the superior corner of the scapula projects away from the chest wall, producing the "scapular sign of Putti,"[156] otherwise known as contractural

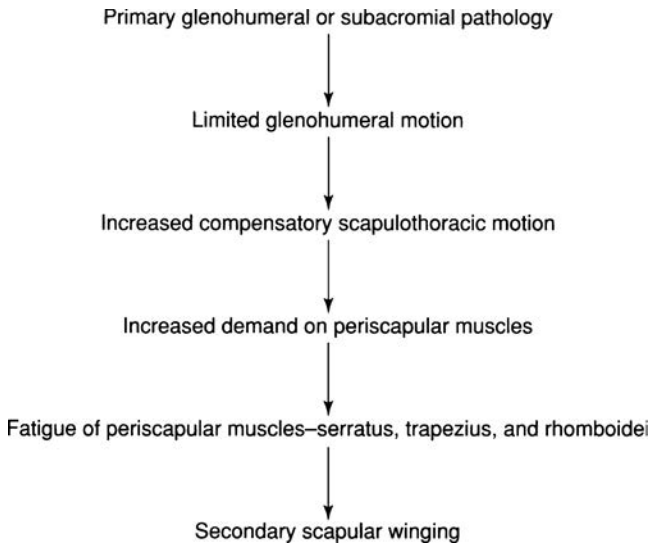

Figure 34-19 Sequence of events leading to secondary scapular winging. (Reprinted with permission from Kuhn JE, Hawkins RJ. Evaluation and treatment of scapular disorders. In: Warner JP, Iannotti JP, Gerber C, eds. *Complex and revision problems in shoulder surgery.* Philadelphia: Lippincott-Raven Publishers, 1997:357–375.)

winging.[4] Contractural winging can also occur with fibrosis of the deltoid muscle in which the winging decreases with arm elevation and increases with lowering of the arm.[175] This condition is thought to be either congenital[148,190] or related to a history of injections into the deltoid muscle[62,124] and is almost always associated with winging of the scapula.[124]

Other more common disorders involving the glenohumeral joint can be a source of secondary scapular winging. This is thought to occur by reflex muscle spasm provoked by some painful condition in the glenohumeral or subacromial areas.[175] This has been associated with rotator cuff tears,[175] nonunion of acromion fractures,[60] malunion of clavicle fractures,[48] fractures of the glenoid,[48] avascular necrosis of the humeral head,[60] acromegalic arthropathy of the shoulder,[48] acromioclavicular joint disorders,[48,170] and shoulder instability.[48,49,154,170] In our practice we have observed secondary scapular winging in patients with adhesive capsulitis, the impingement syndrome, and anterior shoulder instability, and in throwing athletes with secondary impingement due to subtle shoulder instability. We suspect that patients with painful shoulders reflexively limit glenohumeral motion. This forces the periscapular muscles to work in excess as scapulothoracic motion must increase to compensate for the limited glenohumeral motion. With fatigue of the periscapular muscles, particularly the serratus anterior, trapezius, and rhomboids, scapular winging occurs (see Fig. 34-19). As has been shown,[170,175] treatment of the primary glenohumeral pathology will alleviate the scapular winging, and conversely the scapular winging is unlikely to improve until the primary source of pathology is addressed.[170] A scapular rehabilitation program should be added to the treatment of the primary glenohumeral pathology to facilitate recovery in every patient with secondary scapular winging.[127,133]

Voluntary Scapular Winging

Voluntary scapular winging is also very rare.[48,60,149,170] Rowe reported on four patients with voluntary scapular winging. These patients were assured and instructed on the normal muscle firing patterns of the shoulder with "instructions not to tighten or contract their shoulder muscles when elevating the arm."[149] All four patients recovered after this coaching. Gregg et al. described asymptomatic bilateral voluntary scapular winging in an orthopaedic resident.[60] It is important to appreciate that patients with voluntary scapular winging who seek medical attention, like patients with voluntary subluxation of the shoulder, may have unaddressed psychologic issues complicating their care.[150]

SCAPULAR DYSKINESIA

Although static scapulothoracic abnormalities have been recognized in the past, dynamic scapulothoracic dyskinesia was an underappreciated phenomenon until recently. Investigations in normal and athletic patients have demonstrated significant alterations in the dynamic motion of the scapulothoracic articulation when accompanied by shoulder pathology. It is uncertain if the scapular dyskinesis is a primary problem or a secondary problem that develops as a consequence of other glenohumeral joint pathology. A variety of pathologies have been associated with scapular dyskinesis, as scapular motion also determines the location of the glenohumeral joint in space and is important not only to optimize glenoid placement relative to the humeral head to maintain glenohumeral joint stability, but also to elevate the acromion to allow motion without impingement.

Rotator Cuff Pathology

In their study evaluating scapulothoracic motion using Moire topographic analysis, Warner et al. found static scapulothoracic asymmetry present in 32% of patients with glenohumeral instability and 57% of patients with subacromial impingement.[186] Dynamic testing was more sensitive with asymmetric scapulothoracic motion in 64% of patients with glenohumeral instability and all patients with impingement.[186]

The pectoralis minor tendon is thought to be contracted, and painful, which has been shown to influence scapulothoracic kinematics and produce subacromial impingement.[16] Somewhat related, thoracic and scapular posture has profound influences on shoulder range of motion and the range of shoulder motion before impingement symptoms develop.[107]

Glenohumeral Instability

As mentioned above, in their study evaluating scapulothoracic motion using Moire topographic analysis, Warner et al. found static scapulothoracic asymmetry present in 32% of patients with glenohumeral instability.[186] Scapular position seems to be altered in patients with multidirectional instability, which is thought to be causative of failure of humeral head centering.[181]

The Dysfunctional Athlete's Shoulder

Throwing athletes with anterior shoulder instability have altered scapulothoracic mechanics, with the serratus anterior demonstrating a marked reduction in activity during throwing.[55] A consistent firing pattern of the scapular stabilizing muscles has been identified by electromyographic studies in the overhand athlete.[37,93] These studies have determined that throwing and other overhand athletic motions are dependent upon synchronized, coordinated scapulothoracic motion. A coordinated firing pattern of the posterior scapular stabilizing muscles helps to stabilize

the shoulder joint distributing the substantial forces in throwing to the thorax.[93] Alterations in this coordinated activity are thought to uncouple the force relationships required for throwing and lead to decreased efficiency and/or an increased risk for injury. The position of the scapula during the throwing motion will determine the muscle length–tension relationships and allow for maximum muscle force generation and efficiency.[90] Finally, periscapular muscles may be important in providing power and accepting eccentric load, as the scapula is maximally retracted during windup and cocking and maximally protracted during acceleration and follow-through.[55,90,93] Restricted scapulothoracic retraction may limit the power stored in the windup and cocking phases of throwing. In addition, limited protraction may cause the eccentric loading to be transferred to the posterior capsule and posterior rotator cuff tendons of the glenohumeral joint during the follow-through phase of overhead throwing. These excessive repetitive stresses may lead to rotator cuff injury or glenohumeral instability. Overhand throwing athletes often present with abnormal scapular function in the form of winging, poor retraction, poor protraction, poor positioning, or some other form of dyskinesia.

Myers and colleagues studied this concept by measuring scapulothoracic motion in a population of throwing athletes and compared this to scapulothoracic motion in a control population.[128] They showed that throwing athletes demonstrated significantly increased upward rotation, internal rotation, and retraction of the scapula during humeral elevation, implying that throwing athletes may develop these adaptations for more efficient performance of the throwing motion. Su et al. have demonstrated that scapular kinematics may be altered in symptomatic swimmers, an effect that is magnified with fatigue associated with a practice.[173]

Signs and Symptoms

Patients with scapulothoracic dyskinesis will not typically direct the physician toward the scapula, and will complain of pains in the glenohumeral joint. Inspection of the scapulae from the back will demonstrate asymmetry at rest, with the affected shoulder frequently depressed and the scapula protracted and tilted forward. Mild scapular winging may be present with the posterior angle and the medial border of the scapula prominent. Patients will frequently have pain to palpation at the medial coracoid, the insertion of the pectoralis minor. Asking the patient to elevate the arm in the frontal plane and in the scapula plane will reveal asymmetry in scapulothoracic motion. In the presence of rotator cuff pathology, this may be related to decreased firing of the middle and lower trapezius.[29]

Kibler has described the scapular lateral slide test to evaluate patients with abnormal scapulothoracic function.[90] This test evaluates the patient's ability to stabilize the medial border of the scapula during different positions and loads. To perform this test, the arms are held in three different positions and the distance between the medial border of the scapula and the thoracic spinous processes is measured bilaterally. These positions include (a) relative rest in neutral rotation, (b) the hands on the hips with the thumbs pointing posteriorly, and (c) the arms abducted to 90 degrees with maximal internal humeral rotation. In the asymptomatic athlete, symmetry is the general rule, with less than 1 cm side-to-side difference. In symptomatic throwers, more than 1 cm side-to-side difference in position b or c is statistically associated with pain and decreased function.[91]

The clinical implications of this abnormal lateral protraction of the scapula include increased anteversion of the glenoid, opening the anterior half of the glenohumeral articulation. This may create a situation predisposing the patient to increased instability and glenoid labral damage.[90,153] Loss of retraction may prevent optimal energy storage during the windup and cocking phases of throwing, with reduced power. Finally, abnormal scapulothoracic dynamics may limit acromial elevation, producing rotator cuff impingement (see Fig. 34-3).

Burkhart et al. recently described a condition known as the SICK scapula.[19] The acronym SICK stands for Scapula malposition, Inferior medial border prominence, Coracoid pain and malposition, and dysKinesis of scapular movement. The scapula assumes an abnormal position at rest, characterized by a position that is inferior, protracted, and tilted anteriorly. Tenderness is typically found on the medial edge of the coracoid, and the pectoralis minor is thought to be in spasm. The authors recognized this pattern in throwing athletes with shoulder pain.

Diagnosis and Imaging

The diagnosis of scapular dyskinesis is made clinically during the physical examination. While examining patients with shoulder complaints, the back of the shoulder should be inspected at rest and with elevation of the arm. Pain in the rotator cuff can frequently be ameliorated using the scapular assistance test, where the examiner supports the medial border of the scapula and assists its rotation and protraction during arm elevation.[92]

Natural History

As the concept of scapular dyskinesis is relatively new, there are little data on the natural history if left untreated. Although the association between scapular dyskinesis and glenohumeral joint pathology is apparent, it is unclear if the scapular dyskinesis is the primary problem creating

glenohumeral pathology, or if the glenohumeral pathology leads to dyskinesis of the scapula.

Treatment Options

When evaluating patients with shoulder disorders for rehabilitation, it is important to consider and treat abnormal scapulothoracic function, as the scapula is an essential component to most upper-extremity activities. In treating these disorders, rehabilitation begins at the base of the kinetic chain, the legs, hips, and back, and moves distally to the shoulder when the foundation is functioning adequately.[90] Periscapular muscle-strengthening exercises should be an integral component to the complete shoulder rehabilitation program. Strengthening exercises for the rotator cuff should generally be avoided until the scapulothoracic articulation is functioning normally. Kinetic chain-based rehabilitation programs have been recommended,[92,151] as many of the patients with scapulothoracic kinematic abnormalities will have weakness in the core stabilizers of the trunk.

In general, treatment for athletes is nonoperative and requires postural exercises designed to prevent sloping of the shoulders, massage and stretching for a tight pectoralis minor, and hip- and trunk-strengthening exercises.[19,151] Despite these recommendations, there are no series in the literature evaluating the treatment or complications of treatment for scapular dyskinesis. Clearly more work is needed to gain a complete understanding of scapulothoracic problems in the athlete.

SCAPULOTHORACIC CREPITUS

Symptomatic scapulothoracic crepitus has been given a variety of names through the years, including the snapping scapula,[121] the washboard syndrome,[26] the scapulothoracic syndrome,[126] the rolling scapula,[24] the grating scapula,[129] and the scapulocostal syndrome.[161] While Codman himself stated that he was able to make his own scapula "sound about the room without the slightest pain,"[25] Boinet[15] was the first to describe this disorder in 1867. Thirty-seven years later, Mauclaire[114] classified scapulothoracic crepitus into three groups: *froissement* was described as a gentle friction sound and was thought to be physiologic, *frottement* was a louder sound with grating and was usually pathologic, and *craquement* was a loud snapping sound and was always pathologic. These scapular noises are thought to occur from two sources, either anatomic changes in the tissue interposed between the scapula and the chest wall or an incongruence in the scapulothoracic articulation (Table 34-4). Extrapolating from Milch,[121] *frottement* may suggest soft tissue pathology or bursitis, while *craquement* may suggest bony pathology as the source of symptomatic scapulothoracic crepitus. These noises are amplified by the air-filled thoracic cavity, which acts as a resonance chamber, much like a string instrument.[7]

There are a number of described abnormal structures that lay between the scapula and the chest wall that give rise to scapulothoracic crepitus. Pathologic conditions affecting muscle in the scapulothoracic articulation include atrophied muscle,[121] fibrotic muscle,[121,122,187] and anomalous muscle insertions.[166]

The most common bony pathology in the scapulothoracic space that may give rise to scapulothoracic crepitus is the osteochondroma, arising either from the ribs[33] or the scapula[122,123,135] (see Fig. 34-18). Malunited fractures of the ribs or scapula are also capable of creating painful crepitus.[121,122,168] Abnormalities of the superomedial angle of the scapula, including a hooked superomedial angle[123,145] and a Luschka's tubercle (which originally was described as an osteochondroma, but has subsequently come to mean any prominence of bone at the superomedial angle[121,168,183]), have also been implicated as sources for scapulothoracic crepitus. Others[7,148,172] implicate reactive spurs of bone that are created by the microtrauma of chronic, repeated periscapular muscle avulsions.

Certainly, any bony pathology that causes scapulothoracic crepitus is capable of forming a reactive bursa around the

THORACIC KYPHOSIS[19]

A variety of structures interposed between the scapula and thorax may cause crepitus. Similarly, spinal curvatures can cause crepitus by altering the scapulothoracic congruence. (Reprinted with permission from Kuhn JE, Hawkins RJ. Evaluation and treatment of scapular disorders. In: Warner JP, Iannotti JP, Gerber C, eds. *Complex and revision problems in shoulder surgery.* Philadelphia: Lippincott-Raven Publishers, 1997:357–375.)

area of pathology.[31,160] In fact, at the time of resection of bony pathology, a bursa is frequently seen. Bursae can become inflamed and painful in the absence of bony pathology, and may become a source of crepitus on their own right.

Other soft tissue pathology that has been implicated in scapulothoracic crepitus includes tuberculosis lesions in the scapulothoracic region and syphilitic lues.[121] Abnormalities in congruence of the scapulothoracic articulation are the other source of scapulothoracic crepitus. Both scoliosis[58,180] and thoracic kyphosis[24] have been implicated as sources of scapulothoracic crepitus.

Signs and Symptoms

The patient with symptomatic scapulothoracic crepitus may be able to identify the location of the crepitus. A history of overhead activity such as sporting activities[136] or paper hanging may be present.[24] Some suspect there is a familial tendency toward developing symptoms.[24] Patients may relate a history of trauma that precipitates symptoms,[3] and scapulothoracic crepitus may be bilateral in some patients.[23] Upon inspection of the scapula, fullness or winging may suggest a space-occupying lesion in the scapulothoracic space. Palpation or auscultation while the shoulder goes through a range of motion may help to identify the source of the periscapular crepitus.[3,23] A palpable mass, crepitus, prominence at rest, and normal scapulothoracic motion help delineate scapular winging due to a physical mass from neurologic scapular winging. In patients with scapulothoracic crepitus the neuromuscular examination is frequently normal, although some patients may have symptoms of thoracic outlet syndrome with scapulothoracic crepitus.[194]

Diagnosis and Imaging

Supplemental radiographs, which include tangential views of the lateral scapula, CT or MRI scans, may be helpful in identifying anatomic pathology.

Natural History

It is important to realize that scapulothoracic crepitus is not necessarily a pathologic condition. Scapular crepitus has been found in 35% of normal asymptomatic people.[63] As a result of this, patients with hidden agendas or psychiatric conditions may not respond to treatment as well as other patients. However, if the scapulothoracic crepitus is truly associated with pain, winging, or other disorders of the scapulothoracic articulation, then the crepitus is considered to be pathologic.

Treatment Options

A treatment algorithm is offered in Fig. 34-20. Patients with clearly defined bony pathology such as an osteochondroma are unlikely to improve with conservative treatment.[121] Resection of the bony pathology is usually necessary to alleviate symptoms with a high likelihood of success.[122,125,135] Other patients should undergo a trial of conservative treatment, with surgery reserved for those who fail.[111] Conservative treatment seems to be most beneficial if soft tissue disorders are the source of scapulothoracic crepitus.[23,121] These include postural exercises designed to prevent sloping of the shoulders.[23,120] A figure-eight harness may be a useful tool to remind patients to maintain upright posture. Exercises to strengthen periscapular muscles are also thought to be important.[23,121,136] Systemic nonsteroidal antiinflammatory drugs as well as local modalities, such as heat, massage, phonophoresis and ultrasound, and the application of ethyl chloride to trigger points, may also prove useful.[23,121,136] Injections of local anesthetics and corticosteroids into the painful area has also been recommended.[20,24,116,121,136] Caution must be used as there is a risk for creating a pneumothorax.[20] Using these means, most patients are expected to improve significantly[116,136]; however, for those who fail, a number of operations have been described.

Muscle plasty operations include those described by Mauclaire, who reflected a flap of the rhomboids or trapezius and sutured it to the undersurface of the scapula.[114] This is thought to be inadequate, however, because the muscle flap may atrophy with time and symptoms can recur.[121] Rockwood has excised a rhomboid muscle avulsion flap with the elimination of snapping and pain.[20] Partial scapulectomy has also been popular as a means of treating symptomatic scapulothoracic crepitus, including resection of the medial border of the scapula[21] or the superomedial angle.[3,24,96,121,145,172,193]

Surgical Techniques

The surgical technique for the resection of the superomedial border of the scapula begins with the patient in the prone position (Fig. 34-21). An incision based over the medial spine of the scapula is made and the soft tissue dissected down to the spine of the scapula. The periosteum over the spine is incised and a plane is developed between the superficial trapezius and the underlying scapula. Next, the supraspinatus, rhomboids, and levator scapulae muscles are dissected free of the scapula in a subperiosteal plane, starting at the spine of the scapula. The superomedial angle of the scapula is resected with an oscillating saw. Caution is warranted as the resection is carried laterally to avoid injury to the dorsal scapular artery and the suprascapular nerve in the suprascapular notch. After resecting the bone, the reflected muscles fall back into place, and the periosteum is reapproximated back to the spine of the scapula using suture through drill holes.

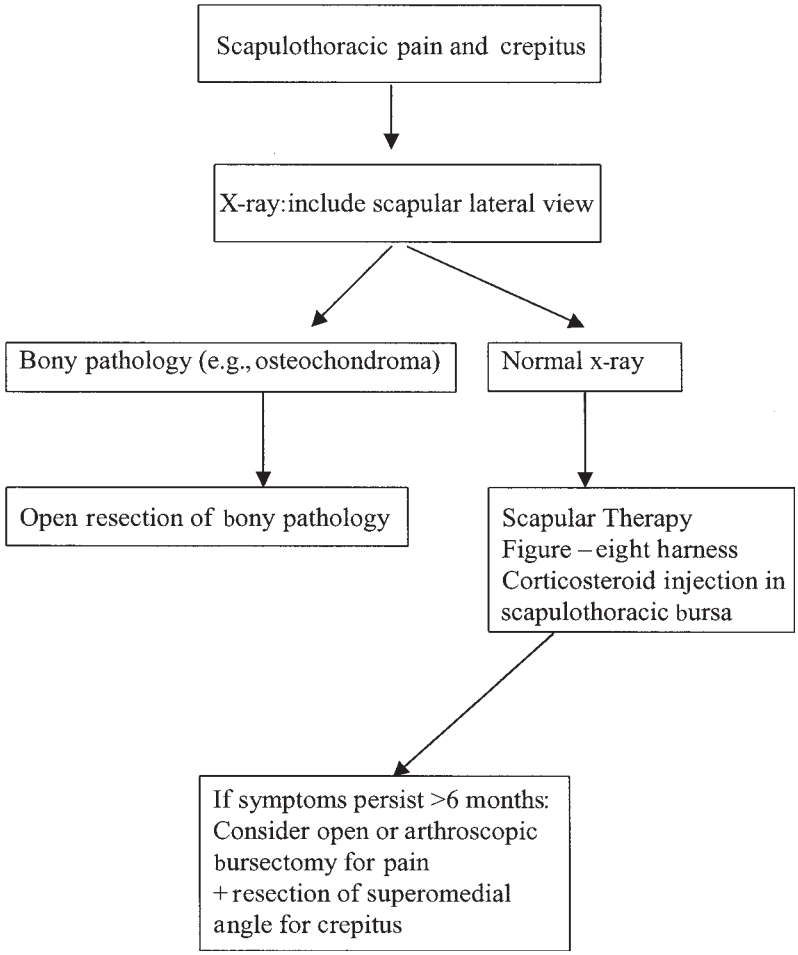

Figure 34-20 Algorithm for treatment of scapulothoracic crepitus.

Postoperative Considerations

Postoperatively, the patient is placed in a sling and begins passive motion immediately. Active motion is begun at 8 weeks, and resistance exercises follow at 12 weeks.

Results of Treatment

Although some authors report mixed results after partial scapulectomy for symptomatic scapulothoracic crepitus,[20] others suggest that this is an excellent option.[24,96,121,145] However most of these reports are case reports or very small series. Arntz and Matsen[3] describe their results after a resection of the superomedial border of the scapula in 14 shoulders in 12 patients with 42 months follow-up. In this relatively large series, 86% of patients obtained complete relief of pain and crepitus. It is important to note that the bone resected appears normal and shows no pathology, which has prompted some to perform bursectomies and avoid a partial scapulectomy.[117,162]

Complications

Complications associated with partial scapulectomy include pneumothorax, postoperative hematoma, and, in younger patients, regrowth of bone. However, this rarely produces symptoms.

SCAPULOTHORACIC BURSITIS

Codman, in his classic text, *The Shoulder,* was clearly one of the first physicians with an interest in scapulothoracic bursitis. He described the bursa of the scapulothoracic articulation and identified and named those bursae in the superomedial border of the scapula that he thought were the cause of symptomatic scapulothoracic bursitis.[25]

Two major or anatomic bursae and four minor or adventitial bursae have been described for the scapulothoracic articulation (Table 34-2, see Fig. 34-7). The first major bursa is found in the space between the serratus anterior muscle and the chest wall. The second major bursa is located between the subscapularis and the serratus anterior muscles.[23,95] These bursae are easily and reproducibly found.[95]

Clinical scapulothoracic bursitis seems to affect two areas of the scapulothoracic articulation: the superomedial angle and the inferior angle of the scapula. When symptomatic, these areas tend to develop inflamed bursae; however, these bursae are not reliably found, and in fact may

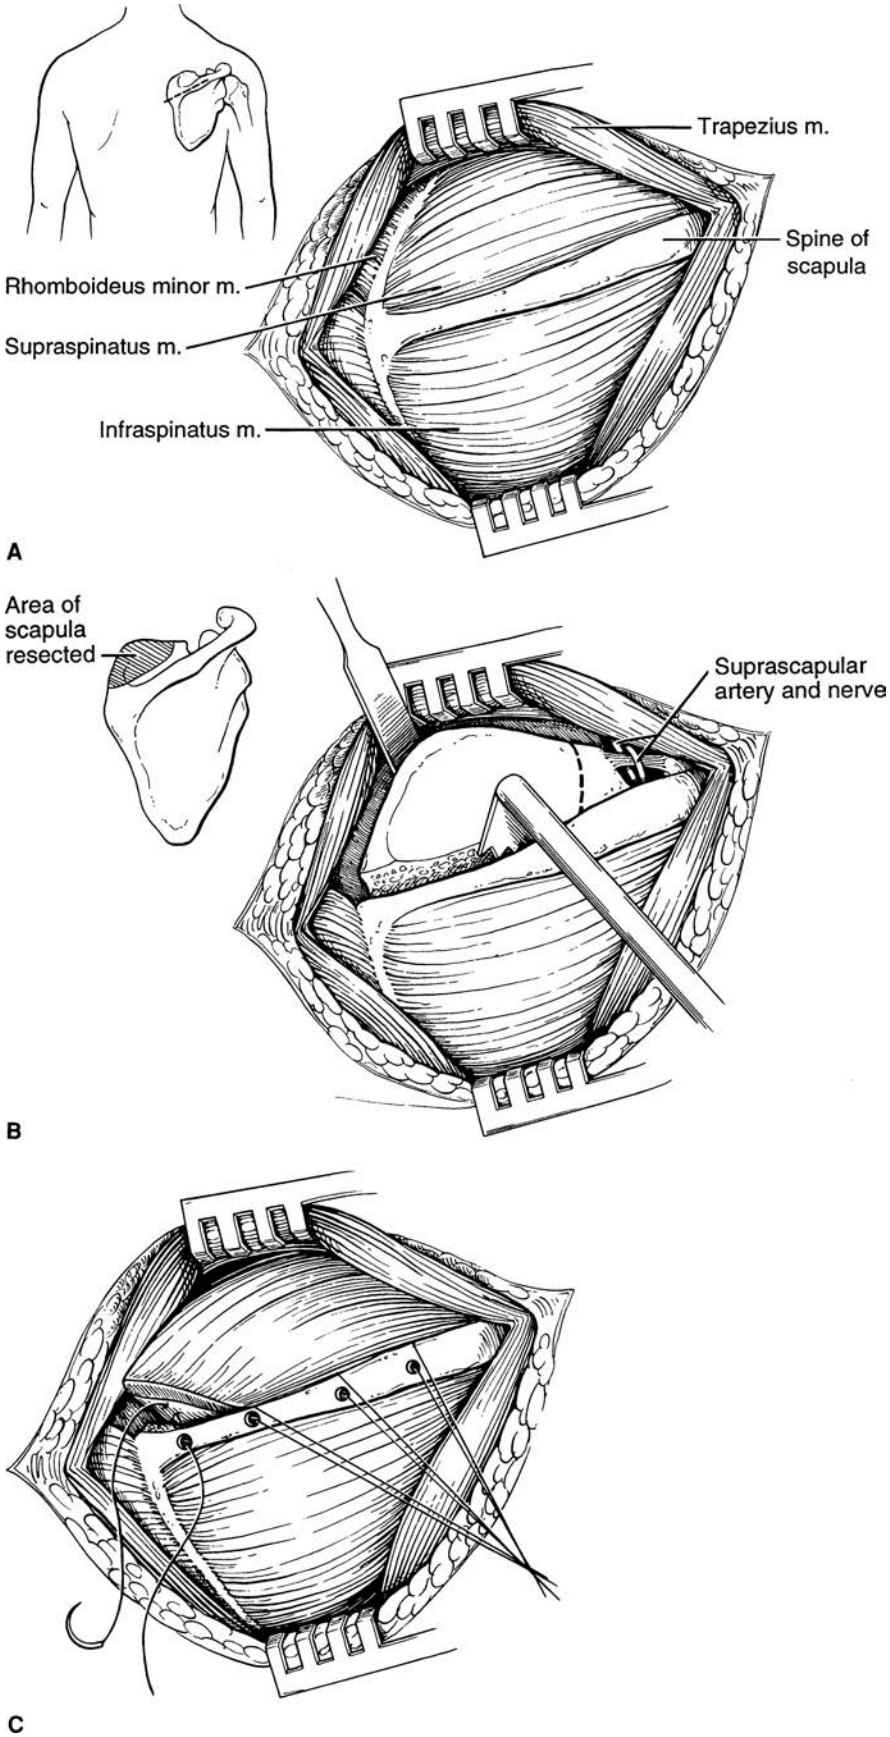

Figure 34-21 Technique for resection of the superomedial border of the scapula for symptomatic scapulothoracic crepitus. **(A)** The trapezius is elevated from the spine of the scapula. **(B)** The supraspinatus, rhomboids, and serratus are elevated in a subperiosteal plane from the medial border, and the superomedial scapula is resected while protecting the suprascapular nerve and artery. **(C)** The supraspinatus is sutured back to the spine of the scapula. (Reprinted with permission from Kuhn JE, Hawkins RJ. Evaluation and treatment of scapular disorders. In: Warner JP, Iannotti JP, Gerber C, eds. *Complex and revision problems in shoulder surgery.* Philadelphia: Lippincott-Raven Publishers, 1997:357–375.)

be adventitious.[24,95,136] With regard to the inferior angle of the scapula, most authors agree that the affected bursa lies between the serratus anterior muscle and the chest wall.[25,121,162] This bursa has been given many names, including the infraserratus bursa[25] and the bursa mucosa.[121,182] The second site of pathology lies at the superomedial angle of the scapula. Here Codman[25] believed this bursa is also an infraserratus bursa, lying between the upper and anterior portion of the scapula and the back of the first three ribs. Von Gruber,[182] on the other hand, identified a bursa in this region between the subscapularis and the serratus anticus muscles, which he called the bursa mucosa angulae superioris scapulae.

A third minor or adventitial bursa, which Codman believed was the site of painful crepitus in scapulothoracic crepitus, was called the trapezoid bursa and is found over the triangular surface at the medial base of the spine of the scapula under the trapezius muscle.[25] Some believe that these minor bursae are adventitial and develop in response to abnormal pathomechanics of the scapulothoracic articulation.[24,95,136] It would not be surprising, then, to find these bursae inconsistently or in different soft tissue planes.

Signs and Symptoms

Scapulothoracic bursitis may accompany painful scapular crepitus or may exist as a separate entity. Patients generally complain of pain with activity and may have audible and palpable crepitus of the scapulothoracic articulation. Usually the scapular crepitus associated with bursitis is of a much lesser quality and nature than that described with bony pathology. Patients relate a history of trauma[3,117] or overuse due to sport or work,[116,117,162] which produces repetitive or constant movement of the scapula on the posterior thorax. This may irritate soft tissues until a chronic bursitis and inflammation develops. The bursa then undergoes scarring and fibrosis, with crepitus and pain to follow.

Diagnosis and Imaging

Unless bony pathology exists, radiographs will be of little help. In severe cases, MRI will demonstrate fluid-filled regions, typically between the serratus anterior and chest wall, with slightly high signal on T1 and high signal on T2 images.[87] However, in many patients, the MRI may appear normal.

Natural History

It is important to note that scapulothoracic crepitus may not be pathologic and may not be associated with pain; however, pain in the periscapular region may be caused by scapulothoracic bursitis, even without accompanying crepitus. The symptom severity seems to be activity related. There are few reports in the literature describing the natural history of untreated scapulothoracic bursitis.

Treatment Options

The initial treatment of scapulothoracic bursitis regardless of its location is conservative, beginning with rest, analgesics, and nonsteroidal antiinflammatory drugs. Physical therapy to improve posture, heat, and local steroid injections has also been recommended.[116,162] Efforts to strengthen periscapular muscles and stretching are frequently added.[116,162] For patients who continue to have symptoms despite conservative treatment, surgery may be beneficial.

Open Surgical Techniques

Sisto and Jobe[162] described an open procedure for resecting a bursa at the inferior angle of the scapula in four Major League baseball pitchers. All pitchers had pain during the early and late cocking phases as well as during acceleration, and could no longer pitch (Fig. 34-22). Only one of the four patients presented with scapulothoracic crepitus, but all had a palpable bursal sac ranging in size from 1 to 2 cm, best seen with the arm abducted to 60 degrees and elevated forward 30 degrees. All four pitchers failed conservative therapy and underwent a bursal excision via an oblique incision just distal to the inferior angle of the scapula. The trapezius muscle and then the latissimus dorsi muscle were split in line with their fibers, exposing the bursa. The bursa was sharply excised and any osteophytes on the inferior pole of the scapula or ribs were removed. The wounds were closed routinely over a drain, and a compression dressing was applied. Physical therapy stressing motion was begun after 1 week and progressed to allow gentle throwing at 6 weeks. This progressed as symptoms permitted return to full-speed throwing. After this procedure, all four pitchers were able to return to their former level of pitching.

Similarly, McCluskey and Bigliani[116,117] performed an open excision of a symptomatic superomedial scapulothoracic bursa in nine patients noting a thickened, abnormal bursa between the serratus anterior and the chest wall at the time of surgery. Their surgical technique involved making a vertical incision medial to the vertebral border of the scapula. The trapezius is dissected free and a subperiosteal dissection is used to free the levator scapulae and rhomboids from the medial border of the scapula. A plane is developed between the serratus anterior and the chest wall. The thickened bursa is resected and any bony projections removed. The medial periscapular muscles and trapezius are reapproximated to the scapula. The skin is closed in a routine fashion.

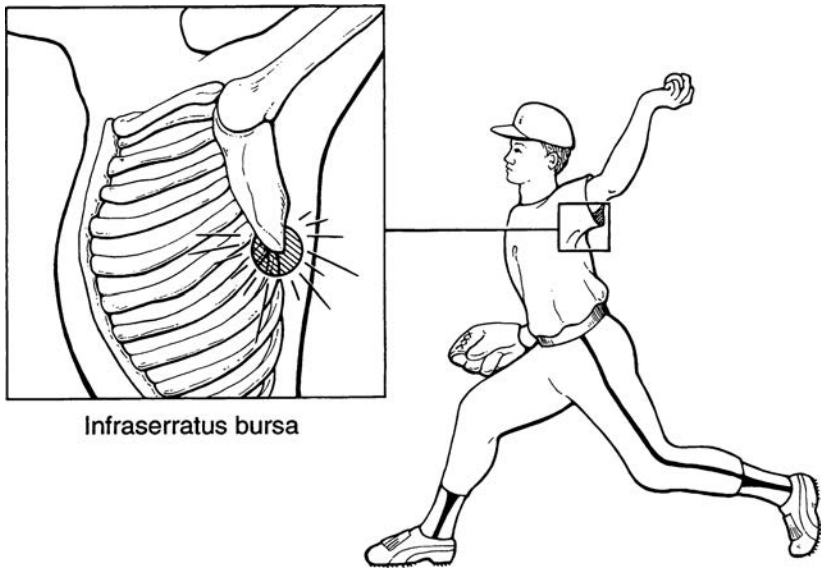

Figure 34-22 Bursae of the inferior angle of the scapula. This bursa has been described in baseball pitchers, and its removal has allowed a return to pitching. (Reprinted with permission from Kuhn JE, Hawkins RJ. Evaluation and treatment of scapular disorders. In: Warner JP, Iannotti JP, Gerber C, eds. *Complex and revision problems in shoulder surgery.* Philadelphia: Lippincott-Raven Publishers, 1997:357–375.)

Endoscopic Surgical Technique

Resection of the symptomatic scapulothoracic bursa has been performed endoscopically as well.[13,23,54,95,113] Ciullo and Jones [23] have the largest endoscopic series to date with 13 patients who underwent subscapular endoscopy after failing a conservative treatment program for symptomatic scapulothoracic bursitis. Débridement was performed for fibrous adhesions found in the bursa between the subscapularis and serratus muscles as well as the bursa between the serratus and chest wall. In addition, débridement or scapuloplasty of changes at the superomedial angle or inferior angle were performed. All 13 patients returned to their preinjury activity level, except for physician-imposed restrictions in a few patients, limiting the assembly line use of vibrating tools.[23]

The technique for scapulothoracic endoscopy has been described by Matthews and colleagues.[113] Patients can be placed in the prone or lateral position; however, the lateral position is preferred as it allows for arthroscopic evaluation of the glenohumeral joint and the subacromial space. In addition, if the arm is extended and maximally internally rotated, the scapula will fall away from the thorax, improving access to the bursae.

Three portals are used, which are placed at least 2 cm from the medial border of the scapula in the region between the scapular spine and the inferior angle. For the middle portal, a spinal needle is inserted into the bursa between the serratus anterior and the chest wall. This needle should be inserted midway between the scapular spine and the inferior angle, at least three fingerbreadths medial to the medial border of the scapula to avoid injury to the dorsal scapular artery and nerve. The bursa under the serratus anterior can be distended with fluid before a stab wound is made in the skin and the blunt obturator and endoscope are inserted. Deep penetration may traverse the serratus entering the axillary space and should be avoided.

Once this initial middle portal has been established, a superior portal placed three fingerbreadths medial to the vertebral border of the scapula just below the spine will penetrate the interval between the rhomboideus major and rhomboideus minor. This portal will allow access to the superomedial angle of the scapula. Portals placed superior to the scapular spine jeopardize the dorsal scapular nerve and artery, the spinal accessory nerve, and the transverse cervical artery and should be avoided. A third inferior portal can be made in a similar fashion at the inferior angle of the scapula.

In the bursa between the serratus anterior and chest wall, landmarks are generally absent except the ribs. A motorized shaver and electrocautery are required to perform the bursectomy and obtain hemostasis. The arthroscopic pump should be kept at low pressure throughout the procedure. After completing the bursectomy, the portals are closed in a standard fashion and the patient is placed in a sling for comfort. Physical therapy beginning with active range of motion is initiated as tolerated by the patient.

Postoperative Considerations

With an open resection, the patient uses a sling for comfort and begins passive motion and pendulum exercises immediately. At 3 weeks active motion is allowed, with strengthening begun at 12 weeks.

Results of Treatment

In general, most patients do well with open resection of painful scapulothoracic bursectomy. With this technique, 88% of patients with symptomatic scapulothoracic bursitis

had good or excellent results. One patient with a fair result also required muscle transfers for trapezius winging.[117] Arthroscopic treatment also reports high rates of success.[13,23,54,95,113]

Complications

Complications associated with open or arthroscopic bursectomy include pneumothorax, postoperative hematoma, potential long thoracic nerve injury, and recurrence of the bursitis. Recurrence is more likely if the patient had bony pathology with crepitus and the bony pathology was not addressed at the time of bursectomy.

CONCLUSIONS

The importance of the scapulothoracic articulation has gained more attention as of late. A variety of pathologic conditions may affect the scapulothoracic articulation. It is not surprising that some are intimately related to problems that affect the glenohumeral joint. A comprehensive evaluation of the shoulder must include an assessment of the glenohumeral joint to look for winging, crepitus, bursitis, and dyskinesis.

COMPLICATIONS OF BRACHIAL PLEXUS SURGERY 1130

ANATOMY

Brachial Plexus

The origin of the brachial plexus is from the fifth through eighth cervical (C5 through C8) and the first thoracic (T1) spinal nerves.[85,127] Small contributions may originate from the fourth cervical (C4) and second thoracic (T2) nerves. The dorsal and ventral rootlets (six to eight rootlets per level) exit the spinal cord, merge to form the spinal nerves, which leave the intervertebral foramina, and quickly divide into dorsal and ventral rami (Fig. 35-1). The small dorsal rami travel posterior to innervate the skin and muscles of the neck and upper back and are not part of the brachial plexus. The ventral rami emerge between the anterior and middle scalene muscles and are designated as the nerve roots of the brachial plexus (Fig. 35-2). The upper roots (C5 through C8) descend toward the first rib, whereas the lower T1 root must ascend over the first rib to form the brachial plexus. Sympathetic fibers join the nerve roots as they traverse between the scalene muscles. C5 and C6 receive fibers from the middle sympathetic cervical ganglion, and C7, C8, and T1 acquire fibers from the cervicothoracic ganglion. These sympathetic fibers control blood-vessel smooth-muscle contraction (vasoconstriction) and sweat gland activity.

The motor cell bodies of the nerve roots for the brachial plexus are located within the ventral horn of the spinal cord gray matter (see Fig. 35-1). In contrast, the sensory cell bodies are positioned outside the spinal cord within the dorsal root ganglia. The dorsal root ganglia transfer afferent fibers to the spinal cord through the dorsal rootlets. The knowledge of the difference in anatomic location of cell bodies between motor and sensory fibers is

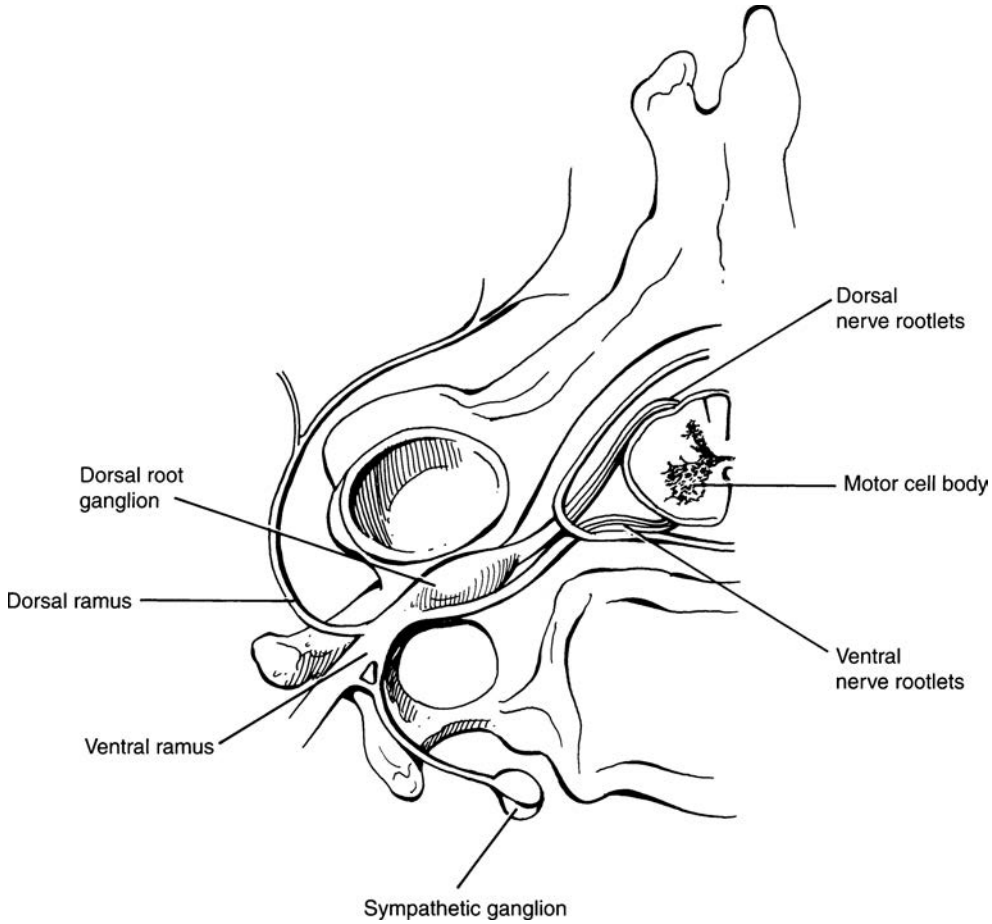

Figure 35-1 Artist's schematic of spinal cord with motor and sensory (dorsal root ganglion) cell bodies.

important for the accurate diagnosis and treatment of proximal brachial plexus injuries.

The ventral rami of C5 and C6 combine to form the superior trunk, the C7 ramus continues alone as the middle trunk, and C8 and T1 unite to form the lower trunk (see Fig. 35-2). The trunks are located in the posterior triangle of the neck, enclosed by the posterior border of the sternocleidomastoid muscle, anterior border of the upper trapezius, and clavicle. The spinal accessory nerve (cranial nerve XI) crosses the posterior triangle to innervate the trapezius muscle. This nerve divides the posterior triangle into nearly equivalent upper and lower parts. The lower portion of the triangle contains the brachial plexus, with the upper and middle trunks superior to the omohyoid muscle and the lower trunk inferior. Each trunk divides into anterior and posterior divisions and proceeds behind the clavicle. The divisions then merge into three cords named in relation to the axillary artery. The anterior divisions of the upper and middle trunks combine to form the lateral cord. The three posterior divisions of the upper, middle, and inferior trunks converge to form the posterior cord. The anterior division of the lower trunk continues as the medial cord.

The cords proceed behind the pectoralis minor muscle into the axilla. Each cord divides into two terminal branches (Fig. 35-3). The lateral cord terminates as the musculocutaneous nerve and a branch to the median nerve. The musculocutaneous nerve perforates and supplies the coracobrachialis muscle and then becomes the principal motor nerve of the flexor compartment of the arm. The posterior cord divides into the axillary and radial nerves. At the level of the glenohumeral joint, the axillary nerve, along with the posterior humeral circumflex vessels, travels inferior to the subscapularis muscle and across the upper border of the teres major to enter the quadrangular space for innervation of the deltoid and teres minor muscles. Compression of the nerve or artery can occur at the quadrangular space from hypertrophy or anomalies of the bordering muscles. The radial nerve is the largest branch of the brachial plexus and passes inferior to the teres major muscle to enter the posterior arm between the long head of the triceps and humerus. The medial cord continues as the ulnar nerve and a branch to the median

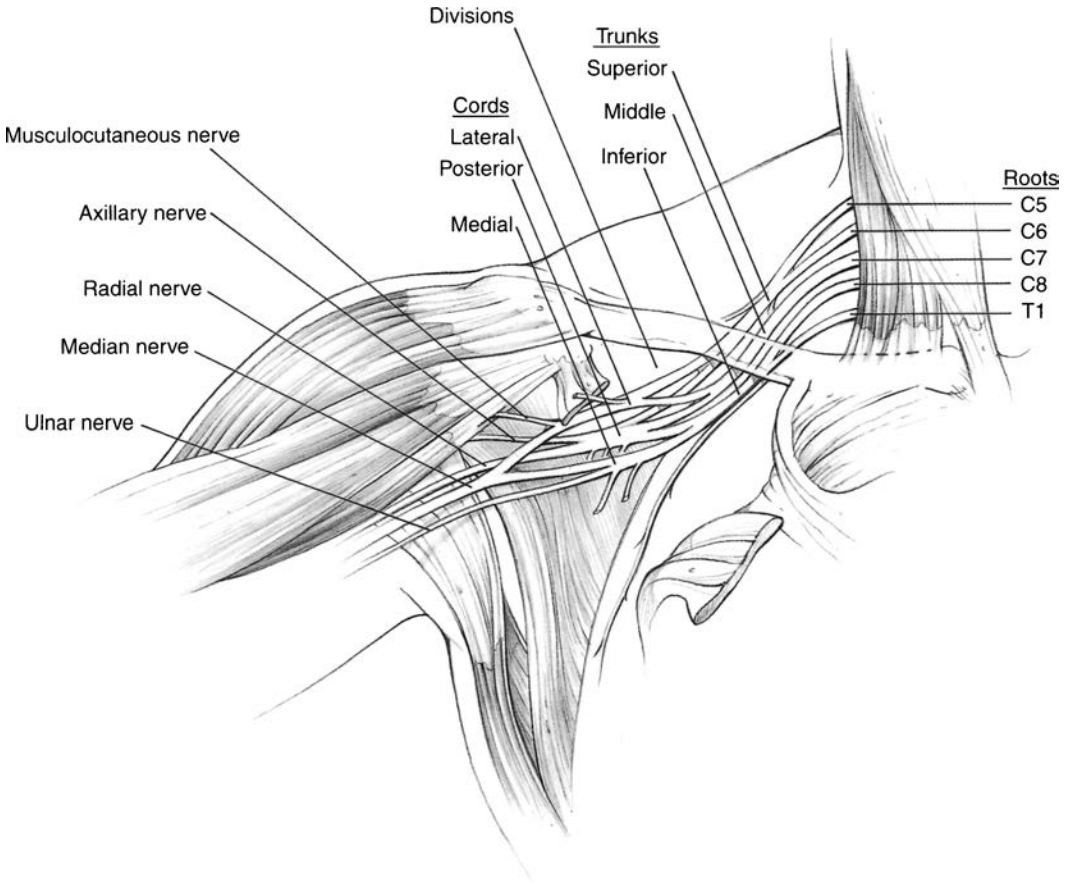

Figure 35-2 Artist's schematic of brachial plexus from roots to branches.

nerve. The ulnar nerve travels down the arm medial to the brachial artery, pierces the medial intermuscular septum, and enters the cubital tunnel. The median nerve forms anterior to the axillary artery from the union of the medial and lateral cord branches and descends into the arm.

Several branches arise from the roots, trunks, and cords of the brachial plexus (see Fig. 35-2). The status of these intermediate nerves provides valuable information about the location of nerve injury. At the root level, the dorsal scapular nerve arises from C5, pierces the middle scalene to enter the posterior triangle of the neck, and innervates the levator scapulae and rhomboid muscles. The long thoracic nerve arises from C5, C6, and C7 just distal to the intervertebral foramina and travels behind the brachial plexus along the chest wall to supply the serratus anterior muscle. The phrenic nerve originates at the root level from C3, C4, and C5 and crosses the anterior scalene muscle to enter the thorax. The phrenic nerve may be injured in nerve root injuries, which results in hemidiaphragm paralysis.

At the trunk level, the suprascapular nerve arises from the superior trunk to travel across the posterior cervical triangle to the suprascapular notch. The suprascapular nerve advances through this notch to innervate the supraspinatus and infraspinatus muscles.

There are no branches from the plexus at the division level. At the cord level, multiple branches are present. From the lateral cord, the lateral pectoral nerve arises to pass anterior to the axillary artery, to perforate the clavipectoral fascia, and to innervate the clavicular part of the pectoralis major. The posterior cord supplies three branches: the upper subscapular, thoracodorsal, and lower subscapular nerves. The upper subscapular nerve innervates the upper portion of the subscapularis muscle. The lower subscapular nerve innervates the lower subscapularis and the teres major muscle. The thoracodorsal nerve originates between the upper and lower subscapular nerves, passes behind the axillary artery, and supplies the latissimus dorsi muscle. The medial cord provides one motor and two sensory branches. The medial pectoral nerve traverses and innervates the pectoralis minor muscle and then continues to supply the sternocostal portion of the pectoralis major muscle. The medial brachial and medial antebrachial cutaneous nerves are the only sensory branches to arise directly from the plexus and supply the arm and forearm, respectively.

The vascular anatomy of the brachial plexus centers about the subclavian and axillary vessels. The subclavian artery originates from the arch of the aorta on the left side and from the brachiocephalic artery on the right. The

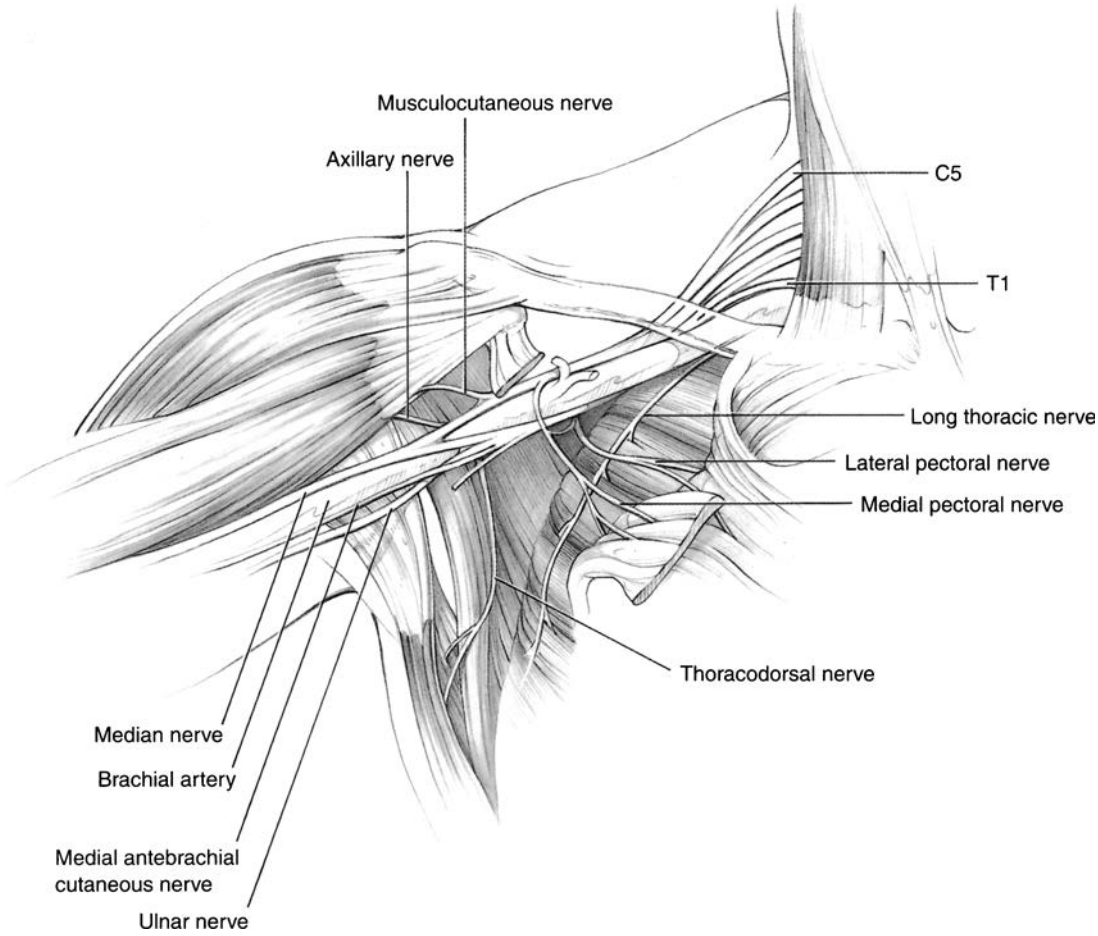

Figure 35-3 Artist's schematic of brachial plexus behind the clavicle pectoralis minor muscle.

subclavian artery ascends over the first rib to reside between the anterior and middle scalene muscles, with the roots and trunks of the brachial plexus. In contrast, the subclavian vein is located anterior to the anterior scalene muscle. The subclavian vessels cross the first rib and become the axillary vessels with the vein medial to the artery. The axillary vessels accompany the brachial plexus behind the pectoralis minor muscle to enter the axilla. The axillary vessels become the brachial vessels beyond the axilla.

There is variability and asymmetry in the neural and vascular anatomy of the brachial plexus.[85,127,190] The plexus is termed *prefixed* when there is a relatively large contribution from C4 and a small allotment from T1. Similarly, a *postfixed* plexus has substantial contribution from T2 with little from C5. There are also variations in cord separation and peripheral branchings of nerves that may or may not affect segmental innervation. Branches may occasionally arise from divisions that usually originate from trunks or cords. The vascular relation to the plexus can be altered, with the axillary artery or vein shifted in position or even piercing a nerve.[115] The subclavian vein can travel with the artery and brachial plexus posterior to the anterior scalene muscle.[128] Anomalies in nerve and/or vascular anatomy should be considered when clinical, diagnostic, and surgical findings do not correspond.

Thoracic Outlet Anatomy

The thoracic outlet begins just distal to the intervertebral foramina and extends to the coracoid process. The outlet is surrounded by anatomic constraints that encompass the brachial plexus and associated vessels (subclavian and axillary). These structures include muscles (anterior and middle scalene muscles), skeleton (first rib, cervical ribs, clavicle, and coracoid), and fascia or fibrous bands. The most common sites of compression in thoracic outlet syndrome are at the superior thoracic outlet, the scalene interval or triangle, the costoclavicular space, or the subcoracoid area (Fig. 35-4; Table 35-1).[6,130,143,153] This compression can be static or dynamic (i.e., dependent on posture and activity).[98]

The anterior border of the superior thoracic outlet is the sternum; lateral boundary in the first rib and the posterior border in the thoracic vertebrae.[203] The inferior trunk must

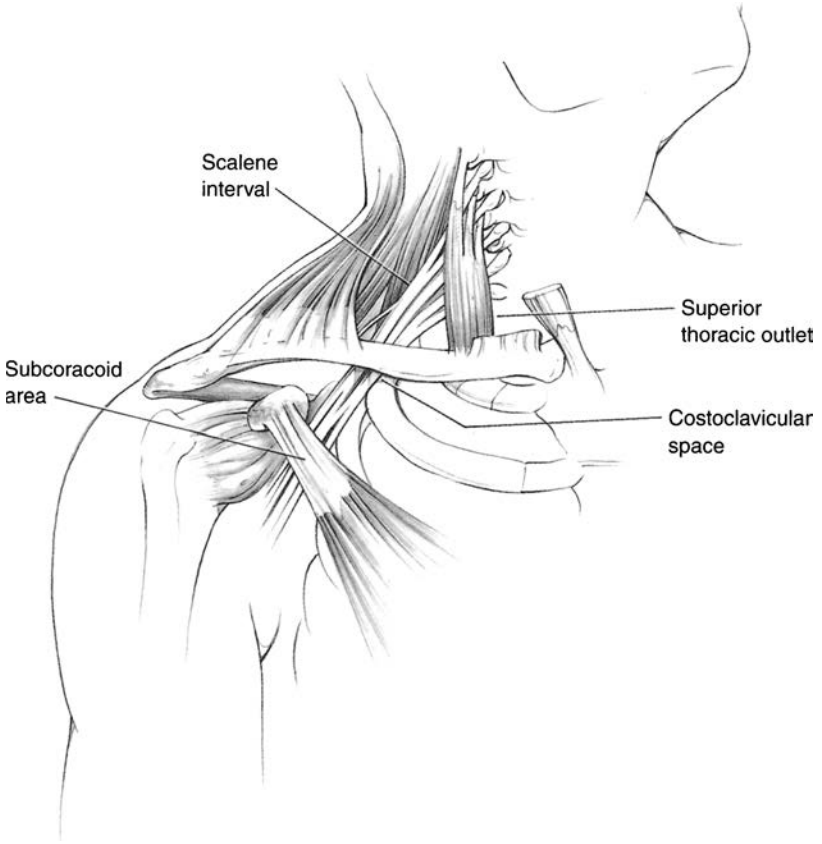

Figure 35-4 Artist's schematic of thoracic outlet compression sites.

ascend from the intervertebral foramina to navigate over the first rib. A postfixed brachial plexus must climb even higher to exit from the thorax. The inferior trunk can be compressed or stretched over the first rib in this area.

The scalene triangle is formed by the anterior and middle scalene attachments on the first rib. These muscles originate from similar transverse processes of the upper and middle cervical vertebrae and diverge to their insertion sites. The scalene triangle has a narrow base (approximately 1 to 2 cm) and elongated sides.[43,87,143] The upper roots (C5 through C7) descend, whereas the inferior roots (C8 and T1) and subclavian artery must ascend to pass through the scalene triangle. The presence of a cervical rib or a fibrous band extending from an incomplete cervical rib to the first rib can reduce the dimensions of the triangle by elevation of its base. This forces the inferior roots and subclavian artery to further ascend to enter the scalene triangle. Cervical ribs are present in 0.5% to 1% of individuals and occur bilaterally 50% to 80% of the time.[6,98,141,169] The width of the scalene triangle can be narrowed by anterior or middle scalene muscle abnormalities, which can precipitate thoracic outlet compression.[43,81,179]

TABLE 35-1
SITES OF COMPRESSION IN THORACIC OUTLET SYNDROME

Site	Principal Cause
Superior thoracic outlet	First rib or cervical rib
Scalene interval or triangle	Scalene muscles or fibrous bands
Costoclavicular space	Narrow clavicle–first rib distance
Subcoracoid area	Coracoid process

The costoclavicular interval is between the clavicle and first rib. Depression of the clavicle reduces this space and can compress the brachial plexus and subclavian vessels. A hypertrophied subclavius muscle or a clavicle with abundant callus formation can narrow the costoclavicular space. The subclavian vein is also susceptible to compression within the costoclavicular interval.

The subcoracoid area can compress the brachial plexus. The coracoid provides a fulcrum across the plexus during abduction and external rotation of the arm. The pectoralis minor and conjoined tendon (short head of the biceps and coracobrachialis) prevents slippage of the plexus from behind the coracoid. Excessive arm elevation can lead to a traction or compressive neuropathy along the coracoid process.[175]

ADULT BRACHIAL PLEXUS INJURIES

Adult brachial plexus injuries may be secondary to vehicular trauma, athletic endeavors, domestic violence, or systemic disease. The causes can be divided into trauma (penetrating and nonpenetrating), entrapment, and infection (Table 35-2). There are other less common causes of brachial plexopathy related to tumors, neuropathies, and iatrogenic causes.[6,69,79,109]

Pathophysiology

The most common cause of brachial plexus injury is traction.[175] The mechanism that yields traction is variable and may be from pulling the extremity, forcible head rotation from the shoulder, or direct depression of the shoulder girdle.[175] Traction causes injury via stretching or straining of the nerve beyond its physiologic limits. There is a direct correlation between strain and reduction of intraneural blood flow. A 15% elongation reduces blood flow approximately 80% to 100%.[35,102,200] The extrinsic vascular system (longitudinal vessels in the epineurium) appears to be more susceptible to stretch than the intrinsic circulation (endoneurial vascular network).[89] Continued elongation will cause overt ischemia and disruption of nerve metabolism. Persisted traction will ultimately disrupt nerve fiber and/or sheath continuity. Therefore, traction can cause a spectrum of nerve injury ranging from a temporary disruption in nerve fiber conduction to functional discontinuity of the nerve fibers and sheath.

TABLE 35-2
CAUSES OF BRACHIAL PLEXUS INJURIES

Trauma
Nonpenetrating (traction)
Penetrating (knife, gunshot wound)
Nerve entrapment
Thoracic outlet syndrome
Infection
Viral plexopathy (Parsonage-Turner syndrome)
Radiation
Fibrosis
Malignant degeneration after radiation
Tumors
Primary (schwannomas or neurofibromas)
Secondary (pulmonary apices)
Neuropathies
Iatrogenic
Axillary or scalene anesthesia
Surgical biopsy
Intraoperative positioning
Median sternotomy
Inadvertent traction

Various factors determine the portion of the plexus injured and the extent of damage incurred. These determinants include the local anatomy, magnitude and duration of the force applied, and the position of the extremity and head at time of accident.[175] The upper roots descend beneath the clavicle, whereas the lower roots ascend over the first rib. Therefore, the upper plexus is taut with the arm dangling at the side, and the lower plexus is taut with the arm abducted and elevated. As a result, the upper roots and trunk of the plexus are most susceptible to traction that increases the distance between the head and neck. In contrast, the medial, lateral, and posterior cords pass beneath the coracoid, which act as a pulley and can direct the force incurred. Therefore, excessive arm abduction elevates the coracoid pulley and places preferential tension across the cords of the brachial plexus. As a result, disruptive forces in the form of traction often direct maximal strain across specific segments within the plexus, which leads to variable injury across the plexus.

Nonpenetrating Trauma

Nonpenetrating trauma is the leading cause of upper brachial plexus injuries. Most brachial plexus injuries result from motor vehicle accidents, especially motorcycle misadventures.[124,156] The injury is more frequently seen in areas where motorcycles are the principal mode of transportation.[29] The incidence of brachial plexus injury following a motorcycle accident has been approximated to be 2%, with a prevalence in young males.[124,125] Interestingly, the incidence has recently increased and is probably related to mandatory helmet regulations and better transportation of trauma patients who previously would have succumbed to their injuries.[125] Associated injuries are common, including head trauma and fractures or dislocations of the cervical spine, shoulder, forearm, and hand.[124,156]

Automobile, bicycle, sporting, and pedestrian accidents are much less common causes of brachial plexus injuries, as are shoulder dislocations or fractures (proximal humerus, clavicle).[73,112] Minor stretch injuries of the plexus (i.e., burners or stingers) are common in contact sports, especially football, because tackling drives the shoulder downward and forcibly flexes the neck toward the contralateral side.[73] The athlete experiences burning pain and paresthesias that radiate from the supraclavicular area into the arm. Transient weakness and sensory abnormalities are present. The vast majority of burners are upper plexus traction injuries. There should not be concomitant neck pain or restricted neck mobility. The signs and symptoms usually resolve spontaneously over a few minutes. Incomplete neurologic recovery or restricted neck motion requires further diagnostic evaluation as the impact could have caused a cervical spine fracture–dislocation or a severe brachial plexus injury. Failure to make a timely diagnosis of cervical spine injury can result in subsequent quadriplegia.

Shoulder dislocations are often related to sporting accidents and can produce nerve injuries of the axillary, suprascapular, or musculocutaneous nerves.[4] These are usually (80% of the time) temporary lesions that resolve over 4 to 6 months (80%) and are covered in Chapter 36.

Penetrating Trauma

Penetrating trauma to the brachial plexus is often secondary to gunshot wounds or stabbings. Gunshot wounds occur at time of war and during domestic violence.[91,133] Bullet injuries act as projectile missiles that cause neural injury by means of a blast effect or less commonly direct nerve transection.[18,91,133] The shock wave (temporary cavity) reverberates, causing a variable degree of nerve injury. The extent of blast correlates with the deformation, fragmentation, orientation, and velocity of the bullet. The part of the plexus injured depends upon the entrance and exit passageway.

In contrast to gunshot wounds, stab wounds transect portions of the plexus or cause vascular injury with secondary nerve compression by expanding hematoma.[18,47] Most stab wounds to the supraclavicular area involve the upper and middle plexus as the clavicle protects the lower portion.[47]

Infection

Infection is an uncommon cause of brachial plexopathy. The exact cause remains unclear, with both viral pathogens and secondary immunologic factors proposed as possibilities. This brachial neuritis, also known as Parsonage-Turner syndrome, presents with acute onset of intense pain about the shoulder girdle without antecedent trauma.[136] Weakness of the muscles innervated by the affected nerves develops after the initial pain subsides. The suprascapular or long thoracic nerve is most commonly affected (Fig. 35-5).

Figure 35-5 A 20-year-old man who awoke with intense shoulder pain and subsequent scapula winging from isolated long thoracic nerve involvement in Parsonage-Turner syndrome.

Electromyographic abnormalities of the denervated muscles are apparent 3 to 4 weeks after the initial pain response, with positive sharp waves and fibrillation potentials. The treatment is conservative management with observation and serial examinations. The natural history of brachial neuritis is resolution of the pain followed by improvement in motor function. However, prolonged recovery time (1 to 2 years) and persistent weakness is not uncommon years after the brachial neuritis.[73,105,120,183]

Classification of Brachial Plexus Injury

The lesion in brachial plexus injury is classified according to the anatomic location and extent of nerve involvement. Supraclavicular lesions affect the roots, trunks, and divisions, whereas infraclavicular injuries involve the cords and branches. A supraclavicular injury can disrupt the rootlet connection with the spinal cord and is called an *avulsion* injury. An avulsion is usually secondary to traction along the affected root(s) and separates the motor cell body in the spinal cord from its axons. The sensory cell body, however, is located in the dorsal root ganglion and remains connected to its axons (see Fig. 35-1). Therefore, the motor portion of the nerve undergoes wallerian degeneration, with degradation of the axons and myelin sheaths. The sensory fibers are spared from wallerian degeneration, but have been irrevocably detached from the spinal cord. The injury will cause a clinical motor and sensory loss, whereas electrodiagnostic studies will reveal abnormal motor findings with intact sensory conduction. In rare instances, the rupture can cause isolated disruption of only the motor or sensory rootlets.

The injury can also interrupt nerve continuity at the trunk level and is called a *rupture.* Ruptures of the plexus separate both motor and sensory cell bodies from their axons and wallerian degeneration occurs across all fibers. The differentiation between avulsion and rupture is a decisive element in the treatment algorithm of brachial plexus traction injuries. Discontinuity by rupture can be treated by various surgical techniques to reestablish nerve continuity. In contrast, avulsion injuries are irreparable and require alternative techniques to restore function. The diagnosis can be difficult, as traction can cause ruptures and avulsions at different levels, which complicates accurate diagnosis.

Supraclavicular lesions account for most brachial plexus injuries (approximately 75%) and are also subdivided into groups according to the pattern of involvement (Table 35-3).[5,119] The Erb-Duchenne palsy involves C5 and C6, or the upper trunk, and is characterized by loss of elbow flexion and weakness of shoulder abduction and external rotation.[46,53] Sensory deficit is apparent in the corresponding dermatome (radial side of forearm and thumb). A C7 injury can accompany an Erb's palsy (a.k.a., extended upper brachial plexus lesion) and adds paralysis

TABLE 35-3
PATTERNS OF BRACHIAL PLEXUS INJURIES

Pattern	Roots Involved	Primary Deficiency
1. Upper brachial plexus (Erb-Duchenne)	C5 and C6	Shoulder abduction and external rotation Elbow flexion
2. Extended upper brachial plexus	C5, C6, and C7	Above plus Elbow and digital extension
3. Lower brachial plexus (Dejerine-Klumpke)	C8 and T1	Hand intrinsic muscles Finger flexors
4. Total brachial plexus lesion	C5, C6, C7, C8, and T1	Entire plexus
5. Peripheral brachial plexus lesion		Variable

of elbow extension, wrist extension (extensor carpi radialis brevis), and finger extension (extensor digitorum communis and propius). The Dejerine-Klumpke palsy involves C8 and T1, or lower trunk, and is characterized by absent intrinsic hand musculature and finger flexors (flexor digitorum profundus and superficialis) with intact shoulder, elbow, and wrist function.[92] Sensory deficit is situated over the ulnar side of the forearm and hand. This isolated lower plexus palsy is uncommon in both adults and children.[57,72] Lastly, the injury can include the entire plexus (C5, C6, C7, C8, and T1), which causes a flail and anesthetic arm.

Supraclavicular lesions can also be isolated to peripheral branches, such as the suprascapular or long thoracic nerve. This can be secondary to trauma, infection, and surgical positioning, or can be iatrogenic.

Infraclavicular lesions are less common (approximately 25%) and usually represent stretch injuries from an associated shoulder dislocation or fracture.[4] These injuries represent peripheral nerve lesions of the plexus. The axillary nerve is particularly susceptible to traction because it is securely anchored as it traverses the quadrangular space. However, injury to the musculocutaneous nerve and other elements of the brachial plexus can occur after severe trauma. These injuries are covered in Chapter 36.

Supraclavicular and infraclavicular nerve injuries can also be characterized by their severity, regardless of the location of injury and extent of plexus involvement. The gradation of nerve injury begins with neurapraxia, extends to axonotmesis, and culminates in neurotmesis (Table 35-4).[163] *A neurapraxia* is a segmental demyelination with maintenance of intact nerve fibers and axonal sheath. A temporary conduction block follows, without axonal damage and wallerian degeneration. Complete recovery occurs over the ensuing days to weeks as remyelinization is completed. Electrodiagnostic studies demonstrate a decrease in nerve conduction without electromyographic changes of denervation within the muscle.[21] An *axonotmesis* is a disruption of nerve fiber integrity with preservation of

TABLE 35-4
SEDDON'S CLASSIFICATION OF NERVE INJURY

Type	Definition	Outcome
Neurapraxia	Interruption of nerve conduction; some segmental demyelination; axon continuity intact	Reversible
Axonotmesis	Axon continuity disrupted; neural tube intact	Wallerian degeneration; incomplete recovery
Neurotmesis	Complete disruption of nerve continuity; loss of axons and neural tubes	No spontaneous recovery; surgery required

the axonal sheath and framework. Wallerian degeneration and nerve fiber regeneration are necessary for recovery. Electrodiagnostic studies exhibit a decrease in nerve conduction and electromyographic changes of muscle denervation (insertional activity, fibrillations, and positive sharp waves).[21] Wallerian degeneration is characterized by the proliferation of Schwann cells that phagocytose myelin and axon debris. The axons distal to the injury degrade from lack of nutrition and loss of blood supply. The regeneration rate is approximately 1 mm/day or 1 in./month. This slow regeneration delays recovery and means that distal nerve injuries have a better prognosis because the extent of wallerian degeneration is decreased and the proximity to the motor endplates is increased. In addition, prolonged denervation of longer than 18 to 24 months results in irreversible motor endplate degradation and muscle fibrosis. In contrast, the encapsulated sensory receptors retain their capacity for reinnervation for many years. These factors lend the overall prognosis for axonotmesis as variable and guarded.

A *neurotmesis* is a disruption of the nerve fiber and axonal sheath. Transection is the classic example of this injury, but severe traction or contusion can produce a similar injury with irreversible intraneural scarring. The prognosis is bleak without surgical resection of the intervening scar and nerve coaptation by direct repair or graft interposition to allow for nerve regeneration. A severe brachial plexus injury often represents a combined lesion, with elements of neurapraxia, axonotmesis, and neurotmesis. This combination injury complicates accurate diagnosis and predictions for recovery.

Evaluation of Adult Brachial Plexus Injury

The clinical evaluation of the patient with a brachial plexus injury begins with a careful history and detailed examination. The examination should include the head and neck, thorax, injured extremity, and neurovascular systems. Knowledge of brachial plexus anatomy and concomitant muscle innervation is a prerequisite to accurate diagnosis. A thorough physical examination is the foundation that will dictate the treatment algorithm. Imaging studies and electrodiagnostic tests provide supplemental information to further clarify the extent of injury. The goal of this evaluation is to precisely define the location and extent of nerve injury. This information will direct treatment, which may range from continued observation to prompt surgical intervention.

Adult brachial plexus injuries are usually not evaluated in the acute setting, but rather referred after treatment of any life-threatening injuries. An inquiry into the mechanism of injury and degree of energy involved is important. The force applied (direction, magnitude, and duration), position of extremity, and concomitant injuries (fractures, dislocations, visceral damage, head trauma, and vascular damage) are important details. Unfortunately, the particulars of the accident are often obscured by loss of consciousness, associated injuries, or amnesia.[125] In sharp penetrating trauma, the timing of neurologic deficit is important. An instantaneous deficit implies nerve laceration, whereas a delayed onset indicates a compressive neuropathy by an expanding hematoma or false aneurysm.[18,47] Important past medical history includes overall general health before the accident, time interval from injury, hand dominance, occupation, and hobbies.

The physical examination begins with observation. The posture of the extremity and the manner by which the patient uses the extremity are important indicators of the segment of the brachial plexus involved. The motor and sensory deficits determined by the physical examination should be correlated with the ancillary studies to define the extent and pattern of injury to the plexus. The basis of the evaluation is to perform a detailed examination to determine the specific motor and sensory deficits. An inventory of the muscles innervated by the brachial plexus is imperative to accurately define the injury and provides a baseline to assess recovery. Physical findings should be recorded on a data sheet, including gradation of muscle strength according to the international muscle scoring system and the presence or absence of sensory deficits (Table 35-5).[2] Sensibility is assessed using two-point discrimination or Semmes Weinstein monofilament testing. This documentation method eliminates inadvertent omission of important elements of the examination and allows serial examinations to be performed by different individuals.

Careful examination of the muscles innervated by the proximal branches from the brachial plexus will help define the proximity of the plexus lesion to the spinal cord (Table 35-6). Disruption of the dorsal rami (paraspinal muscles), dorsal scapular (rhomboids and levator scapulae), and long thoracic (serratus anterior) nerves are suggestive of an avulsion injury. The presence of a Horner's syndrome results in a drooped eyelid, constricted pupil, sunken globe, and sweating deficiency along the affected side of the face and usually implies an avulsion injury at C8 and T1 (Fig. 35-6). However, the false-positive response rate for a Horner's syndrome is 10% and the false-negative figure is 28%.[71] Percussion of the supraclavicular and infraclavicular plexus is performed. A Tinel's sign is indicative of a postganglionic injury (e.g., rupture), for this sign will be absent in a preganglionic lesion (e.g., avulsion) because the link to the spinal cord and brain has been disrupted.

Postganglionic injuries are further localized by examination of the intermediate and terminal branches. The status of the suprascapular (spinati), thoracodorsal (latissimus dorsi), subscapular (subscapularis and teres major), and pectoral (pectoralis major and minor) will further define the injury. Examination of the pectoralis major muscle is particularly helpful because of its dual segmental innervation from the lateral pectoral (C5, C6, C7) and medial pectoral (C8, T1) nerves from the lateral and medial cords,

Muscle Grading Chart

Muscle Grade	Description
5, Normal	Full range of motion against gravity with full resistance
4, Good	Full range of motion against gravity with some resistance
3, Fair	Full range of motion against gravity
2, Poor	Full range of motion with gravity eliminated
1, Trace	Slight contraction without joint motion
0, Zero	No evidence of contraction

respectively. Selective atrophy of the clavicular head (lateral pectoral) or sternocostal head (medial pectoral) facilitates diagnosis, whereas complete atrophy implies a global injury. A peripheral vascular examination with palpation of the radial and ulnar pulses is a fundamental component of the evaluation, for damage to the axillary or subclavian vessels can occur at the time of initial injury. Decreased or absent peripheral pulses, a delayed neurologic deficit (expanding hematoma), and penetrating trauma warrant magnetic resonance angiography or arteriography.[18,47,55,176]

TABLE 35-6
INDICATORS OF AVULSION INJURIES AND POOR PROGNOSIS FOR RECOVERY

Finding	Implication
Denervation paraspinal muscles	Dorsal rami injury
Denervation rhomboid muscles	Dorsal scapular (C5) injury
Scapular winging	Long thoracic (C5, C7, C8) injury
Horner's syndrome	Cervicothoracic sympathetic injury
Absent Tinel's sign	Preganglionic separation from cord
Sensory impairment neck	Cervical plexus injury
Hemidiaphragm paralysis	Phrenic nerve injury
Cervical transverse process fx	Avulsion fracture with root injury
Pseudomeningocele	Dura and arachnoid avulsion injury
Anesthesia and intact conduction velocity	Dorsal ganglion intact, but avulsion from cord

Imaging Studies

Imaging studies are an important part of the evaluation. The information garnered provides valuable information about the level of injury. The radiology tests utilized are plain x-ray films, fluoroscopy, myelography, computed tomography (CT), and magnetic resonance imaging (MRI).

Figure 35-6 A 30-year-old woman involved in a motor vehicle accident with avulsions of C8 and T1 and ruptures of C5, C6, and C7. Persistent subtle left Horner's syndrome years after injury.

The particular studies employed vary with the type of injury, physical examination, imaging strategy, and expertise of the radiologist.

Plain x-ray films of the cervical spine, clavicle, shoulder, and chest are routine after a brachial plexus injury. Various findings are suggestive of particular levels of plexus injury (Table 35-7). The bone and/or ligament injury often represents a failure of the supporting and protective structures about the brachial plexus. For example, transverse process fracture or scapulothoracic dissociation implies a preganglionic avulsion injury while a shoulder dislocation infers a postganglionic nerve injury. Scapulothoracic dissociation is a devastating injury that can cause rapid exsanguination from an avulsion of the subclavian artery and brachial plexus. If the patient survives the injury, the nerve damage is usually extensive with avulsions across the plexus. The prognosis for return of nerve function is bleak, and extensive methods of nerve reconstruction are often required to restore nerve continuity.[49]

Hemidiaphragm paralysis from injury to the adjacent phrenic nerve may occur at the time of brachial plexus injury. Hemidiaphragm paralysis may not be apparent on a static chest x-ray film. Fluoroscopic evaluation during inspiration is required for diagnosis of phrenic nerve injury.

Angiography is indicated if there is any question of the vascular status of the extremity or integrity of the subclavian or axillary vessels. Palpable radial or ulnar pulses may be present (secondary to collateral flow) despite proximal injury.[18] Penetrating trauma or an expanding hematoma also requires angiography.[47,55,176]

Myelography is used to define the presence or absence of a pseudomeningocele, a meningeal pouch filled with cerebrospinal fluid that extends through the intervertebral foramen into the paraspinal area (Fig. 35-7). This pouch represents an extraction of the dural and arachnoidal sleeve through the intervertebral foramen that often occurs during a root avulsion injury. The inability to visualize the

TABLE 35-7
RADIOGRAPHIC FINDINGS IN INJURIES TO THE BRACHIAL PLEXUS

Plain x-ray Film	Findings	Significance
Chest	Elevated hemidiaphragm	Phrenic injury, proximal plexus, and possible preganglionic avulsion
	First-rib fracture	Subclavian or axillary artery injury, lower-trunk injury
C-spine	Fracture or dislocation	Cervical spine injury
	Transverse process fx	Preganglionic avulsion injury
Clavicle	Fracture	Possible traction injury to plexus or pseudoparalysis
Shoulder	Glenohumeral dislocation	Infraclavicular injury
	Scapulothoracic dissociation	Severe neurovascular injury

nerve root on the myelogram further supports the diagnosis of an avulsion injury. However, false-positive pseudomeningoceles have been found in patients in whom the rootlets were intact with isolated dura rupture, and false-negative results have been reported during surgical exploration.[34,57,72] Methods recommended to improve the diagnostic accuracy of myelography are to delay the test for 4 to 6 weeks after injury to allow for resolution of local swelling and intradural blood clots and using CT myelography to visualize small pseudomeningoceles.[125,151]

MRI has become the primary imaging modality in some institutions, based on the scanner available and specialization of the radiologist.[132,134] The MRI provides multiplanar imaging to assess the various components of the brachial plexus.[132] Strong magnetic gradients (greater than or equal to one tesla) and flexible surface coils improve image quality. Varying the pulse sequence will provide high-resolution images that will facilitate identification of plexus pathology. Similar criteria for the diagnosis of root avulsion (pseudomeningocele and nonvisualization of a nerve root)

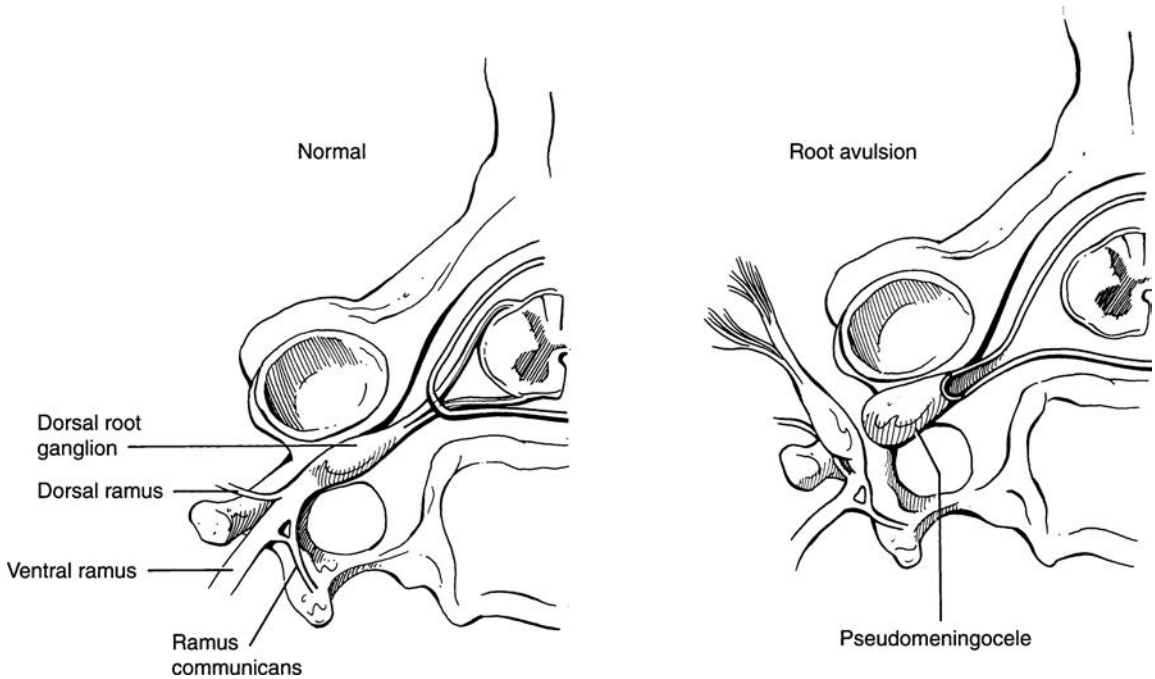

Figure 35-7 Artist's schematic of pseudomeningocele associated with avulsion injuries of the brachial plexus.

are used with MRI. MRI, however, offers better evaluation of the trunks and cords, with potential identification of a neuroma (Fig. 35-8 and 35-9).[132] MRI is also the modality of choice to evaluate neoplasms of the brachial plexus.

Electrodiagnostic Studies

Electrodiagnostic testing plays an integral part in the diagnosis and treatment of brachial plexus lesions.[44] The surgeon and neurophysiologist must have a dependable relationship with reciprocal communication. The results of neurophysiologic testing performed preoperatively, intraoperatively, and postoperatively may directly affect the decision-making process.[122] Methods employed to evaluate brachial plexus injuries are electromyography, nerve conduction velocity measurements, somatosensory-evoked potentials, and nerve action potentials.

Electromyography

Electromyography (EMG) records the electrical activity of muscle fibers at rest and during activation. This signal is recorded by the insertion of EMG needles into the muscle. The normal muscle is silent at rest and active during contraction with progressive recruitment of motor units. A denervated muscle will exhibit spontaneous electrical discharge (fibrillations and positive sharp wave) when the EMG needle is inserted.[21,44] These findings are not present until 2 to 4 weeks after denervation. A reinnervated muscle will begin to show reinnervation or nascent potentials (polyphasic low-amplitude recordings). These electrical changes of muscle regeneration will precede the clinical detection of muscle activity. Therefore, the EMG examination of the muscles innervated by the brachial plexus can provide valuable information about the degree of injury and early recovery. The dilemma with EMG interpretation, however, is the inability to quantify electrical recordings with extent of recovery. In other words, return of electrical activity may not correlate with return of active motion.

An EMG evaluation of the more proximal branches from the brachial plexus can help differentiate an avulsion injury from a rupture (see Table 35-6). For example, fibrillations and positive sharp waves of the paraspinal muscles (innervated by the dorsal rami from the spinal nerve) or serratus anterior (innervated by the long thoracic nerve) imply an avulsion injury, whereas preservation of a normal electrical signal suggests a more distal lesion. The EMG is also useful to differentiate the degree of intraneural injury (neurapraxia, axonotmesis, and neurotmesis) and to follow the progress after injury. A neurapraxia can be differentiated from a more severe nerve injury by the absence of fibrillation potentials and positive sharp waves. An axonotmesis or neurotmesis will exhibit these denervation changes. Serial EMG evaluations can infer an axonotmesis

injury by the spontaneous return of nascent units or reinnervation potentials that will precede clinical recovery of function. A neurotmesis injury will not exhibit EMG signs of spontaneous recovery.

Conduction Velocity

The integrity of the peripheral nerve is determined by the measurement of the conduction velocity. The motor or sensory latency can be measured depending on the recording of the compound motor action potential (CMAP) or the sensory nerve action potential (SNAP). The *conduction velocity* (CV) is the distance between two sites of stimulation divided by the time for the nerve action potential to travel from proximal to distal.[21] A severed nerve will lose the capability to conduct an action potential distal to the lesion as the nerve degenerates. However, the distal portion of the nerve may be able to conduct for several days after injury prior to degeneration. Therefore, early measurement of conduction velocities can produce a false-positive result for nerve continuity. Electrodiagnostic testing is often delayed for 3 weeks to allow time for loss of conduction and denervation changes in muscle.

The status of the SNAP and corresponding sensory nerve conduction velocity is helpful in differentiating preganglionic avulsion injuries from postganglionic lesions. The presence of a normal sensory CV in an anesthetic part of the arm indicates a preganglionic injury. The sensory nerve is not separated from its cell body, which is located in the dorsal root ganglion. The sensory nerve is separated from the spinal cord and sensation cannot be processed within the central nervous system. In contrast, the CMAP or motor CV is absent in both preganglionic and postganglionic injuries and is not a distinguishing factor.

Somatosensory-Evoked Potentials

Somatosensory-evoked potentials (SEPs) are electrical responses of the brain and spinal cord to stimulation of peripheral sensory fibers. Recordings of the conduction from the stimulating electrode to the central nervous system can be useful for the detection of lesions within the sensory system. This technique can be employed to assess conduction across the brachial plexus and during surgery to define irreparable nerve root avulsions. The absence of SEPs recorded over the spinal cord or contralateral sensorimotor cortex on nerve root stimulation indicates a root avulsion and is a contraindication for nerve grafting.[96,122]

Nerve Action Potentials

Nerve action potentials (NAPs) are used intraoperatively to assess lesions in continuity. Stimulating and recording of a nerve proximal and distal to a neuroma can identify the presence or absence of axonal continuity.[91] The presence of NAPs indicates propagation of an action potential along viable nerve fibers. This finding can help the surgeon decide between neurolysis or excision and interposition grafting.[91] This method is useful, but drawbacks include the inability to provide quantitative data and the incapacity to distinguish motor from sensory axons. Technical modifications to record the CMAP in innervated muscles or tetanic stimulation may provide better guidelines for surgical decision making.[44,91,97]

Nonoperative Treatment

The vast majority of adult brachial plexus injuries are initially treated without surgery. Brachial plexus injuries are often associated with other injuries that take precedence. Trauma resuscitation, repair of visceral damage, reconstitution of vascular flow, and stabilization of fractures dominate the acute management period. Brachial plexus injuries with concomitant upper extremity fractures are best treated by fracture fixation because of the high nonunion rate (almost 50%) and the need for early mobilization to prevent contracture, edema, and stiffness.[16] The initial goal of the postinjury period is to precisely define the location and extent of brachial plexus injury. This task is accomplished by a thorough examination and supplemented by the imaging studies previously described.

Following stabilization of the patient, the brachial plexus injury has certain features that require specific management (Fig. 35-10). Range-of-motion exercises and antiedema measures are required to prevent swelling and stiffness that will develop in the flail limb. The passive motion will also maintain supple joint structure and avoid contracture that will limit functional recovery. A sling is often applied to support the shoulder and to prevent additional traction across the plexus. This sling, however, must be removed for therapy as soon as the patient is comfortable. Electrical stimulation to diminish muscle wasting during nerve regeneration may be implemented, but its long-term efficacy is unclear.

Brachial plexus injury may result in neurogenic pain, which may be present after preganglionic and postganglionic injuries.[19] Preganglionic pain may be severe and constant, with a burning or crushing sensation. In most patients, this debilitating pain gradually subsides to a tolerable level. Postganglionic pain is from afferent signals that can still travel to the central nervous system. This pain can also be severe, but it usually dissipates over time to a bearable intensity. Pain management is accomplished by pharmacologic treatment, transcutaneous electrical stimulation, and other analgesic measures. Unfortunately, 5% of patients will exhibit persistent intractable pain that requires valiant attempts for pain relief, including ablation of the dorsal root entry zone (DREZ) or central nervous stimulators.[19,160] Amputation of the affected arm, however, will not relieve recalcitrant neurogenic pain.[196]

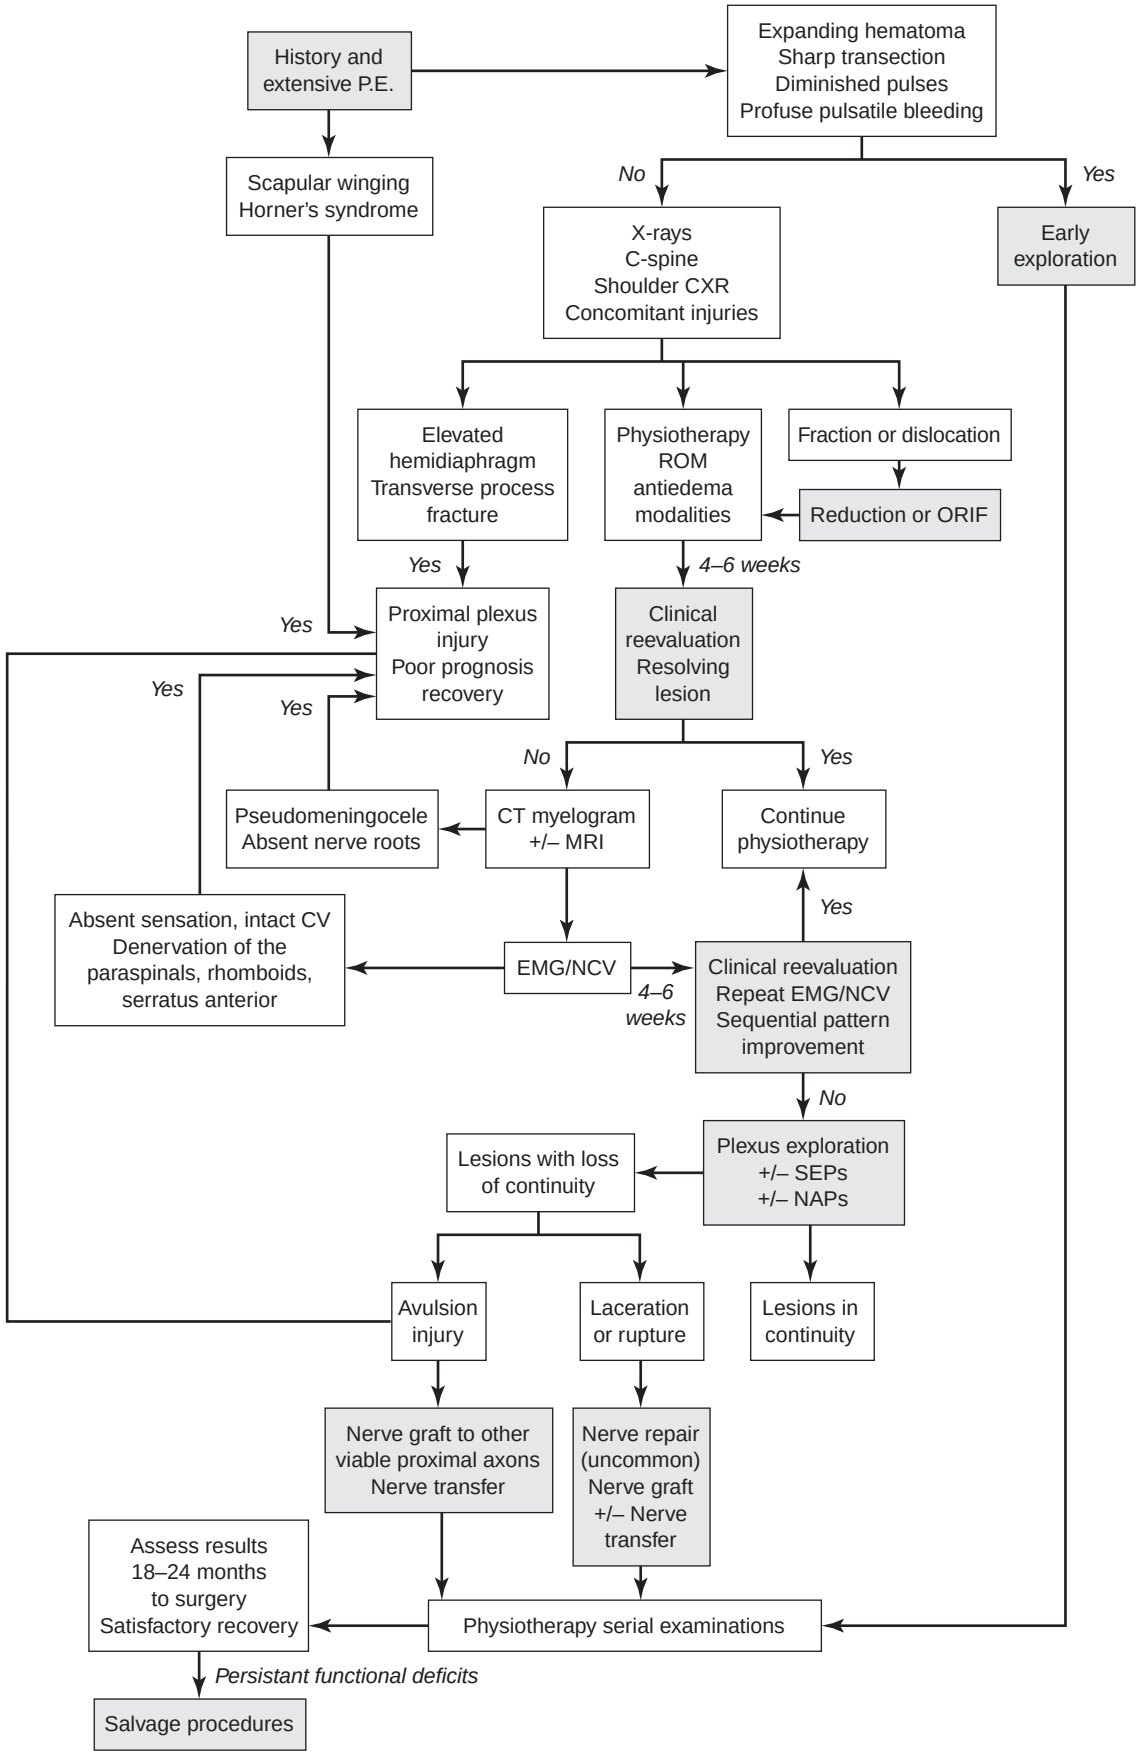

Figure 35-10 Treatment algorithm for adult brachial plexus injuries.

Serial examinations are performed to assess and further define the injury and to evaluate for signs of early recovery. X-rays of the chest, cervical spine, and shoulder girdle are evaluated for radiographic signs associated with a brachial plexus injury (see Table 35-7). Persistent deficits 3 to 4 weeks after injury warrant additional study. Options include advanced imaging studies (e.g., CT myelogram or MRI) and electrodiagnostic testing. Baseline electrodiagnostic studies are performed to assess for muscle denervation and the possibility of nerve rootlet avulsions (see Table 35-6).

Nonoperative management is usually continued for 3 months. Therapy is necessary to maintain passive motion and supple joints. Serial examinations are performed at monthly intervals. Repeat electrodiagnostic tests are often performed 3 months after injury. At this time, the clinical information and the ancillary studies are combined to define the level and extent of injury. The prognosis for recovery is also calculated. This observation period of 3 months is often sufficient time to adequately assess the injury and to decide whether spontaneous recovery is possible. The surgeon must also decide if the injury is amenable to surgical repair or reconstruction. Progressive recovery that follows a sequential pattern warrants continued observation and negates the need for exploration.

In contrast, a neurotmesis injury with loss of continuity (avulsion, rupture, laceration) or severe intraneural damage will not exhibit evidence of improvement at 3 months. In those reparable lesions, surgery is recommended between 3 and 6 months after injury. This time frame for surgery is important to ensure the viability of motor endplates to sprouting axons. A further delay in surgery may jeopardize the integrity of the motor endplates and prevent functional recovery, despite satisfactory nerve repair, grafting, or transfer. There is a trend toward earlier surgery if a nonrecoverable and reparable lesion can be identified to ensure endplate viability.

Infraclavicular lesions from fracture or dislocation are treated by prompt reduction of the fracture or dislocation. The nerve injury is often an isolated peripheral lesion and treated by observation. Neurapraxia and axonotmesis injuries are customary, and the prognosis for recovery is good. Exploration is reserved for those cases without spontaneous recovery.[4,125,126]

Surgical Management

Indications

Immediate surgical intervention for brachial plexus injuries is uncommon and is primarily performed for concomitant vascular injuries to the axillary or subclavian vessels (see Fig. 35-10). Simultaneous inspection of the plexus can be performed with identification of the injured segments. Immediate exploration is often frustrating, as the vascular repair cannot be adequately mobilized for fear of disruption. Once the injured nerve segments are identified, the treatment depends upon the status of the damaged segments. Sharp transections can be managed by direct repair or graft interposition. Primary neurorrhaphy requires approximation of the cut ends without excessive tension.[47,117,164] Primary neurorrhaphy is not recommended for traction or gunshot injuries. Delayed management is preferred to allow demarcation of the zone of injury and extent of nerve damage. Fortunately, most penetrating trauma by missile preserves nerve continuity.[18,91,133]

Delayed surgical management is usually performed 3 to 6 months after injury. The decision to operate is based on locating a repairable lesion that would not experience spontaneous recovery. The compilation of serial examination determines the level and extent of nerve injury. The time frame ensures the viability of motor endplates to sprouting axons via nerve grafting or transfer. Unfortunately, disruptions of the lower trunk (C8, T1) do not respond to nerve grafting in adults and are not an indication for surgery. This poor outcome reflects the distance required for the axons to travel to the motor endplates before irreversible changes.

Surgical Approach

The surgical exploration for brachial plexus injuries requires an extensile exposure of the supraclavicular and/or infraclavicular plexus. The procedure is performed with the patient supine, and ample preparation of the injured extremity, neck, hemithorax, and lower leg(s) for sural nerve grafts. Electrophysiologic testing apparatus may be used during surgery. This requires placement of scalp or cervical spine electrodes for SEPs and bipolar probes for intraoperative stimulation to record nerve action potentials.

The skin incision varies with the extent of plexus exposure. Supraclavicular exposure begins with an incision across the upper border of the clavicle. This incision may be extended in a proximal direction parallel to the posterior border of the sternocleidomastoid muscle (Fig. 35-11). Skin flaps are elevated and supraclavicular sensory nerves are mobilized. The subcutaneous platysma muscle is divided. The external jugular vein, which descends across the posterior border of the sternomastoid to pierce the fascia, is usually ligated. The sternocleidomastoid muscle is partially released from the clavicle to widen the medial exposure. Similarly, the trapezius muscle is partially released from the lateral clavicle to enlarge the lateral exposure. The omohyoid muscle is the "door" to the supraclavicular plexus and must be identified. The omohyoid is divided at its intermediate tendon to expose the scalene muscles and plexus (upper and middle trunks). The transverse cervical artery, which crosses from anterior to posterior across the operative field just cephalad to the suprascapular artery, is mobilized and ligated. The phrenic nerve

Figure 35-11 Artist's schematic of incision for approach to brachial plexus.

travels on the anterior scalene just anterior to the posterior triangle. The phrenic nerve must be protected throughout the dissection (Fig. 35-12). The upper trunk and C5 and C6 roots are isolated between the anterior and middle scalene muscles. The middle trunk and C7 is inferior and posterior to the upper trunk. The lower trunk is difficult to isolate via the supraclavicular approach, as the subclavian

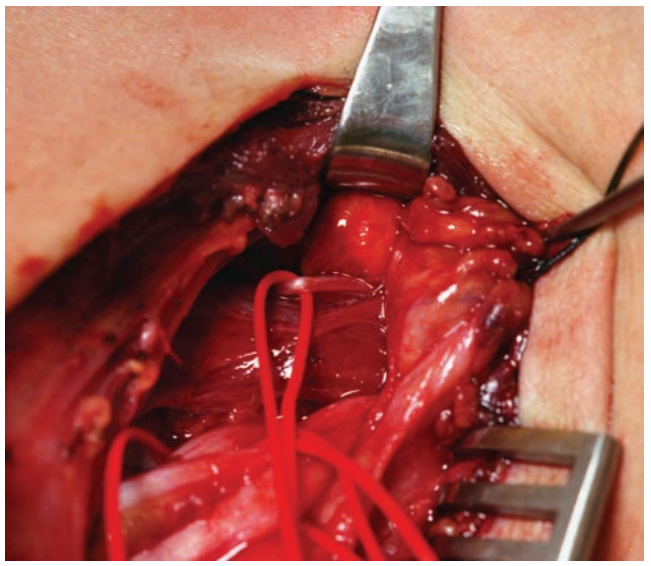

Figure 35-12 Phrenic nerve is isolated and protected. Nerve runs along anterior aspect of the anterior scalene. Patient is supine and head is to the right. (Courtesy of Shriners Hospital for Children, Philadelphia.)

Figure 35-13 X-ray of 17-year-old male with right brachial plexus injury and clavicle malunion. (Courtesy of Shriners Hospital for Children, Philadelphia.)

vessels and clavicle impede inferior dissection. Occasionally, the lower trunk and C8 and T1 can be visualized. Osteotomy of the clavicle and/or infraclavicular exposure will enhance access to the lower trunk. Osteotomy of a clavicle malunion is often necessary to increase exposure of the underlying plexus (Fig. 35-13–35-17).

Combined supraclavicular and infraclavicular exposure necessitates extension of the lateral skin incision downward into the deltopectoral interval (see Fig. 35-11). Isolated infraclavicular brachial plexus exposure requires only a deltopectoral incision. The deltoid muscle is retracted in a lateral direction and the pectoralis major in a medial direction. The coracoid process is identified. The pectoralis minor tendon is the "door" to the infraclavicular plexus. The tendon is tagged with a suture and divided. The infraclavicular plexus

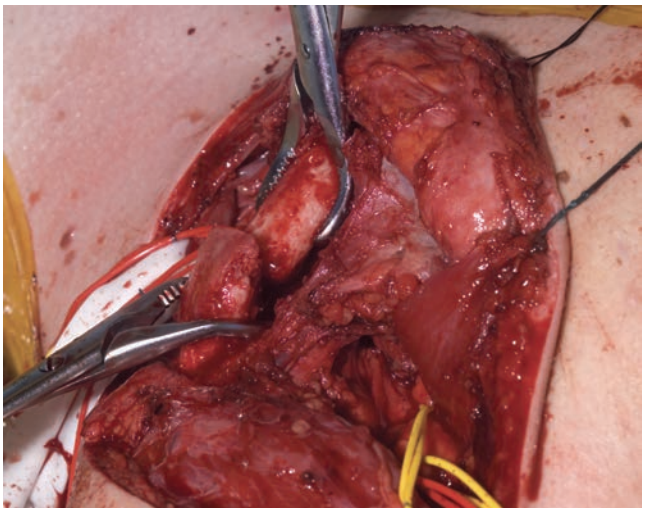

Figure 35-15 Clavicle malunion isolated and bone edges mobilized for better exposure of plexus. (Courtesy of Shriners Hospital for Children, Philadelphia.)

and axillary artery are isolated. The lateral cord (i.e., musculocutaneous and median nerves) is usually the first structure encountered. Identification if the posterior cord (i.e., axillary and radial nerves) and medial cord (i.e., ulnar nerve) requires mobilization of the axillary artery.

Surgical Strategy

The surgery for brachial plexus injury is tedious, as scar envelopes the injured neural elements. Following exposure of the brachial plexus, the injured neural elements are identified. The normal anatomy is often distorted and intraoperative nerve stimulation is helpful to identify specific nerve elements. Direct stimulation of the nerve and observation of any corresponding muscle contraction assists in proper nerve identification. The focus of the

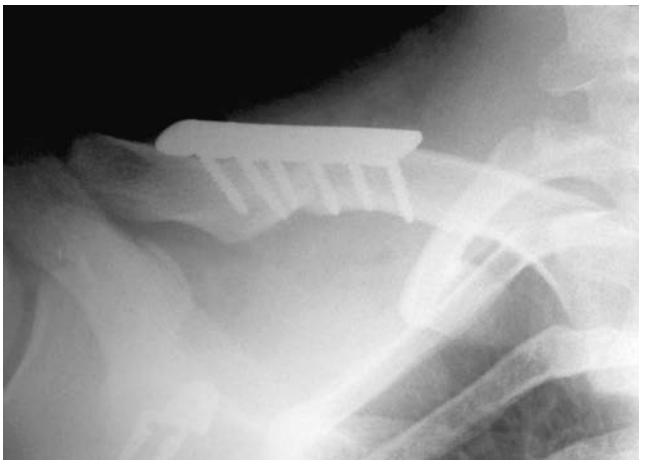

Figure 35-17 Postoperative x-ray reveals marked improvement in clavicle position. (Courtesy of Shriners Hospital for Children, Philadelphia.)

brachial plexus dissection is to differentiate lesions in continuity from those with lesions with loss of continuity. The diagnosis is uncomplicated when the dissection uncovers a transected nerve or avulsed nerve roots. The differentiation, however, can be difficult within dense scar tissue and neuroma formation that intervenes between the proximal and distal limbs of a completely disrupted nerve.[37] In addition, a neurotmesis lesion can occur from severe intraneural damage without overt transaction. This lesion will not recover without excision of the scarred nerve tissue and interposition grafting. Intraoperative determination of SEPs and NAP can facilitate the diagnosis in these equivocal cases, although their usefulness is controversial.

Stimulating a nerve and recording the cerebral cortical response indicates an intact SEP. The presence of a recordable response implies nerve continuity, and the absence of a response indicates nerve discontinuity. This technique can be applied to a spinal nerve to determine the presence of an avulsion injury. The absence of a response from a spinal nerve indicates an avulsion injury and is a contraindication to nerve grafting. The determination of the NAP across the neuroma may be helpful. The sensory NAP is recorded by direct stimulation and recording of the nerve proximal and distal to a suspected lesion. The presence of conduction across the lesion confirms some nerve continuity. Absent nerve conduction indicates fiber discontinuity with complete intraneural scarring.[90,118,122]

Treatment of Avulsion Injuries

Currently, there is no surgical treatment to restore nerve rootlet connection (i.e., an avulsion injury) with the spinal cord.[125] Experimental work with reattachment of the rootlets directly to the spinal cord is ongoing.[23,24] The current treatment for avulsion injuries is nerve grafting using

other viable proximal stumps or nerve transfer from intact adjacent nerves (see Fig. 35-10).

Treatment of Lesions in Continuity

The role of neurolysis for lesions in continuity is controversial. The ultimate effect on neurologic recovery is questionable. Neurolysis of a recovering nerve may induce further damage and reduce subsequent recovery. If neurolysis is performed and fascicular anatomy cannot be identified, resection and grafting is indicated.[118]

Treatment of Lesions without Continuity

After completion of the exposure and preliminary dissection, the lesions with loss of continuity are delineated. The proximal and distal stumps available for nerve reconstruction are defined with exclusion of any rootlet avulsions. The subsequent treatment is to resect the neuroma between the proximal and distal nerve stumps until normal nerve consistency and fascicular anatomy is encountered. The distal stumps are now primed for coaptation with viable inflow for regeneration of axons. The exact connection of proximal and distal stumps requires some decision making, especially in cases with loss of proximal stumps secondary to avulsion. Restoration of continuity can be accomplished by nerve grafting or nerve transfer. Nerve grafting is the placement of intercalary nerve grafts that act as scaffolding for regenerating axons. Nerve transfer is coaptation of an expendable motor nerve into the distal stump to supply axons for ingrowth.

Nerve Grafting

Nerve grafting is the preferred technique for most lesions with loss of continuity. The interposition of a nerve graft links the proximal and distal axons and serves as a conduit to channel the growing axons to the periphery. The donor nerve is usually the one or both sural nerves, harvested at the time of brachial plexus exploration. Other potential nerve graft options are the cervical plexus, ipsilateral medial antebrachial cutaneous, and/or superficial radial nerves. The donor nerve graft is divided into sections that span the defect until a comparable cross-sectional area is obtained for interposition grafting. The nerve grafts are secured between the proximal and distal stumps by epineural sutures and/or biologic adhesives, such as fibrin glue (Fig. 35-18).[47,90,125,126] Biologic adhesives such as fibrin glue can be used to decrease operative time.[57] The nerve grafts are revascularized by vascular ingrowth from the recipient bed.[144,164] Therefore, numerous smaller-diameter grafts are preferable to a single large-caliber graft, to limit necrosis before revascularization begins. Tension is avoided across the proximal and distal coaptation sites because this creates an unfavorable condition for axonal sprouting.[116,118,165] Nerve grafts are best directed toward shoulder and elbow muscles for reinnervation because the distance to the branches is short and axonal regrowth can occur before there is irreversible muscle damage.[125] In addition, the plexus fascicular anatomy shifts rapidly over relatively short distances, which promotes erroneous growth of axons. Therefore, nerve-grafting strategy should attempt to preferentially direct the axons to achieve a defined function. For example, grafts that connect directly to the musculocutaneous, axillary, and suprascapular nerves have less chance of axonal dropout and misdirection compared with grafts placed imprecisely into the cords.

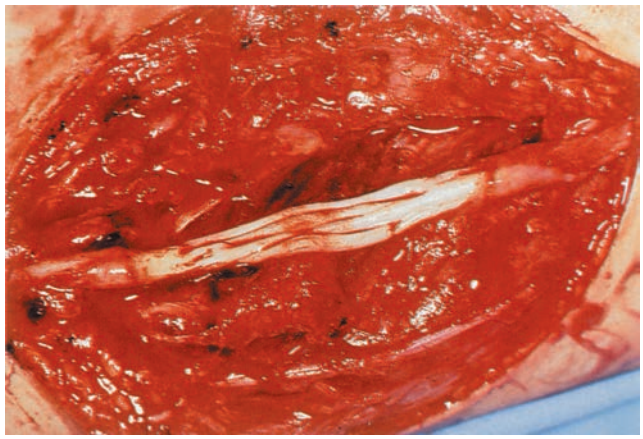

Figure 35-18 A 15-year-old boy, who sustained a gunshot wound to his arm, with transection of ulnar nerve. He was treated with neuroma resection and cable graft with strands of sural nerve.

Nerve Transfer

Nerve transfer is indicated in avulsion injuries and large or extensive defects of the brachial plexus. The indications for nerve transfer increases as the number of avulsed roots multiplies. In addition, long interposition nerve grafts (greater than 10 cm) are limited by available donor nerves and have less chance for recovery.[29]

Nerve transfer involves the connection of an expendable donor motor nerve to provide an axonal source for regeneration of the distal stump. The donor nerves for transfer are mobilized while maintaining their proximal connection and coapted to selected distal stumps, preferably specific peripheral nerves to achieve the desired function. The donor neurons will reinnervate the muscle, and function will require voluntary control of the transferred nerve. Similar to a tendon transfer, activation of the donor nerve to achieve function will require a period of training, and involuntary muscle activation may occur until transformation has taken place. For example, coughing or sneezing will initially activate intercostal nerve transfer, but re-education will occur over time. The technique of nerve transfer can be used in tandem with nerve grafting or may be the only available option in complete avulsion injuries.

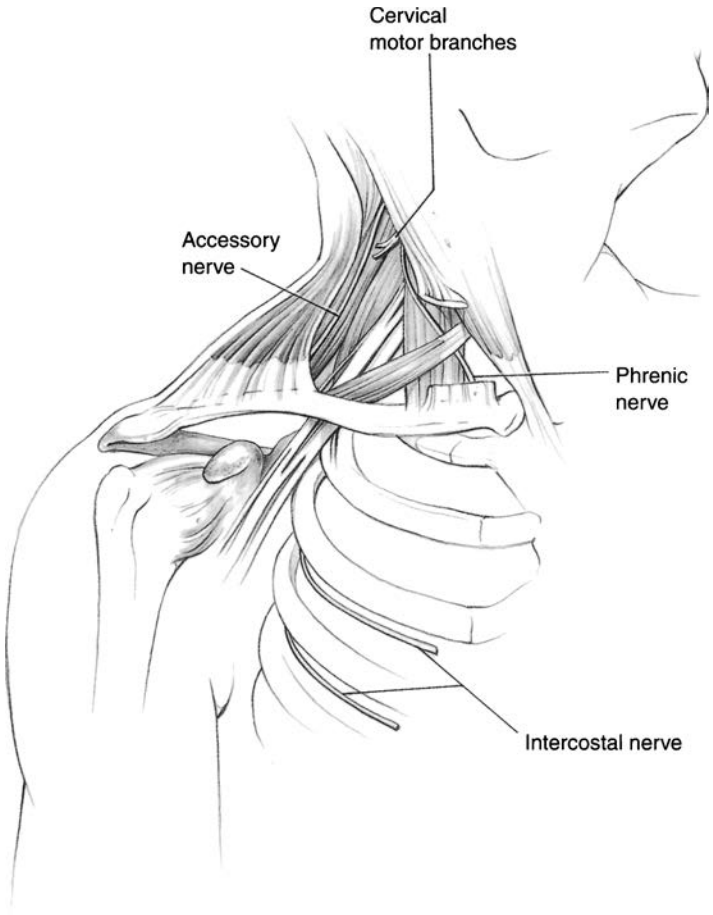

Figure 35-19 Artist's schematic of potential donors for nerve transfer.

Nerve transfers utilize a variety of axonal sources depending upon the level of injury. The number of available nerve transfers is increasing as our knowledge of muscle innervation and its redundancy improves. Options include the spinal accessory nerve, intercostal nerves, a portion of the ulnar nerve, a portion of the median nerve, a portion of the radial nerve, the medial pectoral nerve, the phrenic nerve, and the contralateral C7 nerve root (Fig. 35-19).[11,29,30,31,64,66,100,101,111,125,165,194] Recently, the ipsilateral C7 nerve root has been reported as a potential transfer in cases with isolated avulsion of C5 and C6.[65]

Nerve transfer of the phrenic nerve, the suprascapular nerve, the musculocutaneous nerve, or axillary nerve has been described.[29,30,31,125] Use of the phrenic nerve does reduce pulmonary capacity, which may improve over time.[3,64,125] In infants, the use of phrenic nerve transfer is avoided because the diaphragm is not yet firmly fixed to the vertebral bodies and severe respiratory problems can occur.[30,31]

Transfer of the spinal accessory to the suprascapular nerve for supraspinatus and infraspinatus reinnervation, transfer of the intercostal nerves to the musculocutaneous nerve for biceps function, and transfer of a portion of the ulnar nerve to the musculocutaneous nerve are favored techniques for avulsion injuries of C5, C6, and C7.[30,95,100,101,125,194]

Spinal Accessory Nerve Transfer Technique[11,70] (Fig. 35-20)

After general anesthesia, the patient is positioned on the operating table with a large folded sheet placed in the interscapular region to facilitate access to the trapezius muscle and spinal accessory nerve. The neck is turned to the contralateral side. Muscle relaxant is avoided to allow electrical stimulation of the spinal accessory nerve. A 10-cm transverse incision is made just above the clavicle from the sternocleidomastoid muscle to the acromioclavicular joint. The upper part of trapezius muscle that inserts onto the clavicle and the acromioclavicular joint is divided. The divided portion of the trapezius is retracted in a posterior direction. Dissection is performed along the anterior border of the trapezius muscle looking for the transverse cervical artery and vein. These vessels enter the trapezius muscle at the base of the neck and descend in a vertical direction midway between the vertebral column and the medial border of the scapula. The spinal accessory nerve

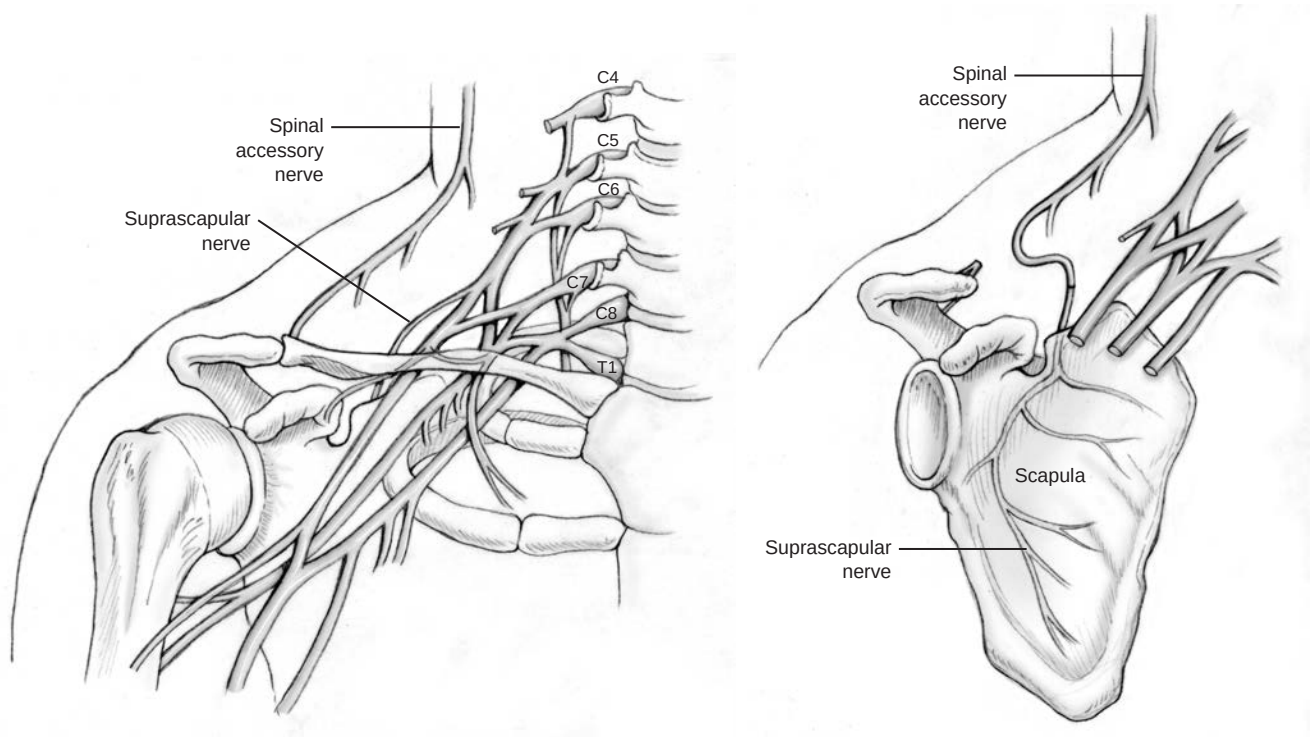

Figure 35-20 Schematic of the spinal accessory to the suprascapular nerve transfer technique.

accompanies the transverse cervical artery and vein. After identification of the vessels, an electrical stimulator is used around the vessels to facilitate identification of the distal part of the spinal accessory nerve. Small branches from the cervical plexus are located in the vicinity; however, electrical stimulation will not result in trapezius contraction.

The spinal accessory nerve is dissected in a distal direction to increase length. A proximal branch to the upper part of the trapezius must be preserved. The terminal division of the nerve is divided and transferred to the supraclavicular fossa for transfer to the suprascapular nerve, which is isolated from the upper trunk.

Intercostal Nerve Transfer Technique[95,119,197]

The intercostal transfer is performed through a transverse thoracic incision in the interspace between the third and fourth ribs, from the midaxillary line to the costochondral junction (Fig. 35-21). The anterior surface of the ribs is exposed by separation of the pectoralis major and minor muscles. The ribs are mobilized by subperiosteal dissection, with protection of the underlying pleura. An umbilical tape is placed around the nerve for traction. The rib is retracted in a cephalad direction and the upper portion of the intercostal muscle spread to identify the motor portion of the intercostal nerve. The nerve is dissected from the costochondral junction to the midaxillary line. This length of dissection will avoid the need for an intervening nerve graft.[184] The third, fourth, and fifth intercostal nerves are harvested in similar fashion (Fig. 35-22). Through a linear incision in the arm, the musculocutaneous nerve is exposed on the undersurface of the biceps brachii muscle. A subcutaneous tunnel is developed between the biceps, axilla, and thoracic incision. The intercostal nerves are then passed to the biceps motor nerve and coapted with epineural sutures and/or fibrin glue.

When transferring the intercostal nerves, two to four nerves are used to provide increased motor fibers to the musculocutaneous nerve, compared with a single-nerve transfer.[28,83,95,119,125] Early reinnervation will be evident during breathing, coughing, and sneezing, which will illicit biceps activation. This involuntary reaction will subside over time as volitional activation becomes predominant.[95,119,122] Intercostal nerve transfer will have a minimal effect on pulmonary function as long as the diaphragm is functional. Diaphragmatic paralysis is a relative contraindication to intercostal nerve transfer.[95,116] In addition, combined transfer of the intercostal and phrenic nerves is not recommended.

Ulnar Nerve Transfer Technique[11,100,101,131,177,194] (Fig. 35-23)

An incision is performed over the medial aspect of the arm, beginning 4 cm distal to the pectoralis major lateral border

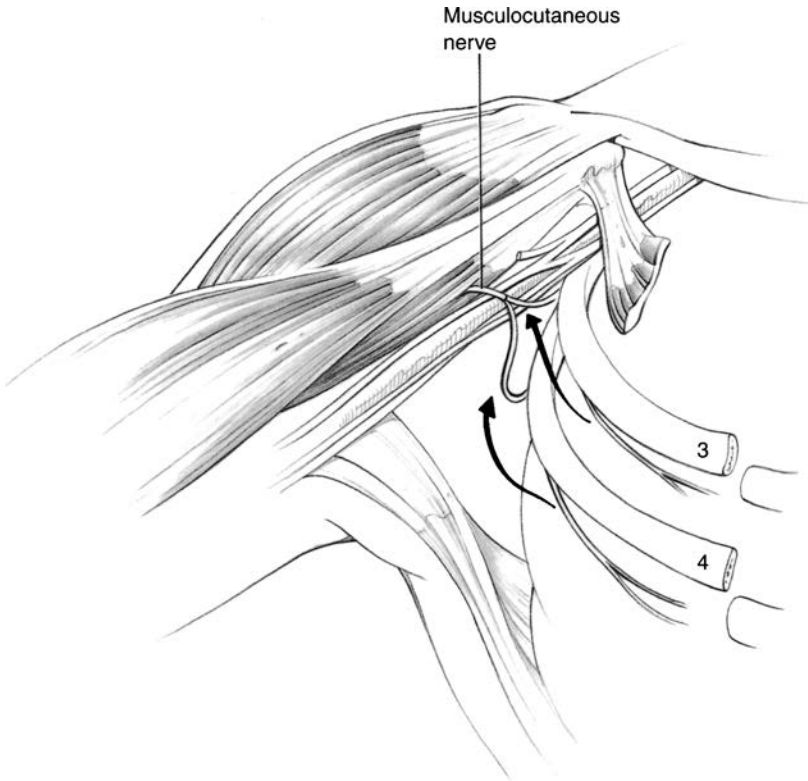

Figure 35-21 Artist's schematic of intercostal nerve transfer to musculocutaneous nerve for elbow flexion.

(Fig. 35-24). The anterior fascia over the biceps muscle is divided and the muscle is dissected from the coracobrachialis muscle. The motor branch of the biceps muscle is identified on the undersurface of the muscle and traced in a proximal direction toward the musculocutaneous nerve. The motor nerve is divided from the musculocutaneous nerve in preparation of transfer.

A second fascia incision is performed posterior to the intermuscular septum and the ulnar nerve is isolated 1 cm proximal to the motor branch of the biceps muscle. Using magnification, a longitudinal epineurotomy is made along the ulnar nerve and the individual group fascicles separated (Fig. 35-25). Usually, three group fascicles are present. Electrical stimulation is used to confirm group fascicles that contain motor fibers to the extrinsic hand muscles. One group fascicle is divided and transferred to the biceps motor branch. The ulnar nerve is coapted to biceps motor branch with epineural sutures and/or fibrin glue. The nerve coaptation is performed with the elbow in extension and the elbow immobilized in flexion to relieve any tension across the nerve repair.

Prioritization in Severe Brachial Plexus Injuries

In each microsurgical case, the reconstruction plan is individualized depending on the extent of injury and available reconstructive options. A priority list must be established in difficult brachial plexus injuries. This roster is based on functional importance and prognosis after nerve reconstruction. Better results are achieved from nerve reconstruction in the proximal musculature. Elbow flexion against gravity holds the highest priority in brachial plexus injuries. Restoration of elbow flexion allows the extremity to be better positioned in space and the hand flexed toward the trunk and mouth for use. Shoulder balance and stability is the next priority for reconstruction, as an unstable or contracted shoulder will impede use of the extremity. The triceps is next on the priority list, for nerve grafting or transfer is reliable by connection directly to the radial nerve

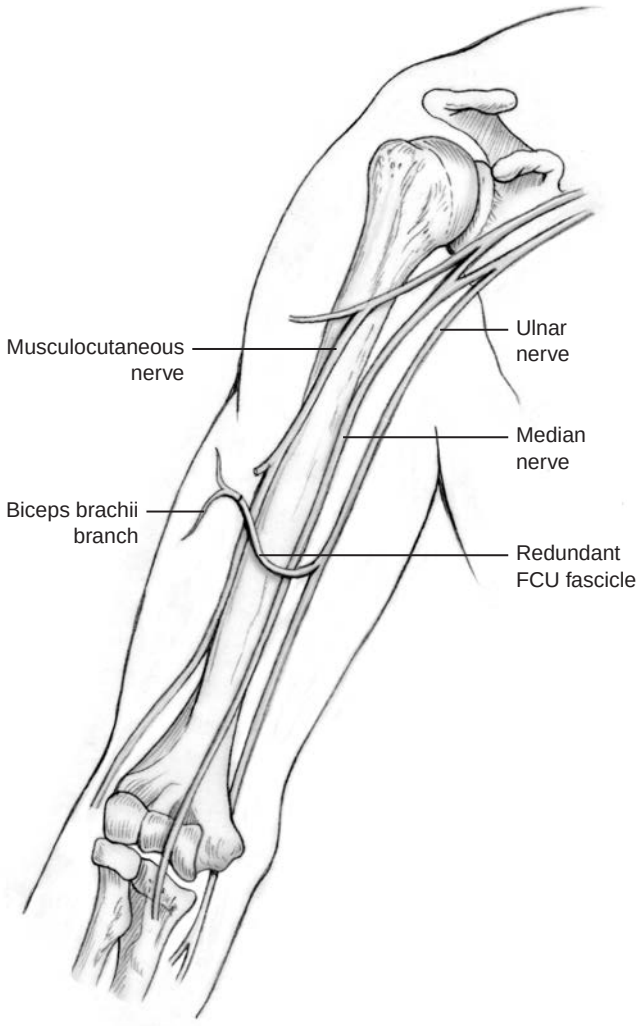

Figure 35-23 Schematic of the transfer of a portion of the ulnar nerve to the musculocutaneous nerve for biceps function.

branches that innervate the triceps. The forearm flexors and digital sensibility (median nerve) are addressed next. The wrist and finger extensors are subsequently considered by linkage to the radial nerve. The ulnar innervated structures are the last priority because of the poor prognosis for recovery.[124–126] The number of axons diminishes as the regenerating axons move toward the periphery, and the hand has the misfortune of being last on the list. Therefore, reconstruction of lower-trunk defects via nerve grafts in adults is usually unsuccessful and is performed only in children that possess the possibility of reinnervation. Nerve transfers, however, are creating options for distal reinnervation as the regeneration distance is diminished.[194]

The priority list provides guidelines for nerve reconstruction in severe cases with limited viable proximal stumps or inadequate donor nerves. The unlimited patterns of nerve lesions in brachial plexus injuries prohibit the development of definitive treatment algorithms for

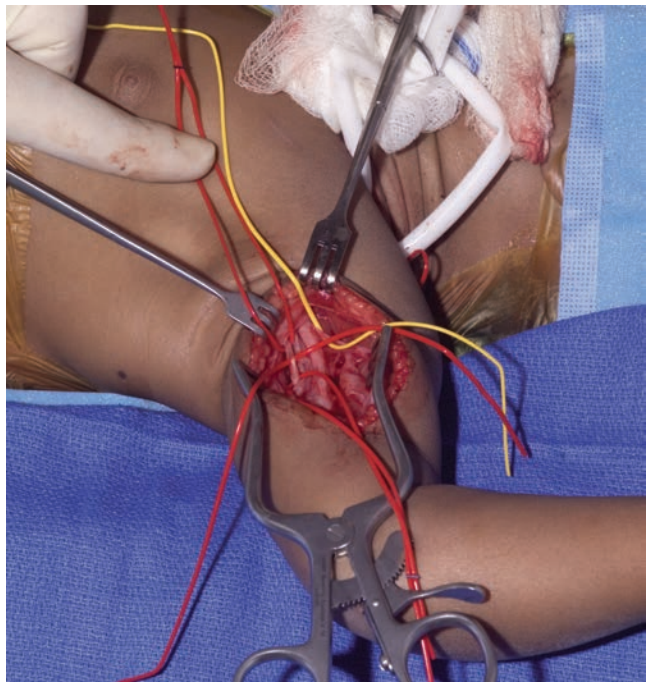

Figure 35-24 Incision over the medial aspect of the arm to identify musculocutaneous and ulnar nerves. (Courtesy of Shriners Hospital for Children, Philadelphia.)

each potential situation. The basic strategy is to precisely define the injury and reconstruct loss of nerve continuity (see Fig. 35-10). Nerve grafts are employed in lesions with viable proximal and distal stumps, with priority given to the elbow (musculocutaneous nerve) and shoulder (suprascapular and axillary nerves). Inadequate proximal

inflow requires nerve transfer with expendable donors. In addition, a combination of nerve grafts and nerve transfers can be utilized during brachial plexus reconstruction.

Postoperative Care

The closure is straightforward with repair of divided structures. An osteotomy of the clavicle requires internal fixation. The omohyoid and/or pectoralis minor tendon are sutured. A layered closure is completed and the arm is placed in a Velpeau dressing. Suture removal is at 2 weeks and immobilization continued for 3 to 4 weeks. Gradual mobilization and physical therapy are instituted within the confines of nerve mobilization. Prolonged therapy is necessary to maintain supple joint structure, as nerve regeneration progresses at a sluggish rate of 1 mm/day. Serial clinical and electrodiagnostic evaluations are performed with assessment for signs of reinnervation. Motor recovery is followed by active motion to restore function of the extremity. Sensory recovery may benefit from sensory re-education.

Results after Brachial Plexus Surgery

The results from nerve reconstruction surgery vary with the degree of damage and complexity of the techniques employed. A result is judged to be successful when the outcome improves function, and this usually requires a strength return greater than gravity. This antigravity strength allows independent use of the extremity without assistance of the other extremity.

Neurolysis and Primary Neurorrhaphy

The reported results of neurolysis of lesions in continuity are generally good, with return of muscle strength against gravity in more than 90% of the cases.[38,47,91,92,133] The efficacy of neurolysis, however, is difficult to prove as spontaneous recovery may have occurred without surgery.[111,133]

Primary neurorrhaphy is usually not an option in brachial plexus injury.[47] However, when primary repair is indicated and is performed without excessive tension, most patients regain strength to overcome gravity.[29,90,91]

Nerve Grafting

The results of nerve grafting are better with upper plexus lesions, shorter graft length, and surgery less than 9 months after injury.[29,38,71,165] Return of sufficient proximal muscle strength after nerve graft interposition occurs in approximately 50% to 80% of cases.[4,38,52,90,111,122,123,182] Nerve grafting for lower plexus lesions in adults is uniformly unsuccessful, but may provide some mild return of extrinsic muscle function and protective sensation.[4,18,90,91,116,165] Secondary tendon transfers and arthrodesis can further enhance function after nerve regeneration.

Nerve Transfer

The results of nerve transfer reveal better results when the transfer is performed early and coapted into a peripheral nerve without an intervening graft.[29,30,95,119,122] A variety of donor nerves have been utilized, including the intercostals, partial median, partial ulnar, spinal accessory, and phrenic. Return of elbow flexion against gravity is achieved in 60% to 88% of cases.[29,30,64,78,83,116,119,182] The ulnar nerve to motor branch of the biceps muscle has resulted in consistent elbow flexion against gravity in approximately 75% of cases.[52,101,113,117,123,131,189] Persistent clinical deficits in ulnar nerve function have not been realized.

The results for return of shoulder function are more variable when using a nerve transfer to the suprascapular nerve or axillary nerve to achieve stability and abduction. The results of transfer for suprascapular function are approximately 50% to 80% successful and axillary function about 40% successful.[31,106,116,118,125] The inferior results for restoration of shoulder function compared with elbow flexion are, in part, secondary to mass innervation.[126] Shoulder function is a coupled movement of scapulothoracic and glenohumeral motion to achieve abduction. Simultaneous contraction of the reinnervated shoulder muscles prevents synchronous motion and diminishes effective abduction. In contrast, elbow flexion requires a relatively uncomplicated motion.

A meta-analysis of the English literature to assess the efficacy of individual nerve transfers for restoration of elbow and shoulder function uncovered 1,038 nerve transfers from 27 studies that met the inclusion criteria.[113] Seventy-two percent of direct intercostal-to-musculocutaneous transfers (without interposition nerve grafts) achieved biceps strength greater than or equal to M3 versus 47% using interposition grafts. Direct intercostal transfers to the

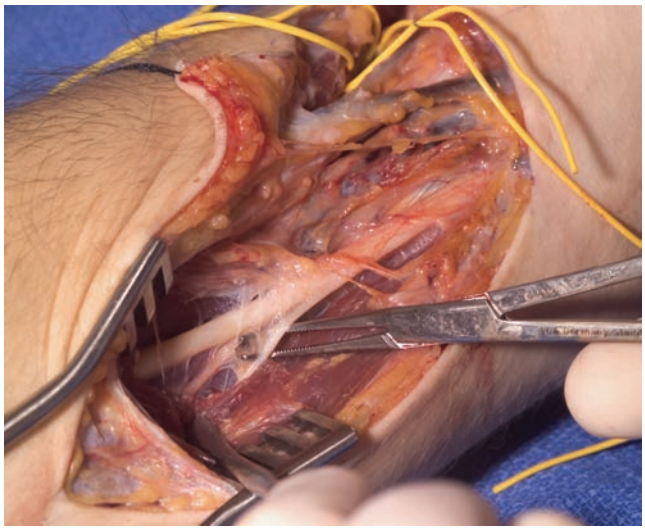

Figure 35-27 Isolation of a redundant FDS branch of the median nerve for transfer to the posterior interosseous nerve (*yellow loop*). (Courtesy of Shriners Hospital for Children, Philadelphia.)

musculocutaneous nerve had a better ability to achieve greater than or equal to M4 elbow strength than transfers from the spinal accessory nerve (41% vs. 29%). The suprascapular nerve fared significantly better than the axillary nerve in obtaining greater than or equal to M3 shoulder abduction (92% vs. 69%).

Nerve transfer for forearm and hand function is less successful, with partial return of function.[83] The use of donor nerves within the forearm, however, may improve the clinical results (Figs. 35-26 and 35-27). Partial median and anterior interosseous nerve transfers to the posterior interosseous and ulnar motor nerve are examples of such transfers.[7,194]

The results of contralateral C7 nerve transfers have been somewhat disappointing. Fortunately, transient weakness and numbness has not persisted into permanent deficits. Sensory and extrinsic motor recovery has been reported in approximately one-third of patients at 3-year follow-up.[66,171]

BRACHIAL PLEXUS BIRTH PALSIES

Pathophysiology

Brachial plexus birth palsies can occur during passage through the birth canal. Traction or stretch across the plexus is the likely mechanism, although the exact timing of stretch is controversial.[45,84,126] The reported incidence has varied from 0.4 to 2.5 palsies per 1,000 live births.[34,63] Brachial plexus injuries have been recreated in stillborns by traction applied to a restrained shoulder.[114] Brachial plexus birth palsies can also occur during caesarean section or breech presentation.[34,97]

Evaluation of Brachial Plexus Birth Injury

The history is extremely important. Prenatal, postnatal, and birth information should be obtained. Risk factors include a difficult or prolonged delivery, large-for-gestational age infants (macrosomia), shoulder dystocia, breech presentation, and forceps or vacuum extraction.[34,53,57,92] Inquiry into the duration of labor, method of delivery, use of forceps or vacuum extraction, fractures of the clavicle or humerus, Horner's syndrome, postnatal position of extremity, and initial extent of involvement is required.

The physical examination of the newborn with brachial plexus birth palsy is difficult because of lack of cooperation. Observation of the affected extremity often provides valuable information regarding the pattern of injury (Fig. 35-28)(see Table 35-3). Upper root (C5, C6) or trunk injuries (i.e., Erb's palsy) present with a typical posture of shoulder adduction and internal rotation, elbow extension, forearm pronation, wrist flexion, and finger flexion. An extended Erb's palsy includes C7 and additional paralysis of elbow and finger extension. Total or global brachial plexus palsy results in a completely flaccid extremity. Isolated lower root (C8, T1) or trunk injuries (i.e., Klumpke's

Figure 35-28 A 6-month-old child with left brachial birth palsy. Posture is indicative of upper trunk palsy with early return of elbow flexion. (Courtesy of Shriners Hospital for Children, Philadelphia.)

palsy) are rare in birth injuries. When present, there is normal posture of the shoulder and elbow, with paralysis of the hand's intrinsic muscles.[34,72] The presence of a Horner's syndrome (ptosis, meiosis, enophthalmos, and ipsilateral facial anhydrosis) is an important observation that implies avulsion injury of the lower trunk, with disruption of the communicating branch supplying sympathetic fibers to the cervicothoracic ganglion. These infants may have an associated phrenic nerve palsy with an elevated hemidiaphragm, which increases the likelihood of an avulsion injury and negates the possibility of spontaneous recovery.

Palpation of the clavicle and shoulder girdle may reveal crepitation or abundant callus formation. An acute fracture will inhibit voluntary movement and mimic brachial plexus injuries (i.e., pseudoparalysis). In addition, the passive shoulder range of motion should be assessed to exclude posterior dislocation. A newborn with a brachial plexus injury should exhibit full passive motion of the shoulder. Limited external rotation implies a concomitant shoulder dislocation.[48] Ultrasound or MRI may be required to confirm this diagnosis because the newborn humeral head is not ossified.[94,121,186,187]

The assessment of motor function in the newborn or infant is a challenging task that requires patience and diligence. The initial goal is to determine the absence or presence of function, as actual grading of muscle strength is impossible. A variety of motor scores have been developed to assess movement (Table 35-8).[33,34,41] In the infant, a collection of toys and rattles is necessary to incite movement of the injured extremity. Tactile stimulation and changing the position of the child to assess weak but functioning muscle can alter the effect of gravity. Motor function for shoulder movement, elbow motion, wrist action, and digital movement is delineated. The newborn can also be aroused by the use of neonatal reflexes, such as the Moro, asymmetric tonic neck, and grasp reflex. The Moro or startle reflex should produce extensor tone in the legs and arms. The grasp reflex should illicit finger flexion via stimulation of the palm. Asymmetry of these reflexes indicates a neurologic deficit. Sensory function is also difficult to assess, as the only reaction obtained may be to painful stimuli, which will erase any chance of further cooperation.

Imaging Studies

Similar imaging studies are used in children and adults. The particular studies ordered vary with the type of injury, physical examination, imaging strategy, and expertise of the radiologist.

Plain x-ray films of the cervical spine, clavicle, shoulder, and chest are routine. Comparable findings suggest particular levels of plexus injury (Table 35-7).

Methods to determine the presence or absence of a pseudomeningocele are less reliable in children (see Fig. 35-9). Myelography, CT myelography, and MRI have been used for assessment. MRI imaging protocols are being developed using adult head coils, smaller slice thickness, and variable-imaging sequences to increase accuracy.[134,170]

Electrodiagnostic Studies

Electrodiagnostic testing is less reliable in children. The presence of motor activity within a muscle has not been an accurate prediction of clinical recovery. Electrodiagnostic testing often underestimates the injury and overestimates the chances of spontaneous recovery.[185]

Nonoperative Treatment

Brachial plexus birth palsies are also treated by a period of observation. The diagnostic evaluation is similar to adult injuries, but complicated by lack of cooperation and small size of the infant (Fig. 35-29). Most brachial plexus birth palsies involve the upper trunk and resolve over time.[62,63,72] However, estimates of complete resolution have been downgraded from 90% to approximately 60% to 70%.[75,142] Permanent sequelae can be a debilitating problem that disturbs synchronous motion and hinders activities of daily living. Impairment about the shoulder is particularly prevalent, especially in external rotation and abduction.

The goals of the observational period are similar in adults and children. The objective is to determine the level and extent of injury. Serial examinations every month during infancy are necessary to forecast outcome and indications for surgical intervention. The number of nerve roots involved is a predictor of spontaneous recovery. Therefore, spontaneous recovery is greatest in Erb's palsy and least in global palsies.

Upper-trunk palsies with or without middle-trunk involvement are treated differently than global palsies. Elbow flexion (biceps and brachialis muscles) is the best indicator of upper trunk recovery. Consequently, the evaluation of elbow flexion is a key indicator of nerve regeneration across the injured segment. Those infants that recover antigravity elbow flexion within the first 2 months of life usually have a full and complete recovery over the first 1 to 2 years of life.[15,57,62,63,97,192] Recovery of elbow flexion between 3 and 6 months of injury infers an axonotmesis injury with subsequent nerve regeneration. The prognosis for recovery is guarded and secondary tendon transfers are often required. Infants who do not recover antigravity biceps strength by 5 to 6 months of life are candidates for microsurgical reconstruction, as successful surgery will result in a better outcome than natural history alone.[13,57,192]

Global birth palsies have a poor prognosis for spontaneous recovery. There is usually a combination of ruptures and avulsions. The outlook is poor without attempts at nerve reconstruction. Surgery is recommended at 3 months of age to maximize the available time for regeneration and reinnervation. Although root avulsions are common, there is almost always at least one root remaining that can be used for reconstruction.[57,68,72] In addition, alternative sources of axons may be available to reconstruct the plexus.

Surgical Management

Indications

Surgery for upper- and/or middle-trunk birth palsies without spontaneous recovery of elbow flexion is performed between 6 and 8 months of age (see Fig. 35-29). Surgery for global birth palsies without spontaneous recovery is performed at 3 months of age.

Surgical Approach/Strategy

The surgical exploration and strategy for brachial plexus birth palsies is similar to adult injuries. An exposure of the supraclavicular and/or infraclavicular plexus is required. Ruptures usually involve the upper trunk and are treated with neuroma resection and nerve grafting.[72,97,192] In the typical upper-trunk rupture, sural nerve grafts are performed from the C5 and C6 roots to the following structures: (a) upper trunk anterior division/lateral cord/musculocutaneous nerve, (b) suprascapular nerve, and (c) upper-trunk posterior division/posterior cord/axillary–radial nerves (Fig. 35-30).

Root avulsions usually involve the lower trunk and are treated by nerve grafting using adjacent roots and/or nerve transfers (e.g., ulnar nerve fascicle to the motor branch of biceps muscle). In infants, phrenic nerve transfer is typically avoided for fear of respiratory compromise.[28] In addition, a combination of nerve grafting and nerve transfers may be used to reconstruct the plexus. In children, nerve reconstruction for lower-trunk injuries is attempted because youth favors nerve regeneration and recovery is possible.[68,72164] Also, salvage procedures that include arthrodesis are avoided in the skeletally immature child.

Results

Similar to adults, there is a limited role for neurolysis in the treatment of brachial plexus birth palsies.[22,34,97,192,202] The recovery of muscle strength results with nerve grafting is superior to neurolysis. Clarke and colleagues[22,34] reported better long-term results after resection and grafting of both conducting and nonconducting neuromas compared to neurolysis, despite an initial deterioration of function with resection.

The results of surgery for brachial plexus birth palsies are more difficult to extract from the literature because complex evaluation is hampered in the child and recovery can be prolonged.[34,57,72,167] In addition, few patients have long-term microsurgery follow-up without secondary surgery. Upper-plexus (C5 and C6) injuries treated with neuroma resection and grafting produce encouraging results, with good recovery of shoulder function in 60% to 80% and reliable return of biceps in approximately 80% to 100%.[15,57,72,97,178] Unfortunately, global palsies have a more pessimistic outcome and more variable recovery.[57,68,72,202] Additional functional improvement can be obtained by secondary surgeries, such as tendon transfer and osteotomy.[27,56,88,93]

Shoulder Problems after Brachial Plexus Birth Palsies

Residual shoulder problems are universal after incomplete recovery of brachial plexus palsy. Incomplete recovery of the upper trunk lesions leads to muscle imbalance with

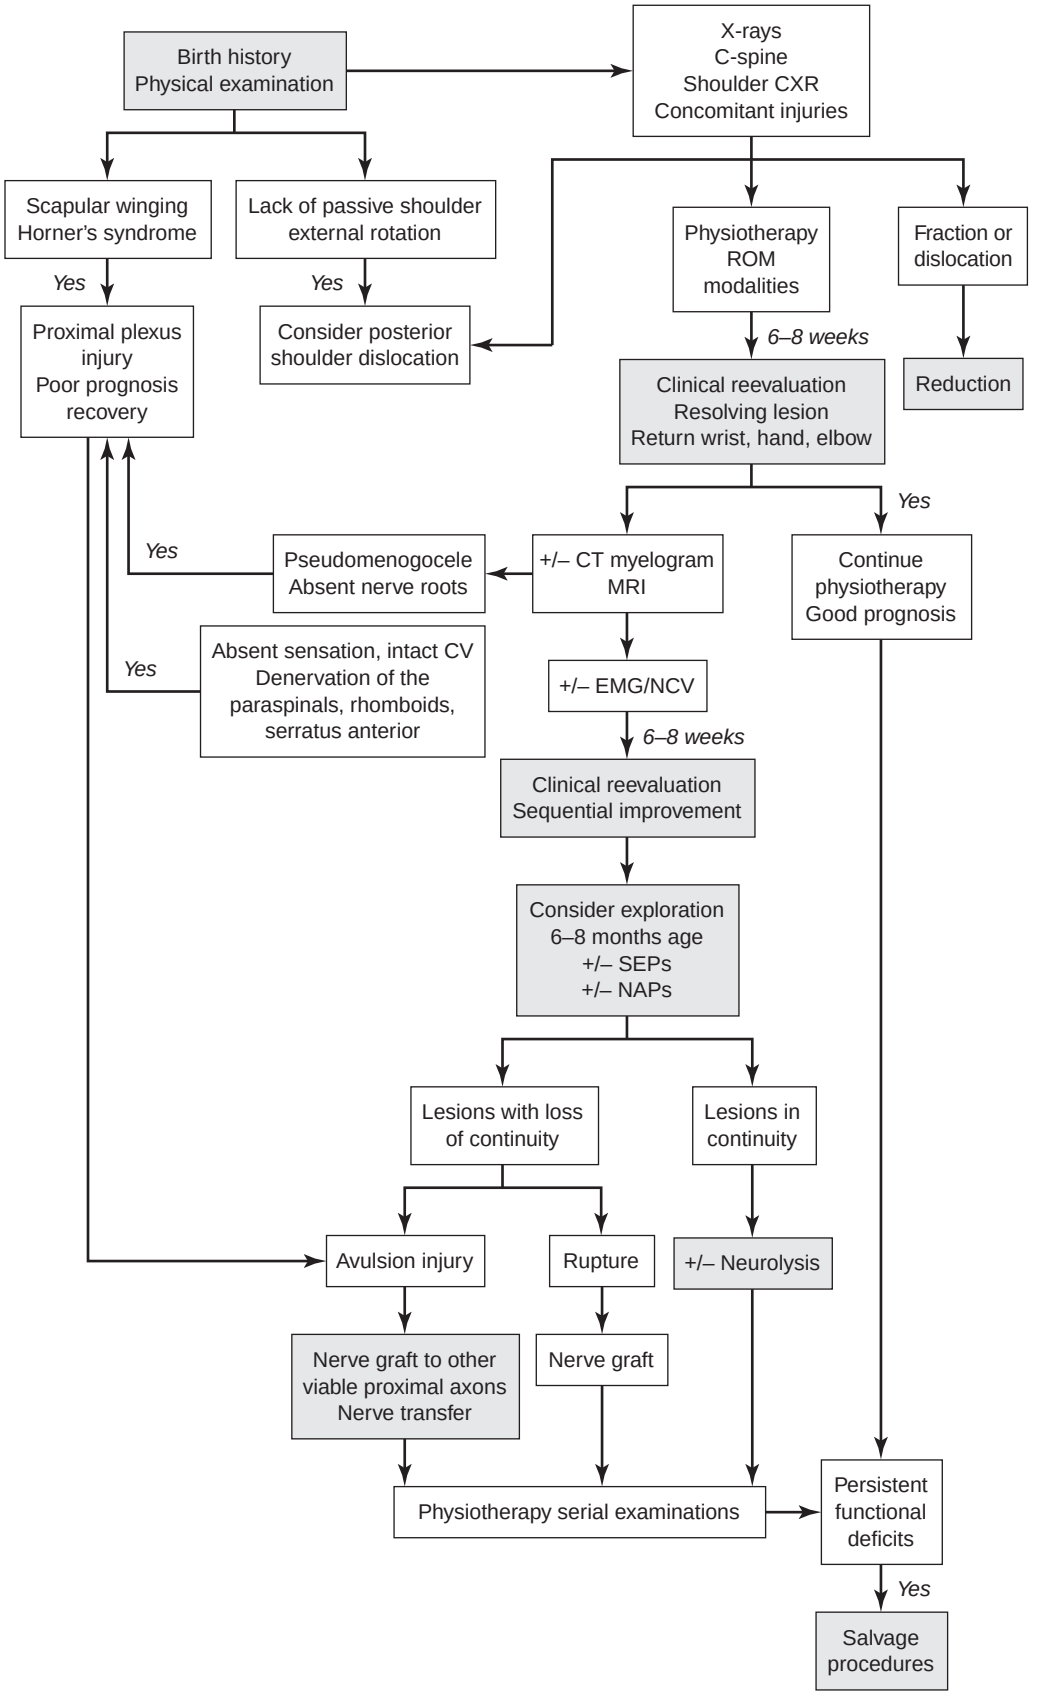

Figure 35-29 Treatment algorithm for brachial plexus birth injuries.

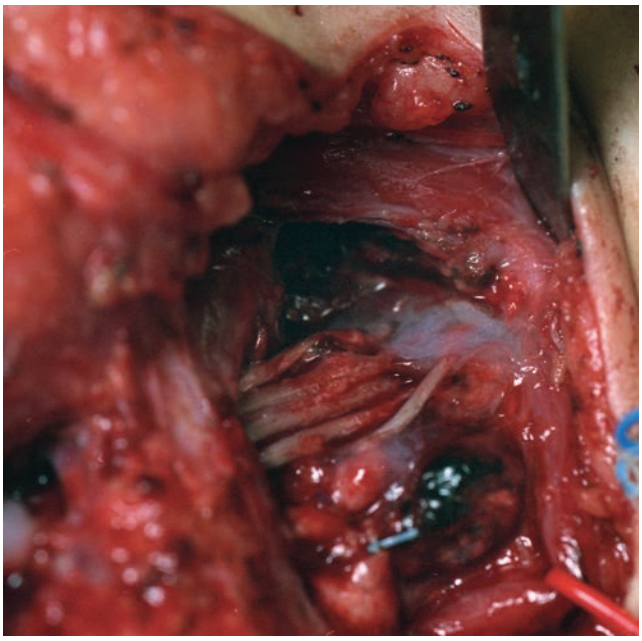

Figure 35-30 A 6-month-old child with left brachial birth palsy. Supraclavicular exposure revealed ruptures of C5 and C6. (Courtesy of Shriners Hospital for Children, Philadelphia.)

strong internal rotators and weak external rotators, which results in an internal rotation contracture that is detrimental to glenohumeral joint development.[76,94,137,168,186,191] The constant position of internal rotation leads to early glenohumeral joint deformity by 6 months of age and advanced deformity by 2 years, which is characterized by increased glenoid retroversion and posterior humeral head subluxation.[10,47,77,94,121,191,193] To achieve hand-to-mouth function, compensatory shoulder or scapulothoracic abduction is required (Fig. 35-31). This abduction allows the hand to be delivered to the mouth despite persistent shoulder internal rotation, but appears abnormal and is inefficient for feeding. In severe deformity, the shoulder may dislocate in a posterior direction (Fig. 35-32), or when the child cannot obtain 80 degrees of abduction and has an internal rotation contracture greater than 45 degrees, hand-to-mouth function is impossible.[195]

Classification and Imaging

The glenohumeral deformity is progressive without management (Table 35-9).[191] The deformity evolves sequentially by grade from normal (I) to increased glenoid retroversion (II); to posterior glenohumeral subluxation with posterior glenoid dysplasia (III); to development of a false glenoid (IV); to flattening of the humeral head and glenoid (V). In addition, on occasion a true infantile glenohumeral joint dislocation (VI) occurs with immediate loss of passive motion.

Figure 35-31 An 8-year-old child with impaired hand-to-mouth function from residual brachial plexus birth palsy and lack of external rotation.

MRI is our preferred modality to evaluate the pediatric glenohumeral joint.[94] MRI visualizes the articular cartilage without ionizing radiation and allows a true assessment of glenoscapular angle and humeral head position. Plain x-rays fail to visualize the cartilaginous structures and do not show the early changes of the unossified glenoid. This deficiency results in a misinterpretation of humeral head position and glenoid version.[67,137]

CT scanning can be used in the older child after substantial ossification of the humeral head and glenoid. Recently, ultrasound has been described as an alternative imaging modality to assess shoulder congruity without the

Figure 35-32 A 10-year-old boy with posterior shoulder dislocation from brachial plexus birth palsy and unbalanced muscle pull.

TABLE 35-9
CLASSIFICATION OF GLENOHUMERAL JOINT DEFORMITY

Type or Grade	Glenohumeral Joint
I	Normal glenoid (<5° retroversion compared to contralateral normal)
II	Minimal deformity (<5° retroversion compared to contralateral normal)
III	Moderate deformity (posterior humeral head subluxation)
IV	Severe deformity (posterior humeral head subluxation with false glenoid)
V	Severe flattening of humeral head ± complete dislocation
VI	Infantile glenohumeral dislocation
VII	Proximal humeral growth arrest

need for anesthesia.[121,158] The diagnostic accuracy of ultrasound appears lower than MRI or CT and the specific glenoid morphology is not visualized.[158]

In an attempt to standardize the cross-sectional slice chosen for measurements, certain criteria for image selection have been established.[94] The axial image selected should be inferior to the coracoid apophysis and spinoglenoid notch. The slice should visualize the subscapularis tendon and often include the tip of the coracoid. Using this image, the glenoscapular angle (the degrees of version) and the percent of humeral head anterior to the middle of the glenoid fossa (PHHA) are measured (Figs. 35-33 and 35-34).[54,147,191]

A line is drawn along the labral surfaces of the glenoid connecting the anterior and posterior margins. A bisecting line is constructed along the axis of the scapula that connects the medial margin of the scapula and the middle of the glenoid fossa. The posterior medial quadrant angle is calculated. Ninety degrees are subtracted from the angle measured to calculate the glenoid version. A negative value indicates glenoid retroversion and a positive value designates glenoid anteversion. In cases with a pseudoglenoid (humeral head articulating with a posterior articular concavity that is retroverted in relationship to the original glenoid), the posterior concavity was measured as the angle of version (Fig. 35-35).[94,137] The PHHA is calculated by measuring the humeral head distances perpendicular to the line along the axis of the scapula. The distance the humeral head projects anterior to the axis line is divided by the diameter. A lower value for PHHA indicated less humeral head anterior to the axis line and more posterior subluxation of the humeral head.

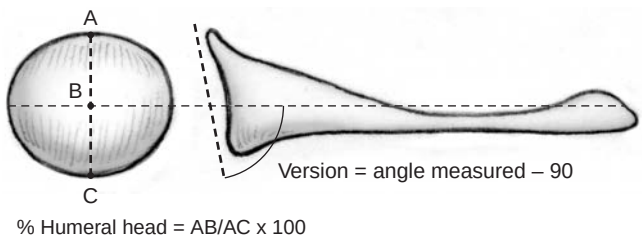

Figure 35-33 Schematic of glenoscapular angle (the degrees of version) and the percent of humeral head anterior to the middle of the glenoid fossa measurements.

Treatment

The goal of treatment is to maintain a reduced glenohumeral joint. Humeral head subluxation and glenoid

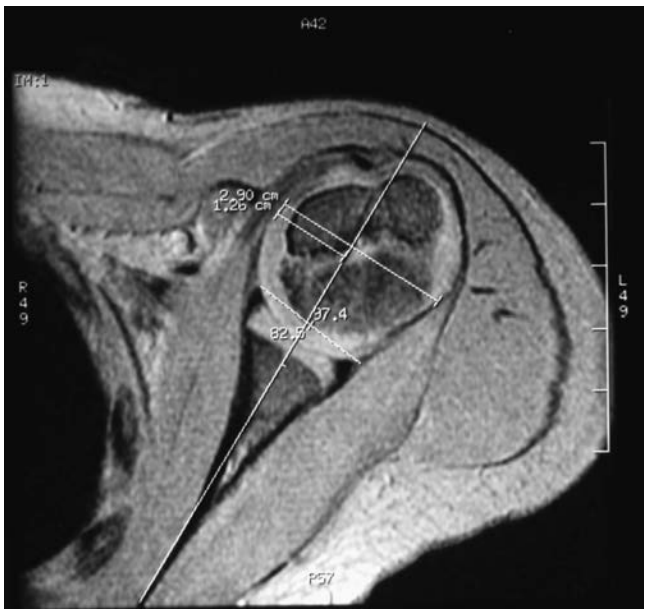

Figure 35-34 Magnetic resonance imaging of normal shoulder. The cartilage is readily apparent around the humeral head and the glenoid cavity is readily visible. The lines for calculating the glenoscapular angle (–7.5 degrees) and percent of humeral head anterior to the middle of the glenoid fossa (43%) are drawn. (Courtesy of Shriners Hospital for Children, Philadelphia.)

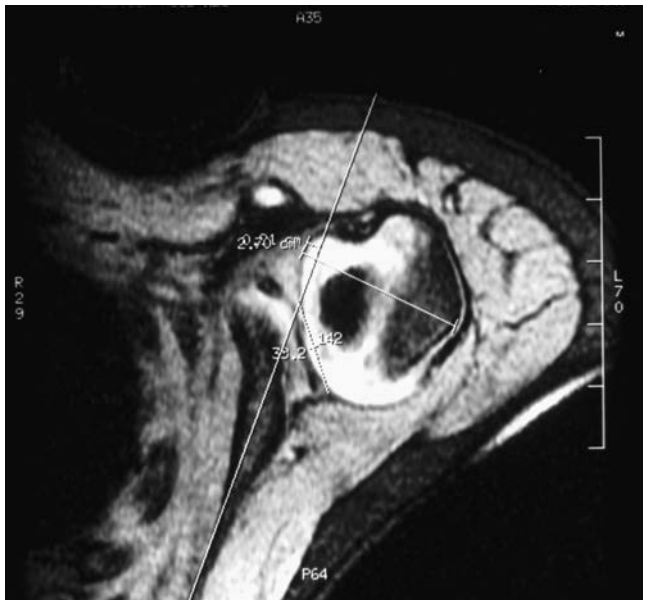

Figure 35-35 Shoulder magnetic resonance imaging of 4-year-old with –10 degrees of passive external rotation. The humeral head articulates with a posterior articular concavity that is markedly retroverted and measures 51 degrees. The humeral head barely crosses the midportion of the glenoid (percent of humeral head anterior to the middle = .21 cm/2.7 cm or 7.7%). (Courtesy of Shriners Hospital for Children, Philadelphia.)

deformity negate normal shoulder development. Early management is passive range of motion to maintain a supple glenohumeral joint. Specific exercises should be prescribed for glenohumeral external rotation combined with scapular stabilization (Fig. 35-36).

Failure to preserve passive glenohumeral external rotation motion beyond the neutral plane of the scapula is an indicator of considerable underlying joint deformity and warrants imaging (e.g., MRI).[94] If the imaging studies reveal maintenance of glenohumeral alignment without substantial humeral head subluxation (grades I and II), therapy may be continued in the young child (less than 3 years of age) or tendon transfers can be performed to rebalance the joint and enhance motion. Tendon transfers appear to halt progressive glenohumeral joint deformity. Considerable glenoid retroversion and humeral head subluxation (grades III and IV), however, warrant joint realignment, as current evidence suggests that concentric joint alignment is necessary to allow joint remodeling over time. Numerous methods can achieve joint reduction depending upon the age of the child and degree of deformity. Hui and Torode[80] performed open reduction and soft tissue release in 23 patients with an average age of 2 years and 5 months. Preoperative and postoperative computerized axial tomograms revealed improvement in the glenoid version of approximately 9% per year. Pearl[138] has advocated arthroscopic release of the thickened anterior capsule combined with subscapularis tenotomy to allow external rotation and glenohumeral joint reduction. This arthroscopic approach is less invasive and our experience has been promising with regard to its ability to achieve glenohumeral joint reduction.[139] Tendon transfers can be performed at the time of joint reduction or delayed until glenohumeral joint motion can be reassessed. In the deferred instance, failure to demonstrate active external rotation or limited abduction warrants secondary transfers.

Figure 35-36 Glenohumeral external rotation exercises must be combined with scapular stabilization. (Courtesy of Shriners Hospital for Children, Philadelphia.)

Certainly, there is a degree of deformity and age that prohibits joint reduction and remodeling. However, the exact age or degree of humeral head subluxation is unknown. We use treatment parameters similar to developmental dysplasia of the hip. In other words, the rare infantile dislocation requires immediate reduction, usually via an open procedure. In progressive humeral head subluxation and glenoid retroversion attributed to muscular imbalance, reduction is recommended for children less than 4 years of age with moderate to severe deformity (grades III and IV). In children greater than 8 years of age with severe deformity (grade V), reduction is usually not recommended, as humeral osteotomy is preferred to reposition the limb (Figs. 35-37 and 35-38).[48,60,88] In children between the ages of 4 and 8 years (i.e., "grey zone"), the treatment depends upon the severity of the deformity and the options are discussed with the parents.

External Rotation Tendon Transfer Technique[50,76,103,140,145,195]

The technique of latissimus dorsi and teres major tendon transfer is performed with the patient in the lateral decubitus position. The extremity and posterior thorax are prepared for surgery. A posterior axillary incision is performed from the tendon of the latissimus dorsi muscle to the posterior acromion (Fig. 35-39). Skin flaps are elevated and the latissimus dorsi, teres major, triceps, and posterior deltoid muscles are isolated. The posterior humeral circumflex artery and axillary nerve are identified between the

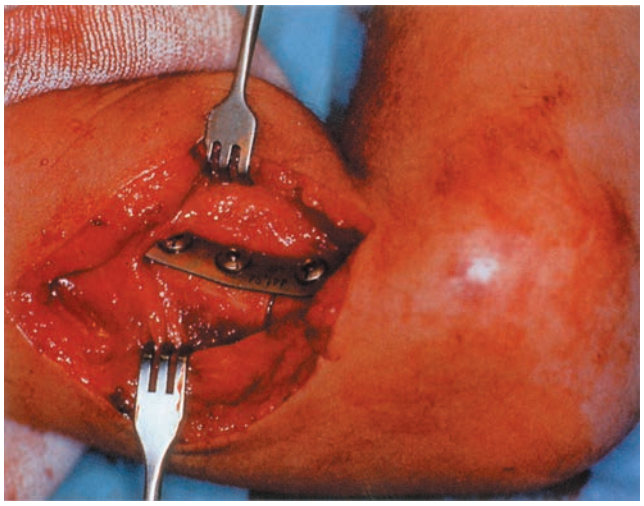

Figure 35-37 Distal humeral osteotomy in a 10-year-old child with a brachial plexus birth palsy, lack of external rotation, and glenohumeral dysplasia.

Figure 35-39 Posterior axillary incision from the tendon of the latissimus dorsi muscle to the posterior acromion. (Courtesy of Shriners Hospital for Children, Philadelphia.)

triceps and teres major muscles. The latissimus dorsi and teres major tendons are traced to their humeral insertion and released with a strip of periosteum (Fig. 35-40). The muscles are freed in a proximal direction until the thoracodorsal neurovascular pedicle is encountered. The interval between the posterior deltoid and triceps is isolated (Fig. 35-41). The posterior deltoid is retracted in a cephalad direction and the undersurface of the acromion is exposed. The subacromial bursa is removed and the humerus is placed into external rotation to expose the supraspinatus and infraspinatus insertions. Sutures are placed at this area into the tendon/periosteum or secured through drill holes (Fig. 35-42). The latissimus and teres major tendons are transferred superficial to the long head of the triceps and fixed firmly using the previously placed sutures. The arm is maintained in external rotation and the wound is closed.

A shoulder spica cast is applied with the shoulder in 90 to 120 degrees of abduction and full external rotation (Fig. 35-43). The spica cast is removed at 5 weeks and active therapy is initiated. Protective splinting is continued for 3 months after surgery.

Arthroscopy Surgical Technique[138,139]

Arthroscopy is performed in a lateral decubitus position using a 2.7-mm arthroscope. A posterior portal is established through the posterior soft spot after localization with a spinal needle and joint insufflation with saline. An anterior portal is made under direct visualization using an 18-gauge spinal needle inserted inferior to the biceps tendon. The anterior capsule, anterior ligaments, and subscapularis tendon are identified. An electrocautery is introduced through the anterior portal. The thickened superior glenohumeral ligament, the middle glenohumeral ligament, and the tendon of the subscapularis are released. If possible, the inferior muscular portion of the subscapularis humeral attachment is preserved. The electrocautery is removed and exchanged for an arthroscopic punch. The inferior glenohumeral ligament is released to the midportion of the axillary pouch with protection of the axillary nerve. The arthroscopic equipment is removed from the joint and the glenohumeral joint is manipulated into external rotation. Marked improvement of external rotation is noted, often with an audible clunk associated with glenohumeral joint reduction. Failure to achieve joint reduction or passive external rotation less than 45 degrees with the arm in adduction requires additional arthroscopic release of the axillary pouch and the tight subscapularis. Concomitant tendon transfers to augment external rotation are often performed in children greater than 3 years of age. The child is placed in a shoulder spica cast with the glenohumeral joint positioned in 45 to 60 degrees of external rotation. The amount of abduction varies according to whether tendon transfers were performed.

Results

Tendon Transfer

Tendon transfers reliably improve abduction and external rotation (Table 35-10). Significant improvement in clinical

scores for overhead motion, external rotation, and hand-to-neck maneuvers are reported, along with measured improvement in active abduction and external rotation motion after surgery. The beneficial effects of motion, however, do not correlate with similar improvements in joint configuration. This lack of association is most likely related to the inability of the tendon transfer to reposition the humeral head within the glenoid.

Joint Reduction

Hui and Torode[80] performed open reduction and tendon lengthening on 23 patients with brachial plexus birth palsy and humeral head subluxation or dislocation. CT scanning was performed before and after surgery. The mean age of surgery was 2 years and 5 months. Mean follow-up was 3 years and 7 months. Concentric reduction was achieved under direct visualization and remodeling occurred during the follow-up period. Bony glenoid retroversion measured by CT scanning decreased by a mean of 31% after open reduction and improved at a rate of 9% per year. The difference between the normal and affected sides also decreased (Fig. 35-44).

Pearl[138] described an arthroscopic technique for contracture release in children with brachial plexus birth palsy. Forty-one children underwent arthroscopic release of the

anterior capsule and subscapularis tendon. The mean age of the children was 3.5 years. Eighteen children were treated with arthroscopic release alone, while 23 children also underwent latissimus dorsi transfer. The arthroscopic contracture release effectively restored passive external rotation in 40 of the 41 children. The single patient that did not achieve external rotation was 12 years of age with advanced glenoid deformity. The status of the glenohumeral joint, however, was not evaluated after surgery.

In our series (SHK and GRW), 20 children with an average age of 46 months (range, 19 to 100) underwent preoperative MRI, arthroscopic surgery, and postoperative imaging in their spica cast.[139] For the uninvolved shoulder, the mean PHHA was 45.2% ± 4.8% and the glenoid version was −7 ± 3%. The involved shoulder preoperative mean PHHA was 16.9% ± 16.1% and the mean glenoid version was −39° ± 17°. The postoperative mean PHHA corrected to 41.4% ± 13.3% and the mean glenoid version improved to −12° ± 12°. There was a significant improvement in the mean PHHA ($p < 0.001$) and mean glenoid version ($p < 0.001$) that approached the values of the uninvolved shoulder. We found that arthroscopic capsular release and subscapularis tenotomy was successful in reducing the glenohumeral joint subluxation in all patients (Fig. 35-45).

THORACIC OUTLET SYNDROME

The diagnosis of thoracic outlet syndrome is controversial and more common when surgeons are convinced this is a valid entity.[6,21] The cause is presumed to be a compressive neuropathy of the brachial plexus because neurologic symptoms predominate in virtually all (94% to 97%) cases, with preferential involvement of the lower plexus. Venous and arterial thoracic outlet syndromes are much less common, appearing in 2% to 3% and 1% to 2%, respectively.[6,130] The potential sites of compression (see Table 35-1) are described in the preceding anatomy section. These anatomic sites are normally not problematic unless additional factors are present that initiate the compressive neuropathy. For example, shoulder muscle atrophy and loss of strength can depress the entire limb and cause the inferior trunk to be compressed against the first rib. Further narrowing of the costoclavicular space can occur from downward pressure on the shoulder girdle from heavy backpacks or pendulous breasts.[74,98] A preceding minor or major trauma may result in fibrosis and scarring within the thoracic outlet, which can directly compress the plexus and cause symptoms.[6,51,162] In predisposed persons, repetitive motion may play a factor, although this remains speculative.[107,159]

Regardless of the pathologic site, intermittent compression causes temporary alterations in nerve physiology that reverses following removal of the compression. Persistent nerve compression yields intraneural edema and alteration of the blood supply, which results in diminished axonal transport to the compressed nerve. The initial nerve response is segmental demyelination (i.e., neurapraxia), but prolonged ischemia will cause wallerian degeneration (i.e., axonotmesis).[6,129,143] The degree of pathology is proportional to the intensity and duration of the entrapment pressure.

Arterial signs and symptoms can be induced by compression along the thoracic outlet. Pressure can be from the tip of a cervical rib, a fibrous band, or costoclavicular narrowing. Subclavian or axillary artery stenosis, with or without poststenotic dilation, is possible. This situation can advance to mural thrombus formation, emboli, and distal ischemia.[6]

Evaluation

The clinical presentation of thoracic outlet syndrome differs drastically from an overt brachial plexus injury. The symptoms tend to be vague and the signs more subtle.[6,98,129,130] Females are more commonly affected (4:1). A thorough examination with provocative maneuvers is required for accurate diagnosis. Virtually all patients present with neurologic symptoms affecting the lower plexus (C8 and T1). The distribution of pain or paresthesias is often the medial side of the arm and ulnar digits. Loss of dexterity during fine manipulation is a common complaint. Vascular thoracic outlet syndrome is much less common (less than 5%) and can affect venous outflow or arterial inflow.[130] Venous thoracic outlet syndrome is more

common than arterial involvement, and edema or vascular congestion may signal vascular outlet obstruction. Arterial compression may produce pain, cold intolerance (similar to Raynaud's phenomenon), and claudication. Rarely, pallor of the limb can result from arterial insufficiency.[39] The history should include inquiry about the onset of symptoms, antecedent trauma, and current activities that produce symptoms. The use of heavy backpacks and frequent maneuvers above the shoulder level are specific activities that can elicit symptoms.[74,159]

The physical examination begins with an assessment of the posture of the individual. Poor posture can narrow the thoracic outlet and provoke symptoms. A careful cervical spine and peripheral nerve evaluation is critical in search of additional sites of compression that can cause a double crush neuropathy. Coexisting entrapment at the carpal or cubital tunnel can be present in thoracic outlet syndrome. Proximal thoracic outlet compression causes the nerve to be more vulnerable to an additional distal compressive neuropathy.[6,129,198] The area of sensory abnormalities should be defined and careful manual muscle testing performed for objective signs of motor weakness that can occur in long-standing thoracic outlet syndrome. The ulnar nerve innervated muscles of the hand are most commonly affected by long-standing neurologic thoracic outlet syndrome and should be specifically assessed for weakness. Two-point discrimination in the ulnar and median nerve distribution should be determined. Sensibility may also be altered in the medial brachial and medial antebrachial nerve distribution.

The presence of edema, venous distension, or cyanosis may indicate a venous thoracic outlet syndrome, whereas pallor, splinter hemorrhages, or ischemic changes suggest arterial involvement secondary to vessel constriction or embolization.[6,162] Symmetry of the radial and ulnar pulses should be ascertained, and transient compression should be evaluated by the provocative maneuvers described in the following paragraph.

The supraclavicular region should be palpated for areas of tenderness, and percussion should be performed to elicit a Tinel's sign, which indicates axonal irritation. Provocative maneuvers are instrumental in the diagnosis of thoracic outlet syndrome, but must be interpreted carefully (Fig. 35-46). A positive test must not only produce the expected outcome, but also reproduce the patient's symptoms to be noteworthy. These tests attempt to narrow the anatomic constraints of the thoracic outlet and compress the neural or vascular elements. The Adson test is performed with the patient seated, placing the arm at the side, and palpating the radial pulse.[1] The patient rotates and extends the head and neck toward the affected side while taking a deep breath. This narrows the scalene triangle, and a pulse diminution or obliteration with corresponding symptoms implies thoracic outlet syndrome. The Wright hyperabduction test is performed by placing the arm in 90 degrees of abduction and external rotation.[201] The loss of a radial pulse and symptom reproduction are considered a positive finding. The overhead exercise stress test and 3-minute stress test are similar and performed by instructing the patient to abduct and externally rotate the shoulder to place the arms above shoulder level. Active opening and closing of the hands is then executed and a positive response will reproduce symptoms such as paresthesias or fatigue.[98,152,154] The diagnostic dilemma with these provocative maneuvers is the lack of specificity for isolation of the entrapment site and the significant rate of false-positive results that occur in both asymptomatic volunteers and in other common entrapment neuropathies of the upper extremity.[130,148,201] For example, shoulder abduction and external rotation places traction across the lower plexus at the level of the first rib, narrows the costoclavicular space, and pulls the plexus around the coracoid process. This maneuver also increases the pressure within the cubital tunnel and can produce symptoms of ulnar neuropathy at the elbow.

Imaging Studies

Imaging studies to evaluate a patient with suspected thoracic outlet syndrome are plain radiographic films, angiography, and MRI. Plain x-ray films of the cervical spine are used to identify cervical ribs, elongated transverse processes, or degenerative disc disease. The incidence of cervical ribs is approximately 0.5% to 1% and may be present in asymptomatic individuals.[6,141,169] A chest radiograph is routine to evaluate the lung apices for tumor.[12] Angiography and other noninvasive vascular studies are used selectively in suspected cases of vascular thoracic outlet syndrome for visualizing a mural thrombus, stenosis, and aneurysmal dilation. However, false-negative and false-positive results can occur.[6,98,188] MRI can be used to visualize the plexus anatomy and identify areas of compression and anomalous bands.[135] This study is both scanner- and radiologist-dependent and may be more applicable as imaging techniques and interpretation skills improve.

Electrodiagnostic Studies

Electrodiagnostic studies can be valuable in the diagnosis of thoracic outlet syndrome. Severe compression will produce denervation of the affected muscles, usually the intrinsic muscles of the hand.[58] Fibrillations and positive sharp waves will be evident upon needle insertion. However, most patients with neurologic thoracic outlet syndrome do not present with atrophy and EMG findings. A reduction of the CV across the pathologic thoracic outlet would seem to be a reliable indicator of this disorder. Unfortunately, this technique is difficult to perform, interpret, and reproduce.[98] Dynamic recording of nerve conduction across

Figure 35-46 Artist's schematic of provocative maneuvers for thoracic outlet syndrome.

the brachial plexus during provocative maneuvers is also logical, but is difficult to perform and to obtain consistent results.

The use of SEPs may play more of a diagnostic role in the assessment of conduction across the plexus than the standard nerve conduction tests.[21,104] Peripheral stimulation at the wrist or forearm with recording at Erb's point, cervical spine, and sensory cortex may demonstrate changes in the pattern or timing of particular waveforms in thoracic outlet syndrome. The interpretation of the SEP signal across the plexus, however, remains difficult and dependent on the proficiency of the neurophysiologist.

Treatment

The mainstay of treatment for thoracic outlet syndrome is conservative management directed at alleviating any compression of the thoracic outlet and avoidance of aggravating factors.[98,129] The patient often has poor posture associated with the weakness of the parascapular muscles, causing the scapula to sag. This position narrows the thoracic outlet and drags the lower trunk over the first rib. Postural exercises and training are instituted and aimed at the correction of poor body mechanics. Activity modification and avoidance of aggravating factors is a key to success. An exercise program, directed at selective muscle strengthening of the shoulder girdle with maneuvers designed to stretch the scalene muscles and relax the first rib, is part of the treatment regimen. Supervision is required to selectively exercise and strengthen the parascapular muscles (trapezium, levator scapulae, and rhomboids) without further compression of the thoracic outlet.[6,143] The goal is to expand the thoracic outlet to allow the brachial plexus to pass unimpeded. A variety of additional therapeutic modalities (ultrasound, biofeedback, and electrical stimulation) have been proposed with ambivalent success.[6]

Women with macromastia may obtain relief from better breast support. Reduction mammaplasty has been recommended in severe cases.[84,98] Ergonomic modification, aimed at the decrease of overhead activity and elimination of any downward force on the shoulder girdle, can also be beneficial. Conservative treatment is effective in improving symptoms in most patients, and only 10% to 30% of patients will be surgical candidates.[130,161,166,180,181]

Surgery

Surgery is indicated for intractable pain, a considerable neurologic deficit, vascular compromise, or when conservative measures have failed to alleviate symptoms.[130,161,166,180,181] The surgery is not without inherent risks and mild discomfort from mild compression is better left alone. The operative procedure is directed at decompression of the thoracic outlet, with release of any anatomic constrictions. There is no consensus on the most efficacious approach or procedure to correct thoracic outlet syndrome.[130] The fundamental components to the described procedures include cervical rib resection, first rib resection, scalenotomy, scalenectomy, excision of anomalous fascial bands, claviculectomy, pectoralis minor release, or a combination of these. The procedure can be accomplished by a variety of approaches, including a supraclavicular, transclavicular, subclavicular, transaxillary, posterior, or a combined approach.

The resection of the first rib, with or without anterior scalenectomy, has become the preferred procedure for thoracic outlet syndrome in most cases (Figs. 35-47 to 35-50).[98,130,154,155] Isolated scalenectomy is preferred for the less common upper plexus thoracic outlet syndrome. The supraclavicular approach favors scalenectomy and upper plexus exploration, but sacrifices complete first rib exposure.[181] Approximately 80% to 90% of the anterior scalene muscle and 40% to 50% of the middle scalene muscle are excised during scalenectomy.[5] The phrenic and long thoracic nerves must be identified and protected.

The first thoracic rib serves as a fulcrum for T1, an attachment site for the scalene muscles, and borders the costoclavicular space. Therefore, removal of the first rib relieves multiple potential sites of compression. The transaxillary route is more cosmetic and affords the best access to the first rib, but precludes scalenectomy and exploration of the upper plexus.[180] Cervical ribs can usually be removed through the axillary approach, and the pectoralis minor tendon can be divided if there is suspected subcoracoid compression. A combined supraclavicular and

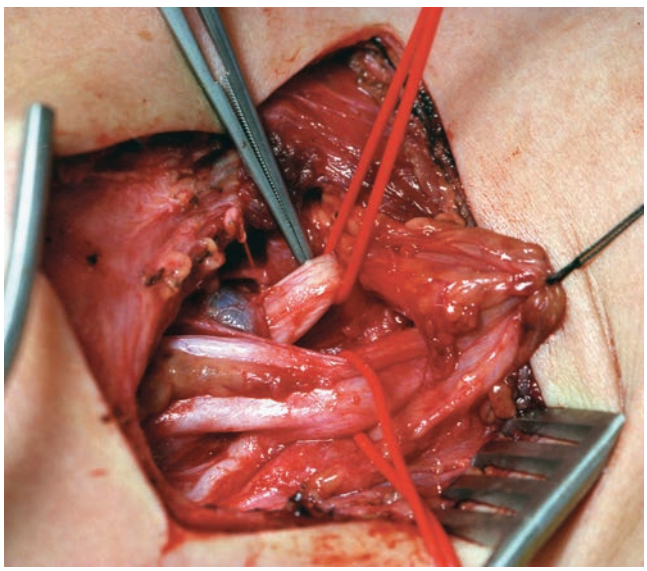

Figure 35-47 A 16-year-old female with recalcitrant thoracic outlet syndrome that failed to improve with therapy. Supraclavicular approach with isolation of the brachial plexus. Figure 35-48 Anterior scalenectomy with protection of phrenic nerve and brachial plexus. (Courtesy of Shriners Hospital for Children, Philadelphia.)

transaxillary method can be used in complicated or recurrent cases.[146]

Intermittent venous or arterial thoracic outlet syndrome can also be treated by decompression. Persistent longstanding venous or arterial thrombosis may require thrombectomy or bypass grafting in recalcitrant cases.

Results

The results of thoracic outlet surgery are highly variable, with success rates dependent on the procedure employed and the definition of success. Isolated anterior scalenotomy has a 50% failure rate, with a significant recurrence rate.[59] The results of first-rib resection are successful (improvement of symptoms) in 37% to 92% of individuals, with lower recurrence rates.[51,99,152] Scalenectomy alone or combined with first-rib resection has reported success rates of approximately 68% to 86%.[6,146,161,162, 180,181] Improvement following thoracic outlet surgery may require 2 years or longer.[6] In contrast, the initial symptomatic relief may be nullified by scar formation, which culminates in recurrent compression. Comparison studies of first-rib resection versus scalenectomy do not reveal any appreciable difference.[162]

Salvage Procedures

Salvage procedures are performed for residual brachial plexus injuries. Persistent deficits may result from irreparable lesions and partial recovery after nerve reconstruction. Early salvage procedures may be recommended in irreparable injuries or elderly individuals with limited capacity for nerve regeneration.[126] The goals of secondary procedures are to improve function of the shoulder, elbow, wrist, and fingers. The specific operation performed will vary with the brachial plexus lesion and residual deficit.

The evaluation of the patient must consider the original injury and treatment performed to date. A review of previous records is recommended. The extent of the initial paralysis and subsequent neurologic recovery is an important factor. The patient's physical and emotional health is a valuable component of the evaluation. The initial injury tends to alter the patient's life forever and the manner of acceptance is a consideration during formulation of

the reconstructive plan. The injury often overwhelms the patient's physical and social life for a time period. Fear of a similar episode of dependence after reconstructive surgery is genuine, and the reconstructive plan should be developed with minimal time away from work and activity. This strategy may require multiple procedures at a single setting.

A general assessment of shoulder, elbow, wrist, and hand function is performed. The balance of each joint complex and absence of a particular motion is noted. Any joint contractures may require therapy or operative release prior to tendon transfer. An inventory of the available muscles for transfer is recorded by completion of a brachial plexus injury sheet that records manual muscle testing (see Table 35-5). A potential donor muscle must have sufficient strength against gravity because transfer will decrease strength by one grade.[8,174] Muscles that have undergone reinnervation often lack normal strength and excursion, which limits usage as a donor for transfer. Ideally, reinnervated muscles would not be used for transfer, although often there are no other available options.[126]

In general, a similar priority is based on elbow flexion to improve arm positioning and encourage hand-to-mouth activity. Shoulder function is addressed concurrently or following elbow flexion. Wrist extension, finger extension, and finger flexion are managed after elbow and shoulder function. In lower plexus lesions, wrist and digit grasp and release assume priority.

Elbow Flexion

The restoration of elbow flexion requires a mobile joint and an available muscle for transfer. The goal of surgery is to regain a functional arc of elbow motion from 30 to 130 degrees. The potential donor muscles are the flexor–pronator group (Steindler flexorplasty), triceps, pectoralis major muscle, latissimus dorsi transfer, and free-muscle transfer.[17,25,26,32,108,172,173,174] The selection of the donor muscle varies with the strength of those donors available and consideration of additional tendon transfers that may use similar muscles. For example, if a latissimus dorsi transfer is planned for deficient shoulder external rotation, then an alternative elbow flexorplasty should be planned. The exact choice of transfer is variable, and each transfer has certain advantages and disadvantages.[9,93,174]

The Steindler flexorplasty transfers the flexor–pronator mass 2 in. proximal to the elbow and reattaches this muscle group to the anterior humerus (Fig. 35-51). Transfer of the flexor–pronator muscle group with a portion of the medial epicondyle and use of a compression screw provides better fixation (Fig. 35-52).[8] The procedure is relatively uncomplicated, but also produces weak elbow flexion.[29,86] Accordingly, this transfer has been used to augment existing weak elbow flexion.[29] In addition, elbow flexion may be accompanied by concomitant fist and forearm pronation, which compromises independent hand function. Technical modifications to reduce the pronation and flexion contracture have been proposed.[110]

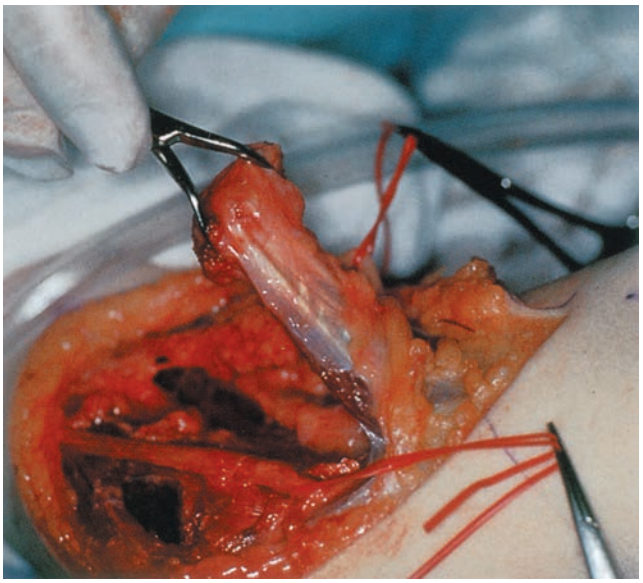

Figure 35-51 A 14-year-old boy with history of C5 to C6 transverse myelitis with absent elbow flexion. He was treated with proximal transfer of the medial epicondyle and flexor–pronator mass to the anterior humerus. Vessel loops around median and ulnar nerves.

The triceps transfer sacrifices elbow extension for flexion.[25] This procedure relies on gravity for elbow extension and is contraindicated in those patients who require powerful extension for transfer or crutch ambulation. This transfer is reserved for those individuals without other options for transfer or when co-contracture of the biceps and triceps is present.[108]

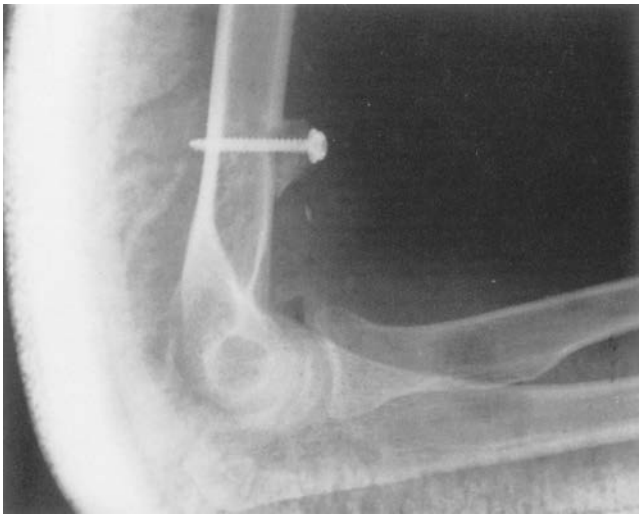

Figure 35-52 Postoperative radiograph of medial epicondyle and attached flexor–pronator mass secured to the anterior humerus with a compression screw.

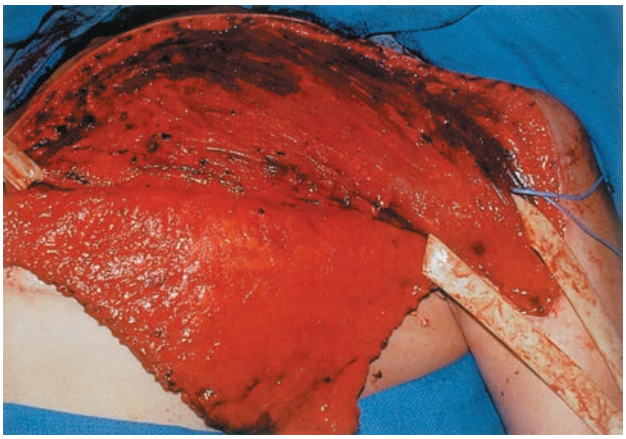

Figure 35-53 A 31-year-old man, status postbrachial neuritis (Parsonage-Turner syndrome), with persistent musculocutaneous nerve palsy. He was treated with bipolar pectoralis major muscle transfer for elbow flexion.

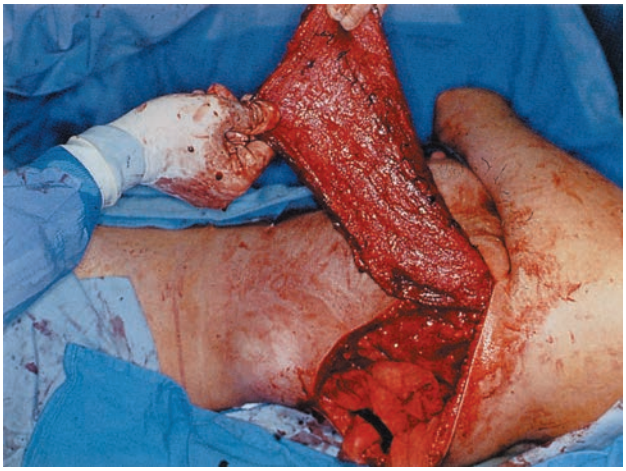

Figure 35-54 A 30-year-old woman with absent elbow flexion after brachial plexus injury secondary to having her arm struck by a moving train. Latissimus dorsi muscle harvested from distal to proximal for elbow flexorplasty. Note stay sutures placed to record resting length.

The pectoralis major muscle may be transferred by a variety of techniques, including elongation of the humeral insertion by tendon graft, transfer of the sternocostal origin to the biceps (monopolar technique), or transfer of the sternocostal origin to the biceps combined with transfer of the humeral insertion to the acromion (bipolar technique).[8,17,26,36,60,61] The bipolar technique provides a more powerful elbow flexion, as the mechanical advantage is improved by transfer of the origin and insertion. Bipolar transfer allows the entire mass of pectoralis major to be used for elbow flexion (Fig. 35-53).[26] However, this technique is technically demanding and cosmetically disfiguring.[108] Nonetheless, the bipolar technique is my preferred technique when the pectoralis major muscle is selected for flexorplasty, as function overrides cosmesis following brachial plexus injuries.

The latissimus dorsi transfer for elbow flexion can also be accomplished by a monopolar or bipolar technique. The bipolar method transfers the origin to the biceps tendon and the humeral insertion to the coracoid process or acromion.[93,204] The unipolar variant does not disturb the humeral attachment. This flexorplasty has certain distinct advantages that make bipolar latissimus flexorplasty my preferred procedure for elbow flexion.[93] The latissimus muscle can be sacrificed with minimal morbidity, provides excellent strength and excursion, and reinforces the anterior support to the shoulder, which may obviate the need for arthrodesis.[20,26] The drawbacks are related to the magnitude of the procedure and the difficult preoperative assessment of muscle grade, because bulk can overestimate strength.

Bipolar Latissimus Dorsi Transfer Technique[93,204]

The bipolar latissimus dorsi transfer is performed with the patient in the sloppy lateral position. The arm and torso are prepared to the midline for adequate exposure. The ipsilateral thigh is also prepared for possible fascia lata graft. A linear incision is performed in the posterior axillary line extending proximal from the thoracodorsal origin of the latissimus dorsi muscle and distal along the muscle belly toward the iliac crest. A large skin flap is elevated over the posterior aspect of the latissimus to the midline. The lateral border of the muscle is identified and elevated from the underlying serratus anterior muscle. Stay sutures are placed on the surface of the muscle to record the resting length. The neurovascular pedicle is identified by palpation at the junction between the proximal one-third and distal two-thirds on the undersurface of the latissimus. The neurovascular pedicle is carefully isolated. The muscle with thoracodorsal fascia is harvested from distal to proximal (Fig. 35-54). Meticulous hemostasis is attained throughout this dissection using electrocautery. The entire latissimus dorsi muscle is harvested on the thoracodorsal neurovascular pedicle. The vascular pedicle is mobilized to the subscapular artery, with ligation of the branch to the serratus muscle. The insertion of the latissimus tendon is tagged and divided. An anterior deltopectoral approach to the shoulder is performed and the latissimus dorsi muscle and pedicle are passed into the anterior wound (Fig. 35-55). Care must be taken not to kink the vessels. A large subcutaneous passage is tunneled from the deltopectoral interval to the antecubital fossa, where the biceps tendon is exposed. The origin is attached to the biceps tendon by a weave technique. The addition of fascia lata interwoven into the latissimus dorsi for augmentation is necessary in certain instances. The elbow wound is closed before setting final tension at the anterior shoulder level. Final tension of the latissimus dorsi flexorplasty is determined by recreating resting length, using the previously placed stay sutures as a guideline and creating a 30-degree-tenodesis effect at the elbow. The humeral insertion is attached to either the

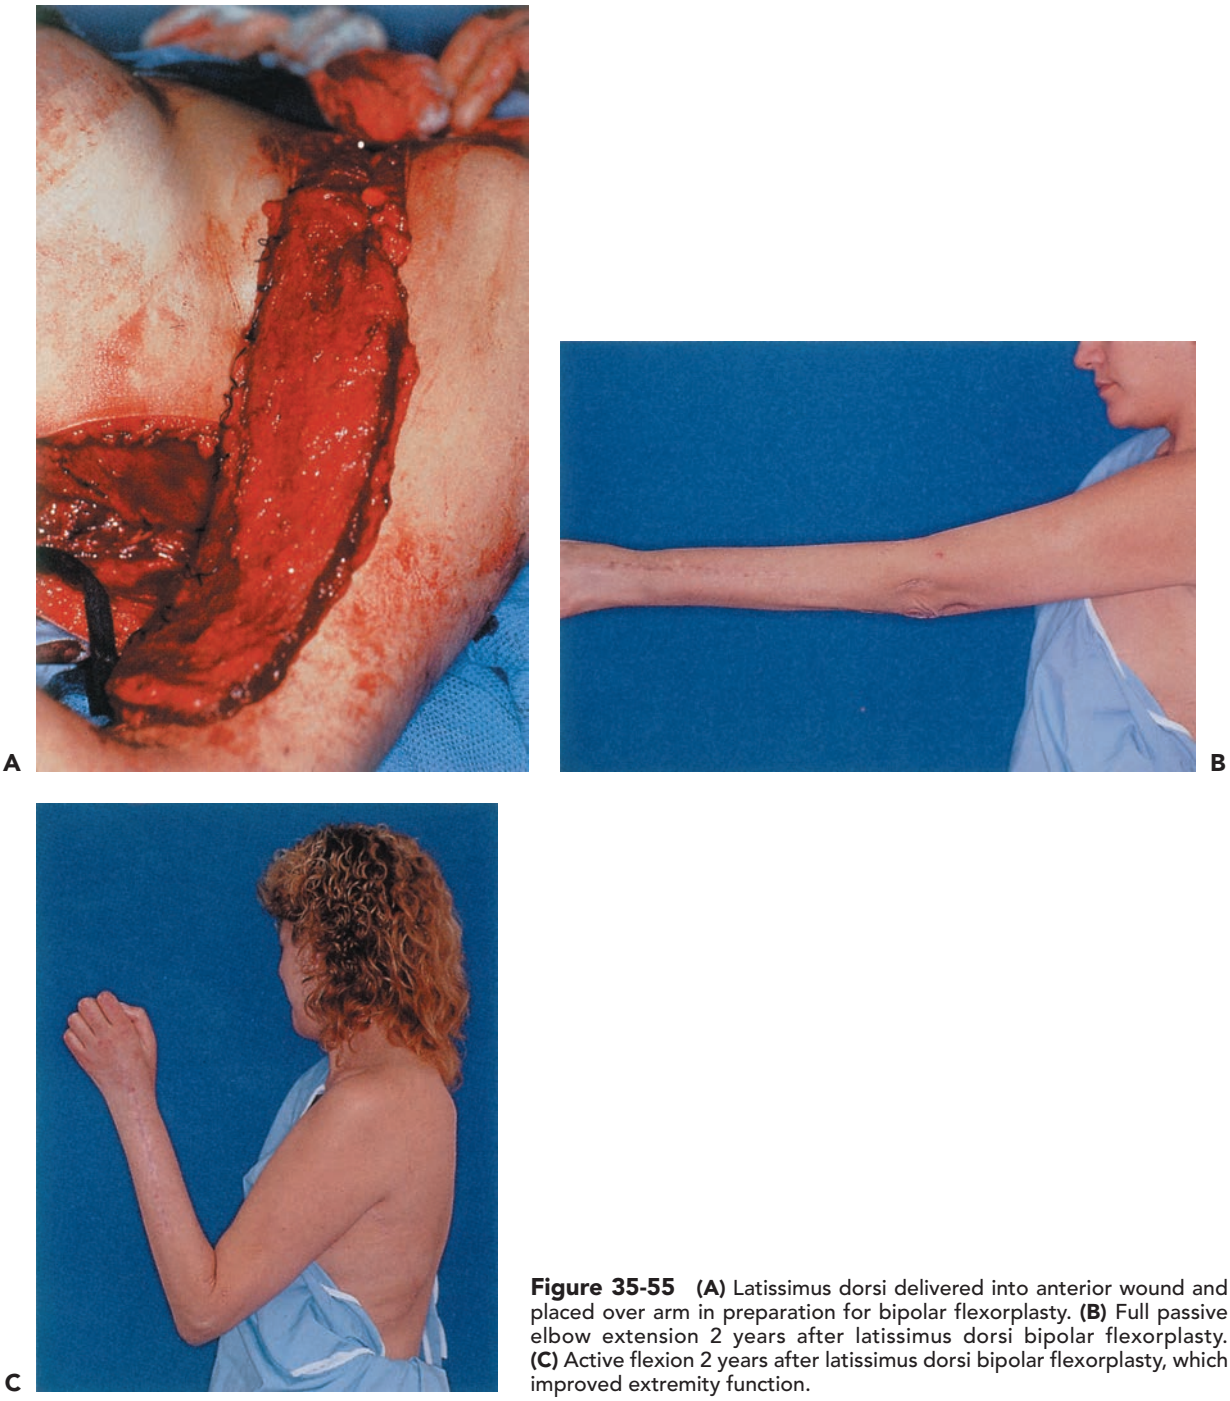

Figure 35-55 **(A)** Latissimus dorsi delivered into anterior wound and placed over arm in preparation for bipolar flexorplasty. **(B)** Full passive elbow extension 2 years after latissimus dorsi bipolar flexorplasty. **(C)** Active flexion 2 years after latissimus dorsi bipolar flexorplasty, which improved extremity function.

coracoid or acromion, depending on which provides the correct tension. Suction drains are placed into the back wound and the arm is immobilized to the chest for 6 weeks before active flexion. Protective extension block splinting is continued until 3 months after surgery.

The results after elbow flexorplasty are generally good, with a return of flexion against gravity (Figs. 35-56 and 35-57).[8,25,26,108,204] These transfers often lack lifting power, but there is considerable improvement in function compared with a paralyzed elbow.[8,29,93] A flexion contracture is common, but this posture also provides a mechanical advantage to initiate flexion. The presence or persistence of poor shoulder control will inhibit use of the transfer and curtail the result.[86,108,204]

Free-muscle transfer with nerve coaptation is a valiant technique to restore flexion.[32,95] This procedure involves a free microvascular muscle transfer of an expendable muscle with coaptation of a viable donor nerve to the motor nerve of the transferred muscle. This technique is indicated when other less complicated procedures are unavailable.

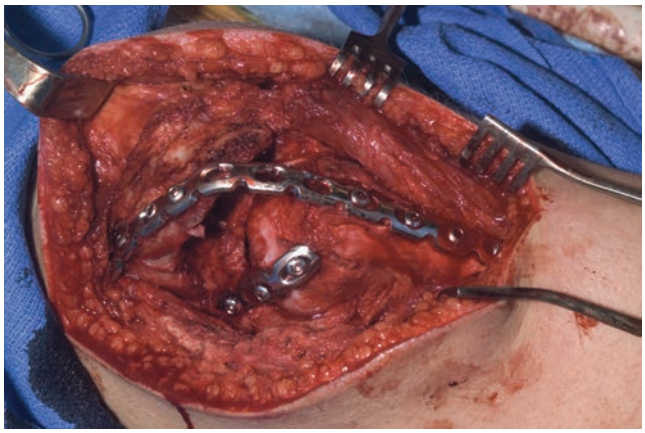

Figure 35-56 A 14-year-old male with flail shoulder after traumatic brachial plexus injury. Treated with glenohumeral arthrodesis using dual plate fixation. (Courtesy of Shriners Hospital for Children, Philadelphia.)

The gracilis is the most common muscle used for neurovascular transfer, with the intercostal nerves or spinal accessory nerve coapted to the obturator motor nerve for reinnervation.[29,32,95] The vascular supply to the gracilis is reestablished by microsurgical anastomosis of the pedicle artery and vein to the brachial artery (end to side) and a local vein (e.g., cephalic vein). The muscle is attached in a similar fashion to a latissimus dorsi flexorplasty with proximal fixation to the coracoid or clavicle and distal weaving into the biceps tendon. The latissimus dorsi muscle has also been used as a free muscle transfer for elbow and finger motion.[45]

The recent results after functioning free-muscle transplantation are impressive, with elbow strength greater than gravity achieved in approximately 75% to 80%, which are similar results to the pedicled latissimus dorsi transfer.[32,95]

Figure 35-57 Shoulder is positioned in 30 degrees of abduction, 30 degrees of internal rotation, and 30 degrees of forward flexion to allow hand–to-mouth activity. (Courtesy of Shriners Hospital for Children, Philadelphia.)

Shoulder Function

Shoulder function is impaired in upper brachial plexus lesions with paralysis of the deltoid and rotator cuff muscles.[50,56] The shoulder may be unstable by muscle absence or unbalanced by asymmetrical muscle pull. The paralysis of the infraspinatus and teres minor muscles prevents external rotation. The subscapularis, pectoralis major, and/or latissimus dorsi muscles position the arm in marked internal rotation. This position is disabling for hand-to-mouth function.[108,145] This problem is particularly relevant in patients with residual brachial plexus birth palsies and has been covered in the previous section.[60,140]

The treatment of residual shoulder deformities is based on tendon transfer to rebalance the shoulder, humeral osteotomy to improve position, or arthrodesis to provide a stable shoulder. The most common tendon transfer is relocation of the latissimus dorsi and teres major tendons to the infraspinatus insertion to restore external rotation.[48,76,140,145,195] This procedure is common in children with residual brachial plexus birth palsy with loss of external rotation (see previous section).

Another tendon transfer about the shoulder for residual brachial plexus palsy involves restoration of glenohumeral abduction. Donor muscles used include the trapezius, levator scapulae, and latissimus dorsi.[50,56,82] The trapezius is transferred with a portion of the acromion to the decorticated posterolateral humerus. The levator scapula is elongated with a fascial graft to reach the tendon of the supraspinatus. The latissimus is transferred on a pedicle similar to the bipolar technique for flexorplasty.[82] Experience with these transfers is small and expected abduction is limited to only 30 to 60 degrees.[157] In persistent cases of shoulder instability or subluxation, arthrodesis is preferred in adult plexopathies.

Shoulder arthrodesis relies on the scapulothoracic muscles for motion and predictably corrects painful glenohumeral subluxation. Absent scapular control is a contraindication for shoulder fusion. The optimal position for fusion is controversial, but should allow hand-to-mouth function with active elbow flexion. The preferred position is 30 degrees of abduction, 30 degrees of internal rotation, and 30 degrees of forward flexion (see Figs. 35-56 and 35-57).[149,150] Numerous operative techniques have been described to achieve union. Rigid internal fixation is preferred, with an AO reconstruction plate across the scapular spine and onto the lateral humerus (Fig. 35-58). AO large cancellous screws are secured from the lateral humerus into the glenoid, and bone graft is added (Fig. 35-59). Postoperative immobilization varies from an abduction pillow to a shoulder spica, depending on the quality of the bone and rigidity of the fixation. Shoulder arthrodesis reliably corrects painful subluxation and provides stability to

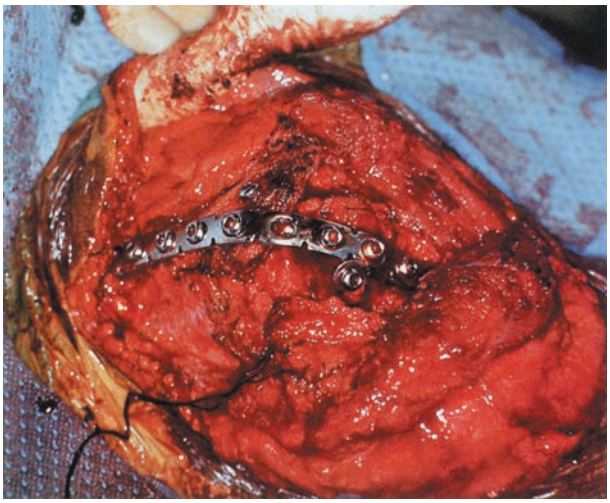

Figure 35-58 Shoulder arthrodesis for an unstable, arthritic, and painful glenohumeral joint after a shoulder dislocation with persistent axillary nerve palsy.

the extremity.[149,150,157] This proximal stability will allow better use of the extremity via scapulothoracic motion and allow further restoration of distal function using additional tendon transfers.

Forearm, Wrist, and Hand

The forearm, wrist, and hand impairment is variable in residual brachial plexus injuries.[14] The goals are to rebalance the extremity by tendon transfer or arthrodesis. Transfer is preferred, but the limited availability of donors is a frequent problem. Wrist arthrodesis can provide a stable platform and will liberate wrist tendons as donors for transfer. The principles are to achieve grasp and release for function. The potential transfers are innumerable, but all must comply with the basic requirements and tenets of tendon transfers. The most common transfer involves restoration of wrist and digit extension with an expendable wrist or finger flexor tendon.

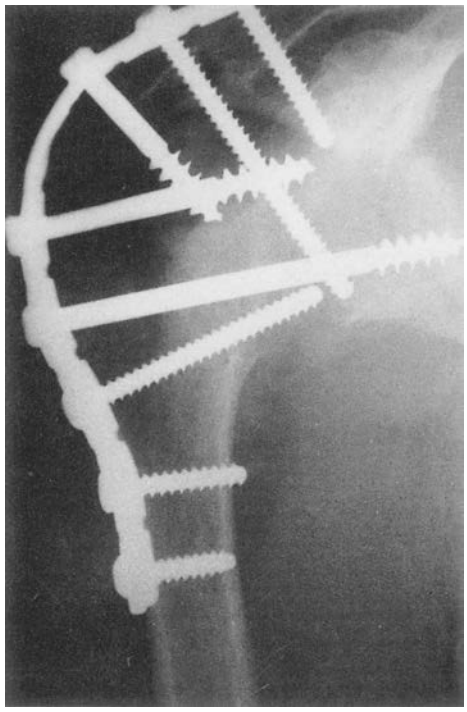

Figure 35-59 Postoperative x-ray film of shoulder arthrodesis performed with reconstruction plate.

COMPLICATIONS OF BRACHIAL PLEXUS SURGERY

Brachial plexus surgery is a considerable undertaking with potential for both minor and major complications. These problems can be mild and transient, or severe and life-threatening. The proximity of major vascular, nervous, lymphatic, and pulmonary structures, coupled with surrounding scar, increases the risk of injury (Table 35-11). Vascular injury can occur during the surgical approach or during separation of the brachial plexus from the surrounding vasculature. The subclavian artery and vein are most susceptible to injury, especially after a previous repair or interposition grafting. Vascular injury can cause profuse bleeding that requires expedient measures to avert a catastrophic complication.

Lymphatic injuries can occur during surgery on the left side of the plexus, and chylous drainage or a chylothoracic sinus may result after unrecognized injury.[6] Pulmonary injury can occur during plexus dissection or harvesting of the intercostal nerves for transfer. During first-rib resection, pleura violation and pneumothorax are not uncommon and require chest tube placement. In addition, direct injury

TABLE 35-11
COMPLICATIONS OF BRACHIAL PLEXUS INJURIES

System	Injury	Treatment
Vascular	Laceration Thrombosis	Repair Thrombectomy
Pulmonary	Pneumothoracic pleural effusion Phrenic nerve	Tube thoracostomy Avoidance
Lymphatic	Thoracic duct	Ligation
Nervous	Laceration Traction Dura puncture RSD	Repair Intermittent relaxation Repair

to the phrenic nerve during anterior scalenectomy will alter hemidiaphragm mobility during inspiration and can cause dyspnea.[6] Supraclavicular dissection can enter a pseudomeningocele and cause cerebrospinal fluid drainage. Signs of cerebrospinal drainage are a diminution in pulse rate and treatment requires immediate repair.[126]

Nerve injuries can result from inadvertent laceration or traction during surgery. Motor and sensory nerves are susceptible. The intercostal brachial cutaneous nerve is vulnerable during axillary dissection for first-rib resection or latissimus dorsi transfer. This nerve emanates from the third interspace and supplies sensation to the medial aspect of the arm. A neuroma or neuritis can develop that can be painful and disabling. Treatment requires localized nerve blocks or excision of the intercostal brachial cutaneous nerve. The lower plexus is particularly susceptible during first-rib resection for thoracic outlet syndrome secondary to traction from arm elevation or direct transection.[42] Intermittent arm relaxation will prevent stretching and ischemia of the lower plexus. The prognosis for recovery after a substantial lower-trunk injury is poor and residual deficits are likely. An injury at this level can also involve the sympathetic fibers and result in a Horner's syndrome. The long thoracic nerve is also in danger during first-rib resection and middle scalenectomy, as the nerve travels along the middle scalene.[199]

SUMMARY 1152

SUPRASCAPULAR NERVE INJURIES

Anatomy

The suprascapular nerve is a mixed motor and sensory nerve arising from the superior trunk of the brachial plexus. Although cadaveric dissections have found contributions from the fourth cervical nerve in up to 22% of specimen, it receives its fibers predominantly from the fifth and sixth cervical nerves.[1,52] The nerve innervates and provides the motor function to the supraspinatus and infraspinatus muscles. It provides sensory input from the coracoacromial and coracohumeral ligaments, the subacromial bursa and the acromioclavicular and glenohumeral joints. Rarely, there may be also be a cutaneous branch of the nerve that innervates the proximal lateral one-third of the arm.[1,42]

After leaving the superior trunk of the brachial plexus, the nerve courses across the posterior cervical triangle parallel to the omohyoid muscle, deep to the trapezius muscle, and adjacent to the posterior surface of the clavicle. Proximally, the nerve is located lateral to the brachial plexus. As it heads toward the superior edge of the scapula and the suprascapular notch, however, the nerve migrates posterior to the plexus. At this location, the nerve runs through the suprascapular notch, most often staying deep to the superior transverse scapular ligament. The suprascapular artery and vein, which travel with the nerve, course superior to the ligament. After passing through the notch, the nerve runs inferiorly along the posterior neck of the scapula before turning medially around the spinoglenoid notch. It then terminates in several branches innervating the infraspinatus muscle (Fig. 36-1).[22,71,78] There has been some controversy regarding the presence of a true spinoglenoid or

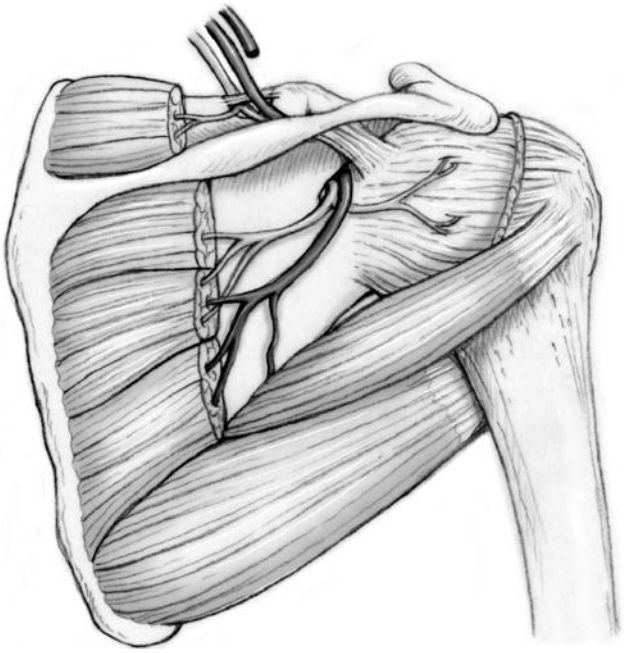

Figure 36-1 Anatomy of the suprascapular nerve. Note that the nerve runs deep to the superior transverse scapular ligament at the suprascapular notch while the vessels run superior to the ligament. After running along the posterior aspect of the scapula neck, the nerve courses through the spinoglenoid notch and heads medially along the inferior border of the scapula spine.

an inferior transverse scapular ligament. A recent anatomic study, for example, demonstrated that a true ligament existed in only 20% of the specimen and that 60% of the specimen contained just a thin fibrous band at that site.[21]

Classification and Etiology

Injuries to the suprascapular nerve are primarily classified according to the location and cause of the lesion. In addition, they may also be characterized by the degree of intraneural damage. The nerve can be injured at any point along its path, but common locations include (1) the supraclavicular or infraclavicular region prior to entering the suprascapular notch, (2) the suprascapular notch, (3) the posterior scapular neck, and (4) the spinoglenoid notch. Suprascapular nerve injuries can be caused by traction, extrinsic compression, and direct trauma. The injuries may be iatrogenic or associated with a generalized brachial plexus disorder.[78]

Traction injuries are believed to occur most commonly at the suprascapular and the spinoglenoid notches, as the nerve has little excursion at these sites. Furthermore, variations in the osseous and ligamentous anatomy may limit the available space for the nerve. For example, a cadaveric study demonstrated that cross-body adduction and internal rotation of the shoulder tightened the spinoglenoid ligament and posterior capsule, which, in turn, stretched the suprascapular nerve underneath the ligament.[26] First described by Kopell and Thompson in 1963, these types of traction injuries may occur following repetitive overhead activities.[49] Anatomic variations of the suprascapular notch have been investigated extensively by Rengachary and colleagues, who created a classification system of these variations (Fig. 36-2).[74] The implication of this classification was that the likelihood of a traction injury is clearly related to the available space for the nerve as well as the sharpness of the bony edges. These characteristics may be more accentuated when the shoulder is hyperabducted, as this would increase the contact between the nerve and the edge of the notch.[75] Rengachary et al. described this mechanism as "the sling effect."[75] Subsequently, clinical case reports of suprascapular nerve injuries have supported this proposed mechanism of injury.[16,81]

Extrinsic compression can also injure the suprascapular nerve. As discussed previously, compression of the nerve may occur at the suprascapular and the spinoglenoid notches by different anatomic structures. In addition, extreme shoulder abduction and external rotation that occur with overhead sports can cause compression of the nerve between the rotator cuff tendons and the scapular spine.[80] The most common cause of extrinsic compression on the suprascapular nerve is a ganglion cyst. These cysts originate from the glenohumeral joint and are often associated with tears in the superior or posterior labrum. The size of the ganglion cyst can vary, which, in turn, can affect the clinical presentation. Thus, for example, larger cysts can cause a more proximal lesion on the nerve and change the presenting symptoms. In rare instances, other masses such as synovial sarcomas, Ewing's sarcoma, chondrosarcoma, renal cell carcinoma, and schwannoma have all been reported to cause suprascapular nerve compression.[32,82]

Trauma is another cause of suprascapular nerve injury. Penetrating injuries, for example, can directly lacerate the nerve.[93] More commonly, however, suprascapular nerve injuries have been associated with blunt and more generalized shoulder girdle trauma such as glenohumeral dislocations and fractures. Nearby fractures in the scapula, particularly those involving the glenoid neck or the suprascapular notch, have caused suprascapular nerve injuries including traction and transection.[10,84]

Vascular insult of the suprascapular nerve has been proposed as a cause of injury. The proposed mechanism involves an intimal injury to the suprascapular artery following repetitive overhead activities. The vascular injury, in turn, is thought to produce microemboli that eventually compromise the blood supply to the vasa nervorum and cause an ischemic injury to the nerve.[76] Unfortunately, however, this hypothesis has not been substantiated clinically.[22]

Rare instances of iatrogenic suprascapular nerve injury have also been reported in the literature. For example, Mallon et al. reported two cases of suprascapular nerve injury

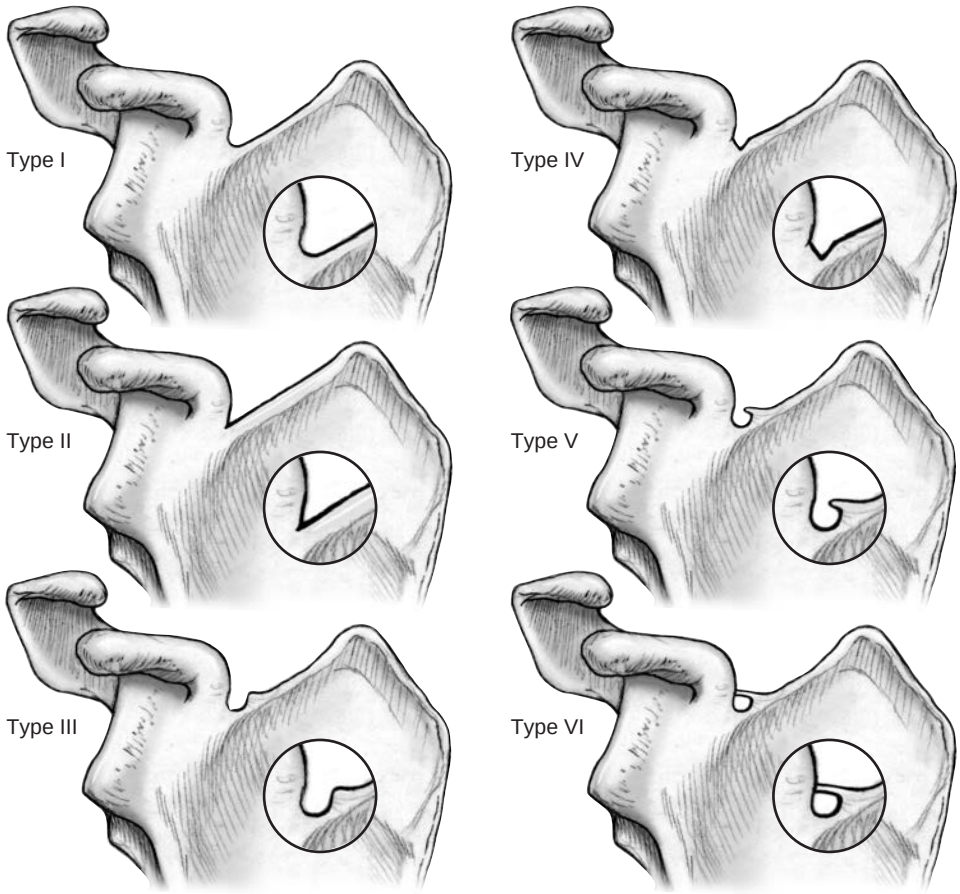

Figure 36-2 Classification of suprascapular notch morphology as described by Rengachary et al.[74] With varying bony and soft tissue anatomy, the potential for nerve compression injury may be increased at this site.

following distal clavicle resection. In both cases, excessive resection of the clavicle was believed to be related to the injury. Hence, the authors recommended that the distal clavicle not be resected beyond 1 cm.[56] In addition to distal clavicle resection, rotator cuff repair surgery may also cause suprascapular nerve injuries. According to a cadaveric study, excessive lateral advancement of the supraspinatus and the infraspinatus tendons may alter the orientation of the nerve's terminal branches by 180 degrees. As such, these authors recommended limiting lateral advancement of the rotator cuff tendons to 3 cm and suggested that further advancement (e.g., repair of massive rotator cuff tendons) may lead to suprascapular nerve injuries.[91] Another rotator cuff repair procedure called the disinsertion-advancement technique allows mobilization of the tendons while altering the orientation of the nerve by only 90 degrees.[24] Unfortunately, however, the first motor branch to the supraspinatus muscle remained trapped under the suprascapular ligament and limited the lateral advancement of the tendons.[91] Although the anatomic data are compelling, clinical studies of massive rotator cuff repairs with significant lateral advancement have not substantiated these concerns.[35,77,96] Other procedures associated with iatrogenic suprascapular nerve injury involve exposure of the posterior glenoid neck. Cadaveric studies have established a "safe zone" for avoiding the nerve. The average distance from the supraglenoid tubercle to the nerve is between 23 and 30 mm. At the base of the spine, as the nerve courses around the spinoglenoid notch, this distance shortens to 14 to 18 mm. Therefore, surgical procedures should remain lateral to this area to avoid an injury to the nerve.[8,83]

Clinical Symptoms

Despite the numerous causes of suprascapular nerve injury, most patients present with similar symptoms. Often, the patients complain of poorly localized but constant "achy" pain over the posterior and lateral aspects of the shoulder. Although the onset of pain may be associated with a specific trauma or change in activity level, most patients report an insidious onset. Activities that involve repetitive overhead motion may exacerbate the symptoms. Pain and weakness tend to be more severe in patients with a proximal nerve lesion. In contrast, patients with a distal lesion often complain of weakness only and may report minimal or no pain. This finding is consistent with the anatomic distribution of the nerve fibers described previously. In rare instances, the patients may be completely asymptomatic. As such, the nerve lesions may represent an incidental finding of unknown clinical significance.[22,30,71,78]

Clinical Evaluation

In addition to a deliberate shoulder examination, a thorough upper extremity and cervical spine examination must be performed on all patients. During the early stages following a suprascapular nerve injury, the examination may only yield nonspecific findings. Chronic nerve injuries, however, may reveal asymmetry of the shoulder girdle musculature, denoting atrophy of the supraspinatus and/or infraspinatus muscles. Due to the overlying trapezius muscle, atrophy of the supraspinatus muscle may be difficult to appreciate in some patients. Atrophy of the infraspinatus muscle, however, should be readily apparent (Fig. 36-3). Palpation along the course of the nerve can reveal focal tenderness at the site of compression. Examination may also reveal mild to moderate loss of strength in shoulder abduction and external rotation. Weakness of abduction will occur only with lesions involving the supraspinatus muscle as it acts in concert with the deltoid muscle to elevate and abduct the humerus.[43] Involvement of the infraspinatus muscle does not always result in external rotation weakness as some patients can compensate with the teres minor and posterior deltoid muscles.[30,38]

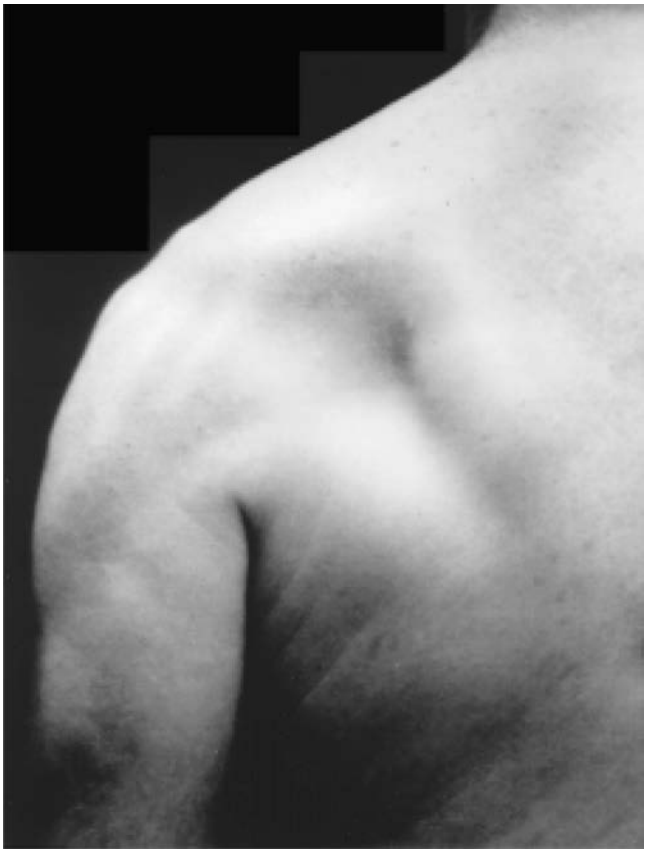

Figure 36-3 Clinical picture of infraspinatus muscle atrophy due to suprascapular nerve compression at the spinoglenoid notch. Note the loss of normal posterior shoulder contour due to the muscle atrophy. (Reprinted with permission from Cummins CA, Messer TM, Nuber G. Suprascapular nerve entrapment. *J Bone Joint Surg Am* 2000;82-A:415–424.)

Unlike other peripheral neuropathies, there are no specific provocative maneuvers to accentuate the symptoms of a suprascapular nerve lesion. Cross-arm adduction of the shoulder may place the nerve under increased tension as it passes under the suprascapular ligament. Hence, if a patient notes increased pain or discomfort with this maneuver, a suprascapular nerve injury may be suspected.[15] It is important to differentiate the exact location of pain, however, as acromioclavicular joint pathology may also cause pain with this maneuver.[28] For some patients whose symptoms are suspicious for a suprascapular nerve lesion, a diagnostic injection can be considered. Injection of the suprascapular notch, for example, may provide excellent alleviation of pain. However, by itself, this test is not specific for a nerve lesion as patients with other types of shoulder pathology may also find pain relief from a suprascapular nerve block.[71,72,78]

Electrodiagnostic Studies

A clinical suspicion for a suprascapular nerve injury should be confirmed with electrodiagnostic studies. The mean normal latencies between Erb's point and points in the supraspinatus and infraspinatus muscles have been determined to be between 2.7 and 3.3 milliseconds, respectively. Increased latency on nerve conduction velocity studies may signify a nerve lesion such as entrapment.[48,50] Denervation injuries typically reveal increased spontaneous activity, polyphasic signals, muscle fibrillations, positive sharp waves, and amplitude reduction on electromyography (EMG).[16,48,71] It must be noted, however, that these tests are both invasive and operator dependent. In addition, positive results will not always accurately locate the lesion or define the pathology.[22,71,78] In one study of patients with preexisting denervation injuries, preoperative EMG changes were predictive of patient outcome after nerve exploration and/or repair. Surprisingly, fewest improvements were observed in patients with minor preoperative EMG changes. The authors hypothesized that more severe denervation was usually associated with an identifiable pathology that can be addressed at the time of surgery and that less severe denervation may not improve with nerve decompression alone.[3]

Imaging Studies

Several imaging modalities can be utilized to identify the potential sites of nerve injury. Standard radiographs of the cervical spine and the shoulder are typically the first imaging studies to be evaluated. When clinically indicated, dedicated clavicle views may be useful. A Stryker notch view, an anteroposterior view of the scapula with the beam directed caudally 15 to 30 degrees, allows visualization of

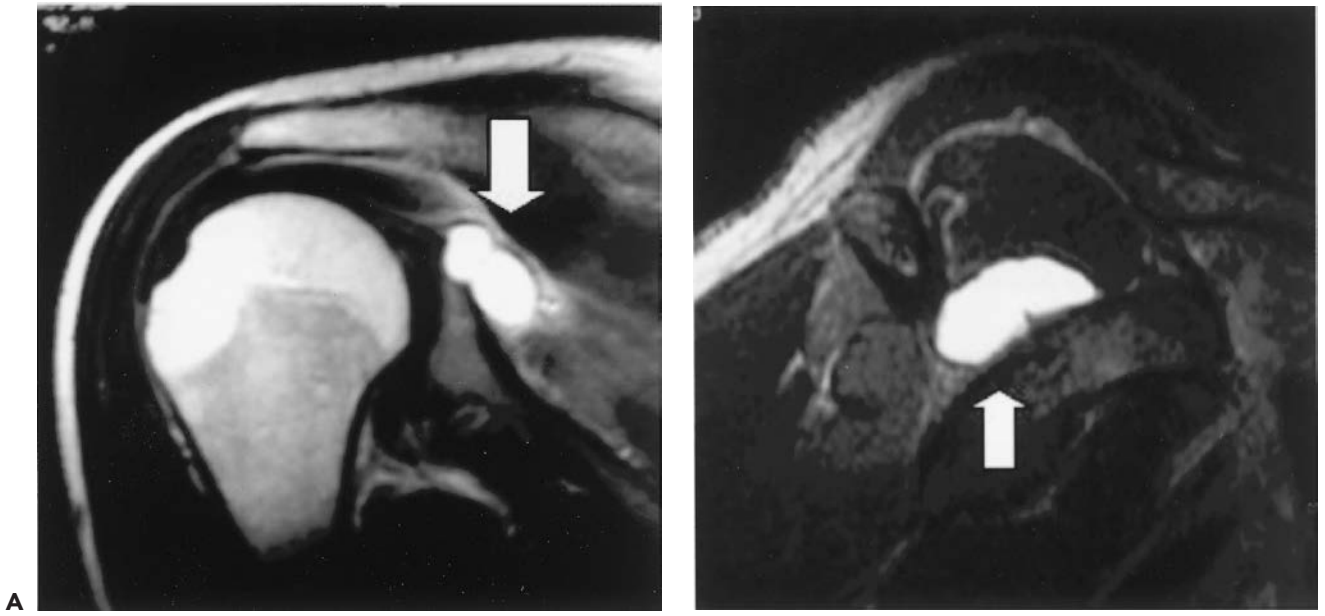

Figure 36-4 Magnetic resonance imaging of a ganglion cyst. Coronal **(A)** and sagittal **(B)** views of T-2 weighted images clearly demonstrate a well-circumscribed homogeneous high-signal intensity mass, consistent with a fluid-filled cyst.

the suprascapular notch. Radiographs are particularly useful for patients with a suspected fracture. In the acute setting, fracture lines may be observed near the anatomically sensitive regions. In more chronic cases, callous or fibrous tissue may compress or entrap the nerve. For the majority of patients, however, radiographs are likely to be unremarkable.[22,70,78] A computed tomography (CT) scan offers better delineation of the osseous architecture. Unfortunately, similar to radiographs, CT scans are often normal and provide little additional diagnostic value.[41]

For most patients with a nerve injury, magnetic resonance imaging (MRI) often provides the most valuable information. MRI allows clear identification of various intraarticular and extraarticular soft tissue pathologies.[41] In addition, it is also particularly effective in identifying soft tissue masses that can injure the suprascapular nerve.[32] Ganglion cysts, for example, are clearly visible on the MRI (Fig. 36-4). On the T-2 weighted images, these cysts are seen as high-signal, well-defined masses originating from the posterosuperior aspect of the glenohumeral joint.[22,33,41,45] If unclear, gadolinium can enhance the visualization of the cyst by increasing the signal intensity of its outer rim.[22] Denervation changes within the muscle mass, such as fatty infiltration and decreased mass, are also well defined on the MRI.[32,45,51] Denervated muscles typically show high-signal changes on the T-2 weighted images and, according to one study, the degree of denervation correlated with the degree of signal intensity.[45] On some MRIs, the actual nerve can be visualized. T-2-weighted oblique sagittal views, for example, can demonstrate the suprascapular nerve as it courses through the suprascapular fossa.[78]

If an MRI is not readily available, ultrasonography may be utilized to identify ganglion cysts and other masses around the shoulder. A ganglion cyst will appear as a hypoechoic, well-defined, homogeneous mass.[39] Ultrasound may also detect muscle atrophy consistent with denervation.[51] However, while ultrasonography offers a cost-effective alternative, it is operator dependent and may not be an accurate imaging modality in the hands of inexperienced operators.

Nonoperative Treatment

A trial of nonoperative therapy is typically the initial treatment of choice for patients with a suprascapular nerve injury. In the majority of patients who do not have a well-defined lesion, most of the symptoms will resolve spontaneously.[57,69] Unfortunately, however, a significant amount of time, perhaps as long as 12 months, is often required for a complete resolution of symptoms.[78] Therefore, patient counseling is a key component to nonoperative treatment. In addition, patients should be instructed to avoid repetitive overhead activities that can cause trauma and irritation to the nerve. Physical rehabilitation should focus on regaining and improving the flexibility, strength, and endurance of the shoulder girdle musculature. The scapular stabilizers are of particular importance in reestablishing proper glenohumeral and scapulothoracic kinematics.

The overall success rate of nonoperative management, however, is not well established in the literature and can vary widely among individual reports. For example, one study reported that all patients in the small series were

successfully treated with a home exercise program, while another series reported that all patients in the study failed nonoperative therapy and required surgical intervention.[27,71] In a retrospective review of 15 patients, Martin et al. reported that five excellent and seven good results were obtained after nonoperative management. The remaining three patients (20%) continued to suffer from persistent symptoms and required surgical management.[57]

Despite these conflicting reports, the likelihood of successful nonoperative management appears to depend primarily on the cause and location of the nerve lesion.[22,78] In general, patients with a distal nerve injury without a discrete lesion respond favorably to nonoperative management. For example, one study reported that most patients with an isolated infraspinatus muscle atrophy were successfully treated nonoperatively as they obtained good pain relief, increased muscle mass, and improved strength at 6 to 12 months.[22] Another study by Ferretti et al. reported similar results as they reviewed their experience with 38 professional volleyball players who were suffering from isolated infraspinatus atrophy.[29] Thirty-five patients (92%) responded well to nonoperative treatment that consisted of physical rehabilitation focusing on external rotation strengthening exercises. The authors noted that isolated infraspinatus muscle atrophy did not affect the competitive performances of these athletes and that surgical intervention should be reserved for those patients suffering from persistent pain.[29]

Nonoperative management of patients with a well-defined lesion, particularly ganglion cysts, appears to be associated with unfavorable outcomes.[2,22,28,57] Cummins et al. performed a review of the literature and identified 21 cases of suprascapular nerve injuries secondary to ganglion cysts that were managed nonoperatively. Five of these patients had complete resolution of their symptoms and

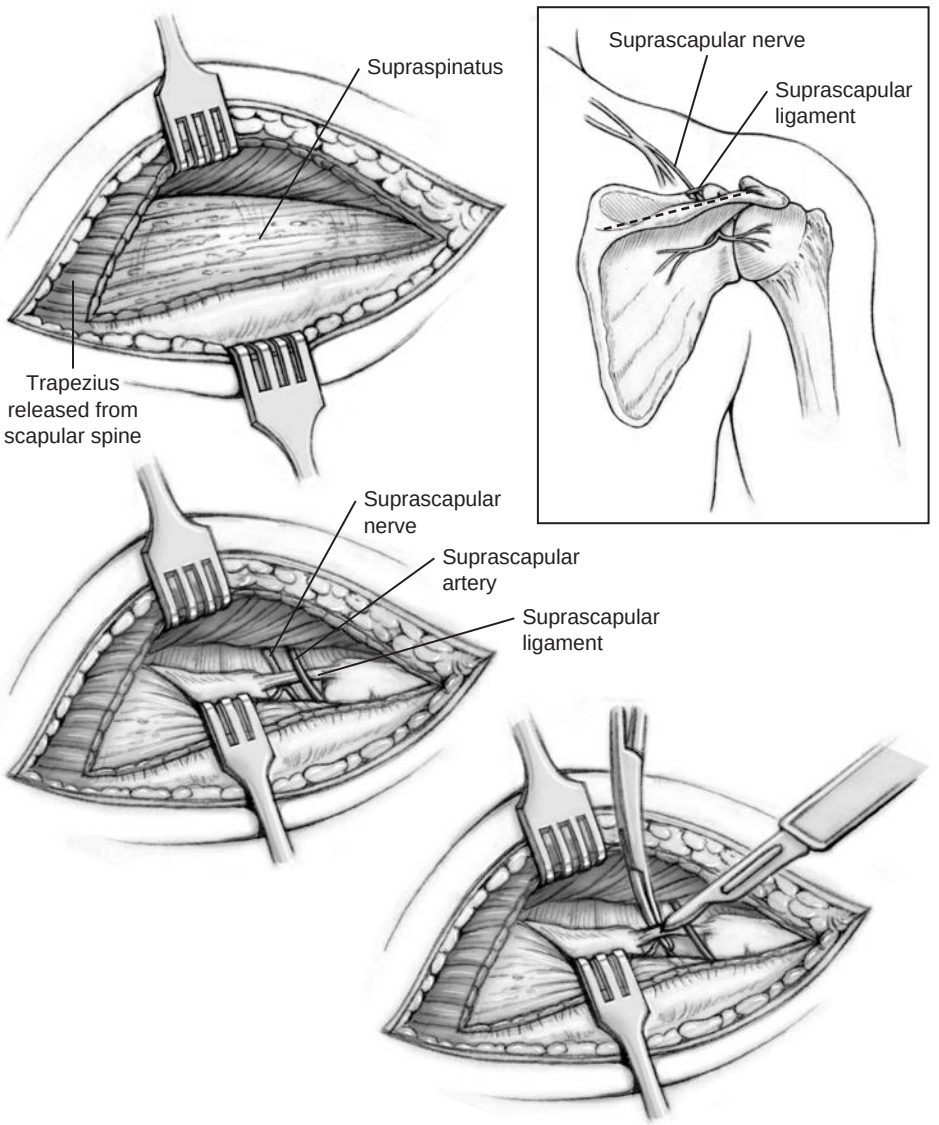

Figure 36-5 Surgical approaches for suprascapular nerve decompression. The nerve is commonly explored using either a posterior **(A)** or a superior **(B)** approach (refer to text for details).

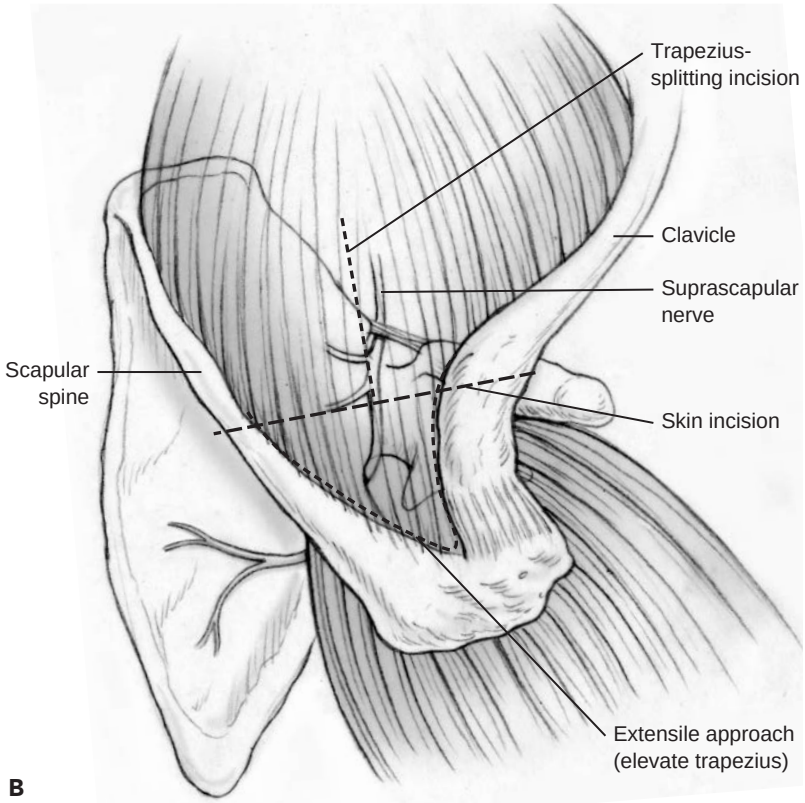
another experienced partial pain relief. The remaining 15 patients (71%) had "unsuccessful" results, with nine patients requiring surgical decompression.[22] Thus, although these patients with a discrete lesion can be initially managed with nonoperative therapy, they should be counseled that they are less likely to have a successful outcome and that they may require surgical intervention.

For some of these patients with a documented ganglion cyst, ultrasound or computed tomography guided aspiration may be useful.[32,39,86] In their review of the literature, Cummins et al. identified eight such cases, and found that these patients all reported satisfactory pain relief at short-term follow-up.[22] The theoretical concern regarding guided aspiration is that it does not allow an opportunity to address the intraarticular pathology involving the glenoid labrum. Hence, over time, the cysts may recur. According to one study, for example, the rate of recurrent cyst formation after aspiration was as high as 48%.[40] Therefore, while promising, further experience with guided aspiration is necessary to document its long-term clinical efficacy.

Operative Treatment: Open

Exploration and decompression of the suprascapular nerve have been the surgical treatments of choice. The surgical approach is usually dictated by the location and cause of the lesion (Fig. 36-5). While an anterior approach to the suprascapular notch has been described, it has not been routinely utilized due to the difficult dissection, increased risk of neurovascular injuries, and poor visualization of the nerve.[62,71,78] Therefore, the majority of the surgeons tend to use either the posterior or the superior approaches to the nerve.

Initially described by Post and Mayer, the advantages of the posterior suprascapular nerve decompression include excellent exposure, limited risk to the neurovascular structures, and avoidance of major muscle damage.[22,70,71] For this approach, the patient is placed in a semiprone position with the arm draped free. The skin incision is made just superior, but parallel, to the scapular spine. The underlying trapezius muscle is then sharply elevated and retracted to expose the supraspinatus muscle. Once the supraspinatus muscle is retracted inferiorly, the superior transverse scapular ligament can be visualized. If the ligament is the source of the nerve lesion, it can be excised in its entirety. Otherwise, it is incised to expose the nerve and any compressing structures. Care should be taken to ensure that the vascular structures that lie just superior to the ligament are not injured. It has also been suggested by some authors that isolated ligament resection may be insufficient to decompress the nerve and that the nerve can still be tethered by its course over the notch.[73] Therefore, in addition to ligament release, all resected edges of bone as well as the notch should be contoured to minimize any potential damage to the nerve.[78]



B

Figure 36-5 *(continued)*

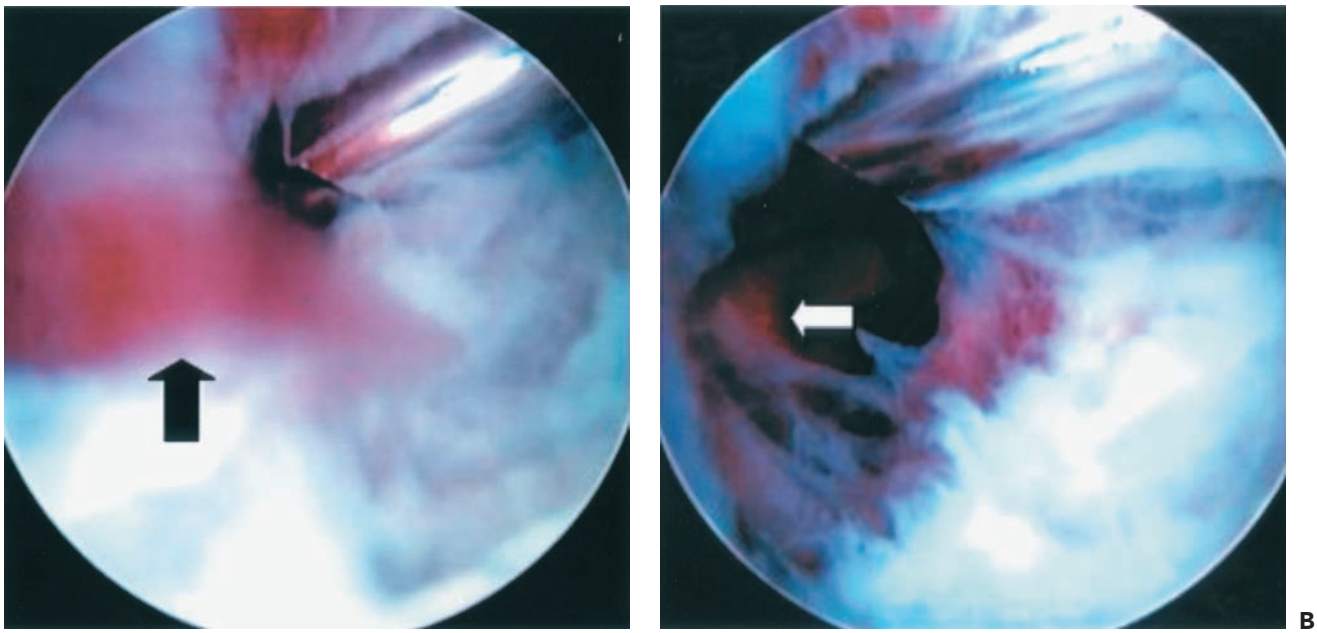


Figure 36-6 Arthroscopic decompression of a ganglion cyst. After incising the superior glenohumeral joint capsule and decompressing the cyst **(A),** gelatinous cyst material (*arrow*) is commonly encountered. Upon completion of the decompression **(B),** the suprascapular nerve may also be visible (*arrow*).

For patients with an isolated ganglion cyst, an alternative posterior approach can be used. While the patient is positioned in a similar manner, the incision is made along Langer's lines 3 cm medial to the posterolateral corner of the acromion. The deltoid muscle is then split in line with its fibers. Once identified, the infraspinatus muscle can then be retracted inferiorly to reveal the ganglion cyst and the terminal branches of the nerve.

Another commonly utilized technique for suprascapular nerve decompression is the superior trapezius splitting approach. The patient is positioned in a beach-chair or lateral position. The skin incision begins 2 cm medial to the acromioclavicular joint and follows Langer's line to the distal third of the scapular spine. The trapezius muscle is then split in line with its fibers to expose the scapula. For a more extensile exposure, the trapezius muscle can be sharply elevated off of the bone and then later repaired using bone tunnels.[61] By identifying and then retracting the supraspinatus muscle inferiorly, the superior transverse scapular ligament is visualized. The ligament is transected and the underlying pathology can be addressed.

Operative Treatment: Arthroscopic

Arthroscopic management of a suprascapular neuropathy has recently gained significant attention due to the high association between this pathology and labral tears.[40,86] Commonly associated labral pathology includes fraying as well as frank tears. Arthroscopic techniques are routinely utilized to address these pathologies. Once the labral pathology is addressed, the ganglion cyst can then be isolated and decompressed by either open or arthroscopic techniques[28,44,78] (Fig. 36-6). Various arthroscopic techniques for cyst decompression have been described. Iannotti and Ramsey, for example, recommended performing a posterosuperior capsulotomy to approach the cyst. If clearly identified, the cyst can then be excised in its entirety. If not, the cyst can be drained into the joint by manually applying pressure to the posterior aspect of the joint.[44] Romeo et al. described another similar technique to identify and excise the cyst. For their approach, however, accessory posterolateral and anterosuperior portals were often necessary to clearly visualize and decompress the cyst.[78] It should be noted, however, that arthroscopic procedures can be technically demanding. Clear identification and visualization of the cyst is crucial to a successful excision. With the nearby suprascapular nerve, poorly performed decompression may actually increase the risk of further neurologic injury.

Postoperative Considerations

Upon completion of the procedure, patients are immobilized in a simple sling for comfort. They are allowed to remove the sling for hygiene purposes as well as to perform daily stretching exercises. As soon as their pain is tolerable, typically 10 to 14 days after the surgery, the immobilization is removed and active motion exercises are instituted.[70] The only exceptions are patients in whom a superficial muscle had to be detached from the bone for surgical

exposure. In such situations, active motion is typically instituted 4 to 6 weeks after the surgery. Once active exercises are initiated, it is important to restore normal kinematics of the shoulder girdle and the periscapular musculature. The majority of patients experience pain relief soon after the procedure. Muscle atrophy and weakness, however, improve gradually over 3 to 6 months.[36,71]

Results and Complications

Although the pathology and the diagnosis are well established, the small number of surgical cases has limited the amount of available information in the literature. In general, however, open surgical treatment of patients with a suprascapular nerve lesion is associated with a good clinical outcome. Callahan et al., for example, evaluated 23 patients who underwent suprascapular ligament release and open nerve decompression and found that 91% of the patients experienced immediate pain relief. The symptoms recurred in four patients, with three requiring a second operation. Overall, they noted that long-term pain relief and resolution of weakness were obtained in 87% of the patients.[16] Similarly, Vastamaki and Goransson reported on their experience of treating 54 patients with a surgical release of the suprascapular ligament. Immediate pain improvement was observed in 39 (72%) patients, with 24 (44%) patients having no residual pain and 15 (28%) having a notable decrease in pain. Improvement in muscle atrophy, however, was more variable. Only 1 of the 16 patients with a preoperative *supraspinatus* atrophy showed any residual atrophy. In contrast, of the 26 patients with a preoperative *infraspinatus* muscle atrophy, 11 noted residual atrophy. The authors conceded that they did not address any pathology at the spinoglenoid notch that could have contributed to the residual atrophy of the infraspinatus muscle.[90] Finally, Post reviewed his experience with 39 patients who had a surgical release of the suprascapular nerve. Twenty-seven patients (69%) had excellent results and returned to work at an average of 3.3 months after the operation. An additional 11 patients (28%) experienced good results, and only one patient had a fair result. The author noted that residual muscle atrophy correlated inversely with a delay to surgical intervention. Therefore, patients with a longstanding and severe muscle atrophy were unlikely to regain full muscle strength.[71]

Similar findings were noted for patients who underwent an operative excision of the ganglion cyst at the spinoglenoid notch. These patients were also able to experience predictable pain relief with variable return of muscle strength.[22,29,37,80] Fehrman et al., for example, reported complete pain relief in five of the six patients who underwent combined arthroscopy and open excision of the cyst. While these patients subjectively felt that their shoulders were normal, objective examination revealed persistent muscle weakness at short-term follow-up.[28] Similarly, Moore et al. reported on 16 patients who underwent either open or arthroscopic excision of the ganglion cyst at the spinoglenoid notch. All but one patient experienced a good to excellent result. The remaining patient with a poor result was subsequently found to be suffering from a missed labral tear. Upon repair of the tear, this patient then experienced a good overall result as well.[61] Finally, Hawkins et al. reported on their experience with 73 patients who were suffering from symptomatic spinoglenoid ganglion cysts. Patients were treated nonoperatively, by needle aspiration, or by arthroscopic decompression. The authors noted that the arthroscopically treated group had the best outcome in terms of pain relief, resolution of atrophy, and return of strength.[40]

AXILLARY NERVE INJURIES

Anatomy

The axillary nerve is a mixed sensorimotor nerve originating from the fifth and sixth cervical nerve roots. It is a terminal branch of the posterior cord of the brachial plexus. Initially, the nerve runs posterior to the axillary artery along the anterior surface of the subscapularis muscle. Typically, it courses obliquely across the inferior border of the muscle, 3 to 5 mm medial to the musculotendinous junction. The nerve then turns posteriorly, entering the quadrilateral space with the posterior humeral circumflex artery. Anterior to the glenohumeral joint, the boundaries of the quadrilateral space consist of the humerus, the triceps longus, the teres major, and the subscapularis. Posterior to the joint, the superior boundary of the quadrilateral space is replaced by the teres minor (Fig. 36-7).[66,85]

During its passage under the glenohumeral joint, it divides into two discrete trunks. The posterior trunk lies medial to the anterior trunk and runs adjacent to the inferior rim of the glenoid. One of its terminal branches enters and innervates the teres minor muscle. Another terminal branch, the superolateral brachial cutaneous nerve, runs inferiorly deep to the posterior deltoid fibers passing around the medial border of the deltoid. In most patients, this branch can be identified approximately 9 cm inferior to the posterolateral corner of the acromion. The last terminal branch of the posterior trunk innervates the posterior deltoid muscle. In a cadaveric study, this branch had some variations in its origin. Rather than arising directly from the posterior trunk, it occasionally originated from the superolateral brachial cutaneous nerve.[5]

The anterior trunk of the axillary nerve circles posterolaterally around the surgical neck of the humerus, traveling on the deep subfascial surface of the deltoid muscle toward the anterior deltoid. Along its course, the nerve generates several branches to the lateral and anterior deltoid muscle.[66,85] In most patients, the nerve can be located 4 to

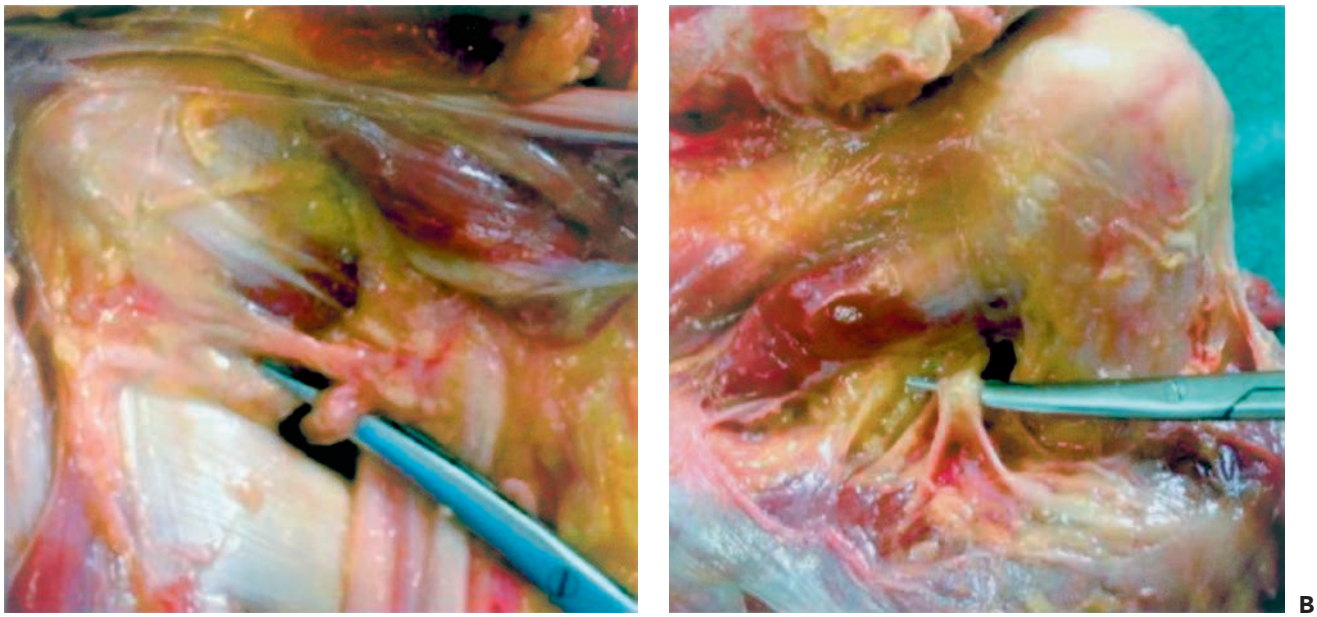

Figure 36-7 Anatomy of the axillary nerve about the scapula. On the anterior aspect of the shoulder **(A),** the nerve runs inferior to the subscapularis muscle before entering the quadrangular space. During its passage within the quadrangular space, the nerve divides into two discrete trunks, which, in turn, separate into additional terminal branches. Therefore, as the nerve exits the quadrangular space in the posterior aspect of the shoulder **(B),** several discrete branches may be seen.

7 cm inferior to the anterolateral corner of the acromion.[13] Based on this anatomy, the axillary nerve is believed to be susceptible to injury at the following locations: (1) its origin from the posterior cord, (2) along the inferior edge of the clavicle, (3) along the inferior aspect of the glenohumeral joint, (4) at the posterior quadrilateral space, and (5) within the subfascial surface of the deltoid.[66]

Classification and Etiology

Similar to the suprascapular nerve, injuries to the axillary nerve may be classified according to the degree of intraneural injury or by location and cause. Most commonly, axillary nerve injuries are discussed in the context of cause. Traumatic mechanisms for injury include direct nerve lacerations, blunt nerve trauma, and traction injuries. Glenohumeral dislocations, for example, have been associated with axillary nerve injuries. Although the true incidence of axillary nerve injuries after glenohumeral dislocations is largely unknown, some authors have reported rates of less than 5% for patients younger than 60 and up to 9% in patients older than 60.[34] These rates were based on clinical findings alone. With electrodiagnostic analysis, however, Toolanen et al. found that 54% of the patients with traumatic anterior glenohumeral dislocations showed EMG changes consistent with an axillary nerve injury.[87] The duration of dislocation appears to be an independent risk factor for axillary nerve injuries, as one report demonstrated that the likelihood of axillary nerve injuries increased significantly if the shoulder was dislocated for more than 12 hours.[65] According to Milton, axillary nerve injury after glenohumeral dislocations is a result of a combined traction and compression.[60] Another common cause of traumatic nerve injury is proximal humeral fractures. Unfortunately, due to pain and associated guarding, axillary nerve injuries may be difficult to identify in patients with acute fractures and is likely to be underreported in this setting.[9]

Blunt trauma and traction injuries have also been observed to result in axillary nerve injuries during contact sports.[6,65,67] Direct blows to the anterolateral deltoid can result in a compression injury to the anterior branch of the axillary nerve as it courses along the humerus in the subfascial deltoid. There may also be a component of traction injury with this mechanism, likely in the region of the quadrilateral space, as many of these patients have weakness of the posterior deltoid as well as sensory deficits along the distribution of the superolateral brachial cutaneous nerve. Additionally, some athletes suffer from axillary nerve injuries following shoulder depression and contralateral neck flexion, which would clearly indicate a traction mechanism.[6,65,67]

Compression of the axillary nerve and posterior circumflex humeral artery within the quadrilateral space has been described as an entity called the quadrilateral space syndrome (QSS).[14] It has been postulated that this syndrome is caused by fibrous bands and hypertrophic muscles that surround the quadrilateral space. As a result, static as well as dynamic compression of the nerve can result in the

clinical presentation of pain and weakness.[14,31,66] Other, and less common, causes of compressive axillary nerve injuries include tumors and aneurysms.[85]

Finally, the axillary nerve can be damaged as a result of an iatrogenic injury during surgical procedures. Open shoulder stabilization procedures, for example, involve exploration of the inferior glenohumeral joint and may place the nerve at risk for injury as it courses along the inferior glenoid rim. Potential mechanisms of injury include tension, suture compression, or direct laceration.[66] In a series of 40 patients who underwent inferior capsular shift procedures, Neer and Foster reported three cases of axillary neurapraxias despite careful protection of the nerve during the surgery.[64] To decrease the likelihood of an iatrogenic axillary nerve injury, some authors have recommended placing the shoulder in external rotation such that capsular incision can be placed more laterally. They also recommended that a blunt retractor be placed superior to the nerve to protect it from sharp instruments.[66] Recently, use of the subscapularis splitting technique has become popular as a method of limiting axillary nerve injury during anterior shoulder stabilization procedures.[47,58] One study examining the use of the subscapularis splitting approach found that only 1 of 128 patients had a temporary axillary neuropathy, and that none had any permanent deficit.[58]

Other commonly performed procedures that have been associated with axillary nerve injuries include open rotator cuff repairs and various arthroscopic procedures. The axillary nerve is vulnerable to injury during open rotator cuff repair surgery if the deltoid splitting approach is used and if this split is carried too inferiorly. As described previously, most surgeons limit the deltoid splitting to within 5 cm of the acromion as the axillary nerve is typically located inferior to this interval.[66] If the deltoid split is carried out more anteriorly, this safe interval of splitting may need to be shortened, as one cadaveric study found that terminal branches course more superiorly in the anterior deltoid.[11] During arthroscopic procedures, the axillary nerve can be injured during the creation and the establishment of a posterior portal. During normal placement of the posterior portal, the trocar may be only 5 to 25 mm from the nerve.[11] As such, the portal must be placed carefully using normal anatomic landmarks. Fortunately, despite this close proximity to the nerve, the incidence of axillary nerve injury after arthroscopy is believed to be quite rare.[2]

Clinical Symptoms

In traumatic situations, patients tend to focus on the primary injury. Therefore, subjective weakness and sensory deficits may be ignored or disregarded in the acute setting. When pain from the initial trauma has subsided, complaints regarding persistent weakness and numbness are voiced. Even in this stage, however, the clinical presentation of axillary nerve injuries can be quite variable. Patients may complain of weakness, numbness, or a combination of both. Although an isolated sensory defect is more common, an isolated motor deficit with normal sensation is also possible. Additionally, these deficits may be complete or partial.[9]

Similar to above, clinical presentation of nontraumatic axillary nerve injuries can also be quite variable. Patients may present with varying degrees of pain, numbness, and weakness that can be insidious or acute in onset. In QSS, for example, patients will often complain of chronic, dull, and aching pain in the posterolateral aspect of the shoulder and arm. This may be associated with subjective deltoid weakness, which can then progress to clinical weakness.[14,66,85] Parsonage-Turner syndrome, in contrast, will present as an episode of severe posterior shoulder pain without prior trauma. The pain is usually short-lived and resolves spontaneously. Upon its resolution, the patient will then develop profound weakness.[89] Although the symptoms may be limited to the axillary nerve, in most cases, Parsonage-Turner syndrome will involve multiple branches of the brachial plexus.

Clinical Evaluation

To document or eliminate the possibility of cervical radiculopathy or brachial plexopathy, patients with a suspected axillary nerve injury should undergo a thorough cervical spine and upper-extremity examination. As a part of the initial inspection, any particular asymmetry in the shoulder contour should be noted. Although acute axillary nerve injuries may not demonstrate changes, chronic denervation can be associated with significant deltoid atrophy (Fig. 36-8). Particular attention should be given to identifying specific denervation patterns as they may suggest the location of the injury. Thus, for example, specific atrophy of the lateral and anterior deltoid muscle with normal posterior deltoid would suggest a lesion distal to the quadrangular or quadrilateral space.

Sensory examination should concentrate on the distribution of the superior lateral cutaneous nerve. Sensation to light touch as well as pinprick should be documented. It should be noted that axillary nerve injuries with motor deficit can exist with intact sensation.[9] Although most patients with an axillary nerve injury do not demonstrate any focal tenderness, patients with chronic QSS may exhibit some tenderness on the posterior aspect of the shoulder joint.[85]

All motion of the shoulder joint should then be examined. Both passive and active motion must be documented. Although axillary nerve injuries should not cause any loss of passive motion, some patients with a chronic lesion may demonstrate mild stiffness in the shoulder. Strength testing should be performed for shoulder flexion, extension, rotation, and abduction. The deltoid muscle plays a significant role in shoulder abduction, but only a minor role in flexion and extension and a minimal role in

Figure 36-8 Clinical picture of deltoid muscle atrophy due to an axillary nerve lesion at the quadrangular space. Note that the overall contour is lost from both anterior **(A)** and posterior **(B)** aspect of the shoulder.

shoulder rotation. Therefore, shoulder abduction strength and endurance is most often affected in patients with axillary nerve injuries. Selective axillary nerve block studies have demonstrated that the deltoid muscle is responsible for approximately 50% of the generated torque about the shoulder.[19] Nevertheless, studies have also shown that most patients can compensate for the loss of deltoid function. By adapting the use of other shoulder musculature, including the rotator cuff, pectoralis major, and coracobrachialis muscles, full active motion may be possible.[4,12,25,66,85] Thus, full active motion of the shoulder does not eliminate the possibility of a nerve injury.

Electrodiagnostic Studies

A clinical suspicion for an axillary nerve injury should be confirmed with electrodiagnostic studies. Increased latency on the nerve conduction velocity examination can confirm a nerve injury. In addition, EMG changes such as increased spontaneous activity, polyphasic signals, muscle fibrillations, and amplitude reduction may demonstrate muscle denervation.

Once obtained, these studies can provide valuable insight into the location of the lesion as well as any associated brachial plexus injuries. They can also establish a reference point to assess recovery. For acute cases with no clinical evidence of recovery, these tests should be performed within 2 to 4 weeks from the injury.[85] For chronic cases, they should be obtained as a part of the initial evaluation. The studies should then be repeated after a period of 3 to 4 months to identify any signs of recovery.

Imaging Studies

All patients should obtain standard radiographs of the shoulder and cervical spine to rule out any abnormal osseous anatomy.[85,95] If a bony abnormality is suspected, CT scans should be considered, as they can further characterize the bony anatomy. In the majority of patients with an axillary nerve lesion, however, the bony architecture will be unremarkable.

Analysis of the soft tissues can be greatly aided by MRI and, therefore, this study is generally recommended for patients with a suspected axillary nerve injury. Soft tissue masses that are compressing the axillary nerve can be visualized with an MRI. In addition, for chronic nerve injuries, involved muscles will demonstrate abnormal signal changes consistent with atrophy and fatty infiltration.[88] In patients with QSS, for example, the teres minor and the posterior deltoid muscles should demonstrate such changes.[55] The diagnosis of QSS can then be confirmed with a subclavicular arteriogram, which will show limited flow through the posterior circumflex humeral artery with shoulder abduction and external rotation.[14,31]

Nonoperative Treatment

Based on the available information in the literature, the natural history of axillary nerve lesion appears to be quite variable. For example, injuries associated with glenohumeral dislocations have rates of recovery that vary from 17% to 100%.[34,54,87,92] Nerve injuries from blunt trauma to the shoulder tend to exhibit less favorable recovery rates.[66]

Penetrating injuries and traumatic avulsion injuries possess even less favorable outcomes. Nevertheless, some patients with persistent axillary injuries can compensate sufficiently to obtain full active motion and the ability to perform activities of daily living. Therefore, nonoperative management of axillary nerve injuries should be the initial treatment of choice in most patients.

After the acute phase of injury, with dissipating pain, range-of-motion exercises can commence. Restoration of motion and avoidance of contractures are essential to obtaining a good outcome. For patients with other shoulder pathology such as rotator cuff tear or a fracture, regaining full motion can be a difficult task.[66] Once the overall level of pain and motion has been stabilized, strengthening exercises can begin. These exercises are utilized to augment the power provided by the remaining musculature of the shoulder girdle. As such, the regimen should concentrate on the rotator cuff muscles as well as the scapula stabilizers. Although these general principles are clear, no single rehabilitation protocol has gained universal acceptance in the nonoperative treatment of patients with axillary nerve injuries. Therefore, specific rehabilitation protocol and physical therapy must be individualized to each patient and injury pattern.

Operative Treatment: General Principles

Operative management of axillary nerve injuries is typically reserved for patients who remain symptomatic and demonstrate no evidence of recovery based on both the clinical examination and the repeated electrodiagnostic studies. Although a general consensus does not exist, surgical intervention can also be considered after an acute penetrating injury. The type of surgery is dictated by multiple factors including patient expectations, likelihood of recovery, nature of the injury, location of the lesion, and chronicity of the symptoms. As such, a number of different procedures such as decompression, neurolysis, grafting, neurotization, and muscle transfers have been used with varying degrees of success. Therefore, as stated previously, the choice for a specific procedure must be individualized to each patient and injury pattern.

Operative Treatment: Decompression

Axillary nerve decompression is utilized in situations where a discrete compressing structure can be identified. Thus, this is typically the procedure of choice for patients with QSS. Although other surgical approaches are available, the quadrilateral space is best exposed using the posterior approach (Fig. 36-9). The skin incision starts just medial to the posterior axillary crease and parallels the inferior border of the scapular spine. Once past the axillary crease, the incision is then curved distally along the posterior aspect of the humerus. Full-thickness skin flaps are then raised to expose the deltoid fascia. The posterior deltoid muscle is then released from its origin on the scapula spine. During closure, this muscle must be adequately repaired back onto its origin, using bone tunnels if necessary. After reflecting the posterior deltoid muscle, the underlying rotator cuff muscles are exposed. The inferior border of the teres minor is carefully dissected and the entire muscle is then retracted superiorly. An alternative approach is to release a portion of the teres minor from the greater tuberosity and then reflecting it medially. Although most surgeons would repair the released tendon back onto its insertion on the greater tuberosity during closure, Cahill and Palmer noted no postoperative weakness even when the tendon was not repaired.[14] Once the neurovascular structures are identified, they are isolated and safely retracted out of the surgical field. All borders of the quadrilateral space, including its anterior compartment, should then be explored to identify any compressing lesions. After excising these lesions, the posterior humeral circumflex artery can be palpated while the arm is abducted and externally rotated. Adequate decompression is thought to be achieved only if the pulse remains in this position. Using this similar exposure, surgeons have also performed neurolysis of the axillary nerve in patients whose nerve was encased and compressed by fibrotic scar tissue.[68]

Operative Treatment: Nerve Grafting or Neurotization

In cases of acute lacerations, neurorrhaphy may be performed. By several weeks after the injury, however, retraction and scarring of the nerve endings may preclude a primary end-to-end repair. In addition, in patients with a blunt trauma that requires excision of a nerve segment or in patients where a neuroma had to be excised, a significant gap may be present between the nerve endings. In these situations, rather than trying to mobilize the remaining nerve, which has minimal excursion, nerve grafting may be the best available surgical option. As expected, exposure for this procedure is dependent on the site of the injury. In patients whose nerve deficit is likely to reside within the quadrilateral space, a combined anterior and posterior approach to the nerve may be necessary. For this exposure, the patient is placed in a lateral decubitus position. The posterior approach is performed in a manner described previously. For the anterior approach to the quadrilateral space, a skin incision is made along the anterior border of the clavicle and then curved distally along the deltopectoral interval. The deltopectoral interval is then developed to expose the subscapularis muscle. The neurovascular bundle can be readily identified in the anterior quadrilateral space just inferior to the glenohumeral joint on the inferior border of the subscapularis muscle. If needed, the pectoralis minor

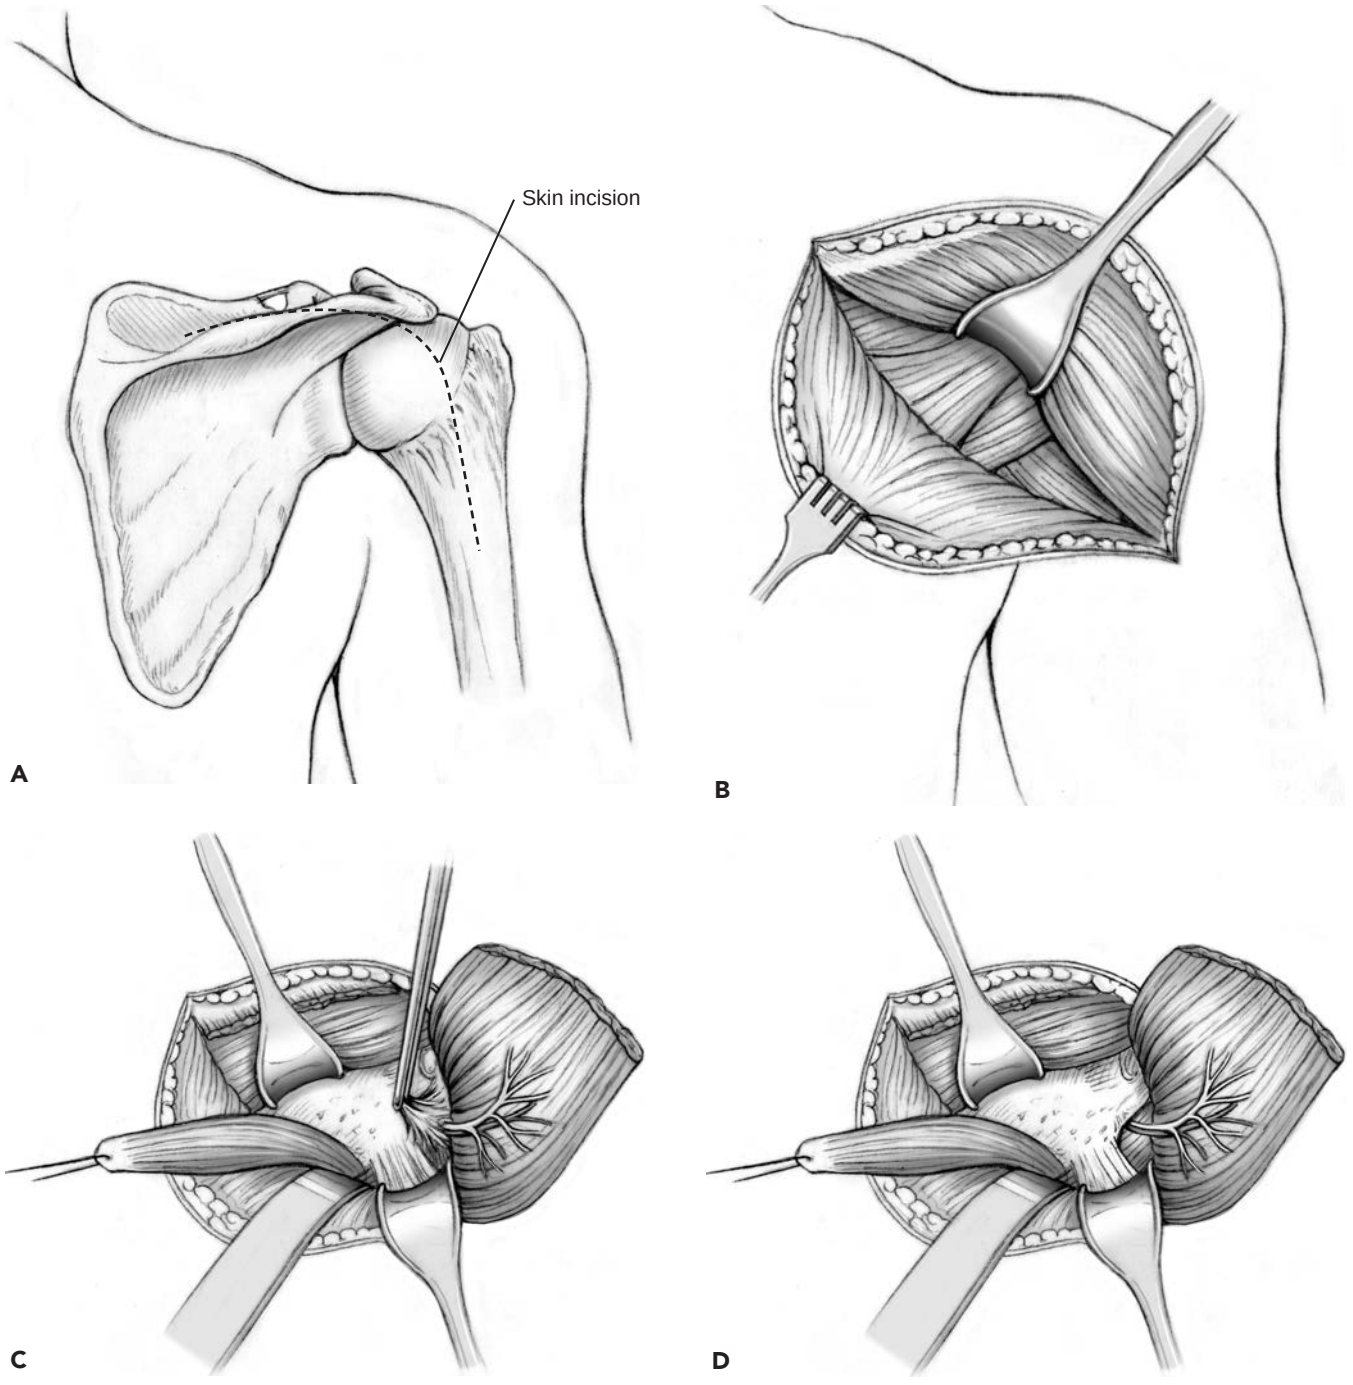

Figure 36-9 Surgical approaches for axillary nerve decompression at the quadrangular space (refer to text for details).

muscle can be detached from the coracoid process and reflected medially to expose the origin of the axillary nerve from the posterior cord.[68] The released pectoralis minor should be anatomically repaired during closure. After identifying this origin, the nerve can then be traced to its location on the entrance of the quadrilateral space. Once the lesion is identified and the gap is estimated, a nerve graft of appropriate length is obtained. Although multiple sources of autologous nerve grafts are available, most surgeons favor the use of sural nerve grafts. The graft is then sutured on to the nerve endings. Care must be taken to ensure that minimal tension is placed on the repair throughout all shoulder motion.

With a similar surgical exposure, some surgeons have performed neurotization of the axillary nerve with mixed results.[17,23] These procedures have been performed

with a number of different graft sources that include the thoracodorsal, spinal accessory, and intercostal nerves. Recently, an anatomic dissection study and case series have presented a new technique of transferring a branch of the radial nerve that normally innervates the long head of the triceps into the anterior branch of the axillary nerve.[53,94] The cadaveric study demonstrated that the nerve to the long head of the triceps muscle could be reliably identified and transferred with minimal morbidity. Histologic analysis also showed that the diameter and the number of axons of the donor nerve were roughly equivalent to the recipient nerve.[94] Although long-term follow-up data from the clinical case series are still lacking, early results of this technique have demonstrated promising outcomes.[53] Thus, neurotization may provide an acceptable alternative to nerve grafting in some patients with isolated axillary nerve injuries.

Operative Treatment: Muscle Transfers

Patients with chronic axillary nerve injuries may demonstrate significant muscular changes such as atrophy and fatty degeneration. In these patients, procedures that repair or restore the nerve function will be of limited benefit. In these select cases, a muscle transfer procedure can be considered. The type of muscle transfer is dependent on the nature of the functional deficit. If, for example, only a portion of the deltoid activity is lost, the remaining portion of the muscle can be transferred to restore the lost function.

If the entire deltoid muscle is denervated, the trapezius can be transferred distally onto the proximal humerus. Originally described by Bateman[7] and then subsequently modified by Saha,[79] this technique involves a saber incision along the scapular spine. The incision is curved anteriorly along the acromion to expose the entire trapezius insertion including the distal clavicle. Bony cuts in the acromion and the clavicle are then made to release the entire muscle insertion. After mobilizing the trapezius muscle, its bony insertions are transferred onto the proximal humerus and fixed with screws. In this fashion, the insertion of the trapezius muscle is transferred distally to augment shoulder abduction and flexion. By transferring the insertion on the anterior or posterior aspect of the humerus, shoulder rotation may also be restored.[79]

Another structure that has been used as a donor for muscle transfer procedure is the latissimus dorsi.[46,63,85] Advocates of this procedure argue that the muscle provides a more physiologic lever arm for flexion, restores normal shoulder contour, and does not disrupt the coracoacromial arch.[46] The original technique described by Itoh and colleagues involves three separate incisions: (1) laterally on the anterior border of the latissimus dorsi to isolate and harvest the muscle; (2) anterolaterally on midhumerus to expose the deltoid insertion site; and (3) superiorly along the acromion and the distal clavicle to isolate the deltoid origin. Alternatively, in addition to the posterior incision for the latissimus dorsi muscle, a single extended incision can be made in the anterior aspect of the shoulder to expose the deltoid in its entirety (Fig. 36-10). Patients are placed in the lateral decubitus position with the entire arm draped free. First, the latissimus dorsi muscle is isolated in its entirety. While preserving its neurovascular pedicle, the muscle is harvested by releasing its origin and insertion. Next, a bed for the muscle transfer is created by exposing the native deltoid muscle. Tunnels are then created deep and superior to the pectoralis major tendon. Through this tunnel, the latissimus dorsi muscle is transferred to the anterior aspect of the shoulder without disturbing its neurovascular pedicle. The muscle is rotated such that its broad origin lies superiorly along the acromion and the distal clavicle. Its tendinous insertion is then laid on top of the deltoid insertion on the midhumerus. The muscle is tensioned with the arm held in 70 to 80 degrees of flexion and then attached to the underlying deltoid muscle or to the bone using bone tunnels. Although this procedure has not been commonly performed, early reports and anecdotal experience demonstrate that some selective patients can recover near-normal function of their shoulders.[46,63]

Postoperative Considerations

During the immediate postoperative period, the type and duration of immobilization can vary widely depending on the performed procedure. As such, recommendations for postoperative immobilization have varied from a simple sling[85] to a Desault-type cast.[68] Recommendations for the duration of immobilization has similarly varied from 1 week to 2 months.[66,68] In general, more reconstructive procedures will require a prolonged period of immobilization to allow healing. Thus, for example, muscle transfer procedures typically require a more rigid immobilization (splint or spica cast) for longer duration in a position that minimizes tension across the fixation sites.

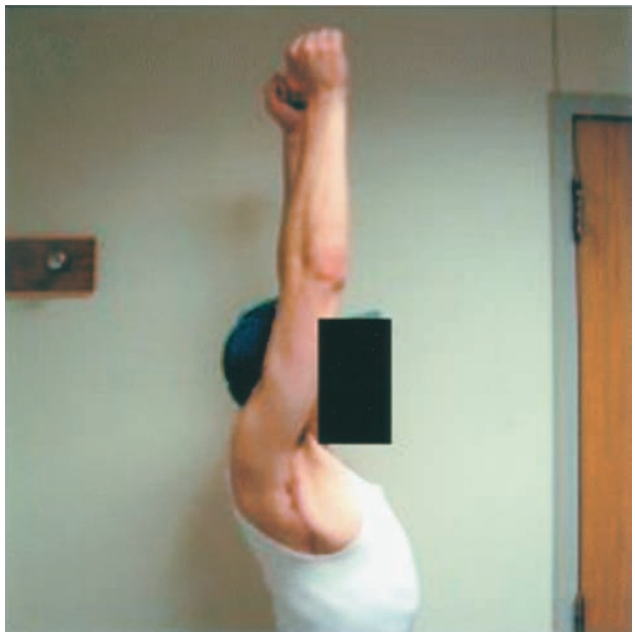
After the initial period of immobilization, passive exercises are initiated to restore shoulder motion. This also minimizes the formation of scar tissue that can encapsulate the decompressed or grafted nerve. Subsequently, active-motion exercises are gradually instituted. Although supervised physical therapy can be very useful, it is crucial to stress to the patients that they are responsible for their own rehabilitation and to perform some of these exercises on a daily basis as a home regimen. Depending on the type of the lesion and the surgical procedure, sensation may gradually return over 3 to 6 months. Strength may be regained in a similar period, but occasionally may take 12 months or longer until maximal strength is restored.[3,14,17,18,31,46,63,66,68]

Figure 36-10 Latissimus dorsi muscle transfer for a 21-year-old male with a permanent axillary nerve injury demonstrated in figure 36–8. After isolating the latissimus dorsi muscle (*arrow*), it is released from its insertion and origin. The muscle is then transferred and laid directly over the atrophied deltoid muscle **(A).** During the transfer, the neurovascular pedicle to the muscle is isolated and protected during the procedure **(B).** Six months after the procedure, the patient exhibits restoration of normal shoulder contour **(C),** abduction **(D),** elevation **(E),** and external rotation **(F).**

Results and Complications

For surgical procedures that directly address the axillary nerve, the best outcomes have been reported when they are performed during the early period. Therefore, most authors suggest that decompression, neurolysis, nerve grafting, and neurotization all possess the highest rates of success if they are performed within the first 6 months of the injury. However, there have also been some reports of good functional improvement in patients with intervention within 1 year of injury. In general, surgery delayed beyond 1 year is believed to be associated with suboptimal outcomes.[18,59,68]

The nerve decompression procedure for QSS is generally associated with a good outcome. Francel et al., for example, reported that all five patients in their series



E

F

Figure 36-10 *(continued)*

experienced improved motion, pain relief, and sensation.[31] In a larger series of patients, Cahill and Palmer noted that only 2 of the 18 patients demonstrated no improvement after the procedure. Of the remaining 16 patients, half of them were completely asymptomatic, while the other half experienced occasional night pain only.[14] Despite these generally good outcomes, as the pathophysiology of this diagnosis is not well understood, some authors still recommend that the procedure be reserved for patients whose symptoms are refractory to nonoperative treatment.[66]

Similar to nerve decompression, neurolysis and nerve grafting procedures are also associated with generally favorable outcomes. Coene and Narakas reported on 27 patients who underwent exploration, neurolysis, and, if necessary, nerve grafting within 6 months of the injury. They found that nine patients recovered full strength while another nine patients recovered to one grade less than full strength. Those who only underwent a neurolysis procedure fared slightly better as 10 of these 13 patients were able to regain either full strength or one grade less than full strength at follow-up. Delaying surgery 1 year or more after the injury resulted in inferior outcomes. Five of these six patients experienced significant residual weakness and less functional recovery than their counterparts who underwent early surgical intervention.[18] In another series of 12 patients who were treated with nerve grafting or neurolysis, Artico et al. reported 50% good and 50% excellent results. They found no difference in the final outcome between the two procedures.[3] Petrucci et al. reported similar success with treating patients with sural nerve grafts, as they noted that eight of the nine patients were able to regain either full strength or one grade less than full strength at a minimum follow-up of 1 year.[68]

Leechavengvongs et al. reported on a series of seven patients who underwent neurotization of the anterior deltoid with the nerve to the long head of the triceps. All patients achieved significant functional recovery with a mean abduction of 124 degrees and all attaining four out of five motor strength. Additionally, there were no subjective complaints regarding any functional deficit from the donor site.[53] Despite these early promising results, however, more long-term outcome data are needed to establish the efficacy of this procedure.

Muscle transfer procedures are typically used to treat patients whose axillary nerve lesion has resulted in a significant and permanent deterioration of the deltoid muscle. As such, it may be expected that these patients experience outcomes that are generally inferior in comparison to those whose nerve lesions have been directly addressed. Itoh et al. reported on 10 cases of latissimus dorsi muscle transfer for deltoid paralysis and found that only six were able to obtain active flexion greater than 90 degrees. Upon further analysis, they noted that the final outcome corresponded with the preoperative function of the rotator cuff muscles. As such, they suggested that concomitant rotator cuff pathology is a relative contraindication for the latissimus dorsi transfer procedure.[46] Subsequently, Narakas modified this procedure by transferring both the latissimus dorsi and the teres major muscle. The latissimus dorsi was still transferred to the anterior deltoid while the teres major was simultaneously transferred onto the infraspinatus

tendon. He noted that the teres major muscle transfer portion of the procedure provided better visualization and mobilization of the latissimus dorsi neurovascular pedicle. Of the six patients who underwent this procedure, five exhibited good to excellent active abduction.[63]

SUMMARY

Injuries to the suprascapular and axillary nerves can have profound effects on shoulder function and cause significant pain and discomfort. Once diagnosed, the prognosis appears to be dependent on the cause and severity of the lesion. Although a trial of nonoperative management is generally recommended for most patients, surgical intervention may be required for a select population of patients. Depending on the cause of the lesion, several procedures exist to correct the pathology and restore nerve function. With appropriate counseling and treatment, a favorable outcome can be achieved for most patients.

AMPUTATION 1198

INTRODUCTION

Each bone of the shoulder girdle—the proximal humerus, the scapula, and the clavicle—can give rise to a primary bone tumor or be involved by an adjacent soft tissue sarcoma.[1] The proximal (upper) humerus is one of the most common sites for high-grade malignant bony tumors in both adults and children, and it is the third most common site for osteosarcomas. Chondrosarcomas also commonly involve the shoulder girdle, often arising from the scapula or the proximal humerus. The bones of the shoulder girdle may also be involved secondarily by high-grade soft tissue sarcomas or metastatic tumors that often require resections similar to those used in the treatment of high-grade primary bony sarcomas. Metastatic tumors often involve the shoulder girdle, and because of the extent of bony destruction and the presence of large extraosseous components, the treatment is sometimes similar to that for primary malignant bony sarcomas. For example, hypernephromas (renal cell carcinomas) have a unique propensity to involve the proximal humerus, often as a solitary metastasis. They commonly result in extensive bony destruction with a large soft tissue component.

Three Phases of Surgical Resection

The surgical treatment of a malignant bony tumor involving the shoulder girdle consists of three stages: (a) wide surgical resection of the tumor, (b) reconstruction of the skeletal defect, and (c) multiple muscle transfers to provide soft tissue coverage, stabilize the shoulder girdle, and restore function to the upper extremity.

The aim is to provide a stable shoulder and preserve a functional elbow and hand. Each of the various surgical techniques currently in use for reconstruction of a segmental defect of the humerus or shoulder girdle offer some degree of stability, function, durability, range of motion, and preservation of motor power.

CLASSIFICATION OF SHOULDER-GIRDLE RESECTIONS

Malawer et al. have developed a six-stage surgical classification system.[3] This system is based on current concepts of surgical margins, the relationship of the tumor to anatomic compartments (i.e., intracompartmental vs. extracompartmental), the status of the glenohumeral joint (intraarticular vs. extraarticular), the magnitude of the individual surgical procedures, and the presence or absence of the abductor mechanism (deltoid muscle, rotator cuff muscle, or both).

The six-stage classification is as follows (Fig. 37-1):

Type I: Intraarticular proximal humeral resection
Type II: Partial scapular resection
Type III: Intraarticular total scapulectomy
Type IV: Intraarticular total scapulectomy and humeral head resection
Type V: Extraarticular humeral and glenoid resection
Type VI: Extraarticular humeral and total scapular resection

Each of the six types is further modified according to a major variable: the presence or absence of the main motor group, the abductor mechanism (i.e., deltoid and rotator cuff muscles). The abductors are either present (subtype A) or partially or completely resected (subtype B). The abductor mechanism is almost always resected when there is extraosseous extension of a bone tumor in this area. The loss of any component of the abductor mechanism tends to create a similar functional disability. Regardless of histology or primary bone involvement, subtype A generally entails an intracompartmental resection, and subtype B an extracompartmental resection (Table 37-1).

TUMOR GROWTH AND ANATOMY

Sarcomas, which arise from mesenchymal tissues (mesodermal embryonic layer), grow in a centripetal manner and form ball-like masses and compress surrounding muscle into a pseudocapsule layer. Sarcomas typically respect fascial borders and generally grow along the path of least resistance. This growth pattern is in contrast to that of carcinomas, which are invasive and usually penetrate compartmental borders. The pseudocapsule layer contains microscopic, finger-like projections of tumor referred to as satellite nodules. Sarcomas spread locally along the path of least resistance. Surrounding fascial layers resist tumor penetration and provide boundaries to local sarcoma growth. These boundaries

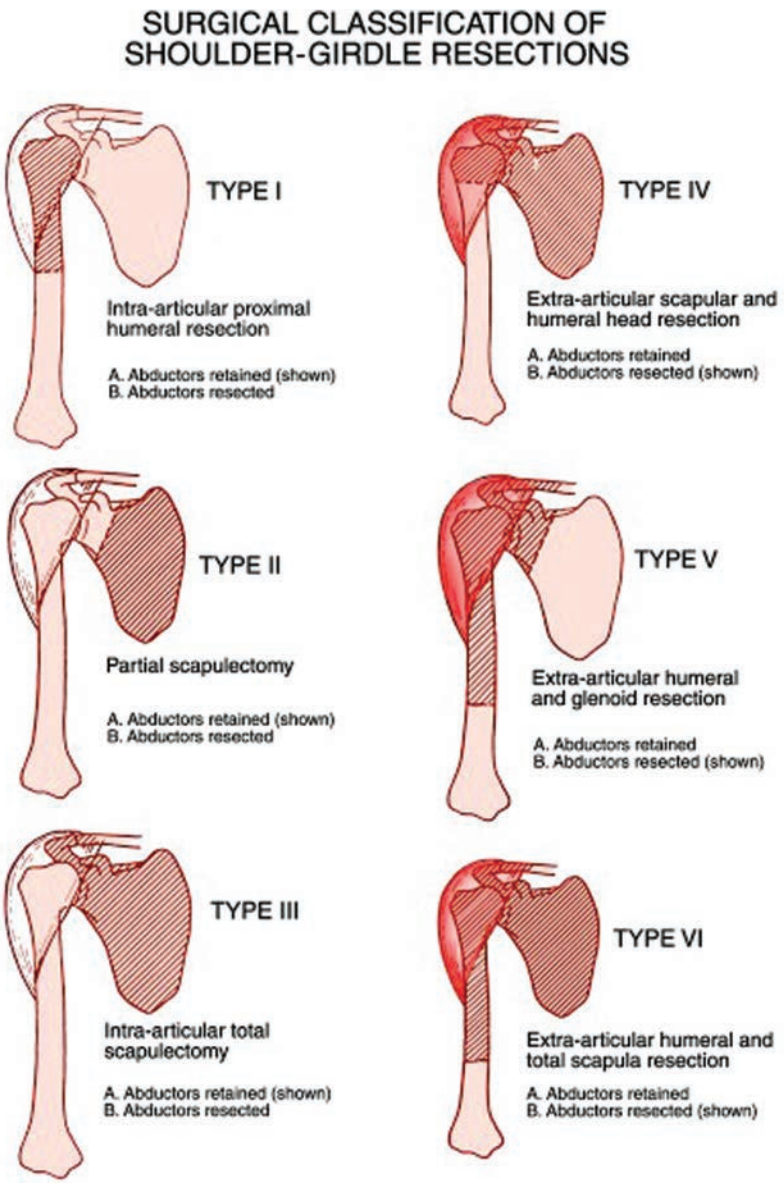

Figure 37-1 Surgical classification of shoulder girdle resections. Shoulder girdle resections are classified as type I to type VI. In general, types I to III are performed for benign or low-grade tumors of the shoulder girdle, whereas types IV to VI are performed for high-grade malignant tumors. In the schematic key, A = abductor muscles retained, whereas B = abductor muscles resected. The main abductors of the shoulder girdle include the rotator cuff musculature and the deltoid muscle. In general, these muscles are resected with high-grade tumors but are retained with low-grade tumors. (From Malawer MM, Meller I, Dunham WK. A new surgical classification system for shoulder-girdle resections. Analysis of 38 patients. *Clin Orthop* 1991;(267):33–44.)

form a compartment around the tumor. A sarcoma will grow to fill the compartment in which it arises; only rarely does a sarcoma extend beyond its compartmental boundaries. With reference to bony sarcomas that extend beyond the cortices into the surrounding soft tissues, the term "functional anatomic compartment" refers to the investing muscles that are compressed into a pseudocapsular layer. These muscles provide the fascial borders of the compartment, which has important surgical implications. A wide resection (i.e., compartmental resection) of a bone sarcoma entails removal of the entire tumor and pseudocapsular layer and must therefore encompass the investing normal muscle layers.

The functional compartment surrounding the proximal humerus consists of the deltoid, subscapularis, and remaining rotator cuff musculature, latissimus dorsi, brachialis, and portions of the triceps.

High-grade sarcomas that extend beyond the bony cortices of the proximal humerus involve and compress the investing muscles that form the compartmental borders and pseudocapsular layer. They grow along the path of least resistance and therefore are directed toward the glenoid and scapular neck by the rotator cuff and the glenohumeral joint capsule. Anteriorly, the tumor is covered by the subscapularis, which bulges into and displaces the neurovascular bundle (axillary vessels and brachial plexus). Only rarely does a proximal humerus sarcoma extend beyond the compartmental borders. In these instances, the tumor usually protrudes through the rotator interval. A wide resection for a high-grade sarcoma must therefore include the surrounding muscles that form the pseudocapsular layer, the axillary nerve, the humeral circumflex vessels, and the glenoid (extraarticular resection).

Most high-grade scapular sarcomas arise from the region of the scapular neck and body. The compartment consists of all of the muscles that originate on the anterior and posterior surfaces of the scapula. Although not one of the compartmental borders, the deltoid, which attaches to a narrow region of the scapular spine and acromion, may be involved secondarily by a large soft tissue extension. In most cases, the deltoid is protected by the rotator cuff muscles. Because the anatomic origin of most tumors is in the neck, the rotator cuff muscles are compressed into a pseudocapsular layer by sarcomas that arise from the scapula. The subscapularis also protects the neurovascular bundle from tumor involvement. The head of the proximal humerus is contained within the compartment surrounding the scapula. The tumor follows the path of least resistance and typically crosses the glenohumeral joint, grossly or microscopically, to involve the humeral head. Direct tumor extension through joints or articular cartilage is rare and typically occurs as the result of a pathologic fracture. Because of the small size of the glenohumeral joint, the tumor almost always involves the capsule or the synovium. The long head of the biceps tendon, which is intraarticular, is another pathway by which the tumor may cross the joint. Wide resection of a high-grade scapula sarcoma must therefore include the rotator cuff and, in most instances, the humeral head.

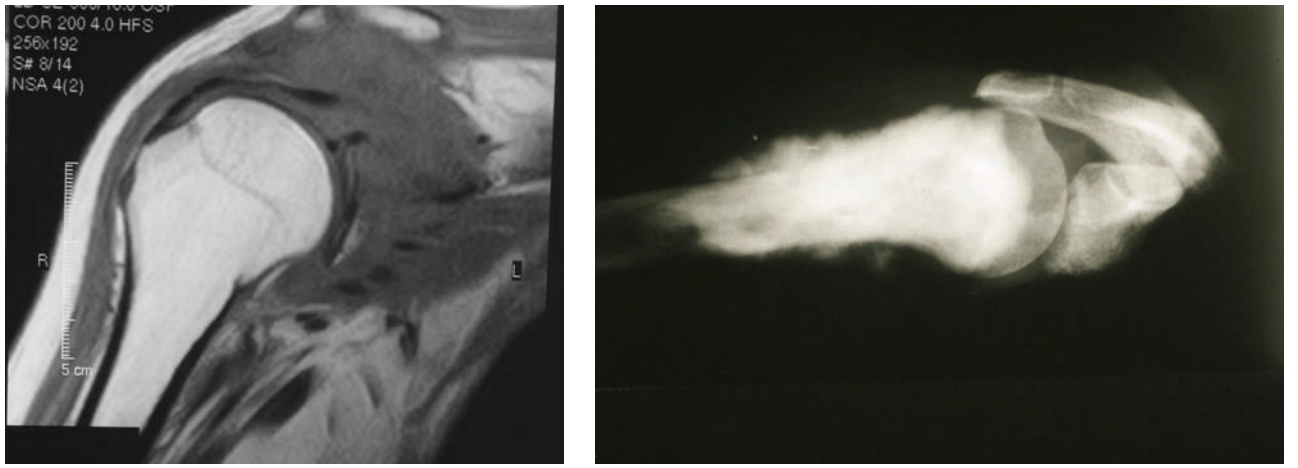
INTRA- VERSUS EXTRAARTICULAR TUMOR EXTENSION

The shoulder joint appears to be more prone than other joints to intraarticular or pericapsular involvement by high-grade bone sarcomas. Figs. 37-2 and 37-3 show the mechanisms of tumor spread. Direct capsular extension, direct tumor tracking along the long head of the biceps, a poorly planned biopsy, and pathologic fracture are mechanisms of glenohumeral contamination and make intraarticular resection for high-grade sarcomas a higher risk than extraarticular resection for local recurrence. A local recurrence in this region often requires a forequarter amputation and may compromise patient survival. (This is in contrast to most clinical experience with resections of the distal femur, which tend to be intraarticular.) Therefore, extraarticular resection is recommended for most high-grade sarcomas of the proximal humerus and scapula.

CLINICAL EVALUATION

History and Physical Examination

Patients with bone sarcomas typically present to their primary care physician with complaints of a dull, aching pain of several months' duration. They often seek medical intervention because the pain has become more severe. This increased pain can be correlated with tumor penetration of cortical bone, irritation of the periosteum, or pathologic fracture. Severe night pain in the affected extremity is common. Some patients may describe regional tenderness, difficulty in moving the arm, or a palpable swelling or mass. Physical examination of the extremity usually confirms the presence of a mass or regional swelling and deformity. Children are especially susceptible to referred pain; for this reason, all regional joints should be examined.



A B

Figure 37-2 **(A)** Magnetic resonance imaging (MRI) scan showing gross tumor involvement within the joint (T1-weighted MRI image). **(B)** Radiograph of an extraarticular resection of the proximal humerus for osteosarcoma. Note that the proximal humerus, glenoid, and distal one-third of the clavicle have been resected en bloc. This procedure is classified as a type VA resection (Malawer classification). Extraarticular resection is often required for high-grade sarcomas of the proximal humerus.

The presenting symptoms for a soft tissue sarcoma are different and nonspecific. Typically, the mass presents as a slow-growing, painless lesion. Tumors arising in the upper extremity are more palpable and identified earlier than those in the lower extremity.

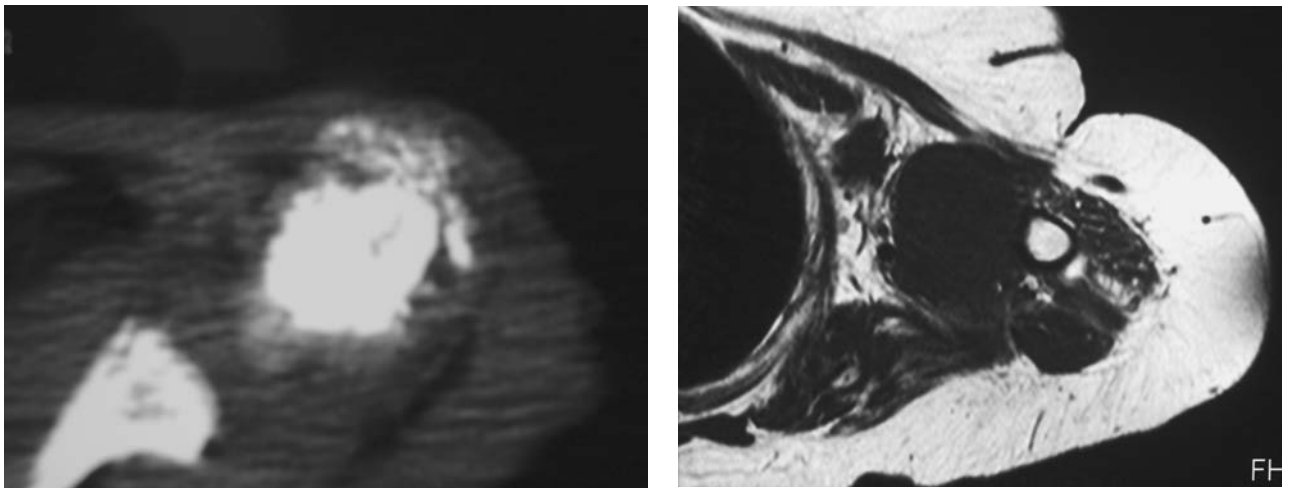
Specialist Referral

All patients with suspected malignancies should be referred to an orthopedic oncologist or a cancer center. A multidisciplinary team approach for patients with malignant tumors is essential to providing the best possible clinical outcome. Patients with aggressive benign tumors (i.e., giant cell tumor, chondroblastoma, or enchondroma) should also be referred.

Unique Anatomic and Surgical Considerations

The local anatomy of a sarcoma determines the extent of the operative procedure required. The following discussion addresses unique considerations of shoulder girdle anatomy that are relevant to surgery in this area.

- The glenohumeral joint generally does not serve as an effective barrier to tumor spread. A lesion may cross the joint by direct extension or indirect mechanisms, as



A B

Figure 37-3 **(A)** Computed tomography scan of the glenohumeral joint showing destruction of the glenohumeral joint by tumor. The typical mechanism of intraarticular involvement by tumor is via direct extension and by capsular involvement. **(B)** Magnetic resonance imaging (MRI) scan demonstrating large tumor component adjacent to the proximal humerus with an adjacent skip nodule or enlarged axillary lymph node. MRI scans of the shoulder girdle are essential in evaluation of neoplastic lesions.

shown (Figs. 37-2 and 37-3). It is often necessary to perform an extraarticular resection for high-grade bone sarcomas of the proximal humerus or the scapula (glenoid region).

- The three major cords of the brachial plexus are in close proximity to the subscapularis muscle, glenohumeral joint, and proximal humerus. Tumors involving the upper scapula, the clavicle, and the proximal humerus often displace the infraclavicular component of the brachial plexus. It may be necessary to sacrifice some of the major nerves if they are encased by neoplasm, or a forequarter amputation may be required.
- The musculocutaneous and axillary nerves are often in contact with or in close apposition to tumors around the proximal humerus, and before proceeding with resection it is necessary to clearly identify both. It is crucial to preserve the musculocutaneous nerve to preserve a functional elbow. The musculocutaneous nerve generally comes from beneath the coracoid and passes through the conjoined tendon or coracobrachialis muscle within a few centimeters of its origin. The position of this nerve does vary, however, and it may lie within 2 to 8 cm of the coracoid. It then passes through the short head of the biceps and into the long head of the biceps before innervating the brachialis muscle.
- The axillary nerve is closest to most large tumors of the proximal humerus. It arises from the posterior cord and, along with the circumflex vessels, courses around the subscapularis muscle and the head and neck of the humerus to innervate the deltoid posteriorly. In patients who have large malignant tumors of the proximal humerus, the axillary nerve usually must be resected because of tumor proximity or involvement, and because it is necessary to remove the deltoid muscle and glenoid to provide a satisfactory margin. With large stage IIB bone sarcomas of the proximal humerus, the axillary nerve and deltoid muscles can rarely be preserved. In contrast, the axillary nerve is usually not involved by scapular tumors and therefore can be preserved along with the deltoid muscle. This allows for functional anatomic reconstruction of the scapula with a prosthetic replacement.
- The brachial artery is surrounded by the three major cords of the brachial plexus and is tethered to the proximal humerus by the anterior and posterior circumflex vessels. A presurgical angiogram is extremely useful to localize the brachial artery and identify the level of the circumflex vessels. Occasionally, one finds anomalous brachial and axillary arteries that would be difficult to identify and explore if not recognized preoperatively. In general, the circumflex vessels are ligated during the initial dissection; this allows the entire axillary artery and the vein and brachial plexus to fall away from the tumor mass. Early ligation of the circumflex vessels is key to the resection of proximal humeral sarcomas.
- The radial nerve courses along the posterior aspect of the axillary sheath and exits from the posterior cord at the inferior border of the latissimus dorsi muscle. Fortunately, most sarcomas are located in the proximal third of the humerus and do not involve this nerve. However, to avoid injury the radial nerve must be isolated and protected prior to tumor resection. Sacrifice of the radial nerve is rarely necessary.

PREOPERATIVE EVALUATION AND IMAGING STUDIES

Appropriate imaging studies are crucial to successful resection of tumors of the shoulder girdle (Fig. 37-4). The most useful preoperative evaluations are computed tomography (CT), magnetic resonance imaging (MRI), arteriography, and three-phase bone scans. For large tumors of the proximal humerus, a venogram may be warranted if there is clinical evidence of distal obstruction.

Computed Tomography

CT is more useful than MRI in determining cortical bone changes, and it is considered complementary to MRI in evaluating the chest wall, clavicle, and axilla. CT is useful for determining the planes of tumor resection. Subtle cortical erosions by adjacent soft tissue sarcomas are better visualized on CT than on MRI. The amount of tumor necrosis can be determined. Often, a reactive rim of calcification can be visualized surrounding tumors that have had a good response to preoperative chemotherapy.

Magnetic Resonance Imaging

MRI is used to determine the extent of soft tissue involvement, especially around the glenohumeral joint, along the chest wall, and into the axillary space. It is often difficult to visualize the suprascapular area in patients with large tumors, which may infiltrate below the subscapularis muscle and exit near the coracoid. MRI is especially useful in identifying the extent of intraosseous tumor, which is necessary to determine the length of the resection. Skip metastases can also be identified, although they rarely occur in this area. MRI is not useful for determining the preoperative tumor response to induction chemotherapy. MRI and bone scan studies accurately demonstrate the soft tissue extension as well as the intraosseous extent of the tumor.

Bone Scan

Bone scintigraphy is routinely used to assess the presence of metastatic and polyostotic bone disease as well as involvement of a bone by adjacent soft tissue sarcomas.

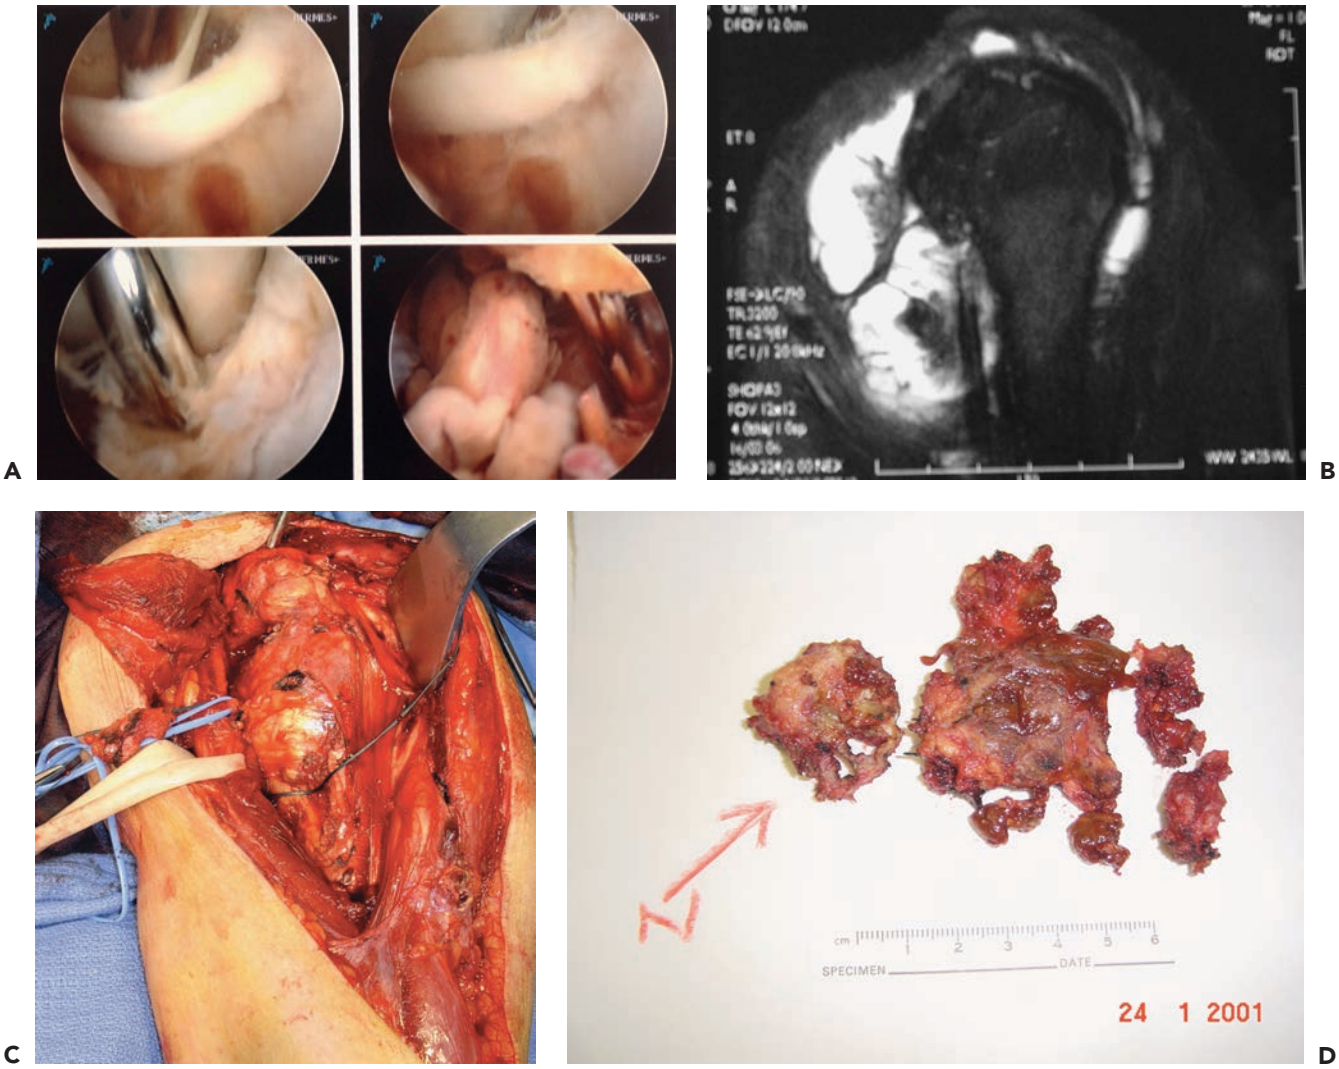


Figure 37-4 Pigmented villonodular synovitis (PVNS) or aggressive synovitis of the shoulder. **(A)** This photograph shows an arthroscopic view of the shoulder joint. Note the brownish pigmentation of the synovium. **(B)** Magnetic resonance imaging scan (T2-weighted fat suppressed) showing a marked distended joint with blood (white area) and bulky synovial disease. **(C)** Intraoperative photograph showing the proximal humerus following detachment of the pectoralis major muscle. Note the large soft tissue mass surrounding the proximal humerus. **(D)** Gross specimen following curettage and resection of tumor (PVNS). Note the brownish pigmentation, which is consistent with hemosiderin deposits and marked histiocytic proliferation.

The appearance of a bone lesion in the flow and pool phases, when assessed by a three-phase bone scan, is useful in determining the biologic activity of the tumor, which may be helpful in determining a diagnosis. Some surgeons utilize the bone scan following induction chemotherapy as an indirect measurement of evaluating tumor response.

Angiography

Angiography is extremely useful and should be done with the arm abducted to determine the relationship of the axillary and brachial vessels to the major tumor, the level of the circumflex vessels, and the presence of any anomalies (Fig. 37-5). The axillary vessels and brachial plexus are often displaced by large tumors in this area. Angiography is also the most reliable means of determining the response to neoadjuvant chemotherapy. The absence of vessels in the tumor or a decrease in tumor vascularity indicates tumor necrosis. If there is a very good angiographic response (i.e., decrease in or absence of tumor blush), it is indicative of a good response to the preoperative chemotherapy. This information is important for determining the extent of surgical margins and also provides prognostic information. For instance, if the tumor has had a good response, it is safe to proceed with

Figure 37-5 Angiogram of a large scapular sarcoma. Angiograms are essential for evaluation of bulky tumors of the shoulder girdle. This scan demonstrates the relationship of the artery to the tumor and the marked vascularity of most tumors. In general, prior to surgery, vascular tumors are embolized.

a limb-sparing resection. The margins may be narrower with less soft tissue resected. If the tumor has had a poor response, the surgeon may elect to take a wider soft tissue margin or perform an amputation. The venous flow phase is useful to demonstrate venous occlusion or tumor thrombi. If there is any suggestion of occlusion, a brachial venogram should be performed (Fig. 37-6A).

Venography

If venous thrombosis or a mural thrombosis is expected, venography should be performed. The most suspicious finding is extremity edema. Axillary vein thrombosis or occlusion is most common with large shoulder osteosarcomas and chondrosarcomas. It is indicative of encasement of the vascular structures by neoplasm and therefore indirectly reflects brachial plexus involvement because of the intimacy of the brachial plexus and the axillary vessels. This finding suggests that the tumor is unresectable (Fig. 37-6B).

Biopsy

Because 95% of bone sarcomas have a soft tissue component, a small needle, or core, biopsy is possible (Figs. 37-7 and 37-8). One exception may be the young patient with a suspected round cell tumor from whom more tissue may be required for cytogenetic and immunohistochemical stains. Another exception would be an older patient in whom a solitary metastatic lesion is suspected and the pathology supports either metastatic carcinoma or a spindle cell sarcoma. This differentiation most often occurs with metastatic renal cell carcinoma. In such a case, a significant amount of tissue may be required to obtain

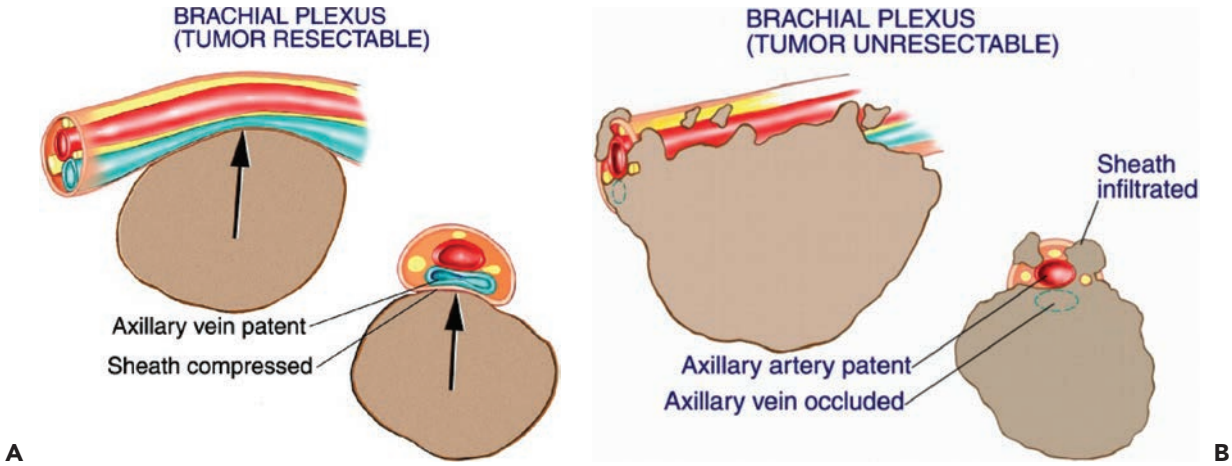

Figure 37-6 **(A)** Schematic diagram showing the relationship of the axillary vessels to tumors arising within the axillary space, either from the scapula, proximal humerus, or axillary space itself. The infraclavicular portion of the brachial plexus is often displaced by a tumor mass. The axillary artery and vein can be seen on angiography and axillary venography, respectively. These vessels are both patent but may be compressed. The clinical implication is that there is no nerve involvement and therefore these tumors are usually resectable. **(B)** Schematic diagram showing an unresectable tumor due to infiltration of the infraclavicular portion of the brachial plexus. An angiogram would still demonstrate a patent artery in this situation, but most importantly, the axillary vein would be occluded and thus the surrounding nerves are infiltrated. Axillary venography has proven to be very important in determining tumor respectability.(From Malawer M, Wittig JC. Resections of the shoulder girdle. In: Malawer MM, Sugarbaker PH, eds. *Musculoskeletal cancer surgery: treatment of sarcomas and allied diseases.* Dordrecht, Netherlands: Kluwer Academic Publishers, 2001:193.)

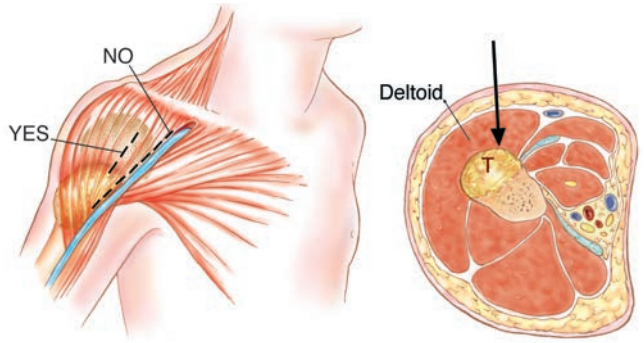

Figure 37-7 Schematic of the shoulder girdle and the preferred site of a needle or a small incisional biopsy for bony tumors. Biopsy should be performed through the anterior one-third of the deltoid to avoid contamination of the pectoralis major and therefore the brachial vessels underneath. A biopsy should never be performed through the deltopectoral interval. Approximately 95% of bony tumors can be correctly identified with multiple cores obtained through a single puncture site performed under computed tomography guidance. (From Malawer M, Wittig JC. Resections of the shoulder girdle. In: Malawer MM, Sugarbaker PH, eds. *Musculoskeletal cancer surgery: treatment of sarcomas and allied diseases.* Dordrecht, Netherlands: Kluwer Academic Publishers, 2001:194.)

immunohistochemical stains that will differentiate the metastatic tumor from a primary sarcoma.

Planning the Biopsy

It is essential to plan and perform the biopsy carefully, because an inappropriate biopsy is a common cause of forequarter amputation. In a patient with a tumor of the proximal humerus, a core biopsy through the anterior third of the deltoid muscle is recommended (see Fig. 37-8). Open biopsies are rarely required and may lead to excessive local contamination. If there is a soft tissue component, which occurs 95% of the time, there is no need to enter the bone. Several samples may be taken from different areas through a single puncture site. Care must be taken to avoid the deltopectoral groove. Contamination of this groove leads to contamination of the pectoralis muscle and, potentially, of the brachial vessels and axillary space (see Fig. 37-7).

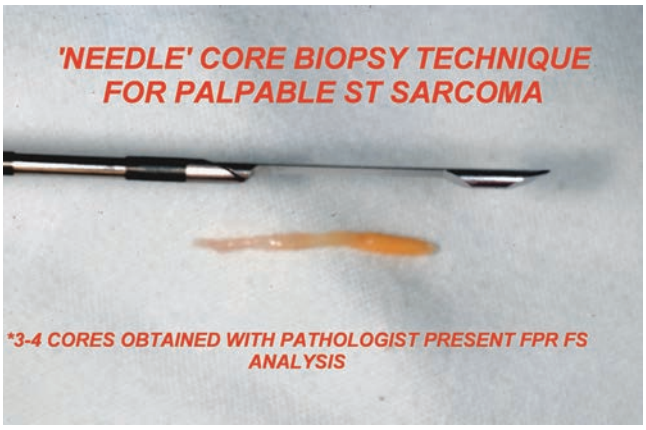

Figure 37-8 Core biopsy showing the needle and specimens that can be obtained. Approximately four or five cores are obtained from the tumor through the same puncture wound by changing the angle of the approach.

Biopsy Technique

The biopsy site is a crucial factor in determining the final operative procedure. For tumors arising within the body of the scapula, a posterior needle biopsy or a biopsy along the axillary border of the scapula is recommended. With lesions involving the scapula and neck, a posterior approach directly through the teres minor is recommended. If an open biopsy is required, a small longitudinal incision in line with the incision that will be used for resection is recommended. Most operative approaches involve an incision along the axillary border of the scapula.

A biopsy of the proximal humerus should be performed through the anterior third of the deltoid, not through the deltopectoral interval. A biopsy through the anterior third of the deltoid results in a limited hematoma that is confined by the deltoid muscle and can be resected with the tumor en bloc (see Fig. 37-7). The axillary nerve innervates the deltoid muscle posteriorly, so the anterior portion of the muscle can be partially resected with minimal loss of function if the remaining deltoid is to be preserved. On the other hand, an open biopsy through the deltopectoral interval will contaminate the pectoralis major muscle and provide a plane for the hematoma to dissect to the chest wall along the brachial vessels. This makes a local resection more difficult and increases the possibility of local recurrence.

Clavicle tumors are biopsied along the length of the clavicle. Unless there is a soft tissue component, a small biopsy is advisable because a needle in this location could injure the brachial plexus and the neurovascular bundle.

Most shoulder-girdle soft tissue sarcomas are easily palpable. Multiple core needle biopsies performed through one puncture site under local anesthesia are recommended. If the mass is not palpable, core biopsies should be performed under fluoroscopic or CT guidance. To obtain multiple specimens from different areas, the surgeon should reintroduce the needle through the same puncture site, varying the angle. Cultures should be obtained routinely, regardless of the suspected diagnosis, because infection may simulate any malignancy. Touch-preps, frozen sections, or both confirm that lesional tissue has been obtained.

INDICATIONS AND CONTRAINDICATIONS FOR SHOULDER-GIRDLE RESECTION

Approximately 95% of high-grade shoulder-girdle malignancies can now be treated safely by limb-sparing surgeries;

forequarter amputation is now rare. The decision to proceed with limb-sparing surgery is based on the location of the cancer and a thorough understanding of its natural history.

Major contraindications for limb-sparing techniques are tumor involvement of either the neurovascular bundle or the chest wall. Relative contraindications include:

- pathologic fracture,
- extensive involvement of the shaft of the humerus,
- infection, and
- tumor contamination of the operative area from hematoma following biopsy or unwise placement of the biopsy incision.

These contraindications are described later in greater detail. General comments on contraindications are as follows:

- A pathologic fracture that has healed during the course of induction chemotherapy is not a contraindication to limb-sparing surgery. The arm is immobilized during this treatment period. With proper surgical treatment, the local recurrence rate is acceptably low and survival rates are not altered.
- The brachial artery is rarely involved by a tumor, although it may be in close proximity to it. The subscapularis, coracobrachialis, and short head of the biceps muscles often separate tumors of the proximal humerus and scapula from the vascular structures and brachial plexus. Occasionally, however, the brachial veins are directly invaded by a tumor and may be the site of tumor thrombi.
- Involvement of the musculocutaneous nerve by the tumor is rare, as is involvement of the three major cords to the brachial plexus, which follow the brachial vessels. The axillary nerve is often involved by tumors arising from the proximal humerus and is therefore resected. Direct tumor extension of the brachial plexus requires a forequarter amputation. Such extension into the plexus occurs most often with axillary or chest wall sarcomas, or metastatic carcinomas or melanoma to axillary lymph nodes.

  If an inappropriate biopsy has contaminated the shoulder girdle, limb-preserving resection is often inadvisable. Today, one of the major causes for amputation of the shoulder girdle is inappropriate biopsy resulting in contamination of the pectoralis major, the chest wall, and the neurovascular structures.
- Infection is a contraindication to limb-preserving surgery. Even with adequate resection, reconstruction of an infected field by arthrodesis, prosthesis, or allograft replacement is extremely risky, considering that all patients with high-grade sarcomas must receive postoperative adjuvant chemotherapy. If an infection cannot be eradicated with the primary resection, amputation is advisable.
- Previous surgeries affect the feasibility of a limb-sparing procedure. The local recurrence rate is increased if a wide resection is attempted following a previous resection around the shoulder girdle.
- On rare occasions, tumors of the scapula or proximal humerus with large soft tissue components invade the chest wall and intermingle with the intercostal muscles and the ribs. This situation usually requires a resection of the adjacent chest wall, but it is not an absolute indication for forequarter amputation because limb-sparing resection may be combined with chest wall resection.
- In the rare instance of lymph node involvement documented by biopsy, a forequarter amputation may be the best way to remove all the axillary nodes as well as the proximal sarcoma. On the other hand, it is not unreasonable to proceed with a limb-sparing resection and an axillary node dissection. This method can provide long-term cure and local control.

Utilitarian Shoulder-Girdle Incision

The utilitarian shoulder-girdle incision was developed by the senior author (MM) to serve as a basic incision for use in all types of shoulder tumors and in all anatomic locations. This incision permits adequate exploration of the bony structures and soft tissues and complete exposure of the axillary vessels and infraclavicular brachial plexus. It consists of three components (Fig. 37-9):

1. Anteriorly, the incision begins at the junction of the medial and middle thirds of the clavicle. This incision extends medial to the coracoid, along the deltoid pectoral interval across the axillary fold, and courses distally along the anteromedial aspect of the arm.
2. The posterior incision begins over the midclavicular region of the anterior incision and travels inferiorly over the lateral aspect of the scapula and curves posteriorly at its tip. Large fasciocutaneous flaps are elevated anteriorly and posteriorly.
3. An incision into the axillary fold can be extended for proximal humerus tumors with axillary extension, for isolated axillary tumors, or for those rare instances when a limb-sparing resection cannot be performed and the procedure must be converted to a forequarter amputation.

PAIN CONTROL

A unique method developed for the postoperative management of pain in patients undergoing major tumor surgery is the use of perineural catheters. This technique involves the direct placement of a silastic (epidural type) catheter within the nerve sheath of the brachial plexus prior to

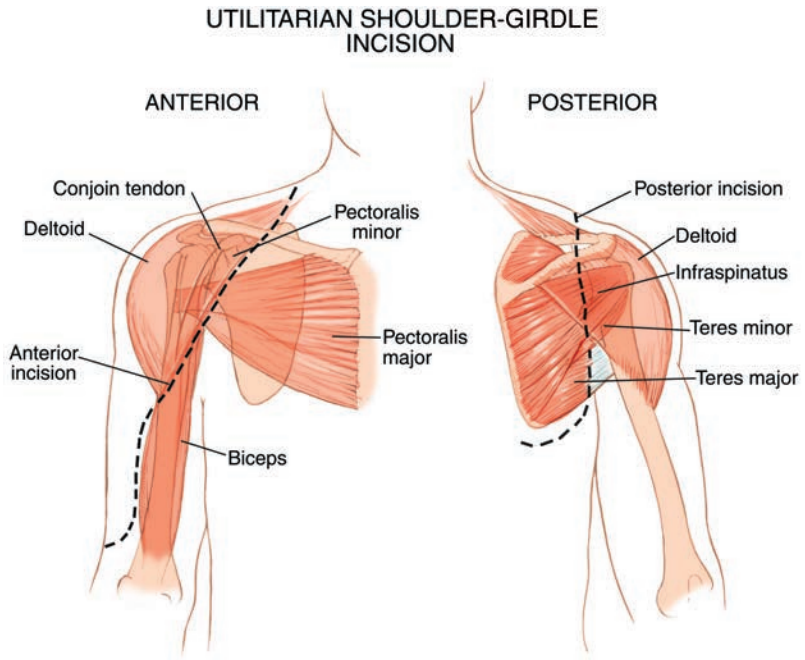

Figure 37-9 Utilitarian shoulder girdle incision. The utilitarian shoulder incision consists of three components: **(1)** A long deltopectoral incision from the midthird of the clavicle through the deltopectoral interval and distally along the medial aspect of the arm. **(2)** A curved incision along the axillary border of the scapula, which permits a large posterior fasciocutaneous flap to be developed to expose the scapula and the periscapular musculature. **(3)** An axillary incision that permits a forequarter amputation in conjunction with the first two incisions. (From Malawer M, Wittig JC. Resections of the shoulder girdle. In: Malawer MM, Sugarbaker PH, eds. *Musculoskeletal cancer surgery: treatment of sarcomas and allied diseases.* Dordrecht, Netherlands: Kluwer Academic Publishers, 2001:191.)

closure of the wound (Fig. 37-10). Twenty milliliters of 0.25% of Marcaine is perfused initially, and then a continuous infusion of 2 to 4 mL/hr of .025% for the immediate postoperative period is given. This technique reduces the postoperative narcotic requirements by about 90%.

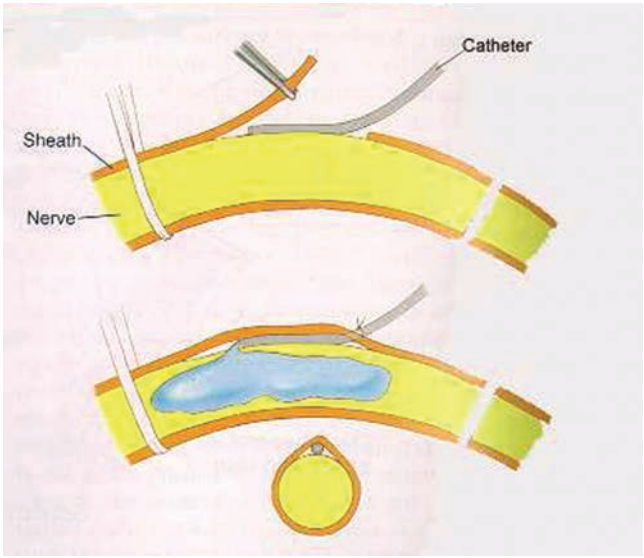

Figure 37-10 Schematic diagram of the perineural catheter utilized for perioperative pain control following most shoulder-girdle resections. At the time of surgery, a small Silastic catheter is placed in the nerve sheath of the brachial plexus. Twenty milliliters of 0.25% bupivacaine are bloused prior to wound closure, and then 4 to 8 mL/hr are infused over the next 48 to 72 hours. This provides excellent pain control for most shoulder-girdle procedures. (From Sugarbaker PH, Bickels J, Malawer M. Above-knee amputation. In: Malawer MM, Sugarbaker PH, eds. *Musculoskeletal cancer surgery: treatment of sarcomas and allied diseases.* Dordrecht, Netherlands: Kluwer Academic Publishers, 2001:360.)

REHABILITATION AFTER SHOULDER-GIRDLE RESECTION

From a rehabilitation perspective, the outcome of resection is clearly superior to that of a forequarter amputation or shoulder disarticulation. Patients undergoing shoulder-girdle resection retain hand function and good elbow function, but they lose some shoulder function, mainly abduction. Shoulder-girdle resection is less disfiguring than amputation and is associated with only minimal pain and edema. Generally, patients' acceptance of the outcome of their surgery is good to excellent.

Rehabilitation begins with an orientation program that often features pictures of patients who have undergone the procedure and demonstrations of what one can do postoperatively. Preoperatively, a shoulder mold is fashioned using the involved shoulder, provided its contours are not distorted. The cosmetic shoulder helps preserve the symmetry and appearance of the shoulder contour and can support a bra strap or heavy overcoat.

The patient uses a sling postoperatively, and motion is restricted until the incision is healed. The sutures are removed about 2 weeks after surgery. Edema is controlled with an elasticized glove or elastic stockinet. Active motion of the elbow and hand is initiated to preserve strength and range of motion and to help minimize edema.

If the incision heals per primam, assistive elbow motion is started within the confines of the sling as soon as the suction catheters have been removed. At about 2 weeks, the sling is removed for passive shoulder range of motion (ROM) and pronation and supination of the wrist. The patient should continue to use the sling intermittently after the incision is healed, primarily for upright activities

in which arm support increases comfort. Once the arm is out of the sling, full ROM of elbow (flexion, extension, pronation, and supination) is performed. Passive ROM to the shoulder (flexion, abduction, and external and internal rotation and pendulum exercise) with the help of a family member or physical therapist is recommended.

Rehabilitation depends on the type of reconstructive technique. In general, patients with endoprosthetic intraarticular allografts or composite allograft reconstruction undergo the same rehabilitation program. Those treated by arthrodesis, allograft, or autograft are immobilized for 4 to 5 weeks to allow early bony union to take place.

TUMORS OF THE PROXIMAL HUMERUS

Despite the complexity of these cases, limb-sparing surgery for both high- and low-grade sarcomas of the proximal humerus is possible in approximately 95% of cases. Forequarter amputation is indicated mainly for large, fungating tumors, tumors with secondary infections, cases in which there is chest wall involvement, and patients who have had a failed attempt at limb-sparing resection. Preoperative neoadjuvant chemotherapy may allow fracture healing if there is significant tumor necrosis.

Most low-grade sarcomas of the proximal humerus can be treated by type I excision with minimal functional deficit. High-grade sarcomas require a modified Tikhoff-Linberg resection (type V). Intraarticular and synovial involvement is more common with high-grade chondrosarcomas and with osteosarcomas of the shoulder girdle than with such tumors at other anatomic sites. Thus, extraarticular, rather than intraarticular, resections are recommended for high-grade tumors of the proximal humerus. Prosthesis, allograft, or allograft prosthetic composite can be used for reconstruction following a marginal resection (type I) for a low-grade lesion. Arthrodesis is rarely performed today. Following resection of a high-grade lesion (stage IIB), the aim is to provide a stable shoulder that will preserve function in the elbow and hand. Regardless of the type of reconstruction planned, the magnitude of the surgical resection depends on the grade of the tumor and its anatomic extent.

A major consideration in the preoperative evaluation and surgical planning is the intraosseous extension of the tumor within the bone marrow. The humerus is shorter than the femur and tibia, the two most common sites of sarcomas, and large tumors of the humerus often require resection of a significantly larger portion of the bone. It is not unusual to resect 50% to 80% of the humerus. Tumors arising within the diaphysis may require a total humeral resection and replacement of the glenohumeral and elbow joints. The surgeon must have various lengths and diameters of intramedullary stems at hand. The final decision about the extent of resection needed is made at the time of surgery.

The abductor mechanism (i.e., the deltoid muscle and the rotator cuff) normally covers the shoulder joint. These structures are usually resected in patients with high-grade proximal humeral sarcomas. Following the resection, joint coverage and stability are essential to eliminate dead space, decrease the risk of infection, and maintain good elbow and hand function. The key muscle transfers in the reconstruction are the pectoralis major, the biceps, and the latissimus dorsi; these must be identified and preserved during the resection.

Specific tumors of the Proximal Humerus (Table 37-2)

Benign Tumors

Giant Cell Tumor

Giant cell tumor (GCT) is a locally aggressive tumor with a low metastatic potential. It occurs slightly more often in females than in males. This tumor is thought to arise in the metaphyseal–epiphyseal junction, and large tumors may extend into the metaphysis or, more rarely, the diaphysis. The descriptor "benign" was first applied to GCT to differentiate it from other bony malignancies that required amputation. GCT is now considered a benign aggressive lesion, although 3% to 5% are primarily malignant or will undergo malignant transformation either after radiation therapy or following several local recurrences (Fig. 37-11).

GCTs are eccentric lytic lesions without matrix formation. They have well-defined borders and a sharp transition between the tumor and host bone. Periosteal elevation is rare unless accompanied by a pathologic fracture. The typical GCT comprises two basic cell types. The stroma consists of polygonal to somewhat spindle-shaped cells. Scattered diffusely through the stroma are benign osteoclast-like giant cells. Extensive hemorrhage, fracture, or previous surgery can alter the usual pathologic picture of GCT and make it resemble that of a primary bone sarcoma. Cystic areas with surrounding hemosiderin pigment and xanthoma cells correspond to the grossly observed cyst. Approximately 5% of all GCTs occur around the shoulder girdle.

Treatment of GCT is surgical removal (curettage) along with administration of an adjuvant cytotoxic agent such as phenol, zinc chloride, alcohol, hydrogen peroxide, or carbolic acid, or, as the authors prefer, curettage and application of a physical adjuvant such as cryosurgery. Treatment of GCT with curettage, burr drilling, and application of cryosurgery has achieved a local recurrence rate of less than 5% (see Cryosurgery section). Type I resection for GCTs is rarely necessary and is reserved for those tumors in which there is insufficient bone remaining for reconstruction with polymethylmethacrylate (cementation). We recommend the treatment of GCT of the proximal humerus with curettage and cryosurgery.

TABLE 37-2
HISTOGENESIS AND ANATOMIC SITE OF TUMORS IN 72 PATIENTS TREATED BY LIMB-SPARING SURGERY OF THE SHOULDER GIRDLE

Type of Tumor	Scapula	P. Humerus	Total

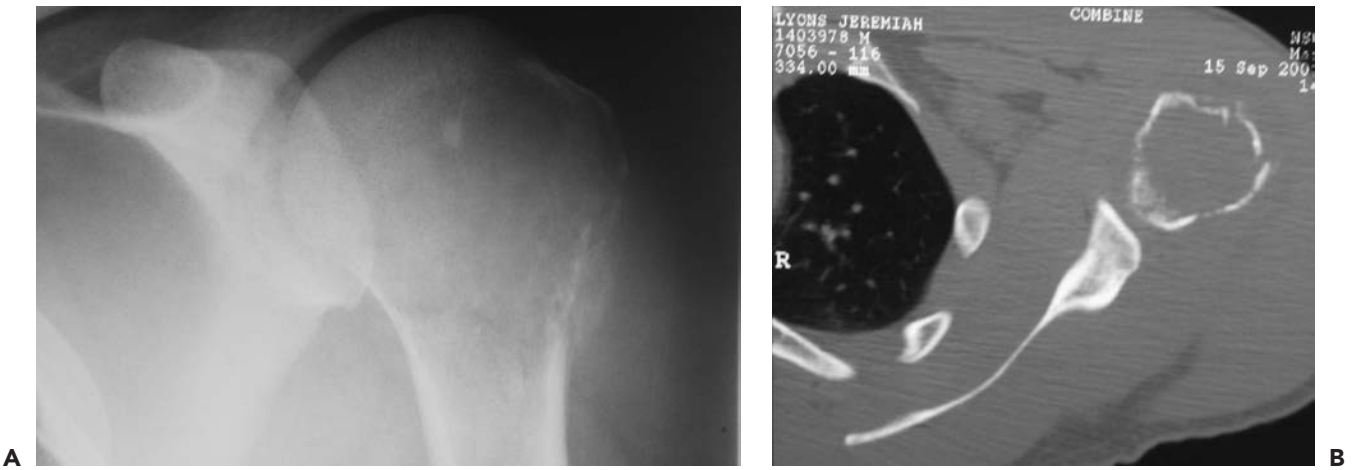
Presented at Surgical Grand Rounds at Georgetown University Medical Center May 2001. Washington DC (not published)

Chondroblastoma (Codman's Tumor)

Chondroblastoma is a benign aggressive tumor that shows a marked predilection for the epiphysis of the bone. This tumor was originally described by Codman as occurring in the proximal humeral epiphysis (thus named Codman's tumor). It is composed of round and spindle cells, some of which resemble immature chondrocytes or chondroblasts, hence the name *chondroblastoma*. Chondroblastomas account for less than 1% of all bone tumors. They are one-fifth as common as GCTs. Most patients are skeletally immature when this tumor occurs: 95% of patients are between 5 and 25 years of age, and most of these tumors occur in teenagers. If a chondroblastoma occurs after skeletal maturity, one must be very suspicious of a clear cell chondrosarcoma. Males are affected twice as often as females. Patients usually present with mild pain that may have been present for several months. About one-third of patients have a joint effusion or fluid



A B

Figure 37-11 Giant cell tumor of the proximal humerus. **(A)** Plain radiograph demonstrating a lytic lesion of the proximal humerus with poorly defined borders and with cortical destruction. There is no matrix formation. **(B)** Computed tomography scan showing marked cortical thinning and destruction. Needle biopsy showed a giant cell tumor. Giant cell tumors of the proximal humerus are very rare and represent less than 1% to 2% of all giant cell tumors.

in the joint, and swelling and limitation of the joint may occur.

Ninety-eight percent of chondroblastomas are located in the epiphysis of the bone. Mature cartilage is present only focally in some tumors. Chondroblastomas are almost always confined to the original bone, but on rare occasions they can penetrate the cortex and enter the joint or the soft tissues. Chondroblastomas may also undergo aneurysmal changes with secondary aneurysmal bone cyst (ABC) formation. In this setting, the tumor undergoes necrosis with hemorrhage and large cystic spaces that are filled with bloody fluid compose a significant portion of the tumor. Since they are aggressive, these tumors can cause extensive destruction of the bone. Treatment is similar to that of GCT and includes a thorough curettage of the tumor and tumor cavity.

Cryosurgery is recommended to eradicate microscopic tumor cells. The tumor cavity may be packed with cement and/or bone graft and may require metallic internal fixation. There have been rare reports of chondroblastoma metastasizing to the lungs; however, patients can still be cured with metastasectomy. In some cases, metastases do not appear for up to 30 years following the initial diagnosis. There are reported cases of chondroblastomas treated with radiation that have later undergone malignant transformation to fibrosarcomas and osteosarcomas. Thus, one should refrain from using radiation to treat this type of tumor. The first procedure should be undertaken with great care to ensure local control of this tumor.

Enchondroma

An enchondroma (sometimes called a central chondroma) is a benign intramedullary tumor of cartilage. It accounts for about 10% of all benign bone tumors. These tumors are believed to arise from cartilaginous nests of cells that are displaced from the growth plate during development. Enchondromas occur in persons of virtually all ages, but 60% of patients are between 15 and 40 years of age. Some patients complain of pain due to stress fractures through the area of the tumor. In other cases, the tumors are asymptomatic and are discovered incidentally on radiographs taken for other reasons. The tumors may also appear as hot spots in patients undergoing a skeletal scan for other reasons. Increased uptake on a bone scintigraphy is not a sign of malignancy but of enchondral ossification, which normally occurs in enchondromas. The proximal humerus is commonly affected.

Enchondromas must be differentiated from chondrosarcomas, and it is particularly difficult to differentiate a low-grade chondrosarcoma (also known as an enchondrosarcoma) from an enchondroma. Special clinical and radiographic criteria are used to differentiate the two entities. In general, low-grade chondrosarcomas are greater than 5 cm in size and cause endosteal cortical erosion through the cortex of the bone. They also typically occur in more-proximal locations than enchondromas do. The presence of pain and the absence of fracture should be regarded as highly suspicious for a low-grade chondrosarcoma. Tumors arising in the digits are rarely malignant. Chondrosarcomas, however, can arise from enchondromas. Thus, enchondromas should be followed with yearly radiographs and treated if they begin to cause pain, to erode into the inner cortex, or to increase to a size that suggests malignancy. Biopsy does not help distinguish a low-grade chondrosarcoma from an enchondroma. Most enchondromas are treated with bone graft and/or polymethylmethacrylate (PMMA). This tumor should not be biopsied because it is pathologically very difficult to distinguish between a low-grade chondrosarcoma and an enchondroma. The two lesions look very similar under a microscope, and if a biopsy from a small area of the lesion is performed, the results will be inconclusive. Thus, the entire tumor should be curetted if there is pain and endosteal scalloping. If radiographic and clinical information suggest that this may be a low-grade chondrosarcoma, then cryosurgery may be performed. The bone may require reconstruction with cement and/or bone graft and stabilization with intramedullary pins. Rarely is a primary prosthetic replacement required.

Unicameral Bone Cysts

A unicameral bone cyst (UBC) is a benign cavity of bone that is filled with clear or bloody fluid. Other terms for this lesion include benign bone cyst and simple bone cyst. UBCs constitute 3% of all primary bone lesions. Most occur in the proximal or midhumerus. UBC does not appear to be a true tumor, and its cause is unknown. It may occur secondarily to intraosseous hypertension and failure of venous outflow in the region of the bone. There is a male predilection of 3:1. Sixty-five percent of UBCs occur in teenagers, and 20% occur in the first decade of life. The patient usually presents with pain. Despite popular belief, fracture of the bone cyst usually does not result in permanent healing. Preferred treatment is aspiration of the cyst followed by high-pressure injection with cortisone and Renografin. The procedure is performed under fluoroscopy to ensure that the entire cavity is filled and that the fluid enters the venous outflow, thus restoring circulation in the area of the cyst. The procedure is done under general anesthesia. The majority of cysts are cured following the first injection; however, some require several injections. Two-thirds of patients are cured with three injections or less. Patients who are not cured in this manner can be treated with curettage and bone grafting or bone-filling substitute. Patients with fractures through the area of the cyst are immobilized until the fracture heals and are then treated with aspiration and injection. Aspirated bone marrow or growth factors may be injected into the cyst to aid with healing (Fig. 37-12).

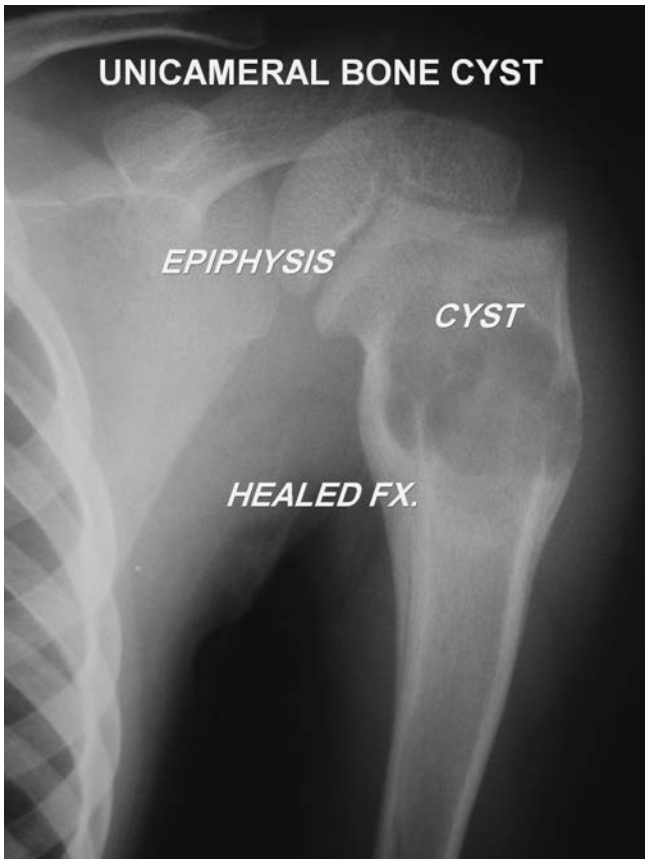


Figure 37-12 Healed unicameral bone cyst (UBC) of the proximal humerus. UBCs are typically asymptomatic until a fracture occurs. Surgical treatment is postponed until the fracture is healed. UBC can be treated by several modalities including aspiration and injection with methylprednisolone, curettage, and filling of the defect with one of many bone substitutes. Alternatively, autogenous bone graft can be utilized.

Malignant Tumors

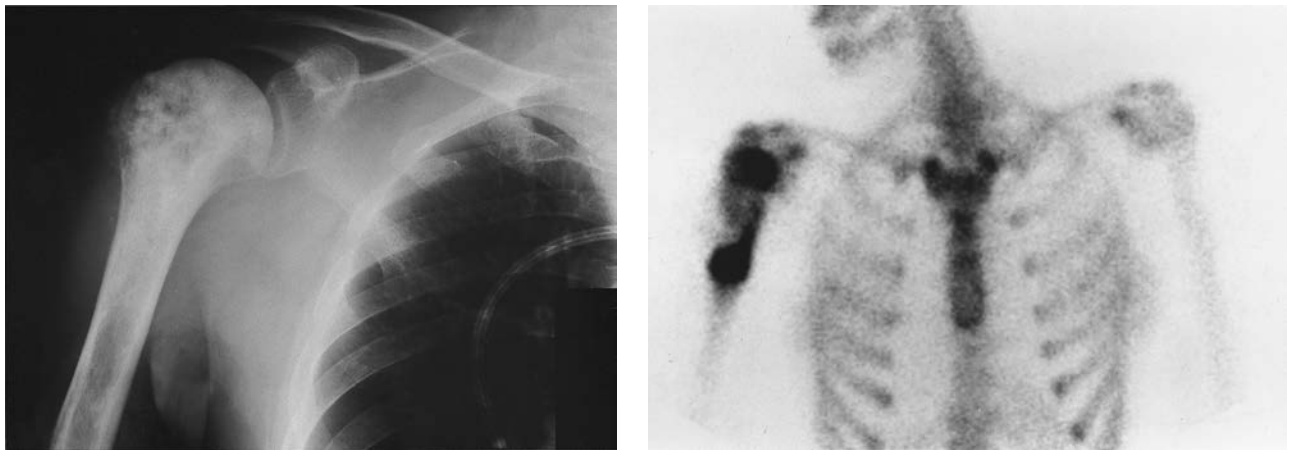
Osteosarcoma

Osteosarcoma is a high-grade, malignant spindle cell tumor that most often arises within a bone. Its distinguishing characteristic is the production of "tumor" osteoid or immature bone directly from a malignant spindle cell stroma.

Osteosarcoma typically occurs during childhood or adolescence, with the peak incidence to be between 10 and 19 years of age. The overall incidence is 2.1 cases per million people per year. When osteosarcoma occurs in patients older than 40 years, it is usually associated with a preexisting condition, such as Paget's disease, irradiated bones, multiple hereditary exostosis, or polyostotic fibrous dysplasia.

Bones of the knee joint and the proximal humerus are the most common sites, accounting for 50% and 25%, respectively, of all osteosarcomas. Between 80% and 90% of osteosarcomas occur in the long tubular bones, and the axial skeleton is rarely affected. With the exception of serum alkaline phosphatase (AP) levels, which are elevated in 45% to 50% of patients, laboratory findings are usually not helpful. Furthermore, elevated AP per se is not diagnostic, because it is also found in association with other skeletal diseases. Pain is the most common complaint. Night pain gradually develops and is a hallmark of skeletal involvement. Physical examination demonstrates a firm, soft mass fixed to the underlying bone with slight tenderness. No effusion is noted in the adjacent joint, and motion is normal. Incidence of pathologic fracture is less than 1%. Systemic symptoms are rare.

The proximal humerus is the third most common site for osteosarcoma. Osteosarcomas in this area tend to have a poorer prognosis than those around the knee, and most have significant extraosseous components (Figs. 37-13 and 37-14). Plain radiographs suggest the correct diagnosis. All



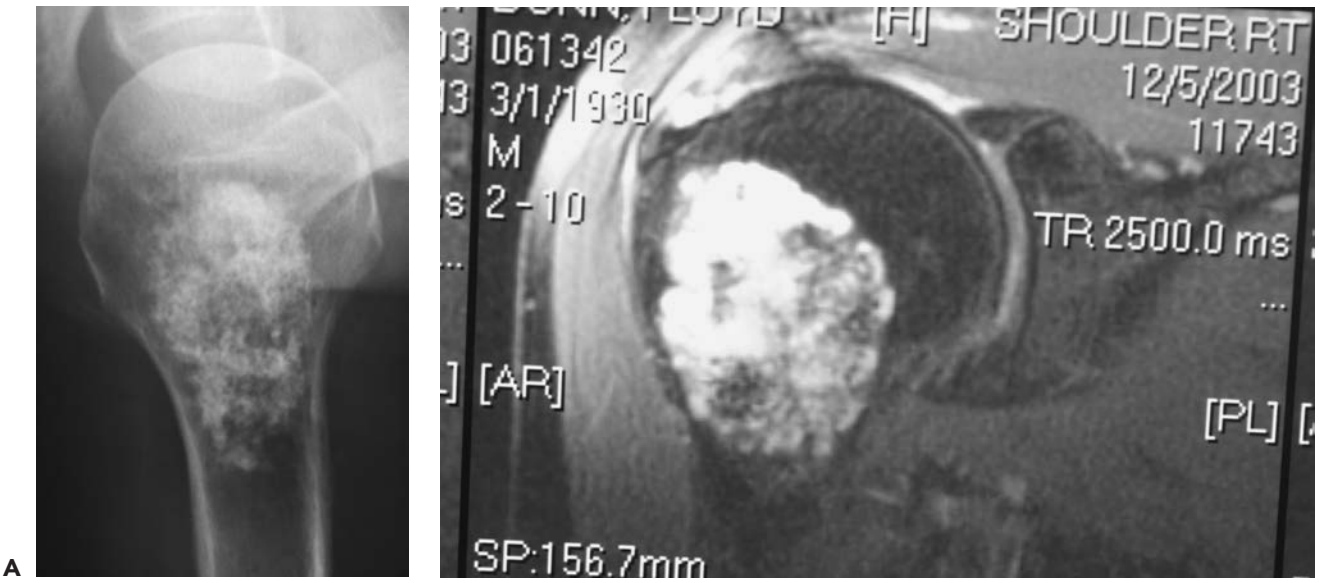
Figures 37-13 Osteosarcoma of the proximal humerus. **(A)** Plain radiograph showing marked sclerosis of the proximal one-third of the humerus with cortical destruction. The tumor extends from the proximal one-third of the diaphysis to the subchondral bone. **(B)** Bone scan (late phase) of the proximal humerus showing marked bony uptake. This bone scan alone is not characteristic of an osteosarcoma, but it is indicative of the extension of the lesion. Note that there is only minimal extraosseous component demonstrated.

Figures 37-14 Osteosarcoma of the proximal humerus with a pathologic fracture. (A) Plain radiograph showing a pathologic fracture prior to treatment with induction chemotherapy. (B) The same patient following 4 months of induction chemotherapy, prior to attempted limb-sparing surgery. Note that the pathologic fracture has healed and that the tumor has undergone ossification (both positive prognostic indicators). Pathologic fracture through an osteosarcoma classically required a forequarter amputation. Today, with induction chemotherapy, most pathologic fractures will heal, indicating significant tumor necrosis.

staging studies are performed prior to biopsy. If the axillary vessels are free of tumor, a limb-sparing procedure, preferably an extraarticular resection, is generally indicated. A modified Tikhoff-Linberg procedure (type VB) provides adequate resection of the proximal humerus for high-grade sarcomas. This includes en bloc removal of 15 to 20 cm of the humerus and shoulder joint, with the deltoid, rotator cuff, and portions of the biceps and triceps muscles. Reconstruction involves suspension of the arm, motor reconstruction, and provision of adequate soft tissue coverage.

Extraarticular resection of the glenohumeral joint by medial scapulectomy is safer than intraarticular resection. A modular prosthesis is used for reconstruction. Soft tissue reconstruction and suspension are essential to stabilize the shoulder, prevent infection, and avoid postoperative pain, instability, and fatigue. Static suspension of the prosthesis is accomplished with Dacron tape. Dynamic suspension is accomplished by transferring the biceps tendon to the clavicle. The prosthesis is covered with the pectoralis major and latissimus muscles. Hand and wrist function is normal after resection. Shoulder abduction and flexion is minimal; however, rotation is preserved. Latissimus dorsi transfer and scapulothoracic motion permit external rotation. The pectoralis major enables internal rotation. Cosmesis is acceptable and can be enhanced with the use of a shoulder pad.

Alternatively, resection of the proximal humerus for osteosarcomas can be performed by an intraarticular resection that preserves the glenoid and the adjacent deltoid muscle. The problems associated with this procedure include significant local recurrence and instability of the reconstructed prosthesis or allograft. When the glenoid and deltoid are preserved in this procedure, minimum margins are obtained along the shoulder joint, deltoid muscle, and axillary nerve. Because of this serious drawback, this technique is not recommended by the surgical author (MM). Less than 5% of osteosarcomas of the proximal humerus (usually those without an extraosseous component [stage IIA]) can be treated by an intraarticular resection. When an intraarticular resection is performed, the senior author recommends reconstruction of the glenohumeral ligaments with a Gore-Tex aortic graft.



A B

Figures 37-15 Chondrosarcoma (enchondrosarcoma) of the proximal humerus. **(A)** Plain radiograph of the proximal humerus showing a large area of calcification with adjacent cortical thinning and destruction. There is a lytic component in addition to the calcified component. **(B)** Magnetic resonance imaging scan showing typical calcification appearance. Calcification is often described as small nodules and curly cues.

Chondrosarcoma

Primary (central) and secondary (peripheral) chondrosarcomas commonly occur in the proximal humerus. Peripheral lesions tend to be large but low grade, whereas central lesions tend to be higher grade. Stage I tumors of the proximal humerus can be treated by excision (type I) with minimal functional deficit (Fig. 37-15).

High-grade sarcomas require a modified Tikhoff-Linberg resection (type V) or, rarely, a forequarter amputation. Intraarticular and synovial involvement with high-grade cartilaginous lesions are more common in this location than in other sites. A prosthesis is recommended for reconstruction following a marginal resection (type I) for a low-grade sarcoma.

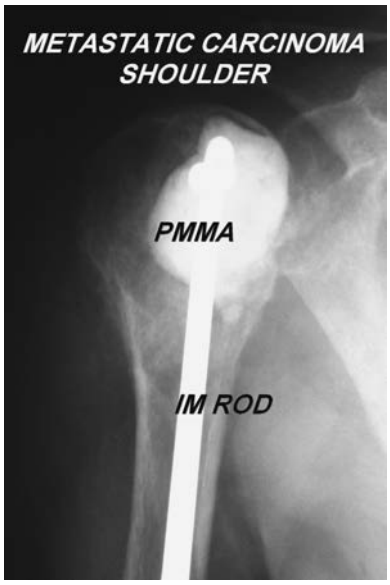
Ewing's Sarcoma

Treatment of Ewing's sarcoma follows the guidelines for other high-grade bone sarcomas of the humerus, even though fewer than 10% of Ewing's sarcomas involve the proximal humerus. The flat bones, specifically the scapula and clavicle, are the most common sites for Ewing's sarcoma. Ewing's sarcomas often decrease dramatically in size following preoperative chemotherapy, in which case the deltoid and axillary nerve may be preserved. Surgery should never precede induction chemotherapy. Often, there is no detectable soft tissue component; in such cases, a type I resection may be indicated. Ewing's sarcomas may dramatically decrease in size following induction chemotherapy. For this reason, intraarticular resections (type I) are recommended. Radiation therapy is not recommended in patients treated with a prosthesis or an allograft because it often leads to severe local complications, such as restriction of motion, infection, severe lymphedema, and secondary amputation.

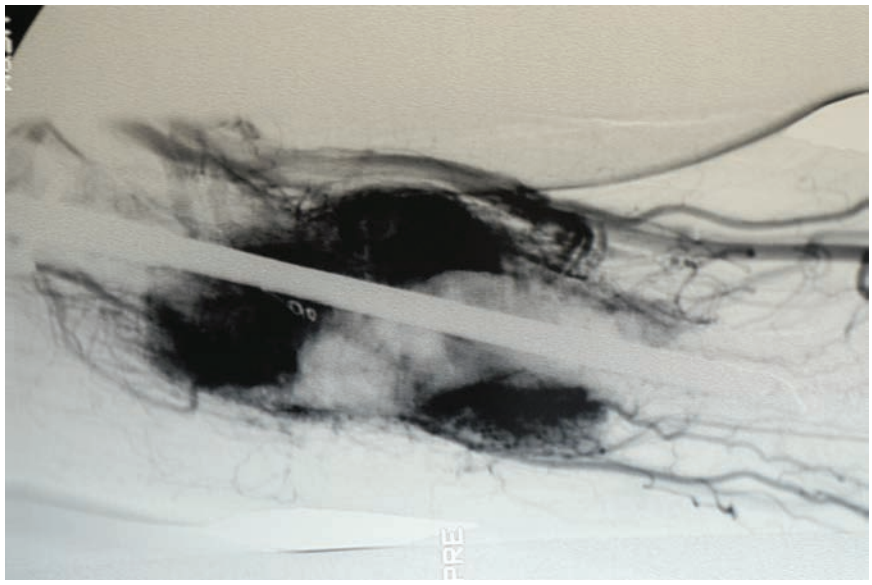
Metastatic Carcinomas

All carcinomas can metastasize to the proximal humerus (Fig. 37-16). Many large metastatic tumors with marked bony destruction may be resected by a primary resection and prosthetic replacement. Hypernephroma, which is extremely vascular and has a predilection for this location, may present a unique problem of uncontrollable bleeding. Radiography often reveals marked destruction and ballooning, much like that seen in ABCs and primary sarcomas. Simple biopsy may lead to severe hemorrhage. Preoperative angiography with embolization is recommended. The anterior and posterior circumflex vessels should be ligated prior to any surgical procedure. If curettage and cementation are not feasible because of severe bony destruction, an intraarticular resection with prosthetic replacement (type I) is indicated.

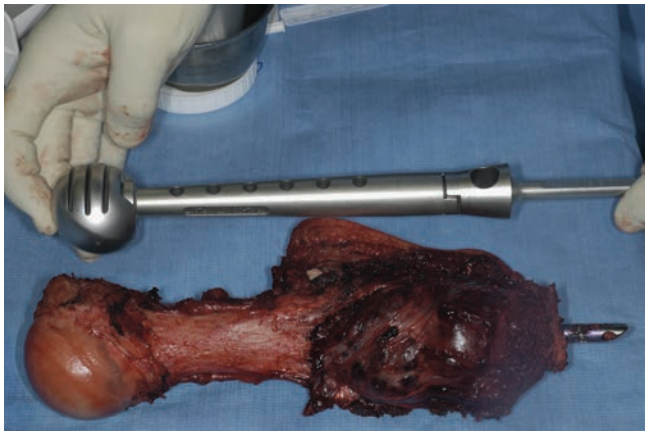
Most metastatic carcinomas of the proximal humerus can be treated with radiation therapy rather than surgery. If there is a pathologic fracture, then curettage through a deltopectoral interval should be performed. The defect is reconstructed with PMMA, intramedullary pins, an intramedullary rod, or a long-stem hemiarthroplasty. Bone graft is not used to fill a defect if a metastatic carcinoma is present.



A



B



C

Figure 37-16 **(A)** Metastatic carcinoma of the proximal humerus treated by intramedullary rod fixation and cementation. Polymethyl methacrylate (PMMA) is used with all metastatic lesions of the humerus when surgery is required. Cementation provides immediate fixation and may prevent secondary loosening if the metastatic tumor recurs. This has become more of an issue as patients are living longer with improved therapies. **(B)** Large recurrent tumor (metastatic hypernephroma) of the humerus. Angiogram shows tumor recurrence around an intramedullary rod. Hypernephromas are often difficult to treat and are very vascular. Radiation has minimal effect on preventing a recurrence. We prefer primary resections of metastatic hypernephromas, specifically those that occur around the humerus. **(C)** A specimen of the proximal two-thirds of the humerus following resection for the recurrent hypernephroma. The segmental prosthesis that will replace the resected bone is shown. IM = intramedullary.

CRYOSURGERY

Cryosurgery extends the margin of curettage and makes it equivalent to that of wide resection. Compared with other techniques, cryosurgery with composite fixation (PMMA combined with intramedullary rods) not only preserves joint function, but also significantly decreases the rate of local tumor recurrence. Although a relatively simple procedure, cryosurgery can cause a significant morbidity if performed inappropriately. Effective and safe procedures must follow these consecutive steps: (1) adequate exposure of the tumor, (2) meticulous curettage and burr drilling, (3) soft tissue mobilization and protection before introduction of liquid nitrogen to the tumor cavity, (4) internal fixation of the tumor cavity, and (5) protection of the operated bone throughout the healing period (Fig. 37-17).

The technique for curettage and cryosurgery is as follows:

- All gross tumor is removed with hand curettes.
- After the tumor tissue is curetted away from the inner wall of the lesion, the reactive wall reveals an irregular contour. This irregularity makes it virtually impossible to remove all the tissue; therefore, high-speed burr drilling is achieved using a Midas Rex or Black Max.
- Liquid nitrogen is applied to the cavity utilizing liquid nitrogen or argon probes or, more often, the Marcove direct-pour method. All bony perforations are identified and sealed, and the surrounding skin, soft tissues, and neurovascular bundle are protected by mobilization and shielding with Gelfoam.
- Using the direct-pour method, liquid nitrogen is poured through a stainless steel funnel into the tumor cavity. Care is taken to fill the entire cavity. The Gelfoam immediately freezes and forms a seal around the funnel. Thermocouples are used to monitor the freezing effect within the bone cavity, cavity wall, and adjacent soft tissue, as well as the rim of bone 1 to 2 cm from the periphery of the cavity. The surrounding soft tissues are continuously irrigated with warm saline solution to decrease the possibility of thermal injury. The liquid nitrogen is left to evaporate, and then spontaneous thaw is allowed to occur over 3 to 5 minutes. Once the

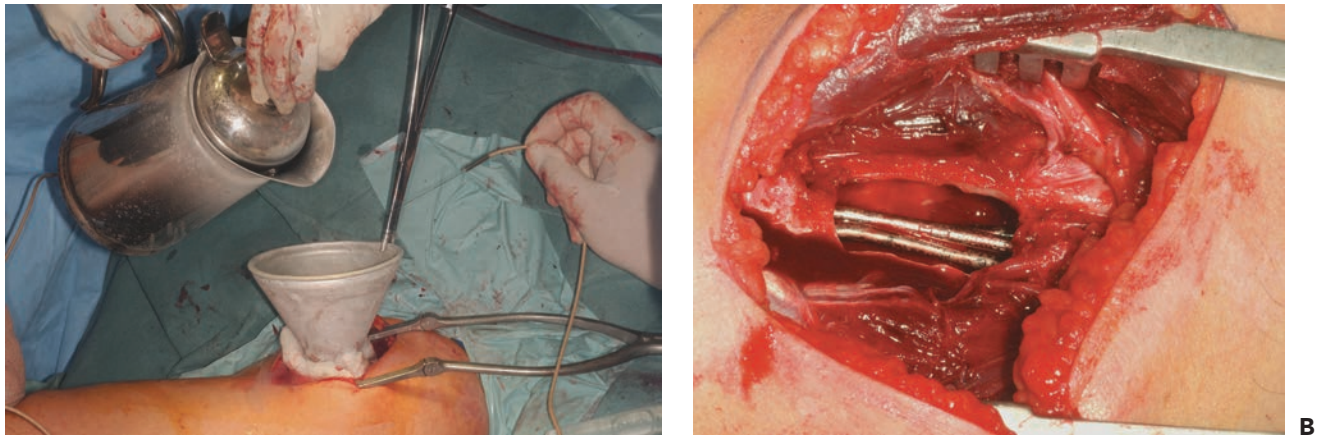


Figure 37-17 Cryosurgery. **(A)** This operative photograph shows the early technique of cryosurgery as developed by Dr. Ralph Marcove using the direct-pour method of liquid nitrogen directly within the tumor cavity. Presently, we use cryoprobes for smaller lesions and the direct-pour method for larger lesions of bone. **(B)** Reconstruction of the curetted defect. It is necessary to reconstruct large defects following curettage resection, especially for giant cell tumors and chondrosarcomas. We prefer the technique of composite reconstruction using Steinmann pins to support the cavity with polymethyl methacrylate cementation.

temperature of the cavity rises above 0°C, the cycle is considered complete. Two to three freeze-thaw cycles are administered, with a saline irrigation occurring between cycles.

Reconstruction is achieved utilizing PMMA, internal fixation, and subchondral bone graft, which provides immediate stability and structural support for large defects and allows early rehabilitation of the adjacent joint.

TECHNIQUE OF TYPE I RESECTION AND RECONSTRUCTION

If an intraarticular (type I) resection is to be performed, the axillary nerve and the deltoid muscle must not be invaded by tumor and must be preservable (Figs. 37-18 to 37-21):

- The utilitarian shoulder incision is utilized.
- The pectoralis major is detached and retracted to expose the axillary vessels and nerves.
- The neurovascular bundle must be dissected out carefully and retracted away from any soft tissue component of the tumor.
- The musculocutaneous nerve, radial nerve, and axillary nerve must all be preserved to ensure optimal hand, arm, and elbow function.
- The pectoralis major muscle is detached and reflected toward the chest wall.
- The pectoralis minor muscle and the conjoined tendon are then released from the coracoid.
- The proximal humerus is now exposed and resection can take place.
- To reconstruct the defect, a Gore-Tex aortic graft is sutured to the remaining portion of the glenoid with Dacron tape.
- The humeral head of the prosthesis is inserted within the Gore-Tex and then sutured through holes in the prosthesis using Dacron tape.

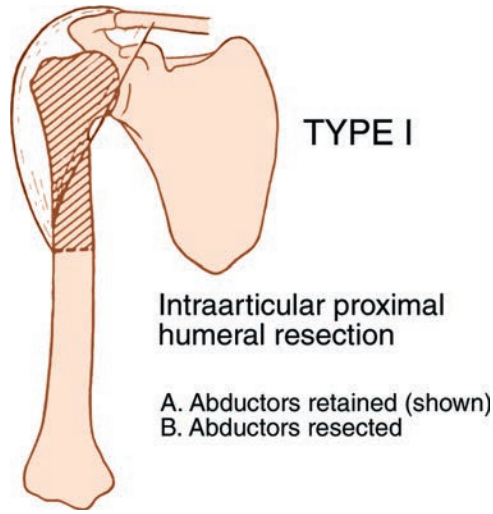

Figure 37-18 Type I shoulder girdle resection. Intraarticular proximal humeral resection with preservation of the deltoid muscle. Type I resections are usually performed for low-grade malignant tumors, such as chondrosarcomas and aggressive giant cell tumors. In general, type I resections are not performed for high-grade sarcomas. (From Malawer M, Wittig JC. Resections of the shoulder girdle. In: Malawer MM, Sugarbaker PH, eds. *Musculoskeletal cancer surgery: treatment of sarcomas and allied diseases*. Dordrecht, Netherlands: Kluwer Academic Publishers, 2001:184.)

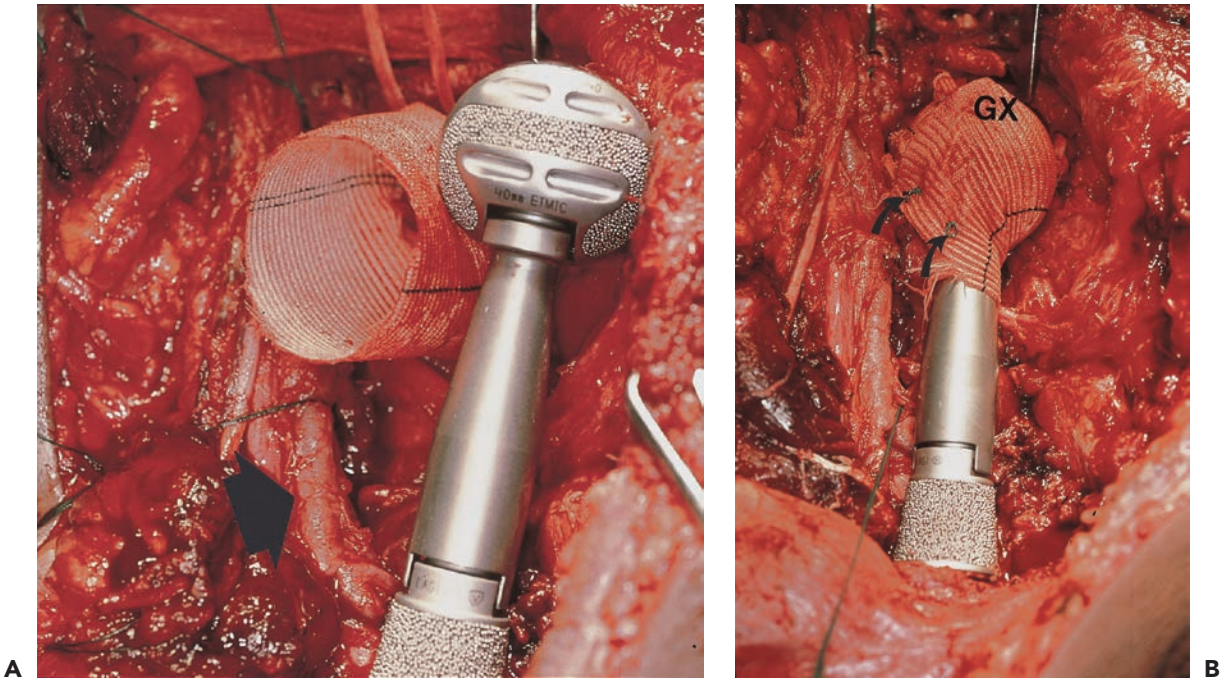

Figure 37-19 Gore-Tex reconstruction in conjunction with a proximal humeral replacement following a type I resection. Gore-Tex graft reconstruction of the capsule is essential to reconstruct shoulder stability. **(A)** The Gore-Tex is sutured to the remaining glenoid rim with Ethibond and Dacron tape. The prosthesis is then placed within this graft and sutured in place with Dacron tape through the Gore-Tex and the holes on the prosthesis. **(B)** Completion of Gore-Tex graft capsular reconstruction. Note the close relationship of the axillary nerve and the infraclavicular portion of the brachial plexus.

- The remaining capsular structure is sutured to the Gore-Tex to reinforce the capsule and the rotator cuff, as well as to prevent shoulder dislocation or subluxation.

TECHNIQUE OF EXTRAARTICULAR PROXIMAL HUMERAL RESECTION AND PROSTHETIC RECONSTRUCTION (TYPE VB)

The technique of extraarticular proximal humeral resection and prosthetic reconstruction may be modified for an intraarticular resection. We recommend an extraarticular (type VB) resection (Fig. 37-22). In general, the deltoid muscle and axillary nerve cannot be preserved for high-grade sarcomas. The anterior and posterior components of the utilitarian shoulder-girdle incision are utilized (see previous text). Three osteotomies are required for an extraarticular resection.

Resection (Figs. 37-23 and 37-24)

- Place the patient in a lateral position, allowing some mobility of the upper torso.
- Prepare the skin down to the level of the midline anterior and posterior to the umbilicus, and cranially past the hairline.
- Start the incision over the junction of the inner and middle thirds of the clavicle, continue along the deltopectoral groove, and then move down the arm over the medial border of the biceps muscle.
- Excise the biopsy site, leaving a 2- to 3-cm margin of normal skin. Do not open the posterior incision until the anterior dissection is complete.
- For exploration of the axilla, open the skin through the superficial fascia.
- Dissect the skin flap anteriorly off the pectoralis major muscle to expose its distal third, and uncover the short head of the biceps muscle. The key to exposure of the anterior shoulder girdle and axilla is the detachment and mobilization of the pectoralis major muscle with partial mobilization medially toward the chest wall.
- Dissect the pectoralis major muscle overlying the axilla free of fat, so that its insertion on the humerus can be visualized. Divide this muscle just proximal to its tendinous insertion on the humerus, and use a suture to tag the portion of muscle remaining with the patient.
- Identify the axillary sheath and visualize the coracoid process. To expose the axillary sheath along its full extent, divide the pectoralis minor, the short head of the biceps, and the coracobrachialis muscles at their insertion on the coracoid process. Tag all proximal muscles with a suture for later identification and use in reconstruction.

D

Figure 37-20 **(A–D)** Clinical photographs of a patient 5 years after a type I proximal humeral resection with Gore-Tex graft reconstruction. Functionally, there is minimal loss of abduction. There is normal internal and external rotation and forward flexion. The Gore-Tex graft avoids subluxation or dislocation, which has been a common problem reported in the literature following proximal humeral replacement.

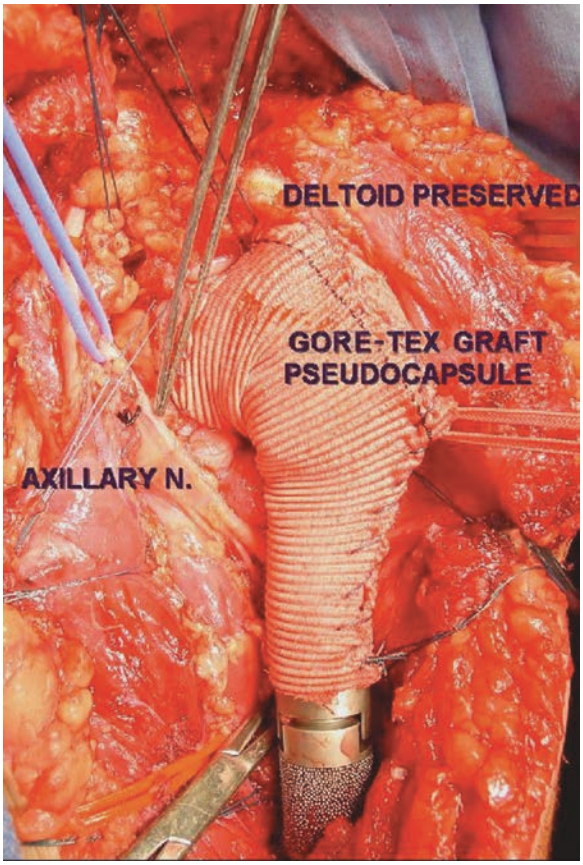

Figure 37-21 Intraoperative photograph showing Gore-Tex reconstruction of the shoulder joint capsule following an intraarticular resection of the humerus. The segmental prosthesis can be seen. The Gore-Tex is sutured to the glenoid and then to fixation holes on the proximal humerus. Gore-Tex reconstruction is always utilized following an intraarticular resection to prevent secondary subluxation or dislocation of the prosthesis.

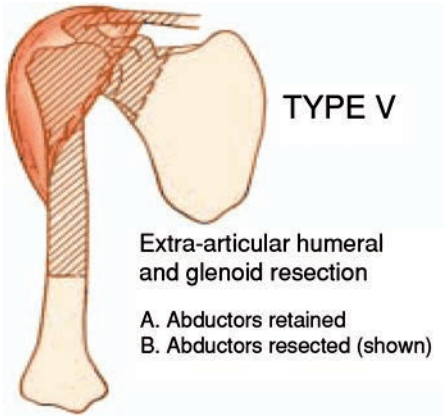

Figure 37-22 Schematic diagram of a type VB shoulder girdle resection. This represents an extraarticular humeral and glenoid resection with removal of the abductor muscles. (From Malawer M, Wittig JC. Resections of the shoulder girdle. In: Malawer MM, Sugarbaker PH, eds. *Musculoskeletal cancer surgery: treatment of sarcomas and allied diseases.* Dordrecht, Netherlands: Kluwer Academic Publishers, 2001:185.)

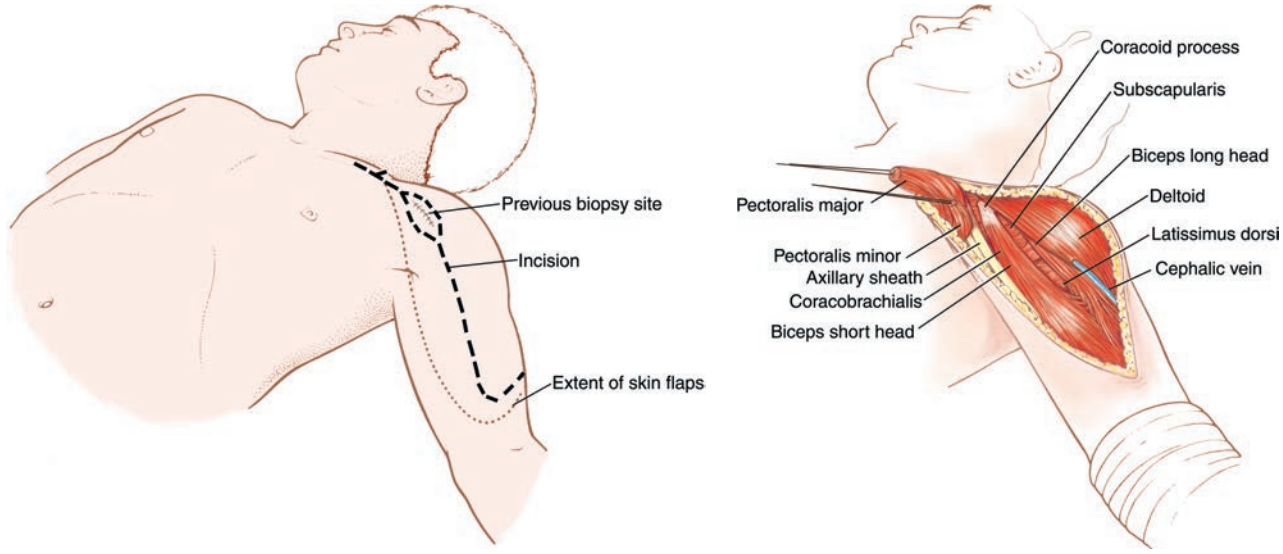

Figure 37-23 Surgical technique of a proximal humeral resection (see text). **(A)** Anterior incision extends from the midclavicle, through the deltopectoral interval, and down the arm as shown. (From Malawer M, Wittig JC. The Tikhoff-Linberg procedure and its modifications. In: Malawer MM, Sugarbaker PH, eds. *Musculoskeletal cancer surgery: treatment of sarcomas and allied diseases.* Dordrecht, Netherlands: Kluwer Academic Publishers, 2001:531.) **(B)** The important first step is identification of and release of the pectoralis major from the proximal humerus and reflecting it upon the chest wall. This exposes the axillary structures. It is important to carefully dissect and identify the infraclavicular portion of the brachial plexus and the nerves (axillary and musculocutaneous) prior to ligation. (From Malawer MM. Tumors of the shoulder girdle, technique of resection and description of a surgical classification. *Orthop Clin N Am* 1991;22:7–35.)

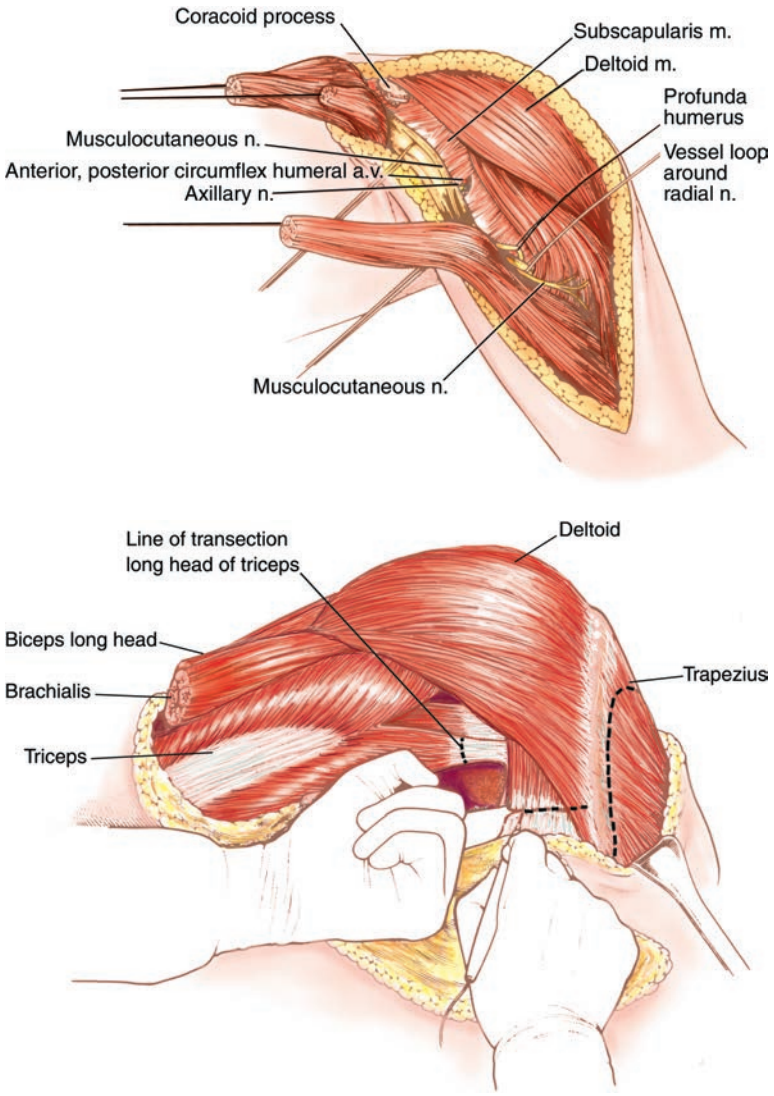

Figure 37-24 **(A)** Second stage of release of musculature of the axillary space. The coracobrachialis is released from the coracoid and the pectoralis minor is released and reflected toward the chest. This exposes the axillary fascia and the axillary vessels. Care is needed to dissect out the individual nerves prior to ligation. The axillary nerve is ligated as well as the anterior and posterior circumflex vessels at the lower border of the subscapularis muscle. The radial nerve is identified, mobilized, and preserved. Radial nerve resection is rarely required. (From Malawer M, Wittig JC. The Tikhoff-Linberg procedure and its modifications. In: Malawer MM, Sugarbaker PH, eds. *Musculoskeletal cancer surgery: treatment of sarcomas and allied diseases*. Dordrecht, Netherlands: Kluwer Academic Publishers, 2001:532.) **(B)** Posterior view showing identification and mobilization of the posterior aspect of the glenoid in which the glenohumeral joint is resected with a Gigli saw (see text). (From Wittig JC, Kellar-Graney KL, Malawer MM, Bickels J, Meller I. Limb-sparing surgery for high-grade sarcomas of the proximal humerus. *Tech Shoulder Elbow Surg*; 2(1):54–69.)

- Before exploring the neurovascular bundle, develop the skin flaps just minimally. If the tumor is found unsuitable for limb-salvage surgery, more-extensive flap dissection would lead to tumor contamination of the skin needed for forequarter amputation.
- In dissecting the neurovascular bundle, pass vessel loops around the neurovascular bundle near the proximal and distal ends of the dissection. Medial traction on the neurovascular bundle allows visualization of the axillary nerve, the posterior circumflex humeral artery, and the anterior circumflex humeral artery. (It is rare to preserve the axillary nerve in large stage IIB sarcomas of the proximal humerus, but if the tumor is small and intraosseous, the nerve can be preserved.) Ligate and divide these three structures.
- If the neurovascular bundle is tumor free, proceed with dissection for a limb-salvage procedure.
- Isolate and preserve the musculocutaneous nerve. It is rarely necessary to sacrifice this nerve to preserve tumor-free margins of resection.
- Divide the deep fascia between the short and long heads of the biceps muscle; this permits easy visualization of the musculocutaneous nerve.
- Identify the radial nerve at the lower border of the latissimus dorsi muscle, where it passes around and behind the humerus in its midportion (spiral groove) into the triceps muscle group.
- Pass a finger around the humerus to move the nerve away from the bone.
- Trace the ulnar nerve down the arm. Divide the intermuscular septum between the biceps and the triceps over the nerve to see it clearly.
- If performing an extraarticular resection, divide the muscle groups anteriorly to expose the neck of the scapula. Separate the short and long heads of the biceps to expose the humerus. Determine the site for the humeral osteotomy, and transect the long head of the biceps and brachialis muscles at this level.
- Identify the inferior border of the latissimus dorsi muscle and make a fascial incision that makes it possible to

pass a finger behind the latissimus dorsi and teres major muscles several centimeters from their insertion.
- Transect the latissimus dorsi and teres major muscles using electrocautery.
- Rotate the humerus externally to expose the subscapularis muscle, which is transected at the level of the coracoid process. Take care not to enter the joint space. Tag the portions of these muscles that will remain with the patient for future reconstruction. Transecting these muscles exposes the anterior portion of the neck of the scapula.
- Now move to the posterior aspect of the patient. Rotate the table, if desired, to provide better visualization.
- Begin the posterior incision anteriorly over the junction of the middle and lateral thirds of the clavicle. Continue down over the lateral third of the scapula past the lower edge of this bone.
- Develop a skin flap by dissecting the skin and subcutaneous tissue between the anterior and posterior incisions from the underlying deltoid muscle down to the level of the midhumerus.
- If removing the entire scapula (type VI resection), make the posterior incision longer and curve it posteriorly to allow the skin flap to expose muscle over the entire scapula.
- Divide the posterior muscle group. Divide the thick fascia that joins the posterior border of the deltoid muscle to the infraspinatus muscle and scapular spine. Leave the deltoid muscle intact to cover the tumor mass.
- Transect the trapezius muscle from its insertions on the scapular spine and acromion.
- Pass the index finger beneath the teres minor up to the area of the planned scapular osteotomy. Transect the supraspinatus, infraspinatus, and teres minor muscles over the neck of the scapula, thus allowing the plane of transection through the neck of the scapula to be exposed. Tag all transected muscles proximally.
- While shielding the radial and ulnar nerves, transect the triceps muscles at the level selected.
- Perform clavicular, scapular, and humeral osteotomies as follows (Fig. 37-25)
  (a) Divide the clavicle at the junction of its middle and inner thirds. This is usually accomplished with a Gigli saw.
  (b) Divide the scapula through its surgical neck medial to the coracoid process, also using a Gigli saw.
  (c) Perform the clavicular and scapular osteotomies before the humeral osteotomy.
  (d) Remove the entire specimen, taking care to protect all the neurovascular structures at each osteotomy site.
- If resecting the entire scapula, take the skin flap back to the medial edge of the scapula. Divide the rhomboid, levator scapula, and trapezius muscles from their insertions on the scapula. It is unnecessary to divide the teres major, teres minor, supraspinatus, infraspinatus, and subscapularis muscles when performing a full scapular resection.
- Transect the humerus 4 to 6 cm distal to the tumor, as determined by preoperative bone scan.
- Obtain frozen sections of tumor margins and touch preparations for cytologic examination of the marrow at the site of the osteotomy.

Proximal Humerus Prostheses

A modular replacement prosthesis is used for large segments of the proximal humerus. The design features of this device are summarized below.

Proximal Humeral Endoprosthesis (MRS, Stryker Orthopedics, Mahwah, NJ)

- Modular components, including stem, body, and humeral head
- Polished intramedullary stems for cement fixation available in multiple diameters and lengths
- Facing reamer to create a perfect seat for the stem–bone interface that protects the stem from bending stresses
- Porous coating (circumferential) at the prosthesis–bone junction for ingrowth of extracortical bone graft and soft tissue to seal the bone–cement–stem interface. Incorporation of extracortical bone graft also protects the prosthetic stem by sharing bending and loading stresses.
- Humeral heads (available in two sizes) with porous coating and metal loops or holes to facilitate muscle and tendon attachment and soft tissue ingrowth

The coracoid and acromion are not recreated on the prosthesis since they serve no function.

TECHNIQUE OF RECONSTRUCTION WITH MODULAR SEGMENTAL PROSTHESIS (MRS)

Endoprosthetic replacement, which has been in use since 1973, is the most common technique for reconstructing large proximal humeral defects (Figs. 37-26 to 37-29). It may be used for both intraarticular and extraarticular defects (i.e., when retaining the glenoid as well as when resecting it with the tumor). Alternatives (although not recommended by the senior author) to reconstructing the defects include allografts, allograft/prosthesis composites, dual fibulas, and vascularized fibulas. Only endoprosthetic replacement will be described in this chapter.

Originally, each patient received a custom-made prosthesis. In 1988, Howmedica (Rutherford, NJ) developed the modular replacement system (MRS), which has since undergone several improvements (see Fig. 37-27). The first MRS prosthesis placed in this location was performed in 1988 in Washington, D.C., for a large stage IIB osteosarcoma of the proximal humerus.

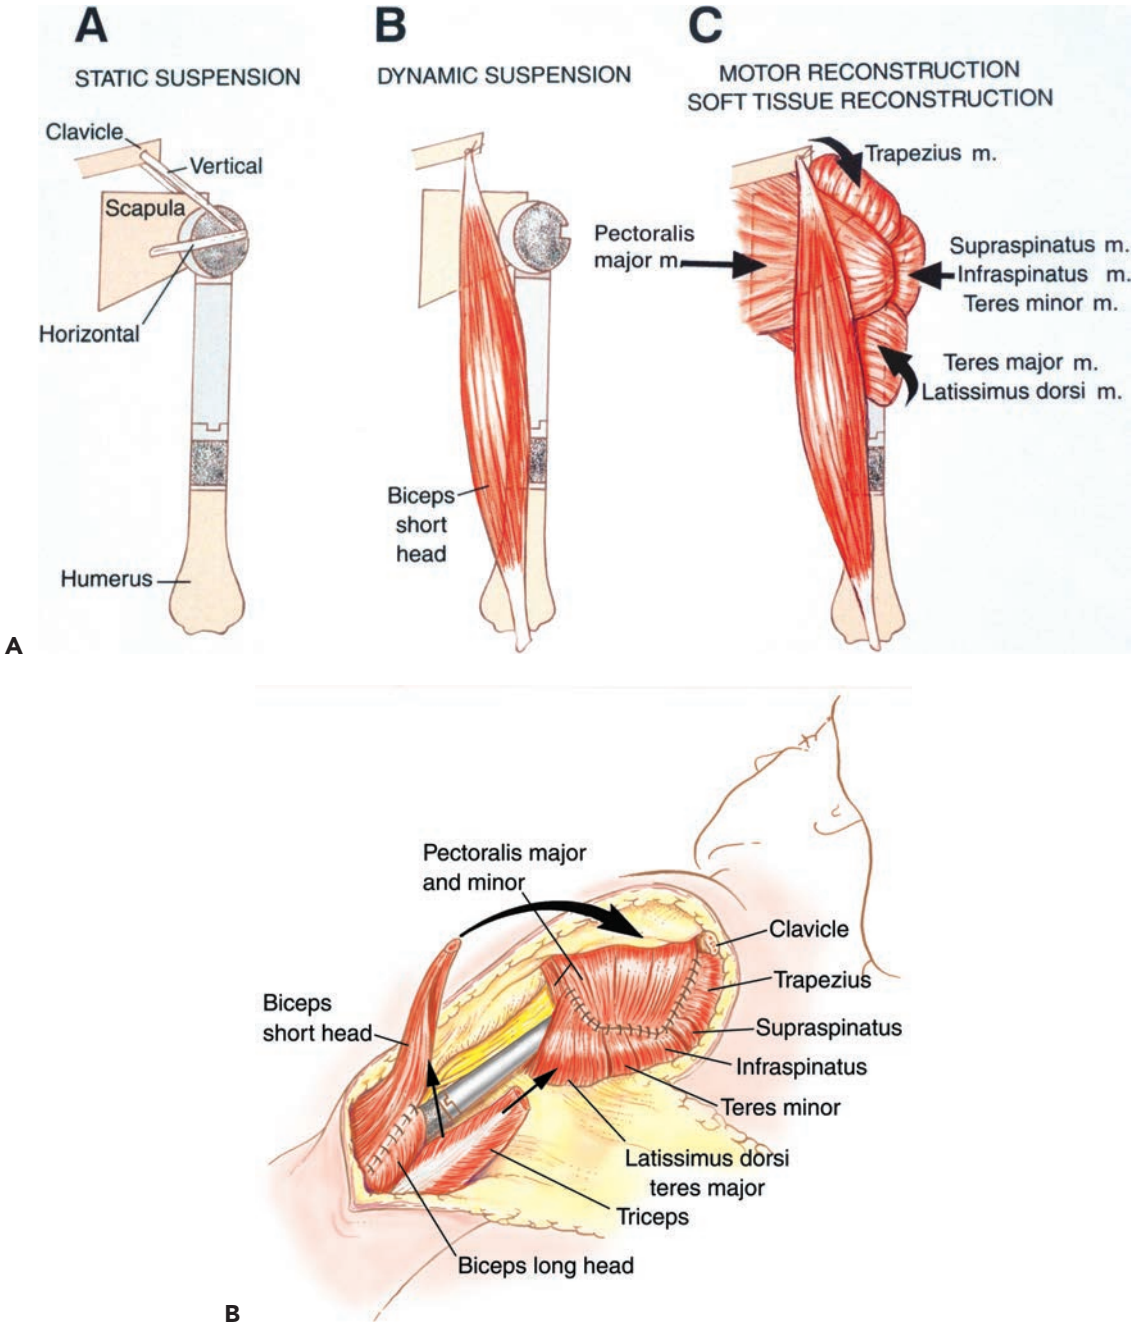

Figure 37-25 Schematic showing the three phases of reconstruction. **(A)** Schematic diagram showing the intraoperative reconstruction of the shoulder girdle musculature. The pectoralis major is sutured to the osteotomized end of the scapula. A prosthesis is placed anterior to the scapula and is covered by the pectoralis major muscle. The remaining muscles are sutured to the pectoralis major, reconstructing the shoulder girdle. The biceps and triceps are tenodesed together and to the muscles. **(B)** The pectoralis major has been sutured to the scapula following prosthetic reconstruction with Dacron tape. The biceps and triceps are then tenodesed to each other to complete the reconstruction. (From Rubert CK, Malawer MM, Kellar KL. Modular endoprosthetic replacement of the proximal humerus. Indications, surgical technique, and results. *Semin Arthroplasty* 1999;10(3):142–153.)

An MRS is used for both intra- and extraarticular reconstructions. The reconstruction is combined with multiple muscle transfers to reconstruct the resected soft tissues. For high-grade bone sarcomas, the deltoid and axillary nerve, along with the glenohumeral joint, are routinely removed (type VB resection). Low-grade tumors are treated with an intraarticular resection and preservation of the abductor mechanism.

Soft tissue reconstruction is essential to cover the prosthesis and create shoulder stability. This is accomplished

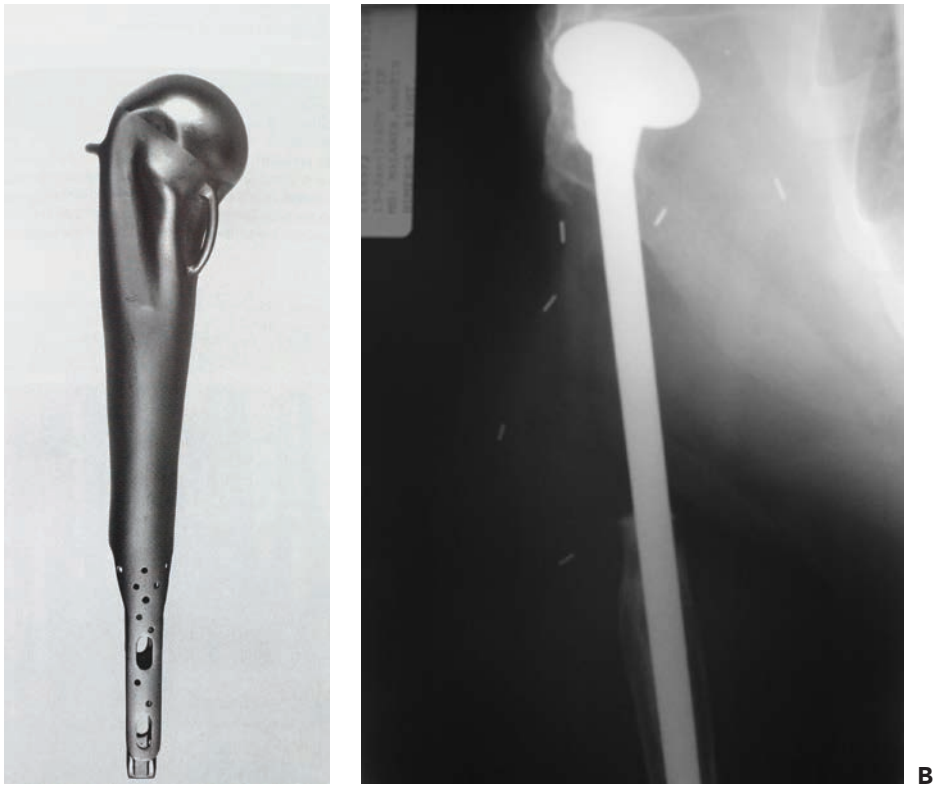

Figure 37-26 Historical prosthetic devices utilized for proximal humeral reconstruction. **(A)** Custom prosthesis with external phalanges for the proximal humerus utilized during the 1960s and 1970s. **(B)** A custom long-stemmed Neer prosthesis utilized by Dr. Ralph Marcove for proximal humerus reconstructions in the 1970s.

through a technique of dual suspension that entails static and dynamic reconstruction. Dacron tape is used to secure the prosthesis horizontally to the scapula and vertically to the clavicle through drill holes. The two sets of Dacron tape provide mediolateral and craniocaudal stability. Dynamic suspension, provided by transfer of the short head of the biceps muscle to the stump of the clavicle, allows elbow flexion. This also restores elbow flexion. Transfer of the trapezius also provides for vertical suspension.

Preservation and transfer of the pectoralis major, trapezius, supraspinatus, infraspinatus, teres minor, teres major, and latissimus muscles provide mobility of the shoulder. These muscle groups offer dynamic support, assist in suspension of the prosthesis, and provide soft tissue coverage, which is essential in preventing skin problems and secondary infection.

Endoprosthetic replacement is highly predictable and successful. There are minimal problems with subluxation following adequate soft tissue reconstruction. Malawer et al.,[3] who have the most extensive experience with replacing the proximal humerus with the MRS, report 95% survival of the prosthesis as determined by Kaplan-Meier analysis at 10 years.

TECHNIQUE OF TOTAL HUMERAL RESECTION

Total humeral resection (i.e., removal of the shoulder and elbow joints) and replacement is an unusual procedure. It is indicated when the tumor involves a large component of the medullary shaft.

Anatomic considerations relative to the proximal humeral component are similar to those previously described. Considerations relating to the midshaft and distal humerus center on the relationship of the tumor to the brachial artery and nerves. Angiography is required to determine the relationship to the brachial vessels medially and the antecubital fossa. MRI and bone scan are used to identify the extent of the humeral involvement, which, in turn, determines whether total humeral resection is required. The entire humerus should be removed in patients who have round cell tumors of the humerus and diaphysis.

The surgical approach is similar to that of a type V resection using multiple muscle transfers and Dacron tape. The resection is similar to that used for lesions of the proximal humerus but continues down to the elbow joint, which is opened anteriorly after mobilizing the brachial vessels and the median nerve through the antecubital fossa (Fig. 37-30).

Resection

- Explore the vessels proximally, release the circumflex vessels proximally, and identify the musculocutaneous, axillary, and radial nerves.
- Mobilize the brachial vessels throughout the length of the arm into the antecubital space to protect them and

Figure 37-27 Modular segmental replacement prostheses. These prostheses consist of three components: a stem of varying diameter, bodies of varying lengths, and humeral heads of various circumferences. Prostheses shown are the trials (holes within the bodies, not to be implanted).

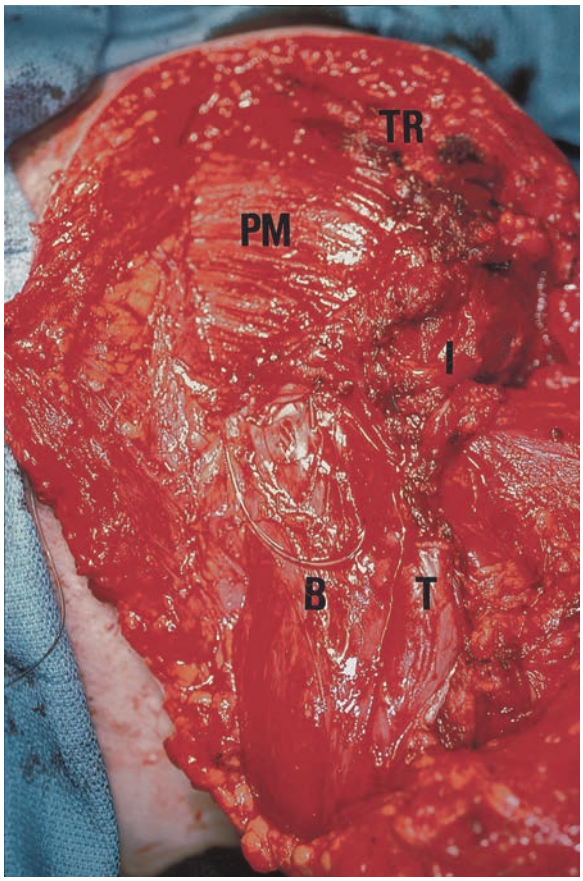

Figure 37-28 Operative photograph showing a completed reconstruction following an extraarticular reconstruction. The prosthesis is covered by muscle. The pectoralis major is the main muscle in the reconstruction and is sutured to the osteotomized scapula. The biceps and triceps are tenodesed to themselves and to the pectoralis major. The remaining musculature of the rotator cuff is tenodesed to the pectoralis major. The trapezius muscle is mobilized and brought down and sutured to the pectoralis major. Intraoperative photograph of completed reconstruction of the proximal humerus. B = biceps; I = infraspinatus; PM = pectoralis major; T = triceps; TR = trapezius.

the accompanying medial nerve. The ulnar nerve passes posteriorly through the intramuscular septum and can easily be identified in the midarm.

- Identify the radial nerve as it passes around the humerus and into the interval between the biceps and brachioradialis muscle, where it becomes the posterior interosseous nerve. Identify and preserve all these nerves, as well as the brachial artery and vein.
- Keep the triceps tendon attached to the olecranon.
- Perform anterior exposure of the elbow joint.
- Explore and identify the brachial vessels and the median nerve.
- Open the capsule of the elbow joint circumferentially; this makes it possible to fit the elbow component and seat it into the olecranon. Avoid a posterior approach to the elbow. Detach the flexor and extensor muscles from their origins on the humeral condyles. Retract the biceps, but do not detach it from its insertion onto the radial tuberosity.

TECHNIQUE OF RECONSTRUCTION WITH TOTAL HUMERAL ENDOPROSTHETIC REPLACEMENT

The senior author recommends total humeral endoprosthetic reconstruction utilizing an MRS with a custom elbow component.

- Use one of the several elbow devices available. An intramedullary stem fixation with PMMA is widely preferred.
- Reattach the forearm flexor and extensor muscles to holes in the prosthesis.
- Transpose the ulnar nerve anteriorly to avoid irritation from the prosthesis. Repair the biceps to the adjacent soft tissue.
- Take care to interpose the capsule between the prosthesis and the neurovascular structures anteriorly.

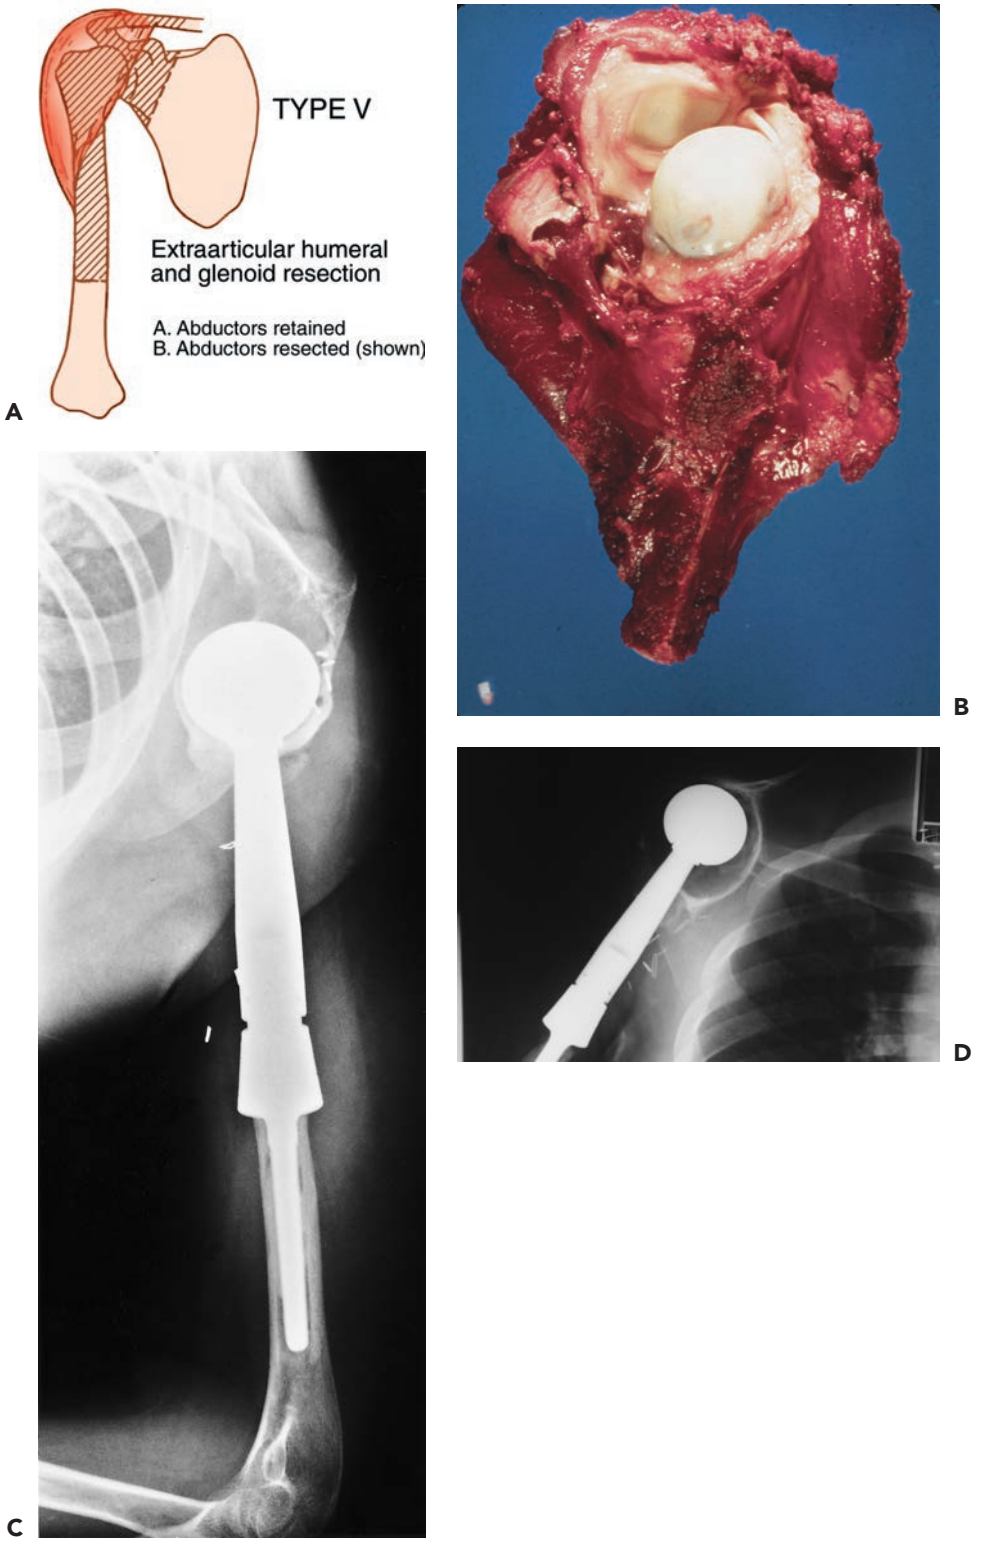

Figure 37-29 **(A)** Schematic of type V resection. This is the most common type of resection for high-grade sarcomas of the proximal humerus. (From Malawer M, Wittig JC. Resections of the shoulder girdle. In: Malawer MM, Sugarbaker PH, eds. *Musculoskeletal cancer surgery: treatment of sarcomas and allied diseases.* Dordrecht, Netherlands: Kluwer Academic Publishers, 2001:186.) **(B)** Gross specimen following an extraarticular resection. Note that the glenohumeral joint has been opened. **(C)** Plain radiograph following an extraarticular resection approximately 5 years postoperatively. Note the new (pseudo) glenoid bone formation around the humeral head. This is a typical finding. **(D)** Plain radiograph following a type VB proximal humeral resection and reconstruction with a modular segmental prosthesis. Note that the prosthesis is placed anterior to the scapula (see reconstructive technique). This is a typical resection for high-grade sarcomas of the proximal humerus. OR Plain radiograph at 5 years follow-up showing metaplastic bone forming a new glenoid. This is a common finding.

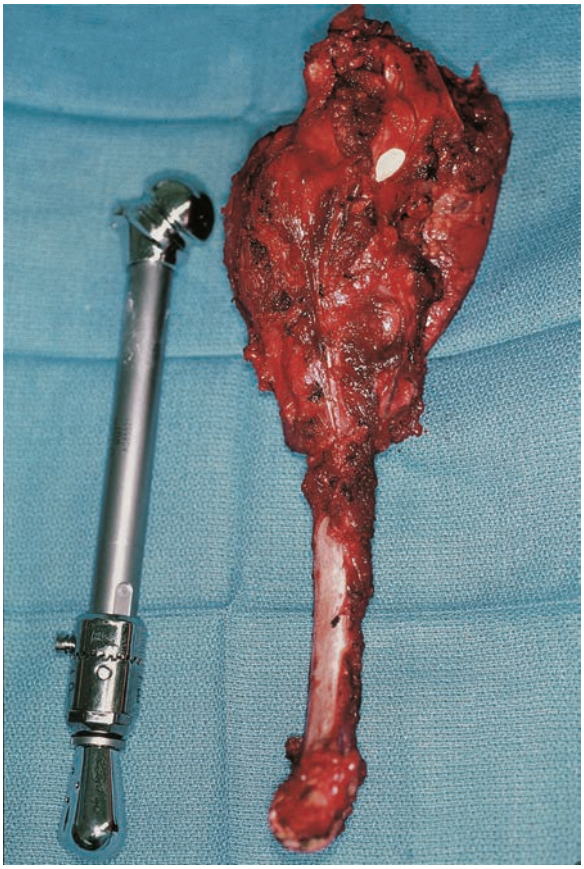

Figure 37-30 Total humeral resection for a large osteosarcoma with intramedullary extension.

Experience with total humeral prostheses is limited, but the duration of these prostheses is reliable. The most critical considerations following total humeral replacement are the potential for arterial thrombosis and occlusion, nerve compression, or neurapraxia.

Rehabilitation

A sling or plaster splint must be worn longer following these procedures than following proximal humeral resections. This is because of the need to allow for soft tissue healing around the elbow and the shoulder girdle. Elevation is required for the first 72 hours. Rehabilitation must focus on both the shoulder and the elbow joints. Fortunately, it is possible to preserve most of the musculature of the shoulder girdle, which allows for an extremely stable shoulder girdle as well as preservation of most of the elbow musculature.

TUMORS OF THE SCAPULA AND PERISCAPULAR AREA

Clinical Characteristics

Tumors of the scapula present with pain, a mass, or both, and they may become quite large before they are brought to the surgeon's attention. Chondrosarcoma is the most common primary malignancy of the scapula. Secondary chondrosarcomas occur from an underlying osteochondroma, but fewer than 2% of osteosarcomas arise from the scapula. In children, the most common malignant scapular tumor is Ewing's sarcoma. Soft tissue sarcomas may involve the suprascapular or the infraspinous musculature and, secondarily, the scapula. Most soft tissue sarcomas of the scapular region occur in adults. In very rare cases, radiation sarcomas of the scapula develop secondary to radiotherapy for breast carcinoma.

Among the unique anatomic considerations associated with this area is that during the early stages of development, a cuff of soft tissue surrounds tumors arising within the scapula. As sarcomas enlarge, they may develop a large axillary component and invade the axillary vessels and brachial plexus. Tumors arising from the neck or glenoid usually involve the periscapular tissue and the glenohumeral joint; this is especially true of chondrosarcomas, osteosarcomas, and Ewing's sarcomas. Important anatomic areas to evaluate for extension are the chest wall, axillary vessels, proximal humeral and periscapular tissues, and rotator cuff. The axillary lymph nodes should be carefully examined, even though they are usually negative. Large suprascapular tumors extend into the anterior and posterior triangles of the neck, making resection difficult or contraindicated, except for palliation.

It is usually possible to satisfactorily treat soft tissue sarcomas arising in the periscapular musculature by removing the adjacent tissue en bloc while preserving the scapula, then following with radiotherapy. Occasionally, a soft tissue sarcoma arising from the deeper structures will involve or encase the scapula, requiring combined scapular resection. If the tumor is distal to the scapular spine, a partial (type IIB) or total (type IIIB) scapulectomy may be adequate. Involvement of the suprascapular musculature or rotators requires an extraarticular resection (type IV).

Specific Tumors of the Scapula

Certain tumors of the scapula and periscapular area require special management (Fig. 37-31). Chondrosarcomas, for example, commonly arise from the scapula; for this reason, any large cartilaginous lesion of the scapula in an adult should be approached with a high index of suspicion. These lesions tend to be low grade and have a large extraosseous component. Cartilage tumors approaching the glenohumeral joint may directly involve the joint space and readily implant on the articular cartilage. In such cases, an extraarticular resection is generally recommended, with no attempt to perform an intraarticular resection. A Tikhoff-Linberg resection (type IV) usually is curative.

Osteosarcomas, of which about 1.5% occur in the scapula, require a limb-sparing resection (type IV) or a forequarter amputation. The limiting factors in performing a limb-sparing procedure are the size and extent of the

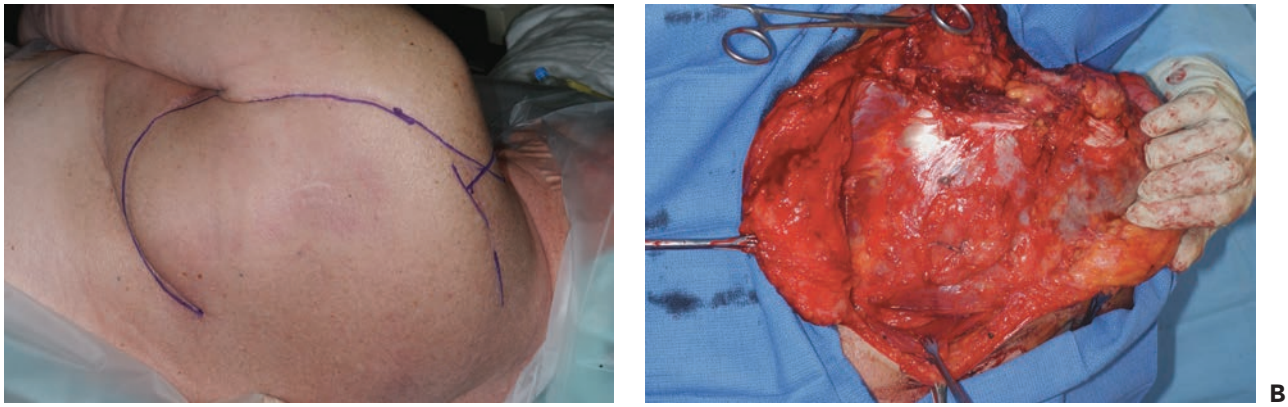

Figure 37-31 **(A)** A large periscapular tumor involving the body of the scapula. A long curvilinear incision is utilized to develop a posterior fasciocutaneous flap to expose the scapula, chest wall, and the supraclavicular area. **(B)** Intraoperative view following fasciocutaneous flap development. A large scapular mass is seen involving the teres and infraspinatus muscles.

extraosseous component. Neurovascular involvement requires a forequarter amputation. Chest wall involvement should be determined before surgery; if present, a partial chest wall resection en bloc with ablation of the primary tumor is necessary.

The traditional treatment for Ewing's sarcoma arising in the scapula has been radiation therapy and chemotherapy, and it has produced excellent functional results. However, the treatment of Ewing's sarcoma is undergoing reevaluation. Recently, total scapulectomy (type IIIA or B), with or without prosthetic replacement, has been recommended in lieu of radiation therapy. Surgery has become increasingly common with the hope of increasing local control, decreasing the morbidity of radiation (especially of late secondary osteosarcomas), and increasing patient survival. The surgery should be planned after induction chemotherapy. Staging should be done in the same manner as in patients with other high-grade sarcomas.

GCTs and ABCs often cause marked ballooning and destruction of the scapula. Small lesions may be treated by intralesional curettage. If the neck of the scapula is not involved, it is possible to perform a partial scapulectomy with minimal loss of function. Large lesions should be treated with total scapulectomy (type IIIA) while preserving most adjacent muscles. Reconstruction involves suspending the scapula from the clavicle by a static and dynamic reconstruction. This is an excellent indication for scapular prostheses, which have recently been developed.

TECHNIQUE OF TIKHOFF-LINBERG (TYPE IVB) RESECTIONS

The Tikhoff-Linberg procedure (extraarticular total scapular proximal humeral resection, type IV) consists of en bloc removal of the scapula, distal clavicle, and proximal humerus and preservation of the arm. The Tikhoff-Linberg procedure was the first true limb-sparing procedure of the upper extremity. The originally description was published in English in 1928 and was performed for periscapular soft tissue sarcomas.[2] Today, the indications for this procedure are low- and high-grade scapular (bony) sarcomas and periscapular and suprascapular soft tissue sarcomas (Fig. 37-32).

Careful preoperative evaluation is imperative. CT and MRI can help determine possible chest wall involvement, and angiography is crucial to determine axillary vessel involvement (Fig. 37-33). Contraindications to the Tikhoff-Linberg procedure are involvement by the tumor of the neurovascular bundle and of the chest wall, both of which require forequarter amputation.

It is important to carefully evaluate the interval between the tumor and vessels; this may require surgical exploration prior to resection. If this interval is clear, the resection may proceed. The surgical team must be prepared to convert from a limb-sparing procedure to a forequarter amputation should the tumor be found to involve the neurovascular bundle. The most medial margin, the paraspinal muscles, and the base of the neck must be explored if there is any possibility of their involvement. It is difficult to evaluate these anatomic areas thoroughly from preoperative studies alone.

Resection includes all the muscles arising from the scapula and inserting on the proximal humerus and an extraarticular excision of the glenohumeral joint. Occasionally, it is possible to preserve the deltoid muscle and the axillary nerve. The deltoid should be preserved whenever possible because it facilitates reconstruction, and soft tissue reconstruction is essential for a stable shoulder.

The surgical guidelines are as follows:

- The utilitarian incision is used, utilizing a combined anterior and posterior approach. The anterior incision is used to explore the axillary vessels, brachial plexus, and axilla.

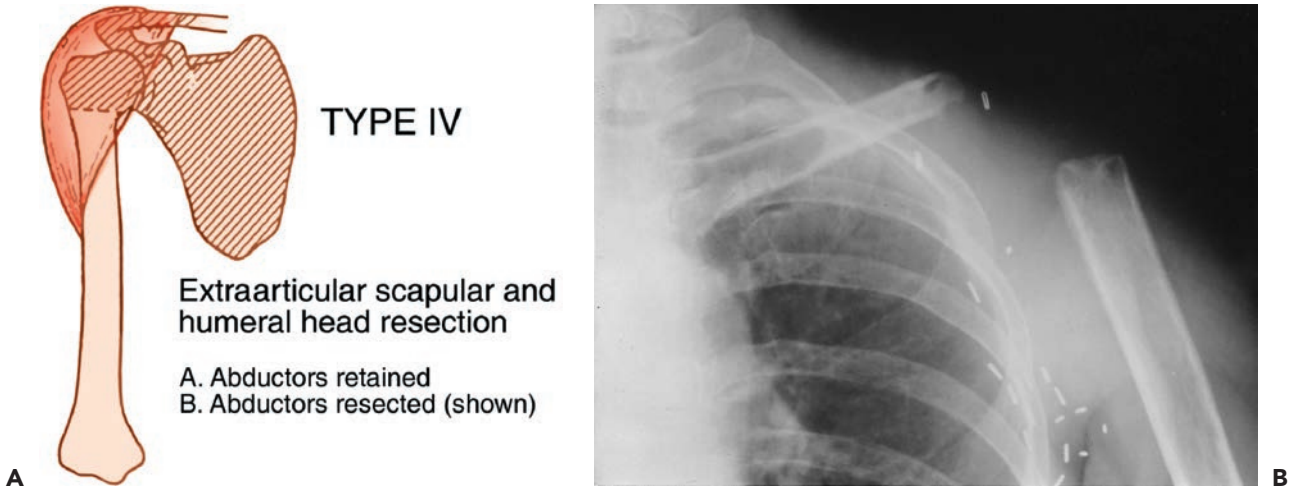

Figure 37-32 **(A)** Type IVB extraarticular scapula and humeral head resection. This is the original type of shoulder-girdle resection as described by Tikhoff and Linberg (see text). The Tikhoff-Linberg resection was the first limb-sparing surgical procedure performed around the shoulder girdle. Resection included the scapula, distal end of the clavicle, and the proximal humerus. Classically, the proximal humerus was suspended from the clavicle by the remaining muscles and/or heavy sutures. (From Malawer M, Wittig JC. Resections of the shoulder girdle. In: Malawer MM, Sugarbaker PH, eds. *Musculoskeletal cancer surgery: treatment of sarcomas and allied diseases.* Dordrecht, Netherlands: Kluwer Academic Publishers, 2001:190.) **(B)** Radiograph following a type IVB resection with soft tissue reconstruction only. Today, we would utilize a scapular prosthesis if the necessary musculature had been retained (see text).

- The pectoralis major muscle is released from the humerus. The pectoralis minor and conjoin tendon are released to permit exposure of the neurovascular structures.
- The glenohumeral joint is exposed anteriorly. The circumflex vessels as well as the axillary nerve are ligated. The joint covered by the subscapularis muscle is not opened.
- The axillary vessels and the brachial plexus are explored and gently retracted anteriorly. The pectoralis major has previously been detached and reflected toward the chest wall for adequate visualization of these structures.
- The posterior portion of the incision allows the release of all muscles that attach the scapula. The rhomboids, trapezius, and levator scapulae muscles are transected. The scapula is then lifted from the chest wall, which permits release of the serratus anterior muscle. It is important to palpate this interval early to determine any chest wall involvement by tumor.
- The glenohumeral joint is removed in an extraarticular manner through the anterior and posterior incisions. The osteotomy is performed below the level of the joint capsule.

To achieve both static and dynamic support, suspension of the proximal humerus is obtained by suturing of the remaining clavicle with Dacron tape (Genzyme Surgical Product Co., Fall River, MA) and muscle transfers. The long and short heads of the biceps and coracobrachialis are sutured through drill holes to the remaining clavicle, and the pectoralis muscle is rotated to cover the defect and to provide stability (Figs. 37-34 and 37-35).

In general, functional results are the same as those following a Tikhoff-Linberg resection (type IVB) and total scapulectomy (type IIIA/B). Patients retain hand function and good elbow function. The shoulder should be stable and no external orthosis should be required. A molded shoulder pad improves cosmesis (Fig. 37-36).

TECHNIQUE OF TOTAL SCAPULECTOMY

Total scapulectomy (intraarticular scapular resection, type III A or B) is indicated primarily for low-grade sarcomas (stage IA/B) of the body of the scapula that involve the suprascapular area, low-grade sarcomas of the glenoid, and soft tissue sarcomas that involve the scapula. Preoperative considerations are similar to those for a Tikhoff-Linberg resection. The neurovascular structures and chest wall must be free of disease. If the tumor extends anteriorly or laterally and involves the rotator cuff or the glenoid, an extraarticular resection (type IVB) should be performed. The skin flaps are similar to those obtained from the posterior limb during a Tikhoff-Linberg resection.

Other guidelines for total scapulectomy are as follows:

- Utilize two incisions: anterior and posterior portions of the utilitarian incision. The anterior incision is used to mobilize the axillary vessels and nerves, especially if there is a large anterior component arising from the scapula. The posterior incision permits exposure of the scapula, rhomboids, latissimus dorsi, and teres muscles.

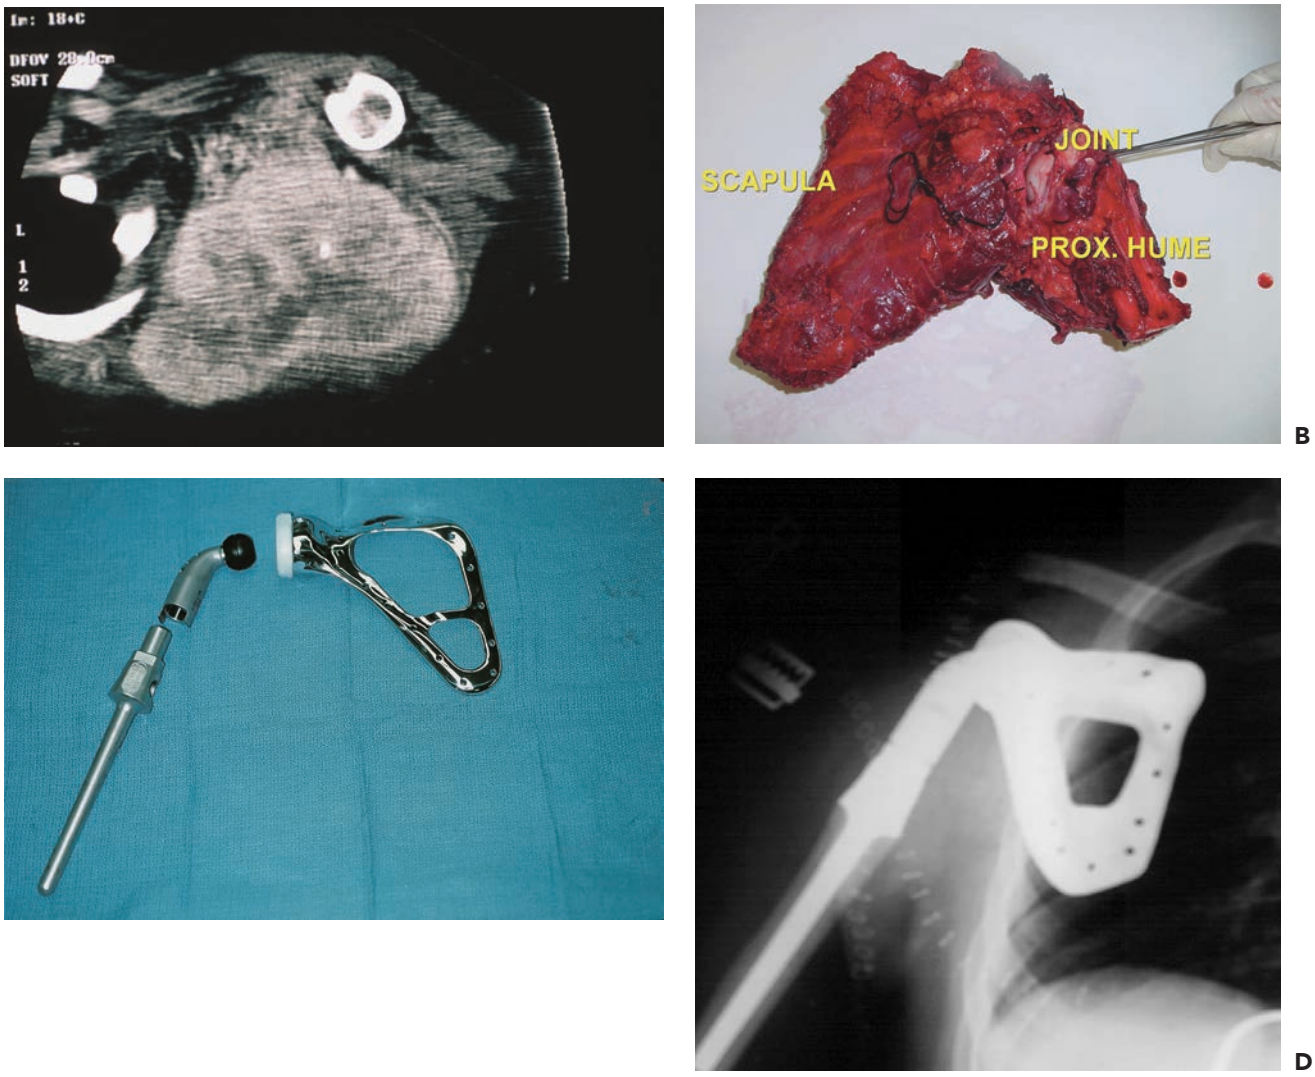

Figure 37-33 **(A)** Computed tomography scan showing a large tumor of the scapula, which is filling the axillary space and involves the proximal humerus. **(B)** Gross specimen following resection of the scapula and proximal one-third of the humerus. This is an extended Tikhoff-Linberg resection (type IVB). **(C,D)** Modular proximal humeral prosthesis and snap fit scapular component (Stryker Orthopedics, Mahwah, NJ).

Figure 37-35 **(A)** Schematic of muscle transfers for a scapular endoprosthesis and proximal humeral component. (From Wittig JC, Bickels J, Wodajo FM, Kellar-Graney KL, Malawer MM. Constrained total scapula reconstruction after after resection of a high-grade sarcoma. *Clin Orthop* 2002;397:143–155.) **(B)** Schematic muscular reconstruction required for shoulder-girdle endoprosthesis. The deltoid and trapezius must be retained to cover the prosthesis superiorly. The inferior portion of the body of the prosthesis is covered by the rhomboids and the latissimus dorsi. In general, the rhomboids and the latissimus muscles are often retained following type IVB resection. The major determinant of the use of a scapular prosthesis is the preservation of the deltoid and trapezius muscles. (From Malawer MM, Wittig JC, Rubert CK. Scapulectomy. In: Malawer MM, Sugarbaker PH, eds. *Musculoskeletal cancer surgery: treatment of sarcomas and allied diseases*. Dordrecht, Netherlands: Kluwer Academic Publishers, 2001:568.) **(C)** Intraoperative photograph of muscle reconstruction over a scapular endoprosthesis (see text). **(D,E)** Intraoperative photographs showing Gore-Tex graft reconstruction.

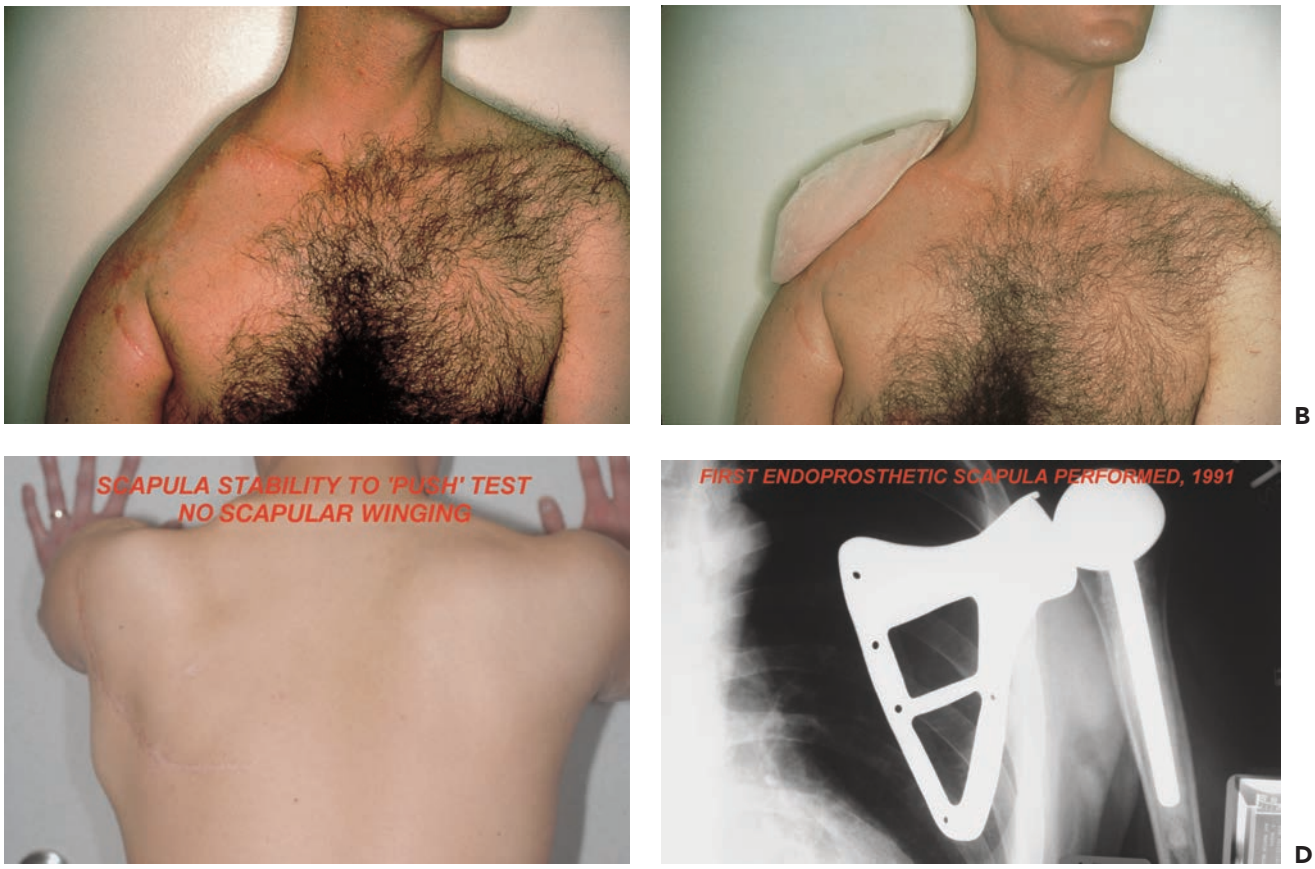

Figure 37-36 Cosmetic appearance following a Tikhoff-Linberg resection. **(A)** Typical clinical appearance. **(B)** Cosmesis is achieved by a contoured shoulder pad. **(C)** Cosmesis following scapular reconstruction with an endoprosthesis. **(D)** Plain radiograph showing a scapula and glenohumeral replacement. Gore-Tex is utilized to recreate the shoulder joint and reattach the humerus to the scapular neck.

- Transect all muscles away from the bone, starting at the lowest point inferiorly.
- Approach the neurovascular structures from the back, as the scapula is retracted away from the chest in a cephalad direction. Take care to avoid injuring the musculocutaneous and axillary nerves near the coracoid and around the subscapularis muscle.
- Be prepared to convert this approach (type III) to a Tikhoff-Linberg resection (type IVB) if the anterior or medial margins are questionable.

Soft tissue reconstruction is mandatory to provide stability and to avoid a flail extremity. Employ a dual-suspension technique using Dacron tape from the clavicle for static support and reattaching the biceps and triceps muscles through drill holes. Tenodesing the deltoid to the pectoralis major and trapezius muscles is essential to provide stability.

The functional results are similar to those with a standard Tikhoff-Linberg resection. If significant soft tissue remains, this defect occasionally can be reconstructed with a total scapula prosthesis. The important muscles for this purpose are the latissimus dorsi, rhomboids, and trapezius.

TECHNIQUE OF PARTIAL SCAPULECTOMY

A partial scapulectomy is indicated for low-grade or benign lesions involving only the body of the scapula. It preserves a cuff of infraspinatus, subscapularis, and serratus anterior muscle. Reconstruction consists of suturing together these muscles to close the dead space and reconstituting the points of origin and insertion of these muscles. A sling is required for 5 to 7 days.

Functional loss after a partial scapular resection (type II) is minimal; in fact, shoulder motion and strength are nearly normal. Total scapular resection (type IIIA/B) causes a significant loss of shoulder motion, but elbow and hand function are normal. The major limitation is the loss of shoulder abduction. Shoulder-girdle function is similar to that following total scapular resection and a Tikhoff-Linberg resection (type VB).

Soft tissue reconstruction is the key to establishing shoulder stability. A compressive arm stocking should be worn immediately after surgery to prevent swelling. The patient should be encouraged to flex the elbow but to

avoid extension until the wound has healed. The patient must wear a sling for 2 to 4 weeks, by which time the transferred muscles provide a stabilizing force to the entire upper extremity. Forward and backward flexion of approximately 30 to 45 degrees is obtained. The goal of rehabilitation is to strengthen the transferred pectoralis major, latissimus dorsi, and trapezius muscles around the shoulder as well as the elbow flexors. A shoulder pad contributes to cosmesis and restores symmetry.

TECHNIQUE OF SCAPULA ENDOPROSTHETIC RECONSTRUCTION

Experience with total scapular replacement, although still limited, is increasing. If most of the musculature is retained (type IIIA), it usually is possible to reconstruct the defect with a custom scapular prosthesis. The most common indications for this procedure are large (stage III) GCTs, low-grade chondrosarcomas, and Ewing's sarcomas following induction chemotherapy. Successful reconstruction poses three primary challenges: (a) replacing the humeral joint, (b) stabilizing the scapula prosthesis within the humeral component (i.e., creating a new glenohumeral joint), and (c) providing soft tissue attachments to both the scapular and humeral components to ensure stability as well as active motion.

Types of Prostheses (Fig. 37-37)

A custom prosthesis is utilized for reconstruction of the scapula. The design features of these prostheses are summarized below:

- Nonconstrained or semiconstrained design (first- and second-generation prostheses)
- Holes along the periphery of the prosthetic scapular body for reattachment of the scapular stabilizing muscles (levator scapulae, rhomboids, and trapezius)
- Holes along the base of the prosthetic scapular neck for capsular reconstruction with Gore-Tex graft
- The body of the scapula is open to permit adjacent muscle tenodesis.
- No attempt is made to recreate the coracoid, acromion, or scapula spine. These structures would create wound complications and closure difficulties.

Technique of Constrained Total Scapula Endoprosthesis Reconstruction

The technique, surgical anatomy, and indications and results of the constrained scapula prosthesis are as follows:

- Tenodese the scapula prosthesis to the remaining trapezius, rhomboids, and latissimus dorsi muscles.
- Place the prosthesis in a pocket between the rhomboids and serratus anterior.
- Use Dacron tapes to tenodese the prosthesis to these muscles. Tenodese the trapezius to the prosthesis and to the deltoid muscle.
- Rotate the latissimus dorsi to cover the prosthesis in entirety with soft tissues.
- Suture a Gore-Tex graft over the proximal humeral component before snapping it into the glenoid for additional stability.
- Reconstruct the glenohumeral joint by sewing an aorta Gore-Tex (W.L. Gore & Associates, Flagstaff, AZ) graft over the scapula neck and the proximal humerus. This

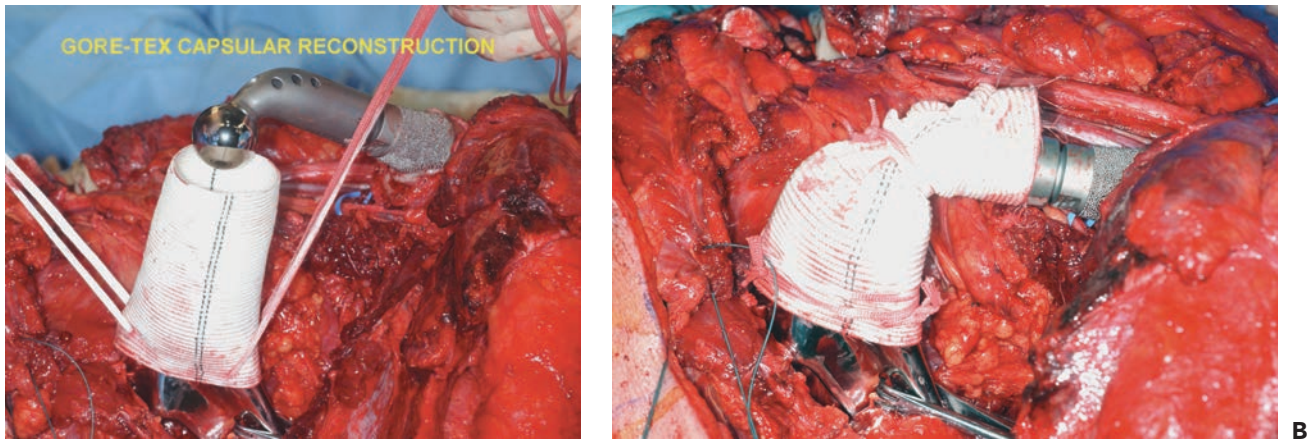

Figure 37-37 Gore-Tex reconstruction in conjunction with a bipolar snap fit head. **(A)** Reconstruction with Gore-Tex graft of a new capsule. Gore-Tex is initially sewn to the neck of the scapula. **(B)** Prosthesis is reduced into the glenoid. Note that the Gore-Tex graft has been placed proximally around the glenoid and scapular component. The Gore-Tex is brought over the proximal humeral component and sutured into place with 3-mm Dacron tape. Completion of the capsular reconstruction is achieved with the Gore-Tex graft. The rhomboid muscles and latissimus dorsi are then closed over the body of the prosthesis.

permits stabilization of the joint and provides additional stability.
- Reattach and tenodese the remaining rhomboids, latissimus dorsi, and teres muscle to the prosthesis and to themselves to achieve reliable and functional soft tissue reconstruction.
- Advance the preserved deltoid proximally and suture it to the trapezius; then close the pectoralis major muscle anteriorly over the new joint.

Wittig et al.[4] reported no infections or local recurrence and superior cosmesis when compared to the traditional Tikhoff-Linberg procedure. It was emphasized that it is essential to retain the deltoid, trapezius muscles, and axillary nerve. All patients had a stable shoulder and good to excellent hand and elbow function, thus providing a functional extremity. Most patients had good forward flexion, abduction, and external and internal rotation. Elevation, protraction, and retraction of the shoulder were preserved.

Wodajo et al.[5] reported a retrospective comparison of patients undergoing scapular resection and reconstruction with and without an endoprosthesis. Patients with endoprosthetic reconstruction had higher Musculoskeletal Tumor Society (MSTS) scores than did patients with no endoprosthesis (86% and 62%, respectively). The former group also had a larger arc of abduction than the latter (60% to 90% and 10% to 20%, respectively) and improved cosmesis. Most bony sarcomas of the scapula are contained by the two surrounding muscles, the infraspinatus posteriorly, and the subscapularis muscle anteriorly and do not involve the deltoid and trapezius muscles. Therefore, most tumors of the scapula, irrespective of size, are amenable to endoprosthetic replacement.

AXILLARY TUMORS

Overview

Several types of malignant tumors may involve the axillary space and may require surgical resection. Primary sarcomas occur within the muscles (i.e., the pectoralis major, latissimus dorsi, teres major, and subscapularis) that make up the borders of the axillary space and rarely within the axillary fat itself. Large metastatic deposits to the regional lymph nodes occasionally create large, matted masses that may require resection. The most common are metastatic melanoma and recurrent breast carcinoma. In addition, certain primary tumors arise from the brachial plexus, either the nerves or the vessels. These include leiomyosarcomas of the axillary vein and neurofibrosarcomas of the adjacent nerves. Secondary extraosseous extension from large tumors of the proximal humerus or scapula often goes into the axillary space and require imaging evaluation and surgical resection. Tumor involvement of the brachial plexus and the major vessels is the main determinant of resectability (Fig. 37-38).

The key to adequate and safe surgical resection of axillary tumors is the complete visualization and mobilization of the infraclavicular portion of the brachial plexus (i.e., the axillary artery and vein and the cords that surround them). Multiple imaging studies are required, but the final decision to proceed with a limb-sparing surgery is made during intraoperative exploration of the axillary space. Gross tumor involvement of the brachial plexus and/or the major vessels is an indication for amputation or for abandoning the attempt for resection. Contraindications to axillary space resection include involvement of the neurovascular bundle and of the adjacent chest wall.

The technique of axillary space exploration via the transpectoralis approach, as described here, has been developed by the authors and has been found to be the most useful in this determination and in the surgical approach.

Unique Anatomic Considerations

Anatomic Borders

The axilla is a pyramid-shaped space between the chest wall and the arm. The apex of the pyramid is formed by the junction of the clavicle and the first rib. The superior border is determined by the scapula. This apex is approximately 1 to 2 cm medial to the coracoid process. The anterior wall of the axilla is formed by the pectoralis major muscle, and the posterior wall is formed by the subscapularis, the teres major, and the latissimus dorsi muscles. The chest wall and the serratus anterior muscle form the medial wall of the triangle. The humeral shaft is covered by the muscle fibers of the coracobrachialis, and the short head of the biceps defines the lateral wall. The axilla is triangular shaped from both the coronal and axial views.

The most significant structures of the axillary space are the axillary artery and vein, which are surrounded by the cords of the brachial plexus as they enter from the apex and pass through the axillary space medial to the coracoid to the medial aspect along the humeral shaft. This space is filled with a fair amount of fat and lymph nodes that follow the axillary vessels. The space is bounded anteriorly by the deep clavicular pectoralis fascia that arises from the clavicle and covers the deep fat below the pectoralis major muscle. Inferiorly, the fascia wraps around the base of the axilla. Identification of this layer is extremely important prior to entering the deeper structures.

Pectoralis Major and Conjoined Tendon Muscles

Two major muscles form the gateway to the axillary space. Lying just below the clavicular-pectoralis fascia, they are the pectoralis minor muscle, which arises from the chest wall and attaches to the coracoid, and the conjoined tendon, which arises from the coracobrachialis and short

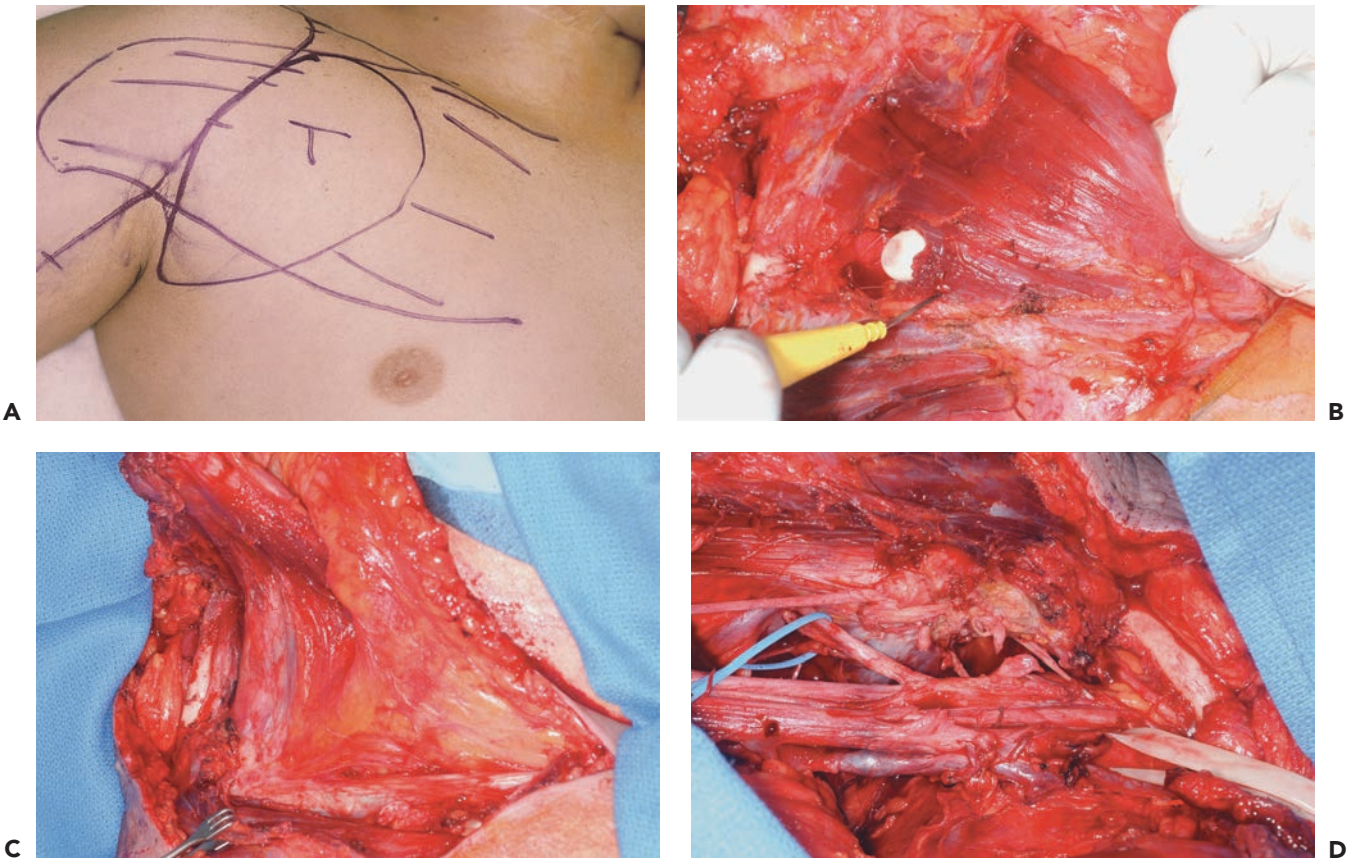

Figure 37-38 Axillary tumor. **(A)** Clinical photograph of a large axillary tumor and its relationship to the pectoralis major muscle. The initial step in the axillary exposure is release of the pectoralis major muscle. **(B)** Intraoperative view of release of the pectoralis major muscle, which provides access to the axilla. The pectoralis is released from the clavicle and its humeral insertion. Care is taken to protect the underlying vessels, which are often displaced anteriorly by a large axillary tumor. **(C)** The second layer of muscles and the axillary fascia are seen once the pectoralis major muscle is detached and rotated toward the chest wall. The second layer of muscle consists of the coracobrachialis and pectoralis minor by inserting on the coracoid. Surgically, both of these muscles are released prior to opening the axillary fascia. **(D)** Completion of exposure in the infraclavicular portion of the brachial plexus. The axillary nerve is within the vessel loop.

head of the biceps from the medial aspect of the humerus. These two muscles must be identified in the clavicular-pectoralis fascia during the surgery. Their identification is the key to accurate identification and dissection of all structures that are located deeper within the axillary fat.

Infraclavicular Brachial Plexus (see Fig. 37-38)

The infraclavicular portion of the brachial plexus is the most significant anatomic component; therefore, it must be thoroughly evaluated and its anatomy completely understood. The axillary artery and vein are contained within a single sheath and are surrounded by the cords of the infraclavicular plexus. The lateral, posterior, and medial cords of the plexus are found at the level of the pectoralis minor muscle. These cords occur in the sheath around the axillary artery and vein. At the lower border of the pectoralis minor muscle, these cords give rise to the five major nerves of the extremity: median, ulnar, radial, musculocutaneous, and axillary nerves.

The lateral cord gives rise to the musculocutaneous nerve, which travels along the medial aspect of the conjoined tendon, moves into the muscle belly of the coracobrachialis, and then enters the short head of the biceps. This nerve is the first to be identified during the exploration. It is located in the superficial axillary fat inferior to the coracoid process. The posterior cord gives rise to the axillary nerve, which travels deep in the space and passes inferior to the glenohumeral joint and the subscapularis muscle. The axillary nerve innervates the deltoid muscle. The main portion of the posterior cord becomes the radial nerve, which travels posterior to the sheath and exits the axillary space along with the axillary sheath. The medial cord gives rise to the median nerve, which is found on the lateral aspect of the sheath and exits the inferior aspect of the axillary space along the sheath. The ulnar nerve arises from the median cord and travels along the most

medial aspect of the sheath and exits distally, along with the sheath. The ulnar nerve is the most common nerve to be involved by tumors arising inferior to the brachial plexus because of its medial position along the sheath. This nerve often displays the first symptom (i.e., weakness or neuropathic complaints) of brachial plexus involvement.

Axillary and Brachial Arteries

The axillary artery is a continuation of the subclavian artery as it passes below the clavicle and the first rib. As it exits the axillary space just distal to the take-off of the circumflex vessels, it is termed the brachial artery. This transition occurs anteriorly at the level of the inferior pectoralis major and teres major muscles. The axillary artery consists of three segments: (a) the portion between the clavicle and pectoralis minor, (b) the area under the pectoralis minor, and (c) the segment between the inferior lateral pectoralis minor border to the point of exit below the teres major muscle. Tumor involvement may occur secondary to lymph node metastases in any of these three locations. The most common sites for axillary sarcomas are the second and third segments. Metastatic carcinomas involving the axillary space can involve any of these areas; however, they most often present as large, matted tumor masses between areas two and three.

Radiographic Evaluation

Three-dimensional imaging of the axillary space is important for accurate tumor localization and surgical planning. CT, MRI, angiography, and three-phase bone scans are used in the same way as in other anatomic sites. In addition, venography of the axillary and brachial veins is essential to the evaluation of tumors of the axilla and brachial plexus.

Computed Tomography

CT is most useful in evaluating the bony walls of the axilla, specifically, the humerus, glenohumeral joint, and scapula. Soft tissue tumors are well defined by CT scans. CT scans with intravenous contrast will aid in the definition of the axillary vessels.

Magnetic Resonance Imaging

MRI is extremely useful in determining the extent of a soft tissue mass in the axillary space and the involvement of the underlying serratus anterior and/or the anterior and posterior walls of the axillary space (pectoralis major, subscapularis, latissimus dorsi, and teres major muscles).

Angiography

Angiography should be part of the evaluation of all tumors of the axillary space. This technique will demonstrate any vascular displacement (very often inferior or anterior) and vascular anomalies of the axillary vessels. In addition, it can provide useful information on any response to induction chemotherapy (e.g., decrease in tumor vascularity).

Venography

Venography is one of the most accurate means of determining brachial plexus and axillary sheath involvement or infiltration by tumor. The arterial wall is thick and almost never shows signs of occlusion, whereas the axillary vein is a thin-walled structure that is easily compressed and infiltrated by tumor. Therefore, occlusion is almost synonymous with vascular sheath and brachial plexus involvement. A venogram should be routinely performed to evaluate the axillary vein. A positive venogram showing occlusion of the vein, in combination with neurologic pain and weakness, is almost always pathognomonic of axillary sheath and brachial plexus involvement by tumor. The triad of axillary vein occlusion, distal motor weakness, and neuropathic pain is a very reliable predictor of tumor infiltration of the brachial plexus sheath.

Biopsy

Biopsy of axillary tumors should be performed utilizing a needle or fine needle aspiration (FNA) technique. If a metastatic lesion is most likely, then FNA is the more appropriate means of identifying carcinoma cells. If a sarcoma is suspected, a needle or core biopsy should be performed. The biopsy site should be inferior through the base of the axillary space and not through the pectoralis major muscle or near the vascular sheath. This can easily be performed under CT guidance. The biopsy site must be removed in its entirety during resection of the tumor. Deep-seated lesions near the chest wall should be approached in this manner. Anterior lesions occasionally may be approached through the lower portion of the pectoralis major.

Surgical Management

Guidelines

1. Use of an anterior utilitarian incision with axillary extension. This incision extends along the deltopectoral interval with preservation of the cephalic vein. It then curves inferiorly and distally over the base of the axilla.
2. Detachment of the pectoralis major muscle. This muscle is detached from its insertion on the humerus and is reflected toward the chest wall while maintaining its vascular pedicles. This permits exposure of the entire axillary space and fascial sheaths.
3. Development of an anterior axillary fascial plane (clavicopectoralis fascia). This thick layer of fascia contains

the entire axillary space and structures. It is extremely well defined. This plane must be developed prior to any further dissection.

4. Release of the pectoralis minor and conjoin tendon. The pectoralis minor and conjoin tendon form the anterior muscle layer within the axillary space. Release of these muscles is key to exposure of the vascular sheath, the brachial plexus, and the numerous vascular branches feeding any large tumors.
5. Initial identification of the musculocutaneous and axillary nerves. The musculocutaneous nerve comes around the lower border of the coracoid under the pectoralis minor muscle. The axillary nerve comes off deeper from the posterior cord and travels toward the shoulder joint.
6. Mobilization of the axillary sheath and brachial plexus. Proximal and distal control of the vascular sheath is obtained prior to tumor dissection. Once the deep fascia is opened and the pectoralis minor muscle is released, the sheath is found very easily by palpating the axillary fat. Vessel loops are placed around the entire sheath; there is no need to dissect the individual components.
7. Resection of tumor. All the feeding branches entering into the mass are serially ligated and transected. Axillary fat is left around the tumor mass as the only true margin.
8. Closure. The pectoralis minor and conjoin tendon are reattached to the coracoid process.
9. Insertion of catheter. An epineural catheter is placed in the axillary sheath for postoperative pain relief.
10. Closure of the empty space. Often following resection, there is a large empty space that is prone to collect fluid and may lead to wound complications and dehiscence. The latissimus dorsi may be released from its insertion onto the humerus and inserted into the defect and sutured to the subscapularis muscle.
11. Suspension and adduction. The arm is suspended and kept adducted at the side of the body to close off this space. Multiple drains are used for 4 to 7 days.

Surgical Technique

- Place the patient in a supine semilateral position. Prepare and drape the arm, shoulder girdle, and chest. Full mobilization of the ipsilateral extremity is essential.
- Use a deltopectoral incision. This incision starts over the junction of the inner and middle thirds of the clavicle, continues along the deltopectoral groove, and curves distally over the anterior axillary fold (inferior border of the pectoralis major muscle).
- Open the superficial fascia, ligate or preserve the cephalic vein, and raise medial and lateral fasciocutaneous flaps.
- Detach the pectoralis major muscle from its insertion to the proximal humerus, leaving at least 1 cm of the tendon for reattachment. Take care to protect the axillary vessels. Large axillary tumors may displace the axillary sheath anteriorly and adjacent to the pectoralis major muscle.
- Divide the short head of the biceps and coracobrachialis (conjoined tendon) and pectoralis minor muscles at their insertion on the coracoid process. Perform the reflection with caution to prevent traction injury to the musculocutaneous nerve, which pierces the substance of the coracobrachialis muscle.
- Detach the pectoralis minor and conjoined tendon. Expose the axillary cavity after detachment and reflection of the second layer of muscles. The coracoid insertion of the pectoralis minor and the coracobrachialis are detached and retracted. Reflect the pectoralis minor muscle medially and the conjoined tendon (coracobrachialis and biceps muscles) caudally. Tag all edges of reflected muscles with a suture for later identification and use in reconstruction.
- The deep axillary fascia, neurovascular bundle, and content of the axillary cavity are now fully exposed. The anatomic relation of the tumor to the neurovascular bundle can be determined and the decision regarding tumor resectability made. At this anatomic site, the artery, vein, and brachial plexus are in close relation, and tumor extension to the neurovascular bundle usually affects all its components and negates resection. Benign tumors and soft tissue sarcomas usually push the adjacent neurovascular bundle; only at a later stage do soft tissue sarcomas break into it. Metastatic carcinomas directly invade the surrounding tissues, irrespective of compartmental borders. For these reasons, resection of large metastases with preservation of the neurovascular bundle is occasionally not feasible. If resection is not feasible, dissect the neurovascular bundle off of the tumor mass, ligate the subscapular and thoracodorsal vessels, and perform hemostasis.
- Resect the tumor with wide margins.
- Reattach the conjoined tendon and pectoralis minor muscles.
- Reattach the pectoralis minor and conjoined tendons to the coracoid process with a nonabsorbable suture. Reattach the pectoralis major to its insertion site on the proximal humerus in the same manner.
- Close the wound over suction drains.

Following surgery, the upper extremity is kept in an arm sling. Continuous suction is required for 4 to 7 days. Perioperative intravenous antibiotics are continued until the drainage tubes are removed. Postoperative mobilization with gradual range of motion of the shoulder joint is then introduced.

CLAVICLE TUMORS

Sarcomas arising from the clavicle are exceedingly rare. ABCs are also rare but are one of the more common neoplasms to arise from the clavicle. Metastatic carcinomas

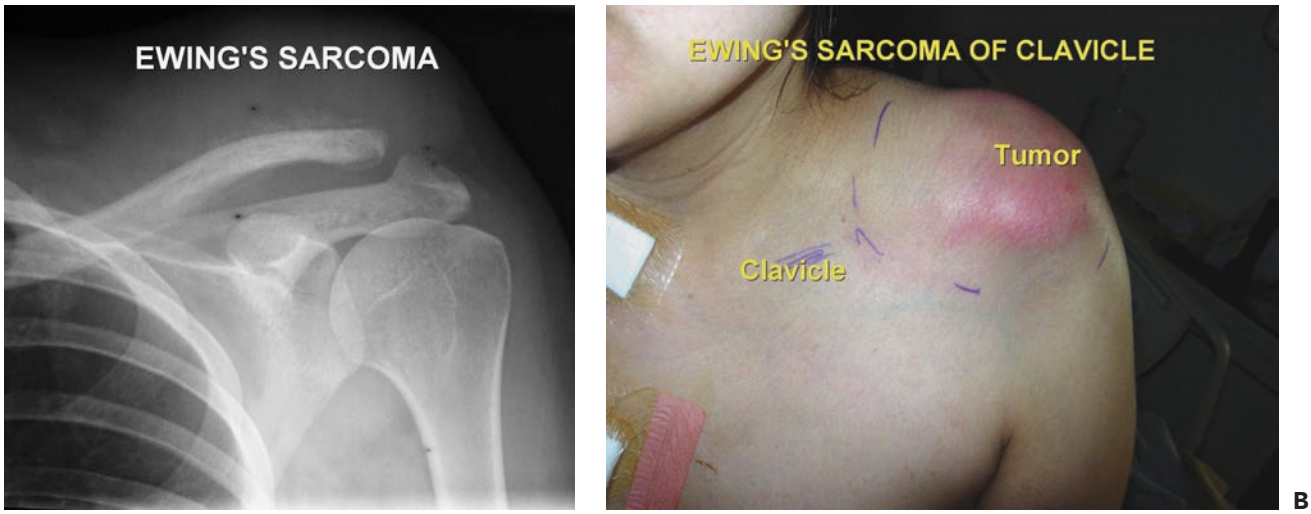

Figure 37-39 **(A)** Anteroposterior radiograph showing sclerosis and destruction of the distal clavicle as well as a large soft tissue mass with no evidence of matrix formation. **(B)** Clinical view of a large Ewing's sarcoma of the clavicle showing a large extraosseous soft tissue mass.

can affect the clavicle. Most can be treated with radiation, although surgical resection may occasionally be indicated for metastatic carcinomas that present with a large soft tissue component that encroaches on the brachial plexus. There is no replacement following radical resection of the clavicle. Most patients will be pain free and have full shoulder motion. The most common postoperative complaint is fatigue of the trapezius muscle (Fig. 37-39).

The key to safe resection of the clavicle is proper dissection and mobilization of the subclavian, axillary vessels and brachial plexus away from the tumor. Proximal exploration and mobilization occur at the base of the neck; distally, the axillary vessels and brachial plexus are explored deep to the pectoralis major muscle and medial to the coracoid process (similar to the axillary approach). Once the pertinent neurovascular structures have been separated from the neoplasm, the clavicle can be resected. A modification of the utilitarian shoulder-girdle incision is used.

The resection proceeds as follows:

1. Extend the incision from the midsternocleidomastoid muscle past the sternoclavicular joint. It extends trans-

Figure 37-40 **(A)** Large recurrent chondrosarcoma of the shoulder girdle. **(B)** Large telangiectatic osteosarcoma of the proximal humerus. Both patients required forequarter amputation. Although amputation is less common today, approximately 5% to 10% of sarcomas of the proximal humerus or axilla are not candidates for limb-sparing surgery and require amputation.

versely across the chest at approximately the third rib level to the deltopectoral groove.
2. Raise a large subcutaneous flap to expose the clavicle, the anterior third of the deltoid, the sternoclavicular joint, and the posterior triangle of the neck.
3. Release the pectoralis major proximally from the clavicle, leaving a margin on the tumor. Transect the pectoralis minor tendon from its insertion on the coracoid. This exposes the axillary sheath. Open the sheath to expose the axillary vessels and brachial plexus.
4. Release the sternocleidomastoid muscle from its insertion and retract it proximally. The fascia overlying the posterior triangle of the neck is opened to expose the brachial plexus. Identify the internal jugular vein (which may be ligated) and carotid artery and dissect distally to the base of the neck, where the subclavian vessels are identified. The subclavian vein, which is located anterior to the scalenus anticus muscle, is often compressed by tumor in this region and is difficult to visualize. The subclavian artery is posterior to the scalenus anticus muscle. Proximal and distal dissection ensures proper identification and a safe resection.
5. Once the subclavian vessels and brachial plexus have been mobilized, osteotomize the clavicle. It may be necessary to resect the sternoclavicular or acromioclavicular joint. Transect the subclavius and deltoid muscles and then remove the tumor.
6. Rotate the pectoralis major muscle proximally and suture it to the trapezius. Rotate the sternocleidomastoid muscle and attach it to the proximal border of the pectoralis muscle to cover the neurovascular structures with soft tissue.
7. Place drains and suture the skin flap in place.

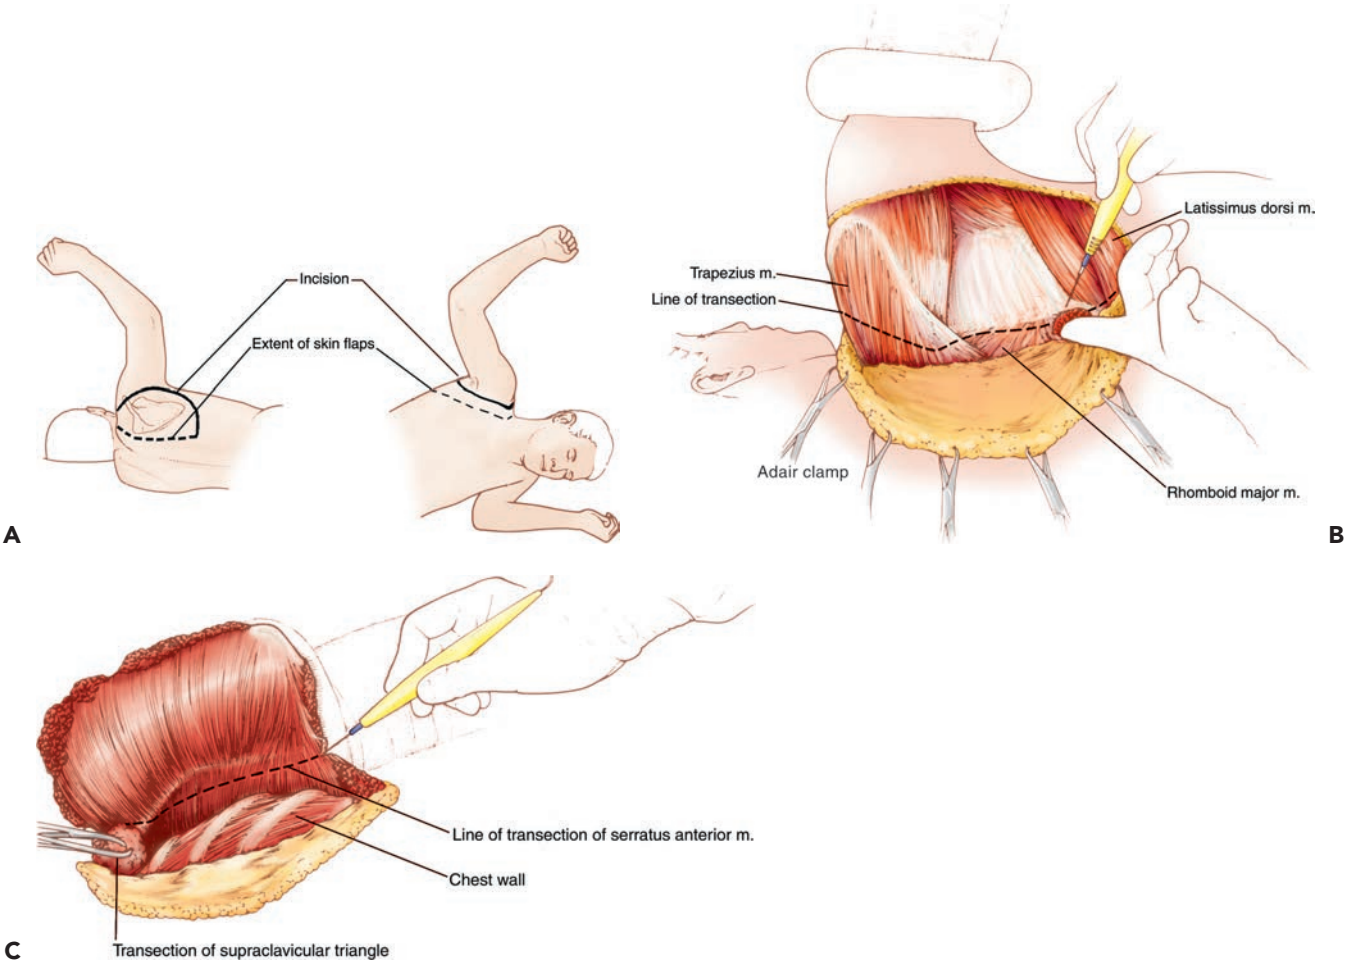

Figure 37-41 Technique of forequarter amputation. **(A)** Incision. **(B)** Release of periscapular muscles. **(C)** Mobilization of scapula and release of the anterior axillary muscles. **(D)** Isolation and ligation of the axillary vessels and brachial plexus. **(E)** Completion of amputation with posterior flap closure. Note that the surgical approach to a forequarter amputation may include initial exploration and ligation of axillary vessels from an anterior incision prior to the posterior approach (see text). (From Malawer M, Sugarbaker PH. Forequarter amputation. In: Malawer MM, Sugarbaker PH, eds. *Musculoskeletal cancer surgery: treatment of sarcomas and allied diseases.* Dordrecht, Netherlands: Kluwer Academic Publishers, 2001:294–296.)

AMPUTATION

As a result of advances in chemotherapy regimens and limb-sparing surgical techniques, forequarter amputations are rare. Only 5% to 10% of patients with primary bone sarcomas and fewer than 5% of patients with soft tissue sarcomas of the shoulder compartment require amputation. In rare instances, however, forequarter amputation may be indicated for palliation of patients with locally advanced, unresectable metastatic carcinomas of the shoulder girdle. These tumors commonly arise from metastatic spread to regional lymph nodes, the proximal humerus, or the scapula. A large soft tissue mass may encase the neurovascular bundle or invade the chest wall. At this point, the tumor becomes unresectable. Patients typically present with the following symptoms: severe intractable pain, a useless extremity, varying degrees of paralysis or sensory impairment, and chronic lymphedema. Continued tumor growth may lead to tumor fungation, sepsis, hemorrhage, and venous gangrene (Fig. 37-40).

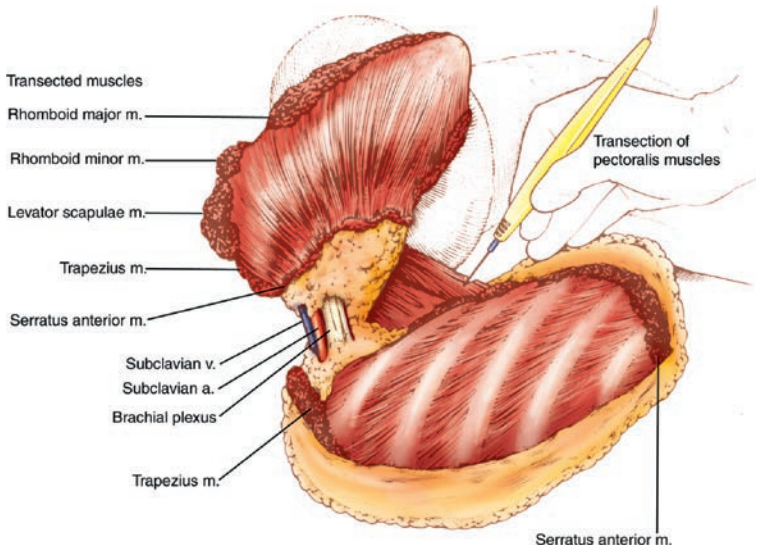
The indications for amputation include extremely large tumors that are associated with pathologic fracture, tumor hemorrhage, fungation, infection, or brachial plexus or axillary neurovasculature involvement. Forequarter amputation is contraindicated when tumor extends to the chest wall or extends to the paraspinal and posterior triangles of the neck structures. The surgeon must not proceed with amputation until after ascertaining that all surgical margins will be free of tumor or for palliation of uncontrolled pain, as this radical procedure is both debilitating and disfiguring and should be avoided in a patient where curative intervention is not anticipated.

Staging studies for an anticipated forequarter amputation are necessary to map out the local anatomy. It is recommended to perform CT, MRI, angiography, and venography prior to surgery. The final decision about proceeding with the amputation is made intraoperatively, after exploration of the tumor and neurovasculature structures.

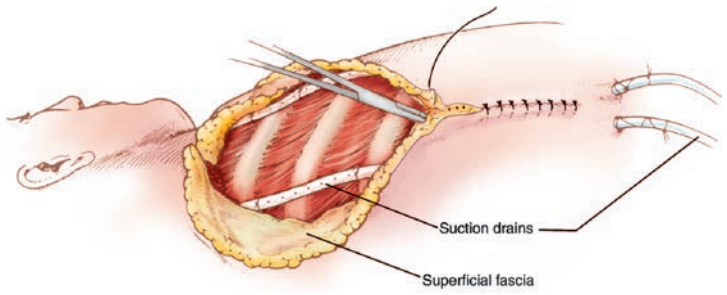
If a preoperative biopsy is required, the biopsy site should follow the incision to ensure that it can be easily removed during the procedure. Care should be taken to avoid contamination of the large posterior flap, the deltopectoral interval, the suprascapular area near the neck, and the pectoralis muscles.

When forequarter amputation is required, the following surgical guidelines are followed (Fig. 37-41):

- Place the patient in a lateral position to facilitate a semilateral approach.
- Expose the brachial plexus and axillary vessels via the anterior portion of the utilitarian incision; at this point, the tumor is determined unresectable.



D



E

Figure 37-41 (*continued*)

- Prepare to explore the anterior vascular vessels by detaching the pectoralis major muscle from the clavicle, using a clavicle osteotomy at the proximal (one-third) junction.
- Clamp the vessels inferior to the clavicle.
- Use the posterior approach to detach the scapula from the trapezius, rhomboid muscles, levator scapulae, and latissimus dorsi.
- Elevate the scapula from the chest wall by detaching the latissimus dorsi to expose the chest wall.
- If no chest wall involvement is noted, the amputation proceeds with extension and connection of the anterior and posterior incisions.
- Remove the forequarter following ligation and transection of the brachial plexus and subclavian vessels.
- Insert perineural catheters bolused with 10 mL of 0.25% bupivacaine into the retained ligated nerves for regional postoperative pain relief.

Close a large posterior flap over the remaining defect and place a chest tube for drainage. A flap may need to be mobilized to accommodate heavily irradiated skin in patients who were previously treated with external-beam radiation therapy.

FUTURE DIRECTIONS 1228

This chapter will address the issues of diagnosis and management of infections involving the shoulder. The major focus is on primary pyarthrosis of the glenohumeral joint. We will also discuss shoulder sepsis associated with osteomyelitis, septic subacromial bursitis, soft tissue infection, infections involving the sternoclavicular and acromioclavicular joints, and postsurgical complications. No attempt has been made to specifically include Lyme disease, brachial plexus neuritis, or nonsuppurative (viral, fungal, or mycobacterial) infections, which may be part of the differential diagnoses of an

infected shoulder joint. For the purpose of presentation, the topic is subdivided into pathophysiology, specific clinical entities, evaluation techniques, treatment, authors' preferred treatment, prognosis, and directions for further study.

PATHOPHYSIOLOGY

Septic arthritis of the shoulder is an inflammation of the glenohumeral joint involving one or more foreign pathogens that cause, or are suspected of causing, the inflammation. These pathogens can be bacteria, viruses, fungi, or parasites, and can gain access to the joint through a number of different means. The defense mechanisms of the host and the properties of the invading organism play an important part in the pathophysiology of septic arthritis, as does the premorbid condition of the joint. Chronic arthritis and trauma resulting in soft tissue damage can predispose a joint to infection.

Joint sepsis may be classified according to pathogenesis. There are three basic mechanisms: direct inoculation, contiguous spread from adjacent osteomyelitis, and hematogenous dissemination.

Hematogenous Septic Arthritis

Hematogenous dissemination from another organ system, such as skin breakdown, urinary system infections, or pneumonia, is the most common. In over 50% of patients with intraarticular sepsis, there is a positive blood culture.[57] Goldenberg and Cohen isolated the pathogen from a distant focus in 50% of the cases.

In the shoulder, branches of the suprascapular and subscapular arteries, along with the anterior and posterior circumflex humeral arteries, form an extracapsular arterial ring, which supplies the proximal humerus (Fig. 38-1A,B).[51] This anastomosis gives off branches that penetrate the capsule and form an intraarticular synovial ring.[69] This has been termed the "transition zone" and is located between the synovium and the articular surface.[126] It is in this area that the arterioles loop acutely toward the periphery, creating a low-flow state, making the area more susceptible to receptor-specific interaction of the pathogen and the cell surface.

Spontaneous shoulder sepsis is the result of joint invasion during bacteremia. Septic arthritis has been shown to occur in experimental animals when bacteremia is created.[92] The abundance of the synovial vasculature and the absence of a basement membrane between the endothelial cells make synovial joints vulnerable to seeding by bacteria. Furthermore, most patients with hematogenous nongonococcal bacterial arthritis have at least one underlying chronic medical risk factor. These factors may be local, such as prosthetic and metallic implants, or they may be systemic, such as

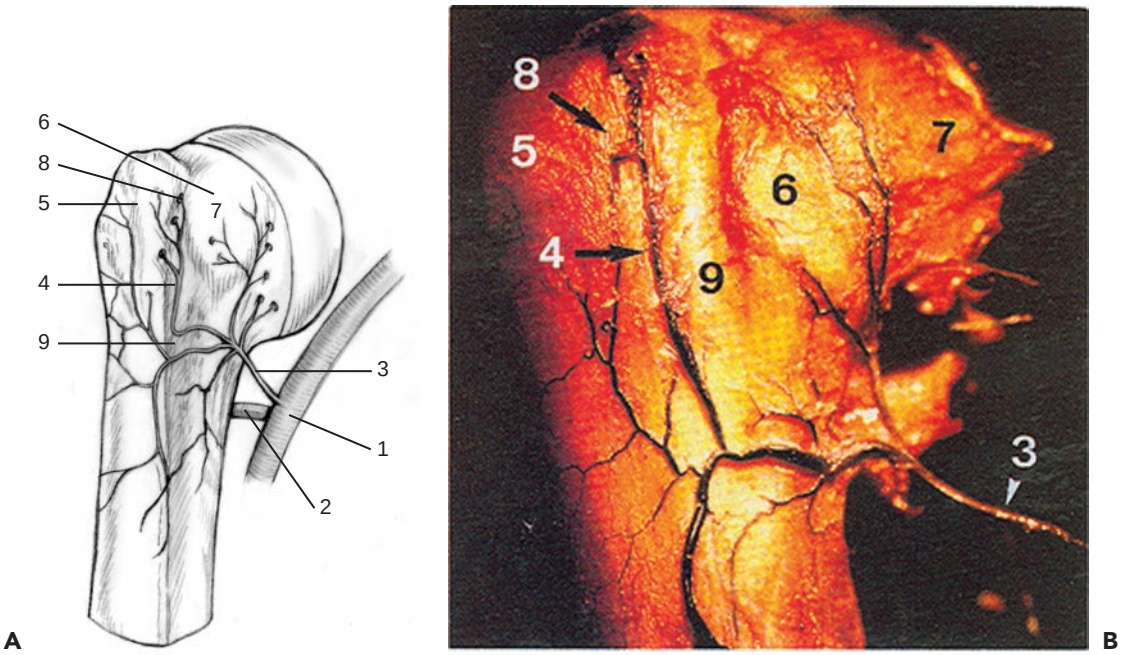

Figure 38-1 **(A)** Graphic representation and **(B)** photograph of the anterior aspect of the humeral head. 1 = axillary artery, 2 = posterior circumflex artery, 3 = anterior circumflex artery, 4 = anterolateral branch of the anterior circumflex artery, 5 = greater tuberosity, 6 = lesser tuberosity, 7 = insertion of the subscapularis tendon, 8 = constant site of entry of the anterolateral branch into the bone, and 9 = intertubercular groove. cancer, cirrhosis, rheumatoid arthritis, and intermittent bacteremic episodes from intravenous drug abuse or indwelling catheters[58] (Table 38-1).

Direct Inoculation

Direct inoculation may be traumatic or iatrogenic. Repeated corticosteroid injections[3] (Fig. 38-2), arthroscopy,[8] and open surgical procedures, such as rotator cuff repair and arthroplasty, have been shown to be associated with pyarthrosis of the shoulder. The incidence of infection following intraarticular steroid injection is extremely small. Hollander reported 18 infections in 250,000 injections,[76] and Gray et al. found only two cases complicating 100,000 injections.[61] The advent of sterile disposable needles and syringes and adherence to meticulous aseptic technique has helped lessen the risk. The existence of foreign bodies in or around the joint, such as nonabsorbable suture, stainless steel, cobalt chrome alloys, methylmethacrylate, and polyethylene, or devitalized bone from trauma can provide a nidus for adhesion and colonization by bacteria.[63,67,69] This nidus allows a glycocalyx biofilm to be expressed by the bacteria, which contributes to antibiotic resistance and limits the effectiveness of the immune response of the host.

Septic Arthritis from Contiguous Osteomyelitis

Osteomyelitis is most often hematogenous in origin and, in particular, is a disease of young children and the elderly. Hematogenous osteomyelitis commonly involves the metaphyseal area of rapidly growing long bones, usually occurring in the hip and knee.[106] When septic arthritis results from a contiguous infection such as osteomyelitis, it spreads from the bone to synovium, then to the joint space. This happens most often in infancy, when there is a vascular anastomosis between the epiphysis and the metaphysis. Studies conducted on the proximal femur by Trueta[145] showed a direct vascular communication between metaphyseal arterioles and the epiphyseal ossicle before 8 months of age. This allows a direct hematogenous communication between an osteomyelitis of the metaphysis and the adjacent joint synovium.[37,109] Between the ages of 8 and 18 months, the last vestiges of the nutrient artery system close down at the growth plate. The open physis at this point provides an effective barrier to the spread of infection to the joint by obliterating this vascular anastomosis.[137] This situation is analogous in the proximal humerus.

At skeletal maturity, there is once again a direct osseous connection between the metaphysis and epiphysis, secondary to closing of the growth plate and reestablishment of anastomoses between the metaphyseal and epiphyseal arterioles.[4] Therefore, infection of the proximal humeral metaphysis may extend to the epiphysis and the joint through the haversian system and Volkmann canals. In addition, the proximal 10 to 12 mm of the metaphysis of the proximal humerus is intraarticular, giving the pathogens of metaphyseal osteomyelitis direct access to the synovium.

Synovial Tissue and Infection

The anatomy of the shoulder joint is intricately involved in the pathogenesis of sepsis. All synovial joints contain synovial fluid, which can act as an excellent growth medium for bacteria and have a relative lack of immunologic resistance.[44] Type B synoviocytes are weakly phagocytic but in most cases are able to limit and clear a blood-borne bacterial infection.[7] Therefore, there must be an imbalance between normal synovial cell function and the invading bacteria for an intraarticular infection to develop.

Synovial tissue is relatively resistant to infection.[7] Examination of joints in which experimental septic arthritis has been produced reveals infrequent colonization of the synovium.[149] Receptors for collagen have been found on several strains of *Staphylococcus aureus*. It may be a lack of ligands or a functional host resistance mechanism that helps to prevent synovial colonization.[69]

Microscopic examination of the synovium shows that it is relatively thin in the area of the transition zone, rarely being more than three or four cell layers thick. The synovial capillaries are superficial, making them more susceptible to trauma. The lack of epithelial tissue in the synovium, and thus the lack of a basement membrane, means that

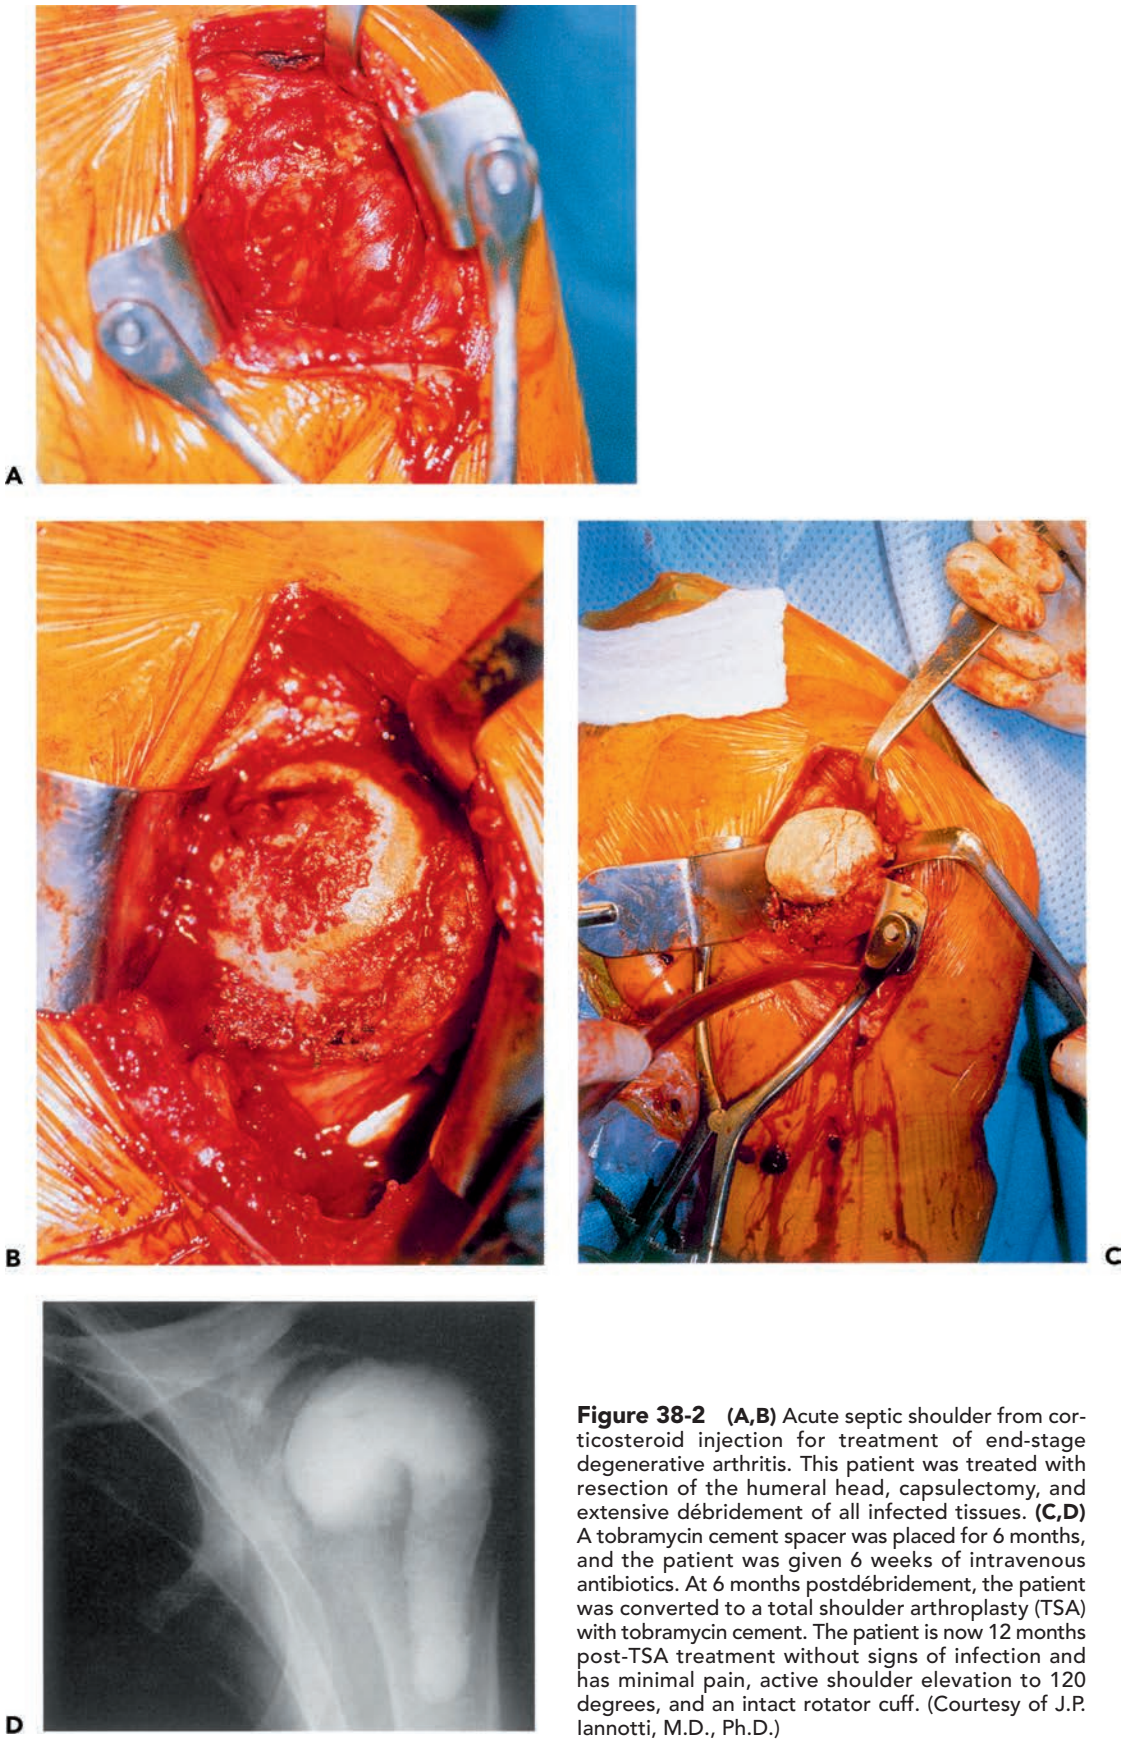

Figure 38-2 **(A,B)** Acute septic shoulder from corticosteroid injection for treatment of end-stage degenerative arthritis. This patient was treated with resection of the humeral head, capsulectomy, and extensive débridement of all infected tissues. **(C,D)** A tobramycin cement spacer was placed for 6 months, and the patient was given 6 weeks of intravenous antibiotics. At 6 months postdébridement, the patient was converted to a total shoulder arthroplasty (TSA) with tobramycin cement. The patient is now 12 months post-TSA treatment without signs of infection and has minimal pain, active shoulder elevation to 120 degrees, and an intact rotator cuff. (Courtesy of J.P. Iannotti, M.D., Ph.D.)

there is no structural barrier to the spread of bacteria from the synovium to the joint. Thus, transient bacteremia and trauma causing intraarticular hemorrhage can play a role in the pathogenesis of septic arthritis.[69]

Bacterial Adhesion

Integral to the pathogenesis of infectious arthritis is the preferential colonization of bacteria to articular cartilage, traumatized bone, or biomaterials that are not integrated with healthy tissues composed of living cells and extracellular matrix proteins.[12,67,69,130,138] Bacterial adhesion involves either very specific receptor–ligand or receptor–lectin– ligand chemical interaction or nonspecific interaction based on charge-related, hydrophobic, and extracellular polysaccharide-based interactions.[66] *S. aureus* has receptors for types I and II collagen,[136] fibrinogen, laminin, fibronectin, thrombospondin, bone sialoprotein, and heparin sulfate.[106] Many factors influence the adherence properties of bacteria, including (a) the surface energy and surface-free energy of the bacteria and biomaterial, (b) the extracellular components of the bacteria, (c) the bacterial interaction in mixed infections, (d) the host immune system, and (e) the extracellular matrix.[44]

All natural, biologic surfaces, with the exception of teeth and articular cartilage, are protected by epithelium, endothelium, or periosteum, which decreases bacterial adhesion by desquamation or by the presence of host extracellular polysaccharide molecules. *S. aureus* is the natural colonizer of cartilage and collagen, because it has specific surface-associated adhesins[33] for sites on collagen, not for enamel. Although the colonization of teeth by *Streptococcus mutans* is a natural symbiotic process that can be slowly destructive, the bacterial colonization of articular cartilage is unnatural and is rapidly destructive.[52,69]

Bacterial adherence is characterized by the production of an extracellular exopolysaccharide, within which the bacteria aggregate and multiply. Bacteria in aquatic environments grow predominantly in these biofilm-enclosed microcolonies adherent to surfaces.[64] Following initial colonization, the microcolonies develop coherent and continuous biofilms[46] that contain more than 99.9% of the bacteria in thick layers, within which they are protected from antibacterial agents[31,64,65] and the host immune defenses. This glycocalyx allows the bacteria to modify their local environment, limiting both the specific and the nonspecific arms of the immune response. Bacteria adherent to bone, methylmethacrylate, orthopedic devices, and surrounding tissue are harder to completely eradicate until the infected tissue and biomaterial are removed. Not infrequently, the infections are polymicrobial and difficult to culture adequately, unless special techniques are used.[54,57,63,65,66]

Microbiology

Patient age and host states help predict the bacterial cause of septic arthritis. Those organisms that frequently cause bacteremia in certain age groups are usually the infecting organisms, since joint sepsis is most commonly caused by hematogenous seeding. However, certain organisms, such as *Neisseria gonorrhoeae* and *S. aureus*, seem to have an avidity for the synovium, causing septic arthritis out of proportion to their incidence of bacteremia.[137] *S. aureus* is the most common cause of adult, nongonococcal bacterial arthritis, occurring in up to 50% of patients.[90] Ward and Goldner[151] noted 77% of infecting organisms to be Gram positive, of which 46% were *S. aureus*. *Propionibacterium acnes* is an anaerobic, Gram-positive bacilli that is found in lipid-rich areas, such as hair follicles and sebaceous glands, and in moist areas, such as the axilla. Although it is rarely the causal organism in other large joint infections, *P. acnes* has frequently been reported as the offending pathogen in shoulder sepsis and should not be dismissed as a skin contaminant.[74] Joint infections with Gram-negative bacilli have been increasing in incidence, ranging from 5% to 30% of all shoulder infections.[43,50,90,143] They most often occur in patients with intravenous drug abuse, malignancy, diabetes, immunosuppression, or hemoglobinopathy.[137] *Escherichia coli* and *Proteus* species are common infecting Gram-negative organisms from the urinary tract, and occur in patients who are not intravenous drug abusers. Although *Pseudomonas* and *Serratia* are the common organisms in intravenous drug addicts, the incidence of *S. aureus* in this population has been increasing.[6,13,43] *Streptococcus pneumoniae* is the most common organism in patients with chronic alcoholism and hypogammaglobulinemia.[107] Polymicrobial infections of the shoulder occur in 5% to 15% of patients, often associated with an extraarticular polymicrobial infection or penetrating trauma, especially in immunocompromised patients.[119]

Incidence

The incidence of shoulder sepsis is increasing as the population ages and the prevalence of chronic, debilitating disease increases.[90,143] Currently, primary shoulder sepsis accounts for 10% to 15% of all joint infections, whereas the hip and the knee account for 20% to 25% and 40% to 50%, respectively.[43] Septic arthritis of the shoulder is a rare occurrence in the young, immunocompetent person. More frequently, it is a disease of the elderly. Most patients have chronic, systemic, immunocompromising conditions such as diabetes mellitus, blood dyscrasias, renal failure, malignancy, and malnutrition.[44,57,90,151] Local factors also play a role in some patients, such as indwelling catheters, intravenous drug use, prior joint disease (rheumatoid or osteoarthritis), trauma, bursitis, or radiation therapy.[44,58,137]

Ward and Goldner reported that 74% of 27 adults with septic arthritis of the shoulder had some systemic condition causing immunocompromise or some type of local tissue abnormality. In 52% of the patients, both were present.[151]

CLINICAL ENTITIES

Natural History of Septic Arthritis

Studies conducted in animals have demonstrated that direct joint inoculation with bacteria is followed by synovial, bone, and cartilage changes within a matter of hours. Experiments have been performed on mice, rats, rabbits, chickens, and hamsters, and most have utilized direct joint inoculation. Septic arthritis caused by *S. aureus* in a rabbit model displays two processes acting simultaneously. The synovium becomes inflamed and hypertrophies within minutes of infection, with an influx of polymorphonuclear cells. This develops into an invading pannus, eroding and undermining the articular cartilage. Bacteria can be identified in and extruded by the pannus, thus maintaining the inflammatory reaction and lysosomal discharge.[118] Within 3 hours, a purulent exudate is observed, and within 24 hours multiple abscesses are seen. By day 5, synovial inflammation is so aggressive that there is extension below the cartilage interface, causing erosion and loosening in this area.

Simultaneously, by day 2, progressive loss of glycosaminoglycan occurs, as observed by a loss of safranin staining. This is most pronounced in the marginal areas near the leading edge of the pannus. The degradation of cartilage occurs through bacterial endotoxin, prostaglandins, and cytokine-mediated events that invoke a host inflammatory response and a release of destructive enzymes by synoviocytes and leukocytes.[44] Total glycosaminoglycan depletion occurs by 14 days, and the protein-polysaccharide–depleted cartilage is susceptible to degradation by collagenases released by the lysosomes.[118,152] The predominant cytokine is interleukin-1 (IL-1), which is released by synovial macrophages and circulating monocytes. IL-1 has been shown to inhibit chondrocyte proliferation and decrease expression of type II and X cartilage, making the articular cartilage more friable and susceptible to bacterial adhesion. Bremell et al., in their studies on septic arthritis in rats, noted the importance of $CD4^+$ T lymphocytes expressing IL-2 receptors, indicating activation. Deletion of T lymphocytes downgraded the intensity of infection, indicating a pathogenic role.[14]

If infection remains untreated for 7 to 10 days, cartilage fissuring and a decrease in height occur, most commonly involving the weight-bearing areas. Continued infection results in joint capsule and ligament dissolution, ending in fibrous ankylosis in 5 weeks in the rabbit model.[118] Antibiotics, administered in this animal model before or at the time of inoculation, significantly reduced joint destruction.[132] Irreversible changes occurred if the joint was not sterilized within 5 days of infection.[106]

Subacromial Septic Bursitis

Pyarthrosis of the glenohumeral joint may extend into the subacromial bursa. Most commonly, the infection occurs by direct erosion through the rotator cuff (Fig. 38-3). However, 10% of the patients may have intact cuffs.[151]

Rarely, subacromial septic bursitis may occur in isolation, as the primary infection,[142] or as a result of hematogenous seeding from a distant source of infection.[29] The diagnosis is made by aspiration of the bursa for Gram stain and culture. Aspiration is performed in an area that will likely have the highest yield, usually where there is maximal tenderness and fluctuation (Fig. 38-4).

Septic Arthritis of the Sternoclavicular Joint

The sternoclavicular joint is an unusual site for infection, comprising 1% of all cases of septic arthritis.[120] Sternoclavicular septic arthritis usually develops in patients with an underlying medical condition or predisposing factor, such as intravenous drug abuse,[13,53,59] diabetes mellitus, rheumatoid arthritis, liver disease, alcohol abuse, renal disease, malignancy, steroid use, or infection at another site.[19,120,155] However, infection may occur via a hematogenous route or by direct inoculation from trauma or subclavian vein catheterization in healthy patients. Ross and Shamsuddin[120] recently reviewed the published reports of sternoclavicular septic arthritis and found 170 cases, 33 of which were associated with intravenous drug abuse. Serious complications such as osteomyelitis (55%), chest wall abscess or phlegmon (25%), and mediastinitis (13%) were common. *S. aureus* was the most common pathogen, responsible for infections in 49% of the cases. *Pseudomonas aeruginosa* was responsible for only 10% of the cases; this represents a dramatic decline in incidence compared to older reports, presumably due to the end of an epidemic of pentazocine abuse among intravenous drug users in the 1980s. Before 1981, *Pseudomonas* was responsible for 9 of 11 cases of sternoclavicular septic arthritis among intravenous drug users. After 1981, 17 of 22 cases in intravenous drug users were caused by *S. aureus.* An earlier review by Wohlgethan et al.[155] found *S. aureus* to be responsible for infections in 8 of 10 patients with rheumatoid arthritis, and three of four patients with renal failure. Of seven patients with a history of alcohol abuse, six were infected with streptococci.

The diagnosis of sternoclavicular septic arthritis is often difficult, and there is usually a delay between the onset of

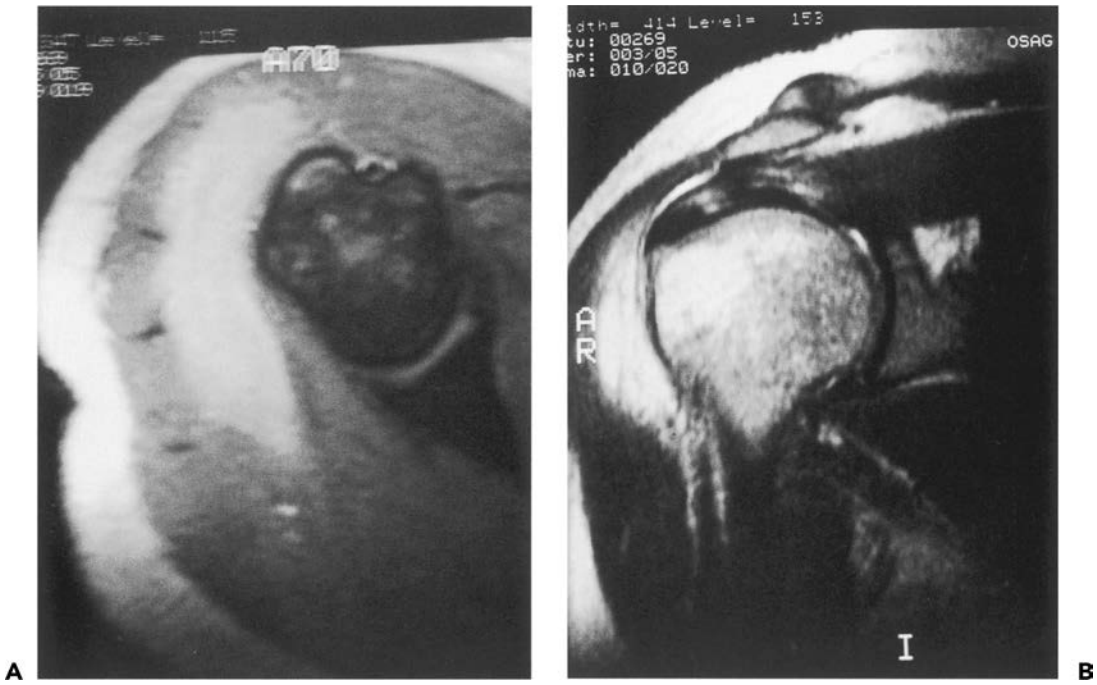

Figure 38-3 **(A,B)** Magnetic resonance imaging of acute subacromial infection with an abscess, following open rotator cuff surgery. (Courtesy of J.P. Iannotti, M.D., Ph.D.)

symptoms and diagnosis. Ross and Shamsuddin's review found that the median duration of symptoms before diagnosis was 14 days (mean 29 days).[120] In those 170 cases, symptoms most commonly involved pain in the anterior chest (78%), shoulder (24%), or neck (2%) long before other signs and symptoms occurred. Fever (more than 38°C) and bacteremia were present in 65% and 62% of patients, respectively. The sternoclavicular joint was tender in 90%, and limited shoulder motion was noted in 17% of patients.[19,48,59,120] Joint aspiration was not feasible in most patients, but when performed, cultures were positive in 50 of 65 patients (77%).[120] Computed tomography or magnetic resonance imaging should be obtained routinely to assess for the presence of chest wall phlegmon, retrosternal abscess, or mediastinitis.

Infection Complicating Hemi- and Total Joint Arthroplasty

Infection of the glenohumeral joint following shoulder arthroplasty is a relatively rare, although potentially devastating, occurrence. Susceptibility is dependent on a number of host factors, such as diabetes mellitus, rheumatoid arthritis, advanced age, remote sites of infection, malnutrition, and immunosuppressive chemotherapy.[154] The reported incidence of postoperative infection from total

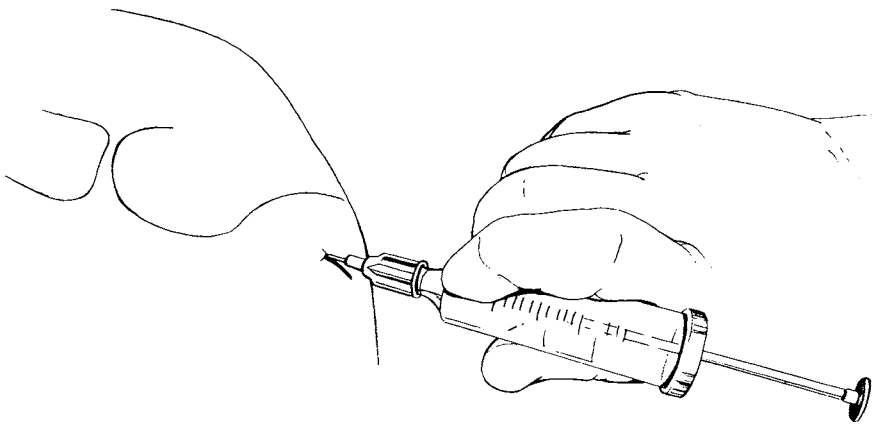

Figure 38-4 Aspiration of the subacromial bursa is usually performed in an area where there is maximal tenderness and fluctuation. The needle is inserted under the acromial edge (laterally in this case) and directed slightly cephalad. This illustration also shows the outline of the acromion and acromioclavicular joint.

shoulder arthroplasty ranges from 0.34% to 2.9%.[26,101] These infections can be divided into acute, subacute, or late. Acute infections are usually the result of intraoperative contamination and usually present within 3 months. Subacute infections occur when there is not a routine postoperative course. An example is a case that is complicated by prolonged wound drainage or fever that spontaneously resolves. This is usually followed by evidence of infection within 12 months, with component loosening. Late infections usually represent hematogenous spread from a distant focus, but could represent a chronic infection acquired intraoperatively.[95] *S. aureus, S. epidermidis,* and *P. acnes* are the most common organisms involved, although *Pseudomonas* and *Candida* species have been reported in the literature.[26,93]

Antibiotic prophylaxis for the prevention of hematogenous seeding of a total joint during the transient bacteremia induced by dental or other procedures is a controversial issue. Approximately 50% of all late prosthetic joint infections are due to staphylococci. This raises the question of overemphasis being placed on infections caused by dental procedures, because *S. aureus, S. epidermidis,* and *P. acnes* are unlikely oral pathogens.[153] Nonetheless, the consequences of prosthetic infection are so grave that bacteremic events should be avoided. In our opinion, prophylactic antibiotics should be administered in anticipation of procedures that cause bacteremia in certain instances. Animal studies have shown that the tendency toward prosthetic infection is greatest in the early postoperative period.[133] Clinical reports of infected prostheses support this finding. Over 50% of infections occur within the first 2 postoperative years.

The current recommendation is to provide prophylaxis for any patient undergoing an invasive procedure that gives the possibility of bacteremia within the first 2 years of prosthetic replacement. Regardless of the timing of the arthroplasty, a procedure performed at a distant site for an acute or chronic infectious process demands prophylaxis. Deacon et al. also believe that any patient with an immunocompromising condition, such as rheumatoid arthritis or hemophilia, should always be treated with prophylactic antibiotics.[38]

There are multiple regimens outlined in the literature, but the choice of prophylactic antibiotic depends on the normal flora of the suspected body region source.[139] The recommendations for prophylaxis during dental, head and neck, chest, and upper gastrointestinal procedures are for an oral cephalosporin, 1 g 1 hour prior to the procedure and 500 mg 4 hours after the procedure is completed.[95,139] Alternately, clindamycin and erythromycin can be used in cases of documented penicillin allergy. With high-risk biliary tract or colorectal surgery, parenteral cephalosporins should be used with clindamycin and an aminoglycoside as an alternative. Obviously, the risk of potential anaphylaxis has to be weighed against the risk of total joint infection during these procedures. Maderazo et al.[95] feel that the morbidity and possible mortality associated with a prosthetic infection warrants the small risk from the antibiotics.

Shoulder Sepsis Following Arthroscopy

Because arthroscopy of the shoulder is a sterile surgical procedure, the infection rates should be very low. They range in the literature from 0.04% to 3.4%.[8,34,84] The use of perioperative antibiotics has reduced the incidence of infection fourfold. Armstrong and Bolding, in a review of seven cases of septic arthritis following arthroscopy, noted a correlation with the use of intraarticular steroids.[3] Four infections occurred in 101 arthroscopies during a 3-month period, and three of these involved the use of intraarticular methylprednisolone. Two of the seven infections involved the glenohumeral joint and were believed to be secondary to unsterile electrocardiogram cables contaminating the operative field. The investigators postulated that the arthroscope was inadequately disinfected between cases in the remainder of the infections. It was noted that on several occasions, the equipment was soaked for less than the 20-minute time period required for disinfection with 2% glutaraldehyde. The review by Armstrong and Bolding demonstrated the importance of adequate patient, equipment, and operating room preparation. For those cases in which an arthroscopic procedure is followed by an open surgical procedure (e.g. mini-open cuff repair), Herrera et al. recommend a second skin preparation with Betadine after the arthroscopy to counteract the decreased efficacy of the initial preoperative skin preparation due to the constant arthroscopic fluid extravasation.[74]

Infection Following Rotator Cuff Surgery, Instability Surgery, and Open Reduction and Internal Fixation

The prevalence of infection after open rotator cuff repair has ranged from 0.27% to 1.7%, while the incidence of infection after mini-open rotator cuff repair has been reported to be 1.9%.[74,96,102] The most common offending bacteria are *S. aureus, S. epidermis,* and *P. acnes.* Infection following rotator cuff repair must be diagnosed quickly and addressed expeditiously to avoid damage to the cuff or the joint itself (Fig. 38-5A,B). Unfortunately, the cuff repair itself is at risk during postoperative pyarthrosis. Residual function depends on the amount and continuity of the remaining rotator cuff[113] (Fig. 38-5C,D). The presentation of deep shoulder infection following rotator cuff repair is often subtle, leading to a delay in diagnosis. Patients usually report pain and restricted motion, but often lack systemic symptoms and fever. White blood cell and neutrophil counts are often normal, but the erythrocyte sedimentation rate is usually elevated.[96,140] Timely diagnosis

Figure 38-5 **(A,B)** Acute infection after open rotator cuff repair. At the time of débridement of the shoulder, the cuff repair was disrupted, and the deltoid origin was detached. The shoulder was débrided and all sutures were removed. The cuff was not repaired, but the deltoid origin was repaired with absorbable suture. The patient was treated for 6 weeks with intravenous antibiotics. **(C,D)** The infection resolved with the one surgical débridement and the deltoid remained intact. Clinically, the shoulder was painless but with poor function. (Courtesy of J.P. Iannotti, M.D., Ph.D.)

depends on attention to risk factors such as age greater than 60 and chronic lymphedema as well as a high index of suspicion.[96] Sperling et al. examined a short series of patients with early and late postoperative infections following surgery for shoulder instability including Bankart, Putti-Platt, and Bristow procedures.[134] All three cases of late infection had a sinus tract leading to a retained nonabsorbable suture. None of the six patients in the series had recurrent shoulder instability following eradication of their infection. Internal fixation of fractures about the shoulder provides an environment for bacterial adhesion and glycocalyx formation, making infection more difficult to eradicate.

One must also beware of the patient with postoperative drainage, slow incisional healing, and drainage around sutures that are extruded from the skin, because occult infection following open reduction and internal fixation is one of the most common causes of infection following total shoulder arthroplasty.[70]

Septic Arthritis Superimposed on Rheumatoid Arthritis

Patients with rheumatoid arthritis are more susceptible to joint sepsis, compared with those without the disease. Their underlying chronic joint symptoms may delay the diagnosis of infection. Furthermore, the acromioclavicular joint may be involved, adding to the complexity of presentation. Gristina et al. reviewed 13 cases of septic arthritis in patients with rheumatoid arthritis and found that most presented with a sudden exacerbation of the usual arthritic pain, abrupt onset of swelling, and increased joint temperature. Only 9 of 13 were febrile. The infecting organism was *S. aureus* in 12 cases and *E. coli* in one case.[68] Several factors may predispose a patient with rheumatoid arthritis to infection, including a poor overall health status with coexisting morbidities (such as diabetes), the chronic systemic administration of corticosteroids and cytotoxic drugs, and the intraarticular use of corticosteroids.[100] It also has been suggested that the synovial leukocytes of rheumatoid patients may have less phagocytic activity than normal, making their joints increasingly susceptible to sepsis.[10] The grave complication of septic arthritis should be suspected in any patient with rheumatoid arthritis when the clinical course worsens acutely, and synovial fluid should be aspirated immediately for examination. Clinical signs and symptoms are variable and inconstant, and the sedimentation rate and roentgenograms are unreliable. Upon diagnosis, prompt surgical therapy and parenteral antibiotics must be instituted, because this complication can carry a high mortality rate.

Disseminated Gonococcal Arthritis

Unlike patients with nongonococcal shoulder sepsis, those with joint infections secondary to *Neisseria gonorrhoeae* are generally young, healthy adults. Disseminated gonococcal infection is the most common cause of hematogenous septic arthritis of all joints. The most common clinical manifestation is a migratory polyarthralgia (70%). However, fever, tenosynovitis (67%), and dermatitis (67%) are commonly discovered on initial examination.[108] Joint aspirate yields a positive Gram stain result in only 25% of the cases, and 50% of cultures test negative.[109] Synovial fluid white cell counts are less than those for nongonococcal septic arthritis, but are still greater than 50,000 white blood cells (WBCs)/mm^3. Urethral, cervical, rectal, and pharyngeal cultures have a much higher yield and should be obtained from any young, sexually active patient suspected of having gonococcal arthritis. The infection shows a rapid response to ceftriaxone, and the arthritis generally resolves in 48 to 72 hours. Surgical decompression is not needed in most cases, because joint destruction is rare.

EVALUATION

Clinical Characteristics

A general workup scheme for pyarthrosis of the shoulder is outlined in Fig. 38-6. The typical clinical presentation of shoulder sepsis consists of complaints of pain, warmth, and swelling of the involved joint. A patient may exhibit a prodromal phase of malaise, low-grade fever, lethargy, and anorexia before the acute onset.[109] The acute phase usually consists of fevers and chills, with severe, incapacitating shoulder pain as the cardinal clinical manifestation. Physical examination reveals local signs of infection such as erythema, edema, tenderness, increased warmth, and limitation in range of motion (ROM). Previous reports have shown that fever is variably present (40% to 90% of patients), and when present may be low grade or transient.[105,119] Rosenthal noted pain in only 48 of 71 patients with septic arthritis, with limitation in ROM being the most consistent clinical sign,[119] helping to differentiate a superficial soft tissue infection from a joint infection. Atypical presentations occur when there is chronic arthritis, immunocompromised states, extreme age, intravenous drug use, or low-grade prosthetic joint infection. Previous use of antibiotics as well as corticosteroids or nonsteroidal antiinflammatory medication may mask symptoms. These factors, plus the low index of suspicion for shoulder sepsis, often lead to a delay in diagnosis. Ward and Goldner, in a review of 30 patients with shoulder pyarthrosis, noted mild symptoms in the 27 adults and a mean delay to diagnosis of 46 days.[151]

Laboratory Studies

Laboratory evaluation should consist of a peripheral WBC count with differential, erythrocyte sedimentation rate, and/or C-reactive protein. The WBC count may be normal to slightly elevated and may not show a peripheral blood leukocytosis, as was demonstrated to be the case in one-third of the patients with shoulder pyarthrosis described by Leslie et al.[90] Erythrocyte sedimentation rate is consistently elevated in patients with septic arthritis, but this may be elevated baseline secondary to chronic inflammatory arthritis. The C-reactive protein is an acute-phase protein produced by the liver in response to bacterial infection. It has been shown to increase more rapidly than the erythrocyte sedimentation rate, and may be of great value in the second, third, or fourth day of treatment to evaluate

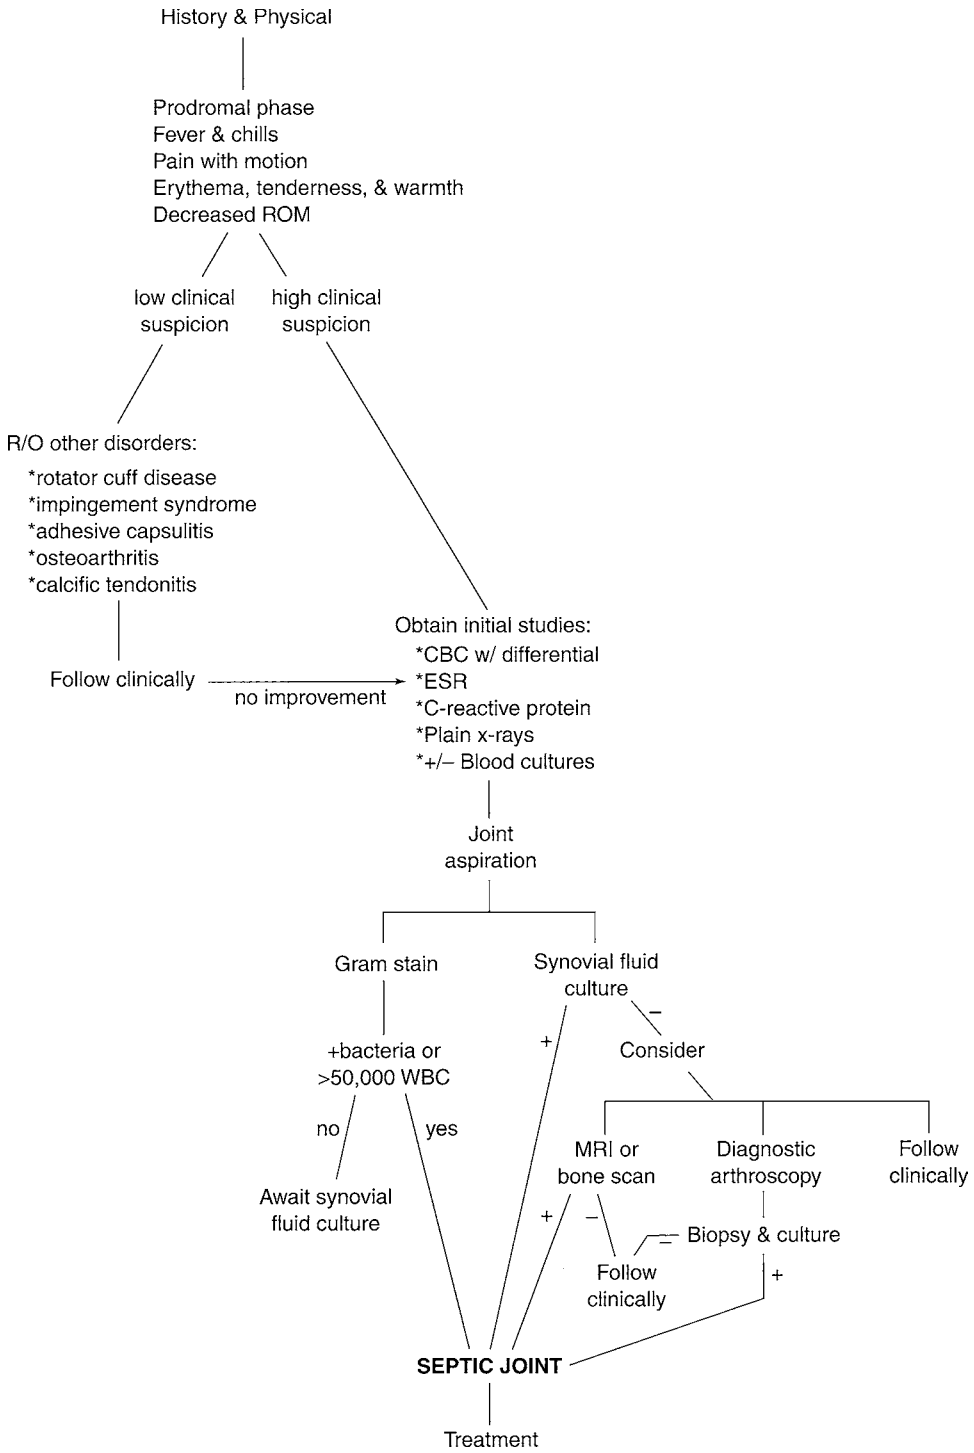

Figure 38-6 A general workup algorithm for infection involving the shoulder girdle.

improvement when the sedimentation rate is still increasing.[147] Blood cultures should be obtained from all patients with clinical signs and symptoms of systemic sepsis. In addition, cultures also should be obtained from any other possible sources of infection before antibiotics are administered.

Given the grave consequences of joint sepsis and the nonspecific clinical and laboratory findings, joint aspiration and culture are essential for making the diagnosis. The procedure must be performed with meticulous aseptic technique, preparing the skin with a povidone solution. Care must be used to enter the joint through intact, uninfected skin. An 18-gauge or larger needle should be used, so that viscous fluid can be aspirated if encountered. If difficulty accessing the joint arises, fluoroscopic guidance or contrast dye can be of assistance. Occasionally, aspirating

fluid from a joint is difficult, and nonbacteriostatic saline may be injected and reaspirated to obtain a sample. Joint aspiration can be painful, and appropriate analgesia and sedation (and, if necessary, general anesthesia) should be used.

Synovial fluid analysis is the key to correctly diagnosing septic arthritis. The fluid should be evaluated for Gram stain, culture, cell count and differential, and polarized microscopy. Cultures should include aerobes, anaerobes, fungi, and mycobacterium. In cases where *N. gonorrhoeae* is suspected, chocolate agar or Thayer-Martin plates should be used. Ideally, the specimen is plated at the bedside; however, this will vary according to each hospital's laboratory procedures. *N. gonorrhoeae* is an extremely fastidious organism, and cultures can be negative in up to 50% of the cases. Polymerase chain reaction is a technique that amplifies small amounts of bacterial DNA and provides a much higher sensitivity than culture alone. If available, it may be helpful when infection is suspected but cultures persistently remain negative.[55]

Examination of synovial fluid is an important step in the diagnosis of shoulder sepsis. Certain fluid characteristics suggest pyarthrosis, but none is absolutely specific. On gross examination, the fluid is often thick, yellow, and cloudy. Leukocyte counts are of limited use even at extreme values, because of the overlap with other types of arthritis. Values greater than 50,000 WBC/mm^3 are suggestive of bacterial arthritis, and values greater than 100,000 WBC/mm^3 are rarely from other causes. Polymorpholeukocytes are predominant, usually comprising greater than 90% of the leukocytes. Synovial fluid glucose levels may be decreased later in the process but are of limited value, unless serum levels are obtained at the same time and after at least 6 hours of fasting. Levels greater than 40 mg/dL below the serum level are consistent with pyarthrosis.[128] The presence of crystals in synovial fluid analysis does not rule out infection, because the two processes may coexist. Joint infection lowers the pH, occasionally causing the precipitation of urate or calcium pyrophosphate.[44] Table 38-2 summarizes synovial fluid findings.

Aspiration of the glenohumeral joint may be performed in one of several ways. The posterior approach (Fig. 38-7) may be the most commonly used route, owing to the ease of locating anatomic landmarks and the patient not being able to watch the procedure. It is performed under aseptic technique, with wide preparation of the skin with Betadine. After local anesthetic is injected into the skin, muscle, and capsule, an 18-gauge spinal needle attached to a syringe is inserted 2 cm inferior and 2 cm medial to the posterolateral edge of the acromion. The needle is advanced in the direction of the coracoid process until the joint is entered. Care must be taken not to contaminate the specimen once it is obtained.

Imaging Studies

Plain radiographs should be the first study obtained when imaging septic arthritis. These are only occasionally helpful in diagnosing primary sepsis of the shoulder within the first 7 to 10 days after infection. They may show joint subluxation or soft tissue swelling, due to either joint effusion or synovial hypertrophy.[16] Later in the infectious process, 40% of patients show abnormalities.[151] As the invading pannus erodes the articular cartilage and adjacent bone within the confines of the capsule, joint space narrowing and marginal erosions appear radiographically.[71] As the septic arthritis spreads to adjacent bone, features of

TABLE 38-2
SYNOVIAL FLUID FINDINGS

Synovial Fluid	Normal	Noninflammatory	Inflammatory	Septic
Appearance	Clear	Clear	Opaque/translucent	Opaque, yellow/green
Viscosity	High	High	Low	Variable
WBC/mm^3	<1,000	<1,000	5,000–75,000	>50,000
Polymorphonuclear cells	<25%	<25%	>50%	>75%
Culture	Neg	Neg	Neg	Pos

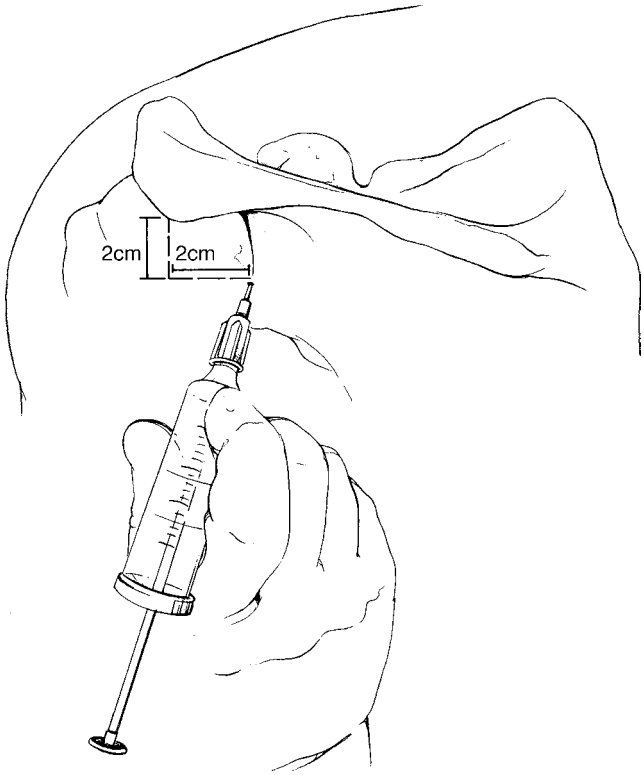

Figure 38-7 Posterior approach to shoulder aspiration. After preparing the skin with Betadine and injecting local anesthetic, an 18-gauge spinal needle attached to a syringe is inserted 2 cm inferior and 2 cm medial to the posterolateral edge of the acromion. The needle is advanced in the direction of the coracoid process until the joint is entered.

osteomyelitis, such as periostitis and bone destruction, are seen.

Plain radiographs become more important in postsurgical infections. They are helpful to assess the presence, condition, and location of hardware that may need removal. This is especially important for suture anchors, which may not be seen at the time of débridement surgery.

Magnetic resonance imaging (MRI) is recommended by some as the next imaging modality utilized if the diagnosis is still in question. MRI gives excellent resolution of soft tissues and fluid collections with an extremely high sensitivity, demonstrating abnormalities within 24 hours. However, it continues to lack specificity. It cannot distinguish infected joint fluid from inflammatory, nonseptic joint fluid.[16] MRI can clearly demonstrate cartilage destruction and small joint effusions, as well as intramedullary bone destruction and marrow edema. Computed tomography (CT) can give better bony resolution than either plain radiographs or MRI, clearly depicting subtle bone destruction.

CT scans also offer an advantage over plain x-rays in joints with complex anatomy or superimposed skeletal structures. In most cases of sternoclavicular pyarthrosis, results of plain radiography are negative, unless late bony destruction has occurred. CT is an excellent modality for diagnosis of sternoclavicular joint septic arthritis and the complication of abscess formation,[40] as well as for preoperative planning if conservative treatment has failed.[19]

Ultrasound is a useful, noninvasive imaging modality in screening for septic arthritis. Sonographic evaluation can reliably determine the presence of either a glenohumeral or an acromioclavicular joint effusion; absence of fluid within a joint makes the diagnosis of septic arthritis extremely unlikely.[32] If an effusion exists, laboratory analysis of the fluid is necessary to determine if the fluid is infectious. Ultrasound may be most useful, therefore, as a guide for joint aspiration in patients with difficult anatomy or large body habitus.

Bone scintigraphy is a physiologic imaging modality and can demonstrate the presence of disease before it appears on radiography. Technetium 99m (^{99m}Tc) is the radionucleotide of choice, although new ones are being developed. A triple-phase scanning sequence should be used. The first phase is the arteriographic phase, where images are obtained every 2 seconds for 1 minute after the ^{99m}Tc bolus. The blood pool phase is obtained at 10 minutes. The third, or bone phase, is obtained 2 to 4 hours after the initial injection.

Septic arthritis manifests as an increased uptake during the first two phases, and during the third phase, there is an increased uptake at the articular ends of the affected bones.[16] This is distinguished from osteomyelitis, in that actual osteomyelitis has a more focal area of uptake. This is a very sensitive, cost-effective study, and a negative scan rules out a septic shoulder. It also may reveal additional sites of joint sepsis in a patient unable to communicate or may diagnose a septic joint in a patient with fever of unknown origin. However, it is not specific, and the findings are the same as in any inflammatory arthropathy. The specificity is increased with labeling of autogenous leukocytes with either indium 111 or ^{99m}Tc. The degree of localization depends on the mechanics of polymorpholeukocyte accumulation. This technique is more sensitive for acute inflammatory lesions. Labeling of immunoglobulin G also has been performed with variable success in detecting joint sepsis.[146] A relatively new technique in orthopedic infection is single-photon emission computed tomography (SPECT). It is reported to have a higher sensitivity and resolution, and can differentiate the radioactivity in inflamed joints or bone from overlying normal soft tissue activity.[146]

Role and Indications for Diagnostic Arthroscopy

Septic arthritis can be a diagnostic challenge. Patients can have negative cultures, because of prior use of antibiotics (i.e., initiation of treatment before specimen is obtained, or treatment for other infections) or because of the presence of fastidious organisms. In such cases, arthroscopy can be a helpful diagnostic, as well as therapeutic, modality.

Arthroscopic examination of a septic joint usually reveals inflamed and friable synovium with fibrinous exudate. Adhesions and loculations of pus also may be present. The articular cartilage may appear normal but more often will have lost its lustrous appearance. In addition to visualization of the joint, direct synovial biopsy and culture of multiple sites can be obtained through the arthroscope.[17] The histology usually will show inflammatory cells with abundant neutrophils. Cultures of synovial tissue biopsy may have a higher yield for the fastidious organisms than the joint fluid cultures.

Classification System

Part of the difficulty in reporting outcomes in infected shoulder patients in the past has been the lack of a uniform classification system for septic joints. A number of systems exist to describe osteomyelitis[23,85,150] or infection around a total joint, but none is universally accepted. In the previous edition we introduced the University of Pennsylvania classification system for septic joints based on (a) the site and extent of tissue involvement; (b) the host's status, systemically and locally; and (c) the duration of symptoms and virulence of the organism (Table 38-3). In this system, the infectious process is staged using four anatomic types, three host physiologic classes, and two clinical settings.

The anatomic types include infection isolated to the periarticular soft tissue only or to the joint only, involvement of the joint and soft tissue, and involvement of the joint and bone. Anatomic type I is periarticular soft tissue infection without pyarthrosis. Such a case may occur in a postsurgical deep wound infection. Isolated glenohumeral sepsis (type II) occurs when the purulent material is confined within the capsule. Anatomic type III exists when there is involvement of the joint and surrounding soft tissue, such as deep wound infection or septic bursitis, along with the joint sepsis. There is no bony involvement in type III. When there is osteomyelitis contiguous with a joint infection, it is classified as type IV. In the shoulder girdle, this usually involves the proximal humerus but may occasionally develop in the acromion, distal clavicle, or glenoid.

The host is classified into either an A, B, or C physiologic group, according to the system of Cierny et al.[23] An A host represents a patient with normal metabolic and immune status. The B host is compromised either locally (BL) or systemically (Bs). Local issues include retained nonabsorbable suture or other biomaterial, local irradiation, scarring from multiple procedures, and lymphedema. Systemic compromise includes extreme age, chronic disease, or any condition causing suppression of the immune system. The C host status is reserved for those patients in whom the risks associated with aggressive treatment would outweigh the negative aspects of the infection. An example of a type C host would be an octogenarian with multiple medical comorbidities, an infected shoulder arthroplasty, and a draining sinus. In this patient, function may be superior with retention of the components, dressing changes, and chronic antibiotic suppression as compared to explantation of the prosthesis and long revision surgery.

The clinical setting takes into account the duration of symptoms and aggressiveness of the organism. We have grouped patients with less than 5 days of symptoms and infection with a less virulent bacterial strain into group 1.

TABLE 38-3
UNIVERSITY OF PENNSYLVANIA CLASSIFICATION SYSTEM FOR SEPTIC ARTHRITIS (MODIFIED FROM CIERNY-MADER OSTEOMYELITIS CLASSIFICATION)

Joint name (glenohumeral, elbow, hip, knee, etc.)
Anatomic type
- I: Periarticular soft tissue infection without pyarthrosis
- II: Isolated septic arthritis
- III: Septic arthritis with soft tissue extension, but no osteomyelitis
- IV: Septic arthritis with contiguous osteomyelitis

Host class
- A: Normal immune system
- B: Compromised host
- B_L: Local tissue compromise
- B_S: Systemic immune compromise
- C: Risk associated with aggressive treatment unwarranted

Clinical setting
- 1: Less than 5 days of symptoms and nonvirulent organism
- 2: Symptoms for 5 days or more, or a virulent organism

Clinical stage for the specific joint
Anatomic type + host class + clinical setting = stage

TABLE 38-4
RECOMMENDATIONS FOR ARTHROSCOPIC OR OPEN SURGICAL DRAINAGE AS OPPOSED TO REPEATED ARTHROCENTESES

Duration of symptoms for 5 days or longer before the initiation of treatment
Aggressive organisms
Methicillin-resistant *Staphylococcus aureus* (MRSA)
Gram-negative bacilli
Enterococcus
Clostridia
Glycocalyx-producing organisms
Elderly[138]
Immunocompromised host
Immunosuppressive therapy
Chronic debilitating illness
Malignancy
AIDS
Malnutrition
Diagnostic dilemma requiring tissue biopsy
Concomitant processes
Rheumatoid arthritis
Osteoarthritis
Periarticular osteomyelitis
Postsurgical infection
Failed repeated arthrocenteses
No or little clinical improvement
Persistent effusions after 5–7 days of treatment

Those patients who are infected with a virulent organism or with symptoms for 5 days or greater fall into group 2. The cut-off was chosen at 5 days because animal studies have shown that irreversible joint damage occurs if septic arthritis persists beyond this time. The virulent organisms may vary between hospitals and geographic locations but generally include methicillin-resistant *S. aureus,* Gram-negative bacilli, vancomycin-resistant enterococcal species, and clostridia (Table 38-4).

The University of Pennsylvania classification system for septic joints provides us a framework with which to approach those patients with septic arthritis, reminding us to consider multiple aspects of the patient including anatomic location, host status, duration of symptoms, and virulence of the offending organism. We believe it is useful for risk stratification, allowing us to make more informed treatment decisions. While we have introduced it in the previous edition of this shoulder text, it can be adapted to other joints.

TREATMENT

Antibiotics

Prompt recognition, correct diagnosis, joint decompression, and an organism-specific antibiotic regimen are essential, if disabling sequelae are to be avoided.[86] Similar to infection of other parts of the body, selection of an antibiotic is ideally based on the identification of the pathogen and its susceptibility profile. However, in some patients, the organism is not isolated; therefore, an empiric treatment must be started for the most likely infecting organism in that clinical setting. This will vary with the patient's age and underlying medical conditions. Furthermore, the choice of drugs must be linked with surgical options and other supportive measures in the overall management of the disease.

Initial empiric antibiotic selection is based on information such as patient age and risk factors, including history of intravenous drug abuse, rheumatoid arthritis, chronic illness, remote sites of infection, and immune status. The treatment may be instituted after a specimen is obtained for the appropriate studies, including Gram stain, culture, and sensitivity. Usually, a penicillinase-resistant antistaphylococcal drug is the initial choice for the typical Gram-positive cocci infection. In the United States, first-generation cephalosporins have been favored, because they are relatively nontoxic and inexpensive.[45] When there is a high likelihood of Gram-negative bacilli or methicillin-resistant staphylococci, the initial antibiotic choice is modified to third-generation cephalosporin or vancomycin, respectively. For patients receiving immunosuppressive agents and those who have developed nosocomial infections, an aminoglycoside needs to be included for additional coverage of *P. aeruginosa.* Initial antibiotics for intravenous

TABLE 38-5
SUGGESTED GUIDELINES FOR EMPIRIC ANTIBIOTICS FOR SEPTIC ARTHRITIS IN ADULTS

Clinical Setting/Gram Stain	Likely Organisms	Drug of Choice	Alternative Drug
Gram-positive cocci	*Staphylococcus aureus*, streptococci	Nafcillin or cefazolin	Clindamycin TMP/SMX Vancomycin
Healthy, sexually active individual with Gram-negative cocci (or negative stain)	*Neisseria gonorrhoeae*	Ceftriaxone	Doxycycline
Gram-negative bacilli	*Pseudomonas aeruginosa*, Enterobacteriaceae	Piperacillin ± gentamicin	Third-generation cephalosporins
Gram-positive bacilli	*Propionibacterium acnes*	Penicillin G	Nafcillin Vancomycin
Intravenous drug abusers	*S. aureus, P. aeruginosa, Serratia*	Cefazolin + gentamicin	Third-generation cephalosporins
Patients with major underlying disease, immunocompromised, or nosocomial infection	*S. aureus, Enterobacteriaceae, P. aeruginosa*, streptococci	Cefazolin + gentamicin	Third-generation cephalosporins
Patients with infected prosthesis	*S. epidermis, S. aureus, Enterobacteriaceae, P. aeruginosa*	Vancomycin + gentamicin	Imipenem

TMP/SMX = trimethoprim–sulfamethoxazole.

drug abusers should be for both *S. aureus* and *P. aeruginosa.* In the young, sexually active individual in whom the Gram stain test is negative for bacteria, gonococcal arthritis should be suspected and ceftriaxone started. Table 38-5 summarizes the guidelines for the initial empiric antibiotic therapy.

After the microbiologic data are available, the spectrum of coverage can be narrowed to maximize efficacy and decrease the risk of systemic toxicity. In light of the differing pathogens, their resistance profile at each hospital, and the advent of newer antimicrobial regimens, we generally obtain consultation with an infectious disease specialist.

The route of antibiotic administration is a subject of some debate. In the past, direct injection of antimicrobials into an infected joint to achieve high local levels was performed on a routine basis.[125] However, animal and human studies of intraarticular antibiotic concentrations have demonstrated that more than adequate levels can be achieved with clinically relevant parenteral doses.[91,124] For example, Frimodt-Moller[49] and Riegels-Nielsen et al.[118] investigated the diffusion (after intramuscular injection) of penicillin G, cloxacillin, clindamycin, and netilmicin into synovial fluid of infected rabbit knees and found sufficient local concentrations of all four drugs. Likewise in humans, similar studies were conducted with penicillin,[41,112] ampicillin,[5,77,104] cephalothin,[104] methicillin,[104,116] cloxacillin,[77] tetracycline,[83,112] erythromycin,[116] chloramphenicol,[83,116] lincomycin,[112] gentamicin,[98] and kanamycin.[5] All the antibiotics evaluated, with the exception of erythromycin, achieved articular concentrations in excess of the level required for bacteriostatic or bactericidal effect.[111] With the presently available agents having excellent synovial fluid penetration and the fact that there are associated risks, intraarticular antibiotic injection has fallen out of favor. Several investigators have reported chemical synovitis secondary to local tissue toxicity[2,44] and sterile abscesses[69] with the administration of intraarticular antibiotic injections. Most authorities now agree that the antibiotic regimen should almost always be given intravenously.[58]

A more controversial issue is the use of oral versus parenteral antibiotics. A number of investigators have shown good efficacy with the use of oral antibiotics to treat osteomyelitis and septic arthritis in children.[28,87,114,141] In all cases, however, the oral regimen was started only after an initial period of intravenous administration, usually 3 to 7 days. Black et al.[9] retrospectively studied this matter in 21 adults. Even though the failure rate was 14.3%, these investigators concluded that oral antibiotics are a "reasonable alternative to inpatient or outpatient parenteral therapy for treating adult patients who have bone and joint infections caused by susceptible organisms." To date, there has not been a well-designed, randomized, blinded, controlled study to determine whether oral antibiotics are as effective as parenterals in treating septic arthritis. Thus, at this time, oral antimicrobials should only be used in acute infections, after an initial period of intravenous administration. Furthermore, there should be ongoing clinical improvement as manifested by improved ROM of the joint, decreased pain, resolution of fever, and normalization of WBC and erythrocyte sedimentation rate.

Oral antibiotic administration has certain advantages, including cost savings, convenience, comfort, and decreased length of hospital stay. Prior to discharge, patients should be evaluated to ensure that adequate serum concentrations are

being achieved. Most clinicians[103,107] have arbitrarily maintained a serum bactericidal titer (SBT) of at least 1:8. However, Prober and Yeager[114] recommend SBT peak levels of 1:16 and trough levels of 1:2. The potential risk of an oral antibiotic regimen is that patients may not take the medication as required, due to lack of compliance or difficulty obtaining the medication. Thus, the importance of a full course of therapy must be stressed, and the patients should be carefully instructed on how to take the medication(s) with regard to proper dosage and timing.

The duration of antibiotic therapy is another issue that is a subject of discussion. There are no controlled studies to document the optimal length of treatment. However, certain guidelines have been established. The total duration of antibiotic regimen varies with the pathogen isolated, the patient's underlying condition, and adjuvant medical or surgical procedures. For gonococcal septic arthritis, 7 to 10 days is generally recommended. For streptococci or *Haemophilus* species, a 2- to 3-week duration is usually adequate. In the cases in which more virulent organisms such as *S. aureus* or Gram-negative bacilli are isolated, a 4- to 6-week course of appropriate antibiotic is required. Immunocompromised patients or those with a slow clinical response will need the full 6 weeks of treatment.[129] It is generally agreed that a septic shoulder in the setting of concurrent osteomyelitis will need 6 weeks of antibiotic treatment after the last major débridement surgery.[22]

Nonsteroidal Antiinflammatory Drugs

Sterilization of the joint with antibiotics and irrigation does not completely remove all the bacterial products. These microbial fragments may persist in the joint for prolonged periods and contribute to "postinfectious synovitis."[123] Nonsteroidal antiinflammatory drugs (NSAIDs) may help to reduce this inflammatory process. In an animal model, it was shown that naproxen, when administered in combination with antibiotics, decreased the amount of glycosaminoglycan and collagen loss.[132] These results suggest that use of NSAIDs in addition to the antibiotic regimen may minimize the destruction of articular cartilage. If used, nonsteroidal drugs should not be started too early in the course of infection, because their action may mask a poor clinical response to the antibiotics. We usually start them after 4 to 5 days of antibiotic treatment.

Antibiotic-Impregnated Polymethylmethacrylate

Since described by Buchholz and Engelbrecht[18] in 1970, antibiotic-impregnated polymethylmethacrylate (PMMA) has been used in the treatment of infections of the soft tissue and joint arthroplasty, as well as osteomyelitis. The main advantage of this treatment is that it allows for a high concentration of antibiotics to be delivered locally while minimizing the risk of systemic toxicity. The antibiotic released is not absorbed systemically, therefore resulting in local concentrations five- to 10-fold higher than when administered parenterally.[72] In vitro and in vivo studies have shown that this mode of therapy is safe and effective. In particular, Adams et al.[1] found that clindamycin, vancomycin, and tobramycin exhibited good elution characteristics and had consistently high concentrations in bone and granulation tissue.

Antibiotic-impregnated PMMA may be utilized in one of several ways: (a) as cement for fixation of prostheses in joint arthroplasty,[144] (b) as a spacer block (see Fig. 38-2C,D) to maintain the soft tissue envelope after resection arthroplasty and débridement,[11,115] or (c) as a string of beads embedded in the soft tissue or bone for chronic infection.[62] Powdered antibiotics are used in the admixture, because adding aqueous solutions of antibiotic to the cement interferes with the prepolymerization process, resulting in mechanically weakened cement.[97] When used for fixation, the fatigue strength of the cement is not significantly altered when 1.2 g of the appropriate antibiotic (usually tobramycin) is mixed per 40 g of PMMA.[36] In the form of a spacer or beads, the fatigue strength of the PMMA is less critical; therefore, a higher concentration of antibiotic may be added to the cement powder. Hofmann et al.[75] described mixing 4.8 g of powdered tobramycin in each 40-g batch of Simplex-P cement (Howmedica, Rutherford, NJ) for use as a spacer block, whereas Cierny et al.[23] reported using 4.8 to 9.6 g of tobramycin per 40 g of PMMA for making the beads.

Elution of antibiotics from the cement occurs by diffusion, in which there is a rapid initial release, followed by a sustained release that progressively diminishes over weeks to months.[47,73] Because the spherically shaped beads have a greater total surface area, more antibiotic per unit time is released when the impregnated cement is used in the form of beads than when used as a spacer block or for fixation.[73] In vitro studies by Marks et al.[97] demonstrated that antibiotics diffused from Palacos-R (Richards, Memphis, TN) in larger amounts and greater duration than from Simplex-P. However, these findings were not substantiated by in vivo studies by these same investigators. In addition, Brien et al.[15] found no statistical difference in the elution characteristics of tobramycin from these two cements.

In shoulder sepsis, antibiotic-impregnated PMMA may be a good adjunct, temporary therapy for those patients with concomitant osteomyelitis of the proximal humerus. They are placed after thorough irrigation and débridement, and the wound is closed. The cement is removed at the time of definitive surgery.

Evacuation and Decompression of the Joint

The goals of treatment of septic shoulder include sterilization and decompression of the joint with removal of all inflammatory cells, lysosomal and proteolytic enzymes,

and fibrinous materials. In non–surgery-related infection, the preferred method of joint decompression remains controversial. Two schools of thought exist. One stems from the medical and rheumatologic literature, suggesting that repeated needle aspirations and appropriate antibiotics may be all that is necessary in a pyogenic arthritis of the shoulder.[58,69] The other is based on the principle that surgical débridement is the best treatment for septic arthritis and osteomyelitis of the shoulder. There are studies to support both views. However, when scrutinized closely, it may be borne out that surgery offers distinct advantages.

Those who advocate repeated arthrocenteses cite extended hospitalization, wound management problems, and anesthetic risks as reasons to avoid surgical intervention. A number of retrospective studies from the 1970s and 1980s, comparing infected joints treated with needle aspirations versus surgical drainage, concluded that septic joints can be medically managed with good results.[56,58,99,119]

In 1980, Rosenthal et al.[119] analyzed 71 nongonococcal septic joints and found that medical therapy (parenteral antibiotics and frequent aspirations) led to good result in 74%, as opposed to only 32% in the open irrigation and drainage cases. Only one patient in their series had a septic shoulder, and was managed successfully without open drainage. A separate study in 59 patients by Goldenberg et al.[56] showed full recovery in 67% of those treated by arthrocentesis versus only 42% of those surgically treated. Only nine of these patients had sepsis of the shoulder with the majority having infected knee joints; results were not specifically reported for the shoulder subgroup. Master et al.[99] reported on a small series of eight septic shoulders in which medical management, including closed drainage, achieved good outcome in four patients (five shoulders). Three patients, however, required open drainage to eradicate the infection.

Like other investigators,[69] we question these data. Clearly, there are weaknesses in these studies. They were all uncontrolled; therefore, the indications for the treatment modality were undefined and determined predominantly by the admitting service. Because of the lack of randomization, there were a number of biases. For example, in the Goldenberg series,[56] 47% of the surgical patients were infected with *S. aureus,* whereas only 26% of the medical patients were infected with this virulent organism (this information is not available in the Rosenthal series). Undoubtedly, infection with a more virulent organism such as *S. aureus* will result in a worse outcome.[50,90] The duration of symptoms prior to treatment (i.e., delay in treatment) will also affect the result.[2,50,56,86] In all three series, there was a greater delay in the group of surgically treated patients who had the poor outcome. Another weakness is the outcome data. No assessment of function or follow-up was reported in the study by Master et al. Although the Rosenthal and Goldenberg series included ROM as part of their assessment, it is unclear how they were able to obtain the premorbid ROM because these studies were retrospective, and the patients were evaluated only after the fact. Of interest, Rosenthal pointed out that of the six patients who failed medical management and subsequently required surgical drainage, three did well. Goldenberg had seven patients undergo surgery after medical failure but did not report follow-up. With the exception of the Master study, most of the cases reported were septic knees, and as such, the generalizability of these studies to the shoulder should be questioned.

If aspiration is the choice of therapy, it should be performed under sterile conditions with a large-bore needle. A long spinal needle may be necessary to penetrate the glenohumeral joint in an obese or muscular patient. Attempts to drain the joint completely are essential and should be repeated frequently (once or twice daily[137]) until the effusion ceases to recur.[58]

Although many internal medicine physicians view incision and drainage as an alternative form of treatment, most orthopedic surgeons believe that shoulder sepsis demands surgical treatment. Proponents of surgical drainage describe technical difficulty with shoulder aspiration, inadequate needle evacuation of purulent material secondary to loculations and adhesions, pain associated with multiple arthrocenteses, and potential iatrogenic needle inoculation of subchondral bone as reasons for surgery.[43] Again, there are only retrospective studies to support this view.

Leslie et al.[90] reviewed 18 cases of septic arthritis of the shoulder with a minimum of 1-year follow-up. Ten patients were treated with arthrocenteses and eight with surgical drainage at the outset. Of the 10 who initially had repeated aspirations, one died, one had no motion, one had only passive abduction and flexion to 90 degrees, and seven required an open irrigation and drainage. Of the latter seven, one died, two had no active motion, one had less than 45 degrees of flexion, and three had greater than 90 degrees of flexion. There were no deaths in the eight patients who underwent an operative procedure from the outset. Two had flexion of at least 90 degrees, two had flexion of 45 degrees or less, and four had no active motion. Although the sample size was too small to yield statistical significance, the investigators noted that arthrotomy resulted in a better outcome than did repeated aspirations. At Bowman Gray School of Medicine, Toby et al.[143] came to the same conclusion after reviewing 15 cases of shoulder infection. Further support for open drainage in joint infections is offered by Lane et al.,[89] who found that patients with a 3 or more day history of knee pyarthrosis and those with *S. aureus* or Gram-negative bacillus infections fared better after open irrigation and drainage.

Without prospective randomized studies to provide conclusive evidence either way, the debate over medical versus surgical drainage of shoulder infections continues. However, mounting evidence is accumulating for the use of

surgical arthroscopy in septic arthritis cases.[17,110] The diagnostic advantage of arthroscopy is that it allows for direct visualization of the entire joint. Visualization is essential in determining the extent of the disease and enabling tissue biopsy in atypical or challenging cases. The therapeutic advantage of arthroscopy is that the joint can be adequately drained, thoroughly débrided, and copiously irrigated. Prognostically, arthroscopic irrigation and drainage reduce hospital stay and allow for early ROM, which may be helpful in preserving joint function.[121] Recommendations for arthroscopic or open surgical drainage, as opposed to repeated arthrocenteses, are summarized in Table 38-5.

Early use of arthroscopy in musculoskeletal infection was entertained mostly for pyarthrosis of the knee. In 1981, Jarrett et al.[81] reported the first successful arthroscopic débridement of an infected knee in a patient who failed medical management but was too ill for general anesthesia and arthrotomy. Since then, a number of small series[79,80,131] have shown good to excellent results with minimal operative morbidity. Stutz et al. demonstrated that arthroscopic irrigation and systemic antibiotic therapy was 91% successful in eradicating septic arthritis in a series of 78 joints including 10 shoulders.[140] Later-stage infections, however, often required multiple procedures to achieve clinical healing.

Suppurative arthritis has also been drained with percutaneous catheters placed under fluoroscopy.[117] A handful of these cases involved the shoulder.[122] Although the investigators state that septic arthritis can be successfully treated with drainage of the joint via a percutaneous catheter in combination with antibiotic therapy, the experience is relatively limited at this time. It remains to be determined whether this modality will have a future role in the treatment of joint infection.

Management of Sternoclavicular Joint Infection

The majority of the cases of sternoclavicular septic arthritis respond to parenteral antibiotics and repeated aspiration or simple incision and drainage. In patients with chest wall phlegmon, retrosternal abscess, or mediastinitis, a more radical débridement including excision of the medial head of the clavicle, intraarticular disc, and portions of the manubrium must be performed.[19,120]

Management of Postoperative Infections

The success of treatment for a postsurgical infection is dependent on obliteration of the infectious organism and the restoration of function. If the infection is superficial and limited to the subcutaneous tissue, meticulous observation, local wound care, and antibiotics are usually sufficient for successful outcome. However, for a deep postsurgical infection, a more aggressive approach is required with débridement of the glycocalyx film, avascular bone, infected sinus tract, soft tissue, and foreign material (Fig. 38-8).

For the infected shoulder in which foreign material is present in or about the joint, management must be individualized to be successful (Fig. 38-9). When the hardware is serving to stabilize a fracture, débridement of bone and soft tissue with adequate drainage may be attempted while preserving the internal fixation in situ. If the infection persists, the hardware must be removed to successfully gain control of the process. On the other hand, if the hardware is loose or not contributing to the fixation, it should be removed at the first débridement. Care must be taken to preserve cuff tissue and the tuberosities if function of the shoulder is to be maintained.

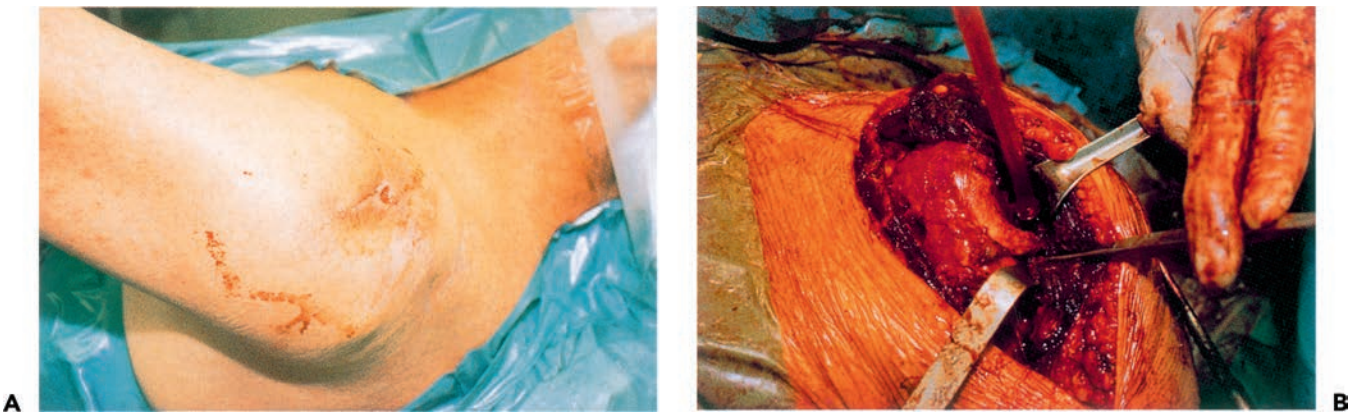

Figure 38-8 **(A,B)** A 2-year chronic shoulder infection occurring after rotator cuff repair treated with multiple limited débridements. The patient presented with a chronic draining sinus and chronic osteomyelitis with a sequestrum. The patient had undergone extensive débridement of all dead bone, soft tissue, sinus tract, and suture material via both an anterior and posterior approach. The wounds were packed open and closed 3 days later, after a second irrigation and débridement. The patient had 6 weeks of antibiotics. The infection resolved without further treatment. The patient was left with a stiff but painless shoulder. (Courtesy of J.P. Iannotti, M.D., Ph.D.)

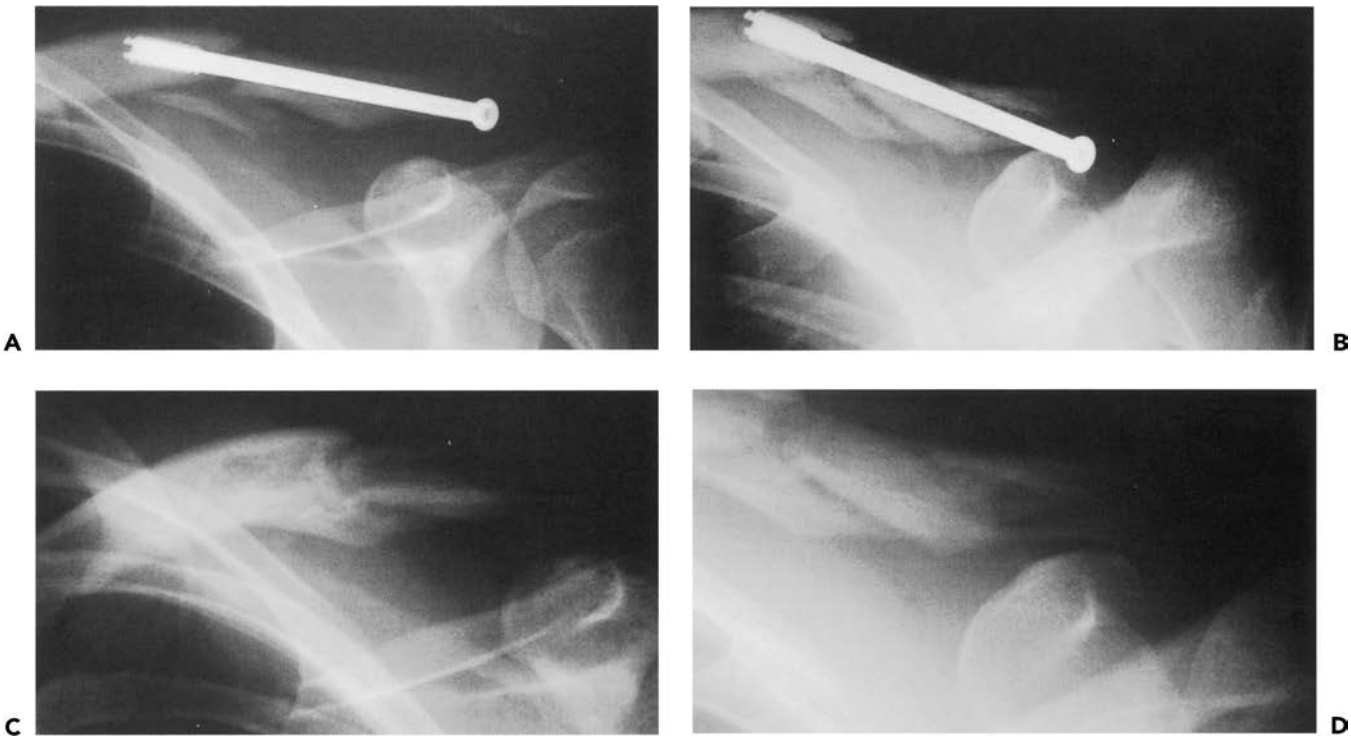

Figure 38-9 **(A)** Immediate postoperative x-rays after open reduction and internal fixation of a comminuted, midshaft, clavicle fracture. **(B)** Four months postoperatively, the osteomyelitis was treated by retention of the hardware and intravenous antibiotics until the fracture healed. **(C,D)** The hardware was removed and the clavicle was débrided, which was followed by another 6 weeks of intravenous antibiotics. The patient has a healed painless clavicle with full function and no signs of infection. (Courtesy of J.P. Iannotti, M.D., Ph.D.)

It has been well established that suture in the wound increases the susceptibility of host tissue to infection. Elek and Conen showed that 7.5×10^6 staphylococci were required to induce an intradermal infection, whereas a bacterial inoculation count of only 300 was needed to produce a similar infection in the presence of silk suture.[42] In 1984, Chu and Williams[20] studied the attachment of bacteria to 10 different suture materials. They concluded that the number of adherent bacteria was dependent on the type of suture material, the specific bacteria, and the duration of contact. Physical configuration (monofilament vs. braid multifilament) and surface area of the suture play a role in bacterial adhesion, but their chemical structure and coating may be even more important factors. These investigators also found that *S. aureus* adhered to sutures more than *E. coli*, and that the adherence is a dynamic process. Thus, in short, suture materials should be treated like any other foreign body. They may be left in place if not grossly contaminated at the time of initial débridement, but may very well require removal to eradicate the infection.

After removal of the foreign material, several additional surgical débridements are usually needed at 2- to 5-day intervals for complete eradication of all compromised tissues. Reconstruction of the defect with bone graft and/or local or microvascular soft tissue transfer may be performed after the wound is culture negative.

Management of Infected Arthroplasty

Fortunately, the incidence of infection after total shoulder arthroplasty is exceedingly low.[101] However, when infected arthroplasty does occur, it represents a potentially devastating complication that is often difficult to manage. Like other joint replacement surgery, septic shoulder arthroplasty can occur early or late. Once the diagnosis is established, the treatment should follow the same principles as the larger joints. Intraoperative frozen sections may be valuable in helping to establish or confirm the diagnosis. As demonstrated by Lonner et al.[94] in revision hip and knee arthroplasties, 10 or more polymorphonuclear cells per high-power field were predictive of infection. Early infections may be managed with wound exploration, irrigation, débridement, wound closure, and antibiotics.[101,154] The implant may be left in place if the components are well fixed.[60] Wirth and Rockwood recommend that early infections with Gram-negative organisms and all late infections be treated with removal of the prosthesis and all cement.[154] Thorough débridement of granulation and scar tissue is also required, combined with 6 weeks of parenteral antibiotics.

Historically, the majority of late infections of shoulder implants have been treated with prosthesis removal and resection arthroplasty. Pain relief usually is achieved in one-half to two-thirds of patients,[25] but resection arthroplasty is often complicated by severely limited ROM as well as loss of strength.[25,135] Recent literature has supported the use of staged exchange arthroplasty with a temporary antibiotic cement spacer as an effective means of treating late infected implants.[24,82,115,127] Jerosch and Schneppenheim[82] and Seitz and Damacen[127] were both able to eradicate infection and achieve good function in each series of eight patients treated with local débridement, intravenous antibiotics, and staged reimplantation with an interim antibiotic cement spacer. Temporary use of an antibiotic spacer offers the advantage of a stable shoulder joint and local therapy with antibiotics while preserving some passive and active motion.[82] Other treatment options include antibiotic suppression, arthrodesis, and amputation.

AUTHORS' PREFERRED METHODS OF TREATMENT

Our generalized treatment algorithm for intraarticular shoulder infections, based on the University of Pennsylvania classification system, is outlined in Fig. 38-10.

Hematogenous, Isolated Subacromial Septic Bursitis

If the infection is limited to the bursa, we prefer needle aspiration of the space, organism-specific antibiotics, and careful observation. Complete evacuation of bacteria and debris is not as critical in this case, because the integrity of the articular cartilage is not in jeopardy.[88] Arthroscopic or open débridement should be performed if the process fails to clear rapidly. Patients who have a protracted course, concomitant osteomyelitis, or glenohumeral sepsis will require surgical drainage and débridement.[17] If the integrity of the rotator cuff or the involvement of the glenohumeral joint is in question, an MRI is obtained for preoperative evaluation.

Hematogenous, Isolated Pyarthrosis of the Glenohumeral Joint

In aspiration-confirmed, nongonococcal hematogenous pyarthrosis of the glenohumeral joint, we initiate appropriate intravenous antibiotic treatment and prefer surgical irrigation and débridement with the arthroscope (Table 38-5). After induction of anesthesia, the patient is placed in the beach-chair position. Preparation and draping are performed in the usual sterile manner for

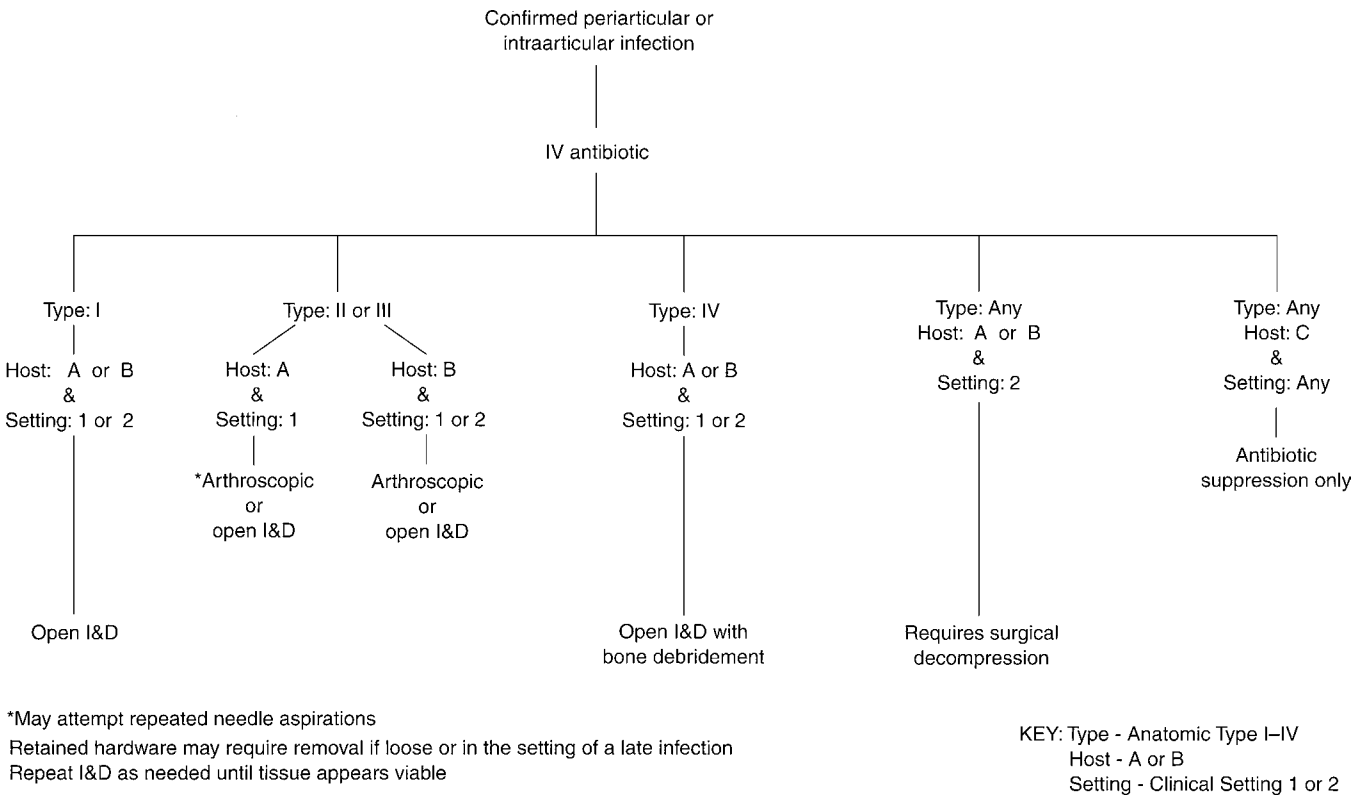

Figure 38-10 The authors' treatment algorithm for pyarthrosis, based on the University of Pennsylvania classification system for septic arthritis (see Table 38-3).

shoulder surgery. The posterior portal is made 2 cm inferior and 2 cm medial to the posterolateral edge of the acromion, in line with the posterior axillary fold. A trocar is then inserted, aiming in the direction of the coracoid. After confirming intraarticular placement by back flow of joint fluid, the arthroscope is inserted, and the joint is inspected. A second (anterior) portal is then made by first advancing a spinal needle from a location halfway between the coracoid process and the anterolateral acromion into the joint under direct arthroscopic visualization. The needle is removed, and a cannula with a trocar is inserted, following the same direction as the needle. Tissue for cultures and histology is obtained. The two portals are used for ingress and egress of irrigation fluid. After irrigation, the entire joint is once again inspected for signs of rotator cuff or articular damage and retained purulent material.

We include a limited open procedure to explore the biceps tendon when there is tenderness along the biceps or if the infection is caused by an aggressive organism. This can also be done by opening the biceps sheath by arthroscopic technique from the subacromial space. When the cuff is intact the biceps tendon and groove should be marked with a spinal needle, which can then be used to locate the sheath from the bursal side of the rotator cuff. Opening the biceps sheath ensures that loculated pockets of purulent material or soft tissue abscesses have not developed from organisms tracking down the bicipital groove. In all cases of sepsis of the glenohumeral joint the subacromial space should be evaluated and irrigated after the glenohumeral joint is thoroughly cleaned.

We recommend débridement via open arthrotomy if the surgeon is less experienced in shoulder arthroscopy. We prefer the deltopectoral approach and opening the rotator

Figure 38-11 **(A–D)** Chronic osteomyelitis after hemiarthroplasty for treatment of an acute four-part fracture. The patient had chronic wound drainage and a painful arm and was initially treated with oral antibiotics. **(E)** The postoperative x-rays showed a detached greater tuberosity and a loose cemented hemiarthroplasty.

Figure 38-11 (*continued*) **(F–H)** Intraoperative photographs showing a chronic sinus tract to the prosthetic stem that was loose and easily removed with the entire cement mantle.

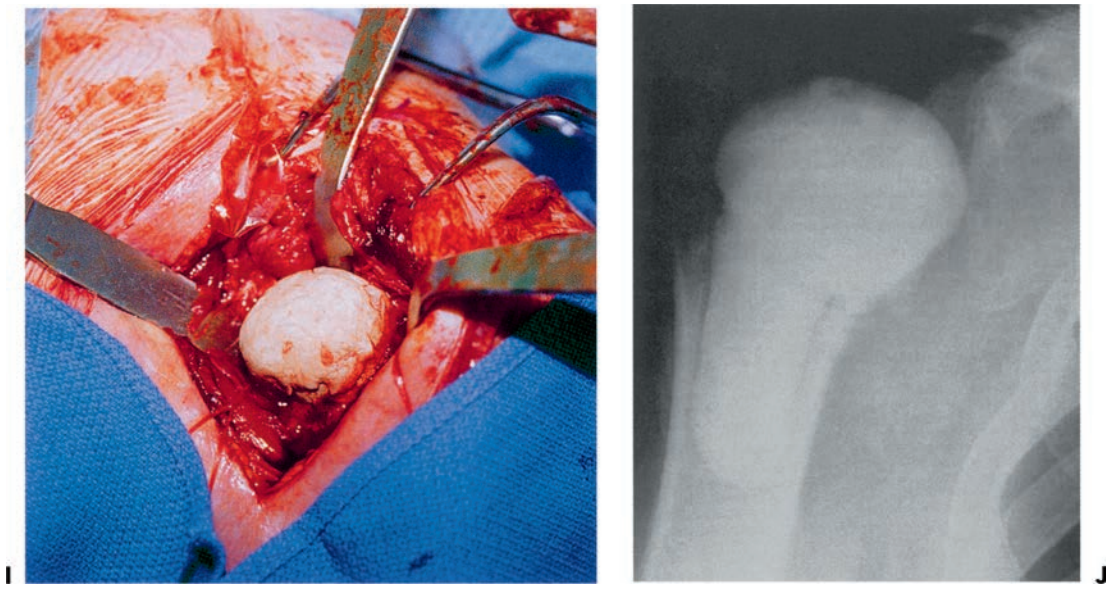

Figure 38-11 (*continued*) **(I,J)** A tobramycin cement spacer was placed for 8 months, during which time the patient was on antibiotics. The erythrocyte sedimentation rate was monitored monthly. It decreased from 92 preoperatively to 20 before revision surgery, 8 months after débridement of the infected prosthesis. At the time of revision, the spacer was removed, a total shoulder arthroplasty was performed with tobramycin cement, and the tuberosity was mobilized and internally fixed to the proximal humeral shaft. (Courtesy of J.P. Iannotti, M.D., Ph.D.)

interval. After irrigation and débridement, a closed suction drain is placed in the joint and the interval is closed with a monofilament, absorbable suture. A second drain can be placed in the soft tissue.

Medical management with antibiotics and repeated aspirations should be reserved for less virulent infections that are diagnosed early and for patients who are medically unable to tolerate surgery. At the time of this writing, we believe that percutaneous catheter drainage is yet to be proven to offer any additional benefits.

Postoperatively, analgesics are adjusted so that the patient can participate in pendulum or passive ROM exercises within 24 hours of surgery. A sling is used for support, as needed, during ambulation. An NSAID is started after a positive clinical response to the antibiotic regimen is established, usually after 4 or 5 days.

Postoperative Wound Infection Complicating Fracture Stabilization or Rotator Cuff Repair

Although some investigators believe there is a role for arthroscopy in postoperative wound infections, we prefer an open wound débridement, including arthrotomy, as needed. The extent of débridement must be individualized for each patient. However, if the infection is caught early, at our first débridement we attempt to irrigate the wound thoroughly, débride any granulation tissue and glycocalyx, and allow the internal fixation device or cuff repair suture to remain. The patient is returned to the operating room at 2- to 3-day intervals for redébridement as needed. Closed suction drainage is used. Every attempt is made to avoid leaving the wound open or changing packing at the bedside because of the risk of introducing a hospital-based resistant organism. Antibiotic beads are inserted if the wound size will allow. Removal of compromised suture and fracture fixation hardware is performed as soon as it becomes obvious that the organism is not responding. We emphasize avoidance of electrocautery for dissection and meticulous soft tissue and bone débridement to have adequate host material at the time of reconstruction or definitive wound closure. If a rotator cuff repair is found to be disrupted during the initial débridement, definitive repair is delayed until the final irrigation and débridement to optimize long-term results.

If the deltoid was taken down for exposure, care must be taken to repair it to prevent postoperative dehiscence. At the time of the definitive procedure, we suture the superficial and deep deltoid fascia directly to bone. We prefer to use monofilament, absorbable sutures in an interrupted manner for this closure.

Postoperative mobilization is restricted to pendulum exercises, depending on the stability of the cuff or fracture repair. In the case of a fracture involving the proximal humerus, fracture healing takes precedence over joint motion.

In extreme circumstances of patient noncompliance or if the soft tissue envelope is severely damaged by the infection or multiple procedures, a shoulder spica cast is used for wound protection. Soft tissue immobilization is maintained in the position of least tension to the repair. In our

opinion, a spica cast is better immobilization than an abduction pillow, because there is less tendency for the arm to shift.

If the nonabsorbable rotator cuff suture has been allowed to remain in situ, parenteral, organism-specific antibiotics are delivered for 6 weeks. In the case of retained fracture fixation hardware, oral antibiotics are continued after the 6 weeks of parenteral antibiotics until the fracture is clinically and roentgenographically healed. After confirmation that healing has indeed occurred, the hardware is removed if the infection persists.

Infection Complicating Hemi- and Total Joint Arthroplasty

Surgical wound infections that develop during or immediately after the index hospitalization are treated aggressively with débridement and irrigation, rather than expectantly, because of the underlying biomaterial.

For late deep infection, our preferred treatment is staged débridement and reimplantation, if possible. An antibiotic-impregnated cement spacer is utilized to facilitate the definitive reconstruction (Figs. 38-11 and 38-12).

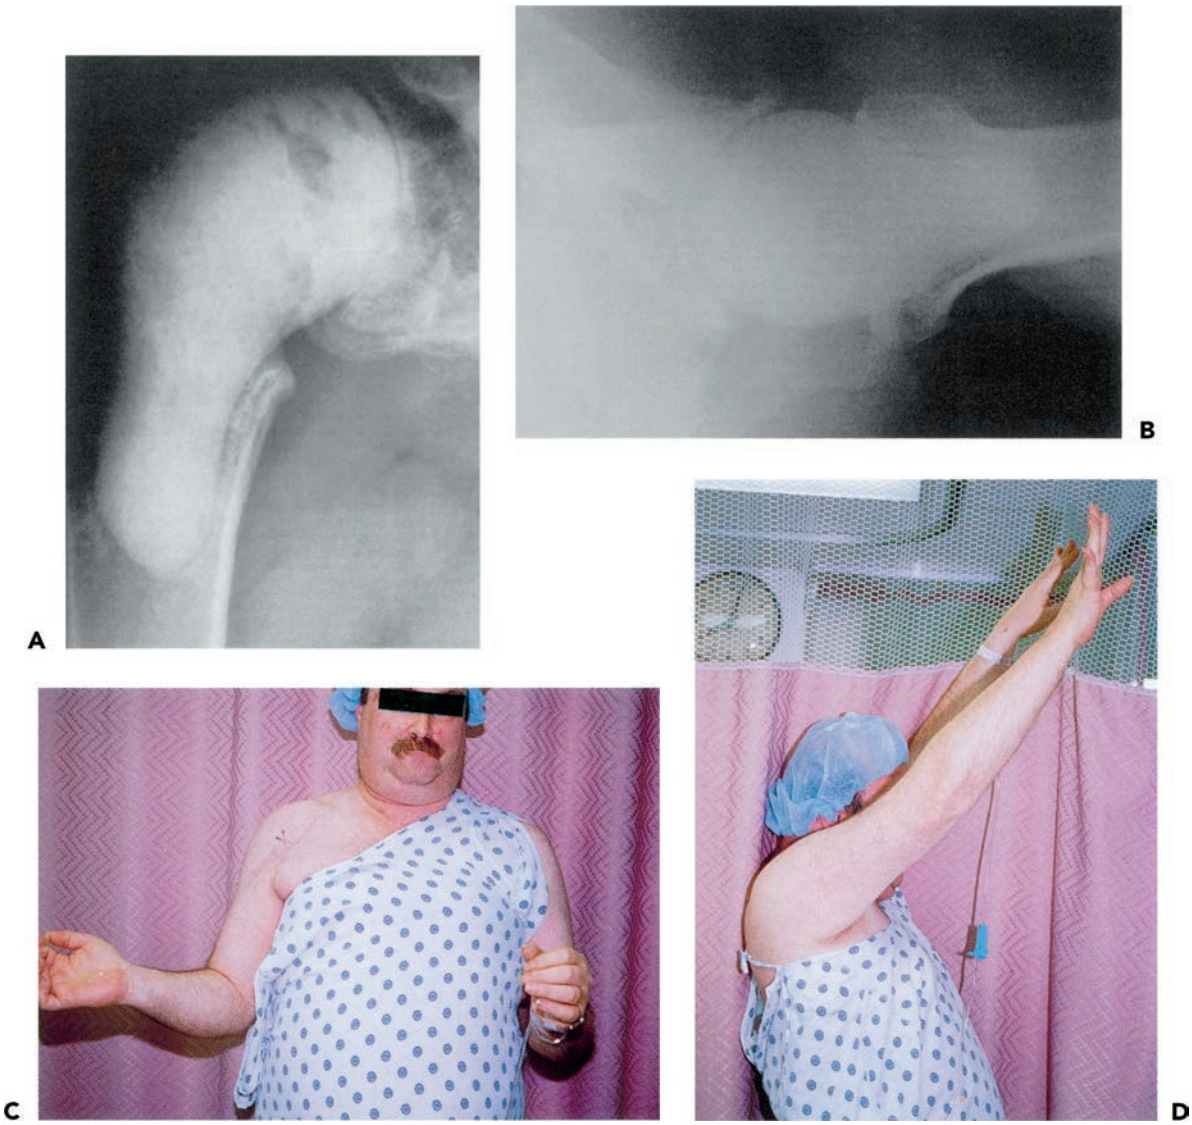

Figure 38-12 **(A,B)** Cement spacer used on the right shoulder for treatment of a late hematogenous seeding of a hemiarthroplasty, placed 18 months prior to infection. The hemiarthroplasty was placed for arthropathy secondary to an excessively tight repair for recurrent instability of the right shoulder, 18 years before the index arthroplasty. The cement spacer maintains the soft tissue envelope for later prosthetic conversion. In some patients, remarkable shoulder function can be maintained with a spacer in place. **(C,D)** This patient had to be called back to have the spacer replaced with a hemiarthroplasty because of progressive glenoid erosion. He maintained excellent function and minimal pain with the spacer 1 year after débridement of the infected joint. His left, uninfected shoulder had less function, due to prior shoulder surgery for treatment of recurrent dislocation 18 years previously. (Courtesy of J.P. Iannotti, M.D, Ph.D.)

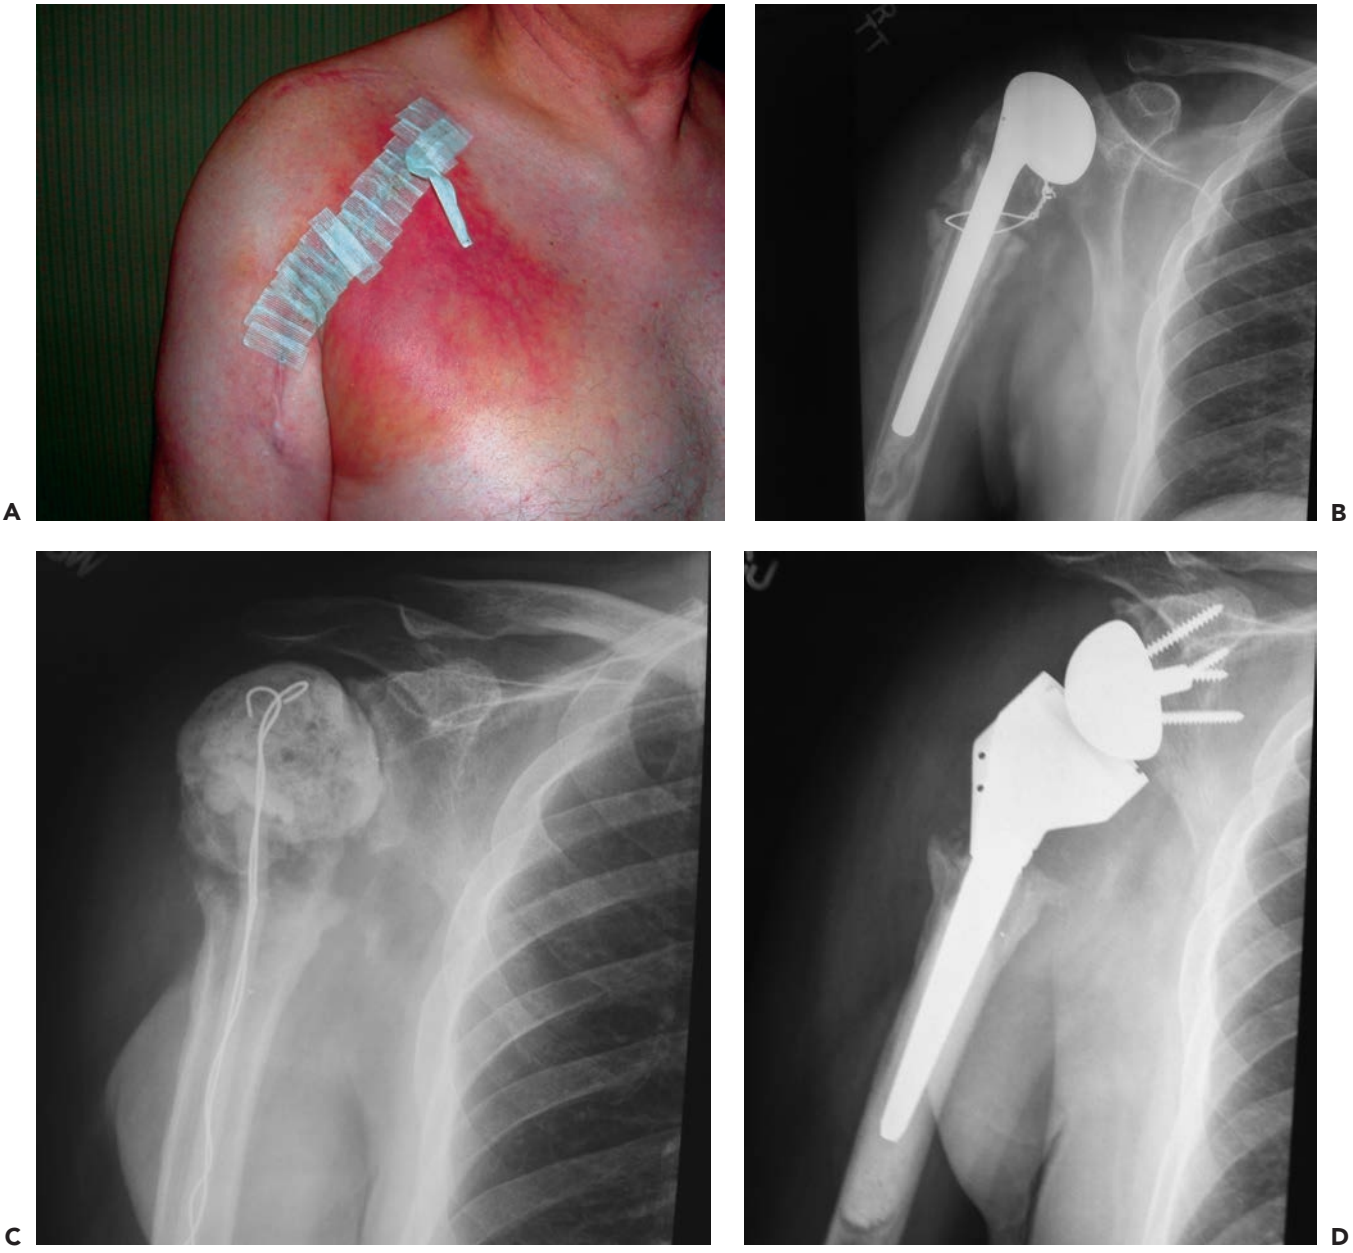

Figure 38-13 **(A)** Clinical infection with Gram-positive cocci (*Staphylococcus aureus*) with **(B)** severe loosening and osteolysis of the humeral component. Patient had hemiarthroplasty performed for proximal humeral fracture with severe rotator cuff and bone loss (tuberosities). **(C)** This patient was treated with a two-stage revision with a vancomycin spacer for 4 months (6 weeks of IV antibiotics). **(D)** Second-stage revision was with a Delta (DePuy, Johnson and Johnson) reverse total shoulder arthroplasty.

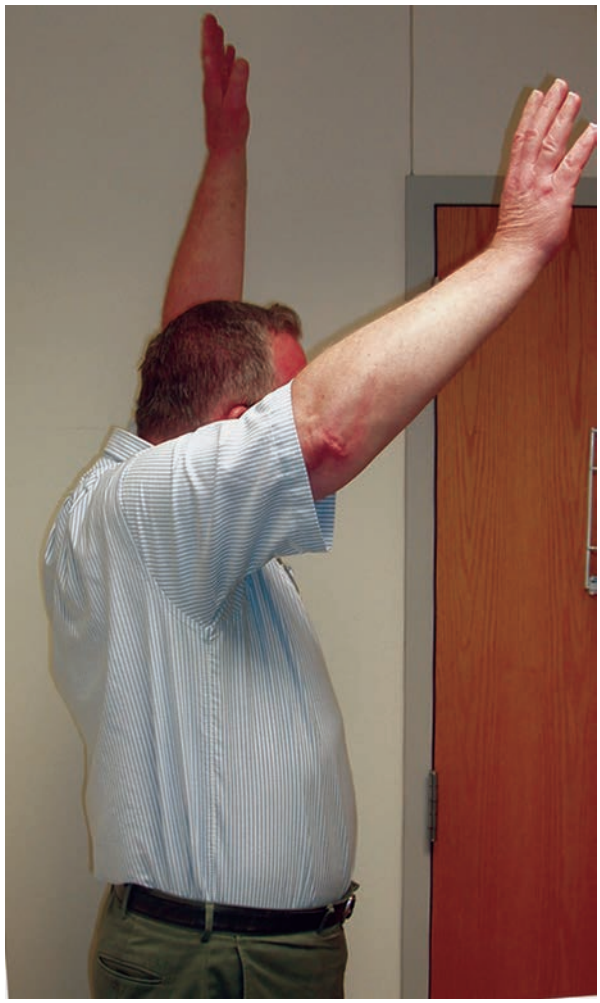
The spacer is usually hand formed to make a smooth spherical shape approximately the size of the humeral head and is made stable by placing at least several centimeters of the cement within the proximal humeral shaft. The cement is allowed to cure in situ and is continuously irrigated to minimize tissue damage from the heat generated from the large amount of cement. We make all attempts to repair the rotator cuff to bone, and if there is a displaced tuberosity with an attached rotator cuff, fix the bone to the humeral shaft or cement mantel. We use a #2 monofilament absorbable suture. The goal of this repair of fixation is to maintain as much length of the soft tissues or tuberosity for later reconstruction. After placement of the spacer we encourage the patient to use the shoulder and upper extremity for all waist- and chest-level activities of daily living. We start them on pendulum exercises during the first week after surgery. Revision arthroplasty is performed at least 3 months after all



E

F

antibiotics are stopped and the erythrocyte sedimentation rate, C-reactive protein levels, joint aspirate, and clinical findings do not demonstrate signs of infection. At the time of surgery intraoperative cultures and frozen sections are obtained and intraoperative antibiotics are then given. When all signs of infection are absent, the prosthetic is implanted with antibiotic cement that is most suitable to the bacteria originally isolated. In cases where the rotator cuff is intact with good deltoid function, an unconstrained hemi- or total shoulder arthroplasty is performed. In cases with major bone or cuff deficiency, a reverse shoulder prosthetic is preferred so long as there is sufficient bone to allow for secure placement of the metaglene (Fig. 38-13). In some cases of severe glenoid deficiency where the infection is cleared, the antibiotic spacer is removed, the glenoid is grafted, and hemiarthroplasty is performed. If the patient is dissatisfied with the function, the infection remains cleared 1 year after being off all antibiotics, and there is incorporation of the bone graft material, the hemiarthroplasty can be converted to a reverse shoulder replacement. The editors have used this protocol for two-stage reconstruction for infected arthroplasty in over 40 patients with over a 90% success in the resolution of active signs of infection. Results of surgery have been quite variable with both unconstrained and constrained arthroplasty but are more reliable for active shoulder-level elevation with the reverse prosthetic.

If a reimplantation cannot be performed, arthrodesis is the next option, if possible, because it yields better function than resection arthroplasty. This is indicated when the functional deficits of a resection arthroplasty are unacceptable to the patient. In these cases it is almost always necessary to use a vascularized fibula to achieve an arthrodesis and compensate for the massive bone loss present in most cases on both the humeral and glenoid sides. However, because there is usually extensive bone loss and this patient population is usually elderly, resection arthroplasty is performed more commonly than

G

Figure 38-13 (*continued*)

fusion. Deep late infection with a nonaggressive organism in an elderly patient is suppressed with antibiotics, if possible.

PROGNOSIS

The prognosis for septic arthritis of the shoulder joint is highly dependent on prompt diagnosis, the nature of the infecting organism, and the patient's immune status. Most patients will not have the typical signs and symptoms of a septic joint, and the laboratory studies may be equivocal. For these reasons, many are initially diagnosed as having bursitis or tendonitis, and the correct diagnosis may not be made for up to 6 months.[90] It is therefore imperative that the evaluating physician have a high index of suspicion and that, if the diagnosis is entertained, the glenohumeral joint be aspirated to rule out pyarthrosis.

Gelberman et al. reported satisfactory results in 8 of 10 patients when treatment was initiated within 4 weeks of the onset of symptoms.[50] Master et al.[99] found that treatment delays of greater than 1 month resulted in therapeutic failures, with persistent infection and poor function. However, other investigators had worse outcomes in their series. Leslie et al.,[90] who defined a poor result as the death of the patient or the absence of active motion of the glenohumeral joint, found that 9 of the 10 poor results were in patients who had been diagnosed with septic shoulder within 4 weeks. Ward and Goldner[151] found that all unsuccessfully treated patients had symptoms for more than 1 week. The discrepancy between the results cited in the above series may be due to a number of factors, such as the aggressiveness of the infecting organisms or the method of treatment. However, it is clear that delay in treatment results in worse prognosis.

Outcomes following treatment of infected shoulder arthroplasties can be promising.[30,78,127,135] In a series of 42 patients (49 infected prostheses) treated with a variety of methods, 71% were able to clear their infection.[30] Although only 6 of 10 patients treated with two-stage prosthetic revision showed no signs of persistent infection (mean follow-up of 34 months), the authors advocated staged reimplantation as the best compromise between eradication of infection and preservation of function. In another series of eight cases followed for an average of 4.8 years, all patients achieved pain relief with no recurrence of infection following staged reimplantation using an interim antibiotic spacer.[127] All eight patients demonstrated a significant increase in their functional capacity; however, each also reported a decrease in motion and strength compared to their normal side. Equally good outcomes have been reported by Ince et al. following one-stage exchange for infected prostheses.[78] After a mean follow-up of 5.8 years, none of the nine patients in their series showed signs of recurrent infection. In each of these studies, early and aggressive treatment of periprosthetic infections was associated with more favorable outcomes compared to delayed treatment.

FUTURE DIRECTIONS

Exciting work is ongoing with reference to the prevention of infection associated with orthopedic biomaterials by coating fracture fixation hardware with antiseptics prior to implantation. Work in the animal model has shown a significant reduction in infection using chlorhexidine and chloroxylenol.[35]

Evaluation of patients with potential joint sepsis is currently imperfect at best. Emerging diagnostic techniques are focusing on detecting a specific host response to infection. Utilizing microarray technology, it has been shown that the synovial fluid leukocytes have a genomic profile that is specific for infection.[39] This genomic technology may lead to simple tests in the future that identify

infection, and may even distinguish bacterial species involved.

Even after the bacteria have been destroyed, the enzymes released from the damaged tissue and by the bacteria and the host defense mechanisms can further degrade articular cartilage proteoglycan. Preliminary work by Cohen at al. has shown that the use of an adenosine A_{2a} receptor agonist reduces joint inflammation and glycosaminoglycan loss in rabbits with septic arthritis, and may be helpful in preventing the early degradative effects of joint sepsis.[27]

SUMMARY 1260

Shoulder rehabilitation is critical to the recovery of patients with shoulder symptoms and following trauma or surgery. Controversy exists regarding how much rehabilitation is required relative to frequency and supervision. Prudent rehabilitation is extremely valuable if a team approach is utilized and open communication fostered. The team is composed of the physician/surgeon, the therapist, and the patient. If the physician, therapist, and patient are actively interacting and fulfilling their responsibilities, the team, individually and as a whole, will be successful.

The components of shoulder rehabilitation and the rationale for intervention will be discussed in this chapter.

PRINCIPLES

Principles of rehabilitation remain constant regardless of whether the patient's status is postinjury or postsurgery. First, pain is always respected and rarely encouraged. Increased symptoms following the introduction of a new exercise or technique indicate the need for reevaluation of the recent intervention. Therefore, to assess the efficacy of treatment interventions, modalities or exercises are introduced one or two at a time. Only then can the clinician identify effective or aggravating treatment interventions.

Second, performing a thorough examination to identify pathology, tissue reactivity, impairments, and functional deficits and disability is critical when developing an effective intervention program. However, constant reevaluation of response to treatment and tissue reactivity is equally essential. Manual therapy by stretching and strengthening allows continuous reevaluation while treating. The real-time feedback gained by manual contact allows immediate

modification of techniques and exercise or correction of the patient's movement patterns. Manual contact is essential in discovering subtle and sometimes blatant problems that only arise with repetitive motion or those that manifest with fatigue.

Tissue reactivity is determined by subjective reporting and objective testing and qualifies the irritability of the involved structures (mild, moderate, or severe). The patient's reactivity becomes the guide for program progression. An iatrogenic plateau is sometimes reached, which essentially means that further recovery is hampered by the very same rehabilitation process that initially allowed some degree of recovery.[49] The plateau is characterized by stagnating mild tissue reactivity. A short but full rest from exercise, lasting 4 to 10 days, is recommended, and typically the tissue recovers, as does the patient's progress.

Third, exercise and techniques are advanced in motion, resistance, and movement planes based on the symptoms and functional demands of the patient. Range of motion (ROM) is progressed from passive ROM, to active assisted ROM, to active ROM. Movement may start in gravity reduced positions and progress to antigravity positions. Strengthening is progressed from isometrics, to short arc, to full arc. Submaximal resistance is initially used, advancing to maximal resistance. Progression of shoulder position or motion plane during exercise is from the nonprovocative to the provocative. Slow controlled exercise using elastic bands, free weights, and manual resistance is progressed to higher-velocity uncontrolled exercise using Plyoballs. Stress and safety zones are identified in Fig. 39-1. The plane of the scapula (POS) lies in the center of the safety zone. These nonprovocative and provocative positions and planes vary based on pathology or surgery, but most commonly the least provocative position is somewhere between 20 and 55 degrees of scapular plane abduction.

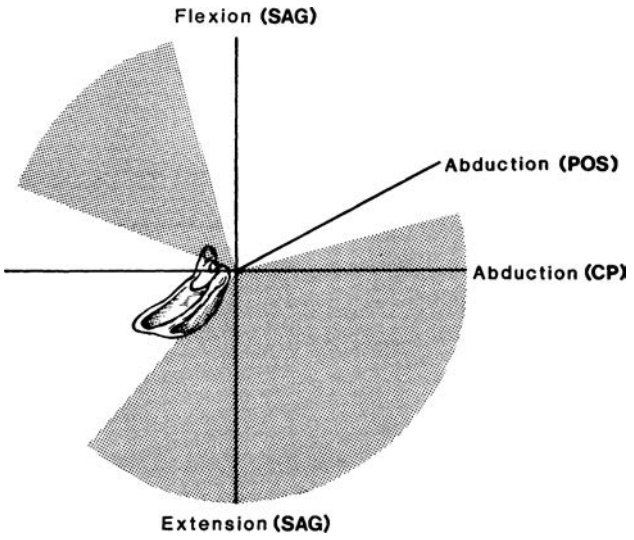

Figure 39-1 Stress (*shaded*) and safety (*white*) zones.

TABLE 39-1
PRINCIPLES OF TREATMENT

No pain—all gain
Constant reevaluation
Utilize the plane of the scapula
Rest when needed
Scapular muscle integration and balance
Nonprovocative → provocative
Submaximal → maximal
Short arc → full arc
Individualize program based on symptoms and functional demands

Keeping the humerus below 55 degrees prevents subacromial impingement, whereas avoiding full adduction minimizes excessive tension across the supraspinatus–coracohumeral complex and/or capsuloligamentous complex (CLC). The POS is advantageous in exercise performance for several reasons. It is an inherently stable position for the glenohumeral joint when working with a patient with instability because tensile and torsional stresses to the rotator cuff and capsuloligamentous–labral complex (CLLC) are minimized during exercise.[45] Additionally, strengthening in the POS utilizes the optimal alignment of the supraspinatus and deltoid.[45] Progression to provocative end-range positions may be required. Consider the throwing athlete who must function at 90 degrees of abduction and full external rotation. This position not only stresses the CLLC and twists the rotator cuff, but it can also cause supraspinatus impingement against the posterior glenoid rim.[18,41,109]

Fourth, balanced scapular muscle function is constantly integrated into all dynamic exercises from simple rotator cuff exercises to sport-specific manual resistance, plyometrics, and possibly isokinetics. We have found this principle to be extremely effective in all patients, especially the high-demand overhead athlete or laborer.

Lastly, the patient's rehabilitation program is individualized based on reactivity, hyperelasticity/hypoelasticity, personality, demand, goals, criteria met, surgical concerns, and complications (Table 39-1).

REHABILITATION GOALS

This section will discuss the goals of rehabilitation, the problems that those goals address, and the rationale for the goals (Table 39-2).

Patient Education

The goal and ultimate success of patient education cannot be underestimated, particularly in light of our current managed care environment. The patient must understand the

TABLE 39-2
GOALS OF REHABILITATION

Goal	Problem	Rationale
Patient education	Patient lacks knowledge	Prevent injury or reinjury
Antiinflammation/ reduce pain	Inflammation exists	Decrease prostaglandin production and reduce swelling
Facilitate collagen healing	Disruption of collagen	Gentle stress assist in collagen orientation and strength
Strengthen muscle tendon unit	Muscle weakness/dysfunction	Improve neuromuscular stabilization and control
Improve ROM	Adhesion/synovitis/contracture	Improve CLC pliability and muscle tendon length
Optimize proprioception	Impaired mechanoreceptor input	Optimize mechanoreceptor input and sensitivity
Endurance	Fatigue	Reduce fatigue effect and vulnerability for injury

CLC, capsuloligamentous complex; ROM, range of motion.

basic concepts of their pathology so instruction regarding modifying irritating activities is understood. Postoperative precautions must be stressed and understood. Patients are instructed in how to promote healing through positioning (Fig. 39-2) and the use of heat and ice. When appropriate, they are instructed in the proper performance of relatively pain-free exercises and, if they are to be discharged, indications for progression of the program. Without effective patient education, the surgical intervention and the rehabilitative process may be jeopardized and slowed, respectively.

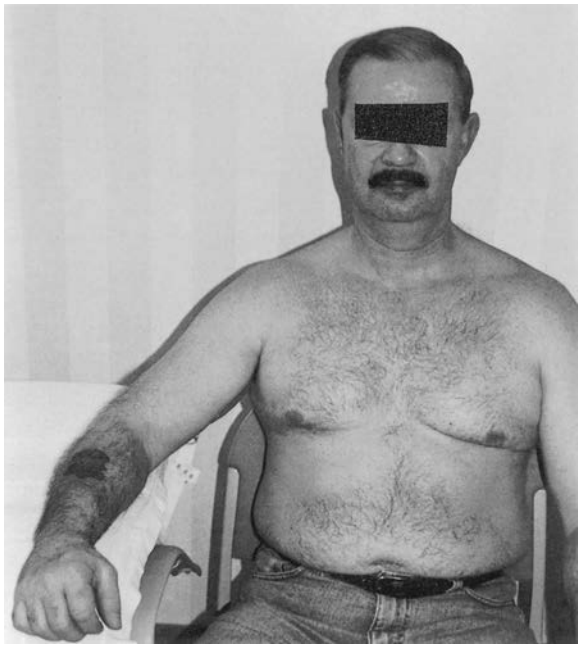

Figure 39-2 Placing the patient in a supported, neutral rotation position reduces pain and discourages contracture.

Antiinflammation and Pain Reduction

Modalities and their antiinflammatory and pain-reducing effects will be discussed later in this chapter. Stopping and modifying aggravating activities is a key to pain reduction. This includes the cessation popular "workout" exercises (i.e., bench press, overhead press, or those prescribed by a health care provider). As rehabilitation specialists, we must recognize that "Mother Nature" is a powerful healer and it is best to work with her.

Strength

Muscular strength refers to the capacity for active tension development by a muscle.[96] This is a simplistic definition of a very complex concept. Strengthening exercises can produce healthy or destructive effects. During exercise, the tension required to produce strength gains must not exceed the tissue/fixation threshold developed in a healing tendon or tendon–bone interface. Strengthening progression is based on time from injury, surgery, and tissue reactivity. In the early phases of strengthening, less activity, and therefore less tension, may protect healing soft tissue. Wise et al.[111] and Gaunt and Uhl[23] investigated what exercises create low rotator cuff activation. More needs to be known about tissue tension overload, particularly due to the reported high retear rate in the literature following large rotator cuff repairs.[8,22,25,27,70]

Multiple factors influence muscle strength. Strength gains occur by two basic types of neuromuscular changes: increased motor unit recruitment and hypertrophy.[56] Significant strength gains have been shown to occur in the absence of hypertrophy due to improved motor unit recruitment and synchronization; in other words, the

muscle learns the task. Appropriately loading a muscle will result in hypertrophy or increased muscle mass because a muscle with a larger cross-sectional area can create more tension. Although improving muscle mass may be a goal in rehabilitation, the concept of enhancing synchronization and the number of motor units recruited—neuromuscular system training—provides the rationale for why most individuals with rotator cuff tendinopathy and glenohumeral instability are placed on a rotator cuff and scapular muscle strengthening program.

The ultimate objective is to teach the glenohumeral and scapulothoracic dynamic stabilizers to work repetitively, in an efficiently integrated manner, throughout the ROM while centering the humeral head on the glenoid.[19,54,84,87]

Proprioception

Proprioception is defined as the sensation of dynamic joint motion and joint position.[66] It is mediated by numerous specialized mechanoreceptors in the muscle, tendons, capsule, and ligaments.[10,66] Stimulation of the mechanoreceptors initiates a neurologic feedback loop, causing protective stabilizing muscle function. When the CLC mechanoreceptors are injured or the CLC mechanism is disrupted, as seen in a traumatic dislocation causing a Bankart lesion, the proprioceptive feedback loop is compromised, resulting in reinjury. Altered proprioception has been demonstrated in individuals with known instability, and was restored following surgical anterior stabilization and rehabilitation.[65] Glousman et al.[30] showed decreased activity of critical muscles during throwing in pitchers with known instability. Rehabilitation must address the effect of a compromised neuromuscular mechanism. When appropriate, strengthening exercises emphasizing muscular "control" must be performed at different degrees of functional elevation, enhancing the neuromuscular system and improving proprioception.

Range of Motion

ROM or stretching exercises are designed to maintain or improve soft tissue pliability and prevent adhesions while protecting the injured or surgically repaired tissues. Exercise categories are typically passive, active assisted, and active. Passive range of motion (PROM) exercise is performed when muscle activity is to be avoided, as in the early postoperative phase of rotator cuff repair. Prophylactic stretching exercises that improve tissue pliability and length, in the absence of pain or pathology, are also considered passive. Active assisted range of motion (AAROM) exercise requires the unaffected arm, therapist, or equipment to assist movement. AAROM allows appropriate muscle activation through a ROM while preventing tissue reinjury or disruption. Active motion is allowed when the affected or repaired tissues at risk have been given adequate healing time or when the patient can independently move the segment without increasing symptoms. The targeted tissue and rationale for ROM exercises may be different, depending on whether the patient's status is postoperative or postinjury, whether the patient has developed a contracture, or whether a pre- and postworkout flexibility program is required.

Facilitate Collagen Healing

The importance of positively influencing connective tissue healing is overshadowed by the other effects of maintaining joint motion and strengthening. Any disruption of connective tissue is followed by collagen healing and remodeling. Gentle ROM exercise and submaximal strengthening in the appropriate time frame following injury or surgery stresses collagen promoting improved tissue alignment and tensile strength.[56]

Endurance

Muscular endurance is the ability of a muscle or muscle group to repeatedly contract and sustain tension over a period of time. Strength and endurance may not always correlate well to one another because an individual may be strong but may have poor endurance. This scenario relates to the worker who must lift a 2-lb drill gun overhead; he may have the strength to do it 1 or 10 times, but can he do it 100 or 200 times in a short period of time? We must not forget that a multitude of muscles from the lower extremities, trunk, and shoulder girdle contract when the arm is lifted. The weak link relative to poor endurance may be the scapular muscles or the trunk extensors, and not the rotator cuff. However, the resulting injury may be manifested at the rotator cuff. Electromyographic (EMG) studies in the industrial population and in athletes have shown that experience, not strength, may have a greater influence on fatigue. Sigholm et al.[97] found that experienced welders were able to avoid fatigue better than their less experienced counterparts. Gowan et al.[31] found that professional pitchers activated all the muscles of the rotator cuff, except the subscapularis, less than amateur pitchers. Endurance and possibly "strength" may relate to the efficient use of the shoulder complex through adaptation or better mechanics. The therapist must work not only on the endurance of individual muscles but also on efficient movement patterns. Another aspect of endurance that cannot be overlooked is cardiovascular endurance. One would expect that the better-conditioned individual is less prone to injury.

INTERVENTION

Modalities

In addition to terminating aggravating activities, modalities have been advocated for antiinflammation and pain

reduction. Much of the evidence for their use is anecdotal or a product of questionable experimental design. A variety of modalities are used during the rehabilitation process. The four main objectives for using modalities are to (a) reduce inflammation, (b) reduce pain, (c) improve motion, and (d) promote muscle reeducation. Most modalities achieve their physiologic effect by the transfer of thermal energy. These modalities include hot packs, cold packs, ultrasonography (ultrasound), diathermy, and infrared. Another mode of achieving a physiologic effect is through the use of electric stimulation. Electric stimulation modalities include transcutaneous electric nerve stimulation (TENS), as well as low-voltage, high-voltage, interferential, and direct current stimulation.

Heat Modalities

Heat therapy may be used to reduce muscle guarding and increase tissue temperature to assist with stretching.[28] Hot packs can be applied before or during ROM exercises. Application of moist heat in conjunction with stretching has shown improvement in muscle elasticity.[40] This may occur by a reduction of muscle viscosity and neuromuscular-mediated relaxation.[95]

Ultrasound

Ultrasound is a deep heating modality used during the subacute and chronic injury stage. Ultrasound is proposed to increase tissue temperature and may be helpful the healing process. The application of ultrasound is typically applied in the 1-MHz and 3-MHz ranges and is dependent on tissue depth and osseous location. Appropriate application of ultrasound is dependent on the type and depth of the soft tissue, injury status, and goal of therapy. Ultrasound has both thermal and mechanical properties that are thought to increase vascularization and elasticity of the tissue.[28] These latter proposed effects of ultrasonography may be the most effective in conditioning the tissue for stretching and strengthening. Muscle regeneration morphology was not established with the application of pulsed ultrasound on rat gastrocnemius muscle.[88] However, this may be dependent on the dosage and mode of the ultrasound application. Ultrasound applied in vitro demonstrated an age-dependent response of a patellar tendon with a correlation between decreased tendon metabolic activity and aging.[2] Recently, Gursel et al.[32] reported that ultrasound, compared with sham ultrasound, brings no further benefit when applied in addition to other physical therapy interventions in the management of soft tissue disorders of the shoulder.

The technique of phonophoresis can be used to drive antiinflammatory medication, usually either hydrocortisone or dexamethasone, through the skin and into the inflamed tissue. Whether this is truly achieved is still controversial.[7] Tissue depth due to adipose and muscle tissue; hydration state of the individual; and application procedures may counteract the effectiveness of phonophoresis.

Cryotherapy

Cryotherapy may be used for pain and swelling control.[1,99,102] Cold is best applied by a conforming pack. Cold has been shown to be beneficial in reducing pain in the postoperative shoulder patient.[99,102] A sterile circulation pad can be applied over the surgical dressing. A pump in the water reservoir circulates the water through the pad at a temperature of 50°. The application time can be from 1 to 3 hours. Singh et al.[99] completed a prospective, randomized investigation on the efficacy of continuous cryotherapy for both open and arthroscopic procedures of the shoulder. Cryotherapy controlled pain by decreasing the severity and frequency while allowing a more normal sleep pattern. In addition, the cryotherapy patients reported less pain during the rehabilitation exercises when compared with the age-matched control group.

Electric Stimulation

Electric stimulation therapies can be employed to reduce pain,[72,100] increase circulation, increase muscle activity for reeducation or strength effects,[100]and reduce spasm (by fatigue).

There are numerous variations of electric stimulation devices based on the type of current delivered (AC or DC), the operating voltage (less than 100 V is called low voltage vs. high voltage, which operates at greater than 500 V), the available frequency (interferential utilizes 4,000 Hz), and wavelength. Different waveforms are utilized dependent on the goals of the treatment program. The following are the different types of electric stimulation that can be utilized: transcutaneous electrical nerve stimulation (TENS), high-voltage pulsed stimulation (HVPS), interferential stimulation (IFS), microcurrent electrical stimulation (MET), and neuromuscular electrical stimulation (NMES).

Shoulder Slings and Braces

Shoulder slings and braces are utilized for protection after injury or surgery and for injury prevention during functional/sports activities. They may vary in design from a simple sling used following an injury to an elaborate multijointed device used to place the shoulder in a specific position to protect soft tissues postsurgically. Use of shoulder slings/braces is specific to acute postinjury/surgery and return to activity/play.

Acute Postinjury

Initial management, regardless of most injuries, requires the patient be placed in a sling for comfort and tissue

protection. The sling needs to support the weight of the arm and prevent motion. Most commonly the arm is placed in adduction and internal rotation providing adequate positioning. Time spent in a sling is variable and dependent upon the injury. Typically, patients are instructed to wean themselves from sling use to prevent a frozen shoulder. The type and length of immobilization is variable, but longer immobilization has not been considered important especially in reducing the recurrence rate of instability.[55,98] However, recent research has shown anterior labrum healing and a lower recurrence rate following traumatic anterior dislocation when an external rotation brace was used.[37] Immobilization in external rotation causes subscapularis tendon tightening across the anterior joint, providing a "counterforce" and promoting the anatomic position of the glenoid labrum.[39,78] Positioning the arm into internal rotation slackens the anterior structures, separating the labrum from the glenoid rim, thereby discouraging healing.[38,39] Itoi et al.[37]compared instability recurrence rates in 80 patients immobilized in external rotation and internal rotation within 3 days of the traumatic anterior dislocation. They found a significant difference between the recurrence rates for those in the external rotation group, 10%, and the internal rotation group, 30%. For individuals under 29 years of age, the recurrence rate for external rotation was 11.5% and internal rotation was 37.5%. Prefabricated braces immobilizing the arm in external rotation are now available (Fig. 39-3).

Fracture

Typically, a sling is used to immobilize a patient following a proximal humeral head fracture. Koval et al.[60] found that those individuals who started motion early, before 14 days, had better results than those who started after 14 days following a minimally or nondisplaced proximal humeral head fracture. Koch et al.[57] demonstrated that 95% of patients obtained good and excellent results and no significant treatment morbidity when Sarmiento bracing was used for humeral shaft fractures. Patients with trauma just to the humerus and no polytrauma had less of a chance for a nonunion and potential need for surgical fixation.

A figure-eight brace has been typically used to stabilize clavicle fractures. The figure-eight brace needs to be applied with proper tension so the shoulder girdle is pulled posteriorly. Overtightening or contact with bony prominences could potentially cause skin irritation and, if left untreated, skin breakdown and infection.

Postoperative

Modifications of the simple sling have been made relative to material used for durability, breathability, and added padding or bolsters. The addition of a small bolster placing the arm in slight abduction may have positive effects not only on comfort but on reducing tissue tension (Fig. 39-4). Several studies have shown that passive tension is increased and can propagate supraspinatus retear when the arm is placed at the side following a rotator cuff repair.[90,113] If a rotator cuff repair is performed "under tension," an abduction pillow may be used to reduce the tension and improve healing. It is not used, however, unless the tendon can be repaired with the arm at the side.

Airplane splints or abduction braces may be used following certain surgical procedures like a latissimus dorsi transfer. The "gunslinger brace" can be used following posterior capsulorraphy to maintain the arm in external rotation and prevent inferior translation of the humeral head.

Return to Activity/Play

Braces used for returning a patient to functional or athletic activity usually address glenohumeral joint instability.

Figure 39-3 Posttraumatic anterior dislocation brace that maintains the arm in slight external rotation.

Figure 39-4 The Ultrasling brace (Donjoy) places the arm in slight abduction.

Figure 39-5 The SAWA ( ) brace for use in athletes with anterior instability but who require overhead mobility.

Choosing what brace to use is based upon the activity/sport and anticipated stresses to which the shoulder will be exposed. A person returning to a collision sport or heavy labor may need to wear a shoulder stabilizer brace. These braces are designed prevent instability events by limiting shoulder flexion, abduction, and external rotation. In addition to restricting motion, neoprene shoulder stabilizer braces have been shown to improve external rotation joint repositioning in patients with known instability.[17] The Dennison-Duke Wyre brace (C.D. Denison Orthopaedic Alliance Co., Baltimore, MD) is commonly used for individuals participating in football and hockey. Other braces like the Sulley or SAWA (BRACE International, Scottsdale, AZ) allow greater excursion during overhead sports like basketball (Fig. 39-5). Buss et al. reported on 27 athletes from various sports who returned to play the same season as having an instability event. Nineteen of the athletes (70%) wore either a Dennison-Duke Wyre or Sulley brace, depending on their sport. All participated in a postevent rehabilitation program of ROM exercises and strengthening. They found that 37% of the athletes suffered at least one other instability episode, while 59% were event free.

The stabilizer brace needs to fit snugly around the body so that good support is provided. The straps can be customized to control the range of motion to protect the joint but also to allow a functional range of motion for the activity being performed. The straps can be adjusted to primarily prevent anterior or posterior translation. The stabilizers typically fit under or on the protective gear. In some sports, the stabilizer may need modifications to prevent injury to another (i.e., wrestling).

Taping

Taping has been proposed for numerous effects about the shoulder, including improving stabilization, reducing pain, inhibiting abnormal muscle activity, improving muscle activation, and improving posture. Unfortunately, no

Figure 39-6 Taping across the medial scapular border provides tactile feedback to the patient with motor control dyskinesia.

studies have shown taping to be efficacious. Lewis et al.[68] studied 60 patients with subacromial impingement who were assessed before and after scapular and thoracic taping. They found taping was effective in changing static scapular position, improving patient range of motion, and increasing range of elevation before symptoms were experienced but did not reduce the symptoms associated with subacromial impingement. The authors use taping sparingly and usually for the tactile feedback effect. As Lewis et al. reported, scapular position can be changed with taping techniques, and this provides approximately 24 to 48 hours of appropriate postural feedback. Taping has also been found to be influential when working with patients with scapular motor control dyskinesia. Placing tape from the acromion to approximately the T10 level provides tactile feedback as the medial border displaces into the tape (Fig. 39-6). The negative aspects of taping are skin breakdown with repetitive use and the need to have someone else available to apply the tape.

Frequency and Supervision

The question of supervision level and optimal visit frequency is difficult to determine. Ideally, high-quality care needs to be maintained while containing cost. The level of supervision and frequency decision should be based upon the pathology, patient reactivity level, cognitive status, whether the patient is postoperative, and surgeon/ physician preference.

Rockwood believed in surgeon directed "ortho" therapy. Following a rotator cuff repair, Leffert and Rowe[63] advocated only home exercise instruction, while others advocated supervised therapy for 40 to 60 visits.[21,24] We examined 75 patients 7 to 9 days following arthroscopic rotator cuff repair and determined the supervision need for therapy over the subsequent 5 weeks based on passive ROM,

reactivity level, cognitive status, and ability to correctly perform the exercises. Those placed on a home program could correctly perform the exercise and had an average passive range of motion of 117 degrees of forward elevation and external rotation of 27 degrees. Patients placed in supervised therapy had either a reactive presentation and less motion (PROM of 90 degrees of elevation and 21 degrees of external rotation) or could not correctly perform the exercises.[64]

Patients with primary frozen shoulder treated with a therapist-instructed home exercise program and intraarticular glenohumeral injection versus 12 supervised visits for 4 weeks were found to have no difference in 1-year outcomes.[15] Dierks et al.[20] followed 77 patients with idiopathic frozen shoulder for 24 months and determined that those who had "supervised neglect" (limited supervised visits) actually had better outcomes measured by the Constant score than those who had structured aggressive physical therapy. McClure et al.[75] found that treating patients with rotator cuff impingement one time a week for 6 weeks using a simple ROM and strengthening program with elastic bands significantly improved range of motion, strength and outcomes related to pain, patient satisfaction, and function. Ginn and Cohen [29] performed a randomized controlled trial on 66 patients with various diagnoses including rotator cuff tendinopathy, frozen shoulder, osteoarthritis, biceps tendinitis, and AC joint arthritis. One group was treated with physical therapy including stretching, strengthening, and neuromotor training for 4 to 10 visits in 1 month, while the second group received no treatment. Significant improvement was noted in the physical therapy–treated group in all outcomes. These studies come to no consensus on how often to treat patients with various shoulder pathologies, but recognize the need of therapist intervention.

Roddey et al.[93] compared home exercise instruction using videotape (therapist available for questions) versus therapist instruction in patients following arthroscopic rotator cuff repair. They found no difference in self-reported outcome measures or self-reported compliance when using the two methods of instruction.[92] Anderson et al.[3] reported on 43 subjects following arthroscopic subacromial decompression who were rehabilitated by supervised therapy versus a self-training leaflet. The Constant-Murley outcome score showed no significant difference between the two rehabilitation methods. Reo and Mercer[91] found that live and videotape instruction were significantly better than handouts alone for learning a shoulder exercise program.

We would advocate that frequency be determined by a team decision between the patient, the surgeon/physician, and a knowledgeable therapist. Our general philosophy favors therapist-instructed programs using intermittent visits as determined by the team and the patient presentation. Patients presenting with less pain, expected ROM and strength, and improving function are seen with less supervision. Those with unexpected protracted pain and stiffness resulting in limited function are seen more often in supervised therapy.

Range-of-Motion/Stretching Exercises

Shoulder ROM exercises can primarily isolate the glenohumeral joint structures as in external rotation stretching or can affect all the shoulder joints and spine as in shoulder elevation stretching. Indications and rationale vary for stretching based upon time from injury or surgery, tissue reactivity, contracture development, or prophylaxis. This section will discuss ROM exercises for the shoulder followed by stretches for the spine structures and scapular muscles. Three phases of stretching and indications for each will be discussed.

Phase I

Phase I exercises are indicated early postinjury or postsurgery. Tissues may be reactive or require protection from overload for 4 to 6 weeks. Painful, aggressive stretching should be avoided, recognizing that pain and reflexive muscle guarding are a normal response following trauma and surgery. Passive ROM exercises are initiated in "relatively" pain-free ranges or restricted ranges to improve or maintain ROM, provide gentle stress to healing collagen tissue,[56] and optimize the subacromial gliding mechanism. Neer et al.[80] found that those individuals who performed early passive motion reached their motion goals for discharge much sooner than did those not involved in a physical therapy program. The stretching effect can be enhanced by applying heat to the shoulder while stretching is performed.[58,59]

Phase I PROM exercises include pendulums, supine elevation, and external rotation (Fig. 39-7). Although we generally consider these exercises passive, research has shown muscle activation with PROM exercises.[112] Elevation stretching can be modified by performing the "chair" stretch or table stretch. The patient places the hand of the involved shoulder on the back of a chair, then steps backward and leans forward (Fig. 39-8). Knowledge of positional effect and tissue tension is necessary for safe and effective stretching. For example, stretching into external rotation with the arm in adduction may place the excessive tension on the rotator cuff repair. This position has been shown to significantly increase tensile load to the repair site and rotator cuff interval.[34,89,113] A less stressful position that will achieve the benefits of passive rotational stretching is placing the arm at 45 degrees in the POS (Fig. 39-7C).

Phase II

When appropriate time from injury or surgery (3 to 6 weeks) has passed and tissue reactivity reduces, phase II ROM

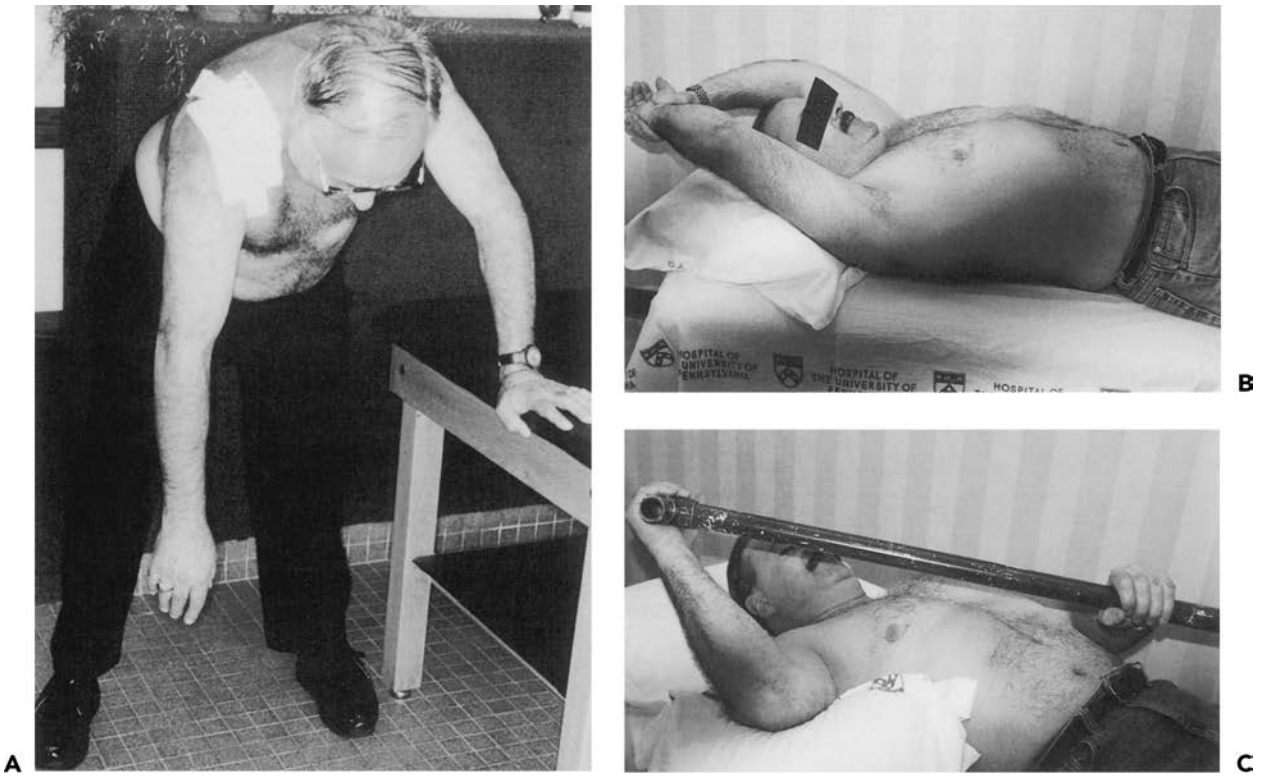

Figure 39-7 Phase I range-of-motion exercises. **(A)** Pendulum. **(B)** Passive elevation. **(C)** Passive external rotation in 45 degrees of elevation in the plane of the scapula.

exercises can be initiated. These include active assisted exercise, therefore muscle activation of the affected shoulder and placing the shoulder in provocative positions, including internal rotation and horizontal adduction, extension, and combination external rotation/elevation (Fig. 39-9). Connective tissue load and muscle activation can be altered based on the provided assistance, lever arm, position relative to gravity, or use of equipment to support the arm. Extension and internal rotation exercises are performed in an active assisted manner while the other two exercises are passive. Patients are instructed to remain "relatively pain free" and hold between 5 to 10 seconds. If the patient presents with greater reactivity the hold time may only be 1 second. Exercises are typically performed 20 times, three to six times per day.

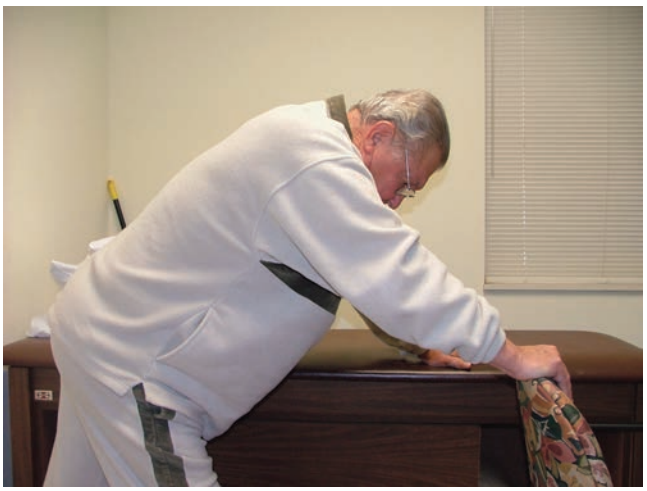

Figure 39-8 Chair stretch is alternative to supine passive elevation stretch.

Pulley use will be discussed separately since this device can be used in different phases and creates different effects. The pulley can be used in phase I for elevation stretching, but the patient must be instructed to relax. Elevation range of motion can be significantly influenced depending on whether shoulder internal versus external rotation is allowed, especially if external rotation is restricted. The patient will achieve greater elevation motion, with less pain, if taught to use the pulley with the affected elbow straight versus flexed (Fig. 39-10). A straight arm allows the arm to elevate with obligatory internal rotation (assuming elevation is occurring toward the sagittal plane). When elevating with the elbow flexed (in external rotation), the CLC is already taught and less motion is available for elevation. Terry et al.[104] suggested that elevation in the sagittal plane, while in external rotation, increased supraspinatus tendon tension. This would be undesirable following a rotator cuff repair.

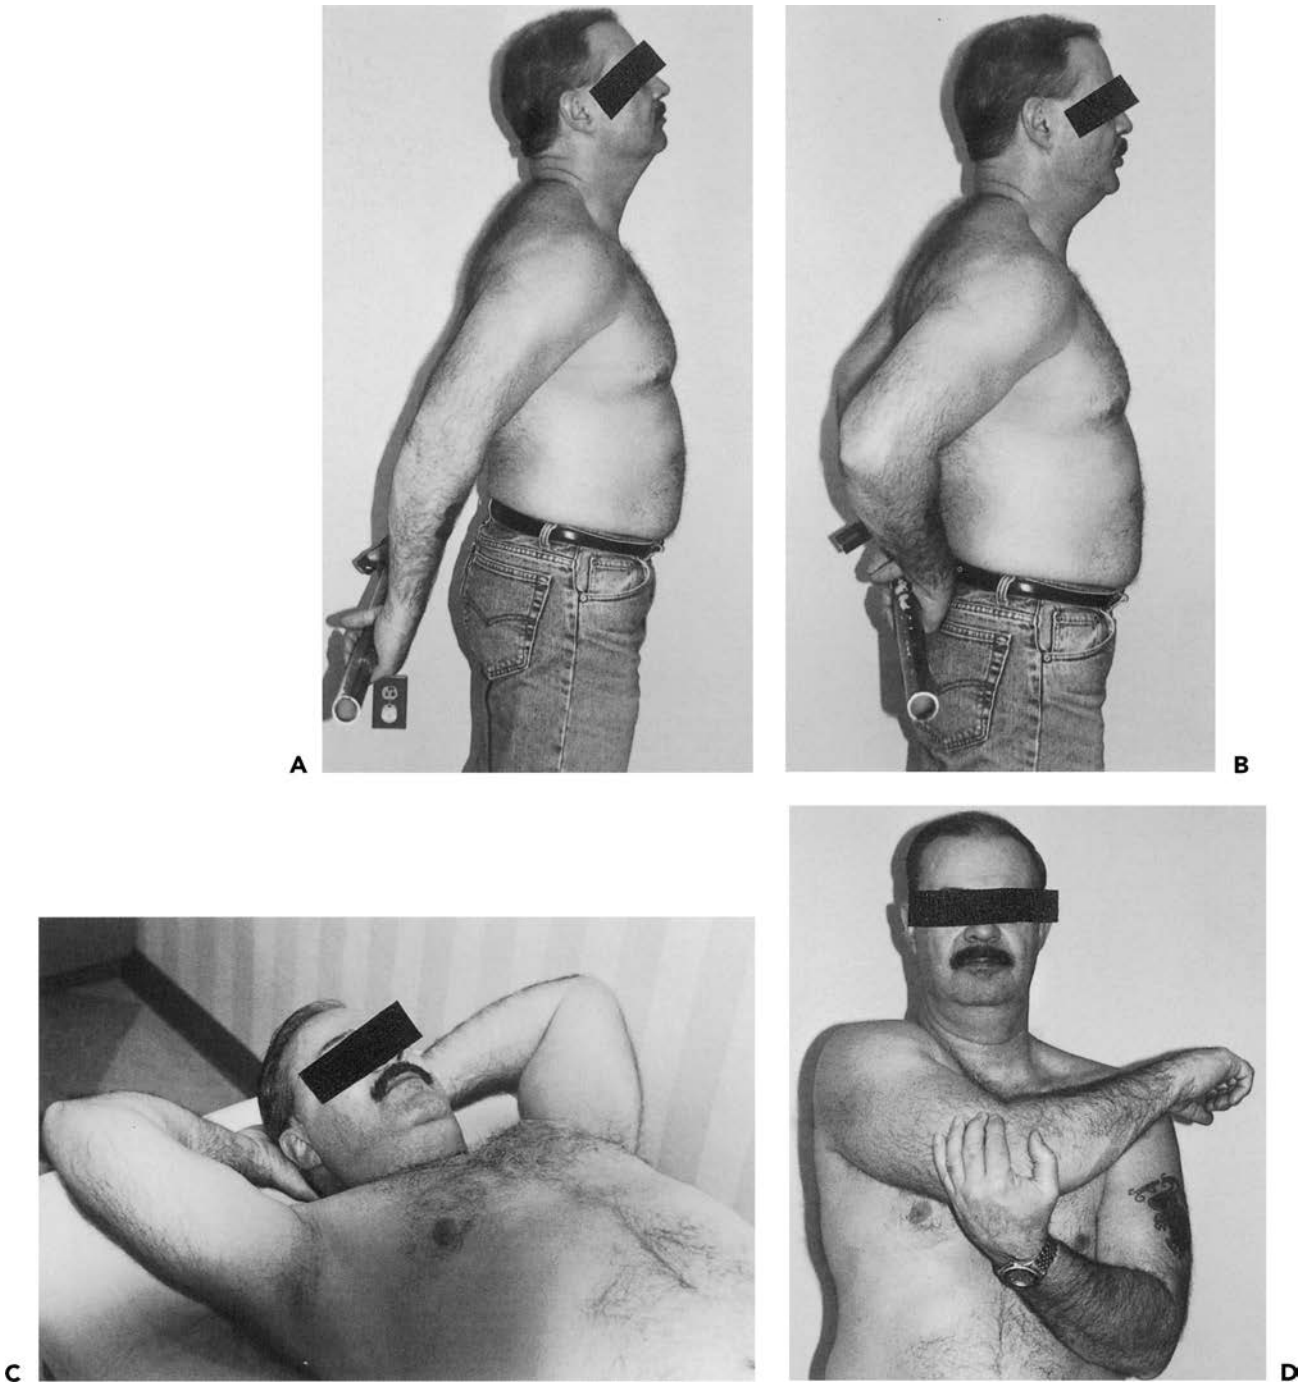

Figure 39-9 Phase II range-of-motion exercises. **(A)** Extension. **(B)** Internal rotation. **(C)** Modified elevation/external rotation. **(D)** Posterior capsule/cuff stretch.

The pulley can also be used in an active assisted manner by "deweighting" the affected extremity by assisting with the unaffected arm or by adding weights to the contralateral pulley handle. Prolonged stretching can be started when the patient can tolerate pain-free end-range positioning.

Although the pulley is an excellent way to gain elevation motion, an active assisted to active progression program is effective between 4 and 8 weeks. Exercises are moved from AAROM to AROM while the tissue integrity is protected from the increasing muscle–tendon tensile forces. McCann showed progressive shoulder muscle activation through Neer's three phases of rehabilitation.[74] Protecting tissue while advancing exercise intensity requires taking advantage of short lever arms, positioning relative to gravity, and

Figure 39-10 Pulley with the elbow straight **(A)** allows greater elevation than with the elbow flexed **(B).**

simple equipment such as a ball or slant board. Wise et al.[111] demonstrated that supported "closed chain" elevation exercises required less supraspinatus activity than an unsupported "open chain" exercise. These authors use the term "closed chain" to describe supported exercise even though the distal segment is moving (i.e., sliding the hand on a table or ball). However, this may be a liberal use of the term "closed chain," which typically refers to having the distal segment fixed while the proximal segment moves (i.e., pushup). We prefer the term "supported active assisted exercise" (SAAE) to describe activity during which the arm is supported by a surface, ball, or device that reduces the extremity weight, provides assistance, or allows use of antagonistic muscles. Fig. 39-11 shows a progression of AAROM and SAAE used to improve elevation ROM. The elevation progression is discussed further in the section on strengthening. These exercises produce low-demand (less than 15%) maximal voluntary contraction (MVC) of the rotator cuff.[23]

Contracture development is a common and sometimes inevitable problem, especially in the frozen shoulder patient and following proximal humeral fractures. Phases I and II stretches are very useful in maintaining or improving motion during contracture development. Two phases of contracture development will be discussed: painful and noninflammatory established contracture. Noninflammatory established contracture exists when the inflammatory stage is extinguished but the tissue is left fibrotic and shortened. However, end-range stretching is relatively pain free (this will be discussed in the next section). Painful contracture is a result of concomitant synovitis/inflammation or angiogenesis and fibrosis as commonly seen in primary and secondary frozen shoulder.[11,81,82] Unfortunately, many individuals with active inflammation cannot tolerate the required time for prolonged stretch to elongate tissue. Short duration hold (less than 10 seconds) ROM exercises performed by a patient having an active synovitis appear to minimize or prevent further loss of motion; however, one must be cautious about being too aggressive with stretching activities because they may aggravate symptoms.[20] Diercks[20] found that patients with frozen shoulder who were treated with "painful stretching" had significantly worse Constant scores at 1-year follow-up. Stretching should be performed near the painful end range and held for short periods of 1 to 10 seconds. Phases I and II stretching exercises form the core program, in addition to the use of a pulley. Static progressive or dynamic splint devices designed for the shoulder tend to be bulky and not tolerated

Figure 39-11 Unsupported active assisted range-of-motion **(A)** and supported active assisted exercise surface **(B),** on ball **(C),** and with Upper Extremity Ranger (Rehab Innovations, Inc., Omaha, NE) **(D).**

well in the painful stage. As tissue reactivity reduces and end-range stretching is tolerated, the length of hold time can be increased from 10 seconds to minutes.

Joint Mobilization

Joint mobilization is a manual stretching technique used to reduce pain and improve joint motion.[47,71] Depending on the degree of tissue reactivity or joint stiffness, grades I and II glenohumeral joint mobilization may assist in pain reduction and motion improvement when the motion is limited by pain. Joint mobilization is a technique in which one joint surface (i.e., the humeral head) is directionally translated relative to the other joint surface (i.e., the glenoid) (Fig. 39-12). Oscillations are performed at the end of the translation. Joint mobilization is usually graded from I to V, although grade V is considered a high-velocity thrust manipulation performed at end range. The proposed effect of joint mobilization is pain relief (grades I to II) and improved ROM by stretching capsuloligamentous tissue (grades III to V). Pain relief is thought to be mediated through a neurophysiologic mechanism beginning in the joint and soft tissue mechanoreceptors and nocioreceptors.[47,71]

By translating the articular surfaces, stimulation and/or accommodation of the receptors are initiated, which results in pain reduction. If the translation force is significant enough, as in grades III and IV, mechanical stretching of the tight soft tissue may result.[47,71]

Phase III

Stretching in the presence of noninflammatory established painless or relatively pain-free contracture is performed to mechanically elongate soft tissue that has lost its normal pliability. Connective tissue must be brought into a plastic range to cause deformation. Prolonged stretch is effective in creating tissue creep opposed to intense short-duration stretching.[58,69] Stretch intensity and time at end range can be increased when the patient presents with relatively painless contracture. Therefore, prolonged end-range positioning is encouraged. Holding a stick or positioning in

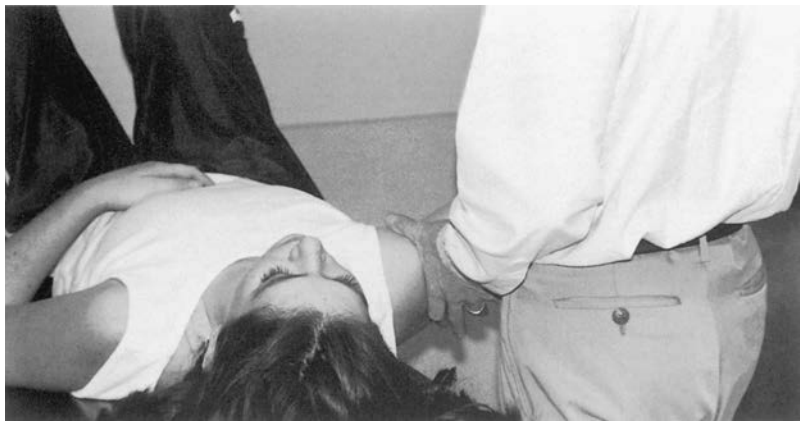

Figure 39-12 Joint mobilization.

elevation and external rotation for 1 to 5 minutes can be effective in assisting the remodeling process (Fig. 39-13). The total end-range time (TERT) concept is utilized. This means that the more time that is spent at end range, the greater the tissue lengthening effect is.[62,69,76] Elevation can be achieved by a door hang stretch (Fig. 39-14) and internal rotation with a towel. Static progressive splints may be indicated with this type of patient since end-range stretching is better tolerated.

Posterior capsule stretching is a recognized necessity in the overhead athlete's shoulder.[12,106,108] Harryman[33] demonstrated increased anterior and slight superior humeral head translation when the posterior capsule was imbricated. Posterior capsule tightness is thought to cause secondary compressive lesions of the rotator cuff.[33,73,77] Burkhart et al. found that excessive tightness of the posterior capsule in throwing athletes resulted in superior–posterior humeral head migration and excessive load on the long head of the biceps, causing the

Figure 39-13 Prolonged stretch into external rotation and abduction.

Figure 39-14 Door hang stretch.

Figure 39-15 Patient performing the "sleeper" stretch for posterior capsule.

superior labrum to "peel back" and tear.[13] A relationship exists between the development of a superior labrum anterior–posterior (SLAP) lesion and limited internal rotation at 90 degrees of abduction of 25 degrees compared to the other side.[14] Excessive loss of internal rotation at 90 degrees of abduction is known as glenohumeral internal rotation deficit (GIRD). The "sleeper" stretch is an effective way of self-stretching the posterior capsule[14] (Fig. 39-15). The patient's posterior capsule can be manually stretched while prone. The patient's hand is placed on their back while the therapist stabilizes the medial scapular border against the thorax and gently moves the elbow anteriorly. This is an aggressive stretch; therefore, the patient's symptoms must be monitored. The posterior capsule and cuff is also stretched in the cross body stretch. Holding a fixed object with the arm across the body can magnify this stretch by gently leaning away as the involved arm is pulled toward the chest and the body rotated toward the involved shoulder (Fig. 39-16).

Figure 39-16 Magnified posterior cuff stretch using body weight.

Prophylactic stretching to maintain or improve pliability of the musculotendinous cuff and CLC is reasonable for recreational or competitive athletes as well as for individuals in the occupational arena. One need only evaluate the external rotation motion of a professional baseball pitcher to recognize that excessive external rotation is required to generate torque to hurl a baseball at 95 miles per hour. The occupational athletes may require a certain degree of glenohumeral/trunk mobility to perform certain tasks. Much attention has been focused on regaining elasticity by stretching the glenohumeral posterior capsule.

Cervical/Thoracic Spine

The cervical and thoracic spine and related structures can negatively impact shoulder function because of poor orientation, dysfunction of any muscle that shares insertion between the spine and scapula, or intrinsic spinal pathology (i.e., radiculopathy).

Poor orientation or posture can influence scapular kinematics.[48,53,67] Keaetse et al.[48] found that a fixed thoracic kyphosis decreased scapular upward rotation and posterior tilt and resulted in increased superior scapular translation. Less shoulder elevation motion was found when the thoracic spine was in excessive kyphosis compared to the erect spine position.[48,67] Improving thoracic extension motion should be considered when treating a patient with shoulder pathology, especially the older individual or the athlete. Postural awareness education by using a lumbar roll when sitting helps to orient the thoracic and cervical spine toward anatomic position. Thoracic extension exercises are encouraged while sitting by performing active thoracic extension and scapular retraction. A passive thoracic stretch is achieved by having the patient lie supine on a towel roll or semi-rigid roll with it oriented perpendicular to the spine at approximately nipple level. The knees are bent and the arms placed over the head to increase the fulcrum effect. The patient breathes deeply to encourage costovertebral joint motion (Fig. 39-17). The patient progresses up to 2- to 5-minute stretches. A similar stretch can be achieved using a therapeutic ball. Trunk lateral bends and rotational stretching are performed to improve both trunk muscular and spinal mobility.

Cervical stretches are performed by side-bend and rotation exercises. Side bending elongates the contralateral trapezius, scalenes, and levator scapula. Direct stretching of the levator scapula is achieved by fixing the scapula (holding the leg of a chair with the involved arm) and combining cervical flexion with contralateral side bend and rotation.

Combination stretches are performed to affect spinal, scapular, or pectoral muscles. An excellent pectoral stretch that influences spinal and scapular position is performed with the patient lying supine on a towel roll or semi-rigid roll positioned inline with the thoracic spine. The patient

Figure 39-17 Thoracic extension stretch using a towel roll.

can lie on the floor or bench and place the arms in 90 to 110 degrees of abduction and relax. The roll enhances the pectoral stretch by "spreading" the chest. A specific pectoralis minor stretch is performed with the roll by actively retracting the scapula or by having the therapist manually place the scapula posteriorly and into elevation. Breathing can further accentuate the stretch by having the patient forcefully exhale as the scapular is displaced posterosuperiorly. Exhaling depresses the ribs and moves the pectoralis minor origin away from the posteriorly displaced coracoid insertion.

Stretching the medial scapular muscles can be difficult because of their oblique orientation. An effective stretch for the rhomboid, middle, and lower trapezius is performed with the patient sitting with the arms folded across the chest. The opposite arm to the side being stretched is placed over the other arm. The "stretching" hand is placed on the posterior shoulder region of the affected shoulder. The patient flexes the lumbar, thoracic, and cervical spine as the stretching hand pulls the shoulder to the opposite knee. Gentle breathing is encouraged (Fig. 39-18).

Figure 39-18 Left medial scapular muscle stretch.

Treatment of intrinsic cervical and thoracic pathology is outside of the scope of this chapter. However, when both shoulder and spinal pathology coexist, the authors use a valuable rule of thumb: Treat the spinal pathology first. Effective spinal intervention clarifies the true shoulder structure symptoms and can eliminate prolongation of symptoms.

Strengthening

Many investigators have performed EMG studies to evaluate muscle activity during exercise,[9,23,74,79,105,111] during athletic activity,[30,42,83,85,94] during occupational use,[46,97] and after nerve block and nerve palsy.[16,36,61] Although these studies give us useful insight regarding muscle function, the rehabilitation specialist must be careful about data interpretation and application to a patient with a pathologic condition. Typically these studies are interested in what exercises create the "greatest" activity; however, treating patients in the early postoperative/injury phase with significant pathology, tissue reactivity, or low demands may require exercises producing "less" activity to protect the soft tissues and minimize pain.[23,74,111]

Phase I

Phase I strengthening exercises are used in patients who are weak and/or in the early postoperative/injury period but can tolerate low-resistance exercise in nonprovocative positions. Strengthening may begin with AAROM and AROM exercises. Connective tissue load and muscle activation can be altered based upon lever arm, position relative to gravity, or the use of equipment to support the arm. The therapist and patient must appreciate a simple biomechanical principle when trying to achieve full active elevation: The patient must be able to lift the weight of the arm against gravity. Arm weight can be considerable, since some patients have very heavy upper extremities due to large bulk or excessive adipose tissue. Elevation requires moving the arm through the 90-degree arc where the arm weight and moment arm are greatest. Inability to lift the arm through the available range can be considered an active lag, analogous to the patient with a weak quadriceps who has an active extensor lag. Consider the patient who is 8 weeks post–rotator cuff repair and can only actively lift the arm to 70 degrees of elevation (due to weakness, not pain). Assuming repair and neurologic integrity, one can determine that the cuff/deltoid complex cannot centralize the humeral head and create the force to lift the arm weight. Exercise should emphasize elevation, but in positions that reduce the weight of the extremity and protect the tendon fixation. Gaunt and Uhl[23] and Wise et al.[111] examined EMG activity during supported and unsupported exercise. They provided us with evidence to guide our early strengthening phase when protecting the soft tissue structures in critical. Earlier in this chapter we

Figure 39-19 Progressive elevation strengthening using ball **(A),** wall tap **(B),** and supine elastic resistance **(C).**

discussed supported AAROM progression, but as the exercise difficulty is progressed, strengthening is achieved. Fig. 39-19 shows an elevation progression demonstrating increased demand on the rotator cuff.[23,111] This principle is also used to increase load on other muscle groups (i.e., external rotators).

Another simple but effective manner of increasing muscle–tendon demand during elevation is "gatching" (Fig. 39-20).[6] This technique uses an elevating surface to change the patient's orientation to gravity, thus increasing the weight of the arm. Gatching can be combined with isometric isolation of muscle groups as one elevates. For example, a ball can be squeezed (increasing internal rotator activation) as elevation occurs (Fig. 39-20B). Aquatic therapy is another alternative approach that reduces the extremity weight and muscle activation.[51]

Pain-free submaximal isometrics and isotonic or elastic band exercises may be started either at the shoulder or the elbow. Commonly, isometrics are reserved for the patient whose symptoms are more reactive. However, caution must be practiced when using isometrics following a tendon repair, since tension overload is the suspected

Figure 39-20 Gatching using no weight **(A)** and weighted ball **(B).**

mechanism for tendon repair failure.[26,27,90,101] We do not know how much is too much, but the tension developed during a maximal or possible intense submaximal isometric exercise may be greater than the tension produced during submaximal isotonic or elastic band exercise. Positioning of the glenohumeral joint in a slightly abducted position by using a bolster may result in less passive tension of the contracting soft tissues.[90,113]

Isometrics can be performed in all directions, but many times resistance into abduction and flexion is painful. Therefore, the following movements are usually performed: external rotation, internal rotation, extension, elbow flexion, and elbow extension. Contractions are held for 3 to 6 seconds, and one to three sets of 10 to 15 repetitions are performed.

Phase I strengthening exercises using free weights of 1 to 3 lb or elastic bands are initiated. Elastic bands are easier to use, can be used in the functional erect position, and allow better integration of scapular muscles (versus side-lying).[79] These exercises include external rotation, internal rotation, and extension (Fig. 39-21). A bolster may be used between the arm and body to reduce passive supraspinatus tendon tension. Additionally, restricting external rotation to 20 to 30 degrees past neutral rotation may prevent tension overload due to the lengthening rotator cuff interval and disadvantaged posterior rotator cuff length–tension relationship as the band resistance increases.[34] Scapular muscle integration is encouraged at all times when strengthening the rotator cuff and deltoid muscles since coactivation allows both muscle groups to be strengthened simultaneously, reinforces synergistic firing patterns, and provides a balanced stable base upon which the compromised rotator cuff muscles may anchor, giving them a biomechanical advantage. Therefore, when performing glenohumeral dynamic strengthening exercises, the scapular adductors should be consciously activated or "set" by pulling the scapula slightly up and back, before the glenohumeral muscles are activated (Fig. 39-22). Research has shown that the commonly performed rotational exercises do not allow for scapular muscle integration.[79] Moseley et al.[79] found minimal activity of any scapular muscles when internal and external rotation strengthening exercises were performed in the side-lying position.

In addition to strengthening the scapular muscles through integration, isolated strengthening can be initiated using elastic band/free-weight resistance, manual resistance, or body weight. Our belief is that scapular muscles are not necessarily weak; instead, lack of coordinated control is the problem. Burkhart et al.[12] discussed numerous "control" exercises for the scapula that help overcome scapular dyskinesia. Kibler[54] is also an advocate of integrating scapular muscles and even includes lower extremity and trunk motion. More aggressive scapular muscle strengthening will be discussed in the phase III strengthening section.

Exercises are often started at two sets of 10 with a particular band or weight (can be the weight of the arm) and progressed to three sets of 10 when the patient has no pain or difficulty with two sets of 10. When three sets of 10 are easy to perform, the patient is progressed to three sets of 15. Progression to the next band resistance/weight is made when three sets of 15 become as easy as three sets of 10. This progression cycle is continued until the appropriate resistance level is achieved. When the patient can achieve three sets of 10 with green elastic bands, they are typically progressed to phase II strengthening. Patients are encouraged to perform the exercises at home one to three times a day depending on the patient and problem

Manual Resistance

If the patient is being seen in a supervised manner, manual resistance can be performed as a form of assessment and

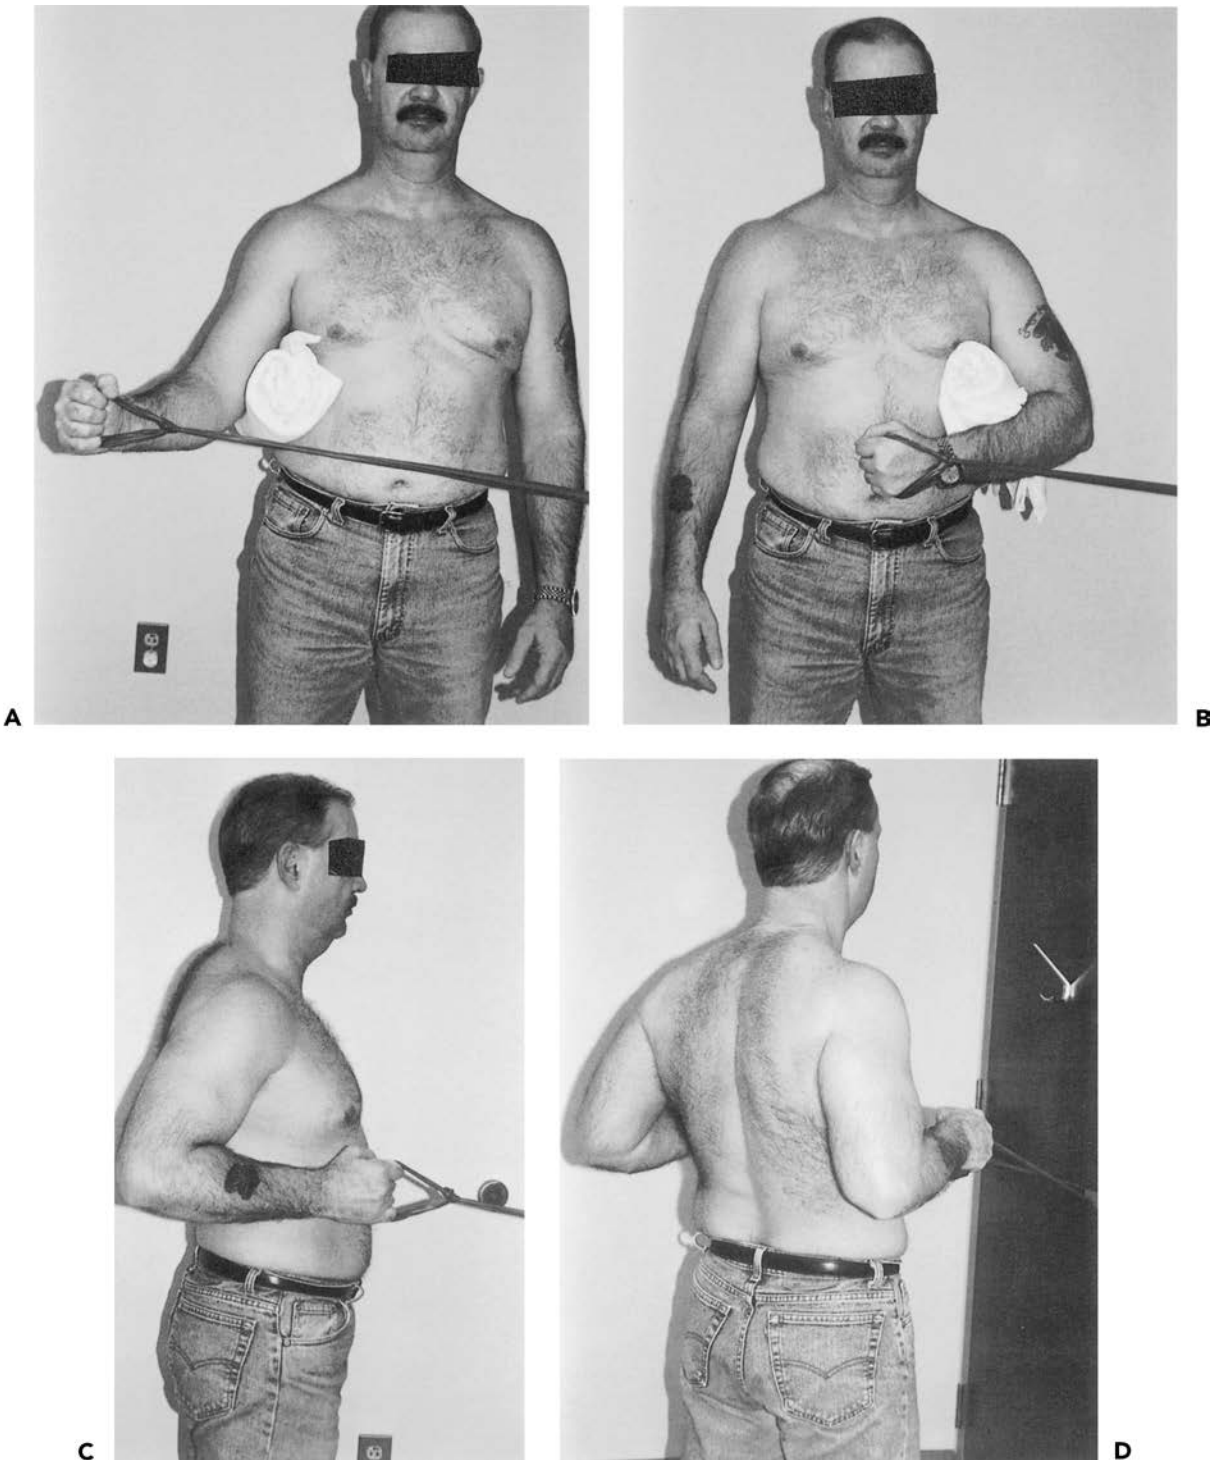

Figure 39-21 Phase I strengthening exercises. **(A)** External rotation to 30 degrees. **(B)** Internal rotation. **(C)** Extension (unilateral). **(D)** Extension (bilateral) to encourage scapular adductor muscle integration.

exercise. Manual resistance can be isometric or accommodating through the range while isolating scapular and glenohumeral muscles or facilitating cocontraction of both. Manual resistance is applied in multiple directions about the shoulder (i.e., internal rotation, external rotation, and elevation) in varying positions of elevation to determine whether a patient is ready for resistive exercises and what positions and/or directions of resistance to choose. The typical start position is in 60 to 70 degrees of elevation in the POS (Fig. 39-23). If pain is felt upon appropriate

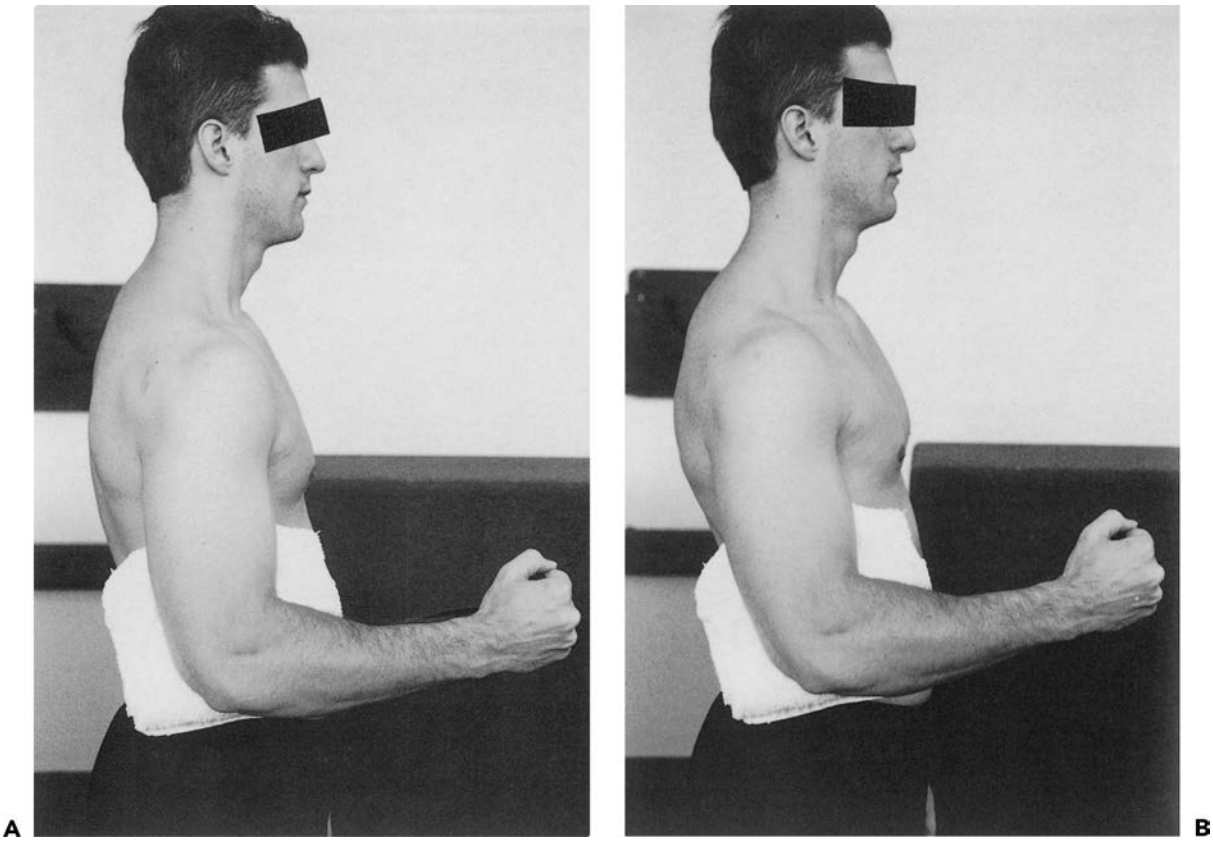

Figure 39-22 External rotation strengthening with bolster. Incorrect scapular position **(A)** and with scapular muscle integration **(B).**

submaximal resistance, the patient will refrain from resistive exercises, or modifications in position are attempted. We advocate the use of manual resistance as a leading form of supervised therapy because it provides immediate feedback from the patient regarding strength, pain, integration of scapular muscles, and appropriate scapulohumeral rhythm. By systematically resisting different muscle groups (i.e., abductors/external rotation or adductors/internal rotation) in varying degrees of elevation or rotation, neuromuscular training can be enhanced and the patient's home resisted-exercise program can be developed and modified.

Figure 39-23 Isometric manual resistance to the glenohumeral abductors and external rotators while encouraging scapular stabilization.

Manual resistance therapy following a rotator cuff repair can be essential to regaining active elevation motion. When a patient cannot actively elevate against gravity, not only does the rotator cuff lack the cross-sectional mass to translate enough force to stabilize and elevate the humerus, but it also "forgets" how. By providing very light resistance or assisting (while resisting) the arm into the elevated positions (90 to 140 degrees of POS abduction), neuromuscular training to facilitate elevation activity is achieved; the elevators (rotator cuff and deltoid) "relearn" how to contract. One advantage of training above 90 degrees, recognizing that the position is in the impingement zone, is that the deltoid's line of pull is improved (relative to below 90 degrees), creating a stabilizing joint compressive force and less shear force.[86] To strengthen in the elevated positions, the patient is placed supine and is first treated with heat, joint mobilization, and stretching to maximize the elevation range. Multiangle isometrics are performed at

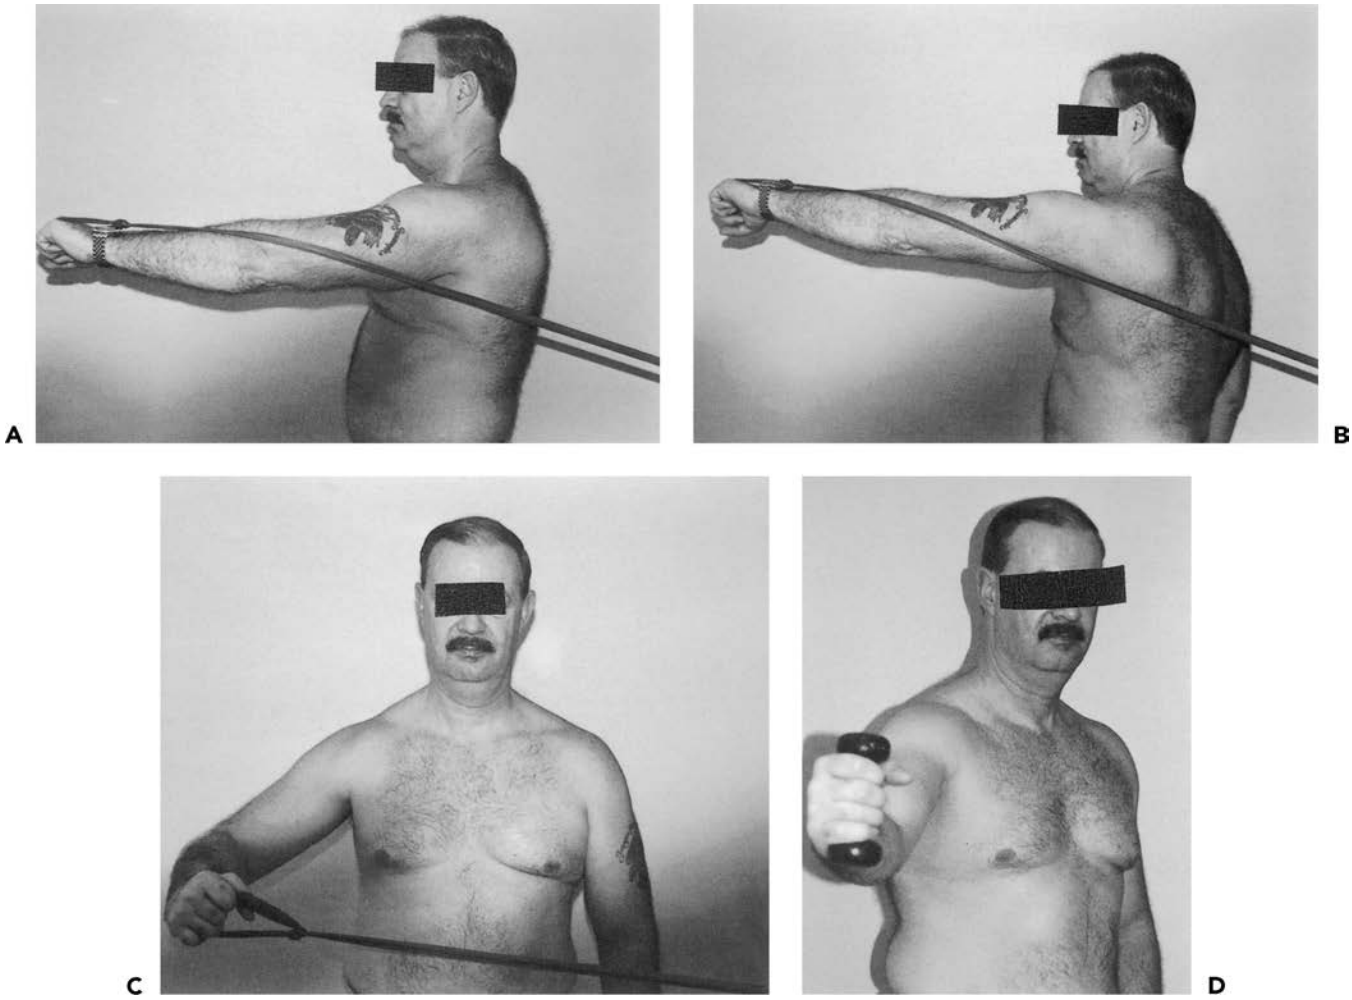

Figure 39-24 Phase II strengthening exercises. **(A)** Flexion. **(B)** Flexion with "plus" to encourage serratus anterior integration. **(C)** Abduction to 45 degrees. **(D)** Abduction to 90 degrees in the plane of the scapula.

different positions of elevation to improve the muscle's ability to contract and to improve the number of motor units recruited. The patient is then placed at 80 to 90 degrees and asked to elevate through the pain-free range while less than the weight of the arm resistance is given. Scapular shrugging is discouraged through verbal and manual cues to reinforce appropriate synergistic scapular muscle activity as the glenohumeral muscles are activated. This sequence has proved very effective in safely strengthening the rotator cuff-deltoid-biceps complex in functional ranges while encouraging scapular muscle integration.

Phase II

Phase II strengthening can be started when the patient can lift the extremity through the full passive range against gravity and when sufficient time has passed postinjury/surgery. Resistive exercise using elastic bands or light free weights is continued, but the resistance is increased and more provocative positions are used. The same set and repetition progression is used as in phase I.

Phase I exercises are continued, but the following phase II exercises are added: abduction, flexion without or with a "plus," supported external rotation at approximately 45 degrees, elbow flexion, and extension (Fig. 39-24). The phase I and phase II exercises form the core of the strengthening program. Some patients may not reach this level or progress beyond phases I and II because of low-demand needs or extensive pathology such as a rotator cuff deficiency. Scapular muscle integration is performed even with resisted elbow flexion and extension. Performing a "plus" maneuver during resisted shoulder flexion enhances serratus anterior activity[79] (Fig. 39-24B). External rotation strengthening is progressed to elevated functional positions but the arm is supported. The patient is progressed to the unsupported position and, if appropriate, to 90 degrees of abduction (Fig. 39-25). Backhand- and forehand-type motions can be initiated to encourage coactivation of

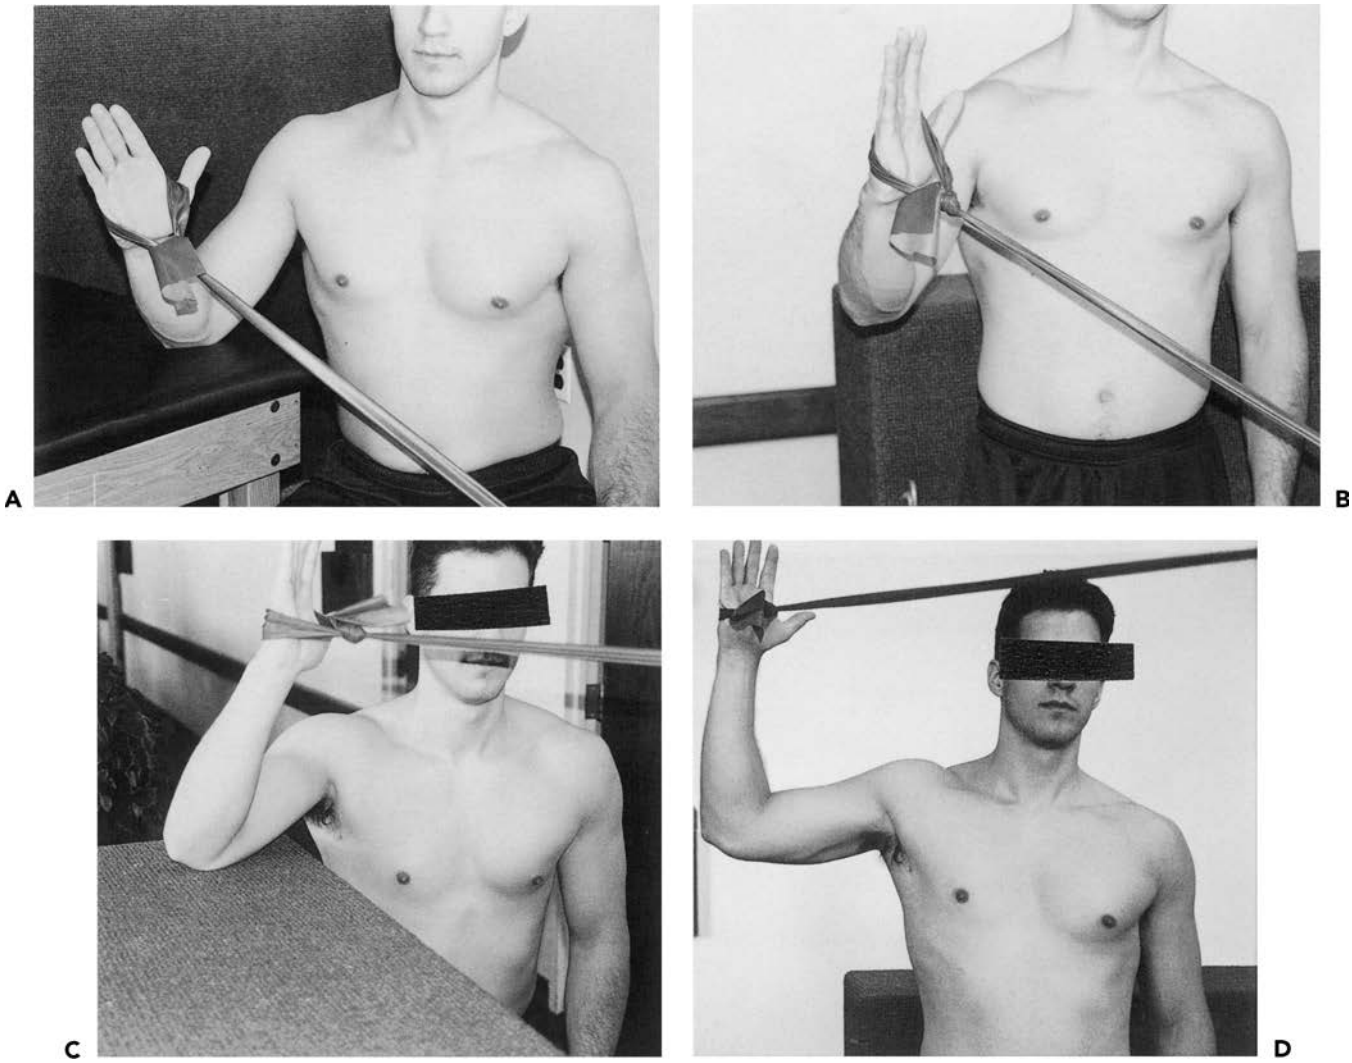

Figure 39-25 Elastic band strengthening progression. **(A)** 45 degrees plane of the scapula (POS), supported. **(B)** 45 degrees POS, unsupported. **(C)** 90 degrees POS, supported. **(D)** 90/90, unsupported. scapulothoracic and glenohumeral muscles in functional positions. The backhand encourages the scapular retractors while the glenohumeral abductors and external rotators work. The forehand activates the serratus anterior and glenohumeral internal rotators.

Scaption (abduction in the POS) with external rotation or internal rotation using the extremity weight or a free weight can be performed. An elastic band may be used, but because such a long lever arm is created and the elastic can be stretched to a point of excessive resistance, light free weights may produce less potential tendon overload. Scaption with external rotation is preferred since sufficient supraspinatus activity is created and rotator cuff and bursal impingement is discouraged.[52] We have found that many patients have increased pain when performing scaption with internal rotation. Although this exercise was found to isolate the supraspinatus[43] and create the greatest muscle activity for the anterior and middle deltoid, supraspinatus, subscapularis,[105] and upper trapezius,[79] motion *above* 90 degrees was required. Although scaption with internal rotation may be beneficial at some stage of rehabilitation, performing it too early can result in further irritation of the rotator cuff due to increased shear forces and direct cuff compression.[35,105] The reader is encouraged to consult the literature on muscle activity based on EMG findings. Although these studies are valuable, direct application of study positions is not always clinically prudent because their use may be contraindicated relative to the patient's symptoms and pathology.

Commonly, exercises are performed in two to three sets of 10 to 15 repetitions, based on the patient's response and the rationale for exercise; however, in some high-demand

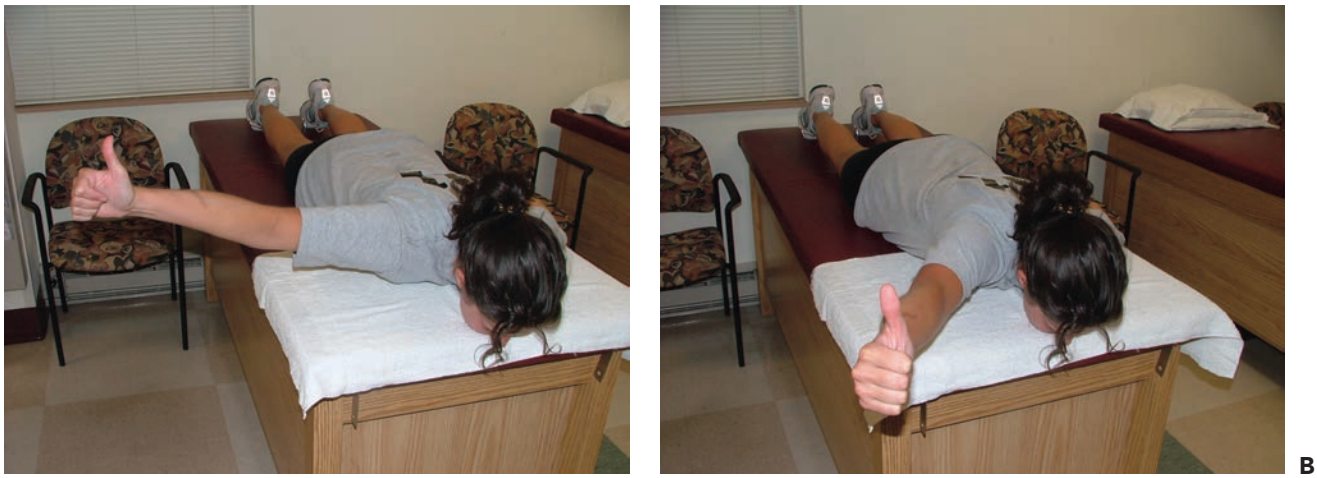

Figure 39-26 Prone horizontal abduction/end-range strengthening at 90 degrees **(A)** and 120 degrees **(B).**

patients, the repetitions are increased to 25 to 30. We feel that increased repetition achieves all the previously stated rationales for resistive exercise in addition to improving shoulder girdle muscle endurance.

Phase III

In this phase the patient should have relatively pain-free active range of motion, be able to perform a full-range stretching program, and be able to perform phases I and II strengthening exercises without symptoms. Individuals who have low demands other than activities of daily living are typically released on a home stretching and strengthening program. Previous rehabilitation literature[5,50,110] and research regarding proprioception and the neuromuscular mechanism[65,66] shows that rehabilitation exercise should be performed in positions of function. We advocate progressing strengthening exercises to functional (and possibly provocative) positions for patients who have high demands or must repetitively function with the arm overhead (i.e., the athlete or laborer). Neuromuscular control, joint stabilization, and strength of the shoulder complex muscles are enhanced as the level of difficulty is advanced. As the patient performs exercises in the elevated positions, appropriate scapulohumeral rhythm should be assessed and facilitated. Many patients who have adequate ROM and strength can still demonstrate abnormal rhythm during elevation. Learned behavior appears to be the reason for the persistent abnormal rhythm and must be identified and then addressed.

Many authors have reported rotator cuff and scapular muscle activation levels during closed chain or provocative position exercises.[9,44,79,105,107] Unfortunately, overenthusiastic and uninformed rehabilitation specialists can injure patients or prolong symptoms with the use of these exercises. The problem is not the research or the position, but the inappropriate use of both for the patient's pathologic condition. These exercises are reserved for the patient meeting phase III strengthening criteria.

Prone horizontal abduction at 90 to 120 degrees in external rotation has been shown to maximally activate the supraspinatus, infraspinatus, middle, and posterior deltoid (Fig. 39-26).[9,105] Caution must be practiced since this exercise is extremely provocative to patients with reactive rotator cuff pathology or anterior glenohumeral instability. Moseley et al.[79] evaluated scapular muscle function using the same exercises as Townsend et al.[105] However, they did not include scaption/internal rotation but only scaption/external rotation. Scaption/external rotation was found to optimally recruit six scapular muscles, but peak activity occurred above 120 degrees. Rowing was advocated due to increased trapezius (all heads), levator scapula, and rhomboid activity. Prone horizontal abduction with external rotation also increased activity of the scapular retractors. The middle and lower fibers of the serratus anterior were significantly recruited during scaption/external rotation as well as during performance of a pushup with a "plus."[79] Again, the patient with rotator cuff tendinopathy or glenohumeral instability must be able to safely tolerate these positions. The rehabilitation specialist must first consider the pathology, tissue reactivity, time from surgery, and target muscle before placing a patient into a provocative position for the potential benefit of maximizing activity of particular muscles. Only patients who have progressed to symptom-free status after adequate healing time has passed should be progressed to the most provocative positions.

Exercise progression continues into more provocative positions based on the patient's response and functional requirements. Later in the rehabilitation process, the exercises are higher demand and may be designed to ready the athlete or laborer. The "throwers ten" program and closed-chain exercises may be utilized when appropriate.[4] Manual

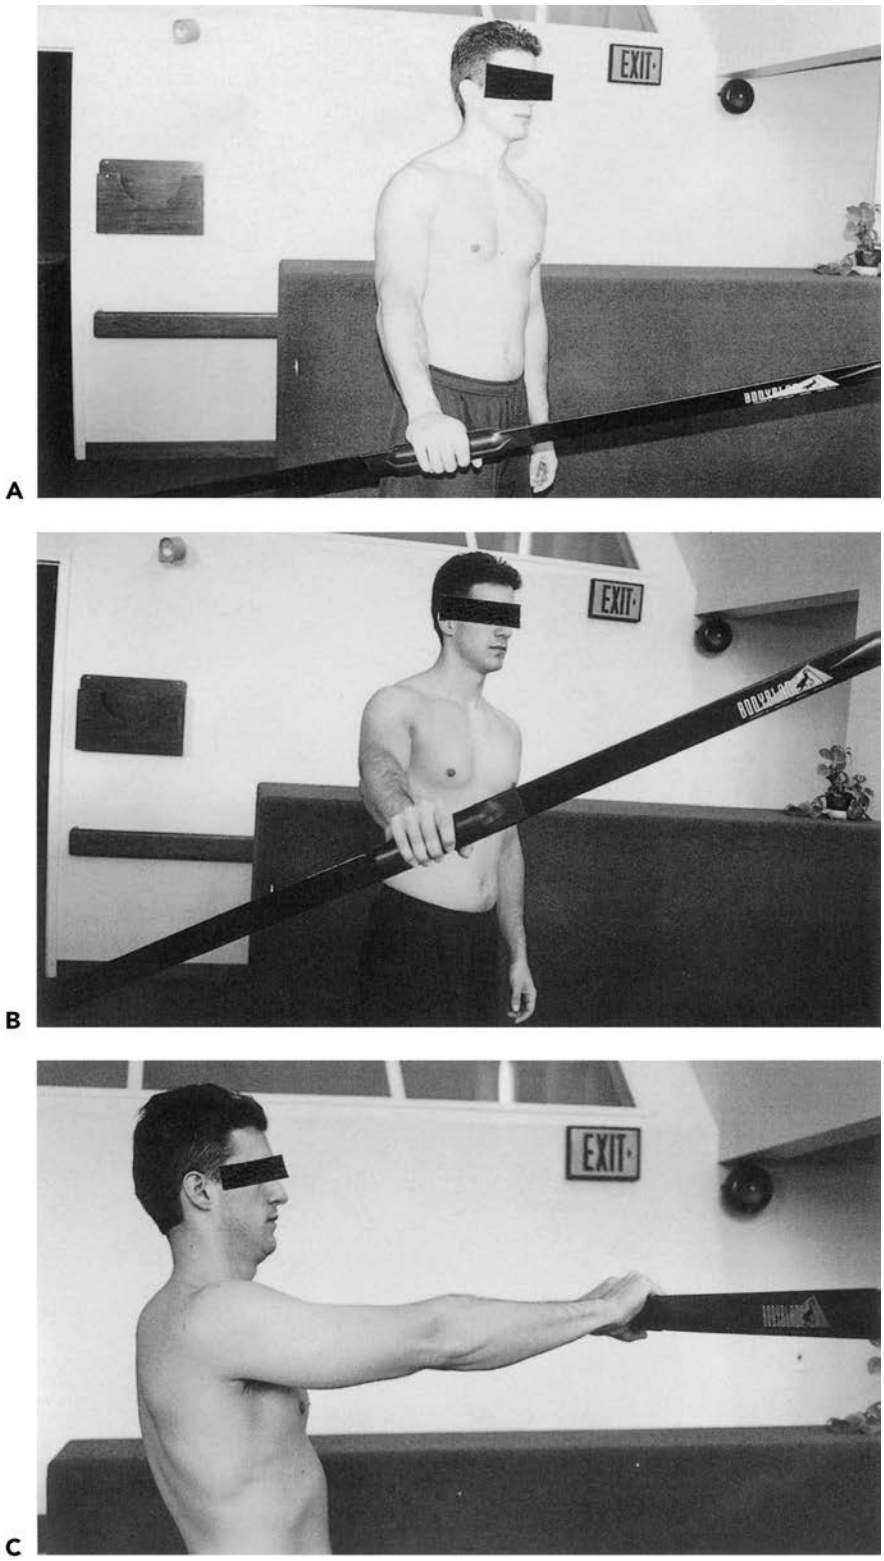

Figure 39-27 Bodyblade progression. **(A)** 30 degrees plane of scapula (POS). **(B)** 60 degrees POS. **(C)** 90 degrees sagittal with "plus." **(D)** Overhead. **(E)** 90 degrees POS. resistance exercises are progressed to full range of motion and increasing resistance. Eccentric activity also may be emphasized. PNF techniques employing diagonal patterns, specific techniques of recruiting and sequencing isometrics, and concentric and eccentric muscle activity are performed.

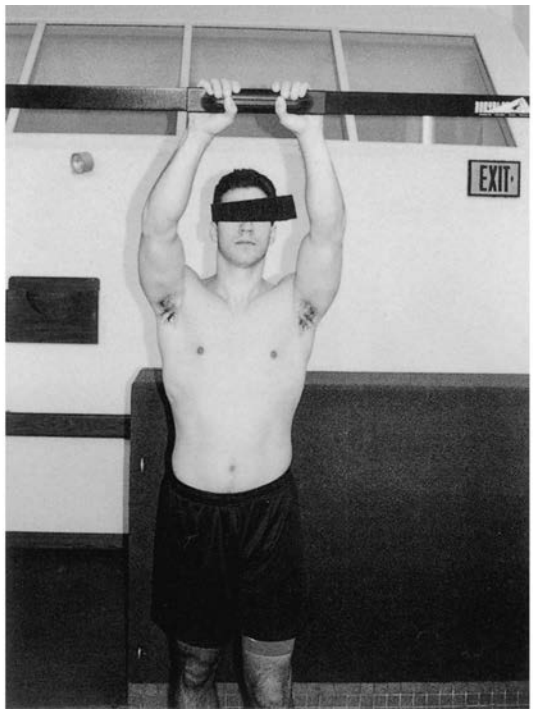
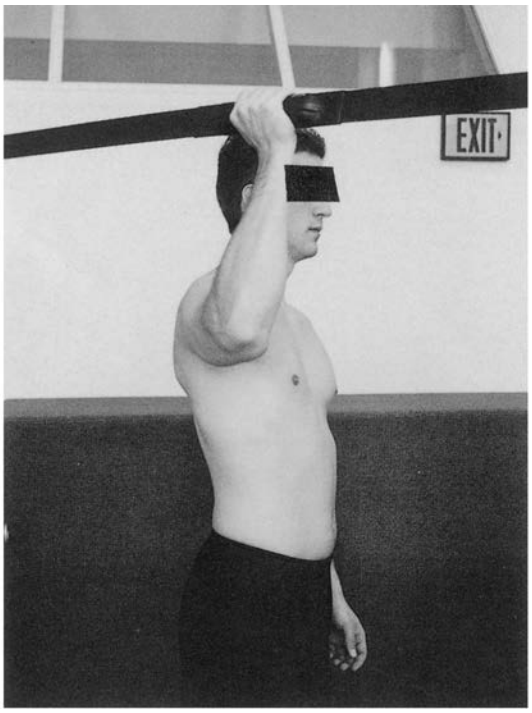
Strengthening Equipment

Weight training using variable resistive devices or barbells is started with the same nonprovocative to provocative philosophy. This program can be progressed in the clinic,



D



E

Figure 39-27 (*continued*)

or the patient can be given indications for progression of the home program. Certain exercises that require shoulder abduction and full external rotation should be prohibited, particularly the military press, chest flies, and behind-the-neck latissimus pull-downs. These exercises may be modified to the POS.

The upper body ergometer (UBE) and rowing ergometer can be used to further improve strength and endurance. The UBE may be used earlier in the rehabilitative process; however, care is always required when considering the patient's position on the UBE. Placing the patient in a sitting position so that the machine's rotation axis is level with the glenohumeral joint requires the patient to repetitively cycle against resistance in the impingement zone. The prudent clinician initially has the patient perform the exercise in the standing position to avoid the potential rotator cuff trauma. Both the forward and backward directions are performed. We find the UBE beneficial in patients who have glenohumeral instability but do not advocate its use in patients with a reactive rotator cuff or postoperative cuff repair. A rowing ergometer can be used and is very effective in improving strength and endurance of the shoulder extensor and scapula retractor muscles while improving the patient's cardiovascular condition. The rowing ergometer is used in high-demand patients who fulfill stages III and IV criteria.

An extremely useful device for rehabilitating patients with rotator cuff tendinopathy and/or glenohumeral instability is the Bodyblade (Hymanson Inc., Playa Del Ray, CA) (Fig. 39-27). This device enhances strength, dynamic control, proprioception, and endurance training. Small to large oscillations of a fiberglass rod are performed in multiple positions (following the nonprovocative to provocative philosophy) and various time intervals of 10 to 60 seconds. Oscillating the blade requires short excursion, high-speed cocontraction muscle activity of the rotator cuff–deltoid–biceps complex in addition to the scapular muscles. Therefore, dynamic stabilizing training is uniquely achieved compared with other forms of exercise. Although exercising with this device may appear easy, it can be extremely difficult and can significantly challenge the patient's shoulder muscle strength, control, and endurance. Because the device can be used in any position, selective patients in phase II can use this device. Typically the patient is placed in a slightly abducted position and oscillates the blade, primarily through elbow flexion and extension. This requires proximal stabilization at the glenohumeral and scapulothoracic joints while the distal elbow is moved. The progression of the Bodyblade is based on the patient's demands. This device is well suited to the patient with glenohumeral instability but is rarely used in the older postoperative patient following a rotator cuff repair.

Plyometric training using weighted balls can be used to enhance neuromuscular control, strength, and proprioception by reproducing the physiologic stretch-shortening

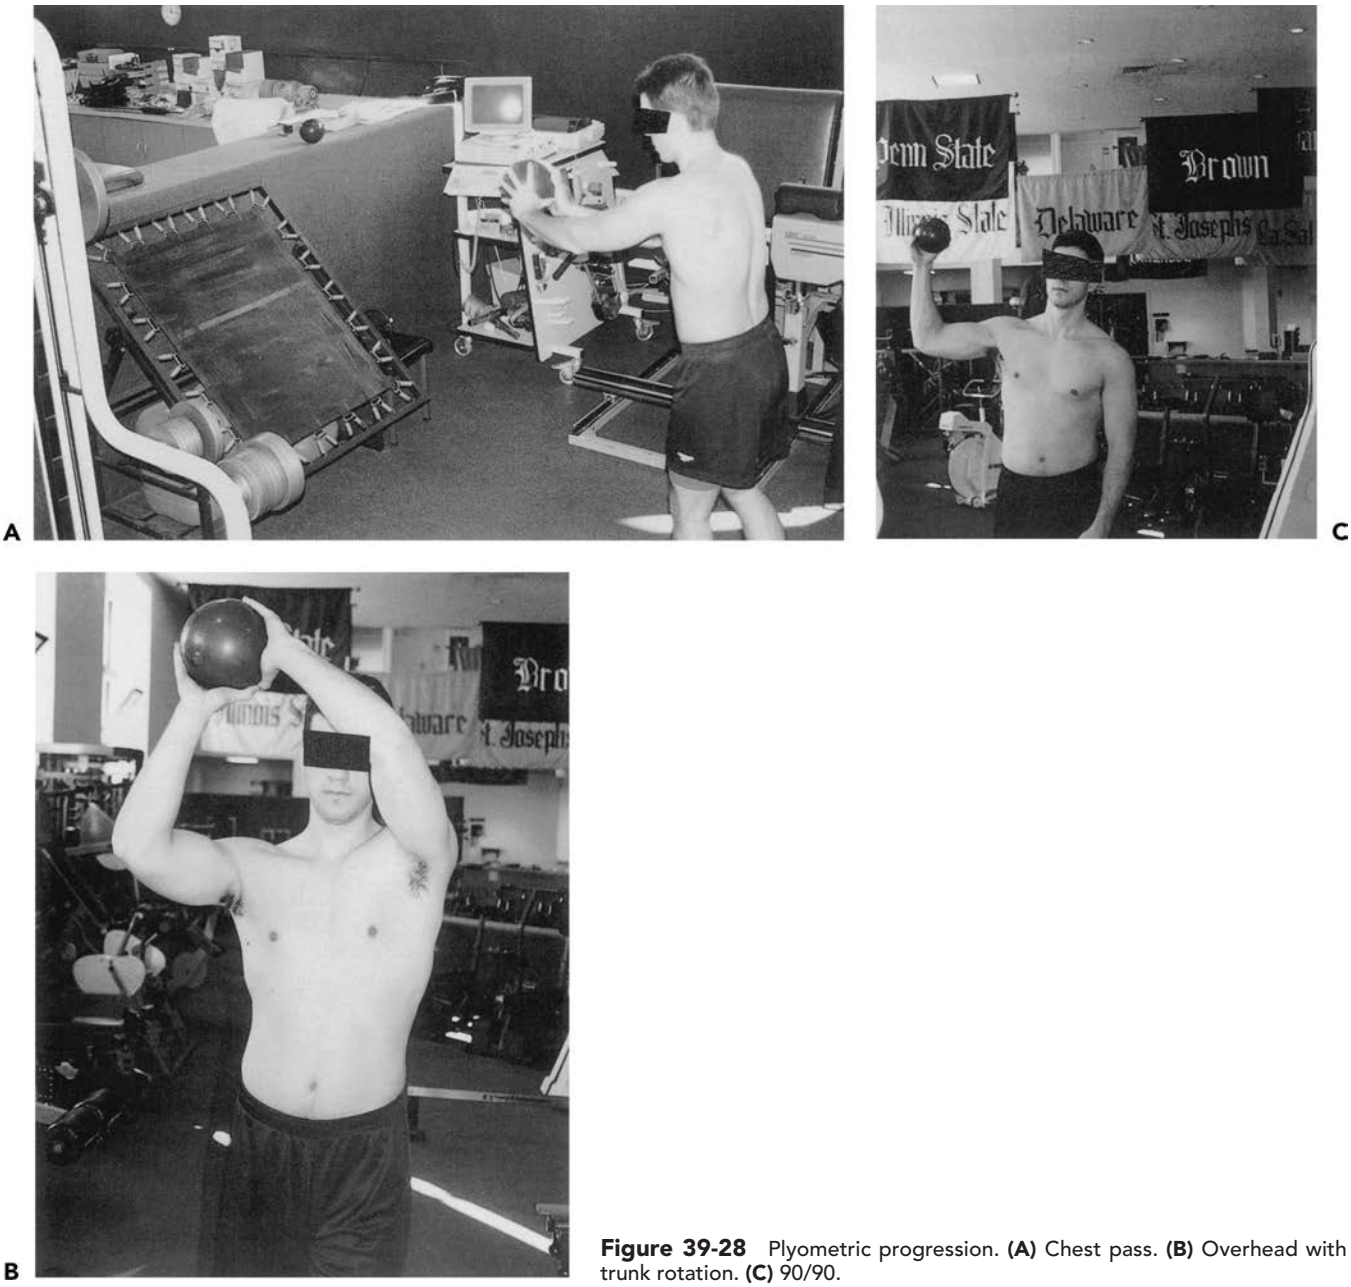


Figure 39-28 Plyometric progression. **(A)** Chest pass. **(B)** Overhead with trunk rotation. **(C)** 90/90.

cycle of muscle in multiple shoulder positions.[103] This activity can be used for any type of patient, but as with isokinetics, it is usually reserved for the younger patient or athlete. By catching and/or throwing a weighted ball (2 to 10 lb), the adductors/internal rotators are eccentrically loaded, and thus stretched, which is followed by a concentric shortening phase. Plyometric exercise creates a "quick" muscle contraction, as opposed to most other strengthening, which is slow and controlled. Initially a chest pass–type throw with both hands is used requiring approximately 90 degrees of elevation at ball release (Fig. 39-28A). The ball can then be arced to incorporate greater elevation (Fig. 39-28B). Sagittal plane motion may be more provocative to the athlete with posterior glenohumeral instability, and progression of difficulty should include horizontal adduction when arcing. True eccentric loading of the internal rotators is begun in the POS at 60 to 80 degrees and progressed to more provocative positions of elevation in the POS, eventually progressing to coronal plane positioning (Fig. 39-28C). The patient is in a functional standing or throwing position. The ball is thrown at the patient, so the velocity can be varied (varying the force of impact), yet placement of the arm may be consistent or varied, which is determined by the rehabilitation specialist. Constant

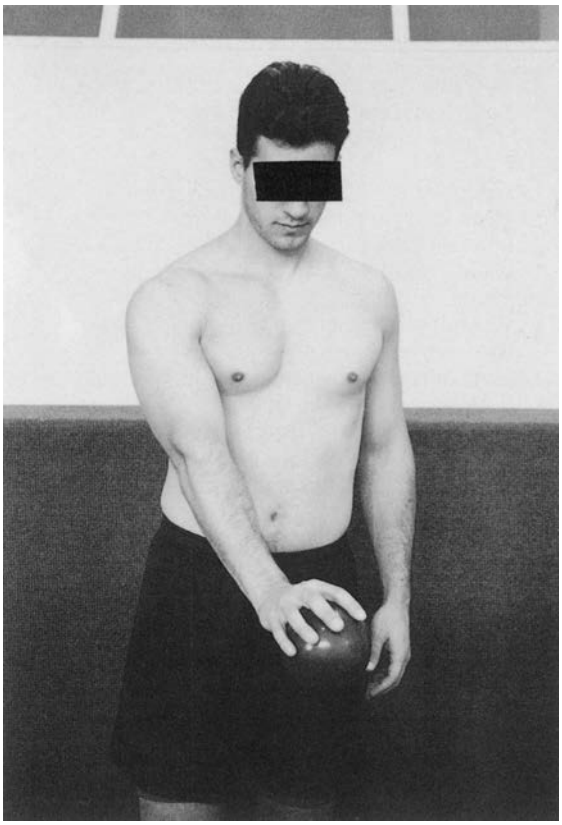

Figure 39-29 Plyometrics emphasizing glenohumeral and scapular decelerators. (Reproduced with permission from Kelly MJ. Anatomic and biomechanical rationale for rehabilitation of the athlete's shoulder. *J Sport Rehabil* 1995;4:122–154.)

assessment is made of the scapular muscle to achieve balance. Typically, with repetitive throwing or catching while in humeral elevation, the patient begins to overcompensate with the scapular elevators and correction is required. Catching the ball from a vertical drop while standing or side lying is a technique to eccentrically load the posterior cuff and scapular decelerators (Fig. 39-29).

The patient who must return to work is gradually progressed to work-simulated activities. Using variable resistance units that require the patient to push, pull, or lift can do this. Specific job activities such as lifting containers can be easily reproduced in the clinic with crates filled with varying weights. Work stations are available in many rehabilitation centers that allow the patient to use tools for various tasks. The task can be elevated or lowered depending on the patient's status. Education regarding lifting, tool use, and modification and ergonomic modification should all be addressed.

Phase IV

The patient is now performing full motion against resistance in provocative positions without symptoms. By this time most individuals other than athletes and laborers should have returned to all necessary activities. If they still have difficulty performing some overhead or lifting tasks such as painting a ceiling or picking up a bag of leaf clippings, they are taught the biomechanics of lifting to modify the task—by using a ladder, splitting the clippings, or using a wagon. In reality, this is usually discussed and performed in the previous phases.

During this phase the athlete should continue with the rotator cuff activities with a bias toward sport-specific positions. They will enter a modified off-season conditioning program. Allowing accommodating reentry philosophies encourages a gradual return to their sport. The pitcher will continue with an interval-throwing program, and the tennis player will continue with a return to noncompetitive forehand and backhand strokes, eventually progressing to technique serving strokes. The swimmer performs low-intensity interval training. Gradually the intensity of the activity is increased.

The laborer may be placed in a structured work-hardening program that is gradually increased in intensity. Education regarding lifting biomechanics and ergonomic modifications should be strongly emphasized during this phase. A functional capacity evaluation may help determine objective capabilities and limitations. Depending on the employer and job requirements, the patient may begin work that specifies job restrictions. This is not always possible; therefore, the patient must stay out of work until symptoms abate and/or soft tissue healing time parameters are satisfied. Occasionally, retraining or reeducation of the individual is required due to excessive job demands.

SUMMARY

This chapter presented principles, goals, rationales, and shoulder rehabilitation interventions. The common goals of the rehabilitation process include reduction of pain and inflammation, facilitation of collagen healing, improvement in ROM and strength, and optimization of proprioception and endurance. Goals are achieved by gradually increasing the program from nonprovocative to provocative positions, progressively increasing the connective tissue load through stretching, and challenging the neuromuscular system. Matching the rehabilitation program to the patient's demands protects the tissue and maximizes outcome.

SUMMARY 1291

Rehabilitation of the shoulder is a critical component to the recovery of function following surgical procedures. However, the quantity of rehabilitation does not always equate to quality. Each patient requires a different level of intervention. Supervised therapy three times per week is not necessary for all patients. Many patients need only instruction in a home program and periodic evaluation and progression of the rehabilitation program. Therefore, it is incumbent upon therapists, surgeons, and the patient to administer the appropriate amount of rehabilitation following shoulder surgery.

We believe in a team approach to shoulder rehabilitation. The team consists of the surgeon, the therapist, and most importantly, the patient. Frequent and effective communication among team members is essential. The surgeon must provide the patient and therapist with surgical findings, precautions, and contraindications. The therapist must instruct the patient on an appropriate program and

guide its progression. The patient needs to receive the information, follow through with adherence to precautions and exercise program, and communicate to the therapist and surgeon about progress. When complications develop or progress is not as expected, the therapist must make necessary modifications to the rehabilitation program. If these modifications fail to yield expected results, the therapist should inform the surgeon and make appropriate recommendations. When all members of the team perform their roles effectively, the result is a successful outcome.

A previous chapter discussed the specific exercises and modalities employed in shoulder rehabilitation (Chapter 39). This chapter will discuss the rehabilitation principles and guidelines for common shoulder disorders utilizing those exercises and modalities. The approach to rehabilitation when complications following shoulder surgery occur will also be discussed.

EXAMINATION

The postoperative rehabilitation program will depend largely on the pathology, type of surgery performed, and tissue healing. The patient's impairments and functional limitations must also be considered. There are a few pieces of information that should be gleaned from the history. It is important to note the patient's age, occupation, and recreational activities, as well as the patient's goals following surgery and rehabilitation. Whether the patient received any presurgery therapy will help the clinician understand the patient's conception of rehabilitation. It is also extremely important to communicate with the surgeon who performed the procedure and, if possible, to obtain a copy of the operative note. Gaining this information helps the clinician understand the quality of the soft tissue that was repaired, as well as any nuances of the surgery that may affect the rehabilitation process. Frequently, patients ask the therapist about what was done during surgery. Having a copy of the operative report or communicating directly with the surgeon will allow the therapist to answer that question and further gain the confidence of the patient.

The postoperative physical examination will not include special tests such as impingement signs or instability testing. The examination will be predicated and modified based on the stage of rehabilitation. For example, active range-of-motion (ROM) testing is almost always contraindicated in the first 6 weeks after surgery.

Pain is a parameter that should always be measured, especially during the first 3 months after surgery. The intensity of shoulder pain may vary depending upon the position or activity the patient is engaging in at any one time. Some patients experience very little pain after surgery, especially when their arm is immobilized. However, when they are able to start moving and using their upper extremity, pain may increase. Therefore, a complete assessment of pain should include pain experienced at rest as well as with activities of daily living and more strenuous activities.

Shoulder ROM is an important outcome of shoulder surgery. However, because of the multiplanar motion of the shoulder, it can be difficult to reproduce and compare with results reported by other clinicians.[1] In response to the need to standardize measurements, the American Shoulder and Elbow Surgeons (ASES) recommend that four functionally important ranges of motion be documented: forward elevation, external rotation with the arm at the side, external rotation in the 90-degree abducted position, and internal rotation with the hand up the back.[2,3] Forward elevation is defined as the maximum angle the arm makes with the trunk when the patient is asked to raise his or her arm above the head with the elbow held straight. It should be noted that this plane of motion is not considered to be true flexion or abduction. Experience tells us that most patients will raise their arm somewhere between true flexion and the plane of the scapula. The angle that the arm makes with the thorax is measured in the upright position for active motion, whereas passive measurement is made in the supine position. We will discuss when it is appropriate to measure each of these motions following specific surgical procedures.

Muscle force assessment is another commonly reported impairment used to document effectiveness of surgical or therapeutic intervention. As with ROM testing, it is important to have standardized testing protocols for reproducibility in a clinical setting. A variety of methods for quantifying muscle performance are available, including manual muscle testing (MMT), handheld isometric dynamometry, and isokinetic dynamometry. MMT is the most widely used method of clinical evaluation of muscle strength.[4] This technique, however, has been criticized for its subjectivity and lack of reliability within the good and normal ranges.[5,6] Isokinetic devices have fallen out of favor for use in the clinic because they are nonportable, are relatively expensive, and require elaborate setup and stabilization procedures.

Handheld dynamometry has been demonstrated to be reliable in both patient and nonpatient populations.[7–11] This method of muscle force measurement is portable, is relatively inexpensive, and does not require elaborate setup. Handheld dynamometry can also detect subtle differences in strength that MMT cannot. To accurately compare results of muscle force measurements, standardization of test position, stabilization, and protocol must be established. Measuring shoulder muscle performance of internal and external rotation with the arm at the side in neutral rotation and forward elevation at 45 degrees in the plane of the scapula has been demonstrated to be reliable and is the authors' preferred method of shoulder muscle force measurement.[11]

Impairment measures alone are not adequate measures of outcome.[12] It is also important to document any functional difficulties the patient may have. Several tools have been developed and used to document outcomes of patients with shoulder pathologies, including generic health status measures and condition-specific tools.[3,13–22] Condition-specific tools have been demonstrated to be more responsive than general health status measures in patients with shoulder disorders.[14] In the authors' practice, we use the Penn Shoulder Score (PSS) and the ASES Shoulder Score Index.[3,22] Outcome measurement is discussed in more detail in a later chapter (Chapter 41).

TABLE 40-1
POSTOPERATIVE PRECAUTIONS AND INSTRUCTIONS

Able to use arm for waist-level activities and basic activities of daily living (in appropriate patient)
No leaning on elbows
No sleeping on the involved side (emphasize arm supported in the plane of the scapula)
No sudden movements
No lifting and carrying with involved arm
No pushing or pulling
Importance of home exercise emphasized
Use of ice emphasized

REHABILITATION PRINCIPLES

The principles of rehabilitation after shoulder surgery remain constant regardless of the type of surgery performed. First, pain is always respected and rarely encouraged. Constant reevaluation after the introduction of a new exercise or technique is necessary to help prevent increased symptoms. Any increase in pain should be addressed through patient education on precautions, positioning, and proper exercise technique. Second, treatment is prioritized based on the impairments identified during the examination. Tissue healing is always taken into consideration prior to initiating any rehabilitation program. Third, exercise and techniques are advanced in motion, resistance, and movement planes based on symptoms and the functional demands of the patient. To assess their effect, modalities are introduced to the program one at a time. Range of motion should be restored in a protected, pain-free manner. Once the appropriate time frame for tissue healing has passed and pain and passive range of motion have improved, active range of motion and muscle performance can be assessed and addressed.

Emphasis is placed on the performance of a home exercise program. As such, no more than two or three new exercises are introduced at any one time. This helps the patient digest the information given and hopefully improves compliance and proper performance of the exercises. It also helps the therapist assess the effect a new set of exercises has on the patient. Improvements in these impairments lead to the introduction of activities to replicate the patient's functional demands.

Patient Education

The importance of patient education cannot be emphasized enough. The patient must understand and adhere to the precautions and instructions outlined by the surgeon and therapist, especially during the first 6 weeks after surgery (Table 40-1). The patient needs to be educated about the healing process and the importance of protecting the surgical repair. The patient should also be instructed in proper positioning of the arm for comfort and to promote healing. Many patients report that while at rest or sleeping, the most comfortable position is with the arm supported in the plane of the scapula. From a biomechanical standpoint, this also appears to be a more advantageous position.

Modalities

In addition to avoiding aggravating activities and positions, modalities have been advocated for pain reduction and relief of inflammation. Much of the evidence for their use is anecdotal or a product of questionable experimental design. A variety of modalities can be used during the rehabilitation process. The four main objectives for using modalities are to (a) reduce pain, (b) reduce inflammation, (c) improve range of motion, and (d) muscle reeducation. Most modalities achieve their physiologic effect by the transfer of thermal energy. These modalities include hot packs, cold packs, ultrasonography, diathermy, and infrared. Another mode of achieving a physiologic effect is through the use of electric stimulation. Electric stimulation modalities include transcutaneous electric nerve stimulation (TENS), as well as low-voltage, high-voltage, interferential, and direct current stimulation.

Range of Motion

Range-of-motion and stretching exercises are designed to prevent adhesions and/or fibrosis, reduce pain, allow collagen healing, and increase tissue length. Postoperative ROM exercises are performed within the direction and protected range allowed with respect to tissue healing and type of surgery performed. Stretching into provocative positions or aggressive stretching should not be performed to avoid putting the surgical repair at risk.

When restoring normal ROM of the shoulder, one should consider which structure might limit the motion. Studies have shown that external rotation with the arm at the side is most limited by the subscapularis and the coracohumeral ligament.[23–25] External rotation with the arm at 45 degrees appears to be limited by the subscapularis and middle fibers of the anterior glenohumeral ligament.[24] The inferior glenohumeral ligament limits external rotation when the arm is abducted to 90 degrees.[24] Gerber and colleagues simulated capsular contractures in cadavers and measured changes in elevation and rotation ROM. They found that restriction of the anterior capsule restricted external rotation ROM and posterior contractures restricted internal rotation ROM.[23] Contracture of the superior capsular structures limited rotation motions with the arm adducted.[23] Contracture of the inferior structures yielded restriction in abduction and rotation in the more elevated positions.[23]

We have divided our ROM exercises into phase I and phase II. They have been discussed in more detail in a previous chapter (Chapter 39). Phase I exercises may be initiated within the first 6 weeks postoperatively and include pendulums, passive or active assisted elevation, and external rotation with the arm positioned at 45 degrees in the plane of the scapula (Chapter 39, Fig. 39-7). Phase II ROM exercises are considered more provocative to surgically repaired tissue and may not be initiated until at least 6 weeks after surgery. These exercises include extension, internal rotation, and cross-body adduction (Chapter 39, Fig. 39-9). The patient is asked to take the extremity to a position of tolerable stretch and hold the position for 10 to 20 seconds. Each exercise is repeated 10 times, three to six times per day at home.

Strengthening

Muscular strength refers to the capacity for active tension development by a muscle.[26] Multiple factors influence muscle strength.[27] Strength gains occur by two types of neuromuscular changes: increased motor unit recruitment and hypertrophy.[28] Appropriately loading a muscle will result in hypertrophy or increased muscle mass and, subsequently, increased muscle force production. However, significant strength gains have been shown to occur in the absence of hypertrophy due to improved motor unit recruitment and synchronization.[27] Enhancing synchronization of the rotator cuff, deltoid, and scapular muscles, also referred to as neuromuscular training, is generally the rationale for improving shoulder function.

There are several methods therapists can use for improving strength and neuromuscular control. These include manual resistance, elastic resistance, free weights, and machines. Regardless of the method, the underlying principle guiding the therapist is that exercises should begin in nonprovocative or supported positions with a gradual progression toward potentially provocative or functional positions.

Our strengthening exercise program is also categorized by phases and has been discussed in more detail in a previous chapter (Chapter 39). Phase I exercises include external and internal rotation with the arm at the side, and extension with elastic resistance (Chapter 39, Fig. 39-21). Patients are typically asked to perform 10 repetitions with the lightest resistance. They are able to add a second set of 10 when the first set is performed without difficulty. A third set is added when there is no difficulty with the first two. When all three sets become easy, the patient may progress to the next level of resistance. Phase II of the strengthening exercise program is added when the patient can perform all three of the phase I exercises with the third level of resistance. These exercises include abduction to 45 degrees, forward elevation below shoulder level, and external rotation with the arm supported at 45 degrees (Chapter 39, Fig. 39-24).

The scapular strengthening program has also been divided into phases. Phase I is meant to address all portions of the trapezius muscle. Scapular retraction can be performed at three different positions: waist level, above the head, and ground level. Retraction with the resistance above the head should only be performed if this is a pain-free position for the patient. Phase II of the scapular strengthening program includes combination movements such as horizontal abduction with scapular retraction, horizontal adduction with scapular protraction, and scapular retraction with glenohumeral external rotation.

Some patients may go on to more strenuous exercises, which we term phase III. These include activities in more provocative and functional positions. Exercises with a Bodyblade (Hymanson Inc., Playa Del Ray, CA) or plyometrics with a weighted ball can be employed to enhance strength, dynamic control, proprioception, and endurance (Chapter 39, Figs. 39-27 to 39-29). Instruction in proper performance and use of variable resistance machines or free weights can also be introduced at this time.

General Rehabilitation Guidelines

As a general guideline, the authors recommend that the patient perform most of the rehabilitation exercises at home during the initial 6 to 12 weeks after surgery. Physical therapy visits are coordinated with the patient's postoperative physician visits at specified time intervals. Individual patient need may dictate more frequent physical therapy visits. The patient typically returns to the physician 7 to 10 days after surgery. In most cases, the patient is instructed in phase I ROM exercises and asked to perform the exercises three to six times per day until their next physician visit at 6 weeks postsurgery. We recommend supervised therapy for patients who fit one or more of the following criteria: unable to demonstrate exercises properly,

passive forward elevation ROM less than or equal to 100 degrees, or less than 10-degree improvement in passive forward elevation during the first visit. When the patient exceeds these criteria, he or she may be allowed to continue with the home program. At the 6-week postoperative visit, patients may be instructed in phase II ROM exercises and phase I strengthening. Phase I of the scapular strengthening exercises may also be introduced at this time. Patients may be progressed to phase II strengthening exercises at the 12-week postoperative visit.

ROTATOR CUFF DYSFUNCTION

Subacromial Decompression with Intact Rotator Cuff

Patients with a prominent anterior acromion who have failed nonoperative management including rest, modalities, nonsteroidal antiinflammatory drugs, exercise, and a subacromial injection of cortisone will be considered for acromioplasty. Open acromioplasty has been an effective procedure with long-term satisfactory results ranging from 80% to 90% in most studies.[29–32] Arthroscopic acromioplasty has demonstrated similar results to open acromioplasty and is now the preferred method of treatment.[33] The major advantage of arthroscopic over open decompression is that deltoid detachment is avoided.[34] Use of the arthroscope allows inspection of the glenohumeral joint, as well as the undersurface of the rotator cuff, and any pathology encountered can then be addressed.[35] Finally, an arthroscopic decompression is less invasive and can be performed more easily on an outpatient basis.[35]

Following the procedure, the patient is sent home with the arm immobilized in a sling. The patient is allowed to remove the sling on the second postoperative day as long as there is no discomfort. The postoperative instruction packet includes instructions for the patient to perform pendulum exercises, elbow active range of motion (AROM), and hand squeezes four to six times per day. Most patients will be seen by a physical therapist for two to three visits after this type of surgery. Andersen and colleagues demonstrated that a self-training exercise program yielded similar results to physical therapist–supervised (six visits) program following subacromial decompression.[36]

The patient will return to the surgeon 7 to 10 days postoperatively for suture removal and further instructions. At this time, the patient will be instructed by a physical therapist in phase I ROM exercises including supine passive forward elevation and external rotation (Table 40-2). A majority of patients will be discharged from therapy with this home exercise program to be performed four to six times per day. The next postoperative visit occurs 4 to 6 weeks after surgery. At this point, the patient is instructed in phase II ROM exercises (extension, internal rotation, cross-body adduction), phase I rotator cuff strengthening (external rotation, internal rotation, extension), and scapular retraction with resistance. At the 8- to 12-week postoperative visit the patient will be progressed to phase II strengthening exercises and, possibly, phase II scapular strengthening exercises. Patients with lower demands (nonathletes or laborers) will continue to progress their home exercise program and possibly add a variable resistance program.

Beyond 12 to 16 weeks postoperatively, the patient who must return to work may be gradually progressed to work-simulated activities. Patients are instructed in proper lifting techniques, tool use, and modification of activities. The overhead athlete will be progressed to activities simulating his or her sport demands. Rotator cuff strengthening at 90 degrees abduction, plyometric exercise with weighted balls, and use of the Bodyblade may all be included in this phase of rehabilitation.

Rotator Cuff Repair

Among the many presentations of rotator cuff tears are degenerative or partial-thickness tears, an acute extension of degenerative or partial-thickness tears, chronic full-thickness tears, massive tears involving more than one tendon, associated biceps tendonitis or ruptures, and associated traumatic arthritis of the glenohumeral joint secondary to cuff deficiencies.[37] The presence of a rotator cuff tear is not necessarily an indication for surgery.[35] The indications for surgical repair of rotator cuff tears are, therefore, the presence of pain or functional deficits that interfere with activities and have not responded to conservative measures.[35] Most surgeons continue nonoperative treatment for at least 3 to 4 months before considering repair; when weakness is prominent or progressive, more timely repair may be considered.[35]

Although the best method for repair of full-thickness rotator cuff tears has been controversial, complete arthroscopic repair techniques have been evolving as an alternative to traditional open and mini-open repairs.[38–41] Neer reported the results of anterior acromioplasty in combination with rotator cuff mobilization and repair in 1972.[31] The surgical fundamentals emphasized in that report substantially improved the reliability of the outcomes of repairs of rotator cuff tears.[38] The fundamentals include (a) preservation or meticulous repair of the deltoid origin, (b) adequate decompression of the subacromial space by resection of any anteroinferior osteophytes, (c) surgical releases as necessary to obtain freely mobile muscle–tendon units, (d) secure fixation of the tendon to the greater tuberosity, and (e) closely supervised rehabilitation including early passive range of motion within a protected range.[38]

The current options for rotator cuff repair include the following: (a) arthroscopically assisted open repair, which consists of arthroscopic subacromial decompression followed

TABLE 40-2
PENN PRESBYTERIAN MEDICAL CENTER SHOULDER AND ELBOW SERVICE ACROMIOPLASTY GUIDELINES—INTACT ROTATOR CUFF

Phase I: 0–4 Weeks Postoperative

Goals:
1. Patient education
2. Permit healing
3. Control pain and inflammation
4. Initiate ROM exercises

Treatment:
Immediately postoperative or postoperative day 1:
1. Immobilized in sling
   Use sling for comfort and public only
2. Pendulums
3. Hand squeezes
4. Elbow AROM
   Supine PROM forward elevation (in appropriate patient)

Postoperative days 7–10:
1. Pendulums
2. Supine PROM forward elevation and external rotation
3. Heat and ice
   Active scapular exercises (shoulder shrugs, scapular retraction)

Phase II: 4–6 Weeks Postoperative

Goals:
1. Improve to full ROM
2. Improve neuromuscular control and strength

Treatment:
1. Continue all stretches
2. Add phase II stretches (extension, IR, and cross-body adduction)
3. Progress to phase II strengthening exercises when at green for all phase I strengthening (abduction, forward elevation, and external rotation at 45 degrees in POS with arm supported)
4. Advanced scapular strengthening
5. Manual resistance for rotator cuff, deltoid, and PNF

Phase III: 6–12 Weeks Postoperative

Goals:
1. Full pain-free ROM
2. Optimize neuromuscular control
3. Improve endurance
4. Initiate return to functional activities

Treatment:
1. Continue all stretches and strengthening; progress rotator cuff exercises into POS abduction
2. Appropriate variable resistance and/or free-weight resistance
3. Strengthening above 90 degrees
4. Plyometrics*/Bodyblade
5. Work-/sport-specific exercise*

Phase IV: 12–16 Weeks Postoperative

Goals:
1. Return to sport,* occupation,* or desired activities
2. Promote concept of prevention

Treatment:
1. Work hardening*
2. Sport-specific training*

by open repair of the rotator cuff through a lateral deltoid-splitting approach; (b) mini-open arthroscopically assisted repair, which includes arthroscopic subacromial decompression, release of adhesions, placement of tagging sutures, and débridement of the tendon edges followed by a mini-open deltoid splitting approach to obtain suture management and bone–tendon fixation; and (c) complete arthroscopic repair, in which subacromial decompression, release of adhesions, and bone–tendon fixation are all carried out in an arthroscopic fashion.[38] Early reported experience with complete arthroscopic rotator cuff repairs has been promising, and the technique has become increasingly popular among experienced shoulder surgeons as a preferred means to obtain repair of the rotator cuff.[38] In experienced hands, the technique appears to offer less pain and morbidity as well as quicker recovery than do alternative techniques such as open or mini-open repair.

Rehabilitation following rotator cuff repair may vary based on surgical technique, cuff tear size, tissue quality, amount of tension at the repair site, patient age, patient goals, functional demands of the patient, and systemic disease processes. The prognosis following repair has been correlated to the rotator cuff tear size, presurgery atrophy, and presurgery ROM restrictions.[42–47] The amount of postoperative interaction the patient has with the surgeon and therapist is dictated by individual patient need. Typically, the therapist sees the patient at the time of postoperative visits with the surgeon. These visits usually occur 7 to 10 days, 6 weeks, 3 months, and 6 months postoperatively. Approximately 70% of patients in our service are managed in this way. More frequent visits to a therapist may be called for if the patient is not progressing as expected. An assessment of the amount of therapy needed in the first 6 weeks after surgery is made at the first postoperative visit. Patients are

expected to achieve the following at that visit: at least 100 degrees of passive forward elevation, at least 30 degrees of passive external rotation, and no difficulty performing the home exercises. Patients who do not meet those criteria will be seen in physical therapy on at least a weekly basis until the range of motion improves sufficiently.

Two studies have demonstrated that patients achieve a good outcome after rotator cuff repair regardless of the amount of contact with a physical therapist.[48,49] Roddey et al. demonstrated that with a therapist available for questions, patients who utilized a videotape method for their home exercise program instruction had self-reported outcomes equal to patients instructed in their home program personally by a physical therapist.[48] However, one must question whether there was really much difference in the treatment technique between the two groups. In addition, 30% of the patients who entered the study dropped out. It is unclear whether they may have entered supervised physical therapy. Hayes and colleagues randomized patients following rotator cuff repair into an individualized physical therapy treatment group and a standardized unsupervised home exercise regime.[49] By 24 weeks postoperative, most patients demonstrated favorable outcomes regardless of rehabilitation mode. However, 6% of the patients in the home exercise group sought individualized physical therapy by 6 weeks postoperative, 19% sought physical therapy by 12 weeks postoperative, and 28% sought physical therapy by 24 weeks postoperative.

The rehabilitation program we are presenting consists of a core set of stretching and strengthening exercises. The timing of when these exercises are introduced to the patient depends on the type of procedure performed and size of the rotator cuff tear (Tables 40-3 and 40-4). We will discuss the rehabilitation process after rotator cuff repair through four phases.

Phase I

When beginning rehabilitation after rotator cuff repair, a therapist must know the size of the tear and tendon involvement, quality of the tissue and ease of tendon mobilization, surgical technique, presurgery treatment, and the patient's goals. Patients who have had repair of a small or medium cuff tear will most likely be immobilized in a sling, with or without a small abduction pillow, to be used for comfort and when they are in public places. The sling is used when dressing or bathing for the first 7 to 10 days. It is then used predominantly when the patient is in a public place.

Patients who have a large or massive rotator cuff repair are oftentimes immobilized in an abduction pillow or brace for the first 3 to 6 weeks postoperatively. The rationale for bracing in this position stems from work to examine the passive tension generated in the supraspinatus musculotendinous unit at the time of repair in patients undergoing repair of long-standing rotator cuff rupture.[50] This study found that shoulder adduction increases the amount of passive tension of the muscle. Therefore, positioning the arm at 30 to 45 degrees of elevation in the plane of the scapula would seem to allow healing while reducing the risk of damage to the rotator cuff repair site. Patients immobilized in this way are only allowed to remove the brace for exercising, bathing, and dressing, but must keep the arm passively supported at 45 degrees in the plane of the scapula during those activities. If possible, it is helpful to instruct a family member in the techniques of donning and doffing the brace and supporting the arm during bathing and dressing. We also recommend that a patient utilize a slightly deflated beach ball for support during bathing.

Patients begin with pendulum exercises, elbow AROM, and hand squeezes within the first week after surgery. At the first postoperative visit, patients are instructed in phase I stretching exercises, which are supine passive forward elevation and external rotation with a cane or stick. Emphasis is placed on the patient achieving a tolerable, submaximal stretch several times per day rather than aggressive short bouts of stretching. The patient is asked to perform 10 to 20 repetitions with at least a 10-second hold, four to six times per day at home. The therapist also must assess whether the patient requires more supervised physical therapy during these initial 6 weeks after surgery. We have found that patients who achieve greater than 100 degrees of passive forward elevation or a 10-degree improvement in forward elevation during the first visit do well continuing with the home program on their own. In addition, patients must be able to demonstrate independence with the performance of these exercises. Patients who do not fit these criteria will be recommended for more supervised therapy. The surgeon may hold off beginning these ROM exercises until 3 to 6 weeks postoperatively for some patients with large or massive cuff tears.

Phase II

This stage typically begins 6 weeks after surgery. Patients are asked to continue performing the phase I ROM exercises. The supine forward elevation exercise may now be performed with a cane or stick to achieve end-range forward elevation passive range of motion (PROM). Patients are instructed in phase II ROM exercises and phase I strengthening exercises at this time. Caution must be employed with patients who have had large or massive rotator cuff tears. Restrictions in internal rotation ROM are to be expected due to the nature of the repair. Therefore, this exercise must be performed submaximally. Pain or weakness with the strengthening exercises may necessitate shorter arcs of motion. In some cases of a complex repair or where the integrity of the repair may be in question, rotator cuff strengthening may not be initiated until 8 to 12 weeks postsurgery.

TABLE 40-3
PENN PRESBYTERIAN MEDICAL CENTER SHOULDER AND ELBOW SERVICE REHABILITATION GUIDELINES FOR SMALL/MEDIUM ROTATOR CUFF TEARS FOLLOWING SURGICAL REPAIR

Phase I: 0–6 Weeks Postoperative

Goals:
1. Patient education
2. Permit healing
3. Control pain and inflammation
4. Initiate ROM exercises

Treatment:
Immediately postoperative or postoperative day 1:
1. Immobilized in sling
   Use sling for comfort and public only
2. Pendulum
3. Hand squeezes
4. Elbow AROM

Postoperative days 7–10:
1. Pendulums
2. Supine PROM forward elevation and ER (at 45 degrees in POS)
3. Heat and ice
4. Active scapular exercises (shoulder shrugs and scapular retraction)

Phase II: 6–8 Weeks Postoperative

Goals:
1. Improve to full ROM
2. Improve neuromuscular control and strength
3. Emphasize normal scapulohumeral rhythm

Treatment:
1. Continue all ROM exercises
2. Add phase II ROM exercises (extension, IR, and cross-body adduction)
3. Phase I strengthening (ER, IR, extension)
4. Submaximal manual resistance (ER/IR) with arm supported
5. Resisted scapular strengthening (with arms below shoulder height)

Phase III: 8–12 Weeks Postoperative

Goals:
1. Full pain-free PROM
2. Optimize neuromuscular control
3. Improve endurance
4. Initiate return to functional activities

Treatment:
1. Resisted scapular strengthening
2. Manual resistance for rotator cuff and deltoid
3. Progress to phase II strengthening (abduction, forward elevation, and ER at 45 degrees in POS with arm supported when at green for all phase I exercises)
4. Appropriate variable resistance and/or free-weight resistance
5. Strengthening in 45- to 90-degree position (keep pain free and in POS)

Phase IV: 16 Weeks–6 Months Postoperative

Goals:
1. Return to sport, occupation, or desired activities*
2. Promote concept of prevention

Treatment:
1. Work- or sport-specific exercises*
2. Work hardening*
3. Gradual return to sport or desired activities*

*Applies to athlete or laborer.
AROM, active range of motion; ER, external rotation; IR, internal rotation; POS, plane of the scapula; PROM, passive range of motion; ROM, range of motion.
Reprinted with permission from Penn Presbyterian Medical Center, Shoulder and Elbow Service.

Patients who are not progressing as expected may be referred to supervised therapy. To help advance PROM, glenohumeral mobilizations and gentle, relatively pain-free manual stretching can be performed. To augment strengthening, manual resistance can be applied with alternating isometrics beginning with the arm supported at 45 degrees in the plane of the scapula (POS) and neutral rotation. Scapular strengthening exercises can also begin at this time period. Exercises should be performed with the arms below shoulder height to avoid increasing pain.

Phase III

This phase begins 12 weeks after surgery. The patient should have nearly full PROM for forward elevation (FE) and external rotation. It should be expected that internal rotation ROM will be only slightly better than at the beginning of phase II. It is important to assess AROM at this point. Many patients, especially those with large or massive rotator cuff repairs, may not be able to achieve greater than 90 degrees of active forward elevation. The therapist must evaluate whether this deficiency is due to weakness, stiffness, or lack of neuromuscular control. If near full PROM is present and there is good rotator cuff strength with the arm at the side, lack of neuromuscular control is the suspected culprit. It may have been 6 to 12 months since the rotator cuff worked in functional positions, and it is reasonable to suspect that it needs to be "retrained" to work in the elevated or end-range positions. In addition, the deltoid has not been used in this manner and most likely lacks the necessary strength to elevate the arm against gravity.

Patients who are unable to actively elevate the arm against gravity should also perform strengthening exercises

TABLE 40-4

PENN PRESBYTERIAN MEDICAL CENTER SHOULDER AND ELBOW SERVICE REHABILITATION GUIDELINES FOR LARGE/MASSIVE ROTATOR CUFF TEARS FOLLOWING SURGICAL REPAIR

Phase I: 0–6 Weeks Postoperative

Goals:
1. Patient education
2. Permit healing
3. Control pain and inflammation
4. Initiate ROM exercises

Immediately postoperative or postoperative day 1:
1. Patients may be immobilized in sling or abduction brace
   If sling, use for comfort and public
   If abduction brace, immobilized for 3–6 weeks
2. Pendulums
3. Hand squeezes
4. Elbow AROM

Postoperative days 7–10:
1. Pendulums
2. Supine PROM forward elevation and ER in appropriate patient
3. Heat and ice

Phase II: 6–12 Weeks Postoperative

Goals:
1. Improve to full ROM
2. Improve neuromuscular control and strength

Treatment:
1. Continue all ROM exercises (add phase I ROM exercises if not performing)
2. Add gentle phase II ROM (IR, cross-body adduction, and extension)
3. Submaximal manual resistance (ER/IR) with arm supported
4. Phase I strengthening (ER, IR, extension)
5. Resisted scapular strengthening (with arms below shoulder height)

Phase III: 12–16 Weeks Postoperative

Goals:
1. Full pain-free ROM
2. Optimize neuromuscular control
3. Improve endurance
4. Initiate return to functional activities

Treatment:
1. Continue all ROM and strengthening
2. Progress to phase II strengthening when at green for all phase I exercises (abduction, forward elevation, ER at 45 degrees in POS with arm supported)
3. Manual resistance for rotator cuff and deltoid

Phase IV: 16 Weeks–6 Months Postoperative

Goals:
1. Return to work, sport, or desired activities*
2. Promote concept of prevention

Treatment:
1. Work hardening
2. Gradual return to work or desired activity
3. Progress Bodyblade into elevated positions
4. Work-/sport-specific exercises

*Applies to athlete or laborer.
AROM, active range of motion; ER, external rotation; IR, internal rotation; POS, plane of the scapula; ROM, range of motion.

in the supine position (Fig. 40-1). In this position, gravity is virtually eliminated and patients can "practice" raising their arm past 90 degrees while strengthening the deltoid. When the patient can comfortably perform 30 repetitions of this exercise, the head is slightly elevated to add the weight of gravity to the exercise. This sequence continues until the patient is able to raise the arm while standing upright. This exercise can be enhanced with the use of weighted balls or elastic resistance tied to the foot (Fig. 40-2).

Patients who are able to raise their arm against gravity and are able to perform the phase I strengthening exercises with green Thera-Band will be instructed in phase II strengthening exercises. These exercises are designed to begin training the rotator cuff and deltoid for functional demands. However, as always, pain is respected and the intensity of the exercises must be monitored.

Phase IV

This phase typically begins at 16 weeks and continues for up to 6 months postoperatively. At this time, lower-demand patients continue to gradually progress their home exercise program. Patients are encouraged to approach overhead activities with caution and whenever possible to use ladders or stools to raise their hand closer to the task so that the elbow can remain below shoulder level. They are again instructed in the biomechanics of lifting in an effort to reduce the risk of rotator cuff overload.

For the athlete, sport-specific training can begin utilizing plyometrics to enhance neuromuscular control, strength, and proprioception. Recommendations and instruction for proper use of gym equipment should also be done at this time. Patients should be encouraged to avoid exercises with the arm behind the plane of the body. Latissimus

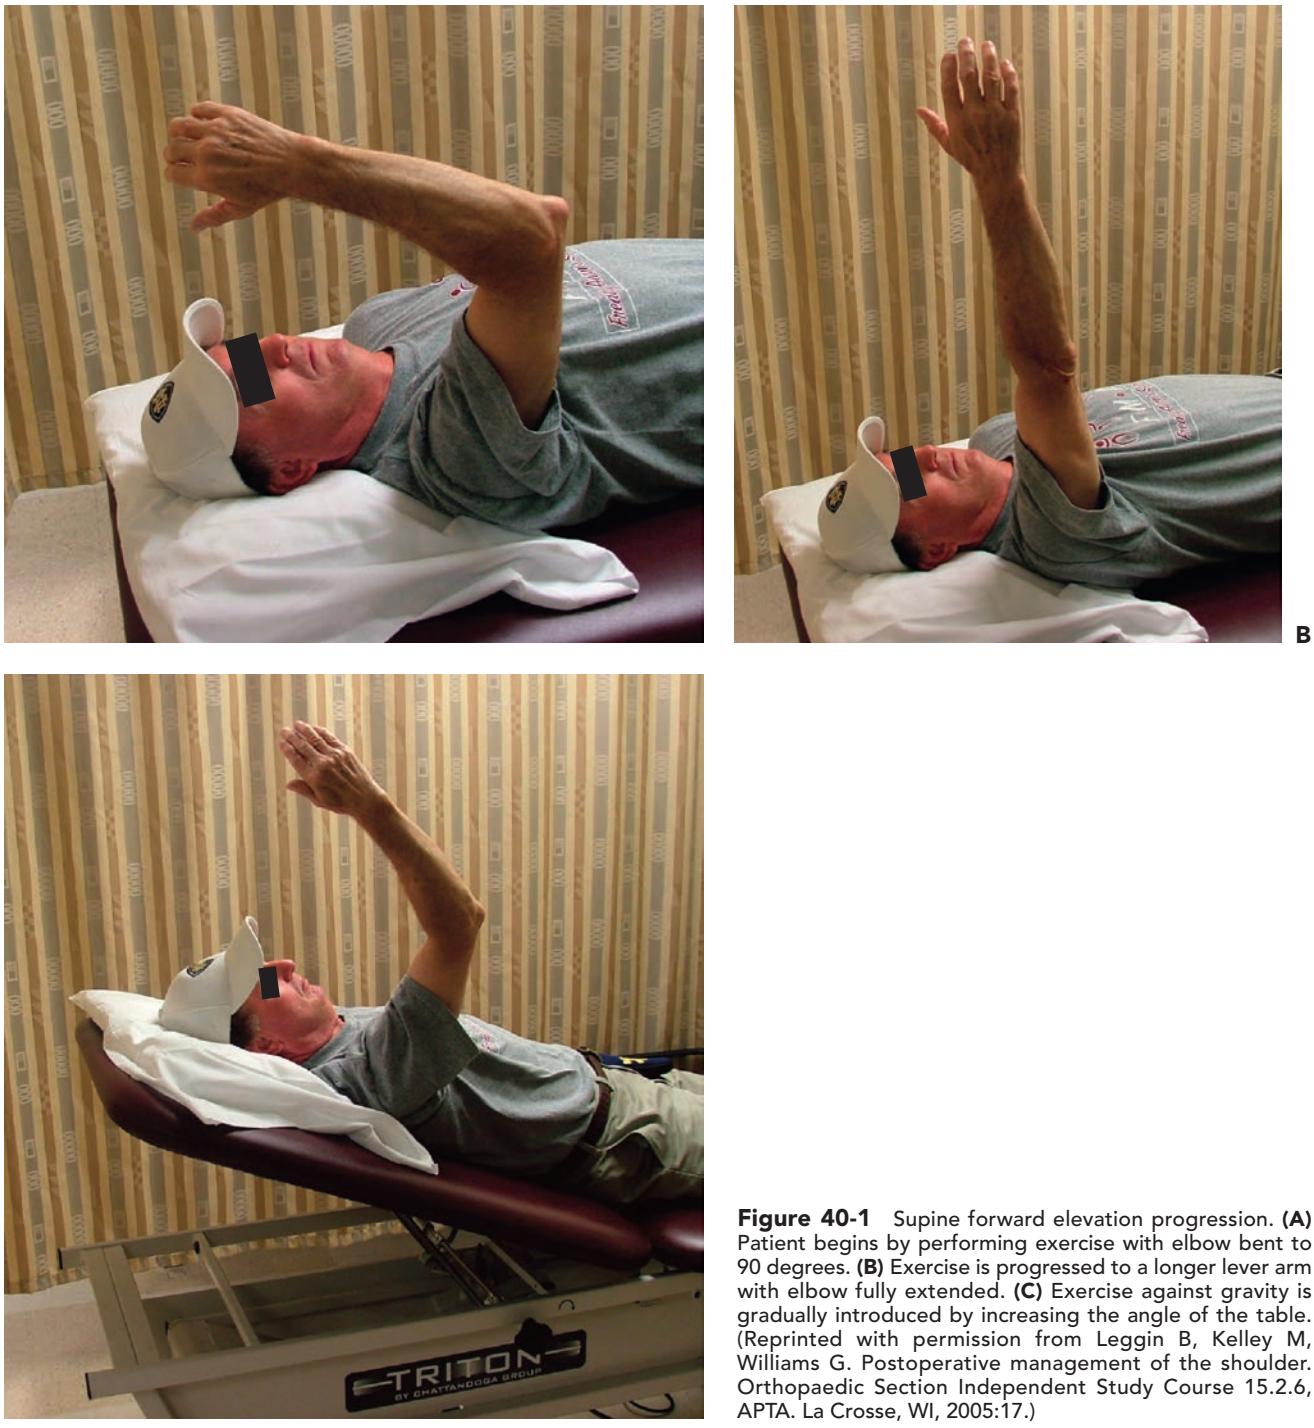

Figure 40-1 Supine forward elevation progression. **(A)** Patient begins by performing exercise with elbow bent to 90 degrees. **(B)** Exercise is progressed to a longer lever arm with elbow fully extended. **(C)** Exercise against gravity is gradually introduced by increasing the angle of the table. (Reprinted with permission from Leggin B, Kelley M, Williams G. Postoperative management of the shoulder. Orthopaedic Section Independent Study Course 15.2.6, APTA. La Crosse, WI, 2005:17.)

pull-downs should be performed to the chest, not behind the head. Caution should be employed when performing any type of "pushing" exercise such as chest press or shoulder press. It is safer to perform these exercises with a machine to allow for greater safety.

The patient who must return to work is gradually progressed to work-simulated activities. Emphasis is placed on simulating work activities in a safe, effective manner. The patient is educated on proper lifting mechanics and ergonomic modifications.

Latissimus Dorsi Tendon Transfer

Irreparable rotator cuff tears are characterized by the inability to achieve a direct repair of the native tendon to the proximal humerus despite mobilization of the remaining

Figure 40-2 Supine forward elevation progression with weighted ball **(A)** and elastic resistance **(B).** (Reprinted with permission from Leggin B, Kelley M, Williams G. Postoperative management of the shoulder. Orthopaedic Section Independent Study Course 15.2.6, APTA. La Crosse, WI, 2005:17.)

tissue with conventional techniques of soft tissue release.[51] Surgical options that restore tendon continuity in recurrent, irreparable defects are limited by the duration of time since injury and inferior tissue quality.[51] Gerber et al.[52] described the technique of latissimus dorsi tendon transfer as a reconstructive option for irreparable posterosuperior rotator cuff defects. By replacing damaged and atrophied rotator cuff tissue with a healthy extrinsic tendon, latissimus dorsi tendon transfer is thought to restore an external rotation moment at the glenohumeral joint through both active contraction of the transferred muscle and the passive effect of tenodesis.[51–53]

Gerber reported that more than 80% of the 16 patients in his original study achieved good to excellent results.[53] The mean gain in active forward flexion was 52 degrees.[53] The mean adjusted Constant score was 73% overall and 82% when patients with a subscapularis lesion were excluded.[53] Aoki et al.[54] reported on 12 shoulders in 10 patients with irreparable rotator cuff tears treated with transfer of the latissimus dorsi. They reported excellent results in four shoulders, good in four, fair in one, and poor in three. Active forward elevation improved from a preoperative average of 99 degrees to a postoperative average of 135 degrees. Electromyography (EMG) revealed that nine of the 12 transferred muscles showed activity that was synergistic with the supraspinatus on external rotation with abduction.

Warner and Parsons[51] compared outcomes for 16 patients who underwent latissimus dorsi transfer as a salvage reconstruction for a failed rotator cuff repair with outcomes for six patients who underwent a primary reconstruction for irreparable cuff defect. There was a statistically significant difference in Constant score between groups, which measured 55% for the salvage group compared with 70% for the primary group.[51] Late rupture of the tendon transfer occurred in 44% of patients in the salvage group compared with 17% in the primary group.[51] Rupture had a statistically significant effect on the Constant score, with a mean decline of 14%. Therefore, these authors concluded that salvage reconstruction of failed prior rotator cuff repairs yields more limited gains in satisfaction and function than primary latissimus dorsi transfer.[51] Factors associated with more limited outcomes among patients in this study included poor tendon quality, severe fatty degeneration, and deltoid detachment.[51]

Rehabilitation following latissimus dorsi tendon transfer is very similar to the rehabilitation following massive rotator cuff tears, with a few caveats. For the first 6 weeks after surgery, patients may be immobilized in an abduction pillow or brace. Patients will perform pendulum exercises, hand squeezes, elbow AROM, supine passive forward elevation, and external rotation. After 6 weeks, gentle phase II ROM exercises (extension, cross-body adduction, internal rotation) will be added.

Six to 8 weeks after surgery, phase I strengthening exercises (internal rotation, external rotation, extension) with elastic resistance can be added. We have noticed that patients who do well following this procedure have greater internal rotation strength on the involved side than the

uninvolved side. Although the insertion of the latissimus dorsi has been relocated to the position of an external rotator, the muscle still contracts upon resisted adduction of the arm. Therefore, the latissimus needs to be retrained to act as an external rotator during elevation of the arm.

We begin to retrain the latissimus dorsi by positioning the patient's arm on a table at 45 degrees elevation in the POS and neutral rotation. The patient is asked to perform an isometric adduction contraction. At the same time the therapist positions the arm in slight external rotation. The patient is asked to hold the arm in this position. This "place-and-hold" technique is performed for all ranges of external rotation until the patient is able to perform a continuous arc of external rotation. The exercise is gradually progressed to greater degrees of elevation up to 90 degrees.

Another training technique we utilize is to position the patient supine with the elbow bent to 90 degrees. The therapist places his or her hands on the medial wrist and medial elbow of the patient. The patient is asked to simultaneously adduct and internally rotate into the therapist's hands while also raising the arm overhead. This simulates active elevation with a contraction of the latissimus to assist with centralization of the humeral head. This exercise is progressed by gradually raising the angle of the table and subsequently adding gravity until the patient can raise the arm against gravity. The latissimus never contracts without volitional control of the patient. Some patients are able to actively contract the latissimus while elevating the arm. These patients seem to achieve greater overhead function and power than those who are unable to learn this maneuver.

Beyond 12 weeks after surgery, emphasis is placed on improving the strength of the deltoid with both the supine elevation progression and elastic resistance in standing. Scapular strengthening exercises may also be added anytime after the 6-week postoperative period. Many patients are able to begin using the arm at shoulder level at this point. The patient will continue performing a home exercise program aimed at maximizing shoulder function for up to 6 to 12 months after surgery.

Glenohumeral Instability

Glenohumeral instability is defined as abnormal symptomatic translation of the humeral head relative to the glenoid. The incidence of anterior instability (80%) far exceeds that of posterior instability; however, some believe the true incidence of posterior instability (greater than 79%) is not appreciated due to spontaneous relocation and poor diagnostics.[55–57] The incidence of instability differs for those above and below 40 years of age, with a recurrence rate of more than 79% in those under 30 and 15% in those over 40.[56,58,59] The difference in recurrence rate is mostly related to activity level but also to connective tissue differences and associated pathology. One should recognize that the incidence of a rotator cuff tear in the older patient (over 40 years) who experiences an anterior dislocation can be as high as 85%.[60,61] Subluxation occurs when partial dissociation of the humerus and glenoid occurs, whereas dislocation occurs when the humerus and glenoid fully separate.

Instability can be classified several ways, the simplest of which are traumatic and atraumatic. Atraumatic instability can be further classified as voluntary and involuntary. Traumatic instability can result from a high-velocity uncontrolled end-range force causing a breach in the capsulolabral–bone interface or Bankart lesion. The acronym TUBS (*t*raumatic, *u*nilateral, *B*ankart lesion, *s*urgery indicated) is used to describe the characteristics of the traumatic group. Commonly these individuals require surgery to repair the Bankart lesion and to remain active and without recurrence of instability. A second acronym, AMBRI (*a*traumatic, *m*ultidirectional, *b*ilateral, *r*ehabilitation effective, *i*nferior capsular shift if surgery), is used to describe those who suffer from atraumatic instability. These individuals have a patulous capsule due to increased connective tissue elasticity, capsular stretching, or a combination of these two factors with dynamic stabilizer weakness. Commonly these individuals have symptomatic translation in multiple directions and are therefore described as having multidirectional instability. A strengthening program for the glenohumeral and scapulothoracic muscles may be beneficial to this group, but if they do not respond, a capsular shift may be required.[62]

A Bankart repair is performed to correct unidirectional shoulder instability by reattaching the detached labrum and associated glenohumeral ligaments with little disruption to the length or attachment of other structures around the shoulder. An open Bankart repair may involve detachment and later reattachment of the humeral insertion of the subscapularis and a reattachment of the labrum to the anterior glenoid with sutures through bone or with suture anchors.[63] It may also be necessary to reduce any capsular redundancy by tightening the anterior capsule with sutures. The disruption of the subscapularis has implications for postoperative rehabilitation. The surgeon will typically assess the amount of external range of motion available at the time of repair of the subscapularis. It is imperative the patient does not or is not stretched beyond this point during the first 6 to 8 weeks postoperatively. Greis et al. reported on several cases of subscapularis rupture within the first 4 weeks following surgery.[64] It should also be noted that open anterior stabilization can be associated with a 12-degree loss of shoulder external rotation.[65]

Recently, arthroscopic techniques to repair anterior unidirectional glenohumeral instability have been advocated. The advantages of arthroscopic repair include less invasive surgery, no damage to the subscapularis, and, therefore, less loss of external rotation than open procedures. Although there is no damage to the subscapularis during the arthroscopic repair, external rotation range of motion should still be restricted to 30 to 45 degrees during the first

6 to 8 weeks after surgery. Patients who have undergone arthroscopic stabilization may be held from performing PROM exercises for the first 6 weeks after surgery if the surgeon feels that they have adequate PROM during the first 7 to 10 days after surgery. These patients typically return 6 weeks after surgery with near full PROM.

A recent study compared two rehabilitation programs following arthroscopic Bankart repair.[66] One group was immobilized for 3 weeks after surgery prior to initiating ROM exercises. The second group began ROM and submaximal isometric exercises on the third postoperative day. There was no difference in recurrence rate, shoulder scores, return to activity, pain score, and ROM between the two groups at the final follow-up evaluation. However, the group who began rehabilitation sooner demonstrated a faster return to functional ROM and activity, as well as more satisfaction with the rehabilitation program.

Rehabilitation Following Bankart Repair

Phase I

Patient education is important in the early phases following surgery. Patients are instructed to use their arm for waist level activities when tolerated. They are cautioned about lifting anything, particularly by pushing the hands together (internal rotation), sleeping on the surgical side, leaning on the elbow, and making sudden movements. They are encouraged to use ice frequently throughout the day. When sitting, the patient is encouraged to position the arm on a pillow or armrest in slight abduction and the arm in neutral rotation. This helps to prevent prolonged internal rotation contractures.

The patient will be shown pendulum exercises the day of surgery and is to perform them four to six times per day (Table 40-5). Hand and wrist exercises are also encouraged.

TABLE 40-5
PENN PRESBYTERIAN MEDICAL CENTER SHOULDER AND ELBOW SERVICE REHABILITATION GUIDELINES FOLLOWING BANKART PROCEDURE

Phase I: 0–4 Weeks (Exercise 4–6 Times per Day)

Goals:
1. Patient education
2. Permit capsuloligamentous labral healing
3. Control pain and inflammation
4. Initiate ROM exercises

Treatment:
Postoperative day 1:
1. Educate patient on precautions
2. Pendulum exercises
3. Elbow AROM, hand-squeeze exercises
4. Ice (instruct patient on use of ice at home)

Postoperative days 7–10:
1. Continue with pendulum exercises
2. Phase I stretching
   Forward elevation
   ER at 45 degrees in POS (limit range to 30 degrees)

Phase II: 4–6 Weeks

Goals:
1. Decreased pain and inflammation
2. Normal arthrokinematics of glenohumeral and scapulothoracic joint
3. Improve strength

Treatment:
1. Continue with above treatment
2. Phase II stretching (extension, IR, cross-body adduction)
3. Manual resistance for glenohumeral and scapulothoracic stabilization
4. Phase I strengthening (at 6 weeks; ER, IR, extension)
5. Add shoulder shrugs and scapular retraction

Phase III: 6–12 Weeks

Goals:
1. Increase strength of rotator cuff and deltoid
2. Increase strength of scapular muscles
3. Increase total arm strength (biceps, triceps, forearms, etc.)
4. Initiate strengthening in provocative positions

Treatment:
1. Continue with above (decrease frequency of stretching exercises)
2. Add phase II strengthening when at green for phase I strengthening (abduction, forward elevation, ER at 45 degrees in POS); progress strengthening to more provocative positions
3. Variable resistance and/or free-weight resistance
5. Bodyblade progression
6. Plyoball progression (begin with chest pass)

Phase IV: 12–16 Weeks

Goals:
1. Initiate return to sport or occupational activity*

Treatment:
1. Bodyblade in overhead positions
2. Plyoball throwing
3. Work-/sport-specific activities*

*Applies to athlete or laborer.
AROM, active range of motion; ER, external rotation; IR, internal rotation; POS, plane of the scapula; ROM, range of motion.
Reprinted with permission from Penn Presbyterian Medical Center, Shoulder and Elbow Service.

The patient will typically be asked to use the sling for comfort or when out in public. At 1 to 2 weeks postoperative, the patient is examined at the surgeon's office. If the surgeon feels that there is inadequate shoulder range of motion, the patient will begin phase I PROM exercises of forward elevation utilizing the opposite hand, and external rotation with the arm at 45 degrees in the POS utilizing a cane or stick. External rotation should not exceed 30 to 45 degrees or the amount of motion achieved in the operating room for an open procedure. Assessment of generalized hyperelasticity and hypoelasticity should be performed and will guide the progression of ROM exercise. If a hyperelastic patient presents with 150 degrees of elevation and 45 degrees of external rotation within the first 6 weeks following surgery, ROM exercises will be discouraged. However, if a hypoelastic patient presents with significant restriction within the first 6 weeks postsurgery, ROM and stretching will be encouraged.

Phase II

Depending on the status of the patient and quality of repair, the patient will be progressed to phase II ROM and phase I strengthening exercises at 4 to 6 weeks. Either an elastic band or free weights (0.5 to 2 lb) can be used. Stretching is continued in all directions. If the patient is being followed in a supervised manner, manual resistance starting at 45 degrees in the POS can be initiated using alternating isometrics. Scapular muscle integration and appropriate scapulohumeral rhythm is encouraged in all strengthening exercises. The patient can be progressed to phase II strengthening if he or she is able to perform phase I exercises with the third level of elastic resistance or a 4-lb dumbbell. If excessive stiffness is demonstrated, more progressive stretching is performed and joint mobilization techniques can be utilized. Rotational strengthening exercises may be progressed to 45 degrees of elevation.

Phase III

At this time the patient can be progressed to light-weight isotonics, using free weights or variable resistance units. Many times these exercises can be initiated in the latter part of phase II. Strengthening of the biceps and triceps can be initiated. The shoulder should remain in a protected position (less than 20 degrees of elevation) and the scapula "fixed" to integrate scapular muscle function into the exercise. A rowing exercise also can be performed with the same type of resistive equipment. Elastic band or free-weight strengthening is progressed in resistance, repetition, and position of elevation. Diagonal patterns (D2 and D1) can be incorporated into the program. The patient can progress to latissimus pull-downs performed in front of the body. The upper body ergometer (UBE) may be used with motion performed in each direction. The Bodyblade may be used in nonprovocative positions with progression to functional positions and increased time intervals of up to 60 seconds (Chapter 39, Fig. 39-27). The Plyoball progression may be used, particularly if the patient is a competitive or recreational athlete or laborer (Chapter 39, Figs. 39-28 and 39-29). Stretching should continue in this phase until full elevation is achieved and external rotation stretching is progressed to 90 degrees of abduction (90/90 position). External rotation at neutral still may be lacking up to 20 degrees, but external rotation at 90 degrees of elevation should be within 10 degrees of the other side. One must remember that collagen tissue continues to remodel for up to 12 months; therefore, further gains will be achieved over time.

The Athlete

The throwing athlete will be progressed at an accelerated pace, relative to external rotation stretching in phase II since this motion is critical to performance; however, stability cannot be sacrificed. In phase III the throwing or swimming athlete will be advanced to the provocative positions for their glenohumeral dynamic stabilizer exercises. Specific manual techniques may be emphasized for the glenohumeral dynamic stabilizers and scapular muscles. Cardiovascular exercise is strongly encouraged in the group.

Phase IV

Patients will be progressed to phase IV at 12 to 16 weeks and can begin to participate in their particular activities. The swimmer is encouraged to perform slow strokes. The basketball player can begin shooting. The thrower can begin light throwing of a tennis ball; the patient then moves back into an interval program over weeks 14 to 20. Patients can progress their variable resistance for a free program. Chest pressing can be initiated after 14 weeks; however, the degree of horizontal abduction may be limited and weight will be added gradually. We also encourage patients to begin chest presses with a machine that will allow restricted and protected movement.

Rehabilitation Following Anterior Capsulorrhaphy

Anterior capsulorrhaphy is performed to reduce the volume within a redundant capsuloligamentous complex (CLC). The degree of CLC redundancy can vary significantly. Thus, one may encounter a throwing athlete with minimal redundancy and "stiff" connective tissue as opposed to an individual with a very patulous CLC and "loose" connective tissue who has undergone unsuccessful stabilization procedures or has true multidirectional instability. These two types of athletes would be progressed very differently, but with the ultimate goal of allowing CLC

healing and optimizing neuromuscular control. In the throwing athlete, near-normal ROM would be encouraged, whereas in the individual with failed previous surgeries, ROM restrictions of 10 to 20 degrees may be encouraged. Phase I may be slightly more protracted after capsulorrhaphy as compared with phase I after an open Bankart procedure.

Phase I

Patient education is emphasized and is identical to that of the postoperative Bankart patient. The patient's arm is placed in a sling following surgery. The initiation of pendulum exercises varies based on the patient's connective tissue elasticity and the surgeon's preference. Pendulum exercises typically are started within the first 4 weeks (Table 40-6). Some patients may not begin any type of ROM exercises until 6 weeks.

Phase II

After 4 to 6 weeks the patient may begin PROM forward elevation with the opposite hand and passive external rotation with the arm placed in 45 degrees in the POS. Forward elevation may be limited to 90 degrees and external rotation may be limited to neutral until 6 to 8 weeks after surgery. At this point, the patient can begin phase II ROM exercises and phase I strengthening exercises using elastic band and/or free weights (0.5 to 2 lb). Elevation exercises are continued, moving toward full range. External rotation stretching may be limited to no more than 45 degrees in the POS. External rotation at 90 degrees in the POS is checked and should not progress beyond 70 degrees. The goal is for this patient to have some degree of tightness by the end of 12 weeks. Approximately 10 to 20 degrees of limited motion in all planes is desired at 12 weeks because continued collagen remodeling will occur over time. This may vary depending on the extent of the capsulorrhaphy

TABLE 40-6
PENN PRESBYTERIAN MEDICAL CENTER SHOULDER AND ELBOW SERVICE REHABILITATION GUIDELINES FOLLOWING ANTERIOR CAPSULORRAPHY

Phase I: 0–4 Weeks

Goals:
1. Patient independent with precautions and home exercise program prior to discharge from hospital (typical inpatient hospital stay = 1 day).
2. Permit capsular healing
3. Control pain and inflammation
4. ROM exercises will be initiated depending on surgeon's preference

Postoperative day 1:
1. Educate patient on precautions
2. Pendulum exercises (25 times in each direction), depending on surgeon
3. Elbow AROM, hand-squeeze exercises
4. Ice (instruct patient on use of ice at home)

Phase II: 4–6 Weeks

Goals:
1. Decreased pain and inflammation
2. Normal arthrokinematics of glenohumeral and scapulothoracic joint
3. Improved strength

Treatment:
1. Continue with above treatment
2. Add phase I stretching (forward elevation and ER in POS); limit ER to 45 degrees
3. Manual resistance for glenohumeral and scapulothoracic stabilization
4. Add phase I strengthening
5. Add shoulder shrugs and scapular retraction
6. Bodyblade in POS

Phase III: 6–12 Weeks

Goals:
1. Increase strength of rotator cuff and deltoid
2. Increase strength of scapular muscles
3. Increase total arm strength (biceps, triceps, forearms, etc.)
4. Initiate strengthening in provocative positions

Treatment:
1. Continue with above (decrease frequency of stretching exercises)
2. Add phase II stretching (extension, IR, cross-body adduction)
3. Add phase II strengthening (abduction, forward elevation, ER at 45 degrees in POS)
4. Variable resistance and/or free-weight resistance
5. Bodyblade in nonprovocative positions with progression to functional positions
6. Plyoball progression (begin with chest pass)

Phase IV: 12–16 Weeks

Goals:
1. Initiate return to sport or occupational activity*

Treatment:
1. Bodyblade in overhead positions
2. Plyoball throwing
3. Work-/sport-specific activities*

*Applies to athlete or laborer.
AROM, active range of motion; ER, external rotation; IR, internal rotation; POS, plane of the scapula; PROM, passive range of motion; ROM, range of motion.
Reprinted with permission from Penn Presbyterian Medical Center, Shoulder and Elbow Service.

and if the patient has hyperelastic tissue. Manual strengthening techniques using alternating isometrics in the midrange are strongly emphasized. Although the capsule has been tightened, it is critical that the glenohumeral dynamic stabilizer function be optimized. Short arc manual resistive exercises and/or the use of free weights are utilized in an effort to maximize these muscles in their stabilization function across the glenohumeral joint. Scapular muscle integration is again strongly emphasized. Use of the UBE may begin, again performed in both directions. The Bodyblade can be started toward the end of the phase at 10 to 12 weeks, starting in the nonprovocative position.

Phase III

The patient follows the same regimen as described for that following the Bankart procedure. Again, strong emphasis is placed in midrange function with strengthening being performed and progressed toward the end range. The use of the Plyoball will be based on the functional demands of the patient. If the patient is an athlete or laborer and therefore requires use of the arm in provocative positions, then plyometrics will be utilized in phase III. Various resistance exercises are also performed.

Phase IV

The patient is progressed to activities of phase IV at approximately 16 weeks. If the patient is a throwing athlete, an interval program is initiated. For a swimming athlete, progression will be slow, with initial work on stroke and technique and finally distance. The patient will not be encouraged to aggressively stretch as many swimmers tend to do because such an action may stretch out the reconstruction. A gradual return of ROM will be encouraged in the next 6 to 9 months.

Rehabilitation Following Thermal Capsulorraphy

The arthroscopic application of thermal energy to selectively shrink the glenohumeral joint capsule has been developed over the past 8 to 10 years.[67–70] Several authors have reported 82% to 93% return to competition following thermal-assisted capsulorraphy procedures in overhead athletes.[71–74] However, the use of thermal capsulorraphy to correct shoulder instability may be declining due to poor outcomes reported with this procedure in some patients.[75]

Phase I

Since the early capsular tensile strength is presumed to be weak, the early rehabilitation program is more conservative than other stabilization procedures.[76] The goal in the immediate postoperative period of 4 to 6 weeks is to allow healing of the tissue. This phase consists of distal arm strengthening exercises and providing pain relief.[76] Patients are encouraged to keep their arm in a sling most of the day and perform hand squeezes and elbow ROM exercises. They are able to use their arm for waist-level activities and basic activities of daily living.

Phase II

This phase begins 4 to 6 weeks after surgery. Range of motion and rotator cuff strength are assessed at this time. Many patients present with full passive forward elevation and little restriction of external rotation. Patients who may have a restriction in these two motions will be instructed in pendulum exercises and phase I ROM exercises such as forward elevation and external rotation. The patient is encouraged to apply a gentle stretch to the end range of motion to allow gradual and progressive restoration of range of motion.

Phase I strengthening exercises with elastic resistance for external rotation, internal rotation, and extension are initiated at this time as well. Scapular strengthening exercises such as scapular retraction without resistance and progressing toward elastic resistance can also be added at this time. Manual resistance for alternating isometrics to promote stability and proprioception are also useful at this stage. Scapular muscle integration and appropriate scapulohumeral rhythm is encouraged in all strengthening exercises. Patients can be progressed to phase II strengthening if they are able to perform phase I exercises with the third level of elastic resistance or a 4-lb dumbbell.

Phase III

Patients should have achieved nearly full or full range of motion and rotator cuff strength relative to the opposite extremity by 12 weeks postoperative.[77] At this time the patient can be progressed to light-weight isotonics, using free weights or variable resistance units. Many times these exercises can be initiated in the latter part of phase II. Strengthening of the biceps and triceps can also be initiated. A seated row exercise with resistive equipment can be performed. Elastic band or free-weight strengthening is progressed in resistance, repetition, and position of elevation. Diagonal patterns (D2 and D1) can be incorporated into the program. The patient can progress to latissimus pull-downs performed in front of the body. It is very important to emphasize this position and discourage the performance of this exercise with the bar brought behind the head due to the potential stress on the anterior glenohumeral joint. The UBE may be used with motion performed in each direction. The Bodyblade may be used in nonprovocative positions with progression to functional positions and increased time intervals of up to 60 seconds (Chapter 39, Fig. 39-27). The plyoball progression may be

used, particularly if the patient is a competitive or recreational athlete or laborer (Chapter 39, Figs. 39-28 and 39-29).

The Athlete

The throwing athlete will be progressed at an accelerated pace, relative to external rotation stretching in phase II since this motion is critical to performance; however, stability cannot be sacrificed. In phase III throwing or swimming athletes will be advanced to the provocative positions for their glenohumeral dynamic stabilizer exercises. Specific manual techniques may be emphasized for the glenohumeral dynamic stabilizers and scapular muscles. Cardiovascular exercise is strongly encouraged in the group.

Phase IV

Patients will be progressed to phase IV at 12 to 16 weeks and can begin to participate in their particular activities. The swimmer is encouraged to perform slow strokes. The basketball player can begin shooting. The thrower can begin light throwing of a tennis ball; the patient then moves back into an interval program over weeks 14 to 20. Patients can progress their variable resistance for a free program. Chest pressing can be initiated after 14 weeks; however, the degree of horizontal abduction may be limited and weight will be added gradually. We also encourage patients to begin chest presses with a machine that will allow restricted and protected movement.

SLAP Lesions

Superior labrum anterior-posterior (SLAP) lesions have been classified into four distinct categories based on the labral injury and the stability of the labrum–biceps complex found at arthroscopy.[78] Subsequent authors have added additional classification categories and specific subtypes.[79–81] Type I lesions denote fraying and degeneration of the superior labrum with a normal biceps tendon anchor. Type II lesions may have fraying of the superior labrum, but their hallmark is a pathologic detachment of the labrum and biceps anchor from the superior glenoid. In type III SLAP lesions, the superior labrum has a vertical tear analogous to a bucket-handle tear in the meniscus of the knee. A type IV pattern involves a vertical tear of the superior labrum, but this superior labral tear extends to a variable extent up into the biceps tendon as well. The torn biceps tendon tends to displace with the labral flap into the joint, whereas the biceps anchor itself remains firmly attached to the superior glenoid. Last, a complex of two or more SLAP lesions may occur, with the most common presentation being a type II and a type IV.[82]

Surgical treatment of SLAP lesions is generally performed as described by Snyder et al.[78,82] Type I lesions, seen as significant fraying about the superior labrum, are débrided with a shaver placed through the anterior portal.[83] Type II lesions, in which the biceps origin and superior labrum are detached from the bony base of the glenoid, are treated, depending on the instability of the lesion and the age of the patient.[83] Some type II lesions are relatively stable and can be treated by débridement and bony abrasion alone.[83] When the labral detachment is significant and it can easily be pulled off of the superior glenoid, either repair or tenodesis should be considered.[83] Younger patients and those who engage in overhead activities are treated with repair. Tenodesis may be preferred for some patients generally over the age of 45 and who do not regularly participate in overhead activities.

Treatment of type III lesions is generally accomplished with débridement of the flapped labrum.[83] Type IV lesions are treated depending on the amount of biceps tearing. Those lesions with less than 25% extension into the biceps tendon are treated with débridement alone.[83] Those with more than 25% extension into the biceps tendon are treated with either repair in younger patients or tenodesis in older patients.[83]

The characteristics of rehabilitation following a SLAP lesion débridement or repair are very similar to those found in the rehabilitation following rotator cuff repair and Bankart lesion. Any position, which may create tension on the biceps, should be avoided during the first 6 weeks following surgery and approached with caution thereafter. These positions include shoulder extension, internal rotation behind the back, and using the arm to carry or lift objects with the elbow extended. In addition, external rotation with the arm at 90 degrees of abduction should be approached with caution. When a biceps tenodesis is performed, any resistive active motion of the elbow, either in flexion or supination, is avoided.[83]

Phase I

Patients are instructed in the precautions as described previously. A sling is used for comfort during the first 7 to 10 days following surgery. Phase I ROM exercises are then initiated and performed to tolerance (Table 40-7). The surgeon may request that external rotation range of motion be limited to 45 degrees in patients who have evidence of a peel-back tear. Patients are expected to achieve full passive forward elevation 6 weeks following surgery.

Phase II

This phase begins 6 weeks after surgery. Active and passive range of motion as well as rotator cuff and deltoid strength are assessed at this time. Patients are instructed in phase II ROM exercises (extension, internal rotation, cross-body adduction) and phase I of the strengthening exercises (external rotation, internal rotation, extension). Scapular retraction exercises with elastic resistance can also be performed at this time.

TABLE 40-7
PENN PRESBYTERIAN MEDICAL CENTER SHOULDER AND ELBOW SERVICE REHABILITATION GUIDELINES FOLLOWING SLAP REPAIR

Phase I: 0–6 Weeks (Exercise 3–5 Times per Day)

Goals:
1. Patient education
2. Permit capsuloligamentous labral healing
3. Control pain and inflammation
4. Initiate ROM exercises

Treatment:
Postoperative day 1—first postoperative visit:
1. Educate patient on precautions
2. Ice (instruct patient on use of ice at home)

Postoperative days 7–10:
1. Educate patient on precautions
2. Instruct in pendulum exercises
3. Phase I stretching
   Forward elevation
   ER at 45 degrees in POS (limit range to 30 degrees)

Phase II: 6–8 Weeks

Goals:
1. Decreased pain and inflammation
2. Normal arthrokinematics of glenohumeral and scapulothoracic joint
3. Improve strength

Treatment:
1. Continue with above treatment
2. Phase II stretching (extension, IR, cross-body adduction)
3. Manual resistance for glenohumeral and scapulothoracic stabilization
4. Phase I strengthening (at 6 weeks; ER, IR, extension)
5. Add shoulder shrugs and scapular retraction

Phase III: 8–12 Weeks

Goals:
1. Increase strength of rotator cuff and deltoid
2. Increase strength of scapular muscles
3. Increase total arm strength (biceps, triceps, forearms, etc.)
4. Initiate strengthening in provocative positions

Treatment:
1. Continue with above (decrease frequency of stretching exercises)
2. Add phase II strengthening when at green for phase I strengthening (abduction, forward elevation, ER at 45 degrees in POS); progress strengthening to more provocative positions
3. Variable resistance and/or free-weight resistance
4. Bodyblade in nonprovocative positions and progress to functional positions
5. Plyoball progression (begin with chest pass)

Phase IV: 12–16 Weeks

Goals:
1. Initiate return to sport or occupational activity*

Treatment:
1. Bodyblade in overhead positions
2. Plyoball throwing
3. Work-/sport-specific activities*

*Applies to athlete or laborer.
ER, external rotation; IR, internal rotation; POS, plane of the scapula; ROM, range of motion.
Reprinted with permission from Penn Presbyterian Medical Center, Shoulder and Elbow Service

Phase III

This phase begins 10 to 12 weeks after surgery and continues until week 16. Patients who are able to perform the phase I strengthening exercises with the green band are instructed in phase II strengthening (abduction, forward elevation, external rotation supported at 45 degrees). Advanced scapular strengthening exercises may be employed at this time. In addition, biceps strengthening with light weights may begin.

Phase IV

This phase typically begins at 16 weeks and continues for up to 6 months postoperatively. Patients are instructed in the biomechanics of lifting in an effort to reduce the risk of overload. For the athlete, sport-specific training can begin utilizing plyometrics to enhance neuromuscular control, strength, and proprioception. Recommendations and instruction for proper use of gym equipment should also be done at this time. Patients should be encouraged to avoid exercises with the arm behind the plane of the body. Latissimus pull-downs should be performed to the chest, not behind the head. Caution should be employed when performing any type of "pushing" exercise such as chest press or shoulder press. It is safer to perform these exercises with a machine to allow for greater safety.

The patient who must return to work is gradually progressed to work-simulated activities. Emphasis is placed on simulating work activities in a safe, effective manner. The patient is educated on proper lifting mechanics, ergonomic modifications, and common sense.

PROXIMAL HUMERUS FRACTURES

Fractures of the proximal humerus can produce as many as four major fracture fragments.[84] These include the head, the greater tuberosity, the lesser tuberosity, and the shaft of the proximal humerus. Neer introduced a four-part classification system based on the anatomic and biomechanical forces that contribute to the displacement of the fracture fragments.[85,86] Displacement is defined as greater than or equal to 1 cm of translation or 45 degrees of angulation from the fragment's normal anatomic position as seen on radiographs.[86] A proximal humerus fracture in which none of the major fragments is displaced is a one-part or nondisplaced proximal humerus fracture.

Management of proximal humerus fractures varies depending on the type and amount of displacement. A majority of proximal humerus fractures are nondisplaced and do not require surgery.[86–89] In these cases, the patient's arm is placed in a sling with the arm at the side. In some two-, three-, and four-part proximal humerus fractures, surgery is indicated. The preferred methods include closed reduction, open reduction and internal fixation, and prosthetic arthroplasty.[90] The type of fracture present as well as the medical and functional status of the patient determine the type of procedure to be performed.[90]

Communication between the therapist, surgeon, and patient is essential to successful rehabilitation following proximal humerus fracture.[85] The rate of exercise advancement is coordinated with the surgeon and depends on the severity of the fracture, stability of reduction, and formation of callus.[85] In most cases, the patient has never had a previous shoulder injury. Therefore, the patient should be educated on the importance of performing a home exercise program, techniques for pain relief, the length of the rehabilitation process, and expected outcome. Several factors affect outcome, including patient age and compliance with the home exercise program, complexity of the fracture, type of reduction, and soft tissue involvement.[85]

A detailed history should be obtained from the patient and should include mechanism of injury, presence of additional injuries, prior functional status, and patient's goals. Proximal humerus fractures result primarily from low bone mass and falls.[91–95] These fractures appear to be associated with fractures and fall history; medical conditions such as epilepsy, depression, and diabetes; use of seizure medication; and left-handedness.[91] To help prevent another proximal humerus fracture, recommendations for those at risk for a proximal humerus fracture may include moderate levels of physical activity, use of calcium carbonate tablets as a calcium supplement, other measures to reduce loss of bone mass and prevent falls, and maintaining a high dietary calcium intake.[91] If the physician has not provided a detailed description of the type and stability of the fracture, the therapist should obtain this information prior to initiating movement of the extremity. The therapist should also perform a good neurovascular examination of the distal extremity.

Phase I

The rehabilitation process may begin when the surgeon is confident that adequate stabilization of the fracture has been achieved. This can be as early as the first postoperative day in many cases. In those cases in which surgery has not been performed or less than ideal fixation has been achieved, the rehabilitation program may require modification.

The importance of performing the home exercise program four to six times per day should be emphasized to the patient. Pain is a major consideration in this population and should always be respected. Many patients with proximal humerus fractures have never had shoulder pain similar to the magnitude they now experience; therefore, it is occasionally more difficult to motivate them to perform their home exercise program. Initial exercises include pendulums, supine passive forward elevation with the opposite hand, and supine passive external rotation with a stick. Patients are slowly advanced to passive extension, internal rotation, and cross-body adduction at approximately 6 weeks postfixation. Special consideration is given to those patients with greater tuberosity fractures because these exercises provide tension to the rotator cuff and its attachment. If excessive tightness is determined, joint mobilization is implemented to facilitate the return of motion.

Phase II

Approximately 6 to 8 weeks postfixation, the patient should have achieved an improvement in passive ROM. Rotator cuff strengthening with isometrics and/or Theraband can begin at this time. In addition, scapular strengthening exercises also may be initiated. If the patient is being followed in supervised therapy, manual isometrics at 45 degrees in the POS can be introduced.

Phase III

Approximately 8 to 12 weeks postfixation, the patient should have 80% full passive ROM and good rotator cuff strength. Phase III strengthening exercises with the elastic band can begin at this time. These exercises include abduction to 45 degrees, forward elevation, and external rotation at 45 degrees. Progression of resistance for shoulder shrugs, scapular retraction, biceps curls, and triceps extension is also accomplished. For patients who are being followed in supervised therapy, manual resistance in unsupported positions can be progressed utilizing alternating isometrics and proprioceptive neuromuscular facilitation (PNF) diagonals.

GLENOHUMERAL ARTHRITIS

Several diseases affect the osteoarticular surface of the glenohumeral joint and can result in the need for surgical intervention. The most common among these disorders include degenerative osteoarthritis, traumatic arthritis, osteonecrosis, arthritis of glenohumeral instability, rheumatoid arthritis, rotator cuff arthropathy, and crystal-induced arthritis.[90,96–98] Other less common disorders include hemophilic arthropathy, Paget's disease, psoriasis, and ochronosis.[90] Arthritic conditions can cause deformity of the normal articulating surfaces, loss of the articular cartilage, and synovitis associated with generalized joint inflammation.[90] As a result, the patient may experience joint pain, instability, limited active and passive ranges of motion, and decreased strength, which limits the patient's daily, recreational, and work activities.[90] The primary indication for prosthetic arthroplasty is pain that limits functional activity and is not improved with conservative management.[90] Limited ROM in the absence of pain is not an indication for surgery.[98]

Prosthetic joint replacement can include total shoulder arthroplasty or hemiarthroplasty (proximal humeral replacement). Indications for hemiarthroplasty include conditions in which the glenoid is intact, such as acute proximal humerus fractures, avascular necrosis, and younger patients.[90,98–100] Another indication for hemiarthroplasty is patients who have massive, irreparable deficiencies of the rotator cuff such as those with cuff tear arthropathy, crystal-induced arthritis, and rheumatoid arthritis.[29,30,100] Patients with massive rotator cuff deficiency have a higher incidence of glenoid component loosening than patients with the same disease process but an intact rotator cuff.[100] Therefore, hemiarthroplasty is the preferred procedure for these patients.[90] Total shoulder arthroplasty in patients with an intact rotator cuff and significant glenoid degeneration will result in improved shoulder mechanics and postoperative pain level.[90,97,98]

Postoperative Rehabilitation

Good communication between the rehabilitation specialist and orthopedic surgeon is critical to successful outcome after shoulder arthroplasty. Rehabilitation after shoulder arthroplasty depends on the underlying diagnosis, integrity of the rotator cuff, and variations in surgical technique. The rehabilitation specialist should know the amount of external rotation and forward elevation achieved by the surgeon at the time of wound closure.[90] The kind of joint stability and quality of the subscapularis repair should be determined. The patient's goals and motivation to participate in the rehabilitation process are also significant factors affecting outcome. Neer recommended classifying patients into standard goals and limited goals categories.[98] Those patients with good preoperative ROM and rotator cuff function are placed into the standard goals category (Table 40-8). Patient's with poor postoperative ROM and/or poor or ruptured rotator cuffs are classified as having limited goals. It is essential for the rehabilitation specialist to have knowledge of as much of these factors as possible prior to initiating the rehabilitation program (Table 40-9).

Phase I

Patients are typically hospitalized for 2 days after surgery. During this time, emphasis is placed on patient education and a core of essential ROM exercises. The rehabilitation process begins the morning of the first postoperative day with patient education. The patient is told to expect swelling and discoloration of the affected extremity and occasionally of the chest wall as a result of the surgery. With the exception of special cases, patients are encouraged to refrain from using the sling unless they are in public or experiencing discomfort. They are also instructed in the use of ice for control of pain and inflammation. Patients can use their extremity for waist-level activities and bring their hand to the mouth with the elbow held at the side. Patients are also asked to not sleep on or make sudden movements with the operated side. In addition, they are asked to avoid lifting, carrying, pushing, pulling, and leaning on the affected side. Evaluation should include documentation of distal neurovascular status and passive arcs of forward elevation and external rotation. In addition, knowledge and documentation of external rotation, forward elevation, and ROM achieved by the surgeon in the operating room is important. To respect the healing of the subscapularis, the patient should be instructed to not exceed the external rotation limitation during the first 6 weeks after surgery.

It should be emphasized that all exercises are to be performed four to six times per day. To help maintain distal upper-extremity strength and decrease distal extremity swelling, the patient is instructed in hand-squeezing exercises and elbow-active ROM. The patient is also instructed in pendulum exercises, which are to be performed 25 times in each direction. Supine passive forward elevation with the opposite hand and external rotation with a stick or the opposite hand holding the forearm are instituted in the afternoon session on the first postoperative day. Patients are asked to perform these exercises in their room when they are not being seen by the therapist. Criteria for discharge from the hospital include independence with the exercise program and precautions, passive forward elevation of 120 degrees, and passive external rotation of 20 degrees.

Patients in the limited goals category often have bilateral shoulder disease or polyarticular arthritis and may require modification of the exercise program. This may include help from a family member or arrangement of home or outpatient therapy.

TABLE 40-8

PENN PRESBYTERIAN MEDICAL CENTER SHOULDER AND ELBOW SERVICE REHABILITATION GUIDELINES FOLLOWING TOTAL SHOULDER ARTHROPLASTY

Phase I: 0–3 Weeks (Exercise 4–6 Times per Day)

Goals:
1. Patient education
2. Allow healing of subscapularis
3. Control pain and inflammation
4. Initiate ROM exercises

Postoperative day 1 (a.m. session):
1. Educate patient on precautions
2. Pendulum exercises
3. Elbow AROM, hand-squeeze exercises
4. Ice (instruct patient on use of ice at home)

Postoperative day 1 (p.m. session):
1. Review precautions
2. Pendulums, elbow AROM, and hand squeezes
3. Supine passive forward elevation stretching in POS
4. Supine passive ER stretching in POS (within limits of range achieved in OR)
5. Ice

Postoperative days 2–5:
1. Continue with above until patient is independent with home exercises and precautions
2. Begin light ADLs (hand to mouth, writing, etc.)
3. Ice

Postoperative days 7–10 (first MD visit postoperative):
1. Review home exercise program
2. Add phase II stretching (if good tissue quality) PROM extension, IR, and cross-body adduction

Phase II: 3–8 Weeks

Goals:
1. Decreased pain and inflammation
2. Increased ADLs
3. Continue stretching until full PROM is achieved
4. Initiate strengthening exercises

Treatment:
1. Review all exercises and precautions
2. Add phase II stretching (if not already)
3. Initiate light isometrics for rotator cuff (may omit IR depending on healing of subscapularis)
4. Progress to phase I strengthening at 4–6 weeks (ER, IR, extension)
5. Scapular strengthening (shoulder shrugs, scapular retraction)

Phase III: 6–12 Weeks

Goals:
1. PROM full and pain free
2. Increase functional activities
3. Increase strength of scapular stabilizers

Treatment:
1. Phase II strengthening (abduction, forward elevation, ER at 45 degrees in POS)
2. Upper-extremity PNF diagonals
3. Progress resistance of shoulder shrugs, scapular retraction, biceps, triceps

Phase IV: 12–16 Weeks

Goals:
1. Full functional activities
2. Return to work or sport*

Treatment:
1. Work- or sport-specific training*
2. Suggest modifications to work, sport, or functional activities*

*Applies to athlete or laborer.
ADL, activity of daily living; AROM, active range of motion; ER, external rotation; IR, internal rotation; OR, operating room; PNF, proprioceptive neuromuscular facilitation; POS, plane of the scapula; PROM, passive range of motion; ROM, range of motion.

Phase II

Patients continue all stretching exercises until full passive ROM is achieved. At 3 to 6 weeks after surgery, patients in the standard goals category should be able to perform many of their waist-level activities of daily living. At 6 weeks after surgery, phase II ROM exercises (extension, internal rotation, and cross-body adduction) and phase I strengthening exercises with elastic bands can be instituted and progressed. When the patient is able to perform all phase I exercises with the green band, phase II strengthening exercises can begin. In addition, shoulder shrugs and scapular retraction exercises can begin.

Patients who are having difficulty achieving full passive ROM may be followed in supervised therapy. Glenohumeral joint mobilizations and gentle manual stretching can be initiated to help improve ROM. The patient may also be given a pulley for home use to help achieve full passive forward elevation. Manual resistance to external and internal rotation with the arm supported at 45 degrees in the POS can be initiated using alternating isometrics.

Patients in the limited goals category will begin the phase II stretching exercises at 3 to 6 weeks postoperatively. They may also initiate submaximal rotator cuff isometrics and scapular strengthening at this time.

TABLE 40-9

PENN PRESBYTERIAN MEDICAL CENTER SHOULDER AND ELBOW SERVICE REHABILITATION GUIDELINES FOLLOWING TOTAL SHOULDER ARTHROPLASTY—LIMITED GOALS

Phase I: 0–3 Weeks (Exercise 4–6 Times per Day)

Goals:
1. Stress importance of precautions and performance of home exercise program
2. Allow healing of subscapularis
3. Control pain and inflammation
4. Initiate ROM exercises (instruct family member, etc., in exercises)

Postoperative day 1 (a.m. session):
1. Educate patient on precautions
2. Pendulum exercises
3. Elbow AROM, hand-squeeze exercises
4. Ice (instruct patient on use of ice at home)

Postoperative day 1 (p.m. session):
1. Review precautions
2. Patient performs pendulums, elbow AROM, and hand squeezes
3. Supine passive forward elevation stretching in POS*
4. Supine passive ER stretching in POS (within limits of range achieved in OR)*

Postoperative days 2–5:
1. Continue with above until patient is independent with home exercises and precautions
2. Add standing AAROM extension with stick
3. Begin light ADLs (hand to mouth, writing, etc.)
4. Ice

Postoperative days 7–10:
1. Review home exercise program

Phase II: 3–8 Weeks

Goals:
1. Decrease pain and inflammation
2. Increase ADLs

Treatment:
1. Review all exercises and precautions
2. Phase II stretching (PROM extension, IR, and cross-body adduction)
3. Submaximal rotator cuff isometrics

Phase III: 8–12 Weeks

Goals:
1. ROM full and pain free
2. Increase functional activities
3. Begin rotator cuff strengthening

Treatment:
1. Continue with above
2. Phase I strengthening (ER, IR, extension)

Phase IV: 12–16 Weeks:

Goals:
1. Return to functional activities
2. Continue to improve strength

Treatment:
1. Continue with all stretches and strengthening
2. Add scapular strengthening
3. Add phase II strengthening if able

*Instruct patient or caregiver.
ADL, activity of daily living; AAROM, active assisted range of motion; AROM, active range of motion; ER, external rotation; IR, internal rotation; OR, operating room; POS, plane of the scapula; PROM, passive range of motion; ROM, range of motion.

Phase III

Twelve weeks after surgery, the patient should have 80% full and pain-free passive ROM, as well as good rotator cuff strength. Phase II strengthening exercises with the elastic band can usually begin if they have not already. These exercises include abduction to 45 degrees, forward elevation, and external rotation with the arm supported at 45 degrees. Progression of resistance for shoulder shrugs, scapular retraction, biceps curls, and triceps extension is accomplished. For patients who are being followed in supervised therapy, manual resistance in unsupported positions can be progressed utilizing alternating isometrics and PNF diagonals. Patients with limited goals should have adequate soft tissue healing and stability of the glenohumeral components and can begin phase I strengthening exercises.

Evaluation of the integrity of the subscapularis may also be performed at this time. Miller and colleagues[101] performed a retrospective review of 41 patients following total shoulder arthroplasty. Terminal internal rotation was evaluated by the lift-off and belly-press examinations. Abnormal results were found for 25 of 37 lift-off examinations (67.5%) and 24 of 36 belly-press examinations (66.6%). Of 25 patients with an abnormal lift-off finding, 92% reported reduced subscapularis function.

Phase IV

The patient will be progressed to this phase at approximately 16 weeks postsurgery. This phase includes work- or sport-specific training as well as suggestions for modification of work, sport, or functional activities. Patients are discouraged from participating in heavy work or recreational

activities that result in high loads and forces to the glenohumeral joint.[90] Golf, swimming, bicycling, aerobics, and running activities are acceptable activities for patients following shoulder arthroplasty. To decrease the load on the shoulder during these activities, the therapist should emphasize proper mechanics and improving overall flexibility. Patients with severe arthritis or poor soft tissues with massive rotator cuff tears typically have lower functional demands and are typically satisfied with their ability to perform normal daily activities.

MULTIDIRECTIONAL AND VOLUNTARY INSTABILITY

Multidirectional instability is defined as dislocation or subluxation in a combination of anterior, posterior, or inferior directions. The basic pathology is congenital or acquired patulous capsuloligamentous complex that lacks the stabilizing barrier and compression effect. The degree of instability may vary from those being able to participate in athletic events to those unable to lift the arm without subluxing. Typically, the labrum is intact but fraying or tearing may occur with repetitive instability events.[102] Often individuals with multidirectional instability are athletes such as swimmers and gymnasts who commonly have generalized hyperelasticity. Patients may describe diffuse achy pain with activity or at rest. Instability can be sensed with normal daily or overhead high-demand activities and weakness or paresthesias may be reported. Atraumatic posterior instability may be most notable.

An interesting patient group labeled as having multidirectional instability are those who habitually or voluntarily sublux. This includes patients who can sublux at will but are asymptomatic and do not require treatment. However, the symptomatic group may sublux/dislocate for secondary gain or psychiatric reasons but some appear to have developed an unconscious coordinated muscle firing sequence resulting in instability. EMG and biofeedback studies have identified several different abnormal firing patterns involving a combination of increased activation of the anterior deltoid and pectoralis major in conjunction with decreased activation of the posterior rotator cuff and serratus anterior.[103–105] Significant medial scapular winging can be associated with voluntary and involuntary instability (usually posterior). Although abnormal muscle activation patterns can result in posterior instability, we also believe that immediate posterior subluxation during elevation causes serratus anterior "shutdown."

Examination

Instability testing typically reveals increased translation in all directions and an excessive sulcus sign. Posture and scapular position are noted. A depressed and downwardly rotated scapula may predispose the joint to instability.[106] Inadequate scapula muscle integration is identified by poor scapular stabilization during active range motion or resisted motion testing in multiple positions. Patients are stratified into those with and without scapular winging. Patients with scapular winging usually are considered to have abnormal firing patterns, symptomatic voluntary instability, or significant compromise of the CLC (i.e., patulous CLC, large SLAP lesions). If patients present with scapular winging during sagittal plane elevation, they are asked to repeat elevation with the arm maintained in external rotation. Elimination of scapular winging confirms posterior instability. This is called an external rotation stabilization maneuver (Fig. 40-3). Our belief is that many patients immediately posteriorly sublux, causing the serratus anterior

A B

Figure 40-3 **(A)** Posterior subluxation and scapular winging present during elevation. **(B)** Scapular external rotation stabilization maneuver reduces the joint and eliminates the winging.

to reduce firing. We have measured multidirectional instability patients who demonstrate significant scapular winging using three- dimensional telemetry and electromyography and found limited scapular upward rotation and posterior tilt in conjunction with dramatic reduced firing of the serratus anterior (16% maximal voluntary contraction). Our studies have shown scapular kinematics and serratus anterior activation to normalize when the patient elevates while maintaining external rotation. Some patients, usually those with voluntary instability or those with an unconscious abnormal firing pattern, require serratus anterior preactivation to reduce the joint and prevent scapular winging. The patient is asked to protract and slightly elevate the scapula with the arms at the side followed by shoulder elevation in the sagittal plane while maintaining shoulder external rotation (Fig. 40-4). The patient must reach slightly forward to suppress attempts to downwardly rotate the scapula. The ability to dramatically reduce scapular winging and improve elevation or achieve full elevation identifies the posterior instability component and abnormal muscle recruitment patterns. If winging persists, the examination algorithm presented in the Scapular Muscle Dysfunction section is followed.

Figure 40-4 Preactivating the serratus anterior by protracting and slightly elevating the scapula while keeping the arms at the side.

Intervention

All patients demonstrating multidirectional instability without scapular winging are initially treated with glenohumeral stabilizer strengthening exercises in nonprovocative positions with scapular muscle integration.[107,108] Special attention is directed toward activating scapular muscles in isolation and then in combination with arm motion. Strengthening must be pain free and the patient's shoulder is palpated to identify subluxation while exercising. Manual resistance is applied since immediate feedback is gained for position or resistance accommodation. Initially, isometrics are utilized in varying planes and degrees of elevation. If stable and pain free, the patient is progressed to short arc motions and eventually full arc motions. Elastic bands or free-weight exercises are progressed from nonprovocative to provocative elevated positions. Functional strengthening and proprioceptive training can be achieved manually with the Bodyblade (Hymanson Inc., Playa Del Ray, CA) and Plyoball as discussed in Chapter 39. Depending on the degree of instability and the patient's demands, a limited or complete upper-extremity strengthening program is initiated. Closed-chain exercises may be utilized in certain athletic populations such as gymnasts or wrestlers. Patients who respond to a conservative approach but are felt to be high risk for future instability events are strongly discouraged from performing bench pressing, flys, overhead presses, or pushups.

Patients with scapular winging and a positive external rotation stabilization maneuver (including those requiring serratus anterior preactivation) are treated with a specific program. First poor resting scapular positioning is addressed through postural retraining and scapular retractor muscle activation. The essential component of intervention with this group is making the patient aware of repetitive subluxations. The vicious cycle of instability, pain, and muscle deactivation resulting in more instability must be broken. We show patients their abnormal movement pattern when elevating either in the mirror or by video. They are then instructed in an accentuated corrected movement pattern by preactivating the serratus anterior (protract and slightly elevate the scapula) and elevating in external rotation. The change in symptoms and range is dramatic and has a significant visual feedback effect if played back on video. The patient is instructed that during daily activities requiring forward reaching, they are to do so by using this accentuated movement pattern. This reduces the number of subluxations, breaking the vicious cycle, and it "uninstalls" the abnormal pattern and "installs" an appropriate pattern. Biofeedback may also be used for muscle retraining.[104,105] Along with postural exercise, the only other initial exercise the patient may receive is to isolate the serratus anterior by protracting and slightly elevating the scapula (arms at side). They are to do this 10 to 20 times 10 times a day. When symptoms and subluxation events reduce, patients are asked to do the

same but lift the arm to 90 degrees in the sagittal plane while maintaining external rotation. If they sublux or the scapula wings, they are not ready to progress. Typically by 1 to 2 weeks, patients have integrated appropriate muscle activation so that elevation occurs with a normal movement pattern, the glenohumeral joint remains stable, and the scapula is fixed on the thoracic wall—they have installed the new program.

Once the symptoms are controlled, subluxation events are significantly reduced, and the movement pattern looks normal, the patient is started on glenohumeral strengthening with scapular muscle integration, already discussed previously. Some patients may require further unconventional strengthening by having them hold a stick with the elbows bent at 90 degrees and in supination. They perform an isometric for the external rotators by attempting to pull the stick apart and elevate the arms in the sagittal plane while maintaining the isometric pull.

Since some patients function with asymptomatic instability, success is returning them to this status. Returning a patient back to a high level of functioning can be difficult.[109] If stability is improved but cannot be fully regained for low-demand activities, surgery is considered. Patients are required to go through a conservative rehabilitation program, especially those with scapular winging. We have found the response to the movement retraining helpful in surgery selection and improved postsurgical outcomes.

Multidirectional instability is a challenge to both the therapist and surgeon. Recognition of the pathology and using a symptom-dependent exercise progression program can return patients back to symptom-free activities. Patients with scapular winging and abnormal firing patterns require special attention since most will fail if the subluxation frequency and abnormal firing patterns are not addressed.

SCAPULAR WINGING AND DYSKINESIA

Scapular dyskinesia is an alteration in the normal position or motion of the scapula during coupled scapulohumeral movements.[110] Scapular winging may be considered a type of scapular dyskinesia characterized by significant scapular medial border displacement during shoulder motion. Quantitative scapular kinematic studies have shown abnormal scapular motion associated with certain pathologies.[111–113] Unfortunately, the equipment used to attain these measurements is not clinically applicable. The clinician is left with visual inspection and linear measurements that have low reliability.[114] Insight regarding the origin, examination, and intervention of scapular dyskinesia continues to develop.

Kuhn[115,116] described a classification system for scapular winging: primary, secondary and voluntary. Primary winging is related to neurologic, osseous, and soft tissue pathology. The two most common reasons for neurologic scapular winging are long thoracic nerve, affecting the serratus anterior, and spinal accessory nerve palsy, affecting the trapezius. Kuhn discussed a rarely seen winging due to rhomboid weakness created by a dorsal scapular nerve palsy or C-5 radiculopathy. Mixed palsies due to brachial plexopathy can also occur. Osseous malformations such as osteochondromas, clavicular malunions, or scoliosis cause scapular winging. Soft tissue abnormalities such as muscle ruptures, congenital absence anomalies, or scapular bursitis can result in scapular winging. Secondary winging is related to pathology at the glenohumeral joint or related tissues and the acromioclavicular joint. Glenohumeral joint instability, typically posterior, is a common cause of scapular winging. Scapular winging or dyskinesia is often related to poor scapular motor control in an intact neural system. This is referred to as motor control dyskinesia, and although it is seen in conjunction with other shoulder pathology, it is commonly encountered among asymptomatic individuals. The third category causing scapular winging is voluntary, nonpathologic and pathologic. Patients without true pathology but who coordinate muscle activity to cause scapular winging represent the nonpathologic group, while those with true pathology (i.e., instability and symptomatic voluntarily wing) are categorized as pathologic.

Examination

Kelley described an examination algorithm for scapular muscle assessment to determine if winging was due to neurologic, secondary causes and motor control dyskinesia.[117] The patient is first observed standing for resting winging and obvious atrophy. If resting winging is noted, the patient is checked for a scoliosis demonstrated by a thoracic rib hump during trunk flexion. Active range of motion of both shoulders is assessed in the standing position by elevating in the sagittal plane. Significant scapular winging that normalizes beyond 90 degrees during sagittal plane flexion elevation is related to motor control dyskinesia (typically the serratus anterior). If medial winging persists beyond 90 degrees, a long thoracic nerve palsy or posterior glenohumeral instability is suspected. Posterior instability causes scapular winging for two reasons: reflexive serratus anterior "shut down" resulting from immediate posterior subluxation or abnormal shoulder girdle muscle activation. The patient is then asked to elevate the arm in the sagittal plane while the arm is maintained in full external rotation to differentiate between instability or a long thoracic nerve palsy. This is referred to as the external rotation stabilizing maneuver (Fig. 40-3). Sometimes preactivating the serratus anterior by scapular protraction and slight elevation is required, especially in those patients who habitually sublux or have developed an unconscious abnormal firing pattern (discussed in the Multidirectional and Voluntary Instability section). Elimination of scapular winging with the external rotation stabilizing maneuver identifies

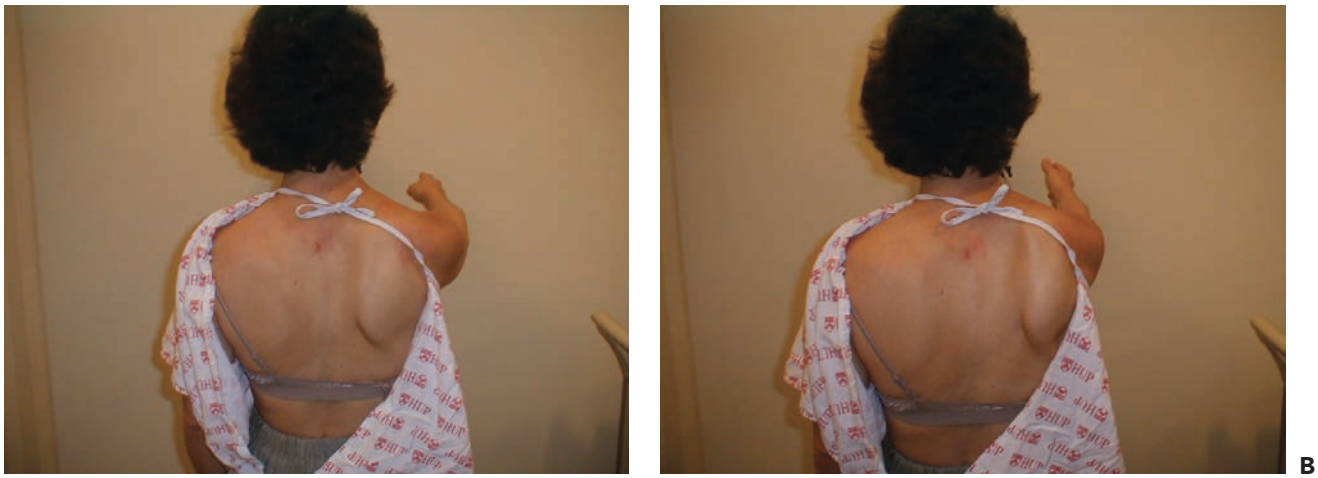

Figure 40-5 **(A)** Plus sign is performed by having the patient elevate to 90 degrees and then reach forward. **(B)** The scapula should protract along the thoracic wall but if winging increases, it is a sign of complete paralysis.

the underlying pathology as posterior instability. Maintaining humeral external rotation during elevation tightens the capsuloligamentous complex in addition to contracting the external rotators, both of which prevent posterior subluxation and allow normal serratus anterior activation. Further instability special tests can be performed to confirm instability.

If humeral external rotation does not eliminate scapular winging, the patient is asked to perform scapular protraction and slight scapular elevation while the arm is at 90 degrees of sagittal plane flexion. This is called a "plus" sign. The lower trapezius commonly attempts to stabilize the medial border during forward flexion in the presence of a long thoracic nerve palsy. When protraction at 90 degrees is performed, the lower trapezius reflexively deactivates due to antagonistic inhibition and the serratus anterior is left to control scapular movement. If scapular winging increases during attempted protraction, the patient is considered to have absent serratus anterior activity. Inability to protract the scapula on the thoracic wall is referred to as a positive "plus" sign (Fig. 40-5). If the patient protracts and the scapula fully moves forward on the thoracic wall or the movement is incomplete, motor dyskinesia or partial serratus anterior activity due to a recovering palsy is suspected, respectively. A recovering long thoracic nerve palsy cannot be ruled out if complete scapular protraction is achieved since enough fibers may be innervated to complete the task. Next the patient is asked to place the arm at 135 degrees of sagittal plane elevation and the examiner resists, pushing into shoulder extension while palpating the scapular inferior border.[118] Easy posterior displacement of the inferior border with minimal resistance is a sign of significant serratus anterior weakness and considered to be a resolving neurologic insult. Patients with very dramatic scapular dyskinesia but an intact neurologic system and void of glenohumeral subluxation will easily maintain the scapula fixed on the thoracic wall during resisted shoulder flexion at 135 degrees.

Identification of a spinal accessory nerve injury is assisted by the presence of trapezius atrophy and a depressed and protracted shoulder girdle. Coronal plane abduction is then performed and scapular movement noted. If good sagittal plane elevation is present but the patient cannot lift above 90 degrees in the true coronal plane (without pain), a spinal accessory nerve palsy is suspected. The trapezius is further examined by performing the "flip" sign.[119,120] The "flip" sign is performed with the examiner standing to the patient's side and resisting the involved shoulder's external rotators. The examiner visually examines the scapula to determine if the scapular medial border "flips" from the thoracic wall.[120] A positive "flip" sign occurs when significant displacement of the medial border occurs off the thoracic wall. The mechanism for this sign is unopposed pull of the infraspinatus and posterior deltoid by the middle and lower trapezius. Interestingly, the rhomboid muscle does not spontaneously activate to stabilize the scapula in this position. Further isolation to determine manual muscle testing strength grade of the middle and lower trapezius can be performed with the patient prone as described by Kendall and McCreary.[118]

Intervention

Rehabilitation will be discussed for patients with neurologic involvement, glenohumeral instability, and motor control dyskinesia.

Neurologic Involvement

Rehabilitation of the individual with either a long thoracic or spinal accessory nerve palsy begins with understanding

pathology. There is nothing we can do to facilitate reinnervation other than creating a friendly environment for nerve regeneration. Postural education and supporting the arm are important to eliminate the dependent weight of the extremity, minimize scapular depression, avoid separation of headed neck, and reduce pain. The most important aspect of rehabilitation in this patient population is improving scapular muscle compensatory activity. Individuals with serratus anterior paralysis are encouraged to activate the rhomboid and trapezius to gain greater stabilization and upper extremity "power." The patient is instructed in exercise to isolate and integrate the rhomboid and middle and lower trapezius by retracting and/or elevating the scapula. Phase I strengthening exercises (external rotation, internal rotation, and extension) are performed by first preactivating the trapezius and rhomboid. Resisted elbow flexion and extension exercises are performed with scapular muscle integration. Teaching scapular muscle preactivation encourages scapular stability during distal functional movement patterns. Diagonal patterns simulating a "backhand" are performed emphasizing scapular retraction. Manual therapy is performed to isolate and challenge the retractors. As the nerve recovers and serratus anterior muscle activation is noted, the serratus may first be activated supine, performing a scapular protraction with the arm positioned at 90 degrees. Exercise is progressed to standing and then with resistance. Progression to weight-bearing exercise is attempted in a graduated manner.

A patient with a spinal accessory nerve palsy is encouraged to isolate and integrate the serratus anterior and rhomboid. The same exercises previously described are performed, in addition to forward flexion with a "plus." The progression includes diagonal patterns and gravity-minimized and antigravity positions.

Intermittent visits are encouraged when treating both long thoracic or spinal accessory nerve palsies in conjunction with a consistent home exercise program since recovery following is time dependent.

Glenohumeral Instability

Rehabilitation of patients with primary instability (usually posterior) and scapular winging is achieved by attempting to stabilize the glenohumeral joint. Commonly, these patients have a history of voluntary subluxation. Voluntary instability or patients trapped in an unconscious pattern activate/deactivate scapular, axiohumeral, and glenohumeral muscles to sublux the glenohumeral joint and create scapular winging. Patients must be made aware of their volitional involvement. Subluxation typically occurs with any attempted forward movement of the arm. The external rotation stabilizing maneuver is performed. This maneuver can prevent the subluxation, suppress abnormal muscle firing patterns, and eliminate scapular winging. The patient must understand the inflammatory nature of the vicious cycle; subluxation leads to pain and joint irritation resulting in reflexive muscle shutdown, which results in instability. The cycle must be interrupted and the frequency of subluxations reduced. Once this is achieved, typical strengthening of the glenohumeral and scapulothoracic stabilizers can be performed.

Motor Control Dyskinesia

Rehabilitation of individuals with scapular motor control dyskinesia requires a thorough examination and integration of anatomechanics and kinesiology. Some degree of motor control dyskinesia is quite common in the general population, but most remain asymptomatic. Weight lifters or those who previously performed heavy bench pressing or high-repetition pushups tend to demonstrate poor eccentric scapular muscle control. Symptomatic dyskinesia occurs in throwing athletes who demonstrate significant resting scapular depression and protraction. Burkhart et al.[121] described the SICK scapula in which the abnormal scapular resting position results in altered kinematics and ultimately rotator cuff tendinopathy and glenohumeral instability. Pectoralis minor stretching helps to reestablish a normal resting position, allowing appropriate scapular posterior tilting and rotation during elevation. Isolation through manual techniques and/or active range of motion is essential to teach scapular muscle control.[121,122] Unfortunately, many therapists believe dyskinesia is related to inadequate "strength"; however, we believe it is related to poor muscle "control." Aggressive scapular muscle strengthening can increase symptoms due to provocative positioning. Once appropriate scapular muscle isolation and coordination is achieved, resistance is applied either manually, with elastic bands, or with free weights. The patient is progressed to strengthening in functional positions and return to activity/sports.

Rehabilitation of scapular winging and dyskinesia requires an algorithmic examination approach to identify the pathology and the appropriate intervention. Aggressive strengthening before motor control is established leads to symptom perpetuation and frustration. Scapular muscle isolation and eventual integration into functional movement patterns will improve outcomes.

SUMMARY

Proper rehabilitation of the shoulder is essential to the recovery of patients treated both conservatively and postoperatively. Successful rehabilitation is dependent on effective communication and interaction between the physician, therapist, and patient. Each of these team members has a defined role in the rehabilitation process and must fulfill his or her responsibilities for the desired outcome to be achieved.

This chapter presented principles and rationales for rehabilitation of various shoulder pathologies. In addition, guidelines for instruction and exercise progression were illustrated. Whether the patient will be followed in regular supervised therapy or seen in the office at specific intervals, extensive patient education is essential to successful rehabilitation. The patient must understand the pathology and rationale for each phase of the rehabilitation process. Constant reevaluation by the physician and therapist is important to make necessary program modifications if the patient is not achieving preset goals.

The common goals of the rehabilitation process include reduction of pain and inflammation, facilitation of collagen healing, improvement in ROM and strength, and optimization of proprioception and endurance. This is achieved by gradually increasing the program from nonprovocative to provocative positions. It is the rehabilitation specialist's and surgeon's responsibility to identify when to implement the appropriate modalities or exercises to improve the impairment and thereby increase the patient's function.

Prospective studies that demonstrate rehabilitation of impairments and functional limitations associated with various shoulder pathologies are needed in the literature. Once these studies exist, a dialogue between physicians and therapists can be further developed. The end result will be more efficient and successful rehabilitation for the most important member of the team—the patient.

SUMMARY 1312

INTRODUCTION

Documenting outcome of medical and therapeutic treatment is receiving increased emphasis from patients, administrators, and third-party payers. To survive in today's health care environment, providers must document quality of treatment, compare results of different forms of treatment, and compare results reported by other clinicians. Keller has stated that the quality of medical care is based on a combination of the "efficacy" of a procedure or technology as proven in laboratory studies, the "effectiveness" of that procedure when used in the community, and the "appropriateness" of the procedure when applied to a given patient.[81]

Patient-oriented outcomes research focuses on the effectiveness and appropriateness of a treatment. Until recently, the orthopedic literature has consisted of efficacy research. Although reports such as these may be related to the success of the procedure, they do not tell us what effect the procedure had on the patient. Because there is little evidence of patient outcome, treatment recommendations have been left to the personal experience of a limited number of surgeons who most often have a special interest or expertise in the area being reported. It cannot be assumed, then, that patients with similar pathologies from different geographic locations are being treated with the same procedure, let alone achieving the same outcome.

Although the recent trend has been toward reporting clinical assessment and patient self-reported outcome, no one system or tool has been widely used and accepted. In a systematic review encompassing 610 articles relating to surgery on the shoulder, a total of 44 different outcome

Figure 41-1 Nagi disablement scheme.

scores were encountered.[63] Of these, 22 (50%) used clinical assessment, 21 (47.7%) used a self-report tool, and 1 (2.3%) used both clinical assessment and a self-report tool.[63] These authors also reported that the overall pattern of the application of an outcome score was highly variable and at times inappropriate.[63] They identified changes made to self-report questionnaires, often without proper testing of the modification and without justification.[63]

Although Codman set the groundwork for reporting outcomes over 80 years ago, there is still much work to be done in this area. Common guidelines and terminology must be agreed upon for an outcome tool to become widely used and accepted. This chapter will present (a) a brief history of outcome reporting, (b) the concept of disablement, (c) criteria for validation of outcome measures, and (d) a review of existing shoulder scales.

DISABLEMENT

Before we discuss measurement tools, it will be helpful to classify outcomes through the use of a disablement scheme. "Disablement" is a global term that reflects all the diverse consequences that disease, injury, or congenital abnormalities may have on human functioning at many different levels.[76] Saad Nagi introduced the first disablement scheme in 1965 (Fig. 41-1).[111,112] The World Health Organization followed with the International Classification of Impairments, Disabilities, and Handicaps in 1980.[66,153] The goal of these schemes is to describe the pathway from active pathology to various consequences. For simplification, we will only discuss the Nagi scheme.

Nagi described active pathology as the interruption or interference of normal processes and the efforts of the organism to regain a normal state.[111,112] Active pathology can result from degenerative disease processes, infection, trauma, or other causes. Attempts have been made to accurately describe pathologies, such as classification of fractures, size of rotator cuff tear, shape and size of acromion, and degree of instability. Follow-up typically consists of x-rays to document fracture healing, arthroplasty position, or acromial shape, and magnetic resonance imaging for size of rotator cuff tear or degree of healing of rotator cuff repair. Again, this tells us about the efficacy of the treatment, but nothing about its effect on the patient.

Active pathology typically leads to an impairment of some kind. Impairment is an anatomic or physiologic abnormality or loss that can be a direct result (e.g., decreased active range of motion [ROM] due to a frozen shoulder) or secondary result (e.g., decreased strength secondary to disuse) of the pathology. Much of the clinical orthopedic literature has focused on impairment data such as pain, ROM, strength, and stability as an outcome.

Pain is one of the most commonly measured impairments in shoulder literature. Pain has been measured and reported in various ways, including visual analog scales (VASs), numeric rating scales, descriptive scales, and the amount and type of pain medication. The visual analog scale has been reported to be reliable and valid.[125,133] The typical VAS consists of a 10-cm horizontal or vertical line with anchor points such as "no pain" and "worst possible pain" at either end of the line. The patient is asked to place a mark on the line indicating the amount of pain he or she is experiencing. Pain is then calculated by measuring the distance of the mark from one of the anchor points. A disadvantage of measuring pain in this way is that it can be very time consuming for the clinician, because every scale must be individually measured. It should also be noted that the 10-cm line will decrease with each photocopy, so printed forms should be used.[68]

Another method used to record pain is a numeric rating scale. Much like the VAS, a numeric rating scale also uses anchor points. However, rather than using a line, numbers are typically arranged from 0 to 10. The patient is asked to circle the number that best correlates to his or her level of pain. Ferraz et al. found the numeric rating scale to be the most reliable among both literate and illiterate subjects.[48] Good correlation of numeric rating scales to VASs has been reported.[152] Williams et al. also favored numeric rating scales for telephone administration and longer-term follow-up.[152]

A descriptive pain scale typically provides the patient with verbal descriptors such as none, mild, moderate, and severe.[33,34,68] "Moderate" is most often chosen, even in patients who rate pain as mild or severe by other methods.[68] Another concern is that there are not enough options for patients to accurately record pain in the same rank order.[107]

Quantifying pain by the amount and type of pain medication, such as over-the-counter, nonsteroidal antiinflammatories, or narcotics, also has been used.[45,121] Although this is useful information to have on hand, the accuracy of this type of pain scale must be questioned, because various psychological and psychosocial issues may taint the results. Pain scales that include descriptors as well as amount of medication in a single item should be regarded with caution, because multiple variables can be confusing for patients.[45]

Shoulder ROM is an important outcome of shoulder surgery. Goniometric measurement of ROM has been reported to be reliable.[22,50,107,122] However, because of the multiplanar motion of the shoulder, it can be difficult to reproduce and compare results reported by other clini-

cians.[122] In response to the need to standardize measurements, the American Shoulder and Elbow Surgeons (ASES) recommends that four functionally important ranges of motion be documented: forward elevation, external rotation with the arm at the side, external rotation in the 90-degree abducted position, and internal rotation.[25,121] Forward elevation is defined as the maximum angle the arm makes with the trunk when the patient is asked to raise his or her arm above the head with the elbow held straight. It should be noted that this plane of motion is not considered to be true flexion or abduction. Experience tells us that most patients will raise their arm somewhere between true flexion and the plane of the scapula. The angle that the arm makes with the thorax is measured in the upright position for active motion, whereas passive measurement is made in the supine position.

External rotation with the arm at the side is measured with the elbow flexed to 90 degrees and the forearm in the sagittal plane. External rotation at 90 degrees of abduction is measured by asking the patient to begin with the arm in the same position as for external rotation at the side. The patient is then asked to abduct the arm to 90 degrees. Once at 90 degrees of abduction, the patient is asked to externally rotate the shoulder. Active motion is measured with the patient upright, whereas passive motion is measured with the patient supine. Internal rotation is measured by the position reached by the outstretched hitchhiking thumb up the back, in reference to the posterior anatomy. Common reference points include the greater trochanter, buttock, sacrum, waist line, and spinous processes of the lumbar and thoracic vertebrae.

Strength assessment is another commonly reported impairment to document effectiveness of surgical or therapeutic intervention. As with ROM testing, it is important to have standardized testing protocols for reproducibility in a clinical setting. A variety of methods for quantifying muscle performance have been available, including manual muscle testing (MMT), handheld isometric dynamometry, and isokinetic dynamometry.

MMT is the most widely used method of clinical evaluation of muscle strength.[102] Some investigators have recommended using MMT when documenting shoulder outcomes.[45,121] This technique, however, has been criticized for its subjectivity and lack of reliability within the good and normal ranges.[7,23]

In an attempt to quantify the results of MMT procedures, handheld dynamometry was introduced in 1949.[102] Although several investigators have demonstrated handheld dynamometry to be reliable in both patient and nonpatient populations, problems include an upper limit to recording muscle force, difficulty in maintaining the device perpendicular to the limb segment, and dependency on the strength of the tester.[1,14–19,27,30,43,89,98,102,115,120,143,151]

Several isokinetic devices have become available for use in the clinic, including those that have the capability of measuring concentric, eccentric, and isometric strength. The reliability of these dynamometers has been well documented.[28,35,44,47,71,86,89,97,117,134] However, these devices are nonportable and relatively expensive, and require elaborate setup and stabilization procedures. Therefore, use in the clinic is time consuming and impractical.

The Isobex 2.1 (Curor Ag, Niederwanten, Switzerland) is an isometric dynamometer that is lightweight and portable. Fixation to a wall is attained by suction cups. A cable mechanically measures force output. Reliability of this device for measuring shoulder strength is comparable with or better than isokinetic and handheld dynamometry.[89]

To accurately compare results of strength measurements, standardization of such variables as test position, dynamometer, stabilization, and protocol must be established. Several studies have advocated testing shoulder strength in the plane of the scapula and 15 to 45 degrees of abduction. Proponents of this test position argue that it avoids the impingement arc, avoids the apprehension position, and reduces passive tension on the rotator cuff.[132] However, positioning the arm in the scapular plane at 45 degrees for rotational testing would require appropriate stabilization of the limb, which may make reproducibility and efficiency in the clinic difficult. Testing elevation at 45 degrees in the plane of the scapula would not require stabilization. A recent study by the authors demonstrated that measuring isometric shoulder strength for internal and external rotation with the arm at the side in neutral rotation is highly reliable. In addition, elevation tested at 45 degrees in the plane of the scapula is also reliable.[89]

Interpreting strength testing data has typically consisted of comparison with the uninvolved extremity and comparison with normative data.[132] It is difficult to compare results with the normative data available in the literature because test position and dynamometer vary for each study. Although we prefer comparing ROM and strength data to the opposite uninvolved side, this method is not without controversy. The influence of hand dominance in both athletic and nonathletic populations has been debated in the literature.[28,117,132] In patients who have bilateral shoulder involvement, age-, gender-, and hand dominance–matched normative values would be ideal.

Instability is also an impairment commonly reported. The ASES recommends grading the amount of instability of the glenohumeral joint in the following way: 0 = no translation, 1 = mild (0 to 1 cm translation), 2 = moderate (1 to 2 cm translation or translates to the glenoid rim), and 3 = severe (greater than 2 cm translation or over the glenoid rim).[141] This should be noted for anterior, posterior, and inferior translation. In addition, the presence of apprehension or a positive relocation test should be noted. The ASES also recommends having the patient rate his or her level of shoulder instability on a VAS.[121]

Although knowledge of these parameters is important to the overall understanding of pathology, they do not describe

the total effect of the pathology on the person. Nagi used the term "functional limitations" to describe limitations in performance at the level of the whole person. Physical functioning involves the patient's ability to perform activities of daily living (ADLs), dress, reach, push, pull, lift, carry, and work. However, all impairments do not lead to functional limitations. For example, a patient with limited shoulder ROM may not be able to reach the back of his or her opposite shoulder. However, this may not be a functional loss, because the patient may use a long-handled scrub brush to wash the axilla and back of the opposite shoulder.

Disability is the limitation in performance of socially defined roles and tasks within a sociocultural and physical environment.[76] A patient who is unable to perform or participate in usual work, school, leisure, and personal care activities can be considered disabled. It is important to note that not all impairments and functional limitations lead to disability. Disability largely depends on the patient's desired activity level. For example, a limitation in the ability to raise the arm above shoulder level may not be a disability for a computer programmer who works below shoulder level. However, this functional limitation would be a devastating disability for a painter or professional tennis player. We also can illustrate disability through the use of shoulder scoring systems. The computer programmer with a shoulder score of 90 on a 100-point scale can have no perceived disability. However, moderate disability can be perceived by the painter or tennis player with the same 90-point score.[34,69]

The disablement process can be halted at each step by appropriate surgical or therapeutic intervention. In addition, the process can be expedited or slowed by several factors, including age, gender, lifestyle, education, social support, motivation, and environment.[75] It is important to determine which of these factors weigh most heavily on patient outcome after shoulder surgery. Self-report questionnaires are now a common way to determine patient outcome after surgical or therapeutic intervention.

DEVELOPMENT OF SCORES

Several instruments have been reported to document outcome with little regard for the process of selecting and constructing the scale. This has caused confusion as to the best way to construct and validate outcome measurement tools for use in the clinic.[84] Clinicians should choose an outcome tool that will best suit the purpose of its use.[84] Kirshner and Guyatt classified outcome assessment tools as either discriminative, predictive, or evaluative.[84] A discriminative index is used when no "gold standard" is available to validate the measure. Items in this type of measure must be important to patients and performed by almost all of the patients to be studied. The most appropriate number of response options in this type of scale is two. Either the patient can or cannot perform the activity. This type of instrument allows comparison among different groups. However, a dichotomous scale such as this cannot detect small changes in a patient's status over time.

A predictive index is used to determine whether a patient has a specific condition or is likely to develop that condition. The patient can then be classified into a specific category. Based on a comparison of other patients in that category, one can predict the outcome the patient will achieve. However, this type of index will not measure outcome.

An evaluative index is used to quantify the amount of change the treatment intervention has provided. An evaluative index must be able to measure all clinically important effects of treatment.[84] These scales must be responsive to change over time. It is this type of scale that we are most interested in to document within-person change over time.

Several investigators have outlined requirements for the development of new outcome measures.[21,56,58,61,74,77,78,81,84,142] For an index to be considered useful in the clinic, there are several steps that must be followed, including item selection, item scaling, item reduction, determination of reliability, determination of validity, and determination of responsiveness.[126]

Item Selection

The first step in constructing an evaluative instrument is to select a set of items that are relevant to the overall function of the type of patient to be evaluated. This can be accomplished through literature review, personal experience, consultation with colleagues, review of existing instruments, and interview with patients.[58,61,84,137] The likelihood that patient response to a particular item will change with medical or therapeutic intervention is an important consideration.[84] In addition, all clinically important treatment effects must be included in the tool.[84]

Item Scaling

Once the items of the instrument are established, the response options or range that patients have for responding to each item must be determined. Each item must be sensitive to clinically important changes in status. Typical response options include a VAS, NRS, or a Likert scale with multiple options. The optimal number of response options for a Likert scale has not been reported. However, increasing response options will increase item responsiveness. The typical Likert scale includes five to nine options. For a tool designed to discriminate between patients who can or cannot perform an activity, a simple "yes" or "no" is all that is necessary. These response options are fine for tools designed to detect between-person differences, but not small changes in an individual patient's status. Therefore, it is recommended that either a Likert scale, an NRS, or a VAS be used with an evaluative tool.

Item Reduction

Because we are interested in measuring change over time, it would be counterproductive to include items in the scale that do not change after a particular intervention. This stage of scale development is item reduction. A method of reducing the items of a scale is to administer the scale to a group of patients before and after an intervention that produces change in a patient's status. Items that are unresponsive to change are then deleted from the questionnaire.

Reliability

Once the questionnaire is in its final format, it is ready for reliability testing. Reliability is the extent to which a measurement is consistent and free from error.[58,61,84,119,129,142] Reliability is tested by administering the questionnaire to the same subject at two points in time. Although there may be small changes in within-person measures, they may be statistically and clinically insignificant.[126] Intrarater reliability refers to the stability of data recorded by one individual across two or more trials.[119,129] Interrater reliability is variation between two or more raters who measure the same group of subjects.[119,129] Test–retest reliability means that a measure will remain stable over repeated measures in time, provided that no change in status has taken place.[129] An intraclass correlation coefficient (ICC) or kappa coefficient statistic is commonly used to express reliability.[119] The extent to which the items of a scale reflect the same dimension is known as internal consistency.[49] Internal consistency also provides an index of a scale's ability to differentiate among clients at an instant in time.[49] A coefficient alpha is typically used to determine internal consistency of a self-report tool.[38]

Error and Change

The error associated with a single application of any clinical or functional measurement tool can be analyzed with the standard error of measurement (SEM). The SEM provides an estimate of how reliably a scale estimates an individual's "true score," that is, the score that would be obtained for the person if the scale measured perfectly, without error.[42,105,126] The SEM is a representation of measurement error expressed in the same units as the original measurement.[13] The SEM can be calculated by using either Cronbach's α or the intraclass correlation coefficient.[49] Whereas error estimates based on Cronbach's α are specific to an instant in time, error estimates derived from test–retest reliability can be generalized over a time interval equal to that applied in the test–retest reliability study.[49] The SEM can be calculated with the formula: SEM = SD × [square root (1 – reliability coefficient)]. The SEM carries with it 68% confidence bounds. To achieve a higher confidence level, the SEM can be multiplied by the z value associated with the 90% confidence level (z = 1.65) or the 95% confidence level (z = 1.96).

The error associated with multiple applications of a clinical or functional measurement tool can be determined by calculating the minimal detectable change (MDC). The MDC can be used to make clinical judgments regarding whether a patient has improved or not. It can be calculated with the formula: MDC = SD × [square root (1 – reliability coefficient)] × square root of 2. The MDC also carries with it 68% confidence bounds. To achieve a higher confidence level, the MDC can also be multiplied by the z value associated with the 90% confidence level (z = 1.65) or the 95% confidence level (z = 1.96).

The minimal clinically important difference (MCID) is the smallest difference in a score that is considered to be worthwhile or important.[64] The approach used to establish the MCID is not fixed.[8] Nine different methods have been used to calculate the MCID for an instrument.[8,150] A commonly used approach is for the patient to rate his or her change on a global scale (much worse to no change to much better).[8,72] The mean change of those who report becoming slightly worse or slightly better is used to calculate the MCID.

Validity

Validity concerns the extent to which an instrument measures what it is intended to measure.[119] Validating a new instrument is an ongoing process as new information becomes available.[49] In a shoulder score, we want to know if it can evaluate change in the magnitude or quality of a variable from one time to another. There are several types of measurement validity including face, content, construct, and criterion.[49]

Face validity is the simplest and weakest form of validity. If the items of an index appear to make sense to the person using it, then the scale has face validity. Content validity is satisfied when it is proven that the scale measures all important aspects of the condition to be examined. A more formal way of measuring validity of an index is to demonstrate that the results of the new scale correlate to an external "gold standard." This is also known as criterion validity.

Construct validity refers to how well one instrument performs when compared with instruments of similar or dissimilar purposes and dimensions.[108] Convergent construct validity examines the correlations among similar instruments.[108] Divergent construct validity is assessed by examining the correlations between dissimilar instruments.[108] Correlation coefficients are calculated for each of these analyses and can range from −1 to 1, with 1 indicating a positive relationship and −1 a negative relationship.[108] A high positive correlation coefficient is desired when the two scales being examined are, in theory, similar in nature. A high negative relationship is expected when assessing divergent validity.

Before we can declare an evaluative index useful in the clinic, it must be able to detect improvement, regression, or stability of a condition over time.[140] "Sensitivity to change," "responsiveness," or "longitudinal validity" are terms that have been used when examining a measure's ability to detect change over time.[2,41,49,96,140] We will use the term "responsiveness" when discussing a measure's ability to detect change. There are several methods for assessing responsiveness.[84] Stratford et al. have discussed several study designs that can be used to determine responsiveness of an index.[140] The simplest design compares an initial score with a follow-up score after treatment intervention. More sophisticated designs compare the outcome of a group who received a treatment of known efficacy with that of a placebo group. Another design involves comparing the clinician's and patient's global ratings of change with the change in score. Whichever design is chosen, an adequate sample size must be selected.

There are many methods of assessing responsiveness. The two most commonly employed methods are the standardized response mean (SRM) and the effect size (ES).[80,90] The SRM is calculated with the formula: SRM = mean change (follow-up scores – initial scores) ÷ SD of change scores. The ES is calculated with the formula: ES = mean change (follow-up scores – initial scores) ÷ SD of initial scores. Interpretation of the SRM and ES values is not standardized.[108] Guyatt et al.[59,61] suggested that an SRM greater than 0.80 demonstrates an acceptable level of responsiveness. Cohen[31] recommended that an ES or SRM of 0.2 represents a small effect, 0.5 a moderate effect, and 0.8 or more a large effect. The greater the "effect" is, the more responsive the measure is and therefore the more likely it is to reflect actual change in a patient's function and disability.[108]

CRITICAL REVIEW OF SHOULDER SCORES

Several tools have been developed and used to document outcome of surgical and therapeutic treatment of shoulder pathology. These include generic quality-of-life or health status measures, region-specific measures, condition-specific tools, and joint-specific tools.[12,29,87] Although many of these tools have been used in various reports, no one tool has been widely accepted and utilized.[55,127] The lack of universal acceptance could be attributed to several factors including the wording of questions, specific content of the scale, allocation of point values, and lack of or inadequate measurement properties.[24]

Shoulder self-report tools should measure components of pain, patient satisfaction, and function.[55] Many tools contain some of these components but do not adequately assess each dimension. For this reason, some authors have advocated the use of a generic health measure, a shoulder-specific measure of function, and a measure of patient satisfaction.[11,52,85] We will discuss the advantages and disadvantages of each type of measure used to assess outcome after shoulder surgery or intervention.

Generic Measures

Generic measures quantify a patient's perception of his or her overall state.[12] The object of using generic measures is to quantify overall health rather than that related to a specific condition.[12] Therefore, they would cover health issues such as heart disease, diabetes, or other comorbid conditions and the shoulder problem.[12] Although generic measures tend to be less sensitive to changes in orthopaedic disorders, they provide a valuable broad view of the patient's overall health.[11,12,20,60,118,123]

The most commonly used generic health measure in the orthopaedic literature is the SF-36.[12,106,144,145,148] This index consists of 36 items derived by Ware and colleagues from the Medical Outcomes Survey.[141,144,145,148,149] It measures eight health concepts: physical functioning (10 items), social functioning (two items), role limitations due to physical problems (four items), role limitations due to emotional problems (three items), mental health (five items), energy/fatigue (four items), bodily pain (two items), and general health perception (five items).

Gartsman and colleagues[52] found that the SF-36 documented significant differences between U.S. general population norms and patients with five common shoulder conditions (glenohumeral instability, rotator cuff tear, adhesive capsulitis, glenohumeral arthritis, and impingement). In the great majority of comparisons in this study, patients with shoulder conditions scored significantly lower than the U.S. general population norms. In addition, they reported that these five common shoulder conditions had an effect on an individual's perception of his or her general health that ranks with those of several major medical conditions (hypertension, congestive heart failure, diabetes mellitus, myocardial infarction, and clinical depression).[52]

However, the SF-36 may not be sensitive enough to document change over time in patients with shoulder pathology. Mossberg and McFarland[110] found lower physical functioning scores in patients with lower-quarter involvement than in those with upper-quarter involvement. They were not surprised by this finding, given that nearly all items in the physical functioning subscale are in some way associated with the use of the lower extremities. Beaton and Richards[11] found lower correlations of five shoulder-specific questionnaires with the SF-36 than with each other. They also found the scores on the physical function section of the SF-36 to be higher than the scores on the shoulder-specific measures in the same patients. Dawson et al.[39] and Angst et al.[3] found similar results in their studies on patients following rotator cuff repair and total shoulder arthroplasty.

Although the authors of the SF-36 considered it a "short-form" measure, some consider a questionnaire with 36 questions too lengthy.[51] Therefore, the SF-12 Health Survey was developed to provide a shorter alternative to the SF-36.[146,147] The SF-12 contains a subset of 12 items from the SF-36 including one or two items from each of the eight SF-36 scales. The SF-12 items and summary scores have reproduced the SF-36 summary measures with the same interpretations.[51,146,147] To date, a comparison of these two measures in patients with shoulder disorders has not been performed.

Disease-Specific Measures

To detect very focused types of changes in patients with shoulder disorders, some investigators have advocated the use of disease-specific assessment tools.[82,83,93,130] Rowe et al. were one of the first to attempt to accomplish this with their Rating Sheet for Bankart Repair.[130] This 100-point scoring system awards 50 points to the patient who reports no recurrence of dislocation, subluxation, or apprehension. The remaining 50 points are derived from ROM and function. There have not been any reliability or validity studies on this scoring system. Although this scoring system appears well suited for the patient with shoulder instability, it would not be useful for a patient who has a comorbid shoulder disorder. Using disease-specific tools makes it difficult to compare the functional limitations and disability associated with different shoulder conditions.

Region-Specific Measures

Region-specific measures are applicable across many joints or disorders and usually are designed for the entire upper limb.[12] They offer a practical alternative to disease-specific or joint-specific tools in that they can be used in the context of all the various disorders encountered in a busy practice.[12] However, a tool must have adequate measurement properties in all the patient groups in which it is applied.

The Disabilities of the Arm, Shoulder, and Hand (DASH) outcome measure is a commonly used tool for the upper extremity.[9,104] The DASH is a 30-item questionnaire that evaluates symptoms and physical function with a five-response option for each item.[9] A scoring algorithm allows a score out of a possible 100 points. A higher score on the DASH reflects greater disability. The measurement properties of the DASH have been examined (Table 41-1).[9,67,99,104]

Joint-Specific Measures

A number of tools that are applicable to any condition of the shoulder are available. Although they have been used extensively in the literature to report outcome of surgical or therapeutic intervention, evidence of psychometric properties is lacking and many times the scales are modified by the authors. The most commonly used scales will be discussed regarding content and measurement properties.

Neer Rating Sheet

Neer published the first system to document outcome in 1972, when he discussed his results of anterior acromioplasty.[113] In 1982, he discussed results of total shoulder replacement, using the same system.[114] Although the Neer rating sheet is not a cumulative scoring system, it does take into account the important aspects of pain, motion, strength, function, and patient satisfaction. Neer graded his results as excellent, satisfactory, or unsatisfactory, depending on a combination of these parameters. In addition, x-ray findings, postoperative complications, patient's compliance with physical therapy, and patient's general physical condition were documented at each follow-up visit. Although no reliability or validity data are available, this early method of tracking shoulder outcomes has formed the basis from which more recent outcome scoring systems have been derived.

Constant Shoulder Score

The Constant Shoulder Score (Fig. 41-2) was described in 1987 by Constant and Murley.[33,34] It is a 100-point scoring system in which 35 points are derived from the patient's report of pain and function. The remaining 65 points are allocated for objective assessment of ROM and strength. A significant contribution of Constant's work is age- and gender-matched normative data based on a study of 900 individuals with no known shoulder dysfunction. The Constant Shoulder Score has been used internationally for reporting outcome of various shoulder conditions.[40,53,54,57,70,73,79,94,116,124,128,135,136,154] This may be why investigators at the 1992 International Shoulder Surgeons' meeting were required to present clinical data using the Constant Shoulder Score.[127] The European Shoulder and Elbow Society also requires results of clinical data to be reported using the Constant Shoulder Score.[87]

The content of the score appears to include all relevant aspects of shoulder outcome, with the exception of whether or not the patient is satisfied with his or her shoulder. However, each item of the scale requires a significant degree of interpretation by the patient. There is only one pain scale in which the patient is asked to rate the most severe pain experienced at rest, during sleep, or with various activities. Clinical experience tells us that patients experience varying degrees of pain with different activities. One pain scale appears to be inadequate to gain a true picture of the patient's pain. There is also concern that report of function is not specific to any particular activity and therefore is left to interpretation by the patient.

TABLE 41-1
CHARACTERISTICS AND PSYCHOMETRIC PROPERTIES OF SHOULDER SCALES

Scale	Dimensions (% of Total Score)	Test–Retest Reliability (ICC)	Internal Consistency	Error Estimate: SEM and MDC	Responsiveness: SRM and ES

None Mild Moderate Severe

Daily work: (work without restriction = 4 points, 75% of normal work = 3 points, 50% of normal work = 2 points, ...etc.; undisturbed sleep = 2 points, interrupted sleep = 1 point, no sleep = 0 points)

Work	Recreation	Sleep
0	0	0
1	1	1
2	2	2
3	3	
4	4	

Ability to work at the level of:

2	the waist
4	the xiphoid process
6	the neck
8	the head
10	above the head

Figure 41-2 Constant Shoulder Score.[1,19] (Adapted with permission from Constant CR, Murley AHG. A clinical method of functional assessment of the shoulder. *Clin Orthop* 1987;214:160–164.)

The objective assessment of external rotation is also questionable.[55] The patient is awarded 4 points for placing the hand behind the head with the elbow held back, whereas 8 points are awarded for hand placement on top of the head with the elbow held back. The difference of shoulder external rotation between these two hand positions seems negligible.

The method of measuring strength has not been standardized. Constant advocated testing isometric abduction strength with a spring balance at 90 degrees of abduction. He also stated that testing can be performed at the highest level achieved by patients, if they are unable to achieve 90 degrees of abduction. This inconsistency makes reproduction of results difficult. Furthermore, Conboy et al. recently questioned the validity of measuring shoulder power in a single arc of movement.[32] Bankes and colleagues[5] proposed a standard method of shoulder strength measurement for the Constant score. Their method involved a fixed spring balance and a standard test position with the arm at 90 degrees of abduction in the scapular plane, elbow extended, and forearm pronated.[5] Patients unable to achieve this test position as a result of pain or deformity are given a value of zero. The patient is asked to pull upward on the spring balance to create a 5-second isometric contraction. The highest value achieved in three maximum pulls provides the strength score.

Although the procedures and statistical analysis for determining reliability are not reported, the investigators report an average observer error of 3% among three different observers testing 100 abnormal shoulders.[33] Conboy and colleagues[32] examined the reliability of the Constant Shoulder Score in 25 patients with either arthritis, dislocation, or impingement. They found an interobserver standard deviation of 8.86 with a 95% confidence limit that the measurement of a single observer would be within 17.7 points of the true score.[32] Therefore, studies examining pre- and postintervention measures using the Constant Shoulder Score should be examined with caution. Another concern is that because such a large portion of the Constant Shoulder Score is derived from objective impairment measures, patients who are unable to return

to the clinic will be lost to follow-up, which may lead to incomplete outcome studies.

American Shoulder and Elbow Surgeons

The ASES Standardized Shoulder Assessment Form (Fig. 41-3) was developed by the Research Committee of the ASES and published by Richards and colleagues in 1994.[121] The instrument consists of a patient self-assessment section and a clinician assessment. The patient self-report section consists of a 100-point scale with two equally weighted dimensions, pain and activities of daily living. Patients are asked to record their pain "today" on a 10-point numeric rating scale with endpoints of "no pain at

Pain:

How bad is your pain today?

0 1 2 3 4 5 6 7 8 9 10

No pain at all — Pain as bad as it can be

Activities of daily living: (Circle the number that indicates your ability to do the following activities
0 = unable to do; 1 = very difficult to do; 2 = somewhat difficult to do; 3 = not difficult)

Activity	Right Arm	Left Arm
1. Put on a coat	0 1 2 3	0 1 2 3
2. Sleep on your painful or affected side	0 1 2 3	0 1 2 3
3. Wash back/do up bra in back	0 1 2 3	0 1 2 3
4. Manage toileting	0 1 2 3	0 1 2 3
5. Comb hair	0 1 2 3	0 1 2 3
6. Reach a high shelf	0 1 2 3	0 1 2 3
7. Lift 10 lb above shoulder	0 1 2 3	0 1 2 3
8. Throw a ball overhand	0 1 2 3	0 1 2 3
9. Do usual work (list): _____	0 1 2 3	0 1 2 3
10. Do usual sport (list): _____	0 1 2 3	0 1 2 3

Figure 41-3 American Shoulder and Elbow Surgeons Standardized Shoulder Assessment Form.[141] (Adapted with permission from Richards RR, An K, Bigliani LU, et al. A standardized method for the assessment of shoulder function. *J Shoulder Elbow Surg* 1994;3:347–352.)

all" and "pain as bad as it can be."[121] The number circled is subtracted from 10 and multiplied by 5 for a possible 50 points for this section. The activities of daily living section consists of 10 questions, each with four response options ranging from "unable to do" to "not difficult." The total of the responses is calculated and multiplied by 5/3 to yield a possible score of 50 points. The measurement properties for this scale have been examined (Table 41-1).[85,109]

Although the index does include the important aspects of pain and function, it does not include the patient's satisfaction with his or her shoulder. In addition, only one pain scale is not specific to activity or time of day. The ADL section includes three items that may not be normal ADLs for some patients. This can present a problem, because there are only 10 items in this section. Sallay and Reed[131] attempted to establish normative ASES scores across age and gender. They found a mean ASES score of 95.8 points in 293 individuals who felt that their shoulder was normal. However, these authors modified the ADL subscale by offering patients an additional response option of "I don't play sports" for that item. This item was dropped from the overall score for the patients who did not play sports and the function score was calculated based on the remaining nine questions. Therefore, these normative data need to be approached with caution since the validated form of this score does not include that response option.

The advantage of this scale is its ease of administration. It can be completed by the patient independent of an examiner or by phone interview. The clinician assessment portion provides a standardized method for clinicians to follow.

Shoulder Pain and Disability Index

The Shoulder Pain and Disability Index (SPADI; Fig. 41-4) was described by Roach and colleagues in 1991.[125] This 100-point system incorporates a VAS for all items. There are five items for pain and eight for functional limitations/disability. Scoring is based on the severity of pain and disability reported. The higher the score is, the more severe the disability is.

The items of this scale relate mostly to self-care and dressing. Therefore, the SPADI does not appear to adequately measure occupational and recreational disability.[65] The investigators report fair reliability with high internal consistency of the scale (Table 41-1). They also report sensitivity to change and good correlation to objective measures of ROM. Williams and colleagues recognized the difficulties posed when using a VAS in the clinic or for

PAIN SCALE

A. How severe is your pain:

			Score
1. At its worst?	No pain	Worst pain imaginable	
2. When lying on involved side?	No pain	Worst pain imaginable	
3. When reaching for something on a high shelf?	No pain	Worst pain imaginable	
4. Touching the back of your neck?	No pain	Worst pain imaginable	
5. Pushing with the involved arm?	No pain	Worst pain imaginable	

DISABILITY SCALE

A. How much difficulty did you have:

1. Washing your hair?	No difficulty	So difficult required help	
2. Washing your back?	No difficulty	So difficult required help	
3. Putting on an undershirt or pullover sweater?	No difficulty	So difficult required help	
4. Putting on a shirt that buttons down the front?	No difficulty	So difficult required help	
5. Putting on your pants?	No difficulty	So difficult required help	
6. Placing an object on a high shelf?	No difficulty	So difficult required help	
7. Carrying a heavy object of 10 lb or more?	No difficulty	So difficult required help	
8. Removing something from your back pocket?	No difficulty	So difficult required help	

Figure 41-4 Shoulder Pain and Disability Index.[3] (Adapted with permission from Roach KE, Budiman-Mak E, Norwarat S, Lertratanakul Y. Development of a shoulder pain and disability index. *Arthritis Care Res* 1991;4:143–149.)

telephone administration.[152] They changed the format to a numeric rating scale, studied the correlation to the original version of the SPADI, and assessed its responsiveness to change over various time periods. The investigators found good correlation between the VAS and numeric scaled SPADI. They also found significant changes at each time period that correlated with the patient's global status rating. Although these studies provided evidence of reliability and validity of the SPADI, it should be noted that all of the patients in the study by Roach et al.[125] were men, and 98% of the subjects studied by Williams et al.[152] were also men. Cook and colleagues[36] reported acceptable reliability and

internal consistency of the SPADI in both nonsurgical and postsurgical shoulder patients.

University of California, Los Angeles End-Result Score

The University of California, Los Angeles (UCLA) End-Result Score (Fig. 41-5) was first used by Ellman and colleagues[45] in 1986. This is a 35-point scale. The items measured include pain (10 points), function (10 points), active forward flexion (5 points), strength of forward flexion (5 points), and patient satisfaction (5 points). A score of 34 to 35 is considered an excellent result and a score of 29 to 33 a good result. Any score less than 28 is considered a poor result.

This scale appears to include all aspects relevant to rating the shoulder. However, the UCLA score uses descriptive items for pain and function. Each item contains multiple descriptions that may make it difficult for the patient to understand. The report of patient satisfaction is also questionable. The patient has two choices for this item. Five points are awarded if he or she is "satisfied and better," whereas 0 points are awarded for "not satisfied and worse." There is no option in between. Limiting patient responses to these two options results in only gross estimates of patients' levels of satisfaction.[36] This method of measuring patient satisfaction also makes it difficult to use this scale prior to treatment, because many patients are typically not satisfied and worse when seeking medical attention.[55] Cook and colleagues[36] were unable to calculate a valid reliability value for this item in a group of 24 nonsurgical patients because eight patients changed their satisfaction responses between test administrations.

Strength of forward flexion is assessed with manual muscle testing. We have already discussed the problems associated with this method of strength testing. In addition, the position of this measurement is not standardized. Reliability has only been examined for the pain and function questions in both nonsurgical and postsurgical patients.[36] Reliability for the satisfaction question has been examined in postsurgical patients only.[36]

	Points
Pain:	
Present all of the time and unbearable; strong medication frequently	1
Present all of the time but bearable; strong medication occasionally	2
None or little at rest, present during light activities; salicylates frequently	4
Present during heavy or particular activities only; salicylates occasionally	6
Occasional and slight	8
None	10
Function:	
Unable to use limb	1
Only light activities possible	2
Able to do light housework or most activities of daily living	4
Most housework, shopping, and driving possible; able to do hair and dress and undress, including fastening brassiere	6
Slight restriction only; able to work above shoulder level	10
Normal activities	
Active forward flexion:	
>150º or more	5
120º–150º	4
90º–120º	3
45º– 90º	2
30º– 45º	1
<30º	0
Strength of forward flexion (manual muscle testing):	
Grade 5 (normal)	5
Grade 4 (good)	4
Grade 3 (fair)	3
Grade 2 (poor)	2
Grade 1 (muscle contraction)	1
Grade 0 (nothing)	0
Satisfaction of the patient:	
Satisfied and better	5
Not satisfied and worse	0

Figure 41-5 University of California, Los Angeles End Result Score. (Adapted with permission from Ellman H, Hanker G, Bayer M. Repair of the rotator cuff: end-result study of factors influencing reconstruction. *J Bone Joint Surg Am* 1986;68: 1136–1144.)

Most likely due to its ease of administration and the fact that it was one of the earlier introduced shoulder scores, the UCLA score has been used frequently in the literature for both retrospective and prospective studies.[2,4,26,45,46,62,92,95,138,139] Burkhart et al.[26] reported pre- and postoperative values for the UCLA score in a study of 14 patients who received partial repair of a massive rotator cuff defect. All but one of these patients were satisfied with their result. However, the average postoperative score was 27.6. This is considered a poor result under the guidelines set forth by the original investigators. Therefore, it would seem more practical to only report numeric results of the UCLA score and omit using terms such as "excellent" or "good."[55]

Simple Shoulder Test

The Simple Shoulder Test (SST) (Fig. 41-6) was developed by the shoulder service at the University of Washington.[6,91,100,101] The questionnaire consists of 12 functional items, derived from a review of other scales and the most frequent complaints of patients seen in their practice. The SST does not directly assess pain, ROM, or strength. Instead, these parameters are evaluated indirectly through each of the items on the questionnaire.[87] Two of the questions relate to pain, seven to function, and three to ROM.[11] Response to each item requires a simple "yes" or "no." The goal of the developers was to provide an assessment tool that does not require a clinician, elaborate equipment, or computer for calculation. Not surprisingly, excellent reliability values have been reported for this scale.[11] Beaton and Richards[11] also reported good correlation of the SST to other shoulder instruments. However, the SST has very poor precision as indicated in reports on its standard of measurement with 95% confidence interval.[37,126]

A dichotomous scale such as the SST provides excellent reliability and discriminates between patients who can and cannot perform a particular activity.[84] However, this type of scale would not perform well as an evaluative index. For example, a patient who had mild pain at night that occasionally disrupted sleep would answer the same as a patient who had severe pain at night that prevented sleep on a regular basis. There is no provision for the patient to assess satisfaction with the function of the shoulder.

Penn Shoulder Score

The Penn Shoulder Score (PSS) (Figs. 41-7 and 41-8) is a joint-specific self-report measure developed by the

Answer each question below by circling "yes" or "no" (please do not leave questions unanswered)

1. Is your shoulder comfortable with your arm at rest by your side?	Yes	No
2. Does your shoulder allow you to sleep comfortably?	Yes	No
3. Can you reach the small of your back to tuck in your shirt with your hand?	Yes	No
4. Can you place your hand behind your head with the elbow straight out to the side?	Yes	No
5. Can you place a coin on a shelf at the level of your shoulder without bending your elbow?	Yes	No
6. Can you lift 1 lb (a full pint container) to the level of your shoulder without bending your elbow?	Yes	No
7. Can you lift 8 lb (a full gallon container) to the level of your shoulder without bending your elbow?	Yes	No
8. Can you carry 20 lb at your side with the affected extremity?	Yes	No
9. Do you think you can toss a softball underhand 10 yards with the affected extremity?	Yes	No
10. Do you think you can toss a softball overhand 10 yards with the affected extremity?	Yes	No
11. Can you wash the back of your opposite shoulder with the affected extremity?	Yes	No
12. Would your shoulder allow you to work full-time at your regular job?	Yes	No

PENN SHOULDER SCORE

Part I: Pain & Satisfaction: Please circle the number closest to your level of pain or satisfaction

	office use only
Pain at rest with your arm by your side: 0 1 2 3 4 5 6 7 8 9 10 No pain … Worst pain possible	_____ (10 – # circled)
Pain with normal activities (eating, dressing, bathing): 0 1 2 3 4 5 6 7 8 9 10 No pain … Worst pain possible	_____ (10 – # circled) (Score 0 if not applicable)
Pain with strenuous activities (reaching, lifting, pushing, pulling, throwing): 0 1 2 3 4 5 6 7 8 9 10 No pain … Worst pain possible	_____ (10 – # circled) (Score 0 if not applicable)
PAIN SCORE:	=____/30
How satisfied are you with the current level of function of your shoulder? 0 1 2 3 4 5 6 7 8 9 10 Not satisfied … Very satisfied	=____/10 (# circled)

Figure 41-7 Penn Shoulder Score pain and satisfaction subscales. (Reprinted with permission from University of Pennsylvania Shoulder and Elbow Service.)

authors.[88] It is a 100-point scale that consists of three subscales including pain, satisfaction, and function. The pain subscale consists of three pain items that address pain at rest, with activities of daily living, and with strenuous activities (see Fig. 41-7). Each item is based on a 10-point numeric rating scale with endpoints of "no pain" and "worst possible pain." Points are awarded for each item by subtracting the number circled from 10. Therefore, a patient can be awarded 30 points for the complete absence of pain. If the patient is unable to use the arm for strenuous activities, 0 points are scored for that item.

Patient satisfaction with shoulder function is also assessed with a 10-point numeric rating scale. The endpoints are "not satisfied" and "very satisfied." A maximum of 10 points for this section indicates that the patient is "very satisfied" with the current level of function of his or her shoulder.

PENN SHOULDER SCORE Part II: Function: Please circle the number that best describes the level of difficulty you might have performing each activity.	No difficulty	Some difficulty	Much difficulty	Can't do at all	Did not do before injury
1. Reach the small of your back to tuck in your shirt with your hand	3	2	1	0	X
2. Wash the middle of your back/hook bra	3	2	1	0	X
3. Perform necessary toileting activities	3	2	1	0	X
4. Wash the back of opposite shoulder	3	2	1	0	X
5. Comb hair	3	2	1	0	X
6. Place hand behind head with elbow held straight out to the side	3	2	1	0	X
7. Dress self (including put on coat and pull shirt off overhead)	3	2	1	0	X
8. Sleep on affected side	3	2	1	0	X
9. Open a door with affected side	3	2	1	0	X
10. Carry a bag of groceries with affected arm	3	2	1	0	X
11. Carry a briefcase/small suitcase with affected arm	3	2	1	0	X
12. Place a soup can (1–2 lb) on a shelf at shoulder level without bending elbow	3	2	1	0	X
13. Place a one-gallon container (8–10 lb) on a shelf at shoulder level without bending elbow	3	2	1	0	X
14. Reach a shelf above your head without bending your elbow	3	2	1	0	X
15. Place a soup can (1–2 lb) on a shelf overhead without bending your elbow	3	2	1	0	X
16. Place a one-gallon container (8–10 lb) on a shelf overhead without bending your elbow	3	2	1	0	X
17. Perform usual sport/hobby	3	2	1	0	X
18. Perform household chores (cleaning, laundry, cooking)	3	2	1	0	X
19. Throw overhand/swim/overhead raquet sports. (circle all that apply to you)	3	2	1	0	X
20. Work full-time at your regular job	3	2	1	0	X
SCORING: Total of columns = ____ (a) Number of "X's" × 3 = ____(b), 60 – ____(b) = ____ (c) (if no "X's" are circled, function score = total of columns) Function Score = ____(a) ÷ ____(c) = ____ × 60 ____/60					

Figure 41-8 Penn Shoulder Score function subscale. (Reprinted with permission from University of Pennsylvania Shoulder and Elbow Service.)

The function subsection (see Fig. 41-8) is based on a sum of 20 items, each with a 4-point Likert scale. The response options include 0 (can't do at all), 1 (much difficulty), 2 (with some difficulty), and 3 (no difficulty). A patient is awarded 60 points if all activities can be performed without difficulty. Because some items in this subscale may not be applicable to all patients, the response option "did not do before injury" is available. For scoring purposes, the total possible points for the function subscale are reduced by 3 when this option is circled. Scoring

Part III: ACTIVE RANGE OF MOTION

Points are based on a % of INV/UNINV shoulder AROM	AROM		PROM		% UNINV	PTS
	INV	UNINV	INV	UNINV		
Forward elevation					%	
External rotation at 0º abduction					%	
External rotation at 90º abduction					%	
Internal rotation (level of hitchhiking thumb)					%	
TOTAL POINTS =						/40

Forward elevation & External rotation AROM scoring	Internal rotation AROM scoring
96 – 100% = 10 points	<2 Spinal levels = 10 pts
85 – 95% = 9 points	
75 – 84% = 8 points	3 – 5 Spinal levels = 8 pts
65 – 74% = 7 points	
55 – 64% = 6 points	6 – 12 Spinal levels = 6 pts
45 – 54% = 5 points	
35 – 44% = 4 points	Sacrum = 4 pts
25 – 34% = 3 points	
15 – 24% = 2 points	Buttock = 2 pts
5 – 14% = 1 point	
0 – 4% = 0 points	Side of thigh = 0 pts

Figure 41-9 Penn Shoulder Score active range of motion (AROM) scoring. INV = involved; PROM = passive range of motion; UNINV = uninvolved. (Reprinted with permission from University of Pennsylvania Shoulder and Elbow Service.)

is based on a percentage of the total possible points. For example, a patient has a total score for the function subsection of 27 points. He or she responded, "did not do before injury" for two items. Therefore, the total possible points would be 54 (60 − 6). The final function score would be calculated: 27 ÷ 54 = 0.5; then 0.5 × 60 = patient's function subscale score of 30 points.

The total PSS maximum score of 100 indicates high function, low pain, and high satisfaction with the function of the shoulder. The PSS can be used in the aggregate or each subscale individually. Most patients complete the scale in approximately 5 minutes, and the clinician can typically calculate the final scores in less than 2 minutes.[108]

The measurement properties of the PSS have been examined (Table 41-1).[88] Two additional studies examined specific attributes of the PSS. Cook and colleagues[37] examined the error associated with the function subscale and compared it to other shoulder scales at differing levels of function. They found that the PSS had much better precision throughout all score ranges than the ASES and SST.[37] The PSS had precision nearly equal to that of the SPADI at the middle-range scores, but exhibited better precision at the high and low scores.[37] Michener and colleagues[109] demonstrated convergent construct validity of the ASES score by reporting correlation with the PSS of 0.78. The PSS has also been used as an outcome measure in two clinical trials involving patients with shoulder impingement syndrome and rotator cuff repair.[36,103]

There is also a separate, clinician- or impairment-based score that may be used in conjunction with the self-report scale. The 100-point impairment score consists of objective measures of ROM and strength (Figs. 41-9 and 41-10). Shoulder active range of motion (AROM) is recorded as recommended by the ASES and includes forward elevation, external rotation with the arm at the side,

Part IV: STRENGTH:				
Device: _____(kg lbs. ft/lbs) (circle one)	INV	UNINV	% Uninv	PTS
External rotation at side			%	
Internal rotation at side			%	
Elevation at 45º in POS			%	
TOTAL POINTS =				/60

Strength Scoring
>90% = 20 points
80 – 89% = 18 points
70 – 79% = 16 points
60 – 69% = 14 points
51 – 59% = 12 points
40 – 49% = 10 points
30 – 39% = 8 points
20 – 29% = 6 points
10 – 19% = 4 points
1 – 9% = 2 points
0% = 0 points

Figure 41-10 Penn Shoulder Score strength scoring. INV = involved; POS = plane of scapula; UNINV = uninvolved. (Reprinted with permission from University of Pennsylvania Shoulder and Elbow Service.)

external rotation at 90 degrees of abduction, and internal rotation.[25,121] All motions are measured in the seated position.

Fig. 41-9 demonstrates the scoring for each of the ROM parameters. Scoring for forward elevation and external rotation is based on a percentage of the opposite uninvolved side. Internal rotation scoring is based on the level that the hitch-hiking thumb can reach, until the patient is able to reach the lumbar or thoracic spinous processes. Scoring then is based on a comparison of the spinal level achieved by the opposite uninvolved extremity. Ten points can be awarded for each ROM parameter for a total of 40 points for this section.

Strength testing should be performed with an isometric dynamometer. Internal and external rotation is measured with the arm at the side and in neutral rotation. Elevation is measured at 45 degrees in the plane of the scapula. Scoring is based on a percentage of the opposite normal side (see Fig. 41-10). Ten points can be awarded for each position for a maximum of 30 points for this section. This method of recording strength has demonstrated good reliability with three different isometric dynamometers.[89] A limitation of basing a score on a percentage of the opposite side assumes that the "uninvolved" side is normal. In addition, this type of scoring would not be useful for patients with two "involved" shoulders or those who have undergone surgery on that shoulder.

SUMMARY

The necessity of documenting outcome of surgical and therapeutic intervention of shoulder disorders is receiving increased emphasis in health care today. More importantly, clinicians must be able to compare results of different forms of treatment, compare results reported by other clinicians, and learn the confounding factors that may affect outcome. To accomplish this, standardized methods must be universally accepted. Available outcome scoring systems must meet the necessary criteria before they can be used. Once these systems are in place, the most effective treatments will be offered for the least cost.

Improving the patient's pain, function, and satisfaction should be the goal of any treatment intervention. Knowledge of the factors that contribute to that improvement is important in determining their relationship to the overall patient outcome. A patient self-assessment tool that measures outcome for the general population of shoulder patients should be used. In addition, the level of improvement in impairments such as ROM and strength should be compared with the patient's assessment of outcome. Use of a generic health status measure provides data as to the effect a shoulder problem has on the patient's overall function. Integrating these data will help to guide treatment and predict outcome, thereby improving the efficiency of our health care system.

Pain is defined by the International Association for Study of Pain (IASP) as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage."[101]

EPIDEMIOLOGY

Pain is one of the most significant health care crises in the United States. Nearly half of Americans see a physician with a primary complaint of pain each year, making pain the single most frequent reason for physician consultation in the United States.[70]

At least 60 million Americans suffer from chronic pain problems. Disability due to pain is a major problem in the United States. Three-fourths of the disablement relate to pain.[89]

CLASSIFICATION

Pain is classified in many ways including acute or chronic, organic or psychogenic, and malignant or nonmalignant.[54–75]

Acute pain is defined as pain temporally related to a precipitating event. It is associated with autonomic nervous system hyperactivity, including tachycardia, increased blood pressure, and anxiety.

Chronic pain is pain lasting more than 3 to 6 months. Objective clinical findings for chronic pain include depression, functional disruptions such as withdrawal from social activities, and personality and lifestyle changes. Therefore, in relation to pain, "chronic" describes not only duration, but also a syndrome with specific therapeutic implications.[49] Chronic pain is classified as organic versus psychologic pain.

Organic pain may be nociceptive or neuropathic.

Nociceptive pain is found in cutaneous or deep tissue (somatic) and organs (visceral). Nociceptive pain

results from direct stimulation of intact peripheral afferent nerve endings that are sensitive to noxious mechanical, thermal, or chemical stimuli.

Somatic pain is characterized as constant and easily identifiable. An example of chronic somatic pain is metastatic bone pain. This pain may be persistent, diffuse, and unrelated to position or movement, or it may be intermittent, localized, and related to position and weight-bearing or physical activity

Visceral nociceptive pain tends to be less well localized and is described as dull, dragging, and deep in nature.

Neuropathic pain is caused by injury or disease of the nervous system. It may be divided into central and peripheral nervous system disturbances and is designated as deafferentation pain. Nervous system injury may result from direct trauma, ischemia (e.g., thalamic syndrome), infection (e.g., postherpetic neuralgia), metabolic derangement (e.g., diabetic neuropathy), or tumor invasion.

Neuropathic pain may be constant and steady or intermittent and lancinating and is described as burning, shooting, or tingling. Pain may be experienced as abnormal or altered sensation (dysesthesia), paresthesia (electrical shock sensation), hyperalgesia (extreme sensitivity to painful stimuli), or allodynia (pain with touch).

Peripheral naturopathic pain is secondary to peripheral hyperexcitability, which is due to a series of molecular changes at the level of the peripheral nociceptor, in dorsal root ganglia, in the dorsal horn of the spinal cord, and in the brain. These changes include abnormal expression of sodium channel activity at glutamate receptor sites, change in γ-aminobutyric acid (GABA-ergic) inhibition, and an alteration of calcium influx into cells.[67]

Psychogenic pain is defined as a somatoform pain disorder, which is a diagnosis of exclusion.[49]

Chronic pain of the shoulder is usually due to somatic or neuropathic pain.

CHRONIC SOMATIC SHOULDER PAIN

Periarticular Soft Tissue

Impingement syndromes
Rotator cuff tear (partial and complete)
Bicipital tendon tear/tendinitis
Adhesive capsulitis/frozen shoulder
Glenohumeral instability

Joints

Osteoarthritis (glenohumeral or acromioclavicular)
Septic arthritis
Rheumatoid arthritis
Gout and pseudogout
Osteonecrosis
Subluxation (acromioclavicular or sternoclavicular)

Bone

Fracture
Osteomyelitis
Tumor

Muscles

Myofascial pain syndrome
Fibromyalgia

Regional Myofascial Pain Syndrome

The hallmark characteristics of regional myofascial pain are (a) localization within a circumscribed muscle or group of muscles in a particular area of the body and (b) the presence of trigger points.[140] Trigger points are hyperirritable nodules that feel like cords of rope within the body of a skeletal muscle or surrounding fascia. Trigger points can develop after different types of trauma, many of which are seemingly insignificant. Quite often, trigger points are the result of repetitive injury (e.g., trigger points with the body of trapezius in a typist).

On physical examination, the trigger point can produce a localized involuntary twitch response to palpation. This involuntary twitch response represents a brief contraction of muscle fibers within an involved muscle. At the same time, a patient also may have a voluntary response to palpation of a trigger point. This voluntary response is most commonly manifested as patient movement or vocalization and has been called the jump sign. Trigger points within specific muscles have well-described, characteristic referral patterns to other areas of the body.[158] These patterns of radiation may not seemingly follow normal anatomic radiation patterns (i.e., radiation along the course of peripheral nerves or dermatomes). However, the somewhat atypical and unusual patterns of trigger-point radiation are well described and reproducible.

The pathogenesis of trigger points is unclear. Injured muscles that do not heal and progress to chronic pain appear to develop problems within the sarcomere early in the natural history of the process. Uncontrolled contraction of the sarcomere may lead to development of a trigger point.[142] On a molecular basis, inability to physiologically utilize calcium may cause actin and myosin to function improperly. Thus, a muscle fibril becomes, in essence, paralyzed and unable to relax.[139]

Treatment of regional myofascial pain involves medical, invasive, and physical therapeutic modalities. Nonsteroidal antiinflammatory medications (NSAIDs) and tricyclic antidepressants (TCAs) have been shown to provide effective analgesia.[25,134]

Muscle relaxants have been widely used in the treatment of myofascial pain, despite the fact that they have not been

rigorously studied to the same extent as NSAIDs and antidepressants. However, some patients will anecdotally report great benefit from the use of muscle relaxants. Membrane-stabilizing drugs have not been shown to produce significant analgesia in regional myofascial pain.

Injection of active trigger points has been advocated by some investigators, although scientific studies have been inconclusive regarding their long-term effects.[134] Trigger-point injections have utilized saline, local anesthetics, and corticosteroids or have been given without medications (dry needling).

Physical medicine modalities are the most important treatment for regional myofascial pain.

Fibromyalgia

Fibromyalgia is a musculoskeletal disorder with marked similarity to regional myofascial pain.[53,98] The prevalence of fibromyalgia in the population is approximately 0.7% to 3.2%.[66] The high prevalence of disability among patients with fibromyalgia represents a significant cost to society in health care dollars.[90]

Although regional myofascial pain and fibromyalgia share many characteristics, they are distinct clinical entities. Myofascial pain is topographically discrete and localized, whereas fibromyalgia is diffuse and widespread. The American College of Rheumatology has developed criteria for the diagnosis of fibromyalgia.[172] When 11 of 18 tender points elicit pain by palpation (in nine paired anatomically defined sites) with concomitant widespread muscular aching, a sensitivity of 88.4% and a specificity of 8l.1% are achieved for the diagnosis of fibromyalgia. Trigger points are deemed to be specific for regional myofascial pain syndrome. Trigger points elicit pain upon palpation of the muscle belly, whereas tender points occur at the muscle–tendon junction. Moreover, trigger points have reproducible patterns of radiation, whereas tender points do not radiate.

Regional myofascial pain syndrome is the result of trauma, microtrauma, or repetitive injury to muscle. On the other hand, fibromyalgia presents without a history of trauma or even an inciting event.

Fatigue and sleep disturbance are found in fibromyalgia but not in regional myofascial pain.[173] The sleep disturbance is characterized by a nonrestorative pattern. The patient awakens each morning feeling unrested.[99]

Fibromyalgia has been reported in conjunction with connective tissue.[167] The prevalence of regional myofascial pain is not increased in rheumatologic disorders in comparison with the general population.

Two of the anatomically defined sites for the diagnosis of fibromyalgia by the American College of Rheumatology lie within the musculature of the shoulder.[172] Thus, pain in the shoulder musculature as a presenting feature of fibromyalgia is not unusual.

The treatment of fibromyalgia should involve interdisciplinary expertise. The cornerstone of therapy is pharmacologic management with NSAIDs and TCAs.[25,134] Use of trigger-point injections has been uniformly disappointing in patients with fibromyalgia because of the diffuse nature of the disease. Physical therapy is paramount in the treatment of fibromyalgia, but many patients reject it because of the painful nature of the disease process. However, all physical therapeutic efforts should be formulated within the framework of a strengthening and conditioning program. Many patients with fibromyalgia lack insight into their disease, as well as coping strategies, and may appear depressed and anxious.[71] Many patients may benefit from psychological intervention, as well as psychotropic medication when appropriate.

CHRONIC NEUROPATHIC SHOULDER PAIN

- Spinal cord lesions
- Cervical pathology
  - Spondylosis
  - Degenerative disc disease
  - Herniated nucleus pulposus
  - Radiculopathy
- Spinal nerve lesions
- Brachial plexopathy
  - Stretch, compression, trauma
  - Avulsion
  - Stingers and burners
  - Intraoperative injuries
  - Brachial plexus neuritis
  - Tumors
  - Radiation neuritis
- Thoracic outlet syndrome (TOS)
  - Neurologic TOS
  - Vascular TOS
  - TOS of pain and sensory symptoms
- Entrapment syndromes

  - Axillary nerve
- Complex regional pain syndrome (CRPS)
  - CRPS I (reflex sympathetic dystrophy)
  - CRPS II (causalgia)

Cervical Pathology

Cervical spondylosis involves osteoarthritic degenerative changes of the joints of the cervical spine: the disc itself, the facet, and the uncovertebral joints. Osteophytes may form at all of the aforementioned joints and encroach upon the nerve root foramina. Changes in the cervical discs themselves consist of chronic degeneration and desiccation.

The discs can flatten and bulge outward with promotion of osteophyte formation.

Disc herniation consists of protrusion of the nucleus pulposus through a tear in the annulus fibrosus. The nerve root may be compressed within its foramen when the herniation occurs in a lateral or dorsolateral direction, thereby potentially generating a cervical radiculopathy. Disc herniation may occur in conjunction with chronic spondylotic changes in the cervical spine.

Cervical radiculopathy and myelopathy may be generated by acute, subacute, or insidious (with the possibility of spinal cord compression) disc herniation. Acute cervical disc herniation is much less common than in the lumbar area. Pain is the predominant symptom of acute cervical radiculopathy. The pain is often widely distributed over the shoulder, scapula, upper chest, and arm, and may be appreciated deep within certain muscles. Radicular pain (paresthesia) is present in a dermatomal pattern. Muscle weakness is usually mild but can be severe. The dermatomal distribution of the radicular pain, as well as weakness within certain muscles (Table 42-1), may be diagnostic aids in determination of the involved root.

Subacute cervical radiculopathy is much more common than acute radiculopathy and results from disc herniation occurring in conjunction with chronic spondylotic changes. Pain and paresthesias are present, as in the acute form. Unlike acute radiculopathy, mild sensory loss or hyperesthesia, along with moderate weakness, is common. The most commonly involved discs are C5–6 and C6–7.[171]

Radicular myelopathy may result from compression of the spinal cord. Cervical degenerative discs, spondylosis of the facet and/or uncovertebral joints, and posterior vertebral osteophytes may be involved in the compressive mechanism. Furthermore, a hypertrophied and inelastic ligamentum flavum may compress the cord with neck extension.[153] The result of these chronic spondylotic changes with spinal cord compression is a myelopathic constellation of symptoms affecting both the arm and legs. In contradistinction to acute and subacute radiculopathy, pain and sensory changes are usually minimal with respect to upper limb symptoms. On the other hand, muscle weakness and wasting may be severe. Abnormalities in the legs include spastic weakness and variable sensory loss (with vibratory sense being most affected). Deep tendon reflexes in the legs are hyperreflexic, whereas those in the arms are hyporeflexic.

Computed tomography (CT), myelography, CT myelography, and magnetic resonance imaging (MRI) are essential

TABLE 42-1
PATTERNS OF MUSCLE WEAKNESS RESULTING FROM BRACHIAL PLEXUS LESIONS

Brachial Plexus	Nerve Branch	Muscles
Trunks		
Upper	Suprascapular (C5–6)	Supraspinatus, infraspinatus
	Lateral pectoral (C5–7)	Clavicular portion of the pectoralis major
	Musculocutaneous (C5–7)	Biceps
	Lateral portion median (C5–7)	Pronator teres, flexor carpi radialis
	Radial (C5–6)	Brachioradialis
	Axillary (C5–6)	Deltoid
Middle	Thoracodorsal (C6–8)	Latissimus dorsi
	Subscapular (C5–6)	Teres major
	Radial (C7)	All radial innervated muscles (except brachioradialis)
	Lateral portion median (C5–7)	Pronator teres, flexor carpi radialis
Lower	Medial pectoral (C8–T1)	Sternal portion of pectoralis major
	Ulnar (C8–T1)	All ulnar innervated muscles
	Medial portion median (C8–T1)	Flexors of hand, median innervated intrinsic muscles of hand
Cords		
Lateral	Musculocutaneous (C5–7)	Biceps
	Lateral portion median (C5–7)	Pronator teres, flexor carpi radialis
Posterior	Thoracodorsal (C6–8)	Latissimus dorsi
	Subscapular (C5–6)	Teres major
	Axillary (C5–6)	Deltoid
	Radial (C5–T1)	All radial innervated muscles
Medial	Ulnar (C8–T1)	All ulnar innervated muscles
	Medial portion median (C8–T1)	Flexors of hand, median innervated intrinsic muscles of hand

Figure 42-1 Anteroposterior view showing cervical interlaminar cervical epidural injection.

for the evaluation and diagnosis of mechanical and radicular cervical spine pain.

Treatment of the pain of spondylosis itself may be amenable to NSAIDs. Acute and subacute radiculopathy may be ameliorated by NSAIDs, cervical interlaminar epidural steroid injections (CESIs)[27–44] (Fig. 42-1), and cervical transforaminal steroid injections,[142,162] with rehabilitation facilitated by physical therapy. Judicious surgical intervention may guard against the devastating effects of radiculomyelopathy.

Cervical Epidural Steroid Injection: Interlaminar Versus Transforaminal Approach

The advantage of the transforaminal approach over the interlaminar one is that the transforaminal route is more target specific as the injectant is delivered to the target nerve and the anterior epidural space (pathology site) in maximum concentration.

The major disadvantage of the cervical transforaminal steroid injection is the higher risk of serious complications: injection in the vertebral or radicular artery, spinal cord or brainstem infarction, and nerve root injury. That is why it should be done only by experienced clinicians under real-time fluoroscopy.[117]

Brachial Plexopathy

Traumatic Injury

Because of its superficial location, the mobility of the shoulder and the neck, and its close proximity to bony structures, the brachial plexus is particularly susceptible to traumatic injury. Stretch (traction) injuries are particularly common after falls and motorcycle accidents, when the head and neck are moved in one direction and the shoulder is moved in the opposite direction. The brachial plexus also may be compressed or crushed between the clavicle and underlying ribs or damaged by bony fragments, displaced muscles, hematomas, or missiles.[150]

Fractures and dislocations of the shoulder frequently damage the brachial plexus.[83] Dislocations of the shoulder without a concomitant fracture more frequently injure the axillary nerve than the brachial plexus itself, however. Bony fragments or hematoma associated with fractures of the clavicle can damage the plexus and cause brachial plexopathy.[175] When damage to the brachial plexus does occur, it is usually diffuse, with varying degrees of injury associated with different parts of the plexus. However, injury may be restricted to just one trunk or cord.

Nerve Root Avulsion

Avulsion of spinal nerve roots involves tearing of the dorsal and ventral roots of one or more spinal nerves from the spinal cord. Of course, avulsion is a particularly serious result of stretch injuries to the brachial plexus. The lower cervical roots (including T1) are most often involved. Neuropathic pain is almost uniformly produced after traumatic root avulsion.[109]

The topographic distribution of pain conforms to the dermatome of the avulsed root(s). (Hand and forearm pain occurs after C6, C7, C8, or T1 root avulsions. Shoulder pain occurs after C5 root avulsion.)

Burning, electric shock, or pressure sensations form a continuous background of severe pain. Superimposed upon this background are paroxysms of pain of unbearable intensity that radiate from the hand to the shoulder and are described as sharp, shooting, or lightning-like. More typical paresthesias following normal dermatomal distributions also occur.

Careful physical examination (Table 42-1) is essential in localization of the injury to a specific area of the plexus. In conjunction with physical examination, radiographic studies and electrophysiologic studies are essential in the diagnosis of root avulsion.

The most optimal assessment of nerve root avulsion and plexus injury combines radiographic visualization with electrophysiologic testing. Electromyography (EMG) can assist in the assessment of nerve root avulsion, because it permits evaluation of the paraspinal muscles (which cannot be evaluated clinically) and because it may indicate the severity of damage. In nerve root avulsion, EMG of paraspinal muscles is abnormal, because damage to the roots is proximal to the dorsal rami.[22] Sensory action potentials recorded from the arm are normal in nerve root avulsion because distal sensory fibers are still viable, because they are not separated from their cell bodies. Sensory action potentials may be normal, even in the face of dense anesthesia in the distribution of the

avulsed root(s).[168] In contrast, sensory action potentials are reduced or absent in brachial plexus lesions, because damage to nerve fibers is distal to the dorsal root ganglion.

During the first 3 to 4 months after avulsion, spontaneous recovery from neurapraxia can occur. During this time period, neuropathic pain should be treated with TCAs and membrane-stabilizing agents. Aggressive physiotherapy is important to prevent contractures and joint ankylosis. If no nerve regeneration is present after 4 months and if electrophysiologic studies show evidence of severe axonal degeneration, the brachial plexus should be surgically explored. Surgical repair of the brachial plexus can restore function and reduce pain.[102,106]

Ablative procedures should not be entertained until the possibility of de novo nerve regeneration or functional recovery has waned. Amputation should not be considered, because it will not relieve the pain of root avulsion. Ablation of the dorsal root entry zone (DREZ) lesion can greatly reduce the pain of nerve root avulsion.[156]

Intraoperative Brachial Plexus Injuries

Damage to the brachial plexus may occur during general anesthesia. Such injuries are due to hyperabduction of the arm and stretch of the plexus because of poor positioning of the patient.[95] Intraoperative brachial plexus injury is particularly common after procedures involving median sternotomy and has been estimated to occur in 5% of all such patients.[81] The lower trunk or medial cord is most commonly involved, although any part of the plexus can be damaged.

Brachial Plexus Neuritis

Acute brachial plexus neuritis can develop at any age for reasons that are obscure. The pain is of great intensity and does not follow a radicular or peripheral nerve distribution. Sensory abnormalities are usually of less intensity than the pain and muscle weakness. The serratus anterior, deltoid, infraspinatus, and supraspinatus muscles are most commonly involved, although involvement of individual muscles or muscle groups is highly variable. Weakness of the musculature may indicate involvement of a single nerve, two nerves, or a discrete part of the plexus, usually the upper trunk. Acute brachial plexus neuritis is asymmetric in only about one-third of cases and is most commonly found as a bilateral condition.[161]

Different causes have been suggested as the key factors in the pathogenesis of brachial plexus neuritis including infections, trauma, vasculitis, and surgical events.[152,175] No cause-and-effect relationship has been definitively demonstrated.[14,151]

Malignant Invasion

Tumors invading the brachial plexus include breast cancer (most common) and Pancoast's tumor. In breast cancer, brachial plexus invasion occurs via spread from lymph nodes or bone metastases. The predominant symptom is shoulder pain that radiates down the arm and forearm into the fingers (depending on the trunk involved). Paresthesias and weakness develop later. Malignant invasion of the brachial plexus is rarely an early manifestation of breast cancer.

In contradistinction, brachial plexopathy presents as an early manifestation of Pancoast's tumor.[82] Pancoast's tumor (superior pulmonary sulcus tumor) is almost always caused by invasion of the lower trunk of the brachial plexus by carcinoma of the lung at the apex. The presenting symptom is usually pain radiating along the inner aspect of the arm. Weakness and sensory changes are usually localized to the lower trunk of the brachial plexus. Almost two-thirds of patients will develop Homer's syndrome, due to infiltration of the inferior cervical sympathetic ganglion.[60]

Radiation Neuritis

Radiation-induced brachial plexopathy with fibrosis of the brachial plexus may occur after radiation to the upper chest wall and supraclavicular area for the treatment of malignant tumors. Radiation damage to the brachial plexus is dose dependent. Onset of plexopathy may be years after irradiation. Radiation-induced brachial plexopathy can occur without any sign of radiation damage to the overlying skin. The presence of nonneurologic signs (e.g., lymphedema and induration) may be found in both radiation neuritis and malignant invasion of the brachial plexus.[157]

Thoracic Outlet Syndromes

The thoracic outlet syndromes comprise three different clinical pathophysiologic entities.[151]

Neurologic Thoracic Outlet Syndrome

Neurologic thoracic outlet syndrome is found mainly in women. It begins to manifest itself as pain along the medial aspect of the arm and forearm. Paresthesias are found extending into the ulnar border of the hand. Muscle weakness and atrophy occur later. Muscle atrophy is selective for the abductor pollicis brevis and the opponens muscles of the thenar eminence. Wasting of all the intrinsic muscles of the hand is possible with progression of the condition. There are no vascular symptoms. Sensory abnormalities are referable to the lower trunk of the brachial plexus.[51]

A well-developed cervical or rudimentary cervical rib with a fibrous band extending to the upper surface of the first rib may impinge on the lower trunk of the brachial plexus (Fig. 42-2). Similarly, anatomic abnormalities of the first rib may stretch and angulate the lower trunk of the brachial plexus. The scalenus anticus syndrome involves hypertrophy of the anterior scalene muscle and compression

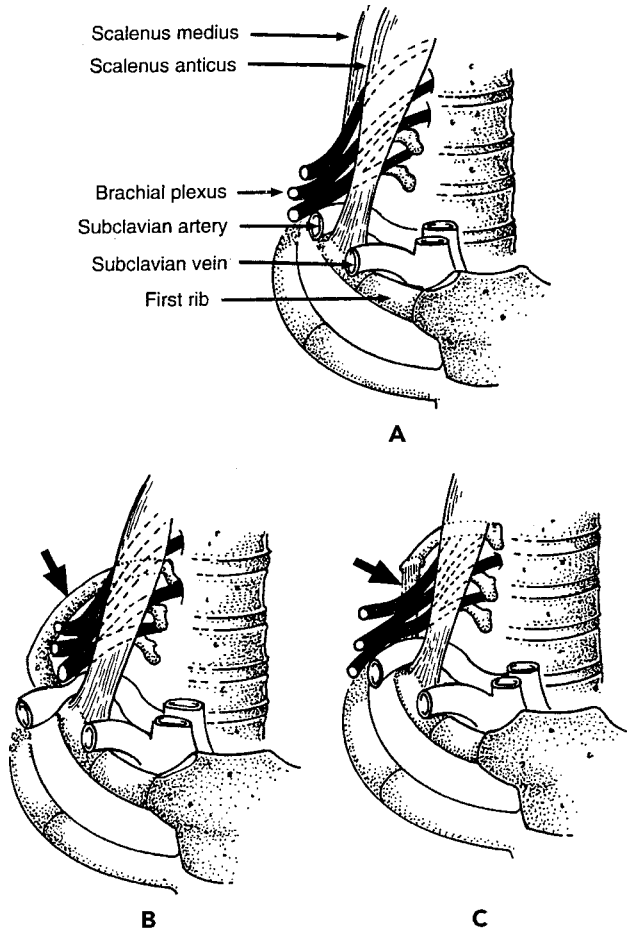

Figure 42-2 **(A)** Normal anatomic relationships of the subclavian artery and the brachial plexus at the cervicothoracic junction. **(B)** Vascular thoracic outlet syndrome. The subclavian artery is angulated over a well-developed cervical rib. The subclavian artery is also sandwiched between the cervical rib and the anterior scalene muscle. Both these anatomic relationships cause stenosis of the subclavian artery and poststenotic dilation of the artery. **(C)** Neurologic thoracic outlet syndrome. The normal anatomic relationships of the first rib, lower trunk, medial cord of the brachial plexus, subclavian artery, and anterior scalene muscle are shown on the right. On the left, a small cervical rib and a fibrous band are depicted. The lower trunk of the brachial plexus is angulated over this band, and this anatomic relationship can generate neurologic thoracic outlet syndrome. (Reprinted with permission from Wyburn-Mason R. Brachial neuritis occurring in epidemic form. *Lancet* 1941;2:662–663.)

of the brachial plexus as it passes through the interscalene groove between the anterior and middle scalene muscles (Fig. 42-3). Hyperabduction syndrome or subcoracoid-pectoralis minor syndrome involves compression of the brachial plexus with lateral abduction of the arm to an elevated position. In this position, the brachial plexus and vasculature are compressed by tension of the pectoralis minor muscle and, to a lesser extent, the coracoid process.[52,88]

Physical examination, roentgenographs, and electrophysiologic studies should be employed in determination of the diagnosis of neurologic thoracic outlet syndrome. Roentgenographs will almost uniformly show the characteristic bony abnormality responsible for the neurologic symptomatology. If a bony abnormality is not seen, then consideration must be given to the presence of fibrous bands, scalenus anticus syndrome, or hyperabduction syndrome. Electrophysiologic studies can differentiate neurologic thoracic outlet syndrome from carpal tunnel syndrome and ulnar neuropathy.[52] Short-latency somatosensory evoked potentials (SSEPs), following stimulation of the ulnar nerve at the wrist, may actually be more useful.[23]

Supraclavicular exploration with release of the compressive anatomy is the most satisfactory treatment for neurologic thoracic outlet syndrome. Patients experience immediate relief of pain. Unfortunately, muscle weakness and atrophy do not usually improve.[51]

Vascular Thoracic Outlet Syndrome

In patients with a well-developed first rib, the subclavian artery may be angulated over the cervical rib and wedged between the anterior scalene muscle and the cervical rib. The subclavian artery will become narrowed and will develop an area of poststenotic dilation. Thrombus may accumulate in the poststenotic dilation, fragment, and embolize to the hand. This produces vascular symptomatology with intermittent blanching of the hands and fingers. Pulses may be diminished or absent. A bruit can sometimes be auscultated in the supraclavicular and/or axillary areas. The vascular thoracic outlet syndrome consists only of vascular symptomatology without neurologic abnormalities. Angiography will confirm the diagnosis. Surgical excision of the cervical rib effectively treats vascular thoracic outlet syndrome.[40]

Thoracic Outlet Syndrome of Pain and Sensory Symptoms

The largest group of patients with thoracic outlet syndrome will present with less clearly defined symptomatology than the aforementioned two rare, but well-defined, thoracic outlet syndromes. Such patients will usually present with a diffuse nagging ache and numbness in the arm. The pain in the arm will be made worse by carrying heavy objects or holding the arm in particular positions. Paresthesias may occur concomitantly with the pain or may be temporally distinct. Paresthesias are usually appreciated in the medial aspect of the arm and forearm and sometimes in the hand.

Various proposed mechanisms include (a) compression of the subclavian artery and/or brachial plexus between the lower end of the anterior scalene muscle and the first rib[51]; (b) vascular factors, venous rather than arterial compression[124]; and (c) costoclavicular syndrome.[42,43] The costoclavicular syndrome suggests that the subclavian artery and/or the brachial plexus are intermittently compressed between the clavicle and a normal first rib. Patients

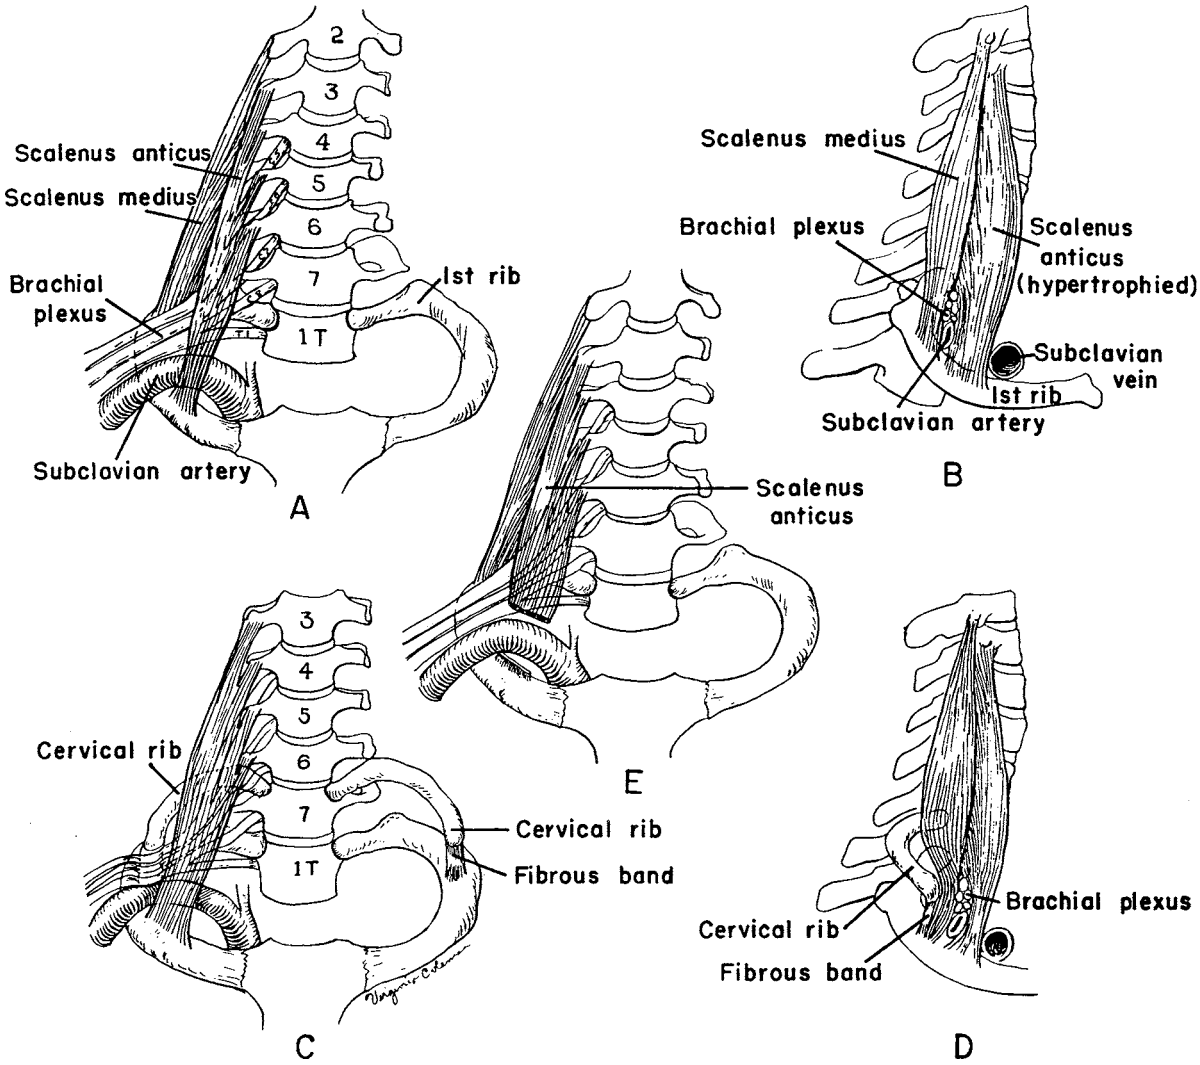

Figure 42-3 Anatomic relationships generating scalenus anticus syndrome in the presence and absence of a cervical rib. **(A)** Normal. **(B)** Hypertrophied anterior scalene muscle compresses the brachial plexus and the subclavian artery. **(C,D)** Compression of the brachial plexus by a cervical rib. **(E)** Relief of compression by scalenotomy. believed to have costoclavicular syndrome are women with long necks and drooping shoulders. Symptomatology has been hypothesized to result from chronic stretching of the brachial plexus.

Investigations to confirm this more common but obscure form of thoracic outlet syndrome are usually unrewarding. Roentgenographs, EMG, nerve conduction studies, SSEPs, and arteriography are usually normal and of limited value.

Exercises to counteract and strengthen the drooping shoulders have been proposed as a possible treatment. First rib resection is often performed in patients with this more obscure but common form of thoracic outlet syndrome. Complete relief of symptoms has been reported in 55% to 85% of patients with partial relief in 7% to 35% of patients.[127]

Entrapment Syndromes

Suprascapular Nerve

The suprascapular nerve contains fibers from C5 and C6 and arises from the upper trunk of the brachial plexus. Coursing underneath the trapezius muscle, it passes onto the scapula through the suprascapular notch to the supraspinatus fossa of the scapula to supply the supraspinatus muscle (Fig. 42-4). A ligament overlies the suprascapular notch and transforms the notch into an actual foramen.[119] The nerve then passes around the spinoglenoid notch and ends in the infraspinous fossa to supply the infraspinatus muscle. Once again, a small ligament may be found at the spinoglenoid notch, which transforms the notch into a foramen.[1]

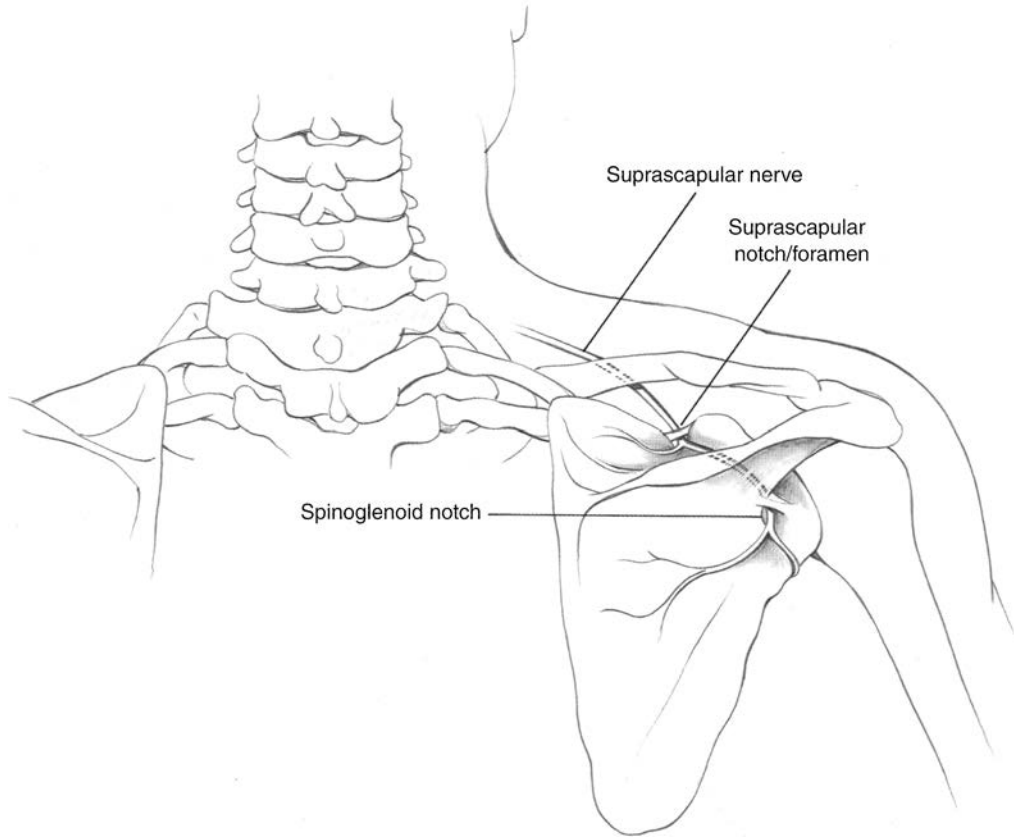

Figure 42-4 Suprascapular nerve entrapment. Posterior view of the left shoulder showing the course of the suprascapular nerve and potential areas of entrapment in the suprascapular notch/foramen and the spinoglenoid notch/foramen. (Reprinted with permission from Petrera JE, Trojaborg W. Conduction studies of the long thoracic nerve in serratus anterior palsy of different etiology. *Neurology* 1984;34:1033–1037.)

Selective wasting and weakness of the supraspinatus and infraspinatus muscles, rather than pain, are the usual presenting signs of suprascapular neuropathy.

Entrapment of the suprascapular nerve within the suprascapular notch or spinoglenoid notch occurs gradually over time. Entrapment of the nerve in either notch may occur from compression by a tight ligament **(61)**, although entrapment in the spinoglenoid notch by this mechanism is a rare event. **(62)** In the suprascapular notch, the presence of a bone spur also may cause entrapment. Fractures and shoulder injuries also may result in chronic compression of the suprascapular nerve in its notch. **(63)**

Treatment should be based on severity of the neuropathy. In the presence of a mild focal neuropathy, injections of local anesthetic and corticosteroid may be helpful **(64)**, otherwise surgical interventions may be indicated.

Long Thoracic Nerve

The long thoracic nerve arises from the ventral rami of C5–6 and sometimes C7. After leaving the brachial plexus, it travels down the internal aspect of the chest wall supplying the serratus anterior muscle.

Patients with a neuropathy of the long thoracic nerve complain of a dull ache around the shoulder girdle at rest or upon abduction of the arm. However, motor dysfunction of the serratus anterior and its sequelae are more prominent features. As the serratus anterior stabilizes the scapula against the chest wall, weakness and difficulty in using the shoulder are the primary symptoms of long thoracic neuropathy.

Because of the formation of the long thoracic nerve from the roots of C5–7 prior to the development of the trunks, long thoracic neuropathy will seldom occur in brachial plexus injuries. Long thoracic neuropathies most often occur in the face of blunt trauma to the shoulder or the anterolateral thoracic wall.[69] The long thoracic nerve also may be injured after a number of common surgeries, including thoracotomy and radical mastectomy.[59] Repetitive or extreme exertional shoulder movement also has been implicated in long thoracic neuropathy. Activity such as chopping wood, playing golf or tennis, and jumping rope have been described as potential factors in the genesis of the neuropathy.[111]

If the injury to the long thoracic nerve is due to excessive or repetitive use of the shoulder, cessation of activity usually results in full recovery. Physical therapy is the primary modality for management of long thoracic neuropathy

after acute blunt trauma or surgical injury. Unfortunately, prognosis is poor. Shoulder braces also may be of value.[160]

Axillary Nerve

The axillary nerve arises from the posterior cord of the brachial plexus. It lies lateral to the radial nerve and passes below the shoulder joint into the quadrilateral space. The boundaries of the quadrilateral space are the neck of the humerus, the long head of the triceps, the teres major muscles, and the teres minor muscles. The axillary nerve courses along the posterior and lateral surfaces of the humerus and divides into terminal branches supplying the deltoid muscle.

Wasting and weakness of the deltoid muscle, with marked impairment in shoulder abduction, are the chief clinical presentations of axillary neuropathy. As in other entrapment neuropathies, sensory abnormalities can be minimal in axillary nerve entrapment. Sensory loss may be present in a small area overlying the deltoid muscle near its insertion.[15]

Shoulder dislocation or fracture of the surgical neck of the humerus are the most common causes of axillary neuropathy.[17] The axillary nerve is usually not injured in isolation, and there may be concomitant trauma to the radial, suprascapular, or musculocutaneous nerves or the brachial plexus itself.[87] Other causes of injury to the axillary nerve include blunt trauma, intramuscular injections and bullet wounds.[135]

If traumatic damage to the axillary nerve is incomplete, no specific therapy is required. If the lesion is complete, some degree of recovery should be expected in several months. If recovery does not occur, surgical exploration and nerve grafting may be considered.

COMPLEX REGIONAL PAIN SYNDROME

To simplify CRPS and develop a rational diagnostic and therapeutic approach, the pain patterns in CRPS can be divided into two states: sympathetically maintained pain (SMP) and sympathetically independent pain (SIP).

Sympathetically Maintained Pain

This describes the pain that is dependent on and maintained by sympathetic input. Two particular features distinguish SMP: The pain is accompanied by signs of autonomic dysfunction and sympathetic blockade generally results in pain relief. Features usually include burning pain, hypersensitivity, allodynia, edema, and sometimes muscle spasms and dystonias.[8] The response to sympathetic blockade is generally good and was the reason behind the original disease nomenclature of reflex sympathetic dystrophy.[41]

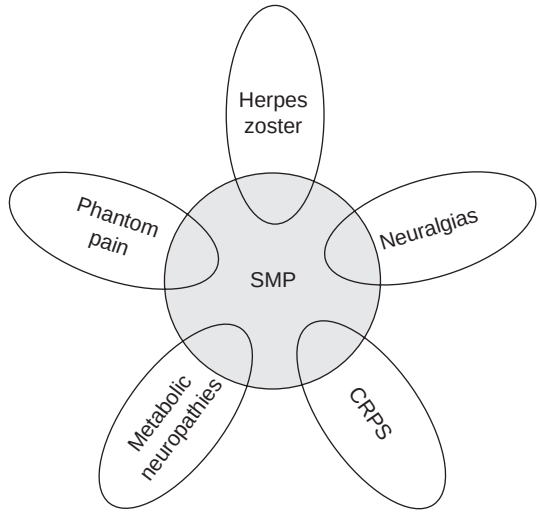

Figure 42-5 Relationship between sympathetically maintained pain and some selected painful conditions. This illustration is intended as a conceptual framework without indication of the quantitative relationship between the intersections. Varied pain disorders may have a component of sympathetically maintained.

It is not exactly known how the sympathetic blocks work, and unfortunately there are no well-controlled studies on the efficacy of the sympathetic blocks. A large number of uncontrolled studies, however, reveal excellent initial pain relief and long-term pain relief in greater than 50% of patients.[86–113] The goal of treatment in this condition is to break the cycle of the pain state while the patients are involved in progressive rehabilitation programs.[146] Occasionally, a single blockade can stop the process, especially if given early in the course of the disease. Many patients will have a progressively prolonged duration of symptomatic improvement following subsequent blockades. However, in some cases the effectiveness of the sympathetic blockade lasts for a short duration, and sometimes as the disease progresses, the sympathetic blocks become less effective. This may be due to decreased contribution of the sympathetic system to the painful state or may be secondary to development of fibrosis around the sympathetic ganglion shielding it from the injected local anesthetic. One must recognize that the term "sympathetically maintained pain" describes a mechanism by which pain occurs, and is not limited to CRPS. SMP occurs in a variety of other neuropathic pain conditions like diabetic neuropathy, ischemic peripheral vascular disease, postherpetic neuralgia, neuroma pain, and phantom limb pain[93] (Fig. 42-5).

Sympathetically Independent Pain

This describes the pain state that occurs most often in later stages of CRPS, where sympathetic blockade or sympathectomy yields no clinical improvement of the pain. The pain characteristics of this clinical subgroup suggest the involvement of various mechanisms.

Diagnosis of SMP

While diagnosis of CRPS is based on the clinical picture, determination of the sympathetic component of the pain can be made primarily by studying the effects of sympathetic blockade on the pain.

Complex Regional Pain Syndrome

CRPS is the new terminology proposed by the IASP to replace the old names (reflex sympathetic dystrophy [RSD], causalgia, etc.). The word "complex" describes varying clinical features of the condition. The *pain*, which is the sine qua none of the clinical entity, is usually *regional* in distribution. CRPS is further divided into CRPS types I and II, type I comprising the old RSD designation and type II encompassing the old causalgia as well as posttraumatic neuralgias. Unlike CRPS-I, CRPS-II occurs consequent to an injury to a specific nerve.[146] CRPS is not limited to adults; cases have been described in children. In adolescents it seems that girls are more affected than boys and the lower limbs more frequently affected than the upper limbs. These patients are usually high achievers and are active in sports.[9]

CRPS Type I

This is characterized by:

1. History of an initiating noxious event, however trivial
2. Ongoing pain or allodynia/hyperalgesia that is ***not*** limited to distribution of a single peripheral nerve, and is disproportionate to the inciting event
3. Evidence of edema, blood flow abnormalities, or abnormal sudomotor activity in the region of the pain
4. This diagnosis is excluded by the existence of conditions that would otherwise account for the degree of pain and dysfunction.

CRPS Type II

This is characterized by:

1. Developing after a nerve injury
2. Ongoing pain or allodynia/hyperalgesia occurring and not necessarily limited to the distribution of the injured nerve
3. Evidence of edema, skin blood flow abnormalities, or abnormal sudomotor activity in the region of pain
4. This diagnosis is excluded by the existence of conditions that would otherwise account for the degree of pain and dysfunction.

Clinical Presentation

Incidence

The epidemiologic data on the incidence of CRPS are sparse. Approximately 10% of patients referred to multidisciplinary pain clinics are diagnosed to have CRPS. SMP involves the upper limb twice as frequently as the lower limb. There is no clear sex prevalence for SMP. Several studies have reported that the incidence of causalgia following peripheral nerve injury varies between 2% and 14%.[119]

Predisposing Factors

Most patients with SMP present with a history of trauma to the soft tissue, bone, or elements of the nervous system that may be the result of accidental injury in the form of sprain, fracture, dislocation, crush, or blunt injury. Surgical or other iatrogenic injuries, or even vaccinations, have been reported to result in SMP. Additionally, SMP has been associated with neurologic diseases such as diabetic neuropathy, stroke, postherpetic neuralgia, and herniated disc lesions. The unanswered question remains: Why, following apparently identical types of injury, does only a small proportion of patients develop the pain and associated trophic changes while the majority of individuals do not? Recent studies suggest a possible genetic predisposition in individuals afflicted with CRPS.[91,163]

Clinical Features

The clinical signs and symptoms of CRPS-I are variable. The characteristic triad of signs and symptoms includes sensory abnormalities, autonomic dysfunction, and motor dysfunction. These signs and symptoms may be present in varying combinations and intensities depending on the severity and duration of the disease.

Sensory Abnormalities. Pain following a trauma that persists beyond the expected normal healing process is an early warning sign of CRPS- I. Spontaneous burning pain and/or pain to light mechanical stimuli are prominent signs of CRPS-I. Pain is typically not limited to the distribution of a specific peripheral nerve. These sensory abnormalities are most pronounced distally in the affected limb; however, symptoms of CRPS often extend beyond the involved extremity. Indeed, recent studies have shown hemisensory impairment, manifested as decreased temperature and pinprick sensation in the part of the body corresponding to the affected limb, in one-third of CRPS patients.[122] These patients, moreover, displayed increased frequency of allodynia and hyperalgesia, suggesting that in addition to peripheral up-regulation in alpha-adrenoceptors, central mechanisms enter into play in the pathophysiology of CRPS.

Autonomic Dysfunction. Altered skin temperature on the hyperalgesic region is often demonstrated in patients with CRPS-I.[16,169] Autonomic dysfunction can be also demonstrated by abnormal responsiveness to cold pressor test. Such abnormalities in the skin may be easily demonstrated by skin temperature measurement, or more accurately and quantitatively by thermographic imaging. Trophic changes such as local edema, abnormal hair and nail growth, and patchy osteoporosis may occur as a consequence of altered

microcirculation.[16,107] Because of their responsiveness to sympathetic blocks, these changes may be due to the hypersensitivity of affected organs to the sympathetic outflow.[12]

Motor Dysfunction. Not uncommonly, dystonia affecting movement in the distal extremity is noticed in patients with early CRPS-I. Muscle strength is reduced and may be lost. However, this is mostly due to disuse atrophy or limited by the pain state.[132] Of note, motor signs and symptoms were not included in the diagnostic criteria of the IASP due to their sporadic occurrence. The dystonia may be focal, multifocal, or diffuse and is notoriously resistant to treatment. A recent study evaluated the efficacy of intrathecal baclofen in CRPS-I patients with multifocal or generalized dystonias. Intrathecal baclofen was found to have a substantial therapeutic value in patients with CRPS-I, especially when the dystonia involves the upper extremities.[164]

The Shoulder in Complex Regional Pain Syndrome

CRPS commonly affects the shoulder and upper extremity. Many patients with sympathetically maintained pain localized in the hand or the wrist also have complaints of pain in the shoulder. Such coexistence of pain symptomatology is often called the shoulder–hand syndrome[148,149] or the shoulder–hand–finger syndrome.[103] Patients complain of pain, stiffness, and limited range of motion in the shoulder, with swelling and vasomotor disturbances in the hand. This limited range of shoulder motion may be passive or active because of pain. Frozen shoulder may occur in severe cases.[125,165]

Laboratory Tests/Diagnostic Procedures

Thermography. Infrared thermographic imaging using quantitative temperature difference has been used as a confirmatory test for CRPS-I (RSD). However, the quantitative temperature difference has inherent problems because skin temperature asymmetry may be present in neuropathic abnormalities, focal inflammation, or vascular disease. Recently, Gulevich et al.[55] used computer-generated side-to-side quantitative and qualitative temperature differences as well as functional autonomic response to cold water stress testing. The authors showed that stress infrared thermography is helpful in confirming the diagnosis of CRPS-I with 93% sensitivity and 89% specificity.

Three-Phase Bone Scan

CRPS-I (RSD) is characterized by pain, diminished function, joint stiffness, skin and soft tissue trophic changes, and vasomotor instability. Bone scanning has some role within the first year of onset of symptoms, and even then the sensitivity is only around 50%.[133,170] However, sometimes it could be of clinical use to help eliminate other differential diagnoses. Three-phase bone scanning usually shows hypervascularity in the affected extremity on early images followed by diffusely increased uptake in distal joints on delayed images.[77]

Quantitative Sensory Testing

Patients demonstrate that the mean threshold for pain to mechanical[137] and thermal stimuli[154] is dramatically decreased on the affected side. Even stimuli that are completely innocuous on normal skin, such as stroking with a camel's hair brush, applying a vibrating tuning fork to a bony prominence outside the hyperalgesic area, or moving a single hair follicle, can cause profound pain.

Response to Sympathetic Blockade

This is still a very important diagnostic test for CRPS, especially if pain is mediated through the sympathetic nervous system. Pain relief that outlasts the duration of the injected local anesthetic is an important diagnostic feature.[145]

Sympathetic blockade can be done either with a stellate ganglion block or using an intravenous regional block (IVRB). Other tests have been used to measure abnormalities of the sympathetic function including Doppler flowmetry,[13,131] infrared thermography,[20,55] sweat tests,[28] skin galvanic resistance tests,[31,153] and scintigraphic vascular[108] and bone scans.[77] Although these tests are indicative of sympathetic dysfunction, their specificity in the diagnosis of SMP has not been well documented.

Stellate Ganglion Block

This provides a more specific and definitive diagnosis of SMP depending on the result of a blockade of the sympathetic plexus that supplies the affected limb (e.g., the stellate ganglion when the upper limb is affected). Nonetheless, errors in the diagnosis of SMP can take place following sympathetic blockade with local anesthetics, and can be either false negative or false positive.

False-negative errors may result from technical failure in adequately blocking the sympathetic efferent fibers. Anatomic variability in sympathetic chain location and shielding of ganglia by adjacent fascial septae contribute to technical difficulties. Therefore, objective demonstration of increased skin temperature to 35°C in the distal extremity corresponding to the sympathetic ganglion blocked, in addition to other clinical signs of sympathetic blockade like Horner's sign or flushing of the skin of the limb, will verify that a proper sympathetic blockade has been achieved.[145]

T2 Sympathetic Blockade

False-negative results are particularly problematic with stellate ganglion blocks as sympathetic efferents from ganglia as caudal as T2 contribute to the innervation of the upper extremity.[12] False positives may occur when pain relief is due to somatic blockade. This can happen because sensory nerves could lie in close proximity to targeted sympathetic

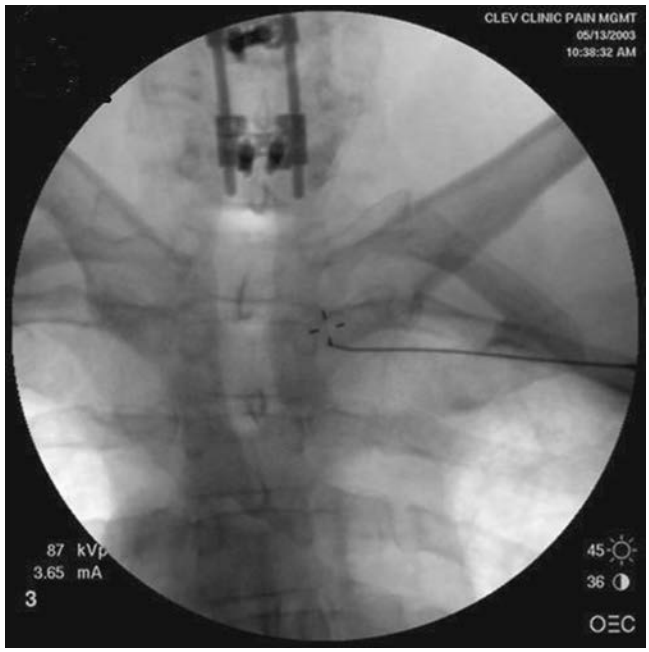

Figure 42-6 Anteroposterior view showing the final needle position at the costovertebral junction in T2 sympathetic block.

fibers at the level of the stellate ganglion. That is why T2 sympathetic blockade may be more selective (Fig. 42-6).

Attention should be paid to the diffusion pattern of the contrast agent to avoid tracking toward neighboring nerve roots. Also, sensory testing to verify that the affected area is not rendered hypoesthetic or anesthetic should be performed regularly.

Intravenous Regional Blocks

There are multiple reports on the analgesic effects of bretylium, guanethidine, reserpine, and others via the Bier block technique, and it has even been suggested as a diagnostic tool. However, there are no well-controlled studies supporting their effectiveness, and a recent meta-analysis looking at 21 such randomized clinical trials found insufficient numbers in most studies and important methodologic differences among the various trials, rendering conclusions difficult.[110]

A general pitfall to this technique is the possible confounding effect of an ischemic block of large-diameter afferent fibers. This can be differentiated by the dissimilar time course. Ischemic nerve block usually recovers within a few minutes, while sympathetic blocks due to sympathetic blockers last longer.

Moreover, false negatives with IVRB can occur in the presence of a sympathetic–afferent nociceptive interaction proximal to the tourniquet or by way of a sympathetic sudomotor (cholinergic) interaction with afferent nociceptors.[12]

Intravenous Phentolamine Test

It has been shown that the peripheral tissues express or upregulate alpha-adrenoceptors on the nociceptive primary afferent neurons at the site of injury. Activation of these nociceptors by the release of norepinephrine on previously inactive alpha-adrenoceptors results in pain.[37–32] Nociceptor activity leads to sensitization of the pain-signaling neurons (wide dynamic range neurons [WDR]). When sensitized, a minor input from the low threshold mechanoreceptors will induce pain. The systemic administration of the α-adrenergic blocking agent phentolamine has been suggested as an alternative test for the diagnosis of SMP. Intravenous phentolamine infusion has an advantage over the paravertebral sympathetic blockade in that it allows the injection of saline to test for placebo responders.[5,116] On the other hand, the drawbacks of IV phentolamine are the associated hypotension and tachycardia, which limit the benefit of this test in patients with coronary artery disease. These side effects can be avoided by pretreating the patients with IV fluids and beta-blockers if necessary. A major drawback of this test is that only a partial alpha-adrenoceptor blockade is achieved.[12]

Differential Diagnosis of CRPS

Although CRPS tends to present in an extremity in most cases, it may occur elsewhere in the body. Differential diagnoses include posttraumatic vasoconstriction from thrombophlebitis, arthritis, infection, soft tissue damage, tenosynovitis, fasciitis, fracture, and radiculopathy.

Management of CRPS

Physical Therapy and Rehabilitation

This is the fundamental step in the treatment of CRPS. Aggressive physical therapy and rehabilitation programs should be individually designed with the ultimate goal of regaining function of the affected extremity. Exercise includes various modalities and, more specifically, stress loading and increased endurance of the affected extremity.[145]

Sympathetic Blockade

The idea of the sympathetic blockade is to attempt to arrest the cycle of sympathetic hypersensitivity and to provide pain relief, which facilitates the physical therapy rehabilitation process. Various methods of sympathetic blockade can be used—stellate ganglion blocks, IV regional blocks, or repeated IV phentolamine infusion—if more than one extremity is involved or in patients where sympathetic blocks are contraindicated (e.g., anticoagulation).

Psychological Factors

Severe pain engenders emotional suffering and promotes behavioral changes that are subject to misinterpretation. The behavioral response to CRPS ranges from fully preserved function to complete invalidism. Such behavioral responses may be especially important in CRPS because of disuse, overprotection, and immobilization of the affected limb. These may lead to exacerbation of edema, vasomotor

changes, and demineralization associated with CRPS. Furthermore, major psychiatric illnesses could both exacerbate and reduce the ability to cope with CRPS-associated pain. For example, depression occurs in CRPS as in other chronic pain syndromes, and it also exacerbates the overall suffering. For these reasons, it is very important to address the psychological issues/psychiatric illnesses/personality disorders in an individualized basis and as a part of multidisciplinary program to treat CRPS.[50]

Adjuvant Medications

Pharmacologic treatment of neuropathic pain, including CRPS, is notoriously difficult, and there are very few well-designed trials addressing this subject. Numerous medications including tricyclic antidepressants, alpha-blockers, calcium channel blockers, membrane stabilizers, and alpha-2 agonists have been used to treat CRPS.[145] The efficacy of such agents still needs to be determined in case-controlled studies.

Continuous Infusion of Epidural Opioids and Local Anesthetics through a Tunneled Cervical Epidural Catheter

This modality has shown good outcomes in patients with CRPS, with acceptable rates of complications/side effects over periods of weeks to months. Favorable results were mainly noticeable when this treatment modality was initiated within 1 year of the onset of symptoms.[21,104,145] When contemplating surgery on an affected shoulder, it is imperative to implant a cervical epidural catheter to provide surgical anesthesia and maintain postoperative epidural analgesia for a variable period of time depending on the extent of the procedure and the severity of the illness, lest marked exacerbation of CRPS will occur (Fig. 42-7).

Peripheral Nerve Stimulation

Recently, peripheral nerve stimulation (PNS) has been used in the treatment of severe, intractable CRPS-II or causalgia. Criteria for patient selection for PNS include patients with severe intractable symptoms that are entirely or mainly in the distribution of one major peripheral nerve. Significant decreases in spontaneous pain as well as allodynia were noted up to 4 years following PNS placement, with 20% of patients returning to part-time or full-time employment.[57]

Spinal Cord Stimulation

Recent studies have shown that spinal cord stimulation (SCS) has a proven value in the management of refractory CRPS[72–121] (Fig. 42-8). It is worth noting that these patients had failed all other modalities of management. Improvements were noted in visual analog pain scales and perception of pain, in daily living and quality of life, and in a substantial decrease in analgesic consumption. The SCS-induced pain relief in CRPS is independent of sympathetic or vasodilatory effects.[73] No clinically relevant progress occurred in trophic

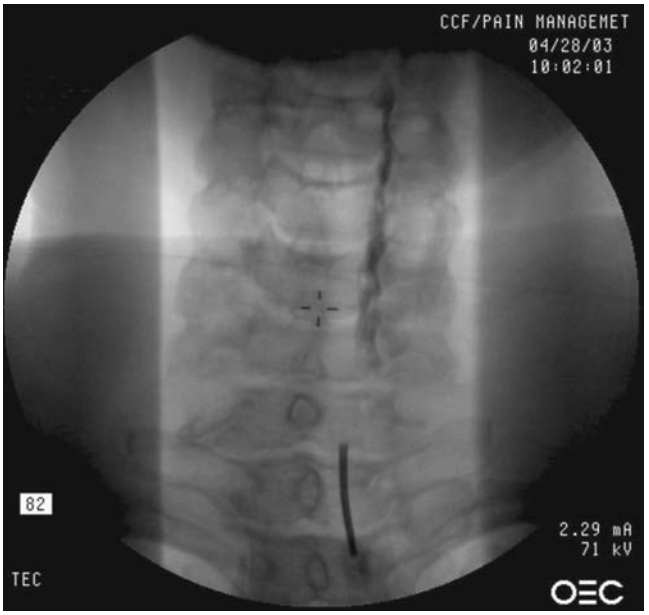

Figure 42-7 Anteroposterior view showing tunneled cervical epidural catheter with right-sided spread of the contrast agent.

alterations such as musculoskeletal changes or in the functional status of patients, but there was a clear propensity to return to work and productivity in implanted patients.[74–121]

PHARMACOLOGIC MANAGEMENT OF CHRONIC SHOULDER PAIN

Chronic pain is more of a treatment challenge; the pathogenesis may be unclear, with less opportunity to predict the course of recovery. The goal of pain management should include reconditioning, reducing pain, and improving function, sleep, and mood.

Figure 42-8 Anteroposterior view showing cervical spinal cord stimulation lead.

A multidisciplinary, comprehensive treatment plan is optimal, including:

- Individual psychosocial counseling in conjunction with patient/family education
- Noninvasive or minimally invasive procedures, such as massage therapy, physical therapy, transdermal or transcutaneous electrical nerve stimulation (TENS), or acupuncture
- Up-to-date pharmacologic and/or anesthetic therapies
- If necessary, surgical intervention and physical medicine and rehabilitation focused to enhance the patient's functional status[10,94]

Pharmacotherapy plays a key role in the management of chronic pain, as drug therapy may help to turn off noxious stimuli or dampen the underlying neuropathic disturbance.[4]

Nonopioid analgesics, which include acetaminophen, NSAIDs, and salicylate, provide first-line therapy for managing chronic pain and are classified as step 1 of the World Health Organization's (WHO) cancer-pain management ladder, which also has been applied to other, nonmalignant, chronic painful conditions.[49]

Acetaminophen

Acetaminophen inhibits prostaglandin synthetase in the central nervous system (CNS). Its action may be mediated through a central cyclooxygenase (COX)-2 mechanism, and also COX-3 has been proposed as a potential site of action. It has no or minimal effect on inhibition of peripheral prostaglandin synthesis, which accounts for the lack of antiinflammatory.[10,49]

Metabolism occurs in the liver, primarily by cytochrome P-450 (CYP-450), 1A2, 3A4, and 2E1.[10]

Acetaminophen has an excellent safety profile with regard to the gastroduodenal mucosa, platelet function, and nephrotoxicity but may cause hepatotoxicity at chronic doses higher than 6 g/day. Acute intoxication at a dose higher than 15 g/day can cause fatal hepatic necrosis.[4]

Prolonged use of acetaminophen in patients with severe liver disease and chronic alcoholism is not recommended. No more than 3 to 4 g of acetaminophen daily is currently recommended.[10]

Acetaminophen and NSAIDs have a ceiling dose effect for analgesia; beyond the recommended doses, no further pain relief occurs.[4]

Nonsteroidal Antiinflammatory Drugs

NSAIDs are among the most commonly used medications in the world. They constitute 4% of all filled prescriptions at a yearly cost in excess of $2 billion.[18,128] They are commonly used in the treatment of mild to moderate pain.[85]

Pharmacologic effects of NSAIDs include analgesia, antiinflammation, antipyresis, sodium retention and hyponatremia, the development of renal failure, vascular tone changes, gastric irritation, platelet inhibition, hepatic dysfunction, and CNS effect such as dizziness, sedation, and confusion.[4]

The ability of NSAIDs to exert analgesic and antiinflammatory effects is mediated by two mechanisms. The first is through suppression of proinflammatory and pain-enhancing prostaglandin synthesis at the site of inflammation. The second mechanism is through the modulation of neutrophil intracellular signaling function, which decreases the numbers of neutrophils migrating to inflammatory sites, resulting in a down-regulation of the release of free radicals and destructive enzymes at these sites.[128]

Two isoforms of COX enzyme exists: COX-1 and COX-2. COX-1 is found in most times throughout the body. It is expressed constitutively in both the gastroduodenal mucosa and platelet, and inhibition of COX-1 at these sites may predispose the patient to gastroduodenal ulceration and bleeding, respectively.

COX-2 is usually undetectable in most tissues but is expressed in response to inflammatory stimuli.

COX-1 and COX-2 are also expressed constitutively in the kidney, and inhibition of one or both of these isoforms may predispose the patient to renal adverse events, including renal insufficiency and hypertension. Traditional NSAIDs are nonselective inhibitors of both COX isoforms.[62,85]

Pharmacologic Classifications of NSAIDs

Carboxylic acids
Salicylic acids
Acetylsalicylic acid (aspirin)
Nonacetylated salicylates
  Choline magnesium trisalicylate (Trilisate)
  Salicyl salicylate (Disalcid)
  Diflunisal (Dolobid)
Acetic acids
Indole acetic acids
  Indomethacin (Indocin)
  Sulindac (Clinoril)
  Etodolac (Lodine)
Pyrrole acetic acids
  Tolmetin (Tolectin)
  Ketorolac (Toradol)
Phenyl acetic acids
  Diclofenac (Voltaren)
Naphthyl acetic acid
  Nabumetone (Relafen)
Propionic acids
Phenyl propionic acids
  Ibuprofen (Motrin)
  Fenoprofen (Nalfon)

Flurbiprofen (Ansaid)
Ketoprofen (Orudis)
Naphthyl propionic acids
Naproxen (Naprosyn, Anaprox)
Anthranilic acids
Fenamates
Meclofenamic acid (Meclomen)
Mefenamic acid (Ponstel)
Oxicams
Piroxicam (Feldene)
Pyrazoles
Phenylbutazone (Butazolidin)

The salicylate group of NSAIDs includes aspirin, choline magnesium trisalicylate, and diflunisal. Aspirin is commonly used not only as an antiinflammatory agent, but also for platelet-inhibiting effects in prevention of cerebrovascular accident and myocardial infarction.[4]

Aspirin produces irreversible inhibition of platelets. This inhibition is near complete and is sustained for at least 48 hours after a single dose.[76] A recent study suggests that concurrent treatment with ibuprofen may limit cardioprotective effects of aspirin by inhibiting aspirin's prolonged effect on platelet aggregation.[85]

Common side effects of aspirin include nausea and emesis, gastrointestinal (GI) hemorrhage, peptic ulcer, gastritis, and liver function abnormalities. Aspirin is the most nephrotoxic of the NSAIDs and has been associated with Rye's syndrome in children and adolescents. Prolonged use of high doses (more than 100 mg/kg/day) may result in chronic salicylate toxicity.[4]

Indole Acetic Acid Derivatives

Indomethacin, sulindac, and etodolac are indoleacetic acid derivatives.

GI side effects are quite common with indomethacin. Other adverse effects include psychosis, headache production, depression, hypertension, and fluid retention. Sulindac produces fewer side effects than indomethacin; however, a causal relationship to liver disease has been suggested. Etodolac is a mixed COX-1 and COX-2 inhibiting activity and therefore seems to have less toxicity.[4]

Pyrrol Acetic Acid Derivatives

Ketorolac is the only NSAID that is available as an injection in the United States. It is effective against pain of somatic origin. Concurrent use with opioids allows reduced dosing of opioids because it promotes release of endogenous opioids. Analgesic action of ketorolac is through the CNS. It has GI and renal toxicity. To avoid such toxicity, short-term use (less than 5 days orally and less than 48 hours parenterally) is recommended.[4,36]

Phenyl Acetic Acid Derivatives

Diclofenac (Voltaren) is used in the management of gout, low back and neck pain associated with degenerative joint disease, osteoarthritis, and rheumatoid arthritis. It has GI side effects, and there is a small risk of hepatic inflammation, so liver function tests must be done within 8 weeks of administration.[4]

Propionic Acid Derivatives

Ibuprofen, ketoprofen, and naproxen all have GI side effect. Naproxen is recognized as having more GI side effects than ibuprofen.[4]

COX-2 Selective Inhibitors

Celecoxib (Celebrex), valdecoxib (Bextra), and rofecoxib (Vioxx) were the first of a long line of COX-2 inhibitors to be available in the United States. These drugs have 200- to 300-fold selectivity for inhibition of COX-2 over COX-1.[18,85]

Celecoxib is the only COX-2 inhibitor available now in the United States, as rofecoxib (Vioxx) and valdecoxib (Bextra) were withdrawn from the market.

They are comparable to the traditional NSAIDs in their analgesic effects but have marked reduction in the gastrointestinal side effects.[62,85]

Two large outcome studies—the Vioxx Gastrointestinal Outcomes Research (VIGOR) trial[18] and the Celecoxib Long-term Arthritis Safety Study (CLASS)[138]—suggest that COX-2 selective inhibitors should be used whenever NSAIDs are indicated in patients with osteoarthritis or rheumatoid arthritis. The COX-2 selective inhibitors have comparable efficacy to nonselective NSAIDs in these patients.

In patient not taking low-dose aspirin, the risk of confirmed upper FI events including symptomatic ulcers and the risk of confirmed complicated upper GI events is significantly reduced in patients taking COX-2 selective inhibitors compared with those taking nonselective NSAIDs, particularly ibuprofen and naproxen.[138]

Caution needs to be exercised, however, in the use of COX-2 selective inhibitors in patients with uncontrolled hypertension, mild to moderate renal insufficiency, or congestive heart failure, as the renal adverse effects of COX-2 selective inhibitors are similar to those that occur with nonselective NSAIDs.

COX-2 Inhibitors and the Cardiovascular System. COX-2 selective inhibitors may increase the risk of serious cardiovascular thrombotic events, especially myocardial infarction, as these agents do not inhibit platelet aggregation.

In the VIGOR trial, the incidence of cardiovascular events was higher in patients receiving rofecoxib than in those receiving naproxen. However, in the CLASS trial, there was no increase in the incidence of cardiovascular events associated with celecoxib compared to ibuprofen and diclofenac.[105]

Recently, a large trial (not published yet) showed a twofold increase in acute myocardial infarction with rofecoxib compared to placebo. This prompted the voluntary withdrawal of rofecoxib (Vioxx) from the U.S. and worldwide markets in September 2004.

In April 2004, the U.S. Food and Drug Administration (FDA) requested Pfizer, Inc. to voluntarily withdraw Bextra (valdecoxib) from the market. This request was based on the lack of adequate data on the cardiovascular safety of long-term use of Bextra, increased risk of adverse cardiovascular events in short-term coronary artery bypass surgery (CABG) trials, and reports of serious and potentially life-threatening skin reactions (go to http://www.fda.gov/medwatch/SAFETY/2005/safety05.htm#Bextra for more information).

The FDA has also asked manufacturers of all prescription NSAIDs, including Celebrex (celecoxib), a COX-2 selective NSAID, to revise the labeling to include a boxed warning to highlight the potential cardiovascular and GI risks (go to http://www.fda.gov/medwatch/SAFETY/2004/safety04.htm#vioxx for more information).

NSAIDs and Gastrointestinal Complication

In patients taking NSAIDs, the clinical ulcer rate is in the range of 1% to 4% and a complicated ulcer rate is around 1%.[58] Increased risk of GI complication is dose related, and there is evidence of an interaction with concomitant glucocorticoid and acetaminophen therapy.[62] Dyspepsia is the most common side effect of NSAID therapy. It occurs in around 30% of chronic users and leads to cessation of therapy, switching therapy, and time-consuming and expensive investigations such as endoscopy.[33]

Risk factors for serious upper GI complications in patients treated with nonselective NSAIDs include older age, male sex, history of peptic ulcer disease or prior upper GI bleeding, concomitant use of oral glucocorticoids or anticoagulants, and, possibly, smoking and alcohol consumption. Ibuprofen has the lowest risk of gastrotoxicity among nonselective NSAIDs.[61,62]

Celecoxib at dosages greater than those indicated clinically was associated with a lower incidence of symptomatic ulcers and ulcer complications, compared with NSAIDs at standard dosages.

Upper GI toxicity was strongest among patients not taking aspirin concomitantly. It is also better tolerated than NSAIDs.[138]

NSAIDs and Renal Complication

Intake of nonselective NSAIDs is associated with about a twofold increase in risk of developing renal failure, the increase being dose related. Risk factors for acute renal failure in patients treated with nonselective NSAIDs include age greater than 65 years; presence of intrinsic renal disease, usually defined as a serum creatinine greater than 2.0 mg/dL; hypertension and/or congestive heart failure; and concomitant use of diuretics and angiotensin-converting enzyme inhibitors.[62]

Edema and salt and water retention are the most common adverse renal effects associated with NSAIDs, occurring in 2% to 5% of patients. Other rare renal effects include hyperkalemia, allergic interstitial nephritis, chronic interstitial nephritis, and nephrotic syndrome.[3]

Celecoxib appears to be associated with less renal toxicity compared with NSAIDs, and it does not increase the risk of cardiovascular thromboembolic events.[139]

NSAIDs and Hypertension

NSAIDs, with the possible exception of sulindac and aspirin, may, at least in the short term, increase blood pressure. Changes in mean arterial pressure are small, in the order of 3 to 5 mm Hg. The precise mechanism by which NSAIDs raise blood pressure remains obscure, but there is evidence for both an effect on the vascular tone, through decreased angiotensin-dependent prostaglandin release, and volume control (sodium retention).[34]

Hypertension and cardiovascular risk with the use of NSAIDs are more pronounced in elderly people and patients with preexisting hypertension. Among the NSAIDs, indomethacin, fenoprofen, and phenylbutazone are most strongly associated, while sulindac, aspirin, and ibuprofen are the least likely to be associated with this effect.[34]

Antiepileptics

Antiepileptic drugs have been used for many years, since the 1960s, in the treatment of neuropathic pain.[56,85] The older agents include phenytoin, carbamazepine, and valproic acid. The newer agents include gabapentin, lamotrigine, topiramate, zonisamide, and oxcarbazepine. The newer agents are more often used in the management of chronic pain than the older agents, because of lack of organ toxicity and lesser need to monitor therapy with blood tests.[49,56,85]

Possible mechanisms of actions are enhanced gamma-aminobutyric acid inhibition (valproate, clonazepam) or a stabilizing effect on neuronal cell membranes. A third possibility is action via *N*-methyl-D-aspartate (NMDA) receptor sites. By preventing bursts of action potentials, these drugs can eliminate the severe lancinating pain of trigeminal neuralgia and other neuropathic syndromes. The most common adverse effects are impaired mental and motor function, which may limit clinical use, particularly in the elderly.[56]

- **Drugs that block voltage-dependent sodium channels**
  Phenytoin
  Carbamazepine
  Oxcarbazepine
  Lamotrigine
  Zonisamide
- **Drugs that affect GABA metabolism**
  Tiagabine
  Vigabatrin
- **Drugs that affect calcium currents**
  Ethosuximide

- **Drugs with multiple mechanisms of actions**
  Topiramate
  Valproate
  Felbamate
  Pregabalin
- **Drugs with unknown mechanism of action**
  Gabapentin
  Levetiracetam

Phenytoin (Dilantin)

Phenytoin has been used to treat a number of pain syndromes, including postherpetic neuralgia, diabetic neuropathy, and complex regional pain syndrome, and it was the first drug to be used for trigeminal neuralgia. Phenytoin blocks Na^+ channels and reduces neuronal excitability of pain fibers mainly by this mechanism.[68]

Long-term treatment requires blood tests, and side effects include gingival hyperplasia, facial hair growth, rare cases of Steven-Johnson syndrome, and even peripheral neuropathy.[85]

Because of side effects, drugs such as carbamazepine, oxcarbazepine, and lamotrigine have replaced phenytoin, but phenytoin's availability for intravenous infusion makes it suitable for breaking an acute attack of neuropathic pain.[68]

Carbamazepine (Tegretol)

Carbamazepine is considered a drug of choice for the treatment of trigeminal neuralgia. It is also effective in migraine prophylaxis, postherpetic neuralgia, and painful diabetic neuropathy,[85] although the newer antiepileptic drugs show considerable promise in the management of cluster headache and trigeminal neuralgia.[159]

The effect of carbamazepine on pain suppression is probably mediated via central and peripheral mechanisms. It decreases sodium and potassium conductance and suppresses the spontaneous activity of A-delta and C fibers responsible for pain without affecting normal nerve conduction. Dosage of carbamazepine ranges from 300 to 2,400 mg/day in divided doses.[159]

Side effects of carbamazepine include somnolence, dizziness, and gait disturbances. It is also associated with chronic diarrhea, syndrome of inappropriate secretion of antidiabetic hormone (SIADH) and hyponatremia, rash, and, rarely, aplastic anemia, thrombocytopenia, cardiac arrhythmia, and hepatocellular jaundice. Complete blood count (CBC) and liver function tests should be monitored.[85,159]

Oxcarbazepine (Trileptal)

Oxcarbazepine is chemically similar to carbamazepine, has Na^+ channel-blocking actions, and is used in the treatment of partial seizures. It may be better tolerated than carbamazepine; however, the incidence of hyponatremia may be higher.

It has demonstrated efficacy in trigeminal neuralgia, and studies are under way to examine its role in other neuropathic pain syndromes.[68,85]

Lamotrigine (Lamictal)

Lamotrigine is a phenyltriazine derivative and was initially approved for treatment of partial complex seizures. It blocks voltage-dependent Na^+ channels with the inhibition of glutamate release.

Lamotrigine, 50 to 400 mg/day, has demonstrated efficacy in relieving pain in patients with trigeminal neuralgia refractory to other treatments, painful diabetic neuropathy, and pain related to multiple sclerosis.[159]

Adverse effects include dizziness, constipation, nausea, somnolence, diplopia, and skin rash.[159]

Oral lamotrigine, 20 mg/daily, is a well-tolerated and moderately effective treatment for central poststroke pain (CPSP).[166]

Tiagabine

Tiagabine is a nipecotic acid derivative that enhances GABA-mediated inhibitory neurotransmission. This antiepileptic drug inhibits presynaptic neuronal and glial GABA uptake by binding reversibly and saturably with GABA uptake carriers GAT-1 and GAT-3.[159]

Its antinociception effect appears to be mediated by GABAb receptors since it can be completely antagonized by pretreatment with selective GABAb receptor antagonists.[159] Tiagabine also has Na^+ channel-blocking action.[68]

Tiagabine, indicated as adjunctive therapy for treatment of complex partial seizures, is also being tried in a variety of neuropathic pain syndromes. Maintenance doses range from 32 to 56 mg/day in divided doses.[85]

Topiramate (Topamax)

Topiramate is a sulfamate-substituted derivative of D-fructose. It has several mechanisms of action: It blocks Na^+ channels-enhanced GABA activity, diminishes NMDA-mediated excitation, and blocks voltage gated Ca^{70+} channels.[10,68] Absorption is rapid with bioavailability of about 80%. Metabolism is minimal, with 70% of a dose recovered unchanged in the urine. Elimination half-life is 18 to 23 hours.[10]

In a randomized, double-blind, placebo-controlled trial using oral topiramate, 200 mg twice a day for weeks, a statistically significant reduction in average pain scores was reported.[159]

Side effects of topiramate include paresthesia, anorexia, and renal calculi. CNS-related side effects are dose related and generally not observed at doses less than 250 mg/day.

Cognitive motor slowing and speech or work difficulty are seen only in a minimal percentage of patients when high doses are initiated.[10,159]

Valproic Acid

Valproic acid will prolong repolarization of voltage-activated Na^+ channels and inhibition of sustained neuronal firing. It also increases the amount of GABA in the brain.[159]

Valproic acid is used in the prophylactic treatment of migraine headache. It is associated with weight gain, tremor, and alopecia.[56]

Pregabalin

Like gabapentin, pregabalin is a GABA analog without proven agonistic effect on GABA receptors. Pregabalin does not appear to interact directly with Na^+ channels, Ca^{70+}channels, or neurotransmitter responses (GABA, glutamate). A randomized controlled trial comparing three different doses of pregabalin (75, 300, and 600 mg/day orally) with placebo in 337 patients with diabetic neuropathy reported significant improvement in pain, sleep, and clinical and global impression of change scores for those who took 300 mg or more daily.[159] Dizziness, somnolence, and peripheral edema were the most frequent adverse effects reported in this trial.[159]

Felbamate

Felbamate is a dicarbamate that has Na^+ channel-blocking action, inhibits NMDA-evoked potential, and enhances GABA-evoked responses in hippocampal neurons. Clinical experience with felbamate in neuropathic pain is limited to a few case reports.[159]

Given its potential for fatal toxicity of the bone marrow and the liver, the use of felbamate is restricted to some patients with refractory epilepsy. Its use in treatment of pain conditions is not warranted given the existence of many other alternatives.[159]

Gabapentin (Neurontin)

Of the new generation of antiepileptic drugs used for treatment of neuropathic pain, gabapentin is perhaps the best agent studied so far. Gabapentin has an effect on alpha-2-delta types of calcium channels and acts as an antagonism of NMDA receptors. It has no direct GABAergic action and it does not affect GABA uptake or metabolism.[124,159]

Two large randomized clinical trials have established the efficacy of gabapentin for relief of neuropathic pain in patients with postherpetic neuralgia and painful diabetic neuropathy.[7,126]

Gabapentin has been used in different pain syndromes, including trigeminal neuralgia and painful tonic spasms associated with multiple sclerosis, reflex sympathetic dystrophy, painful HIV-related peripheral neuropathy, and neuropathic cancer pain, postpoliomyelitis pain, central dysesthetic pain following spinal cord injury and erythromelalgia, and headache syndromes.[124,159]

Gabapentin is not metabolized in humans and is eliminated unchanged in the urine. Renal impairment will consequently decrease gabapentin elimination in a linear fashion with a good correlation with creatinine clearance. Gabapentin is removed by hemodialysis, so patients in renal failure should receive their maintenance dose of gabapentin after each treatment. The recommended starting dose in the treatment of neuropathic pain is 300 mg three times a day with titration if necessary to a maximum of 3,600 to 4,200 mg as tolerated.[124]

Gabapentin is as efficacious at treating neuropathic pain with no significant difference in minor adverse effects as other anticonvulsants and antidepressants. A prospective open label trial reported that gabapentin was safe at doses of 26 to 78 mg/kg in 52 children and adolescents. An 8-week trial at doses of 1,800 to 2,400 mg daily should be used before treatment can be deemed a failure.[56]

The most common side effects are somnolence (20%), dizziness (18%), ataxia (13%), and fatigue. The most serious adverse effect is convulsion (0.9%) and Steven-Johnson syndrome.[124]

Opioids

The opioid analgesics interact with three opioid receptor types (μ, δ, and κ). These opioid receptors belong to the "G" protein–coupled receptor family and they signal via a second messenger (cyclic adenosine monophosphate) or an ion channel (K^+).[65]

The μ (mu) receptor mediates the analgesic, which is closely associated with the μ_1 subset of μ-receptors and adverse effects of morphine including supraspinal analgesia, respiratory depression, euphoria, and increased sedation, which are associated with the μ_2 receptors.[49,65] μ-Opioid receptors are found in the periphery (following inflammation), at pre- and postsynaptic sites in the spinal cord dorsal horn (laminae I–II), and in the brainstem, thalamus, and cortex, in what constitutes the ascending pain transmission system. In addition, μ-opioid receptors are found in the midbrain periaqueductal gray, the nucleus raphe magnus, and the rostral ventral medulla where they comprise a descending inhibitory system that modulates spinal cord pain transmission.[65]

δ-Opioid receptors have been found in cerebral and cerebellar cortex, hippocampus, thalamus and hypothalamus, brainstems, and medullary and spinal cord dorsal horns (particularly in laminae I–II).[92]

κ-Opioid receptor agonism produces effective spinal analgesia but is associated with miosis and significantly more sedation than is μ-receptor agonism.[49]

Drugs with high σ (sigma) receptor affinity cause dysphoria, psychomotor stimulation, and hallucination.

There exists a general overlap between distribution pattern of NMDA and opioid receptors within the CNS. Among all three types of opioid receptors (μ, δ, and κ), κ-opioids may have a unique role in antagonizing NMDA receptor–mediated electrophysiologic events by directly interacting with the NMDA receptor per se.[92]

At a cellular level, opioids decrease Ca^{70+} ion entry, resulting in a decrease in presynaptic neurotransmitter release (e.g., substance P release from primary afferents in the spinal cord dorsal horn), enhance potassium ion efflux resulting in the hyperpolarization of postsynaptic neurons and a decrease in synaptic transmission, and inhibit GABAergic transmission in a local circuit.[65]

Endogenous classic opioid peptides include the enkephalins, endorphins, and dystrophins and appear to function as neurotransmitters, neuromodulators, and, in some cases, neurohormones.[65]

Indications

There is strong consensus that opioids should be used aggressively when needed to relieve severe acute pain and pain associated with terminal cancer.[112] Severe pain with a clear diagnostic basis, supportive objective findings, and responsiveness to opioids deserve a trial of opioid therapy if other therapies are ineffective.[92]

Route of Administration

Opioids may be administered by oral, transmucosal, rectal, intravenous, subcutaneous, transdermal, and intraspinal routes. For the management of chronic pain, the oral and transdermal routes are generally preferred because they are readily available and less invasive than other routes and most often can provide satisfactory analgesia even when high doses are required. When these routes are not reasonable, parenteral routes or intraspinal may be indicated.[130]

Opioid Drug Choices

Opioids are classified according to their pharmacologic actions with the receptors as agonists, agonists–antagonists, or antagonists.

Factors to consider in selecting opioid analgesics are relative affinities to the different opioid receptors, pharmacokinetic characteristics that influence onset and duration of action, and whether the opioids are weak or strong with respect to analgesic properties. Morphine is the opioid analgesic of choice because it is relatively inexpensive, is available in a wide range of dosage forms, and is the most extensively studied and used opioid.[49]

Morphine

Morphine is generally considered the prototype of all opioids. Morphine is available for oral, parenteral, rectal, and intraspinal use. Morphine's oral bioavailability varies from 35% to 75%.[65,85]

Morphine's plasma half-life (2 to 3.5 hours) is somewhat shorter than its duration of analgesia (4 to 6 hours), which limits accumulations during repetitive administration. Its pharmacokinetics remain linear and there does not appear to be autoinduction of biotransformation even following large chronic doses.[65] Morphine accumulates in the kidneys, liver, and skeletal muscle.[85] The drug is metabolized via the hepatic system by phase II process to glucuronide metabolites (55%), which are then renally excreted.[75,135] Morphine-6-glucuronide (M-6-G) is an active metabolite of morphine (about 5% to 15%) and is a more potent μ-receptor agonist than morphine. M-6-G is eliminated by the kidneys and will accumulate relative to morphine in patients with renal insufficiency.[65] Morphine-3-glucuronide (M-3-G), the predominant metabolite of morphine (about 50%) in humans, is devoid of opioid activity but may be responsible for the neuroexcitatory effects sometimes seen with large chronic morphine dosing.[65]

Patients should be initially titrated on immediate-release morphine and once stabilized converted to the delayed release. To manage acute "breakthrough" pain, "rescue" medication (immediate-release morphine) should be made available to the patient receiving delayed-release preparation.

Morphine is the preferred drug for the management of moderate to severe chronic cancer pain. The best route of administration is by mouth, because it is simple, safe, convenient, inexpensive, and effective. Nonoral modes of administration should only be considered if (a) the oral route becomes unavailable or (b) there is documentation of failure of maximal doses of oral morphine and coanalgesic drugs.[2]

There are coincidental developments of morphine tolerance and tolerance-associated hyperalgesia. Repeated treatment with opioids could set up a condition mimicking ongoing nociceptive input through interaction between opioid and NMDA receptors. This concept is the basis for recommending a combined use of opioids and clinically available NMDA receptor antagonists.[97]

Hydromorphone

Hydromorphone is a semisynthetic opioid agonist and is a hydrogenated ketone of morphine. Hydromorphone is commonly used for moderate to severe pain. It is available in oral, rectal, parenteral, and intraspinal preparations. It is highly lipid-soluble and generally well tolerated, especially in the elderly when compared with morphine or meperidine.[85] The potency ratio for hydromorphone to morphine has been variously reported as between 3:1 and 7.5:1, depending on the route of administration.

Hydromorphone appears to be a potent analgesic as predicted for the μ-opioid receptor agonist. This effect is dose related. The adverse effect profile of hydromorphone is also predictable and similar to other strong opioid agonists. The evidence available does not convincingly demonstrate clinical superiority of hydromorphone over the other strong opioid analgesics.[114]

Codeine

Codeine is a narcotic agonist rarely used for management of mild to moderate pain because of its low analgesic potency. It is more frequently used as an antitussive. Codeine, unlike other commonly used opioids, has a "ceiling effect," above which additional doses fail to produce additional analgesia. Unfortunately, there does not appear to be a "ceiling" for side effects. Codeine is available in oral and parenteral preparation, but the oral product is only two-thirds as effective as the parenteral preparation for pain.[85] Codeine is metabolized to morphine, and this hepatic metabolism occurs through the CYP-450 2D6 pathway.[10]

Oxycodone

Oxycodone is available both as an immediate-release and a continuous-release (8 to 12 hours' duration) preparation (OxyContin), and these dosage forms can be used for moderate to severe pain. Oxycodone is commonly available as combination analgesia in conjunction with aspirin (Percodan) or acetaminophen (Percocet). The fixed-dose oxycodone combinations should not be used chronically in large doses for more severe pain because of the risk of dose-related toxicity from the nonopioid ingredient. For patients who require treatment for an extended period, it is beneficial to convert patients from immediate-release to controlled-release preparation. The controlled release tablets should be swallowed whole and never be broken. Taking broken tablets leads to rapid absorption and potentially fatal doses.[65,85]

Fentanyl

Fentanyl is a synthetic opioid commonly used as an analgesic and as an anesthetic because of its cardiac stabilizing effect. Fentanyl is approximately 80 to 100 times as potent as morphine and has a faster onset of action but a shorter duration of action. Fentanyl is highly lipid-soluble. This allows it to easily cross the blood-brain barrier and is responsible for its rapid onset of action.[65,85]

Fentanyl is extensively metabolized in the liver, so doses should be reduced in the setting of underlying liver disease. Doses should also be reduced in the elderly. Elderly patients are twice as sensitive to the effects of parenteral fentanyl as the younger population.[85] Parenteral fentanyl is used usually only in anesthesia and in the postoperative recovery period. Transmucosal and transdermal fentanyl are used in the management of chronic pain. Transmucosal fentanyl is available either as a lozenge (Oralet) or lozenge on a stick (Actiq). These transmucosal products are indicated only in the management of breakthrough pain in patients with cancer who are already receiving and are tolerant to opioid therapy.[85] Fentanyl lozenges are designed to be sucked, not chewed. Chewing and swallowing the medicine results in lower peak concentration and lower bioavailability of the drug.

Transdermal fentanyl is usually used to provide continuous analgesia, and the initial dose should not be greater than 25 mg/hr. It is important for the physician to recognize that it may take 1 to 2 days for transdermal fentanyl to provide proper analgesia. Patients should be advised to avoid exposing the fentanyl application site to direct heat (e.g., a heating pad, a nearby lamp, or a hot tub), because there is a temperature-dependent increase in fentanyl released from the transdermal system. Patients with fevers should also be monitored for side effects or signs suggesting a higher than appropriate dose of fentanyl.[85,130]

Methadone

Methadone oral bioavailability is 85%, and single-dose studies have estimated an oral–to–parenteral potency ratio of 1:2. Its plasma half-life averages 24 hours, whereas the duration of analgesia is often only 4 to 8 hours.[65] Repetitive analgesia doses of methadone lead to drug accumulation because of the discrepancy between its plasma half-life and the duration of analgesia. Sedation, confusion, and even death can occur when patients are not carefully monitored and the dosage is not adjusted as needed during the accumulation period, which can last from 5 to 10 days.[65] The normal starting dose for analgesia is 2.5 to 10 mg every 6 to 8 hours. Dosage should be adjusted in renal failure. No such dosage adjustments are necessary in liver disease unless it is severe.[85]

Methadone is inexpensive when compared with continuous-release opioid preparations and is often an excellent choice for many patients requiring long-term opioid therapy of pain on an around-the-clock basis. Caution should be used when increasing doses, especially in frail or elderly individuals, because of potential for accumulation of long-acting metabolites and multiple drug interactions.

The dosage form of methadone that is used is a racemic mixture of equal amounts of L-isomer, an opioid, and D-isomer, which has only weak opioid activity. Both the L- and D-isomers of methadone bind to the NMDA receptor, and the D-isomer has functional NMDA-receptor antagonist activity in animals, including antihyperalgesia and antiallodynia activity in animal models of painful peripheral neuropathy and the ability to prevent the development of morphine tolerance.[65]

Meperidine

Meperidine, an opioid with a short half-life, is used for the treatment of moderate to severe pain. Meperidine is only one-tenth as potent as morphine, but it has a quicker onset

of action.[10,85] The duration of action is 2 to 4 hours. Aside from analgesia, meperidine is also used for premedication, prevention, and treatment of postoperative shivering.[85,159]

The main drawback to meperidine is its side-effect profile. Ninety percent of meperidine is metabolized in the liver to normeperidine, a metabolite that has a half-life of its own up to 40 hours.[85] It has neuroexcitatory effects including mood effects, followed by tremors, multifocal myoclonus, and occasionally seizures.[65,85] These effects are more pronounced in the elderly or in cases of renal failure.

Propoxyphene

Propoxyphene, a weak μ-agonist, is a synthetic opiate analgesic with chemical similarity to methadone. It has low analgesic efficacy and is indicated for mild to moderate pain.[10,85] It is metabolized in the liver to norpropoxyphene, which is eliminated in the urine. Norpropoxyphene is not an opioid, has a long half-life, and is associated with neuroexcitation, proarrhythmic lidocaine-like effects, and pulmonary edema. Naloxone does not reverse the effects of norpropoxyphene.[10,85]

Long-term use of this agent is highly discouraged, and use in elderly patients is not recommended. It has little, if any, advantage over nonopioid analgesia.[130]

Opiate Agonist-Antagonists

The agonist-antagonist opioids, which include drugs such as pentazocine, nalbuphine, and butorphanol, have predominantly κ-agonist analgesia effect while antagonizing the μ-receptor.[65,130] They are relatively short acting and not available in continuous-release preparations. The agonist-antagonist drugs have reduced analgesic efficacy compared to pure μ-agonists and exhibit a ceiling effect.[65,130] In therapeutic doses, they may produce certain self-limiting psychotomimetic effects in some patients, and pentazocine is the most common drug associated with these effects.[65] These drugs play a very limited role in the management of chronic pain because the incidence and severity of the psychotomimetic effects increase with dose escalation and because they are not available in convenient oral dosage forms.[49]

Because of their antagonist activity, they may reverse analgesia and precipitate withdrawal in individuals who are physically dependent on μ-opioids; therefore, they cannot be used to manage acute pain or breakthrough pain in patients taking pure μ-agonists.[65,130]

Opiate Partial-Agonists

The partial agonist, buprenorphine, may precipitate withdrawal in patients who have received repeated doses of morphine-like agonists and developed physical dependence.[65]

Buprenorphine is a partial μ-agonist opioid that is used in addiction treatment for both withdrawal and maintenance therapies, as well as for pain relief.[130]

Adverse Effects of Opioids

Adverse effects appear to depend on a number of factors including age, extent of disease and organ dysfunction, concurrent administration of certain drugs, prior opioid exposure, and the route of drug administration.[65] The most common adverse effects are sedation, nausea, vomiting, constipation, and respiratory depression.

Central Nervous System

Opioids produce sedation and drowsiness, which can be expected to be a least additive with the sedative and respiratory depressant effects of other sedative hypnotics such as alcohol, barbiturates, and benzodiazepine.[65,85] Concurrent administration of dextroamphetamine in 2.5- to 5-mg oral doses twice daily has been reported to reduce the sedative effects of opioids. Tolerance usually develops to the sedative effects of opioid analgesics within the first several days of long-term administration.[65]

Opioids inhibit the hypothalamic release of both gonadotropin-releasing hormone and corticotropin-releasing hormone. In women, an opioid-induced decrease of follicle stimulating hormone (FSH) can cause anovulation and amenorrhea. In men, luteinizing hormone decreases during opioid administration, causing decreased testosterone release, decreased libido, and reduced sperm motility. Opioids can evoke the release of antidiuretic hormone, causing fluid retention.[96] Opioids can also cause paradoxical excitation, which is dose-dependent and is usually observed with high doses of potent opioids.

Respiratory System

Respiratory depression is the most dangerous complication and occurs in 0.1% of patients receiving oral or rectal opioids.[35] Opioids cause a dose-dependent respiratory depression. Activation of μ_2-receptors blunts the sensitivity of chemoreceptors in the brainstem to carbon dioxide.[65,96]

Individuals with impaired respiratory function or bronchial asthma are at greater risk of experiencing clinically significant respiratory depression in response to usual doses of these drugs.[85] Respiratory depression can be reversed by administration of the specific opioid antagonist naloxone.[65]

Cardiovascular System

Opioids cause bradycardia and decreased sympathetic tone. This may lead to hypotension, especially in the hypovolemic patient.[65,85,96]

Gastrointestinal Tract

Adverse GI effects include esophageal reflux, spasm of the sphincter of Oddi, and decreased pancreatic, biliary, and intestinal secretions.[96]

Opioids produce nausea and vomiting by an action on the medullary chemoreceptor trigger zone. The incidence of nausea is from 10% to 40%, but tolerance develops

rapidly. Nausea can be prevented by the use of antiemetics, such as prochlorperazine or metoclopramide.[65,85,96]

Constipation is probably the most common side effect associated with opioid therapy, occurring in 35% of patients taking opioids. These drugs act at multiple sites in the GI tract and spinal cord to produce a decrease in intestinal secretion and peristalsis, resulting in a dry stool and constipation. Tolerance develops very slowly. A diet rich with fiber and fluids combined with surfactant agents (e.g., docusate sodium) and lubricants (e.g., fish oil gel capsules) should routinely be prescribed with opioids. Stimulant laxatives (e.g., bisacodyl) and osmotic laxatives (e.g., lactulose) are also often necessary. An aggressive "bowel regimen" is particularly important in those most likely to experience constipation.[85]

Urinary System

Opioids can cause bladder spasm and an increase in sphincter tone leading to urinary retention, particularly in elderly patients.[65,85,96] These effects may be attributed to activation of μ- and δ-receptors supraspinally or spinally or to direct effects on the urinary system.[96] The severity of urinary retention may lessen with chronic use.[78]

Musculoskeletal Side Effects

At high doses, all of the opioid analgesia can produce multifocal myoclonus. This complication is most prominent with the use of repeated administration of large parenteral doses of meperidine.[96]

Muscle rigidity occasionally occurs with opioids, more commonly with higher doses of the potent, rapidly acting drugs. This is a dangerous side effect, potentially leading to difficulty in ventilation.[85]

Immune System

In vitro assays and animal studies indicate that opioids such as morphine can suppress a number of immunologic variables.[65] In the Palm et al. study, morphine did not affect cellular immune function. However, those patients with chronic pain produced smaller amounts of immunoglobulin than controls, and immunoglobulin production was reduced further by morphine.[65a]

Tolerance, Dependancy, and Addiction

Physical dependency reflects a state of neurophysiologic adaptation, which is present when withdrawal phenomena occur on abrupt cessation or precipitous decrease in doses of the medication or administration of an antagonist.[130]

Tolerance is present when increasing doses of an opioid are required to produce the initial effects of the drug.[56] The pain-facilitating systems including the NMDA receptors, nitric oxide, and COX systems may play important roles in opioid tolerance.[64]

Addiction in the context of opioid therapy of pain is reflected in a constellation of maladaptive behaviors, including loss of control over the use of the opioids, preoccupation with opioid use despite adequate pain relief, and continued use of opioids despite apparent adverse consequences because of their use.[130] Patients at risk of prescription opioid addiction are those with a history of substance or alcohol abuse, with a family history of addiction, using short-acting opioids, and with psychological problems.

Abuse in the context of opioid therapy of pain suggests that an individual is using the medication in a way that may cause harm to self or to others or is using it for an indication other than that intended by the prescribing clinician.

Pseudoaddiction refers to the perception by observers of apparent drug-seeking behavior in patients who have severe pain and have not received effective treatment of pain.[130]

The onset of *withdrawal* is characterized by the patient's report of feelings of anxiety, nervousness, and irritability and alternating chills and hot flushes. A prominent withdrawal sign is "wetness," including salivation, lacrimation rhinorrhea, and diaphoresis, as well as goose flesh. At the peak intensity of withdrawal, patients may experience nausea, vomiting, abdominal cramps, insomnia, and, rarely, multifocal myoclonus. Abstinence symptoms will appear within 6 to 12 hours and reach a peak at 24 to 72 hours following cessation of a short–half-life drug such as morphine, whereas onset may be delayed for 36 to 48 hours with methadone. The detoxification dose is equal to approximately one-fourth of the previous daily dose, which is divided to four doses and then decreased by half every 2 days until a total daily dose of 10 to 15 mg/day (in morphine equivalent) is reached. After 2 days on this dose, the opioid can be discontinued.[65]

The opioid contract or agreement maybe an appealing tool for managing many of the potential difficulties related to chronic opioid therapy for noncancer pain. It is also recommended that patients have a primary care physician who must also sign the opioid contract. The primary care physician signature indicates agreement with the decision to begin chronic opioid therapy and to become the prescriber once the patient's regimen has stabilized.[46]

Antidepressants

Most patients with chronic pain could benefit from antidepressants, especially if they have comorbid psychiatric conditions such as depression and sleep disorders; psychological factors affecting physician conditions; anxiety; somatization disorder; or somatoform pain disorder. There is a documented role for antidepressants in the treatment of chronic pain syndromes.[155] The rationale of prescribing antidepressants as analgesics is that they block reuptake of neurotransmitters (e.g., norepinephrine and serotonin) important to pain modulation.[6] There are consistent data that antidepressants do have an antinociceptive effect for various forms of chronic pain. Data for the efficacy of antidepressants are stronger for neuropathic pain than other types of pain.[45] Imipramine, amitriptyline, and desipramine have

demonstrated efficacy in painful diabetic neuropathy[167,170], with the latter two drugs being found to be analgesic in postherpetic neuralgia.[155]

The role of selective serotonin reuptake inhibitors (SSRIs) in neuropathic pain is more controversial than that of TCAs.[156] Fluoxetine has demonstrated analgesia properties in experimental animal pain models, but has failed to show analgesic effects in a clinical trial for neuropathy. Paroxetine is the first SSRI shown to be a highly effective analgesic in a controlled trial for the treatment of diabetic neuropathy.[155]

Antidepressants could be effective for pain associated with some specific pain syndromes such as osteoarthritis or rheumatoid arthritis, fibrositis, or fibromyalgia. Immediate or early analgesia effects occur within hours or days and probably are mediated through inhibition of synaptic reuptake of catecholamines. The later analgesic effects that peak over a 2- to 4-week period probably are due to the effect on receptors.[100,155] Antinociceptive effects of antidepressants seem to be independent of their effect on depression. Pain generally is felt to respond to a lower dosage than does depression.[155]

Antidepressant medications may be divided into four general categories: TCAs, monoamine oxidase inhibitors (MAOIs), SSRIs, and others. Further discussion of individual antidepressants is beyond the scope of this chapter.

Centrally Acting Agents

Tramadol Hydrochloride

Tramadol is a synthetic 4-phenylpiperidine analog of codeine. Tramadol is a weak μ-opioid receptor agonist and inhibits the uptake of norepinephrine and serotonin.[115–136]

The affinity of tramadol for μ-opioid receptors is 6,000-fold less than morphine, 10-fold less than codeine, 60-fold less than propoxyphene, and 1,000-fold less than methadone. Analgesia begins within 1 hour of oral administration and peaks in 2 to 3 hours. Tramadol is metabolized in the liver and exerted primarily in the urine.[84]

Tramadol has been shown to be effective in the treatment of various acute pains including postoperative pain after orthopedic and abdominal gynecologic surgery. The recommended oral dosage is 50 to 100 mg every 4 to 6 hours. The most common adverse effects of oral tramadol in patients with chronic nonmalignant pain occurred with the following frequencies: dizziness or vertigo, nausea, vomiting, constipation, headache, somnolence, pruritus, CNS stimulation, dry mouth, sweating, and diarrhea. Respiratory depression is significantly less than with morphine sulfate. Tramadol has caused seizures in humans receiving large oral or IV doses.[84] Predisposing risk factor for seizures include a history of epilepsy, head trauma, metabolic disturbances, alcohol or drug withdrawal, or a CNS infection. The risk of seizures was increased in patients taking agents that lower the seizure threshold, such as TCAs, SSRIs, anorexiants, MAOIs, and neuroleptics. In cases of tramadol overdose, naloxone may increase the risk of seizures.[84] Tramadol causes minimal dependency and tolerance; however, several cases of tramadol abuse have been reported, mostly in patients with a history of addiction or dependence on opiate agonists.[84]

There is potential for chronic tramadol use to induce withdrawal of the clinical opioid type upon abrupt cessation. Studies show that one in eight Ultram (tramadol hydrochloride) withdrawal cases presents as a mixture of classical opioid withdrawal with unusual features such as intense anxiety, depersonalization, delusions, confusion, hallucinations, and other symptoms. The rate of withdrawal is approximately 1 per 100,000 patients exposed.[136]

Local Anesthetics/Antiarrhythmics

Lidocaine and mexiletine, class 1b antiarrhythmic agents, have each been shown to relieve a variety of neuropathic pain disorders, such as peripheral nerve injury, chronic diabetic neuropathy, and postherpetic neuralgia. Clinically effective plasma concentrations of local anesthetic antiarrhythmic drugs suppress abnormal neuronal discharges from injured primary afferents through Na^+ channel blocking.[47]

Mexiletine attenuated hyperalgesia and mechanical allodynia in neuropathic rats with selective nerve root ligation.[29] Studies of experimentally induced neuromas in animals, as well as studies in cancer patients, suggest that systemic administration of these agents may be able to target spontaneously active nerves while sparing conduction in normal nerves. In particular, lidocaine appears to suppress spontaneous neuronal discharge in Aδ- and C-fibers by blocking sodium channels.[49]

Even temporary responsiveness to intravenous lidocaine does not predict success with other local anesthetic agents given orally, such as mexiletine hydrochloride. Several studies have documented the benefit of mexiletine in chronic pain. A dose of 450 mg/day appears to be optimal.[4] Systemic adverse effects of antiarrhythmic agents include both neurotoxicity and cardiotoxicity.[49]

CONCLUSIONS 1362

This chapter is written as a resource for practicing orthopedic surgeons. The objectives of this chapter are to provide preoperative evaluation information that is essential for the preparation of the orthopedic surgical patient; a discussion of the anesthetic options and why they are selected for a particular patient for a given shoulder surgery; a description of the regional anesthetic technique including the preoperative preparation of the patient and insertion of the interscalene block; and a discussion on postoperative pain management. The authors have focused on the postoperative pain management techniques as we believe this is a critical component to the management of the orthopedic surgical patient.

PREOPERATIVE EVALUATION

With the increasing complexity of the surgical procedures and the increasing severity of the coexisting illness present in surgical patients, the anesthesia team is required to evaluate and optimize the patient's health status. In this section we describe medical conditions that influence the health status of the patient and discuss how they are evaluated and optimized prior to surgery.

The patient's visit to the preoperative assessment clinic should provide the anesthesiologist with a number of important pieces of information that can be utilized to best care for the patient. These included the current list of medications, past anesthetic history, patient's concerns and desires regarding the planned anesthetic management, and an indication of major physical illness that will affect their anesthetic management. This visit also provides the opportunity for the anesthesiologist to discuss the anesthetic plan, to discuss any invasive monitors or special techniques that may be needed, and to obtain informed consent from the patient. In summary, the goal of the anesthesia team is to provide active, informed consent after complete evaluation of the patient's health status. This is performed after the surgery team has presented the traditional discussion of the risks and benefits of the proposed surgical procedure. The American Society of Anesthesiologists (ASA) physical status (Table 43-1) is a standard benchmark used for the evaluation of all surgical patients. Patients classified as ASA physical status 1 to 2 may be evaluated as late as the day of surgery. However, patients classified as ASA status 3 or higher should be evaluated sooner to avoid presurgical delays.

TABLE 43-1
THE AMERICAN SOCIETY OF ANESTHESIOLOGISTS' PHYSICAL STATUS CLASSIFICATION

ASA Class 1	A healthy patient (no organic, physiologic, biochemical, or psychiatric disturbance)
ASA Class 2	A patient with mild to moderate systemic disease Examples: Essential hypertension, diabetes mellitus, chronic bronchitis
ASA Class 3	A patient with severe systemic disease that limits activity but is not incapacitating Examples: Heart disease that limits activity, poorly controlled hypertension, diabetes mellitus with vascular complications, angina pectoris
ASA Class 4	A patient with incapacitating systemic disease that is a constant threat to life Examples: Congestive heart failure, advanced renal, pulmonary, or hepatic dysfunction
ASA Class 5	A moribund patient who is not expected to survive for 24 hours with or without an operation Examples: Pulmonary embolus, cerebral trauma, ruptured abdominal aneurysm. In the event of an emergency operation, the number is preceded with an E.

PREOPERATIVE LABORATORY TESTING

Preoperative laboratory testing is an area where rapid change is occurring. It is increasingly apparent that routine lab tests may actually hinder the preoperative process logistically and medically. The rate of detection of real medical problems by routine screening tests is extremely low by comparison to the cost of these tests and the number of patients subjected to unnecessary further workup. Routine screening of blood counts and electrolytes, electrocardiograms, or chest radiograms are probably not reasonable without indication, such as age, disease states, and medication. Specific noninvasive and even invasive testing may be indicated if suggested by the screening history and physical. Knowledge of the implications of the surgical procedure and common coexisting illnesses associated with that procedure could further focus the attention at preoperative screening. Occasionally, anesthetic techniques and procedures will be an indication for specific preoperative testing (i.e., regional anesthesia, invasive monitoring, and assessment of coagulation).

COEXISTING DISEASE—RHEUMATOID ARTHRITIS

Rheumatoid arthritis is a disease of synovial membrane destruction that causes many patients to present for orthopedic surgery. Virtually every joint in the body can be a target, although the pattern is variable by individual.[29] The consequences of this disease and its treatment present a number of preoperative issues.

Due to the existence of synovial joints at a variety of locations, the management of the airway in rheumatoid patients is the most common and often the most serious preoperative issue. The cervical spine, temporomandibular joint (TMJ), and arytenoid bodies are all subject to this disease process. Decreased or absent range of motion of the neck may predict difficult airway management. When this is combined with decreased mouth opening due to TMJ involvement, fiberoptic visualization may be the only possible approach to intubate the patient.

When synovial destruction progresses far enough to cause weakening of stabilizing ligaments, cervical spine instability can occur at the fixation of the axis of C2 to the ventral side of C1[28,42] or erosion of the axis.[53] In both cases, dorsal translocation of C2 on C1 places the spinal cord at risk.[18,43] This can occur even in a neck with limited range of motion at other sites.

When early instability is identified, it is assumed that progression will occur. Documentation with lateral neck x-rays is mandatory prior to anesthesia, unless fusion has been verified. Conventional airway management involves neck extension, and traumatic injury or even complete disruption of the cervical spinal cord has been reported. Simple

lateral films are not adequate, since instability may only be detectable with movement. The standard x-ray workup of the rheumatoid neck must include forced flexion and extension and open mouth odontoid views.

A preoperative dilemma occurs when the rheumatoid patient without known instability presents for elective surgery. While the patient may be asymptomatic, the incidence of silent C-spine instability is not rare. Some centers will require flexion-extension films for elective surgery. If intubation can not be performed without spine manipulation, either x-ray evaluation or awake intubation will be indicated. In cases of extreme instability, even awake intubation by itself may not be totally safe, and prior mechanical stabilization of the neck such as the halo device or cranial tongs with traction may be necessary. Emergency airway management requires manual in-line stabilization of the neck.

Other stigmata of rheumatoid arthritis can result in pulmonary compromise including greatly reduced range of motion of the thorax and destruction of pulmonary parenchyma leading to restrictive pulmonary disease.

The generalized loss of tissue stability presents positioning risks, especially in rheumatoid patients on chronic steroid therapy or cytotoxic drugs. These patients may have extremely thin skin with reduced tensile strength, which is subject to injury, with minor pressure or removal of adhesive tape. Bed surfaces need to be padded and surgical devices to stabilize the patient (bean bags, kidney rests) need to be applied with the decreased tensile strength of the skin in mind.

In some rheumatoid patients, chronic synovial effusion can lead to accumulation of a transudate in the pericardium. A large pericardial effusion can exist with minimal symptoms and create unexpected tamponade physiology during anesthesia care. Rheumatoid patients with limited activity should have echocardiography. Patients on chronic steroid therapy should be considered adrenal suppressed, and full stress-dose steroid given.

CARDIOVASCULAR DISEASE

Hypertension

There are no data available to evaluate the risk of hypertension in the orthopedic surgical patient. The information available applies to elective surgery in general and is conflicting, due to variation in study design and outcome definitions. Later work designed to address the need for perioperative control of blood pressure seemed to suggest that hypertensive patients have better perioperative care if their blood pressure was controlled prior to anesthesia. It is clear that poorly controlled hypertensive patients have more hemodynamic instability. It should also be noted that preexisting hypertension may limit the ability to safely decrease the blood pressure to the surgeon's desired limit for the surgical procedure.

Hypertension may influence the anesthesiologist to avoid the addition of epinephrine to the local anesthetic solution utilized for regional anesthesia blockade. These patients should be instructed to continue taking most hypertensive medications right up to the morning of surgery with the exception of diuretics, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers. If the diastolic blood pressure exceeds 110 mmHg, there is a reasonable indication for therapeutic adjustment of antihypertensive therapy. To facilitate monitoring and control of the blood pressure, the anesthesiologist may consider placement of an arterial line catheter for patients with uncontrolled blood pressure in the emergent setting.

CORONARY ARTERY DISEASE

The objective in preoperative screening is to identify those patients requiring further diagnostic evaluation and perhaps further medical or surgical procedures. It is also especially important to identify those patients who are scheduled for high-risk surgical procedures for whom the perioperative risk of myocardial ischemia is great so that the patient may make an informed decision. If there has been a prior event such as a myocardial infarct, angioplasty, or coronary artery bypass grafting, the anginal pattern since the event should be determined to detect those patients at risk for perioperative ischemia. Patients at risk for silent ischemia (such as diabetics) may present an indication for more aggressive diagnostic testing prior to elective major orthopedic surgery.

The simple electrocardiogram (ECG) is indicated as a screening test in patients with cardiac risk factors such as family history, hypertension, and diabetes mellitus. Any patient with known cardiac disease should have a current ECG, and it should be compared to a prior tracing to detect interval change. New arrhythmias, ST segment changes, Q waves, or signs of ischemia at rest must be further evaluated prior to elective surgery. Specifically, the new diagnosis of atrial fibrillation or left bundle branch block may oftentimes require a specific workup that may delay the scheduled surgery if the patient is being seen in the preoperative evaluation clinic on the day prior to surgery.

If the patient's history indicates that a stress test may be needed, then it should be performed in the preoperative evaluation phase. If the patient is unable to tolerate exercise testing due to arthritic joints, then pharmacologic stress testing may be chosen such as an echocardiographic dobutamine stress test or Persantine thallium or reperfusion imaging.

Knowledge of the function of the left ventricle (LV) can be important in planning the anesthesia for the orthopedic patient with previously known LV dysfunction. The least

invasive of the tests is echocardiography. The properly conducted transthoracic echo will reveal left ventricular ejection fraction almost as accurately as cardiac catheterization and will detect wall motion defects indicative of ischemia or prior infarct. It can also estimate the function of the major cardiac valves. Stress testing and echocardiography will provide information regarding ischemic risk, left ventricular function, and valvular disease. The primary component remaining to be evaluated if disease were present would be the degree of stenosis in the coronary vessels, obtainable through cardiac catheterization.

Cardiac catheterization is the most definitive and invasive preoperative evaluation of the myocardium. The major benefits to be gained are precise knowledge of the coronary anatomy and exact indicator of left ventricular filling and function. In some preoperative patients who have indications for cardiac catheterization, lesions will be found, which require revascularization prior to elective major orthopedic procedures. Undetected, these lesions could cause myocardial infarct, congestive heart failure, or sudden death in the perioperative period. It should be noted that a coronary artery that requires a stent prior to orthopedic surgery may require antiplatelet medications. This may result in the delay of an elective orthopedic surgical procedure. There may be a positive role for beta blockade in patients who are at risk for cardiac ischemia.[3] Given the low cost and low risk for this intervention, cardiac patients should be evaluated for perioperative beta blockade.

VALVULAR HEART DISEASE

The preoperative evaluation of the patient with valvular heart disease will be essentially the same as that of coronary artery disease, with the exception of quantifying the degree and clinical significance of the valvular lesion. This is particularly important in the stenotic lesions of the left ventricle and mitral and aortic stenosis. The coexistence of coronary artery disease must be suspected in patients with aortic stenosis since the combination of stenosis and significant coronary artery disease is common and poorly tolerated in the perioperative period. Function of the left ventricle is also important to evaluate, since most valvular lesions induce hypertrophy of the myocardium in response to increased work and the potential for cardiomyopathy or congestive heart failure.

PULMONARY DISEASE

The preoperative evaluation of the orthopedic patient with pulmonary disease is designed to identify correctable problems that could lead to pulmonary complications in the postoperative period. To be effective, intervention requires accurate timing since optimization requires time for treatment. The goals involve the elimination or suppression of all active infections, maximum treatment of bronchospasm, facilitation of sputum clearance, cessation of smoking, and treatment of any serious nonpulmonary sequelae of pulmonary disease.

If there is a question of adequate function, chest x-ray, room air saturation, arterial blood gas analysis, and formal pulmonary function testing (PFT) or bedside spirometry may be indicated. Short-term cigarette abstinence will favorably influence carboxyhemoglobin levels. If small airway disease is serious, diffusion studies may be necessary. With either serious obstructive or restrictive disease, flow-volume loops may help to quantify the degree of limitation. Diffusion capacity, carbon monoxide (DLCO) can help distinguish among obstructive lung disease between fixed lesions (decreased DLCO) and bronchospastic disease (normal DLCO).

Orthopedic patients with obstructive pulmonary disease should be optimally prepared for elective surgery. Evidence of acute infection must be sought, and if present, it requires delay of surgery in most instances. Any component of airway obstruction that is reversible with bronchodilator therapy during pulmonary function testing must be effectively treated. If theophylline therapy is part of the chronic prevention of bronchospasm, the blood levels should be therapeutic. If steroid therapy has been required, it is mandatory to continue steroid therapy through the perioperative period. If the forced expiratory volume (FEV_1)/functional residual capacity (FRC) ratio is less than 40% or if there is a 40% or greater reduction in diffusion capacity, the morbidity in the perioperative period greatly increases.

THE HIGH-RISK PATIENT

Patients with severe cardiovascular, pulmonary, or other serious illness can seek surgical intervention for orthopedic problems, such as total joint replacement. The severity of the coexisting disease can be so severe that purely elective surgery would not be reasonable due to the anesthetic and postoperative risk. However, some of these patients with a reasonable life expectancy have such extreme symptoms from their orthopedic pathology that they are extremely motivated to have elective surgery. The first step in dealing with a high-risk, elective orthopedic patient is to verify that all parties involved have the same understanding of the events. The medical specialist caring for the patient must understand the perioperative risk of the surgical procedure and the rehabilitation. It must be clear that all correctable conditions have been treated and that the serious coexisting disease has been optimally prepared. The preoperative planning must include informed consent, and the patient must be aware of what specific risks he or she is accepting. Pertinent family members involved in postoperative care

must also be aware of the potential outcome. Documentation must be explicit and detailed prior to anesthetic intervention.

ANESTHETIC OPTIONS

General and Regional Anesthesia Considerations

Shoulder surgery can be successfully performed under general anesthesia, regional anesthesia, or a combination of the two. In the authors' institution, the protocol is to place an interscalene brachial plexus block in the majority of patients undergoing shoulder surgery (Table 43-2). In general, patients who do not receive an interscalene block are those who have any contraindication to an interscalene block or are having surgical procedures that would not require an interscalene block for postoperative pain relief. The final anesthetic plan is based on the complexity of the planned surgical procedure and patient preference. A general anesthetic as the sole technique avoids the "disadvantages" associated with a regional anesthetic, including the time associated to place the regional anesthetic, the chance that the regional anesthetic might be inadequate, any patient discomfort associated with the placement of the regional anesthetic, and the need for special equipment such as nerve stimulators that might be necessary to place the regional anesthetic.

However, utilizing a general anesthetic as the sole technique does not offer the patient the valuable benefit of postoperative pain relief and preemptive analgesia. Preemptive analgesia, where the analgesic interventions are initiated prior to the surgical incision, may prevent peripheral hypersensitivity and thus result in a decrease in the overall pain experienced postoperatively by the patient. There exist concerns regarding the clinical relevance of preemptive analgesia and how to best study the claims that preoperatively administered analgesics provide long-lasting analgesia from 7 to 10 days postoperatively.[16] With regard to interscalene block for elective shoulder surgery, Wurm et al. found that patients who received an interscalene block prior to surgery versus those who were administered postoperatively had superior pain control for the first 12 hours. However, this benefit was not maintained during the week after discharge.[77] The decision regarding the anesthetic plan revolves around whether the procedure can be completed under the sole technique of an interscalene block versus a combined technique of general anesthesia plus an interscalene block.

The combined technique is selected when patient preference for unconsciousness is strong, such as unusual levels of anxiety or known claustrophobia, since the sterile field requires the patient's face to be nearly covered.[20] Certain surgical procedures may require a combined technique when anatomic areas are not anesthetized by an interscalene block. For example, incisions that extend onto the pectoral prominence are not covered by brachial plexus block. Anesthetic coverage of the pectoral prominence would require the somatic block of the first and second intercostal nerves (Fig. 43-1). This can be achieved with

TABLE 43-2
INTERSCALENE BLOCK IN ADDITION TO GENERAL ANESTHESIA—ADVANTAGES AND DISADVANTAGES

Advantages	Disadvantages
Enhanced pain control	Requires trained personnel to perform interscalene anesthesia
Minimal general anesthetic requirements	May require additional time to perform block if no induction room available
Earlier discharge for outpatient surgery	Known side effects of block include phrenic nerve blockade, hoarse voice, etc.
Reduction in recovery room of analgesic use with subsequent decreased side effects	Requires availability of nerve block equipment and resuscitation equipment
Increased patient satisfaction with postoperative pain control	Complications include small risk of pneumothorax, subarachnoid, and epidural block.

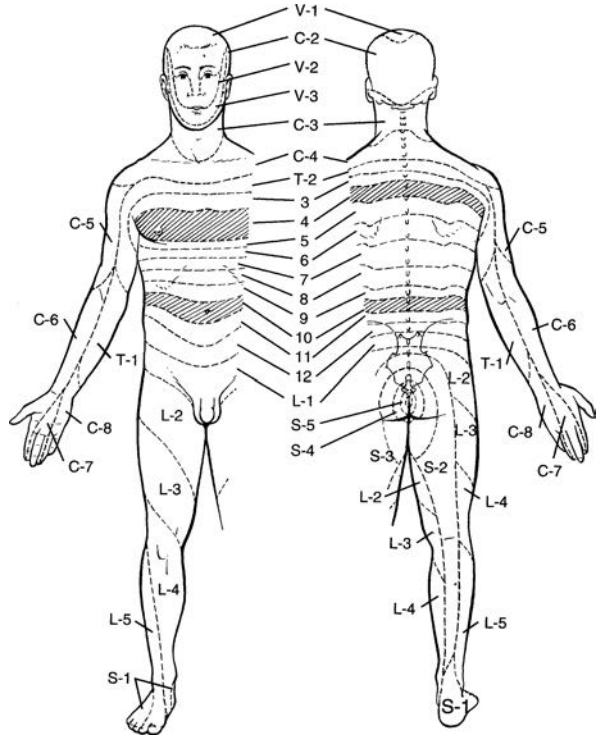

Figure 43-1 Posterior cutaneous innervation of the shoulder.

paravertebral blocks.[51] The combined technique may be required for procedures that require profound muscle relaxation, complex procedures that may require an extended amount of time in the operating room, or procedures that require positioning that could be uncomfortable for an awake patient.

General Considerations for Shoulder Surgery

There are general considerations regarding shoulder surgery that are independent of anesthetic technique. Standard monitoring is required for all shoulder surgery. The patient should have at least one functioning intravenous catheter. The patient should be checked for generic positioning concerns and all pressure points should be padded. Blood products may be made available for more complex procedures including some cancer surgeries and revision arthroplasties. Routine type and cross for blood products is not necessary for routine shoulder surgeries.

Accessibility to the Airway

During shoulder surgery, access to the airway is limited due to the surgical proximity to the airway. In patients with sleep apnea, where the ability to use sedation is limited, general anesthesia with a secured airway combined with the interscalene block for postoperative analgesia may be a reasonable choice. Interscalene block as a sole anesthetic may require urgent airway management.

Severe Airway Obstruction During Arthroscopic Shoulder Surgery

There have been case reports of patients who presented with severe airway obstruction caused by tracheal compression due to extraarticular arthroscopic fluid accumulation during arthroscopic shoulder surgery.[8] This resulted from massive swelling of the ipsilateral chest and anterior portion of the neck extending to the face. The initial management required tracheostomy, but with cessation of pressurized arthroscopic fluid injection, manual ventilation became possible and the patient was able to be orotracheally intubated.

Response to Methylmethacrylate

Methylmethacrylate is used to secure the prosthetic components used for total shoulder replacement. When the monomer form enters the circulation, venodilation and histamine release have hemodynamic consequences, which can be exaggerated if the patient is hypovolemic, if the patient has diminished cardiac function, or if the cement is injected under high pressure. Because the amount of cement is significantly less with shoulder replacement compared to hip or knee replacement, hemodynamic instability is less common and severe.

Beach-Chair Position

Beach-chair position (Figs. 43-2 and 43-3) presents risks accentuated by the uniquely physical aspects of orthopedic surgery. The need for traction, manipulation, and other physical interventions such manipulation of bone place even the most careful positioning of body parts at risk. Frequent reassessment after periods of aggressive movement is important. In the "beach chair," which is a semi-sitting modification of the supine position, the head is raised as much as 45 degrees and the body is shifted to the edge of the bed on the side to be operated on. Positioning devices that suspend the arms overhead in the supine position can cause stretch to the brachial plexus if either extreme abduction or anterior flexion is performed and especially if combined with contralateral neck rotation. Venous air embolism is a potential issue since the wound area is above the heart, although the clinical experience has not demonstrated this to be a major concern. Spontaneous hypotension and bradycardia during shoulder surgery and interscalene block have been attributed to the Bezold-Jarisch reflex.[17] The cause is related to venous blood pooling (induced by the sitting position) and a heightened cardiac contractile state (induced by the beta adrenergic effects of epinephrine in the local anesthetic solution for the interscalene block) that may be activating this reflex.[39]

Figure 43-2 The surgical view of the draped patient in the beach-chair position.

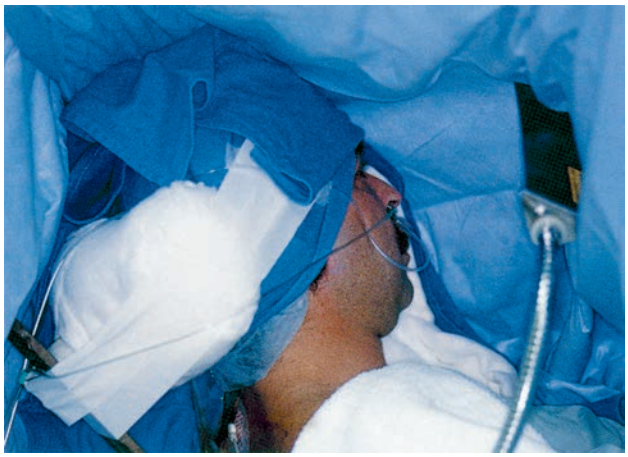

Figure 43-3 The anesthesia care provider's view of the draped patient in the beach-chair position. This demonstrates the reduced access to the face and airway of the shoulder surgery patient.

Lateral Position

Many of the positioning issues in the supine position also apply when the patient is in the lateral position. In addition, the pressure of the body on the dependent parts presents additional risk to nerves, muscle, and skin. The brachial plexus is at risk in the lateral position in both the dependent and the superior limb. The superior brachial plexus is at risk in those cases where extreme position causes traction, stretch, and subsequent ischemia to the brachial plexus. When the arm is moved superior, to above the level of the head, hyperabduction is possible, with the brachial plexus stretch occurring between the humeral head and the coracoid as lever points.

The dependent limb is at risk because the brachial plexus may be compressed between two bony structures, the rib cage and the head of the humerus. To avoid this, the weight of the thorax must be kept off of the humerus to protect the dependent brachial plexus. On the dependent limb, placing a foam or axillary roll of the proper size in the axilla and verifying that it is positioned properly prevents compression (Fig. 43-4). If the limb is positioned improperly, vascular embarrassment may be detected by venous engorgement or poor capillary refill. Pulse oximeter waveform and signal also should be checked on the dependent limb. It is important to remember that orthopedic surgery involves considerable physical movement of the body and that correct positioning can evolve into a position where the brachial plexus could be at risk, and should be checked at regular intervals.

General Anesthesia

General anesthesia with field avoidance usually requires that the airway be securely under control prior to surgical incision. While it may be possible to do these cases with laryngeal mask ventilation under general anesthesia, the airway must be very easy to manage and the provider skilled, because movement associated with airway adjustment would be disruptive to the surgical procedure. The need to suddenly intubate the trachea during the surgical procedure would be both difficult to accomplish and very disruptive, particularly if the sterile field had to be broken. The endotracheal tube must be protected from dislodgment, and it is important to remember the potential for accidental injury to the head from sharp or heavy objects placed on the drapes by the surgical team over the face and neck.

Regional Anesthesia

At the authors' institution it is the usual practice to place the interscalene block preoperatively in the awake patient in a special induction room area. Interscalene block is not placed in patients under general anesthesia, unless compelling reasons exist. The risk of interscalene block under general anesthesia is highlighted in a case where permanent neurologic deficit resulted after a nerve stimulator–guided interscalene brachial plexus block was performed during general anesthesia.[48] It was concluded that if the patient had been awake, there could have been feedback identifying intraneural placement of the needle and subsequently damage to a neural structure could have been avoided. This would have served as a protective mechanism allowing the anesthesiologist to discontinue the injection. In addition to this case, Benumof[6] has reported a series of four cases where interscalene blocks were placed under general anesthetics, resulting in cervical cord lesions visible on magnetic resonance imaging. Additionally, it should be noted that a successful regional anesthetic includes anxiolysis or, conversely, if the patient is extremely anxious the regional technique may fail as the sole anesthetic.

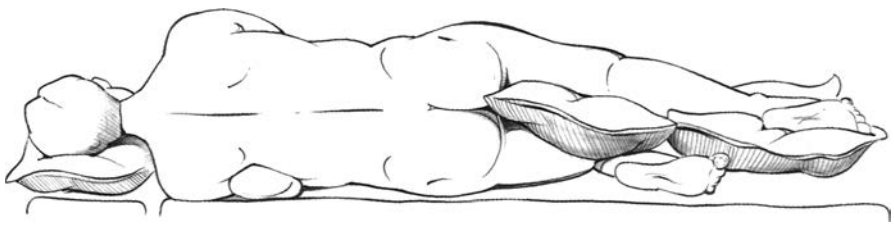

Figure 43-4 Patient in the right lateral decubitus position demonstrating a chest roll in place to protect the neurovascular bundle in the axilla.

Successful Block

Verifying a successful nerve block is important to ensure that the tissue within the surgical field is anesthetized. Although the interscalene block can provide complete anesthesia to the shoulder joint and surrounding muscles, this may not be adequate if the surgical incision extends into the upper axillary area or into the posterior aspect of the shoulder. The duration of the block may be a consideration if there is an unpredictable length of surgery. Blocks that are of a longer duration provide anesthesia throughout the duration of the surgery and then also into the postoperative period. Another surgical consideration is for adequate muscle relaxation, especially in very muscular patients and for more complicated procedures including complex and revision arthroplasties. While bupivacaine does exhibit some muscle relaxation at 0.5%, mepivacaine at 1.4% tends to provide complete muscle relaxation, especially when bicarbonate has been added.

Comfortable Patient

Many patients experience anxiety when considering being awake for a surgical procedure. They also have concerns about the pain experienced when the interscalene block will be placed. These patients can be reassured with constant communication and rapport established in the preoperative visit and throughout the perioperative processes. After consent is obtained and the patient's questions are answered, the administration of sedatives and/or analgesics helps to comfort the patient. Deep sedation should be avoided to prevent masking of paresthesias during the placement of the interscalene block. The nursing and surgical team will need to be cognizant of their behaviors as the awake patient may be listening to the sounds and conversations occurring during the operation.

Optimal Operating Conditions

These conditions include both the operating room management aspects of regional anesthesia and the surgical team's comfort with operating on an awake patient. The awake patient, at the conclusion of the procedure, can assist in the placement of braces and special dressings.

Uncomplicated Postoperative Course

The patient should understand the expected duration of the block and care should be taken to explain how to protect the anesthetized limb. This includes describing the risks of the excessive pressure or poor positioning on the limb. The patient may be instructed to take an oral analgesic at the initial sign of discomfort as this will establish analgesia before the block wears off completely. Specifically, in the outpatient setting, early treatment of pain may be associated with reduced analgesic requirements and higher patient satisfaction.

Preparation for Regional Anesthesia

Equipment and Supplies

If the block is to be performed in an induction room, then the room should be fully equipped with monitors and the ability to induce general anesthesia along with airway management devices providing the ability to ventilate and oxygenate. The anesthesia provider must be able to deal with outcomes resulting from intravascular injection of local anesthetic. These events could result in a spectrum of side effects ranging from a mild anesthetic toxicity to the abrupt onset of generalized seizures. High subarachnoid, epidural, or subdural injection is also possible and would result in hemodynamic collapse and unconsciousness. With the proper resuscitation equipment readily available, these complications can be easily managed.

The equipment required to place the interscalene block depends upon the technique selected by the anesthesia care provider. There are two main methods to perform an interscalene block: intentional elicitation of paresthesias and the nerve stimulator technique. Several different types of needles are available for the different techniques that may be utilized.[47] (Fig. 43-5). An additional technique includes the use of combination needles that have the capability of ultrasound guidance and stimulation. These needles initially stimulate through the cutaneous layer and then are advanced with stimulation.

Preparation of the Patient

To avoid undue anxiety, the patient should have a full understanding of the process of the placement of an interscalene block. The patient should also have an understanding of why the block is being placed and how that will affect his or her postoperative outcome, including how the patient will remain relatively pain-free for a number of hours in the postoperative period and have a motor block for several hours postoperatively, depending on which local anesthetic is injected. Additionally, common side effects such as the probability of decreased functioning of the ipsilateral phrenic nerve, stellate ganglion, and ipsilateral recurrent laryngeal nerve should be presented so that the physical experience will not surprise the patient. Altered chest excursion, dry eye, droopy eyelid, and hoarse voice should be described in advance. If there are any questions about the capability of the block to serve as the sole anesthetic for the surgical procedure, it may be wise to proceed with a general anesthetic with the utilization of the interscalene block for postoperative pain purposes. This avoids the situation where a patient is uncomfortable "under the drapes" and disrupts the surgery with sudden movements.

INSERTION OF THE BLOCK AND INTRAOPERATIVE CARE

The interscalene approach to the brachial plexus is the most proximal and cephalad brachial plexus block.[76] It is performed at the level of the trunks of the plexus, and most often at the site of the origin of the superior trunk over the transverse process of C6. Both the effect of the block and the types of complications are related to this proximal site of approach.[74]

Applied Anatomy of the Brachial Plexus

The anatomic basis for the interscalene block is the reliable location of the brachial plexus in the groove formed by the overlap of the anterior and middle scalene muscles at the level of the cricoid cartilage. This occurs over the transverse process of the vertebral body of C6. The entire brachial plexus is theoretically accessible at this point since the sheath of the brachial plexus is formed, and any injection within this sheath will have access to the entire brachial plexus at the level of the trunks (Fig. 43-6). Since the sheath is thin, due to the need for hypermobility of the neck, confirmation of needle placement within the sheath is necessary. Confirmatory signs must be identified by dermatome to confirm placement. If the needle stimulates the brachial plexus at this site, the terminal nerves likely to respond are the axillary and musculocutaneous, sometimes in conjunction with the radial nerve. When there is a motor-evoked response or a paresthesia in the arm, it is important to be able to identify the nerve of origin, both to confirm needle placement within the sheath and to predict outcome. Knowledge of branches of the plexus that occur high in the neck will allow identification of cases where these nerves are stimulated, since injection of the drug at these sites is not within the sheath of the brachial plexus and will not result in a block. The suprascapular nerve, the long thoracic nerve, and the distal aspects of the axillary nerve after it leaves the sheath are examples. A paresthesia to the anterior chest or to the area of the scapula should not be mistaken as a confirmatory sign of brachial plexus entry.

The entry at the cephalad aspect of the plexus predicts the nerves most and least likely to be blocked by the classical interscalene block. The site closest to the injection will receive the highest exposure to local anesthetic at the injecting concentration. Those areas within the sheath that are furthest away, geographically, will receive the least.[38] This is why the interscalene block is best suited to the postaxial and proximal upper-extremity surgery. The dermatomes served by the most caudad aspects of the plexus (the ulnar nerve) will be incompletely blocked in a finite number of cases. This makes the interscalene approach less ideal for hand and wrist surgery. The work of Winnie[76] with contrast injected into the sheath of the brachial plexus suggests that at high volumes, the sheath should be equally well filled from any site. The clinical work of Anderson et al.[2] demonstrates otherwise, with a 30% sparing of the ulnar nerve with classical interscalene block, even with high volumes. The variability within the sheath of the brachial plexus demonstrated by Thompson and Rorie[69] in the axillary area may explain this effect in the interscalene sheath area.

The interscalene brachial plexus can be identified by elicitation of paresthesia or motor-evoked response. Active confirmation of proximity to nerves is important, as opposed to regional techniques based on feeling the sheath, since the interscalene brachial plexus sheath is so thin that elicitation of an active sign is the only way to achieve a high success rate.

Locating the Interscalene Groove

The patient is positioned supine with the head turned to the contralateral side. The external landmarks are identified: the

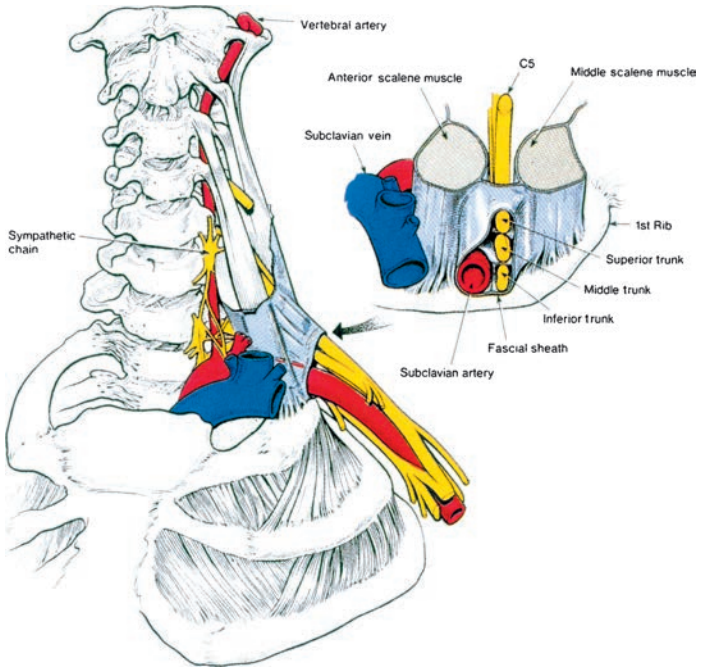

Figure 43-6 Brachial plexus sheath and scalene muscles. Note the brachial plexus sandwiched between the anterior and middle scalene muscles, and the prevertebral fascia splitting to enclose scalenes and then forming a fascial sheath around the brachial plexus. Note also the relationships to the vertebral artery, subclavian artery, and sympathetic chain. (Reprinted with permission from Bridenbaugh L. The upper extremity: somatic blockade. In: Cousins M, Bridenbaugh P, eds. *Neural blockade*, 2nd ed. Philadelphia: JB Lippincott, 1988:387–416.)

cricoid cartilage, the external jugular vein, and the prominence of the posterior boarder of the clavicular head of the sternocleidomastoid (SCM) muscle[15] (Fig. 43-7). The interscalene brachial plexus is most easily approached in the interval between the anterior and middle scalene muscle, just caudad to the level of the cricoid, over the transverse process of C6. To identify this position, the nondominant hand of the anesthetist is placed at or below the horizontal level of the cricoid cartilage on the posterior border of the SCM and swept from medial to lateral. As the prominence of the SCM is no longer felt, there is an open space, which the inexperienced regionalist may perceive as the

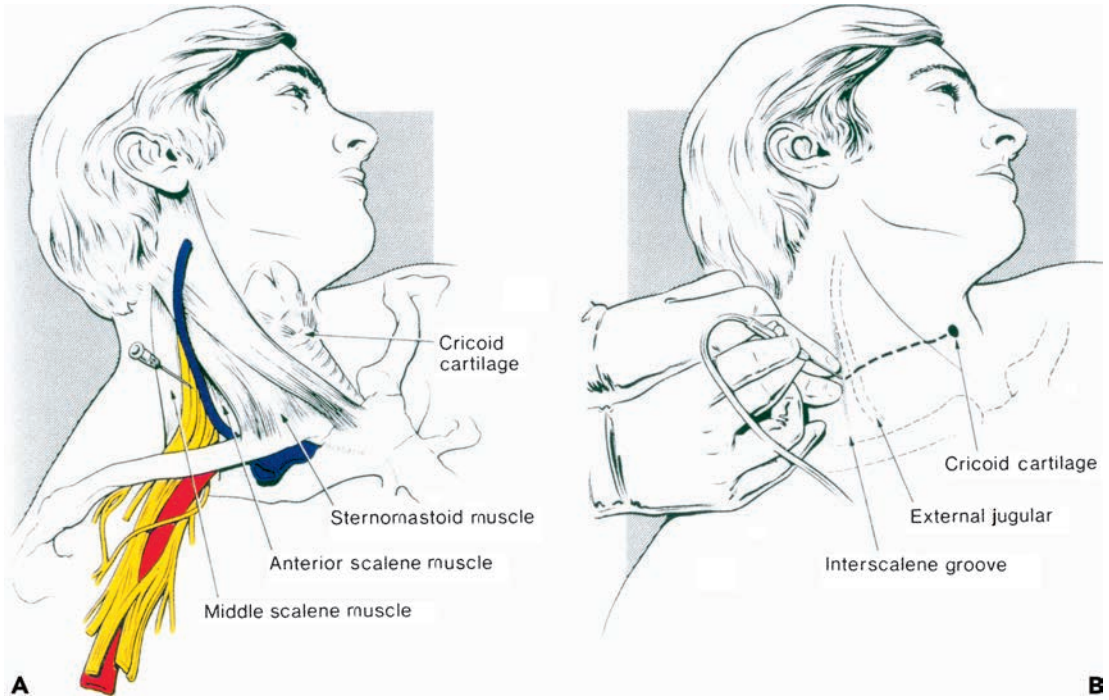

Figure 43-7 Interscalene block: anatomic landmarks. (Reprinted with permission from Bridenbaugh L. The upper extremity: somatic blockade. In: Cousins M, Bridenbaugh P, eds. *Neural blockade*, 2nd ed. Philadelphia: JB Lippincott, 1988:387–416.)

"interscalene groove." The only structure in this area is the lateral border of the internal jugular vein, and the brachial plexus will not be found in this interval. As the fingers move more lateral, an up-slope is encountered, which is the medial aspect of the anterior scalene muscle. As the flat belly of the muscle is encountered, an indentation is eventually felt. This occurs where the middle scalene and the anterior scalene muscle cross each other. It is this crossing that creates the "interscalene groove," and directly dorsal to this will be found the superior trunk of the brachial plexus.[60]

Different Techniques to Determine Location of Block

Paresthesia and nerve stimulator techniques are widely accepted in clinical practice and result in high rates of successful blockade. Studies have been done to evaluate the comparative placement of needles with respect to the two different types of techniques. Urmey and Stanton utilized a paresthesia technique to locate where the interscalene block injection should take place.[71] After fixing the needle in place, they applied a nerve stimulation with up to 1.0 mA with a pulse width of 0.2 million seconds and found that only 30% of the patients exhibited any motor response to electrical stimulation. Urmey and Stanton also noted that there was no relation between the site of paresthesia and associated motor nerve response. These results may be related to the location of the motor nerve fibers in relation to the sensory nerve fibers.

Paresthesia Technique

The paresthesia technique is performed with a short, blunt-beveled needle. It is assumed that the short-beveled needle tends to push the nerve aside instead of cutting, as a sharp-beveled needle would do. This author favors the use of paresthesias, performed in an awake responsive patient who is able to cooperate while the block is being performed. Success rate with the utilization of the paresthesias technique for interscalene block is over 90%.[68]

For paresthesia technique, a 25-gauge, blunt-beveled needle, less than 1 in., is selected. It is connected to an extension set resulting in the "immobile needle" of Winnie for smoother operation.[75] After appropriate sterile technique, skin wheal is placed, most often just lateral to the prominence of the external jugular. The needle is directed perpendicular in all planes, except slightly caudad and mesiad, to approach the plexus straight on as opposed to a tangent, which decreases the target area. Prior to advancing the needle, the patient is told what to expect; the paresthesia is described, and the patient is told that correctly identifying the paresthesia is required to perform the block. The patient should be told to first identify a feeling to stop the movement of the needle, and then be asked to locate the feeling. The lag between feeling and being able to localize the sensation is long enough that needle placement will not be as accurate. A clue of impending paresthesia is a change of facial expression consistent with the feeling of stimulating any nerve in the human body. When a sensation is identified originating in the neck, passing through the shoulder and into the arm, perhaps as far as the thumb (radial nerve), the patient needs to identify this and injection occur directly over the superior trunk of the brachial plexus. It may be helpful to describe the paresthesia in terms of the feeling that most people have had when they strike their ulnar nerve at the elbow, the "funny bone." Perceived feeling anywhere in the arm is a reliable indicator of the superior trunk; paresthesia appreciated in the area of the scapula, the acromion, or the pectoral area is an indicator of the suprascapular, axillary, or long thoracic nerves, which are not located reliably within the sheath of the brachial plexus and should not be accepted as confirmation of placement within the brachial plexus sheath.[55] With elicitation of the correct paresthesia, pressure should be applied cephalad to the needle and injection of 40 mL of a local anesthetic solution in incremental doses should be completed. Given the proximity of the vertebral artery and the epidural/subarachnoid space, the first injection should be a very small amount. The elicited paresthesia may briefly accentuate to a mild degree. Any dramatic increase should be taken as a sign of potential intraneural injection and the needle withdrawn very slightly. Then a very small first injection should be repeated. One excellent indicator of intravascular injection is the local anesthetic solution with 1:200,000 epinephrine added; 3 mL of this solution contains 15 μg of epinephrine, which if rapidly injected should cause a rapid, transient 30% or greater increase in the heart rate in most patients. Unless the vascular structure happens to be the carotid or vertebral artery, this should not be enough of any local anesthetic to cause a toxic reaction. The potential for vertebral artery injection must be detected by the profound patient response to the first, very small injection. Once test dosing has been completed, incremental injection follows, with frequent, gentle aspiration to rule out migration into vein, artery, or the subarachnoid space. The brief augmentation of the paresthesia should be rapidly followed by complete resolution of the feeling. When rapid- or intermediate-onset local anesthetic solutions are selected, there may be early signs of the onset of the block such as warmth in the arm, tingling, or areas of noticeable numbness in proximal dermatomes prior to the completion of the injection.

Nerve Stimulator Technique

The nerve stimulator technique can be utilized in one-shot block technique or can be utilized for the placement of an interscalene catheter that may provide postoperative pain relief. The selection of the use of a nerve stimulator to place an interscalene block seems to be more a function of

the "comfort level" anesthesia care providers experience than any other reason. Both methods are well described and accepted in the literature, with no overwhelming differences in complications or side effects. Interestingly, the utilization of a nerve stimulator to perform an interscalene block has been associated with the rare complication of prolonged hemidiaphragmatic paralysis.[23]

When a nerve stimulator technique is chosen, a 22-gauge, blunt insulated regional needle is utilized with a variable voltage nerve stimulator. The landmarks and approach is the same and the endpoint is a motor-evoked response in the arm. After the motor-evoked response is elicited at 1 mA or greater, then stimulating current is decreased to determine the lowest amount of current to produce a stimulus. If the lowest current output is 0.6 mA or higher, then the success rate of the block will only be 36%.[7] However, when the lowest stimulating current is 0.5 mA to 0.3 mA, then localization is adequate and block success rate is 82% to 93%.

Placement of the Interscalene Catheter with a Nerve Stimulator

Generally, most practitioners who place an interscalene catheter utilize a nerve stimulator technique. This can be achieved by using a catheter-through-the-needle versus a catheter-over-the-needle technique. The interscalene brachial plexus is identified using a nerve stimulator connected to the proximal end of the metal inner needle, with the endpoint of contraction of the upper-extremity muscles being obtained with a current of less than 0.5 mA with an impulse duration of 0.1 millisecond. When utilizing the cannula-over-needle technique, the catheter is introduced distally and advanced between the anterior and middle scalene muscle up to 2 to 3 cm. The catheter will be subcutaneously tunneled 4 to 5 cm through an 18-gauge intravenous cannula and fixed to the skin with adhesive tape. Advances in needle design permit the use of insulated Touhy-type needles through which catheters can be placed, including stimulating and nonstimulating catheters for achieving continuous brachial plexus blockade.

Assessing the Block

It is essential when you perform a regional anesthesia to be able to assess if the block will be successful for the intended purpose. Depending upon the local anesthetic that was utilized, the block will generally start to "set up" within 3 to 5 minutes and should have sensory and motor components initiated by 20 minutes. This author utilizes the "numb thumb" sign, where the thumb on the side of the interscalene block becomes tingly and numb. If this occurs within 5 to 10 minutes of completion of the block, clinical experience has demonstrated that the block will be appropriate for a surgical anesthetic. Other authors have reported that adequate surgical anesthesia is present when, within 20 minutes after the administration of the local anesthetic, there existed a sensory block with the inability to recognize cold temperature on the first and third fingers and a motor block with the inability to extend the arm involving the radial and median nerve.[24]

SELECTION OF A LOCAL ANESTHETIC

The choice of agent for interscalene block depends on the anticipated duration of the surgical procedure, the degree of motor block required, and the plans for regional anesthesia for postoperative pain relief.[70] There are a number of concentrations and doses of medications used for interscalene block anesthesia (Table 43-3). One factor influencing the selection of a medication and its concentration is the desire for a motor blockade. The degree of motor block required varies from complete motor block necessary for open shoulder procedures to insignificant when soft tissue procedures of the proximal upper extremity are performed, unless the dissection is so tedious that minor movement would be either disruptive or dangerous to the structures being operated on. As the concentration of the agent is decreased from the maximum commercially available, the degree of motor block decreases. With mepivacaine and lidocaine, the concentration can be varied from complete motor block to variable motor block. This is especially true with bupivacaine, where excellent sensory analgesia can be provided with minimal motor block. While this is an ideal property for obstetrics and postoperative analgesia for extended use after surgery, it can be less than ideal for surgical anesthesia for proximal arm and shoulder surgical procedures. With the volume required to achieve complete blockade, the stronger concentrations of bupivacaine, particularly 0.75%, can be toxic and the lower concentrations may achieve only partial motor block. There are several medications that may be routinely added to local anesthetics to modify their block characteristics, including bicarbonate,[67] epinephrine, and clonidine[30] (Table 43-4)

When revision surgery or technical difficulty is expected, long-acting blockade may be important. The longest-acting agent for conduction blockade is bupivacaine, with 8 to 12 hours of surgical anesthesia likely and pain relief for much longer than this. Given the cardiac toxicity issues with bupivacaine, an alternative long-acting agent is tetracaine. Since the onset is slow and variable with tetracaine, it is most often compounded with a short- or intermediate-acting agent like mepivacaine ("supercaine") or lidocaine to take advantage of their more rapid onset. As long as the concentration exceeds 0.15%, the motor block achieved with tetracaine should be complete and last 6 to 8 hours, with pain relief much longer, although not quite as long as bupivacaine. 2-Chloroprocaine will provide 45 to 60 minutes of surgical anesthesia and may not be useful unless used with a catheter technique or

TABLE 43-3
REGIONAL ANESTHESIA MEDICATIONS—DOSING AND COMMENTS

	Medication Dosing	Comments
Primary surgical anesthetic	1.4% mepivacaine with 0.2% tetracaine, epinephrine 1:2000,000 and bicarbonate with 35 mL injected	Provides a quick onset of sensory and motor blockade, with excellent postoperative pain relief lasting 8 to 12 hours
Postoperative analgesia	0.2% ropivacaine with 2 μg/mL of clonidine with 20 mL injected	Provides excellent postoperative analgesia with minimal motor block lasting 8 to 12 hours
Blockade placed at time of the catheter placement	0.5% bupivacaine or 0.5% ropivacaine with 30 mL injected	Provides surgical anesthesia
Continuous catheter infusion	0.125% bupivacaine or 0.2% ropivacaine at 6 mL per hour continuous infusion	Provides a good postoperative analgesia

compounded with a longer-acting agent. Lidocaine and mepivacaine at 1.0% or greater will provide complete surgical anesthesia for 2 to 3 hours when used with epinephrine (slightly longer for mepivacaine).

Complications of Interscalene Nerve Block

The most common complications of the interscalene block occur when adjacent nonbrachial plexus nerves are blocked. As described earlier, a 30% to 100% block rate of the ipsilateral phrenic,[33,58,72] recurrent laryngeal nerves,[59] and stellate ganglion[1,31] is expected. As long as the patient is seated and the physical effects are presented in advance to avoid frightening the patient, these are not associated with morbidity in most instances. Morbidity can occur with phrenic nerve block in the patient with pulmonary disease who may not tolerate either the subjective dyspnea or the minor loss of functional residual capacity when respiratory function must run from one side of the diaphragm only.

The serious complications of interscalene block are intravascular injection, high central block,[4] and nerve injury. The anatomy previously described makes it obvious that the interscalene block may be associated with a risk of

TABLE 43-4
MEDICATIONS ADDED TO LOCAL ANESTHETICS TO MODIFY BLOCK CHARACTERISTICS

Medication	Desired Effect	Concerns/Side Effects
Bicarbonate	Quicker onset and more solid motor block. Dosing is routinely one equivalent of bicarbonate for every 10 mL of local anesthetic solution	May cause mepivacaine to precipitate in catheter. Needs to be "freshly" added to mixture
Epinephrine	Prolonged duration of block and utilized for determination of intravascular injection	Tachycardia may occur with absorption
Clonidine	Prolonged duration of block	Systemic hypotension, bradycardia, and sedation are seen with 150 μg dosing

intraarterial injection.[49] Since two of the major arteries at risk are direct feeders of cerebral circulation (carotid, vertebral), central nervous system (CNS) toxicity would obviously be rapid and severe. The vascularity of the anterior neck is dense, so the potential for rapid vascular uptake of agent injected correctly is high at this site, compared with other approaches to the brachial plexus. Signs of intravenous injection would be slower than the abrupt onset of seizure activity expected with intraarterial injection at this level. Rapid vascular uptake would be slower yet, with easily defined progression from prodrome, through excitation prior to seizure activity. Obviously, the slower the toxic CNS level is achieved, the more potential there is for therapeutic intervention to raise the seizure threshold and prevent seizures. The relatively short distance to the heart from this venous circulation will accelerate the progression by comparison with the arm or especially the leg.

High central block at either the epidural, subdural, or subarachnoid spaces is possible due to the close proximity of the dural sleeve, directly behind the transverse processes at the intervertebral foramina.[4] If the needle selected is long enough and the direction medial enough, any of these spaces can be reached. Aspiration will not detect location in the epidural or subdural space, and the dural sleeve placement may allow entry into the subarachnoid space without easy aspiration of cerebrospinal fluid. The onset will be most rapid and abrupt in the subarachnoid space with apnea, unconsciousness, and the profound hemodynamic compromise associated with total sympathectomy. The onset of epidural block will be slower, and since the epidural space ends at the foramen magnum, unconsciousness is variable. Subdural injection is very slow and patchy, involves cranial nerves, and is a diagnosis of exclusion. Episodes of hypoxia following interscalene blockade have been reported,[56] including an episode of asymptomatic profound oxyhemoglobin desaturation following interscalene block in a geriatric patient.[64]

Nerve Injury

Nerve injury from interscalene block occurs because of either directed intraneural injection or needle trauma to the nerves during attempted block, especially during repeated attempts to relocate the brachial plexus after local anesthetic has already been injected. Avoidance of paresthesia or care to avoid searing paresthesia associated with intraneural injection should decrease this risk. The complications of indwelling interscalene catheters will be discussed as a part of the postoperative pain management discussion.

Postoperative Pain Management

Postoperative pain is a significant issue in the management of shoulder surgery patients. The ability to be pain-free at the end of the procedure may play an important role in the instance where early mobilization is encouraged. Methods of postoperative pain relief include regional anesthesia with a long-acting local anesthetic medication, a cervical epidural catheter, or a continuous interscalene catheter. Other methods of postsurgical pain control, which may be used as the primary method or as an adjunct to the local anesthetics, include oral narcotics, nonsteroidal antiinflammatory drugs (NSAIDs), and intravenous patient-controlled analgesia with opioids.

Local Anesthetics

Due to the nature of orthopedic surgery, there can be numerous applications of regional anesthesia for surgical anesthesia. Knowing that the acute postoperative pain is severe after reconstructive orthopedic procedures, the long-acting local anesthetics are often selected to provide acute postoperative pain control. These can be applied at any level from skin infiltration, conduction block, or central block with and without the addition of opioids.

Preoperative Single-Shot Interscalene Block for Postoperative Pain Relief

Single-shot interscalene placement of meperidine was reported by Davidas et al.[21] with a long duration of analgesia (up to 24 hours) after open shoulder procedures. Brandl and Taeger advocated interscalene block with bupivacaine as a part of a balanced anesthetic technique for both intraoperative anesthesia and extended postoperative analgesia for up to 24 hours after open shoulder procedures.[14]

Interscalene Catheter

If the postoperative pain plan includes the need for a prolonged local anesthetic blockade, a catheter can be placed into the sheath of the brachial plexus at the level of the interscalene groove, with continuous infusion of low concentrations of local anesthetic. If an interscalene catheter is inserted, it could be maintained into the postoperative period with low-dose local anesthetic and used during physical therapy sessions. With continuous interscalene analgesia, pulmonary function improves,[41,45,50] opioid needs decrease,[26] and the conditions for rehabilitation improve.[73]

When compared to patient-controlled analgesia (PCA) with morphine, an interscalene catheter with patient-controlled dosing provided superior analgesia with reduced side effects attributable to morphine, such as nausea or pruritus.[13] The same benefit can be achieved with ambulatory patients when an interscalene catheter and a disposable local anesthetic delivery device are compared to parenteral opiates in the postanesthesia care unit and oral narcotics for ambulatory analgesia.[35] The techniques for patient-controlled interscalene analgesia have been studied, and it

was reported that a continuous infusion combined with patient-controlled doses improved the quality of analgesia compared with the patient-controlled doses without the basal infusion.[62] The safety of interscalene catheters and continuous infusion of 0.25% bupivacaine has been established by showing acceptable plasma levels up to 52 hours after the start of the infusion.[34]

Tuominen et al.[70] described the technique, noting the technical difficulty of placing and maintaining a catheter in the neck. Fixation of the catheters to the skin was felt to decrease catheter dislodgment during physical therapy. Haasio et al.[26] reported minimal need for supplemental opiates after shoulder surgery with an interscalene catheter, although 10% of the patients experienced at least mild signs of local anesthetic toxicity within the 24 average hours that the catheter was used.

There have been more reports of technical difficulties with the placement and maintenance of interscalene catheters than with any other peripheral catheter technique. Tuominen et al. reported six catheter failures and one pump failure among 24 patients.[70] The use of continuous interscalene block resulted in severe bupivacaine toxicity in a case reported by Pere[49] involving the migration of the catheter into an artery at a prolonged interval after the placement. Use of an epidural needle and catheter may improve this failure rate.[9] Continuous interscalene block will maintain the decreased function of the diaphragm based on ipsilateral phrenic nerve block[12] and could be associated with a decrease in ventilatory function.[50] Even reduction of the concentration of the bupivacaine to 0.125% or further reduction with the addition of fentanyl did not decrease this potential adverse effect.[50] Hassio et al. reported ventilatory compromise in one patient, CNS toxicity in four patients, and catheter failure in five patients in a series of 40 patients.[26] Despite the technical issues and potential adverse effects, the use of interscalene catheters is significantly increasing.[40]

There are a number of complications associated with indwelling interscalene catheters. One of the obvious concerns is the risk of infection. Other complications include lower lobe collapse,[57] pleural effusion and chest pains,[66] and intrapleural migration of the interscalene catheter.[65]

Signs of infection at the site of catheter insertion are always a concern, and in a study of 700 patients by Borgeat et al., six patients (0.8%) demonstrated signs and symptoms of infection.[11] Local pain, redness, and induration were noted in one patient after 3 days and in four patients after 4 days. All five of these patients were successfully treated with antibiotics. One additional patient required surgical drainage and after 10 days of antibiotics had a complete recovery. Ekatodramis et al.[24]reported a study of 27 patients in which one patient (3.7%) had the interscalene catheter removed at 18 hours because of the appearance of painful swelling at the site of catheter insertion and complete paralysis of the affected arm. It is not clear from the publication if this was an infection or resulted from some other cause.

Suprascapular Nerve Block

The suprascapular nerve has sensory fibers to the acromioclavicular joint, the subacromial space, and the posterior capsule of the glenohumeral joint. The suprascapular nerve supplies 70% of the sensory innervation of the shoulder joint. Richie et al.[54] found that utilizing 10 mL of 0.5% bupivacaine with 1:200,000 epinephrine resulted in no complications in 25 arthroscopic shoulder surgery patients. In the immediate postoperative period, there was a reduction in morphine utilization and decreased incidence of nausea along with a decreased duration of hospital stay, versus a control group of patients who received a sham block with saline. However, when comparing pain relief after arthroscopic shoulder surgery, Singelyn et al.[61] found that interscalene block is the most efficient analgesic technique with a significant reduction in morphine consumption and a better satisfaction score than suprascapular block or intraarticular injection. They did conclude that suprascapular nerve block would be a clinically appropriate alternative.

Additional Techniques of Pain Control

Hadzik et al.[27] compared local wound infiltration after general anesthesia with brachial plexus anesthesia for outpatient rotator cuff surgery and found that patients with brachial plexus blocks experienced a better recovery profile including bypassing the first phase of recovery more frequently, having less pain, ambulating sooner, and being ready for discharge sooner. Despite the simplicity of local wound infiltration, interscalene blocks provided a superior analgesia for outpatients. Intraarticular injection of opiates seems to have a benefit. There is evidence that local anesthetics injected into joint spaces may be more effective if there is opioid in the solution.[22,52] This is based on the discovery that there may be peripheral opioid receptors that could modulate the expression of nociceptive signals on the tissue level. Intraarticular placement of a catheter may seem to be technically appealing from the surgical aspect, but analysis reveals that the analgesia is superior with interscalene plexus blockade.

Cervical epidural anesthesia has been shown to provide effective relief of pain after shoulder reconstruction.[5,10] The advantage of a cervical epidural catheter is enhanced stability for prolonged postoperative use. The catheter should be placed under fluoroscopic guidance and the tip of the catheter should be preferentially located closer to the nerve roots of the affected side. Tunneled cervical catheters have been used to provide several weeks of prolonged postoperative analgesia.

Opioids

The use of narcotic analgesics as a part of surgical anesthesia has a rational basis during orthopedic surgery, since the manipulation of bone and soft tissue results in a high density of nociceptive stimuli from these structures. Many of the synthetic narcotic analgesics available for general anesthesia have the advantage of a rapid onset, with stable hemodynamic profile. They also have a relatively limited duration, which limits their use to control pain into the postoperative period unless administered by PCA devices. The termination of the analgesic properties of the short-acting, synthetic narcotics in the fentanyl family is rapid enough that they have limited postoperative analgesia even after short surgical procedures. Longer-acting narcotics, like morphine and meperidine, can be used for their general anesthetic effects and their prolonged duration of analgesia into the postoperative period. If parenteral narcotics will be the primary means of acute pain control after general anesthesia, it may be more rational to use these medications during the final minutes of the surgical procedure. The onset will occur prior to emergence and the patient will get the maximum possible analgesic duration. The only limitation is that the sedative and respiratory depressant properties of the narcotics can interfere with awakening from general anesthesia. If the medication is administered during a period of spontaneous, assisted ventilation during surgical wound closure, the respiratory rate and depth can be used as a guide to prevent excessive narcotic treatment. If administered in incremental doses during spontaneous ventilation and stopped at the first sign of respiratory depression, it is unlikely that excessive opioids will be administered.

Nonsteroidal Antiinflammatory Drugs

It is also possible to administer nonnarcotic analgesics, like NSAIDs, during emergence from anesthesia. There has been an increase in NSAID use since the release of ketorolac. Intramuscular, intravenous routes can be chosen with ketorolac,[19,37] and with other NSAIDs such as ibuprofen and indomethacin, the oral and rectal routes are possible. There is good evidence of efficacy in orthopedic patients from these compounds, but there is caution because of the effects of NSAIDs on the coagulation cascade.[36] It is still to be determined whether intraoperative administration of ketorolac increases the postoperative bleeding. Rectal indomethacin did not.[44] This is a critical issue with reconstructive orthopedics, both from the perspective of transfusion and the issue of hematoma formation, which increases the risk of wound infection, especially when there is instrumentation left in the operative site. Caution should be exercised in the utilization of NSAIDs in patients who are hypovolemic, as this will inhibit prostaglandin synthesis and thus lead to unopposed renal vasoconstriction, which may result in a precipitous decline in renal function. This effect could be even more pronounced in patients who have chronic renal failure preoperatively. It should be noted that a cyclooxygenase-2 inhibitor, rofecoxib, was withdrawn by the U.S. Food and Drug Administration because of adverse cardiovascular effects. Initially investigators may have concluded that the difference in cardiac events from the rofecoxib group and naproxen group was due to the cardioprotective effects of naproxen. By utilizing meta-analysis, it has been demonstrated that naproxen has only a small cardioprotective effect, thus resulting in the conclusion that rofecoxib has a significant cardiovascular risk.[32] Controversy still exists as to why the manufacture and drug licensing authorities did not continuously monitor this risk, which was suspected in the literature as early as the year 2001.[46]

Patient-Controlled Analgesia

PCA devices may be ideally suited to orthopedic patients. The procedures cause considerable pain, and patients know this prior to the surgery. The preoperative instruction required to select any PCA pain-control choice serves as a reassurance to the patient that there will be acute pain control available as soon as the surgery is completed. If general anesthesia is chosen, the patient can count on the PCA pump to be available as soon as the patient is able to operate the pump. The spirit of preemptive analgesia is served by continuing the interruption of the pain cycle from one modality to another without interruption.

CONCLUSIONS

Regional anesthesia techniques play an important role in the management of pain in the perioperative period surrounding shoulder surgery. The surgical procedure may be conducted under a general anesthetic, regional anesthetic, or a combination of both. Many patients and surgeons enjoy the benefits conferred by regional anesthesia, including its utilization for postoperative analgesia. Indwelling catheters may be utilized for prolonged postoperative analgesia. Despite advantages attributable to the utilization of regional anesthesia for shoulder surgery, there continues to still be a limited utilization of these blocks. Some authors have attributed this to the limited number of regional anesthesia instructors available in teaching institutions in addition to the focus on general anesthetics in residency programs. A nationwide survey of anesthesiology residents demonstrated that the majority of third-year residents expressed a low confidence in their ability to perform most peripheral nerve blocks.[63] Evans et al.[25] in a general review of peripheral nerve blocks and continuous catheter techniques concluded that to foster the continued use of peripheral nerve blocks for postoperative analgesia, it is

essential to improve practitioner-teaching modalities and that additional research may be needed in demonstrating improved patient outcomes to further their expanded use. Continuous interscalene catheters may have a role in providing extended analgesia, but the ultimate risk and benefit ratio still remains to be determined.

structures providing stability to, 815f
Glenoid process fracture, 799f, 800–821
anterior approach to, 800–801
posterior approach to, 801, 801f
superior approach to, 801–802
surgical approach to, 800–803
Glenoid rim
bony lesions of, 302
computed tomography of, 361f
retracted tendon tethered to, 72f
Glenoid rim fracture, 556, 804, 807f
after frozen shoulder, 556
computed tomography scans of, 865
Glenoid surface of scapula, 283–284
normal scapulothoracic rotations positions of, 297f
superior tilt of, 284f
Glenoid vault
shape of, 637
Glenolabral articular disruption lesions, 363
Glenoscapular angle
schematic of, 1116f
Global CAP, 715f–716f
Global fatty infiltration index, 106
Glucose tolerance tests
with frozen shoulder, 543
Goats
rotator cuff disease models, 28
Golfers
with deltoid muscle ruptures, 269
with latissimus dorsi muscle ruptures, 271
long thoracic nerve injury in, 1067
Gout
glenohumeral joint, 603–604, 605f, 606f
clinical presentation of, 605
imaging of, 605
incidence of, 604
laboratory findings, 605
pathogenesis of, 604
sternoclavicular joint, 1023
Grafts
for glenohumeral arthritis, 667–668
Grammont Delta reverse shoulder prosthesis, 740
problems with, 742–743
Grammont's reverse arthroplasty, 650f
Grashey's view, 610f
Grating scapula, 1077
Greater tuberosity
of biceps tendon, 892
debridement, 172
freeing of
proximal humeral fractures hemiarthroplasty, 893f
isolated
proximal humeral fractures, 875
posterior displacement, 862
proximal humeral fractures
anterior shoulder dislocations, 866
anteroposterior view of, 861f
axillary view of, 861f
management of, 867
two-part
fracture dislocation, 853f, 866f
proximal humeral fractures, 878
proximal humerus malunions, 915–917, 917–918, 918–919, 919–921, 920f
Growth factors, 30
synthesis of, 32
Guidewires
glenoid cavity fractures, 805f
Gunshot wounds
causing brachial plexus injuries, 1093
ulnar nerve transection, 1105f
Gunslinger braces, 1240
with fascioscapulohumeral dystrophy, 1073
for multidirectional instability, 454
Guy rope technique
for rotator cuff partial tears, 61–62, 61f
Gymnasts
glenohumeral anterior subluxation, 343
long thoracic nerve injury in, 1067
with multidirectional and voluntary instability, 1287, 1288
residual capsular laxity, 499

H

Haemophilus influenza
sternoclavicular joint, 1017
Half-shoulder spica cast
midclavicular clavicle fractures, 954
Hand
impairment in brachial plexus injuries, 1130
Handheld dynamometry, 1266, 1297
Handheld plate press, 684f
Hand squeezes
for glenohumeral arthritis rehabilitation, 1284
for latissimus dorsi tendon transfer
for rotator cuff tears, 1275
for rehabilitation following thermal capsulorrhaphy, 1280
for rotator cuff repair rehabilitation, 1271
for subacromial decompression, 1269
Hand-to-mouth function, 1129f
after humeral rotational osteotomy, 1118f
Hawkins' impingement sign, 44f
with frozen shoulder, 546
Hawkins' test, 41
Heat
moist, 1239
Heat therapy, 1239
for rotator cuff tears, 49
Hemangiopericytoma
of shoulder girdle, 1169t
Hemangiosarcoma
of shoulder girdle, 1169t
Hematogenous septic arthritis
of shoulder girdle, 1202–1203
Hematoma
with bursectomy, 1083
with pectoralis major rupture surgery, 266
with scapulothoracic crepitus, 1079
Hematoma block
midclavicular clavicle fractures, 954
Hemiarthroplasty
bipolar
overstuffing shoulder, 735, 735f
vertical orientation of, 735, 735f
complications of, 755, 756t
for glenohumeral arthritis, 1284
humeral, 650
for surgical neck proximal humerus nonunions, 933–935, 935f, 936f
indications for, 700
infection complicating, 1207–1208
nerve injuries after, 756
outcomes for, 903f
proximal humeral fractures, 875
for RCDA
indications for, 736
stability of, 736
surgical technique, 736–739, 736f
survival rates of, 700

Hemiarthroplasty (*continued*)
vs. total shoulder arthroplasty
for implants in unconstrained prosthetic arthroplasty for glenohumeral joint arthritis, 717–718
patient satisfaction with, 718
results of, 718
Hemidiaphragm paralysis, 1097
Hemophilia arthropathy
glenohumeral joint, 617, 617f
Hemopneumothorax
with scapula fractures, 836
Hemothorax
clavicle fractures, 951
Heterotopic ossification, 155–158, 257
anteroposterior and axillary radiographs, 157f
etiology and prevention of, 155–156
evaluation of, 156–157
treatment of, 157–158
High-voltage pulsed stimulation, 1239
Hill-Sachs lesion, 342, 373, 500–502
anterior dislocation in, 301f
anterior instability, 520
anterior shoulder instability, 302f
Bankart repair of, 303f
computed tomography of, 362f, 410f
extraarticular, 502
glenohumeral anterior subluxation, 343
humeral bone loss, 300–301
magnetic resonance imaging of, 361f
in overhead athletes, 326
posterior approach to, 503f
Histiocytoma
malignant fibrous
misdiagnosed as frozen shoulder, 547
of shoulder girdle, 1169t
History
after failed repair of instability, 529–530
of biceps tendon, 234–236
of dislocation, 584
of fascioscapulohumeral dystrophy, 1072
of frozen shoulder, 544, 545
of frozen shoulder syndrome, 545
of glenohumeral instability, 346–347
of long thoracic nerve injury, 1068
of osteoarthritis, 703–704
of proximal humeral fracture-dislocations, 864
of rhomboideus major/minor palsy, 1071
of rotator cuff calcifying tendinitis, 196–197
of rotator cuff tears, 39–40
of scapular dyskinesia, 1076–1077
of scapulothoracic bursitis, 1081
of scapulothoracic crepitus, 1078
of shoulder girdle tumors, 1160–1161
of SLAP lesions, 235
of spinal accessory nerve palsy, 1064–1065
of stiff shoulder, 545
of trapezius muscle winging, 1064–1065
of unconstrained prosthetic arthroplasty, 697–698
Hockey players
instability in
braces for, 375
Homan retractor, 780
for glenoid exposure in unconstrained prosthetic arthroplasty, 712, 713f
for hemiarthroplasty for RCDA, 737f
for rotator cuff deficiency arthropathy unconstrained and constrained arthroplasty, 745f
Home exercise programs
for proximal humeral fractures rehabilitation, 1283
Hooded arthroscopic burr, 151
Hooded glenoid component
in unconstrained total shoulder arthroplasty for
rotator cuff tear arthropathy, 732f
Horner's syndrome, 1095, 1097f
Hot packs, 1239
Hourglass biceps, 227
Housewives

TUBS acronym, 340, 370, 435, 1276
Two-part surgical fractures
degree of angulation, 867
Two-part surgical neck fractures, 862, 866
fluoroscopic assessment of, 862
Two-point discrimination, 1095
Two-step acromioplasty, 149

U

UCLA shoulder rating scale, 852
UCLA Shoulder Scale, 1302t, 1307–1308, 1307f
Ulnar nerve, 1088–1089
fascicle isolation of, 1109f
identification of, 1109f
transfer of, 1109f
Ulnar nerve transfer technique, 1107–1108
Ulnar neuritis
with triceps tendon avulsion, 275
Ultrasling brace, 1240f
Ultrasonography, 1239
advantage of, 238
glenohumeral joint, 566
limitations of, 240
pectoralis major muscle ruptures, 264
rehabilitation, 1239
rotator cuff, 242
rotator cuff calcifying tendinitis, 196
rotator cuff tears, 174
subluxated biceps tendon, 239f
therapeutic
for glenohumeral arthritis, 658
Unconstrained prosthetic arthroplasty
founding of, 697–698
history of, 697–698
for inflammatory arthritis
results of, 723
for rheumatoid arthritis
results of, 723
Unicameral bone cysts
of shoulder girdle, 1170, 1171f
Ununited anterior acromial fragment, 152f
Ununited midclavicular clavicle fractures, 956f–957f
Upper body ergometer, 1258
for rehabilitation
following anterior capsulorrhaphy, 1280
following arthroscopic Bankart repair, 1278
following thermal capsulorrhaphy, 1280
Uric acid
for glenohumeral arthritis, 568
Urinary system
opioids effects on, 1341

V

Valdecoxib
for chronic shoulder pain, 1334
Valgus-impacted four-part proximal humeral fractures, 875
treatment of, 883
Valgus-impacted proximal humeral fracture fragments of, 881
Valproic acid
for chronic shoulder pain, 1337
Vancomycin
for infections following rotator cuff surgery, 162
for septic arthritis, 1216t
Variable resistance units
for rehabilitation following arthroscopic Bankart repair, 1278
for rehabilitation following thermal capsulorrhaphy, 1280
Vascular insult
causing suprascapular nerve injuries, 1136
Vascularized autogenous bone grafting
with glenohumeral arthrodesis, 688–689
Vascularized fibular graft
technique of, 689f
Vascular problems
in overhead athletes, 330–331
Ventral ram, 1088
Vertical height gauge
illustration of, 895f
2.0 Vicryl
proximal humeral fractures hemiarthroplasty, 898
Vioxx
for chronic shoulder pain, 1334
Visceral nociceptive pain
definition of, 1320
Viscosupplementation
for glenohumeral arthritis, 659
Visual analog scales, 1296
Volleyball players
glenohumeral joint instability
repetitive injury, 300
Voltaren
for chronic shoulder pain, 1334
Voluntary scapular winging, 1075
V-Y repair configuration, 165

W

Wallerian degeneration, 1095
Warner's technique
latissimus dorsi muscle transfer
for irreparable posterosuperior rotator cuff tears, 119–125
for pectoralis major muscle transfer
for anterosuperior rotator cuff defect, 130–135
postoperative care, 135

Washboard syndrome, 1077
Water polo players
  glenohumeral joint instability
    repetitive injury, 300
Water skiers
  with pectoralis muscle ruptures, 263
Watson-Jones, Reginald, 153
Weakness
  with axillary nerve injuries, 1145
  brachial plexus, 1322t
  with fascioscapulohumeral dystrophy, 1072
  rotator cuff, 39
Weight-bearing exercise
  for scapular winging and dyskinesia, 1291
Weight lifters
  glenohumeral anterior subluxation, 342
  instability, 372
  long thoracic nerve injury in, 1067
  with triceps tendon avulsion, 274
Weights
  free, 1236, 1268
    for multidirectional and voluntary instability, 1288
    for posterior instability, 412
    for rehabilitation following anterior capsulorrhaphy, 1280
    for rehabilitation following arthroscopic Bankart repair, 1278
    for rehabilitation following thermal capsulorrhaphy, 1280
    for scapular winging and dyskinesia, 1291
    for strengthening, 1251
Welders
  fatigue, 1238
Wiley tricortical iliac bone graft, 734f
Windup
  in baseball pitching, 315
Winging of scapula, 545, 1093f, 1287, 1287f
  and dyskinesia
    examination of, 1289–1290
    rehabilitation for, 1289–1291
  with frozen shoulder, 545
  with multidirectional and voluntary instability, 1288
  pectoralis major transfer for, 1070f
  with posterior instability, 414
  postoperative considerations, 1070
  primary, 1073–1074
  secondary, 1074–1075, 1074f
  serratus
    symptomatic, 1068
  symptomatic, 1072
  trapezius muscle, 1064
  treatment of
    complications of, 1070
  voluntary scapular, 1075
Wire loop
  retractable, 83f
Withdrawal
  from opioids, 1341
Wrestlers
  instability in
    braces for, 375
  long thoracic nerve injury in, 1067
  with multidirectional and voluntary instability, 1288
  with pectoralis muscle ruptures, 263
Wrist
  impairment in brachial plexus injuries, 1130

X

X-rays
  of brachial plexus injuries, 1097
Xylocaine
  for acute synovial inflammation, 159
  for interscalene block, 1358–1359
  for rotator cuff tears, 50
  weakness from rotator cuff tear *vs.* pain inhibition, 41
  weakness *vs.* pain in range of motion limitation, 40

Y

Yergason's test, 236

Z

Z-plasty
  of subscapularis and anterior capsule, 504
