It may be difficult to initially determine the cause of recurrence of instability in these cases. The index operative note may describe a Bankart-type repair as intended. With the increased use of suture anchors during Bankart-type repairs, the location of the anchors on a radiograph can be of assistance (Fig. 16-2). If the integrity of the anteroinferior glenoid labrum and IGHL are not restored, a Bankart repair was not accomplished and instability recurrence is predictable.

Technical errors leading to instability recurrence also plague non-Bankart repairs. For the Bristow procedure, correct placement of the transferred coracoid tip is essential to success.[108] If the coracoid tip is secured too medial or superior on the glenoid neck, recurrent instability would be expected. If the procedure is to be successful, the transferred coracoid process must be placed at the anteroinferior quadrant to act as a bone block against anteroinferior humeral translation. A surgeon cannot rely on the "sling" of conjoined tendon to prevent humeral subluxation.[235]

Figure 16-2 Radiograph of a 19-year-old man who had two previous "Bankart" repairs for recurrent, traumatic anterior instability. Placement of suture anchors in this superior position is unlikely to result in repair of the inferior glenohumeral ligament origin.

Failure to Restore Glenoid Concavity

The shoulder is often described as inherently unstable owing to the shallow glenoid fossa. Relative to the acetabulum, the glenoid fossa is shallow. However, just as a golf ball on a tee, the humeral head gains a great degree of stability from its position within a concave glenoid fossa, and should actually be considered inherently stable. Howell and Galinat determined the depth of the glenoid fossa to be 9 mm in the superior-to-inferior direction and 5 mm in the anteroposterior direction.[112] Half of the depth was attributed to the effect of the glenoid labrum, with the other half coming from the combined effect of the bony glenoid structure and the peripherally thickened chondral surface. This depth confers a great deal of stability to the glenohumeral articulation.

Even without ligamentous support, glenoid concavity plays a surprisingly effective role in providing glenohumeral stability. Lippitt et al. defined the *concavity–compression* mechanism of glenohumeral stability as the combined stabilizing effect of a spherical humeral head contained in

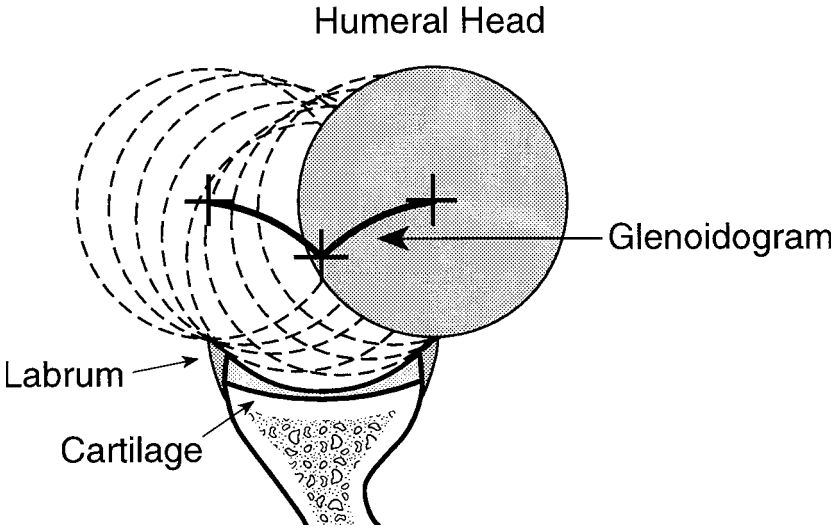

Figure 16-3 The "glenoidogram" defines the glenohumeral stabilizing effect of glenoid concavity. For the humeral head to translate anteriorly, posteriorly, or inferiorly out of the glenoid, it must initially move laterally, against the stabilizing force of the rotator cuff.

a deep glenoid fossa, held there by muscular compressive action.[154] These investigators used a graphic representation, referred to as the glenoidogram, to define glenoid depth. The glenoidogram demonstrates that lateral displacement of the humeral head is first necessary before anterior translation can occur (Fig. 16-3). They also used the *stability ratio,* a factor defined by Fukuda et al. as the humeral translating force required to cause a glenohumeral dislocation divided by the humeral compressive load maintaining stability, multiplied by 100, to analyze the effectiveness of glenoid concavity in promoting stability.[73] Normal glenoids were noted to have significant concavity, equating with an ability to provide a tremendous stabilizing effect (stability ratios as high as 63%). Excising the glenoid labrum caused a reduction in the stability ratio of approximately 20%.

To relate the concept of concavity–compression more directly to the diagnosis of recurrent traumatic anterior instability, Lazarus et al. measured glenoid concavity and stability ratios before and after creation of an anteroinferior glenoid chondral–labral defect.[144] This defect was designed to be similar to that which might be found after numerous anterior glenohumeral dislocations (Fig. 16-4). This investigation demonstrated significant reduction in the effectiveness of concavity–compression after creation of the instability defect. Glenoid concavity and stability ratios could be normalized with a simulated surgical reconstruction of the glenoid concavity (Fig. 16-5). Halder[90] confirmed previous studies that suggested that the stability ratio and effective depth of the glenoid socket

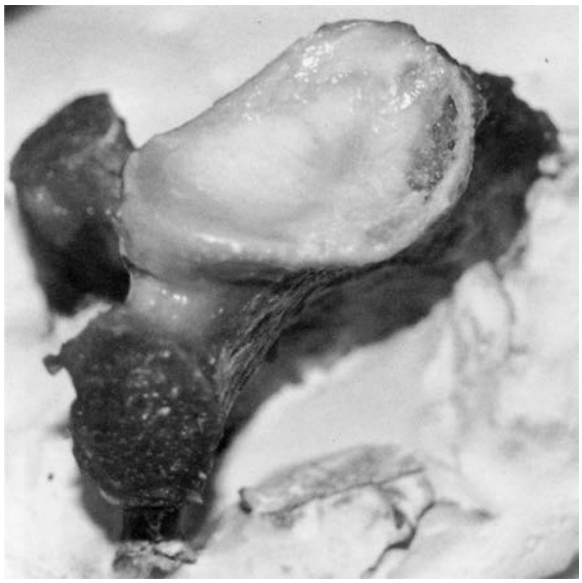

Figure 16-4 Surgically created anteroinferior glenoid labral and chondral defect to simulate the findings of glenoid concavity loss in recurrent, traumatic anterior instability.

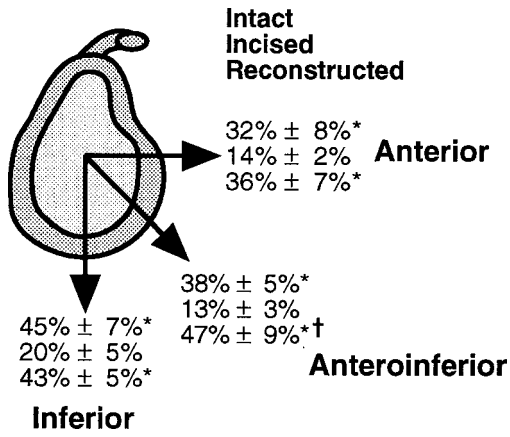

Figure 16-5 Stability ratios (humeral translating force/compressive load × 100) for intact specimens, those with surgically created anteroinferior chondral–labral defects, and those surgically reconstructed. Notice that, by restoring and even enhancing glenoid concavity, stability ratios can be corrected (*$P < 0.0001$ vs. incised, $P < 0.0001$ vs. intact).

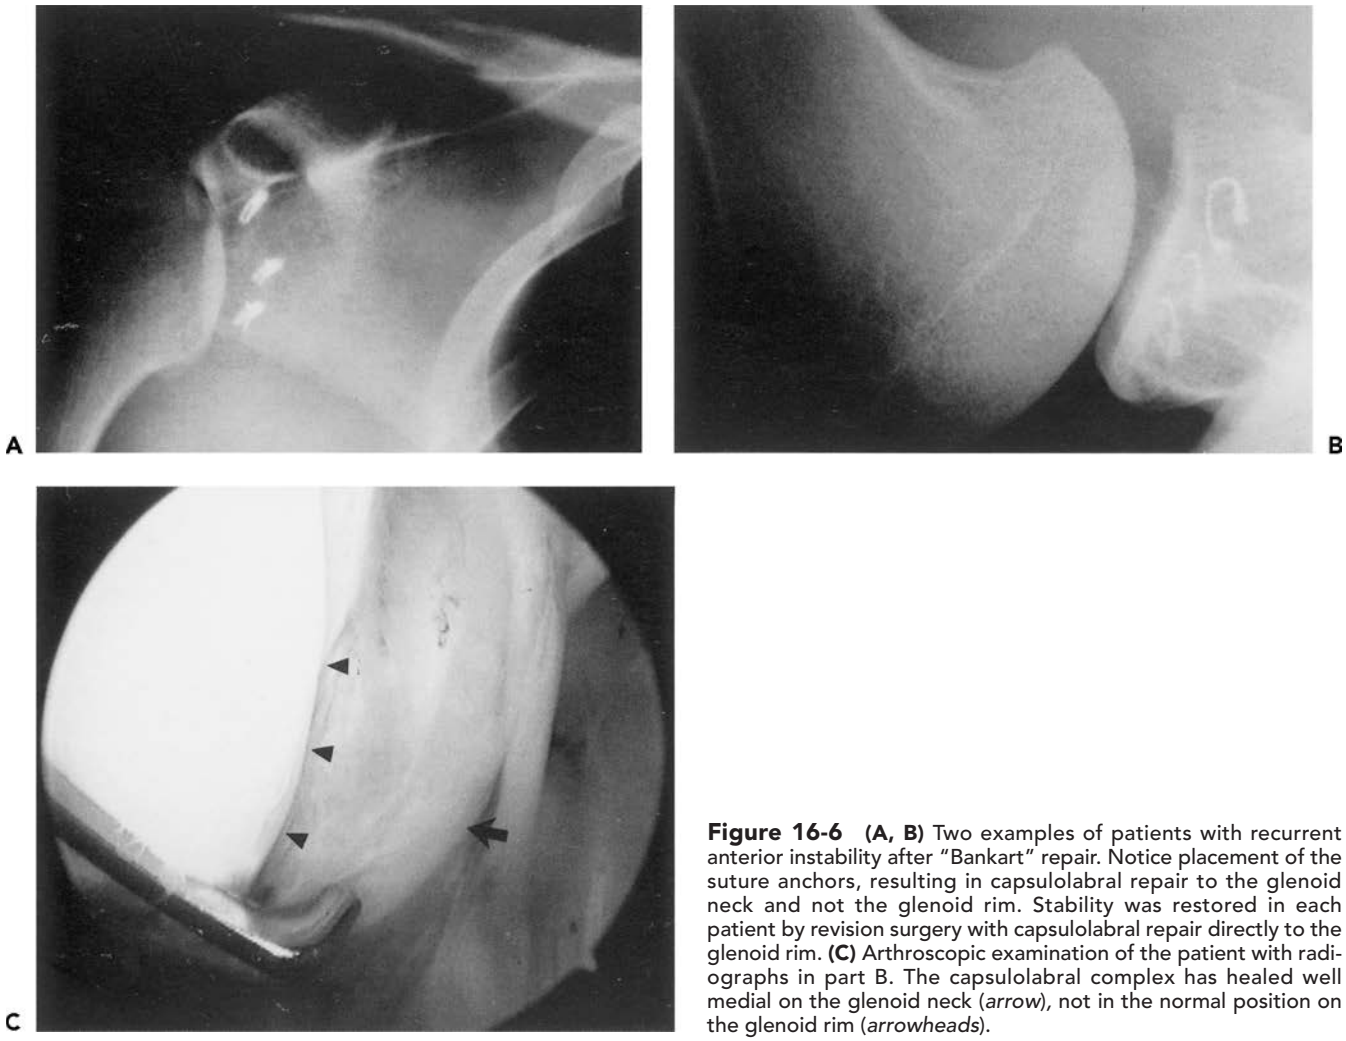

Figure 16-6 **(A, B)** Two examples of patients with recurrent anterior instability after "Bankart" repair. Notice placement of the suture anchors, resulting in capsulolabral repair to the glenoid neck and not the glenoid rim. Stability was restored in each patient by revision surgery with capsulolabral repair directly to the glenoid rim. **(C)** Arthroscopic examination of the patient with radiographs in part B. The capsulolabral complex has healed well medial on the glenoid neck (*arrow*), not in the normal position on the glenoid rim (*arrowheads*).

were linearly correlated. As compressive loads increased, the stability ratio decreased. Finally, Itoi[121] performed a cadaveric study in which osteotomy of the anterior–inferior glenoid was performed and then the Bankart lesion repaired. Stability to anterior translation was decreased significantly after the repair if the osseous lesion exceeded 21% of glenoid width. Severe external rotation loss of 25 degrees per centimeter of defect was observed.

The normal glenoid labral attachment is directly to the glenoid rim. Instability repairs that result in a capsulolabral repair to the glenoid neck and not to the glenoid rim fail to restore the normal glenoid architecture and can result in surgical failure. This type of repair is more commonly seen with the use of auxiliary fixation devices, particularly tacks, staples, and suture anchors (Fig. 16-6). Either because of their size or because of the surgeon's reluctance to place these devices near the articular surface, use of these tools can result in medial placement and subsequent inadequate repair. Although the integrity of the IGHL may be restored with this type of repair, normal glenoid concavity is diminished and the concavity–compression mechanism of stability is impaired (Fig. 16-7).

Revision surgery in cases of medial capsulolabral repair requires an attempt to restore normal glenoid anatomy and depth. Usually, the anterior capsular complex is found healed to the neck of the glenoid and requires mobilization. Care is taken to preserve the thickness of the glenoid labrum and capsular tissue. Once this tissue is freed from the glenoid neck, traditional repair to the rim of the glenoid is accomplished. For revision surgery, we recommend the technique of Thomas and Matsen.[259] A standard deltopectoral approach is used with a low axillary incision. Scar and adhesions between the overlying deltoid, acromion, and conjoined tendon and the underlying rotator cuff and humeral head are mobilized. Often these adhesions are extremely thick and require a sharp incision. Care should be taken not to be too superficial and risk injury to the axillary nerve as it travels on the deep surface of the deltoid. Scar on the superficial surface of the subscapularis should be excised only up to the lateral border

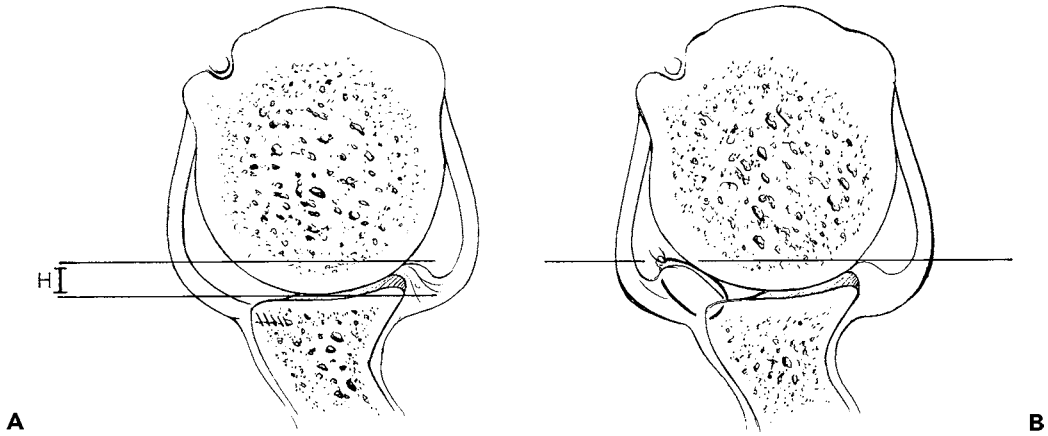

Figure 16-7 **(A)** Capsulolabral repair to the glenoid neck fails to restore normal glenoid concavity. **(B)** Capsulolabral repair to the glenoid articular margin restores normal glenoid concavity.

of the conjoined tendon. Subscapularis mobilization is completed after complete incision of the tendon.

The subscapularis and capsule are sharply incised as a single unit, approximately 1 cm medial to the lesser tuberosity. A small elevator can be passed through the rotator interval and deep to the subscapularis and capsule before incision, to gauge the combined thickness, protect the long head of the biceps, and protect the underlying humeral articular surface. After capsulotomy, the subscapularis can be completely mobilized by using traction sutures to pull the tendon laterally and cause adhesions on the undersurface of the conjoined tendon to present themselves lateral to the tendon.

Upon capsulotomy, capsulolabral repair to the glenoid neck is found. This repair is mobilized by either a small periosteal elevator or sharp dissection. The anterior, nonarticular glenoid surface is burred, using the burr to contour a new glenoid rim (Fig. 16-8A). Three to four bone tunnels are created using a 1.5-mm wire-passer burr and a 3-0 angled curette. Each of these holes is filled with a no. 5 Ethibond suture, passed with a no. 5 curved Mayo needle (Fig. 16-8B). Finally, the trailing medial edge of capsule is repaired with simple suture passes, taking care to mobilize the capsule superiorly with repair (Fig. 16-8C). The subscapularis and capsulotomy are closed end to end. We prefer an "all inside" repair performed through transosseous bone tunnels in the anterior glenoid rim because we believe this type of repair has a bunching effect on the labrum, further enhancing anterior glenoid concavity.[166,186,259] Capsulolabral repair with suture anchors can also be successful, as long as the anchors are placed directly on the glenoid rim. Typically in these situations, repair of the capsule and labrum to its true anatomic position is successful in achieving glenohumeral stability.

Postoperatively, these patients are managed as a primary instability repair. A sling is worn for 3 weeks, the patient removing the sling five times each day to perform supine active assisted forward elevation to 90 degrees and external rotation to neutral. At 3 weeks postoperative, the sling is discontinued, and full motion is permitted. At 6 weeks postoperative, resistance exercises are begun, including rotator cuff strengthening and scapular stabilization. Noncontact athletics are permitted at 3 months postoperative, with full contact at 6 months.

Larger concavity defects occur with fracture of the glenoid rim. It has been well reported that glenoid rim fractures are associated with recurrent anterior instability.[18,106,140,168] Treatment options in the face of a glenoid rim fracture include excision of the fragment and capsulolabral repair to the remaining glenoid rim versus direct internal fixation of the anterior glenoid fragment. Most authors recommend repair of the fragment if it constitutes more than 25% of the glenoid width.[18,294]

The accurate preoperative evaluation of a potential clinically significant osseous glenoid lesion is critical. Special radiographic studies, including a Garth view and West Point axillary view, should be obtained. Even with good-quality images, however, only large or distinct osseous fragments may be visible. A computed tomography (CT) scan may be needed to adequately visualize and size a glenoid rim defect. Sugaya et al.[253] used CT to evaluate 100 shoulders with recurrent unilateral glenohumeral instability and found that 90 had pathologic lesions. Fifty had osseous defects and 40 had blunting of the normal glenoid contour suggesting compression or erosion at the glenoid rim. Glenoid rim deficiency of less than 25% of the articular width can be effectively treated by simple repair of the capsulolabral complex into the defect. If the defect involves more than 25% of the glenoid articular width, however, it must be repaired or reconstructed for successful revision surgery. Failure to account for and reconstruct an anterior glenoid rim fracture can be a cause of instability recurrence after surgery[18] (Fig. 16-9A).

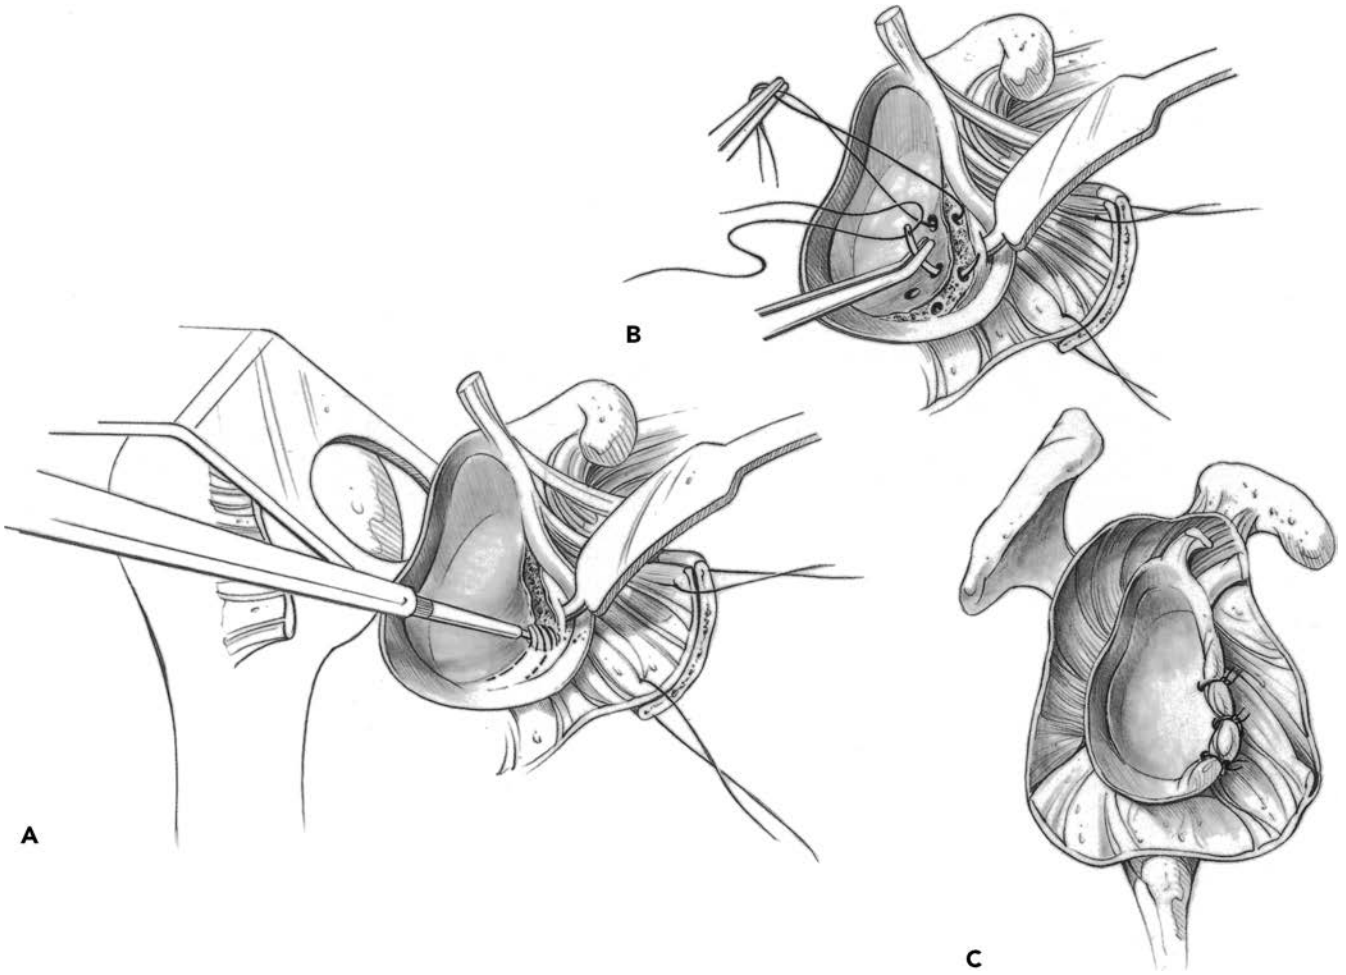

Figure 16-8 **(A)** The previous medial capsulolabral repair is elevated from the glenoid neck. A high-speed burr is then used to create a lip to the typically rounded anterior glenoid rim. **(B)** Bone tunnels are made in the glenoid rim and each receives a no. 2 braided, nonabsorbable suture. **(C)** By passing the sutures in simple fashion (all-inside technique), the labrum is bunched on the glenoid rim, restoring glenoid concavity.

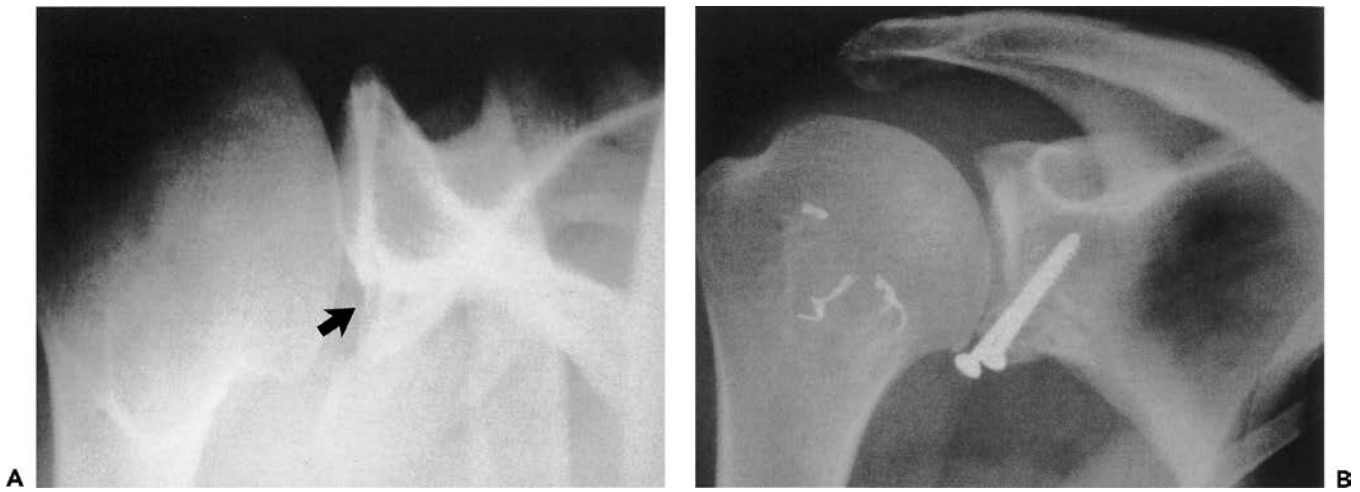

Figure 16-9 **(A)** Garth apical oblique view demonstrating a large anteroinferior glenoid osseous defect (*arrow*). **(B)** Same patient after repair of the osseous lesion. (Courtesy of Douglas T. Harryman II, University of Washington Medical Center, Seattle, WA.)

Gerber has reported work on the effect of loss of the anteroinferior glenoid rim on stability.[76] Instead of measuring the percent loss of the glenoid rim, he recommended measuring the shortest distance from the glenoid rim just superior to the defect to the intact rim at the inferior aspect of the defect. In his study, if this distance was greater than 15 mm, the stability to translational force was decreased by over 60%. More importantly, the stability could not be corrected by ignoring the osseous lesion and repairing the capsule and labrum into the defect.

If, during revision surgery, the residual bone fragment appears viable, direct internal fixation of the fragment should be performed (Fig. 16-9B). In these situations, we alter the standard Bankart approach by dividing the subscapularis and capsule as two distinct layers. The subscapularis is divided approximately 1 cm medial to the lesser tuberosity. Then, using sharp dissection or an electrocautery, the subscapularis tendon is elevated, in a medial direction, from the underlying capsule. The tendon must be freed in a medial direction past the glenoid rim fragment. The anterior capsule is then incised, allowing visualization of the glenoid articular surface. The glenoid fragment is usually found partially healed to the anterior glenoid neck and requires mobilization (Fig. 16-10A). The osseous bed is then prepared by a high-speed burr, and the fragment is repaired with bicortical lag screws, taking care to not leave the screws long posteriorly where they may injure the suprascapular nerve (Fig. 16-10B). Usually the anterior glenohumeral ligaments are attached to the osseous fragment and, therefore, are restored with union of the repair.

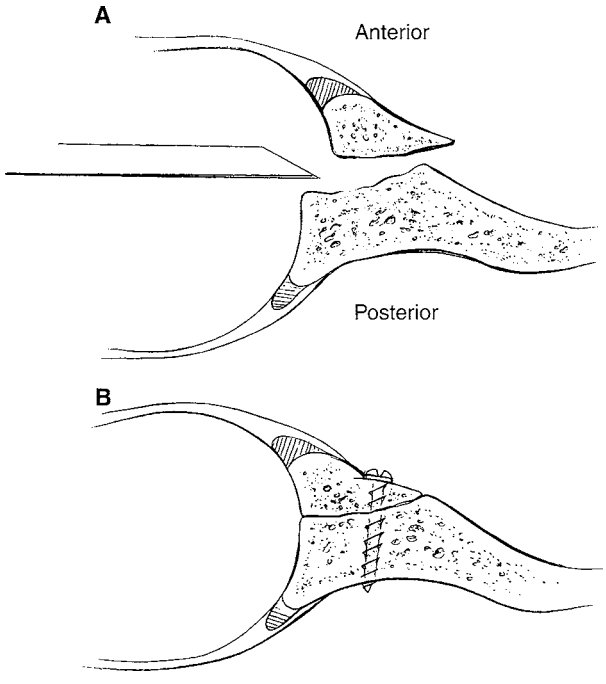

Figure 16-10 **(A)** For repair of a large osseous Bankart lesion, the bone fragment is mobilized from its partially healed position on the anterior glenoid neck. **(B)** Fixation is by two 3.5-mm bicortical lag screws or 4.0-mm cannulated screws.

If, however, the fragment has eroded or appears nonviable, the glenoid rim must be reconstructed. Gerber has discussed reconstruction of the glenoid rim by placement of autogenous iliac crest graft, secured with bicortical screws, and fashioned to match the curvature of the native glenoid.[76] In a preliminary report, he found that the technique restored stability in 12 of 13 patients, with the final patient having questionable recurrence of subluxation only. In a similar study, Gill et al.[78] reconstructed the anterior glenoid with iliac crest bone graft in 12 patients with CT-confirmed anterior glenoid bone loss. There was no recurrence in any patient at average 2-year follow-up. The only patients who developed progressive degenerative change were those who had some degree of degeneration preoperatively. Other authors echo these results. Bodey and Denham,[27] Haaker et al.,[89] and Hutchinson et al.[116] all reported high patient satisfaction with a low recurrence rate for iliac crest grafting. Warner[273] reported on 12 patients with anterior–inferior glenoid deficiency who underwent intraarticular reconstruction of the anterior–inferior glenoid utilizing tricortical iliac crest autograft and capsular shift. At follow-ups ranging from 24 to 61 months, there were no reported cases of instability and CT confirmed osseous union absent arthritic changes.

Our preference in these difficult situations is to use autogenous bone to fashion a graft for the rim, similar to Gerber. The surgical approach is as described earlier. The remaining atrophic glenoid fragment is excised, taking care to preserve the full length of the anterior capsuloligamentous structures. A pine cone burr is used to freshen and prepare the bed. A tricortical graft is harvested from the iliac crest. With a pine cone burr, the graft is fashioned to approximately conform to the curvature of the glenoid. If sufficient capsular length exists to place the graft in an extracapsular position, sutures of no. 2 Polydek are placed under the graft for later capsulolabral repair (Fig. 16-11A). The graft is then secured with bicortical lag screws, taking care to closely observe the articular surface for screw penetration and to not leave the screws long posteriorly where they may irritate the suprascapular nerve. Finally, the pine cone burr is again used to complete fashioning of the graft in situ (Fig. 16-11B). With use of the previously placed sutures, the capsule is repaired directly to the native glenoid rim, leaving the bone graft in an extracapsular position (Figs. 16-11C and 16-12). If capsular repair to the host glenoid–graft junction will result in excessive loss of external rotation, drill holes are placed in the rim of the graft and the capsulolabral complex is repaired to the rim of the graft. The subscapularis and capsule are then closed side to side. The postoperative regimen is as previously described for Bankart repair.

An alternative to bone grafting is a Bristow or Laterjet coracoid transfer. Either of these procedures would be technically easier than bone grafting of the anterior glenoid

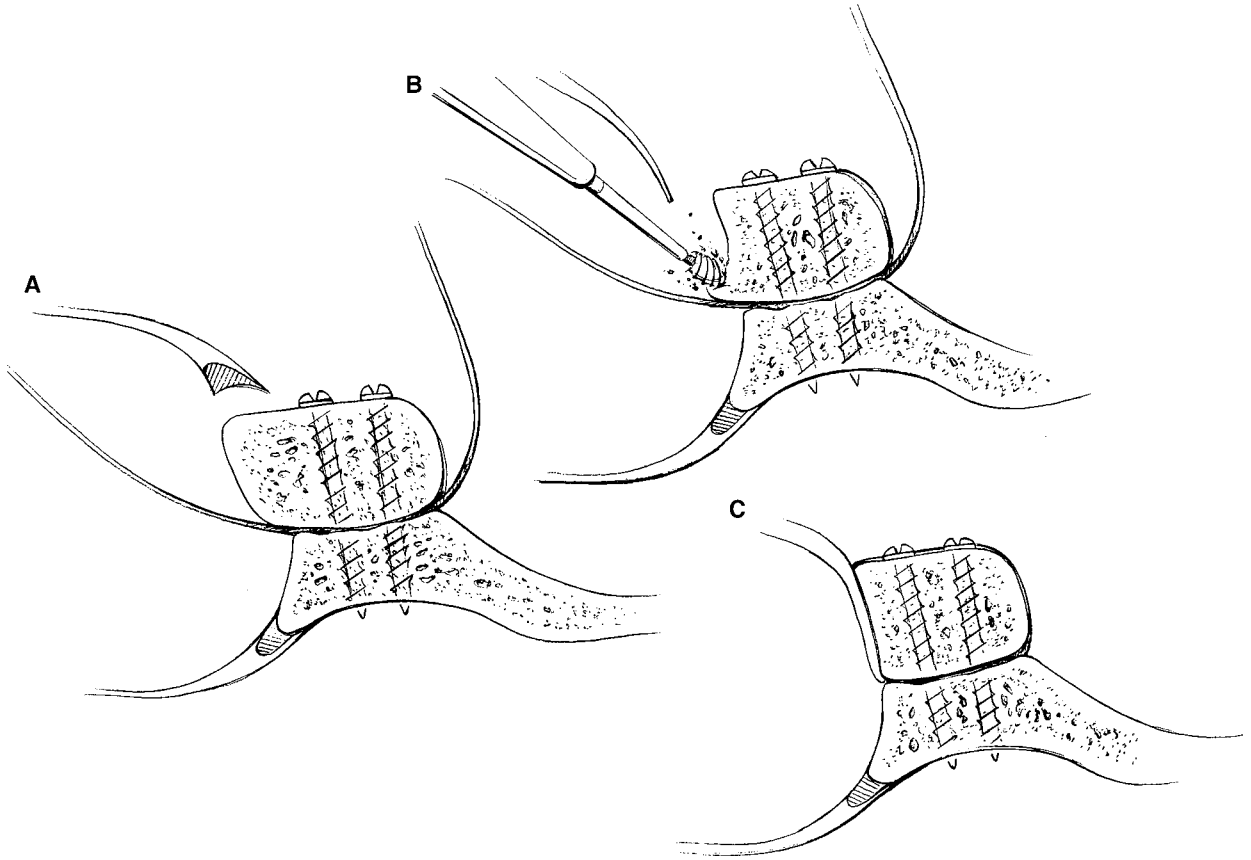

Figure 16-11 **(A)** For a large osseous Bankart lesion that requires grafting, a tricortical graft is taken from the iliac crest and applied to a prepared bed on the anterior glenoid neck. Sutures are placed under the graft for later capsular repair. **(B)** The graft is burred to conform to the curvature of the normal glenoid. **(C)** When burring is completed, the anterior capsule is repaired over the graft using the previously placed sutures. This repair leaves the graft in an extracapsular, supportive position.

rim. Coracoid transfer procedures, however, provide only a block to dislocation and do not reestablish the glenoid curvature, thereby leaving the patient susceptible to continued anterior subluxation.

Finally, an osteochondral allograft can be used to reconstruct large anteroinferior glenoid defects. Swarm and Lazarus[254] reported on the use of this procedure in two patients, successfully eliminating instability in both (Fig. 16-13). Advantages of allograft over autogenous iliac crest graft include the ability to near anatomically size the glenoid rim, lack of donor-site morbidity, the presence of a smoother articulating surface, and the presence of labral and capsular tissue on the graft to assist in the reconstruction of combined osseous, chondral, labral, and capsular deficiencies. Clearly, the disadvantages are the theoretical possibility of disease transmission and the cost.

Residual, Abnormal Anteroinferior Capsular Laxity

In the science of shoulder instability, there is currently ongoing debate over the presence or absence of plastic deformation of the IGHL in patients with recurrent traumatic anterior instability and, if present, its clinical significance. Bigliani et al. demonstrated plastic deformation of the IGHL before the ultimate failure by avulsion from the glenoid rim during stress to failure of the IGHL complex.[24] Reeves had previously confirmed these findings in older cadaveric shoulders, but found isolated capsular avulsion without plastic deformation in shoulders of younger cadavers, within the age group most likely to suffer recurrent traumatic anterior instability.[214] Speer et al.[246] studied cadavers with simulated Bankart lesions and found increased translation anteriorly and inferiorly that were small, averaging only 3.5 mm. The authors concluded that some degree of capsular injury must occur for instability recurrence.

On the contrary, McMahon et al. presented work that demonstrated capsulolabral avulsion in 8 of 12 cadaveric shoulders when the application of stress was performed with the arm positioned in the critical abducted and externally rotated position.[182] More importantly, the amount of plastic deformation of the anterior capsule was only 2.3 mm, a finding of questionable clinical significance.

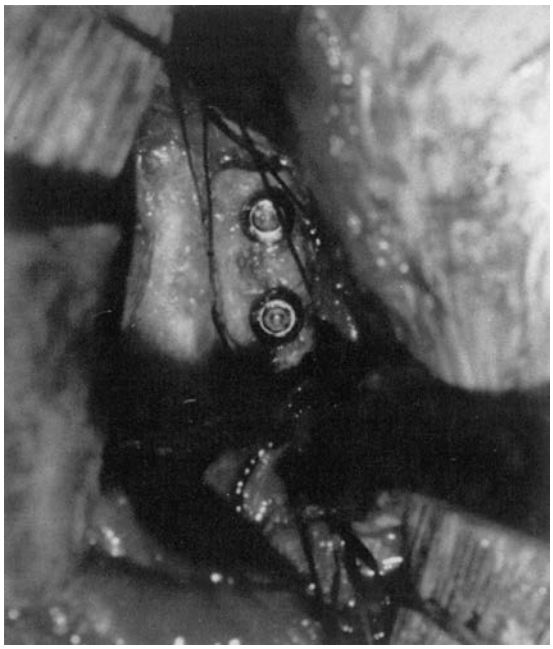

Figure 16-12 Intraoperative photograph of autogenous iliac crest graft used to reconstruct an anterior osseous glenoid deficiency. Note placement of sutures under the graft for later capsulolabral repair. (Courtesy of Douglas T. Harryman II, University of Washington Medical Center, Seattle, WA.)

These studies leave in question the occurrence of stretch of the IGHL as a component of recurrent traumatic anterior instability. In addition, if such plastic deformation was confirmed in the laboratory, the clinical significance is still unclear. For instance, a period of immobilization after initial dislocation might be expected to lead to scar and contracture of interstitial IGHL injury, not lengthening. Also, if a concomitant Bankart lesion was present, repeated dislocations would be expected to occur with less stress applied to the interstitial fibers of the IGHL.

Several authors have blamed residual capsular laxity as the cause of recurrent anterior instability after Bankart repair.[35,98,175,221,228,282,292,294] At the time of revision surgery, the presence of a redundant or patulous anteroinferior capsule was noted by these investigators. This finding was purely observational and no specific measurements were recorded. Rowe et al. described a method whereby the arm is placed in adduction and in 90 degrees of external rotation and the anteroinferior capsule is grabbed with a clamp and pulled upward.[228,294] If the capsule can be mobilized greater than 1 cm, this indicates residual capsular laxity. All of these authors described some type of capsular shifting or imbricating procedure as an integral component of the revision repair.

The difficulty in judging residual capsular redundancy, however, is differentiating capsular stretch from normal capsular laxity. As discussed previously, Speer et al. found only minor increases in laxity after creation of a Bankart lesion.[246] This result seems to indicate that plastic deformation of the IGHL is a necessary component of recurrent traumatic anterior instability. Laxity and instability, however, are two properties that are not only different, but also they may not be related. Laxity is defined as the amount of movement of the humeral head across the glenoid fossa in response to a small applied translational force (for instance, the force applied by an examiner during a drawer or sulcus test). The maximum amount of humeral translation in a given direction is a shoulder's *laxity.* Glenohumeral *instability* is the inability to keep the humeral head centered within the glenoid fossa. Lippitt et al., performing in vivo measurements of laxity in shoulders of normal subjects and those of patients with recurrent instability, failed to demonstrate differences in laxity between these groups[152] (Fig. 16-14). Hawkins et al., who used radiographic examination under anesthesia in normal subjects and those with unstable shoulders, also found significant overlap in laxity between the two groups.[112] Finally, Sperber and Wredmark found no differences in intracapsular volume or capsular elasticity in unstable shoulders when compared with normal shoulders.[278] Therefore, whether or not residual capsular laxity exists as a cause of postoperative instability remains controversial. Moreover, the exact method by which a surgeon can intraoperatively differentiate residual capsular redundancy from normal capsular laxity is equally unclear.

Finally, glenohumeral dislocation under load does not occur as a gradual event, as replicated by measuring translational laxity, but occurs as a sudden and explosive event, with minimal translation before the moment of sudden dislocation (Fig. 16-15). The absence of significant translation before the moment of dislocation implies that glenohumeral articular congruity and glenoid concavity are the major determinants of glenohumeral stability, with ligamentous integrity serving as the final checkrein against dislocation.[61,144,154,166,245] The clinical significance of relating laxity measurements to glenohumeral instability, therefore, is unknown.

Most cases of recurrent traumatic anterior instability are attributable to the presence of an anteroinferior capsulolabral avulsion from the glenoid rim and are successfully managed by repair of this defect without any further capsular tensioning.[16,166,168,169,259] There are situations, however, for which true and demonstrable clinical instability exists, yet either a Bankart tear is not present, the tear appears too small to account for the patient's degree of instability, or there are obvious findings of capsular injury (Fig. 16-16). In these cases, some plication or shifting of the anteroinferior capsule may be necessary to restore stability. However, considering the unavoidable capsular tightening that occurs simply by repairing a Bankart lesion and side-to-side closure of a capsulotomy, combined with the typical postoperative scarring and contracture of the anterior soft tissues, residual or unrepaired anterior capsular laxity as a cause of postoperative instability should be considered a diagnosis of exclusion.

In vivo quantification of the laxity of normal and unstable glenohumeral joints. *J Shoulder Elbow Surg* 1994;3:215–223.)

Residual capsular laxity as a cause of recurrence of instability after surgical repair should be considered in the following situations:

1. When true and clinically demonstrable glenohumeral instability was present at the time of the index operation and either no or a small Bankart tear was noted at entrance into the glenohumeral joint
2. When an appropriate and technically correct Bankart repair was performed at the time of the index operation and, at revision surgery, that repair is still intact despite true and clinically demonstrable instability
3. When obvious and large differences in translation on anterior drawer testing compared with the patient's contralateral shoulder are present in the absence of a large Bankart tear
4. When either no or a small Bankart tear is present in the patient with a history of repetitive microtrauma, such as throwing, swimming, or gymnastics

When other causes of instability recurrence are ruled out and one or more of the previously mentioned conditions exist, stability can be restored by an anteroinferior capsular shift.[7,168,282] There are several descriptions in the literature on the technique of capsular shift, and the exact procedure is not critical (see Chapter 12). What is important is to contract the excessively lax anterior and inferior capsule without overtightening the shoulder.

Anterior Capsular Deficiency

One reason for the wonderful results after primary instability surgery is tissue quality. Typically, patients requiring

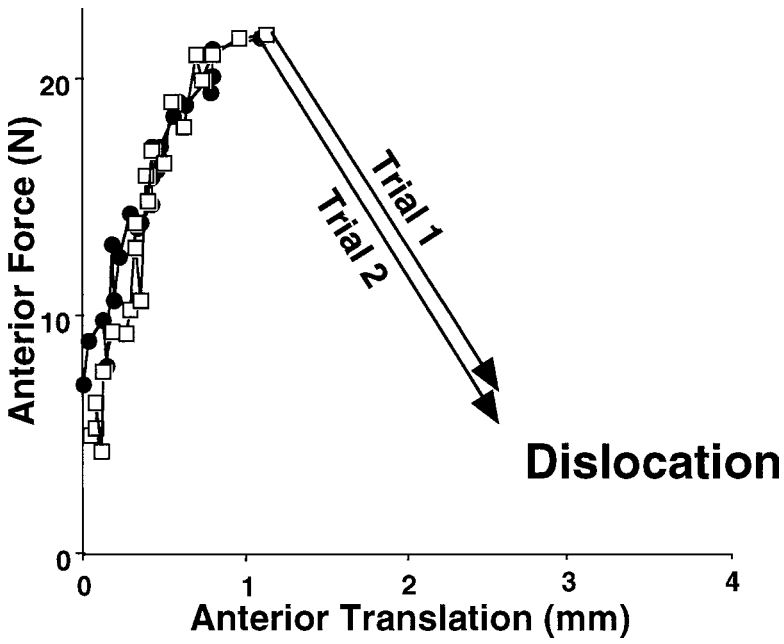

Figure 16-15 Translation before dislocation in a loaded, cadaveric shoulder. Even in an older cadaveric shoulder, there is minimal humeral translation before the explosive moment of dislocation. (Permission from JBJS, ref. 81.)

Figure 16-16 Arthroscopic image of a patient who suffered recurrent anterior dislocations after a prior arthroscopic Bankart repair. The labrum was completely healed but capsular disruption occurred lateral to the labral attachment.

surgery for recurrent traumatic anterior instability have thick, healthy anterior capsular tissue that permits a robust repair. After repeated attempts at anterior repair, however, the anterior glenohumeral capsule may become a thin, attenuated remnant, incapable of being repaired. Preoperative workup may reveal subscapularis deficiency in these individuals (discussed later). In these difficult cases, the surgeon needs both a specific plan of attack as well as availability of alternatives to the usual capsuloligamentous repair.

Revision surgery begins by defining the humeroscapular motion interface, that plane between the underlying rotator cuff and the overlying deltoid, acromion, and conjoined tendon.[166] Initially, the surgeon may be fooled by the intact and often thickened clavipectoral fascia. However, this fascia will not move as one with the humerus during humeral rotation, being clearly differentiated from the subscapularis. All scar and adhesions within this interface are excised and the axillary and musculocutaneous nerves are located. At this juncture, the amount and quality of the subscapularis and anterior capsule can be assessed. A Joker or Freer elevator can be passed through the rotator interval and deep to the combined anterior capsule and subscapularis to gauge the combined thickness of these structures.

Occasionally, when incising the clavipectoral fascia, it instantly becomes clear that the anterior capsule and subscapularis are completely deficient. In these situations, reconstruction of the capsule is necessary. Capsular reconstruction begins by identifying the interval between deficient and normal capsule. Typically, the posteroinferior capsule is normally present. By performing a limited posteroinferior capsular shift, this normal posteroinferior capsule can be mobilized to reconstruct the anteroinferior quadrant.

Gallie and LeMesurier recommended use of fascia lata to reconstruct the anterior glenohumeral capsule as a treatment for recurrent instability.[67] Iannotti et al.[117] studied seven patients with recurrence of anterior instability due to capsular deficiency treated with capsular reconstruction using 2-cm strips of the Iliotibial band folded on one another. The most superior strip recreated the rotator interval, while the middle and inferior limbs recreated the middle glenohumeral ligament and anterior–inferior glenohumeral ligament, respectively. Bony glenoid defects were excluded. At 45-month average follow-up, there were no reports of recurrent instability and range of motion was maintained. Lazarus and Harryman described use of semitendinosus allograft to reconstruct the superior (SGHL) and middle (MGHL) glenohumeral ligaments[143] (Fig. 16-17). Using a pine cone burr (4 mm in diameter), holes are created in the glenoid and the humeral head, these holes corresponding to the origin and insertion sites of the SGHL and MGHL. A single strip of autograft tendon is passed from lateral to medial to recreate the SGHL and then from medial to lateral to reconstruct the MGHL. With the humeral head reduced and the arm in neutral rotation, the reconstruction is tightened. Patients must be aware that they will have permanent motion restrictions, sacrificing normal motion range for stability. Postoperatively, a sling is placed for 3 weeks, with abduction and external rotation isometrics being the only exercise program. After 3 weeks, the sling is removed three to five times each day for gentle supine active assisted forward elevation and external rotation exercises. Particularly with external rotation, patients are shown the neutral rotation point and are cautioned against attempting to stretch beyond this range. At 6 weeks postoperative, the sling is discontinued, and a gentle rotator cuff and scapular strengthening program is begun. No lifting of greater than 10 lb (4.5 kg) is permitted for 6 months. In addition, patients with heavy-labor occupations or those involved in contact sports are encouraged to discontinue these activities permanently. If necessary, the graft can also be used to reconstruct a deficient labrum and capsule simultaneously (Fig. 16-18). Lazarus and Harryman reported use of this procedure in 17 patients with capsular insufficiency and recurrent, disabling instability after multiple attempts at anterior stabilization. In 70% of cases, the procedure was successful in eliminating instability.[143] Thorough knowledge of the scapular and humeral attachments of the superior, middle, and anterior band of the inferior glenohumeral ligaments is essential to the success of this reconstruction.[264]

Hill-Sachs Deformity

Posterolateral osteochondral impression fracture of the humeral head, the so-called Hill-Sachs deformity, is a common finding in patients with recurrent instability.[107,111,168,169,275] The role of this defect in causing continued anterior instability after surgical repair, however, is

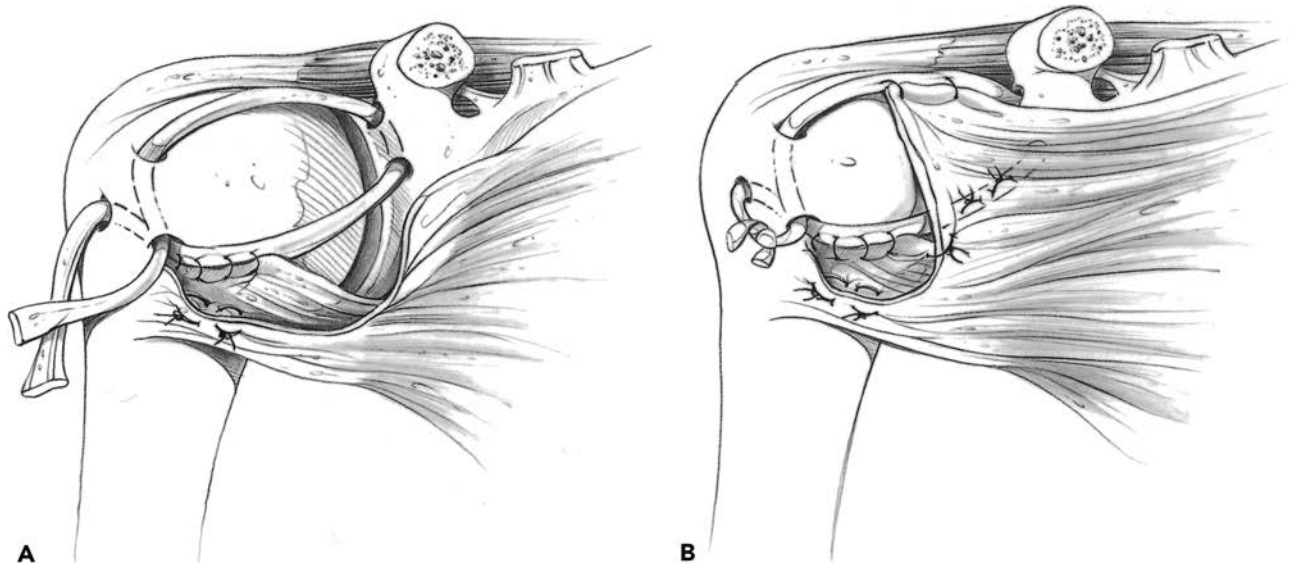

Figure 16-17 **(A)** Technique to reconstruct severe loss of anterior subscapularis and capsular tissue. The posteroinferior capsule is shifted to reconstruct the anteroinferior quadrant. Autogenous tendon graft is then woven through drill holes in the glenoid and humerus. This graft recreates the superior and middle glenohumeral ligaments. **(B)** The graft is secured with the glenohumeral joint located and the arm in neutral rotation. Remnant subscapularis tendon can be secured to the shifted capsule and the tendinous autograft.

unclear. Rowe et al. found Hill-Sachs lesions in 76% of shoulders that had recurrence of instability after surgical repair.[231] Previously, Rowe and colleagues had noted a slightly higher incidence of redislocation in those patients who had moderate or severe Hill-Sachs deformities.[228]

It is rare for a humeral head defect to play an isolated role in recurrent anterior instability. The combination of a large humeral head defect and a glenoid rim defect, however, dramatically decreases the amount of humeral rotation necessary to engage the osteochondral lesion onto the anterior glenoid rim, potentially leading to glenohumeral dislocation (Fig. 16-19). A surgeon who is considering the effect of a Hill-Sachs lesion should obtain a CT scan preoperatively to measure the dimensions of the defect to help select the most appropriate surgical option.

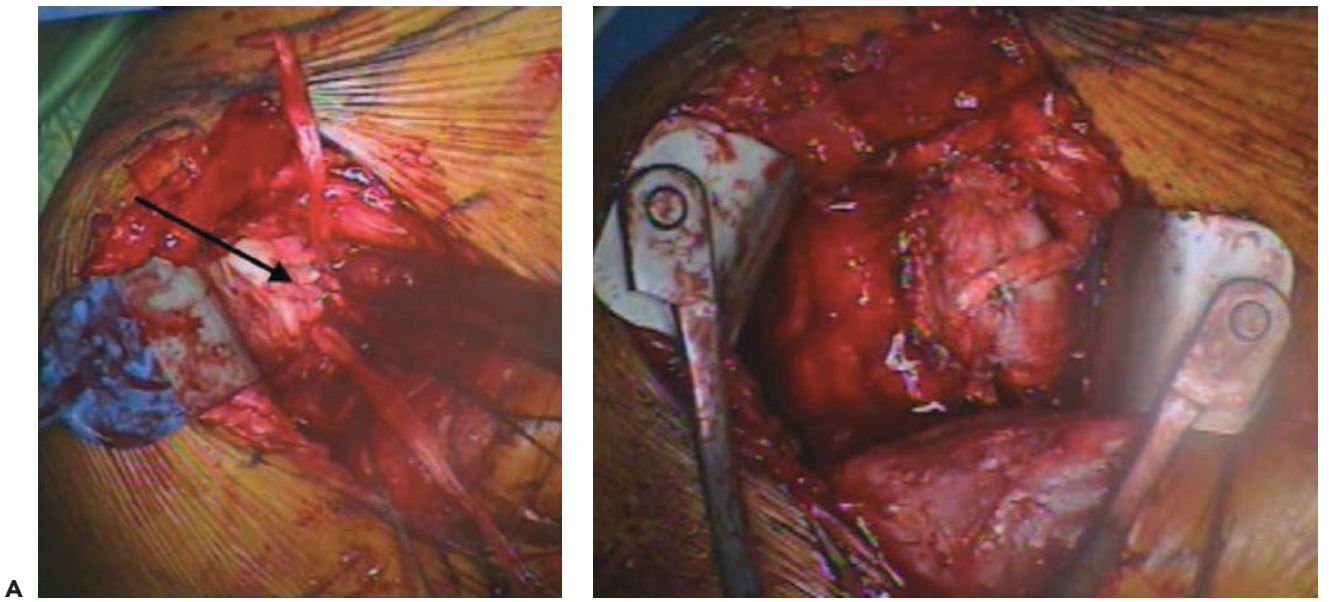

Figure 16-18 A semitendinosus graft used to reconstruct a deficient labrum **(A)** and anterior capsule **(B).**

Figure 16-19 Axillary radiograph of a 26-year-old man with continued anterior instability after a Bankart repair and capsular shift procedure. The combination of a large Hill-Sachs deformity and osseous Bankart lesion results in contact of the Hill-Sachs lesion with the glenoid rim with minimal glenohumeral rotation.

At surgery, when a posterior Hill-Sachs lesion comes in contact with the anterior glenoid rim before terminal external rotation, several solutions exist. The simplest and often the most effective answer is to limit the patient's external rotation by a slight imbrication of the capsule or subscapularis. Surprisingly little decrease in external rotation is required to exclude the Hill-Sachs lesion from contact. Each centimeter of capsular or tendinous shortening diminishes humeral rotation by approximately 20 degrees.[94]

Another method to account for a large Hill-Sachs lesion is to render the defect extraarticular. Connolly has reported transfer of the infraspinatus with a portion of the greater tuberosity into the defect, thereby leaving the lesion extraarticular.[43] Subsequently, with humeral external rotation, the lesion can no longer contact the anterior glenoid rim.

Humeral osteotomy has also been described as a method of treating a large Hill-Sachs defect. Weber et al.[3] have reported humeral rotational osteotomy as a treatment for severe posterolateral humeral head defects, the goal being to rotate the Hill-Sachs lesion away from potential glenoid contact.[303] They reviewed 207 rotational osteotomies performed for large (greater than 4 cm) defects of the humeral head. They reported a redislocation rate of 5.7% after this procedure, but it is important to recognize that they include subscapularis shortening as part of their technique.

On rare occasions, the posterolateral humeral defect will be so severe that it involves more than 40% of the articular surface of the head. In this situation, the lesion will contact the anterior glenoid with minimal external rotation. To preserve any glenohumeral external rotation while providing stability, some extension of the humeral articular surface is required. Gerber and Lambert have reported on the successful treatment of a reverse Hill-Sachs deformity with placement of an osteochondral allograft into the defect.[75] We have had some success in the treatment of large Hill-Sachs deformities by reconstruction of the defect using an osteochondral femoral head allograft (Fig. 16-20). Miniaci et al.[205] reported on 18 patients treated with allograft for engaging Hill-Sachs lesions greater than 25% of the articular surface. Simultaneous capsulolabral repairs were undertaken. At a mean of 50 months postoperatively there were no redislocations, and two patients experienced partial graft collapse requiring hardware removal.

In rare cases, a humeral hemiarthroplasty or total shoulder arthroplasty (TSA) is indicated for older patients with more than 45% of the articular surface damaged or concomitant glenoid arthritis. Flatow[65] studied nine patients treated with TSA for large posterolateral defects of the humeral head and found that eight of nine had satisfactory results.

Voluntary Instability

In 1973, Rowe et al. published their comprehensive and classic description of voluntary glenohumeral instability.[227] In that study, patients with underlying psychiatric dysfunction did poorly with all types of treatment. For most patients, a rehabilitation program for muscle strength and coordination was recommended.

In any patient for whom multiple surgical reconstructions have failed to provide stability, voluntary instability should be considered. It is important to recognize, however, that having the ability to volitionally subluxate or dislocate the shoulder does not necessarily place a patient in this category.[63,100,267] Wall and Warren separated volitional instability into positional and muscular types.[267] The positional group can cause an instability event by arm movement. The muscular group can cause instability by simple muscle contraction. Surgery in this second group is unlikely to be successful. Neer has long discussed the difference between the patient who can cause an instability event and the one who either has great secondary gain in the event or who has a desire to cause instability.[195,267] It is in this second group that surgery should be avoided.

The normal humeral articular surface (*medial*) is to the right. **(B)** Reconstruction of the Hill-Sachs lesion with placement of an osteochondral allograft. **(C)** Postoperative radiograph demonstrating extension of the humeral articular surface by the allograft.

Severe Traumatic Event

The literature is somewhat unclear about the role of trauma in causing failure of an instability repair. Some investigators have found recurrent trauma in the face of an adequate index repair to be a significant cause of instability after repair.[35,98] Others have determined that failure of instability repair typically occurs secondary to a failure of diagnosis or technique, not secondary to trauma.[175,228]

Clearly, if significant force is applied to the hand or arm while in a vulnerable abducted, extended, and externally rotated position, failure of even the strongest of repairs can occur. Trauma as the sole cause of failure, however, should be a diagnosis of exclusion. Only when misdiagnosis and persistent structural pathology are ruled out can significant trauma be blamed for instability recurrence.

Loss of Motion

Possibly the most common nonphysiologic outcome after surgery for recurrent traumatic instability, but infrequently reported as an actual complication, is loss of motion. In fact, limiting external rotation to a certain value is often stated as a desired surgical goal.[168] Often, some imbrication or "shifting" of the anterior capsule is recommended to correct presumed plastic deformation. If, however, a normal length of fibrotic, shortened capsule

is imbricated at the time of Bankart repair, motion restriction will occur.

Limitation of a patient's normal, physiologic glenohumeral external rotation may have serious consequences. Minor deficits in external rotation can lead to a decrease in a patient's ability to assume the late-cocking position and, therefore, can decrease the velocity of a throw or serve.[104,157,262] Major reductions in external rotation may not only limit functional activities, but can have disastrous consequences. Harryman et al. described obligate humeral translation, whereby the tightened anterior capsule at terminal external rotation forces the humeral head to translate posteriorly.[93] Hawkins and Angelo reported on seven patients in whom previous Putti-Platt procedures with overtightening of the anterior structures resulted in glenohumeral arthritis.[96] When the anterior structures are too tight, obligate humeral translation occurs with minimal external rotation, forcing the humeral head in a posterior direction and creating a shear force on the posterior glenoid, resulting in articular degeneration. This degenerative process, which Matsen has referred to as capsulorrhaphy arthropathy, is not only related to the Putti-Platt procedure, but can also be seen in any patient who has nonphysiologic, asymmetrical tightening of the capsule or rotator cuff tendon unit.[166]

The treatment for an excessively tight anterior capsulorrhaphy is to reverse the altered biomechanics. Specifically, abnormally shortened anterior soft tissues must be lengthened. If the original surgical procedure involved an imbrication or transfer of the subscapularis, a subscapularis release can be performed as described by MacDonald et al.[162] The technique begins with release of the subscapularis from its insertion (original or transferred). The humerus is then externally rotated to the desired position. With external rotation, the subscapularis tendon is drawn medially. At the point of desired external rotation, the subscapularis tendon is repaired to the underlying glenohumeral capsule.

If capsular contracture is also anticipated or if greater than 20 degrees of rotational correction is necessary, a coronal Z-plasty of the combined subscapularis and anterior capsule is required.[166,195] The technique is begun by passing a small elevator through the rotator interval and posterior to the anterior glenohumeral capsule to gauge the combined thickness of the subscapularis and capsule. Using sharp dissection and beginning approximately 1 cm medial to the lesser tuberosity, the superficial subscapularis tendon is cut in a longitudinal fashion until 50% of the combined subscapularis–capsular thickness is divided. Then, in the coronal plane, the superficial subscapularis is elevated off the underlying deep capsule. This coronal division is taken medially to a point just lateral to the palpable glenoid rim. The deep layer is then longitudinally incised, making sure to remain lateral to the glenoid labrum. The medial capsulolabral glenoid attachment should not be disturbed during this technique. At arthrotomy, débridement of osteophytes, loose bodies, and hypertrophic synovium can be accomplished. By repairing the lateral edge of the superficial flap to the medial edge of the deep flap, as much as 2 cm of length (40 degrees of rotation) can be gained. To date, we know of no patient who has redeveloped anterior instability regardless of the amount of external rotation gained by this method.

Capsulorrhaphy Arthropathy

Capsulorrhaphy arthropathy occurs after surgical stabilization when overtightening the anterior capsule and subscapularis leads to internal rotation contracture. Repeated attempts at external rotation against anterior capsular restriction may lead to capsulorrhaphy arthropathy via altered glenohumeral mechanics.[96,166] Typical findings are severe glenohumeral destruction, eccentric posterior glenoid wear, and posterior subluxation (Fig. 16-21). Anterior capsular release and subscapularis lengthening is recommended if the joint surfaces are intact. For established capsulorrhaphy arthropathy with subluxation, subscapularis lengthening and anterior capsular release are unlikely to provide any long-standing benefit. If symptoms warrant, the most successful treatment is shoulder arthroplasty. Because of the tendency toward posterior glenoid deficiency and subluxation, humeral hemiarthroplasty alone may lead to continued posterior subluxation. Therefore, despite the often young age of these unfortunate patients, total shoulder replacement is usually indicated.

Neer et al.'s work on total shoulder arthroplasty included those shoulders that had prior instability surgery. Approximately 7% of the total shoulder arthroplasties were performed on patients with prior instability surgery.[194] The average age for arthritis after instability was 38 years versus 60 for primary osteoarthritis.[195] Sperling et al.[251] studied 31 patients treated with total shoulder arthroplasty or hemiarthroplasty for capsulorrhaphy arthropathy at average 7 years follow-up. For both groups improvements were noted in pain relief, external rotation, and abduction. Revision rates were high, with 8 of 21 patients with total shoulder arthroplasty requiring revision and 3 of 10 hemiarthroplasties requiring revision. The authors concluded that pain relief and increases in motion could be achieved, but that revision rates remained high.

Bigliani et al. reported on 17 patients who underwent shoulder arthroplasty for end-stage capsulorrhaphy arthropathy.[25] The average time between instability repair and arthroplasty was 16 years. At a mean follow-up of 3 years, 77% of patients obtained a satisfactory result. Although these results are good, they are less than what would be expected after arthroplasty for osteoarthritis. Specific surgical problems were distorted anatomy, anterior soft tissue contracture, and posterior glenoid deficiency. Green and Norris[83] studied 19 patients with advanced glenohumeral arthritis after failed anterior

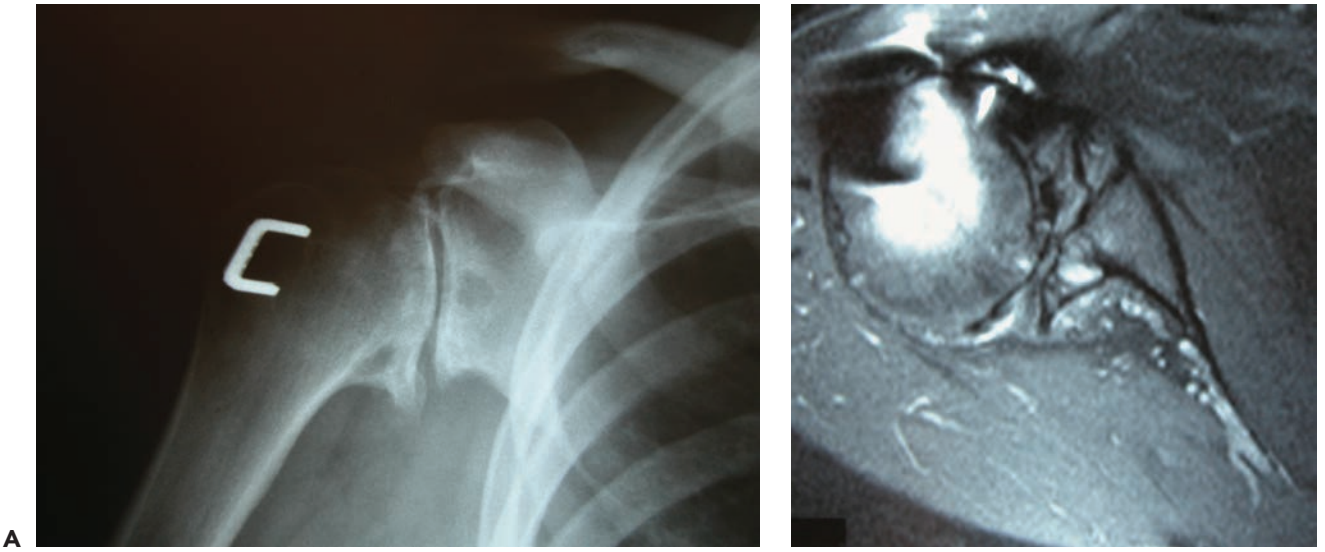

Figure 16-21 Capsulorrhaphy arthropathy in a patient who underwent a Magnuson-Stack procedure (lateral transfer of the subscapularis) twelve years prior **(A).** Notice the typical posterior subluxation and eccentric glenoid wear seen on magnetic resonance imaging scan **(B).**

instability procedures. Severe internal rotation contracture and posterior glenoid bone loss were the most common findings. Active and passive motion improved in all planes and subjective rating of pain showed improvement in 94% of patients treated with total shoulder arthroplasty or hemiarthroplasty.

Subscapularis Failure

Rupture of the subscapularis after an anterior instability repair is increasingly recognized as a cause of surgical failure and postoperative disability.[86,295] Patients usually present with pain that fails to subside postoperatively, weakness, tenderness over the lesser tuberosity, apprehension, and possibly recurrent instability. Physical examination reveals an increase in passive external rotation relative to the normal side, weakness or pain on active internal rotation, and inability to perform a lumbar lift-off test as described by Gerber and Farron.[72] The diagnosis can be made on physical examination alone but, if uncertainty remains, magnetic resonance imaging (MRI) may be helpful (Fig. 16-22). Usually the patient will give a history of persistent postoperative pain that fails to abate during the normal rehabilitation period or a traumatic event in the early postoperative period that initiates symptoms.

The initial step in the management of subscapularis repair failure is prophylaxis. Greis et al. have questioned whether early, aggressive mobilization after instability surgery may lead to an increase in subscapularis failure.[96] Motion exercises within the first 3 to 6 weeks after instability repair should not be performed to the point of tension on the subscapularis repair.

Sachs et al.[231] studied 30 patients treated for unidirectional anterior instability with open Bankart repair. Seven of the 30 had incompetent subscapularis muscles at 4-year follow-up. Of the patients with incompetent subscapularis, only 57% rated their results as good or excellent and would have the surgery again. The authors concluded subscapularis function was the ultimate determinant of success and warned that aggressive rehabilitation should be avoided.

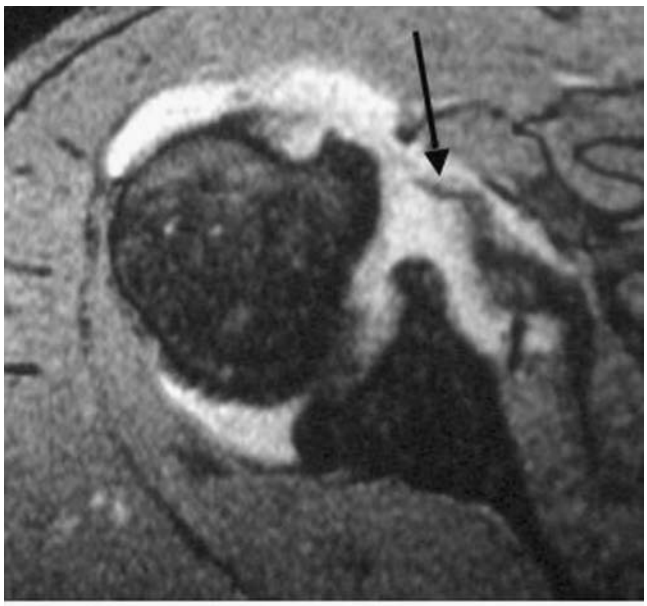

Figure 16-22 Magnetic resonance imaging scan demonstrating subscapularis failure after prior open stabilization.

Mobilization and repair of the ruptured subscapularis tendon can be a challenging undertaking, especially if the patient presents late after subscapularis failure.[295] The subscapularis tendon will often retract under the conjoined tendon, where it adheres to the surrounding tissues. Subsequent attempts at mobilization can be extremely hazardous to important neurovascular structures. Also, the upper, middle, and lower subscapular nerves usually insert more lateral than would be expected.[42,293] Dissection medially on the superficial surface of the subscapularis may result in denervation.

Repair of the ruptured subscapularis, once it is adequately mobilized, can also be formidable. If sufficient quality tendon tissue remains on the muscle and bone insertion, direct tendinous repair is performed. If the lower half of the subscapularis tendon remains intact, it is separated from any remaining capsule and transferred superiorly. Usually, the humeral side has only a remnant of tissue and repair of the tendon through bone tunnels at the articular margin adjacent to the lesser tuberosity is required. On occasion, we have found patients who have extremely poor subscapularis tissue. In these circumstances, we have reinforced the subscapularis repair with a Dacron graft or xenograft (Fig. 16-23). The graft is used primarily to protect and augment the tendon repair or reinforce large defects. We do not use the graft to span a full-thickness defect, but only to reinforce thin tissue.

The optimal treatment of an irreparable, full-thickness subscapularis defect is controversial. Wirth et al. have recommended superior transfer of the clavicular head of the pectoralis major to restore stability, with excellent results.[314] Resch et al.[216] studied 12 patients with irreparable tears of the subscapularis treated with transfer of the upper one-half to two-thirds of the pectoralis major tendon routed under the conjoined tendon. Average follow-up was 28 months, with 9 of 12 demonstrating excellent or good results. Jost et al.[125] transferred the entire pectoralis tendon anterior to the conjoint tendon in 30 repairs, with 25 very satisfied or satisfied with the results. Less favorable results were obtained when an irreparable supraspinatus tear was also present. Klepps et al.[136] performed a subcoracoid pectoralis transfer of the upper half to two-thirds of the tendon in 14 patients. Decreased pain and improved forward flexion were seen in 9 of 14 patients.

Hardware Complications

Any foreign object placed within the vicinity of the glenohumeral joint has the potential to loosen and migrate. The great range of the glenohumeral joint and significant soft tissue tensile loads put enormous demands on any fixation device. Hardware failure or loosening can be seen at any point in the postoperative period, from within weeks to years after surgery. Metal that was safely away from the articular surfaces at placement can later become a constant articular gouge during glenohumeral motion. More seriously, loose hardware in the shoulder can migrate significant distances to threaten vital structures.

The largest series in the literature of problems in the shoulder after placement of hardware was reported by Zuckerman and Matsen.[296] Screws and staples placed to secure a transferred coracoid or to plicate an anterior capsule were usually at fault. Most of the patients required reoperation and 41% had significant chondral injury noted

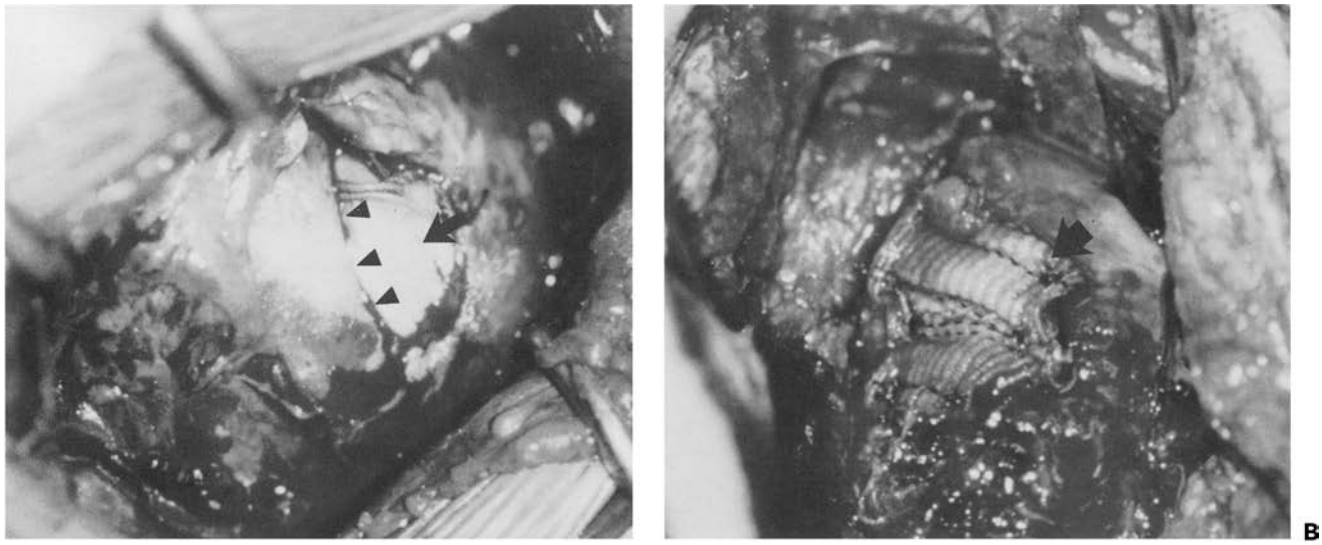

Figure 16-23 **(A)** Intraoperative photograph of the left shoulder of a patient who had failure of the subscapularis repair after a previous Bankart repair. The *arrowheads* demonstrate the retracted subscapularis edge with the arrow showing the underlying exposed humeral head. **(B)** Repair of the subscapularis and reinforcement of thin tissue with a Dacron graft (*arrow*).

at reoperation. Norris and Bigliani noted "avoidable" hardware complications in 40% of the patients in their series of failed instability repairs.[198] In particular, coracoid screws placed during the Bristow operation have caused problems[14,56,119,199,296] (Figs. 16-24 and 16-25).

The simplest method of preventing complications of hardware is to not use it at all. All anatomic repairs for anterior instability can be performed without implanted devices. Although metal suture anchors may shorten operative time and are safe in virtually all cases, they are not without risk; anchors can loosen or become prominent, hastening chondral degeneration.

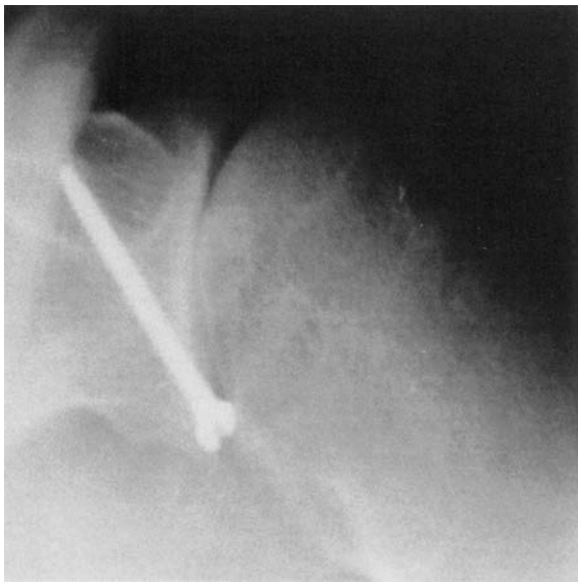

Figure 16-25 A 36-year-old man, 12 years after a Bristow reconstruction, presented with increased pain and decreased range of motion. The screw head has begun to erode the humeral articular surface.

If the patient requires revision surgery, creating strong bone tunnels in an anterior glenoid that has been filled with suture anchors can be a formidable challenge. Often, suture anchors are placed medial to the anatomic glenoid rim. During revision, we have had success using the residual bone defect after removal of the suture anchor as the nonarticular side of the bone tunnel for suture placement. We will often place a small amount of cancellous autograft into the remaining defects (Fig. 16-26). Fracture of the glenoid rim, however, is a greater risk during revision surgery requiring anchor removal.

Neurovascular Injury

Anterior instability surgery may jeopardize the anterior neurovascular structures. Richards et al. have reported on neurologic injury after anterior instability surgery, specifically Putti-Platt and Bristow operations.[219] The most common nerve involved was the musculocutaneous nerve, with the axillary second (Fig. 16-27). Flatow et al. have performed anatomic dissections of the musculocutaneous nerve and found the nerve to enter the conjoined tendon as near as 2 cm to the coracoid process.[60] The nerve, therefore, is particularly at risk during procedures that involve coracoid osteotomy or transfer.

Because of its direct relation to the inferior glenohumeral capsule, the axillary nerve is at particular risk during instability surgery.[158] Richards et al. reported two axillary nerve injuries in their series, one of these caused by a suture around the nerve.The single best way to avoid injuring the axillary nerve is to constantly be sure of its location. We always directly localize the nerve after incision of the clavipectoral fascia, as recommended by Matsen et al.[168] Throughout the procedure the nerve is palpated and localized. Finally, before closure, the nerve is once again palpated or visualized. This final step is critical in postoperative

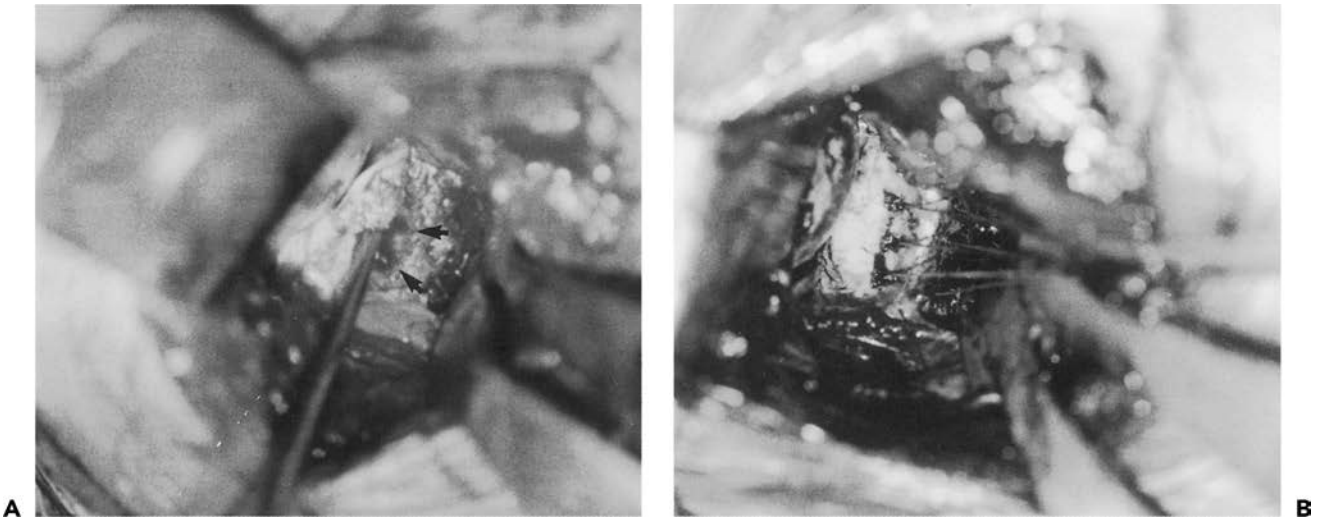

Figure 16-26 **(A)** Intraoperative photograph of a right shoulder during revision Bankart surgery after previous suture anchor repair. Because of their location and size, the suture anchors required removal, leaving large osseous defects in the anterior glenoid neck (*arrows*). **(B)** The osseous defects were used as the nonarticular side of the bone tunnels and a nonabsorbable, braided suture has been passed for capsulolabral repair. The defects are then packed with cancellous graft.

decision making should the patient awake with an axillary nerve palsy. If the nerve was palpably or visually intact at the end of the procedure, the surgeon can be much more comfortable with a provisional diagnosis of neurapraxic injury and may wait for recovery.

Ho and Cofield recently reported an incidence of neurologic injury in patients undergoing instability surgery of 8.2%.[105] These were predominantly neurapraxic injuries of the brachial plexus. All patients showed signs of neurologic recovery by 3 months after surgery and, at a mean of 8.4 years of follow-up, 19 of 24 patients had complete recovery.

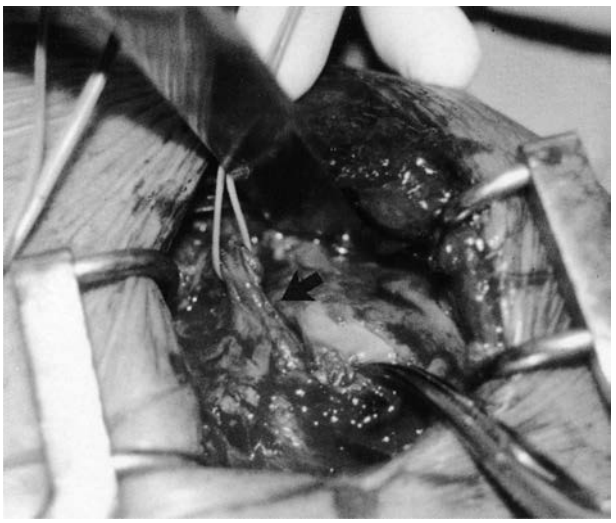

Figure 16-27 A 28-year-old man with complete absence of musculocutaneous nerve function after a reported revision Bankart repair with capsular shift. On exploration, a subscapularis repair suture (hemostat) was found around the musculocutaneous nerve (*arrow*).

We advocate that if the procedure lasts longer than expected, the retractor should be occasionally released to restore blood flow to the brachial plexus.[94]

If postoperative examination reveals a mononeuropathy involving the axillary or musculocutaneous nerve, and the nerves were not palpated and known to be intact before closure, an electromyography (EMG) study should be performed immediately. EMG within the first 24 hours of injury should be able to demonstrate axonotmesis. If axonotmesis is confirmed, immediate nerve exploration with removal of offending suture or nerve repair is indicated. Because most injuries are neurapraxic, any mononeuropathy involving nerves that were palpably intact at closure or any polyneuropathy can be treated with observation. Neurologic deficit that does not reverse itself within 6 weeks postoperative requires an EMG. If the EMG is consistent with neurapraxic injury, further observation is appropriate and, as demonstrated by Ho and Cofield, clinical signs of neurologic recovery should become obvious by 3 months.[105] Should the findings be consistent with axonal interruption, however, immediate exploration with possible repair or cable graft is necessary.

Vascular injuries secondary to instability surgery are exceedingly rare. Most of the reports in the literature concern late axillary artery problems secondary to loose Bristow screws.[14,56,119] Both Artz and Huffer[14] and Iftikhar et al.[119] described axillary artery pseudoaneurysms caused by loose Bristow screws. The diagnosis was initially made clinically by neurologic loss associated with the compressive effects of the pseudoaneurysm, with the diagnosis confirmed by arteriography. In both of their reports, despite prompt diagnosis and exploration, permanent neurologic loss ensued.

OPEN REPAIRS FOR POSTERIOR INSTABILITY

Posterior shoulder instability represents approximately 5% of all instability cases.[220] About half of these patients will recall a distinct injury to the shoulder. Dislocation is rare, however, with approximately 25% with a documented posterior shoulder dislocation requiring reduction in an emergency room.[220] Open surgical procedures for posterior instability can be divided into osseous, soft tissue, or combination.

Bony procedures include glenoid osteotomy, posterior bone block (reverse Eden-Hybbinette), and proximal humeral rotation osteotomy. Soft tissue procedures include posterior capsular shift, reverse Bankart repair, and reverse Putti-Platt procedures. Combination procedures incorporate elements of both categories.

Recurrence of Instability

The actual incidence of recurrent instability after open posterior repair has been reported as extremely variable and dependent on the index procedure. Rates as high as 30% to 50% have been reported.[260] There may be several reasons to explain the high recurrence rate. Unlike anterior instability, there appears to be no "essential lesion" of posterior instability. Recurrent instability is thought to be a pathologic process incompletely understood with several causes making treatment more difficult. As would then be expected, the results of surgery for unidirectional posterior instability are variable and often much less gratifying than those for anterior instability.

Boyd and Sisk reported their results of posterior capsular imbrication, with and without posterior transfer of the long head of the biceps tendon, and found no recurrences at longer than 2 years postoperative.[28] Hurley and colleagues, on the other hand, reported a recurrence of instability rate of 72% after soft tissue reconstruction for posterior instability.[114] When Hawkins et al. reviewed their cases of posterior capsular and infraspinatus imbrication, they found a recurrence rate of 83%.[100] Regardless of the technique used, the overall recurrence rate in that study was 50%. Tibone and Ting reported recurrence of instability in 6 of 20 patients who underwent staple posterior capsulorrhaphy.[261] Bigliani and colleagues reported the results of posteroinferior capsular shift in 35 patients with posterior instability.[23] At a mean follow-up of 5 years, only four patients suffered from recurrence.

Most authors, however, cite posterior capsular redundancy as the most common intraoperative pathology. The wide recurrence range likely also depends on the sample group. The results of treatment are not often reported on one well-defined subgroup. Besides patients with unidirectional posterior instability, many patients with MDI have painful posterior subluxations, making this their primary direction. There is no general agreement regarding classification of posterior instability. Multiple variables, such as trauma, MDI, and voluntary or involuntary components, are difficult to integrate into a reproducible accepted classification system. Nevertheless, posterior instability has been broadly classified into acute or chronic. Chronic can be further subdivided into "locked" (missed) and recurrent voluntary or recurrent involuntary. Structural abnormalities including labral injury or rotator interval injury may exist. Structural abnormalities also may include bony defects like increased glenoid retroversion or posterior glenoid erosion.

The causes of failure after posterior instability repair mimic those of anterior repairs. There are, however, several failure mechanisms unique to posterior repairs (Table 16-3). The causes of recurrent posterior glenohumeral instability as well as the best surgical correction remain uncertain.

Incorrect Diagnosis

Many of the causes for postoperative instability are similar to those after anterior reconstruction. Specifically, accurate diagnosis is critical. Because recurrent anterior instability is much more common in frequency than recurrent posterior, it is easy to misdiagnose a posterior dislocator simply on a statistical basis (see Fig. 16-1). Multidirectional instability must also be excluded as a diagnosis. Wolf et al.[285] studied open posterior capsular shift and labral repair in 44 shoulders from 2 to 22 years of follow-up for posterior instability. His study group consisted primarily of traumatic posterior subluxors or dislocators. Recurrence of instability was found in 19% of patients. All patients had examination under anesthesia and it was documented that 11 cases had MDI. In those cases with MDI recurrence was 40% versus 10% for those patients with posterior inferior instability. The authors emphasized the need to document MDI at the time of surgery. Burkhead and Ritchie[35] reviewed 23 patients with postoperative instability and found 5 of 23 patients had missed MDI. Rockwood and Gerber[221] found missed MDI in 68% of their study patients with postoperative instability.

Once MDI, scapular winging, and anterior instability have been ruled out, the examiner must first attempt to answer two questions. First, what is causing the symptoms? Is it true posterior instability or is there another potential cause of the symptoms? Second, what is the pathology that

TABLE 16-3
CAUSES OF FAILURE OF OPEN POSTERIOR REPAIR

Recurrence of instability
Degenerative arthritis
Coracoid impingement syndrome

accounts for the symptoms? These are best assessed using clinical examination and history.

Clinically, recurrent subluxation typically presents as achy activity-related pain exacerbated by overuse. A history of trauma and volitional instability should be sought and habitual dislocators should undergo psychologic examination. Other potential causes for posterior shoulder pain include suprascapular nerve compression, Bennet lesion (posterior glenoid spur), quadrilateral space syndrome, osteoarthrosis, tumor, scapular winging, or cervical radiculopathy.

Physical examination attempts to reproduce symptomatic posterior translation. The signs, however, may be nonspecific. Athletes may have nonpathologic posterior humeral head translation of 50% and little discomfort. If the patient has painful posterior translation, the position of the arm and scapula should be noted. Patients with true posterior instability typically demonstrate subluxation with the arm in 80 to 90 degrees of forward flexion. Bidirectional instability patients typically require 110 to 120 degrees of forward flexion. Any inferior component to the instability is noted as it implies either rotator interval laxity or a redundant inferior capsule.

Regardless of the test performed, it is critical to demonstrate reproducible symptomatic posterior instability in the clinic setting and to confirm the direction of instability in the operating room with examination under anesthesia.

Failure of Operative Technique

The most common surgical error is a failure to address all components of the instability.[24,220,274] Open procedures for posterior instability typically involve fixation of labral tears, posterior capsular shift, and, in some instances, posterior glenoplasty to correct retroversion. The treatment, whether open or arthroscopic, should address all lesions of the shoulder.

Capsular laxity, at present, is felt to be the primary cause of recurrent atraumatic posterior instability. A redundant capsule is the most common finding at surgery. Cadaveric and biomechanical studies have reinforced the importance of the inferior glenohumeral ligament and rotator interval when evaluating posterior instability. Warren et al.[274] demonstrated in cadaveric sections damage to the anterior–superior capsule with posterior dislocation. They coined this injury the "circle" concept, emphasizing capsular injury on both sides of the capsule for dislocation to occur. Blaiser et al.[26] demonstrated that the coracohumeral ligament contributed to posterior stability with the arm forward flexed to 90 degrees in neutral rotation. He also demonstrated that the IGHL contributed to posterior instability with the arm in internal rotation.

Lesions of the labrum have been primarily implicated as contributing to traumatic posterior instability. Lippitt et al. reported that loss of the posterior labrum reduced resistance to posterior–inferior glenohumeral translation by 20%.[151] Lesions of the superior labrum also contribute to instability. Cadaveric studies by Pagnani et al.[205] demonstrated increased anterior–posterior translation in cadavers with superior labrum from anterior to posterior (SLAP) tears. Wolf et al.[285] studied open posterior capsular shift and labral repair in 44 shoulders from 2 to 22 years of follow-up. Their study group consisted primarily of traumatic posterior subluxors or dislocators. Reverse Bankart lesions were found in 18 shoulders and were the most common finding at surgery. Recurrence of instability was found in 19% of patients.

More recently, Misamore and Facibene[186] reported on 14 athletes with unidirectional posterior instability treated with open posterior capsular shift and repair of labral defects. Thirteen of 14 patients had no instability or apprehension on follow-up. Fuchs et al.[65] found recurrence of 23% in 26 patients treated with posterior capsular shift with labral repair, but three of six recurrences were in patients having previously undergone instability procedures.

Despite variability in recurrence, posterior capsular shift with labral repair if necessary is the mainstay of open surgical treatment of traumatic posterior shoulder instability. Good or excellent results can be obtained over short and intermediate terms.

It is unclear how much of a role increased glenoid retroversion accounts for recurrent posterior subluxation.[29,65,74,115,183,212] If a patient suffers recurrence of instability after a soft tissue procedure, osseous abnormality should be investigated. Fuchs et al.[65] identified posterior IGHL complex redundancy in 68% and lesions of the posterior labrum in 50% of 26 patients treated with open posterior capsular shift and labral repair. Glenoid retroversion was 12 degrees in recurrent subluxors versus 6 degrees in stable shoulders. Some studies have confirmed increased glenoid retroversion in patients with posterior subluxation while others have discounted it.[29,74,115,183] The most common osseous procedure performed is posterior glenoid osteotomy. Preoperatively, a CT scan is indicated to accurately evaluate glenoid version. If greater than 10 to 20 degrees of retroversion is found, a posterior opening wedge osteotomy is indicated as part of the revision procedure (Fig. 16-28). Scott reported the use of posterior glenoid osteotomy to treat recurrent posterior instability.[236] In his initial report of three patients, one of the three suffered from anterior instability postoperatively. When using a similar technique, Kretzler reported a recurrence rate of posterior instability of 14%.[139] Hawkins used CT scan to analyze shoulders after posterior glenoid osteotomy.[99] He noted several potential complications, including undercorrection of version, intraarticular fracture, graft extrusion, and osteoarthritis. The rate of instability recurrence was 17%. Osseous procedures alone often leave a redundant inferior capsular pouch or labral pathology, which may account for their high rates of recurrence. As such, these techniques in isolation are no longer recommended.

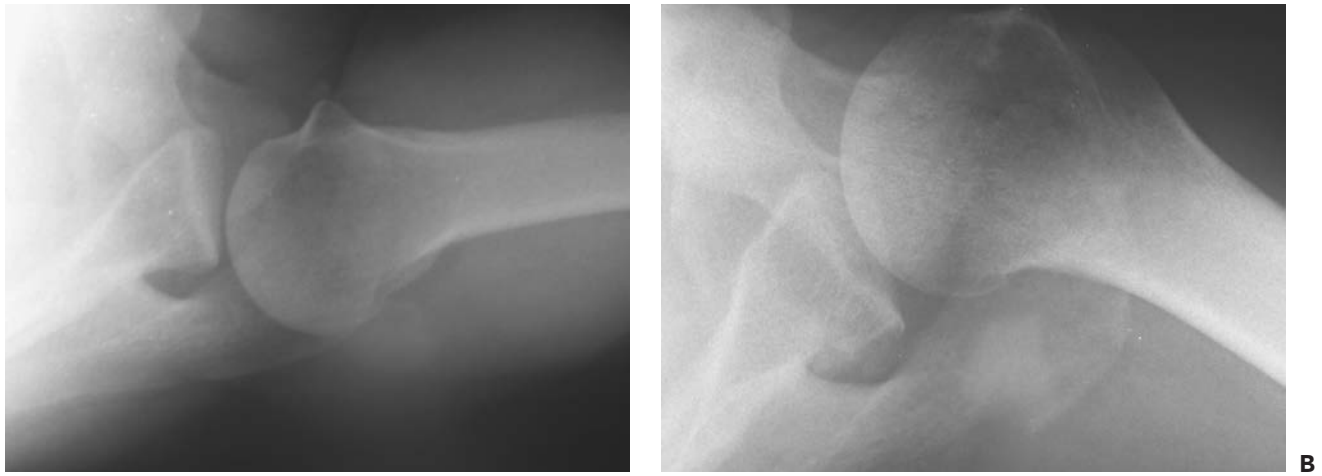

Figure 16-28 Preoperative radiograph of a patient that had failed multiple soft tissue stabilization attempts for posterior instability **(A).** Successful treatment with posterior glenoid osteotomy and posterior capsulorrhaphy **(B).**

Some investigators have reported better results and lower recurrence rates with posterior instability repairs while others have not. Fronek et al. reported 11 patients who underwent posterior capsulorrhaphy with or without posterior bone block and found recurrence of instability in only one of those patients.[63] In 1984, Hawkins et al. reported a recurrence of instability rate of 41% after posterior glenoid osteotomy, posterior capsular plication, and infraspinatus imbrication.[100]

Failure of Rehabilitation

Postoperative rehabilitation is individualized and often begins with immobilization for a period of 6 weeks. Rotator cuff strengthening and scapular stabilization is then undertaken. Full range of motion can be expected by 6 months. If rehabilitation progresses too rapidly, the potential to stretch the capsule exists, potentially leading to instability recurrence.

Miscellaneous Complications

Degenerative Joint Disease after Glenoid Osteotomy

The technique of posterior glenoid osteotomy is fraught with difficulty. Of particular note is the possibility of extension of the osteotomy into the articular surface. The classic technique is described as ending at the anterior glenoid neck such that the glenoid can be "cracked" open and hinged on the anterior cortex. Unfortunately, it is dangerously easy to enter the joint with the osteotomy cut or for the crack to propagate into the joint (Fig. 16-29). Entrance into the glenoid articular surface will predispose the shoulder to arthritic degeneration.

Johnston et al. described a case of glenohumeral arthritis requiring total shoulder arthroplasty in a patient 5 months after posterior glenoid osteotomy.[124] The authors blamed possible intraarticular extension of the osteotomy

Figure 16-29 Intraarticular extension of a posterior glenoid osteotomy. This patient is at increased risk for necrosis of the isolated posterior glenoid fragment or for glenohumeral degeneration.

as the cause of the rapidly progressive chondral degeneration. Hawkins et al. reported avascular necrosis of an isolated posterior glenoid rim fragment after extension of the osteotomy into the joint.[100] Hawkins noted osteoarthritis in 1 of 12 patients after posterior glenoid osteotomy.[99]

The treatment of glenohumeral degeneration after posterior glenoid osteotomy is difficult. Ultimately, most of these patients will require total shoulder arthroplasty, regardless of their young age. Technically, restoring normal glenoid component version may require posterior support, including bone grafting.

Coracoid Impingement Syndrome

Posterior glenoid osteotomy is a surgical option in the treatment of recurrent posterior instability. Theoretically, if the glenoid version is overcorrected, the humeral head will have a tendency toward anteromedial orientation. This nonphysiologic alignment can result in contact between the anterior humeral head and the coracoid process, the so-called coracoid impingement syndrome (Fig. 16-30).

Gerber et al. reported a combined clinical and anatomic study on the consequences of posterior glenoid osteotomy.[73] They presented a case report of significant, symptomatic coracoid impingement after glenoid osteotomy treated with resection of the inferolateral aspect of the coracoid process. In a corresponding anatomic study, 13 cadaveric shoulders displayed evidence of coracoid impingement after posterior glenoid osteotomy. Humeral contact against the coracoid and coracoacromial ligament was effectively relieved in the cadaveric shoulders by resection of the coracoacromial ligament and inferolateral coracoid process.

Summary

Operative treatment for recurrent posterior subluxation or dislocation carries a higher recurrence rate than unidirectional anterior instability. The poor results are believed to be secondary to inappropriate patient selection, incorrect diagnosis, failure to treat all the pathology associated with the instability, and poor compliance with rehabilitation. The optimal treatment to treat posterior instability is evolving, but a course of physical therapy is warranted before operative intervention is pursued. Good success can be achieved for patients with nonvolitional recurrent persistent symptomatic instability. A lesion-specific approach is most successful. Repair of posterior labral pathology and concomitant capsular shift is the mainstay of treatment, with glenoplasty reserved for patients with confirmed retroversion or posterior glenoid erosion contributing to the instability.

OPEN REPAIRS FOR MULTIDIRECTIONAL INSTABILITY

The literature on the surgical treatment of multidirectional instability is not as vast as that for traumatic instability. Yet, many of the complications that plague surgery for traumatic instability are analogous to those for multidirectional instability.

Recurrence of Instability

Overall, the rate of instability recurrence after capsular shift for an appropriate diagnosis of multidirectional instability is low. In 1980, Neer and Foster reported 40 patients who had undergone capsular shift for multidirectional instability, with only one patient suffering a recurrence.[193] Altchek et al. described recurrent instability (posterior) in 1 of 40 patients who underwent a T-plasty Bankart repair for multidirectional instability (anterior and inferior).[7] Cooper and Brems reported recurrence in 4 of 39 patients after capsular shift.[44] Most recently, Pollock et al.[210] treated 49 shoulders with open inferior capsular shift for MDI. There was a 4% recurrence after 61 months of average follow-up. Excellent or good results were found in 94% of their study group.

The causes of instability recurrence after capsular shift can be divided into mechanical and biologic. The capsular shift procedure is predicated on decreasing capsular volume in the appropriate regions, as defined by the patient's instability pattern. Preferential imbrication of one side of the capsule may result in instability in the opposite direction in patients with circumferential multidirectional

instability.[7] To correctly perform a capsular shift for patients unstable anteriorly, inferiorly, and posteriorly, the inferior humeral capsule must be released well past the inferior humeral margin, back to the posteroinferior quadrant. With subsequent superior capsular shift, anterior, inferior, and posterior capsules will all be equally tightened.

Although past investigators have concentrated on reducing the inferior capsular pouch, more recent attention has been directed toward the superior capsule, particularly in the treatment of inferior instability. Basmajian and Bazant hypothesized the primary importance of the superior capsule in preventing inferior instability.[19] Rowe and colleagues reported the presence of a defect in the rotator interval in patients with recurrent subluxations.[229] Recent basic science has further defined the rotator interval capsule (coracohumeral ligament and superior glenohumeral ligament) as the primary inferior stabilizer of the adducted shoulder,[92,270] and other investigators have noted the clinical importance of rotator interval repair.[197] Considering these data, imbrication of the rotator interval should be considered an integral aspect of the capsular shift procedure.

Of all the patients referred to our clinic with a diagnosis of recurrent instability after capsular shift procedure for multidirectional instability, the most common direction of persistent instability is inferior. This pattern of instability is also extremely disabling because carrying is a significant aspect of activities of daily living. Often, these patients can have dramatic sulcus signs even with stress by gravity alone (Fig. 16-31). Sometimes, because of repeated attempts at capsular shift, the patients are overtightened in the anterior and posterior directions, yet continue to display instability in the inferior direction, caused by uncorrected incompetence of the rotator interval (Fig. 16-32). Revision surgery, therefore, needs to primarily address this defect. We will usually imbricate the rotator interval capsule with the glenohumeral joint held located and the arm in approximately 20 degrees of external rotation. If the degree of inferior instability is severe, less external rotation is applied, sacrificing external rotation at the side for stability. Finally, since the long head of the biceps tendon parallels the course of the SGHL and CHL, a reverse tenodesis can be helpful. In this technique, the biceps tendon is left attached at its origin but is released distally. The tendon is then inserted into the humeral head through a bone tunnel with the apex of the tunnel at the insertion of the SGHL. The biceps is then sutured to itself with the humeral head reduced and the arm held in neutral external rotation.

Recurrence of instability after capsular shift can also occur in the anterior or posterior directions. If the patient indeed has recurrent multidirectional instability, consideration should be given to combined anterior and posterior approaches at the time of revision. Neer and Foster suggested this strategy in their initial description of the inferior capsular shift procedure for multidirectional instability.[193] Specifically, they recommended Bankart repair, if necessary, through an anterior approach, with a concomitant posterior approach for capsular shift. The technique is also useful, however, in the absence of a Bankart lesion. Through the posterior approach, complete access is gained to the posterior and posteroinferior capsule. From anteriorly, the anteroinferior, anterior, and rotator interval capsular regions can be addressed.

Postoperatively, these patients are placed in a neutral position brace with the arm positioned in neutral external rotation but with the entire humerus and shoulder girdle superiorly displaced. This brace is maintained for 6 weeks,

Figure 16-31 A 24-year-old woman after six previous surgical stabilization attempts. She has continued inferior instability, even to gravity stress. (Courtesy of Frederick A. Matsen III, University of Washington Medical Center, Seattle, WA.)

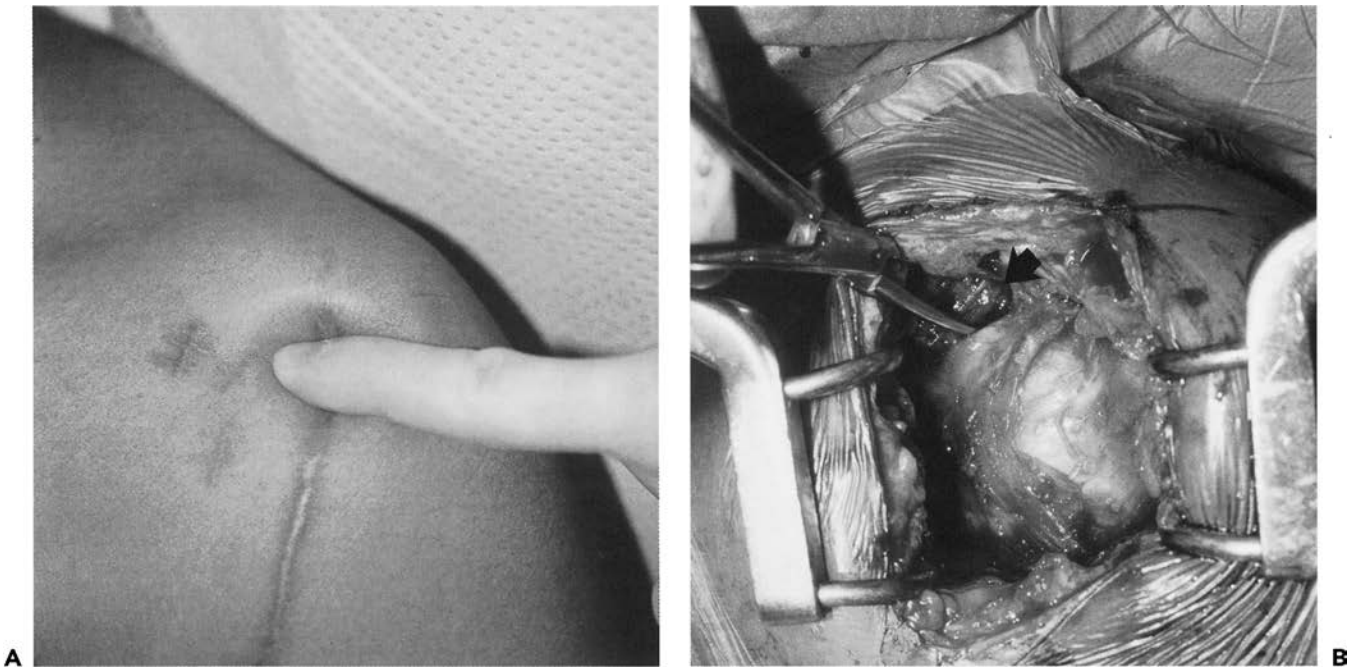

Figure 16-32 **(A)** Persistent inferior instability in a patient who had undergone four previous capsular shift procedures. The rotator interval was not addressed in any of the previous surgeries. **(B)** Intraoperative photograph of the same patient. The rotator interval capsule was noted to be completely deficient and the interval was widened (*arrow*).

with the patient performing abduction and external rotation isometrics in the cast. At 6 weeks postoperative, the cast is removed and a sling is placed. The patient is permitted to remove the sling for activities of daily living, but he or she is encouraged to wear the sling for activities during which the arm may be expected to hang to gravity. At 10 weeks postoperative, the patient is begun on a gentle, supine, active assisted motion program, rotator cuff strengthening against resistance, and a scapular stabilization and balancing program. Contact athletics and heavy lifting are restricted for 1 year.

Despite our mechanical knowledge of the ligamentous support of the glenohumeral joint, multidirectional instability is not a pure mechanical problem. It has long been recognized that patients with multidirectional instability are often systemically ligamentously lax. Neer and Foster discussed not only an increase in capsular volume, but also abnormal capsular compliance in these individuals.[193] McNab and McNab reported on the poor-healing potential in patients with multidirectional instability, implying an overall collagen defect in this disorder. Rodeo et al. found that, in patients with multidirectional instability, there was a decreased cysteine content of the capsule, possibly indicating a higher prevalence of less stiff collagen type III. In addition, the skin of these patients had smaller collagen fibril diameters, again suggesting an underlying defect of collagen.[223]

Patients with recurrence of instability after capsular shift often appear to have abnormal healing. Skin incisions seem to be wider than usual. The patient may say that there was an "opening" of the incision in the initial postoperative period, indicating wound dehiscence. On revision surgery, the amount of deltopectoral and humeroscapular interface scarring appears minimal, and can often be divided by finger dissection. Most importantly, the capsuloligamentous structures are almost always attenuated and deficient. Occasionally, this deficiency may also include the subscapularis tendon and may extend to the point of tissue absence.

We as surgeons do not yet have a good method of overcoming the biologic deficiency in these patients. We tend to treat these patients in a manner similar to that discussed earlier for traumatic instability with anterior capsular deficiency. The surgical approach begins by defining the humeroscapular interface and judging the presence and amount of anterior subscapularis and capsular tissue. In cases of anterior deficiency, we resort to an autologous tendon graft to reconstruct anterior capsuloligamentous defects (see Fig. 16-17).

End-Stage Instability

Rarely, a patient will continue to suffer from disabling glenohumeral instability despite numerous attempts at surgical reconstruction. Although this condition can occur after any type or direction of instability, it is most common with multidirectional instability. These persons usually have impairment of most if not all of their stabilizing

mechanisms, including loss of glenoid concavity, absence of capsuloligamentous restraint, severe Hill-Sachs lesions, and severe scapulohumeral dysfunction.

Diaz et al.[51] reported on eight patients who underwent fusion for end-stage instability. Each had an average of seven previous attempts at surgical stabilization. At a mean follow-up of 35 months there was no reported recurrence of instability. Time to fusion averaged 3.5 months. All patients had subjective improvement and the authors emphasized that this is a viable salvage treatment for refractory instability. Ruhmann et al.[230] studied 43 patients retrospectively for complications of arthrodesis with average follow-up of 6.7 years. Screw arthrodesis and screw and plate arthrodesis were utilized. Patients rated the surgery as excellent, good, or satisfactory in 91% of cases. There were no reported incidents of recurrent instability. Pseudoarthrosis averaged 10% to 15%.

Richards et al. have reported the results of glenohumeral arthrodesis for patients with terminal instability.[218] After fusion, four of six patients with atraumatic instability had not only poor results, but also continued to have the sensation of episodic instability, despite clinical and radiographic evidence of solid fusion. In patients with end-stage instability, we have also resorted to arthrodesis when all other reconstructive methods have failed (Fig. 16-33). Many patients with atraumatic instability are prone to also have problems of the scapulothoracic joint, particularly ptotic posturing, pseudowinging, and snapping scapulae. In this population, glenohumeral arthrodesis initiates or worsens scapulothoracic symptoms. Regretfully, despite the high incidence of continued symptoms, glenohumeral arthrodesis remains the only surgical option for the treatment of end-stage instability.

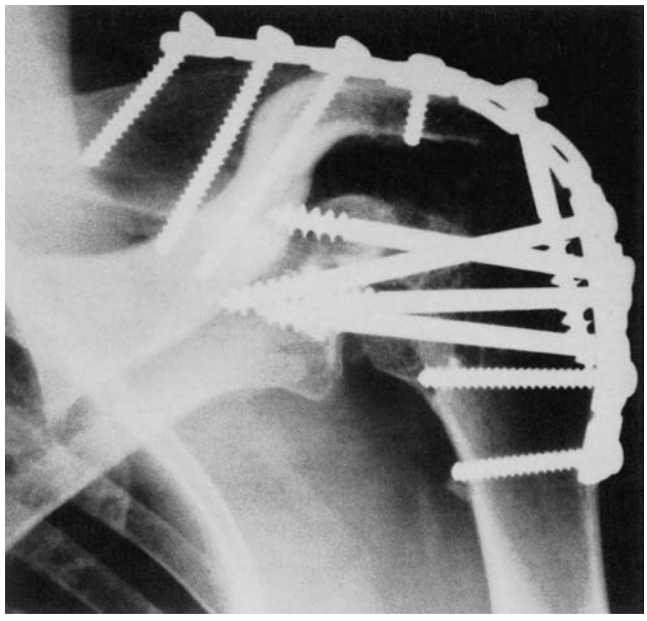

Figure 16-33 Glenohumeral arthrodesis for end-stage instability.

ARTHROSCOPIC REPAIRS FOR ANTERIOR INSTABILITY

Introduction

Over the past two decades shoulder arthroscopy has developed from a diagnostic tool into a valid treatment option for the management of shoulder instability. Arthroscopic repair offers the potential advantages of quicker surgery, with less surgical morbidity, better cosmesis, decreased postoperative pain, more selective anatomic repair, without violating the normal adjacent soft tissues, and recovery of more normal range of motion.[12,85,271] The shoulder, however, has been identified as the joint with the highest rate of arthroscopic complications.[35,242,243] Some of the previously mentioned complications of open instability repair apply equally, if not more so, to arthroscopic surgery. Recurrence rates of 0% to 70% for arthroscopic stabilization have been reported. Arthroscopic repairs are also subject to unique complications specific to the repair method (Table 16-4). Avoiding pitfalls of arthroscopic stabilization surgery requires diligence on the part of the surgeon and advanced arthroscopic skills.

Recurrence of Instability

Incidence

The literature is extremely varied on the recurrence rate of glenohumeral instability after arthroscopic repair. Much of the variability probably relates to the wide array of different arthroscopic repair techniques, differences in surgeons' experience, and short follow-up. When viewed as a whole, the reported recurrence rate of instability after arthroscopic repair ranges from 0% to 70%. Shaffer and Tibone reviewed recurrence of instability and found rates of 16% to 33% for staple capsulorrhaphy, 0% to 60% for transglenoid suturing , 0% to 37% for tack stabilization, and 0% to 30% for suture anchor repair.[238] Overall, this rate of recurrence of instability is higher for arthroscopic repairs when compared with open.[12,20,80,82,85,97,134,141,146,189]

Arthroscopic techniques for shoulder instability can be divided into several main categories: metal fixation such as

TABLE 16-4
CAUSES OF FAILURE AFTER ARTHROSCOPIC REPAIR

Recurrence of instability
Loss of motion
Neurovascular injury
Hardware complications

screws or staples, absorbable devices, suture-based repairs, and thermal treatment. Each technique offers unique advantages. However, each can also result in unique complications and causes for instability recurrence.

Initial arthroscopic Bankart repairs were performed by staple capsulorrhaphy. Johnson's staple repair technique, which formed the basis for many other subsequent approaches, had an initial failure rate of 21%.[123] This high recurrence rate was somewhat related to allowing patients early range of motion postoperatively. The failure rate was cut by a third with immobilization for 4 weeks postoperatively.

Lane et al.[142] retrospectively reviewed 54 patients undergoing arthroscopic staple capsulorrhaphy followed for 39 months. The found a 33% recurrence rate, and a 19% revision rate to open stabilization. Fifteen percent had loose staples on follow-up radiographs and only 43% returned to preinjury level of athletics. Other authors continued to report high recurrence rates after arthroscopic staple capsulorrhaphy.[31,46,87,97,123,142,172,213,243,278,281] The use of this technique is no longer recommended.

As a response to the problems of staple capsulorrhaphy, other investigators developed arthroscopic suture techniques,[12,20,40,52,62,71,80,82,141,189,190,196,206,224,266,277,290] based on the transglenoid open Bankart repair procedures of Reider and Inglis.[215] Some initial reports listed failure rates using this suture technique at less than 8%, but these rates have ranged from 0% to as high as 69% in both short and long-term follow-up.[12,20,40,62,71,80,82,85,146,189,215,240,271,288] Many studies have shown excellent short-term results (no recurrence of dislocation or subluxation) using the transglenoid technique in acute dislocators.[20,189] Recurrence rates, however, can be fairly significant after this technique. Landsiedle,[141] using this technique, showed 14% postoperative dislocation over 24 to 60 months (no mention of subluxation). Hubbell[113] studied 30 patients treated with arthroscopic transglenoid fixation and found a 17% rate of dislocation and 60% rate of subluxation. He concluded that open repairs were more successful in the young athletic population. Manta's review of 38 shoulders, stabilized with the arthroscopic transglenoid suture technique, demonstrated a 10% failure rate at 2 years and a 40% failure rate at a minimum 5 years of follow-up.[165]

Steinbeck and Jerosch[252] compared open Bankart reconstruction using bone anchors to transglenoid fixation arthroscopically and found that in 32 patients followed for 3 years the rate of redislocation for transglenoid fixation was 17% versus 6% for the open procedure. They concluded the higher dislocation rate was related to the poor condition of the inferior glenohumeral lesion at arthroscopy, less time of postoperative immobilization, high level of activity, and number of preoperative dislocations. Hayashida et al.[102] found similar reasons for redislocation. He followed 82 patients for 40 months and found contact sports participation, residual labrum and capsular tear, thin labrum–ligamentous complex, and a repair using less than four sutures to be positive predictors for recurrence of instability using the transglenoid repair.

Another method developed for arthroscopic Bankart repair utilizes absorbable tacks for labral attachment. A commonly used absorbable fixation device is the Suretac (Acufex Microsurgical, Mansfield, MA), composed of polyglyconate polymer. It is a cannulated tack with head and body molded separately and then attached to one another. The tack dissolves by hydrolysis and loses 50% of its strength by 2 weeks and 100% at 4 weeks. Although the device loses its strength as it resorbs, it acts as a temporary compressive fixation for what is thought to be a sufficient time to allow healing of the capsulolabral separation.[207,247] Even in experienced hands, the overall rate of instability recurrence is approximately 12% to 21%.[237,248] Speer and colleagues published results of arthroscopically assisted repair of the anterior aspect of the labrum with the use of a bioabsorbable tack. Their reported failure rate of 21% (11 patients) included four secondary to traumatic and seven resulting from atraumatic reinjury.[248] Common technical errors when using this device include medial placement of the anchor, inadequate abrasion of the glenoid rim, inadequate superior/medial shift of the IGHL, and inadequate compression of the capsular tissue to the glenoid rim. Any of these errors may lead to recurrent instability.

The other common method of arthroscopic labral repair involves use of suture anchors, either absorbable or permanent.[207,247,249,268,269,271] Arthroscopic Bankart repair with suture anchors have been utilized with success ranging from 70% to 93%.[15,118,130] Ide et al.[118] utilized absorbable anchors for acute Bankart repair in 55 athletes with no glenoid bone loss followed for 42 months with 93% success. Mazzocca et al.[174] studied collision athletes and found an 11% redislocation rate after a 37-month follow-up. Burkhart and DeBeer[33] noted that the rate of recurrence for this technique for athletic patients with anterior glenoid defects was 89%. Without significant bone loss the recurrence rate dropped to 6.5%, similar to Ide's study. Similarly, Bacilla et al.[15] reported 91% return to athletic competition without redislocation in 32 patients and Kim et al.[130] reported only 4% recurrent instability in a group of 167 patients (53% contact athletes) followed for 44 months. Koss et al.,[138] however, reported 30% redislocation in 27 patients followed for 40 months with failure associated with more than five preoperative dislocations. Guanche[98] reported 33% resubluxation or dislocation in 15 patients followed for 17 to 42 months.

Causes of Recurrent Instability after Arthroscopic Repair

The higher rate of recurrence of instability after arthroscopic procedures when compared with open ones may

simply reflect our comparing apples and oranges. The wide array of lesions, differences in patient populations, surgical techniques, multiple scoring systems, and short-term follow-up make comparison of open and arthroscopic repairs difficult. As such, the causes of instability recurrence after arthroscopic repair are not necessarily the same as those after open repair (Table 16-5).

Incorrect Diagnosis

Some of the reasons for instability recurrence after arthroscopic repair are similar to those after open repair. Accurate diagnosis is essential to obtain a good outcome. Failure to identify the patient with MDI will lead to higher percentage failures. In the surgical suite, Oliashirazi et al.[204] found 83% sensitivity and 100% specificity to identify unilateral anterior instability using examination under anesthesia with the affected arm tested in neutral, 40 and 80 degrees of external rotation, and 20 degrees of abduction. They also added the directions anterior–inferior and posterior–inferior in 70 to 80 degrees of abduction to the more standard anterior, posterior, and inferior tests.

Manta and Pettrone found a high failure rate of transglenoid repair in females (70%), particularly those with multidirectional instability.[165] Landsiedle attributed failures to poor suture technique and poor patient selection, including those patients with nontraumatic dislocation and the absence of a Bankart or Hill-Sachs lesion.[141] Warner et al. suggested that success of the procedure may improve by selecting only patients with unidirectional, traumatic, anterior instability who have a discrete Bankart lesion and well-developed ligamentous tissue.[268] Speer and colleagues have commented that their high rate of recurrence (21%), when compared with open procedures for instability, was related to an underestimation of the degree of overall capsular laxity at the time of initial arthroscopic treatment in those patients with atraumatic instability.[248]

Recurrence of Bankart Tear

Either failure of healing of the Bankart lesion or recurrence may lead to postoperative instability. Warner and colleagues sought to clarify the issue of Bankart repair healing by analyzing a group of patients who underwent a "second-look" arthroscopy to evaluate and treat pain or recurrent instability following arthroscopic Bankart repair with the Suretac device. Second-look arthroscopy was performed at an average of 9 months for recurrent instability in seven patients, pain in six, and pain and stiffness in two. In the seven patients with recurrent instability, the Bankart repair was completely healed in three (43%), was partially healed in one (14%), and had recurred in three (43%). In the remaining eight cases with stable shoulders, the Bankart repair had completely healed in five cases (62.5%) and partially healed in three patients (37.5%).[268]

Mologne et al.[188] assessed failed arthroscopic Bankart repairs at open surgery and found that 40% of the redislocators had Bankart lesions at the time of surgery. The presence of the postarthroscopic Bankart lesion correlated significantly to redislocation.

Defects of Glenoid Concavity

As with open repair, failure to correct defects of glenoid concavity will result in higher rates of surgical failure. The glenoid has an average depth of 9 mm in the superior–inferior direction and 5 mm in the anterior–posterior direction. The labrum contributes as much as 50% of the socket depth. In general, concavity–compression results from the compressive force generated by surrounding muscles to center the humerus in the bony glenoid. A Bankart repair that places the labrum medially off the glenoid rim will result in a persistent concavity loss and can result in instability recurrence. Warner and colleagues analyzed eight cadaver shoulders that underwent arthroscopic repair of an experimental Bankart lesion using the Suretac device.[269] These shoulders were then dissected to reveal the placement of the Suretac and the adequacy of the Bankart lesion repair. There were several technical errors that occurred, including medial placement of the Suretac relative to the articular margin. As noted earlier, medial anchor placement fails to adequately restore glenoid contour and concavity and may lead to instability recurrence.

As with open surgery, failure to account for anterior glenoid osseous loss can result in failure of arthroscopic Bankart repair. Anterior inferior glenoid bone loss has been reported in 22% of first time dislocators and 73% of recurrent dislocators. Biomechanical investigations have been conducted to determine the effect of anterior glenoid bone loss on stability. Burkhart et al.[32,33,156] studied glenoid bone loss and found that 25% to 45% of the glenoid must be missing to create an "inverted pear" glenoid. He showed that arthroscopic Bankart repair resulted in a redislocation rate of 4% without bony defects and that the rate of redislocation increased to 61% if an inverted pear was

present. Bony defects in contact athletes resulted in an 89% redislocation rate versus a 6.5% redislocation if no glenoid defect existed. Burkart et al.[32] further showed that the degree of bone loss can be determined arthroscopically by measuring the distance from the bare spot of the glenoid to the posterior rim. This distance is almost identical to the distance from the bare spot to the anterior rim. The percentage of bone loss can therefore be determined. If greater than 25% bone loss exists, the author recommends consideration for glenoid osseous reconstruction or coracoid bone block procedure. Other authors have noted worse results after arthroscopic repair in the presence of either an osseous lesion of the anterior glenoid rim or severe labral deficiency.[47,84,165,206,266]

Residual Capsular Laxity

Failure to address residual capsular laxity has been thought to be an important cause of recurrent instability after arthroscopic repair. Guanche and colleagues have reported a 27% revision rate in arthroscopic cases that did not address capsular laxity as compared with 8% in open cases.[88] Both Landsiedle and Manta and Pettrone reported worse results in those patients with hyperlaxity.[141,165] Manta and Pettrone, Pagnani et al., and Walch et al. all documented failure to definitively address inferior laxity as a contributing factor to failure.[165,206,266] Speer and colleagues have recently reported on arthroscopic reoperations for recurrent anterior instability, in which seven of eight patients had completely healed Bankart lesions. In these patients, the anteroinferior aspect of the capsule was felt to be patulous in each patient.[248] Mologne et al.[188] assessed capsulolabral lesions in 20 patients having failed arthroscopic Bankart repairs. Forty percent had recurrent Bankart lesions and 75% were felt to have redundant anterior capsules. They concluded that capsular laxity, while difficult to quantify, should be addressed at revision surgery.

As discussed in the section on failures of open instability repairs, normal shoulders can have a great degree of capsular laxity, and the significance of residual and unrepaired capsular laxity remains unclear (see Fig. 16-14). Moreover, the exact techniques used to differentiate excessive capsular laxity from normal laxity are unknown and are difficult to perform even in the open setting. Kim et al.[138] described intraoperative methods for evaluating capsular redundancy. The capsule was redundant if thumb-to-forearm distance is less than 4 cm, the sulcus sign is greater than 2+, and a large anterior pouch is seen with insufflation of the joint. Because we do not arthroscope normally lax shoulders, we do not know how many normals would have arthroscopic signs of persistent laxity. Although it is easy to blame persistent laxity as a cause for failure after arthroscopic repair, it remains to be proved that residual laxity after arthroscopic repair is abnormal. Laxity does not necessarily equal instability; therefore, persistent laxity as a cause for instability is a diagnosis of exclusion. Proponents of plastic deformation of the capsule support a modified Bankart repair, which includes a limited capsular shift.[126] Adequate tensioning of the anterior capsule is accomplished by utilizing a shift of the anterior–inferior capsular tissue superior and lateral with the arm in a position of 20 degrees of external rotation. It is unclear, however, if their reported success rates are increased by the addition of the capsular shift.

Rotator Interval Defect

Selective cutting studies have confirmed the rotator interval's role in preventing inferior and posterior instability. For patients with acute anterior dislocation combined with inferior instability, imbrication of the interval is recommended if examination under anesthesia confirms inferior subluxation not resolved with external rotation of the arm and a normal examination of the contralateral unaffected extremity. Arthroscopic findings consistent with rotator interval pathology include redundancy between the supraspinatus and subscapularis and discrete tears of the superior glenohumeral ligament. Redundancy may be difficult to determine arthroscopically and exact criteria to define this don't exist. Additionally, fraying of the biceps tendon or upper rolled border of the subscapularis may be seen, though these findings are nonspecific. Failure to address a rotator interval defect in the patient with inferior instability can lead to recurrence. Speer et al. performed arthroscopic evaluation of eight patients with recurrence of instability after previous arthroscopic Bankart repair. In seven of the eight patients, the Bankart repair had healed. An open lesion of the rotator interval was seen in five of these seven patients.[248]

The Humeral Avulsion of Glenohumeral Ligaments Lesion

Avulsion of the capsulolabral complex at the glenoid (Bankart lesion) is a well-known cause of anterior shoulder instability. Wolf[318] and colleagues have reported on the importance of recognizing a lesser known entity, the humeral avulsion of glenohumeral ligaments (HAGL). HAGL lesions can exist in isolation or with other associated pathology. Recurrent instability without Bankart lesion should be considered a HAGL lesion until proven otherwise (Fig. 16-34). The incidence of recurrent instability from a HAGL lesion has been reported to range from 2% to 9.3%.

Wolf arthroscopically evaluated 64 shoulders with the diagnosis of anterior instability. Six shoulders had HAGL lesions (9.3%), 11 shoulders had generalized capsular laxity (17.2%), and 47 shoulders had Bankart lesions (73.5%). In other authors' experience the rates of HAGL lesions may be lower. Kon et al.[137] noted an incidence of 2.4% in his patient population. In patients with documented anterior instability without a demonstrable

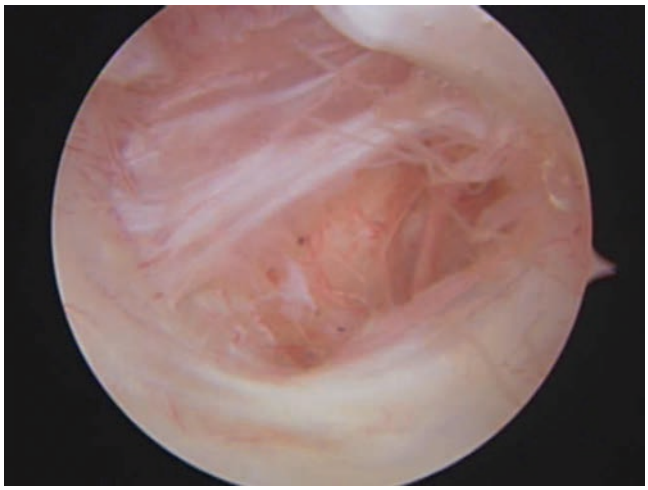

Figure 16-34 Humeral avulsion of the glenohumeral ligament in a patient who had recurrent anterior subluxations after arthroscopic Bankart repair.

Bankart lesion, a HAGL lesion should be ruled out. This lesion is readily recognized arthroscopically from the anterior portal or posterior portal using a 70-degree arthroscope, and its appropriate repair can restore anterior stability.[106] Failure to address a HAGL lesion may result in persistence of instability. Kon et al.[137] described three cases of all-arthroscopic repair of a HAGL lesion. The authors emphasized proper placement of the anchors on the humeral insertion, use of a 70-degree arthroscope, and a transsubscapular portal as critical to their success. Richards and Burkart[217] also described an all-arthroscopic repair of HAGL lesions. They emphasized the use of a 70-degree arthroscope and a "5 o-clock" transsubscapular portal.

Strength of Repair

Because recurrence of the Bankart lesion has been demonstrated as the major source of failure after arthroscopic repair, fixation strength of the repair technique probably plays some role in lesion healing. Arthroscopic repair techniques have varied in their ability to accomplish a robust fixation.

McEleney and others looked at the initial failure strength of eight repair techniques using a previously described canine model of Bankart repair. Intact capsule-to-bone complexes failed at the bony interface at 236 N. Traditional Bankart repair failed at 122.1 N (two sutures) and 74.7 N (one suture), Acufex TAG rod (Acufex Microsurgical, Mansfield, MA) at 143.5 N (two sutures) and 79.8 N (one suture), transglenoid suture technique (two sutures) at 166.6 N, Mitek GII (Mitek, Norwood, MA) (one suture) at 96.4 N, Zimmer Statak (Zimmer Inc, Warsaw, IN) (one suture) at 95.2 N, and Acufex bioabsorbable Suretac at 82.2 N. The two-suture repairs were statistically equivalent in strength to each other, as were the one-suture repairs and the Suretac device. Two-suture repairs were significantly stronger than one-suture repairs ($P < 0.01$). In the single-suture specimens, failure occurred by suture breakage in 46% (18 of 39) of specimens and soft tissue failure around the suture in 54% (21 of 39). Failure in the two-suture techniques occurred primarily by soft tissue failure (23 of 25). No device broke or pulled out of bone.[176]

Shall and Cawley evaluated three mechanical soft tissue fixation devices (SuperAnchor, Suretac, and the Instrument Makar [IM] Bioabsorbable Staple) in a cadaveric model by examining ultimate tensile failure and modes of failure in simulated Bankart repairs. They attempted to realistically evaluate the strengths of soft tissue reattachment procedures at the anterior glenoid under worst-case conditions—load to failure. The mean load at failure for the SuperAnchor was 217.32 N; for the IM Staple, 132.32 N; and for the Suretac, 122.37 N. The load at failure for the SuperAnchor was statistically greater ($P < 0.001$) than the IM Staple and Suretac. There was no statistical difference between load at failure for the Suretac and the IM Staple. The most common failure mode for the Mitek was suture breakage (71%). Anchor pullout from bone was the most common failure mode for the IM Staple (75%) and Suretac (94%).[239]

In a labral repair model, Gohkle and colleagues compared the strength of suture anchor repair to the standard Bankart procedure and the intact anterior capsule.[79] The mean load at failure for the suture anchor repairs varied from 90 to 115 N and was lower than in the standard Bankart procedure (127 N). All suture anchors demonstrated similar holding strength with the exception of an absorbable wedge ($P < 0.05$).[79]

When utilizing the suture anchor technique arthroscopically, recurrence may result from the failure to tie adequate knots arthroscopically. Lo and Burkhart[155] tested Ethibond and FiberWire arthroscopic knots and evaluated knot security and loop security. Knot security was defined as the ability of the knot to resist slippage and loop security as the ability to maintain a tight suture loop as the knot is tied. Several common arthroscopic knots were evaluated including the surgeon's knot, SMC, Tennessee slider, Nicky's knot, Roeder knot, Weston knot, and Duncan loop. A standard surgeon's knot demonstrated the highest force to failure (102 to 197 N) and tightest loop circumference. All sliding knots demonstrated force to failure of less than 75 N and loose loops. Loutzenheiser and Harryman also have demonstrated that some failures may relate to the challenge of tying secure knots arthroscopically. Many knots tied arthroscopically commonly consist of an initial slip knot to remove slack and a series of half-hitches. Half-hitches, instead of square throws, are difficult to avoid and result when asymmetrical tension is applied to the suture strands. For this reason, the security of knots tied arthroscopically may not be equivalent to square knots and a greater rate of failure may occur. The most secure knot configurations were achieved by reversing the half-hitch throws and alternating the posts. These knots performed significantly better than all other knots tested ($P < 0.002$).

Thus, the surgeon can control the holding capacity and minimize suture loop displacement by properly alternating the tying strands and reversing the loop when placing the hitches.[159]

The importance of strength of fixation of suture anchor repair in the Bankart reconstruction is unknown because we do not stress these patients early on in the healing process. Because failure of Bankart repair is a complication of arthroscopic repair, however, strength of fixation may play a role in this repair failure.

Engaging Hill-Sachs Lesion

Impression fractures of the posterior humeral head are seen with both recurrent dislocation and acute dislocation. They are more common in the recurrent dislocator. Instability resulting from a Hill-Sachs lesion is dependant on size, orientation, and location of the defect. Lesions occupying 20% of the humeral head are rarely significant, while lesions of 40% or more are likely important contributors to instability.[59,256] Lesions between 20% to 40% have variable impact.

Lesions of clinical significance will engage the anterior glenoid rim in functional ranges of motion. The degree of involvement may be determined on axillary radiographs. Historically small Hill-Sachs lesions have been addressed by soft tissue procedures that limit external rotation. This prevents the Hill-Sachs lesion from engaging the anterior glenoid. Surgical options are those discussed in the section on failures of open Bankart repair.

Rehabilitation and Early Mobilization

Because the fixation strength is probably less after arthroscopic than after open repair, the period of postoperative immobilization likely plays an important role in preventing recurrence of instability. Johnson determined that he could cut his recurrence rate (of about 20%) after arthroscopic staple capsulorrhaphy by one-half if he increased the period of postoperative immobilization from less than 3 weeks to 4 weeks.[123] Three to 4 weeks of strict immobilization has also been recommended by other investigators.[6,40,189] Limiting early trauma is also thought to be extremely important. If the patient desires to return to contact sports, a 6-month delay has been reported to lower the rate of instability recurrence.[244] Recently Kim et al.[131] has investigated an accelerated rehabilitation program in nonathletes who underwent arthroscopic Bankart repair. Sixty-two patients were followed for an average of 31 months. One group underwent a "traditional" rehabilitation program consisting of 3 weeks of immobilization in an abduction sling and the other group was managed with accelerated rehabilitation. Motion and strength exercises were begun from the first postoperative day in this group. Recurrence of instability was the same between the two groups, with two patients from each group experiencing postoperative apprehension. Patients in the accelerated group had earlier return of functional range of motion and had earlier return of functional activity. Accelerated rehabilitation also resulted in decreased levels of pain and increased patient satisfaction.

Loss of Motion

It has become increasingly evident that shoulder motion, especially external rotation, need not be sacrificed for stability. In theory, by not incising the subscapularis or violating the humeroscapular motion interface, arthroscopic repair offers the potential for better preservation of glenohumeral motion than does open repair. Despite the potential advantages over open repairs, the incidence of postoperative stiffness following arthroscopic stabilization ranges from 2% to 15%.[47,191]

After arthroscopic Bankart repair, most patients can anticipate a reliable return of motion that is nearly symmetrical with that of the contralateral shoulder.[255] Arciero et al. treated 25 patients by arthroscopic Bankart repair using a cannulated bioabsorbable fixation device. Nineteen patients with an average follow-up of 19 months had an average loss of external rotation of 3 degrees.[11] Warner and Warren reported on 26 patients with a minimum of 24-month follow-up, treated with the Suretac device, who had an overall recurrence rate of 8%. They noted an average loss of external rotation of 7 degrees, with five of eight throwing athletes and four of four swimming athletes being able to return to their premorbid level of athletic participation.[271] Finally, Uribe and Hechtman reported on 11 young athletes with acute anterior Bankart lesions treated with the transglenoid suture repair. When using the Rowe scale, there were nine excellent and two good results. All eventually achieved full external rotation in adduction and 90 degrees of abduction compared with the opposite side.[265] Fabbriciani et al.[54] compared open and arthroscopic repairs in equivalent patient populations. They found that outcome measurements such as pain, recurrence, function, and strength were equivalent. Postoperative motion for the arthroscopic group was better than that seen after open repairs.

Wall and colleagues reported that their postoperative protocols commonly expect normal motion by 10 to 12 weeks in nonthrowing athletes and 6 to 8 weeks in throwing athletes. If after these time periods there is restricted motion, especially external rotation less than 10 degrees or abduction below 90 degrees, there is cause for concern. If aggressive physical therapy fails to regain motion, manipulation under anesthesia or arthroscopic release may be employed. The authors describe using an anterior release for limitations of external rotation and axillary pouch release for abduction contractures, sometimes using electrocautery or lasers as an adjunct. For lesser degrees of motion restriction, they will wait 6 months to treat arthroscopically.[267]

Neurovascular Complications

Vascular complications after arthroscopic shoulder surgery are thankfully rare. Burkhart[34] reported a case of deep venous thrombosis in a patient who subsequently was identified as having a hypercoagulable state. Pseudoaneurysm[38] and cephalic vein laceration[47] have also been reported.

The incidence of neurologic injury following shoulder arthroscopy has been reported as high as 30%.[178] Mechanisms of injury include traction from the lateral decubitus position, fluid extravasation, direct injury, tourniquet-like complications from wrapping of the upper extremity, and regional sympathetic dystrophy. Pittman et al.[209] noted that traction neurapraxia occurred in 10% of their study group and recommended somatosensory evoked potentials to monitor this complication. Segmuller et al.[2] noted direct nerve injury with 7% of their study group demonstrating transient sensory deficits. Permanent deficits requiring tendon transfers have been reported.[171]

Careful well-padded positioning, limited fluid extravasation, less than 7 kg of arm traction (for lateral decubitus position), and accurate portal placement are required to limit neurologic complications. Most neurologic injuries are transient, with resolution the rule and not the exception.

Conclusion

As with open repairs, treating anterior shoulder instability arthroscopically requires an accurate diagnosis, selection of correct operative procedure, appropriate equipment and training, and correct rehabilitation procedures. Patients with traumatic unidirectional anterior instability, confirmed Bankart lesion, and robust capsulolabral complex who do not participate in contact athletics and have no anterior glenoid bone loss or engaging Hill-Sachs lesion represent ideal candidates for arthroscopic stabilization. Without accurate identification and correction of the pathology, any arthroscopic procedure will have a high failure rate. Arthroscopic stabilization offers less morbidity, shorter surgical time, improved cosmesis, improved range of motion, and less postoperative pain. With improving techniques and by addressing all pathologies, results of arthroscopic repair rival that of open repair.

ARTHROSCOPIC REPAIRS FOR MULTIDIRECTIONAL INSTABILITY

Introduction

MDI was originally defined by Neer and Foster in 1980.[193] Their study group demonstrated instability anteriorly, posteriorly, and inferiorly. Capsular redundancy was demonstrated intraoperatively and was eliminated with an open humeral based capsular shift. Caspari first reported on arthroscopic techniques for MDI.[41,180] His technique utilized multiple sutures to shift the posterior–inferior glenohumeral ligaments, anterior–inferior glenohumeral ligaments, and anterior glenohumeral ligaments superiorly, thereby reducing capsular volume. Excessive capsular laxity is considered the primary pathogenesis of MDI. It can be congenital or acquired. Despite a general agreement that capsular laxity is the "essential lesion" of MDI, increased laxity alone cannot explain MDI, which often occurs in the midrange of motion when capsular ligaments are loose. Other contributing factors may include concavity–compression (muscle forces of the rotator cuff) and geometric conformity of the glenohumeral joint provided by labrum and articular cartilage.[180] Kim[132,133] identified labral pathology in all of his patients with either MDI or posterior–inferior instability. Additionally, there is evidence that the amount of translation in symptomatic shoulders with MDI is not significantly different from the laxity found in painless shoulders with MDI.[149,150,177] This implies that pathology other than capsular volume may contribute to painful MDI.[149,152,179]

Recurrence of Instability

Incidence

Reports of recurrent instability after arthroscopic treatment of MDI are scarce. Gartsman et al.[68] reported on 47 patients treated with multiple suture anchors for MDI with just 1 of 47 experiencing recurrent instability. McIntyre[181] reported a 5% recurrence rate using multiple sutures.

Arthroscopic transglenoid treatment was first described by Duncan and Savoie[52] and later by McIntyre et al.[180] McIntyre utilized a transglenoid approach in 19 patients over 34 months with anterior sutures brought out posteriorly and tied over the infraspinatus fascia, and the posterior sutures brought out anteriorly through a supraclavicular portal and down through a drill hole in the scapular spine and tied down over bone. Only 1 of 19 patients experienced recurrent instability. Treacy et al.[263] reviewed 25 patients treated with arthroscopic shift via the transglenoid technique. At 60 months of follow-up 22 of 25 had stable shoulders.

Causes of Recurrent Instability

Incorrect Diagnosis

As with open repair, incorrect diagnosis may lead to recurrence. The physician should note the primary direction of instability during provocative testing. Volitional dislocators should be identified and those with psychiatric problems must be identified. Connective tissue disorders such as Marfan's or Ehlers-Danlos syndrome must be elicited. True scapular winging must be diagnosed if present.

Surgical Errors

The pathology of MDI that can be addressed arthroscopically includes increased capsular volume, labral deficiencies, and a deficient rotator interval. Failure to address these variables may result in a technical failure. Suture "pinch-tuck" imbrication and pinch-tuck plication of the capsule to the labrum combined with rotator interval closure is an effective method of achieving these surgical goals. Kim[133] reported good or excellent outcomes in 30 of 31 patients studied over 51 months using this technique. Gartsman et al.[68] was 94% successful with 47 patients studied over 35 months utilizing these techniques. Treacie et al.[263] reported on 25 patients with MDI after arthroscopic stabilization followed for 5 years with 88% satisfaction and 12% resubluxation but no dislocation.

Conclusion

Treatment of MDI first requires patience. A trial of nonoperative rehabilitation emphasizing scapular stabilizers and rotator cuff strengthening should be employed with anticipated success rates of 80%. If instability persists after 6 months, arthroscopic stabilization may be undertaken. Preoperative gadolinium MRI may confirm labral lesions or loss of the chondrolabral contour, suggesting tears. This is especially true posterior–inferior. Examination under anesthesia should confirm laxity in all three directions and be compared to the contralateral extremity. Arthroscopic labral repair and capsular shift (posterior and anterior) and rotator interval closure is then completed. Rehabilitation for a period of 4 to 9 months is conducted before contact sports allowed. With advanced arthroscopic skills, success rates over the short and intermediate term of 80% to 95% can be anticipated. Perhaps the greatest advantage of arthroscopic evaluation and treatment of MDI is that it allows treatment of a spectrum of pathoanatomy. With MDI, variation of pathoanatomy is common.

ARTHROSCOPIC REPAIRS FOR POSTERIOR INSTABILITY

Introduction

Posterior shoulder instability is present in approximately 2% to 4% of all instability cases. It represents a continuum of problems that remains poorly understood.[280] No single lesion is thought responsible for the development of posterior instability. Most researchers distinguish between acute traumatic dislocations and chronic atraumatic posterior instability. The former is typically caused by a single traumatic event while the latter develop insidious laxity and instability over time. Pain and instability are caused from abnormal posterior translation of the humeral head relative to the glenoid. Rehabilitation of the rotator cuff, especially the infraspinatus, remains the first line of treatment for posterior instability. If rehabilitation fails and symptoms persist, operative intervention including posterior Bankart repair and/or capsulorrhaphy may be indicated.

Recurrence of Instability

Recurrence of instability for arthroscopic repair techniques is extremely variable. Rates of 0% to 50% have been reported.[10,81,128,280] These high rates of recurrence may reflect the technical difficulty associated with addressing all potential sources of posterior instability. It may also reflect study groups with different types of posterior instability. In general, recurrence after arthroscopic shoulder repair is secondary to incorrect diagnosis/patient selection, surgical errors, or inadequate rehabilitation.

Etiology of Instability Recurrence

Incorrect Diagnosis

Failure to recognize MDI instead of unidirectional posterior instability may lead to surgical failure. Patients with posterior instability typically complain of mild shoulder pain, mechanical symptoms (catching, clicking, clunking), and laxity in positions of flexion, adduction, and internal rotation. Trauma with the arm in this position is usually described. They usually present in their teens or 20s. They may or may not have pain. Hawkins[111] reported that 40% of patients with posterior subluxation had no complaints of pain. This was true even in the face of ongoing subluxation. Activity-related pain or discomfort is common and ranges from dislocation to repeated subluxations. Physical examination should confirm unidirectional posterior instability.

Failure to recognize glenoid hypoplasia, retroversion, or posterior erosion may lead to surgical failure if one utilizes a soft tissue–only procedure. Standard radiographs, including anteroposterior, lateral, and axillary views should be obtained to rule out a retroverted, posteriorly eroded, or dysplastic glenoid. In the setting of failed arthroscopic repair for posterior instability, a CT scan should be considered to assess glenoid version and posterior glenoid erosion. If greater than 20 degrees of retroversion is present, a soft tissue–only procedure may lead to high recurrence. MRI with gadolinium enhancement is useful to evaluate the posterior–inferior capsulolabral complex. Kim et al.[129] identified four types of posterior labral pathology identified on MR arthrogram.

Kim et al.[129] also found that retroversion of the chondrolabral glenoid was present in posterior instability (5 to 8 degrees) when compared to controls (1.7 to 2.9 degrees). Failure to correct for labral pathology and/or chondrolabral retroversion may lead to increased recurrence.

Failure of Operative Technique

Surgical intervention begins with an examination under anesthesia. Cordasco et al.[45] studied patients with isolated

posterior or inferior labral tears but no clinical instability. On examination under anesthesia, all had posterior instability. MDI, if present, should be confirmed and the direction of maximal translation recorded and correlated to the patient's symptoms. Failure to identify MDI may lead to recurrence. Arthroscopically, attention is paid to defects in glenoid concavity or other bony pathology. The posterior–inferior labrum is thoroughly assessed. Lesions in this location may vary from labral tears to more subtle deep lesions on the chondrolabral junction (Kim's lesion). Kim's lesion may be evident after liberating the superficial chondrolabral surface and thus exposing the loose underlying labrum. Failure to rectify all potential pathology may lead to recurrence.

Suture anchor capsulorrhaphy restores the posterior–inferior labral height and capsular tension. In the revision situation, the repair may be performed arthroscopically or open. The repair may be augmented with suture capsulorrhaphy. Kim et al.[1] recommended augmenting the repair with a posterior capsular shift, anterior capsular shift, and rotator interval (RI) closure if anterior translation and/or inferior translation coexist. They studied 31 patients over 51 months. Thirty of 31 had good or excellent results by the Rowe grading system with 3% recurrent instability. Williams et al.[280] studied 27 shoulders over 5 years treated with posterior suture anchor capsulorrhaphy and found 8% recurrence of instability. Mair et al.[164] studied nine patients treated in similar fashion with no recurrence at a minimum of 2 years of follow-up. Goubier et al.[81] treated 11 patients for posterior instability with suture anchor capsulorrhaphy and had no recurrence of instability at 34 months.

Although there are several techniques available for arthroscopic suture capsulorrhaphy, either with or in the absence of a labral lesion, we prefer a "pinch-tuck" technique. Through the posterior portal a Linvatec Spectrum (Linvatec, Largo, FL) device is introduced and pierces the capsule approximately 1 cm lateral to the labrum. The hook then reenters the capsulolabral junction and sutures are tied arthroscopically. Care is taken to incorporate the posterior IGHL and to achieve a shift of the capsule superiorly. If the posterior capsule is tenuous or torn, the infraspinatus tendon may be incorporated into the repair. Wolf and Eakin[286] reported on 14 patients treated with either suture anchor capsulorrhaphy or suture capsulorrhaphy with recurrence in one patient over 33 months. Posterior capsular redundancy was found in all patients and labral pathology was present in 86%. Provencher et al.[211] reported on 35 patients treated likewise at follow-up after 25 months and found good or excellent results in 31 of 35. There were five recurrences.

Role of the Rotator Interval

Cadaveric models have been used to study the role of the rotator interval on stability. Harryman et al.[92] found that sectioning the rotator interval capsule allowed increased amounts of laxity in all three directions. They also found that imbrication of the interval decreased inferior and posterior translation. Field et al.[57] reported on 15 patients with MDI whose intraoperative findings were only a hole or defect in the rotator interval capsule. Closure of this defect led to good stability at average follow-up of 3.3 years. Rowe and Zarins[226] identified holes in the rotator interval in 20 of 37 patients undergoing open procedures for instability. Kim et al.[129] recommended RI closure on patients with large sulcus and predominantly inferior instability. Failure to address a rotator interval defect may be associated with instability recurrence.

Conclusion

Unlike anterior instability, there likely is no agreed upon "essential" lesion of posterior instability. Several lesions may contribute to posterior–inferior instability and including capsular laxity, stripping of the capsule and synovial tissue, erosion of the cartilage, labral tears or bony defects, and bony or chondrolabral retroversion.[10] This variation in pathology makes treatment decisions difficult and failure to address the pathology can be associated with instability recurrence. Preoperative CT scans and MR arthrograms should be considered for patients who have failed prior attempts at soft tissue repair to evaluate glenoid version, hypoplasia, posterior glenoid defects, labral pathology, and chondrolabral retroversion. For glenoid retroversion of greater than 20 degrees, glenoid osteotomy with a soft tissue procedure should be considered. Lesser degrees of retroversion may be treated with suture anchor capsulorrhaphy plus or minus capsular shift to restore labral height and chondrolabral version. Arthroscopic management of posterior instability should address all potential causes of instability including posterior labral defects, capsular redundancy, and the rotator interval defects. Success using arthroscopic techniques for posterior instability range from 75% to 94% at short and intermediate follow-up.

Neurovascular Injury

Neurovascular injury has been an infrequent but potentially devastating complication of arthroscopic instability repair. These complications can be separated into those resulting from positioning and setup, portal placement, or suturing techniques.

Positioning

Shoulder arthroscopy has classically been performed in either the lateral decubitus or beach-chair position. The lateral decubitus position has a potential disadvantage in that the necessary use of a traction device may endanger the brachial plexus.[272] Andrews and others have recommended that longitudinal traction of 15 lb (6.8 kg) be

applied with the patient in the lateral decubitus position and with the arm in 15 degrees of forward flexion and 70 degrees of abduction.[9] Traction setup used for shoulder arthroscopy in the lateral position should not exceed 15 lb, with 10 lb usually being sufficient. Careful attention to excessive shoulder abduction and extension should be paid to prevent potential neuropraxia.[22,267] It is recommended that traction be maintained at less than 20 lb (9.1 kg) to minimize the risk of neurapraxias.[222] The beach-chair position has been used by many surgeons, and no episodes of brachial plexus nerve palsy have been reported. There is one case report of a hypoglossal nerve palsy, thought to result from change in position of the head and subsequent compression beneath the angle of the mandible.[192] The reported rate of neurapraxia after shoulder arthroscopy has ranged from 0% to 30%.[9,135,203,209,222,242,243] Small reported on a prevalence of less than 0.1% of neurologic complications. These included three brachial plexus traction injuries (two subsequent to arthroscopic anterior staple capsulorrhaphy) and one axillary nerve injury (during an arthroscopic anterior acromioplasty).[243] Ogilvie-Harris and Wiley reported one transient musculocutaneous nerve palsy after a total of 439 shoulder arthroscopies, a prevalence of 0.2%.[203] Andrews and Carson reported on three neurologic injuries, one musculocutaneous neurapraxia and two involving the ulnar nerve, after 120 arthroscopies, a prevalence of 3%.[8] Klein et al. cited a prevalence of transient paresthesias of about 10%; however, no specific numbers were given.[135] Pitman reported on two transient neurapraxias in 20 patients, one involving the lateral antebrachial cutaneous nerve and the other with diffuse hypoesthesia of the lateral aspect of the arm and forearm with paresis of the wrist extensors.[209] Weber and Jain[276] studied interscalene blocks for routine arthroscopic shoulder surgery and found a 13% failure rate in 218 patients. They further reported high use of postoperative narcotics despite use of the block and included reports of cardiovascular collapse, pneumothorax, and permanent nerve injury when using this technique. They concluded that complications of interscalene blocks necessitate a detailed discussion of risks and benefits with the patient prior to attempting this technique.

Klein and colleagues studied the strain on the brachial plexus that results from traction loads applied at various arm positions and correlated this with visibility through the arthroscope. They mounted strain gauges to the upper trunk, lateral cord, median nerve, and radial nerve of five fresh human cadavers. Each cadaver was placed in a lateral decubitus position, with the head fixed in a neutral position, as for shoulder arthroscopy, and the strain on the plexus was measured as a function of arm position and traction load. A final cadaver was used to determine the accessibility and visibility in the arthroscope at each of the arm positions. At a given flexion angle, increasing abduction was associated with decreasing strain. At a given abduction angle, increasing flexion resulted in decreased strain. The minimum overall strain was noted at 90 degrees of flexion and 0 degrees of abduction. Visibility at this position was limited. Klein et al. concluded that the ideal arthroscopic position is a combination of two positions that would maximize visibility while minimizing strain to the nerves. These two positions are 45 degrees of forward flexion and 90 degrees of abduction in combination with 45 degrees of forward flexion and 0 degrees of abduction.[135]

Somatosensory evoked potentials (SEPs) were recorded by Pitman during shoulder arthroscopy in 20 patients to monitor the musculocutaneous nerve, ulnar nerve, and either the median or radial nerve. In all 20 cases, abnormal SEPs of the musculocutaneous nerve were demonstrated. In 16 patients, this was produced on initial joint distention; in 15 patients, by traction; in 11, by longitudinal traction of greater than or equal to 121 lb; and in 6, by perpendicular traction of greater than or equal to 7 lb. In 10 patients, there were varying combinations of median, ulnar, and radial nerve involvement. There were two cases of clinical neurapraxia in this series. One resolved in 24 hours and one in 48 hours. Pitman concluded that there is a real potential for neurologic damage during shoulder arthroscopy and that the musculocutaneous nerve is the most vulnerable. Factors responsible include joint distention, excessive traction, extravasation of fluid, and tension on the musculocutaneous nerve as it was stretched over the humeral head with the shoulder in extension, abduction, and external rotation.[209]

Because most neurologic insults are neurapraxic-type injuries, the initial approach should be observation. If no nerve recovery is seen by 3 weeks, one should consider an EMG, and then serial EMGs based on the clinical examination. In neurapraxic injury, the surgeon should expect neurologic function to be fully recovered by approximately 3 months.

Portal Placement

Knowledge of the local anatomy is essential in portal placement. Matthews and others reported on one proximal median nerve palsy in 47 shoulder arthroscopies, a prevalence of 2%. The presumed cause was injury during anterior portal placement.[173] For anterior portals, staying superior and lateral to the coracoid within the "safe triangle" avoids injury to the musculocutaneous nerve.[173,202] Wolf has done cadaveric studies describing an anteroinferior portal that lies 1.5 to 4 cm from the musculocutaneous nerve, and provides a more useful working angle for stabilizing the anteroinferior labral ligamentous complex. This distance increases with adduction; thus, he recommended placing this portal with the arm in less than 30 degrees of abduction.[172,289]

Laceration of the cephalic vein may also occur during anterior portal placement. Ligation is indicated, and

meticulous hemostasis intraarticularly is essential to prevent hemarthrosis. The use of epinephrine in the irrigating fluid, proper joint distention, and hypotensive anesthesia may also aid in controlling bleeding.[22]

Suturing Techniques

Arthroscopic stabilization procedures can be complicated by neurovascular injury. The most notorious of these complications is injury to the suprascapular nerve during transglenoid suturing. Mologne et al. reported the clinical outcome of arthroscopic labral reconstruction using a transglenoid suture technique in 49 shoulders.[187] Suprascapular nerve palsy occurred in three cases (6%).

Bigliani and colleagues studied the course of the suprascapular nerve and its distance from fixed scapular landmarks in 90 cadaveric shoulders. In an additional 15 cadavers, three pins were passed at various angles in an anterior-to-posterior direction through the middle of the glenoid neck just inferior and lateral to the base of the coracoid process. The distance between the exit site on the posterior glenoid neck and the suprascapular nerve at the base of the scapular spine was recorded for each pin. Inferiorly directed pins were the furthest from the suprascapular nerve and averaged 16 mm. On the basis of these data, a relative safe zone was described in the posterior glenoid neck.[24] Morgan recommended that the anterior starting point for transglenoid drilling should be at the 2 o'clock position (right shoulder) and directed 30 degrees inferior to the transverse plane and 15 degrees medial to the plane of the glenoid to minimize injury to the suprascapular nerve.[189]

In patients undergoing transglenoid drilling, the presence of suprascapular nerve injury postoperatively should signal a prompt workup. An EMG may be indicated in the first 24 hours to rule out axonotmesis. If no recovery is seen in 24 to 48 hours, early exploration should be considered.

Hardware Complications

Mechanical Complications

Numerous hardware problems have been seen after arthroscopic staple capsulorrhaphy. The earliest staples were made malleable so that they would not break. This proved to be a problem in that they were easily bent by forceful direction change during insertion. Subsequent generations were less malleable and thus the complication of staple loosening (usually as a result of reinjury or dislocation), impingement, breakage, and eventual migration was seen.[123]

Another staple complication involved placement of the staple in an incorrect perpendicular orientation to the anterior glenoid. Even if oriented correctly, the staple may be placed only partly (one tine only) in bone or be placed too deep into the bone, thus amputating the glenohumeral ligaments or cutting into the labrum. If placed too superior, the staple may end up in the coracoid process. The staple head may also cause irritation to the subscapularis tendon. Placement of the metallic staple at the anterior glenoid margin may cause erosion of the humeral head cartilage (Fig. 16-35).

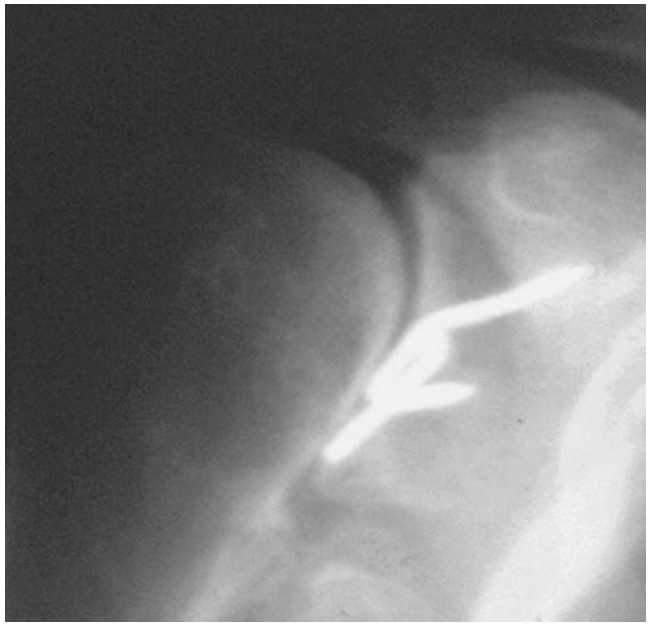

Figure 16-35 Radiograph demonstrating a painful intraarticular staple that had been placed arthroscopically.

Clearly, any implant can loosen and cause pain or chondral injury. This complication is not specific to staple capsulorrhaphy. If a patient who has undergone instability repair with a metallic implant develops pain, crepitation, or locking sensation, radiographs and possibly a CT scan are mandatory to ensure the implants are secure in bone (Fig. 16-36). For a patient that has had prior placement of absorbable anchors

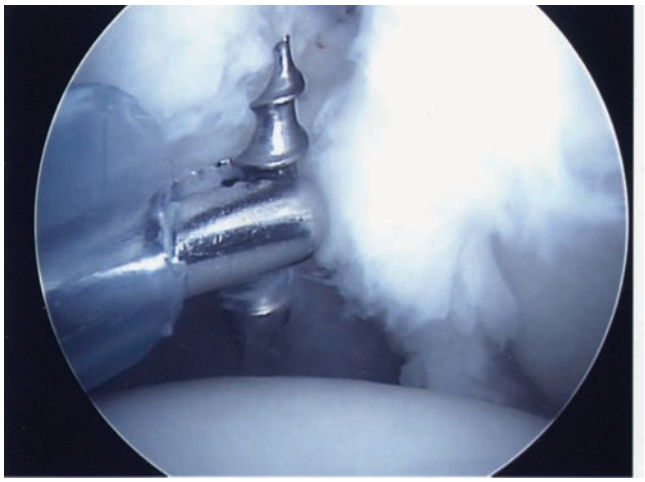

Figure 16-36 Loose metallic anchor after prior arthroscopic Bankart repair. There was significant chondral wear found during arthroscopic anchor removal.

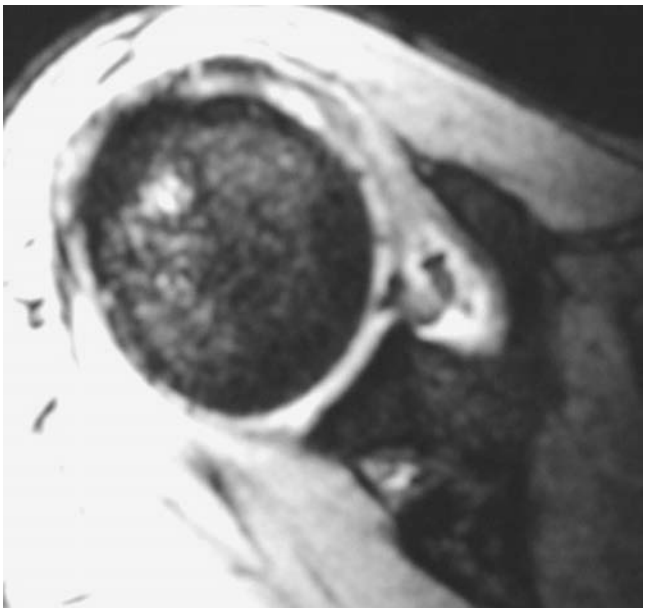

Figure 16-37 Magnetic resonance imaging scan demonstrating a loose absorbable anchor in the subcoracoid recess.

or tacks, an MRI scan should be obtained to investigate any mechanical complaints (Fig. 16-37).

Biologic Response to Absorbable Implants

In recent years, bioabsorbable implants have been used in arthroscopic stabilization procedures with good success. Bioabsorbable anchors have some potential advantages over metallic implants. Gradual load transfer to healing tissues, radiolucency, and reduced need for hardware removal are reported advantages. Both polyglycolic acid (PGA) and polylactic acid (PLA) tissue anchors are currently available for use. PLA has a slower biodegradation rate than PGA. They are not without potential complications. By definition, absorbable devices erode from a biologic response. If this response becomes exaggerated, clinical implications may result. Although clinically significant reactions to polyglyconate and polylactic acid anchors have been infrequent, they clearly can occur (Fig. 16-38). As seen with other biomaterials, the extent of the biologic reaction is usually material-specific.

Warner et al. reported two cases of biopsy of the repair site on "second-look" arthroscopy 6 to 8 months after labral repair using the Suretac device, a polyglyconate absorbable suture anchor. The authors found residual polyglyconate polymer debris surrounded by a histiocytic infiltrate.[268] Tetik et al. reported on humeral head damage after Suretac placement for a SLAP lesion 2 years after index procedure. Arthroscopy revealed prominent indentation at the implant site, hypertrophied labral tissue, and humeral head wear.[257] Edwards and colleagues have reported on adverse reactions to the Suretac absorbable anchor in five of their patients. All patients complained of increasing pain and loss of shoulder motion. They all required arthroscopic lavage and débridement of the intracapsular synovitis. Nonspecific granulomatous reactions were identified histologically in all cases and no organisms were grown from the operative specimens. One specimen had a dense inflammatory response surrounding refractile material (presumably particles of the Suretac).[33]

Poly-L-lactic acid has also been implicated in hardware failure. Wilkerson et al.[279] reported on four patients treated with polylactic acid tacks. Three had polylactic acid anchors placed for arthroscopic SLAP stabilization and one for a rotator cuff tear. All four had evidence of hardware failure and tack debris 3 to 10 months postoperatively at second-look arthroscopy. The authors theorized that increased demand across the shoulder joint and increased absorption rate of the tacks in soft tissue led to implant fracture and failure.

Any patient who develops symptoms of worsening pain, decreasing motion, increasing warmth, or erythema within 4 to 6 weeks of surgery should have an infection workup. In addition, one should consider an early arthroscopic exploration with removal of residual anchor debris and synovectomy.

Miscellaneous Complications

Fluid extravasation into the adjacent tissues is a very common complication of shoulder arthroscopy. This fluid may

Figure 16-38 Magnetic resonance imaging scan demonstrating fluid collection and osteolysis around two absorbable Suretac devices.

increase compartment pressures in the arm, potentially leading to compartment syndrome. Lee and colleagues measured the intramuscular deltoid pressure using a slit catheter. Although they found that the intramuscular pressure became transiently elevated during the arthroscopic procedures, in every case the pressures promptly returned to normal levels within 30 minutes postoperatively. The clinical swelling and tenseness remained for a longer period. Despite a sometimes alarming amount of swelling during shoulder arthroscopy, intramuscular pressure elevations were only sustained for a short time and returned to normal levels very quickly after the cessation of fluid infusion.[145] There are several ways to control this extravasation, including making small, tight portals around cannulas, decreasing operative time, and carefully monitoring fluid inflow pressures.[123] Case reports of compartment syndrome have been presented.[208] Injury to the rotator cuff is also a possible consequence of incorrect portal placement. These punctures may produce permanent rotator cuff defects. Creating a cuff defect is best avoided by making the superior portal with the arm adducted and the posterior portal with the arm adducted and internally rotated.[201]

COMPLICATIONS OF THERMAL CAPSULORRHAPHY

Recurrence of Instability

Introduction

The use of thermal energy to shrink lax or redundant connective tissues is not new. Hippocrates treated recurrent shoulder instability with a red-hot iron inserted into the axilla.[167] Thermal shrinkage of capsular tissue has been proposed as a means to reduce capsular redundancy associated with shoulder instability. The goal of such a procedure, either primary or adjunctive, is to restore stability to the shoulder with similar success of more traditional open or arthroscopic means.

Initial reports suggested highly successful clinical application of this technique based on short-term follow-up. Thabit et al.[258] used a holmium:YAG laser to achieve 90% good or excellent results at 6 months. Lyons et al.[161] reported 89% satisfactory results at an average follow-up of 27 months. Fanton and Khan[55] were the first to use a radiofrequency (RF) probe and reported 90% excellent results in 54 patients at a 2-year follow-up. Patients with MDI had a 90% success rate at 1 year, which dropped to 75% by year 2. Their best results were in unidirectional instability of "mild to moderate" degree. Their success in these patients was high, with a 5% reoperation rate.

Although early reports were optimistic, concern over failures, especially in MDI, have been observed with longer follow-up. D'Alessandro et al.[48] studied 84 patients with traumatic anterior instability, recurrent anterior–inferior subluxation, and multidirectional instability for an average of 46 months. Overall unsatisfactory American Shoulder and Elbow Surgeons (ASES) scores at 3 years were found in 37% of the patients and 12% underwent revision surgery for recurrent instability. The failures in the MDI group reached 41% and repeat surgery in this group resulted in only a 50% satisfaction rating.

Levy et al.[148] reported a 36% failure rate for laser-assisted treatment of MDI and 24% failures in those treated for MDI with an RF probe. Frostick et al.[64] reported a 16% failure rate at 26 months for patients with MDI, and Miniaci and McBirnie[184] reported recurrence of instability in 9 of 19 patients treated for MDI at 9 months.

Postoperatively it may take as long as 12 weeks for thermally modified tissues to regain normal strength.[234] Connective tissues show an immediate loss of stiffness after thermal shrinkage. More shrinkage results in a greater loss of stiffness. Thus, tissues treated in this fashion become weaker and more compliant in the postoperative period. When thermally treated tissues are subjected to physiologic loads postoperatively, within 4 weeks they can stretch to preoperative length.[234] One study has demonstrated increased reducible cross-links in pathologic tissue. This would suggest that pathologic tissue is more susceptible to thermal shrinkage and may be weaker in the immediate postoperative period.[103]

Results of thermal shrinkage as an adjunctive procedure have been more encouraging. Mazzocca et al.[174] treated 18 collision athletes with unilateral anterior instability with arthroscopic stabilization and adjunctive thermal treatment of the anterior–inferior glenohumeral ligament. Two of 18 experienced redislocation over a 2-year period. Savoie and Field[233] studied MDI in 30 patients treated with thermal shrinkage and arthroscopic suture plication of the rotator interval. At 28 months 93% of the patients were satisfied with the results. Gartsman et al.[69,70] reported on the use of thermal or laser energy for both MDI and bidirectional instability as an adjunct to arthroscopic suture techniques. Limited use of a holmium:YAG laser to augment capsular tightening resulted in 91% good or excellent results at 34 months of follow-up. In another study by Gartsman et al.,[69] 94% of patients had good or excellent results at 35 months when rotator interval closure was combined with RF thermal treatment.

Capsular Necrosis

Case reports of capsular necrosis and chondrolysis following thermal capsulorrhaphy have been reported[13] (Fig. 16-39). This devastating complication makes revision surgery difficult. For mild cases, areas of capsular necrosis can simply be closed, either arthroscopically or open. For more advanced cases of capsular necrosis, capsular reconstruction with auto or allograft tendon is necessary.

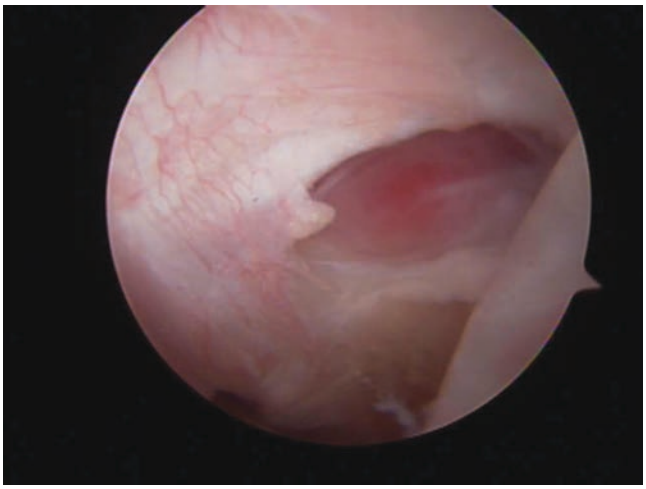

Figure 16-39 Capsular necrosis in a patient who had undergone a thermal capsulorrhaphy for multidirectional instability.

Chondrolysis

The relationship between chondrolysis and use of a thermal device is controversial. The temperature of arthroscopic fluid during thermal capsulorrhaphy can influence chondrocyte survival. Lu et al.[160] studied the temperature of the lavage solution while utilizing monopolar radiofrequency probes to smooth grade II chondromalacia changes in human knees. A higher lavage temperature (37°) resulted in less chondrocyte death than a lower lavage temperature (22°). The authors concluded that a higher lavage temperature allowed the monopolar probe to reach the preset temperature in a shorter time, thereby allowing less energy delivery to the tissues. Both temperatures, however, caused chondrocyte death.

Two patients in a study by Levine et al.[147] experienced glenohumeral joint destruction within 12 months of thermal capsulorrhaphy. Both patients went on to glenoid resurfacing with lateral meniscal allograft and humeral resurfacing with Copeland resurfacing humeral arthroplasty. This complication, while rare, is likely much more common than the few case reports would suggest. Unfortunately, given that thermal capsulorrhaphy is usually performed in the young, chondrolysis is devastating (Fig. 16-40).

Nerve Injury

Axillary nerve injury after thermal capsulorrhaphy was studied by Williams et al.[291] and found to be 1.4%. Most cases involved the sensory portion of the axillary nerve with resolution within 2 to 3 months. Anatomic studies by Bryan et al.[30] demonstrated that the axillary nerve is on average only 3 mm from the inferior aspect of the capsule. The amount of radiofrequency energy needed to impose irreversible axillary nerve injury is not known. Caution should be exercised if shrinking this portion of the capsule. Most authors recommend either "striping" this area or using the probe only on the posterior portion of the inferior glenohumeral ligament.

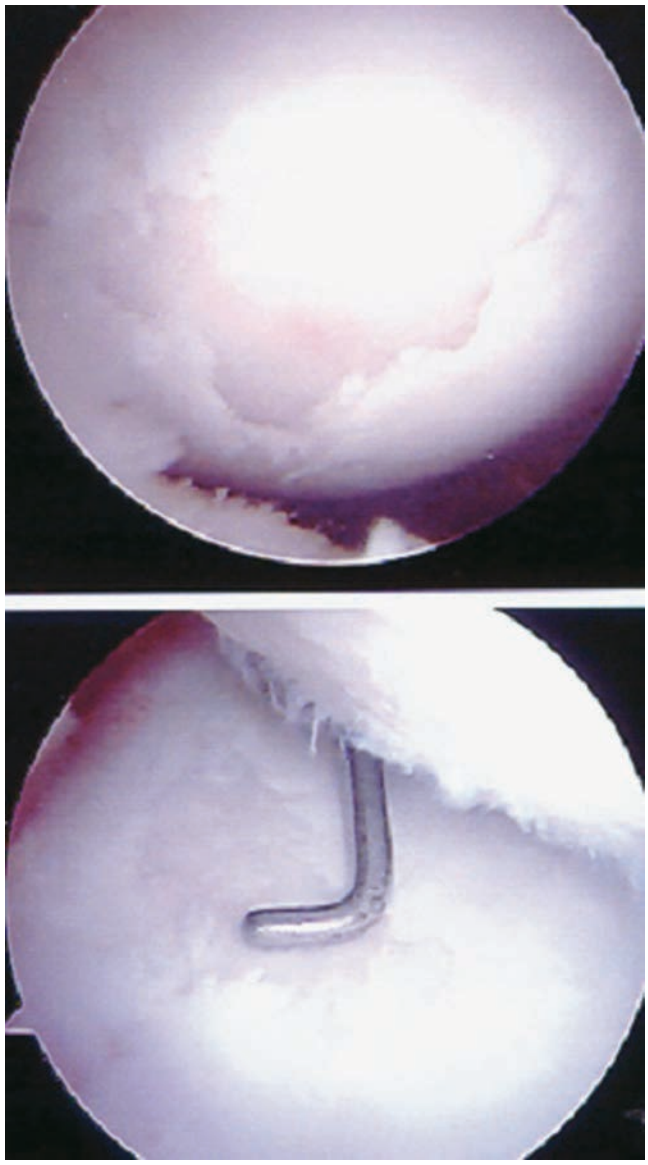

Figure 16-40 A 16-year-old baseball pitcher with potential for a scholarship developed worsened pain after a thermal capsulorrhaphy. Arthroscopic evaluation revealed significant chondrolysis.

Conclusion

Use of thermal energy as a primary method for arthroscopic treatment of instability is no longer recommended. Its use to augment more traditional means of restoring stability is a matter of ongoing debate and the surgeon should proceed with caution. It should be remembered that thermal shrinkage occurs at 65°C but significant cell death can occur at temperatures as low as 45°C. Thus, even when "striping" the capsule and ligaments, a significant amount

of cell death may occur even in untreated tissues. Treated tissues lose stiffness postoperatively and are subject to creep, which limits rehabilitation for up to 3 months. Complications including recurrence (16% to 37%), axillary nerve injury, or chondrolysis have been described. Revision surgery, if needed, is generally more difficult, with attenuated or ablated capsule reported in 18% to 33% of patients requiring revision surgery after failed thermal capsulorrhaphy.[291]

PATIENT EVALUATION AFTER FAILED INSTABILITY REPAIR

It is clear that "failure of instability surgery" encompasses multiple diagnoses. A careful and thorough approach is necessary to elucidate the problem and arrive at the appropriate treatment plan, particularly if the problem is recurrent instability or motion loss (Figs. 16-41 and 16-42).

History

The most important aspect of the patient history is questioning about the initial instability event. It is clear from the literature that failure of diagnosis is the most common cause of error. The patient, therefore, should be questioned about the activity that caused initial dislocation, the position of the arm at the time of dislocation, and the severity of the initial trauma. The physician should question about subsequent instability events, again determining arm position during these incidents. A history of contralateral shoulder instability may indicate multidirectional instability.

The patient should be questioned in detail about current symptoms. Once the unique feeling of instability is defined for the patient as such, it is a feeling that is never forgotten, that sensation forming the basis for the apprehension test. The patient should be questioned as to whether he or she still feels unstable. Was there a period after the operation when he or she was improved? Was there a significant

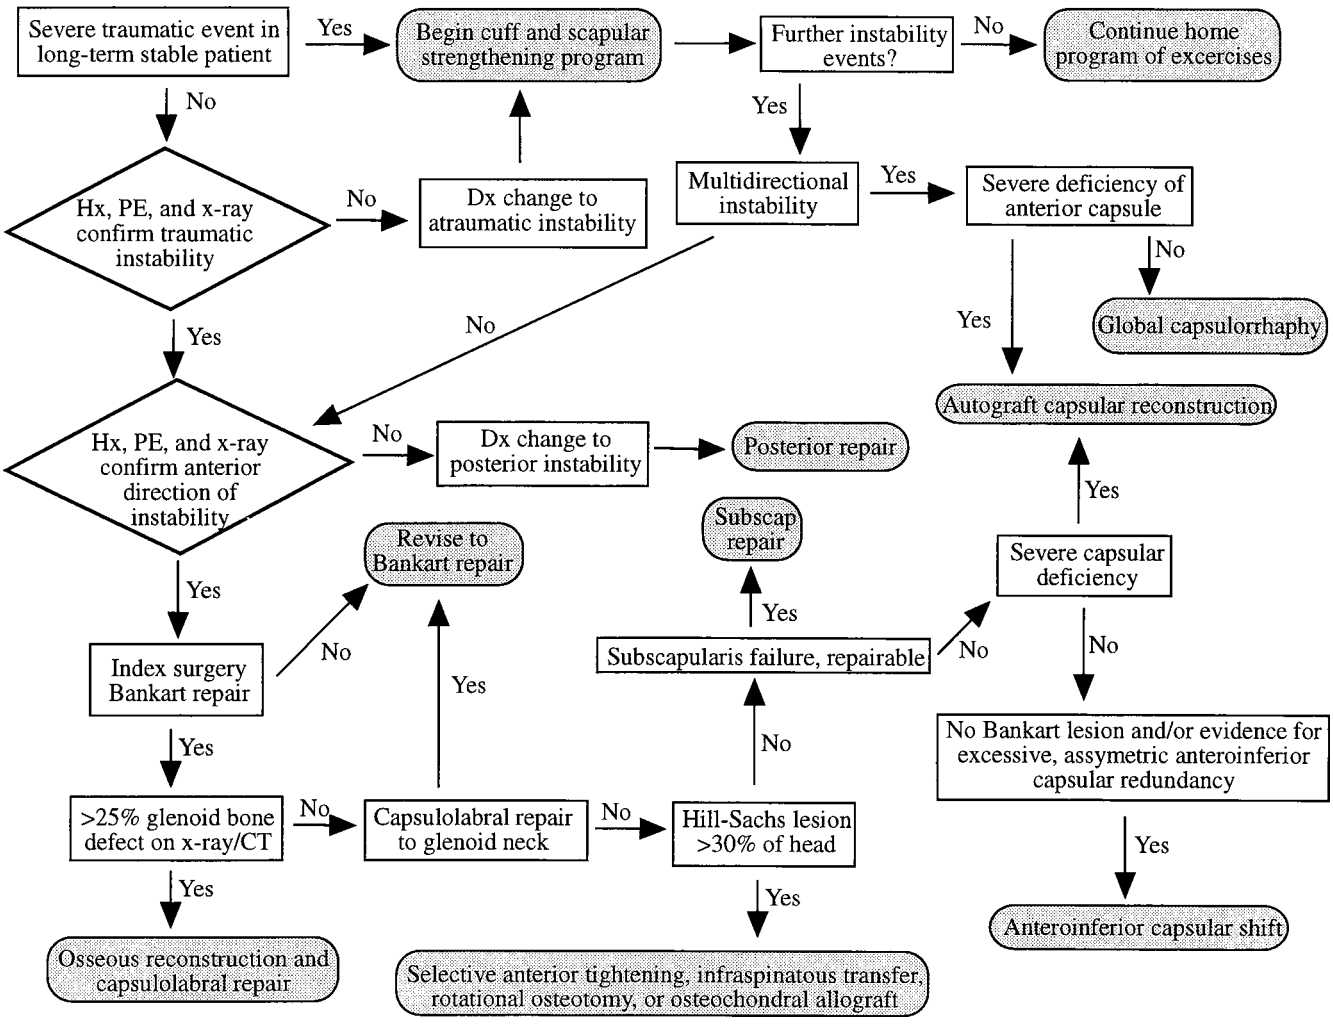

Figure 16-41 Algorithm for the management of recurrent instability after previous surgical repair.

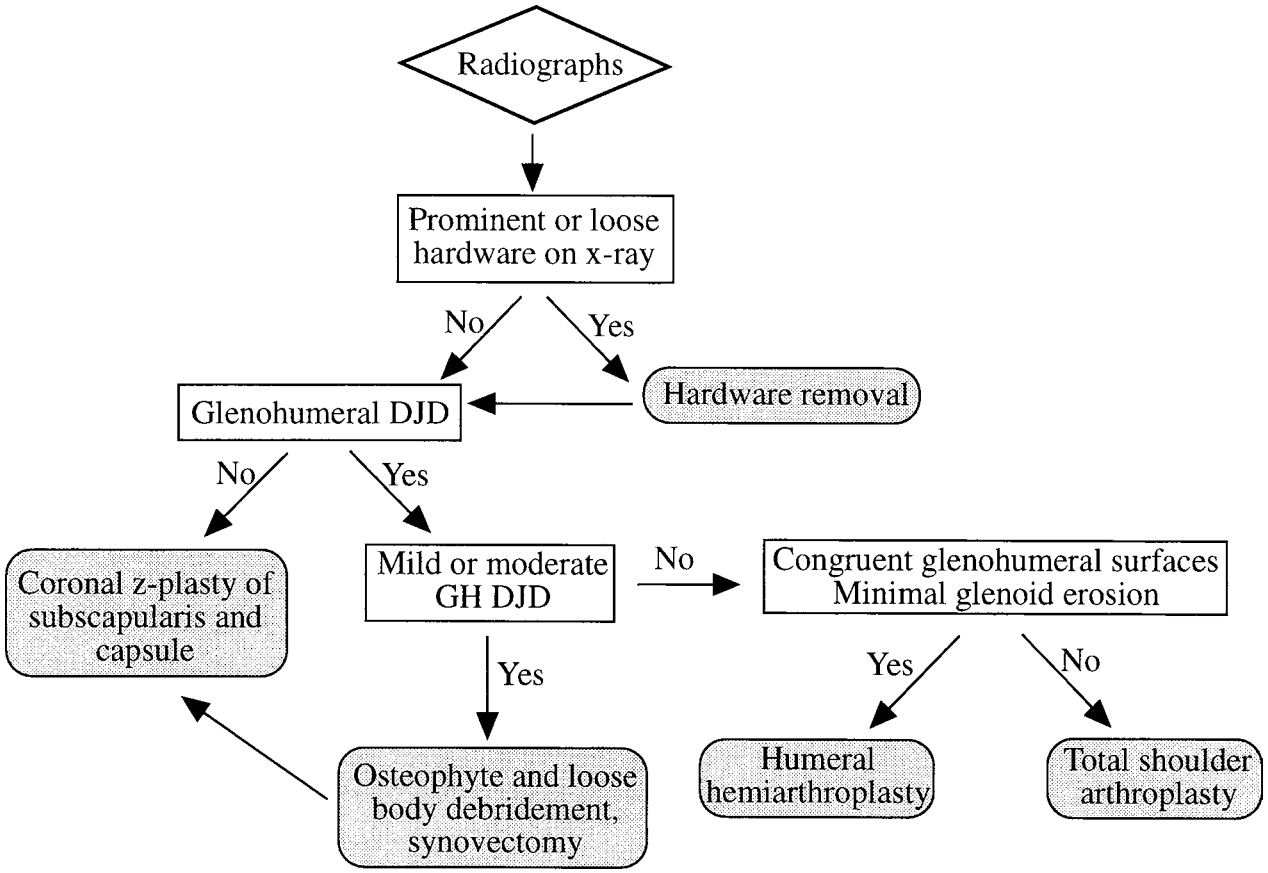

Figure 16-42 Algorithm for the management of motion loss (external rotation less than neutral) after previous instability repair.

postoperative traumatic event? Which humerothoracic positions are associated with instability events?

In cases of stiffness, the degree of functional impairment should be assessed. The patient should be questioned on the difficulty with activities of daily living, sporting activities, and hobbies. One should attempt to ascertain the degree of patient compliance with his or her index postoperative rehabilitation.

Operative notes from prior procedures should be obtained. Those notes should be reviewed to determine the exact approach used and intervals incised as, in cases of postsurgical contracture, these locations are likely to contain the most adhesions. Knowing the technique of prior repair can help determine the cause of failure in situations of postoperative instability.

Physical Examination

The shoulder should be observed for prior incisions. A thorough examination for range of motion should be performed. Severe limitation of external rotation indicates a "too-tight" repair. Increased passive external rotation in the position of humerothoracic adduction suggests subscapularis failure. A complete examination for instability is necessary, concentrating on laxity tests and directions of apprehension. The patient should be asked to voluntarily dislocate the shoulder. If he or she is able to perform this maneuver with muscular contraction and not by arm positioning, the patient should be questioned further to elucidate a true history of voluntary instability. Tests of rotator cuff function are necessary, specifically the lumbar lift-off test for subscapularis integrity. A complete neurologic examination is indicated, concentrating on axillary and musculocutaneous function.

Diagnostic Tests

Every attempt should be made to obtain radiographs taken from before the index operation, for these studies may assist in either confirming or correcting the diagnosis. If hardware was used at the time of index operation, initial postoperative radiographs should be reviewed and compared with recent studies. In our practice, new radiographs including a true scapular anteroposterior view in both internal and external humeral rotation, an axillary lateral, a West Point lateral, and a Garth apical oblique view are

obtained. If the plain radiographic studies indicate an osseous glenoid deformity or a Hill-Sachs lesion, a CT scan is used to further define these abnormalities. An MRI scan is usually not needed in cases of failed instability, although it may be helpful in defining subscapularis failure in the face of an equivocal examination. To differentiate a recurrent labral tear, capsular laxity, or HAGL lesion, an MR arthrogram or even diagnostic arthroscopy may be necessary. If there is any examination evidence for neurologic dysfunction, EMG studies should be performed.

SUMMARY

Obtaining stability while retaining mobility is the goal of both arthroscopic and open instability procedures. The optimal method for accomplishing this is evolving. Lesions of the anterior–inferior capsulolabral complex can be effectively or ineffectively treated with open or arthroscopic procedures. Evaluating and treating the patient who has had a failed instability repair can be a daunting task. Broadly, surgical failures can be categorized into failure of diagnosis or patient selection, failure of surgical procedure, and failure of rehabilitation. A complete evaluation is needed to define the problem and determine appropriate solutions. The most important technique that will result in an excellent result from revision surgery is assuring the exact diagnosis. Once that diagnosis is confirmed, the appropriate surgical intervention can be applied. At revision, the surgeon should be prepared for a complete range of pathology, from soft tissue contractures and adhesions to osseous and soft tissue deficiencies. The goal in treatment is to restore stability and motion with minimal alteration to normal anatomy.

DEFINITION

Frozen shoulder or adhesive capsulitis is one of the most common, yet one of the most poorly understood disorders of the glenohumeral joint. This is primarily due to difficulty defining and differentiating it clearly from other conditions with similar symptoms and findings but with distinctly different causes. Codman described the disorder known as frozen shoulder as a "condition difficult to define, difficult to treat, and difficult to explain from the point of view of pathology."[26] Neviaser coined the term "adhesive capsulitis."[86] When he described the contracted, thickened joint capsule with chronic synovitus. The common teaching has been that the disease is a self-limiting condition with a natural history lasting 1 to 3 years.[103] Others have argued that 15% to 50% of patients have a persistent refractory course that is unresponsive to conservative treatment.[111]

Frozen shoulder is a condition of uncertain cause characterized by the spontaneous onset of pain with significant restriction of both active and passive range of motion of the shoulder.[103] In this chapter, frozen shoulder will be discussed in terms of classification, pathophysiology, clinical evaluation, treatment, and complications.

CLASSIFICATION

Classifying frozen shoulder into primary or secondary frozen shoulder can be difficult. Most cases of frozen shoulder have an idiopathic cause in an otherwise healthy individual, are characterized as primary, and can also be considered the classic presentation of adhesive capsulitis. Frozen shoulder is often divided into either primary frozen shoulder or secondary frozen shoulder[71] (Fig. 17-1). Secondary frozen shoulder is often defined with an association with a

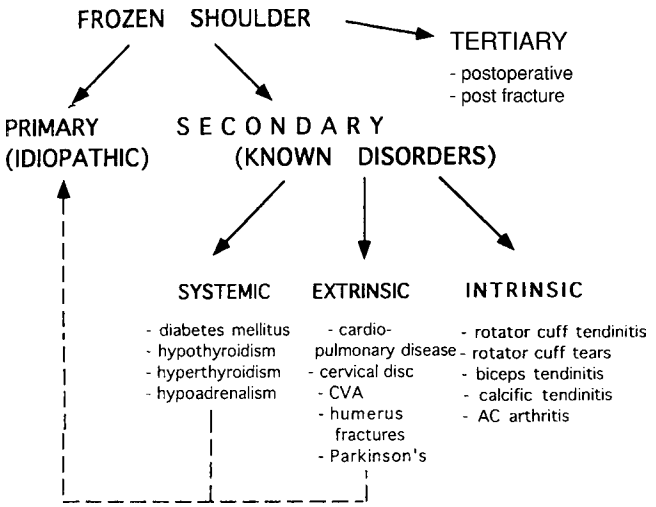

Figure 17-1 Proposed pathways for the development of frozen shoulder syndrome. AC = acromioclavicular; CVA = cerebrovascular accident.

known intrinsic, extrinsic, or systemic pathology. Secondary frozen shoulder could also be defined as a frozen shoulder that develops with an underlying intrinsic condition such as a rotator cuff tear, biceps tendon pathology, or calcific tendonitis. A third category has also been suggested for the stiff shoulder that develops after surgery or fracture (Fig. 17-1, schema). The postoperative frozen shoulder is often more resistant to both nonoperative and operative treatment. However, some patients do not fit clearly into one category or the other. Patients with a frozen shoulder and a small rotator cuff tear often are classified as having a secondary frozen shoulder but can often be treated as one would a primary frozen shoulder. Diabetic frozen shoulders often act differently than either a primary or secondary frozen shoulder. Future studies may need to address this to better characterize frozen shoulder so that cause and treatment can better be determined.

Reeves studied the natural history of 49 cases over 10 years and identified three phases of frozen shoulder.[103] Phase I consists of pain with progressive stiffness that lasted 2 to 9 months. Phase II is the stiff, contracted phase, which last 4–12 months. Phase III is the thawing phase where motion gradually improves over 12–42 months. Hannefin and Chiaia[44] identified four stages of adhesive capsulitis. Stage 1 occurs during the first 3 months of the disease. It is characterized by pain with range of motion with minimal or no loss of motion. Arthroscopy reveals diffuse synovitis of the anterosuperior capsule. Stage 2 is known as the freezing stage and occurs between 3 and 9 months after the symptoms begin. This stage is characterized by pain with decreased range of motion awake and under anesthesia with diffuse synovitis at arthroscopy. Stage 3 or "frozen stage" occurs at 9 to 15 months and is characterized by minimal pain except at the extremes of motion with loss of motion and a rigid end feel. Arthroscopy reveals a thickened, fibrotic capsule with no hypervascularity of the capsule. Stage 4 is the "thawing phase" with minimal pain and progressive improvement in range of motion. It occurs 15 to 24 months after the disease begins.[44]

PATHOLOGY

Shoulder motion is a combination of movements that occur at the glenohumeral and scapulothoracic joints at a ratio of 2:1. The normal shoulder is an inherently loose articulation that permits the large range of motion required for normal shoulder function. The capsule of the shoulder is normally a loose structure of which the surface area is almost twice that of the humeral head. The capsuloligamentous structures are the primary static stabilizers, especially at the extremes of rotation and translation. Thickenings of the joint capsule form the superior, middle, and inferior glenohumeral ligaments, while the tendons of the rotator cuff thicken the capsule anteriorly, superiorly, and posteriorly. At arthroscopy, several recesses may be identified in the normal shoulder. Anteriorly, a synovial recess is often present between the superior and middle glenohumeral ligaments, known as the rotator cleft or subscapular recess. There is a posterior outpouching of the capsule also, just deep to the infraspinatus muscle, known as the infraspinatus bursa. There is an inferior recess of redundant capsule forming a pouch-like fold when the arm is at the side.

In the pathologic state of frozen shoulder syndrome, the capsule becomes thickened and noncompliant with loss of the capsular recesses. Neer suggested that the tightened coracohumeral ligament restricts external rotation in frozen shoulder.[82] This contracted capsule does not allow the normal free movement of the shoulder which causes the scapula to move excessively in upward rotation to compensate for the loss of glenohumeral rotation as described by Nicholson.[90]

Numerous pathologic mechanisms have been proposed to explain the cause of frozen shoulder, but all remain largely theoretic. The syndrome of frozen shoulder was first described by Duplay in 1896. He introduced the term "scapulohumeral periarthritis," and felt that the initiating lesion was an obliteration of the subdeltoid bursa.[32]

Myer,[81] from a study of postmortem specimens, suggested that the initiating lesion was a breakdown on the intraarticular portion of the biceps tendon. His observations were supported subsequently by Pasteur[96] and Lippmann[65] and more recently by DePalma.[29] Codman, however, believed that the changes in the biceps tendon were of little etiologic significance.[26]

McLaughlin, one of the earliest investigators to describe the changes in the rotator cuff, stressed the importance of contracture of the subscapularis in the development of the syndrome.[76,77] Bateman reported his observations on the development of a hypertrophic inflammatory synovitis associated with intraarticular adhesions.[3] Several investigators

have proposed an autoimmune basis for frozen shoulder.[6,19-21,47] Although some clinicians have reported a high incidence of human leukocyte antigen B27 in patients with frozen shoulder,[19] others have not confirmed this association.[58,91,107,115] In later studies, serum immunoglobulin A (IgA) levels were significantly lower in patients with frozen shoulder, and the immune complex and C-reactive protein levels were increased.[6,20,21] In general, however, sufficient evidence to support immunologic therapy has been lacking.

A relation to myofascial pain syndrome has been proposed. A syndrome of active trigger points about the shoulder, specifically within the subscapularis muscle, has been suggested as a possible cause of frozen shoulder syndrome.[116] *Trigger points* are defined as locally tender, self-sustaining, hyperirritable foci located in the skeletal muscle or its associated fascia. The trigger points are also characteristically related to a zone of referred pain when the trigger is stimulated. Once activated, perpetuating factors may be responsible for the chronicity of pain. Another characteristic of the myofascial pain syndrome is palpable bands of muscle fibers that undergo a local twitch response when the trigger point is stimulated with a snapping palpation.[12,113,124]

Travell and others theorized that the subscapularis trigger points exert an influence on the sympathetic vasomotor activity, leading to hypoxia of the periarticular tissues. It is further theorized that the hypoxia leads to a local proliferation of fibrous tissue about the shoulder capsule, resulting in the clinical picture of frozen shoulder syndrome.[81,116] A biochemical basis for frozen shoulder has been proposed. Lundberg, in his analysis of the capsules from patients with frozen shoulder, found an increase in glycosaminoglycans and a decrease in glycoprotein content. These biochemical changes in the capsule, however, are consistent with the process of fibrosis, and they may represent the effect of frozen shoulder, rather than its cause.[70,71]

Neurologic dysfunction has been postulated to be a cause of frozen shoulder syndrome. In 1959, Kopell and Thompson[61] proposed suprascapular compression neuropathy as a possible cause of frozen shoulder, but electromyography (EMG) and nerve conduction studies have not supported this theory. Others have suggested that frozen shoulder is a result of autonomic dysfunction and represents a form a reflex sympathetic dystrophy.[107] Sufficient evidence to support these hypotheses has not been provided.

Bunker et al. prospectively studied 50 patients with the diagnosis of primary frozen shoulder. These authors were able to identify increased serum lipid levels in these patients compared with those of age- and sex-matched control subjects. The fasting serum triglyceride and cholesterol levels were significantly elevated in the frozen shoulder group. Increased serum triglyceride levels have also been found in patients with diabetes as well as Dupuytren's disease, suggesting that hyperlipidemia may be the common thread that links these three disorders.[22,23]

Various endocrine disorders are associated with frozen shoulder. In particular, patients with diabetes mellitus manifest a much greater incidence of frozen shoulder than their nondiabetic counterparts. Bridgman found that the incidence of frozen shoulder in 800 diabetic patients was 10.8%, compared with 2.3% in 600 nondiabetic controls.[15] A second study identified abnormal glucose tolerance test results for 28% of patients with frozen shoulder, compared with 12% in age- and sex-matched controls with other rheumatologic conditions.[64] Frozen shoulder has also been reported to occur with increased incidence among patients with thyroid disorders,[13,35] as well as those with hypoadrenalism[122] or corticotropin deficiency.[24]

Trivial trauma has been postulated to be an important factor, particularly when it is followed by a prolonged period of immobilization.[29,100] This does seem to be the sequence of events in some patients who develop frozen shoulder. The association of frozen shoulder with major trauma to the shoulder or other parts of the upper extremity is recognized. The association with minor trauma that may be forgotten is difficult to document and may be overlooked.[26,77] Most patients who sustain minimal trauma, even when combined with a period of immobilization, do not develop frozen shoulder. This has led some investigators to conclude that there are some patients who possess a "constitutional" predisposition to develop a frozen shoulder. Support for this theory is provided by the significant incidence of bilateral frozen shoulders.[19,25,92,103,125]

The role of psychologic factors has been considered in the development of frozen shoulder. Some investigators have suggested that a certain personality structure, coupled with untoward life events and inappropriate responses to stress, may serve as a predisposing or precipitating factor for its development.[27,35,68,107] Coventry chose the term "periarthritic personality" to describe one component of a three-part theory on the pathogenesis of frozen shoulder in a group of patients with painful stiff shoulders. He observed that most patients had "a peculiar emotional constitution in which they were unable to tolerate pain, expected others to get them well, and refused to take any personal initiative in their recovery."[27] Other studies, however, have found no evidence for a characteristic personality disorder.[92,125] It would appear, therefore, that a specific periarthritic personality type is difficult to identify. The role of psychologic factors should be considered, at best, a secondary factor in the management of these patients.

Fibromatosis has also been implicated in the causation of frozen shoulder syndrome. The pathomechanics are believed to be found in fibrous tissue contracture formed in response to cytokine, lymphocyte, or monocyte products. Platelet-derived growth factor is a potent mytogenic polypeptide for mesenchymal cells. Immunocytochemistry was performed with monoclonal antibodies on the rotator ligaments excised from 12 patients with resistant frozen

shoulder. Bunker and Anthony report that the pathologic process is active fibroblastic proliferation accompanied by some transformation to a smooth-muscle phenotype (myofibroblasts). The fibroblasts lay down collagen that appears as a thick nodular band or fleshy mass. These appearances are reportedly very similar to those seen in Dupuytren's disease of the hand, with no inflammation and no synovial involvement. The contracture acts as a checkrein against external rotation, causing a loss of both active and passive movement.[22]

Frozen shoulder associated with a known underlying disorder is considered to be secondary, and this group includes intrinsic, extrinsic, or systemic disorders. Intrinsic shoulder abnormalities include rotator cuff tendinitis, rotator cuff tears, tendinitis of the long head of the biceps tendon, calcific tendinitis, and acromioclavicular arthritis. Extrinsic disorders, which represent pathologic conditions remote from the shoulder region, include ischemic heart disease and myocardial infarction,[79,125] pulmonary disorders including tuberculosis,[55] chronic bronchitis, emphysema,[111] tumor,[28] cervical disc disease and radiculopathy,[2,56,125] cerebral vascular hemorrhage,[14,16] previous coronary artery bypass graft surgery,[113] previous breast surgery, lesions of the middle humerus,[114] and central nervous system disorders, such as Parkinson's disease.[106] Systemic disorders represent generalized medical conditions that are known to occur in association with frozen shoulder. Such conditions and poor prognostic indicators include diabetes mellitus, hypothyroidism, hyperthyroidism, and hypoadrenalism.

Epidemiologically, the exact prevalence and incidence of frozen shoulder are not known, but the cumulative risk of at least one episode of frozen shoulder has been estimated to be a minimum of 2%.[25] It is most frequently found in patients between the fourth and sixth decades of life, and it is more common in women than men.[2] The nondominant extremity appears to be more commonly involved, with most reported cases being described as affecting the left side.[25,29,65] Bilateral involvement occurs in 6% to 50% of cases, although only 14% of these bilateral cases manifest simultaneously.[2,6,21,25,107] When a history of bilateral involvement is identified, the possibility of a constitutional predisposition should be explored.[3,25,107] The same shoulder is rarely involved again with adhesive capsulitis.[6,7]

There is significant controversy over the natural history of frozen shoulder relative to both objective and subjective outcomes. Historically, frozen shoulder has been touted as a condition for which "recovery is always sure and may be confidently expected."[26] Several investigators using a variety of treatment methods have reported that a high percentage of affected patients achieve full range of motion.[26,39,65] In addition, they have found complete or near complete symptomatic relief.[39,47] More recent investigators have questioned the early optimistic reports, finding measurable restriction at follow-up in 39% to 76% of patients[18,25,79,80,103] and persistent symptoms in up to 45%.[6,100]

The time course of adhesive capsulitis has been described as classically lasting 18 to 24 months.[6] Recent studies have challenged this commonly held belief. Reeves noted that the mean duration of symptoms was 30 months.[103] Patients describing themselves as functionally recovered tend to underestimate their loss of motion.[19] Reeves described some restriction in shoulder motion in more than 50% of patients in a 5- to 10-year follow-up, but functional impairment was identified in only 7%.[103] Clark et al. found that 42% of patients had persisting limitations of motion after 6 years of follow-up.[25] Binder et al., in a prospective study, noted that 90% of patients did not regain the minimum range of motion when matched for age and sex with a controlled group 6 months after diagnosis.[6] They also reported that 40% of patients failed to regain a minimum range of motion when matched for age and sex with a controlled group when followed for a minimum of 3 years. In a retrospective study, performed by Schaffer et al., of a carefully selected group of patients with frozen shoulder, almost half remained symptomatic many years after the onset of symptoms, and up to 56% had residual restriction in one or more planes.[111]

Despite the subjective and objective outcome of this disorder, there seems to be widespread agreement on the seeming lack of significant or frequent functional disability documented at cessation of treatment. Regardless of objective restriction or the presence of symptoms, few patients are reportedly functionally restricted to any significant degree.[6,25,66,103] The lack of correlation between subjective and objective findings has been noted consistently.[6,8,18,25,47,80] Symptomatic patients frequently have no measurable restricted range of motion in any plane. Conversely, those patients with the most significant motion restriction were often pain-free. Whether this is due to adaptation to such restriction or whether restriction in motion is unimportant for daily living activities is an unresolved issue. According to Neer, however, the presence of such restriction depends on the functional demands of the patient. Even in the active patient, the presence of 150 degrees of active elevation, 50 degrees of external rotation, and internal rotation to the eighth thoracic vertebra is probably sufficient for normal function.[82] In Schaffer et al.'s report of an older population whose functional demands were surely less than the aforementioned, the degree of restriction tolerated in any plane was certainly even greater. They stated that the preeminent importance of forward flexion and elevation in daily activities superseded the findings of restriction predominantly in the abducted and externally rotated positions, which resulted in little functional impairment.[111]

In general, the natural history of frozen shoulder is uncertain, and additional randomized, prospective studies are needed. Difficulty exists in performing these studies owing to the ethical dilemma of assigning patients to an untreated group.

CLINICAL EVALUATION

Frozen shoulder represents a disease process that is diagnosed with careful history and physical examination rather than with diagnostic tests. Patients often report a gradual onset of pain that often was initiated by a minor event. Common initiating events include reaching to put on a coat, reaching into the backseat of the car, or a minor tug on the arm. Pain can be anywhere from minor to severe in intensity and often exists for many months prior to presentation. Pain is usually present over the deltoid muscle with occasional pain that radiates into the forearm. Many patients experience a fullness or swelling in the upper arm with an occasional subjective tingling sensation. Pain that wakes them at night is often their primary complaint. Patients with this condition often report a gradual loss of shoulder function that is exacerbated with use. Overhead and behind the back activities become increasingly difficult to perform as motion is diminished with progressive scarring. The symptoms of frozen shoulder closely resemble those found in rotator cuff pathology. Careful physical examination needs to be performed to identify a frozen shoulder, especially in those patients who present with a magnetic resonance imaging (MRI) diagnosis of partial-thickness rotator cuff tear.

The physician also needs to take a careful history of related risk factors, especially diabetes mellitus, thyroid disease, cardiovascular disease, or cervical disease. The rate of frozen shoulder among diabetic patients is much higher than in the normal population, with bilateral presentation in as many as 77% of cases.[96] Patients who have taken insulin for more than 10 years have a significantly higher incidence of ongoing disability than other patients, despite treatment of the diabetes.

Often patients have undergone treatment for rotator cuff tendonitis with cortisone shots in the subacromial space and physical therapy with rotator cuff strengthening.

HISTORY

An integral component to the evaluation of a patient with a frozen shoulder is a careful clinical history. Patients typically report a vague discomfort in the upper arm and deltoid region that may be present for a protracted period of time before presentation. Often the symptoms start in an insidious fashion with minimal or no trauma. Other patients report a specific incident that they report as the inciting event. Common presenting complaints include pain reaching to put on a coat, reaching in the back seat of the car, or reaching out the car window at a drive-through. These events most likely represent the first recognition of the condition rather than the inciting event. Pain also may radiate down the arm into the forearm with a number of patients complaining of a vague tingling sensation.

Pain is a critical component to the frozen shoulder condition with the pain at night, pain with dressing and daily activities, and pain exacerbated with use. Often the intensity of the pain varies during the course of the disease. Early in the inflammatory phase, patients often complain about an intense burning pain compared to a dull fullness during the contracted stage. Functional deficits often become prominent as loss of motion occurs. Gradual loss of motion occurs as the condition progresses into this contracted phase. Activity overhead or behind the back becomes especially difficult to perform. Early in the course of the disease, the symptoms closely resemble those found in rotator cuff pathology. As the shoulder stiffens, there is a progressive loss of glenohumeral motion. The most significant loss of motion is usually with external rotation with a smaller loss of abduction and internal rotation. Sharp pain at the endpoint of restricted shoulder motion is the hallmark of frozen shoulder. Most patients complain about reaching, putting on a coat, or fastening a bra. Pain about the scapula is probably secondary to increased scapulothoracic motion attempted to compensate for the decreased glenohumeral motion.

The physician also needs to inquire about risk factors such as diabetes, thyroid disease, or cervical disease. Among diabetic patients, the risk of frozen shoulder is much higher than in the normal population, with bilateral presentation in as many as 77% of cases.[110] Frozen shoulder has been reported to affect 20% of patients afflicted with diabetes versus an incidence of approximately 5% in the general population. Diabetic patients have also been found to have poorer outcomes with treatment.[40]

Certain medications also have been associated with frozen shoulder. Protease inhibitors used to treat HIV have been reported to cause frozen shoulder. Barbiturates and antituberculosis agents have also been associated with frozen shoulder.[37]

PHYSICAL EXAMINATION

Physical examination is critical in the diagnosis of frozen shoulder, especially early in the disease when it is commonly confused with rotator cuff pathology. The physical examination should begin with a careful clinical inspection. The patient needs to be in a gown that allows exposure of both shoulders both in the front and the back. Swelling or erythema about the shoulder could represent infection as a cause of a painful, stiff shoulder. Inspection for atrophy, especially about the deltoid, could represent an axillary neuropathy or cervical radiculopathy as a cause of pain and loss of active motion. Scapular winging should always be noted, although compensatory winging can sometimes be difficult to differentiate from long thoracic nerve palsy. Masses about the shoulder could indicate a musculoskeletal tumor as the cause of a stiff shoulder.

Finally, careful palpation of the bones about the shoulder may localize an area of pain or crepitation from a fracture about the shoulder girdle.

A loss of active or passive range of motion of the glenohumeral joint is the clinical hallmark of frozen shoulder (Fig. 17-2). Careful assessment and recording of range of motion in all planes during each office visit are important to follow the progress achieved by the treatment employed. The examiner must be careful to identify and control compensatory motions to measure only pure glenohumeral motion. Patients with glenohumeral stiffness often exhibit relatively good motion secondary to increased scapulothoracic motion or trunk lean. Also, the limits of motion caused by firm endpoints need to be measured rather than muscular guarding caused by pain. Pain is usually absent within its free range and only present at the extremes of motion.

Active shoulder elevation is measured in the plane of the scapula, with the patient seated, and is referenced to the patient's thorax, not to a line vertical to the floor. Internal rotation is measured behind the back along the lumbar or thoracic vertebrae. Active external rotation is measured with the arm at the side and in 90 degrees of abduction. Passive motion should be evaluated with the scapula fixed by placing the patient supine on the examination table. This restricts excessive scapulothoracic movement and trunk tilt, thereby providing a more accurate assessment of glenohumeral motion. Passive forward elevation, external rotation with the arm at the side, and internal and external rotation at 90 degrees of abduction are measured. A firm endpoint is often appreciated with pain at the extremes of motion. There is often no single capsular pattern seen in patients with frozen shoulder.[109]

A complete shoulder examination should include palpation about the acromioclavicular joint, sternoclavicular joint, and anterolateral acromion over the rotator cuff insertion. Identifying concomitant rotator cuff pathology can be a difficult diagnostic dilemma. Impingement sign, Hawkins' sign, and Jobe's test are often unreliable secondary to the capsular irritation caused by the synovitis associated with a frozen shoulder. The abdominal compression test and lift-off test to identify subscapularis pathology are often limited by the loss of active internal rotation. Any shoulder examination would not be complete without an evaluation of the cervical spine to identify loss of motion,

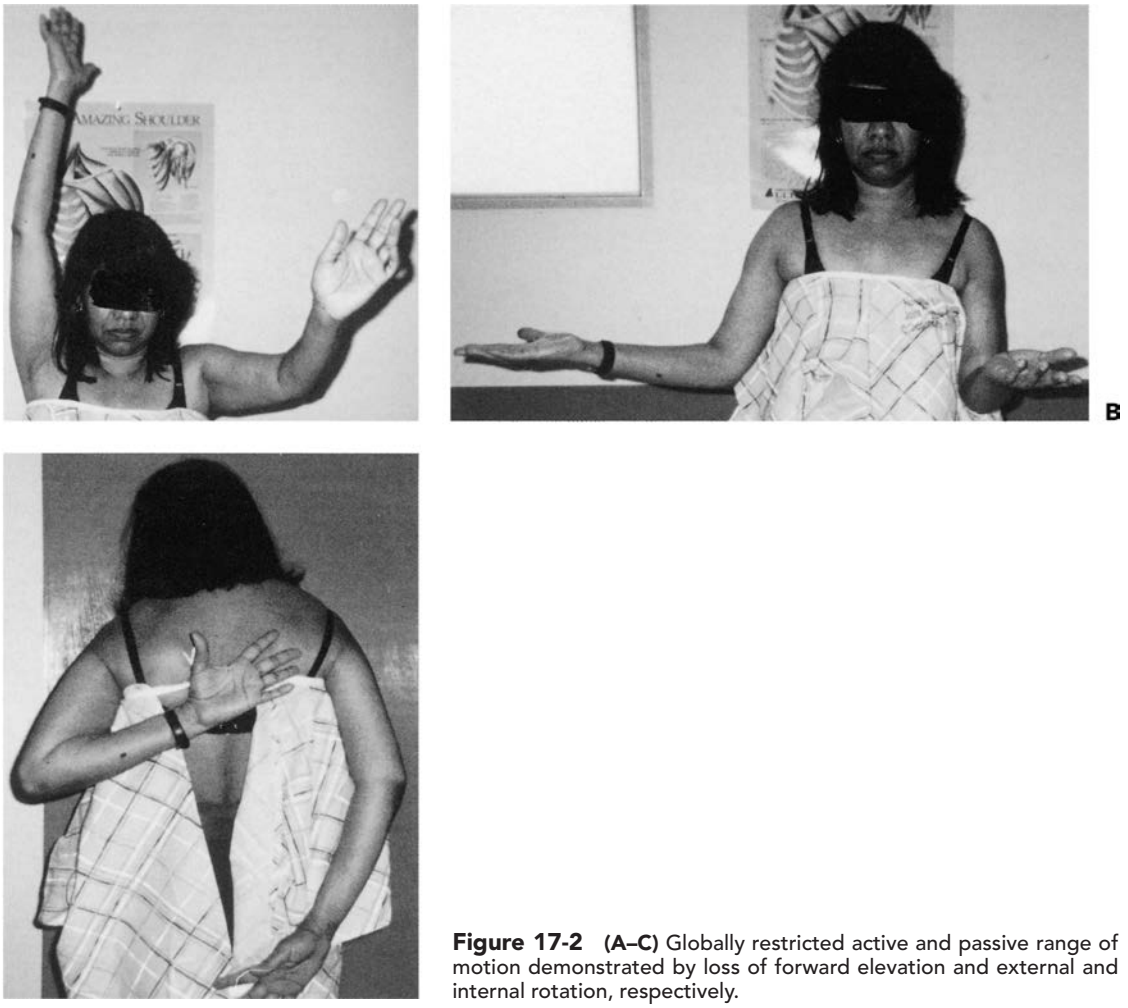

Figure 17-2 **(A–C)** Globally restricted active and passive range of motion demonstrated by loss of forward elevation and external and internal rotation, respectively.

pain, or radicular symptoms that may identify concomitant cervical disease. A neurologic examination may help to identify a brachial plexus palsy or reflex sympathetic dystrophy.

Recognition of the different patterns of motion loss is important in determining the cause as well as planning treatment strategy. Motion loss often correlates with the location of the capsular contracture. Limitation of external rotation with the arm abducted is usually associated with scarring of the anteroinferior region of the capsule. Limitation of external rotation with the arm in adduction is associated with contracture of anterior and superior capsule from the rotator interval to the middle glenohumeral ligament. Loss of the subscapularis recess is associated with this contracture. Limitation of internal rotation in adduction and abduction is associated with scarring in the posterior capsule. Extraarticular contracture in the subdeltoid space can cause global motion loss in cases of postsurgical contracture.

A helpful adjuvant to the history and physical examination is the lidocaine injection test. If loss of motion is felt to be secondary to pain from a rotator cuff tear, an injection of 10 mL of 1% lidocaine into the subacromial space can help eliminate pain-inhibited motion. Loss of motion secondary to true capsular contracture will not be improved with a lidocaine injection.

IMAGING STUDIES

A complete set of radiographs should be obtained in all cases of frozen shoulder. Anteroposterior films in internal and external rotation and supraspinatus outlet and axillary views should be obtained to exclude other disorders causing loss of motion. The axillary view will help exclude a locked dislocation or fracture about the glenohumeral articulation. A locked posterior dislocation can present as a loss of external rotation without an adequate axillary radiograph. Radiographs are also important to rule out destructive changes within the bone as seen with primary or metastatic bone tumors or infectious processes. A recent report described five case reports of malignant shoulder girdle tumors misdiagnosed as a frozen shoulder. The cases cited included Ewing's sarcoma in a 60-year-old, malignant fibrous histiocytoma in a 42-year-old, chondrosarcoma of the glenoid in a 50-year-old, and metastatic squamous cell to the supraspinatus muscle belly.[99] Most tumors about the shoulder have a soft tissue mass or characteristic radiographic changes; however, approximately 10% have normal radiographs. Primary chest wall tumors can also present as a painful stiff shoulder. In a high-risk patient, the lung should be considered.[28]

An evaluation of the glenohumeral articulation looking for inferior osteophytes or joint space narrowing will help exclude degenerative arthritis as a cause of decreased range of motion. Primary frozen shoulder usually has unremarkable radiographs, although disuse osteopenia is possible.

Technetium bone scanning often exhibits increased uptake about the proximal humerus. Findings of increased uptake, although nonspecific, are probably secondary to hypervascularity. Wright and Haq noted a favorable association between an increased pertechnetate uptake about the shoulder and rapid response to corticosteroid injection.[125] Binder and associates observed that over 90% of their patients had an increased uptake on diphosphonate scans, with 29% having more than a 50% increase in uptake compared with the opposite shoulder. These authors, however, could not find any association between the bone scan finding and the duration of symptoms, the initial severity of the disease, the arthroscopic findings, or the eventual recovery.[8]

Shoulder arthrography for the diagnosis of frozen shoulder was described by Neviaser, which gave a better understanding of the underlying joint pathology. He described the combination of decreased joint volume, an irregular joint outline, and variable filling in the bicipital tendon sheath.[89] The reduction in the shoulder joint capsule capacity to less than 10 to 12 mL and the variable lack of filling of the axillary fold and subscapular bursa are the current accepted characteristic findings (Fig. 17-3).[1,48,69,87,89] Binder and coworkers noted that, although arthrography is useful in the diagnosis of frozen shoulder, arthrographic findings do not indicate the type of onset (i.e., primary or secondary) or the rate or extent of recovery.[8] Other authors confirm that such findings also have not had any productive value in terms of disease severity or prognosis.[53,69]

Arthrography has also been used to document tearing of the joint capsule during manipulation under anesthesia. Lundberg found that tears of the capsule allowed dye to escape into the extracapsular space but found no tears of the rotator cuff following manipulation under anesthesia.[71]

MRI reports are often read as normal; however, radiologists continue to explore their ability to diagnose a frozen

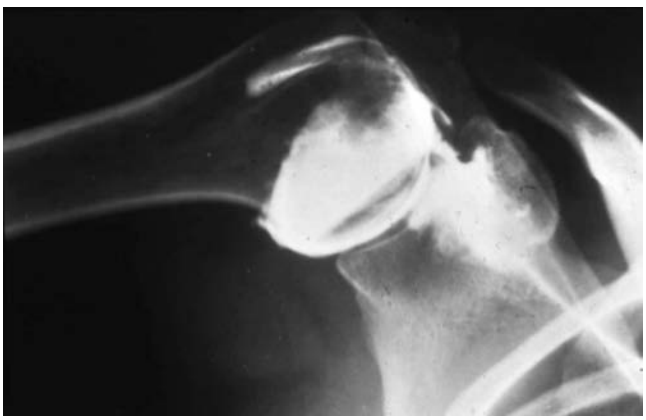

Figure 17-3 Arthrogram in a patient with a frozen shoulder showing absence of the inferior capsular pouch and marked decrease in the capsular volume.

shoulder with this modality. Significant thickening of the coracohumeral ligament and rotator interval can be seen on MRI, which is correlated with what is seen at arthroscopy. The inferior capsule has not been found to be thickened despite the decreased volume of the recess. Complete obliteration of the subcoracoid triangle sign between the coracohumeral ligament and coracoid process was found to be 100% specific for frozen shoulder but only 32% sensitive.[79] Others have recommended using MR arthrography to help in identifying frozen shoulder. Lee et al. found significant increase in the thickness of the inferior capsule and a decreased filling ratio of the fluid-distended axillary recess when comparing controls to patients with arthroscopically proven adhesive capsulitis.[62] The practical use may be limited by the fact that the procedure depends on distending the joint fully without rupturing the capsule. MRI is currently not useful to diagnose frozen shoulder but is useful in identifying other causes of frozen shoulder, such as infection or tumor, which may mimic a stiff shoulder. It is also useful to identify concomitant pathology such as rotator cuff tears.

LABORATORY STUDIES

Routine laboratory studies are usually normal in a patient with frozen shoulder. The erythrocyte sedimentation rate may be elevated in as many as 20% of patients, which can make this test difficult to use as a way to differentiate from a shoulder infection. A complete blood cell count can be helpful in these situations, although it may be normal early in the infection or in an immunocompromised patient. A chemistry profile can be useful to identify diabetes mellitus, which is a common cause of frozen shoulder. Rheumatoid factor and antinuclear antibody may be helpful to identify an underlying inflammatory disease.

There remains ongoing controversy about the significance of the reported increased levels of immune complexes in patients with frozen shoulder.[19,20,57] Bulgen and associates reported 40 patients with clinical signs of frozen shoulder who had shown an increase in immune complex levels including C-reactive protein and impaired cell-mediated immunity.[20]

TREATMENT

Options

The overall goal in the treatment of patients with frozen shoulder is to relieve pain and restore motion and function. Ideally, efforts should be directed toward prevention of this syndrome by identifying the patient at risk and initiating early intervention. Early in the course of the disease, patients may only present with vague pain characterized by pain with terminal stretch. The most important point to consider is to avoid the misdiagnosis of other shoulder disorders that may require surgery. Surgery addressing other pathology may dramatically worsen the pain and stiffness of frozen shoulder.

Most patients present with many months of pain that has progressed to significant loss of motion. The clinician must design a treatment plan that is individualized and based on the severity and chronicity of the patient's symptoms, as well as previous therapeutic efforts. Treatment may have to be modified based on the patient's clinical response and perceived disability. Some patients tolerate a protracted conservative treatment plan with range-of-motion exercises, while others necessitate a more aggressive approach.

As in other medical conditions for which the pathophysiology is poorly understood, many different forms of treatment are used. The first objective in the treatment of any patient with frozen shoulder is to relieve pain so as to allow the patient to perform the appropriate exercise program to improve motion and function. Pain-relieving methods include nonsteroidal antiinflammatory medications, corticosteroid injections, or transcutaneous electrical nerve stimulation (TENS). The routine use of narcotics should be avoided because of the protracted course of the disease and risk for dependency. Nonsteroidal antiinflammatory medications can be effective, but no controlled studies to document their efficacy have been performed.[31,52,104] Oral corticosteroids have been recommended, but their exists little evidence to support their routine use.[7,10,11,33,85] One randomized, double blind placebo-controlled trial of 50 patients treated for 3 weeks with 30 mg of oral prednisolone demonstrated a short-term benefit for 3 weeks in pain relief and range of motion, which was equal to placebo at 12 weeks.[17]

Intraarticular injections are a helpful adjuvant to relieve pain in the inflammatory or painful phase of frozen shoulder. This may allow patients to participate in their rehabilitation protocol. Hollingworth reported 50% improvement in range of motion in 26% of cases.[49a] The ability of the physician to adequately inject the joint may limit the effectiveness of the injections.[105] In one study, a technically satisfactory arthrogram could not be achieved in 12% of patients.[121] The use of intraarticular injections has theoretical benefits to decrease the synovitis associated with a frozen shoulder, but, in general, the evidence is equivocal. Patients with significant pain and capsular irritation with terminal stretch may benefit from an intraarticular injection. However, steroid injections have not been shown to improve the rate of return of shoulder motion.[71,101]

Nonoperative Treatment

Patients with frozen shoulder should be placed on an exercise program with the aim of maintaining and regaining range of motion (Fig. 17-4). Indications for treatment of

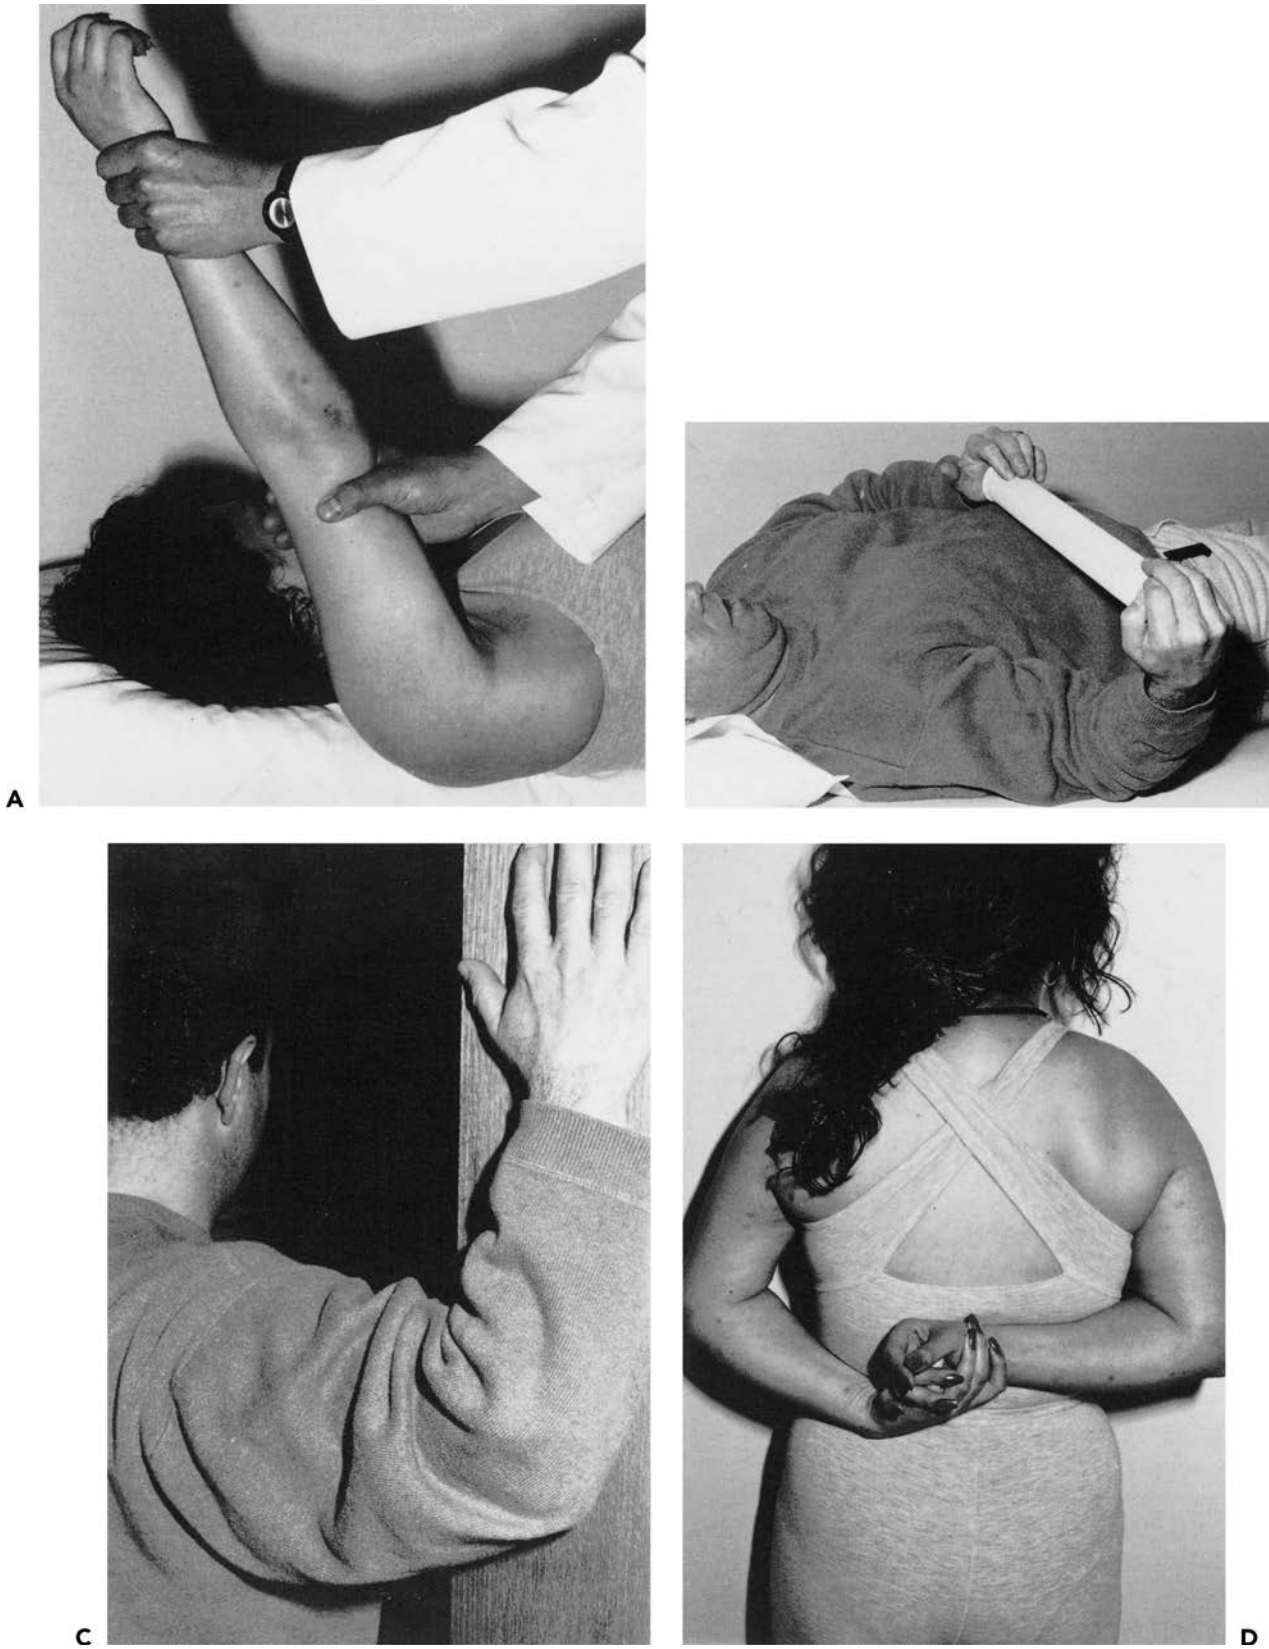

Figure 17-4 **(A–D)** Passive stretching exercises performed for overhead elevation, external rotation at side, 90 degrees of abduction, and internal rotation behind back.

the frozen shoulder in general are based on the chronicity and cause of the stiffness. Nonoperative treatment is indicated for those primary or secondary frozen shoulders with stiffness less for than 6 months and or no previous treatment. Each patient should begin an active assisted range-of-motion exercise program complying with gentle, passive, stretching exercises. These exercises should be performed four to five times per day, including forward elevation, internal and external rotation, and cross-body adduction. They can be performed standing or sitting, but are most readily performed in the supine position. It is most important to perform four or five short sessions per day, lasting 5 to 10 minutes, rather than one long session, because the shoulder will become stiff again in between each session. It is important to perform these exercises gently, but it needs to be stressed that at each session the arm should be pushed slightly past the point of pain; otherwise, no progress in the range of motion would be expected. Forward elevation may be assisted by using the opposite arm or a pulley to pull the arm up over the head. External rotation is aided with a cane while the patient is lying supine and holding the arm at the side, resting the elbow on a pillow. Internal rotation is performed by pulling the arm up behind the back with the assistance of the opposite arm or a towel. Using the opposite extremity, the affected limb is stretched to its limit and slightly past it, held in place for a count of 5 to 10 seconds, and then brought to a resting position. Periods of rest in between each session are necessary to relieve muscle tension and pain.

To encourage continued exercises, daily bar charts are helpful to document progress because small improvements in range of motion might otherwise be unnoticed by the patient, especially those who are easily discouraged. Local modalities consisting of heat at the initiation of the exercise session and ice at its conclusion may be helpful to increase flexibility and reduce inflammation, respectively. These modalities are not curative, but can aid in decreasing discomfort, which will allow greater ease in performing the exercises.

Forward elevation of the shoulder is performed with the extremity in the plane of the scapula as it is grasped either at the wrist or behind the elbow and pushed upward gradually. This is best performed supine to keep compensatory factors such as trunk tilt to a minimum. A pulley can also be used to accomplish this motion, which is best performed seated with the back of the patient to the pulley. Similarly, cross-body adduction is performed as the affected extremity is pulled across the chest toward the contralateral shoulder. This maneuver assists in stretching the posterior portion of the capsule, which is of utmost importance in obtaining internal rotation. External rotation is performed supine with the elbow close to the body. A stick is held in the hand with the elbow flexed to 90 degrees and is used to rotate the affected extremity away from the body. Internal rotation is performed by pulling the wrist of the affected extremity into extension first behind the back, then bringing the hands up between the shoulder blades. It may also be assisted with a towel or by grasping a door handle behind the back and performing a deep knee bend. In the early stages of the exercise program, one should start with simple stretching, such as Codman's pendulum exercise, to gently loosen and relax the shoulder. The patient bends at the waist while balancing with the good arm on a firm surface. This allows the affected arm to swing with gravity in a circular motion with the hand turned inward and outward. Overly forceful stretching exercises are contraindicated in the early phases of the frozen shoulder syndrome and may exacerbate symptoms. Constant reassurance from the physician is necessary to promote continued compliance.

The physical therapist plays a major role as a teacher, explaining to the patient that it will take time to resolve symptoms and that pain will decrease as motion improves. Whenever possible, the therapy program should be performed under the supervision or in addition to a physical therapist on a weekly basis. The patient should be instructed that the success or failure of the therapy largely depends on his or her compliance in performing the exercises as directed, not only with the therapist but four or five times daily on his or her own. In a loosely supervised physical therapy program, most patients will improve with time, although it may take months. Thus, in most cases, more invasive treatment is generally not required. Griggs et al. found 90% satisfaction with nonoperative treatment, with only 7% requiring manipulation or capsular release. However, despite significant improvements in patient satisfaction, pain, and range of motion, there was still a significant difference when compared to the unaffected shoulder.[40]

Capsular Distention or Brisement

The method of capsular distention, referred to as distention arthrography or brisement, has been advocated as a means of expanding the contracted capsule.[1,34,36,51,69,94] This procedure involves injecting fluid into the glenohumeral joint in sufficient enough volume to generate pressures high enough to cause capsular disruption that is evidenced by a significant decrease in the pressure necessary to continue injection. This procedure has been performed in a variety of ways: with injection of contrast as part of an arthrogram (Fig. 17-5)[36,69,94,103]; with injection of saline and local anesthetic, such as hydraulic distention[34,42]; and arthroscopically.[51] As with all other methods of treatment for frozen shoulder syndrome, the reported results have been variable and difficult to interpret because the procedure often is combined with other procedures such as manipulation or corticosteroid injections, and the experience has been limited. The addition of these variables makes it difficult, if not impossible, to compare reports. Some have found that capsular distention was not

Figure 17-5 Distention arthrography with disruption of the inferior pouch and leakage of contrast from the capsule.

as effective in the face of advanced disease with significant stiffness.[1,117] Vad et al. recommended performing capsular distention for those patients who had failed physical therapy and were in Hannafin stage II disease, with early loss of motion before the capsule becomes thickened.[117]

Rizk and Pinals examined 16 patients with adhesive capsulitis of the shoulder treated in an open trial of capsular distention with intraarticular injection of 30 mL of fluid containing 8 mL of 1% lidocaine, 2 mL of corticosteroid, and 20 mL of radiocontrast material. A capsular tear during arthrography occurred in all cases, usually at the subscapular bursa or subacromial bursa, as documented by extravasations in either of these areas. Rupture at the distal bicipital sheath occurred in two patients and was not associated with pain relief. Thirteen of 16 patients experienced immediate pain relief and increased shoulder mobility. This improvement was maintained over a follow-up interval of 6 months. Given these results, the authors felt that disruption of the contracted capsule by hydraulic distention seemed to be the mechanism for achieving symptomatic relief in adhesive capsulitis.[108]

Manipulation under Anesthesia

Manipulation under anesthesia has been the mainstay of operative treatment of frozen shoulder.[47,48,49] It results in a rapid return of shoulder motion, although some authors disagree about whether it shortens the disease course.[71,80] The timing of manipulation remains controversial, but lack of improvement in motion after 3 to 6 months of physical therapy is often cited. It is important to emphasize that operative treatment of primary adhesive capsulitis should not be considered while the patient is experiencing the severe pain seen in the inflammatory phase of frozen shoulder. Despite the initial improvement, patients may experience quick deterioration of motion secondary to capsular injury during the painful inflammatory phase.[88] It is important to wait until pain is present only at the extremes of range of motion.

Manipulation can be performed either under general anesthesia, regional anesthesia, or both. The addition of regional anesthesia (i.e., scalene block) allows the patient to awaken from the procedure without pain and to observe the recovered motion. The block may be administered as a single long-acting block or by placement of an indwelling interscalene catheter.[97] If a single injection is used, a long-acting agent such as bupivacaine should be used, which will provide approximately 12 hours of anesthesia. The interscalene block has the added risk of complications associated with the block, which can include pneumothorax, peripheral paresthesias, brachial plexus palsies or neurapraxias, and hoarseness. There is also the risk of the block being ineffective for intraoperative or postoperative anesthesia. Therefore, intraarticular pain catheters using bupivacaine are used by some with reported excellent pain relief without motor blockade.[126]

Manipulation should be performed in a gentle, controlled fashion with the patient in a supine position to control for scapular mobility. A gentle forward flexion maneuver is performed by grasping the humerus close to the axilla to avoid injury by decreasing the lever arm of the humerus. This maneuver usually results in rupture of the inferior portion of the joint capsule[87,89] (Fig. 17-6). External rotation is increased by applying firm external rotation force with the arm close to the body and in abduction. Great care must be employed because of the risk of torquing the humerus and causing a spiral fracture. If

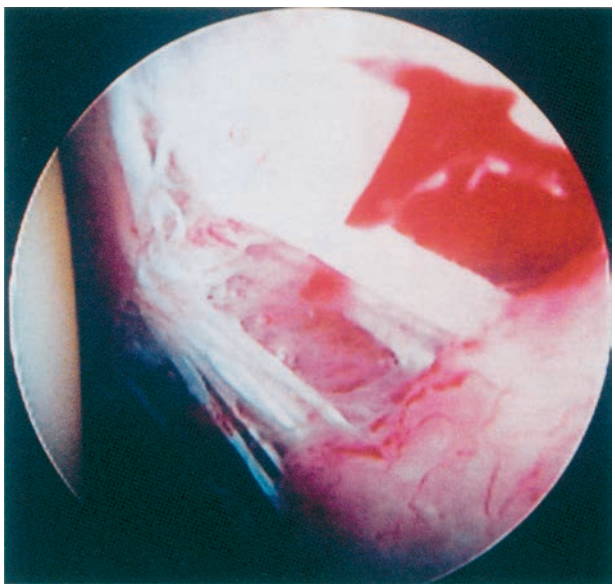

Figure 17-6 Tom labrum and capsule in inferior axillary pouch postmanipulation.

release does not occur, an alternative method to obtain external rotation should be employed. Internal rotation is increased by stretching the arm in internal rotation with the arm in abduction.

Attention must be placed on gentle manipulation. If a firm endpoint is felt, excessive pressure should not be applied because of the risk of fracture. If manipulation under anesthesia fails to restore symmetrical motion equal to the opposite side, converting to an arthroscopic release should be considered.

Complications of manipulation are best avoided by gentle, controlled pressure. Humeral fractures, glenohumeral dislocation, rotator cuff tears, and radial nerve injuries have been reported. Manipulation should be avoided in the elderly, osteoporotic patient with high risk of fracture as well as those with reflex sympathetic dystrophy. Manipulation is also ill advised in the patient with stiffness secondary to previous surgery or fracture with risk of disruption of the soft tissue repair. Loew et al. evaluated 30 patients with an arthroscope after a manipulation under anesthesia to evaluate for intraarticular lesions. They identified four superior labral anterior and posterior (SLAP) tears, three partial-thickness subscapularis tears, three anterior labral detachments, and one small osteochondral defect in the anterior inferior glenoid.[67]

Postmanipulation rehabilitation is of paramount importance to maintain the motion gained. In the outpatient setting, physical therapy is begun before discharge or the following day. Encouragement of removing the sling after the block has resolved and performing passive range of motion and active assisted range of motion with a home pulley is recommended three to four times per day. Continuous passive motion machines have also been used after manipulation, but there has been no long-term, controlled studies to verify their efficacy.

The use of corticosteroids with manipulation under anesthesia has also been debated. Many feel injection after manipulation allows less pain after surgery with ease of performing range-of-motion exercises. However, efficiency of corticosteroids is debated. A randomized study comparing manipulation with and without corticosteroid injection showed no significant difference.[60] A prospective clinical study was performed by Bulgen and coworkers examining the evaluation of three treatment regimens for frozen shoulder, including intraarticular steroids, mobilization, and ice therapy as compared with no treatment at all. In this prospective study of 42 patients followed for 8 months, the authors stated that there was little long-term advantage in any of the treatment regimens, but that the steroid injections may have been of benefit for pain and range of movement in the early stages of the condition.[18]

Manipulation of the shoulder has been advocated as a safe and effective means of enabling these patients to return to functional motion about the shoulder area.[30] Haggart and coworkers looked at 97 patients treated with manipulation of the shoulder.[41] They found that 95% had excellent or good results with 4 to 9 years of follow-up. Hamdan and Al-Essa evaluated 100 patients with frozen shoulder treated with manipulation alone or with methylprednisolone or a large volume of saline followed by physiotherapy. Their findings showed improved results with manipulation under anesthesia combined with a large volume of saline.[43] Harmon reported 400 manipulated shoulders on three separate follow-up studies.[45] He found that there was full painless motion in 64% to 94% of the patients. In a study by Hill and Bogumill, 9 of 12 (75%) of the patients with frozen shoulder syndrome had painless full range of motion of the shoulder at the time of follow-up postmanipulation, whereas 3 of 12 (25%) continued to complain of minimal aching about the shoulder joint after vigorous activity, but did not feel that this was impairing their ability to function.[49] All of the patients felt they were able to perform satisfactorily at their job, during activities of daily living, and during recreational activities. These authors stated that manipulation was found to be a safe means of treating adhesive capsulitis and significantly shortened the course of the disease. A higher incidence of failure was found among diabetic patients with frozen shoulder.[43]

Arthroscopic Capsular Release

If manipulation under anesthesia fails to restore symmetrical motion or if manipulation is felt to be deleterious, an arthroscopic capsular release should be considered. A controlled release of contracted tissue without the risk of fracture or injury to normal structures is a significant advantage. Arthroscopy also provides diagnostic information on concomitant disorders such as labral tears, chondromalacia, biceps pathology, rotator cuff tears, large anterolateral acromial spurs, or calcium deposits. Arthroscopic release is also beneficial for postsurgical contracture because it allows precise, selective capsular release of intraarticular contracture as well as subacromial and subdeltoid scar tissue. It also allows more immediate, aggressive range of motion than after open release.

The operative technique involves three basic components: **anesthesia;** preferably interscalene block with or without general anesthesia; and **manipulation** of the shoulder performed either before, during, or after the **arthroscopic release**. The procedure can be performed in the beach-chair position, which allows exposure to both anterior and posterior portals and allows for the free manipulation of the arm. A lateral decubitus position is preferred by some surgeons. In a cadaver study, the axillary nerve was found to be the furthest from the glenoid with the arm in abduction and external rotation. The nerve is at greatest risk the closer one gets to the humeral head at the 5 to 7 o'clock position.[54] A careful assessment of range of motion in all planes before and after treatment is documented. A blunt trocar is used to enter the joint through a

standard posterior viewing portal and carefully sliding over the humeral head owing to joint contracture. Care should be taken to avoid cartilage injury or inadvertent entrance into the humeral head in the contracted shoulder. To increase joint volume, a gentle manipulation can be performed prior to insertion of the trocar. A blood-filled joint is encountered after manipulation and needs to be lavaged prior to inspection of the joint. An anterior portal is made with a spinal needle localization between the biceps and subscapularis tendons. An outflow cannula is useful to allow fluid flow and to prevent fluid extravasation onto the operating room floor. A systematic inspection should be undertaken to identify synovitis and contracted tissue as well as to identify ruptured structures after manipulation. A complete evaluation of the joint may not be possible until after release owing to the contracted volume of the joint. The biceps tendon and superior border of the subscapularis tendon should be identified first. A hooked electrode is introduced through the anterior portal and release of the rotator interval is performed from the upper edge of the subscapularis tendon to the biceps tendon. The thickened interval is released full thickness until the overlying conjoined tendon fibers are seen running longitudinally from superior to inferior (Fig. 17-7). The rotator interval division releases the coracohumeral ligament and anterosuperior capsule, which often inhibits external rotation with the arm at the side.

The anterior capsule over the subscapularis tendon is released next to reopen the subscapularis recess. Care must be taken to divide the capsule but preserve the underlying tendon and muscle belly. Significant contracture of the middle glenohumeral ligament is often encountered with obliteration of the recess and significant loss of external rotation. The release proceeds from superior to inferior with the depth marked by the rolled border of the subscapularis tendon and muscle fibers. This release is carried down to the anterior band of the glenohumeral ligament. The axillary nerve is certainly a concern inferiorly. The teres minor branch of the axillary nerve is found on average to be only 12.4 mm from the glenoid rim at the 6 o'clock position.[98] Performing the release close to the glenoid rim (~1 cm) decreases the likelihood of encountering the axillary nerve. The subscapularis muscle also acts as a buffer in the adducted position, which is one reason the beach-chair position is advantageous. Capsular scissors to separate the capsule from the underlying tissue is performed by some surgeons, while others use electrocautery using a hooked probe. Avoidance of muscle relaxation during use of electrocautery can be helpful in identifying when the nerve is near. Use of a posterior–inferior portal for the cutting instrument while viewing from either the standard posterior portal or anterior portal will allow greater ease of cutting the inferior capsule. Berghs et al. reviewed 154 patients with primary frozen shoulder, of which 25 underwent arthroscopic capsular release. They demonstrated dramatic improvements in pain and range of motion within 2 weeks of the procedure in 88% of the patients, which did not deteriorate over a 1-year follow-up. The patients who did poorly early in the postoperative rehabilitation also did poorly long term. In this study, the authors did not release the inferior capsule arthroscopically, but with a manipulation to avoid injuring the axillary nerve.[5]

The superior capsule is released above the glenoid rim until the underlying supraspinatus muscle belly can be seen. The release is carried from the rotator interval release to the posterior portal. A restriction in cross-body adduction and internal rotation generally indicates further constriction in the posterior capsule, warranting posterior capsular release. In these cases the viewing and working portals are switched and a posterior capsular release is performed near the rim until the infraspinatus muscle belly is seen. The arthroscopic release of the posterior capsule must be performed about 1 cm from the glenoid rim to prevent dividing the infraspinatus tendon.

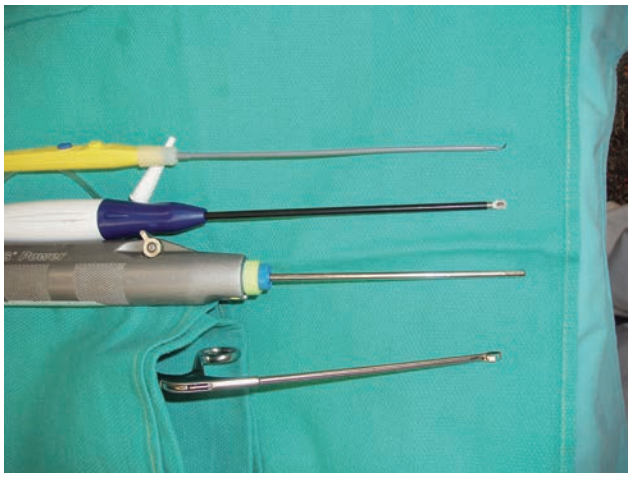
A small subset of patients may have an isolated posterior capsular contracture characterized by motion loss primarily limited to internal rotation, cross-chest, or horizontal adduction and flexion, with relative preservation of external rotation. This type of posterior capsular contracture has been implicated in impingement-type pain and may result in non–outlet-type impingement caused by increased anterosuperior translation during shoulder elevation and internal rotation. This condition is treated with posterior capsular release to restore lost motion and normal kinematics.[120]

Postoperative rehabilitation begins with immediate continuation of the range-of-motion exercises. Demonstrating the postoperative range of motion to the patient in the recovery room with the block in place is helpful to the patient's psyche. The patient is encouraged to perform the range-of-motion exercises three to four times per day. The sling is removed on the first postoperative day and the arm is used for daily activities. Any lifting, pulling, or pushing is avoided.

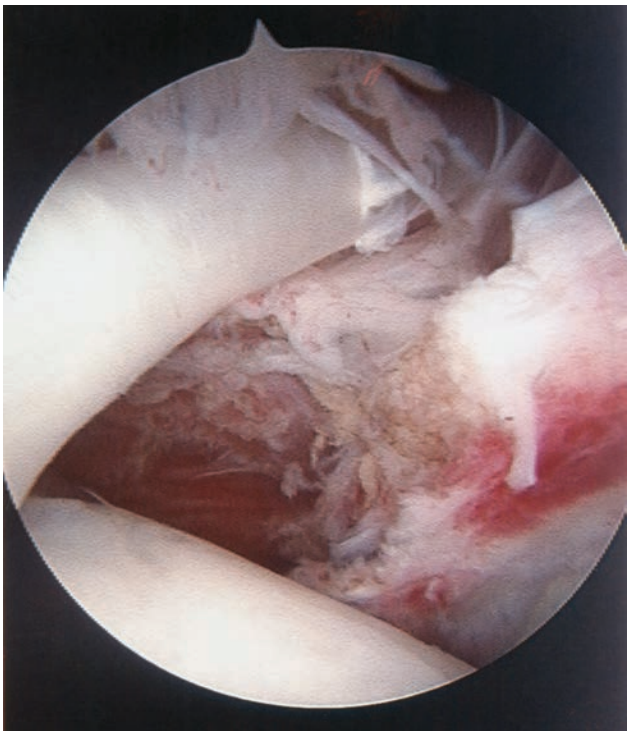
Arthroscopic capsular release has also been shown to increase range of motion in patients with secondary frozen shoulder seen after a previous operation or fractured shoulder.[50] Patients with postoperative frozen shoulder often have an extensive subacromial scar that can be resected arthroscopically. The scar is best excised with the scope brought in from a lateral portal and the shaver brought in posteriorly. Great care needs to be taken to protect the previous rotator cuff repair by keeping the open portion of the shaver at an angle to the tissue.

Open Release

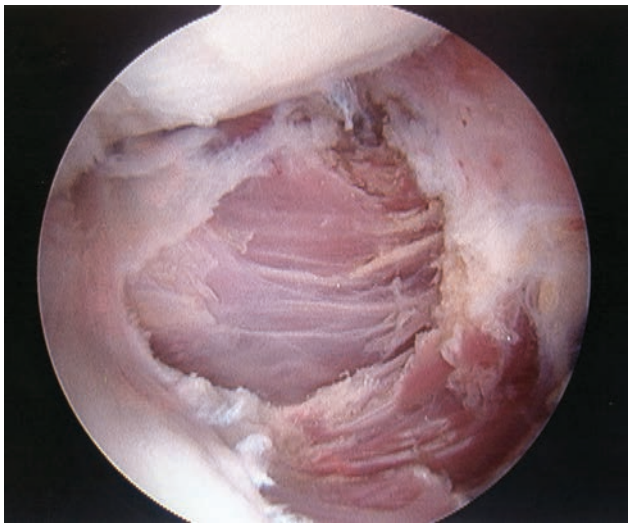
Open surgical release is reserved for those patients for whom manipulation or arthroscopic release does not allow them to regain range of motion or for patients in



A

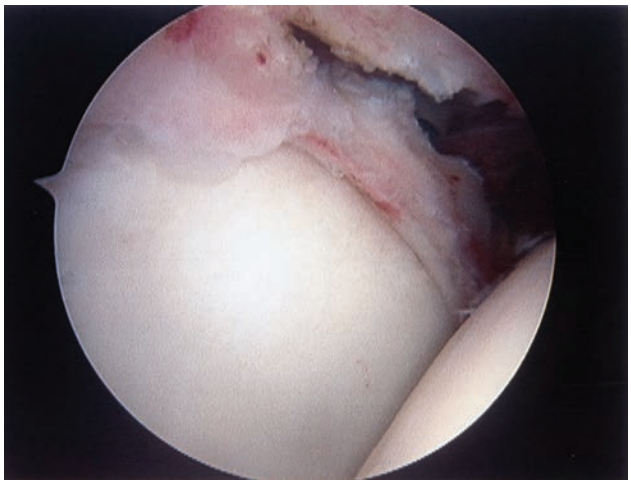


B



C

D



E

Figure 17-7 **(A)** Instruments used for arthroscopic capsular release. **(B)** Intraarticular view of the anterior superior release. **(C)** Release of the inferior capsular pouch, which is often performed using the posterior inferior portal **(D)** and the posterior release **(E).**

whom the adhesions are primarily extraarticular. Frozen shoulder in the setting of prosthetic arthroplasty is best done by open surgery. In most cases of severe stiffness after arthroplasty, prosthetic malposition may also be a factor and open release alone may not be sufficient. Previous open repairs, especially involving the subscapularis tendon, may have scar tissue that may be difficult to release from a purely arthroscopic technique. In general, the goal of this procedure is to release contracted structures so that the range of motion can be increased while maintaining

glenohumeral stability. The advantage of open surgical release is that it can free up both sides of the joint with less risk to soft tissue or bony injury.

Open surgical releases generally have been successful, but experience and reports of large series have been limited.[59,73,74,84,86] The major advantage of this procedure is that it offers direct visualization of the structures undergoing release or lengthening. However, disadvantages include increased postoperative pain affecting ability to perform postoperative exercises as well as the risk of disruption of any lengthened tissues (i.e., subscapularis tendon). The structures released include subacromial and subdeltoid adhesions,[59,96] the coracohumeral ligament and rotator interval,[59,63,84,85,96] circumferential perilabral capsular release, and subscapularis release and lengthening.[7,94]

After induction of general and/or interscalene block anesthesia, a deltopectoral approach is employed for an open release of adhesions between the deltoid, acromion, coracohumeral ligament, coracoid, and strap muscles from the underlying rotator cuff. First, adhesions between the deltoid and the humerus are released either sharply or bluntly. Great care must be undertaken to protect the axillary nerve on the back side of deltoid approximately 3 cm distal to the acromion. The dissection is made easier with the shoulder in the abducted position, which allows the deltoid to become lax and more easily retracted. Dissection is started lateral to the coracoid and conjoined tendon to protect the axillary nerve. Internal rotation of the arm while gently retracting the deltoid muscle will allow release of the subdeltoid adhesions in an anterior to posterior manner until the deltoid can move freely over the proximal humerus when the arm is rotated. Within the subacromial space, the coracoacromial ligament should be incised with electrocautery and the extensive scar in the subacromial space excised. Care must be taken to identify the underlying rotator cuff and protect it.

Dissection deep to the conjoined tendon is performed next, with the surgeon being careful to use a combination of blunt and sharp dissection to protect the neurovascular structures. A plane can usually be developed above the subscapularis and beneath the conjoined tendon and a retractor placed to protect the neurovascular structures.

The coracohumeral ligament and rotator interval are next released by dissecting the supraspinatus and subscapularis from the coracoid process. The interval between the tendons is released sharply from the humerus to the coracoid.[84,86,96] A gentle manipulation can be performed to see if full motion can be achieved. If external rotation is still limited, the subscapularis tendon and anterior capsule need to be addressed. This can be achieved by splitting the subscapularis or by performing a tenotomy from the lesser tuberosity and sharply developing the plane between the muscle and the capsule, followed by excision of the capsule while protecting the subscapularis. Another technique involves a coronal Z-plane lengthening, where a vertical incision is made in the superficial fibers of the tendon at its insertion on the lesser tuberosity. The subscapularis is then separated from the underlying remaining tendon and capsule and reflected medially. The superficial half of the tendon remains attached to the muscle, with the remaining deep half divided at the glenoid and remaining attached to the lesser tuberosity. The deepened or remaining tendon and capsule are then incised from the labrum medially. This technique is usually reserved when the prior surgery involved shortening the subscapularis. The orientation of the coronal dissection can be guided by determining the thickness of the scarred tendon and capsular tissue once the rotator interval region has been opened. The subscapularis is usually entrapped in scar tissue. To achieve full mobility, it may be necessary to visualize and dissect the axillary nerve. With the nerve adequately visualized and protected, the subscapularis can be released circumferentially on its superior, inferior, deep, and superficial surfaces.

If abduction and internal rotation are still limited, the inferior and posterior capsule can be released. With the axillary nerve identified and protected, the inferior capsule is released just lateral to the labrum and extended into the posterior capsule. To aid in visualization of the posterior capsule, a humeral head retractor may be placed to displace the humeral head posteriorly. At the end of the release, the Z-plasty is closed with nonabsorbable suture by stitching the lateral end of the superficial subscapularis to the deep end of the tendon and capsule. Each centimeter of length gained from the lengthening increases external rotation by approximately 20 degrees (Fig. 17-8). Range of motion is assessed again to determine where there is tension on the soft tissue repair and thus define a safe zone for early passive range of motion and rehabilitation.

The results of open release of recalcitrant chronic adhesive capsulitis of the shoulder and the role of contracture of the coracohumeral ligament and rotator interval were evaluated in a study by Ozaki et al. Seventeen patients who failed to improve with standard nonoperative measures underwent open release through an anterolateral incision. Release concentrated on the hypertrophied coracohumeral ligament and contracted tissues within the rotator interval at operation. The major cause of restricted glenohumeral movement was contracture of these structures. Histologic study revealed fibrosis, hyalinization, and fibrinoid degeneration in the contracted connective tissues, as well as fibrosis of the subsynovial tissue and absence of the synovial cell layer on the joint side of the rotator interval. Once release had been performed within the rotator interval, the glenohumeral joint was then gently manipulated through a full range of motion, also mobilizing the biceps tendon within its groove.

Immediately postoperatively, active mobilization of the shoulder was begun. At an average follow-up of 6.8 years, 16 patients were reported to have full range of motion, with one presenting with a slight limitation of motion. The

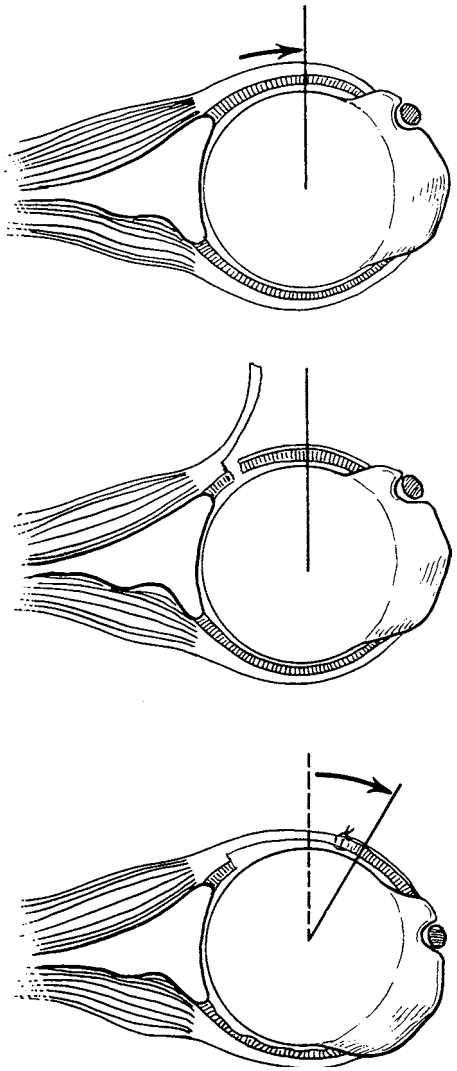


Figure 17-8 Contracted subscapularis and anterior capsule (*top*) limit external rotation. This condition is treated by incising the subscapularis from the lesser tuberosity laterally (*middle*) and suturing it to the medial end of the capsule, which is transected close to the glenoid (*bottom*). This release results in substantial lengthening of these structures. Each centimeter of length gained increases external rotation by approximately 20 degrees.

authors stated that they felt the essential changes in the tissue at the time of surgery could have been related to an intrinsic disorder of collagen and therefore recommended open release of contracted tissue.[96]

COMPLICATIONS

In most patients, frozen shoulder runs a self-limited course and will improve over time. Complications associated with frozen shoulder are usually iatrogenic and are the result of the treatment used. Potential complications of manipulation include fractures about the proximal humerus and shaft, fractures about the glenoid rim, dislocation of the glenohumeral joint, rotator cuff tears, labral detachment, or brachial plexus stretch injury. Additional complications include recurrent stiffness or axillary nerve injuries secondary to arthroscopic or open release.

Proximal humeral or shaft fractures represent a significant risk with manipulation, especially in the osteoporotic elderly population. Another risk factor is the osteopenia that occurs with regional pain syndromes and frozen shoulder. Treatment of the fracture is directed at early mobilization by performing an open reduction, internal fixation of the fracture. The best treatment consists of avoidance of the complication with gentle manipulation and avoidance of torquing the humerus, especially in external and internal rotation. The advent of arthroscopic capsular release allows direct lysis of adhesions in a controlled fashion without the risk of fracture.

Glenoid rim fractures or labral detachments may occur secondary to the pull of the ligaments during manipulation. These complications would go unrecognized except for the advent of the arthroscopic evaluation after manipulation. Instability is a rare complication and no repair is warranted. In fact, repair of these lesions would lead to further stiffening and loss of motion.

Rotator cuff tears rarely occur as a result of manipulation. Most tears were probably present prior to the advent of the stiff shoulder and its treatment. Repairing a rotator cuff tear in the presence of a frozen shoulder markedly increases the risk of pain and stiffness. Acute large retracted tears can be repaired with a concomitant capsular release and early postoperative rehabilitation. Leaving these large tears unfixed for a long duration may make them difficult to fix on a delayed basis, and the pain and dysfunction from the tear may make treatment of the stiffness difficult. Repair of small chronic tears, especially partial-thickness tears, should be reserved until after the stiffness resolves. Repair of these lesions may lead to severe postoperative pain and stiffness.

Instability is a rare complication after manipulation despite the extensive release of the capsule. Overhead suspension of the arm should be avoided in the regional blocked extremity. Inadvertent subluxation or dislocation may go unrecognized with risk to the axillary nerve. Overhead suspension can also be a source of a neurologic stretch injury.[89] Traction injuries of the brachial plexus and peripheral nerves have been reported after closed manipulation of the shoulder.[9] These injuries are usually neurapraxias that should recover spontaneously over time. It is critical to maintain passive motion while the nerves are recovering to avoid recurrent stiffness. Although a sling should be used to prevent excessive traction on the plexus while it is recovering, it should be removed for physical therapy and home exercise sessions. The patient and the physical therapist need to be made aware of the problem so that extremes of range of motion, particularly forward elevation and

abduction, are avoided to prevent further nerve injury. The diagnosis of middle and lower plexus injuries can be made almost immediately with somatosensory-evoked potentials. Diminished sensory nerve action potentials at 5 days after the injury may also be helpful in diagnosing an early plexopathy. Definitive electrodiagnostic studies can be performed 3 weeks after the injury to evaluate the extent of nerve damage and the potential for recovery.

INTRODUCTION

Regardless of the cause or the location of the joint, the pathologic changes of arthritis have the greatest effect on the articular cartilage and underlying bone. Initially, the soft tissue involvement includes only the synovium, but later it may involve, both directly and indirectly, the joint capsule, ligaments, and adjacent tendons. The progression of arthritis is not only influenced by the existing disease processes, but also by the extent and rate of joint loading by mechanical forces.

The predominant clinical feature of arthritis is pain. For most major joints, this is on the basis of the intraarticular changes of arthritis. Unlike other joints, however, the shoulder is more often affected by periarticular soft tissue disorders, which may coexist with glenohumeral arthritis and influence its clinical course. The functionally important musculotendinous cuff, along with the capsule and supporting ligaments, may undergo secondary changes as a result of glenohumeral joint arthritis. These include muscular weakness, pathologic musculotendinous shortening, and attenuation of ligamentous tissue. With articular disease progression and the associated direct or indirect involvement of the unique soft tissue envelope of the glenohumeral joint, the clinical effect will be profound.

The glenohumeral arthritides and associated disorders can be among the most challenging diagnoses. The clinician is required to use the acquired skills of careful history taking, thorough physical examination, and prudent use of cost-effective testing. Glenohumeral arthritis and allied conditions include osteoarthritis, posttraumatic arthritis, arthritis of dislocation, osteonecrosis, rheumatoid arthritis, crystalline arthritis, rotator cuff tear arthropathy, noninfectious inflammatory arthritis, and miscellaneous arthropathies.

Shoulder pain is not only a very common symptom that clinicians are asked to evaluate, but also the chief complaint of patients with glenohumeral arthritis. Acute traumatic shoulder pain is reviewed elsewhere in this textbook. This chapter will highlight the major causes of glenohumeral arthritis and profile the characteristics of each disorder.

Clinical Presentation

Although the shoulder is no less susceptible than other diarthrodial joints to arthritic conditions, arthritis is not a typical cause of shoulder pain. Probably as few as 5% to 10% of patients with shoulder pain have arthritis as a part of a polyarticular systemic disease, or a monarticular disease process. Painful dysfunction is more often a disorder of one or more of the soft tissue elements of the shoulder.

There exist more than 100 different types of arthritis. They may be defined as inflammatory or degenerative, polyarticular or monarticular, and acute or chronic. Distinction is made from historical factors, physical findings, radiographic analysis, and tissue sampling, including synovial fluid analysis and serum studies.

The predominant symptom of patients with arthritis is pain, usually intensifying with use and interfering with sleep. Shoulder motion is restricted by synovial membrane inflammation and increased fluid production. The synovium and capsule are richly innervated structures easily irritated by distention from the accumulation of synovial fluid. Exacerbation of discomfort with rotary movement with the elbow at the side is a characteristic physical finding of an inflammatory condition of the glenohumeral joint. Degenerative conditions are more tolerant of passive range of motion. Tenderness over the posterior joint line, as noted by Neer, is notable in glenohumeral osteoarthritis.[361] Tenderness lateral and inferior to the coracoid process, the anterior joint line, is very suggestive of an inflammatory disease. It is commonly not elicited in rotator cuff disease or noninflammatory conditions.

Imaging

Green and Norris have provided an excellent review of imaging strategies to be employed for patients with glenohumeral arthritis.[163] Initial evaluation of the painful shoulder will almost always include plain radiographs.[246] The most commonly employed views for the orthopedic surgeon are the true anteroposterior (AP) of the glenohumeral joint orthogonal to the plane of the scapula and the transaxillary lateral. Glenohumeral arthritis is easily distinguished from other soft tissue conditions and is classified based on features identified on plain films (Fig. 18-1).[430] These include alignment and relation of the humerus to the glenoid and acromion process, the width of the articular cartilage, osseous erosions, productive changes including osteophytes, and the presence of soft tissue swelling and calcification.

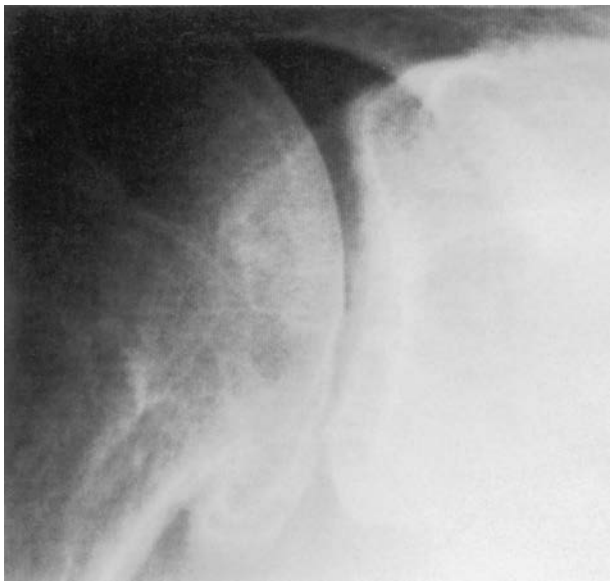

Figure 18-2 Humerus in 35 degrees of external rotation, profiling the articular surface in the true anteroposterior plane of the scapula.

Distinction of the articular cartilage space is best made when the x-ray beam is directed tangent to the joint surface. For the shoulder, this requires accurate patient, shoulder, and extremity positioning. Once the plane has been determined, the humerus can be externally rotated to approximately 35 degrees (Fig. 18-2). This will profile the load-bearing portion of the articular surface so that the earliest narrowing does not escape detection, and it is also the position favoring visualization of marginal humeral head osteophytes.[247] Apple et al. have suggested a weighted abduction Grashey shoulder method as a more sensitive means of detection of loss of articular cartilage.[13] When the disease is more advanced, positioning the humerus in external rotation is difficult and cannot be done exclusive of the position of the scapula (Fig. 18-3). For Nelson and colleagues, plain radiography, as opposed to magnetic resonance imaging (MRI), computed tomography (CT) arthrogram, and ultrasonography, was most useful for the diagnosis of osteoarthritis.[367]

Although shoulder arthrography is employed mostly for detection of rotator cuff tears, the articular surfaces and contours of the synovial lining of the joint can be easily visualized.[503] The arthrographic features may be enhanced by the use of poly- or computed tomography.[459] Filling defects may be observed in the cartilaginous surfaces and the thickness of the residual cartilage estimated. Magnetic resonance arthrography using gadopentetate dimeglumine may offer a more sensitive method for detection of intraarticular abnormalities.[265,384] These techniques, for practical

Figure 18-3 More advanced osteoarthritis, requiring total rotation of the humerus with the torso, a result of fixed internal rotation contracture of the glenohumeral joint.

There is posterior glenoid erosion that has a radius of curvature distinctly different than the anterior glenoid, where a small amount of articular cartilage persists. Peripheral humeral head osteophytes are apparent.

purposes, are rarely employed by the author for the routine assessment of glenohumeral arthritis.

Ultrasound study of the glenohumeral articulation has a very limited, yet undefined, role in the evaluation of the articular surfaces.

Although generally not required for the diagnosis of articular disorders, a CT scan can be quite helpful to delineate the extent of bone involvement and assess glenoid orientation (Fig. 18-4).[142,348] Glenohumeral morphology can be detailed, as can the quality and quantity of the glenoid. CT scanning will also help detect subtle cortical erosions, deposits of calcium, and the presence of newly formed bone. A more accurate assessment of glenohumeral relations may be realized by CT when extreme stiffness or deformity does not allow the shoulder to be positioned for optimal plain film study.

Perhaps the best imaging study for detecting early chondral injury or damage is MRI, even though assessment of the articular cartilage can be technically challenging.[156] Hayes et al. stated that an accurate MRI scan of articular cartilage requires good spatial resolution for the detection of small defects, good subject contrast and image contrast for the detection of signal intensity changes in articular cartilage, reliable distinctions for the detection of signal intensity changes in articular cartilage, and reliable distinction between articular cartilage and adjacent subchondral bone and joint fluid.[192] Broderick et al.'s study drew attention to the tendency for cartilage abnormalities to be underestimated with MRI when compared with arthroscopic observations.[43] The use of injectable contrast agents to enhance the accuracy of articular cartilage is not generally necessary.[62,265,324]

There is a consensus that normal articular cartilage can be imaged by MRI, perhaps to the extent of "zonal" analysis.[77,337,387,441] Three-dimensional imaging data can provide information about joint surface topography utilizing refined techniques.[17,61,390,391,418,501] Quantitative MRI is under investigation as a means of earlier detection and as a tool for monitoring the response of the articular cartilage to certain clinical conditions and to treatment.[176,517]

With few exceptions, scientific studies of MRI of articular cartilage involve the knee.[34,77,171,175,205,324,325,390,418] Huber et al., in one of the earliest published reports on MRI of the normal shoulder, cited the failure of MRI to effectively define articular cartilage.[212] The literature was replete with studies of MRI of the shoulder that had assessed features of the rotator cuff and capsulolabral morphology in impingement and instability disorders, respectively, and rarely mentioned the findings of the glenohumeral articular cartilage. Recent monographs and textbooks concerned with MRI of the shoulder and shoulder imaging inadequately address arthritis imaging by MRI, particularly the articular cartilage changes.[468,512,556] The preferred timing, sequences, and technical parameters have not been determined with uniform success and are evolving.[204] Therefore, MRI applications for glenohumeral

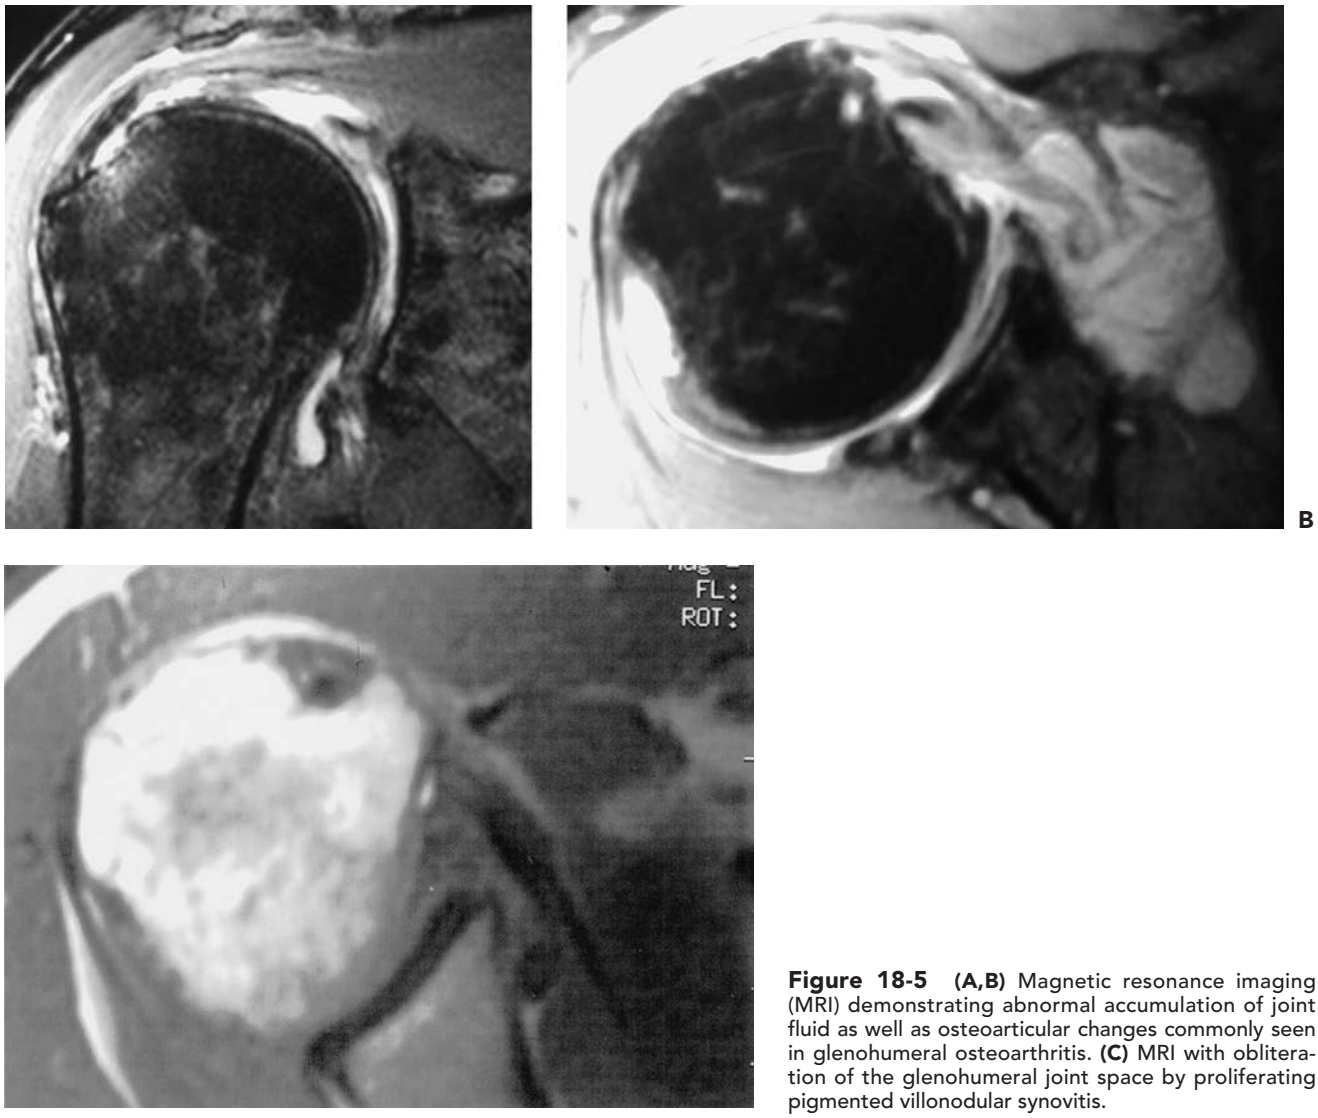

Figure 18-5 **(A,B)** Magnetic resonance imaging (MRI) demonstrating abnormal accumulation of joint fluid as well as osteoarticular changes commonly seen in glenohumeral osteoarthritis. **(C)** MRI with obliteration of the glenohumeral joint space by proliferating pigmented villonodular synovitis.

articular disorders are not yet as extensive as for the knee. Zlatkin has stated that MRI is rarely required to assess patients for glenohumeral osteoarthritis alone.[557] MRI arthrography utilizing gadolinium compounds may prove to be an effective technique to enhance the glenohumeral articular surfaces.[170,265]

A shortcoming of conventional radiographs is failure to detect soft tissue details, although in some cases swelling can be identified. Joint effusions may be suspected on plain films, but are best evaluated by ultrasound, CT, or MRI. The MRI is probably the most useful, accurate, reliable, and expensive.[512,541]

In normal shoulders, the MRI findings show only a thin rim of joint fluid around the biceps tendon sheath and narrow bands in the axillary recess and subscapularis bursa.[460] The volume has been observed to be increased with age.[460] Accumulation of glenohumeral joint fluid is abnormal; usually it is related to rotator cuff tears or osteoarthritis (Fig. 18-5 A,B).[460] The intravenous administration of gadopentetate dimeglumine will enhance the MRI of joint fluid, although the response is slower and less vigorous than synovium.[540]

Use of MRI allows direct visualization of inflammatory synovitis and synovial proliferation within the joint, as well as its penetration into the adjacent bone and periarticular soft tissues (Fig. 18-5 C).[422,542] Contrast enhancement with the use of gadolinium provides a more specific assessment of synovitis or pannus.[262,422] The rate and intensity of synovial enhancement may vary, depending on the activity of the synovium as a reflection of the activity of the disease process, as well as the image timing.[540]

Radionuclide isotope uptake in tissue reflects the rate and extent of blood flow through the tissue and, in bone, is a measure of bone metabolism, especially osteoblastic

activity. Scintigraphy, in particular triple-phase bone scan, may prove useful in distinguishing soft tissue inflammation from osteoarticular changes.[153,302,510] It is very sensitive, but it does not distinguish acute inflammatory disease from bone and joint sepsis.[509] Technetium scans have been used to confirm the presence of rheumatoid arthritis before the appearance of radiographic abnormalities.[110] Indium-111 chloride has been used for detection of rheumatoid arthritis as well as for following the course of disease activity.[450,467] Immune complex scintigraphy holds promise for monitoring disease activity and response to treatment.[96,251] MRI may have clinical application in the early detection of rheumatoid arthritis, its staging, and the assessment of treatment outcomes.[29,44,554] Uptake defects can exist in osteonecrosis and can be enhanced with single photon emission computed tomography (SPECT) images.[511,531] White cell–labeled scans are useful when an infectious disease process is being considered.[510,520]

Laboratory

Serum studies may be helpful, but only rarely can a diagnosis be obtained from this information alone. Complete blood count, autoantibodies (rheumatoid factor [RF] and antinuclear antibody [ANA]), uric acid and acute-phase reactant measurements, erythrocyte sedimentation rates (ESRs), and C-reactive protein (CRP) are most often performed as an initial screening battery and most helpful when the diagnosis is in question.[144,453] Acute-phase reactants are serum proteins formed in the liver and include coagulation, transport, complement, and miscellaneous reactive proteins. Their production is accelerated in the presence of inflammatory states and tissue necrosis.[145,272,454] The ESR is a rough, indirect quantification of their serum levels. The CRP level has been used more recently. Both are serum markers that reflect the extent or degree of inflammation and can be used for assessment of disease activity or response to treatment over time.[76,272] CRP levels (normally less than 1 mg/dL) may exhibit moderate elevation (1 to 10 mg/dL) in most connective tissue diseases; marked elevation (more than 10 mg/dL) may signify an acute bacterial infection such as septic arthritis.[342]

Clinically detectable effusions are uncommon in most arthritides. When present or suspected, however, a fluid sample should be obtained and submitted for analysis.[493] It should also be obtained any time the patient's history, physical examination, and radiographs support the diagnosis of arthritis but a diagnosis has yet to be determined.[147] The findings of joint fluid analysis have been shown to change a clinically suspected diagnosis, and often treatment, in 20% of samplings.[120] Particularly in acute arthritis, synovial fluid analysis is of major diagnostic value.[493]

Arthrocentesis of the shoulder can be performed from the anterior or posterior approach. Anteriorly, the tip of the coracoid process is palpated. After locally instilled anesthesia, an 18- or 21-gauge spinal needle is passed through the deltoid muscle at a point approximately 1.5 cm inferior and 1.5 cm lateral to the tip of the coracoid process. The cephalic vein is nearby and may be inadvertently punctured. Entry into the joint is gained with passage through the subscapularis muscle and the joint capsule. Posteriorly, the point of entry is two to three fingerbreadths inferior and one to two fingerbreadths medial to the posterolateral corner of the acromion process. Directed toward the coracoid process, the needle will penetrate the deltoid and infraspinatus muscles to enter through the capsule into the joint.

As much fluid as possible is withdrawn and its volume is determined. It is characterized as shown in Table 18-1.[80] The gross characteristics are noted. These include viscosity and color, which is normally clear and yellowish tinged. The fluid is typically not bloody, although blood tinging may suggest a traumatic tap or the existence of a pathologic lesion.

Fluid in normal joints is present in quantities that may preclude sampling by arthrocentesis. Recht et al. detected fluid in 14 of 20 shoulders by MRI in 12 asymptomatic young volunteers; in none was more than 2 mL evident.[419] If the joint fluid is obtained, the white count is less than 200 and predominantly monocytic as opposed to polymorphonuclear, and there are no red cells.[147]

Additional joint fluid types have been noted.[147] Noninflammatory fluid has a white cell count usually less than 2,000.[80] The fluid is transparent or nearly so. This type of fluid can be seen in trauma, osteoarthritis, systemic lupus erythematosus (SLE), sarcoid, and hypothyroidism.

Inflammatory fluid may show varying degrees of clarity and color. The white cell count is more than 2,000, but usually not more than 50,000.[80] This is commonly seen in rheumatoid arthritis, gout, and possibly some infectious disorders. It is also associated with Reiter's syndrome, ankylosing spondylitis, psoriatic arthritis, and juvenile rheumatoid arthritis.

Pyogenic fluid is opaque or grossly purulent. The white cell count exceeds 50,000, often higher, and is predominantly polymorphonuclear cells.[80] This is typical of infectious arthritis and, in some cases, gout or other very inflammatory arthritides.

Nonpyogenic fluid has variable characteristics. The white blood cell count is usually less than 20,000.[80] Additionally, joint fluid can be characterized as hemorrhagic. This will occur in cases of trauma, hemophilia, and other bleeding disorders.

Microscopic identification of crystals is a laboratory test with notable problems in sensitivity, specificity, and

TABLE 18-1
SYNOVIAL FLUID ANALYSIS

	Normal	Noninflammatory	Inflammatory	Pyogenic	Nonpyogenic
Gross analysis					
Volume	1–4 mL	Increased	Increased	Increased	Increased
Color	Clear, pale yellow	Yellow (xanthochromic)	Yellow-green, white	Yellow, white, gray	Variable
Clarity/turbidity	Transparent	Transparent	Transparent to opaque	Opaque, purulent	Variable
Viscosity	Very high	High	Low	Very low/variable	Decreased/variable
Mucin clot	Good (tight)	Good/fair	Fair/poor (friable)	Poor (friable)	Fair/poor
Spontaneous clot	None	Often	Often	Often	Variable
Microscopic analysis					
Leukocytes	<200	200–2,000	2,000–50,000	15,000–200,000	10,000–20,000
Neutrophils	<25%	<25%	25%–75%	>75%	50%–75%
Organism stains	Negative	Negative	Negative	Positive	Variable
Predominant cell types	Mononuclear	Mononuclear	Polymorphonuclear	Polymorphonuclear	Polymorphonuclear
Chemical analysis					
Fluid/serum glucose	1:1	0.8–1.0	0.5–0.8	<0.5	<0.5
Protein (g/dL)	<2.5	<2.5	2.5–8.0	2.5–8.0	2.5–8.0
Lactic acid	Plasma	Plasma	>Plasma	>Plasma	>Plasma
Culture	Negative	Negative	Negative	Positive	Positive

From ref. 38, with permission.

interobserver differences.[463] Despite this observation, the fluid should routinely be examined for calcium pyrophosphate and uric acid crystals that are further characterized by polarized light microscopy. Gout crystals are pointed and negatively birefringent.[148,396] Calcium pyrophosphate crystals are rhomboid and positively birefringent.[148,396]

Synovial fluid glucose levels are normally approximately 20 mg/dL less than the serum. Lower concentrations may be observed in joint sepsis. Synovial fluid protein is often increased in inflammatory disease. The utility of synovial fluid glucose and protein levels is questionable.[493] Appropriate organism stains and cultures should be obtained when there is even the most remote suspicion of an infectious process.

OSTEOARTHRITIS

Definition

Recognized as the most common of all arthritis, osteoarthritis is an irreversible, slowly progressive arthropathy characterized by the focal loss of articular cartilage, with hypertrophic reaction in the subchondral bone. Its cause is unknown. Although it does not seem to be a single disease, common features are found during the evolution of the disorder as it arises in a number of different conditions.

Incidence

The occurrence of osteoarthritis at the glenohumeral joint is much less common than at the hip or knee.[351] It is more likely to be found in women than men and in patients over 60 years of age.[351] Its incidence increases with age, and it is the site with the oldest average age of onset.[91,234] Difficulty in determining the early diagnosis, the timing of its onset, and the absence of longitudinal data make estimates of the prevalence of osteoarthritis and its incidence imprecise.

DePalma had an early interest in the aging shoulder and carefully studied its morphologic aspects.[100,102] On the glenoid side, from his study of cadavers ranging in age from 14 to 87, he determined that the degenerative process reached its maximum by the sixth decade. The most significant changes seemed to be located at the superior aspect of the glenoid. At the glenoid site of labral attachment, particularly in the anterior and anteroinferior regions, there was a marginal proliferation of bone and cartilage. This was believed to be secondary to traction forces applied to the soft tissues in these

areas, with a resultant functional response to stress loading. Over time, a generalized thickening of the synovial membrane was observed. This occurred secondary to proliferation of the fibrous stromal elements in the synovial areas, resulting in an increased number of villous projections. On the humeral side, articular surface changes were never profound. The changes were certainly never equal to those seen on the glenoid side and were felt to be attributable to the mismatch of the humeral to glenoid surface area (4:1).

Cadaver studies by others have confirmed the relative absence of humeral cartilage thinning with increasing age.[330,393] Petersson and Raedlulnd-Johnell radiographically reviewed the glenohumeral joint spaces in normal persons and concluded that, with age alone, the joint space does not decrease.[392]

Pathogenesis

Age is the greatest risk factor for the development of primary (idiopathic) osteoarthritis in all joints.[39,395] Additional systemic factors (gender, nutrition, race, ethnicity) and intrinsic joint vulnerabilities (previous damage, bridging muscle weakness, misshaped joint, malalignment, proprioceptive deficiencies) may increase one's susceptibility to osteoarthritis, and under the influence of loading conditions (obesity, trauma, physical activities), osteoarthritis may evolve or progress.[87–90] Bone density may play a role, as noted by the apparent inverse relation between osteoarthritis and osteoporosis.[257] There are no special associations in glenohumeral arthritis, except a coexistence of degenerative changes, including tearing, of the rotator cuff.[84,92–95] Feeney et al. identified a strong correlation between tears of the rotator cuff and degenerative changes of the articular cartilage that was independent of the factor of age.[130] However, the area of cartilage damage does not necessarily increase as the size of the tear increases.[211] Moreover, the incidence of full-thickness rotator cuff tears in osteoarthritis is low.

Pathophysiology

For details on the pathophysiology of osteoarthritis in general, the reader is referred to major textbooks of rheumatology, recent monographs, and reports discussing articular cartilage and osteoarthritis.[97–102] Most epidemiologic, clinical, and in vivo data come from studies of osteoarthritis of the large weight-bearing joints, the hip and the knee, as opposed to the glenohumeral joint. Suffice to say, the pathophysiology of osteoarthritis is poorly understood.

Osteoarthritis may not be so much a disorder of the articular cartilage as a response within the joint as an organ that ultimately fails.[412] Stresses applied to the joint exceed its capacity to repair what initially may be reversible changes. Radin and others have advocated the critical role of subchondral bone in the diseases process.[413] Day et al. suggest that subchondral stiffening is compatible with the process of normal bone adaptation.[95] Bone turnover may be increased severalfold, a process that ultimately may weaken the subchondral plate with the induction of altered properties of mechanical support for the articular cartilage.[21]

Normal cartilage is maintained in homeostasis by the repair capacity of chondrocytes within the cartilaginous matrix.[513] A general hypothesis for the initiation of osteoarthritis is that altered mechanical forces initiate metabolic activity change within the chondrocytes.[108–113] Loading characteristics, fluid mechanics, and joint congruity each contribute in special ways. Presuming that normally a feedback mechanism exists between the regulation of activity and mechanical stimulation, an imbalance of cartilage activity may result when the mechanical signal, or its transduction mechanism, is changed. The precise mechanism is unknown, but Mow and others suggest that the process is mediated by altered chondrocyte activity.[347] A cascade of events leads to the formation of a structurally impaired and weakened matrix that has irreversibly changed load–response characteristics.[347] Fragments of extracellular matrix proteins have been shown to bind to receptor sites on chondrocytes, inducing chondrolysis.[428] As a result, the capacity for cartilage to repair appears to fail, a dysfunction that ultimately leads to its loss.

Another hypothesis is that with increasing age, by the phenomenon of senescence, the chondrocytes lose their ability to replace their extracellular matrix, resulting in the deterioration in the structural and function properties of the cartilage and thereby increasing the risk of osteoarthritis.[306] Subject to the simplest biomechanical stress, the failing chondrocytes may produce proinflammatory cytokines (interleukin-1 and tissue necrosis factor-alpha) and chemokines that further contribute to the dysregulation of the chondrocytes, ultimately leading to progressive degradation of the cartilage matrix.[38,159] The local production of nitric oxide, prostaglandins, and hydrogen peroxide unfavorably alter the chondrocytes' response as well.[158] Anabolic mechanisms that normally support cartilage health are impeded.[507] It is compelling to meld aspects of both theories and envision a plausible scenario whereby altered mechanical forces are imposed upon chondrocytes with declining activity and responsiveness, the end result being osteoarthritis.

The major forces on articular cartilage result from contractions of the muscles that impart stability and motion to the joint.[421] Although the glenohumeral joint in normal persons is not truly weight bearing, the forces across the joint are not insignificant: 0.9 × body weight when the arm is held between 60 and 90 degrees of abduction.[401,402] Factors of load magnitude, its direction and duration, as well as the distance between the point of application and the

joint may influence the force applied to the articular cartilage. In a finite element analysis model, higher forces were expected on the posterior glenoid as the osteoarthritic shoulder, with its altered geometry, and normal shoulders are externally rotated.[47]

In addition to normal load, a depletion of articular cartilage may occur from joint trauma. Whereas chronic overloading of normal joints or subtle changes in joint mechanics may evolve slowly into osteoarthritis, significant joint injuries may precipitate significant osteoarthritis within a short time. An analogy for the shoulder would be the fate of the glenohumeral joint with glenoid dysplasia or hypoplasia, compared with one sustaining a comminuted displaced intraarticular glenoid fracture that resulted in an unfavorable malunion.[479,544]

Repetitive stresses may play a role, depending on the type of force transmitted to the joint. Articular cartilage can withstand significant shear forces without incurring irreversible damage.[291] Harryman et al. showed a wide variety of measurable translation in normal shoulders, implying an internal shear component during physiologic glenohumeral motion.[183]

With another in vitro model, the amount of glenohumeral translations was significantly influenced by the degree of humeral external rotation.[240] Higher than normal stresses on the articular cartilage leading to osteoarthritis may result from chronic posterior subluxation of the humeral head due to excessive glenoid retroversion.[525]

The thickness of articular cartilage is unfavorable for effective shock absorbency.[411] Impact loading forces are thereby delivered to the subchondral bone and the surrounding joint soft tissues.[197,411] The major bone load is transmitted to and attenuated by the cancellous subchondral trabeculae and the interposed fluid marrow elements.[372,413] This concept may help explain the observation concerning the inception of osteoarthritis predominantly on the glenoid side: less surface area, less cancellous bone volume.[101,416]

Acute ligamentous injuries alter the mechanics and biologic properties of the joint, especially its articular cartilage. The most extensively studied animal model for this condition has been the canine anterior cruciate ligament transection.[136–138] The mechanical and biomechanical components combine to progressively change the articular cartilage, not unlike that known to occur in osteoarthritis in the humans.[40]

Impact loading by mechanisms of trauma results in a more rapid or sudden increase in the force acting upon the articular cartilage. Experimental studies have demonstrated cellular changes with increased hydration and increased cellular activity, suggesting a repair or a remodeling capacity.[111,502] The overall effect is a weakening of the cartilage.

Just as there are conditions that alter joint load applied to normal cartilage, there are also those that infiltrate the cartilage or alter cartilage metabolism, rendering it vulnerable to physiologic loading alone. Primary disturbances in cartilage metabolism may occur in disorders such as hemochromatosis (iron), ochronosis (homogentisic acid), Wilson's disease (copper), gout (urate crystals), and calcium pyrophosphate dihydrate deposition disease, which result in the deposition of metabolic byproducts into the articular cartilage matrix.[142–147] Degeneration of the cartilage as a result of loss of its compliance, or chondrocyte injury, leads to osteoarthritis. Endocrine disorders, such as acromegaly, may also influence the quality of the cartilage.[32] Skeletal dysplasias may predispose the joint to increased susceptibility to mechanical forces (Fig. 18-6).[259,550]

Figure 18-6 Osteoarthritis: Axillary lateral view with enlargement and flattening of the humeral head. There is concentric erosion of the glenoid.

At the same time certain catabolic activities within the joint are taking place in the cartilage, anabolic activities are under way, including angiogenesis.[35] Together these activities promote remodeling and hypertrophy of bone. Increased subchondral bony plate density or sclerosis is observed radiographically.[66] The tidemark advances with new bone formation in the basal layers of the calcified zone. Cartilage supported by this abnormally dense bone is exposed to more intense stresses, in itself contributing to the cartilage degradation. Degeneration of the cartilage decreases its capacity to distribute stress and causes higher peak stresses in the subchondral bone. Focal pressure necrosis of bone may occur.[333] In response to these changes in stress, additional bone is deposited.

Defects sometimes develop within the exposed subchondral bone plate. If there is excessive intraarticular pressure, fluid may be forced through these defects and into the subchondral marrow spaces.[277,424] Increasing accumulations of pressurized fluid, coupled with the secondary resorption of surrounding trabeculae, may result in the formation of cysts contiguous with the joint surface.[376] New bone formation may occur in areas that are loaded. The osteophytes enlarge the joint surface and may be covered by newly formed hyaline and fibrocartilaginous cartilage.[39,50] Intraarticular bodies, formed from fragmentation of surface cartilage or bone, may float in the joint or become sessile, maintaining potential for enlargement.[334]

Pathoanatomy

Damage to the joint and reaction to it may result in an early, subclinical stage of arthritis that may exist for years or decades. The degeneration takes the form of thinning and softening of the articular cartilage. Surface fibrillation and, in the deeper layers, fissures and vertical clefts develop as the cartilage succumbs, exposing subchondral bone. The classification of Outerbridge, initially proposed for chondromalacia of the knee, has been modified recently for the staging of articular cartilage lesions of the glenohumeral joint (viewed arthroscopically).[380,532] Stage I is softening or blistering of the cartilage. Stage II is fissuring and fibrillation. Stage III is deep ulceration, and stage IV is exposed subchondral bone. Its limitation is that stages II and III do not take into account accurately the depth of the lesion, although it is implied. There may be evidence of fibrocartilaginous repair.

The synovium thickens in response to the joint debris produced by the reactive changes in the articular cartilage and bone. Villous hypertrophy with random synovial cell hyperplasia may characterize the membrane. It may be filled with cartilage fragments and foreign body giant cells.[50] Loose or sequestered osteocartilaginous bodies may be seen.[50] The subsynovial region stroma may be filled with a mild chronic inflammatory reaction.[157]

The gross pathologic findings of glenohumeral osteoarthritis are fairly consistent and have been characterized by Neer.[356,357,361] Thinning or absence of the cartilage of the humeral head is most pronounced in a position corresponding to 60 to 90 degrees of abduction, the area of maximum joint reaction force.[217] The normally convex humeral head flattens. The exposed bone becomes eburneous and sclerotic, acquiring a marble-like appearance, often stippled with small reddish-brown vascular proliferations and fibrocartilaginous plugs (Fig. 18-7). Osteophytes appear circumferentially at the margin of the articular surface of the humeral head, resulting in its apparent enlargement (Fig. 18-6). The large inferomedial osteophytes, which have been termed "the goat's beard" by Matsen, may envelope and tension the adjacent capsule, contributing to limitations of external rotation (Fig. 18-7).[309] Subchondral cysts are often present on the glenoid as well as the humeral head.

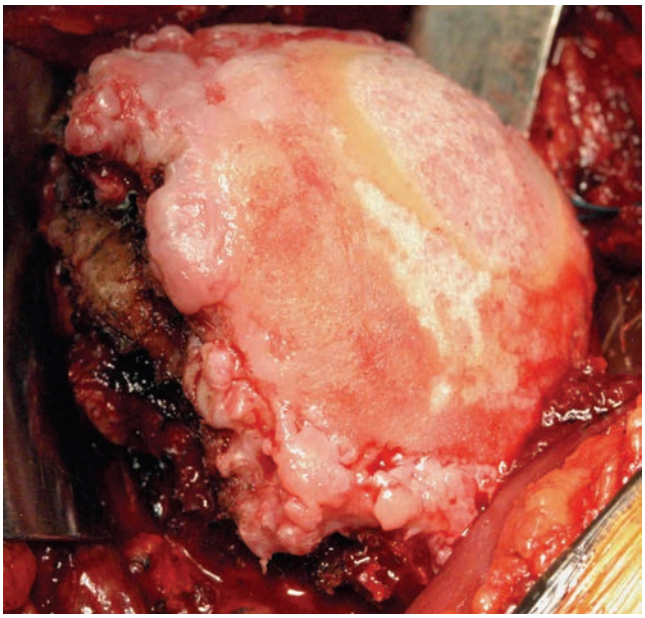

Figure 18-7 Osteoarthritis: Humeral head at the time of total shoulder arthroplasty. Flattening and enlargement of the humeral head is seen. Large proliferative osteophytes are noted circumferentially with predominance inferomedially, the "goat's beard." Punctate cystic lesions dot the eburneous bone.

The rotator cuff and the biceps tendon long head are intact in 87% to 95% of cases.[72,73,356,362,527] Neer believed that their integrity and capability to generate essential glenohumeral compressive forces are a prerequisite for the development of osteoarthritis.[362] He further believed that an enlarged osteoarthritic head helps prevent upward migration, resulting in fewer impingement-type rotator cuff tears.[362] Rupture of the biceps tendon long head can rarely occur, but the mechanism is in response to the presence of spurs in the intertubercular groove and not by the process of impingement against the coracoacromial arch.[362] The subacromial bursa has been noted to be thickened in the absence of acromial pathology in a high percentage of patients.[532] During arthroscopic evaluation and treatment of glenohumeral arthritis, the incidence of a concomitant lesion requiring treatment was 47%.[56]

Although primary glenohumeral osteoarthritis usually begins on the glenoid, the glenoid cartilage is typically spared anteriorly (Fig. 18-8).[416] The wear is more pronounced posteriorly, and a true crista (Fig.18-9) may be formed as a demarcation between intact articular cartilage and exposed subchondral bone. Disease progression favors excessive glenoid bone erosion posteriorly with resultant posterior humeral head subluxation. This stretches and attenuates the posterior capsule while the anterior capsule

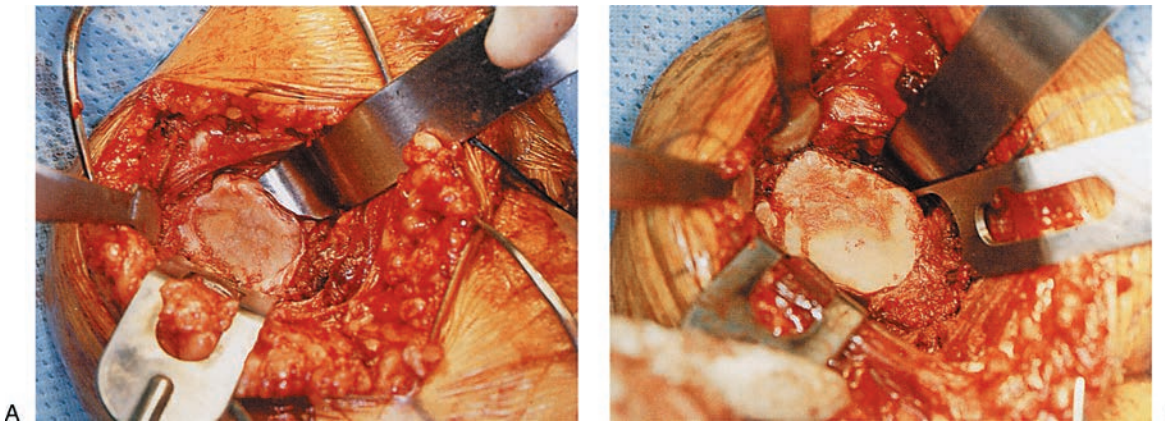

Figure 18-8 Osteoarthritis: Glenoids at the time of total shoulder arthroplasty demonstrating **(A)** demarcation between intact anterior cartilage and posterior eburneous subchondral bone. Peripheral osteophytes are seen. **(B)** Significant circumferential osteophyte formation.

significantly thickens and contracts. Peripheral osteophytes may "enlarge" the glenoid (Figs. 18-8B and 18-10). Osteocartilaginous bodies, either loose or attached, seek the recesses of the synovial cavity, especially the subscapularis bursa (Fig. 18-11). They may enlarge and become intimately attached to the adjacent bony structures, significantly distorting the normal anatomy. The soft tissue envelope tightens further as it drapes over the osteocartilaginous bodies and osteophytes. A morphologic study of the glenoid in osteoarthritis has enabled the classification of a well-centered humeral head, a posteriorly subluxed humeral head, and a retroverted, primarily dysplastic glenoid.[119,526,527]

The same findings are observed in secondary osteoarthritis. In addition, in cases of ochronosis, the characteristic blackening of the articular cartilage caused by homogentisic acid deposition is noted.

Clinical Evaluation

Patients may present for evaluation and treatment as early as age 40 to 50. Their lives are clearly altered by the disease process manifesting primary complaints of shoulder pain and loss of range of motion.[146,308] The source of pain may be local, peripheral, or central in origin.[107] Joints effusions, bone marrow lesions (edema), synovial hypertrophy, tendonitis, and bursitis are nocioreceptive structures shown to be involved in osteoarthritis.[132] More than 50% of patients are unable to sleep on the affected side and cannot perform common functional tasks.[314] Unremitting progression of the disease process will lead to more intense symptoms, failure of conservative management measures, and consideration for surgical treatment. The gender distribution is equal for this active and generally healthy subset of patients.[362] The dominant arm is involved to a greater extent than the nondominant arm.

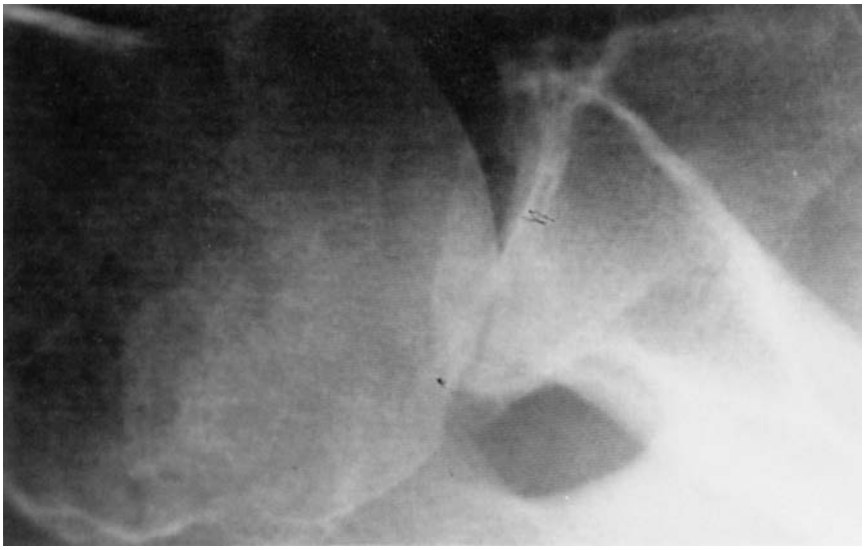

Figure 18-9 Osteoarthritis: Axillary lateral view demonstrating preservation of the anterior cartilage, posterior subluxation of the humeral head, and preferential wear of the posterior aspect of the glenoid.

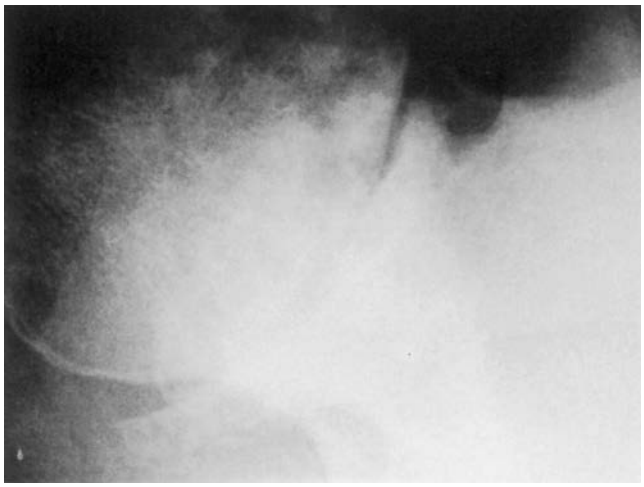

Figure 18-10 Osteoarthritis: Enlargement of the glenoid without evidence of significant preferential posterior wear.

Generalized atrophy of the shoulder is often notable, especially when the disorder is unilateral. Early in the disease, motion changes are minimal and difficult to detect, unless the most sensitive testing position—supine—is used. As the glenohumeral changes become more advanced, motion of the soft tissues is restricted, with a significant diminution of external rotation (Fig. 18-12). This is a more sensitive test of intraarticular activity than is the loss of elevation. A specific point of localized tenderness is over the posterior joint line, more easily elicited as the humeral head becomes subluxed with advancing disease. Attempts at active and passive motion are painful and may produce catching and squeaking sounds from the rough glenohumeral articulation. Synovial thickening and a large joint effusion may be palpable in thin individuals.

Figure 18-11 Osteoarthritis: Osteocartilaginous bodies are seen in the subscapularis bursa and in an unusually exaggerated inferior recess of the glenohumeral joint.

Figure 18-12 Osteoarthritis: Significant loss of external rotation is seen before total shoulder arthroplasty.

Imaging

Plain films are most helpful for making the diagnosis of osteoarthritis, but probably underestimate the extent of pathologic osteoarticular changes.[416] The AP view of the humeral articulation to the scapular plane and a high-quality axillary lateral view are all that is needed. They enable one to ascertain joint orientation, the amount of erosion of the glenoid, humeral head position, and the extent of disease activity. Weighted views may prove useful to help identify reduction of the glenohumeral cartilage space by as little as 1 mm.[514] Because of soft tissue contractures or pain, optimum films are sometimes not possible to obtain. In those instances, a CT scan will prove extremely useful in assessing glenoid morphology, glenohumeral relations, the presence of osteocartilaginous bodies, and the determination of the volume of the glenoid vault (Fig. 18-13).[20] Other findings of osteoarthritis are densification of subchondral bone, subchondral cysts, and peripheral osteophytes along the glenoid margins and adjacent to the articular surface of the humeral head, especially inferiorly. The humeral head may be flattened and enlarged. A triple-phase bone scan may prove beneficial when the plain films show early changes of glenohumeral arthritis (Fig. 18-14).

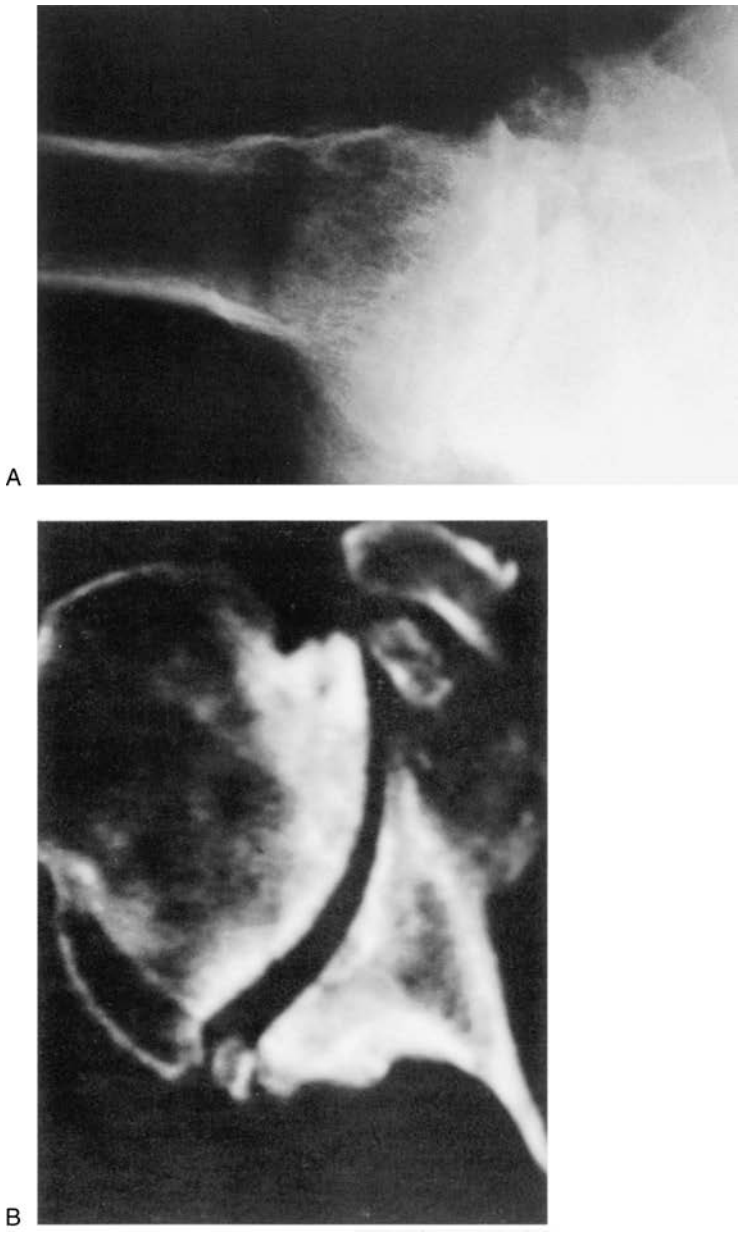

Figure 18-13 **(A)** Osteoarthritis: Findings on axillary lateral view may fail to define the pathoanatomy with accuracy. **(B)** Significant deformity noted on computed tomography scan. Loose bodies have attached to the anterior glenoid. External rotation limitation can be appreciated, due to contact of the posterior humeral head and osteophyte against the glenoid.

Laboratory

Laboratory studies are rarely helpful in the evaluation of primary osteoarthritis. However, investigators are in pursuit of promising identifiable disease markers such as COMP, antigenic keratin sulphate, hyaluronic acid, YKL-40, type III collagen N-propeptide, and urinary glucosyl-galactosyl pyridinoline.[409] Blood studies and synovial fluid analysis may help identify an underlying cause of secondary osteoarthritis. Synovial fluid levels of biochemical markers (aggrecan-aggregates) of catabolic activity within the articular cartilage enable the detection of all stages of glenohumeral osteoarthritis, with a high degree of accuracy.[416] The identification of the disorder before radiographic changes are present may prove extremely useful to expand treatment options and to monitor disease progression and response to treatment.[416]

Adjunctive Diagnostic Tests

Arthroscopy of the glenohumeral joint can improve the diagnostic accuracy when the clinical diagnosis is suspected and the radiographs do not show advanced stages.[121,416]

POSTTRAUMATIC ARTHRITIS

Injury and death of articular chondrocytes and the resiliency of the matrix macromolecular framework to withstand or recover from traumatic loading are fundamental

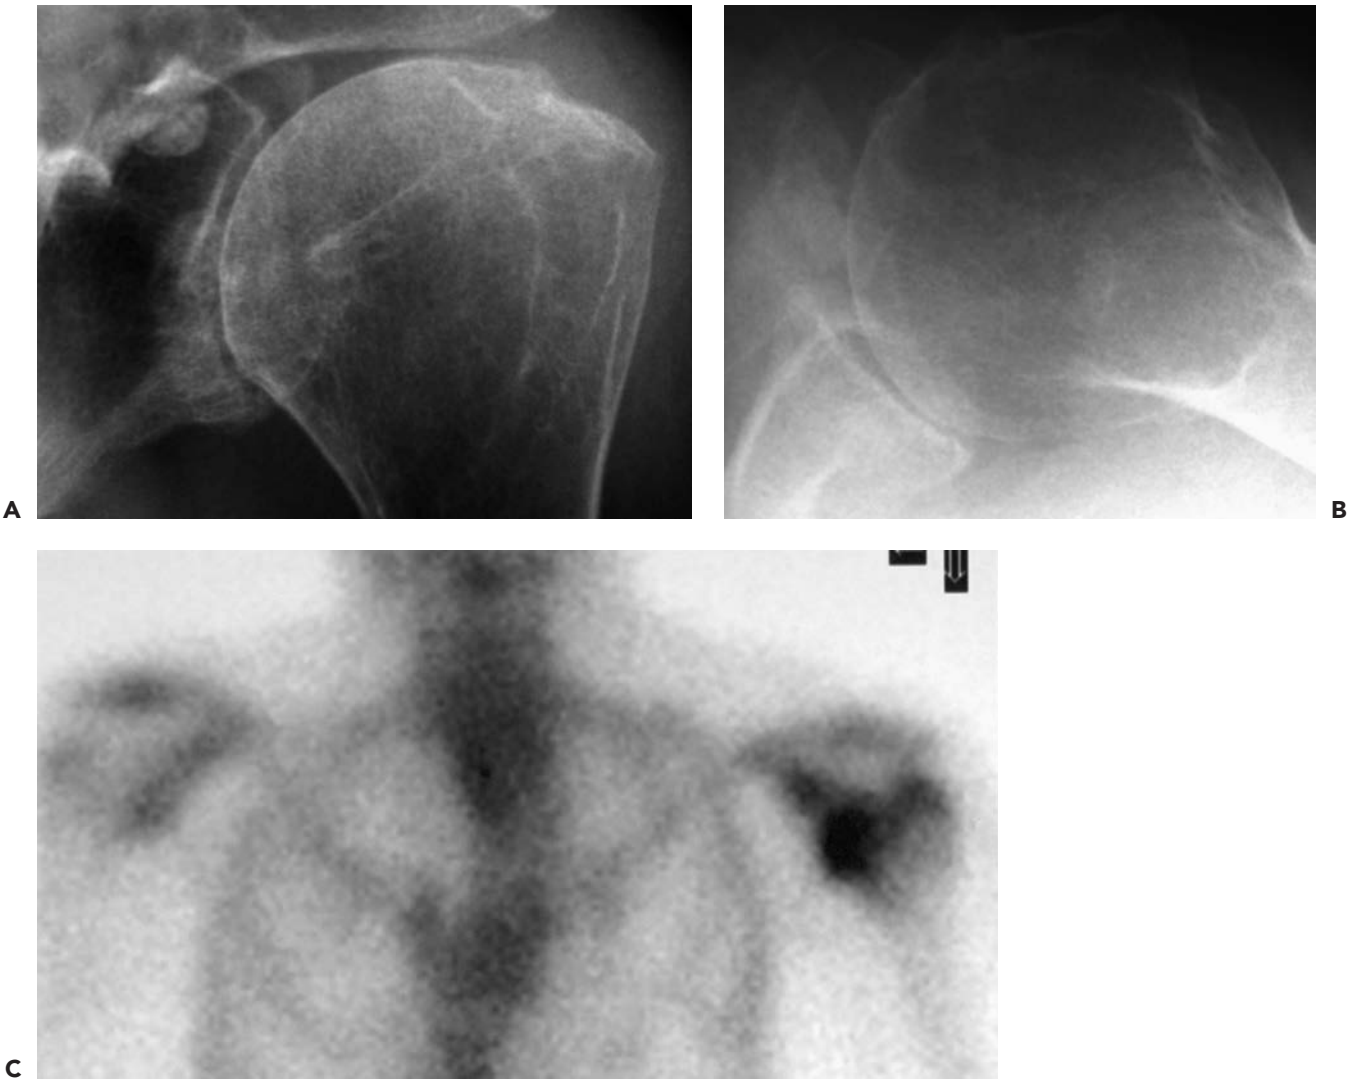

Figure 18-14 **(A,B)** Plain radiographs of mild glenohumeral osteoarthritis. **(C)** Delayed phase of bone scan with increased uptake of radionuclide in the glenohumeral joint.

elements in the pathogenesis of posttraumatic arthritis.[37,109,250,350,524] Major articular surface incongruities that exist at the completion of intraarticular fracture healing will inevitably lead to the deterioration of the joint quality (Fig. 18-15).[328,329] Tolerance of any joint to withstand minor variations in surface contact are dependent on many factors: the severity of the event of injury, surface geometry, surface area, specific load-bearing characteristics, and the integrity of associated joint-supporting soft tissues.[48] The discrepancy in the surface area of the humeral head and the glenoid is assurance that a small portion of the humeral head is in contact with the glenoid at any moment. It would appear, therefore, that a significant glenoid articular surface step-off or gap would have far greater influence on the development of posttraumatic arthritis than a corresponding one on the humeral side. Extraarticular fractures of the proximal humerus (surgical neck) may result in reorientation of the articular segment relative to the shaft or relative to the glenoid (Fig. 18-16). Up to 45 degrees of angulation are seemingly well tolerated without significant posttraumatic arthrosis or functional impairment.[358]

In many instances, the precise cause of posttraumatic osteoarthritis cannot be determined. In others, the cause is more apparent (Fig. 18-17). Varying combinations of joint incongruity from malunion, joint instability from adjacent soft tissue injuries, circulatory disturbance, and intraarticular fibrosis will have a bearing on the fate of the joint (Fig. 18-18). Zyto reported a 64% incidence of osteoarthritis in patients sustaining displaced four-part proximal humerus fractures and 25% for three-part fractures.[559] One of the more common forms of posttraumatic arthritis is that seen following glenohumeral instability.[57,207] This is further discussed in the next section.

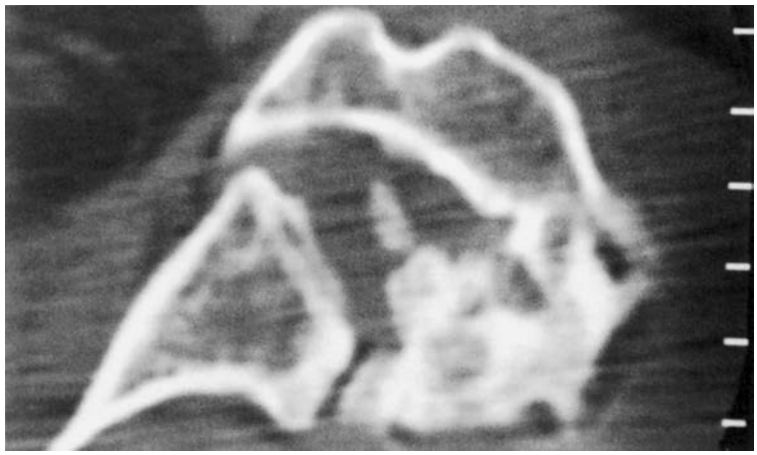

Figure 18-15 Posttraumatic osteoarthritis: Changes resulting from proximal humerus fracture, demonstrating joint incongruity and loss of humeral articular surface.

Chronic dislocations will result in disturbances of circulation and malnourishment of the articular cartilage surfaces (Fig. 18-19). The absence of stress to the underlying bone results in softening. Rapid deterioration of the joint is seen following closed and open reduction of these chronic dislocations, unless the surface abnormalities have been addressed.[191–193]

Proximal humerus fractures and their sequelae are given consideration in the section "Osteonecrosis." This may be the most common complication of proximal humerus fracture that will lead to posttraumatic arthritis. Proximal humerus nonunions may result in the formation of fibrous ankylosis of the glenohumeral joint, predisposing to posttraumatic arthritis.

ARTHRITIS OF DISLOCATION

Definition

Glenohumeral joint dislocations occur more frequently than any other major joint dislocation. Acute complications related to the initial dislocation include fracture, musculotendinous rupture, neurologic injury, vascular interruption, and recurrent glenohumeral instability. A late debilitating sequela to glenohumeral instability and its surgical treatment was, in one form, first appreciated by Hindmarsh and, in another, initially observed by Neer.[199,355] The term "dislocation arthropathy" spawned and included those occurrences of glenohumeral arthritis with a well-documented

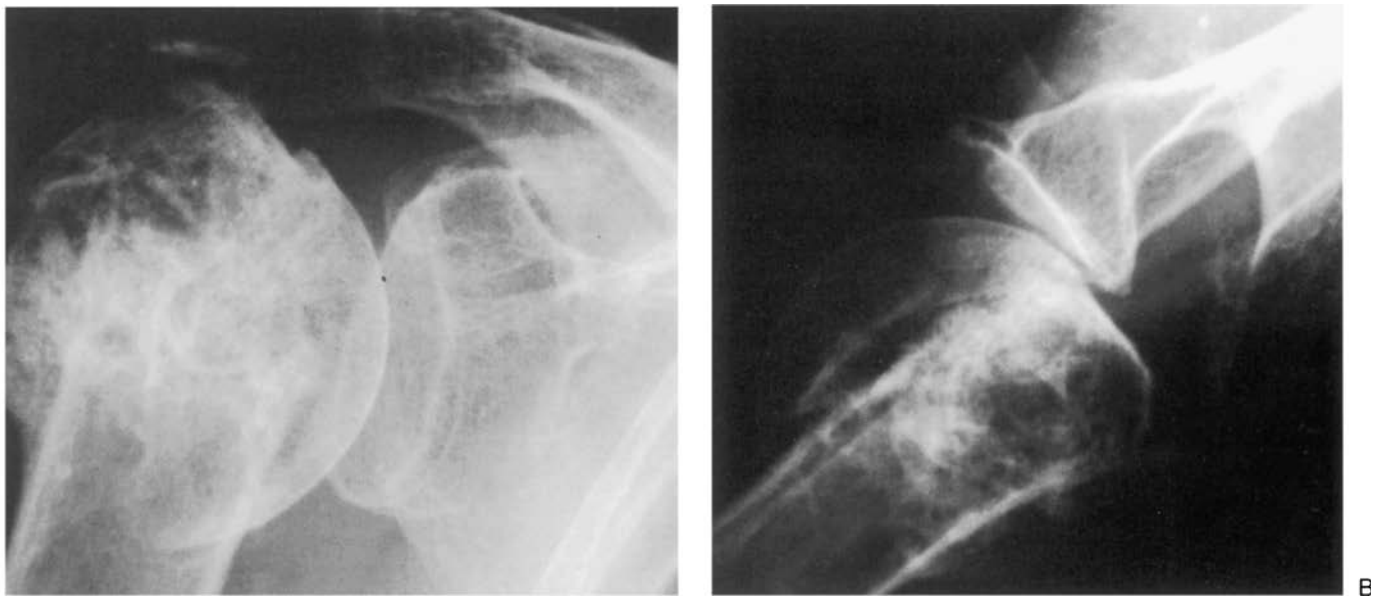

Figure 18-16 **(A,B)** Posttraumatic arthritis. Proximal humeral malunion with distortion of proximal humeral anatomy. Early arthritic changes are observed. Dysvascular changes are not present in the articular segment.

history of glenohumeral dislocation, often in patients having undergone surgical treatment (Fig. 18-20).[356,445]

Incidence

The incidence of this disorder has not been accurately established. Hovelius et al. performed a 10-year prospective study of patients younger than the age of 40 to assess the outcome of a primary anterior dislocation of the shoulder treated with closed reduction, both with and without immobilization.[207] The incidence of glenohumeral arthrosis was 20%. The degree of involvement was mild in 11% and severe in 9%. Cameron et al. determined the overall prevalence of osteoarthritis after either acute or chronic glenohumeral instability to be small, if not rare.[57] It was not influenced by the direction of the instability. They noted that the risk of osteoarthritis increased with the time from injury. In other series of patients treated surgically for anterior glenohumeral instability, the incidence of preoperative arthritis has ranged from 0% to 20%.[197–200]

Figure 18-19 Posttraumatic arthritis: Chronic locked posterior dislocation with gross incongruity of the glenohumeral joint.

In the large series (570 patients) reviewed by Buscayret et al., as well as earlier series, the factors of age at the onset of instability, osseous glenoid rim lesions, humeral head impaction fractures, and interval between the onset of instability and surgical treatment correlated with the preoperative development of arthritis.[53,209,445,473] Marx et al. noted that glenohumeral dislocation requiring reduction was found to be associated with a 10- to 20-fold increase in the risk for the subsequent development of severe arthrosis sufficiently severe to warrant shoulder arthroplasty.[307]

By far the most common cause of arthritis of dislocation is iatrogenic. It has been termed "capsulorraphy arthropathy" by Matsen et al.[310] With rare exception, its existence is acknowledged by most experts in the field of shoulder surgery, although its incidence cannot be accurately determined.[315] In series with greater than 10 years follow-up, the incidence of significant arthritis ranges as high as 72%.[8,210,261,433,439,516] Interestingly, in patients with no preoperative arthritis, at a mean 6.5 years after surgical treatment, postoperative arthritis occurred in nearly 20% of patients.[53] Once again, age at the time of the initial instability episode seemed to be most important. Other important factors were age at the time of surgery and a longer interval of follow-up. In contrast to Rachbauer et al., the presence of arthritis was influenced by the number of instability episodes prior to surgery.[410] Findings regarding decreased external rotation were inconclusive. With consideration of these observations, Buscayret suggested that

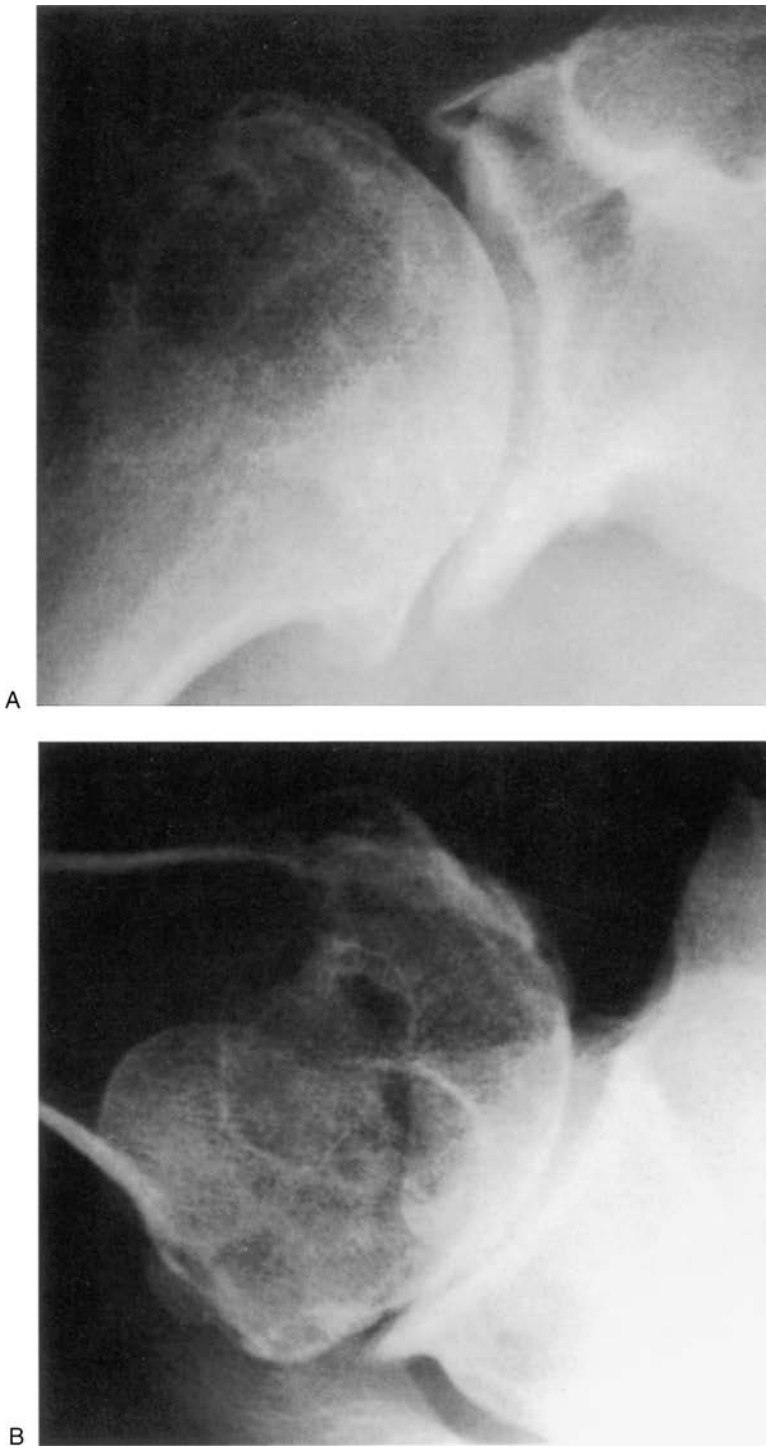

Figure 18-20 **(A,B)** Arthritis of dislocation: The sequelae to two previous surgeries including anterior stabilization and subsequent staple removal.

surgery does not influence the risk factors for the development of arthritis in shoulders that undergo attempts at surgical stabilization.[53]

Pathogenesis

Hovelius' data suggested no relation between dislocation arthropathy and the number of recurrent dislocations or the treatment rendered either operative or nonoperative.[207] The lack of association with the number of dislocations was confirmed by others.[53,307] Hovelius' study pointed out further that advanced glenohumeral arthritis may occur even after a single anterior glenohumeral dislocation treated without surgery.[207] Traumatic shoulder dislocations are the result of a significant force applied to the glenohumeral joint and generally involve damage to soft tissue

including the capsule, labrum, and rotator cuff, as well as bone and cartilage.[498]

Morrey and Janes prudently observed that looseness of the joint played a role in the development of surgical failures after the performance of a unidirectional repair.[343] Factors shared by these patients included a positive family history, occurrence of bilateral glenohumeral instability, and the coexistence of posterior instability in the shoulder that was operated on. Neer introduced the term "multidirectional instability," perhaps for the same subset of patients.[355] He was also the first to draw the association between the disorder and arthritis of dislocation.[356] It was his belief that multidirectional instability existed on the basis of lax ligaments, repeated minor injuries, or a combination of both. The most frequent cause of multidirectional instability was felt to be an acquired laxity, explained on a heritable basis. The initial instability episode in this group of patients most often occurred without high forces, major injury, or significant associated injuries. Typically, if a dislocation was present, it reduced spontaneously or required minimal, usually self-manipulative, effort. Generalized ligamentous laxity was often recognized. Examination of the contralateral shoulder revealed excessive anterior and posterior translations, as well as inferior translation, as evidenced by the "sulcus sign." The presence of this so-called sulcus sign was pathognomonic for multidirectional laxity. Neer concluded that "by far the most frequent etiologic mechanism for the development of arthritis of recurrent dislocation is a 'standard' operative procedure intended to remedy recurrent unidirectional dislocations that is unsuspectingly performed on a loose, multidirectional shoulder."[363] He observed that the "procedures displace(d) the humeral head in a loose shoulder away from the side of the repair, creating a fixed subluxation. The subluxed head wears unevenly on the glenoid, and arthritic changes can develop surprisingly fast."[363]

It was actually Hindmarsh, however, who first implicated the role of stabilization surgery in the production of moderate to severe glenohumeral arthritis.[199] A variety of surgical procedures performed in an attempt to stabilize the glenohumeral joint and prevent recurrences led to glenohumeral arthritis.[188,189,214,297,299,356,369,373,487,536] When a unidirectional repair, such as the Putti-Platt,[208,254,261,410] Eden-Hybinette-Lange,[46,53,536] Magnuson-Stack,[445] Bristow-Laterjet,[8,206,210,295,369,473] DuToit,[373,445,474,558] or Bankart[208,210,369,445] was performed to eliminate instability recurrences, the stage was set for further glenohumeral joint deterioration. The incidence of osteoarthritis was notably less with anatomic repairs (Bankart) when compared with nonanatomic repairs.[433,439]

Pathophysiology

The more widespread recognition of this late sequela to instability reconstruction has led to hypotheses about its mechanism. When unidirectional surgery is imposed on a normal joint, or more often, a multidirectional lax glenohumeral joint, glenohumeral biomechanics are altered.[355,533] This occurrence has been assigned predominant responsibility for the development of the arthritis of dislocation.[41] Even in the presence of normal laxity, a unidirectional repair, resulting in excessive tightening of the soft tissues, forces the humeral head in the direction opposite that of the repair.[183,189] When this is performed for anterior instability, there is a significant limitation of external rotation. As external rotation is performed, contact compression and shear forces at the glenohumeral articulation increase. This results in translation of the humeral head posteriorly, with a shift in the center of rotation. Eccentric loading forces are concentrated on a smaller glenoid surface area with deterioration in the quality and quantity of articular cartilage.[138,481] Over the time period dating from the index procedure, ranging from a few months to more than one-half century, there is a progressive development of glenohumeral degenerative changes.[315,483,516] Those procedures that transpose bone to create a blockade carry the additional risk of humeral articular surface scraping against the bone or metal hardware fixation devices.[19,206,295,536,555]

Samilson and Preito noted that the occurrence of arthritis was much more common after posterior glenohumeral dislocation (Fig. 18-21).[445] This was thought to be because of the delay in diagnosis and treatment of posterior glenohumeral dislocation, especially chronic occurrences. In Samilson and Preito's series, the number of dislocations did not determine the severity of glenohumeral

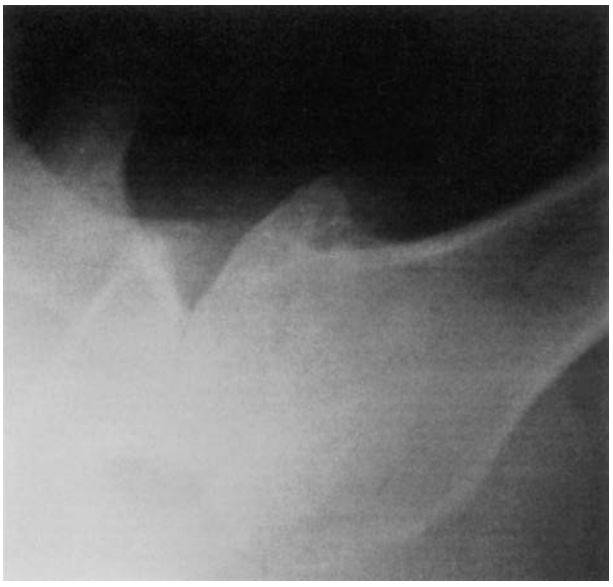

Figure 18-21 Arthritis of dislocation: The result of recurrent posterior glenohumeral instability. Note significant posterior humeral subluxation and eccentric wear of the posterior two-thirds of the glenoid.

joint arthrosis.[445] Of the group of patients with moderate to severe arthrosis, 71% had experienced only one glenohumeral instability event. In this same group of patients, 26% had recurrent instability. No correlation was recognized in the presence of a Hill-Sachs or bony Bankart lesion. Those patients who were slightly older at the time of their index glenohumeral instability event had more severe arthrosis. In Bigliani et al.'s study, 7 of 17 patients continued to have instability in the presence of arthropathy.[31]

The pathophysiologic process that leads to dislocation arthropathy after one or more glenohumeral dislocations is less clear. A more severe arthritis existing in patients with a single dislocation suggests a direct relation between the forces dissipated to the articular cartilage and the restraining soft tissues. In so-called "tight" shoulders, higher forces may be necessary for traumatic dislocation, whereas more lax shoulders require less force. The development of postdislocation arthrosis may result from recurrent episodes of instability because eccentric loading during pathologic translocation transmits greater shear and compression forces at the articular interface. Progressive bone loss in the anteroinferior quadrant, in addition to the loss of the labrum, was found to have the effect of causing further increases in mean contact pressures and peak pressures and a decrease in contact area across the glenohumeral joint.[166] It is possible that surface imperfections and impression fractures of the humeral head could further damage the articular cartilage with each successive dislocation event. The resultant accumulations of particulate joint debris and newly formed osteocartilaginous loose bodies could theoretically contribute a third body wear mechanism. These detrimental effects could coexist and become additive in their potential for joint destruction.

Pathoanatomy

The pathology encountered is often dependent on the index stabilization operation. In general, excessive scarring and adhesions are the predominant finding.[31] Operations involving greater manipulation of the soft tissues, such as the Bristow procedure, often result in encasement of all anterior soft tissue structures, sometimes including the axillary nerve.[31] The subcoracoid, subacromial, and subdeltoid planes of motion are usually scarred. The subscapularis musculotendinous unit will be contracted, as is the anterior joint capsule. Occasionally, the subscapularis integrity will be preserved, such as in a Magnuson-Stack procedure.[301]

Transferred bony blocks may overhang the lateral margin of the anterior inferior glenoid.[8]

The articular surface contours may appear normal with simply posterior subluxation and instability of the humeral head. More often, the glenoid articular surface involvement is quite significant (Fig. 18-22). The anterior glenoid cartilage may be reasonably preserved, whereas the more posterior cartilage demonstrates thinning and erosion to subchondral bone. In advanced cases, posterior glenoid bone erosion and loss is observed. The humeral head shows concomitant wear changes. The penetration of metallic fixation devices into the intraarticular space may be observed in open as well as arthroscopic procedures, with associated articular surface changes, including arthropathy (Fig. 18-23).[19,121,235,373,425,470,555,558] Severe arthrosis is not usually present.

Figure 18-22 Arthritis of dislocation: Capsulorrhaphy arthropathy with significant deterioration of the glenohumeral articulation, total loss of joint space, and secondary changes within the humeral head.

When operative care has not been rendered, the findings are essentially those of glenohumeral osteoarthritis. Preferential glenoid wear or humeral head subluxation may be observed in the direction of the instability. Variable soft tissue changes may exist.

Clinical Evaluation

The patient, often younger than 40 years of age, usually presents to the surgeon for evaluation many years after the glenohumeral stabilization operation or the index dislocation occurrence.[31,42,189,356] Most of these patients have not had interval recurrences or symptoms. Within 2 to 3 years of presentation, shoulder symptoms have begun to evolve. At the time of the evaluation, the chief complaints are related to intense, often disabling pain. Almost all patients have had long-standing limitation of range of motion, especially external rotation.[483] Many develop an internal rotation contracture. Moderate to severe functional disability is present secondary to pain

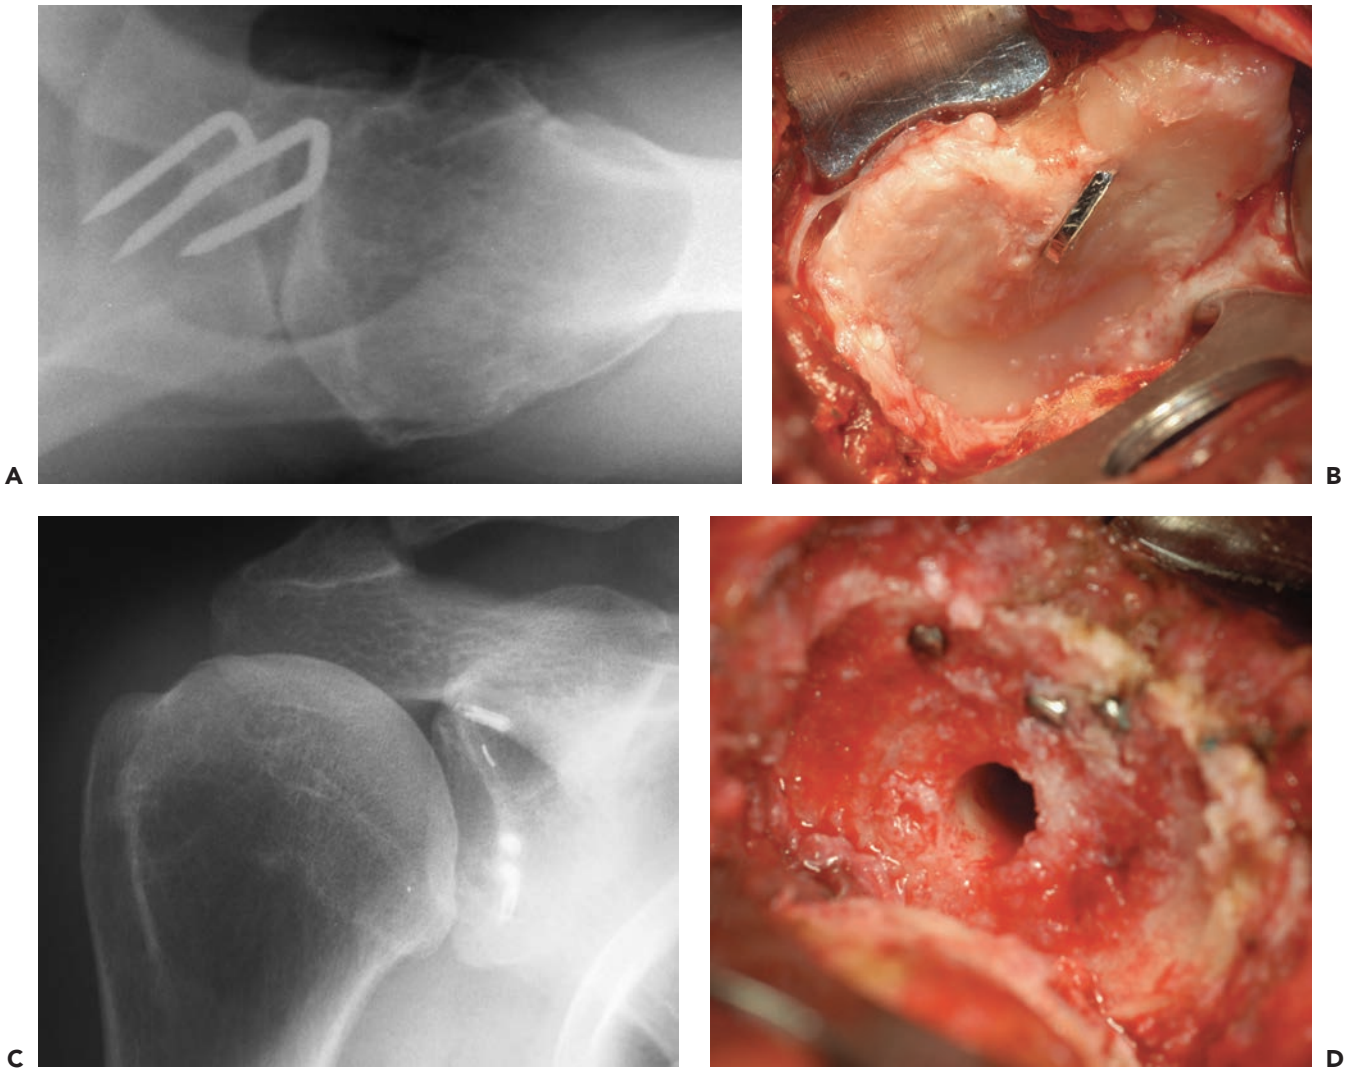

Figure 18-23 **(A,B)** Arthritis of dislocation: Advanced degenerative changes of the glenohumeral joint following prior anterior stabilization. Metallic staples are noted to be intraarticular with secondary effect upon the humeral head. **(C,D)** Arthroscopically placed metallic suture anchors in violation of the glenohumeral joint, necessitating glenohumeral arthroplasty.

and altered range of motion. Some have had multiple surgical procedures.

The physical examination of these patients is consistent. They are usually younger, healthy-appearing men, often muscular with the exception of the affected shoulder. One or more scars may be present, frequently hypertrophic. For those who have undergone anterior reconstructions, the coracoid is often prominent. When viewed from overhead, the prominence of the posteriorly subluxated humeral head may produce posterior fullness. Examination from the side may demonstrate a posterior attitude to the arm as it hangs at the side. Focal tenderness is often present at the posterior joint line. Active and passive glenohumeral joint motions produce crepitation. Examination of the contralateral shoulder will often demonstrate signs of multidirectional laxity including a positive jerk test, positive drawer testing, and a positive sulcus sign. Limitation of external rotation of the symptomatic shoulder is often pronounced; the more advanced the arthrosis is, the more significant the loss of external rotation is.[164] Samilson noted 62 degrees of external rotation with mild involvement, 23 degrees of external rotation with moderate involvement, and 14 degrees of external rotation with severe involvement.[445] This compared with 72 degrees on the contralateral side. Hawkins observed an average of –5 degrees of external rotation and Bigliani identified 17 patients with an average external rotation of –2 degrees.[31,189]

Imaging

Conventional imaging studies that include a true AP view of the glenohumeral joint and an axillary lateral view are

Figure 18-24 Arthritis of dislocation: Grossly altered glenohumeral articulation with large osteophyte formation, obliteration of the joint space, and humeral head flattening.

often all that are needed. The CT scan is helpful when a high-quality axillary lateral cannot be obtained; MRI examination is unnecessary.

The humeral head is usually posteriorly subluxed, with eccentric wear of the glenohumeral joint cartilage. Posterior glenoid erosion may be extreme.[164] The additional findings of glenohumeral osteoarthritis are often severe. Signs of previous surgery also include the presence of periarticular and, sometimes, intraarticular metal fixation devices (Fig. 18-24). Osteopenia from disuse may be present.

Laboratory

Specific laboratory investigation is not necessary.

Clinical Significance

A single common cause does not exist for the arthritis of dislocation. Nonoperative treatment was successful in preventing recurrences in 52% of patients in Hovelius et al.'s study.[207] Nearly one-fourth of the patients with more than two recurrences "spontaneously" stabilized. Their study also showed that glenohumeral arthropathy can result from the trauma of a single dislocation without recurrences. The subset of patients treated nonoperatively was not exposed to the surgical risk factors predisposing to capsulorrhaphy arthropathy. When operative treatment for instability is rendered, additional risks of some degree are inevitably entailed. It is incumbent that the diagnosis of the extent and direction of instability be accurately established. Failure to recognize multidirectional instability and generalized ligamentous laxity can lead to a disastrous outcome when a unidirectional repair is performed, especially if the soft tissues are excessively shortened and remain so permanently. It is therefore important not to treat all glenohumeral instabilities with one operative procedure. The direction of instability must be determined and the appropriate side stabilized appropriately. The surgeon should be familiar with the complications related to the use of metal and avoid the circumstances that place the glenohumeral joint at high risk for penetration.[298,558] Arthroscopic evaluation and treatment of glenohumeral instability may traumatize the joint from direct damage to the articular surfaces with the scope, instrumentation, and fixation devices.

Natural History

With few exceptions, available data have not permitted prospective evaluation of consistently homogeneous groups of patients with glenohumeral instability.[207] It appears that an increased risk of arthritis is not seen in voluntary subluxation of the glenohumeral joint in children.[213].

The work of Edelson identified skeletal specimens with findings of instability.[118] Coexistent findings of diffuse arthritic changes about the glenohumeral articulation were not observed. The data did not support the concept of prophylactic stabilization to prevent arthritic changes from developing. Hovelius' study would lend support to this concept, because a number of shoulders, even after one or more recurrences, stabilized over time without surgery.[207] Inappropriate stabilization in these cases may have led to the unnecessary development of dislocation arthropathy.

The natural history of established arthritis of dislocation is the progressive development of severe wear and, ultimately, glenoid deficiency (Fig. 18-25). Prevention would have the greatest influence on this destructive entity of the glenohumeral joint. Accurate diagnosis of the unstable shoulder and, when necessary, appropriate surgical treatment are mandatory. Early recognition of the condition plays a role if the joint is to be surgically salvaged without implant arthroplasty.[297,299]

OSTEONECROSIS

Definition

Osteonecrosis, sometimes termed avascular necrosis or aseptic necrosis, is simply bone death, both the osteocytes

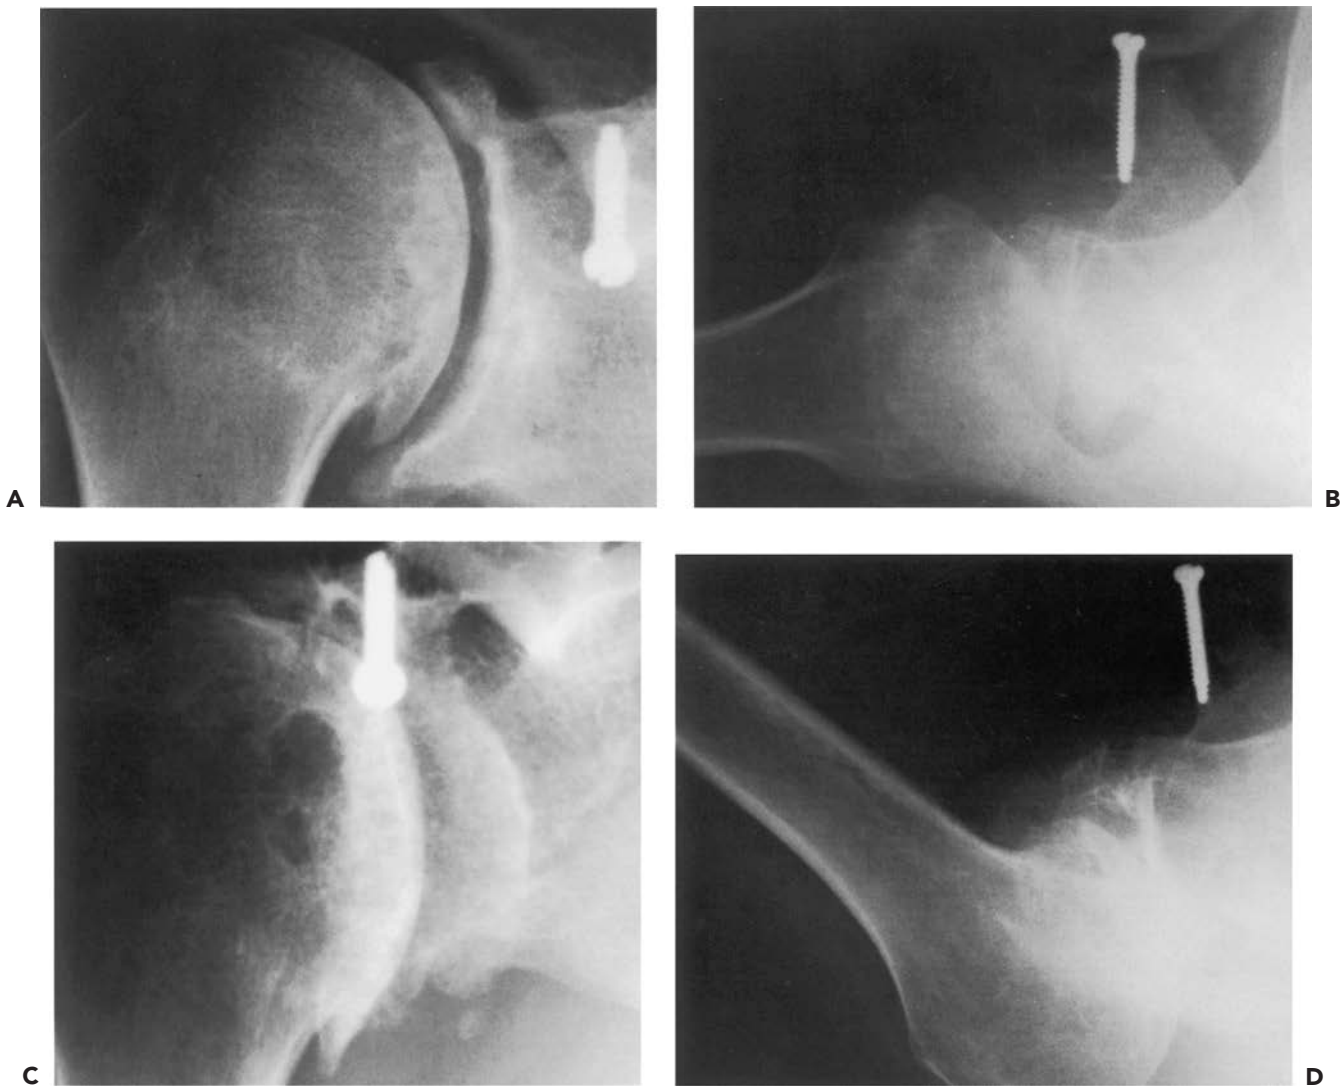

Figure 18-25 **(A,B)** Arthritis of dislocation: Ten-year interval following anterior stabilization procedure with moderate glenohumeral arthritis. **(C,D)** Now 18-year interval depicting further progression, with the formation of increased subchondral density, subchondral cysts, osteophytes, and loose bodies. Significant posterior wear and subluxation are seen.

and the marrow contents. However, it is the bone's failure of repair that leads to destructive changes within the joint. The earliest reports of implant arthroplasty for the shoulder include patients with osteonecrosis after proximal humerus fracture or dislocations.[268,353]

Osteonecrosis of the humeral head is best classified as traumatic or atraumatic. Fractures of the proximal humerus or fracture dislocations involving the glenohumeral joint place the articular segment of the proximal humerus at risk for osteonecrosis. The atraumatic category includes those occurrences of osteonecrosis that result from disease processes, highlighted in one of the earliest reports on the subject by Cruess.[87]

Incidence

The incidence of posttraumatic osteonecrosis has been difficult to determine. Factors including the severity of the fracture, the amount of displacement, and, to some extent, the type of treatment rendered will have influence on the occurrence of posttraumatic osteonecrosis. The incidence of osteonecrosis is highest after three- and four-part fractures, but can also occur after certain two-part fractures and even open anterior dislocations.[114,140,165,173,258,267,284,381,490,491] Closed treatment of displaced three-part fractures has resulted in a 3% to 14% avascular necrosis rate.[173] In four-part fractures treated closed, the incidence has ranged

from 13% to 34%.[114,173,258,359,397,462,484,492,559] For any method of treatment, anatomic neck fracture occurrences approach 100%.[99,220,358,359]

It has been suggested that operative treatment carries a higher risk of osteonecrosis because of the wide surgical exposure necessary to provide for adequate internal fixation.[490] The incidence of avascular necrosis in three-part fractures that have been treated operatively ranges from 12% to 34%.[173,190,266,346,490] Four-part fractures treated with open reduction and internal fixation have a much higher rate of avascular necrosis and malunion.[173,221,266,267,359,381,449,484,490,492,496,534] Neer believed the incidence to be as high as 90%.[359]

Osteonecrosis of the humeral head has been described in an adolescent treated surgically for recurrent anterior glenohumeral instability.[386]

Although it can be associated with many different conditions, the incidence of atraumatic osteonecrosis cannot be determined.[92,184,294] It is probably the third or fourth most common indication for glenohumeral implant arthroplasty. From a group of over 1,000 patients managed for osteonecrosis of any joint, humeral head was 7%.[340] A high incidence of corticosteroid use (82%), hip involvement (81%), and bilateral disease (74%) was noted in the same cohort. For patients with humeral head involvement, L'Insalata et al. reported a 76% incidence of osteonecrosis at another site.[292]

Cytotoxic drugs

Pathogenesis

Some common causes of osteonecrosis and their relation to the disorder are summarized in Table 18-2. Proximal humerus fractures and dislocations have most clearly been established to jeopardize the circulatory integrity of the humeral head.

Neer's classification of proximal humerus fractures and glenohumeral fracture dislocations gave better understanding of the pathomechanics and the prognosis following treatment of these injuries.[358] He cited the importance of the vascularity of the articular segment and the relation of the articular segment to other parts of the proximal humerus and to the glenoid.

When the proximal humerus fractures, the wider the displacement of the articular segment from the shaft or from the tuberosities is, the higher the incidence of osteonecrosis is. More than 80% of the proximal humerus fractures are minimally displaced, according to Neer's criteria, keeping them at low risk for osteonecrosis (Fig. 18-26).[360] The unusual and unexpected trauma to the humeral head received at the time of extracorporeal shock wave lithotripsy for calcifying tendonitis resulted in the developments of osteonecrosis of the humeral head.[115]

Disturbance of microcirculation can be the result of elevated intraosseous and interstitial pressures, such as with marrow hypertrophy, infiltration, or replacement.[92,215,429,448,497] Venous congestion as a mechanism has been popularized.[216] Although most of this information has come from studies of the femoral head, there is less knowledge of the specific occurrences within the humeral head.[339] Occlusion of the microcirculation may take place also by infiltration of hematopoietic marrow spaces with metabolic byproducts.

Thrombosis of vessels may occur in vascular disorders or coagulopathies. The process of intravascular coagulation is capable of initiating the cascade of events that result in osteonecrosis and may be triggered by various conditions.[154,155,230,231] Jones et al. assessed 45 patients with nontraumatic osteonecrosis for nine coagulation factors and identified a high incidence of thrombophilic and hypofibrinolytic coagulation abnormalities.[232] Nearly half the patients had abnormal concentrations of two or more factors. A hypercoagulable state has been suggested as a mechanism for osteonecrosis in HIV infection, as have alterations in lipid function.[18,45,151] Kubo et al. reported a possible relationship between type I congenital thrombophilic antithrombin III deficiency and multifocal osteonecrosis.[269] Embolization phenomena with vasocclusion occur in sickle cell disorders (sickled cells), caisson disease (nitrogen bubbles), and possibly microscopic lipid droplets.[67–69,93,136,226-229,239,335,464,543] Repetitive trauma may play a role.[245]

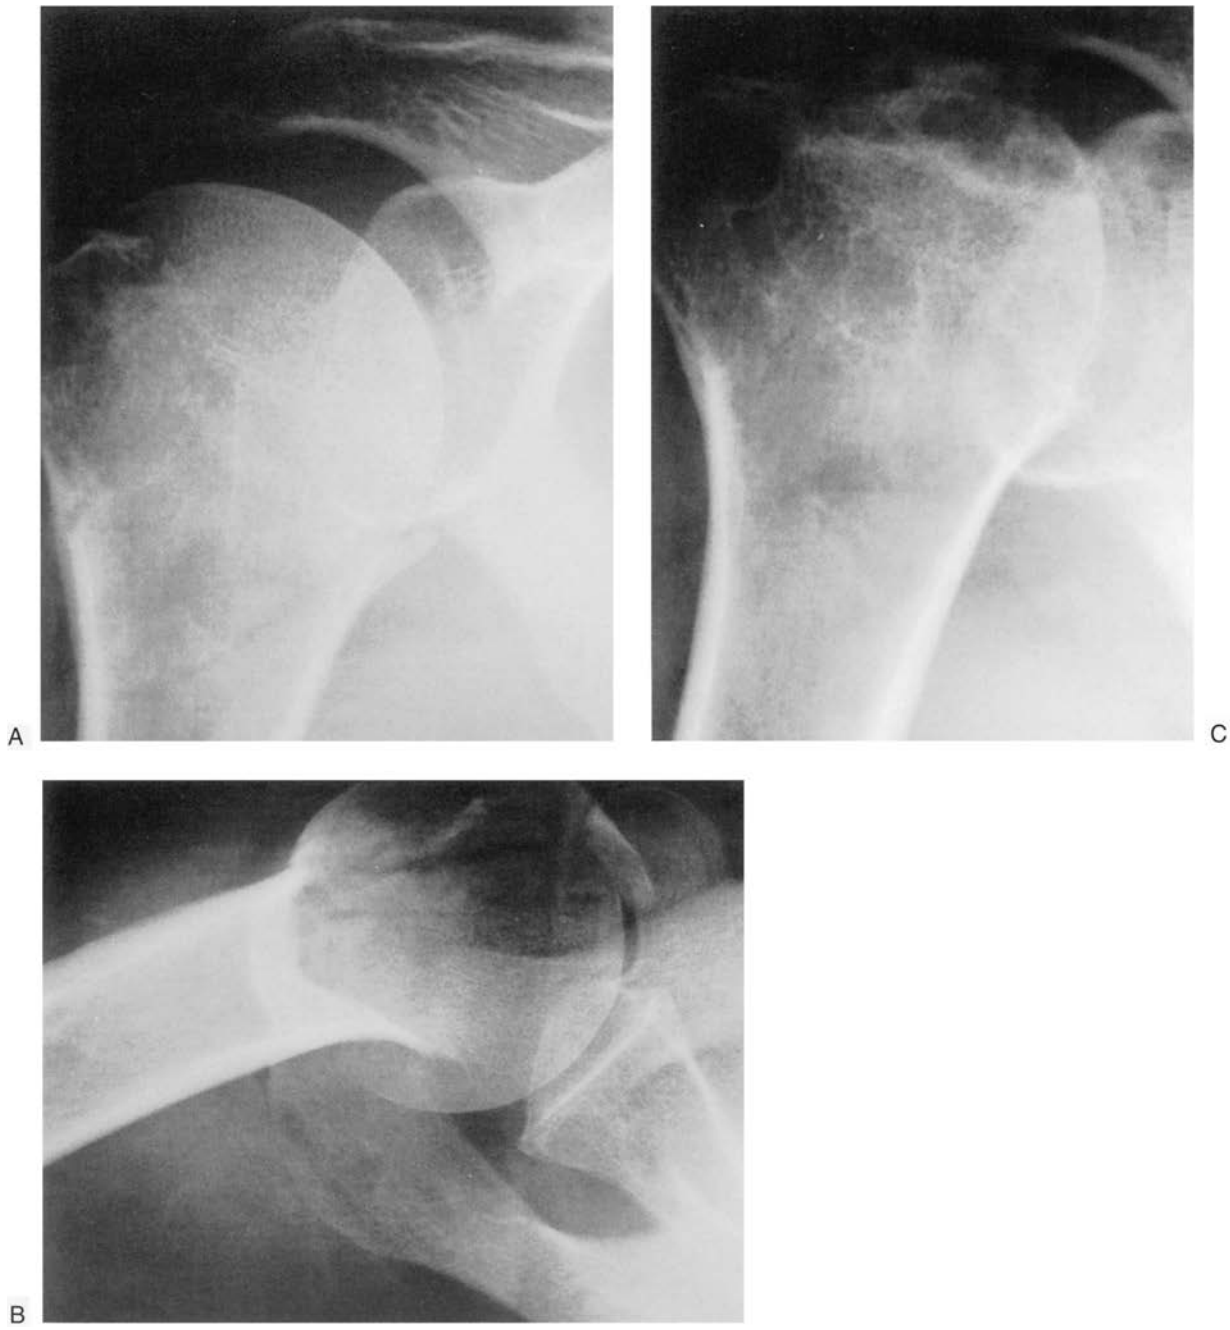

Figure 18-26 **(A,B)** Osteonecrosis: Minimally displaced fracture of the proximal humerus, managed with closed treatment. **(C)** However, posttraumatic segmental osteonecrosis developed, requiring hemiarthroplasty reconstruction.

Steroid ingestion is the predominant identifiable risk factor.[84,340,515] The precise mechanism of occurrence is unknown, although an initial reduction of blood flow has been reported when high-dose methylprednisolone is administered to a porcine model.[86,87,113,529] There is alteration in serum lipid content and concentration with associated fatty change within the liver. Systemic fat emboli may occur.[137,229] Osteonecrosis may follow short-term use as well as intraarticular injections.[11,85,128,279,371,378,499]

L'Insalata et al. reviewed a series of patients who had symptoms for 9 years.[292] The shortest interval from the completion of steroids to the onset of symptoms was 1 year. The shortest course of steroids was 1 week. In Cruess's study, the interval to the development of symptoms was not less than 6 months from the onset of steroid ingestion, the longest interval being 18 months.[85] L'Insalata et al. observed that 76% of patients using steroids developed osteonecrosis at sites other than the shoulder: the hip and

knee, most commonly.[292] Mont et al. observed that the incidence could not be correlated with the dosage or the duration of steroid ingestion.[340] In 74% of cases, bilateral disease was identified.

The excessive intake of alcohol is associated with the development of osteonecrosis.[216,219,377] In an experimental study with rabbits, alcohol ingestion induced adipogenesis, decreased osteogenesis in bone marrow stroma, and produced intracellular lipid deposits resulting in the death of osteocytes.[530]

Gaucher's disease is a well-known cause of osteonecrosis.[429,497] This autosomal recessive disorder is characterized by the accumulation of sphingolipid within the macrophages of the reticuloendothelial system (Gaucher's cells) due to the deficiency of glucocerebroside hydrolase. Gaucher's cells tightly pack the hematopoietic marrow leading to circulatory embarrassment of the surrounding bone. Risk factors for osteonecrosis in patients with type I Gaucher's disease are splenectomy and male gender.[429]

Other causes of osteonecrosis include sickle cell disease and other hemoglobinopathies, tobacco intake, hyperbaric exposure, decompression sickness, pancreatitis, familial hyperlipidemia, renal or other organ transplants, lymphoma, bismuth encephalopathy, gout, Cushing's disease, radiation, electrical shock, chemotherapy, Hodgkin's disease, myxedema, peripheral vascular disease, psoriasis, pregnancy, renal dialysis, systemic lupus erythematosus, and idiopathic diseases.[124,160,184,196,228,278,294,327,408,435]

Pathophysiology

The blood supply of the proximal humerus plays a critical role in the development of posttraumatic avascular necrosis; the incidence is not uncommon after displaced fractures of this region (Fig. 18-27). Most of the blood supply

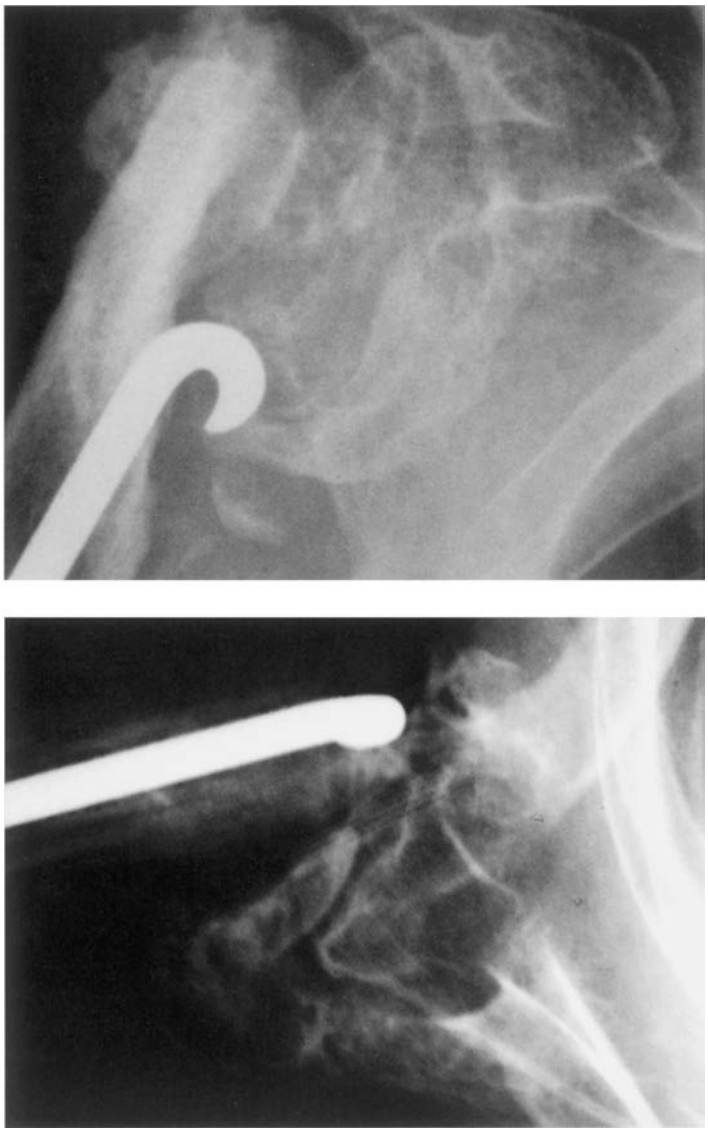

Figure 18-27 **(A,B)** Osteonecrosis: Displaced comminuted fracture of the proximal humerus, treated by open reduction and internal fixation (ORIF), resulting in total resorption of the avascular articular segment.

to the humeral head derives from the anterior humeral circumflex artery through its ascending branch.[275,344,417,436] Entry into the humeral head is in the region of the biceps groove. The arcuate artery is the intraosseous communication that arborizes and becomes the major blood supply to the head (Fig. 18-28).[150] Collateral circulation, normally not present to a great extent in the shoulder, will become insufficient if the fragments are widely displaced. The posterior humeral circumflex artery through rotator cuff attachments will provide a small amount of collateral flow. In addition, the more anterior portion of the cuff will receive other branches of the anterior humeral circumflex, which provides collateral circulation for the articular segment.[344,417,436]

It is possible that the event of circulatory arrest leading to humeral head osteonecrosis occurs at the moment of injury. Forceful manipulative attempts at reduction or surgical intervention may further disturb precarious circulation to the articular segment. When indirect reduction techniques were utilized, the incidence of osteonecrosis was reduced to 4%.[195] Although commonly felt to favor prevention of osteonecrosis in the hip, the effect of prompt reduction and stabilization on the incidence of osteonecrosis of the humerus is unknown. Because the vascular supply plays such a critical role in proximal humerus fractures, classifications based on this fact alone have evolved, allowing prognosis after injury and treatment.[220]

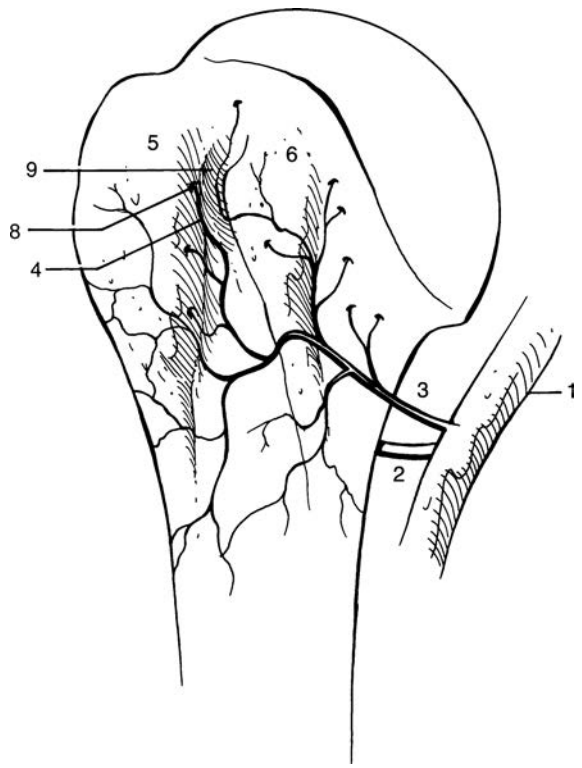

Figure 18-28 Graphic representation of the anterior aspect of the humeral head depicting the arterial vascularization: **(1)** axillary artery, **(2)** posterior circumflex artery, **(3)** anterior circumflex artery, **(4)** anterolateral branch of the anterior circumflex artery, **(5)** greater tuberosity, **(6)** lesser tuberosity, **(7)** constant site of entry of the anterolateral branch into bone, **(8)** intertubercular groove. (From Gerber C, Schneeberger A, Vinh TS. The arterial vascularization of the humeral head. *J Bone Joint Surg Am* 1990;72: 1489, with permission.)

Whereas the underlying diagnosis in femoral head osteonecrosis is often elusive and determined to be idiopathic, the cause of nontraumatic osteonecrosis of the humeral head is often identifiable. Despite the etiologic factors involved in the development of osteonecrosis, a common pathway is followed as the disease process evolves. Unlike the usual arthritides that begin with the involvement of the articular cartilage, osteonecrosis initially involves the subchondral cancellous bone in the portion of the humeral head under the greatest load. Later, the articular surface may be altered and, eventually, more extensive damage extends to the glenoid.

Osteonecrosis from disease processes probably results from repetitive insults leading up to a threshold of vascular embarrassment. The resultant ischemia of the marrow elements and osteocytes eventually leads to infarction. Pain may or may not be present at this stage. Discomfort may be related to increased intraosseous pressure in the absence of collapse of the articular surface. What role increased intraosseous pressure plays at this point is uncertain, although its presence has been clearly documented.[134,264]

Pathoanatomy

The repair process is initiated soon after the initial vascular insult. The response is vascular ingrowth in attempt to remove necrotic marrow and to rebuild necrotic bone. The repair process is ongoing, even continuing in the presence of vascular insults. Continued stress on viable bone resulting in microfractures, trabecular collapse, and compression may establish a front impenetrable by the repair granulation tissue. At the time of collapse, the overlying subchondral bone and cartilage remain intact. Initially, this occurs in the area of maximum joint reaction force and creates a gap, which radiographically is known as the "crescent sign." With further loading, there is complete segmental failure with incongruity of the subchondral bone.

Articular surface damage may take place even though the cartilage remains viable (Fig. 18-29). Depending on the extent of involvement, the humeral head undergoes progressive secondary degeneration. As a result of bearing against the morphologically altered humeral head, the glenoid eventually develops osteoarthritic changes.

Clinical Evaluation

The chief complaint of patients with osteonecrosis is pain. The onset is usually insidious and discomfort is not initially severe. In sickle cell disorders, the clinical distinction

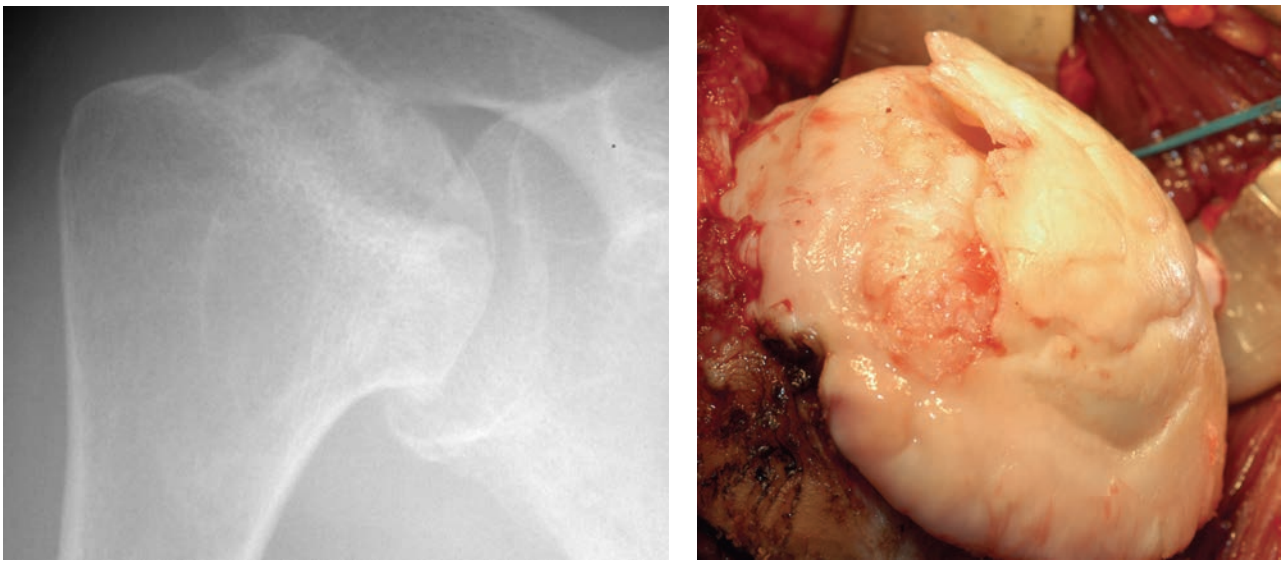

Figure 18-29 **(A)** Stage IV osteonecrosis of the humeral head. **(B)** The articular cartilage appears viable despite near-complete detachment from the underlying subchondral bone. Secondary osteoarthritic changes are present.

between a crisis, bone or synovial infarction, and incipient osteonecrosis may be extremely difficult.[452]

Proximal humerus fractures, with anatomic or near anatomic reductions and stable fixation, may achieve a satisfactory result even in the presence of osteonecrosis.[149,200,534] Hattrup and Cofield reported a series of 200 patients with humeral head osteonecrosis in which more than 25%, regardless of stage, were managed nonoperatively in a satisfactory manner for 2 to 14 years.[186] Greater deformity of the humeral head is better tolerated by the shoulder due to the extent of loading ("non–weight bearing") and because of the maintenance of scapulothoracic motion.[335,515] For other patients, shoulder pain may later intensify with progressive involvement of the head or owing to alterations of the articular surface. Not only will there be an intense synovial response, but mechanical symptoms of locking or catching ensue. Early in the disease, the shoulder range of motion is maintained with guarding at the extremes. Gradually, the range diminishes to that required for essential functional tasks, later accompanied by atrophy and weakness. Crepitation of articular origin can be elicited as the shoulder actively or passively rotates.

Imaging

Imaging studies include tomography, MRI, bone scintigraphy, and CT to assess the amount of humeral head involvement, bone loss, and the distortion of underlying anatomy. McCallum and Walder offered a classification scheme that separated humeral head, neck, and shaft involvement from juxtaarticular lesions.[316] In the latter, the earliest findings were dense areas with an intact cortex. Spherical segmental opacities and linear opacities were noted. When structural failure occurred, a translucent subcortical band could be seen. Later, the articular cartilage would collapse and the cortex would be separated. The final stage was osteochondrosis.

The radiographic progression of the disease has been more recently staged according to the system of Ficat and Arlet, as modified by Cruess (Fig. 18-30).[85,86,134] Stage I includes subtle changes within the humeral head. Pain may or may not be present. The plain films show that the humeral head is round, with some mottling present: MRI examination will pick up this early finding. Stage II is the development of focal sclerosis without collapse. The anteroposterior view of the humerus in external rotation is often diagnostic at this stage, as is the MRI. The cartilage surface can be round, but there is some ballotability of the affected segment. Stage III is the development of collapse or a crescent sign (Fig. 18-31). There is no displacement of the articular surface more than l or 2 mm. The cartilage may loosen as a flap, creating symptoms of internal derangement. At this point, the glenoid is normal. Stage IV results in a displaced cartilaginous flap accompanied by humeral head softening and collapse (Fig. 18-32). Stage V is wear of the cartilage and the bone of both the glenoid and humerus. The joint becomes incongruent with secondary degenerative changes (Fig. 18-33). The MRI findings of humeral and femoral heads with osteonecrosis are similar.[285] In femoral heads with MRI-proven osteonecrosis, bone scintigraphy demonstrated sensitivity, specificity, accuracy, positive predictive value, and negative predictive value of 65%, 81%, 77%, 54%, and 87%, respectively.[444] In femoral heads, subchondral fractures have been more

reliably demonstrated with CT scan rather than MRI.[489] Kishida et al. showed that the diagnostic ability of three-dimensional spoiled gradient-echo (3D SPGR) MRI provided more accurate measurements of the area and volume of a necrotic lesion than T1-weighted SE imaging.[253]

Laboratory

Laboratory studies may be important for the detection of underlying diseases.

Natural History

The necrotic segment size may vary in traumatic occurrences of osteonecrosis. Smaller areas of involvement may be sufficiently revascularized and stabilized before the stage of collapse. Larger necrotic segments remain isolated from incoming circulation, inevitably progressing to collapse and eventual head destruction. Sometimes, however, the glenohumeral joint congruity will be preserved, allowing maintenance of adequate function.[149,284,346]

Almost three-fourths of patients with atraumatic osteonecrosis will have progression of their disease to the extent that will require surgery, or will result in significant pain or disability.[85,87,426] At the time of presentation, 20% of patients in L'Insalata et al.'s series required surgery on the basis of pain alone.[292] Thirty-four percent responded initially to conservative care for an average period of 2 years, and then required surgery. Forty-six percent responded to conservative care for an average of 10 years.

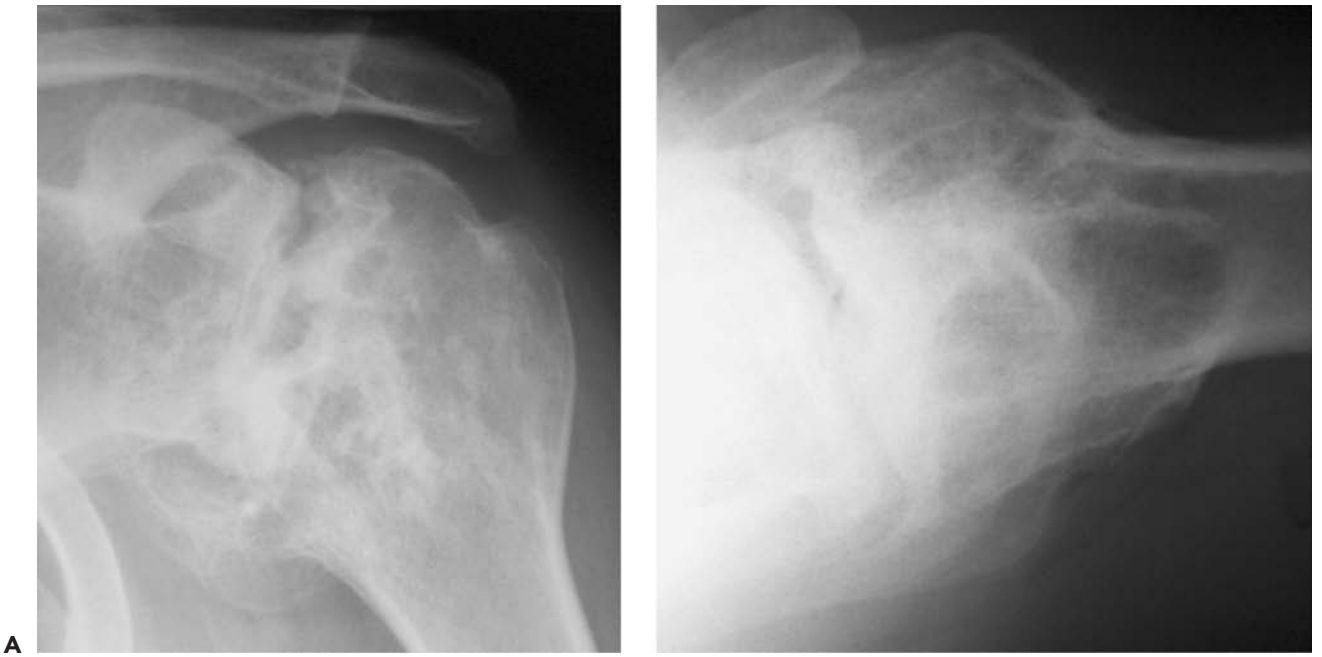

Figure 18-33 **(A,B)** Osteonecrosis: Stage V. Secondary osteoarthritic changes of the humerus and the glenoid following proximal humerus osteonecrosis.

Half of these patients were satisfied and half were unsatisfied with their outcome. At 4.5 years after presentation, 80% of Rutherford and Cofield's patients with stage II and III disease had no clinical progression.[442] In a follow-up study at the same institution, Hattrup and Cofield remarked that the need for shoulder arthroplasty was dependent on the underlying diagnosis and the extent and Cruess stage of humeral head involvement.[186] At a 3-year interval, traumatic etiology versus steroid intake was more likely to result in surgical treatment, 80% versus 43%. Three-fourths of patients initially treated nonoperatively continued to be pain-free, or have only moderate discomfort, almost 9 years after diagnosis. Clearly, radiographic progression is commensurate with a poor outcome. This is particularly true with radiographic stage III, or greater, and evidence of disease progression. L'Insalata et al. observed that poor outcomes were more common in women than in men and that patients with steroid-induced disease had a better prognosis.[292]

RHEUMATOID ARTHRITIS

Definition

Rheumatoid arthritis is a systemic autoimmune disorder of unknown cause. It is believed to occur in individuals who are genetically predisposed in response to an arthritogenic agent or antigen, perhaps environmental. Although its effects may be systemic, its major distinctive feature is chronic, often symmetrical erosive synovitis of the peripheral joints.

Incidence

Rheumatoid arthritis is the most prevalent inflammatory arthropathy in adults, occurring in 1% to 2% overall and 2% to 2.3% in the geriatric population.[415] It is most prevalent in the fourth and fifth decades.[88] There is considerable variation in the prevalence and incidence of rheumatoid arthritis among different populations. In Northern Europe and North America, the prevalence of the disease is 0.5% to 1.0%, with the mean annual incidence of 0.02% to 0.05%.[4]

The incidence of rheumatoid arthritis is approximately 20 to 40 in 100,000 adults. Women have a two- to threefold greater risk, and the disease is more prevalent with advancing age.[203]

The shoulder is invariably involved, usually as a clinical feature of progressive disease.[167,336] It is not commonly one of the first manifestations of the disease; never is it the only one. Its presence is usually bilateral.[88] The actual incidence of glenohumeral involvement, depending on which patient group or what stage of the disease is selected or studied, ranges from 20% to 90%.[82,288,394] The incidence is 50% to 60% when polyarticular rheumatoid disease exists.[289,427,482] The incidence is highest in patients undergoing surgical intervention, whereas shoulder occurrences are much less frequent with those patients who manifest minor symptoms of the disease.

It may be the first joint to be involved in approximately 4% of the cases with rheumatoid arthritis as well as the most common large joint to be affected at the time of presentation.[185,375] When it is the presenting joint (up to 21% of cases), the illness soon becomes systemic and polyarticular.[375] Therefore, only rarely can rheumatoid arthritis account for a chronic monarthritis of the shoulder.

Pathogenesis

Although connective tissue, wherever it is present, is susceptible to the effects of rheumatoid disease, its greatest effect is on the internal aspects of the joint, especially the synovial membrane. A single primary cause has not been determined.[336] Risk factors are genetic susceptibility, sex and age, smoking, infectious agents, hormonal, dietary, socioeconomic, and ethnic factors.[4] Infectious agents, autoimmunity, and heritable factors, their activities perhaps interrelated, may have a role.[336] Rheumatoid factor (IgM) may be found in 3% of healthy people. Its role in rheumatoid arthritis may be to amplify rheumatoid inflammation, but it does not appear to serve as a primary etiologic agent or as a trigger.[453]

Pathophysiology

The exact sequence or cause of events leading to symptomatic rheumatoid arthritis has not been determined. The initial pathologic event appears to be activation and injury of subsynovial microvascular endothelial cells.[458,476] T lymphocytes transgress the vascular endothelium and come to lie in the subsynovial areas around small capillaries, where their surfaces acquire antigens, processed and presented by tissue macrophages.[222,405] These cells, as well as B-cell lymphocytes and their products—proinflammatory cytokines (interleukin-1 [IL-1], tissue necrosis factor-alpha [TNF-α], and immunoglobulins)—proliferate in a poorly restrained manner.[494] Metalloproteinases, nitrogen oxide, hydrogen peroxide, TNF-α, and interleukin-beta accumulate in cytotoxic concentrations, further activating collagenase and stromelysin.[476] Complex pathways of oxygen metabolism resulting in reactive oxygen species exhibit toxicity to cellular and molecular components and contribute to the mediation of the inflammatory response.[202] The normally flimsy, one- to two-cell–thick lining layer and sublining synovial membrane may thicken by as much as 100 times through the process of hypertrophy and activation of the connective tissue stroma.[382] Joint fluid volume increases with activation and proliferation of the synovial cells. Inflammatory cells and chemical mediators of inflammation accumulate and weaken the supporting soft tissue structures of the synovium.

The synovitis resembles both tumor growth and wound healing, relying on new blood vessel proliferation—angiogenesis—to sustain its expansion.[270,488] These abnormal cells develop abrasive qualities that take on the behavior of malignancy and advance onto the adjacent cartilage and bone.[127] This tissue, which continues to proliferate, develops invasive properties, and bears resemblance to granulation tissue, is known as pannus.[182] Whether its initiation is pathologic or reparative has not been clarified.[182] It can invade adjacent tendons, tendon sheaths, ligaments, bone, and articular cartilage. As the cartilage is eroded, breaks in the underlying bone may develop. Cysts may form and subsequently coalesce into large subchondral defects with potential for collapse in areas of greatest load.

Pathoanatomy

Crossan identified three pathologic phases of synovial inflammation: exudative, infiltrative, and degradative.[83] The exudative phase begins at the articular cartilage margin. There is increase in capillary permeability, initially with the efflux of fluid into the interstitial space. The infiltrative phase is marked by the escape and movement of cells into the subsynovial and periarticular tissues. Monocytes and lymphocytes invade the inflamed synovium when earliest biopsies are obtained. The development of lymphoid follicles may occur, but they rarely have germinal centers. When this takes place, an increased number of plasma cells follow. Multinucleated giant cells may exist in the subsynovial layers. The activated synovial surface appears villous and papillary as different portions exist in different stages of development. The degradation phase begins with peripheral marginal injury to the avascular hyaline cartilage. The result is disorganization and loss of the intercellular matrix, yielding to limited repair attempts by fibrosis. Chondrocyte and matrix loss results in cartilage thinning. Pannus may undermine the subchondral and marginal bone and result in osteoclastic bone destruction, observed as the periarticular erosion seen on radiographs.

The entire shoulder structure may become involved in the rheumatoid process. Earliest changes are in the adjacent soft tissue, including the subacromial bursa, rotator cuff tendons, and the long head of the biceps. In the early stages, the rotator cuff is vulnerable to infiltration by rheumatoid synovium. This may result in attenuation or rupture of the cuff and the formation of subacromial bursal effusions. From 20% to 50% of patients acquire full-thickness tears and a smaller number, partial-thickness tears.[125,143,356,365] In patients undergoing total shoulder arthroplasty for rheumatoid arthritis, approximately one-third will have a full-thickness rotator cuff tear.[143,356,406] Arthrography fails to demonstrate up to one-third of intertubercular grooves, implying biceps tendon stenosis within the canal.[104] In later stages, when destruction of the humeral articular cartilage is prominent, up to two-thirds of the biceps tendons rupture.[383] Poor bone quality, subchondral cysts, and soft tissue contractures are often recognized.

The characteristic erosions of glenohumeral rheumatoid arthritis occur in the superior aspect, medial to the greater tuberosity at the synovial reflection, and correspond to the most common site of rotator cuff tearing. The humeral head may ascend with secondary erosive changes owing to glenohumeral incongruity. A classification of shoulder disease in 100 patients with rheumatoid arthritis undergoing lower extremity surgery described these changes.[83] Forty percent of shoulders initially manifested only erosive changes, often involving the acromioclavicular joint. The humeral head remained spherical, and the glenohumeral articulation remained normal. In 40%, proximal subluxation of the humeral head occurred. In half of these, the acromiohumeral interval was less than 6 mm as a result of significant soft tissue damage. The humeral head remained spherical and the glenoid preserved in approximately one-half of the cases. End-stage disease occurred in the remaining 20%. The humeral head was destroyed with associated destructive changes of the glenoid. Resorption was a common feature. The acromiohumeral interval was significantly diminished, and there were gross distortions in glenohumeral relations.

Clinical Evaluation

The symptoms and manifestations of glenohumeral rheumatoid arthritis usually have an insidious onset and slow progression. Adaptive and compensatory mechanisms by the elbow and wrist enable most patients to maintain their functional status while the disease progressively takes its toll on the glenohumeral joint and soft tissues. As a result, advanced changes often manifest at initial presentation. The shoulder symptoms typically do not correlate with the general severity or activity of the disease. In the later stages of the disease process, patients with rheumatoid arthritis have a tendency toward more significant impairment of shoulder function than patients with osteoarthritis, while their overall health status is significantly worse.[308]

Pain is the most common symptom reported by patients with glenohumeral rheumatoid arthritis and is reported by 67% to 91% of patients.[286] In 20% of these patients, it is the result of moderate or severe glenohumeral joint destruction within the first 15 years of the disease.[286] The pain may be intense, even before radiographically advanced changes of severe bone loss, osteopenia, erosions, and humeral head translocations are observed. Unlike other involved joints, night pain is more typical when the shoulder is involved. Patients sense an awareness of stiffness. Functional loss may occur early in the disease.

The physical findings include those related to inflammation: tenderness, often diffuse, but sometimes more localized to the joint line posteriorly, as well as the infracoracoid region corresponding to the anterior joint line. Tenderness is seen more commonly in older patients and in more severe disease.[375] There may be increased overlying cutaneous warmth when compared with the adjacent areas. Erythema is not common. Swelling from a glenohumeral joint effusion may be present, although not always prominent. More often, the swelling is observed superiorly in the subacromial bursa from an extension of articular fluid through a defect in the rotator cuff. Atrophy of the shoulder girdle may be present, although the presence of swelling and effusions may make recognition more difficult. Motion restriction may be attributable to several causes. Reflex activity limitations because of discomfort will accompany most conditions that cause pain. Active range-of-motion losses and weakness may occur because of rotator cuff tears. Some motion loss may be noted from weakness because of muscle atrophy. Joint capsule contractures may inhibit both active and passive range of motion. Large effusions and articular surface changes may contribute to diminished range of motion.

Imaging

Larsen et al. presented the first radiographically refined and standardized grading system for the radiographic severity of rheumatoid arthritis.[280] This method was applied to multiple small and large joints, including the shoulder (Table 18-3).

Radiographically, Neer identified three clinical types of rheumatoid glenohumeral arthritis.[364] The dry type is characterized by loss of the joint space, formation of subchondral cysts, sclerosis, and marginal osteophytes, not unlike osteoarthritis (Fig. 18-34). Marginal erosions are infrequent. Patients have more difficulty mobilizing the shoulder involved with this type of rheumatoid arthritis. A wet type results from the proliferation of exuberant granulation tissue at the articular margins (Fig. 18-35). Marginal erosions, sometimes quite large, are characteristic of this pattern. The proximal humeral architecture, altered by a gradual loss of humeral head and tuberosity contours, acquires a "pointed appearance." The wet and resorptive phase is the most destructive, characterized by "centralization" (Fig. 18-36). This phenomenon evolves in response to a rapid and severe articular cartilage and bone loss. Medial migration with the loss of bone mass results in a loss of the normal physical contour of the shoulder (Fig. 18-37). In 1954, Laine et al. proposed a similar classification based upon clinical and radiologic findings.[274]

The radiographic findings are dependent on the duration and extent of the disease, and may reflect the quality of medical management. Symmetry is characteristic of rheumatoid arthritis. The initial radiographic features may be normal, but later, because of disuse or local inflammation, osteopenia may be observed (Fig. 18-38). Osseous erosions appear at sites of synovial tissue concentrations, most commonly the anatomic neck, superior and medial

TABLE 18-3
LARSEN RADIOGRAPHIC STAGING FOR RHEUMATOID ARTHRITIS

Grade	Description	Anatomic findings
0	Normal	
I	Slight abnormality	One or more: periarticular soft tissue swelling, periarticular osteoporosis, slight joint space narrowing
II	Definite early abnormality	Erosion and joint space narrowing
III	Medium destructive abnormality	Erosion and joint space narrowing
IV	Severe destructive	Erosion and joint space narrowing; bone deformity
V	Mutilating	Disappearance of original articular surfaces; gross deformity

From ref. 166, with permission.

to the greater tuberosity. Lehtinen et al. observed that a significant joint space reduction did not occur until Larsen grade 4 destruction.[287] At the same time, they observed that extensive erosions on the glenohumeral joint are followed, not preceded, by joint space narrowing. With the gradual concentric loss of articular cartilage and erosion of the subchondral bony plates, the glenoid and the humeral head move closer together (Fig. 18-39). In rare instances, osteophytes may secondarily occur. Invasive biceps tenosynovitis may produce surface erosions of the intertubercular groove.

The position of the humeral head relative to the glenoid and to the acromion is controlled by several factors. Initially, there may be ascent of the humeral head because of weak muscles. Later, with attrition and rupture of the rotator cuff, the acromiohumeral interval narrows further. It has been observed that upward migration precedes medialization and gross destruction of the glenohumeral articular surfaces.[286] Progressive upward migration is an inevitable consequence of rheumatoid destruction in the glenohumeral joint. A significant step in this process was observed between the Larsen grades of 3 and 4, where the mean distance turned negative, indicating rotator cuff disease.[287] During the end stages of disease, the acromiohumeral interval may become obliterated with the formation of a new acromiohumeral articulation. At this point, gross destruction of the glenohumeral articulation may be observed. Large cysts, subchondral sclerosis, and secondary

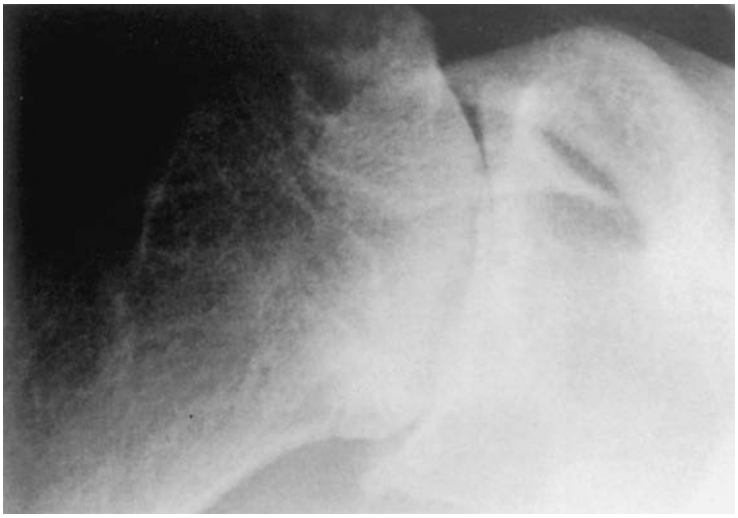

Figure 18-34 Rheumatoid arthritis: Dry type, characterized by loss of joint space, sclerosis, and marginal osteophytes.

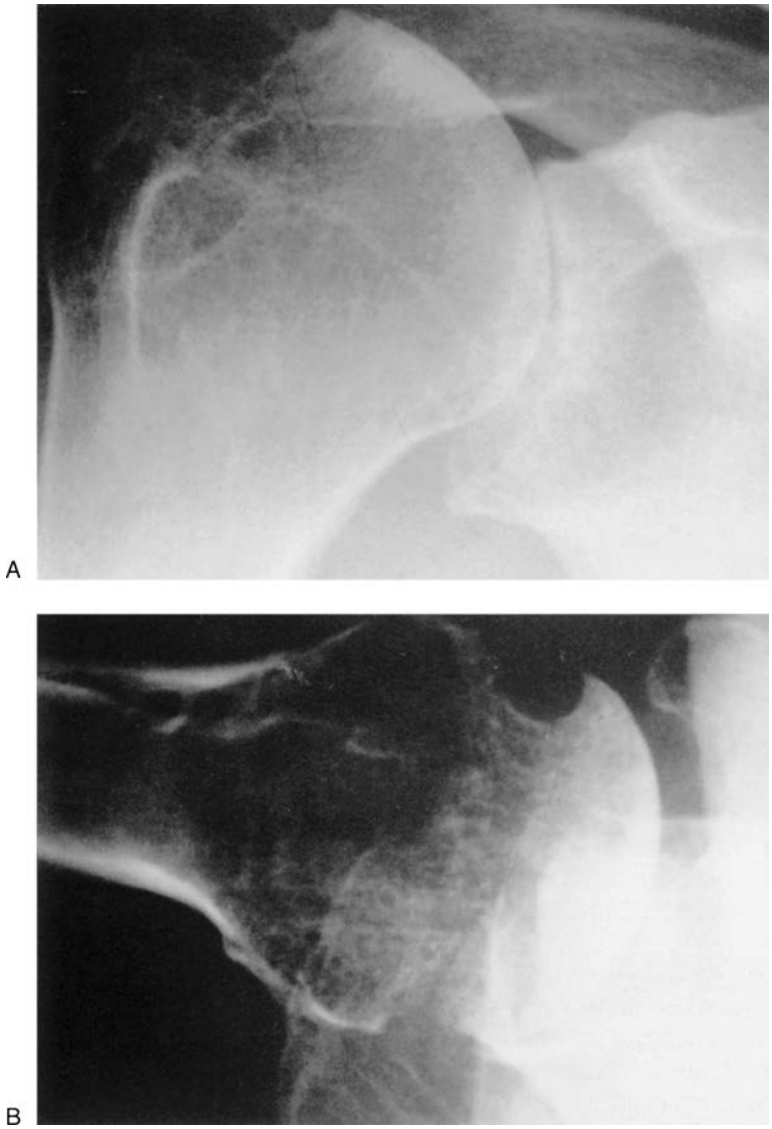

Figure 18-35 **(A,B)** Rheumatoid arthritis: Wet type, with large erosions characteristically found at synovial attachment sites.

osteoarthritis may develop (Fig. 18-40). There may be overall centralization of the joint due to extreme glenoid erosion (Fig. 18-41). The humeral head may resorb and collapse onto the glenoid (Fig. 18-42).

Hirooka et al. observed that certain radiographic findings apparent at 5 to 10 years are capable of predicting the prognosis for shoulder joint destruction at 15 to 20 years, implying the opportunity for treatment stratification.[201]

Computed tomography scanning will help to better define the extent of the erosions and cyst formation within the humeral head and glenoid.[7] A determination of the volume and orientation of the glenoid vault can be made in preparation for arthroplasty reconstruction.[142] Significant centralization may result in a wafer-thin glenoid, which would yield to the preparation and placement of a prosthetic glenoid component. Mullaji noted that only one-half of the surface area of the rheumatoid glenoid was supported by sufficient bone.[348] Humeral bone quality in rheumatoid arthritis may be underestimated by CT.[7]

Arthrography can be used to discriminate an acute rheumatoid flare from a full-thickness rotator cuff tear. When there is significant stiffness, adhesive capsulitis can be assessed. Chronic synovitis is often diagnosed on the basis of filling defects within the joint. Distension of the biceps tendon sheath may be observed.[103]

When the initial radiographs are unrevealing, sonography and MRI can provide supplementary information about the disease process.[6,193] With sufficient experience, sonography can be useful to image the osteoarticular changes about the shoulder resulting from rheumatoid arthritis.[193] Sonographic abnormalities may be present both in patients with and without shoulder complaints as well as in patients with normal findings on physical

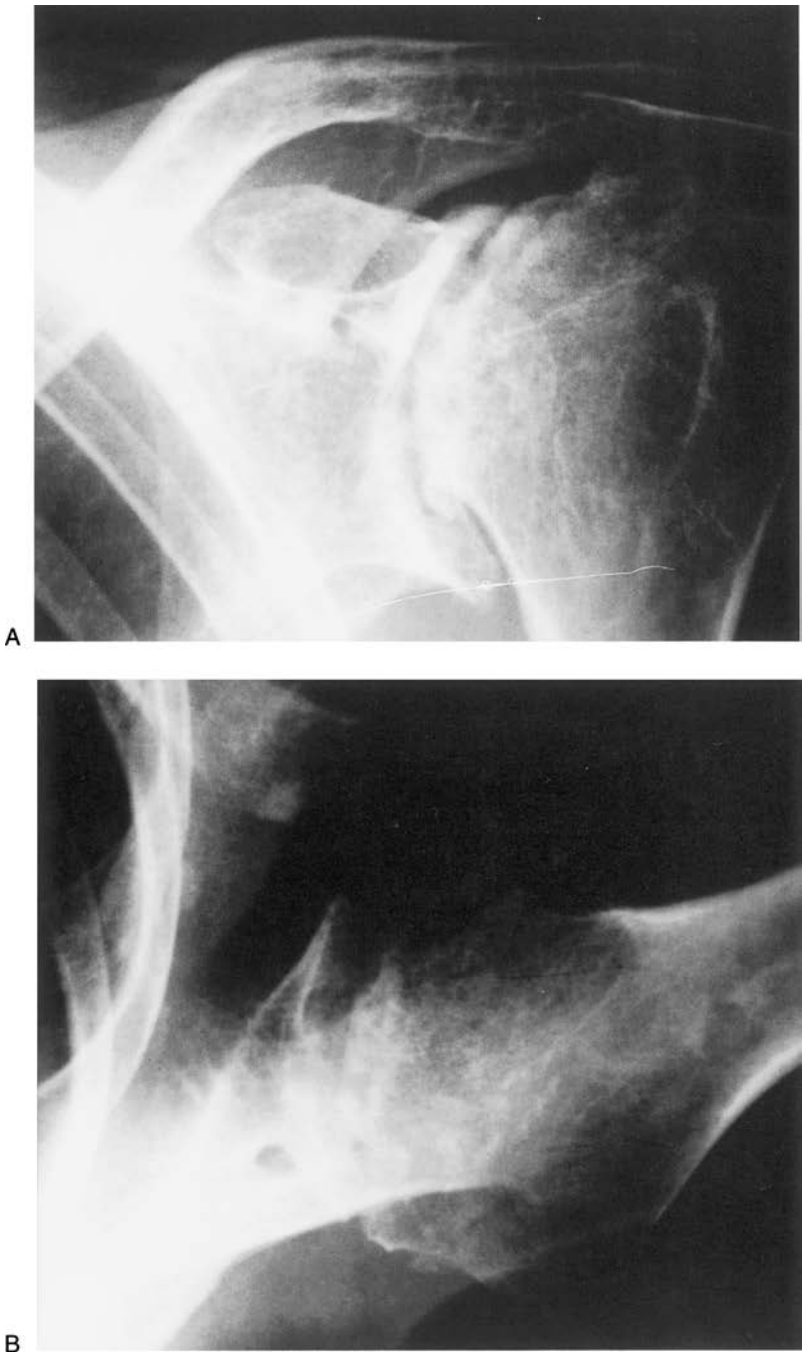

Figure 18-36 Rheumatoid arthritis: **(A,B)** Wet and resorptive type. Subchondral cyst formation and erosion of the glenoid and humeral head.

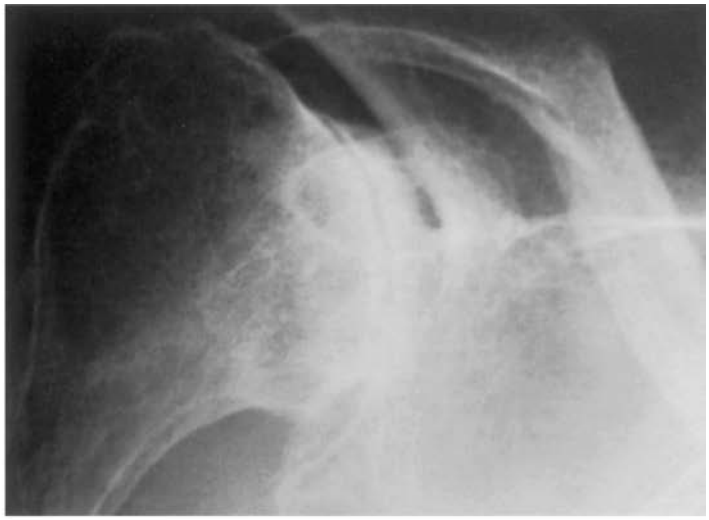
examination.[352] Sonography has not proven useful to distinguish glenohumeral synovitis from a joint effusion.[528] It has been shown to be more useful early in the disease process before the normal anatomy and motion are significantly altered.[5]

MRI is probably the best overall imaging modality for rheumatoid arthritis capable of detection with a high degree of accuracy and detection of the earliest changes in the soft tissue and damage to articular cartilage and bone.[480] An MRI scan can accurately determine the presence of synovial fluid, estimate its volume, and trace the extent of its dissection through the periarticular tissues. The rotator cuff integrity and quality can be assessed. In the rheumatoid knee, subchondral cyst contents and dimensions may become more apparent with MRI, their detection dependent on size, location, and perhaps biologic activity.[399]

Laboratory

Blood work is important for the evaluation of patients suspected of having rheumatoid arthritis.[64] Anemia is



C

D

Figure 18-36 (*continued*) **(C,D)** More severe involvement with advanced centralization of the joint is noted with generalized loss of the glenoid.

sometimes present, but generally there is a normal white blood cell count. Rheumatoid factor is positive in 75% to 90% of cases.[14,545] Acute-phase reactants (ESR, CRP) may be present and elevated.[23,453] Their usefulness may be more appropriate for monitoring the activity of rheumatoid arthritis.[379] Synovial fluid analysis is confirmatory for inflammation.

Natural History

The rate of progression of rheumatoid disease involvement of the shoulder is unknown. Three main patterns of shoulder involvement have been suggested.[83] These include acute rotator cuff tear, progressive cuff attrition, and medial head displacement. In a few patients, acute rotator cuff tear occurs. This is usually the result of acute synovitis that has involved the synovium adjacent to the insertion of the supraspinatus tendon. The synovium will infiltrate the adjacent tendon, with resultant spontaneous rupture. Progressive cuff attrition is the result of end-stage disease. With progressive muscular and tendinous weakening, there is ascent of the humeral head and diminution in the available acromiohumeral interval. The glenohumeral joint becomes incongruous and

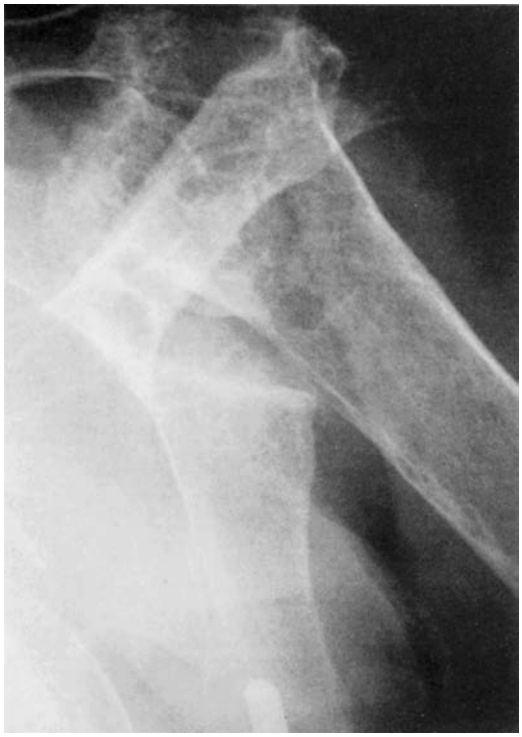


Figure 18-37 Rheumatoid arthritis, end stage, with total distortion of glenohumeral anatomy.

develops progressive erosion. Glenohumeral deformity soon follows. Medial head displacement is rarely an early event. Only when there has been significant cuff attrition and proximal migration does medial head displacement occur. A significant toll is taken on the articular and subchondral osseous tissues. Pannus formation within the glenoid fossa results in a significant loss of supporting bone stock. As the shoulder comes under load, the forces progressively collapse the weakened glenoid. Repair cannot keep pace with the mechanical overload of the weakened glenoid. The humeral head assumes a more medial position as the glenoid gradually disappears.

Neer pointed out the pathologic variations in glenohumeral rheumatoid arthritis.[364] A low-grade type of involvement showed the slow development of articular surface changes and bone loss. An intermediate type was associated with the formation of osteophytes, indicating a response to the ongoing process. In the most severe pattern, there was rapid loss of the articular space and collapse of the underlying bone, with narrowing of the acromiohumeral interval.

Non-Hodgkin's lymphoma has been reported as an unexpected diagnosis made in the surgical specimen of a patient with long-standing rheumatoid arthritis taking immunosuppressive medication and being treated with total shoulder arthroplasty.[16]

CRYSTALLINE ARTHRITIS

Calcium Pyrophosphate Dihydrate Deposition Disease

Calcium pyrophosphate dihydrate (CPPD) deposition disease is a disorder of the articular tissues resulting from the liberation and deposition of CPPD crystals. A prerequisite for diagnosis of the disorder is identification of the deposition of CPPD crystals into fibrocartilage and hyaline cartilage. The relation between CPPD and osteoarthritis is unclear, but notably strong.[131] Unlike gout, there is not a metabolic disturbance.

Incidence

The incidence of clinically symptomatic disease is at least half that of classic gout, with the knee most commonly involved, followed by the wrist, then the shoulder.[104] Clear associations with end-stage secondary osteoarthritis of the shoulder have been reported.[349] Okazaki et al. reported an incidence of up to 50%.[374] CPPD deposition disease does not favor one gender. A familial form is common in the shoulder.[181]

Clinical Evaluation

Two stages of the disorder have been recognized.[109] First is the occurrence of acute attacks of synovitis precipitated by the liberation, accumulation, and reactivity from calcium pyrophosphate crystals within the intraarticular space. Termed "pseudogout," these attacks clinically resemble gout.[109,260] Often the acute events are imposed on a joint with chronic arthropathy. Patients present with an acute severely painful shoulder with motion limitation. Tenderness, swelling, and increased warmth overlying the joint may be appreciated. Fever is not uncommon. If left untreated, symptoms may persist for weeks.

In the second stage, CPPD arthropathy will evolve from repeated attacks and the accumulation of deposition pyrophosphate crystals within the articular cartilage. Secondary degenerative arthritis will develop, accompanied by chronic pain. A propensity for elderly women is recognized with this form.[332]

Pathogenesis

The mechanism of crystal shedding into the joint is unclear. The association of trauma, infection, or illness has not been established, but there may be a predisposition for joints with degenerative changes.[117] McCarty proposed six types: sporadic, pseudorheumatoid arthritis (multiple joints), pseudoosteoarthritis, asymptomatic, chondrocalcinosis, and neuropathic-like.[319] Occurrences at the time of surgery

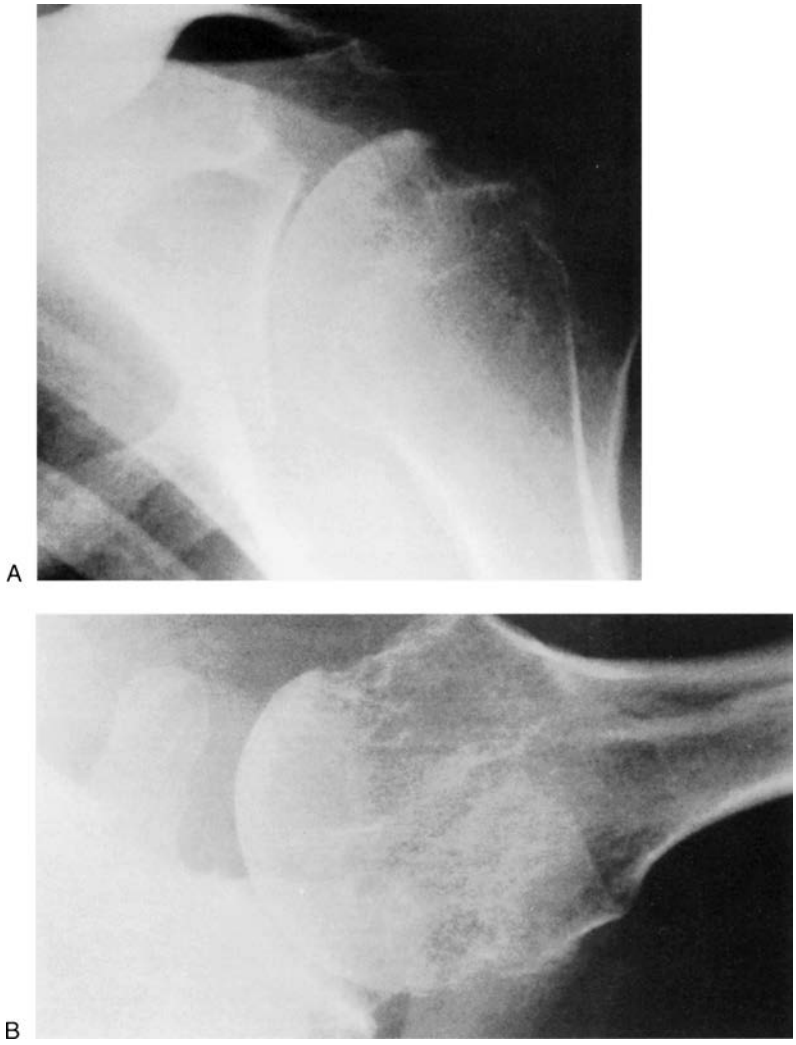

Figure 18-38 **(A,B)** Rheumatoid arthritis: Early disease with preservation of the glenohumeral articular surface; periarticular osteoporosis, particularly in the humeral head.

Figure 18-39 Rheumatoid arthritis: Concentric loss of the articular space and osteopenia. Erosions are not prominent.

Figure 18-40 Rheumatoid arthritis: Secondary osteoarthritic changes are present.

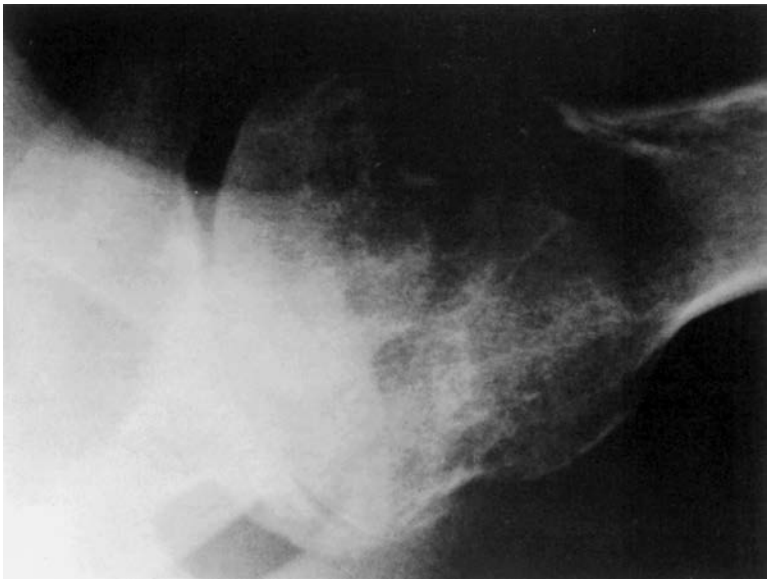

Figure 18-41 Rheumatoid arthritis: The morphology of the humeral head is satisfactorily preserved. There is significant "centralization."

are not uncommon. An increasing incidence with age suggests that the disorder may be a part of the aging process.

Chondrocytes within the articular cartilage possess enzyme systems capable of regulating pyrophosphate and CPPD concentrations within the cartilage.[547] If chondrocyte damage occurs, normal pyrophosphate homeostasis is disturbed. The crystal form accumulates and is liberated into the joint when concentrations exceed a critical threshold. A synovial inflammatory response ensues: Chemotactic factors are released and propagated by polymorphonuclear phagocytosis. Further articular cartilage damage leads to the additional release of calcium pyrophosphate crystals.

Imaging

The disorder may present incidentally on plain radiographs (Fig. 18-43A). Known as chondrocalcinosis, these opacities in articular and fibrocartilage are observed

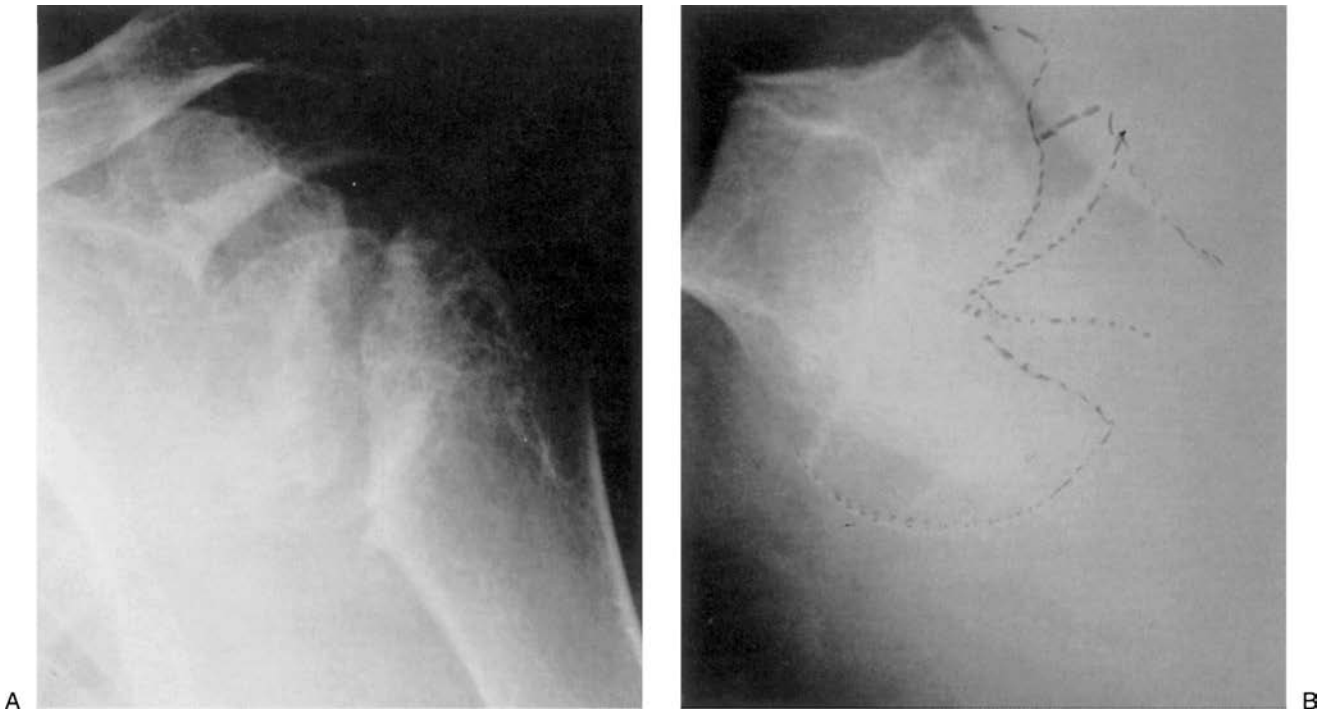

Figure 18-42 **(A,B)** Rheumatoid arthritis: Significant osteopenia is observed. There has been collapse of the humeral head in the absence of significant trauma, in essence, a pathologic fracture dislocation.

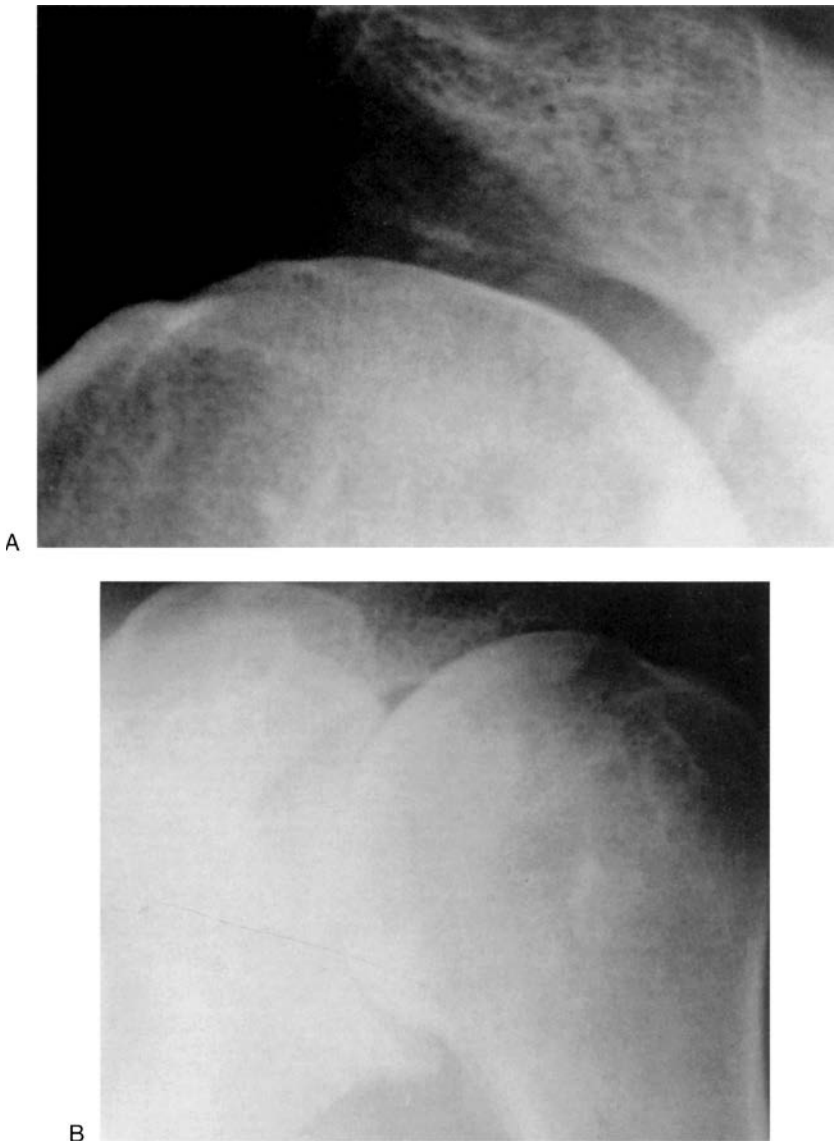

Figure 18-43 Calcium pyrophosphate dihydrate deposition disease: **(A)** Crystal deposition is observed in the articular cartilage of the humeral head. **(B)** Progressive deterioration of the glenohumeral articulation is seen.

in CPPD as well as diabetes, hyperparathyroidism, hemochromatosis, ochronosis, gout, and hypophosphatemia syndromes.[181] Radiographs of CPPD arthropathy are essentially comparable with osteoarthritis (Fig. 18-43B). Particular radiographic features of calcium crystal deposition disorders help to distinguish them from each other and from other arthropathies.[30,486]

Laboratory Findings

Laboratory investigation might include routine screening serum studies for the foregoing disorders, especially if the patient is 55 years or younger with atypical osteoarthritis or polyarticular chondrocalcinosis.[549] Appropriate screening would include serum calcium, alkaline phosphatase, magnesium, ferritin, and thyroid function tests. The diagnosis is made on the basis of synovial fluid analysis. The fluid is often thicker than normal and, at times, turbid, especially in elderly women. At other times, recurrent hemarthroses may exist.[332] It may be indistinguishable from purulent joint fluid. The cell count is representative of inflammatory rather than infectious fluid. Characteristic rhomboid-shaped positively birefringent crystals are identified (Fig. 18-44). Some are intracellular, following engulfment by polymorphonuclear cells. Alizarin red staining enhances the opportunity to identify CPPD crystals in synovial fluid specimens.[551]

Gout

Gout is a disease characterized by hyperuricemia and resultant accumulation of sodium urate crystals within tissues and joints. The clinical manifestations of gout caused by urate crystal accumulations include acute and

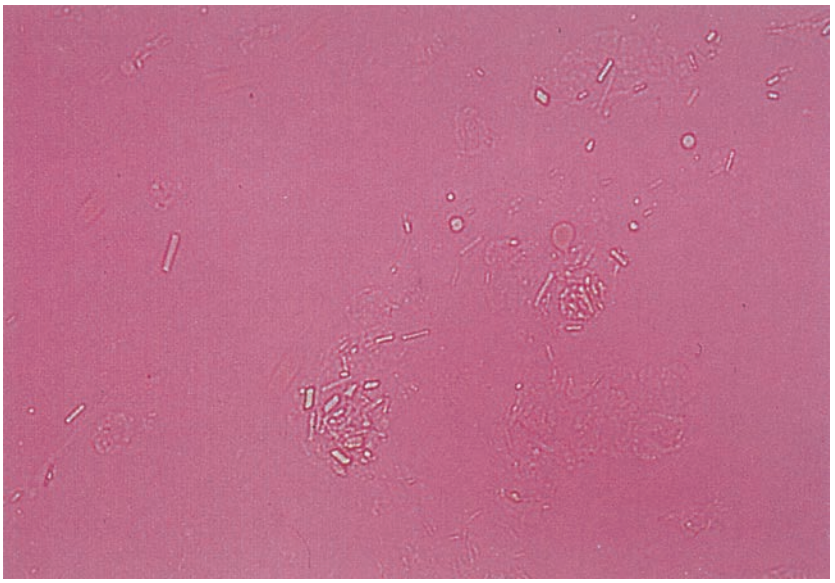

Figure 18-44 Calcium pyrophosphate dihydrate deposition disease: Rhomboid-shaped, positively birefringent crystals.

chronic arthritis, tophi (tissue deposits of crystals), and nephropathy.

Incidence

The incidence is difficult to determine because of the relapsing–recurring nature of the disorder. However, it is believed that the incidence is increasing and is related to changes in dietary habits that lead to the development of the insulin resistance syndrome.[385] Males significantly outnumber females (20:1). It is the most common inflammatory arthropathy in men older than 40 years of age and peaks in the fifth decade.[438] Ninety percent of initial acute attacks of gout are monarticular and rarely involve the glenohumeral joint, unless widespread disease is present.[172,242] In some reports, glenohumeral involvement is not even mentioned. When it is affected, it is rarely early in the disease. It may be the presenting joint in a postoperative flare and in postmenopausal women. Glenohumeral occurrences are much more common in elderly patients, particularly those taking diuretics.[36]

Pathogenesis

Uric acid is the end product of purine catabolism. Humans, as a species, lack the enzyme uricase that governs the degradation of uric acid to allantoin.[75] This conversion is necessary to eliminate the highly insoluble uric acid in the form of the highly soluble compound allantoin. In human tissues, therefore, urate metabolism does not exist, necessitating elimination. Two-thirds of uric acid disposition is by the kidney and approximately one-third is by the gut by bacterial oxidation.[75] Hyperuricemia may be the result of overproduction or undersecretion. Overproduction results from increased synthesis or, much less commonly, alterations in the purine metabolic pathway. The elimination capacity of the kidney is exceeded with supersaturation of serum with uric acid. Up to 90% of cases are the result of deficits of renal excretion.[290]

Most evidence supports the concept of crystal formation in acute attacks of gouty arthritis.[321,461] The mechanisms leading to precipitation of urate crystals are still not well understood. Serum and synovial fluid urate concentrations typically, but not always, are at supersaturated levels.[320] Underlying joint disorders may favor urate crystallization.[495] Proteoglycan concentration, cation (Na^+, Ca^+) concentration, synovial fluid dynamics and pH, intraarticular temperature, and other local factors may play a role.[238,293,471,472,535] Liberation of monosodium urate crystals may also be explained on the basis of tophi present in the synovium.[252] These result from uric acid precipitation caused by increasing circulatory levels. Polymorphonuclear cells invade the synovium and target and then phagocytose the crystals.

Whether the crystal–white blood cell interaction takes place within the joint or within the synovium, a common pathway ensues. The monocytes–macrophages present in the synovial fluid appear to modulate the consequences of the crystal–cell interaction.[385] Mediators of inflammatory response, including chemotactic factors, lysozymes, collagenase, oxygen radicals, and prostaglandins, are released. The synovium is stimulated and proliferates; an acute inflammatory cellular infiltrate rapidly develops. When the joint has been subject to repeated attacks, a local foreign body reaction ensues with the synovium and results in the local resorption of the adjacent cartilage and bone. Radiographically, this is what is seen as the "punched-out" lesions without an associated bony response.

The pathology of the tophi is a chronic foreign body granuloma around a urate crystal. The tophi are often encapsulated. There is an associated inflammatory reaction that involves monarticular cells and giant cells.

Clinical Presentation

With glenohumeral joint involvement, patients will present with an acute onset of shoulder pain. They may previously have had symptoms attributable to gout in another joint. These patients are often obese; most are men and, sometimes, have excessively ingested alcohol. A previous history of renal dysfunction may be obtained, and diuretics may be in use. Occasionally, there is an abrupt reduction in serum uric acid, as might occur with hyperuricemic treatment or the cessation of alcohol ingestion. These factors will result in the dissolution of uric acid from disrupted tophi.[252]

Physical findings of acute gouty arthritis include decreased range of motion of the shoulder, overlying warmth, tenderness, and, perhaps, swelling. Occasionally, these patients will have fever. Chronic gout often exists in the presence of secondary arthritis, the symptoms of which have been discussed earlier.

Imaging

Plain radiographs are usually unremarkable, unless there have been repeated attacks. In such cases, radiographs will show juxtaarticular osteopenia and perhaps juxtaarticular tophi. Sharply outlined erosions, punched out with sclerotic margins and overhanging edges, will be present. Chronic arthropathy from gout results in secondary osteoarthritis and is indistinguishable radiographically (Fig. 18-45).

Laboratory

Only a minor fraction of individuals with elevated serum uric acid levels will develop symptomatic gout. Therefore, the diagnosis cannot be made on the basis of uric acid alone. Sometimes leukocytosis is present. Synovial fluid analysis is diagnostic, with the presence of monosodium urate crystals, often intracellular, visualized with a polarizing microscope. The needle-like crystals are negatively birefringent (Fig. 18-46).

Apatite Deposition Disease

This disorder, sometimes known as apatite gout, has been described by many authors.[106,144,236,317,456] It is associated with the presence of intraarticular hydroxyapatite crystals. The link between the crystals, arthropathy, and osteoarthritis is unclear. There is a predisposition for large joints. McCarty et al. popularized the condition as "Milwaukee shoulder."[317]

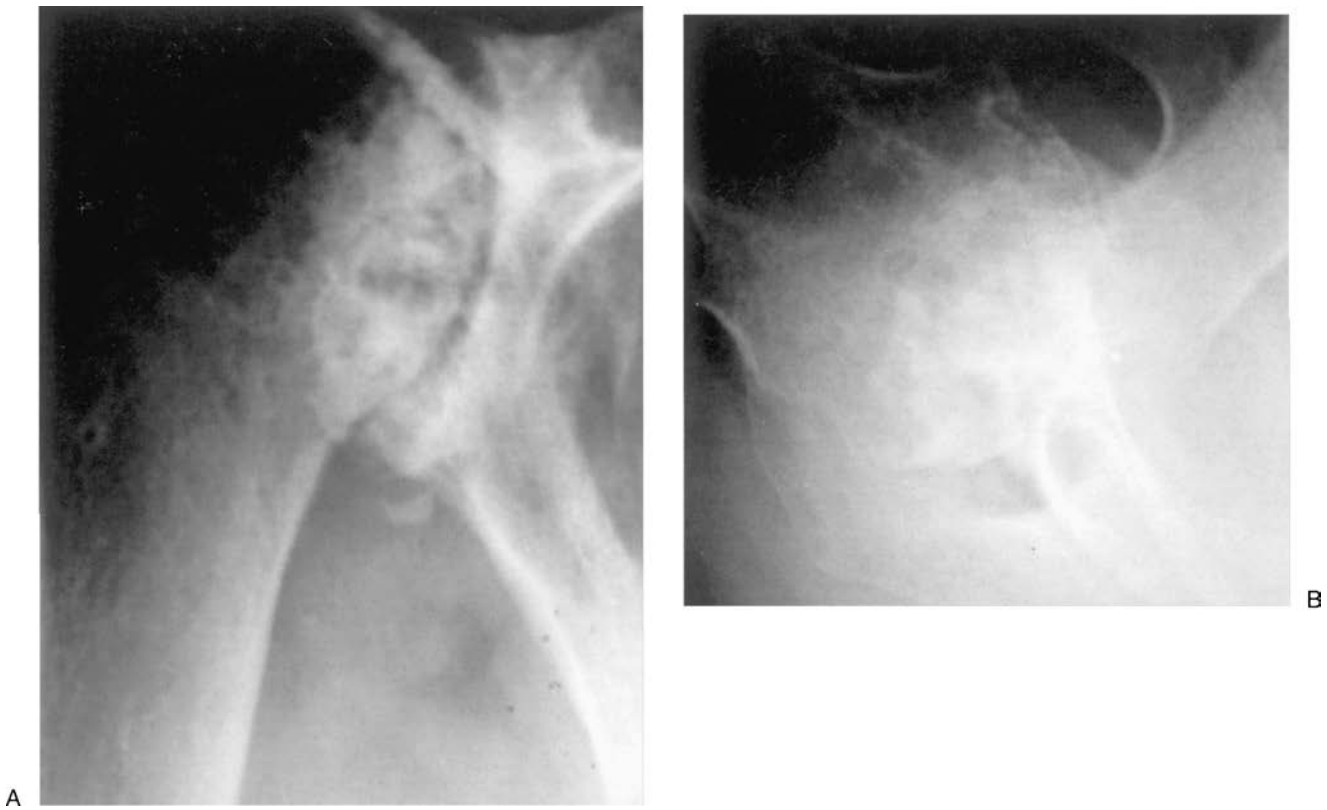

Figure 18-45 **(A,B)** Gout: Arthropathy with loss of glenohumeral joint cartilage and subchondral cyst formation.

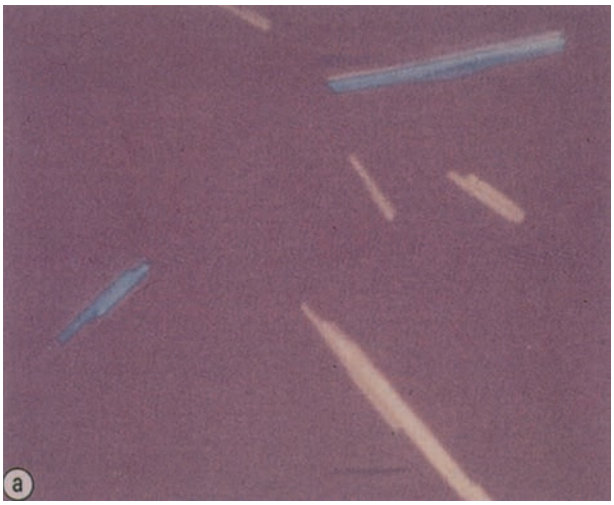

Figure 18-46 Gout: Monosodium urate crystals—negatively birefringent.

Figure 18-47 Rotator cuff tear arthropathy. Of note is the superior subluxation of the humeral head with obliteration of the acromiohumeral interval. The joint has incurred secondary osteoarthritic changes.

It typically involves the shoulder and occurs in older women.[60] Hydroxyapatite crystals do not excite the same degree of synovial response as do sodium urate crystals.[60] As a result, over a period of weeks or months, chronic mild discomfort typically evolves. Physical examination is characterized by a boggy effusion and limitation of motion. This is associated with radiologic soft tissue calcification, ascent of the humeral head, and destruction of the glenohumeral relations. Joint fluid often contains debris as well as calcium crystals, but relatively few inflammatory cells, predominantly monocytes.[105] Blood-stained fluid is common.[317] The effusion may rupture into the adjacent soft tissue planes, creating additional symptoms and signs, sometimes interpreted as venous occlusive disease.[546] A rotator cuff tear is common. The calcium hydroxyapatite crystals are not seen by light microscopy because of their size. They require alizarin red S staining of the synovial fluid preparation.[194] Electron microscopy may be more reliable, but is generally less available. Synovial collagenases and neutral proteases are present in high concentrations, indicative of underlying enzymatic action.[177]

Further discussion will be given to this entity in the next section.

ROTATOR CUFF TEAR ARTHROPATHY

A special condition originating in the tendinous socket of the shoulder, which leads to arthritic changes in the glenohumeral joint, has been recognized clinically for over a century (Fig. 18-47).[2,3,477,478] It is characterized by recurrent, often hemorrhagic, effusions containing biochemically active enzymes; the complete absence of the rotator cuff; advanced degenerative glenohumeral joint changes with humeral head collapse; and erosion of the acromion process, the acromioclavicular joint, and the distal clavicle. Codman made reference to a case of rotator cuff tear with hygroma.[70] McCarty and associates in 1981 recognized this clinical entity and it became popularized as the Milwaukee shoulder.[144,178,317] Neer and others in 1983 recognized a subset of patients with similar clinical and radiographic findings and designated the lesion "cuff arthropathy."[354]

The pathogenic role of calcium phosphate crystals (hydroxyapatite) in the deterioration process was touted by McCarty and continues to draw interest.[179,317] Neer, on the other hand, believed that glenohumeral instability resulted from the massive rotator cuff tearing, with resultant impaired cartilage nutrition, bone softening, collapse, and bone destruction.[354,362] Its genesis continues to be a source of debate and speculation, but essential elements of each theory are often present within the same shoulder.

Milwaukee shoulder is also known as apatite gout and has been mentioned earlier. Forming in the synovium and articular cartilage, hydroxyapatite, octacalcium phosphate, and tricalcium phosphate crystals, whose origin is unknown, are released into the joint fluid.[323] A phagocytic response is induced, leading to the release of matrix-degrading metalloproteinases, collagenase, and stromelysin and subsequent destruction of the rotator cuff and articular cartilage. With further destruction, the cycle is propagated. It is characteristically found in older female patients. Often, their symptoms are bilateral and have been chronic for many years, with periodic exacerbations of more

intense discomfort. Physical examination is remarkable for atrophy, weakness, and shoulder effusion. Synovial fluid analysis by electron microscopy or alizarin red is diagnostic but difficult, and usually not necessary. Imaging studies will demonstrate full-thickness rotator cuff tears.

The destruction of the osteoarticular elements of the shoulder appears to result from the progressive formation of a massive, irreparable, rotator cuff tear and its mechanical sequelae.[79,309,354] Joint debris and biomechanical products of an active synovial lining also play a role in disease progression. Their presence is the likely result of glenohumeral instability, a consequence of losing rotator cuff integrity.

Progressive narrowing of the acromiohumeral interval by ascent of the humeral head is a prominent feature of rotator cuff arthropathy. With the loss of the stabilizing effect of the rotator cuff, the humeral head displaces upward.

On the basis of their anatomic positioning, the musculotendinous units of the rotator cuff serve as glenohumeral joint compressors, as opposed to acting as humeral head depressors. The force generated by the muscles pulls the humeral head into the concavity of the glenoid and serves as its primary stabilizer. The creation of this efficient fulcrum enables the humeral head to resist the upward force vector of the contracting deltoid muscle. By this mechanism, the hand can be placed overhead or away from the body. An entirely intact rotator cuff is not necessarily required; many patients are capable of overhead mobility with full-thickness defects. The arm can be elevated, as long as there is sufficient muscle activity for compressive stabilization of the humeral head.

A secondary humeral head–stabilizing system includes the acromion, coracoid process, coracoacromial ligament, and distal clavicle. This coracoacromial archway is the final functional restraint to superior humeral head migration, when the primary stabilizing system has failed.[283]

Pathophysiology and Pathoanatomy

Muscular weakness and degenerative tendon fiber failure are age-related changes that inevitably occur within the rotator cuff.[71,311] Initially, only the supraspinatus tendon is involved. Eventually, further interstitial tendon fiber failure, often clinically interpreted as tendonitis, may lead to partial- and, later, full-thickness tears of the supraspinatus. With continuing activity, the tear may enlarge as adjacent fibers are loaded beyond their elastic limit, and it predictably extends to involve the infraspinatus and, later, the subscapularis. Subtle superior humeral head migration occurs as the concavity compression forces diminish. Initially, this phenomenon is satisfactorily tolerated in terms of comfort and presents little or no functional deficit.

Once the superior forces have exceeded the medially directed forces, abrasive contact occurs against each side. Impingement of the rotator cuff tissue against the acromion accelerates the loss of tendinous tissue. When the cuff tendon tissue superior to the humeral head axis of rotation has vanished, contracture of the lower half of the cuff and the deltoid will create a fixed "boutonniere" deformity of the humeral head against the coracoacromial arch.[312] As a result of the increased friction against the nonarticular and nonconforming undersurface of acromion, the articular surface of the humerus begins to wear.

In response to increased pressure, tensioning of the coracoacromial ligament may result in the formation of an anterior or inferior acromial traction spur. This bony projection may potentially gouge the underlying tendinous tissue and articular cartilage, inducing further damage. In response to load, the acromion process develops the characteristic changes of eburnation and erosion, whereas the coracoacromial ligament may hypertrophy. Stress fractures of the acromion process resulting from unremitting load by the upwardly thrust humerus have been reported (Fig. 18-48).[98] When the primary stabilizers have failed, limited although purposeful function may be maintained, in spite of the unopposed action of the deltoid, by the secondary stabilization within the coracoacromial arch.[283] Although initially adequate, further articular cartilage degradation and further rotator cuff tendon damage are incurred.

This disorder does not spare the glenohumeral articulation. As a failure of containment, the humeral head subluxes superiorly with force concentration on the narrower

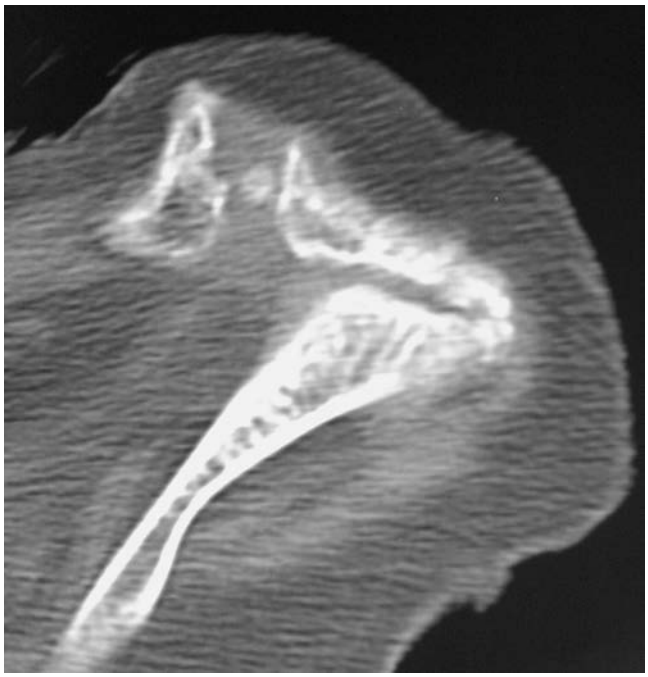

Figure 18-48 Acromial insufficiency fracture due to extreme overloading of the unyielding acromion process by the upwardly displaced humeral head.

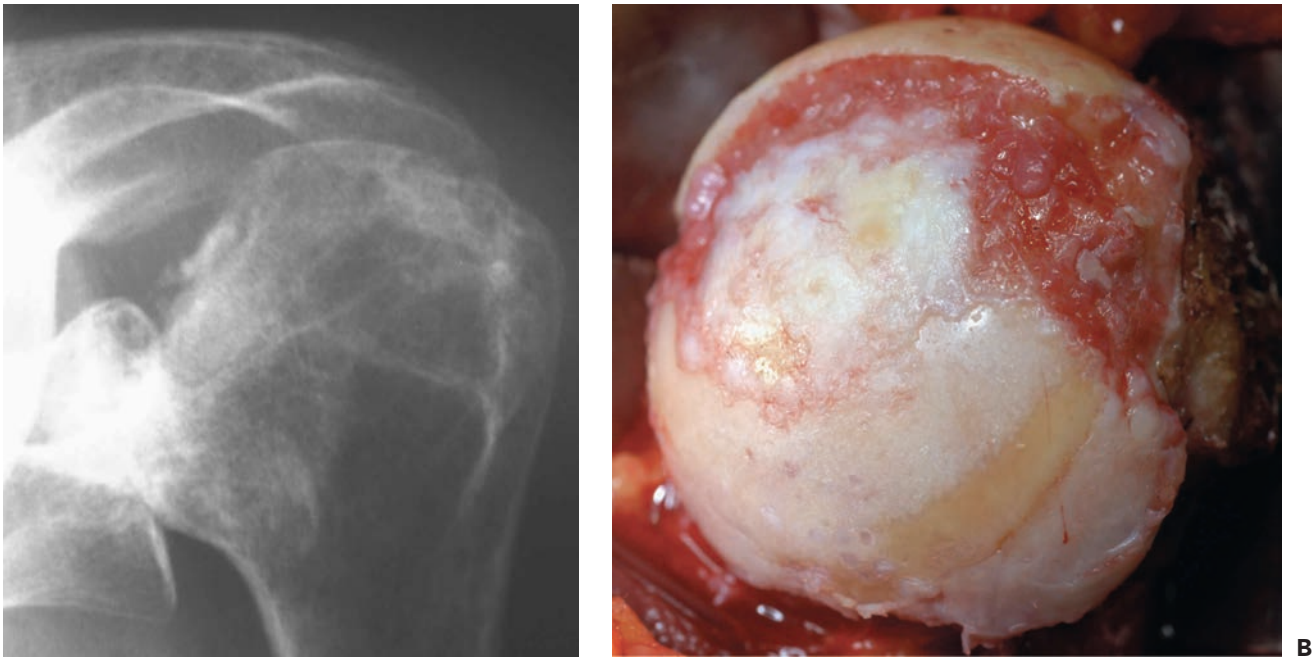

Figure 18-49 **(A)** The superiorly subluxed humeral head manifests collapse and superior glenoid and acromial humeral erosion along with early secondary osteoarthritis. **(B)** The gross specimen at the time of humeral head replacement demonstrating collapse, erosion of the articular cartilage with reparative granulation tissue, and eburnated bone.

superior glenoid. An even greater demand is placed on the primary and secondary stabilizers. Articular surface wear is accelerated and is soon followed by a collapse and degradation of the underlying subchondral bone of the humeral head.

When articular cartilage fragments and underlying areas of softened, and often nonviable, bone are exposed, particulate debris is shed into the joint (Fig. 18-49).[177,317] In response, the synovium proliferates with the development of large effusions, often contained only by a weakened, and sometimes surgically altered, deltoid muscle. "Subcutaneous effusions" may evolve as the fluid herniates through the soft tissue pathways of least resistance. Sometimes, the fluid accumulates superior to the acromioclavicular joint, recognized as the "geyser sign" on shoulder arthrogram.[81]

The effusions may be predominantly bloody.[24,141,218,322,475,546] The source of bleeding may be a crater in the humeral head resulting from impingement on the medial acromion process.[447]

Rotator cuff arthropathy is not likely an obligate end stage of the so-called impingement syndrome and rotator cuff tendon failure. Neer et al. stated that only 4% of rotator cuff tears will progress to develop cuff tear arthropathy.[354] From a purely mechanical basis, as long as the humeral head can be maintained concentrically opposed to the glenoid by the balanced action of residual intact columns of the anterior and posterior cuff, the shoulder is protected from the requisite instability that may lead to rotator cuff arthropathy.[52] A limited degree of superior subluxation of the humeral head can apparently be tolerated without progressively erosive changes of the bony surfaces. Certain rotator cuff tears may be at risk for progression to arthropathy if elevated crystal levels are identified in the joint fluid.[12]

Clinical Evaluation

When presenting for evaluation, patients with rotator cuff arthropathy complain bitterly of unrelenting pain. For years before the acute and intolerable exacerbation, the disorder has been in slow evolution with periodic exacerbations. Not only is the pain felt in the depth of the shoulder, but it is often referred to the deltoid insertion. Weakness, crepitation, and sudden sharp pain often limit the attempted use of the extremity for lifting or overhead activities. Significant night pain exists. Minor traumatic experiences are common, and patients will often deny a history of major shoulder injury. Although symptoms may exist bilaterally, one shoulder is often more significantly affected. One or more arthrocenteses accompanied by corticosteroid instillation may have been performed. The typical patient is a woman and is older than 70 years of age. In 60% of cases, the disorder will be bilateral.[223] In some instances, the family history is curiously positive for the same disorder among the older generations.[400]

Figure 18-50 The characteristic ecchymotic appearance of the cutaneous manifestation of recurrent shoulder hemarthrosis. Intense staining of the tissue with the products of blood breakdown may persist long after resolution of the acute ecchymosis.

The disorder is characterized by physical findings indicative of the chronic nature of the disorder. Atrophy of the spinati and, sometimes, the deltoid musculature is prominent. Sometimes, a large effusion will obscure the presence of atrophy. The effusion may contribute to the formation of a unique dermatitis.[113] The localized vesicular rash is created by the subcutaneous seepage of "dermal mucin" in the absence of frank fistula formation. Recurrent hemarthrosis may result in an ecchymotic appearance of the shoulder and upper brachium (Fig. 18-50). A superiorly subluxed humeral head may rest directly beneath the deltoid muscle anterior to the acromion process. Profound weakness results in a significant restriction in active range of motion. Restraints to passive movement include pain, contracture, and glenohumeral incongruity. Invariably, crepitation, arising from many different sources, often indistinguishable, will be present. The physical findings may exist bilaterally.

Imaging

Sophisticated imaging studies are unnecessary to diagnose rotator cuff tear arthropathy or to adequately identify the pathology, especially in its later stages (Fig. 18-51).[79] Plain films, which may include the weighted abduction Grashey's view, represent the most cost-effective means of evaluation, as well as the most accurate (Fig. 18-52). Osteopenia, superior migration of the humeral head, narrowing or obliteration of the acromiohumeral interval, acromial erosions, and superior glenoid bone loss are the characteristic findings.[446] The humeral head may be collapsed, a finding felt by Neer to necessary for the diagnosis of cuff tear arthropathy (Fig. 18-53).[354] Osteophytes, irregular cystic formation, subchondral sclerosis, and loss of tuberosity prominence may also be seen. The glenohumeral joint takes on the appearance of the hip.[313] "Acetabularization" results from sculptured erosion of the acromion, superior glenoid, and coracoid bone and contact of the humeral head against the coracoacromial arch.[313] Likewise, reciprocal "femoralization" of the proximal humerus includes tuberosity round-off and loss of the bicipital groove, resulting in a large spherical head.[313] The findings on MRI are often dramatic but simply reiterate the findings noted on the physical examination and plain radiographs (Fig. 18-54).

Visotsky et al. presented Seebauer's analysis of the radiographs of patients with cuff tear arthropathy in which Seebauer recognized variations that implied biomechanical differences among shoulders with cuff tear arthropathy and conceived a radiographic classification for cuff tear

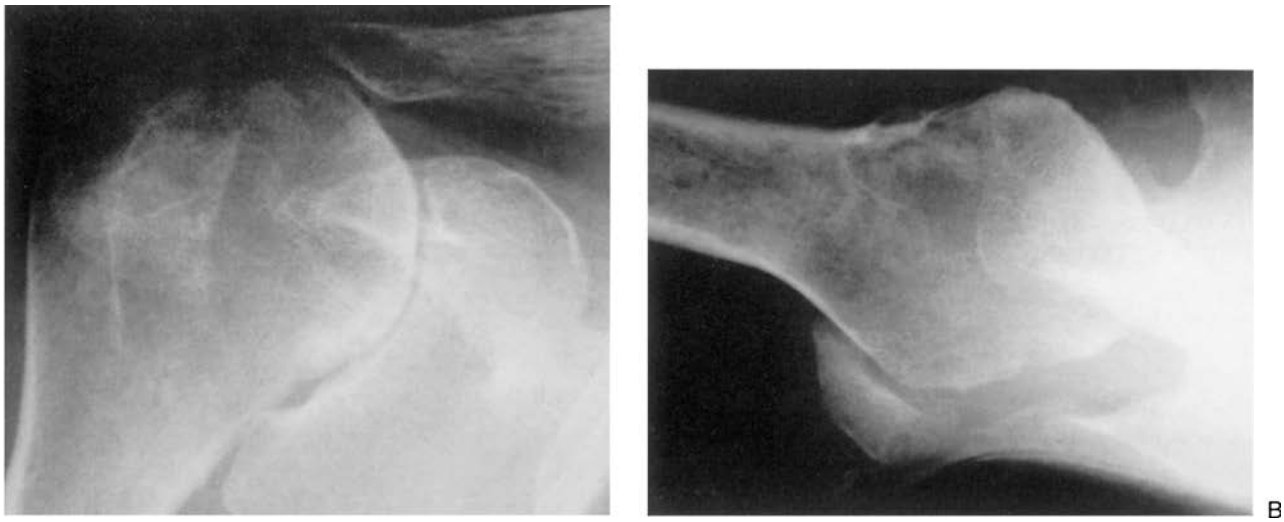

Figure 18-51 **(A,B)** End-stage rotator cuff arthropathy with significant superior glenoid erosion into the acromioclavicular joint and insufficiency fracture of the acromion process.

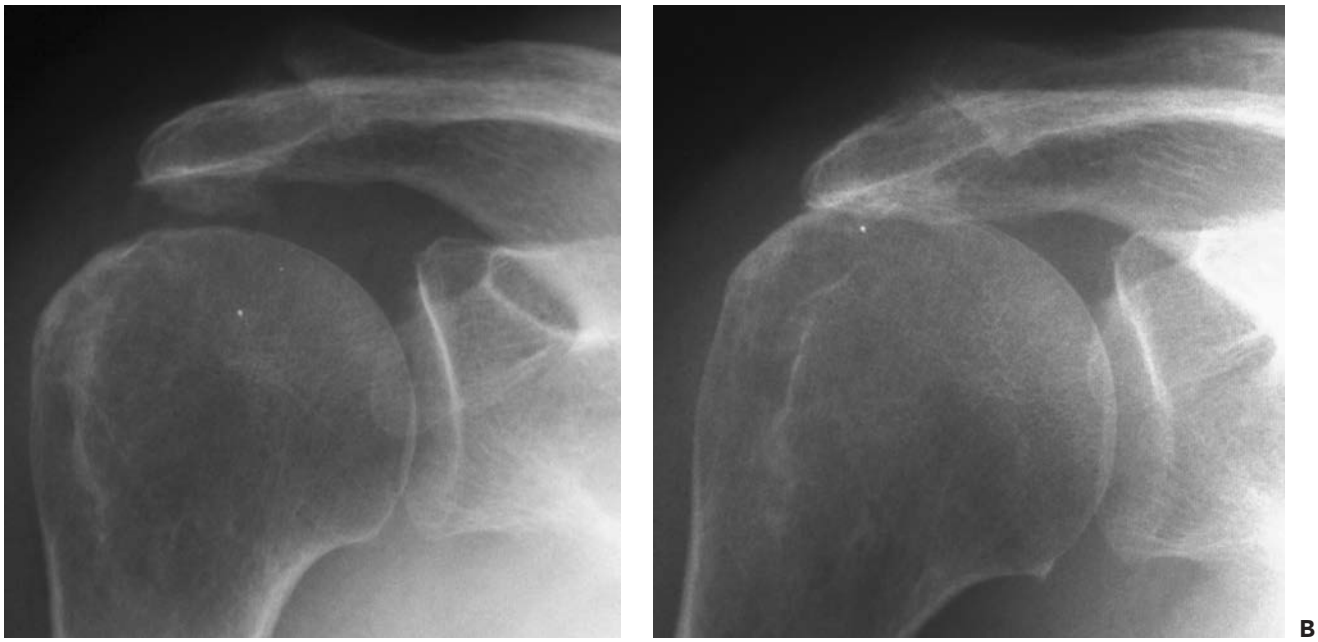

Figure 18-52 **(A)** Grashey's view. **(B)** Weighted abduction Grashey's view. The acromiohumeral interval is obliterated as the humeral head ascends as a result of muscle imbalance due to rotator cuff tear.

arthropathy based on the location of the center of rotation of the humeral head, the sufficiency of restraining structures, and the degree of instability (Table 18-4).[521] The classification may prove to be a useful tool in the treatment decision making for rotator cuff tear arthropathy.

Laboratory

Synovial fluid analysis is usually not necessary. If it is performed, the fluid is often blood streaked or straw-colored. Routine demonstration of calcium phosphate crystals is extremely difficult, requiring special staining techniques or electron microscopy.

OTHER ARTHROPATHIES

Rheumatoid Arthritis of the Elderly

This condition presents typically in older persons (Fig. 18-55). Involvement is most often confined to the shoulders and wrists. Over a 4- to 6-month course, it can become very disabling. The rheumatoid factor is negative and ESR

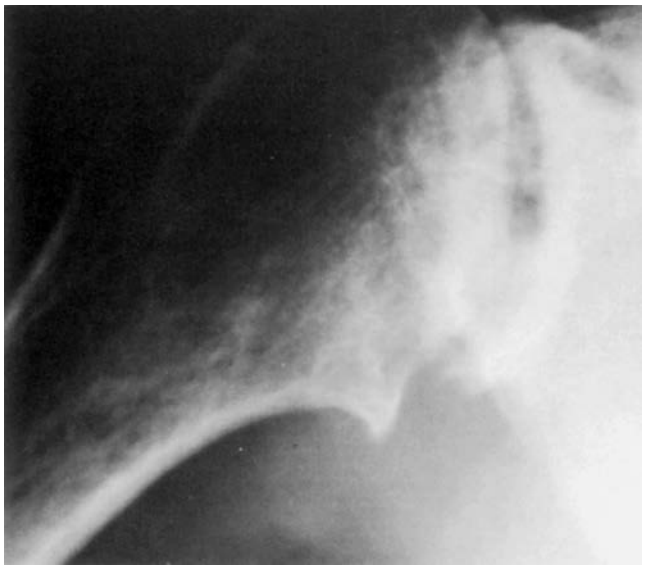

Figure 18-55 Rheumatoid arthritis of the elderly.

Figure 18-56 Adult-onset Still's disease with distortion of the glenohumeral articulation and moderately severe glenohumeral arthritis.

is elevated. A significantly higher frequency of shoulder involvement is observed in elderly-onset rheumatoid arthritis (more than 60 years old).[22]

Juvenile Rheumatoid Arthritis

The shoulder is not typically involved early in the various forms of juvenile rheumatoid arthritis (JRA). When juvenile spondylitis or the polyarticular form exists, shoulder involvement is more likely, up to 25%. It is less common in the pauciarticular form. Typically, when the patients are seropositive, a rapidly destructive and severe glenohumeral involvement can be observed.[437]

Adult Still's disease, a rare inflammatory disease accompanied by polyarthritis with features similar to the systemic form of JRA, may affect the shoulder in up to 43% of cases at the time of presentation (Fig. 18-56).[90,97,404,548] Thirty percent to 50% of patients with more chronic arthropathy will have glenohumeral involvement.[281,404]

Rheumatoid Syndrome

Neer identified a select group of patients who manifested symptoms, signs, and radiologic changes consistent with rheumatoid arthritis.[366] Members of this group were almost exclusively women between the ages of 35 and 55. The involvement spared other joints and was almost always confined to the shoulder. Bilaterality was common; involvement was of the dry low-grade type. The rheumatoid factor was positive. Radiographic changes include glenohumeral joint space loss, cysts, and sclerotic changes (Fig. 18-57). Progressive disease over a short time was observed.

Figure 18-57 Rheumatoid syndrome with a "dry-type" appearance to the glenohumeral articulation.

Rapidly Destructive Articular Disease

Rapidly destructive articular disease (RDAD), an unusual form of arthropathy recognized most often in the hip, has been suspected of causing a similar condition in the shoulder.[33,58,255,282,368,434,443,504] It is most commonly observed in elderly females. Osteoporosis-induced subchondral insufficiency fracture may play a significant role in the pathogenesis of the disorder.[504,552,553] It is similar radiographically, in its final stages, to rotator cuff tear arthropathy and Milwaukee shoulder (Fig. 18-58). Sometimes, RDAD shares certain gross, microscopic and synovial fluid features of those disorders.[58,255,282] Crystals or large cuff defects, as well as the typical findings of osteonecrosis and osteoarthritis, may be notably absent.[504]

Figure 18-58 **(A)** Rapidly destructive articular disease at the time of presentation. **(B)** Three months later. **(C)** Advanced destruction well depicted with computed tomography (CT), three-dimensional CT, and magnetic resonance imaging.

Dialysis Arthropathy

As many as 50% to 69% of patients receiving treatment with long-term dialysis for end-stage renal disease experience musculoskeletal problems.[26,65,420] The most common of these is "dialysis arthropathy" and may affect the shoulder up to one-third of the time.[271,465] The extent of involvement parallels the duration of dialysis and are manifest earlier in older patients.[271] Both end-stage renal disease and the process of dialysis contribute to the pathophysiology of dialysis arthropathy. Most frequently implicated is amyloid depositions, oxalosis, nonbacterial infections (including hepatitis C), apatite crystal deposition, and iron or aluminum overload.[26,133,271,420,465,469] Clinical manifestations are painful, diminished range of motion. Early in the course of the disease, even including patients requiring surgical treatment, the plain radiographic findings are unremarkable.[78] At this time, MRI will demonstrate synovial proliferation. Periarticular bone cysts, articular erosions, and destructive spondyloarthropathy are often late findings, even persisting after successful renal transplantation (Fig. 18-59).[27,420,465]

Spondyloarthropathy

Spondyloarthropathies are a group of environmentally triggered diseases identified in those who are genetically

Figure 18-59 **(A)** Dialysis arthropathy. Osteopenia and extensive erosion of the humeral head (*arrow*). **(B,C)** Accumulations of amyloid within the humeral head.

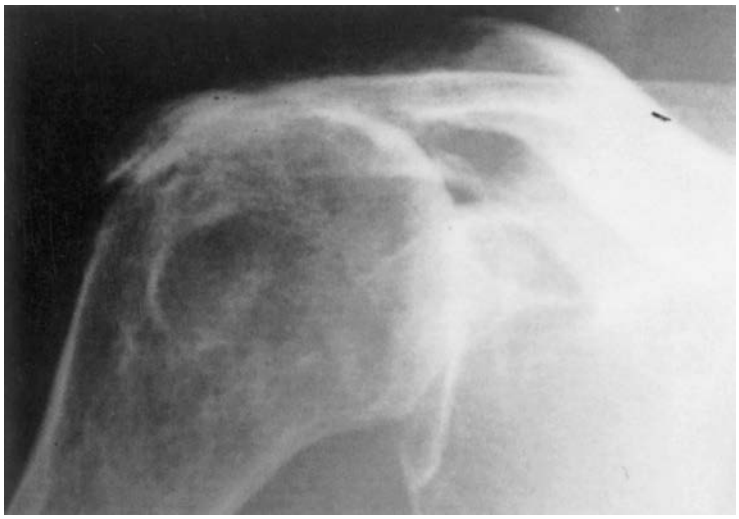

Figure 18-60 Ankylosing spondylitis with accompanying loss of the rotator cuff.

predisposed.[249] The axial joints are typically involved, including the shoulder. Involvement of the shoulder typically occurs somewhat early in the disease process. Entities such as psoriatic arthritis, enteropathic arthritis, and ankylosing spondylitis are known to involve the shoulder.[139]

In ankylosing spondylitis, the frequent involvement of the hip and shoulder (50%), although clinically mild, follows the appearance of spinal disease.[123,248,305] Shoulder symptoms and loss of shoulder mobility are common but not frequently disabling.[537] Sometimes, the first symptoms are in the shoulder. Bilateral involvement is common. The radiographic changes include osteoporosis, joint space narrowing, and bone exostosis (Fig. 18-60).[276,423] The "hatchet sign," a characteristic destructive abnormality, involves the superior lateral aspect of the humeral head.[432] A rotator cuff tear often accompanies this lesion.

Psoriatic arthritis involves the shoulder in 30% to 50%.[500] A rapidly destructive form of glenohumeral change may occur.

Reiter's disease may present as an acute arthritic attack, often following an enteric or urogenital infection. There may be an associated fever. There appears to be some genetic susceptibility. Acute shoulder pain will occur in 8%.[519] Seventy percent of patients are HLA-B27 positive. The shoulder is not involved to the extent of the subtalar, ankle, and hip joints. If the attack of Reiter's disease is protracted, patients are more likely to have shoulder involvement.[519] Clinically, this cannot be distinguished from other seronegative arthropathies.

Enteric arthritis parallels the activity of the inflammatory bowel disease.[198,338] Shoulder involvement occurs in 5% to 10% and is usually associated with sacroiliitis and spondylitis.

Neuropathic Arthropathy

Neuropathic arthropathy may affect the shoulder.[25,187] Syringomyelia is the most common cause; arthropathy occurs in 20% to 40% of patients with the disease, the shoulder more often than the elbow.[55,538] Other causes are diabetes, syphilis, and peripheral neuropathies.[9] The pathogenesis is uncertain but favors the theory of "neurotrauma," whereby joint destruction ensues in response to altered sensory innervation of the joint, and the theory of "neurovascular," whereby the neurologic changes of the underlying disease induce hypervascularity within the subchondral bone with resultant bone atrophy, subchondral bone collapse with disorganization of the joint.[9] Mild pain and neurologic symptoms and signs are usually present.[187] Deformity secondary to instability is sometimes present. More often, the physical signs are subtle (Fig. 18-61). The imaging data varies with the course of the disease. Plain radiographs may suggest glenohumeral instability, often confirmed with CT scanning (Fig. 18-62). Advanced imaging, at this point, is often dramatic (Fig. 18-63). With time, the joint is unrecognizable (Fig. 18-64).

Hemophilia Arthropathy

Glenohumeral arthropathy has also been observed as a sequela to hemophilia.[15,54,126,300] Properties of the synovium are pivotal in the pathophysiology with invasive capacity not unlike rheumatoid arthritis or pigmented villonodular synovitis.[296] Blood and products of blood metabolism are the pathologic agents of the disorder.[431,485] Hemosiderin deposition in the synovium induces inflammatory hypertrophy, which inevitably leads to arthropathy

Figure 18-61 Neuropathic arthropathy. The right shoulder is swollen.

C

Figure 18-62 **(A)** Neuropathic arthropathy. The anteroposterior radiograph is unremarkable. **(B)** The axillary lateral reveals anterior subluxation of the humeral head, **(C)** whereas the computed tomography scan documents posterior dislocation in the same shoulder.

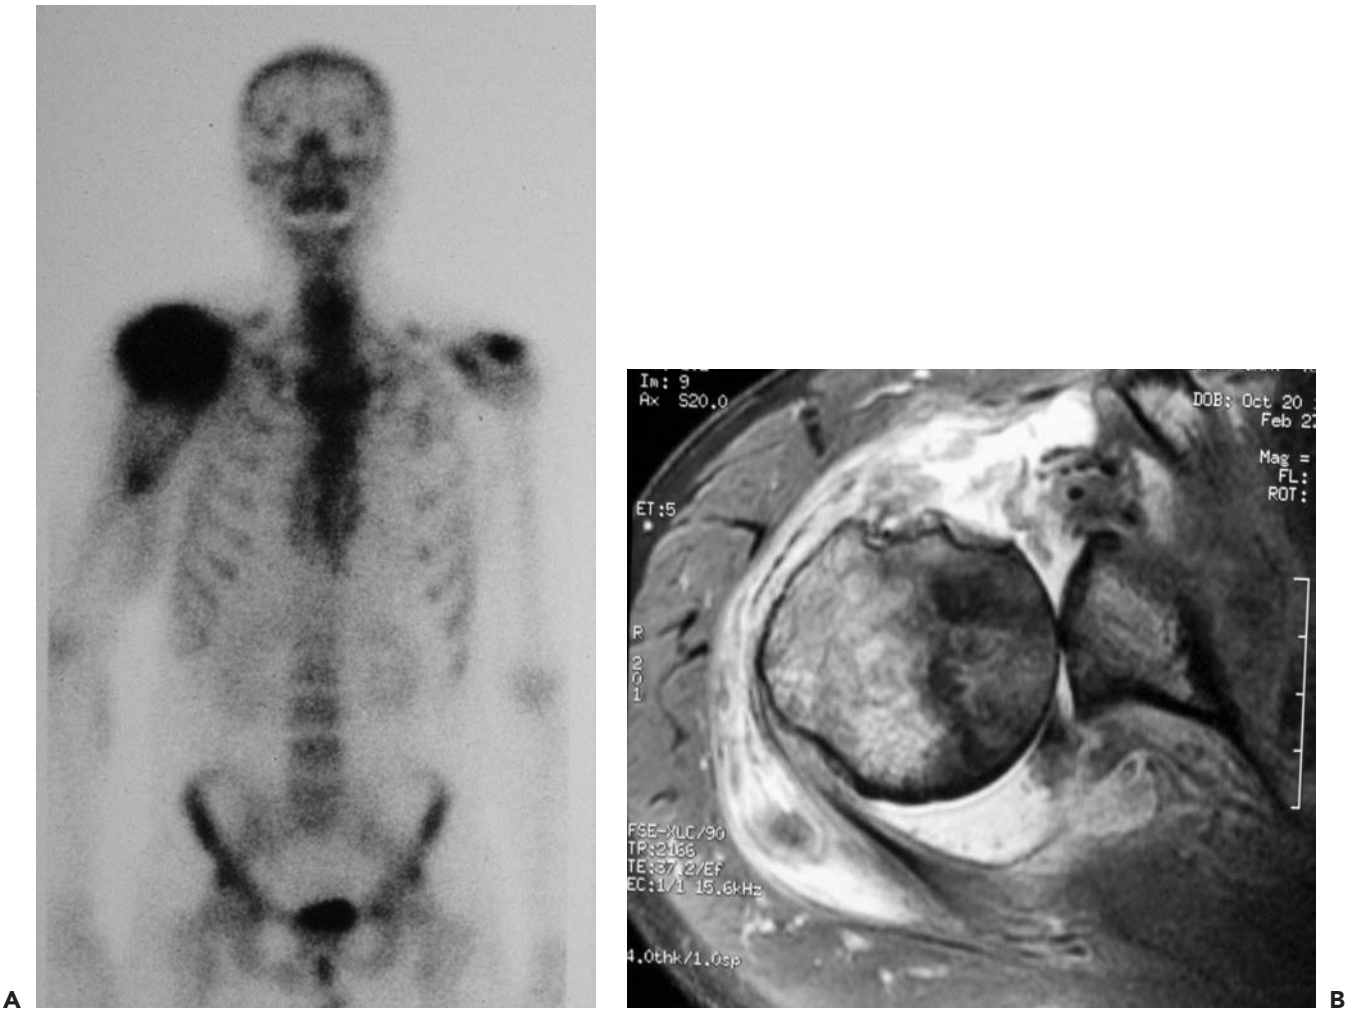

Figure 18-63 **(A)** Neuropathic arthropathy. The bone scan shows extremely radionuclide uptake in the shoulder. **(B)** Magnetic resonance imaging reveals fluid accumulation, disruption of normal soft tissue planes, and arthropathic changes of the glenohumeral articulation.

and arthrofibrosis.[296,485] As with other arthropathies, the severity of symptoms correlates directly with the radiologic involvement (Fig. 18-65).[54] Shoulder involvement is more common in adults than in juveniles and proceeds slowly over the years and manifests as erosions and thinning of the glenoid.[296]

Endocrine and Metabolic Arthropathy

Arthropathy associated with hemochromatosis can affect the shoulder, typically late in the disease course.[116,180,233,341,414] The mechanism whereby this inborn error of iron metabolism leads to arthritis is unknown. Ochronosis arthropathy affecting the spine and hips precedes shoulder involvement by many years.[161] Acromegaly can result in peripheral joint arthropathy, most commonly occurring in large joints, including the shoulder.[28,32,398] Articular cartilage hypertrophy, a condition unique to this disorder and prone to degeneration, leads to eventual osseous disruption (Fig. 18-66). Glenohumeral arthropathy has also been observed as a sequela to hyperparathyroidism.[370]

Synovial-based Arthropathy

Synovial chondromatosis, a cartilaginous metaplasia of synovium, rarely affects the glenohumeral joint (Fig. 18-67).[224,523] Secondary arthropathy associated with coarse intraarticular crepitation can follow years of intermittent or continuous pain (Fig. 18-68).[326,403,518] Malignant transformation has been reported.[94,389]

Pigmented villonodular synovitis has the potential to cause destructive arthropathy of the shoulder sufficient to warrant shoulder arthroplasty (Fig. 18-69).[505]

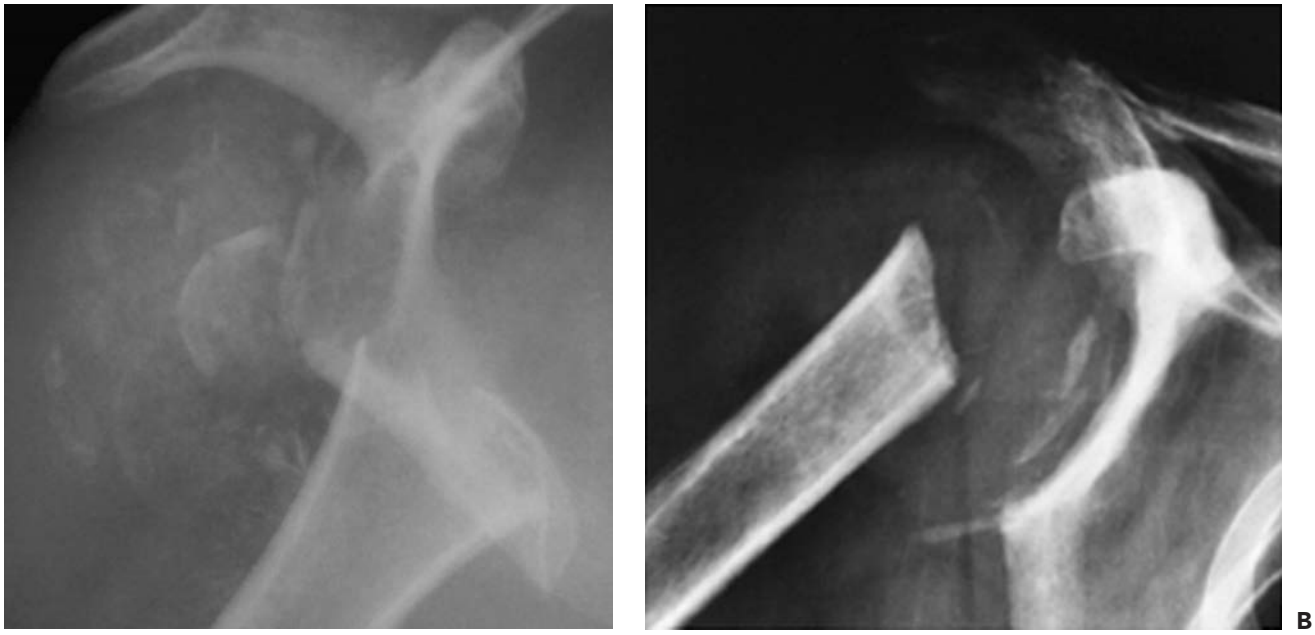

Figure 18-64 **(A,B)** Neuropathic arthropathy: The late stage of the disease with complete destruction of the normal joint architecture.

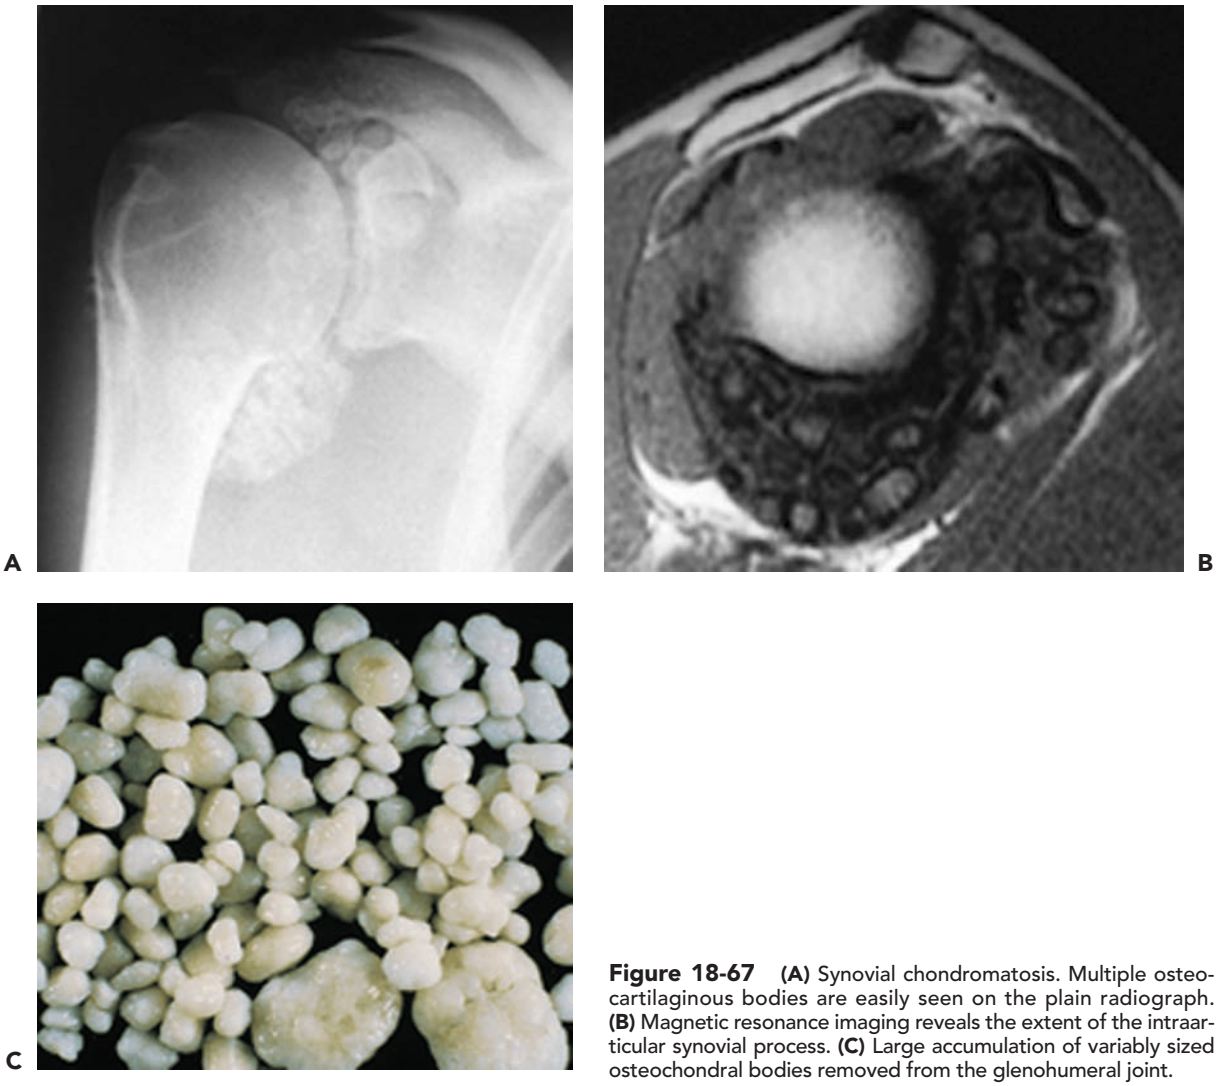

Figure 18-67 **(A)** Synovial chondromatosis. Multiple osteocartilaginous bodies are easily seen on the plain radiograph. **(B)** Magnetic resonance imaging reveals the extent of the intraarticular synovial process. **(C)** Large accumulation of variably sized osteochondral bodies removed from the glenohumeral joint.

Miscellaneous Arthropathies

Erythema nodosum may result from sarcoidosis, tuberculosis, drug ingestion, inflammatory bowel disease, Behçet's disease, and beta-hemolytic streptococcal infections. Acute shoulder involvement can be as high as 36%.[508]

Patients with sarcoidosis, a heterogeneous multisystem granulomatous disease, will develop arthritis in 15% to 25% of cases.[506,522] One-fourth of these patients will have shoulder involvement (Figs. 18-70 and 18-71).[169,539]

Systemic lupus erythematosus (SLE) and other connective tissue diseases may have significant shoulder involvement, but these occurrences are uncommon. Sixty percent to 90% of SLE patients will develop arthritis, the most common manifestation of the disease.[273] Osteonecrosis occurs in 10% to 52%, not always associated with steroid ingestion.[1]

Amyloid deposition disease will involve the shoulder in 68% of cases.[89,129] Usually this is not related to glenohumeral destruction, but is a problem in the soft tissues.[237] The pathognomonic "shoulder pad pattern" is always associated with shoulder involvement. Osteopenia with associated joint destruction is a very late phenomenon.[74]

Polymyalgia Rheumatica

Polymyalgia rheumatica is a pain and stiffness syndrome that commonly affects the elderly. It may be difficult to distinguish from late-onset rheumatoid arthritis.[152] Constitutional symptoms include fever, malaise, and weight loss. Symmetrical shoulder involvement is common, sometimes expressed as synovitis, although large effusions are uncommon, with no propensity for joint destruction. Acute-phase reactant serum markers are invariably elevated and strongly support the diagnosis.[453]

SUMMARY 651

INTRODUCTION

The normal glenohumeral joint is often referred to as a ball-and-socket joint. The hip joint is another well-known ball-and-socket joint whose bony socket covers two-thirds of the ball. Compared to the hip joint, however, the glenohumeral joint is much less constrained. Its osseous anatomy is more like a golf ball on a golf tee. Despite this lack of constraint, the glenohumeral joint exhibits a kinematic pattern that closely approximates the purely rotational motion seen in true ball-and-socket joints. This normal kinematic pattern requires a complex interaction between articular surface anatomy, capsular constraints, and rotator cuff, deltoid, and scapular muscle forces. The goals of unconstrained prosthetic replacement of the glenohumeral joint are to anatomically reconstruct the articular surfaces, to restore flexibility to the capsular constraints, and to repair or rehabilitate the rotator cuff, deltoid, and periscapular muscles so that pain-free, normal motion is restored. In some disease processes, such as cuff tear arthropathy, rotator cuff deficiency may be irreparable and anatomic reconstruction of the joint may not be possible. Under these circumstances, prosthetic reconstruction with nonanatomic devices (i.e., reversed prostheses) may be required.

Several anatomic and biomechanical factors have been identified that may affect prosthetic design. Important anatomic factors include humeral head size and its

orientation in three-dimensional space; humeral head shape; humeral head offset; humeral neck–shaft angle; glenoid size, shape, and orientation; glenoid offset; and lateral glenohumeral offset. Biomechanical factors that may influence prosthetic design and performance include glenohumeral articular conformity, glenohumeral articular constraint, periarticular muscular forces, and ligamentous restraints. Certain prosthetic characteristics, such as variability in humeral neck–shaft angle and version, humeral head offset, glenoid fixation and the shape of its interface with the native glenoid, glenoid metal backing, and material properties of the articulating surfaces, may influence prosthetic performance and clinical outcome. The purposes of this chapter are to review the current knowledge regarding relevant anatomic and biomechanical factors that potentially influence glenohumeral prosthetic design and to discuss the possible effects that variations in these design parameters may have on prosthetic performance.

ANATOMIC FACTORS

Humeral Head Size

Given the assumption that the humeral head is a sphere, the volume (i.e., size) of the articular segment is determined by the humeral head radius of curvature and humeral head thickness or neck length (Fig. 19-1). Humeral head radius, humeral head thickness, and humeral head size are all variable. Mean humeral head radius is approximately 24 mm, with a range of 19 to 28 mm (Fig. 19-2).[51,86] Mean humeral head thickness is approximately 19 mm, with a range of 15 to 24 mm (Fig. 19-3).[51,86] Both humeral head radius and thickness correlate strongly with humeral shaft length and patient height.[51,86] However, the ratio of humeral head thickness to humeral head radius of curvature is remarkably constant at approximately 0.7 to 0.9, regardless of patient height or humeral shaft size.[51,86] The surface arc of the humerus available for

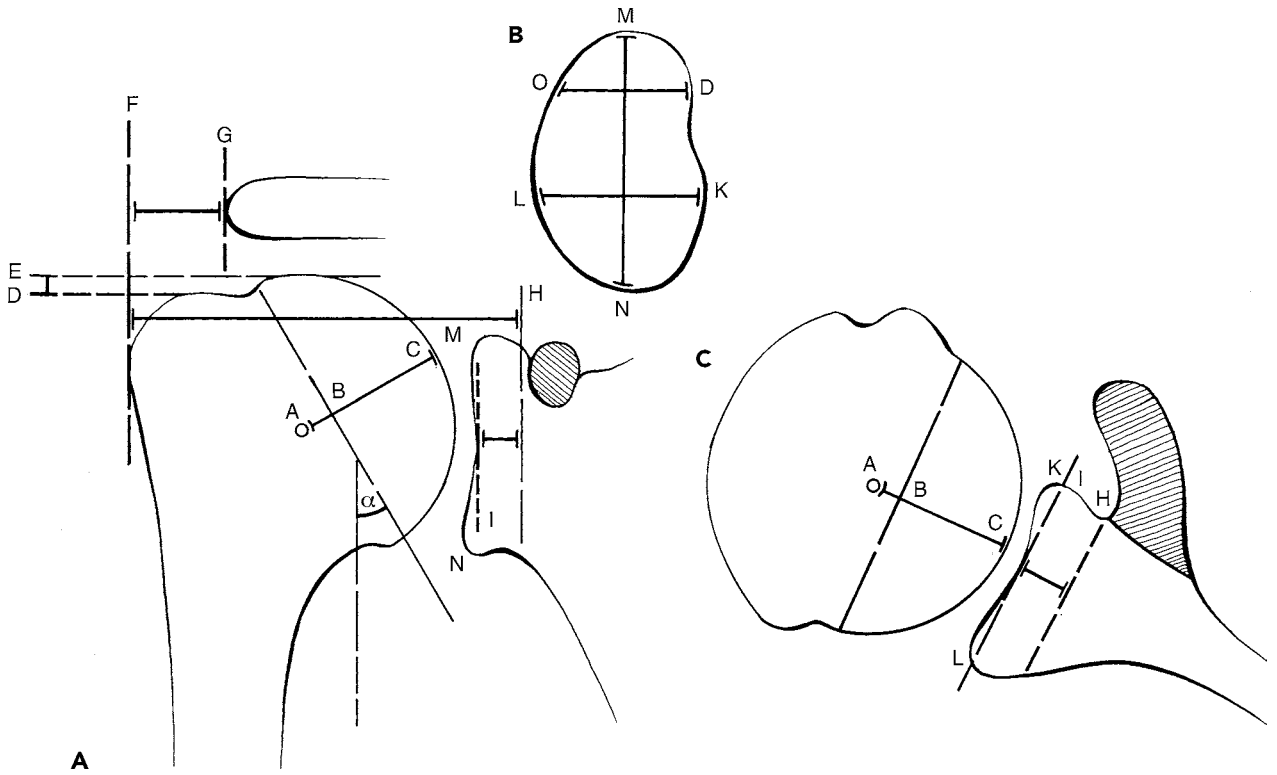

Figure 19-1 **(A)** Normal glenohumeral relationships depicted in the coronal plane include the humeral head center (*A*), humeral head radius of curvature (*AC*), humeral head thickness or neck length (*BC*), humeral neck–shaft angle (α), lateral glenohumeral offset (*HF*), greater tuberosity to acromion distance (*FG*), greater tuberosity to humeral head distance (*DE*), superior–inferior glenoid dimension (*MN*), and glenoid offset (*HI*). **(B)** The glenoid dimensions measured in the sagittal plane include the superior–inferior dimension (*MN*), the anterior–posterior dimension of the upper half (*OD*), and the anterior–posterior dimension of the lower half (*KL*). **(C)** The glenohumeral relationships in the axial plane include the humeral head center (*A*), the humeral head radius of curvature (*AC*), the humeral head thickness or neck length (*BC*), the anterior–posterior dimension of the glenoid (*KL*), and the glenoid offset (*HI*). An anatomical study of one hundred and forty shoulders. *J Bone Joint Surg Am* 1992;74:491.)

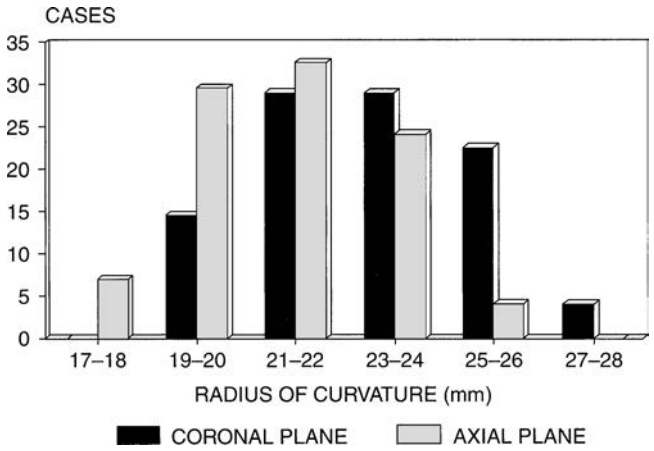

Figure 19-2 Humeral head radius of curvature fits a Gaussian distribution with a mean of 23 to 24 mm and a range of approximately 19 to 28 mm. Note that the axial plane radius is slightly smaller than the coronal plane radius. (Reprinted from Iannotti JP, Gabriel JP, Schneck SL, et al. The normal glenohumeral relationships. An anatomical study of one hundred and forty shoulders. *J Bone Joint Surg Am* 1992;74:491.)

contact with the glenoid is directly proportional to the ratio of humeral head thickness to humeral head radius and is, therefore, also relatively constant, irrespective of humeral shaft length or patient height.[54,86]

Humeral Head Shape

The assumption that the humeral head is spherical is only partially accurate. The central 80% of the articular surface is spherical, with the coronal plane and axial plane radii of curvature being equal.[1,21,51,69] However, in the peripheral 20% of the articular surface, the radius of curvature in the axial plane is, on average, 2 mm less than in the coronal plane (see Fig. 19-2). Therefore, the peripheral 20% of the humeral articular surface is elliptical, with the ratio of the axial plane radius to the coronal plane radius being 0.92.[51] The clinical significance of this anatomic finding remains unclear, as almost all current prosthetic systems utilize spherical humeral heads, and cadaver studies evaluating the range of motion and three-dimensional kinematics of natural joints and joints reconstructed with spherical humeral heads show no difference.[56]

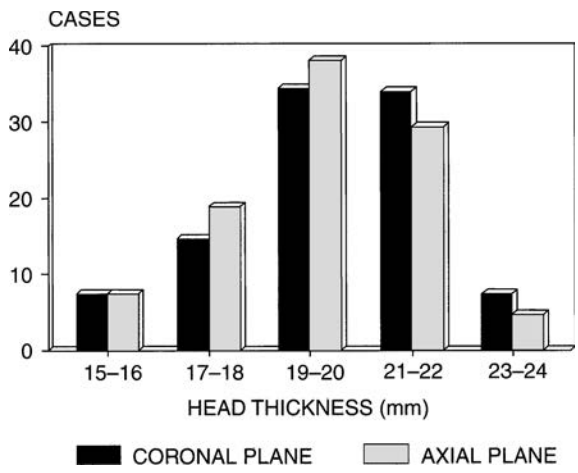

Figure 19-3 Humeral head thickness also demonstrates a bell-shaped distribution with a mean of 19 mm and a range of 15 to 24 mm. (Reprinted with permission from Iannotti JP, Gabriel JP, Schneck SL, et al. The normal glenohumeral relationships. An anatomical study of one hundred and forty shoulders. *J Bone Joint Surg Am* 1992;74:491.)

Humeral Head Offset

The center of the humeral head does not coincide with the projected center of the humeral shaft. Alternatively, the point in the proximal humeral metaphysis that corresponds to the center of the humeral head (assuming that the humeral head is a sphere) does not lie on a line projected proximally into the humeral metaphysis from the central axis of the intramedullary canal of the humeral diaphysis.[6,12,72,86,95] The distance between the center of the humeral head and the central axis of the intramedullary canal is defined as the humeral head offset.[6,12,86,95] Although humeral head offset is undoubtedly three-dimensional, it is commonly described in two planes, coronal and axial. Like most other proximal humeral anatomic parameters, reported humeral head offsets are variable.[6,12,72,86,95] In the coronal plane, the humeral head offset is approximately 7 to 9 mm medial to the central axis of the intramedullary canal; in the axial plane, the humeral head offset is 2 to 4 mm posterior to the central axis of the intramedullary canal (Fig. 19-4).[6,12,86,95]

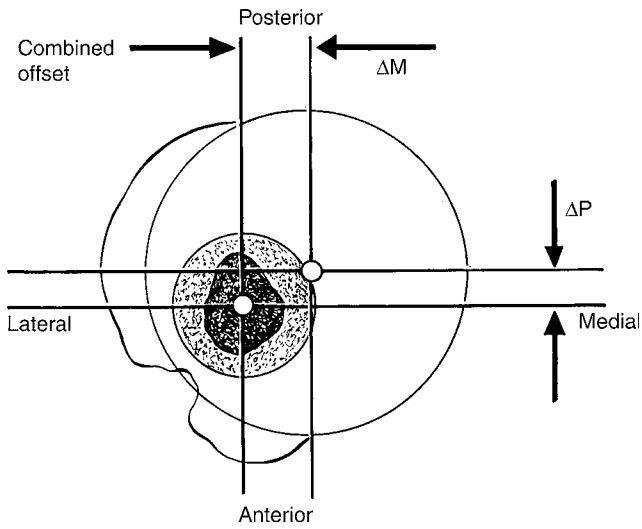

Figure 19-4 This axial plane section reveals the combined posterior and medial humeral head offset with respect to the central axis of the intramedullary canal. (Reprinted with permission from Boileau P, Walch G. The three-dimensional geometry of the proximal humerus. Implications for surgical technique and prosthetic design. *J Bone Joint Surg Br* 1997;79:857.)

Humeral head offset is correlated with humeral head radius and humeral head thickness.[86] However, for a given humeral head radius, humeral head thickness, and humeral head offset in the coronal and axial planes, the location of the humeral articular surface may vary with respect to angle of rotation about the central intramedullary axis (i.e., humeral retroversion) and superior–inferior translation along the central intramedullary axis (i.e., head to greater tuberosity height). Humeral retroversion averages 20 to 30 degrees with a wide range of approximately 20 to 55 degrees.[12,63,86,95] The vertical distance between the highest point of the humeral articular surface and the highest point of the greater tuberosity (i.e., head to greater tuberosity height) is approximately 8 mm and shows a relatively small range of interspecimen variability.[51,86]

Humeral Neck–Shaft Angle

The neck–shaft angle is defined as the angle subtended by the central intramedullary axis of the humeral shaft and the base of the articular segment (see Fig. 19-1). The average neck–shaft angle is 40 to 45 degrees.[12,51,72,86] However, more importantly, the humeral neck–shaft angle demonstrates significant individual variation with a range of 30 to 55 degrees.[12,51,72,86] One study has shown a correlation between humeral head radius and neck–shaft angle, with larger humeral heads demonstrating larger neck–shaft angles (Fig. 19-5).[51]

Glenoid Size and Shape

The size and shape of the articular surface of the glenoid can be defined by its linear superior–inferior and anterior–posterior dimensions as well as by its radius of curvature (see Fig. 19-1).[51,72] The mean superior–inferior dimension

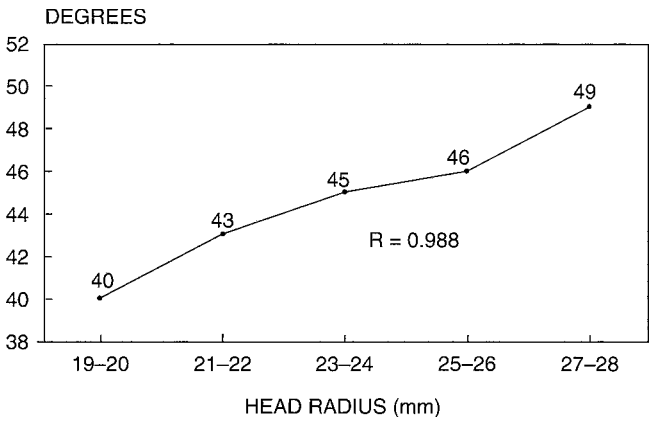

Figure 19-5 Humeral neck–shaft angle has been shown to correlate with humeral head size. (Reprinted with permission from Iannotti JP, Gabriel JP, Schneck SL, et al. The normal glenohumeral relationships. An anatomical study of one hundred and forty shoulders. *J Bone Joint Surg Am* 1992;74:491.)

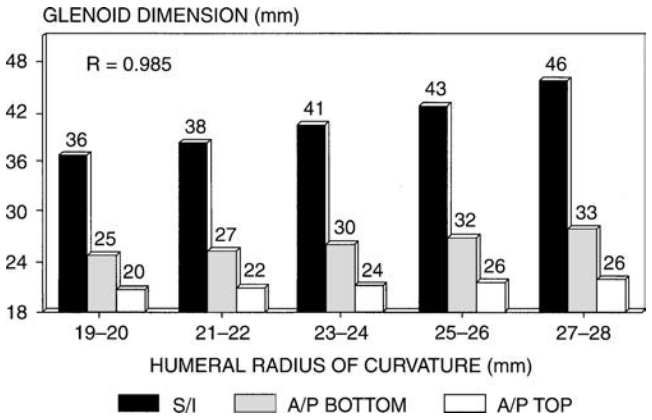

Figure 19-6 Humeral head size correlates with the superior–inferior dimension of the glenoid, the anterior–posterior dimension of the upper half of the glenoid, and the anterior–posterior dimension of the inferior half of the glenoid. A/P = anteroposterior; S/I = Superoinferior. (Reprinted with permission from Iannotti JP, Gabriel JP, Schneck SL, et al. The normal glenohumeral relationships. An anatomical study of one hundred and forty shoulders. *J Bone Joint Surg Am* 1992;74:491.)

of the glenoid (excluding the labrum) is approximately 39 mm (range 30 to 48 mm).[51] The anterior–posterior dimension of the superior half of the glenoid is shorter than the inferior half of the glenoid, resulting in a pear-shaped or comma-like appearance. The mean anterior–posterior dimension of the superior half of the glenoid (excluding the labrum) is approximately 23 mm (range 18 to 30 mm), and the mean anterior–posterior dimension of the inferior half of the glenoid (excluding the labrum) is approximately 29 mm (range 21 to 35 mm).[51] The ratio of the superior–inferior dimension to the anterior–posterior dimension of the larger, inferior half of an average glenoid is 1:0.7.[51] The humeral head radius correlates with the size of the glenoid in both the superior–inferior and anterior–posterior dimensions (Fig. 19-6).[51]

The glenoid vault has a complex geometry with a regular shape that can be approximated by a model of stacked triangles.[9] The glenoid vault shape is consistent among a wide patient population and is independent of glenoid size or patient gender (Fig. 19-7).[9]

Controversy exists with regard to the relationship between the glenoid and humeral articular radius of curvature.[51,59,72,101] This controversy exists because of differences in measuring techniques, differences in sample sizes, and large individual variations in anatomy. The thickness of the articular cartilage of the glenoid increases toward the periphery of the articular surface and must be included when measuring the glenoid radius of curvature.[101] However, even when the articular cartilage is included in the measurement, the radius of curvature of the glenoid articular surface does not equal the radius of the humeral articular surface in all specimens.[51,59,72,101] Iannotti and colleagues[51] observed that, on average, the glenoid radius of curvature in the coronal plane was 2.3 mm larger than the

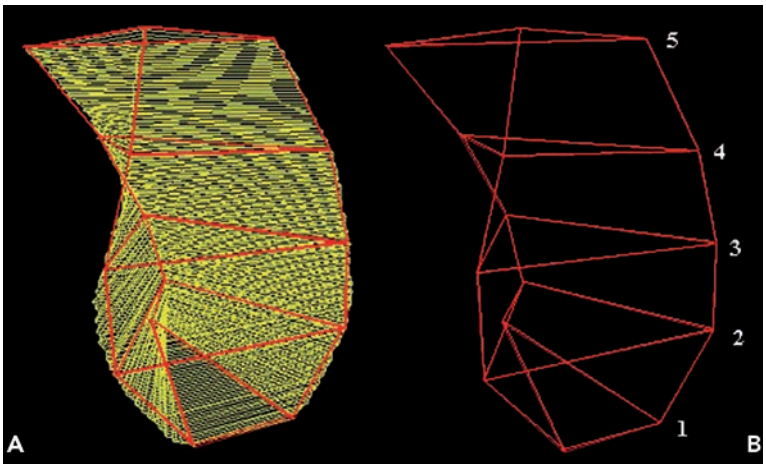

Figure 19-7 The shape of the glenoid vault can be approximated using a model of stacked triangles. (Reprinted with permission from Bennetts C, Gordiev K, Powell K, et al. Quantitative image analysis of glenoid vault shape. J Shoulder Elbow Surg (in review).

coronal plane humeral radius of curvature in the same specimen. Soslowsky and coworkers[101] reported a difference between humerus and glenoid radii of curvature of less than 2 mm in 88% of specimens and less than 3 mm in all specimens. Kelkar and associates[59,60] reported a mean humeral radius of curvature that was 2 mm less than the mean glenoid radius of curvature. In addition, as the humerus is abducted from a neutral position, the percentage of glenoid contact increases significantly, indicating that the functional conformity may increase during active elevation.[115]

Glenoid Offset

The glenoid offset is defined as the perpendicular distance between the base of the coracoid process and the deepest portion of the glenoid articular surface (see Fig. 19-1). This distance determines the location of the glenohumeral joint line and is not correlated with humeral or patient size.[51] The average glenoid offset is approximately 2 mm (range −5.0 to +5.0 mm).[51]

Lateral Glenohumeral Offset

The lateral glenohumeral offset can be defined as the perpendicular distance from the base of the coracoid process to the most lateral extent of the greater tuberosity (Fig. 19-1).[51] The distance from the most lateral extent of the greater tuberosity to the lateral edge of the acromion process correlates with the lateral glenohumeral offset and is easily measured intraoperatively (Fig. 19-1). Lateral glenohumeral offset is important in shoulder function because it determines capsular tension, resting length of the rotator cuff muscles, and the moment arm for the deltoid muscle. Lateral glenohumeral offset averages approximately 54 to 57 mm (range 43 to 68 mm), and the distance from the greater tuberosity to the lateral margin of the acromion process averages 17 mm (range 15 to 21 mm).[51] Since the glenoid offset is less than 5 mm in all normal shoulders, it has little effect on lateral glenohumeral offset.[51] However, both lateral glenohumeral offset and greater tuberosity to acromion distance correlate with humeral head size, which in turn correlates with patient height (Fig. 19-8).[51]

BIOMECHANICAL FACTORS

Glenohumeral Articular Conformity

Conformity of the articular surfaces refers to the difference between the radii of curvature of the humerus and glenoid. Congruent or conforming articulations are characterized by glenoid and humeral surfaces with equal radii of curvature. Incongruent or nonconforming articulations exist when the

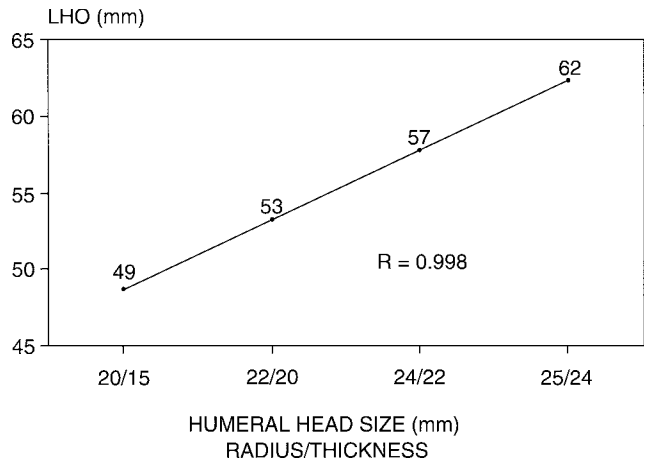

Figure 19-8 Lateral glenohumeral offset is defined as the distance from the base of the coracoid process to the lateral aspect of the greater tuberosity and is correlated with humeral head size. LHO = lateral humeral offset. (Reprinted with permission from Iannotti JP, Gabriel JP, Schneck SL, et al. The normal glenohumeral relationships. An anatomical study of one hundred and forty shoulders. *J Bone Joint Surg Am* 1992;74:491.)

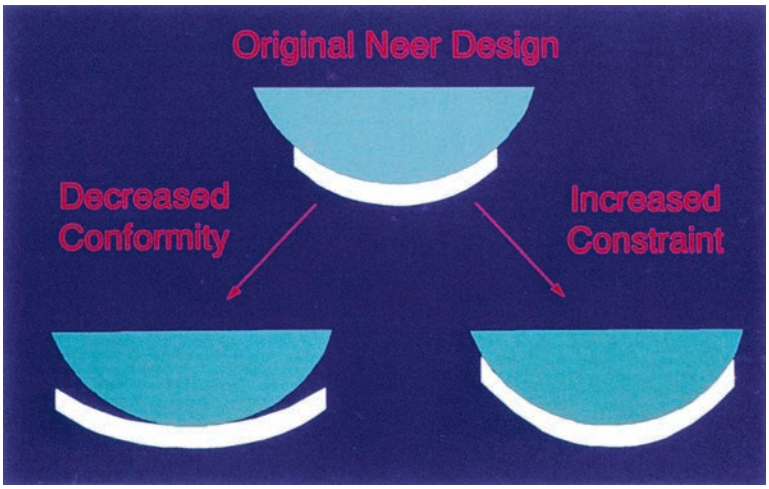

Figure 19-9 Conformity refers to the difference between the humeral head radius and the glenoid radius. Constraint is determined by glenoid wall height and is independent of conformity. Two articulations may have identical conformity and different constraints and vice versa.

humerus and glenoid radii of curvature are not equal. In the normal shoulder, the components of the articulating surfaces include the humeral articular cartilage, glenoid articular cartilage, and glenoid labrum. The humeral articular cartilage is uniform in thickness throughout the entire articulating surface. As mentioned previously, the glenoid articular cartilage is thicker at the periphery than in the center.[101] The glenoid labrum extends the arc of the articular cartilage and deepens the glenoid socket, but does not change the radius of curvature of the glenoid surface.[49] The articular cartilage and glenoid labrum are reversibly deformable tissues. Therefore, for practical purposes, normal glenohumeral joints can be considered to be conforming if the humeral head radius of curvature is equal to or larger than the glenoid radius of curvature.[58] Normal glenohumeral joints are considered to be nonconforming when the humeral head radius is less than the glenoid radius.[58]

Conformity or congruence of the normal glenohumeral articulation is variable, as mentioned above in the section on glenoid size and shape.[35,51,58,59,72] In the majority of specimens reported, the humeral head radius is within 2 to 3 mm of the glenoid radius.[51,58,59,72] However, even small amounts of articular incongruence or nonconformity have important implications with regard to glenohumeral kinematics during active motion.[58]

Glenohumeral Articular Constraint

Constraint is defined as the ability of the articular surfaces to resist translational motion of the humerus on the glenoid. The most extreme example of a constrained articulation is one in which the glenoid and humeral components are mechanically coupled to one another. In normal shoulders, where the glenoid and humerus are obviously not mechanically coupled, articular constraint is a function of the percentage of the humeral head covered by the glenoid. Articular constraint is correlated with glenoid wall height or, alternatively, socket depth, and is independent of articular conformity. In other words, different articulations may have equal conformities but different constraints, and vice versa (Fig. 19-9).

The normal glenoid is more constrained (i.e., has greater depth) in the superior–inferior direction than in the anterior–posterior direction.[49,72] Additionally, the depth of the normal glenoid is contributed to equally by the articular cartilage and the glenoid labrum.[49] In the superior–inferior and anterior–posterior dimensions, the glenoid articular cartilage and labrum combine to yield a socket that is 9 mm and 5 mm deep, respectively.[49] Glenoid depth can also be thought of in terms of coverage of the humeral head.[72] In the superior–inferior direction, the glenoid covers approximately a 65-degree arc of the humeral surface, compared to a 50-degree arc of coverage in the anterior–posterior direction.[72]

Periarticular Muscular Forces

The interactions between the many muscles that control motion of the shoulder girdle are extremely complex and beyond the scope of this chapter. However, in a simplified sense, the deltoid muscle provides power movement to the glenohumeral joint while the rotator cuff muscles compress the humeral head into the glenoid socket to provide a steering and stabilizing function.[7,37,87–89,100,114] In a normal shoulder, the sheer force imparted by the deltoid and other large muscles is counterbalanced by the axial or compressive force imparted by the rotator cuff. This results in decreased humeral translation and increased joint stability.[68] Pathologic conditions that result in altered rotator cuff function, such as cuff tear arthropathy, may exhibit altered glenohumeral kinematics because of muscular imbalance between the rotator cuff and deltoid. In the worst-case scenario, the deficient rotator cuff may be unable to provide a sufficient enough fulcrum to allow

elevation of the arm. Under these circumstances, anatomic prosthetic designs that depend on soft tissue integrity for stability and function will not restore overhead function.

Ligamentous Restraints

The glenohumeral ligaments are thickenings of the joint capsule that are somewhat variable in their appearance.[20,32,82,110,116] They act as checkreins to excessive rotation or translation of the humeral head at the extremes of glenohumeral motion.[20,82,116] Although various regions of the capsule act reciprocally to help stabilize the shoulder at extremes of motion, the ability of various ligaments to control glenohumeral motion depends upon their location within the capsule as well as the arm position. The rotator interval capsule occupies the gap between the upper portion of the subscapularis and the anterior border of the supraspinatus. It consists of the superior glenohumeral ligament and coracohumeral ligament.[27,43,117,118] The rotator interval capsule is primarily responsible for limiting external rotation and inferior subluxation of the humerus with the arm at the side.[27,43,116,117] The middle glenohumeral ligament limits external rotation and anterior subluxation of the humerus with the arm in midabduction.[82]

The inferior glenohumeral ligament consists of an anterior band, an axillary pouch, and a posterior band.[81,110] It is taut in abduction and therefore limits the degree of abduction as well as inferior translation of the humeral head in full abduction. The anterior band tightens in combined abduction and external rotation and therefore limits the amount of abduction and external rotation possible as well as anterior translation with the arm in this position.[81,110,118] The posterior band is taut in abduction and internal rotation. Therefore, it limits the amount of simultaneous abduction and internal rotation possible and also limits posterior humeral translation with the arm in this position.[81,110,118] The anterior and posterior bands can be made even more taut by passively positioning the abducted humerus posterior and anterior to the scapular plane, respectively.

Tension in any of the glenohumeral ligaments will cause obligate translation in the opposite direction. For example, tension in the anterior band of the inferior glenohumeral ligament will result in posterior translation of the humeral head.[43,45,58] Pathologic conditions that result in capsular contracture, such as glenohumeral arthritis, may lead to altered humeral rotation and translation because of premature capsular tightening. One of the most important goals of prosthetic reconstruction is to release capsular contractures to restore joint flexibility and, presumably, improve kinematics.

Normal Kinematics

Glenohumeral motion is composed of translation and rotation of the humerus on the glenoid. When the humerus is moved from one point in space to another, the motion occurs as a combination of rotation and translation. The percentage of that motion that occurs as rotation is variable and depends on the rotator cuff forces, capsular tension, and joint conformity.[58] If the motion were purely rotation, the shoulder would be considered strictly a "ball-in-socket" joint. Conversely, if the motion were entirely translation, the shoulder would be considered a planar joint.

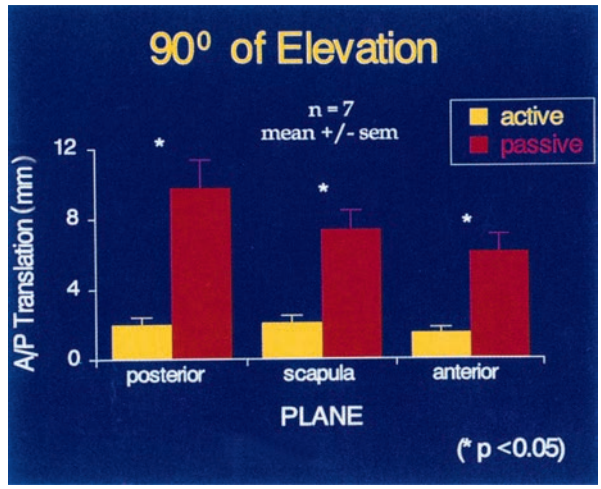

Figure 19-10 This figure depicts anterior–posterior humeral translation during both active and passive positioning from maximum internal to maximum external rotation at 90 degrees of total elevation (i.e., 60 degrees glenohumeral and 30 degrees scapular) in 30 degrees anterior to and 30 degrees posterior to the scapular plane. Note that anterior–posterior humeral translation is smaller (2 mm) during active joint positioning and larger (8 mm) during passive joint positioning. A/P = anteroposterior.

Humeral head translation during active joint positioning with a normal rotator cuff and no capsular contracture is variable but small.[10,58,61] Under these conditions, glenohumeral motion approaches "ball-in-socket" kinematics. Anterior–posterior translation and superior–inferior translation are approximately 2 mm (Fig. 19-10).[58] Rotation occurs about a relatively fixed point that is located within 1 to 3 mm of the geometric center of the humeral head.[10,59,61] Although the translations are small, they are correlated with conformity of the articular surfaces. Nonconforming joints exhibit more translation during active motion than conforming joints (Fig. 19-11).[58]

Humeral head translation during passive joint positioning with a nominal centering force is much larger than during active joint positioning with normal rotator cuff forces and is independent of joint conformity (see Figs. 19-10 and 19-11).[45,46,58] Anterior–posterior passive translation is approximately 8 mm, fourfold greater than active translations.[58] Passive superior–inferior translation is approximately 4 mm, twofold greater than active translations (see Fig. 19-10).[58]

The range of motion achievable during passive joint positioning, with only a nominal centering force applied, is much larger than during active joint positioning.[58] The

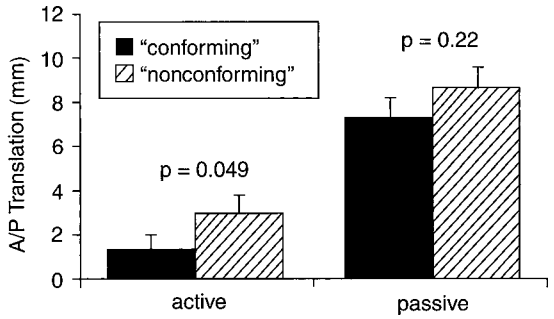

Figure 19-11 Nonconforming joints have significantly greater translation during active joint positioning than conforming joints. A/P = anteroposterior. (Reprinted with permission from Karduna AR, Williams GR, Williams JL, et al. Kinematics of the glenohumeral joint: influences of muscle forces, ligamentous constraints, and articular geometry. *J Orthop Res* 1996;14:986.)

increased humeral translation observed during passive joint positioning occurs at the extremes of rotational motion not achievable during active joint positioning. In fact, if passive and active humeral translations are compared over the same range of motion (i.e., midrange), the difference is insignificant (Fig. 19-12).[58] Moreover, the increased passive translations that occur at the extremes of motion correlate with increased ligament length (i.e., tension) on the side of the joint opposite the translation.[58] For example, anterior translation with the humerus in 90 degrees of elevation in the scapular plane occurs with increasing internal rotation and is associated with increasing length of the posterior band of the inferior glenohumeral ligament.[58]

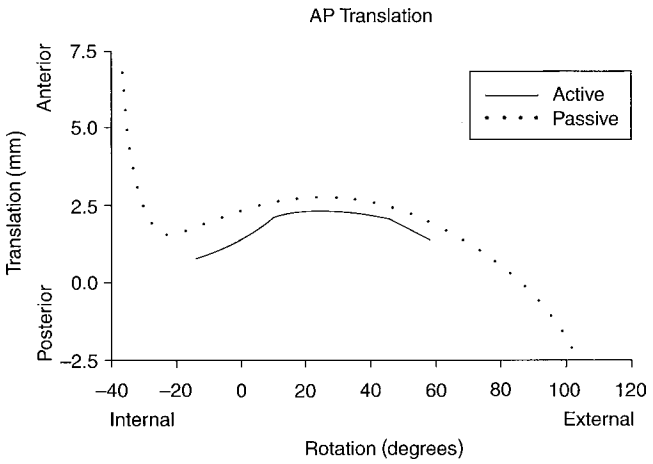

Figure 19-12 This representative plot of translation versus range of motion demonstrates that the increased translations seen during passive joint positioning occur at the extremes of rotation not achievable during active joint positioning. Humeral head translations during active and passive joint positioning over the same range of rotation are not significantly different. AP = anteroposterior. Kinematics of the glenohumeral joint: influences of muscle forces, ligamentous constraints, and articular geometry. *J Orthop Res* 1996;14:986.)

Prosthetic Kinematics

In general, the relationships between active translations, passive translations, joint conformity, and ligament length observed in the normal shoulder are also present in the shoulder with a normally functioning rotator cuff and restored joint flexibility that has been reconstructed with anatomic, nonconstrained prostheses.[56] Humeral head translations observed during active joint positioning are small (0.3 to 1.7 mm) and strongly correlated with prosthetic component conformity (Fig. 19-13).[56] Humeral head translations during passive joint positioning are large (5 to 9 mm) and independent of prosthetic component conformity.[56] The increased passive translations that occur at the extremes of motion are correlated with increasing length of the capsule (i.e., ligament) on the opposite side of the joint to the translation.[56] The degree of prosthetic radial mismatch that produces a kinematic pattern of active motion that most closely resembles the natural joint is unknown and likely to vary from individual to individual. However, in one study of seven cadaver shoulders, prosthetic radial mismatch of approximately 4 mm produced active translations that most closely resembled the specimen mean prior to prosthetic arthroplasty (see Fig. 19-13).[56]

IMPLICATIONS FOR NONCONSTRAINED PROSTHETIC DESIGN

The ability of a particular prosthetic design to achieve anatomic reconstruction of the glenoid and humeral articular surfaces and to restore normal glenohumeral kinematics is obviously limited by the ability of the surgeon to restore soft tissue balance and correct any bony deficiencies. Certainly, prosthetic design alone cannot overcome pathology that is too severe to be corrected. Moreover, the choice of

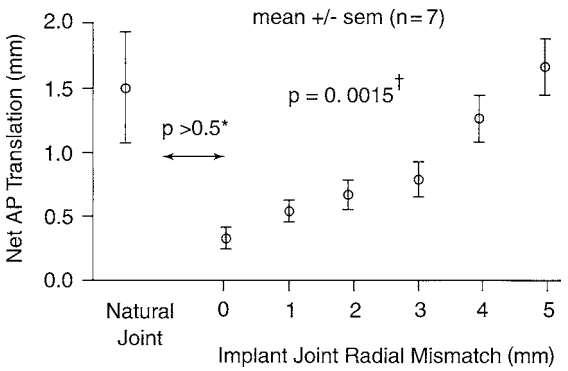

Figure 19-13 Humeral head translation during active joint positioning following prosthetic arthroplasty is correlated strongly with component conformity. AP = anteroposterior. implant cannot substitute for skillful surgical technique. However, assuming that all other variables are equal, the implant that is able to place a humeral head of the same size as the normal head, in exactly the same position on the humeral metaphysis as the normal head and in articulation with a glenoid component that anatomically restores both the location and inclination of the joint line, has the best opportunity for restoring normal glenohumeral kinematics.

Anatomic Factors

Theoretically, 85% of all humeral heads can be reconstructed to within 2 mm of their natural dimensions with eight head sizes (Fig. 19-14).[51] Maintaining the ratio of humeral head radius to humeral head thickness to a narrow range will allow maximization of humeral surface area available for contact.[51,86] Except in unusual situations with extraordinary bone loss or soft tissue deficiency, humeral heads with small radii of curvature and large thicknesses (or vice versa) are undesirable. Heads with inappropriately large neck lengths for their radii of curvature have a larger volume than the natural head that was removed and will result in overstuffing of the joint, increased soft tissue tension, and decreased range of motion or subscapularis rupture.[44]

Modular humeral systems offer some advantages over one-piece designs. The ability to place any humeral head on any humeral body results in less inventory. In addition, if revision is required, the head can be removed without removing the body.[99] However, modularity is also accompanied by some potential disadvantages. First, the head and body can become disassembled.[28] Second, in some designs, there is a large gap between the body of the implant and the head. This results in loss of available articular surface and potential contact between nonarticular portions of the proximal humerus and the glenoid component (Fig. 19-15).[54,86] If this gap is combined with beveling of the edge of the humeral head, thus creating a nonspherical implant, loss of available articular surface can be substantial.[5]

The normal variability of the humeral neck–shaft angle creates some difficult choices with respect to prosthetic design. An implant with a fixed neck–shaft angle can result in an anatomic reconstruction of the articular surface only if its neck–shaft angle matches the neck–shaft angle of the natural humerus in which it is being implanted. Differences in neck–shaft angle between the implant and the

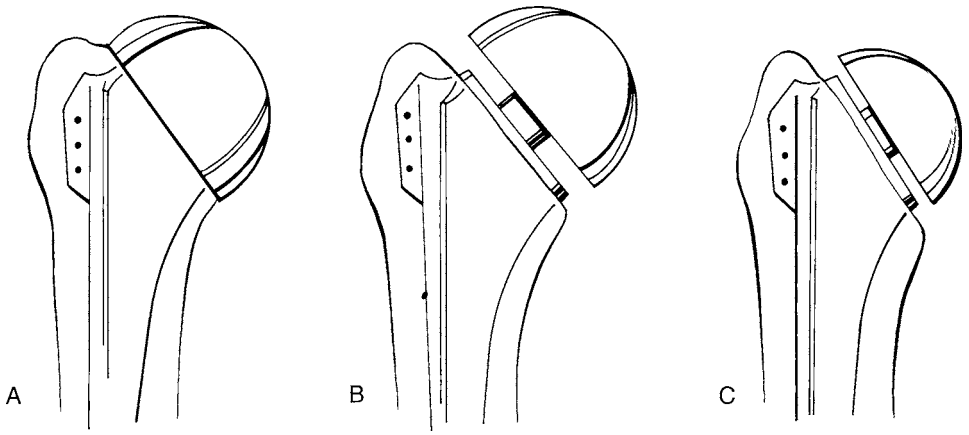

Figure 19-15 **(A)** A prosthesis whose neck–shaft angle matches the neck–shaft angle of the native humerus and whose articular surface rests flush against the cut surface of the humerus offers the most anatomic reconstruction with maximal surface area for contact with the glenoid. **(B)** A modular prosthesis that has a large gap between the head and the collar can overstuff the joint and also lead to internal component impingement because of diminished surface area for contact, even if the neck–shaft angle and head size are anatomic. **(C)** If the prosthesis is undersized to account for the gap between the head and the body, the tuberosity to head distance is altered (i.e., the greater tuberosity is prominent) and the surface area available for glenoid contact is diminished.

natural humerus cannot be corrected by changing humeral head thickness, radius, or offset without placing the articular surface of the head in a nonanatomic location or changing head volume.[86] If the neck–shaft angle of the implant is less than the natural humerus' (i.e., varus cut), the position of the prosthetic humeral head will be too low on the humeral metaphysis and the greater tuberosity will be too high (Fig. 19-16). If the prosthetic neck–shaft angle is more than the natural humerus' (i.e., valgus cut), the articular surface will be located superior and lateral to the anatomic location. Furthermore, the joint will contain the volume of the remaining natural head as well as the added volume of the prosthetic head. This overstuffing cannot be avoided by decreasing the humeral head size without also decreasing the surface area available for contact.[86]

Ideally, the prosthetic humeral head should be placed in the center of the cut surface of the humeral metaphysis. Since the center of the humeral head often does not coincide with the central axis of the intramedullary canal of the humeral diaphysis, the prosthetic humeral head must also be offset with respect to the intramedullary canal. This requires that the prosthetic humeral head be offset with respect to the prosthetic humeral body or that the prosthetic head and body together be offset with respect to the intramedullary canal. The latter scenario can be accomplished by undersizing the prosthetic humeral body and cementing it in the intramedullary canal so that the head and body are centered on the cut surface of the metaphysis rather than within the intramedullary canal. The former situation can be accomplished through prosthetic design by providing a coupling mechanism, such as an offset taper, between the humeral head and body that allows the surgeon multiple placement options of the head on the body.

The relationship between prosthetic anatomic variability (i.e., variable neck–shaft angle, variable humeral head offsets, etc.) and accuracy of humeral reconstruction with press-fit humeral stems has been highlighted by Pearl and colleagues.[84,85] They used a computerized optimization algorithm and cadaveric anatomic data to show that four commonly used press-fit humeral stems with fixed neck–shaft angles and one medial–lateral offset per humeral head size were unable to accurately reconstruct the humeral articular surface.[84] More specifically, despite optimized stem and head placement, the humeral head center was displaced 14.7 mm (range, 3.3 to 31.4 mm) from its original position and resulted in a decrease in the size of the humeral articular surface arc of 26 degrees (range, 11 to 41 degrees). In comparison to the position of the native humeral head, the optimized prosthetic head was smaller and shifted superiorly up the slope of the humeral osteotomy.[84] The addition of greater prosthetic anatomic variability in the form of variable neck–shaft angles and humeral head offsets resulted in more accurate recreation of the humeral articular surface, with center of

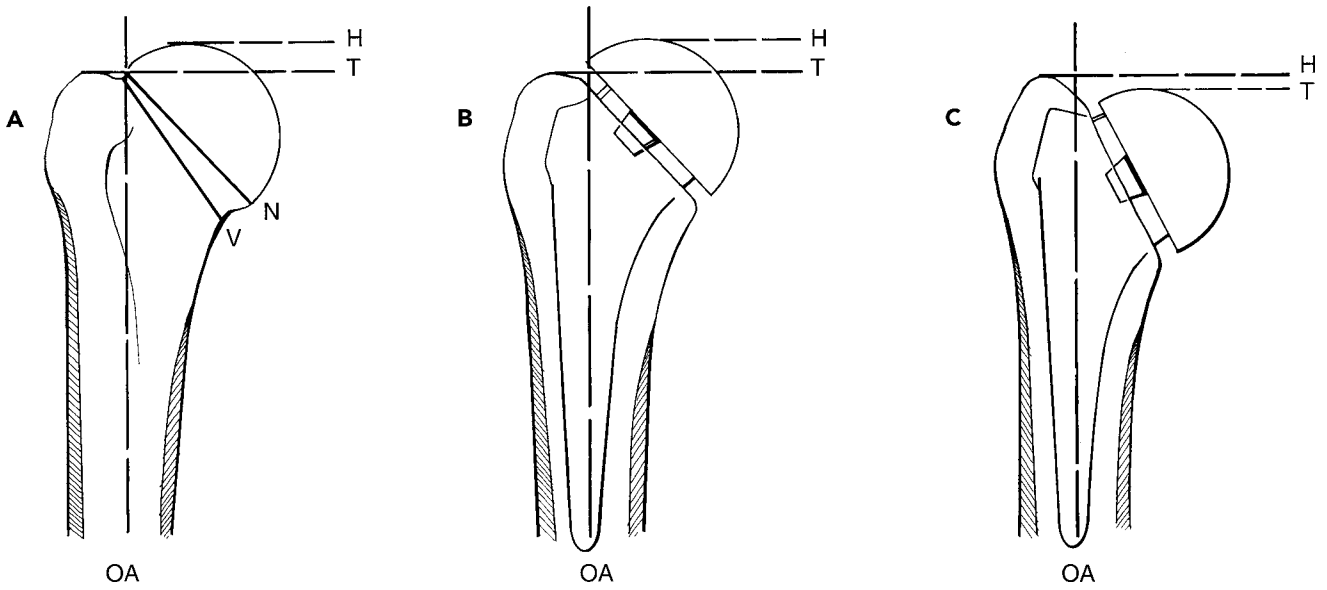

Figure 19-16 The greater tuberosity to head distance (*HT*) can be altered by the type of humeral osteotomy performed—normal (*N*) or varus (*V*) **(A).** If the neck–shaft angle of the prosthesis matches the neck–shaft angle of the native humerus, the humerus undergoes a normal cut (*N*), and the prosthetic humeral head is the appropriate size, the greater tuberosity to head distance will be anatomically reconstructed **(B).** However, if the prosthesis has a neck–shaft angle that is less than the neck–shaft angle of the native humerus and calls for a varus cut (*V*), the greater tuberosity to head distance will be less and may even become negative, even if the head is anatomically sized **(C).**

rotation displacement of 2.1 mm and decrease in surface arc of 12 degrees.[85]

The consequences of nonanatomic placement of the humeral head with respect to the humeral diaphysis are unknown. However, several potential problems can be identified. First, if the prosthetic humeral head is malpositioned anteriorly on the humeral metaphysis, the edge of the implant could overhang the anterior cortex of the humeral metaphysis and produce excessive tension on the subscapularis repair (Fig. 19-17). In addition, the anteriorly displaced humeral head will leave the posterior portion of the metaphysis uncovered. When the humerus is placed in abduction and external rotation, this uncovered humeral metaphysis may impinge against the posterosuperior glenoid and interfere with further motion or cause damage to the glenoid component (see Fig. 19-17).[54] Inferior malposition of the humeral head results in a decreased or reversed greater tuberosity to humeral head distance. When the humeral head is then centered within the glenoid, the greater tuberosity may impinge against the acromion or coracoacromial ligament (Fig. 19-18).

If one assumes that anatomic reconstruction of the humerus is a desirable goal, the question of exactly how anatomic the reconstruction needs to be still remains. In one cadaver study, as little as 4 mm of inferior displacement of the humeral head resulted in abnormal subacromial contact.[122] In addition, articular malposition of 4 mm in any direction resulted in small changes in range of motion and translation of the humeral head during both active and passive joint positioning.[122] The authors recommended reconstruction of the humeral articular surface to within 4 mm of the native humerus to minimize subacromial contact and maximize range of motion.[122]

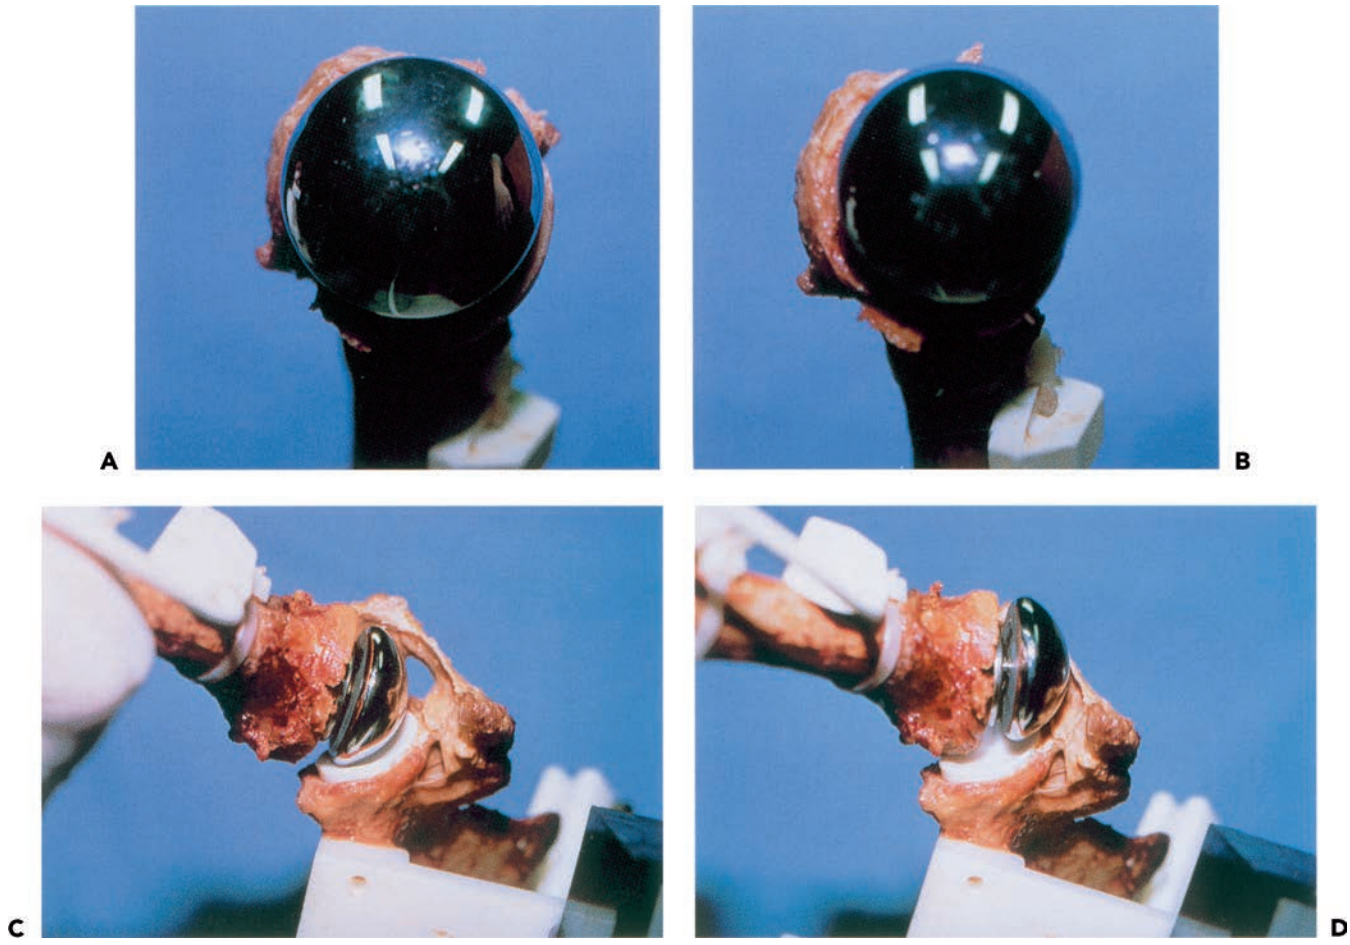

Figure 19-17 **(A)** Ideally, the prosthetic humeral head should be positioned in the center of the cut surface of the humeral metaphysis. **(B)** If the humeral head is offset anteriorly with respect to the metaphyseal center, it may overhang the anterior cortex of the humeral metaphysis and place tension on the subscapularis repair. **(C)** A head that is centered on the metaphysis allows full abduction and external rotation without impingement of the nonarticular portion of the humerus against the glenoid component. **(D)** An anteriorly offset humeral head leaves the posterior portion of the metaphysis uncovered, which can impinge against the glenoid component when the arm is positioned in abduction and external rotation.

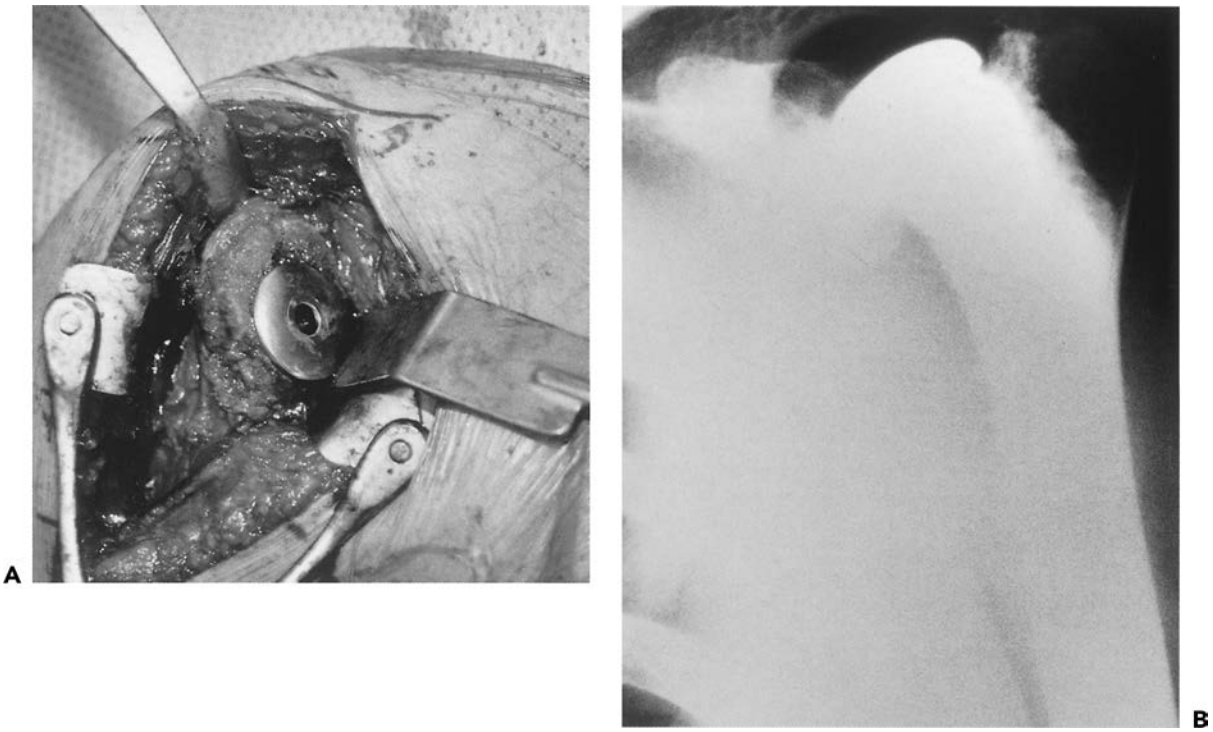

Figure 19-18 **(A)** Inferior placement of the humeral stem intraoperatively may occur from a number of causes, most commonly a varus cut. **(B)** This will lead to a reversed greater tuberosity to head distance and potential subacromial impingement.

The number of glenoid sizes required to fit all glenoids is probably less than the number of humeral head sizes required to fit all humeri. However, if articular mismatch is considered to be important and is to remain constant, a matching glenoid must be available for every humeral head. If articular mismatch were to remain within a narrow range, rather than constant, fewer glenoids would be necessary.

The bone of the natural glenoid should support the prosthetic glenoid component in its entirety. A pear-shaped component would seem to offer the best opportunity to provide the largest amount of glenoid articular surface without overhanging the anterior or posterior margins of the superior portion of the natural glenoid. If the anterior–posterior dimension of the superior and inferior portions of the glenoid component is equal (i.e., the component is oval), the humeral head may articulate against the unsupported anterosuperior and posterosuperior portions of the component. This may result in bending moments at the component rim, which could stress the component anchoring point or deform the rim. In addition, the increased anterior–posterior dimension of the superior portion of an oval glenoid component may facilitate contact between the edges of the component and nonarticular portions of the proximal humerus. However, many, if not most, arthritic glenoids have lost their natural pear shape and are more oval. For these reasons, there is no clear consensus with regard to the use of either pear-shaped or oval glenoid components.

The concept of nonarticular portions of the prosthetic humerus contacting the glenoid component has been mentioned as a potential consequence of nonanatomic reconstruction. In the nonprosthetic shoulder, this phenomenon has been termed internal glenoid impingement.[53,54] Nonanatomic prosthetic designs may result in component impingement.[53,54] Nonanatomic features that may predispose to the development of internal component impingement include decreased humeral surface area, increased glenoid anterior–posterior size, and nonanatomic humeral head placement. These potentially predisposing factors are especially relevant when glenohumeral motion following prosthetic replacement is normal or near normal. In the presence of diminished glenohumeral motion, internal component impingement may only occur with large deviations in prosthetic sizing or placement.

Biomechanical Factors

Elastic deformation of the glenoid articular cartilage and labrum in the normal shoulder can accommodate the small humeral head translations observed during active motion with a normal rotator cuff and no capsular contracture. Polyethylene does not have the same loading characteristics as articular cartilage and labrum. In a completely conforming prosthetic articulation, humeral translation can only occur with subluxation of the humeral

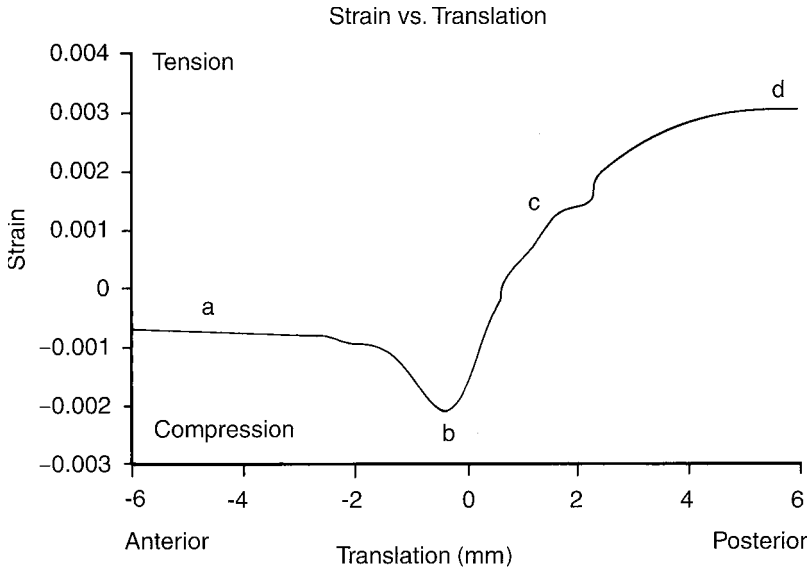

Figure 19-19 As the humeral head is translated from the anterior glenoid rim to the posterior glenoid rim, strain on the anterior surface of the keel changes. The strain begins as a compressive strain, which increases to a maximum when the humeral head is positioned over the deepest portion of the glenoid component. The strain reverses and becomes tensile and reaches a maximum tensile strain when the humeral head reaches the posterior glenoid rim. Increasing component conformity is associated with an increase in maximum tensile strain. Decreasing component conformity is associated with increasing maximum compressive strain. (Reprinted with permission from Karduna AR, Williams GR, Iannotti JP, Williams JL. Total shoulder arthroplasty biomechanics: a study of the forces and strains at the glenoid component. *J Biomech Eng*, 1998;120(1):92–99)

component and subsequent rim loading. This rim loading may result in permanent deformation of the glenoid component, unusual wear of the glenoid component, or rocking of the glenoid anchoring points.

Strain patterns on the surface of the keel of a cemented glenoid component are dependent upon articular conformity.[55] As a simulated humeral head is translated across the glenoid surface, from the anterior rim to the posterior rim, strain along the anterior surface of the keel starts out as mildly compressive and reaches a maximum compressive strain when the humeral head reaches the midpoint of the glenoid. As the humeral head continues to translate posteriorly, the strain becomes increasingly tensile until it reaches a maximum at the posterior glenoid rim (Fig. 19-19). The maximum tensile strain increases with increasing conformity, indicating the presence of an increasing bending moment. However, the maximum compressive strain observed when the humeral head is at the midpoint of the glenoid increases with decreasing conformity.[55] The clinical significance of these alterations in component strain is not currently known.

The force required for dislocation of a prosthetic glenohumeral joint with a constant joint reaction force is a function of component constraint (i.e., wall height), not component conformity.[57] If wall height and joint reaction force remain constant, the force required for dislocation of the prosthetic components remains the same, regardless of conformity. As articular conformity decreases, the amount of humeral translation permitted before the glenoid wall is encountered increases. However, continued translation to the top of the glenoid rim requires the same force, irrespective of decreasing component conformity (Fig. 19-20).[57]

Articular nonconformity of prosthetic components seems desirable if reproduction of normal glenohumeral kinematics is a goal of prosthetic reconstruction. However, the ideal amount of articular mismatch is not known. There is probably an acceptable range of articular nonconformity. Too much nonconformity may decrease contact area and increase contact stresses to a level that could threaten the integrity of polyethylene. In addition, given the small dimensions of the natural glenoid, a glenoid component that is both excessively flat and small enough to fit on the surface of the natural glenoid will have a diminutive wall height and may be prone to instability. Conversely, too little nonconformity limits humeral translation and encourages glenoid component rim loading. This results in increased tensile strain at the anchoring

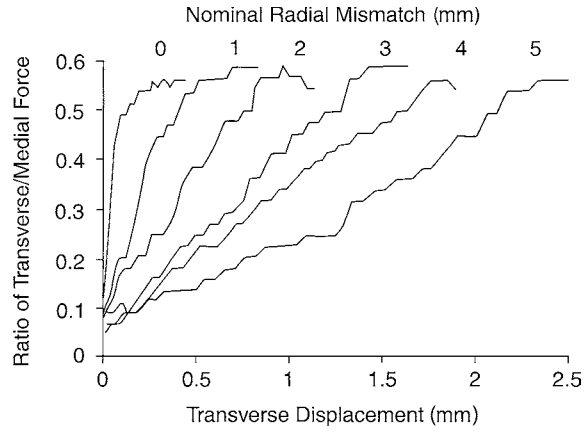

Figure 19-20 This graph plots force versus transverse displacement as a function of conformity. As component conformity decreases, there is more humeral head translation permitted for the same normalized displacement force ratio. However, the force required for maximum displacement (i.e., dislocation force) does not change appreciably. (Reprinted with permission from Karduna AR, Williams GR, Williams JL, et al. Joint stability after total shoulder arthroplasty in a cadaver model. *J Shoulder Elbow Surg* 1997;6:506.)

point of the glenoid component and may lead to increased component wear, peripheral component deformation, or early loosening.

Walch and colleagues studied the effect of prosthetic articular mismatch on the presence of glenoid radiolucent line formation postoperatively.[113] In this retrospective study of 319 total shoulder arthroplasties, a significant linear relationship was found between articular conformity and radiolucent line scores. Increasing nonconformity was associated with lower (i.e., better) radiolucent line scores, with the best scores associated with implants with radial mismatches of greater than 5.5 mm.[113]

Component Positioning and Fixation

As mentioned above, glenoid version shows substantial individual variation. However, on average, normal glenoid version is 0 to 2 degrees of retroversion.[19] In osteoarthritis, glenoid retroversion is increased, presumably as a result of posterior glenoid wear or congenital hypoplasia.[38,112] This increase in glenoid retroversion results in increased stresses to the posterior glenoid and posterior subluxation during external rotation.[18] In addition, increased glenoid retroversion may be a predisposing factor for anterior rotator cuff tears.[108] Therefore, except in the most severe cases of congenital hypoplasia, the goal of shoulder arthroplasty is to return glenoid version to normal so that the stresses on the glenoid and rotator cuff are normalized. This is accomplished most often through asymmetric glenoid reaming, glenoid bone grafting, or a combination of the two. Although the possibility of using a built-up glenoid component exists, currently there has been little experience with this technology.

In cases where the glenoid version cannot be normalized without glenoid bone grafting, altering humeral version has been suggested as an alternative. Theoretically, altering humeral version may alter the lines of action of the rotator cuff and improve function. However, since the prosthetic humeral head is a sphere with approximately 5 mm of offset from the stem axis in most arthroplasty systems, modest changes (i.e., 15 to 20 degrees) in humeral version will not change stability (Fig. 19-21).[102] Therefore, if correction of posterior instability in the presence of increased glenoid retroversion is desired, it must be accomplished by normalizing glenoid version.

Humeral component fixation can be accomplished through cemented or cementless means. In general, aseptic humeral loosening is an uncommon problem, especially with cemented components.[78,96] However, there have been reports of humeral component subsidence with press-fit cylindrical stems with proximal low profiles.[23,97] The use of implants with larger proximal profiles and the addition of surface coatings to encourage biologic in-growth have been shown to improve the rate of humeral lucency.[70,97,103] One study documented better performance using press-fit stems with a metaphysis-filling implant.[70] In this prospective study of 131 shoulder arthroplasties, no component subsidence was identified, 50 shoulders showed no radiolucency, 75 shoulders showed radiolucency around the distal tip, and two shoulders showed radiolucency around the metaphyseal region of the prosthesis. Only 11 radiolucencies were greater than 1 mm. Neutral stem alignment was less likely to be associated with radiolucency. The prevalence of radiolucency was unrelated to length of follow-up and the presence of a glenoid component.[70] Conversely, other studies have documented increased humeral radiolucency with longer follow-up and in total shoulder arthroplasty as compared to hemiarthroplasty.[97,103,104]

The prevalence of radiolucent line formation around the glenoid component is much higher than the humeral component and has been reported to occur in 30% to 96% of components.[11,22,33,47,65,73,105,109,113] Although the rate of clinical glenoid loosening (0% to 12.5%) is much lower than the rate of lucent line formation, a loose glenoid component is the most common prosthesis-related cause for revision surgery.[4,14,16,25,48,75,119,121,124] Certain aspects of glenoid preparation and fixation may influence the rate of lucent line formation and loosening. Initial stability of the glenoid component, which may be related to lucent line formation and loosening, is enhanced by concentric reaming of the glenoid bone surface so that its shape matches the back of the glenoid component.[26] Moreover, components with a curved back have been shown in one study to have better loosening performance than components with flat backs.[2] Finite element analysis comparing flat-back and curved-back glenoid components reveals that curved-back components have less shear stress and less slip than flat-back components and that these differences are increased if the component is malpositioned in retroversion (Fig. 19-22).[50] Consequently, most current arthroplasty systems provide specialized glenoid reamers to create such matching concave surfaces.

Methods of glenoid component fixation have evolved over time and will probably continue to evolve as long as glenoid loosening remains a prominent cause of failure. Neer's original glenoid component was a cemented, all polyethylene design with an axisymmetric keel with respect to the frontal plane.[76,77] It was introduced in 1973 and became the most popular type of glenoid component for many years.[77] Changes in keel geometry, specifically placing the keel in an offset position with respect to the central axis of the articular surface, could potentially improve loading characteristics.[74,83] The rationale for an offset keel design is that the deepest portion of the glenoid vault lies anterior to the central axis of the articular surface.[74] When the keel is centered to the articular surface, it may contact the posterior cortical bone of the vault.[74] A stress analysis of an anterior offset keel design using finite element modeling showed that, under a variable joint load, the stresses in the offset keel design were lower than

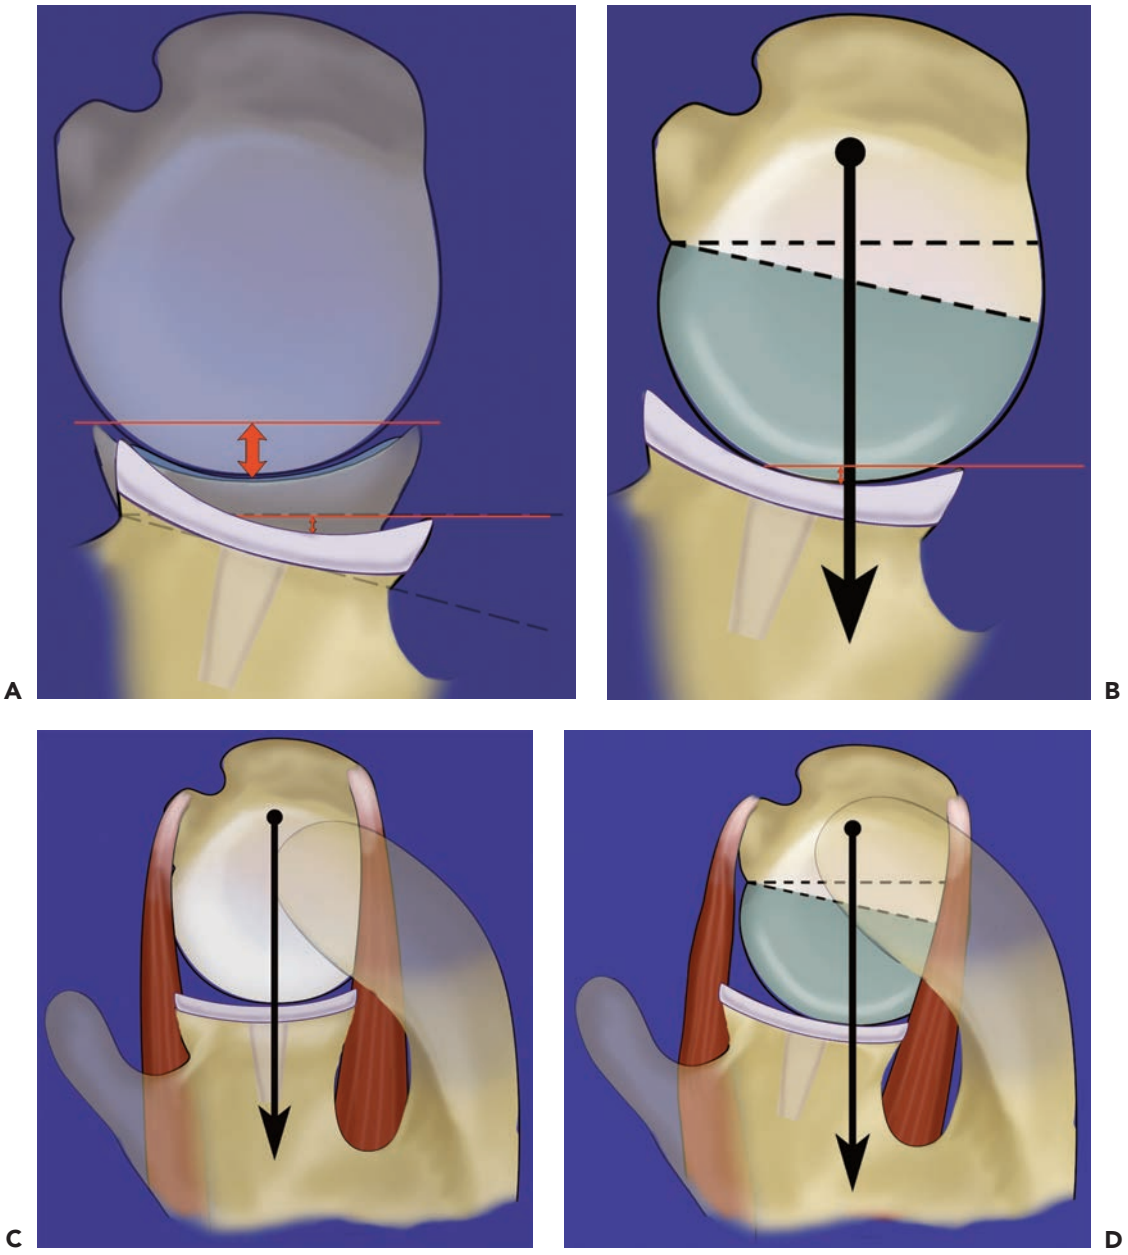

Figure 19-21 When the glenoid is retroverted, stability is not increased by decreasing humeral retroversion by 15 degrees. This is likely due to the fact that the functional wall height of the glenoid component is decreased with glenoid retroversion as the humeral head shifts posteriorly with the glenoid component **(A,B).** This shift is unchanged with changes in humeral component version. In addition, the force vectors of the rotator cuff muscles are not affected by changes in humeral component version as only the head is rotated and the position of the tuberosities to the scapula remain the same, resulting in a more posteriorly directed vector **(C,D).** (Reprinted with permission from Spencer EE Jr, Valdevit A, Kambic H, et al. The effect of humeral component anteversion on shoulder stability with glenoid component retroversion. *J Bone Joint Surg Am* 2005;87:808.)

those in a conventional center-keel design.[74] This is thought to be due to the anterior placement of the keel resulting in the keel being positioned more directly under the line of action of the maximum glenohumeral force (90 degrees of abduction). This ultimately results in less bending of the component. The offset keel has lower cement stresses than the center keel, as the cancellous bone in the posterior region of the glenoid has been shown to have a higher stiffness when compared with the anterior region. Also, insertion of the offset keel prosthesis results in removal of low stiffness bone, leaving the higher stiffness bone of the posterior region to support the prosthesis.[74]

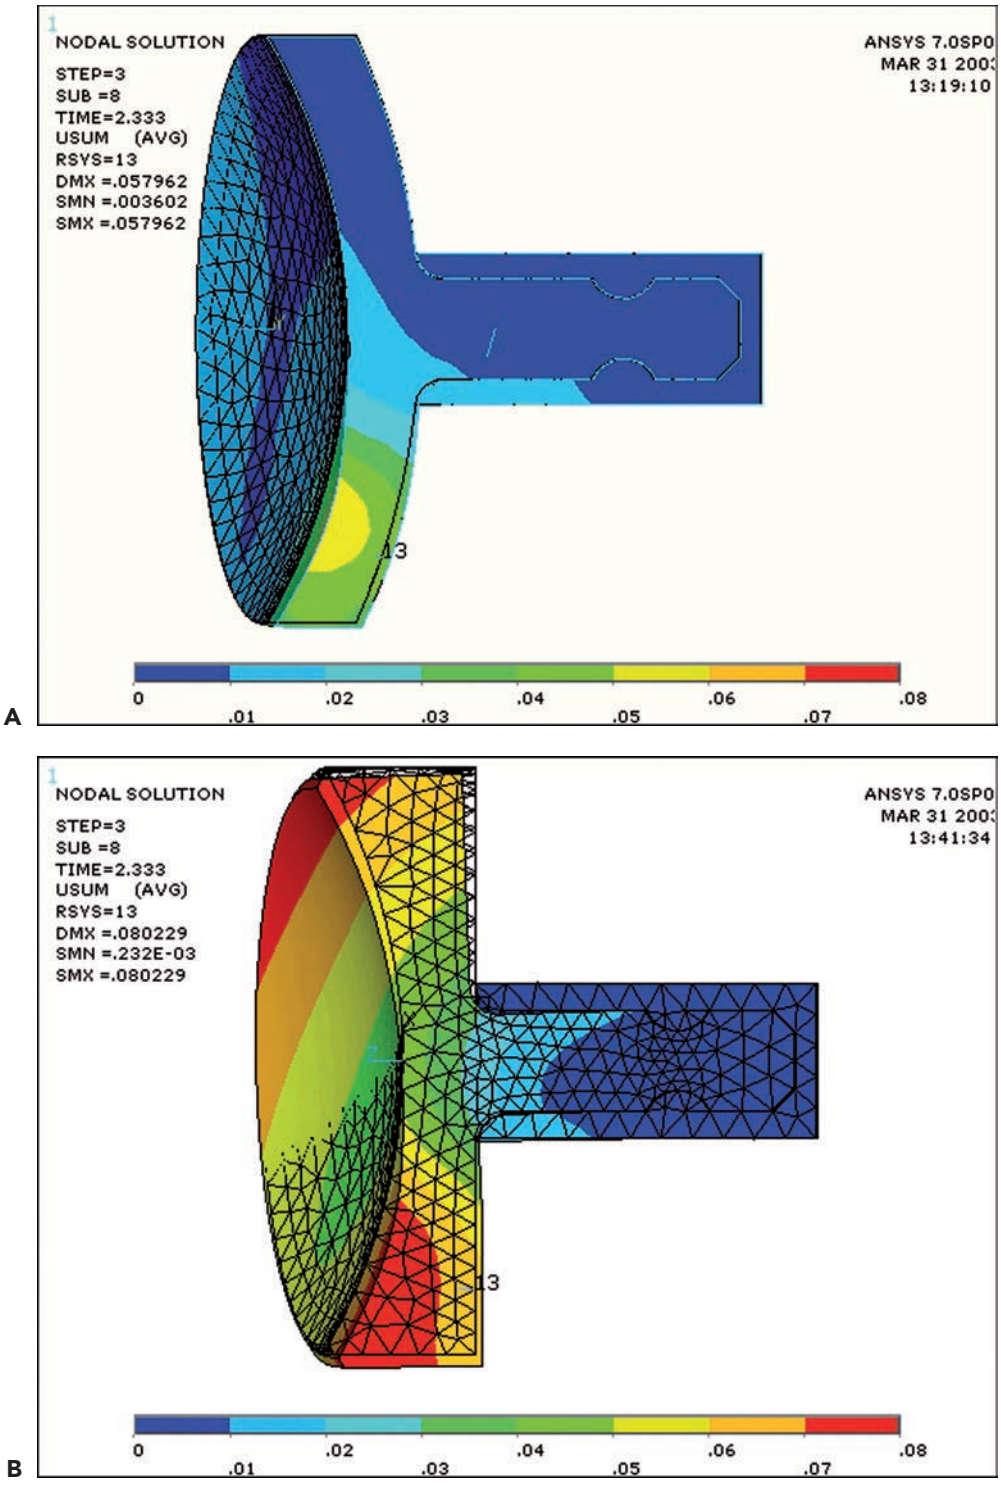

Figure 19-22 Finite element analysis reveals increased component shift in flat-back **(A)** versus curved-back **(B)** glenoid components. The increased amount of green, yellow, and red in A indicates greater amount of shift. These differences are increased when the component is malpositioned in retroversion. (Reprinted with permission from Iannotti J, Spencer EE Jr, Winter U, et al. Prosthetic positioning in total shoulder arthroplasty. *J Shoulder Elbow Surg* 2004;14:111S.)

Despite these potential advantages, offset keel designs have not gained in popularity.

More recently, glenoid component fixation using multiple pegs—rather than a keel—has been introduced. The peg-shaped anchorage systems provide greater stability against shear forces. As long as they are spaced far enough apart, pegs in any implant act individually to resist shear.[41] Anglin and colleagues documented better loosening performance in pegged versus keeled designs.[2,3] Lazarus and colleagues evaluated the radiographic outcomes of cemented pegged versus cemented keeled glenoid components in total shoulder arthroplasty.[65] They concluded that radiolucencies at the cement–bone interface and incomplete component seating occurred more frequently with keeled components versus pegged components.[65]

Wirth and colleagues also compared a pegged component with a central specialized cementless peg versus cemented keeled components in a canine model.[123] They found that the histology and the radiographs for the keel design supported the conclusion that the implant was not well integrated into the bone. The peg design allowed a "biologic" fixation between the implant's central peg and bone (Fig. 19-23). The fixation strength of the pegged design more than doubled by 3 months after surgery. The pegged glenoids demonstrated excellent osseous integration, adaptation, and increased bone density.

Parametric studies have evaluated the influence of fixation peg design on implant stability.[41] The parameters included were number and size of the fixation pegs as well as the aspect ratio (length/diameter). Five peg geometries of various shapes and sizes were tested for sheer stability. The results suggested that components with multiple small pegs create a uniform stress distribution in the anchoring material and provide more sheer stability per unit volume than implants with fewer, but larger pegs.[41] In addition, pegs with a rough surface rather than a smooth one have better fixation strength.[2] Because of these potential advantages, most current arthroplasty systems offer both keeled and pegged glenoid component designs.

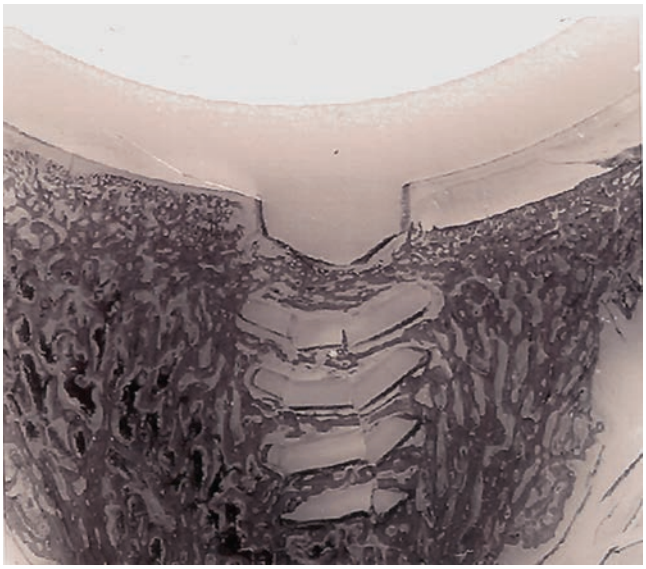

Figure 19-23 Histology reveals bone that has grown between the flutes of the central peg, presumably yielding improved fixation over time. (Reprinted with permission from Wirth MA, Korvick DL, Basamania CJ, et al. Radiologic, mechanical, and histologic evaluation of 2 glenoid prosthesis designs in a canine model. *J Shoulder Elbow Surg* 2001;10:140.)

Cementless glenoid component fixation offers the theoretical possibilities of preservation of glenoid bone and biologic fixation that improves over time. Except for the component described by Wirth and colleagues above,[123] most cementless designs utilize metal backing—often with textured surfaces to encourage biologic in-growth.[11,23,24,39,71,121] The obvious advantage of cementless, biologic in-growth technology is permanent fixation of the glenoid implant to bone. However, some potential disadvantages of metal backing also exist. Given the difference between the modulus of elasticity of glenoid bone and metal, the potential for stress shielding and loss of glenoid bone stock exists,[106,107] although one study suggested the possibility of improved stress transfer to bone with metal backing.[83] The most important problem, which has yet to be solved, is the effect on articular surface (i.e., polyethylene) wear of metal backing. Metal backing causes an increase in contact stresses and potentially a higher wear rate.[106,107] In addition, many metal-back designs utilize a metal tray fixed to the glenoid bone, into which a polyethylene component is placed. This two-piece design may result in significant additional wear between the polyethylene component and the metal (i.e., backside wear), resulting in the generation of wear debris that may lead to early loosening or polyethylene failure. Metal-back components with a one-piece design, in which the articular surface is permanently bonded to the metal, may eliminate backside wear. However, when the articular surface wears out, retrieving the permanently fixed metal backing may be difficult. Research into biologic fixation options will undoubtedly continue because of the potential advantages.

The vast majority, if not all, of currently available nonconstrained total shoulder prostheses have articular surfaces consisting of a metal (usually cobalt-chrome alloys) humeral head and a polyethylene glenoid. Since the ultimate cause of failure of properly implanted total shoulder prostheses is articular surface (i.e., polyethylene) wear, interest in alternative articular surfaces with superior wear characteristics has surfaced. Alternative bearing surface materials include cross-linked polyethylene, ceramics, and highly polished metals. The wear characteristics of these materials exceed traditional polyethylene. Glenoid components made from cross-linked polyethylene will soon be commercially available. However, further work is required to determine the exact role of alternate bearing surfaces in total shoulder arthroplasty. Some of the anatomic

requirements of shoulder prosthetic components, such as the relative thinness of the glenoid component, make the designing of alternative bearing surfaces difficult. The interest in alternative bearing surfaces will undoubtedly continue with the goal of identifying articular surface materials that will last the patient's lifetime and lend themselves to biologic fixation options.

IMPLICATIONS FOR CONSTRAINED PROSTHETIC DESIGN

Nonconstrained implants, as described in the sections above, are indicated when the rotator cuff is intact, when small tears can be reconstructed, or when there is enough rotator cuff remaining, so that the proximal pull of the deltoid can be converted into a rotational moment through the establishment of a fulcrum between the humeral head and glenoid. In the normal shoulder, this is done very effectively, since glenohumeral motion approaches ball-and-socket kinematics. In some cases of rotator cuff deficiency, there is more than the 2 mm of translational motion seen in normal shoulders but a fulcrum is eventually established and the arm can be raised. In other cases, particularly if there is coracoacromial arch insufficiency, deltoid contraction results in almost no rotational motion and the humeral head translates anterosuperiorly, out of the glenoid fossa. When arthroplasty is required under these circumstances, replacement with nonconstrained implants, even with tendon transfers and partial rotator cuff repairs, does not predictably result in improved function. The ability to create a glenohumeral fulcrum is irretrievably lost. Humeral hemiarthroplasty may result in some pain relief but function will remain severely compromised.

Renewed interest in implants with a fixed-fulcrum design has occurred because of the failure of nonconstrained devices to produce improvement in function in patients with arthritis and massive rotator cuff deficiency.[13,15,30,31,36,40,42,52,64,94,98,111,120] Constrained arthroplasties of various designs were performed decades ago with high rates of loosening and component failure.[17,29,34,62,66,67,90–93] It is thought that one potential factor important in component failure was the placement of the center of rotation markedly lateral to the glenoid, thus imparting substantial bending moments to the glenoid anchoring points. The more recent designs have used a reverse ball-and-socket design, with the ball on the glenoid side and the socket on the humeral side.[36,42] This renewed interest was initially driven by Paul Grammont, a French orthopaedic surgeon.[42] The important features of his prosthesis are a relatively large, low-profile (i.e., no neck) ball whose center of rotation lies within the glenoid vault and a relatively horizontal (155 degrees) inclination of the humeral cup compared to the normal neck shaft angle (Fig. 19-24).[42] These features result in shifting the center of rotation distally and medially, thereby improving the moment arm and strength of the deltoid, on which elevation and function of the arm depends. The relative valgus inclination of the humeral cup resists dislocation of the implant during early elevation.[13] However, this combined with the relatively low profile of the ball results in impingement of the polyethylene liner of the humeral cup against the inferior glenoid.[80] This contact between the polyethylene liner and the scapula may result in premature, localized polyethylene wear and notching. This impingement can be theoretically improved by lateralizing the instant center of rotation slightly[36] or by moving the ball inferiorly.[79]

Although the relative experience with these implants is short term, the initial results are very promising in a difficult group of patients that have few, if any, other options. There is reliable improvement in function and pain. The complication rate is higher than with nonconstrained implants, but not nearly as high as previous constrained devices.[8,15,36,42,52,94,98,111,120] Further follow-up and research is required to determine the durability of these implants, the significance of inferior notching in the medialized design,[13,42] any differences between the medialized[42] and lateralized[36] designs with respect to results and complica-

Figure 19-24 Grammont's reverse arthroplasty (Delta Prosthesis, Depuy, a Johnson and Johnson company, Warsaw, IN) consists of a relatively large glenoid sphere, whose center of rotation lies within the glenoid vault, and a relatively horizontal (i.e., neck–shaft angle 155 degrees) humeral cup.

tions, and the need for any additional design changes. However, the early results of these modern reverse prostheses justify continued work, since they provide improved elevation and strength in a way that replacement with anatomic, nonconstrained devices and soft tissue reconstruction cannot.

SUMMARY

Glenohumeral component design should be based on known anatomic and biomechanical relationships of the normal shoulder. The goals of prosthetic reconstruction of the glenohumeral joint should continue to be anatomic reconstruction of the articular surfaces with restoration of normal glenohumeral kinematics. Given the severe soft tissue and occasional osseous abnormalities that are encountered in patients with glenohumeral arthritis, this goal may not be attainable in all patients. However, so long as bone stock and soft tissue quality are adequate, prosthetic designs that most closely mimic normal anatomy and allow the most intraoperative flexibility with regard to prosthetic sizing and placement are likely to improve our chances of attaining these goals. The important features of most current anatomic implant systems are modular, anatomically correct humeral heads with offset capabilities; press-fit stems with porous coating and/or proximally filling geometries; low-profile, smooth, distally tapered stems for use with cement; and all polyethylene glenoids with both keel and peg configurations. Intense investigation continues with regard to cementless glenoid fixation and alternative bearing surfaces. For shoulders with such severe soft tissue destruction that anatomic reconstruction will not result in improved function, reverse arthroplasty shows good early promise. However, it should be remembered that shoulder replacement is and always will be a technique-dependent process. Therefore, no prosthetic implant can substitute for good surgical technique.

INTRODUCTION

The last century has witnessed the evolution of shoulder arthroplasty from simply a novel surgical technique to the current standard for restoring function in patients with debilitating end-stage glenohumeral arthritis. Unfortunately, as with any artificial prosthetic device, results are not perfect and there also exists a substantial population that may not be ideal candidates for prosthetic replacement of the glenohumeral joint. Such patients include those with coexisting medical morbidities that would prevent arthroplasty, and those young and active patients in whom a prosthetic replacement may be subject to excessive risk of failure. Even as the search for the ideal prosthetic arthroplasty has continued, it is this challenging group of patients that has

driven the exploration of nonprosthetic treatments for glenohumeral arthritis. Furthermore, until shoulder replacements reach the utopian ideal of perfect functional restoration with essentially no risk of prosthetic complication, surgeons should explore nonprosthetic alternatives in an attempt to provide both longitudinal pain relief and durable functional restoration (see Treatment Algorithms I and II).

Causes of Pain in Glenohumeral Arthritis

The results of nonprosthetic management of shoulder arthritis are quite variable depending on the cause of the arthritis. Because of this, it is important to understand the causes of pain in both osteoarthritis and rheumatoid/inflammatory arthritis.

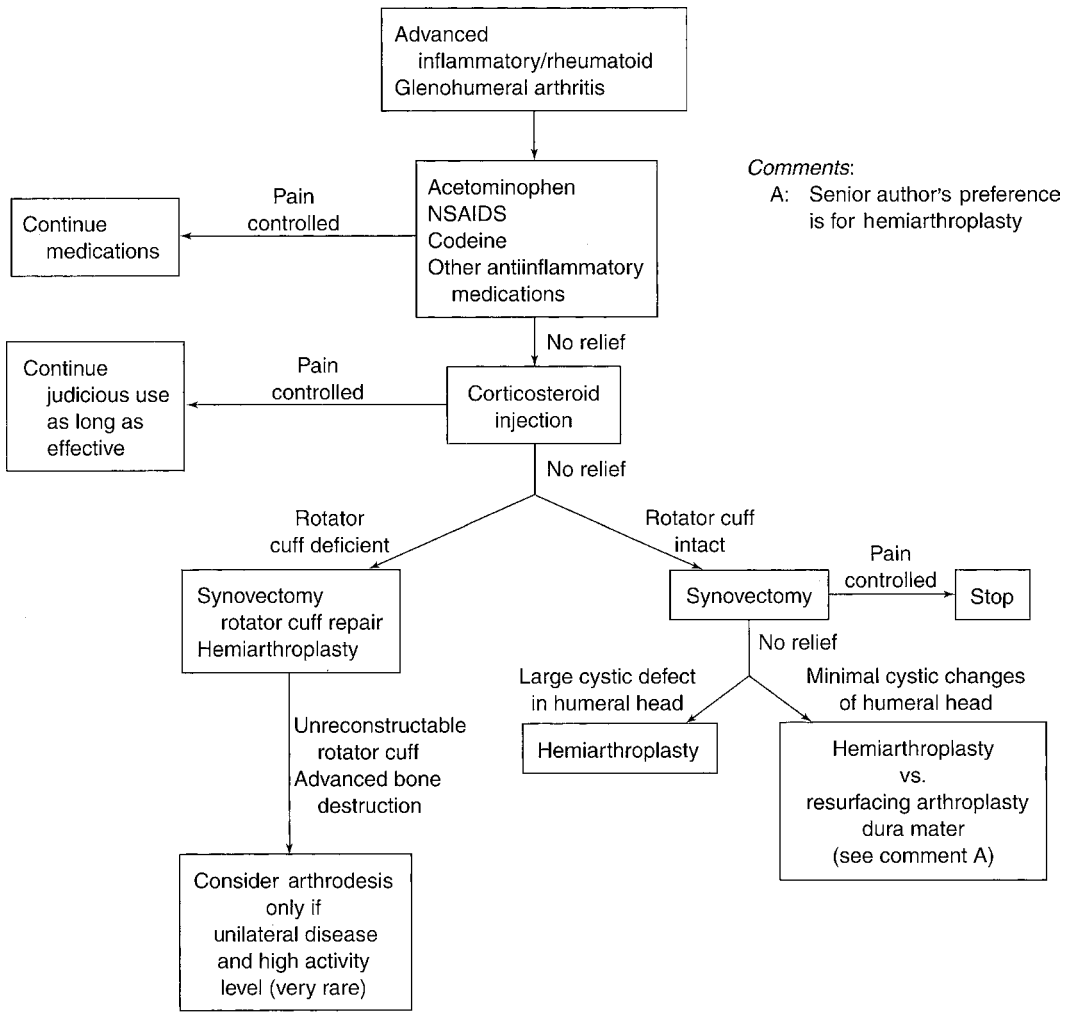
Osteoarthritis

The relative importance of factors that control the development of symptoms in osteoarthritis (OA) is still disputed.[24,25,27] Although roentgenographic features seen in this disease primarily result from the loss of articular cartilage and changes in the adjacent bone,[96] this disease process affects all periarticular tissues.[12,53,86] To some extent this may explain the often poor correlation between clinical symptoms and roentgenographic changes in various arthritic joints.[14,53] Many patients with this disease have mechanical, inflammatory, and psychological components to their pain.[22,107]

The shoulder joint is an uncommon site of primary OA, except in elderly women.[20] However, in relatively young individuals, OA of the shoulder may be seen as a consequence of trauma.[84] Specifics of the pathoanatomy of this posttraumatic diagnosis have been detailed by Neer.[72]

Rheumatoid and Other Inflammatory Arthritides

Glenohumeral joint involvement is common in patients with rheumatoid arthritis (RA), and is usually part of a polyarthropathy.[83] Laine et al.[99] defined the spectrum of



ALGORITHM 20-I

Algorithm for treatment of glenohumeral osteoarthritis. NSAIDs = nonsteroidal antiinflammatory drugs; OA = osteoarthritis.

shoulder disease in 277 hospitalized patients with RA.[52] Glenohumeral arthritis was detected in 47% of patients and many also had symptoms arising from the coracoacromial arch. Of note, 16 (6%) patients, with a mean age of 31 years, had shoulder arthralgia without demonstrable roentgenographic changes. Petersson similarly documented that 91% of patients with RA reported shoulder problems.[83] Thirty-one percent of these patients had such severe shoulder disability that they considered it to be their main problem.

Patients with symptomatic RA of the shoulder are typically rheumatoid-factor–positive women between 35 and 55 years of age. The destructive process may be quite advanced before significant symptoms are noted.[18] In addition to loss of motion, two common complaints in patients with RA are fatigue and muscle weakness. Rotator cuff defects occur in approximately 25% of these patients.[30,88] Many symptomatic patients with early stages of arthritis, regardless of cause, appear to benefit from noninvasive forms of therapy.

NONOPERATIVE TREATMENT

Education

An initial explanation of the arthritic process and discussion of its probable future implications is an important

first step in treating all patients. This helps ensure that patients' expectations are consistent with their prognosis. Education and encouragement also promote compliance with appropriate exercise and avoidance of detrimental activities. The goals of treatment and anticipated improvements should also be discussed. Typically this means that patients may need to adjust expectations since they may not be able to regain previous levels of sporting and other physical activities. If a patient is a manual laborer, the early realization that he or she may be unable to continue this occupation will facilitate early retraining.

Patients with arthritis must be taught to interpret their own symptoms to provide information important in determining appropriate therapy. They should both contribute to the exercise plan and assume responsibility for its implementation. The patient's active contribution to treatment fosters a sense of control over the effects of the disease. An insightful essay by R. E. Jones[46] discusses how patient satisfaction is strongly influenced by the personality and manner of the physician, as well as the quality of the physician–patient relationship. Applying the basic principles discussed by Jones will help physicians teach these patients how to manage and best enjoy the highest quality of life that is possible through the technologic achievements of present-day operative and nonoperative interventions for their arthritic shoulders.

Physical Therapy

General Principles

Although nearly all patients with glenohumeral arthritis will benefit from physical therapy, those who benefit most begin with decreased range of motion and weakness in the presence of minor roentgenographic findings.[62] In some patients, especially those with painful inflammatory arthropathies, an initial period of rest may be beneficial. However, an excessive period of rest can contribute to muscle atrophy, joint contractures, and worsening functional abilities. The aim of physical therapy is to increase range of motion and strength.[55] Nevertheless, therapy should not be considered a failure if the result is only the maintenance of the existing range of motion. Exercises are designed specifically for the needs of each patient—this includes gentle passive motion and isometric strengthening.[55] Preferential strengthening of specific muscle groups is especially beneficial for patients with mild OA whose symptoms are exacerbated by instability.[23,36]

Although acting in nearly diametric ways, heat and cold are therapeutically useful when employed at appropriate times in chronic and acute phases of inflammatory pain.[54,56] Cold treatment is useful in treatment of acute inflammatory flare-ups; the analgesic effects have been attributed to the ability of cold to depress the excitability of nerve fibers and muscle spindles, thereby increasing the pain threshold.[51,98] Cutaneous vasoconstriction and resulting reduction in blood flow reduce edema even in deeper tissues.[110]

When inflammatory pain is chronic, then the application of heat, usually in the dry form, is useful in temporizing pain and enhancing joint motion by increasing tissue elasticity.[3,50,52,57,98] Increased tissue metabolic activity also accompanies the increased blood flow resulting from vasodilation. Heat can be delivered superficially by using hot packs, hot water, or convective fluid therapy, while therapeutic ultrasound can be used for deeper penetration (see later section).

Hydrotherapy

The therapeutic efficacy of water therapy cannot be overstated. This remains a mainstay in the rehabilitation of any glenohumeral joint, and especially in the arthritic one. Buoyancy effects of water help to reduce stress exerted on muscles and joints during therapeutic shoulder exercises.[87] The patient's exertion can also be regulated because of the direct relation between the speed of movement and the resistance encountered. Adjustments in water temperature and agitation enhance the beneficial effects of hydrotherapy.

Therapeutic Ultrasound

The clinical usefulness of therapeutic ultrasound is based primarily on its capacity to increase blood circulation and temperature in deep tissues. Tissue temperature can be elevated at depths up to 5 cm from the point of application on the patient's skin, and peak temperatures occur in bone.[48,49] When the treatment objective is to heat muscle tissue, the most effective modality currently available is shortwave diathermy.[98]

Application of heat and cold, hydrotherapy, ultrasound, and range of motion and strengthening exercises are commonly used modalities for helping restore mobility to the stiff shoulder.[45,55,87] These and other nonoperative therapeutic interventions are contraindicated in patients who have severe pain and a rapidly deteriorating condition.[98] This scenario could imply concomitant occult sepsis, especially in the rheumatoid patient.

Occupational Therapy

Functional limitations are second only to pain in frequency of complaints of patients with glenohumeral arthritis. Impaired ability to dress and perform personal hygiene are particular problems. Occupational therapists can assist these patients by providing assistive devices and by teaching alternative ways to accomplish these tasks. For patients who desire to continue their gainful employment, analysis of job requirements is helpful in identifying problematic work practices.

Antiinflammatory and Pain Medications

Oral analgesics, such as salicylates, acetaminophen, and codeine, can be very effective in treating arthritic pain. The role of nonsteroidal antiinflammatory drugs (NSAIDs) in treating patients with symptomatic inflammatory arthropathies is well established.[44] However, for use in OA, it is controversial whether NSAIDs are any better than simple analgesia.[24] NSAIDs may have deleterious effects on articular cartilage in addition to the risk of untoward effects on gastric, renal, and liver function, which are particular problems in elderly patients.[24,44] Nevertheless, in a randomized trial examining pain relief in patients with OA of the knee treated with NSAIDs versus simple analgesics, NSAIDs were clearly superior in providing better quality of life and pain relief at the time of true inflammation.[71] Recently introduced COX-2–specific inhibitors have produced controversy both with regard to efficacy as well as potential for exacerbating medical comorbidities. At this time, Food and Drug Administration (FDA) approval for such medications remains in force, though physicians should seek to utilize any NSAID or other medication both judiciously and appropriately.

Nonoperative medical management of patients with intractable arthritic shoulder pain can be difficult. They may be best treated initially with a trial of interventions managed by a team of specialists trained in treating chronic pain. These specialists can manage depression, manipulate medication intake, inject trigger points, perform nerve blocks, and administer other modalities including low-dose narcotic medication. Such low-dose narcotics have demonstrated symptomatic efficacy in treating elderly patients with chronic pain. A neurologic workup is also often necessary to rule out cervical radiculopathy, brachial plexopathy, reflex sympathetic dystrophy, or other disorders.

Corticosteroids

Local anesthetic injections are of great value in diagnosing shoulder conditions by localizing the anatomic site of the pain generators. Appropriate steroid injections have also been documented to have significant therapeutic value.[8,35] Although the use of intraarticular steroids can be effective in abating symptoms in joints afflicted with RA, they are generally of comparatively limited value in OA, typically providing relatively short-term relief of symptoms.

Dacre et al.[23] studied the prospective, randomized, blinded results of local steroid injections or physiotherapy in treating patients with painful or stiff rheumatoid shoulders. Sixty consecutive patients of similar age, sex, diagnosis, and disease severity were allocated into three groups to receive either local steroids, 6 weeks of physiotherapy, or both. Results showed that physiotherapy alone was just as effective as local steroid injections or a combination of these two methods. In the uncomplicated case, a local steroid injection was the most cost-effective treatment.

Similarly, recently published meta-analyses of the peer-reviewed literature regarding the use of corticosteroid injections used for periarticular and intraarticular shoulder pain document variable success.[8,11] Patients with subacromial pathology (such as rotator cuff disease) and patients with varying degrees of stiffness/capsulitis statistically benefited from use of corticosteroids. Results for treatment of OA remained difficult to interpret. Anecdotally, we have found that, if a single intraarticular water-soluble corticosteroid injection is helpful, then another can be performed at a 6-month interval (no more often than two injections per year). If the first injection provides minimal relief (assuming a truly intraarticular position of the injection—if there is any doubt, fluoroscopic imaging should be considered), then further corticosteroid injections are likely to have little potential benefit.

Viscosupplementation

Peer-reviewed publications over the past decade have documented the apparent statistical benefit of intraarticular injections of hyaluronic acid in the treatment of knee and hip osteoarthritis for pain relief.[53,109] Unfortunately, neither in vitro nor in vivo studies have demonstrated a chondroprotective effect of either low- or high-molecular-weight hyaluronic acid, and the likely effect of these substances on the human joint (if any) appears to be symptomatic relief of joint pain. Further work is ongoing regarding the use of intraarticular glucosamine as both a chondroprotective and pain-relieving agent.

Viscosupplementation of the glenohumeral joint has demonstrated much more variable clinical results. There remains no peer-reviewed, double-blinded, prospective, randomized clinical trial documenting any benefit of such injections when compared to simple corticosteroid injections in the shoulder. Nevertheless, as with any other treatment modality, there may still be a benefit in certain patients who seek to avoid operative treatment for their glenohumeral arthritis. These indications as yet have not been clarified.

Nutritional Supplements

The past 5 years have seen the introduction of many adjuvant nutritional supplements, or "nutraceuticals," for the amelioration of all musculoskeletal complaints including arthritis. Animal work has demonstrated a reduction in the clinical, inflammatory, and histologic components of arthritis with the use of both glucosamine and chondroitin sulfates in combination. The apparent mechanism of glucosamine/chondroitin is to favorably shift cartilage biology toward matrix synthesis instead of degradation.

Human clinical trials with regard to knee arthritis demonstrated little radiographic change, but symptomatic improvement of pain and function has been documented.

However, randomized controlled in vivo human studies are clearly necessary to evaluate the efficacy, long-term effects, and quality of these substances. No peer-reviewed report has documented the efficacy of these substances in patients with isolated glenohumeral arthritis, though patients with concomitant arthritis in other joints have anecdotally reported an overall relief.

OPERATIVE TREATMENT: ARTHROSCOPIC PROCEDURES

Arthroscopic Débridement

Arthroscopic débridement or lavage for arthritis has been successfully used in the weight-bearing joints of the lower limb, particularly the knee.[38,41,70] In many cases, this may be the result of a strong placebo effect.[63] In contrast to the knee, the benefits of, and indications for, arthroscopic débridement in the shoulder are not as clear, although most orthopedic surgeons know of anecdotal evidence suggesting that this can benefit some patients.[74,76] In some cases, arthroscopy will reveal previously unrecognized grade 2 to 4 osteochondral lesions.[37] Cofield reported[18] that in eight patients with glenohumeral arthritis, the use of arthroscopy confirmed or modified the diagnosis, or altered the course of treatment, in all cases. Ellman et al. reported[29] on 18 patients who underwent shoulder arthroscopy for impingement syndrome and, at surgery, were found to have coexisting glenohumeral degenerative joint disease, which was not apparent during preoperative, clinical, and roentgenographic evaluation.

Indications

While extrapolation of ideal indications remains difficult, arthroscopic débridement may be considered for patients with mild to moderate glenohumeral joint disease without structural alteration of the joint.[111] Those patient with mechanical symptoms secondary to loose bodies, or small lesions of the humeral head secondary to avascular necrosis, may also benefit. It is unlikely that any patient with motion loss or progressive joint alteration (such as biconcave glenoid erosion from OA) will benefit from simple joint débridement alone. There are also several reported cases in whom synovial chondromatosis of the shoulder, associated with arthritic changes, has been adequately treated by arthroscopic débridement.[19,81,103]

Surgical Technique

Standard glenohumeral anterior and posterior arthroscopic portals are utilized in either the beach-chair or lateral decubitus positions. While standard diagnostic glenohumeral arthroscopy is performed, special attention must be paid to the humeral and glenoid articular surfaces. Cartilaginous "lesions" or "flaps" should be gently débrided (often the use of a blunt-tip probe is enough) to prevent mechanical engagement. Exposed bony lesions should be identified and possibly considered for procedures such as microfracture or abrasion arthroplasty. The recess behind the subscapularis tendon and the axillary pouch (both anterior and posterior) should be carefully examined for loose bodies. Osteophytes can be removed from the inferior portion of the humeral head.

Postoperative Management

Immediate motion is paramount, and a sling should be used for no longer than 1 night (if used at all). Immediate physical therapy exercises emphasizing motion in external rotation and forward flexion are undertaken. Dietary modification to include glucosamine/chondroitin substances can be discussed.

Results of Arthroscopic Débridement

Generally, results of arthroscopic débridement for OA of the shoulder depend on the extent of degenerative changes.[40,66–68] Ogilvie-Harris and Wiley[75] reviewed 54 patients with OA of the shoulder who were followed for 3 years. When degenerative changes were mild, successful outcome occurred in two-thirds of cases; when changes were severe, successful outcome occurred in only one-third of cases. An additional group of patients who did well were those who had débridements of degenerative labral tears.

In another study, a group of 27 patients, with a primary diagnosis of degenerative joint disease of the glenohumeral joint, underwent arthroscopic débridement.[98] Average follow-up was 30 months (range 9 to 63), and their average age was 42 years (range 27 to 72). These patients presented with moderate to severe pain and had failed conservative treatment. The average time from onset of symptoms to surgical treatment was 24 months (range 3 to 60). Arthroscopic treatment included simple joint lavage, loose body removal, débridement of degenerative cartilage, débridement of labral or soft tissue, and subacromial space bursectomy. Although there were no significant changes in range of motion, a significant improvement in pain relief and function was obtained. Overall, there were 78% satisfactory results (excellent and good) and 22% unsatisfactory (fair and poor). There were no surgical complications. Sixty-seven percent of the patients involved in recreational sports (unspecified) were able to return to their previous activities. Of the unsatisfactory results, some pain relief was obtained in all patients for a minimum of 8 months before deterioration. Additional surgical treatment had been recommended for 11% of the patients. These authors concluded that in patients with mild glenohumeral osteoarthritis, with concentricity maintained, arthroscopic débridement is a useful

procedure. However, a subacromial procedure was included in all of these patients.

In contrast, Norris and Green[73] were less enthusiastic about the usefulness of arthroscopic débridement in the glenohumeral joint. In their series of patients, only a small percentage obtained any long-lasting pain relief. They concluded that arthroscopic débridement did not alter the natural history of glenohumeral arthritis. However, no subacromial procedures were performed in this series.

Capsular Releases

In 1990, Hawkins and Angelo[35] recognized OA in 10 patients (11 shoulders) who had had Putti-Platt capsulorrhaphies for anterior shoulder instability. They hypothesized that this resulted from excessive stress imparted to the cartilage during the abnormal glenohumeral motion caused by the excessively tight anterior capsule imbrication. In seven shoulders the complication was treated successfully with periodic administration of NSAIDs, supplemented by gentle range-of-motion exercises and occasional mild analgesic medications. The remaining four shoulders were treated operatively; two of these received nonconstrained total shoulder replacements. All four of these shoulders received anterior capsular releases for improving motion and decreasing abnormal forces on the glenohumeral joint. Hawkins and Angelo expected that this procedure would improve pain and retard the degenerative process in the two cases where it was done without resurfacing arthroplasty. With this rationale, it has been suggested that in similar cases in whom mild to moderate OA is associated with limited motion, especially external rotation, capsular releases should be considered.

Indications

Any patient with mild to moderate shoulder arthritis and restriction of motion, especially external rotation, relative to the contralateral side should be considered for arthroscopic capsular releases. Those patients with concomitant metabolic abnormalities (such as diabetes or thyroid abnormalities) and glenohumeral arthritis may be particularly responsive to capsular procedures that reduce the pain from the adhesive capsulitis component of their arthritic shoulders.

Surgical Technique

After routine diagnostic glenohumeral arthroscopy as described above, an ablation device is inserted into the anterior cannula and used to release the tight rotator interval capsule from the anterior edge of the supraspinatus to the superior edge of the subscapularis tendon until the fibers of the coracoacromial ligament can be seen. The coracohumeral ligament is released above the biceps tendon. The middle glenohumeral ligament is released from the edge of the labrum, and the anterior capsule is released adjacent to the labrum to expose the fibers of the subscapularis to approximately the 5 o'clock position to increase the amount of external rotation. The inferior capsule is left alone to protect the axillary nerve, as rupture of the inferior capsule will occur with the postarthroscopy manipulation in passive forward flexion. The arthroscope is then switched to the anterior portal for release of the posterior capsule if there is no evidence of posterior subluxation of the humerus on the glenoid (both radiographically and/or arthroscopically) and if there is a lack of internal rotation compared to the contralateral side. An angled incisor blade is then placed into the posterior portal and used to resect approximately 1 cm of posterior capsule adjacent to the labrum. The ablation device is then placed into the posterior portal and the release is completed to the 9 o'clock position. The arthroscopic instruments are then withdrawn, and the glenohumeral joint is passively manipulated into full forward flexion, full external rotation at side, full external rotation in the 90-degree abducted position, and full internal rotation in the 90-degree abducted position.

Postoperative Management

As this procedure is designed to increase motion, patients should be considered for a long-acting interscalene block or catheter (minimum 18 to 24 hours postoperatively) so that continuous passive motion (CPM) can be performed in the hospital. A CPM chair is utilized in the hospital and for 8 hours per day for the first postoperative week. Immediate physical therapy is also instituted, emphasizing external rotation, and no arm sling is used.

Results

Similar to what Hawkins reported, Ogilvie-Harris and Wiley[66] reported that in 54 patients with OA of the shoulder who were treated with arthroscopic débridement, 14 had an associated frozen shoulder. In these cases severely restricted motion was restored either by cutting or removing adhesions, or by manipulation. In general, if there was more than 20 degrees loss of passive motion compared with the opposite shoulder, then an arthroscopic capsular release was performed with symptomatic benefit.

We have reported on the use of capsular releases as a combined procedure for glenohumeral arthritis.[50] Thirty-three consecutive patients with a mean age of 62 years and minimum 2-year follow-up were evaluated. Excellent results were reported in 15 patients (46%) and good results in 10 patients (31%). Overall, 77% achieved a satisfactory outcome (excellent or good result). Five patients (15%) reported fair results and three patients (8%) reported poor results. Three patients required revision to arthroplasty at an average of 28 months (range 12 to 48) after arthroscopy. All three cases initially presented with a biconcave glenoid

as diagnosed by axillary radiographs. The mean patient pain score (0 = no pain; 10 = worst pain) improved from 6.3 preoperatively to 2.8 at final follow-up, with 80% of patients indicating that they would have the surgery again. Average postoperative motion increased for forward elevation by 42 degrees and for external rotation by 32 degrees. Worker's compensation patients obtained inferior subjective results overall; however, improvements in pain and function were found in all patients.

Subacromial Procedures

While a small percentage of patients with glenohumeral OA will have full-thickness tears of the rotator cuff, peer-reviewed reports in the medical literature have documented the efficacy of subacromial injections in providing pain relief for these patients. It does appear that there is a component of pain in the arthritic shoulder that can be ascribed to the subacromial bursa and space, and decompression of the acromiohumeral articulation can be beneficial for glenohumeral pain relief.

Indications

Any patient undergoing arthroscopic débridement of the arthritic shoulder, without a structurally important rotator cuff tear or cuff tear arthropathy, is a candidate for decompression of the subacromial space. Relatively osteopenic patients with inflammatory arthropathies should be judiciously evaluated prior to recommending this as part of the arthroscopic procedure.

Surgical Technique

After glenohumeral arthroscopy, the arthroscope is placed into the subacromial space and an anterolateral working portal (2 to 2.5 cm lateral and distal to the anterolateral corner of the acromion) is established. The ablation device is used to débride the coracoacromial ligament and periosteum off of the anterior acromion. An arthroscopic burr is used to flatten the undersurface of the acromion. We prefer not to resect the anterior acromion, but rather to simply create a flat acromion with an inferior acromioplasty. The arthroscope is transferred to the anterolateral portal and the burr to the posterior portal. The remaining inferomedial spur on the acromion is visualized and resected with the burr. An arthroscopic shaver is then placed into the posterior portal and a complete bursectomy (paying special emphasis to the "posterolateral gutter" between the infraspinatus muscle belly and the subdeltoid shelf) is performed.

Postoperative Management

Patients begin immediate motion as described previously. Special emphasis should be paid to heat and cold modalities in an attempt to reduce the subacromial space postoperative inflammation.

Results

The efficacy of subacromial decompression in providing pain relief in the face of established glenohumeral arthritis has been demonstrated in two recent studies. Simpson and Kelley[99] performed an acromioplasty and bursectomy in 24 patients with rheumatoid arthritis with radiographic evidence of advanced glenohumeral disease. They were able to achieve good pain relief and improved range of motion in 19 of these patients. Ellowitz et al.[31] also evaluated the results of subacromial decompression in a group of 21 patients who were noted to have Outerbridge grade IV osteoarthritic changes in the glenohumeral joint on preliminary arthroscopic evaluation. They reported uniformly good results and concluded that subacromial decompression provided adequate pain relief in this group of patients.

In our combined series, as reported above, all patients underwent a concomitant subacromial decompression with a positive impact on the functional results.

Surgical and "Medical" Synovectomy

Beneficial effects of synovectomy in the treatment of inflammatory arthropathies of some joints are well established.[18,46,100,101,113] The knee has historically been considered one of the most appropriate joints for this procedure, and open synovectomy was the means by which this was accomplished.[46,70,90] An early reported case of synovectomy in the shoulder was in 1965 when Wilkinson and Lowry reported on a series of 69 synovectomies, one of which was in a shoulder and was done without the arthroscope.[112]

In proliferative synovitis of the shoulder, surgical synovectomy gives good pain relief and increased mobility and function.[106,115]

Indications

Open synovectomy of the shoulder is no longer considered absolutely necessary unless carried out in conjunction with débridement of cystic bone lesions,[91] extensive disease,[73] rotator cuff repair,[66] or osteotomy (see later discussion); otherwise, arthroscopic synovectomy is adequate.[13]

Synovectomy done early in the inflammatory disease process will slow its progression; however, the procedure may need to be repeated several times, but it is associated with low morbidity. Although abnormal synovium may regrow after synovectomy for rheumatoid arthritis,[72] patients typically enjoy a relatively pain-free period with improved function.

In the early effusive stages of inflammatory shoulder disease or in OA with synovitis, synovectomy can also be accomplished medically by the use of sclerosing agents or

radiocolloids such as yttrium 90.[59,89] Yet these methods have an overall success rate of only about 50% and, similar to surgical synovectomy, often require multiple treatments. Radiocolloid synovectomy should be considered in patients who are not medically stable for arthroscopic shoulder synovectomy.

Surgical Technique

As described previously, routine glenohumeral arthroscopy is performed. An ablation device is utilized to remove synovitis from the glenohumeral capsule. Special care should be taken to avoid iatrogenic damage to either cartilage or tendon.

Postoperative Management

Management should follow guidelines previously indicated. For patients with aggressive and proliferative synovitis, consultation with a rheumatologist for medical management should be considered.

Results

In an attempt to better evaluate the results of open surgical synovectomy in late stages of rheumatoid disease, Tressel et al.[106] reviewed 75 cases in 53 patients with average follow-up of 6 years. Only 4% of shoulders had early-stage disease. Swelling and motion improved in approximately 70% and pain was diminished in approximately 50%, irrespective of the site and degree of joint destruction (Table 20-1). Overall, 75% of patients were satisfied with their results. The best outcomes were obtained when the shoulder joint alone was involved and the poorest outcome occurred with more extensive soft tissue involvement (e.g., adjacent bursa and rotator cuff).

In a study using yttrium 90 on various joints, Stucki et al.[100] reported poor results in the shoulder and suggested that this may be due to established pathologic involvement of the all-important rotator cuff, which would not be influenced by synovectomy.

TABLE 20-1
RESULTS OF OPEN SYNOVECTOMY IN LATE-STAGE RHEUMATOID DISEASE

Direction of Motion	Stages I and II (*n*=20)	Stage III (*n*=44)	Stage IV (*n*=11)
Flexion beyond 90°	85%	66%	45%
Abduction beyond 90°	70%	52%	66%
Internal rotation beyond 20°	75%	66%	80%

Authors' Preference for Arthroscopic Management

After failure of nonoperative measures, we prefer to attempt an arthroscopic management of glenohumeral arthritis if patients meet the following criteria:

1. Preservation of joint space on axillary lateral radiograph
2. No or minimal biconcave posterior erosion of the glenoid
3. Preservation of acromiohumeral distance greater than 6 mm
4. External rotation beyond the neutral (0-degree) position

Patients with inflammatory arthritis who have proliferative synovitis are also considered for arthroscopic management.

We prefer to perform four procedures with any arthroscopic débridement for glenohumeral arthritis:

1. Intraarticular débridement and/or synovectomy as necessary
2. Capsular releases
3. Subacromial decompression
4. Distal clavicle resection

The addition of the distal clavicle resection (5 mm in females and 7 mm in males) has been demonstrated by the senior author (WZB) to decompress the motion interface between the scapulothoracic articulations and the glenohumeral articulations, and may improve not only pain relief but also overhead motion in these arthritic patients through compensatory scapulothoracic motion.

OPERATIVE TREATMENT: OPEN SURGICAL PROCEDURES

Periarticular Osteotomy

Indications

Although uncommonly performed in the United States, periarticular osteotomy is a well-established treatment for symptomatic degenerative joint disease associated with biomechanically abnormal articulations.[114] In addition to abnormal transarticular force transmission, subchondral venous hypertension may be one of the causal factors in the symptoms associated with OA in these patients.[10] This hypothesis resulted in the development of osteotomies for decreasing venous pressure in joints afflicted with OA. Other suggested benefits of such osteotomies may be the enhancement of local perfusion that, presumably, accompanies healing of the osteotomy.

In general, periarticular osteotomy is not commonly performed and has not been reported by other surgeons in peer-reviewed publications. This is probably because endoprosthetic replacement provides more consistent pain relief and improvement in motion, and has a low reoperation rate.[18]

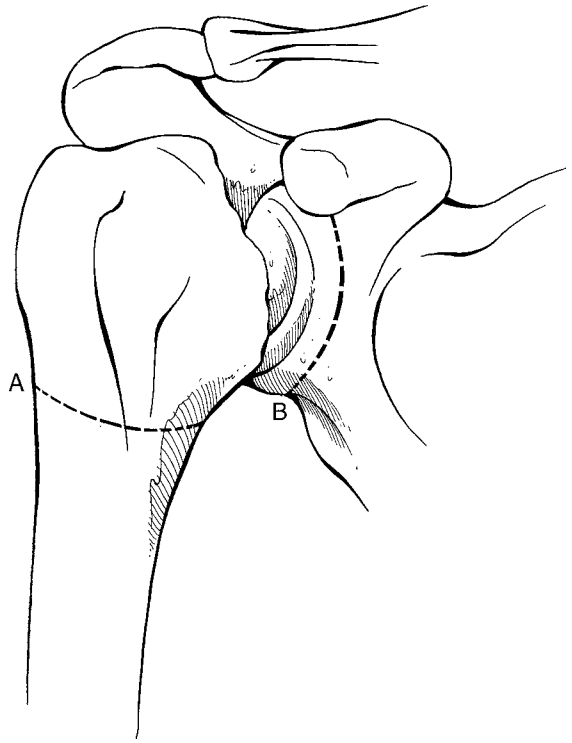

Figure 20-1 Schematic representation of the Benjamin double osteotomy. **(A)** Humeral osteotomy. **(B)** Glenoid osteotomy. (Reproduced with permission from Jaffe R, Learmonth ID. Benjamin double osteotomy for arthritis of the glenohumeral joint. In: Lettin AFW, Petersson C, eds. *Rheumatoid arthritis surgery of the shoulder. Rheumatology.* Basel: Karger, 1989;12:52–59.)

Surgical Technique

On the basis of these principles and noted benefit in arthritic knees, Benjamin et al. described a double osteotomy for the arthritic shoulder.[6] An anterior approach is used, and the subscapularis is incised medial to its insertion, exposing the neck of the glenoid. The glenoid is osteotomized 5 to 10 mm medial to the articular surface. The posterior cortex is not cut, but it is manually cracked so that the posterior periosteum maintains position and stability. Transverse osteotomy of the humeral neck is then performed just distal to the capsule; again the posterior cortex is cracked to preserve the posterior periosteal hinge (Fig. 20-1). The osteotomies are not fixed.

Postoperative Management

Passive shoulder motion is begun with 1 week, and activity is gently progressed.

Results

In Benjamin's series of 16 patients, the procedure was performed for OA in four cases, adult RA in 10 cases, and adult or juvenile RA in two cases.[7] Average patient age was 51 years; average time to evaluation was 2 years and 11 months. All of these patients reported substantial pain relief and had an average of 50 degrees' increase (range 10 to 150 degrees) in active abduction. The increased motion was from both scapulothoracic and glenohumeral joints.

When using this double osteotomy for arthritic shoulders, Jaffe and Learmonth[42] reported similar improvement in pain and active motion in 32 shoulders of 28 patients followed up for 8 to 72 months (mean 35 months). Twenty-seven patients had rheumatoid arthritis, four had degenerative arthritis, and one had avascular necrosis.

Tillmann and Braatz, however, achieved less improvement in their series of 24 surgeries carried out entirely for RA.[103,105] This discrepancy may be the consequence of the mixed diagnoses or the lower mean age (about 9 years) of patients in the study of Jaffe and Learmonth.[42]

With this procedure, long-term maintenance of pain relief and motion has been less than ideal.[61,94] Most authors suggest that this procedure should be reserved for relatively young patients with severe RA, and for patients with limited functional goals, poor rehabilitative capacity, or poor compliance. In contrast, interpositional arthroplasty (see later discussion) is recommended for patients with good bone stock, an intact rotator cuff, and an ability to comply with the postoperative regimen.[94]

Corrective Osteotomy for Dysplasias and Acquired Deformities

Humeral osteotomy has been described for correcting rotational deficits and abnormal shoulder biomechanics associated with malunited fractures and glenohumeral instability. In theory, this procedure abates the early development of degenerative joint disease in these conditions. External derotation osteotomy of the humerus is also effective in relieving pain in selective cases of shoulder rheumatoid arthritis associated with internal rotation contractures.[1]

It has been suggested that posterior glenohumeral instability may, occasionally, result from increased retroversion of the glenoid.[9,26,36] However, there is no documented evidence clearly showing that this leads to the development of degenerative disease of the glenohumeral joint. Radiographic projection-effect error may also errantly demonstrate significant (more than 7 degrees) glenoid retroversion. In some symptomatic individuals with significant retroversion or fixed subluxation and early eccentric glenohumeral arthritis, osteotomy of the scapular neck may be an effective treatment by correcting the abnormal biomechanics of the joint (Fig. 20-2).[37] Complications of these osteotomies include infection, nonunion, and arthritis secondary to glenoid penetration by metal hardware.

Destructive osteoarthritic changes in the glenohumeral joint have rarely been described in patients who have glenoid hypoplasia.[75,77] Although glenoid hypoplasia is very uncommon, progressive degenerative joint disease, which can be quite symptomatic, develops in a small percentage of

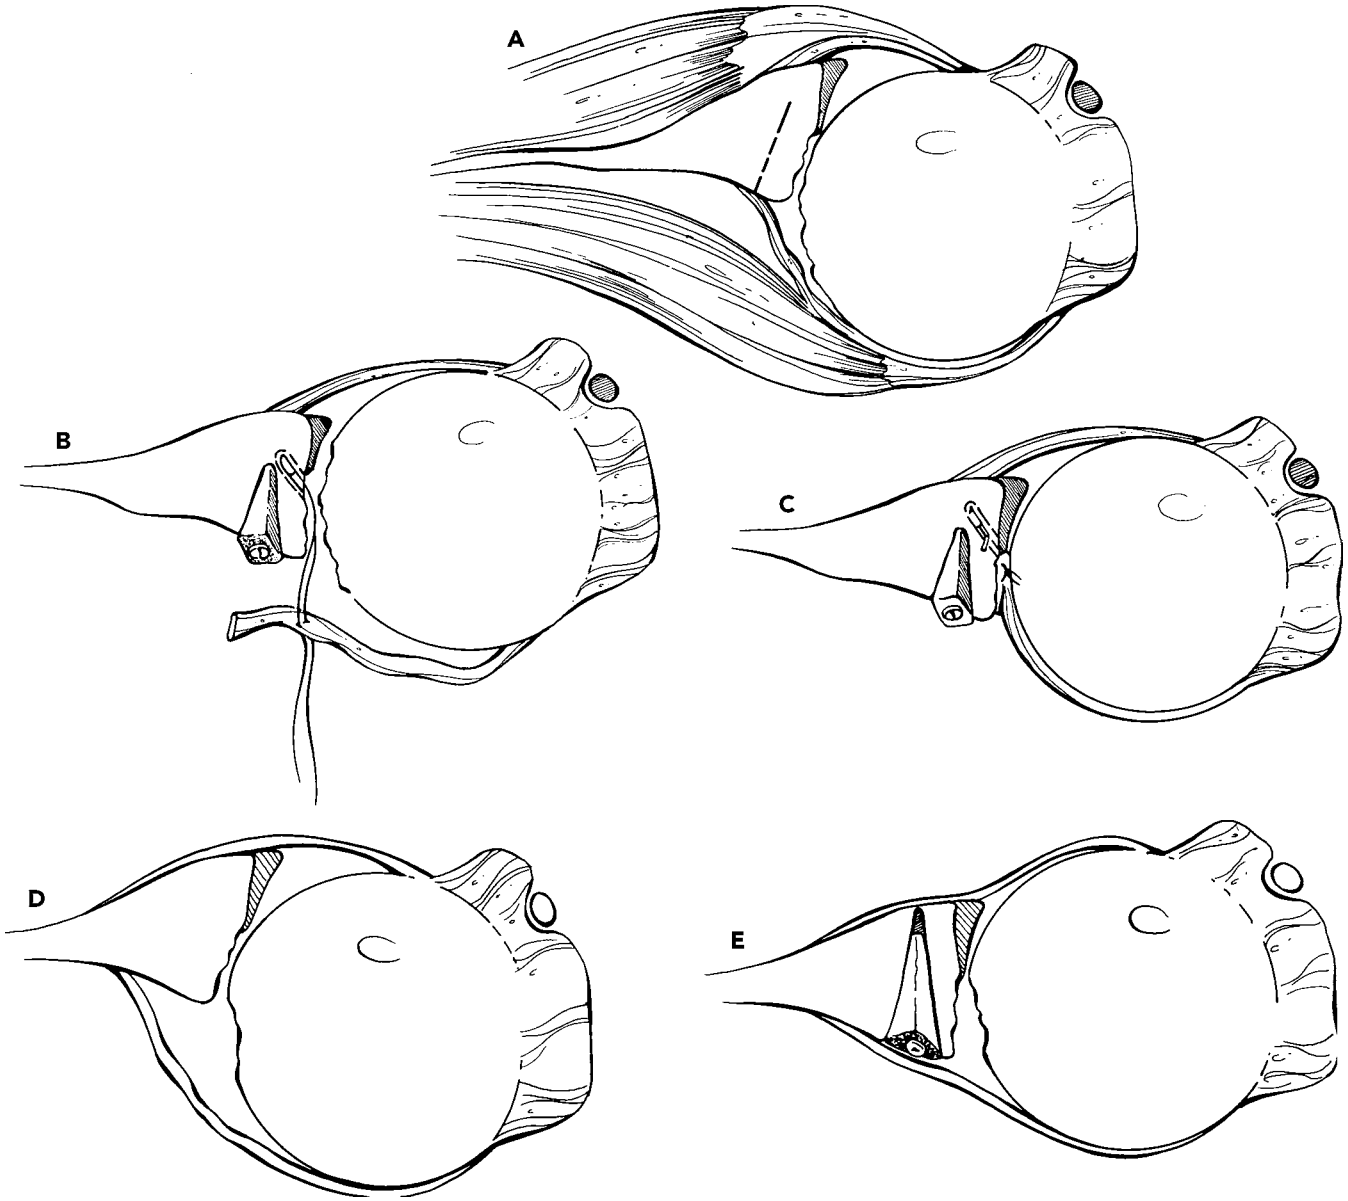

Figure 20-2 Interposition arthroplasty with wedge osteotomy for eccentric glenohumeral wear. **(A)** Posterior subluxation: The *dotted line* demonstrates depth and direction of osteotomy. **(B)** Proper position of iliac crest wedge graft and placement of suture anchor in glenoid. **(C)** Final construct with interposed posterior capsule in area of eccentric wear. **(D)** Symmetrical posterior eccentric wear with posterior subluxation of the humeral head and "relative" redundancy of the posterior capsule. **(E)** The osteotomy is carried out to the anterior cortex, and the anterior periostomy capsule sleeve is kept intact to improve stability of the glenoid fossa. The wedge is opened and bone is grafted with an opening posterior wedge. The capsule is tightened and the head is recentered. (From Hertling D. Autobilization techniques of the extremity. In: Kessler RM, Hertling D, eds. *Management of common musculoskeletal disorders.* Philadelphia: Harper & Row, 1983:178–191, with permission.)

patients.[102] Nearly all patients can be managed with a specific rehabilitation program for the shoulder.[102]

Resection Arthroplasty

The reluctance of most surgeons to undertake shoulder arthroplasty for glenohumeral arthritis in younger high-demand patients resulted in the development of techniques for resecting, débriding, or reshaping the articular surfaces of the glenohumeral joint. Resection of the humeral head has been advocated in the past as a treatment for severe fracture or sepsis, but only occasionally for degenerative or inflammatory arthropathies.[18] After humeral head resection, chondroid tissue forms between the remaining humeral head and the glenoid. The pseudarthrosis formed is important in achieving a good functional result.

Rather than resecting the humeral head, some authors have reduced its diameter.[92] If stability is a concern, then adjustments in the version of the newly fashioned head can also be made. For example, in situations of rotator cuff deficiency, increasing retroversion by some 10 degrees can reduce the chance of dislocation. However, the results of this procedure have not been reported in peer-reviewed publications by these or other surgeons.

Glenoidectomy has also been advocated for treatment of the painful arthritic shoulder.[31,97,108] Gariepy described resecting 7 to 8 mm of the glenoid surface, leaving a new flat surface.[34] More recently, this has been carried out, albeit with more limited bone resection, in conjunction with a humeral hemiarthroplasty and biologic interpositional arthroplasty over the glenoid fossa (Fig. 20-3).[11] Glenoidectomy is probably performed relatively infrequently because of both the limited indications for its use and the greater predictability of prosthetic replacement.

Interposition Arthroplasty and Biologic Glenoid Resurfacing

The use of biologic tissue to form an interpositional arthroplasty has been successful in treating some patients with arthritic joints. In the shoulder this technique was first described in 1918 by Baer, who used a pig's bladder.[4] Tillmann and associates[103,104] described an interpositional arthroplasty using lyophilized dura mater to cover the surfaces of the glenohumeral articulation (Fig. 20-4).

Biologic glenoid resurfacing was developed in 1988 as an alternative to total shoulder arthroplasty in selected younger patients with primary, posttraumatic, or postreconstruction glenohumeral arthritis as a method to improve the results of humeral head replacement. A variety of biologic surfaces have been combined with an uncemented hemiarthroplasty including anterior capsule, autogenous fascia lata, tendo Achilles allograft, and recently human dermal collagen allografts as well as meniscal allografts.

Indications for Interposition Arthroplasty

The main indication for modern techniques of shoulder interpositional arthroplasty is in the rheumatoid patient who has late-stage disease and a well-preserved rotator cuff, and who is capable of complying with postoperative rehabilitation. Contraindications include the presence of large cysts in the humeral head or major defects in the rotator cuff.

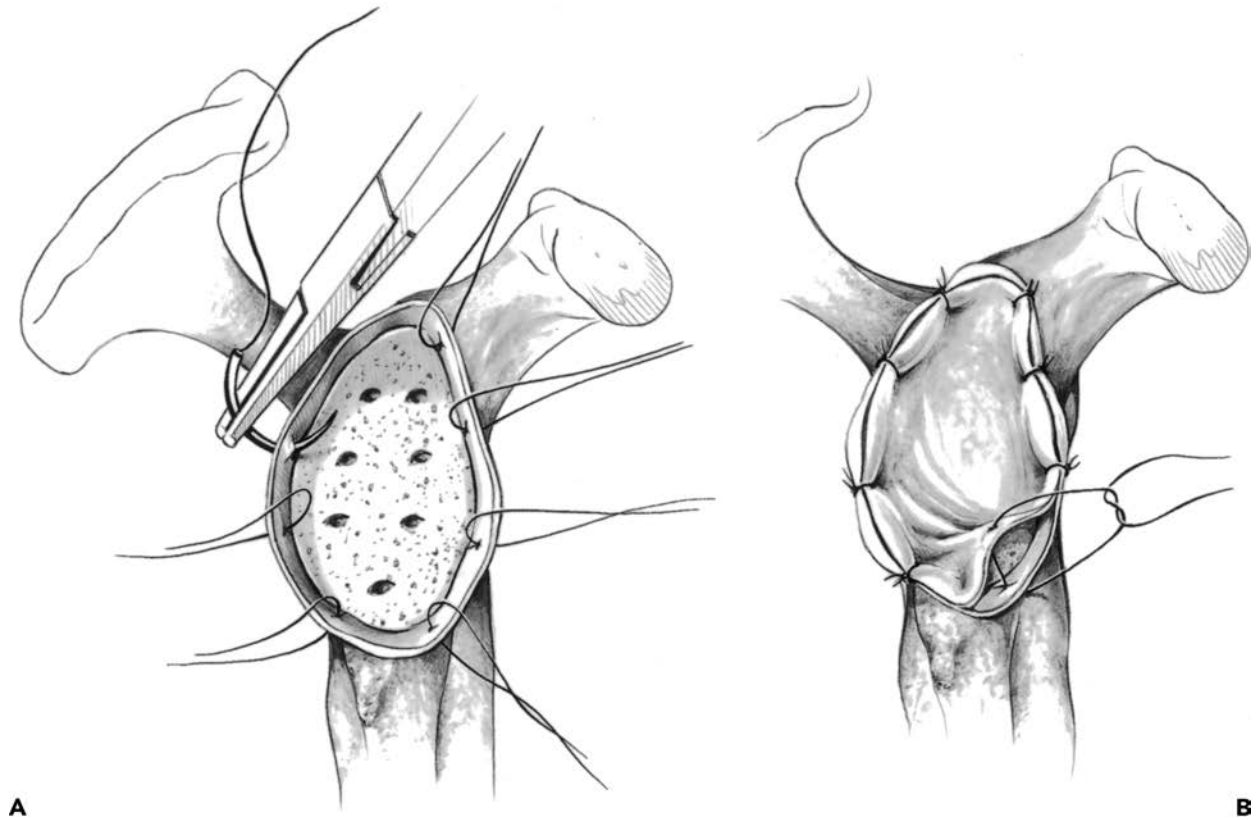

Figure 20-3 **(A)** Preparation of the glenoid, showing marginal suture placement and central drill holes to enhance incorporation of the graft. **(B)** Final glenoid construct demonstrating graft material sutured to the glenoid surface. A suture anchor placed in the central glenoid helps to firmly appose the graft. (From Buchbinder R, Green S, Youd JM. Corticosteroid injections for shoulder pain. *Cochrane Database Syst Rev* 2003;1:CD004016, with permission.)

Indications for Biologic Glenoid Resurfacing

Biologic glenoid resurfacing is indicated in the following patients: young, active patients who may loosen a standard glenoid implant; rheumatoid arthritic patients with irreparable cuffs and/or poor glenoid bone stock; patients with either rotator cuff tear arthropathy or irreparable cuffs and eccentric glenoid wear; and revision arthroplasties with glenoid removal and poor glenoid bone stock.

Graft Choices

Anterior capsule or autogenous fascia lata have been used extensively in the early reports documenting the nonprosthetic biologic resurfacing of the glenohumeral joint. Unpredictable outcomes and concerns regarding the durability of those tissues have led to a predominance of allograft usage for either interposition arthroplasty or biologic resurfacing.

Tendo Achilles allograft remains the more durable, lower cost, and readily available graft choice. The collagen makeup of the Achilles tendon lends itself very well to beneficial wear characteristics on the glenoid surface. Our recent work has demonstrated the significant intermediate-term and longer-term wear characteristics of the tendo Achilles allograft in resisting glenoid erosion and maintaining glenohumeral joint space.

Human dermal collagen allografts have recently been utilized. While these grafts incur a larger expense, the potential gain is a durable surface much like the tendo Achilles graft that is easier both to handle and work with in the surgical setting. The reduced "bulk" of this type of graft

choice, when compared with the tendo Achilles allograft, may promote a more anatomic restoration of glenohumeral anatomy. Nevertheless, the durability of this graft over time is still unknown.

Similarly, recent reports have documented success with the use of a human meniscal allograft as a bearing glenoid surface. The attractive nature of this graft is the noted durability of its natural capacity in the human knee. Unfortunately, this graft choice is more expensive and less readily available, and peer-reviewed reports still document only short-term outcomes with regard to progressive glenoid erosion.

Surgical Technique for Interposition Arthroplasty

Tillman and associates describe a transacromial approach to expose the glenohumeral joint. The anterior two-thirds of the rotator cuff, including the cranial half of the infraspinatus insertion, are dissected off the bone. After a complete synovectomy, the humeral head is reshaped to a smaller radius of curvature that facilitates reconstruction of the usually deficient rotator cuff; retroversion is also increased by 10 degrees to reduce the chance of dislocation. Lyophilized dura mater is then sutured around the circumference of the reshaped head. The rotator cuff is then reattached under appropriate tension.

Milbrink and Wigren[69] have described a modification of the procedure of Tillman in which the glenoid and humeral head of rheumatoid shoulders are covered with a biologic membrane. If necessary, the surface of the glenoid may be smoothed. A sheet of lyophilized dura mater is folded and sutured at the fold to the posterior wall of the glenohumeral joint capsule. The remaining portions of the graft are then sutured, one to the rim of the glenoid and the other over the humeral head.

Surgical Technique for Biologic Glenoid Resurfacing (Authors' Preferred Technique Using Tendo Achilles Allograft Combined with Prosthetic Humeral Hemiarthroplasty)

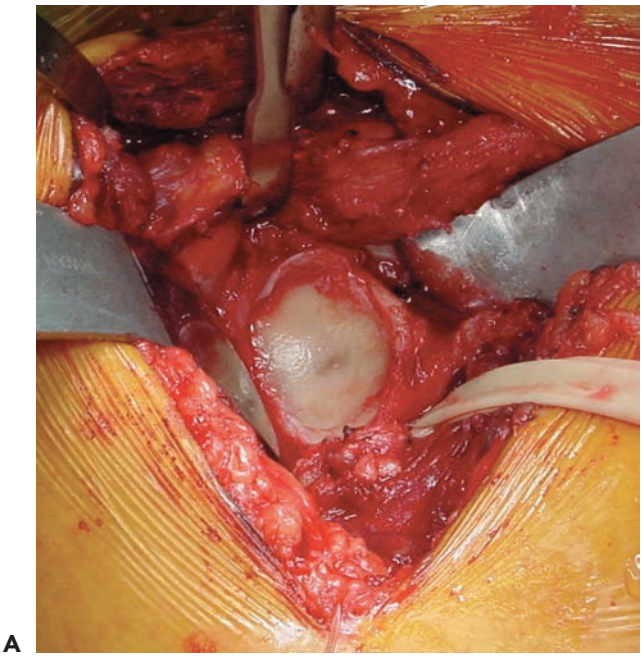
We prefer to expose the glenohumeral joint through a modified 2.5- to 3-in deltopectoral approach, although an anterosuperior transacromial approach may be used. The deltopectoral interval is identified and the cephalic vein is retracted medially with the pectoralis major. We do not "nick" the pectoralis major tendon. The clavipectoral fascia is opened just lateral to the conjoined tendon musculature, and the axillary nerve is identified and protected throughout the entirety of the procedure. The tendon of the long head of the biceps (if still present) is released at the supraglenoid tubercle systematically and will be tenodesed at the end of the procedure.

Once the subscapularis is exposed on its three borders, the anterior humeral circumflex vessels ("three sisters") are ligated. The subscapularis is examined for both integrity and quality and then is released from the lesser tuberosity with a small "flake" of bone. This bone flake aids in reattachment at the end of the procedure with transosseous sutures and also provides a postoperative radiographic marker for indicating whether the subscapularis has healed or has torn. At this point, the anterior and inferior capsular tissue is divided while protecting the axillary nerve. This step is critically important for adequate glenoid exposure.

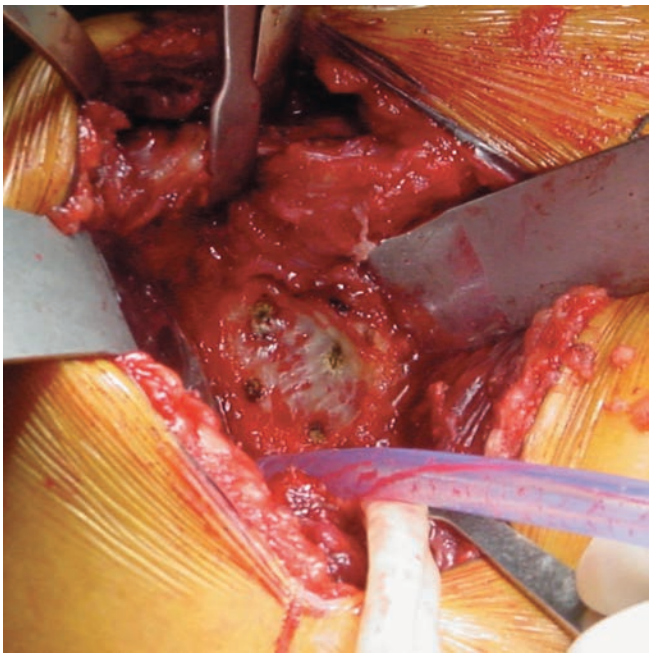
The glenoid is exposed with retractors on its posterior, anterior, and superior rims, and the axillary nerve is protected inferiorly (Fig. 20-5A). Once the glenoid is exposed, we use a standard glenoid reamer to remove the cartilaginous surface and also to "contour" the glenoid to a bleeding subchondral bony surface (Fig. 20-5B). We also attempt to "normalize" the version of the glenoid perpendicular to the scapular spine. This can also be done in a "free hand" technique using a small (3- or 4-mm) hand bur. If the glenoid has previously been replaced and this is a revision operation, the previous component is removed and the glenoid vault is packed with cancellous chips and then reamed or burred to create a relatively smooth bleeding surface. At this point, four bioabsorbable anchors (Mitek Panalok 3.5 Anchors, Mitek USA, a Johnson and Johnson Company, Norwood, MA) with #2 Ethibond suture (Ethicon USA, a Johnson and Johnson Company, Boston, MA) are placed. Four anchors are placed at the "cruciate corners" of the glenoid—the positions on the glenoid that correspond to the positions on a clock face of 12, 3, 6, and 9 o'clock. If desired, a fifth anchor is used in the direct center of the glenoid face. If the glenoid center is deficient (such as after removal of a loose glenoid component), the central anchor is not used. These anchors provide the "anchor" fixation of the biologic resurfacing (Fig. 20-5C).

The tendo Achilles allograft is prepared by removing the calcaneal bone first in a subperiosteal manner with a scalpel (Fig. 20-6). The graft is then folded on itself two or three times ("doubled" or "tripled," depending on the thickness of the Achilles tendon) to form a cushion. We size the superior–inferior dimension of the graft to the native glenoid, and this is easily performed by using a prosthetic glenoid trial as a "sizer." The graft is then "whipstitched" in a mattress fashion with a heavy nonabsorbable suture around the entire periphery of the folded portion (Fig. 20-7)—this performs three important functions:

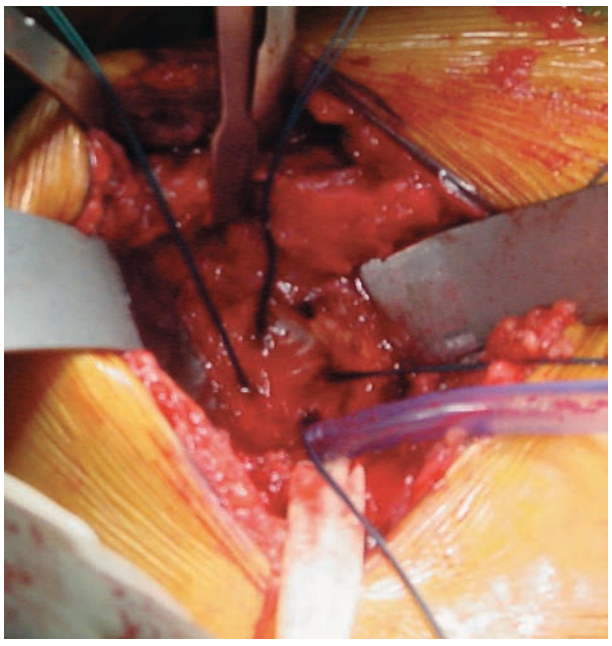
1. It maintains the graft in a folded position.
2. The mattress peripheral whipstitch "rolls" the edges of the graft into a bumper (similar to a Bankart labral repair that restores the labral bumper).
3. It allows for a central "softer" portion of the folded graft, so that the graft becomes concave in the center and convex on the periphery.



A



B



C

Figure 20-5 Biologic resurfacing of the glenoid: **(A)** exposure of the glenoid surface; **(B)** glenoid surface prepared to bleeding bone; **(C)** suture anchors placed for graft fixation.

Using the sutures from the suture anchors in a horizontal mattress fashion, all sutures are brought directly through the graft and the graft is reduced to the bleeding glenoid surface (Fig. 20-8). The sutures from the suture anchors are now tied, producing four points of fixation for the graft to the glenoid. The periphery of the graft is then sutured directly to the glenoid rim using a minimum of four transosseous Bankart type sutures of #2 Ethibond (Ethicon USA, a Johnson and Johnson company, Boston, MA) (Fig. 20-9). (Note that this operative technique is combined with standard humeral hemiarthroplasty using a prosthetic component.)

Postoperative Management

A simple Velpeau sling or shoulder immobilizer is worn for 4 weeks postoperatively. Passive range-of-motion exercises are begun immediately, with the parameters of full anterior elevation and restriction of external rotation based on final postoperative external rotation after subscapularis repair. No active motion is allowed until the sling is removed.

Once the sling is removed, active-motion exercises are begun, allowing for a full range of glenohumeral motion. Resistance exercises are begun at 10 weeks after surgery.

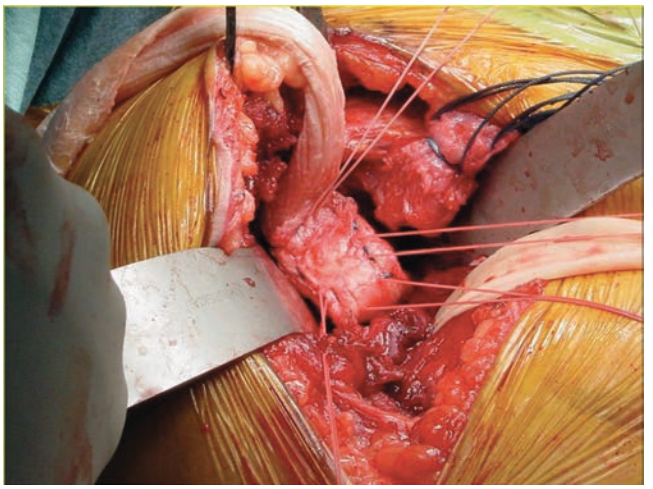

Figure 20-8 Sutures from suture anchors passed through graft prior to final "inset" of the graft.

Results of Interposition Arthroplasty

In Tillman's series,[104] a 4- to 10-year follow-up in 29 patients showed good pain relief and approximately 80-degree increased range of movement in combined flexion and abduction. During the course of follow-up there was no deterioration in either pain relief or range of motion.

Miehlke and Thabe[68] evaluated the results of interpositional arthroplasty performed on 32 shoulders and evaluated at an average of a 20-month follow-up. The diagnosis was rheumatoid arthritis in 29 of the 32 cases. Twenty-seven shoulders had mild or no pain, three had moderate pain, and two had severe pain. Range of motion improved in all cases. In 23 of the 32 cases, a rotator cuff tear was present and subsequently repaired. Complications included three cases of dislocation of the lateral part of the acromion. (The acromion was osteotomized in the surgical approach.) One case was revised, and the other remained asymptomatic and was not treated. The third case had an associated rotator cuff tear in addition to acromial dislocation; ultimately, arthrodesis was performed for biomechanical instability resulting from severe muscular deficit.

In Milbrink and Wigren's series,[69] results reported in 10 patients with late-stage shoulder RA at 6 months to 1 year of follow-up showed very good pain relief and improvement in range of motion. There was also significant improvement in strength by the end of the first postoperative year. However,

Figure 20-7 Prepared tendo Achilles allograft. Graft is "whip-stitched" around its periphery to form the size of the native glenoid.

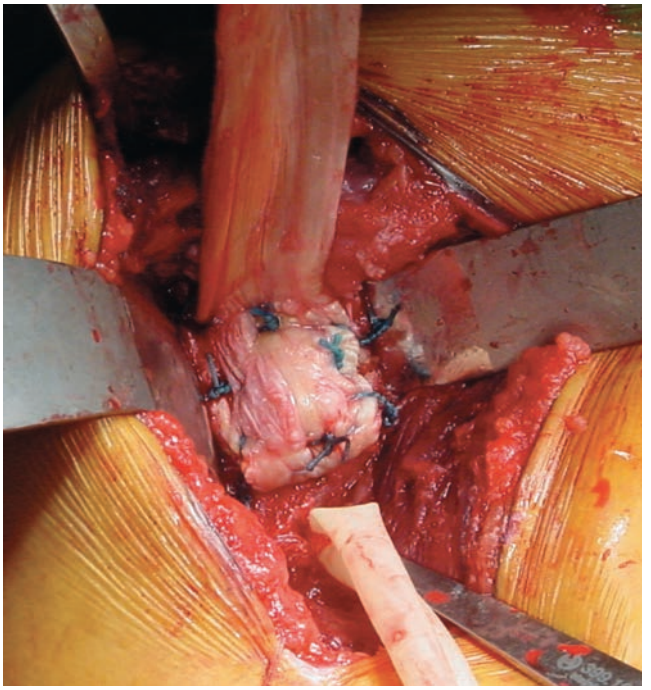

Figure 20-9 Final biologic resurfacing of the glenoid. Graft is secured by mattress sutures from the suture anchors and simple peripheral transosseous sutures.

it is important to emphasize that the follow-up in this study averaged only approximately 6 months.

Results of Biologic Glenoid Resurfacing

In our series, from November 1988 to November 2001, 24 patients (26 shoulders) were followed prospectively. There were 22 males and two females, with an average age of 52 years (range 30 to 75). Fourteen of 26 shoulders had undergone previous surgery. The diagnosis was primary glenohumeral osteoarthritis (9 of 26), posttraumatic arthritis (4 of 26), avascular necrosis (1 of 26), and postreconstructive arthritis (12 of 26). Anterior capsule was used for seven cases, autogenous fascia lata for 12 cases, and tendo Achilles allograft for eight cases. Five- to 13-year results demonstrated 12 of 26 excellent (46%), 9 of 26 satisfactory (35%), and 5 of 26 unsatisfactory results (19%). Glenoid erosion averaged 7.2 mm, stabilizing at approximately 5 years. Joint space averaged 1.3 mm. There were no revisions for humeral loosening. Complications included infection (2 of 26), instability (3 of 26), brachial plexitis (1 of 26), and deep vein thrombosis (1 of 26). Factors associated with unsatisfactory results were use of anterior capsule, infection, and early reinjury. Three of five poor results were revised to total shoulders with conventional polyethylene glenoid implants (two with excellent results and one with poor results). Based on this midterm review, we recommend the use of tendo Achilles allograft as the bearing surface and do not use either anterior capsule or autogenous fascia lata. Other bearing surfaces (human dermal collagen allograft and meniscal allograft) are currently under review.

Arthrodesis

Although advances in the development of shoulder prosthetic arthroplasty have greatly reduced the indications and frequency of shoulder arthrodesis as a primary procedure, arthrodesis remains an excellent salvage procedure in a small percentage of patients with glenohumeral arthritis.[5,78,80,82] Indications for glenohumeral arthrodesis include recurrent or indolent infection, severe soft tissue deficiency including massive rotator cuff tear and coracoacromial deficiencies, poor function of the deltoid, brachial plexus palsy, or persistent symptomatic instability. It is also a viable option in patients operated on multiple times. Patients with both neurogenic pain (e.g., owing to brachial plexus injury) and glenohumeral pain (caused by arthritis) will not have relief of neurogenic pain with a shoulder arthrodesis. However, if function is improved, then the neurogenic pain is generally better tolerated by the patient.[79,80]

In times past, shoulder arthrodesis, coupled with spica immobilization, did not predictably produce solid fusion and was not tolerated well by individuals at risk for surgical complications.[2,15,17,18] However, with the use of internal fixation, autogenic and allogenic bone graft material, and aggressive medical management, glenohumeral fusion is more predictable in these patients.[2] The procedure is contraindicated for patients who cannot cooperate with the program of rehabilitation.[80] Sufficient motion of the scapulothoracic muscles and strength of the trapezius and serratus anterior muscles are important for good function of the arthrodesed shoulder.[58,79]

In a review of a series of 71 shoulder arthrodeses performed for a variety of conditions, Cofield and Briggs[17] reported a pseudarthrosis rate of 4%. Other potential complications include reflex sympathetic dystrophy, acromioclavicular joint arthritis, infection, and failure of the internal fixation. In a review of a series of 41 arthrodeses carried out solely for rheumatoid arthritis, Rybka et al.[92] reported that 90% of shoulders had solid bony fusion at an average of 6 years of follow-up (range 6 months to 20 years). The remaining shoulders had not yet achieved fusion or had fibrous ankylosis. The range of scapulothoracic movement improved by an average of 60% (includes active abduction plus sagittal flexion). Results were rated as excellent or good in 68%, and fair in the remaining 32%.

Current techniques for shoulder arthrodesis are described elsewhere in this textbook.

SUMMARY 693

OPTIONS

The advent of total shoulder arthroplasty and the refinement of other reconstructive procedures have narrowed the indications for glenohumeral arthrodesis.[39] Nevertheless, arthrodesis of the glenohumeral joint continues to provide a valuable method of shoulder reconstruction for specific indications.[15,22,61] Although the procedure is infrequently performed, it reliably provides patients with a stable, strong shoulder. Albert first attempted glenohumeral arthrodesis in 1881. Since then a voluminous literature has evolved outlining different indications for the procedure and a variety of surgical techniques for performing glenohumeral arthrodesis. Controversies have developed in the literature about the indications for the procedure and the optimum position for glenohumeral arthrodesis.[1,52] More recently, discussion has arisen of the functional results that can be achieved with the procedure.[11] In this chapter I will address the complex and revision problems and then discuss the complications and the results of glenohumeral arthrodesis.

Arthrodesis is an important method of shoulder reconstruction. The procedure has stood the test of time and continues to deserve a place in the shoulder surgeon's armamentarium. For certain specific indications it provides the best method of restoring function to the shoulder.

INDICATIONS

Glenohumeral arthrodesis can effectively restore shoulder function to highly selected patients. Successful glenohumeral arthrodesis reliably results in a strong and stable

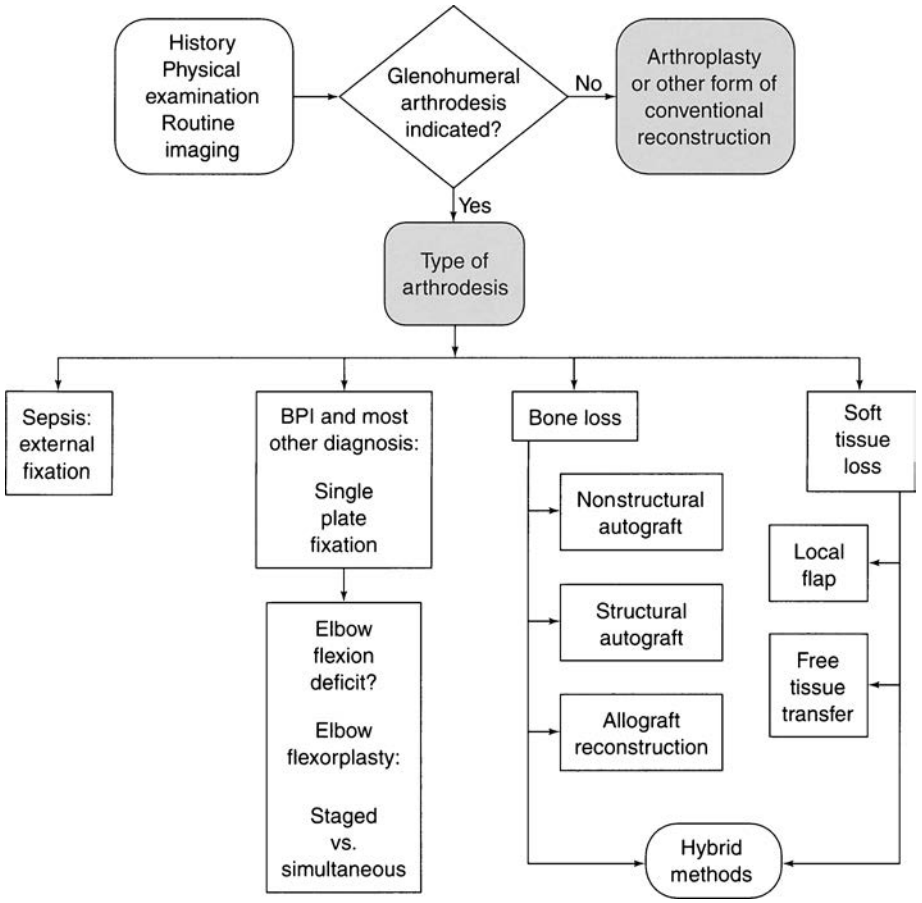

Figure 21-1 Algorithm for evaluation and management of patients presenting to be considered for glenohumeral arthrodesis. BPI, brachial plexus injury.

shoulder. However, the procedure sacrifices all rotation through the glenohumeral joint. Wherever possible, shoulder arthroplasty is preferable to glenohumeral arthrodesis, if for the particular patient there is a choice between the two procedures (Fig. 21-1). Shoulders can be fused if an arthroplasty fails, although fusion in this situation is a technical challenge. The indications for surgery in the author's personal series are illustrated in Fig. 21-2.

Paralysis

All authors agree that the presence of a flail shoulder is an indication for glenohumeral arthrodesis. Patients with anterior poliomyelitis, severe proximal root, and irreparable upper trunk brachial plexus lesions and some patients with isolated axillary nerve paralysis are candidates for glenohumeral arthrodesis.[49,51] These patients have good function in their elbows and hands, but are unable to optimize their upper extremity function because of their inability to place their hand in space. If such a patient has good function in the periscapular musculature, particularly the trapezius, levator scapula, and serratus anterior, glenohumeral arthrodesis stabilizes the extremity and allows effective hand function.[46] Such patients can then fully utilize their upper extremity potential and can work effectively at bench level. In addition, many patients with flail shoulders develop inferior subluxation of the glenohumeral joint owing to periarticular paralysis (Fig. 21-3). This condition is uncomfortable and, in some patients, frankly painful. Such patients often find that they must keep their arm in a sling to avoid injuring it. Painful inferior subluxation of the shoulder provides another indication for stabilization of the glenohumeral joint.

Patients who have the combination of a flail shoulder and flail elbow need both shoulder and elbow reconstruction. In this situation, glenohumeral arthrodesis combined with elbow flexorplasty improves the result of the elbow flexorplasty. Without shoulder stabilization elbow flexion tends to drive the humerus posteriorly, resulting in shoulder extension, rather than elbow flexion. Arthrodesis of the shoulder in some flexion and abduction helps prevent this phenomenon and optimizes the result that can be achieved with the elbow flexorplasty. Patients with flail shoulders often have a tendency to internally rotate their upper extremity to their chest when some function remains in the powerful internal rotators of the shoulder (pectoralis major, latissimus dorsi) and no function remains in the external rotators. Shoulder stabilization either in the form of arthrodesis or L'Episcopo tendon transfer reduces this undesirable tendency.[46]

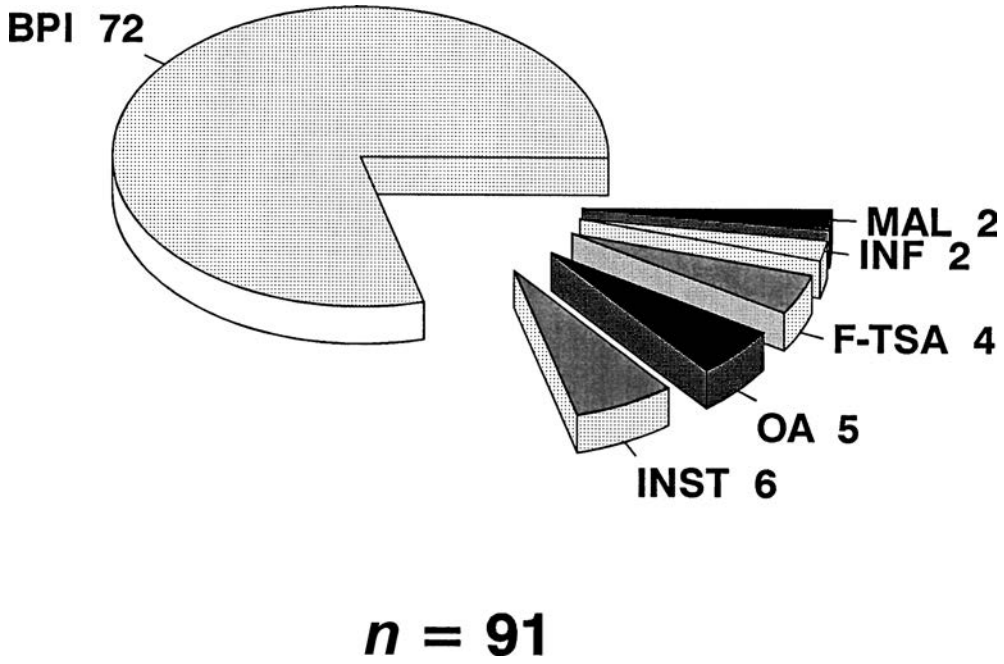

Figure 21-2 Indications for glenohumeral arthrodesis in the author's personal series. BPI, brachial plexus injury; F-TSA, failed total shoulder arthroplasty; INF, infection; INST, instability; MAL, malunion; OA, osteoarthritis.

There is a wide degree of variability in the disability caused by axillary nerve paralysis, and I have seen many patients who have virtually full motion following paralysis of the axillary nerve, providing the rotator cuff musculature is undisturbed (endurance is never normal). Patients with isolated paralysis of the axillary nerve can be treated by either muscle or tendon transfer or glenohumeral arthrodesis. Numerous reports exist in the literature on the value of muscle and muscle tendon transfer to restore shoulder function following paralysis of the axillary nerve.[20] It is generally agreed that multiple transfers are necessary to restore deltoid function and that significant problems can occur with gliding of transfers over the acromion. It is often necessary to harvest autogenous tissue, such as fascia lata, to prolong the transfers, and the process of rehabilitation is challenging following such procedures. In my experience such transfers are indicated primarily for pediatric patients and adult patients who have only partial paralysis of the axillary nerve.[20] However, pediatric patients do well with glenohumeral arthrodesis, and some authors feel they are better able to adapt to the procedure.[31] If total paralysis of the axillary nerve is present and significant limitation of shoulder function ensues, I would recommend glenohumeral arthrodesis, recognizing that the alternative of muscle transfers may be available in carefully selected patients. Glenohumeral arthrodesis is useful in such patients, provided their symptoms justify the procedure.

Figure 21-3 Severe inferior subluxation of the glenohumeral joint in a patient with brachial plexus palsy. The patient is severely disabled, in spite of good hand and wrist function, because he is unable to position the hand in space.

Reconstruction Following Tumor Resection

En bloc resection of periarticular malignant tumors often requires sacrifice of the rotator cuff or the deltoid, or both. If the resection requires sacrifice of these tissues, reconstruction of the shoulder with an arthroplasty is inadvisable owing to the high risk of instability if an unconstrained prosthesis is used and to the certainty of loosening if a constrained prosthesis is used. Glenohumeral arthrodesis is

the procedure of choice to reconstruct the shoulder following wide resection of periarticular malignancies. Specific techniques have been recommended for glenohumeral arthrodesis following tumor resection.[30] These include the use of specialized fixation devices and bone-grafting techniques. Vascularized bone grafts and massive allografts are sometimes necessary because of the large defects created by tumor resection.[28] These techniques will be discussed later.

Shoulder Joint Destruction by Infection

Destruction of the shoulder joint by septic arthritis remains an indication for glenohumeral arthrodesis. In the past, tuberculous arthritis was a common indication for glenohumeral arthrodesis. Worldwide, this condition remains prevalent, although in the Western world it has become extremely uncommon. Septic arthritis continues to occur, and when it does, the shoulder joint can be destroyed with resultant pain and limitation of function. Most surgeons would agree that in a young patient with shoulder dysfunction, for this reason, arthrodesis of the shoulder, as opposed to total shoulder arthroplasty, would be indicated. Although total shoulder arthroplasty can be performed in patients with a remote history of sepsis, if there is a recent history of sepsis or if the patient is young, arthrodesis provides a more satisfactory alternative.

Failed Total Shoulder Arthroplasty

I have seen several patients who have had multiple unsuccessful shoulder arthroplasties. Although the results of shoulder arthroplasty are generally good, there are some patients in whom loosening, sepsis, and implant breakage occur. These patients often have severe loss of humeral and glenoid bone stock (Fig. 21-4). In this situation the surgeon must choose between attempting a repeat revision of the shoulder arthroplasty and reconstruction of the shoulder joint by arthrodesis. The results of revision total shoulder arthroplasty are suboptimal when compared with the results of primary arthroplasty for other reasons. The decision between these two alternatives must be made on the basis of the patient's age, the presence or absence of active sepsis, the bone stock that remains in the proximal humerus and glenoid, the symptoms the patient is experiencing, the quality and function of the rotator cuff and the deltoid, and the technical experience and expertise of the surgeon. In several patients who were significantly disabled I have carried out glenohumeral arthrodesis following failed total shoulder arthroplasty and found it to be a helpful procedure for the patient. It is my belief that glenohumeral arthrodesis must be considered when the reconstructive surgeon is confronted with a patient with a history of multiple failed total shoulder arthroplasties.

Figure 21-4 Excision arthroplasty of the glenohumeral joint after several failed total shoulder arthroplasties. The patient is disabled by severe unremitting pain with any activity. Glenohumeral arthrodesis is indicated to provide the patient with a stable, relatively painless shoulder.

Shoulder Instability

Virtually all patients with shoulder instability can be treated by soft tissue or bony reconstructive procedures to stabilize the glenohumeral joint. Rarely, a patient will present with chronic shoulder instability after multiple attempts at surgical stabilization. If every surgical therapeutic alternative has been exhausted, the patient's shoulder remains symptomatically unstable, and the patient does not wish to wear a thoracobrachial support, arthrodesis can be indicated to restore shoulder stability. In this situation careful assessment of the patient's psychologic makeup must be carried out and one must be certain the patient has a full understanding of the implications of the procedure. Much has been written about the difficulties in managing such patients and further elaboration here is not necessary.[47,53]

Rotator Cuff Tear

Severe shoulder dysfunction can result from massive rotator cuff tears.[17] Most rotator cuff tears can be managed by coracoacromial decompression and repair of the cuff. In patients who have massive rotator cuff tears that cannot be repaired, some authors have reported good results with débridement of the cuff tear and coracoacromial decompression.[50]

Long-standing rotator cuff tears can lead to cuff tear arthropathy as reported by Neer et al.[40] This difficult pathologic entity can be treated by prosthetic arthroplasty with limited goals. Glenohumeral arthrodesis should be kept in mind as a possible alternative form of reconstruction in such patients when the technical skill of the surgeon or the available tissues do not permit cuff reconstruction and the patient is sufficiently symptomatic to exchange the loss of glenohumeral motion for the relief of pain. In my experience, this situation rarely, if ever, develops.

Malunion

Glenohumeral arthrodesis is rarely indicated for posttraumatic deformity. Most patients with posttraumatic deformities, such as osteonecrosis of the humeral head, chronic fracture dislocations, tuberosity impingement, or a malunion of the proximal humerus, are best treated by shoulder reconstruction using either osteotomy, arthroplasty, or a combination of both. If these procedures are not possible, then glenohumeral arthrodesis can be considered.

Osteoarthritis

The presence of glenohumeral osteoarthritis in an otherwise normal shoulder is an indication for total shoulder arthroplasty. However, almost all patients with glenohumeral osteoarthritis are of sufficient age that they are excellent candidates for total shoulder arthroplasty. If the patient were to develop osteoarthritis at a relatively young age, then glenohumeral arthrodesis might be considered,[2] particularly if the patient was a laborer and modified work was not available to him or her. The results of total shoulder arthroplasty are so much superior that arthrodesis is rarely indicated for patients with this diagnosis.

Rheumatoid Arthritis

Patients with rheumatoid arthritis affecting the glenohumeral joint commonly have multiple problems in their upper extremity. Glenohumeral arthrodesis is recognized as a procedure that can decrease pain arising in the glenohumeral joint.[24,43,56] Obliteration of glenohumeral motion has a negative influence on the upper extremity function. Frequently both upper extremities are involved. It is my belief that patients with rheumatoid arthritis are much more effectively treated by total shoulder arthroplasty.[18] Favorable reports of the combination of shoulder and elbow arthroplasty have appeared in the literature, and I would advocate this method of reconstruction for such patients.

CONTRAINDICATIONS TO GLENOHUMERAL ARTHRODESIS

Glenohumeral arthrodesis should not be performed if an alternative method of shoulder reconstruction is available. Many patients are amenable to arthroplastic reconstruction that preserves glenohumeral motion and has greater potential to restore function. Glenohumeral arthrodesis places a significant functional demand on the patient, requiring a major effort on the part of the patient to rehabilitate the shoulder following surgery and to strengthen the thoracoscapular musculature. The procedure is contraindicated in a patient who cannot cooperate with such a program of rehabilitation. Similarly, the procedure is contraindicated in any patient with a progressive neurologic disorder who may experience paralysis or weakness of the trapezius, levator scapula, or serratus anterior. Glenohumeral arthrodesis relies on these muscles to motor the extremity, and significant weakness will grossly impair shoulder function following the procedure.

RESULTS

Review of Literature

Many techniques for glenohumeral arthrodesis have been reported. Some authors have used extraarticular arthrodesis, others have reported on methods of intraarticular arthrodesis, and still others have combined the two methods. In reviewing the literature it is apparent that internal fixation has been employed more frequently in recent years. Historically most authors have recommended external immobilization, although recently reports of glenohumeral arthrodesis without external immobilization have appeared.[27,49] I will now discuss extraarticular arthrodesis, intraarticular arthrodesis, the use of internal fixation, and the use of external fixators.

Extraarticular Arthrodesis

Extraarticular arthrodesis is primarily a historical procedure used before the antibiotic era to treat tuberculous arthritis. This treatment method was used to avoid entering the tuberculous joint and to obliterate motion at the joint without activating and spreading the infection. Watson-Jones[60] described a technique utilizing a Cubbin's approach[12] to the shoulder, decorticating the superior and inferior surfaces of the acromion. A bone flap was then cut into the greater tuberosity and both the clavicle and the acromion were osteotomized. The arm was abducted and the acromion positioned to lie between the two edges of the bone flap in the proximal humerus. A spica cast was applied for 4 months.

Putti[42] described a technique whereby the spine of the scapula and the acromion were exposed subperiosteally. The spine of the scapula was detached, the acromion split, and the medial and lateral portions and the upper end of the humerus exposed. The lateral surface of the humerus was split similar to the method described by Watson-Jones and the spine of the scapula driven down into the humerus with the arm abducted. Spica cast immobilization was necessary following this procedure. Neither Watson-Jones' nor Putti's technique was truly extraarticular because the shoulder joint was usually entered when creating the split in the proximal humerus.

Brittain[6] described a true extraarticular arthrodesis. This arthrodesis used a large tibial graft that was placed between the medial humerus and the axillary border of the scapula. The graft was maintained in position by its "arrow" shape (the pointed end was inserted into the humerus and the opposite, notched, end into the axillary border of the scapula). The graft was stabilized by its shape and adduction of the arm, which produced a compressive force along the long axis of the graft. DePalma[14] reported that the failure rate of the arthrodesis was high owing to fracture of the long tibial graft.

Intraarticular Arthrodesis

Gill[19] combined intraarticular and extraarticular arthrodesis. Gill used a U-shaped incision centered 2 cm below the acromion combined with a downward limb to the incision. Gill denuded the superior and inferior surface of the acromion and excised the rotator cuff. The glenoid fossa was decorticated as was the cartilaginous surface of the humeral head. An osseous flap was elevated from the anterolateral surface of the humerus, and a wedge-shaped slice of bone, with its base superiorly, was removed from the humerus. The arm was then abducted and impacted onto the acromion. The position was maintained by suture of the capsule and rotator cuff to the periosteum on the superior surface of the acromion. This technique is predicated on the assumption that it is desirable to fuse the glenohumeral joint in a large amount of abduction. This can be desirable in children when internal fixation is not used because, with time, the amount of abduction decreases. The technique is undesirable in adults owing to the likelihood of excessive abduction being retained following arthrodesis.

Makin[32] has reported on a method of glenohumeral arthrodesis in children that preserves the growth potential of the proximal humeral epiphysis. Makin fused the shoulder in 80 to 90 degrees of abduction, fixing the humerus to the glenoid with Steinman pins inserted first into the humerus in a proximal–distal direction and then driven in the reverse direction into the glenoid. Makin followed his children to adult life and noted that there was only a small loss in humeral length and no change in position of the fused shoulder. He recommended this technique, stating that this amount of abduction was necessary to maintain the growth potential of the proximal humeral epiphysis. I have had no experience with this technique. If this amount of abduction was maintained, the shoulder would be dysfunctional in adulthood.

Moseley[36] reported division of the rotator cuff insertion and excision of the intraarticular portion of the biceps tendon. Moseley advocated suture of the biceps tendon into the bicipital groove after division of its origin. This is an important step to remember in those patients who have functioning biceps, to avoid the unsightly cosmetic deformity identical with that seen in rupture of the long head of the biceps tendon. The author performs a biceps tenodesis during glenohumeral arthrodesis in all patients who have a functional biceps. Moseley denuded the inferior surface of the acromion as well as the articular cartilage of the humeral head and glenoid fossa. This is an important step in performing glenohumeral arthrodesis because the humeral head presents such a small area to the glenoid across which fusion can occur.

Beltran et al.[4] performed glenohumeral arthrodesis through an anterior approach. They osteotomized the coracoid and created a tunnel that crossed the humerus and entered the glenoid cavity. They utilized a screw for internal fixation and in addition used a Cloward reamer to position a fibular graft from the proximal humerus into the infraglenoid area. Other techniques for glenohumeral arthrodesis have been described by May[33] and Davis and Cottrell.[13]

Internal Fixation

A variety of methods of internal fixation have been advocated for glenohumeral arthrodesis. It is generally agreed that internal fixation is desirable because it maintains the position of the arthrodesis and can decrease the length of time that plaster immobilization is necessary to obtain an arthrodesis. Makin advocated the use of Steinman pins in children who are undergoing glenohumeral arthrodesis at an early age. Carroll[6] reported on the use of a wire loop to maintain the position of glenohumeral arthrodesis. Carroll advocated the use of 22-gauge wire passed through the head of the humerus and the anterosuperior lip of the glenoid. He employed this method of arthrodesis in 15 patients, and all patients achieved solid bony union between the third and fourth month following surgery. Carroll noted that it was possible to manipulate the shoulder following surgery and change the position of the arthrodesis. As time has gone by, most authors have advocated more rigid forms of internal fixation. At present, few surgeons would use a wire loop as a method of internal fixation when performing glenohumeral arthrodesis.

Other authors have reported the use of screws to obtain fixation during glenohumeral arthrodesis. May[33] used a single stabilizing wood screw crossing the humerus and

entering the glenoid fossa. Davis and Cottrell[13] used a similar technique and added a muscle pedicle bone graft that was fixed in place with wood screws. Cofield and Briggs[11] and Leffert[29] also reported on the use of compression screw fixation without the use of a plate. Beltran[4] developed a special fixation device using a screw bolt and washer to obtain glenohumeral arthrodesis. In addition, Beltran used an acromiohumeral screw and a fibular graft as methods of internal fixation.

The Association for Osteosynthesis (AO) group first advocated the use of plate fixation in 1970. They described this method of arthrodesis as not requiring supplementary plaster immobilization. The AO group advocated the use of two plates for internal fixation.[37] The first plate was applied along the spine of the scapula and then bent down over the humerus, maintaining a position of 70 degrees of abduction between the vertebral border of the scapula and the humerus. The object of this position was to obtain a clinical position of 50 degrees of abduction, 40 degrees of internal rotation, and 25 degrees of flexion. They anchored this plate to the scapula with a long screw placed down through the plate and the acromion and into the neck of the glenoid (Fig. 21-5). They also noted that fixation could be improved by the insertion of two long screws inserted through the plate and the humeral head and into the glenoid. "If necessary," a second plate applied posteriorly was advocated to improve the internal fixation. I have rarely found it necessary to use two plates when performing glenohumeral arthrodesis.

Figure 21-5 Appearance of the humerus and scapula after glenohumeral arthrodesis with a single plate. Screws have been passed from the spine of the scapula through the plate into the area of the coracoid base. Excellent fixation in the scapula can be obtained with this technique.

Kostuik and Schatzker[27] have reported on the use of the ASIF technique. They did not use external immobilization postoperatively and reported good results in their patients. Riggins[49] reported on shoulder fusion without external immobilization in 1976. Both the AO group and Riggins supplemented their arthrodeses with bone grafts. Riggins treated four patients with the use of a plate for internal fixation. Two of the patients had above-elbow amputations. The arthrodesis was successful in each case. Miller et al. analyzed five fixation techniques for shoulder arthrodesis biomechanically and found double plate fixation to provide the highest bending and torsional stiffness in comparison to single plate fixation, external fixation with screws, external fixation alone, and screws alone (techniques listed in decreasing level of stiffness). Ruhmann et al.[55] found the strength of three humeroglenoid screws and three acromiohumeral screws to be similar to plate arthrodesis.

My colleagues and I have reported on the results of a modified method of glenohumeral arthrodesis using internal fixation in 14 adult patients with brachial plexus palsy.[44] We first used a single 4.5 AO/ASIF dynamic compression (DC) plate applied over the spine of the scapula onto the shaft of the humerus. We advocate placement of two cancellous compression screws passing through the plate and the proximal humerus into the glenoid first to achieve compression at the glenohumeral arthrodesis site. The plate is anchored to the scapula with a long screw passing through the spine of the scapula into the area of the coracoid base. Anchorage of the plate by this method, as opposed to the AO method, which inserts the screw into the glenoid neck, provides good fixation, yet leaves room for the large compression screws in the glenoid, which are felt to be more important in obtaining arthrodesis. Initially, we advocated the use of a postoperative spica cast because adult patients with brachial plexus injuries generally have significant osteoporosis, poor muscular control, and decreased proprioception, resulting from their neurologic injury. Bone grafts were not used in this series, and no nonunions occurred. More recently, we have begun to use thermoplastic thoracobrachial orthoses when performing glenohumeral arthrodesis and no longer use a spica cast (see following discussion).

We reported a modification of the technique described in 1985.[45] The current technique uses a malleable plate for internal fixation. In the modified procedure a single 10-hole 4.5 AO pelvic reconstruction plate is used for internal fixation. This plate, although weaker than the 4.5 DC plate, is much easier to contour in the operating room and is much less prominent as it passes over the acromion onto the shaft of the humerus. None of the 11 patients whose shoulders were fused by this method complained of plate prominence. Fusion was obtained in each instance without failure of the internal fixation device. External cast immobilization was used for 6 weeks postoperatively. Plate

prominence can also be decreased postoperatively by notching the acromion laterally where the plate crosses this structure.

External Fixation

Charnley and Houston[8] reported a method of compression arthrodesis of the shoulder utilizing two Steinman pins. The first Steinman pin was inserted posterosuperiorly into the base of the acromion and then into the main mass of the scapula just proximal to the glenoid. The second pin was inserted posterolaterally in relation to the shaft of the humerus and perpendicular in relation to the axis of the humerus to transfix the region of the surgical neck. A compression apparatus was then applied to the two pins. After application of the compression apparatus, a plaster spica cast was applied and worn for an average of 4.8 weeks. After removal of the pins and compression clamps, a second plaster cast was applied for an average of 5.3 weeks. Other methods of external fixation have been reported.[23,26,38,57]

Currently, the indications for glenohumeral arthrodesis using external fixation are limited. I have used this method occasionally in patients with active septic arthritis of the shoulder and in patients with massive trauma resulting in bone and soft tissue loss. I have utilized pins placed through the clavicle and acromion and a second set of pins inserted in a separate plane into the spine of the scapula and neck of the glenoid. Two half-frames are then constructed to stabilize the shoulder. The two half-frames can be cross-connected for increased stability. This technique is desirable if there is an open, infected wound draining from the shoulder joint. This method allows dressing changes and care of the soft tissues without the increased dissection and soft tissue disruption necessary to place an internal fixation device. If the soft tissue envelope improves, internal fixation can be performed later.

AUTHOR'S PREFERRED TREATMENT

Position of Arthrodesis

A wide variety of different positions for glenohumeral arthrodesis have been advocated in the literature. Perusal of the literature reveals that no two authors agree on exactly the same optimum position for glenohumeral arthrodesis. There was sufficient controversy in the literature that the American Orthopaedic Association established a committee to determine, among other things, the optimum position for glenohumeral arthrodesis. This committee reported in 1942[1] and concluded that the optimum position for glenohumeral arthrodesis was 45 to 50 degrees of abduction (measured from the vertebral border of the scapula), forward flexion from the plane of the scapula 15 to 25 degrees, and 25 to 30 degrees of internal rotation. This report caused a great deal of controversy in the literature following its publication. Part of the controversy revolved around the method of measurement of abduction. Some authors recommended using the angle formed by the vertebral border of the scapula and the axis of the humerus to determine abduction, whereas others argued that the angle between the arm and the side of the body was more appropriately measured (clinical abduction).

Rowe noted in 1974 that the amount of abduction that had been recommended was excessive for adults.[52] This position had been recommended primarily for patients who were having their shoulders fused as children in whom internal fixation was not used. In this situation, the amount of abduction present at the time of surgery was commonly lost during the period required for arthrodesis to become secure, as well as during continued growth. If the same position were used in adults, excessive scapular winging would occur and the scapula would not comfortably rest at the side. Furthermore, Rowe noted that the measurement of clinical abduction was more practical and recommended this method, rather than measuring abduction from the vertebral border of the scapula. Rowe recommended that the arm be placed nearer the center of gravity of the body, with enough abduction to clear the axilla and sufficient flexion and internal rotation to bring the hand to the midline of the body.

Other authors have recommended a variety of positions for glenohumeral arthrodesis. All authors agree that abduction and forward flexion are desirable. Most have recommended internal rotation. In my opinion, the optimum position for glenohumeral arthrodesis is one that brings the hand to the midline anteriorly so that with elbow flexion the mouth can be reached. The amount of abduction should not be excessive so that the arm can rest comfortably at the side. I recommend a position of 30-degrees abduction (measured clinically), 30-degrees forward flexion, and 30-degrees internal rotation. The so-called 30-30-30 position is easily obtained in the operating room and usually provides patients with the ability to reach their mouth, their front pocket, and their back pocket. It must be recognized that the position cannot be measured exactly at the time of surgery. I have found in my series of shoulder arthrodeses that it is usually possible to arthrodese the shoulder within 10 degrees of the desired position.

Technique

The patient is placed in the semisitting position.[3] The arm is free draped. An incision extends from the spine of the scapula to the anterior acromion and down the anterior aspect of the shaft of the humerus. Uematsu has recommended a posterior approach when performing glenohumeral arthrodesis.[59] Other authors have described arthroscopically assisted glenohumeral arthrodesis.[35] The deltoid muscle is detached from the anterior acromion and

Figure 21-6 The undersurface of the acromion is decorticated (*shaded area*). Decortication of the acromion provides a much larger area across which fusion can occur. When the arm is placed in the "30-30-30" position, the superior aspect of the humerus, when it is brought proximally, abuts against the undersurface of the acromion.

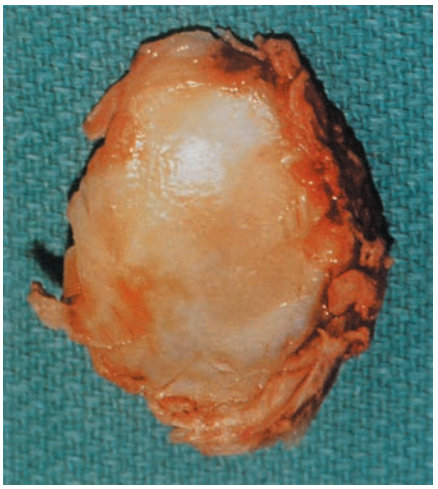

Figure 21-7 The glenoid articular surface, the glenoid labrum, and the underlying subchondral bone are resected. This is most easily accomplished with a curved osteotome.

its fibers are split distally. Because deltoid function is not present in patients with brachial plexus palsy undergoing glenohumeral arthrodesis, denervation of the muscle is not usually a concern. If deltoid function is present, the incision should be curved over to the deltopectoral interval and the shoulder approached in this fashion. By using this approach, deltoid bulk will be maintained and the patient will experience a more satisfactory cosmetic result. Sparing the deltoid may prevent the development of pain from neuromas arising from the axillary nerve postoperatively. The rotator cuff is resected. The undersurface of the acromion and the humeral head are decorticated (Fig. 21-6). An attempt is made to obtain arthrodesis of both the glenohumeral and acromiohumeral articulations because the glenoid fossa offers such a small area for fusion with the humeral head. Decortication of the undersurface of the acromion increases the potential fusion area. The articular surface of the glenoid, the glenoid labrum, and the subchondral bone are resected with a curved osteotome (Fig. 21-7). A 10-hole 4.5-mm pelvic reconstruction plate is used for internal fixation during the procedure (Fig. 21-8).

After resection of the rotator cuff and decortication of the joint surfaces, the shoulder is supported in 30-degrees flexion, 30-degrees abduction, and 30-degrees internal rotation. Abduction is measured from the side of the body. This method of measurement does not accommodate for individual variations in muscle mass or body fat. However, clinical experience has shown it to be accurate within 10 degrees in any plane. The humeral head is brought proximally to appose the decorticated undersurface of the acromion. When the humerus is abducted and flexed 30 degrees, the humeral head apposes both the undersurface of the acromion and the glenoid fossa (Fig. 21-9). The position is maintained by supporting the arm with sterile folded sheets. An assistant is assigned to maintain the position while the plate is contoured. Thirty degrees of internal rotation brings the hand to the midline. I have not found it necessary to measure abduction radiographically.

Handheld bending irons are used to contour the plate along the spine of the scapula, over the acromion, and

Figure 21-8 Specially modified 4.5 pelvic reconstruction plate used for shoulder arthrodesis. The plate is bent as it crosses the acromion and twisted just past the bend. The plate can be easily bent in all planes with the handheld bending irons.

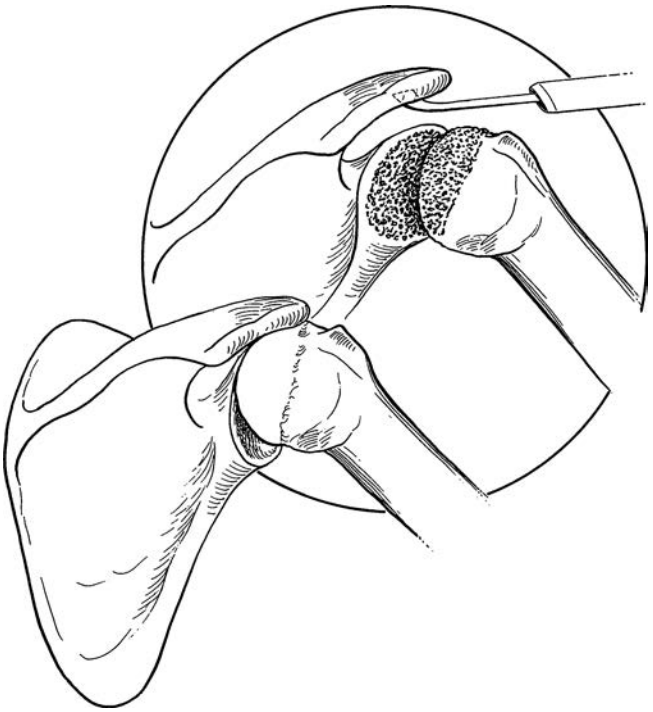

Figure 21-9 The glenoid, humeral head, and undersurface of the acromion are decorticated and shaped so that the humeral head has the greatest surface area contact. This technique increases the likelihood of a solid fusion.

down onto the shaft of the humerus (Figs. 21-10 and 21-11). The malleable nature of the plate allows precise intraoperative contouring of the implant to the specific local anatomy in any given patient. The plate must be bent 60 degrees over the acromion and twisted 20 to 25 degrees just distal to the bend to appose the shaft of the humerus. The reconstruction plate has holes that allow angulation of the screws as they are passed through the plate.

The screws passing through the plate and the humeral head into the glenoid fossa are inserted first (Fig. 21-12).

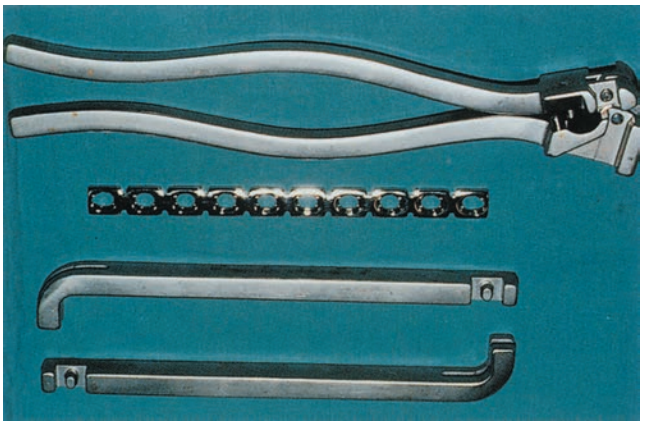

Figure 21-10 Handheld plate press and bending irons used to contour the pelvic reconstruction plate intraoperatively.

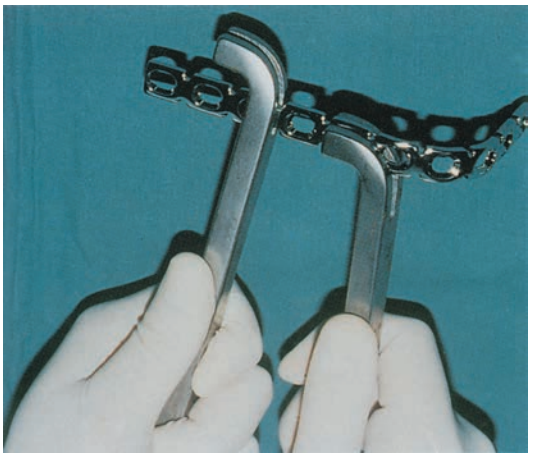

Figure 21-11 Plate must usually be contoured in the sagittal plane to appose the surface of the underlying humerus.

Two (usually) or three (sometimes) 6.5-mm compression screws can be inserted in this fashion. If the glenoid is dysplastic, only one screw can be used. These screws compress the arthrodesis site. A screw should be directed next from the spine of the scapula into the base of the coracoid process. Because of the cortical bone in this region, care must be taken not to break the drill bit when drilling into the scapula. Another cancellous screw is placed across the acromiohumeral fusion site, and the remaining holes of the plate are secured with cortical screws (Figs. 21-13 and 21-14). The acromion is not osteotomized, for it is used to augment fixation of the scapula to the humerus. Creating a notch in the lateral acromion may reduce plate prominence in this area (Fig. 21-15). Autogenous bone graft is not used routinely. If there is deficiency of the glenoid or humerus, a bone graft should be used. This is often the situation when the procedure is performed for failed total shoulder arthroplasty (see later discussion).

The arm of the patient is supported postoperatively with a pillow and swathe. A thermoplastic thoracobrachial

Figure 21-12 Transluminated scapula: There is little bone available for fixation in the scapula except in the area of the glenoid and coracoid base. Apart form the borders of the scapula, these are the only areas that do not transluminate.

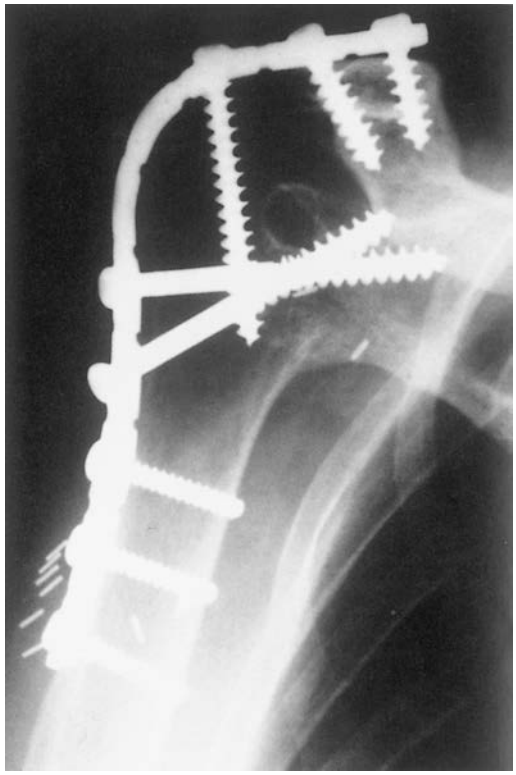

Figure 21-13 Anteroposterior radiograph following glenohumeral arthrodesis with a single plate. Two screws have been inserted into the glenoid to provide fixation. These screws are inserted first to compress the arthrodesis site and augment the fixation by interdigitation of the cancellous bone surfaces.

orthosis is applied 24 hours postoperatively (Fig. 21-16). If possible, the orthosis can be fabricated preoperatively and then adjusted in the postoperative period as necessary. The orthosis is worn for 6 weeks postoperatively. During this time it can be removed for short periods while the patient showers, providing the arm is supported. If quality of the patient's bone is good, the fixation obtained intraoperatively solid, and the patient reliable, sling immobilization alone, without the use of an orthosis, can be considered. Six weeks postoperatively the patient is examined radiographically, and the stability of the fusion is tested manually in a gentle fashion.

If there is no radiographic sign of loosening of the internal fixation after 6 weeks, the patient's arm is placed in a sling (Fig. 21-17). Gentle range-of-motion exercises are allowed until radiographic union is achieved. It is difficult to be certain when fusion occurs radiographically because the fixation is sufficiently rigid that very little callus forms around the arthrodesis site. Muscle strengthening is encouraged after removal of the thermoplastic thoracobrachial orthosis, but return to strenuous activity is delayed for at least 16 weeks postoperatively. Thoracoscapular strengthening and mobilization exercises can usually be started 3 months following surgery.

The plate and screws are not routinely removed. If the internal fixation device is prominent and the overlying soft tissues tender and/or subject to irritation from clothing or prosthetic harnesses, the fixation should be removed. If the internal fixation is removed, the patient should be informed that there is an initial risk of humeral fracture due to the stress-raising effect of the screw holes until the local bone has a chance to respond to the change in stress distribution created by the loss of the support provided by the fixation device.

Special Problems

Elbow Flexorplasty

Some forms of elbow arthroplasty can be performed at the time of glenohumeral arthrodesis. If arthrodesis of the shoulder and elbow flexorplasty can be accomplished under one anesthetic, morbidity and the time required for rehabilitation can be decreased. Pectoralis major tendon transfer is an example of a form of elbow flexorplasty that can be performed at the time of glenohumeral arthrodesis (Figs. 21-18 and 21-19). When performing this type of flexorplasty at the same time as glenohumeral arthrodesis, it is important to not set the tension on the transfer until the position of the shoulder has been secured with a plate.

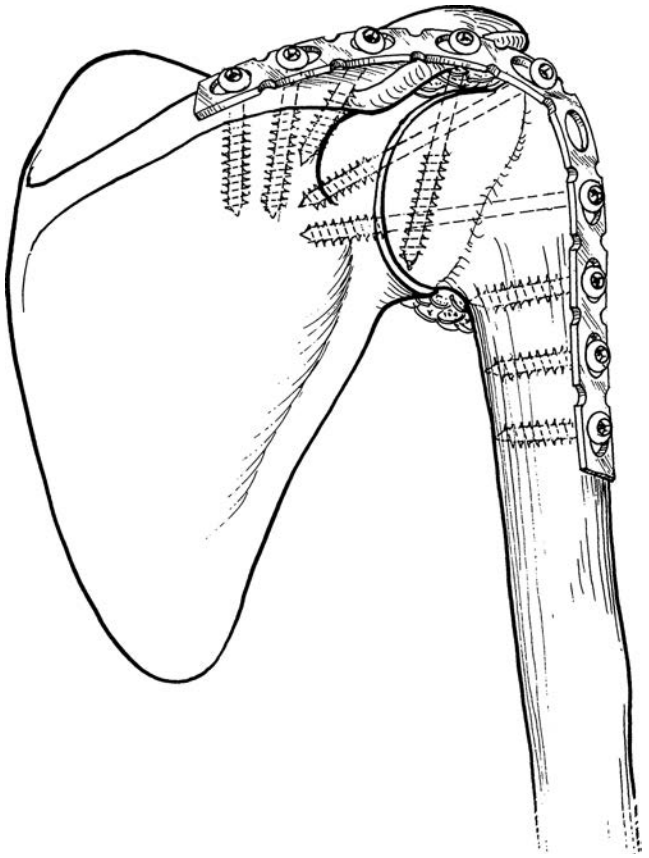

Figure 21-15 Drawing of a 10-hole Association for Osteosynthesis (AO) reconstruction plate applied to stabilize the arthrodesis. The humeral head contacts the acromion and the glenoid, and there is cancellous bone graft packed into the interval between the inferior humeral neck and the glenoid.

Figure 21-16 Patient wearing a thermoplastic thoracobrachial orthosis a few days following glenohumeral arthrodesis. The orthosis can be constructed preoperatively and adjusted in the immediate postoperative period. The orthosis is worn full time for 6 weeks and part time (when out of the house) for another 6 weeks postoperatively.

This type of reconstruction can accomplish a great deal for the patient with a flail elbow and shoulder who has a favorable type of brachial plexus injury (Figs. 21-20 and 21-21). Doi et al.[16] have reported on the use of free tissue transfer in conjunction with shoulder arthrodesis and other procedures for upper extremity reconstruction following complete avulsion of the brachial plexus.

Bone Loss

Bone loss can be a significant problem when performing glenohumeral arthrodesis. The usual etiologic factors are trauma, previous glenohumeral joint arthroplasty, and tumor resection. The extent of bone loss should always be assessed preoperatively. It is usually possible and practicable to assess the extent of humeral bone loss on conventional radiographs. It is harder to assess the extent of glenoid bone loss on plain films; therefore, a computed tomography (CT) scan may be required. Certainly, if the patient has had a previous glenoid replacement or has a scapular tumor, additional imaging is required. If bone loss is present, bone grafting must be performed in conjunction with glenohumeral arthrodesis. The various types of bone grafting are discussed in the following section, and the method selected will depend on the extent of bone loss determined preoperatively.

Bone Grafting

Routine bone grafting is advocated by some authors during glenohumeral arthrodesis. The AO/ASIF group recommends prophylactic bone grafting at the termination of a plate if a plate is used for internal fixation. Of Cofield and Briggs' 71 patients, 11 had autogenous bone grafts at the time of their initial procedure.[11] Richards et al. obtained successful arthrodesis without primary bone grafts in patients with significant osteoporosis.[45] I do not routinely use bone grafts in adults when performing glenohumeral arthrodesis. Bone grafting is indicated to fill large defects in patients who are undergoing glenohumeral arthrodesis for complex and revision problems. Bone grafting is also indicated following tumor resection. If large defects have been created following such resection, free vascularized bone grafts may be indicated. Nonunion of shoulder arthrodeses should be treated by revision of the arthrodesis combined with bone grafting. An attempt must be made to obtain rigid internal fixation during the arthrodesis. This method of treatment has, in my own experience, been successful when used.

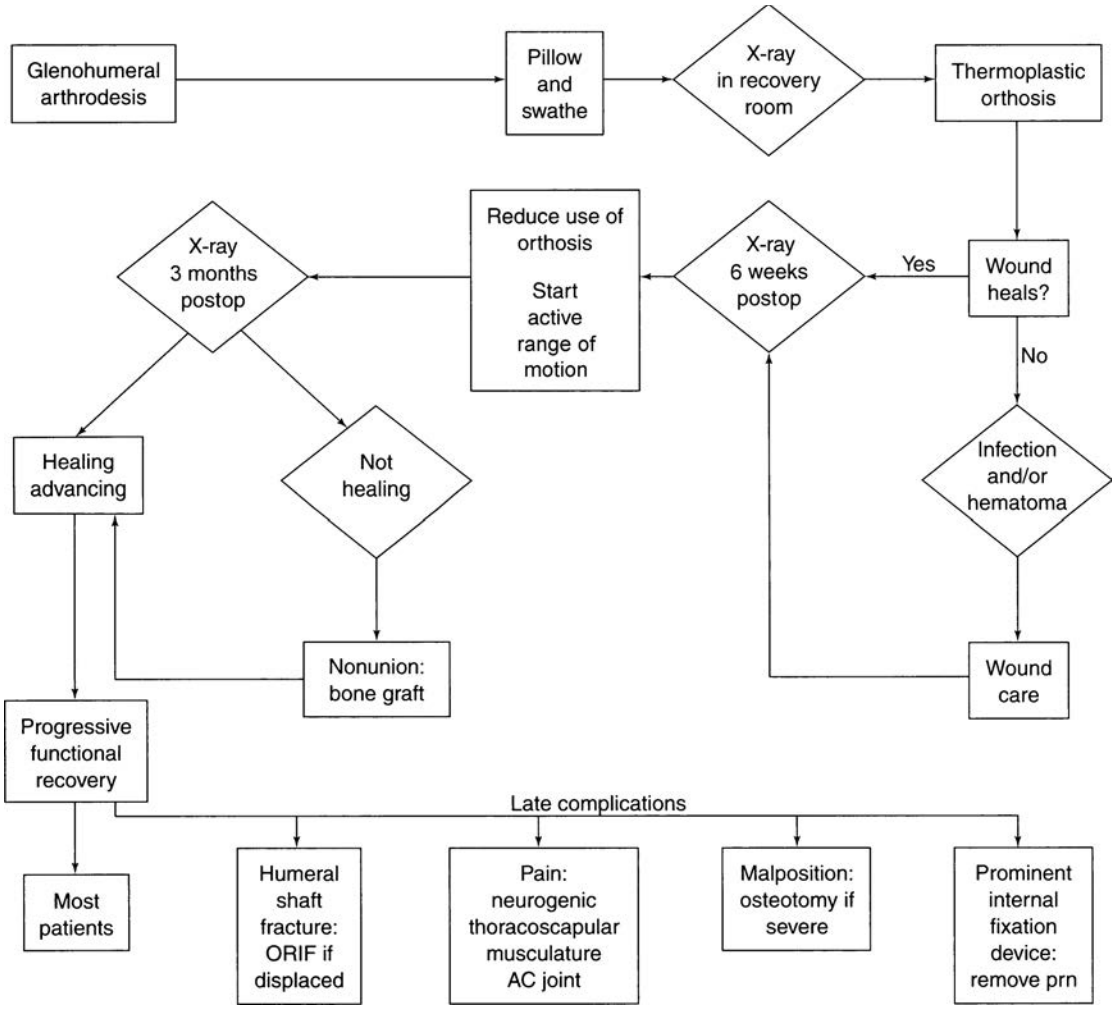

Figure 21-17 Algorithm for management following glenohumeral arthrodesis. AC, acromioclavicular; ORIF, open reduction, internal fixation.

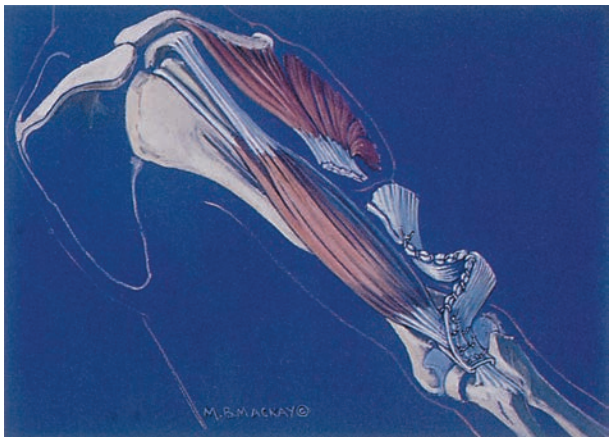

Figure 21-18 Simultaneous glenohumeral arthrodesis and elbow flexorplasty. A tube of fascia lata harvested from the opposite thigh is sewn to the biceps tendon distally. The fascia lata is passed subcutaneously proximally to the area of the pectoralis major insertion.

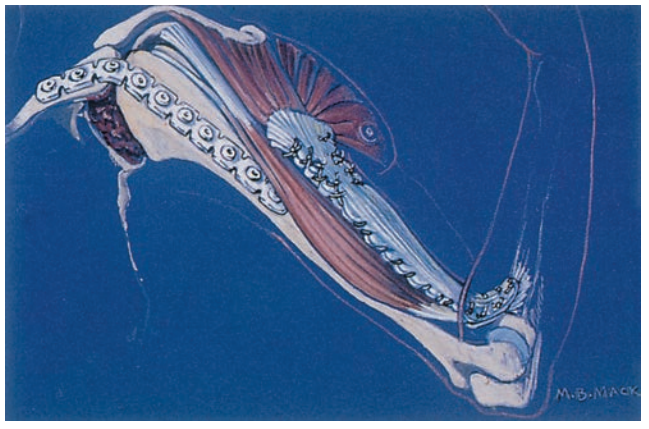

Figure 21-19 After stabilization of the glenohumeral arthrodesis with a plate, the fascia lata is sewn at the appropriate tension to the pectoralis major tendon. Patients are treated in a thermoplastic orthosis as described in Figure 21–16.

Figure 21-20 Male patient with an irreparable lesion of the brachial plexus a few months following simultaneous glenohumeral arthrodesis and elbow flexorplasty using fascia lata to the pectoralis major tendon.

Figure 21-21 The patient can actively flex his elbow through a functional range. The pectoralis major tendon transfer is seen as a web in the anterior axillary fold.

Nonstructural Autogenous Bone Grafting

Autogenous bone grafting can be used to provide osteoinductive and osteoconductive material at or in the arthrodesis site to increase the likelihood of successful fusion. Some authors routinely use cancellous bone harvested from the humeral head when performing glenohumeral arthrodesis. In complex and revision cases the humeral head usually is not present, and it is necessary to look elsewhere for autogenous bone. My preference is to harvest bone from the inner aspect of the iliac crest when a nonstructural autogenous graft is required. This is conveniently performed with the patient in the semisitting position unless the patient is obese, in which case the bone graft must be harvested with the patient supine and the position changed after closure of the iliac crest wound. I resect the superior and inner cortex of the iliac crest with a sagittal saw. A Capener gauge is then used to excavate strips of cancellous bone. If large amounts of bone are required, it may be necessary to use both iliac crests. If the patient has had previous surgery in these areas, a bone graft can be harvested from the posterior aspect of the iliac crest, although the position of the patient must be changed intraoperatively. Alternatively, nonstructural autogenous bone can be obtained from the greater trochanter or provided by morselized rib grafts.

Structural Autogenous Bone Grafting

Structural autogenous bone grafting uses an anatomically intact bone graft, such as a full-thickness iliac crest or fibular strut graft. Following unsuccessful glenohumeral joint arthroplasty, there is a significant defect relating to the often extensive resection of the humeral head and excavation of the proximal humerus. A full-thickness (tricortical) iliac crest graft can be harvested and incorporated into the fusion mass (Fig. 21-22). I have placed such grafts underneath the plate with screws passing through the plate and the tricortical iliac crest bone graft, and into the glenoid. Such a graft will maintain the contour of the shoulder and provide autogenous osteoconductive tissue across which fusion can occur. The disadvantage of an anatomically intact graft is prolonged time required for incorporation. Accordingly, when such a graft is used, it should be supplemented with small chips of cancellous bone. It is usually necessary to harvest the cancellous bone from the other iliac crest. I have not used fibular grafts when performing glenohumeral arthrodesis except in conjunction with a vascularized fibular graft. Nonvascularized fibular grafts consist of dense cortical bone, have a limited biologic (but initially a good structural) potential, and probably should not be used in isolation.

Vascularized Autogenous Bone Grafting

Vascularized autogenous bone grafting has the advantage of providing tissue with great biologic potential. When the surgeon is faced with an intercalary defect that is larger

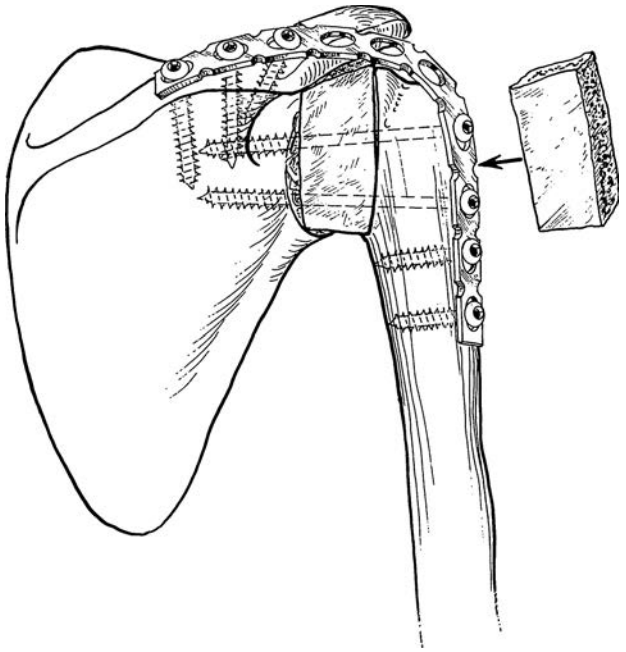

Figure 21-22 A corticocancellous block of autogenous iliac crest graft can be used to promote a fusion in the setting of proximal humeral deficiency, as may occur after a failed arthroplasty procedure.

than 6 cm, a vascularized bone graft should be considered. Following tumor resection, intercalary defects of this magnitude are common, and I have used vascularized fibular bone grafts in this situation. The bone grafting is performed in conjunction with plate fixation. My preference is to use a very long heavy plate spanning the entire intercalary defect (Fig. 21-23). The vascularized fibular bone graft should be fixed in position with a minimum amount of internal fixation at each bony juncture. Vascularized fibular bone grafts of up to 25 cm can be used to span very large defects. The vascular anastomosis is performed between the peroneal artery and its vena comitantes and a branch of either the axillary or the brachial artery. Vascularized fibular bone grafts should be supplemented with chips of autogenous bone at each juncture to maximize the likelihood of fusion occurring.

Vascularized full-thickness iliac crest bone grafts can be used to provide both bone and soft tissue. The use of such a bone graft creates a significant donor deficit, but can be considered if a bone and soft tissue defect coexist. The shape of the iliac crest limits its usefulness somewhat for long intercalary defects, although the graft can be osteotomized to straighten it. Alternatively, vascularized iliac crest bone grafts can be used in conjunction with a nonvascularized fibular graft or an allograft.

Allograft Reconstruction

Allograft reconstruction can be considered in conjunction with bone grafting when performing glenohumeral

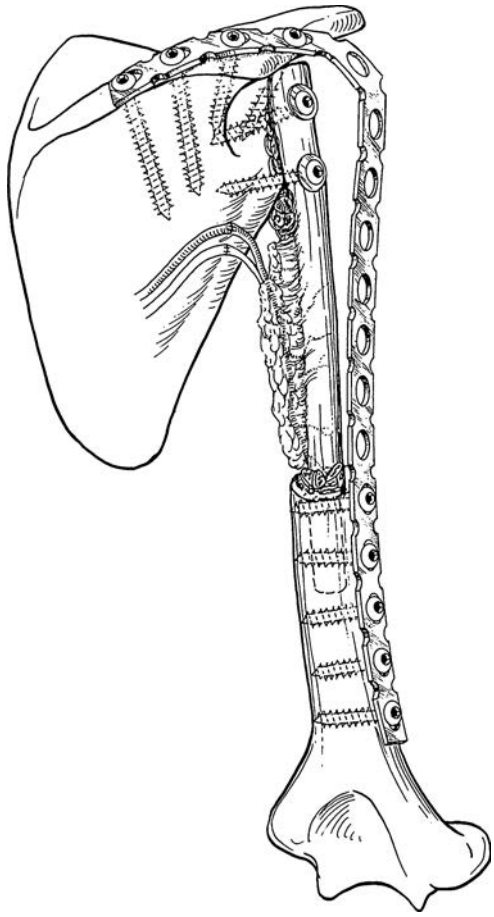

Figure 21-23 Drawing of the technique of vascularized fibular graft used to span a deficiency of the proximal humerus. Cancellous bone graft has been placed at both ends of the fibular graft.

arthrodesis for complex and revision cases.[9] It is my preference, wherever possible, not to use allograft bone if autogenous bone is available. For instance, if bone grafting is required to supplement a vascularized fibular graft, I would consider using the contralateral fibula or iliac crest graft to supplement the vascularized fibular graft in preference to an allograft. At times, allograft must be used owing to the nonavailability of autogenous bone. Both structural and nonstructural allograft bone can be used. More commonly, allograft is used in conjunction with a large implant to perform an arthroplastic reconstruction following tumor resection. This is discussed elsewhere in Chapter 37.

Soft Tissue Loss

Soft tissue loss can be caused by trauma or the necessity to resect soft tissue to obtain clear margins following tumor resection. The most common soft tissue deficiency about the shoulder relates to the rotator cuff. Isolated rotator cuff deficiency does not require special consideration and, in fact, our conventional method of glenohumeral arthrodesis involves resection of the rotator cuff in its entirety.

Local Flap Techniques

If deltoid resection is required for tumor ablation or if the deltoid has been lost as a result of trauma, consideration should be given to augmentation of the soft tissue envelope. In particular, it is important to have well-vascularized muscle surrounding the arthrodesis site. The presence of good muscle coverage is associated with enhanced bone formation and enhanced revascularization of autogenous dysvascular or avascular bone as seen following bone grafting.[48] Fortunately, local, pedicled, and free flap techniques are available to provide a stable soft tissue envelope about the shoulder. The latissimus muscle provides a local source of autogenous tissue that can be rotated to cover the shoulder. The entire latissimus muscle can be elevated on its vascular pedicle and rotated easily to cover the shoulder. The latissimus has an excellent blood supply, and most surgeons are familiar with its dissection. The flap can be rotated as either a pure muscle flap or as a myocutaneous flap, depending on the patient's requirements. If the nerve supply to the latissimus is kept intact, it can also be used as a flexorplasty, as described by Zancolli and Mitre.[62] The requirement to use a latissimus flap in this manner might be seen following trauma to the shoulder and proximal humerus resulting in the loss of biceps function. The latissimus flap should be considered to be the mainstay of treatment when soft tissue is required locally. Hasan et al.[22] have described the use of a pedicled forearm musculofasciocutaneous flap elevated just before above-elbow amputation and subsequently transposed to the shoulder to provide coverage of hardware used to perform shoulder arthrodesis in three patients.

Free Tissue Transfer

If a latissimus flap cannot be used, consideration can be given to a free tissue transfer. Such a transfer is required relatively infrequently about the shoulder. The trapezius should not be used to cover a soft tissue defect following glenohumeral arthrodesis. Good function of the trapezius is required to motor the shoulder girdle following arthrodesis, and its anatomy should not be disturbed.

"Hybrid" Methods of Reconstruction

Complex and revision problems about the shoulder require special techniques when performing glenohumeral arthrodesis. In some cases a combination of techniques is required and such hybrid methods of treatment are in the patient's best interest when faced with complex bone and soft tissue deficits. For instance, following tumor resection, it may be necessary to perform a vascularized fibular bone graft, a pedicled latissimus muscle flap, an autogenous iliac crest bone graft, and a pectoralis major to scapular transfer (owing to long thoracic nerve palsy) to stabilize the shoulder girdle and provide enough tissue so that arthrodesis can occur. The timing and staging of such complex procedures must be assessed on an individual basis.

PERSONAL SERIES

I have performed 91 glenohumeral arthrodeses. The ages have ranged from 19 to 64. Seventy-two patients were operated on for irreparable lesions of the brachial plexus, six patients for recalcitrant shoulder instability, five patients for osteoarthritis, four patients for failed total shoulder arthroplasties, and two patients for sepsis. The technique used was that of combined glenohumeral and acromiohumeral arthrodesis, as described earlier. In my home community tumor surgery is almost exclusively performed by other colleagues. Accordingly, I have had less experience with glenohumeral arthrodesis for this indication.

Results

Solid arthrodesis has usually been obtained with the primary procedure. Two patients developed only an acromiohumeral fusion and one of these patients developed a broken screw. This patient had a secondary bone-grafting procedure. Infection occurred in only one case. Clinical examination showed all shoulders to be fused within 10 degrees of the desired position. We have not used special techniques to assess the position of the arthrodesis.[25] Eighteen patients have required surgery for plate removal, and two patients sustained fractures of the humerus distal to the plate.

Activities of Daily Living

In a review of 33 patients we assessed functional outcome in detail.[47] The patients' ability to perform specific activities of daily living (ADLs) following their glenohumeral arthrodesis were ranked as seen in Table 21-1.

TABLE 21-1
ACTIVITIES OF DAILY LIVING*

Working at waist level	29
Getting dressed	29
Sleeping	27
Lifting bags	25
Using knife	25
Washing face	25
Reaching front pocket	23
Working at shoulder level	21
Doing up buttons	21
Reaching opposite axilla	20
Eating	17
Managing toileting	13
Reaching back pocket	11
Bathing	7
Washing back	6
Doing hair	5

*Number of patients/Total patients (33)

The ability to perform ADLs was heavily dependant on the adequacy of hand function in patients with brachial plexus injuries. Regression analysis revealed the underlying indication (preoperative diagnosis) for glenohumeral arthrodesis to be the single best predictor of the ability of patients to perform their ADLs following glenohumeral arthrodesis. The patient's compensation board status was also a predictor of outcome. Patient satisfaction was highest in those patients undergoing the procedure for a brachial plexus injury, osteoarthritis, and failed total shoulder arthroplasty.

Five patients who had neurogenic pain preoperatively continued to complain of significant neurogenic pain postoperatively. Several other patients who had compensable injuries continued to complain of postoperative pain in spite of solid arthrodesis. Most patients can reach both their front and back pockets following surgery, and many have returned to fairly heavy occupations. These occupations have included tool and dye manufacture, gardening, heavy equipment operation, and brick laying. Patients who had glenohumeral arthrodesis for compensable injuries did not return to their previous occupations. The author has not experienced acromioclavicular joint problems following glenohumeral arthrodesis. Some authors recommend excision arthroplasty of the acromioclavicular joint following arthrodesis in an effort to maximize shoulder motion.[41] I have not found it necessary to perform this adjunctive procedure in my series of patients. In the following paragraphs I will discuss fusion, function, and pain following glenohumeral arthrodesis in more detail.

Fusion

Fusion rates following glenohumeral arthrodesis are high. Most older series do not report any nonunions. Recent series that have used internal fixation devices report high union rates. It is often difficult to judge radiographic union in patients who have had internal fixation. The internal fixation device commonly obscures the arthrodesis site, and rigid internal fixation prevents the formation of periarticular new bone. Because I routinely use rigid internal rotation, I tend to arbitrarily discontinue or decrease external immobilization by 6 or 8 weeks. The shoulder is examined clinically and, assuming that the patient is comfortable, the patient is placed in a sling at this time. Any attempt to actively mobilize the thoracoscapular musculature is avoided until at least 3 months after arthrodesis. By using this method of postoperative rehabilitation, I have found delayed union or nonunion to be distinctly uncommon.

Function

The amount of improvement in shoulder function following arthrodesis is dependent on the function that was present preoperatively. Patients who have flail shoulders experience a significant improvement in glenohumeral function following arthrodesis because they can actively position their extremities in space (Fig. 21-24). Shoulder subluxation is relieved, and function is significantly improved. Most, but not all, patients can use their extremity to lift, dress, tend to personal hygiene, eat, and comb their hair (Figs. 21-25 and 21-26). In Cofield and Briggs' series, hair combing was the most difficult task to perform following arthrodesis of the glenohumeral joint.[11]

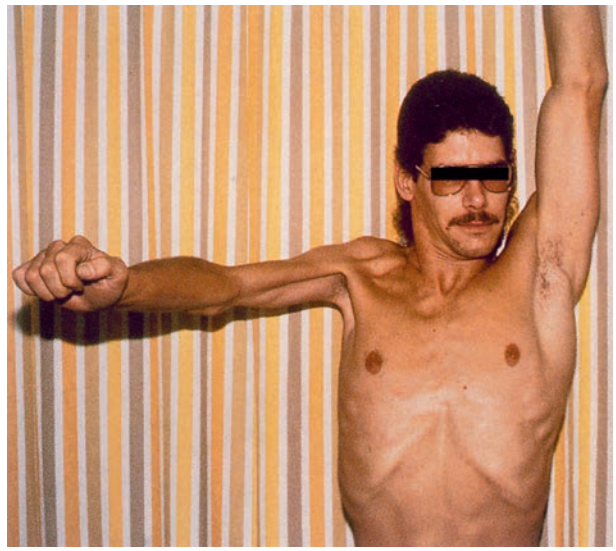

Figure 21-24 Range of shoulder elevation following glenohumeral arthrodesis. Most patients recover approximately two-thirds the normal range of motion following glenohumeral arthrodesis. The procedure effectively prevents glenohumeral rotation.

Chammas et al.[7] report that glenohumeral arthrodesis improved function in patients who had recovered active elbow flexion after brachial plexus even when the hand remained paralyzed.

Pain

Pain relief is not universal following glenohumeral arthrodesis. In fact, some pain is commonly present in patients whose shoulders have been successfully arthrodesed. The presence of moderate to severe pain following successful glenohumeral arthrodesis is difficult to explain, but occurs not infrequently. It is thought that such pain is related to the contiguous soft tissues. Glenohumeral arthrodesis places a substantial amount of strain on the periscapular musculature and requires the patient to make a profound functional adjustment. Pain surrounding successful fusions has also been reported following hip and knee arthrodesis. Most patients experience less pain with longer follow-up periods, and this suggests that with time the periscapular musculature adjusts to the changes imposed on it by glenohumeral arthrodesis. Clare et al.[10] have reported that excessive abduction or flexion of the arthrodesis is associated with chronic postoperative pain.

Figure 21-25 An anteroposterior clinical photograph of a patient following successful glenohumeral arthrodesis in the functional position. The arm can drop comfortably to the side even through thoracoscapular movement even though the glenohumeral joint has been arthrodesed in the 30-30-30 position.

Patients with neurogenic pain caused by brachial plexus injury will not experience pain relief following glenohumeral arthrodesis. Shoulder function is improved in these patients, but they should understand fully that the procedure is being performed to improve function and not to relieve pain. It has been our impression that if function is improved, such neurogenic pain is generally better tolerated by the patient. Therefore, we concentrate on the restoration of limb function, rather than on relief of pain by neurosurgical means.

Figure 21-26 Most patients can reach their mouth, their ear, their front pocket, and the side of their hip following glenohumeral arthrodesis.

Acromioclavicular Joint Pain

Acromioclavicular joint pain has been reported following glenohumeral arthrodesis.[41] Some methods of glenohumeral arthrodesis require osteotomy of the acromion. Such osteotomies disturb the normal acromioclavicular relation. If pain arises from the acromioclavicular joint postoperatively, excision arthroplasty is indicated if local injections confirm that the pain is arising from the acromioclavicular joint. Some authors have reported anecdotally that excision arthroplasty of the acromioclavicular joint improves motion following glenohumeral arthrodesis.[41] In our experience, acromioclavicular joint pain is rare following glenohumeral arthrodesis when the acromion is left in the anatomic position. Therefore, I do not recommend acromial osteotomy to approximate the acromion to the superior surface of the humeral head. I do advocate moving the humerus proximally to appose both the acromiohumeral and glenohumeral arthrodesis sites. The glenoid presents a small surface to the humeral head across which arthrodesis can occur. This is why decortication of the undersurface of the acromion as well as the glenoid and humeral head is advocated. The presence of a broader surface across which arthrodesis can occur is desirable, and it is believed that this increases the arthrodesis rate.

COMPLICATIONS

Nonunion

Nonunion following glenohumeral arthrodesis is surprisingly infrequent in view of the magnitude of the procedure, the high stresses across the arthrodesis site, and the difficulty of postoperative immobilization. In Cofield and Briggs' series of 71 shoulder arthrodeses, only three patients went on to nonunion.[11] All three patients' shoulders were successfully fused following a second operative procedure. If nonunion occurs following glenohumeral arthrodesis, a repeat operation with revision of the internal fixation device is indicated. Bone grafting should be used to augment the arthrodesis site if a nonunion has occurred. I have seen a few patients who have obtained an acromiohumeral fusion, but have not fused solidly at the glenohumeral joint. In one such patient the internal fixation device failed and bone grafting was necessary.

Infection

Infection is relatively uncommon following glenohumeral arthrodesis owing to the excellent vascularity of the periarticular tissues. Infection following glenohumeral arthrodesis

should be treated with surgical drainage and the appropriate parenteral antibiotics. The internal fixation should not be removed if it is providing stability at the arthrodesis site. An attempt should be made to obtain solid arthrodesis before removal of any fixation device.

Malposition

Excessive abduction of the extremity during glenohumeral arthrodesis can place a substantial strain on the thoracoscapular musculature. Adult patients have great difficulty adapting to positions of greater than 45 degrees of abduction. Hyperabduction at the arthrodesis site causes significant winging of the scapula for the arm to drop to the patient's side. Indeed, in some patients the arm will not approximate the trunk if the shoulder has been arthrodesed in too much abduction. Women in particular are unhappy with the cosmetic appearance of a shoulder that has been fused in too much abduction owing to the significant prominence of the scapula that is created when the arm is adducted.

Fusion of the shoulder in too much internal rotation can occur. If this occurs, the patient cannot easily bring his or her hand to the mouth and cannot reach either his or her front or back pocket. Rotational osteotomy of the humerus may be necessary for patients whose extremities have been positioned in too much internal rotation.[54] I have performed three such osteotomies for this indication. Suprascapular nerve entrapment has been reported following glenohumeral arthrodesis.[58]

Prominence of the Internal Fixation Device

Many patients who have had internal fixation devices applied over the spine of the scapula have significant skin tenderness in the area of the appliance. This can be particularly troublesome when the patient must wear a prosthetic harness, and skin irritation and ulceration has been reported.[44] Cofield and Briggs[11] report a significant incidence of tenderness over the internal fixation device, which required its removal in 17 of their patients. My experience has been similar, although use of a malleable reconstruction plate has decreased skin tenderness and made the need for removal of internal fixation less frequent.[45] The development of appliances specifically designed for glenohumeral arthrodesis is likely to decrease the incidence of tenderness of the skin overlying internal fixation devices even further.

Fracture of the Humerus

Fracture of the humerus at the distal end of the internal fixation device is sufficiently common that the AO group has recommended prophylactic bone grafting of this area.[37] Cofield and Briggs[11] report a fracture in the fused extremity occurring in 10 of their 71 patients. This complication has occurred in our series as well in association with significant trauma to the arthrodesed shoulder. If an unstable fracture does occur at the end of the internal fixation device, I advocate removal of the device together with internal fixation of the fracture if the arthrodesis has solidly healed. If the fracture is relatively undisplaced, it can be treated by closed means, but in our experience this is uncommon (Fig. 21-27).

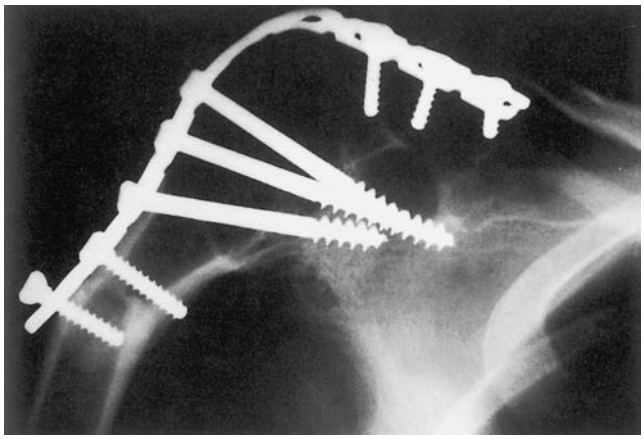

Figure 21-27 Fracture of the humerus at the end of the plate. This particular patient had a solid glenohumeral arthrodesis when he fell onto his arthrodesed arm. The fracture is minimally displaced in this case and can be treated nonoperatively, unless further displacement were to occur.

SUMMARY

Glenohumeral arthrodesis remains an important procedure that should be part of every shoulder surgeon's armamentarium. The procedure is indicated for patients with paralytic disorders, those who require en bloc resection of their glenohumeral joint together with the rotator cuff or deltoid for tumor, and those whose shoulder joints have been destroyed by septic arthritis. The procedure has been useful in a few patients with failed total shoulder arthroplasties and shoulder instability. It is rarely indicated for patients with rotator cuff tears, periarticular malunions, osteoarthritis, or rheumatoid arthritis.

Although a variety of different positions for glenohumeral arthrodesis has been advocated in the literature, my recommendation is a position of 30-degrees abduction (measured clinically), 30-degrees flexion, and 30-degrees internal rotation. This position brings the hand to the midline anteriorly so that, with elbow flexion, the patient can reach his or her mouth. With the shoulder fused in this position the arm drops comfortably to the side. I recommend fusion of both the acromiohumeral and glenohumeral articulations and the use of internal fixation when performing glenohumeral arthrodesis. Complications following glenohumeral arthrodesis are relatively infrequent and most can be dealt with successfully if they do occur.

The improvement in shoulder function following glenohumeral arthrodesis is dependant on the patient's preoperative shoulder function. Patients with flail shoulders experience a significant improvement in function. Patients with significant mechanical pain in the glenohumeral joint experience relief following the procedure. Glenohumeral arthrodesis does not relieve neurogenic pain and requires a significant functional adjustment on the part of patients who have had the procedure. Glenohumeral arthrodesis is primarily indicated to restore function. Bone grafting is routinely used for complex and revision procedures. The procedure is contraindicated in any patient with a progressive neurologic disorder affecting the periscapular musculature.

INTRODUCTION

History

The first replacement arthroplasty of the glenohumeral joint dates to 1893 when a French Surgeon, Pean, used a platinum and rubber implant to replace the proximal one-half of the humerus in a patient suffering from tuberculous arthritis of the shoulder.[110] The implant required removal approximately 2 years later for persistent, uncontrollable infection. Additional materials used in replacement of the proximal humerus predating the modern era of shoulder arthroplasty included fibular autografts, resurfacing grafts of fascia lata, and ivory and acrylic prostheses.[1,83,94,142]

The modern era of unconstrained shoulder arthroplasty was founded in the early 1950s, when prosthesis design

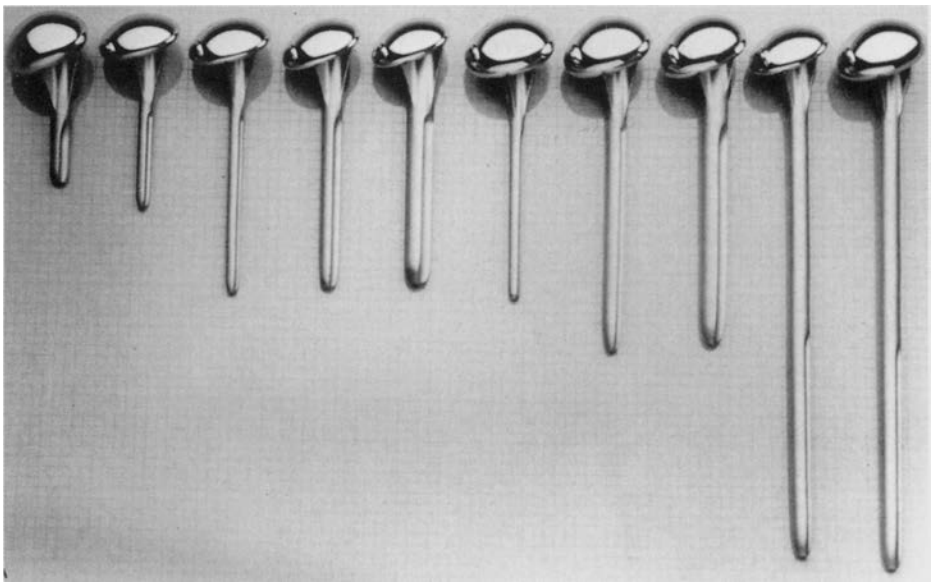

Figure 22-1 The Neer II system nonconstrained prosthetic arthroplasty system. Humeral components with two stem diameters, two neck lengths, and three stem lengths; standard polyethylene component; standard metal-backed component; revision 300% glenoid component. (From Neer CS II. Glenohumeral arthroplasty. In: Neer CS II, ed. *Shoulder reconstruction.* Philadelphia: W.B. Saunders Company, 1990:143, with permission)

sought to replicate the anatomic shape of the humeral head. The specific geometries of the earliest nonconstrained components were derived from measurements taken from cadaveric humeri.[97,128] In 1951 Krueger reported the implantation of the first anatomically designed humeral head prosthesis for a patient with aseptic necrosis.[97] The short-term results of this single surgery demonstrated promise, with relief of pain and favorable function being achieved. At the same time, Neer, being prompted by his observation of the unsatisfactory results of conventional surgical treatments for proximal humeral fracture–dislocations, was designing his first anatomic prosthesis, which was introduced in a report in 1953.[128] In 1955 Neer described the use of his second prosthesis, a redesigned vitallium humeral head replacement (Neer I prosthesis) in 12 cases, including patients with acute four-part proximal humeral fractures or proximal humeral fracture–dislocations and patients with avascular necrosis from prior fractures.[123] The short-term results in which 11 of 12 patients were free from pain provided momentum, furthering the application of humeral head replacement surgery. In 1964 Neer published a follow-up report in which the indications for the procedure expanded to include patients with degenerative arthritis of the glenohumeral joint.[129] With a follow-up ranging from 2 to 11 years, results remained favorable and supported the use of a humeral head replacement for acute trauma, posttraumatic arthritis, and both inflammatory and noninflammatory degenerative arthritis.

In the early 1970s, several authors reported on the implantation of a polyethylene glenoid component for the humeral head prosthesis to articulate with and, as such, the age of total shoulder arthroplasty arrived.[52,91,124,176] Neer designed a new humeral head prosthesis (Neer II prosthesis) for implantation with any of his glenoid component designs or as a humeral head replacement independent of a glenoid (Fig. 22-1). The Neer II system was the most widely used and reported nonconstrained shoulder replacement throughout the 70s and 80s.

Poor functional results with unconstrained prosthetic implants in certain patients with rotator cuff deficiency resulted in the development of constrained and semiconstrained devices. Constrained total shoulder arthroplasty conceptionally seemed desirable because of the inherent stability achieved at the articulating surfaces and the belief that, with the maintenance of a stable fulcrum of rotation, the deltoid would be able to assume the role of the rotator cuff in a cuff-deficient shoulder. A variety of designs were introduced, most of which used a fixed fulcrum ball-and-socket type construction (Fig. 22-2). Neer and Averill designed three constrained prosthetic systems, each with a modification to improve on the previous design.[130] In 1974 Neer abandoned the use of any constrained prosthesis because of dissatisfaction with mechanical failure.[125] Although pain relief was satisfactory in many cases of constrained total shoulder arthroplasty, these designs lost popularity owing to relatively high rates of component mechanical failure, disassembly, and loosening at the bone–implant fixation sites.[42,104,139,140]

Grammont and Baulot reintroduced the concept of constrained arthroplasty in cases of irreparable rotator cuff deficiency in the early 1990s.[71] Their design is a reverse ball-and-socket design with a relatively large glenoid sphere with no neck (Fig. 22-3). This places the center of rotation within the glenoid vault, thereby reducing the lever arm on the glenoid anchoring point.[19,71] This medialization of the center of rotation improves the deltoid moment arm and allows for improved function. Subsequent to Grammont and Baulot's prosthesis, Frankle et al. introduced a reverse ball-and-socket design with a slightly more lateralized center.[61] Early and midterm results demonstrate promising results and better survivorship than earlier constrained

Figure 22-2 A constrained total shoulder design with a reversed ball-in-socket articulation.

Figure 22-3 The Delta (Depuy, Warsaw, IN) prosthesis, introduced by Paul Grammont, is characterized as a reverse ball in socket with a relatively large metal sphere with no neck.

arthroplasties.[12,13,21,61,71,82,101,144,148,165,173] It is likely that constrained reverse prostheses will continue to have a role in the management of glenohumeral arthritis with irreparable cuff deficiency. The biomechanics, indications, and results of these prostheses are discussed in more detail elsewhere in this book.

Semiconstrained glenoid components or hooded glenoid components were designed to articulate with anatomic humeral head components for patients with rotator cuff–deficient shoulders. These glenoid components were modified with a roof-like extension or hood at the superior rim[127] (Fig. 22-4). The purpose of the hooded modification was to block superior translation of the humeral head from superiorly directed displacement forces inherent to rotator cuff deficiency. In theory, the semiconstrained design should allow the deltoid to independently achieve greater degrees of arm elevation. In the few articles that report on the use of semiconstrained prostheses, improvements in active arm elevation, if they occurred at all, were not dramatic, although pain relief was satisfactory.[29,50] The need for revision surgery and the number of complications were higher than in nonconstrained designs.[29,50,54]

Nonconstrained prostheses are the devices of choice for glenohumeral replacement with an intact and functional rotator cuff. Most arthroplasty systems utilize a stemmed humeral component in conjunction with a polyethylene glenoid component. However, humeral head resurfacing without an intramedullary stem has proponents, particularly when the glenoid is not being resurfaced.[2,57,106,108] Controversy exists with regard to the indications for glenoid resurfacing. This controversy arises predominantly as a result of the lack of well-controlled comparison data between total shoulder arthroplasty and hemiarthroplasty. Moreover, there may be a difference between hemiarthroplasties performed with stemmed implants and resurfacing arthroplasties.[161]

The topic of this chapter is replacement arthroplasty for conditions characterized by an intact or reparable rotator cuff. The two most representative conditions are osteoarthritis and avascular necrosis. Therefore, these two conditions will be considered most prominently. However, some cases of inflammatory (i.e., rheumatoid arthritis) and posttraumatic (i.e., arthritis of instability) arthritis fall under this category. The surgical technique is similar in these conditions and, therefore, is discussed all inclusively. Technical points germane to each individual diagnosis are inserted where appropriate.

Indications

In general, the indications for prosthetic replacement in osteoarthritis and avascular necrosis are similar to those

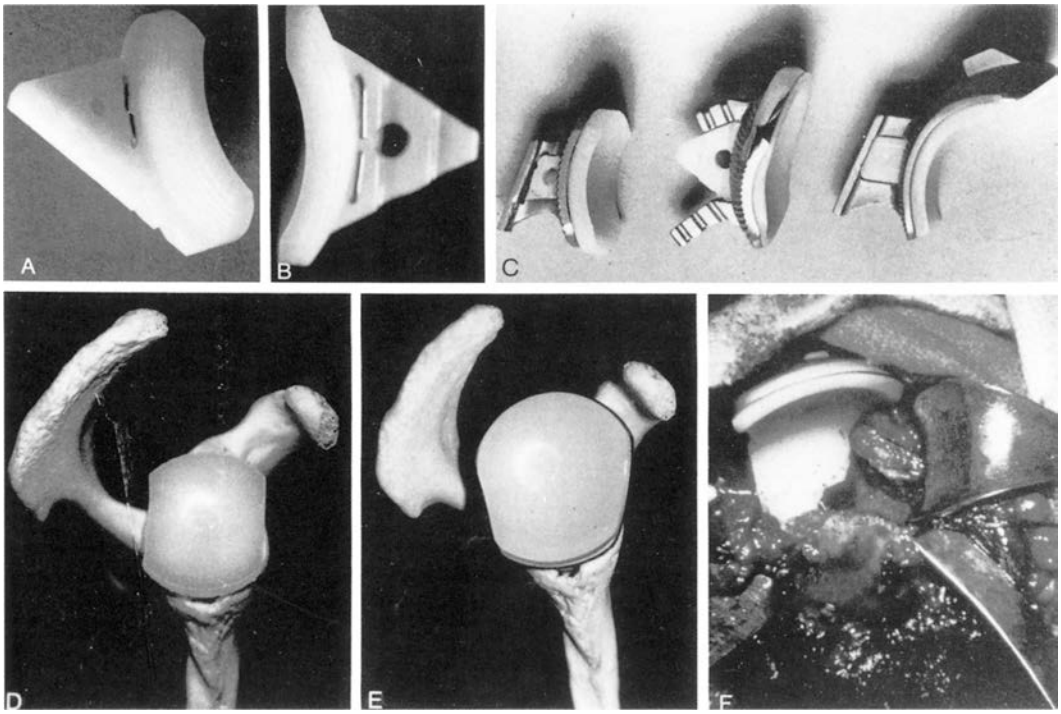

Figure 22-4 **(A)** The initial Neer glenoid component; **(B)** the modified all-polyethylene component; **(C)** the Neer initial design of the metal-backed glenoid components showing **(D)** the standard surface area glenoid; **(E)** the 200% surface area glenoid; and **(F)** the 600% surface area glenoid. (From Neer CS II. Glenohumeral arthroplasty. In: Neer CS II, ed. *Shoulder reconstruction.* Philadelphia: W.B. Saunders Company, 1990:143, with permission).

stated for the other pathologic processes discussed in this text. Severe pain that has failed to respond to conservative measures and a degree of dysfunction that is unacceptable to the patient are the primary reasons to consider arthroplasty. The average age of patients undergoing shoulder replacement is younger than those of other major joint replacements (i.e., hip and knee). Fortunately, less weight is borne by the shoulder than hips or knees. However, 15-year survival rates of 73% and 84% for hemiarthroplasty and total shoulder arthroplasty, respectively, have been reported for patients 50 years and younger.[155] Therefore, total shoulder arthroplasty is generally reserved for patients over the age of 50, while hemiarthroplasty is considered for patients younger than 50 and older than 40. These ages are only general guidelines and should be considered in addition to other variables such as activity level, degree of glenoid wear, degree of humeral head collapse, and general medical condition.

Patients 40 and younger, or older patients who are extremely physically active, with symptomatic glenohumeral arthritis with an intact rotator cuff requiring surgical intervention present a significant treatment dilemma. Prosthetic replacement puts them at high risk for multiple revisions. Other surgical options such as débridement, interposition arthroplasty, and resurfacing arthroplasty should be considered as alternatives to traditional hemiarthroplasty or total shoulder arthroplasty in these patients. These options are best presented as temporizing measures, used to provide some symptom relief and functional improvement without compromising bone stock required for future arthroplasty or other surgical options such as arthrodesis.

Little information is available regarding the longevity of resurfacing and interpositional arthroplasty. Levy and Copeland's review of their series of resurfacing arthroplasties revealed that those patients with primary osteoarthritis had the best outcome, and that only 8% required revision during the 5- to 10-year follow-up.[107] Long-term studies are needed to provide more information about the indications and life span of these prostheses. A simple treatment algorithm for osteoarthritis is shown in Fig. 22-5.

Surgical indications for patients with avascular necrosis are very similar to those for osteoarthritis. Osteonecrosis patients are generally much younger than their counterparts with osteoarthritis. However, with associated diseases such as sickle cell anemia or renal failure, their life span may be shorter. Therefore, the indications for hemiarthroplasty and total shoulder arthroplasty are based more upon the stage of avascular necrosis present, the projected life span of the patients, and the activity level of the patients, rather than their age. Stage I disease is silent and, therefore, generally does not require treatment. There is debate about whether core decompression of the humerus changes the incidence of late collapse. Obviously, if it does, stage I disease may be an

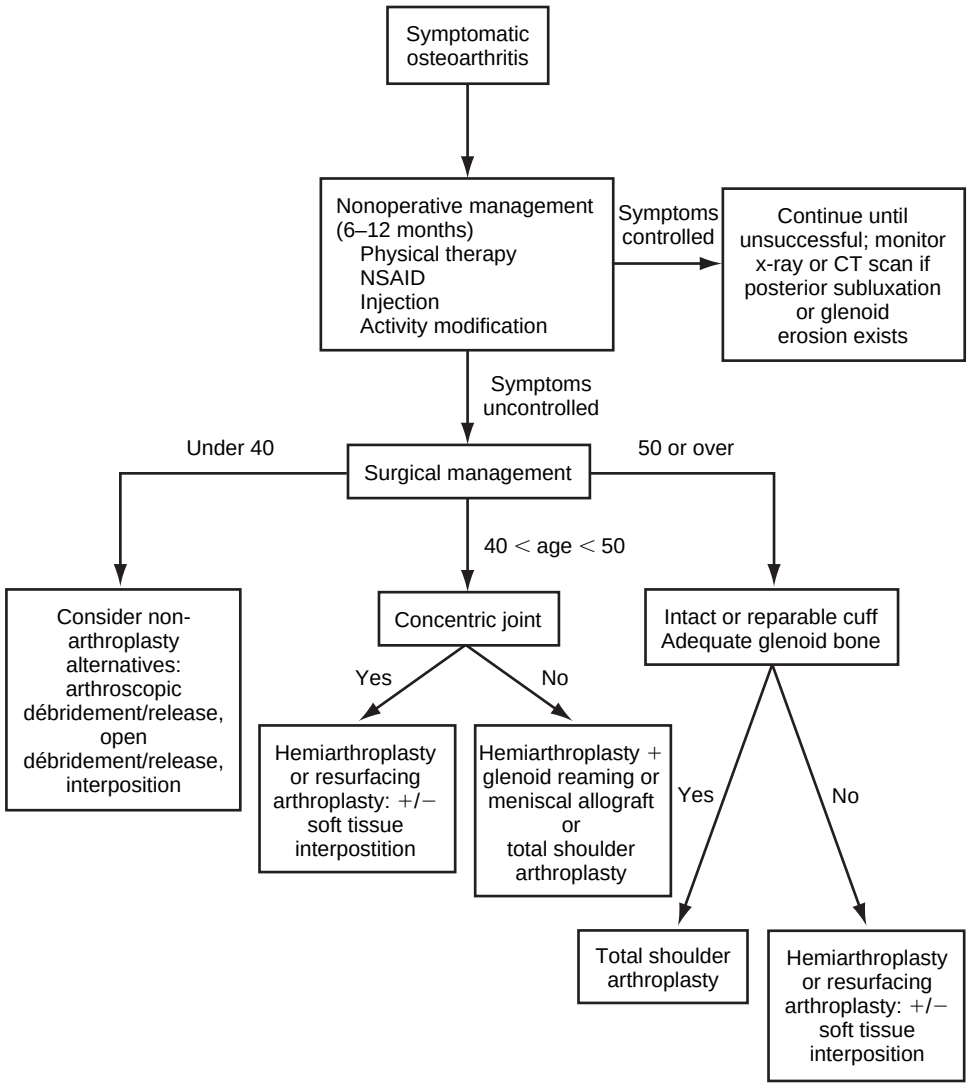

Figure 22-5 Treatment algorithm for osteoarthritis of the shoulder. CT = computed tomography; NSAID = nonsteroidal antiinflammatory drug.

indication for humeral head decompression. Until these data are available, most patients with stage I avascular necrosis are not surgical candidates. In stage II disease that does not respond to standard nonoperative treatment, core decompression with or without bone graft is indicated. Stage III (subchondral fracture) and IV (collapse) avascular necrosis may be indications for hemiarthroplasty, depending on the degree of collapse and patient activity level. Stage V osteonecrosis (glenoid involvement) is an indication for total shoulder arthroplasty so long as the cuff is intact or reparable and the activity level and life expectancy are appropriate. In active patients with a normal or near-normal life expectancy, an alternative to total shoulder arthroplasty is hemiarthroplasty with soft tissue interposition. A simple treatment algorithm for avascular necrosis is shown in Fig. 22-6.

The only absolute contraindication to prosthetic arthroplasty is active infection. Relative contraindications include concomitant rotator cuff *and* deltoid dysfunction, Charcot arthropathy, and severe brachial plexopathy.[75] Arthroplasty in patients with a remote history of infection should be approached cautiously. Although it is impossible to predict for certain the likelihood of recurrent infection, the risk is lower in patients with greater time intervals from the original infection, normal erythrocyte sedimentation rate, normal C-reactive protein, and negative cultures.

Risks of Nonoperative Treatment

The concept of risk associated with nonoperative management may not initially seem valid. However, if one assumes that a given patient with osteonecrosis or osteoarthritis will eventually require prosthetic replacement, the development or worsening of concomitant conditions known to have a negative effect on prognosis following arthroplasty is a relative risk of nonoperative treatment. Two such conditions in patients with osteoarthritis are stiffness (external rotation less than 10 degrees) and posterior subluxation.[81] Therefore, patients with osteoarthritis and mild stiffness or posterior

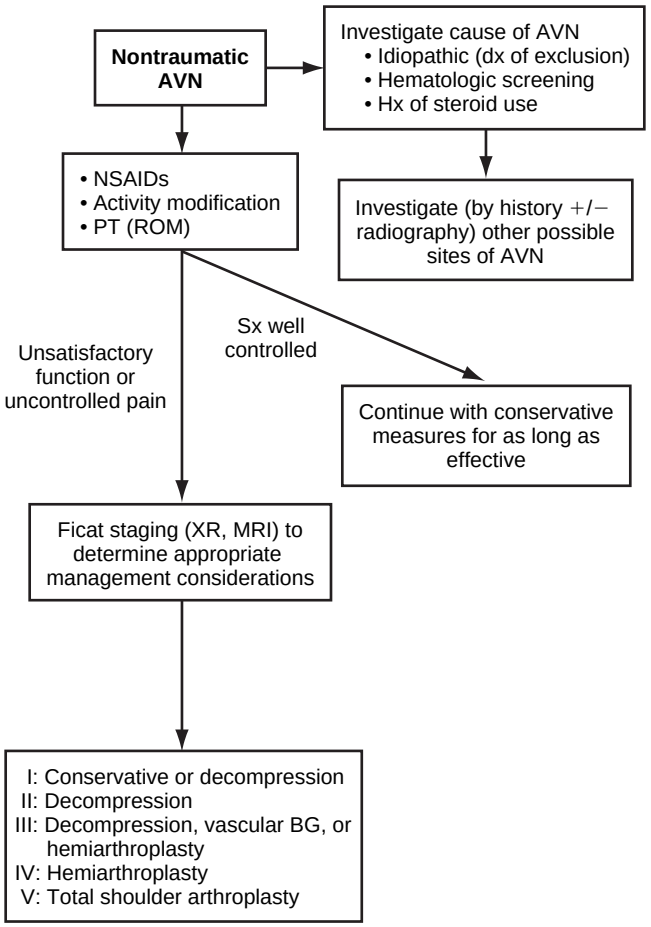

Figure 22-6 Treatment algorithm for osteonecrosis of the shoulder. AVN = avascular necrosis; MRI = magnetic resonance imaging; NSAIDs = nonsteroidal antiinflammatory drugs; PT = physical therapy; ROM = range of motion; XR = x-ray.

erosion should be counseled about the effect on prognosis of stiffness, pronounced posterior glenoid erosion, and posterior subluxation should they develop with further nonoperative management. Young patients (less than 50) with avascular necrosis should likewise be told that nonoperative management prolonged enough to develop significant glenoid involvement may subject them to the premature need for a glenoid component. Moreover, rheumatoid patients with an intact and functional cuff and good bone stock should be cautioned about the development of irreparable cuff deficiency and nonreconstructible bone loss with further nonoperative management. These treatment decisions are difficult and should be individualized; ultimately, the patient must decide between the relative risks of prosthetic replacement and nonoperative treatment.

Results

Results specific to individual diagnosis are discussed at the conclusion of this chapter. However, several comments regarding the results of shoulder arthroplasty in general deserve mention here. First, it is difficult to compare the results of shoulder arthroplasty from multiple publications and often difficult to assess the results within individual publications for several reasons. Data for pain, motion, function, patient satisfaction, and overall results have not been reported between publications with uniform methods. Factors such as method of component fixation and the status of the rotator cuff vary from report to report as well. Patients within a publication often represent a mixed group from whom the results of several diagnostic categories are tallied together and reported as a single data point. At times, results of patients receiving a humeral head replacement are not separated from patients receiving a nonconstrained total shoulder arthroplasty.

Neer et al. noted that the main factors influencing the overall results—the condition of the rotator cuff and deltoid musculature and the required details of surgery—varied depending on the diagnostic category being addressed.[127] As such, Neer et al. emphasized the importance of grouping patients to diagnostic categories when assessing the results of total shoulder arthroplasty.

Neer et al. reported their results using an overall results grading system that subdivided patients into two categories.[127] Depending on the status of the rotator cuff and deltoid musculature and the stability of the implant at the completion of surgery, patients were assigned to either a full rehabilitation category or a limited-goals rehabilitation category. A patient was assigned to a full rehabilitation category if the muscles were intact or reparable and component stability was verified intraoperatively.[127] Clinical results for full rehabilitation patients were graded as either excellent, satisfactory, or unsatisfactory, depending on the degree of patient satisfaction, pain relief, strength, and motion. An excellent result required that the patient had no pain or slight pain; had active abduction within 35 degrees of normal and 90% of normal external rotation; and was satisfied with the result. A satisfactory result was achieved if the patient had no pain, slight pain, or moderate pain only with vigorous activities; had active abduction of more than 90 degrees and 50% of normal external rotation; and was satisfied with the procedure. An unsatisfactory rating required failure to achieve any of these criteria.

A limited-goals rehabilitation category was assigned if the muscles were detached and not capable of recovering function after repair because of fixed contracture or denervation, or if the stability of the implant was judged to be problematic.[127] Clinical results for the limited-goals category were graded as either satisfactory or unsatisfactory, depending on patient satisfaction, pain relief, and restoration of limited, but useful, shoulder function. A satisfactory result required no pain, slight pain, or moderate pain only with vigorous activity, active abduction of more than 70 degrees, and external rotation of more than 20 degrees.

Pain relief is the most predictable benefit of total shoulder arthroplasty and appears to vary little between diagnostic categories. Approximately 90% of patients can be expected to attain good or excellent pain relief. When inadequate pain relief occurs, the source is often explained by an identified intraoperative or postoperative complication. More common reasons for inadequate pain relief include glenoid component loosening, malpositioning of the components, improper soft tissue balancing, rotator cuff tears, inadequate postoperative rehabilitation, and infection. In our experience it is uncommon for inadequate postoperative pain relief to lack explanation.

Range of motion has been a difficult area of assessment because only recently has a standardized system for measuring motion been recognized.[143] Assuming the arthroplasty was technically well performed, postoperative rehabilitation has been adequate, and the patient is motivated, active range of motion most directly correlates with the status of the rotator cuff and deltoid musculature. Osteoarthritis and osteonecrosis rarely have rotator cuff tears and most consistently obtain the greatest motion. Full or close to full active range of motion is not unusual postoperatively.[10,35,77,127] Gains in motion in rheumatoid arthritis patients are more variable, and several factors are likely responsible. The severity of disease varies and often affects other joints that interfere with the ability to rehabilitate the shoulder. The quality of the rotator cuff tissue is often compromised, being either atrophic or possessing tears of variable size and thickness.[35,90,119] In general, the longer the disease process persists, the more atrophic the deltoid musculature becomes and the greater the rotator cuff involvement is. Therefore, it should be anticipated that rehabilitation in rheumatoid patients will require more time.[127,131]

The functional results of nonconstrained total shoulder arthroplasty have been obtained by measuring the patient's ability to perform specific tasks of daily living. Most functional grading systems include activities that require varying degrees of forward elevation of the arm, with many being performed at waist level and fewer being performed at shoulder level or higher. Functional evaluation systems vary from report to report, making comparison between studies difficult. In the publications in which patients are separated into groups, based on diagnosis, functional scores are consistently higher in osteoarthritis than in rheumatoid arthritis. Functional scores tend to be lower for arthroplasty performed for old trauma.[9,10,127] The functional results of shoulder arthroplasty are dependent on both pain relief and gains in active range of motion. A patient who does not obtain gains in motion, but has less pain, is more inclined to use the extremity in functional activities within the range of motion available to him or her. This is especially so in patients who require only low-demand use of the extremity within limited arcs of motion. However, if significant gains in active range of motion are also achieved, the patient can participate in a broader spectrum of functional activities.

Our review of the literature yielded over 50 publications reporting the results of nonconstrained shoulder arthroplasty for glenohumeral arthritis and an intact or reparable cuff.[4–8,10,11,14,20,22,26,30,31,33–36,38,40,41,43,44,47,49,51,54,55,60,62,66,68–70,72,73,77,86,89,90,93,107–109,111,112,113,114,116–118] Reports of patients with rheumatoid or inflammatory arthritis were included, despite the fact that some of the included patients had dysfunctional or irreparable rotator cuffs. Only 10 of these reports had a minimum 5-year follow-up and, therefore, were considered at least midterm follow-up.[40,44,72,109,112,150,154,155,162,164] Only two studies had a minimum 10-year follow-up[44,156] and only five provided predicted survivorship.[26,44,112,154,155] While the data from these reports are not completely comparable, some conclusions can be made. First, shoulder arthroplasty results in predictable and durable pain relief. Second, functional results vary with rotator cuff integrity but are also predictable and durable in patients with an intact or reparable cuff. Third, rotator cuff disease continues after arthroplasty in many patients with inflammatory arthritis as evidenced by progressive proximal humeral migration.[150] Finally, survivorship varies with age and activity level but, in general, is 95% to 98% at 5 years, 93% to 97% at 10 years, 84% to 88% at 15 years, and 80% to 85% at 20 years.[44,112,155]

Plain film evaluation has shown the prevalence of glenoid radiolucent lines to range between 30% and 80% at various periods of follow-up.[10,24,35,127] However, the high prevalence of radiolucent lines has not correlated strongly with the presence of symptoms. As such, the significance of these lines remains a controversial subject. Of 46 reoperations performed at the Mayo Clinic between 1976 and 1988 addressing complications of nonconstrained total shoulder arthroplasty, 13 (28%) were for glenoid loosening.[39] As in the Mayo Clinic article, most articles report that the most common prosthetic-related complication of total shoulder arthroplasty is glenoid component loosening. The need for reoperation for this problem was summarized from 19 reports (1,413 procedures) by Brems.[23] At an average of 5 years of follow-up, radiolucent lines were present in 546 (38.6%) procedures, and in 42 (2.9%) reoperation was required for glenoid component loosening. The rate of radiolucent lines requiring revision glenoid surgery was 7.7% (42 of 546). Therefore, relatively few of these radiolucencies became symptomatic at midterm follow-up. The incidence of radiographic evidence of glenoid component loosening appears to increase with longer periods of follow-up.[27,163]

PREOPERATIVE EVALUATION

History

Patients with primary osteoarthritis typically present with an insidious onset of pain, which has been slowly progressive over past years. Progressive stiffness is often associated with the discomfort. As is the case in other arthritic joints, the

pain is often activity-related. Stiffness is most notable after a period of immobilization, and improves with gentle motion.

Patients' complaints will often relate to functional limitations such as difficulty internally rotating to reach their back pocket or fastening a brassiere. Questioning patients as to how their symptoms have interfered with their daily routines will provide insight into the degree of pain and disability. Understanding the patients' occupation, hobbies, and activity levels also helps gauge the impact of their disease. Documentation of treatments that have been or are being used also gives information about disease course and severity.

Awareness of the patients' profile of comorbidities is important not only for presurgical screening, but also as a means of evaluating what other conditions might limit activity and rehabilitation.

Patients suspected of having avascular necrosis should also be questioned regarding the onset, course, severity, and impact of their symptoms as this is valuable information in management decision making. Typically, these patients are younger than those presenting with osteoarthritis. Identification of risk factors can aid in determining the cause of osteonecrosis. Exposure to steroids, alcohol use/abuse, liver pathology, and personal or family history of coagulation disorders should be addressed. Careful questioning about pain in the contralateral shoulder and other joints at risk (hips, knees, ankles, etc.) is also important. Although only 3% of patients with osteonecrosis have multifocal involvement,[99,100] 80% of patients with multifocal osteonecrosis will have humeral head involvement.[99]

Physical Examination

A complete shoulder examination should be performed with particular attention to range of motion. Typically, both osteoarthritis and avascular necrosis cause progressive global loss of motion, with particular loss of external rotation. Postcapsulorrhaphy often has the most severe loss of external rotation. Any internal rotation contracture must be noted and documented as it dictates how the subscapularis release is managed at the time of surgery. Active and passive motion should be compared and the rotator cuff strength noted. This can sometimes be difficult to determine on physical examination alone, as there is often pain-related weakness. Painful crepitus is common. Tenderness to palpation over the acromioclavicular joint can indicate arthritis, which potentially can contribute to the symptom complex. This is an important finding to identify as it can also be addressed at the time of surgery if needed.

Imaging Studies

Plain radiographs are the single most important investigation required in the diagnosis of osteoarthritis and arthroplasty planning. A standard x-ray series (anteroposterior [AP], transscapular lateral, and axillary lateral) is typically performed, and each provides different information required for preoperative preparation. The AP x-ray, which often is done in internal and external rotation, allows assessment of bone quality, identification of inferior osteophytes, and diameter of the humeral canal. Preoperative templating is performed using the AP and axillary views. Also, although not universally reliable because of slight variations in angle-of-beam projection, evaluation of the acromiohumeral distance can suggest the presence of significant rotator cuff deficiency if the distance measures less than 7 mm. The axillary radiograph is useful in identifying glenoid version as well as the posterior glenoid wear and resultant posterior subluxation that is often associated with osteoarthritis (Fig. 22-7).

Figure 22-7 Axillary radiograph revealing posterior glenoid erosion associated with posterior subluxation that is commonly seen in osteoarthritis.

A computed tomography (CT) scan provides a more definitive assessment of glenoid bone stock and version. It also allows accurate determination of whether glenoid replacement is feasible and if bone grafting may be necessary (Fig. 22-8). One radiographic study of a series of patients with primary glenohumeral osteoarthritis who were awaiting shoulder arthroplasty found that 45% have posterior subluxation.[167] Average glenoid retroversion in this population was found to be 15.4 degrees (normal being 1 to 2 degrees of retroversion).[63] Humeral version can also be accurately determined from CT pictures of the humeral head and its relation to the transcondylar axis.[78] Since posterior glenoid erosion and posterior subluxation are common with severe internal rotation contracture, CT scanning is ordered in all patients with external rotation of 30 degrees or less.

Magnetic resonance imaging (MRI) may be useful in cases of suspected rotator cuff tear. In general, full-thickness rotator cuff tears are exceedingly uncommon in patients with osteoarthritis or osteonecrosis (5%). However, in patients who have had prior rotator cuff surgery or demonstrate a decreased acromiohumeral distance on plain radiography,

Figure 22-8 Computed tomographic scanning can be used to quantitate the amount of posterior glenoid deficiency and posterior subluxation.

rotator cuff tears may be more common. Under these circumstances, MRI scanning can reveal glenoid erosion, abnormal glenoid version, and full-thickness rotator cuff tears.

MRI is also useful in staging avascular necrosis. Moreover, avascular necrosis in certain disease states, such as renal failure, may be associated with rotator cuff deficiency. Therefore, MRI scanning is performed frequently in patients with early avascular necrosis, particularly when it is associated with renal failure.

Implant Choices

When considering the humeral side, the choice of implants generally is between traditional stemmed humeral replacement and humeral head resurfacing. The advantages of traditional stemmed implants include easier glenoid exposure, greater familiarity, and a larger and longer experience. However, replacement of the humeral head with a stemmed implant requires greater bone removal, potentially more extensive exposure, and potentially a greater number of implant choices to recreate normal humeral anatomy. Humeral head resurfacing without a stemmed implant is a very reasonable option in patients with adequate bone stock, a concentric or minimally diseased glenoid, and a need for bone preservation (i.e., a young patient with high likelihood for revision). Although glenoid resurfacing is possible without removing the head, it is more difficult than with the head removed. The results of humeral head resurfacing are promising but sparse. Levy and Copeland's review of their series of resurfacing arthroplasties revealed that those patients with primary osteoarthritis had the best outcome, and that only 8% required revision during the 5- to 10-year follow-up.[107]

Stemmed humeral head replacements are the most popular humeral implants for shoulder replacement, particularly when the glenoid is also being resurfaced. There are many stemmed humeral implants available and none has been shown to be superior to others with regard to clinical outcome. Principles that have gained in popularity and have some basis in scientific evidence include humeral head modularity, humeral head offset, and anatomic reconstruction.[18,56,80,136]

There is a large variety of glenoid replacement prostheses also available for shoulder arthroplasty. These include all-polyethylene designs, metal-backed designs, and hybrid designs with metal peg sleeves but no metal backing. There is also variability with regard to articular conformity and constraint. There is some evidence to show that arthroplasties characterized by nonconforming radii of curvature yield more physiologic translations and exhibit lower loosening scores than conforming designs.[88,168] However, more data are necessary to confirm this. At the very least, the surgeon should be familiar with the conformity characteristics of the glenoid being used so that excessive contact stresses are not created.

SURGICAL APPROACHES

This section will discuss the preferred surgical approach, anesthesia, patient positioning, surgical technique, and implant considerations for shoulder arthroplasty, with particular emphasis on considerations specific to osteoarthritis, avascular necrosis, and other conditions characterized by an intact or reparable rotator cuff.

Preferred Approach

Shoulder arthroplasty is a demanding surgical procedure, the outcome of which is at least partially the result of balancing the concepts of surgical exposure and preservation of soft tissues. Several surgical exposures have been described for shoulder replacement, including superior acromial splitting, superior deltoid reflecting, anterior deltoid reflecting (with and without clavicular osteotomy), posterolateral posterior cuff reflecting, superolateral deltoid reflecting, and anterior deltopectoral deltoid-sparing approaches.[46,65,87,95,98,124,127,141] The deltoid-reflecting approaches offer superior exposure at the expense of potential deltoid morbidity or osteotomy nonunion. Fortunately, in cases of primary osteoarthritis and nontraumatic avascular necrosis, virtually every reconstructive situation encountered can be adequately performed through the deltopectoral approach described and popularized by Neer, without detaching the deltoid origin or insertion. This is even true in cases of osteoarthritis requiring posterior glenoid bone grafting. Therefore, our preferred approach for primary osteoarthritis, nontraumatic avascular necrosis, and other conditions with an intact or reparable cuff is an extended deltopectoral approach.[124,127]

Disease-Specific Considerations

Preoperative Planning

Prior to surgery, several important planning steps should be undertaken to ensure smooth execution of the surgical plan. Any medical comorbidities should be optimally treated, and medical clearance, if indicated, should be obtained. In addition, medical consultation to assist in perioperative medical management of conditions such as sickle cell anemia, renal failure, and diabetes mellitus should be sought. Orders should be written and arrangements made for perioperative antibiotic prophylaxis. A first-generation cephalosporin is generally the agent of choice as it covers the usual skin contaminants.[45,53,74,96,137,146,157] Vancomycin or clindamycin is commonly used in the face of a penicillin allergy.

Controversy exists with regard to the usefulness of preoperative templating of radiographs. With the popularity of modular systems and offset humeral heads, templating affords the surgeon a reasonably accurate assessment of the size of the implants needed at surgery and whether or not an offset or centered humeral head will be necessary. In addition, having a good idea of the size of the humeral canal prior to surgery may prevent inadvertent perforation because of a misaligned reamer. For instance, if the preoperative templating revealed a 12-mm humeral canal but the surgeon is having difficulty getting an 8-mm reamer to pass into the canal, it is likely that the entry point is inaccurate and the reamer is in valgus, or more likely, varus.

Anesthesia and Patient Positioning

Anesthetic options for shoulder arthroplasty include general anesthesia, regional anesthesia (i.e., interscalene block), or a combination of general anesthesia and an interscalene block. Each of these choices has advantages and disadvantages; the choice of anesthetic method is always left to the patient after a thorough discussion with the anesthesiologist, who usually obtains a separate informed consent for the anesthetic portion of the procedure. Interscalene block, in the hands of an experienced anesthesiologist, is safe and provides muscle relaxation as well as intra- and postoperative pain relief to facilitate early postoperative motion.[28,158] The block also reduces the depth of general anesthetic required (when used in combination with general anesthesia), thus diminishing anesthesia-related morbidity.[28,158] However, the use of an interscalene block may result in added preoperative induction time and increased risk of neurologic, pulmonary, and vascular complications.[16,138,170,171] Using a combination of general anesthesia and an interscalene block combines the advantages of both methods, namely, excluding interactions with the patient during surgery and prolonged postoperative pain control. For these reasons, a combination of anesthetic methods is often used.

Following induction of anesthesia, the patient is placed in the beach-chair position, with the torso at approximately 45 degrees to the horizontal. The head and body should be stabilized and all pressure points padded appropriately. The affected arm should be free enough to be placed into a fully extended and adducted position (to allow dislocation of the humeral head) without restriction by the bed or positioning devices (Fig. 22-9). Once the patient has been positioned as desired, a final review of passive range of motion should be noted (especially external rotation) with the patient under anesthesia. The entire shoulder and upper extremity is sterilely prepped, and an impermeable stocking is placed over the hand. Draping should allow access to the medial clavicle proximally and to the wrist distally.

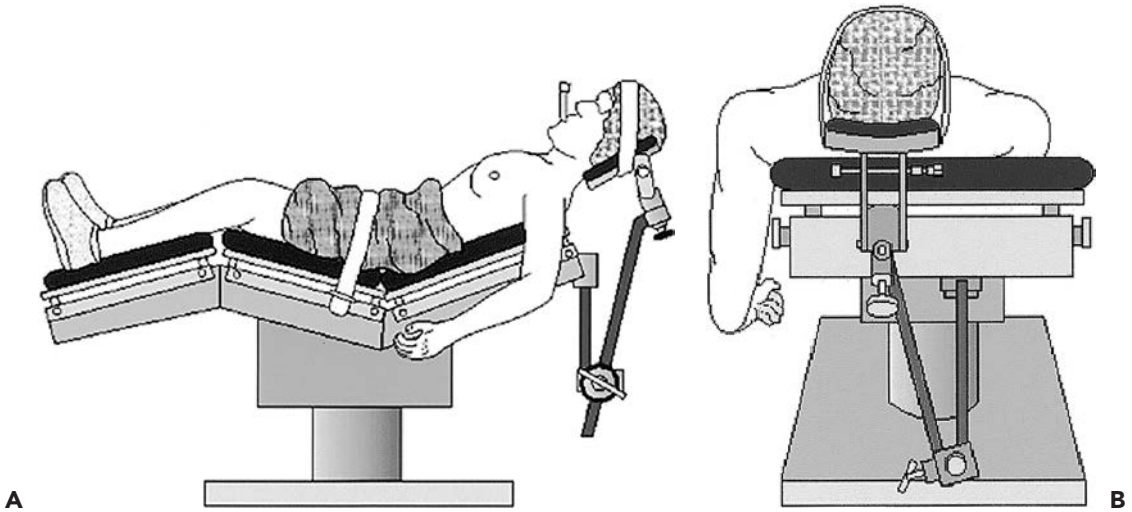

Figure 22-9 Total shoulder arthroplasty requires that the patient be placed in a beach-chair position **(A)** with the operative shoulder completely off the edge of the table to allow adduction and extension **(B).**

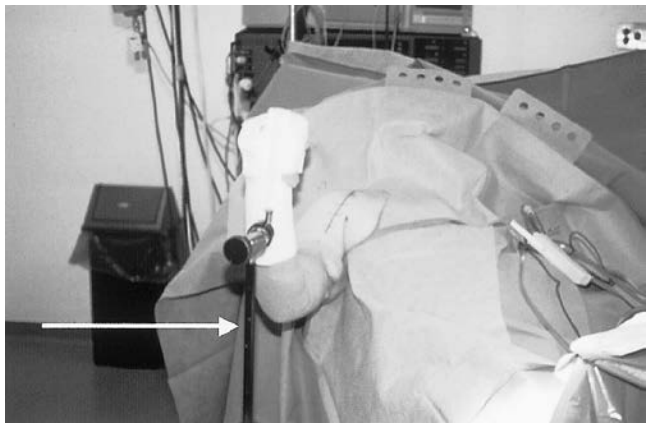

Figure 22-10 A sterile, mechanical arm-holding device makes arm positioning very convenient. (From McConnell Arm Holder, Ft. Worth, TX.)

Several portions of a shoulder arthroplasty procedure require the arm to be held or supported. This can be done using an assistant, a padded Mayo stand, or a mechanical arm-holding device. The latter can be very useful, as it consists of an articulated extension that is sterile and can attach to the arm via a sterile, disposable arm sleeve. This construct attaches to a universal ball joint that is suspended from the operating table. A foot peddle releases the ball joint and allows optimal arm positioning; when this position has been reached, the peddle is released and the arm stays in the previously selected position (Fig. 22-10). Even with this articulated arm holder, shoulder arthroplasty is easiest when performed with a knowledgeable assistant and scrub technician.

Incision and Superficial Exposure

The deltopectoral approach begins with a skin incision approximately 10 to 15 cm long, beginning at the clavicle just superior and medial to the tip of the coracoid and extending distally along the estimated location of the deltopectoral groove. When the arm is placed in approximately 30 to 40 degrees of abduction, this should be a straight incision (Fig. 22-11).

Subcutaneous fat is split in line with the incision and the cephalic vein is identified, serving as a landmark for the deltopectoral groove. The cephalic vein is a large draining tributary for the upper extremity. Therefore, its preservation seems intuitive and is supported by most shoulder surgeons. This is particularly true in patients with potential venous outflow difficulties such as those with a history of ipsilateral radical mastectomy or irradiation.

There is less consensus, however, with regard to which direction the vein should be retracted to ensure its preservation. Two general schools of thought exist. The first school bases its logic on the fact that most of the contributing branches to the cephalic vein in the brachium enter from the deltoid side. Therefore, the vein should be retracted laterally, with the deltoid. The second school correctly observes that the vein crosses the surgical field from lateral to medial in the superior portion of the wound to

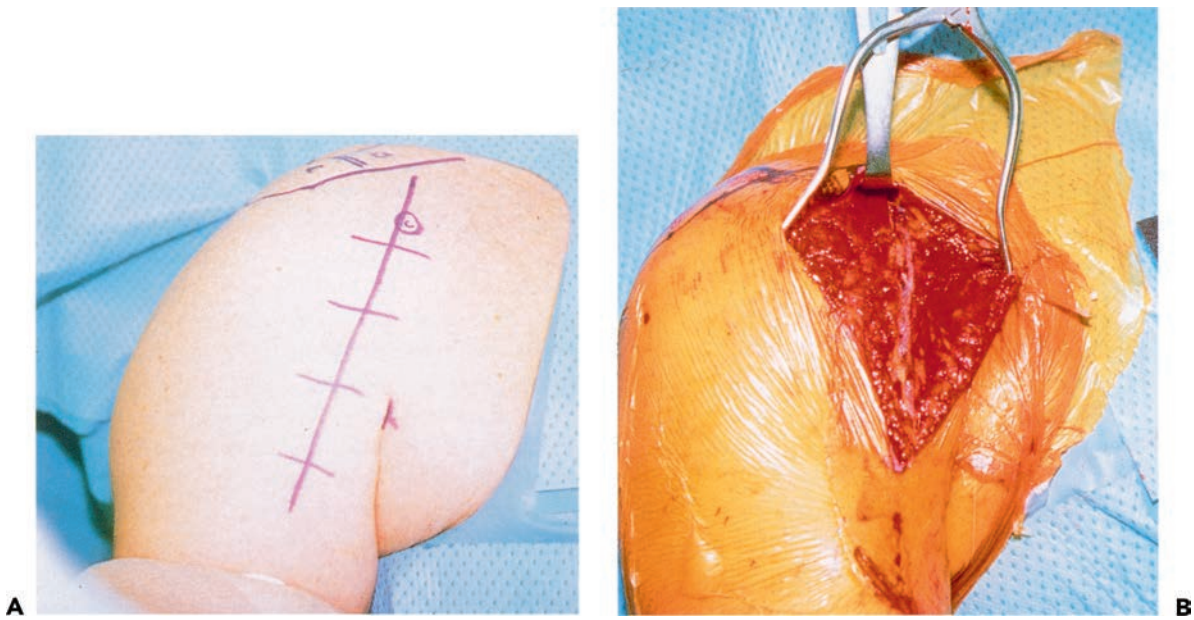

Figure 22-11 **(A)** The skin incision for a routine total shoulder arthroplasty is centered over the deltopectoral interval and the tip of the coracoid. The incision begins near the lateral third of the clavicle and extends near the deltoid tuberosity. **(B)** The cephalic vein is exposed and may be dissected medially with the pectoralis major or laterally with the deltoid. The latter technique is generally preferred.

enter the clavipectoral fascia. This course puts the vein at risk when it is retracted laterally. Consequently, disciples of the second school advocate taking the vein medially with the pectoralis major to prevent excessive traction and subsequent rupture of the vein. There is a certain amount of truth in both schools of logic. However, if one exercises atraumatic soft tissue handling and protects the vein during periods of vigorous retraction with a moist sponge, it is usually possible to retract the vein laterally and preserve it throughout the procedure (see Fig. 22-11).

The first step in gaining adequate exposure is freeing the deltoid from the pectoralis major, starting at the clavicle and extending to the deltoid insertion on the humeral shaft. The deltoid is then retracted laterally and the interval between the surgical neck of the humerus and the overlying deltoid is bluntly dissected using a Cobb elevator. Care is taken to keep the tip of the elevator on bone because the axillary nerve traverses the deep surface of the deltoid in this region. A sponge can then be used to sweep away any deltoid adhesions from the underlying humerus all the way to the deltoid tuberosity. This sponge can be left in place during the procedure, between the humerus and distal deltoid insertion, to tamponade any small bleeding vessels.

The tip of the coracoid process is next identified and the overlying pectoralis major muscle belly is separated from the conjoined tendon of the short head of the biceps and the coracobrachialis. The pectoralis major muscle belly is retracted anteriorly, away from the underlying conjoined tendon, and the tendinous insertion on the distal portion of the lateral lip of the bicipital groove is identified. The upper 1 cm of the pectoralis insertion may then be released from the humerus, if necessary, to improve exposure of the inferior portion of the humeral head and to aid in correction of any internal rotation contracture. A self-retaining retractor, such as the Koebel retractor, is placed with one limb under the deltoid laterally and one limb under the pectoralis major medially. With the deltoid and pectoralis major retracted, the deep exposure can be carried out.

Deep Exposure

The lateral edge of the conjoined tendon is identified. The associated muscle bellies of the short head of the biceps and coracobrachialis usually extend more lateral than the conjoined tendon itself. The clavipectoral fascia is incised at the most lateral extent of the conjoined tendon and associated muscles. This incision is carried distally to the level of the inferiormost extent of the subscapularis and proximally to the coracoacromial ligament. Digital palpation is used to identify the axillary nerve as it courses along the superficial surface of the subscapularis to reach the quadrilateral space at the inferior aspect of the glenohumeral joint. The musculocutaneous nerve enters the deep aspect of the conjoined tendon a variable distance from the tip of the coracoid.[58] Therefore, it cannot always be palpated within the surgical field. One should attempt to palpate it, however, because it can enter the conjoined tendon within 1.5 to 2.0 cm from the tip of the coracoid. In this position, the nerve could be injured while retracting the conjoined tendon.

The incision in the clavipectoral fascia stops superiorly at the anterior border of the coracoacromial ligament. This ligament is an important restraint to anterosuperior subluxation, especially in patients with large or massive rotator cuff tears.[59,102,151,174] Rotator cuff tears in osteoarthritis of the glenohumeral joint or in avascular necrosis are uncommon, usually small, and reparable.[48,81,124,127,132] Therefore, in theory, the coracoacromial ligament may be incised, excised, or partially excised in these cases to improve visualization of the superior glenoid. However, exposure is almost always adequate without coracoacromial ligament sacrifice. Moreover, rotator cuff tears can develop after shoulder arthroplasty. Therefore, the coracoacromial ligament can be completely preserved during shoulder arthroplasty for osteoarthritis and avascular necrosis, even if the rotator cuff is intact. In patients with inflammatory arthritis, even if the cuff is intact, the coracoacromial ligament is preserved.

Adequate visualization of the humeral head during arthroplasty requires that the humerus be completely delivered into the wound. Several important steps are necessary for this to occur. One of the earliest of these steps is clearance of any and all adhesions between the acromion and underlying rotator cuff. This is done by passing a Cobb elevator between the leading edge of the coracoacromial ligament and the supraspinatus tendon. Sharp dissection of this interval may be required in patients who have a history of prior surgery. The acromiohumeral interface can be completely freed of adhesions by sweeping the elevator over the top of the humerus. At this point, a reverse retractor, such as a modified Taylor or Brown deltoid retractor, can be placed, superior to the lateral limb of the Koebel retractor. The medial limb of the Koebel retractor is moved from the superficial side of the conjoined tendon to the deep surface. If the musculocutaneous nerve has been found to have a high penetration into the conjoined tendon, excessive pressure on the conjoined tendon should be avoided. With the conjoined tendon retracted medially and the deltoid retracted laterally, the humerus is externally rotated approximately 30 degrees and the anterior humeral circumflex vessels are clamped, cut, and tied off or coagulated.

Subscapularis and Capsular Incision

Subscapularis management is predicated on the amount of internal rotation contracture present. The goal is to restore optimal subscapularis length with the assumption that optimal function will follow. In almost all cases of primary osteoarthritis, significant loss of external rotation exists. Avascular necrosis is also characterized by joint stiffness with preferential loss of external rotation, but to a lesser degree. Postcapsulorrhaphy arthropathy often exhibits the

greatest degree of internal rotation contracture, especially if the prior surgical procedure involved subscapularis shortening (i.e., Magnuson-Stack or Putti-Platt).

When the internal rotation contracture is mild (passive external rotation is greater than 30 degrees with the arm at the side, under anesthesia), the subscapularis is incised intratendinously and repaired anatomically. Alternatively, the subscapularis can be reflected with the lesser tuberosity with subsequent bone-to-bone repair.[67] With moderate degrees of internal rotation contracture (passive external rotation of 30 degrees but not less than −30 degrees), the subscapularis is removed from the lesser tuberosity with maximum length and is advanced medially and repaired to the cut surface of the humeral osteotomy. In the most severe cases of internal rotation contracture (passive external rotation of less than −30 degrees), a coronal z-plasty of the subscapularis and capsule is performed (Fig. 22-12).

When intratendinous incision of the subscapularis is indicated, the incision is made approximately 2 cm medial to the lesser tuberosity insertion site. It starts at the superior border of the subscapularis tendon, is taken full thickness through both the tendon and the underlying capsule, and stops at the fleshy inferior one-third of the subscapularis.[92] At the superior border of the subscapularis tendon incision, the incision is taken superomedially, across the rotator interval, to the superior aspect of the base of the coracoid process. At the inferior extent of the subscapularis and capsular incision, a blunt elevator is used to develop the interval between the intact, fleshy portion of the subscapularis and the underlying anteroinferior capsule. The subscapularis is retracted distally, along with the more superficial axillary nerve. The remainder of the subscapularis and anterior capsule is released from the humerus.

An alternative approach involves osteotomy of the lesser tuberosity and reflection of the entire subscapularis.[67] Tenodesis or tenotomy of the biceps is routinely performed with lesser tuberosity osteotomy. As with the transtendinous approach, the interval between the inferior one-third of the

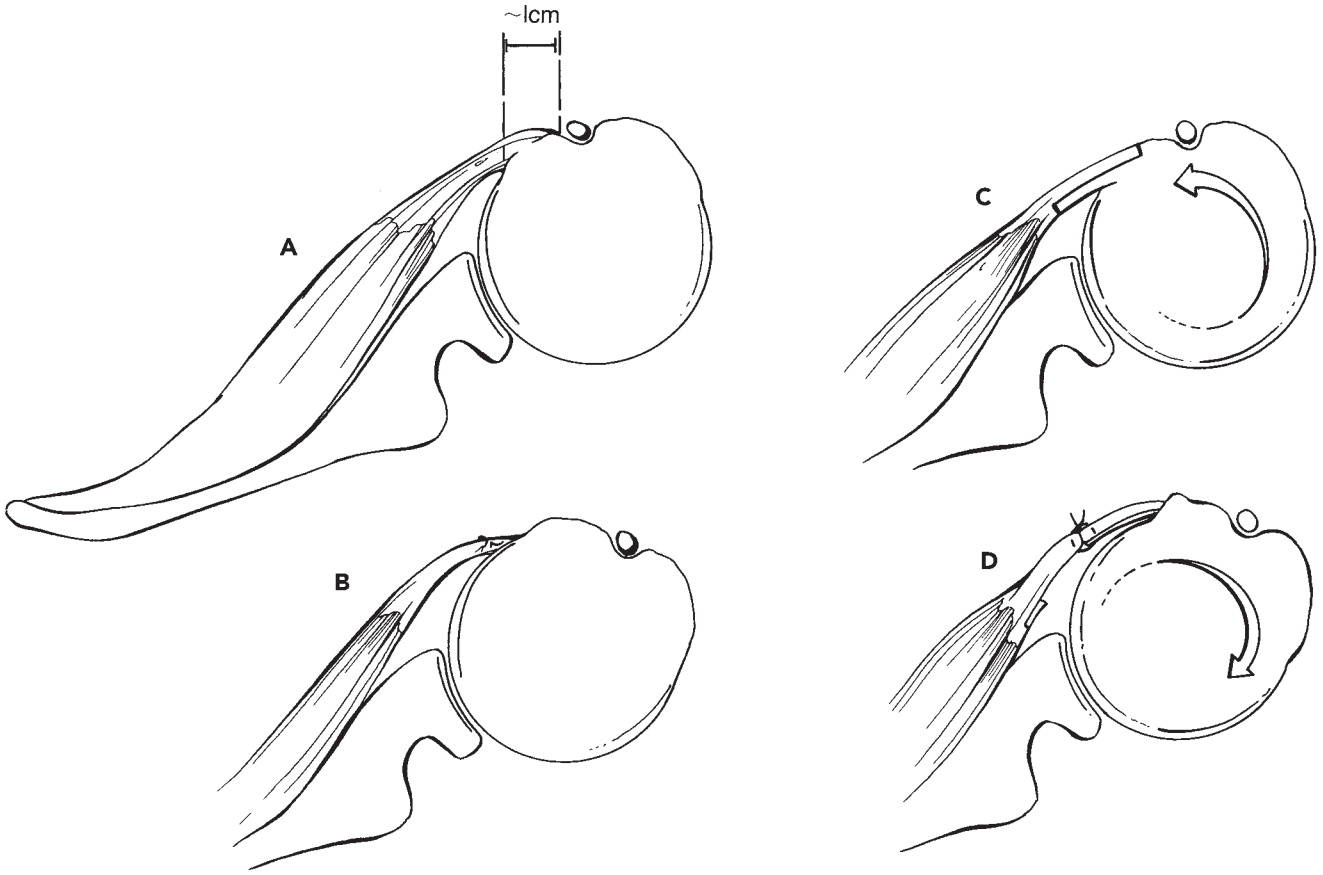

Figure 22-12 In cases with −30 degrees < external rotation <30 degrees, the subscapularis is released from the lesser tuberosity **(A)** and advanced to the osteotomy site at closure **(B),** thereby gaining approximately 1 cm of length and 30 degrees of external rotation. When preoperative external rotation <−30 degrees, a z-lengthening is performed by releasing the subscapularis from the lesser tuberosity and the capsule from the glenoid **(C),** and sliding the flaps on one another to gain appropriate length at closure **(D).** (From Iannotti JP, Schenk T. Prosthetic arthroplasty for glenohumeral arthritis and an intact or reparable rotator cuff: indications, techniques, and results. In: Iannotti JP, Williams GR, eds. *Disorders of the shoulder: Diagnosis and management*. Philadelphia: Lippincott Williams & Wilkins, 1999.)

subscapularis and the capsule can be identified, allowing complete release of the inferior capsule from the humeral neck. The potential advantages of this approach are preservation of the entire subscapularis attachment to bone, bone-to-bone healing, the ability to identify postoperative subscapularis detachment with a radiograph, and better postoperative subscapularis function.[67] The potential disadvantages include the possibility of intraoperative damage to the anterior humeral metaphysis during posterior humeral retraction and lesser tuberosity nonunion. It is tempting to consider a lesser tuberosity osteotomy in all cases, even those with substantial internal rotation contracture. However, the contribution of the subscapularis to the internal rotation contracture and the principle of subscapularis lengthening may limit the usefulness of this technique in some cases.

In cases of moderate internal rotation contracture, subscapularis advancement is indicated. The subscapularis is incised at its most lateral extent and is elevated along with the humeral capsule. At the superior subscapularis border, the rotator interval capsule is incised superomedially to the superior border of the base of the coracoid process. Inferiorly, the subscapularis and capsule are released in a single layer until the inferior one-third of the subscapularis is encountered, which is also released from the humeral insertion. This portion of the subscapularis is muscular, even at its humeral attachment site, and the interval between it and the inferior capsule can be easily identified. A blunt elevator is used to develop this interval. An electrocautery or knife is used to release the remaining subscapularis and anterior capsule.

With any of the above-mentioned methods of subscapularis and capsular release, the inferior capsule must be released to or past the 6 o'clock position. At the anteroinferior aspect of the humeral head, electrocautery is used to raise a periosteal/capsular flap that includes the upper 1 cm of the latissimus dorsi, the inferior periosteum, and the anteroinferior capsule to at least the 6 o'clock position. This can be done safely by progressively externally rotating the humerus and using a blunt Homans retractor between the inferiormost portion of the humeral head and the overlying capsule. As the incision gets close to the 6 o'clock position, the electrocautery is switched to a surgical knife to avoid inadvertent electrical injury to the axillary nerve by conduction through the metallic retractor. This inferior soft tissue release is a critical maneuver to allow not only adequate delivery of the humerus into the wound, but also adequate glenoid exposure.

Rarely is subscapularis z-lengthening required. In all instances but the most severe cases of internal rotation contracture, subscapularis advancement to the cut surface of the osteotomy is adequate. However, when z-lengthening of the subscapularis is required, the subscapularis must be elevated separately from the anterior capsule. The subscapularis is released from its attachment as far laterally as possible. As the tendon is being reflected medially, the interval between the capsule and subscapularis can be determined distally, where the inferior third of the subscapularis attachment is muscular rather than tendinous. This interval is bluntly dissected to provide the appropriate interval for dissection. The subscapularis tendon is then completely detached and reflected medially. A small portion of the tendon and muscle can be left behind on the anterior capsule for reinforcement.

With the subscapularis released and retracted medially, the capsule is released from its glenoid attachment, starting superiorly and extending to the 6 o'clock position on the glenoid. With the axillary nerve retracted, the capsule is then incised in a medial–lateral direction from the inferior glenoid margin to the humerus. This then creates a laterally based capsular flap that can be used to lengthen the subscapularis during closure. The remainder of the inferior capsule is released from the inferior humerus along with a small portion of latissimus dorsi and inferior humeral periosteum as described above.

The humerus is delivered into the wound using simultaneous adduction, external rotation, and extension. All humeral osteophytes are removed using a combination of an osteotome and rongeur. This allows the surgeon to estimate the location of the anatomic neck. Details about the humeral osteotomy and preparation are included later in this chapter.

Glenoid Exposure

Obtaining adequate glenoid exposure may be the most difficult part of total shoulder arthroplasty. Even if the glenoid is not going to be resurfaced, virtually every soft tissue release required for glenoid exposure should still be carried out to maximize postoperative range of motion following hemiarthroplasty. Therefore, the integral maneuvers for total shoulder arthroplasty[32] and hemiarthroplasty are the same.

There are five basic requirements for adequate glenoid exposure, all of which are within the control of the surgeon or surgical team: adequate muscular paralysis, adequate humeral bone resection, proper arm positioning, appropriate soft tissue contracture releases, and proper glenoid retractors. Each of these requirements is important. However, their importance is even more magnified in certain patients. Glenoid exposure is easiest in thin, small patients in whom there is little tissue between the skin and the glenoid. In more massive patients, particularly muscular males, glenoid exposure can be extremely challenging and all of the above-mentioned "requirements" take on added importance.

The easiest factor to control is muscular paralysis. If an interscalene block has been used, this alone can produce excellent muscular relaxation. However, in cases where a general anesthetic alone has been used or in cases where muscular relaxation from an interscalene block is not sufficient, muscular paralysis can be obtained by the anesthesiologist using various paralyzing agents. The degree of paralysis can be followed using a twitch monitor.

Failure to resect enough humeral bone may also lead to difficulties in glenoid exposure. In cases where a traditional stemmed humeral implant has been chosen, the line of humeral head resection should approximate the original anatomic neck. The rotator cuff attachment marks the most lateral or distal extent of potential bone resection. It is important to note that the cuff attachment is closer to the anatomic neck in the region of the supraspinatus insertion than it is in the infraspinatus and teres minor regions. Therefore, even if the most superior extent of the osteotomy is flush with the supraspinatus insertion, there will still be a small amount of bone remaining between the osteotomy and the infraspinatus and teres minor insertion sites. There is usually very little bone (2 to 3 mm at most) between the normal anatomic neck and the anteriormost fibers of the supraspinatus. The osteotomy should be made so that it exits at or very close to (within 5 mm) the anterior supraspinatus insertion site. Even 5 mm of extra bone can make a difference in glenoid exposure.

The persistence of humeral osteophytes is another source of inadequate bone resection in cases of osteoarthritis. The inferior humeral osteophyte is the largest and most obvious of the humeral osteophytes. It should be removed entirely before attempted glenoid exposure and, preferably, before humeral resection. However, osteophyte formation on the humeral head occurs circumferentially. Any bony structure that makes the humerus wider than normal will make posterior displacement of enough humerus to adequately expose the glenoid difficult. Therefore, humeral osteophytes should be excised circumferentially before attempted glenoid exposure. Care should be taken not to remove normal anterior cortex along with the anterior osteophytes, because this may lead to tuberosity fracture from the humeral head retractor.

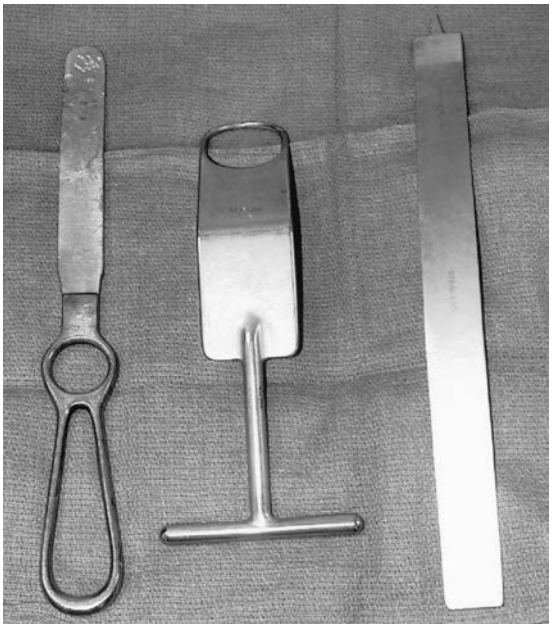
During glenoid exposure, the arm should be positioned such that the intact soft tissues will allow maximum posterior humeral displacement. Assuming that the anterior and inferior capsule has been adequately released or excised and that there are no other remaining soft tissue tethers, only the posterior and superior capsule remains. These two capsular regions are made slack by a combination of abduction, extension, and external rotation. Therefore, this is the preferred position for the arm during glenoid exposure. The arm can be held in this position using an assistant, a padded Mayo stand, or a mechanical arm-holding device.

Soft tissue releases are the most important steps in glenoid exposure. The anterior and inferior capsular regions have been released from the humeral side as far posteriorly as the 6 o'clock position during humeral exposure and preparation. The humerus is retracted posteriorly with a humeral head retractor. A small, sharp rake is used to pull the lateral aspect of the subscapularis and capsule anteriorly. A capsular incision is then made, starting at the superior glenoid near the base of the coracoid and extending to the 5 o'clock position (right shoulder). The incision is made at the capsular–labral junction and parallels the anterior glenoid rim. A periosteal elevator is passed through the capsulotomy, between the anterior scapular neck and the subscapularis muscle belly. A blunt elevator is then passed between the anteroinferior capsule at the 5:30 position (right shoulder) and the subscapularis muscle. The elevator is then replaced with a blunt Homans retractor, which is used to retract the subscapularis and protect the axillary nerve. The anteroinferior capsule is excised (if it appears thickened and pathologic) or released past the 6 o'clock position.

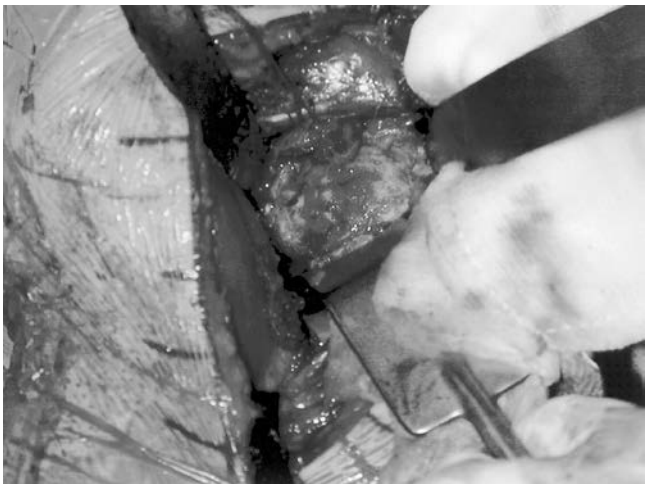
The biceps and superior capsule may also prevent posterior humeral displacement and should be palpated during attempted humeral retraction. If glenoid exposure is inadequate and the long head of the biceps becomes taught with attempted posterior humeral retraction, it is likely to be scarred or tenodesed within the bicipital groove. This is not uncommon in patients who have had prior rotator cuff surgery. Under these circumstances, the biceps should be released from the supraglenoid tubercle and the intraarticular portion should be excised. The remaining biceps can be tagged with a suture and incorporated into the rotator interval repair at the completion of the procedure. If after biceps release the superior capsule still appears to be taught, it can be released from the glenoid margin.

The last step in soft tissue releasing is labral excision. The labrum is excised circumferentially, except superiorly in the region of the biceps insertion if the biceps has not required release and subsequent tenodesis. Posterior labral excision accomplishes at least a partial release of the posterior capsule, which may aid in maximizing the amount of posterior humeral displacement. In cases of severe posterior glenoid bone loss and posterior subluxation, the posterior capsule can be spared until it becomes obvious that excessive posterior translation of the trial prosthesis does not occur. Excessive posterior translation of the prosthesis because of posterior capsular insufficiency, however, is uncommon. When there is preoperative humeral head subluxation of more than 25% of the humeral head diameter, a posterior capsulorrhaphy may be required to balance the soft tissues and maintain stability of the humeral head.

The choice of retractors and their placement are key elements in attaining good glenoid exposure. The basic retractors include a humeral head retractor (i.e., a Fukuda ring), a large Darrach retractor, and a single pronged Bankart retractor or reverse Homans retractor. The Fukuda ring retractor is placed between the humerus and glenoid, with the ring cupping the posterior glenoid rim and the T-handle of the instrument retracting the humerus posteriorly. The large Darrach retractor is placed through the anterior capsulotomy along the anterior glenoid neck, deep to the subscapularis. It is used to retract the anterior soft tissues anteriorly. When the Fukuda is being levered posteriorly and the Darrach is being levered anteriorly, there is potential for axillary nerve traction. Therefore, when using either one of



A



B

Figure 22-13 Retractors for glenoid exposure may include a Fukuda ring, large Darrach, and a single-pronged Bankart retractor **(A).** When the Fukuda ring is placed into the joint to retract the humeral posteriorly, when the large Darrach is placed on the anterior scapular neck to retract the anterior soft tissues, and when the single-pronged Bankart retractor is placed on the posterosuperior glenoid rim to retract the deltoid and posterosuperior cuff, excellent glenoid exposure is usually obtained **(B).**

these retractors vigorously, the other should be reciprocally relaxed. The final basic retractor is the single pronged Bankart retractor, which is placed posterosuperiorly, under the long head of the biceps (or in its place if it was released). A moist, folded sponge is placed between the deltoid and the Fukuda ring and Bankart retractor to protect the cephalic vein and the deltoid muscle fibers. These three retractors (the Darrach anteriorly, the Fukuda ring posteriorly, and the single pronged Bankart posterosuperiorly) are usually adequate for excellent glenoid exposure (Fig. 22-13). Occasionally, it is useful to place a fourth retractor (i.e., a reverse Homans) inferiorly. However, this is not routinely necessary. Having a variety of humeral head retractors, of different types and sizes, may also be helpful.

The two most challenging steps in glenoid preparation from the standpoint of exposure are concentric reaming of the glenoid surface and placement of drill holes for pegged glenoid designs, particularly if one of the drill holes is posterior and inferior on the glenoid surface. Concentric glenoid reamers for many implant systems are circular or make up some portion of a sphere. Often, the humeral head retractor (i.e., the Fukuda ring) interferes with seating of the reamer on the surface of the glenoid. If difficulty arises from the fact that the ring is too small to accommodate the reamer, a larger ring can be used. If this still is not satisfactory, removing the humeral head retractor entirely and using the shaft of the reamer to displace the humerus posteriorly to expose the glenoid works well. This method is used in over half of the cases in our practice. This can be done whether the reamer shaft is straight or angled, as some systems have angled reamers available. We prefer the straight reamer shaft in all cases. In addition, the reamer can be undersized by one size if the radius of curvature of the reamers in the system are the same between the reamer sizes.

Gaining adequate glenoid exposure to place posteroinferior glenoid drill holes for glenoid component pegs can be difficult. Four steps can be taken to potentially improve the situation. First, the surgeon should confirm that the five steps mentioned above have been accomplished, namely adequate muscular relaxation, adequate humeral bone resection, optimal arm positioning, complete soft tissue release, and appropriate retractor placement. Second, the Fukuda ring can temporarily be rotated so that the inferior portion is rotated posteriorly and laterally, away from the posteroinferior glenoid. Third, a blunt Homans retractor can be placed between the humerus and glenoid and used as a humeral head retractor, either with or instead of the Fukuda. We prefer to place the blunt Homans through the ring of the Fukuda so that, when the tip of the blunt Homans passes posterior to the posterior glenoid rim, the transverse component of the Fukuda ring is between the levering tip of the blunt Homans and the posterior glenoid bone (Fig. 22-14). Fourth, the humeral broach, which should be left in the humeral canal to protect against humeral injury, can be seated more deeply into the humerus so that less of the collar protrudes. One must allow enough of the collar to sit

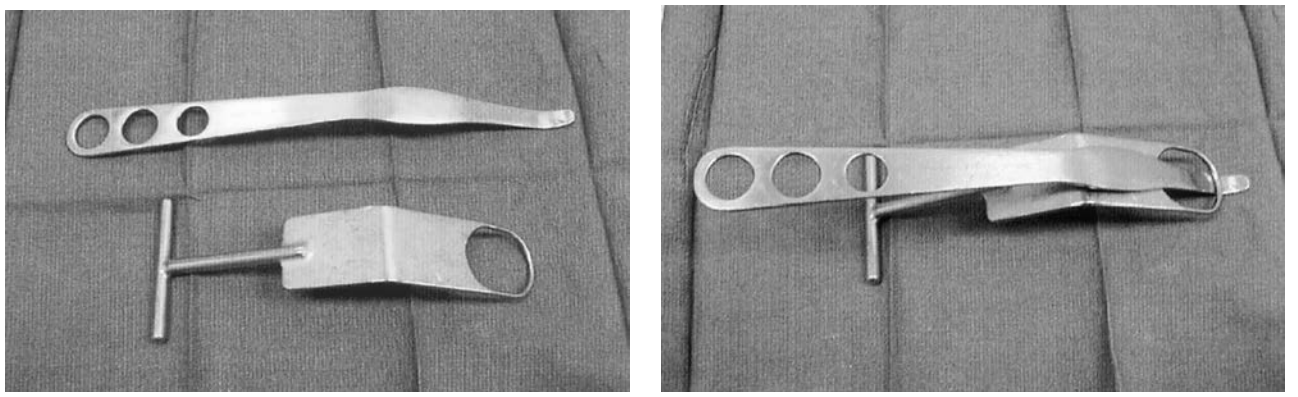


Figure 22-14 When added posterior glenoid exposure is needed, it may be accomplished by placing a blunt Homans retractor through the hole in the Fukuda ring **(A)** and onto the posterior glenoid **(B).** When the blunt Homans is levered posteriorly onto the surface of the Fukuda ring, posterior glenoid exposure is improved. Care must be taken to relax the anterior retractor simultaneous to this added posterior humeral translation to minimize axillary nerve traction.

above the humeral surface to accomplish complete seating and locking of the taper on the real implant, however. Using a combination of these four steps, one should be successful in implanting a glenoid component in all cases, assuming adequate bone exists to accept one.

Closure

The most important component of wound closure is a secure subscapularis repair. If the subscapularis was incised intratendinously, it is repaired anatomically, tendon to tendon. Even if the underlying anteroinferior capsule were pathologic and therefore excised, a portion is left attached to the deep surface of the retracted subscapularis tendon to provide a reinforcing layer to the subscapularis repair. A grasping-type suture, such as a modified Kessler, is placed in both the lateral tendon stump and the medial reflected tendon using heavy, nonabsorbable suture. Two of these sutures are placed (one superior and one inferior) within each side of the tenotomy. The sutures are then tied to one another so that the suture knot lies between the approximated tendon edges. In this way, tendon-grasping sutures are present on both sides of the repair site. Alternatively, if the subscapularis was reflected with a lesser tuberosity osteotomy, the osteotomy is approximated using two tension-band sutures that pass through the proximal humerus near and within the bicipital groove and then around the humeral stem. The two free ends of these sutures are passed through the subscapularis tendon at the tendon–bone interface.

The rotator interval is then closed laterally with an additional heavy, nonabsorbable suture, incorporating the biceps if it has been released.

If the subscapularis was released from its insertion at the lesser tuberosity because of the need for tendon lengthening, it is repaired to the anterior edge of the humeral osteotomy. This is done by placing three drill holes along the anterior humeral metaphysis, approximately 1 to 1.5 cm from the osteotomy edge. They are aligned from superior to inferior, starting at the superior margin of the lesser tuberosity, with at least 1 cm between them. Three heavy, nonabsorbable sutures are placed into the retracted edge of the subscapularis, which also contains the most lateral extent of the anterior capsule as reinforcement, using a modified Mason-Allen configuration. The most superior suture is placed approximately 1.5 to 2.0 cm inferior to the most superior edge of the tendon. This leaves adequate tendon tissue above the most superior reattaching suture to close the rotator interval laterally. The sutures are then passed through the anterior drill holes and tied over anterior bony bridges (Fig. 22-15). The rotator interval is then closed laterally using an additional

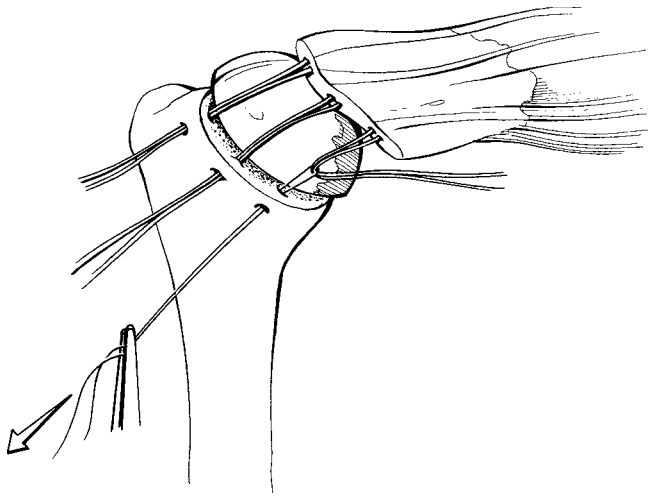

Figure 22-15 The technique for repair of the subscapularis will be dependent on the technique by which the tendon was excised. If the tendon was removed by subperiosteal dissection from the lesser tuberosity, the tendon is repaired to the osteotomy surface by transosseous sutures using 1-mm Dacron sutures. The sutures are passed through the tendon using a modified Mason-Allen or Kessler technique.

heavy, nonabsorbable suture, with incorporation of the biceps if it has been released.

The subscapularis repair is performed with a z-lengthening in cases of severe internal rotation contracture. There are two flaps of anterior soft tissue that are used to perform this repair: the medially based subscapularis tendon and the laterally based capsular flap that may contain some remaining subscapularis tendon and muscle fibers. The laterally based flap is brought deep to the medial flap and horizontally based mattress sutures are passed through the two superimposed flaps from deep to superficial. The sutures are passed so that external rotation of 45 degrees with the arm at the side is permitted without untoward tension on the sutures. The lateralmost extent of the medially based subscapularis tendon is then sutured to the underlying lateral capsular flap, more lateral than the previously placed sutures. The rotator interval is then closed laterally. All sutures are heavy, nonabsorbable sutures. The biceps is incorporated into the lateral rotator interval repair if it has been released.

The deltopectoral interval is sutured closed over a closed suction drainage system using absorbable suture. The subcutaneous tissue and skin are closed routinely with interrupted absorbable and running subcuticular monofilament suture.

Implant Considerations

The following sections will attempt to cover aspects of glenoid and humeral preparation particularly relevant to specific scenarios that might be encountered during shoulder arthroplasty for primary osteoarthritis, avascular necrosis, or other conditions with an intact or reparable cuff.

Humeral Preparation

Regardless of the type of humeral prosthesis to be implanted or the method of humeral head removal, the humerus must be completely delivered into the wound and cleared of all osteophytes. Removing the osteophytes before making any humeral cuts makes recognition of the previous anatomic neck and the rotator cuff attachment sites much easier. Therefore, the preferred first step, after dislocation of the humeral head, is removal of all humeral osteophytes.

Resurfacing Arthroplasty

In certain younger patients with a need to preserve bone for later revision or in patients in whom reaming of the intramedullary canal may not be prudent (i.e., previous osteomyelitis), humeral resurfacing, without humeral head excision, is indicated. In fact, if humeral bone stock is adequate, humeral resurfacing might be indicated in all patients undergoing hemiarthroplasty with a concentric glenoid. Although resurfacing arthroplasty has been described for both total shoulder arthroplasty and hemiarthroplasty in patients with osteoarthritis and avascular necrosis,[106] glenoid exposure is more difficult than it is when the humeral head has been resected. For this reason, we do not perform humeral resurfacing without humeral head resection during total shoulder arthroplasty. When humeral resurfacing is performed, even if the glenoid is not being resurfaced, the soft tissue releases described above for glenoid exposure may still need to be performed to maximize postoperative range of motion.

Humeral resurfacing is similar in concept to the cup arthroplasty performed for hip arthritis or avascular necrosis.[3] In humeral head resurfacing, the humeral head is retained and contoured to fit into a metallic shell using specialized contouring reamers.[106] The resurfacing arthroplasty used in our practice has five different head diameters (40 mm, 44 mm, 48 mm, 52 mm, and 56 mm) and two neck lengths with each head diameter (15 and 18 mm with the 40- and 44-mm heads and 18 and 21 mm with the 48-, 52-, and 56-mm heads). After delivering the humeral head into the wound and removing all osteophytes, the center of the head is estimated using a helmet guide and a guidewire is driven through the head at this center point and into the lateral cortex of the proximal humerus. The orientation of this guidewire is perpendicular to the plane of the anatomic neck. The appropriate head size will have been selected from preoperative templating. This size is verified intraoperatively and the appropriate reamer is chosen. The reamer is passed over the guidewire and is taken to the level of the cuff insertion. The humerus is trialed and a cruciform punch is used to cut the path for the stem. The selected head is then impacted onto the humerus in a press-fit manner. Bone graft can be placed between the humeral head and the native humerus. This implant can be used in patients with avascular necrosis so long as there is adequate live bone remaining (Fig. 22-16).

Replacement Arthroplasty

In all cases of total shoulder arthroplasty in our practice and in those cases of hemiarthroplasty in which resurfacing is not indicated, humeral preparation includes humeral head resection and reaming of the intramedullary canal. There are two basic methods of humeral head resection that are based on whether the implant used has a fixed neck–shaft angle or a variable neck–shaft angle. Most implants with a fixed neck–shaft angle employ either extramedullary or intramedullary cutting guides to assist the surgeon in making the humeral osteotomy at the appropriate angle for the prosthesis. Most variable neck–shaft angle implants encourage "free hand" resection of the humeral head, using the estimated anatomic neck or articular margin as a guide. Adaptability within the prosthesis itself will then allow the surgeon to place the humeral implant into a variety of positions.[166] In theory, this allows the surgeon to match the "normal" neck–shaft angle of the native humerus.

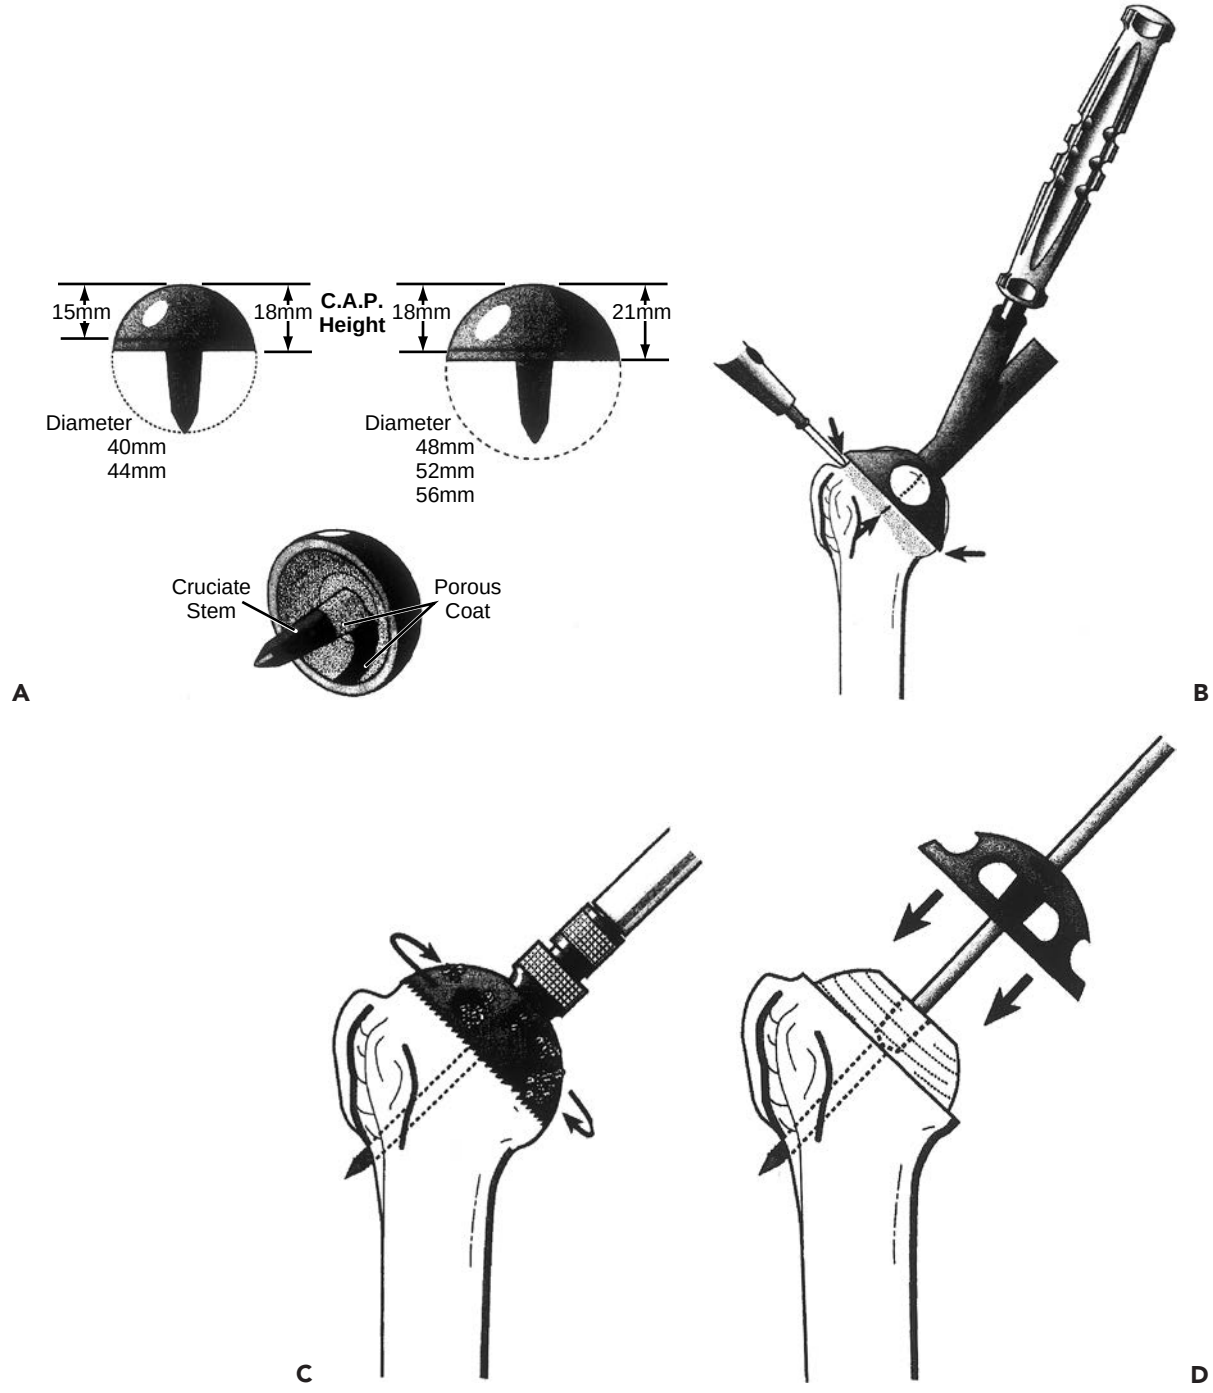

Figure 22-16 The Global CAP (Depuy, Warsaw, IN) has five head diameters with two neck lengths in each size **(A).** After osteophyte removal, humeral head size and center are selected with a helmet guide **(B)** and a guide pin is driven through the humeral head center into the lateral cortex. A reamer is then passed over the guidewire to shape the proximal humerus **(C).** The trial implant is placed and removed **(D);** the cruciform punch creates a path for the implant stem **(E)** and the guidewire is removed. The implant is then seated on the humerus **(F).**

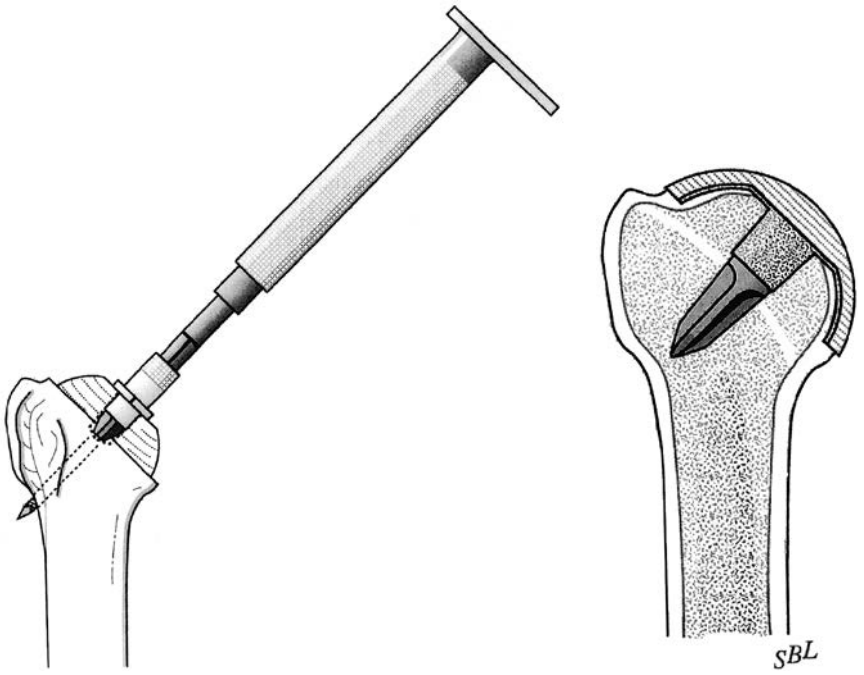
The use of humeral prostheses with variable neck–shaft angles is based on the observation that the neck–shaft angle in normal humeri is variable and that anatomic reconstruction of the articular surface is desirable.[18,80,166] The disadvantage of this approach lies in the difficulty in identifying the normal neck–shaft angle in an arthritic humerus, even if the osteophytes have been removed. In the worst-case scenario, the humerus could be cut nonanatomically and reconstructed nonanatomically because of the ability of the prostheses to adapt to many



E F **Figure 22-16** (*continued*)

neck–shaft angles, even nonanatomic ones. Although it has been shown that anatomic reconstruction of normal cadaveric humeri is more likely to occur with prostheses with variable neck–shaft angles,[134,135] the same has not been demonstrated in humeri with primary osteoarthritis or avascular necrosis. However, it seems logical that using a prosthesis with an infinite number of neck–shaft angles within a preselected range, assuming that the native neck–shaft angle can be accurately identified, may encourage anatomic humeral reconstruction. More data are necessary to prove this, however.

In many cases, recreation of the normal humeral relationships is possible with a prosthesis with a fixed neck–shaft angle and the option of an offset humeral head. If one is going to use a fixed neck–shaft angle device, the humeral cut must be accurate for the prosthesis to sit flush against the cut surface of the humeral osteotomy. Therefore, a cutting guide is desirable. In many systems, the cutting guide is an extramedullary device that sits on the external surface of the humerus (Fig. 22-17). The guide is typically visually aligned with the shaft and held in place and the anterior humeral neck is marked. This defines the entry point for the humeral cut. The direction of the cut is determined by the amount of desired retroversion. In theory, the cut should approximate the retroversion of the native anatomic neck. In practice, the retroversion of the cut can be preselected at some average fixed number (i.e., 20 degrees) determined using the guide or the distal humeral epicondylar axis, or an attempt can be made to approximate the native retroversion using the posterior cuff attachment as a guide for the exit point of the cut. In either case, one should err on the side of removing too little posterior bone. Additional bone can be removed, but if too much bone is removed initially and the posterior rotator cuff attachment has been sacrificed, the situation cannot be salvaged.

Assuming that the humeral shaft is normal (i.e., straight), intramedullary cutting guides potentially offer

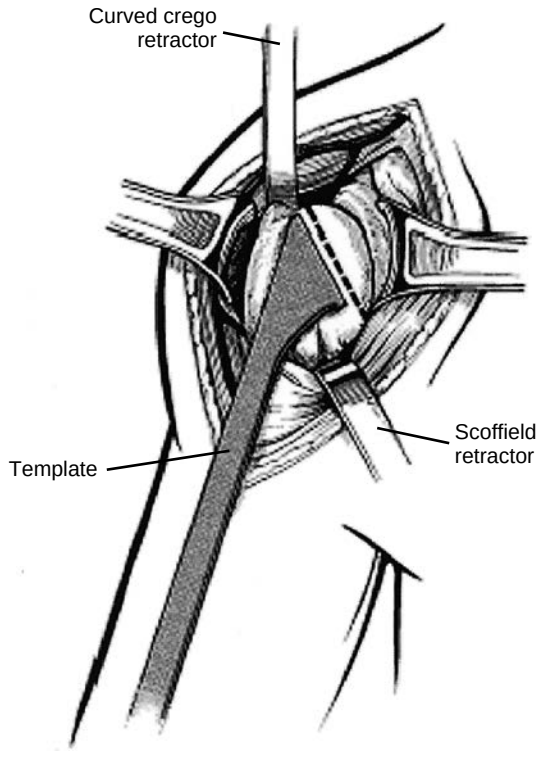


Figure 22-17 In many arthroplasty systems, an extramedullary guide is used to make the humeral osteotomy.

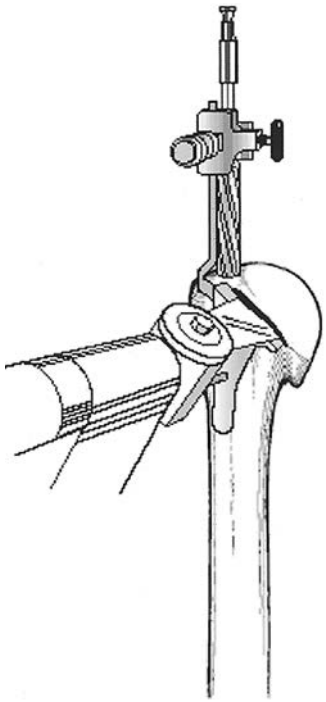

Figure 22-18 An intramedullary guide, based off the reamer, may also be used and may make a more accurate cut.

a more reproducible humeral cut. In this scenario, the humerus is reamed before the humeral cut has been performed (but after the osteophytes have been removed) and a cutting guide is attached to the reamer (Fig. 22-18). The entry point for the reamer on the superior surface of the humeral head should be the superior extension of the humeral intramedullary axis. In general, this point is approximately 1 to 1.5 cm posterior to the bicipital groove and approximately 0.5 to 1.0 cm onto the humeral articular surface. The humerus is reamed with sequentially larger reamers until the size that was estimated on the preoperative templating is reached. If there is too much resistance, even before the pretemplated size has been reached, the reamer is probably not coincident with the intramedullary axis. Under these circumstances, the surgeon removes the reamer and reams only the metaphysis with sequentially larger reamers until a reamer that is one or two sizes larger than the pretemplated reamer has been passed. Then he or she replaces the reamer that had been difficult to pass down the canal and redirect it. Overreaming the metaphysis will allow the reamer to be redirected down the shaft. If the pretemplated reamer still will not pass, the surgeon gets an intraoperative x-ray to evaluate reamer position and adjusts accordingly.

Once the final reamer has been passed, the surgeon leaves it in place. The cutting guide is then attached to the reamer. This guide will enforce the prosthetic neck–shaft angle. The height and retroversion of the guide should be such that the cut exits superiorly at the supraspinatus insertion site and posteriorly within 5 mm of the infraspinatus and teres minor attachment site. Again, one should err on removing too little bone, as more bone can always be removed. The remainder of the humeral preparation (i.e., broaching) is relatively straightforward and varies depending on the system used.

One caveat regarding humeral preparation in patients with avascular necrosis should be mentioned. The presence of hard, necrotic bone within the humeral metaphysis may make passage of the reamers and broaches difficult or even dangerous. If passage of the initial reamer is difficult, the surgeon uses a drill to make a hole in the metaphysis as large as the initial reamer, and then passes the reamers as usual. Once the humeral head has been resected, he or she is certain to remove enough of the hard, necrotic bone from the metaphyseal region to allow the footprint of the body of the broach to pass. The surgeon does not rely on the broach to compress the metaphyseal bone enough to allow complete seating. In the worst-case scenario, the increased hoop stresses resulting from the unyielding avascular bone may cause fracture of the proximal humeral metaphysis.

Glenoid Preparation

The prime decision to be made regarding glenoid preparation is whether or not the glenoid is to be resurfaced at all. In all other stages of avascular necrosis but stage V, the native glenoid surface is not diseased enough to require resurfacing. Patients with postcapsulorrhaphy are often young and quite active, making glenoid resurfacing potentially undesirable. In osteoarthritis, however, the native glenoid is abnormal in all but the earliest of stages of the disease process. The decision between hemiarthroplasty and total shoulder arthroplasty has been a controversial one, although the more recent data would support the use of a glenoid component in most cases of osteoarthritis.

Hemiarthroplasty Versus Total Shoulder Arthroplasty

Both hemiarthroplasty and total shoulder arthroplasty are considered acceptable treatment options in the face of the advanced degenerative change of osteoarthritis and osteonecrosis. Neer's initial description of prosthetic replacement for osteoarthritis included 47 hemiarthroplasties and one total shoulder arthroplasty.[124] Subsequent results of humeral head replacement at midterm follow-up have been favorable.[124,129] Some of these patients will, however, have persistent pain, and intuitively it seems that if glenoid wear is present that both sides of the joint should be addressed at the time of surgery. Recurrent or persistent pain after hemiarthroplasty is not uncommon, and it has been shown that later revision to a total shoulder arthroplasty results in symptomatic improvement and an increased range of motion.[155] In the interest of avoiding the need for a second surgery, many have tried to define what degree of glenoid involvement warrants resurfacing.

Greater technical difficulty and the increased incidence of glenoid-related complications have tempered enthusiasm for routine glenoid resurfacing in all patients.

Many reports describe the incidence of lucent lines under the glenoid, but few include exclusively osteoarthritic patients. Overall, lucent lines under the glenoid are seen radiographically in approximately 30% to 50% of patients immediately postoperatively.[68,103,145] The large majority of these lucencies, however, do not signify loosening and are not correlated with poor outcome.[35,145,172] However, there is some concern that longer follow-up will result in a correlation between lucent lines and loosening in some cases.[35,162] If "glenoid loosening" is defined as migration, dislocation, or a complete radiolucent line measuring greater than 2 mm, the overall reported rate is approximately 10% at 10 years.[10,22,79,127]

Boyd et al. compared patient satisfaction and functional improvement in patients who received either hemiarthroplasty or total shoulder arthroplasty. They found that only those patients with inflammatory arthropathy had significantly better pain relief, range of motion, and overall satisfaction with total shoulder replacement as opposed to hemiarthroplasty. They recommended hemiarthroplasty for patients with osteoarthritis and avascular necrosis, provided that they had a concentric glenoid and absent synovitis preoperatively.[22]

Iannotti and Norris reviewed[81] the results of total shoulder arthroplasty and hemiarthroplasty in 160 patients (176 shoulders) with primary osteoarthritis. The choice of hemiarthroplasty was left up to the surgeon, with no control for the degree of glenoid involvement. Patients with asymmetric glenoid wear fared better with total shoulder arthroplasty than hemiarthroplasty. In this series, patients with an intact cuff, with minimum glenoid wear, and without humeral head subluxation had statistically better results with total shoulder arthroplasty.

In Cofield et al.'s series,[40] patients with osteoarthritis who received a hemiarthroplasty were less satisfied than a group of patients with rheumatoid arthritis after the same procedure. In fact, in this series, 18% of the patients with osteoarthritis later underwent conversion to a total shoulder arthroplasty because of poor pain control. Moreover, conversion to total shoulder arthroplasty was successful in relieving pain in most patients.

In another series of patients who underwent hemiarthroplasty for osteoarthritis, Levine et al. found that satisfactory results were obtained in only 74%, and that poor outcome most significantly correlated with the degree of posterior glenoid wear.[105] These authors also concluded that hemiarthroplasty should be reserved for patients with a concentric glenoid.

More recently, Gartsman et al. randomized a group of 51 shoulders awaiting prosthetic replacement to receive either hemiarthroplasty or total shoulder arthroplasty. After an average follow-up of 35 months, no significant difference was found in shoulder scores, but they did identify that patients undergoing total shoulder arthroplasty experienced greater pain relief and had greater internal rotation. Total shoulder arthroplasty was associated with an estimated increased cost of approximately $1,177 per patient.[66] However, three of the patients who initially underwent hemiarthroplasty had inadequate pain relief requiring revision to total shoulder arthroplasty. The mean incremental cost per patient for these conversions was approximately $15,998.

Edwards and colleagues[49] compared 601 total shoulder arthroplasties with 89 hemiarthroplasties performed for primary osteoarthritis. Although improvement in pain, mobility, and activity was seen in both groups, total shoulder arthroplasty provided superior results.

Clearly, more data are needed to determine whether there is any difference in pain relief or outcome score between hemiarthroplasty and total shoulder arthroplasty in patients with osteoarthritis. However, it seems that the only reason for not replacing a diseased glenoid is the potential for greater glenoid complications. We prefer to pay extreme attention to those details that are known to affect glenoid longevity (cement technique, circumferential bony support of the glenoid component, component orientation, patient age and activity level) and resurface the glenoid in all patients of appropriate age or activity level (discussed under indications above) with adequate bone, an intact or reparable rotator cuff, and a diseased glenoid.

Technical Aspects of Glenoid Resurfacing

Many of the technical details regarding glenoid resurfacing are implant specific. However, there are two principles that are universal and will be emphasized here. These principles are normalization of glenoid version and concentric osseous support for the entire glenoid component.

Restoration of normal glenoid version, by definition, is only required when the orientation of the native glenoid is abnormal. In most cases of avascular necrosis, glenoid orientation or version is normal. However, primary osteoarthritis and postcapsulorrhaphy arthropathy are often associated with posterior glenoid deficiency, increased glenoid retroversion, and posterior humeral subluxation. When these deficiencies are not congenital in nature (i.e., Erb's palsy or congenital hypoplasia), an attempt should be made to correct them. The simplest way is to asymmetrically ream the high (anterior) side so that the remaining glenoid is concentric and oriented with proper retroversion. This can be done so long as the amount of anterior glenoid to be removed does not compromise the base of the coracoid process or the amount of bone left in the glenoid vault to accept a prosthesis. In most cases, 1 to 1.5 cm is the limit for asymmetrical reaming. Since the glenoid cavity is funnel-shaped, the more medial the surface taken is, the narrower it gets. Furthermore, as the anterior aspect of the glenoid is asymmetrically reamed, the center point of the glenoid surface will move

closer to the anterior edge. Therefore, we prefer to change glenoid version with a reamer that does not key off the center of the surface and to switch to a piloted reamer that sits in a central drill hole to fine tune the surface reaming.

In cases of posterior bone loss that is greater than 1 to 1.5 cm with respect to the anterior glenoid rim, posterior glenoid bone grafting may be necessary (Fig. 22-19). This can be estimated on preoperative CT scans or MRI scans. If the need for glenoid bone grafting is suspected on the basis of preoperative studies, asymmetrical anterior glenoid reaming should not be initially performed but may be performed after the graft is securely placed. The goal of anterior glenoid reaming is to achieve a concave surface that matches the contour of the posterior aspect of the glenoid component

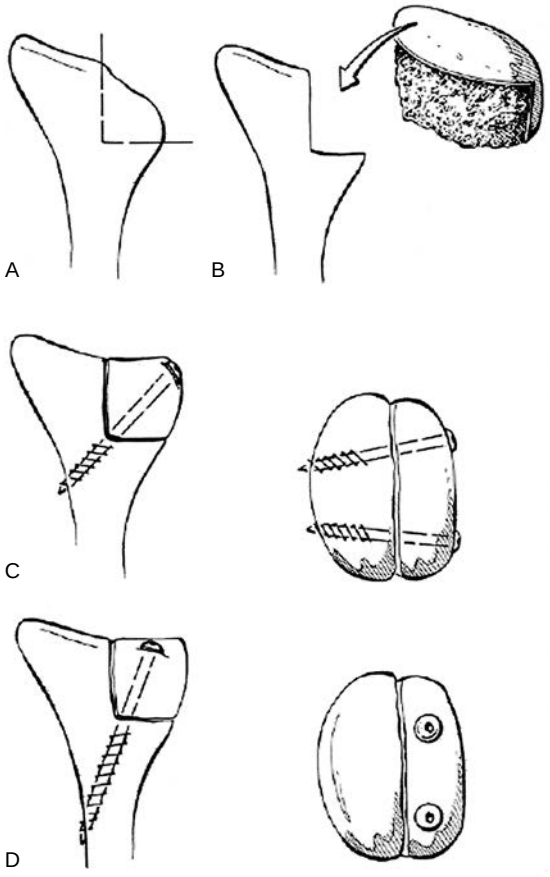

Figure 22-19 Glenoid deficiency (e.g., posterior) can be managed by creating a perpendicular surface on the native glenoid using a burr **(A)** and using a piece of the humeral head to recreate the glenoid surface in appropriate version **(B).** Screws used to hold the graft in place can be passed through the posterior edge of the graft from posterior to anterior—usually through a separate posterior stab wound **(C).** Alternatively, the screws can be passed in a more medial to lateral direction through the lateral surface of the graft **(D).** In the latter case, the screw heads should be recessed below the surface of the graft so as not to interfere with seating of the component. (From Iannotti JP, Schenk T. Prosthetic arthroplasty for glenohumeral arthritis and an intact or reparable rotator cuff: indications, techniques, and results. In: Iannotti JP, Williams GR, eds. *Disorders of the shoulder: diagnosis and management.* Philadelphia: Lippincott Williams & Wilkins, 1999.)

up to at least the midpoint of the glenoid surface. The surface of the glenoid will then be biconcave, with an anterior half in the appropriate version with a radius of curvature that matches the back of the glenoid component and a posterior half that slopes from the higher center edge to the lower posterior cortical margin. A burr is used to create a flat surface, perpendicular to the scapular axis, without removing any of the remaining posterior cortex. A graft is fashioned to fit this perpendicular surface and is provisionally held with superior and inferior peripheral K-wires. The graft is then secured with two screws countersunk so that their heads are 2 to 3 mm below the graft surface. The K-wires are then removed (Fig. 22-20).

The glenoid is then prepared to receive the glenoid component. If a keeled component is to be used, a slot is made for the glenoid keel. If a pegged design is chosen, it is important to place some, if not all, of the pegs within the bone of the native glenoid rather than the graft. A burr is used to contour the posterior bone graft to fit the back of the glenoid component. The component is then cemented into place. Other alternative methods of glenoid bone grafting have been described. The complication rate (early loosening, hardware loosening or migration, or hardware breakage) is higher with any grafting technique than with glenoid replacement without the need for bone grafting.[80,126,156]

Cemented Versus Uncemented Implants

The use of cement in the fixation of both humeral and glenoid components is also controversial. Many humeral components consist of a thin, distally tapering stem that is somewhat cylindrical, even in the proximal metaphyseal portion of the implant. Although these implants are often used successfully in a press-fit mode, reports of subsidence or loosening have surfaced.[37,155,162] It is possible that a surface coating encouraging biologic in-growth will improve the situation.[153] In addition, radiographic follow-up of press-fit prostheses that are enlarged proximally to fill the metaphysis have shown low loosening rates.[115] However, one must be careful in attempting to gain distal fixation with this implant in elderly patients with an enlarged canal because the larger the stem is, the larger the proximal body is. It is possible to encounter a situation in which the distal portion of the implant fits the shaft but the proximal portion is so large that it may fracture the metaphysis. We prefer this proximally filling implant without cement in almost all cases of primary osteoarthritis, avascular necrosis, and postcapsulorrhaphy and most cases of rheumatoid arthritis. Some rheumatoid patients have such poor bone quality that cement is necessary. The one combination that deserves caution because of difficulty in revision is the use of an implant coated with a surface to encourage biologic in-growth in the presence of cement.

The reported experience with uncemented glenoid components is much less extensive than the experience with

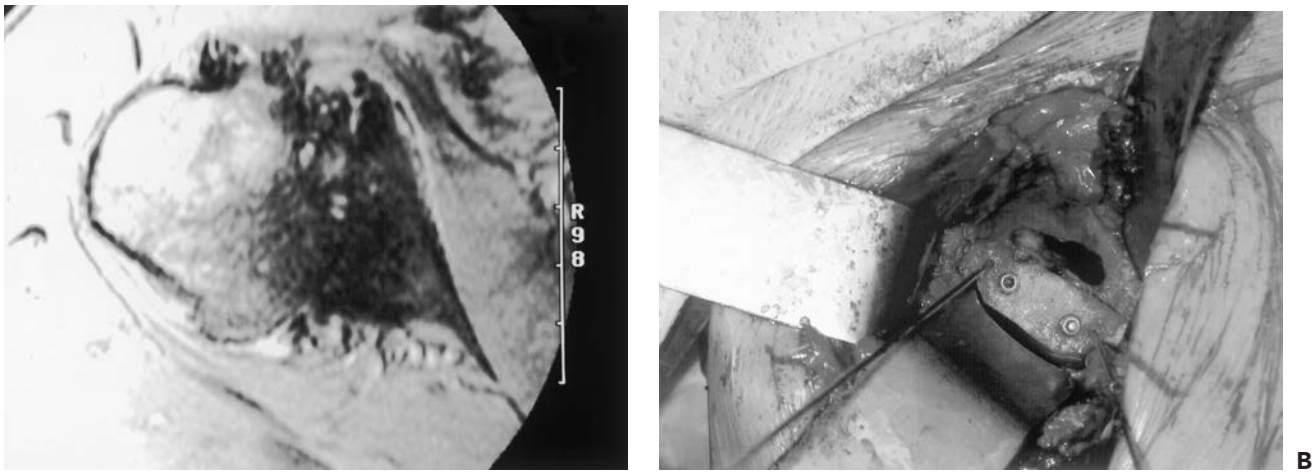

Figure 22-20 **(A)** Preoperative magnetic resonance image demonstrating greater than 1.5 cm of posterior glenoid bone loss and **(B)** intraoperative photograph with posterior bone graft in place. The K-wires will be removed and the screws countersunk before placement of the glenoid component.

uncemented humeral components.[17,34,37,38,120,153] In addition, the experience, until very recently, has not been outstanding. Cofield has the earliest and longest experience with uncemented glenoid components. His glenoid is a metal-backed component with a porous coating to encourage biologic in-growth. Early experience with this implant has been cautiously encouraging. However, concern for increased polyethylene wear and polyethylene dissociation has limited its use to patients with bone loss too severe to allow cementing of a keeled component and certain patients with intuitively good quality glenoid bone.[34,37,38,153]

A recent randomized controlled study directly compared the radiographic appearance and longevity of cemented polyethylene glenoid components and uncemented metal-backed components.[17] It was found that cemented polyethylene glenoid components have a much higher incidence of radiolucency on immediate postoperative x-rays, but that this line was rarely associated with progression and almost never a prognostic indicator. On the other hand, uncemented metal-backed components rarely have a lucency present on initial x-rays, but when they do, it usually is associated with progression and loosening. The overall incidence of loosening is higher in some metal-backed components, and thus metal-backed components are not used by most surgeons at this time.[17] However, continued research in this area is warranted because of the prospect of permanent biologic fixation.

Soft Tissue Balancing

Restoration of the proper tension in the deltoid and rotator cuff myofascial sleeves is the hallmark of shoulder arthroplasty. Only restoration of appropriate soft tissue tension and muscular length can restore optimal range of motion, strength, and function. Although restoration of normal soft tissue tension may not be possible in all cases, it should be the goal of all shoulder arthroplasties performed for avascular necrosis, primary osteoarthritis, and other conditions with an intact or reparable cuff.

The term "soft tissue balancing" is often used in shoulder arthroplasty. Tightening of tissues that are too loose is infrequently required. More often, "soft tissue balancing" requires releasing or lengthening of tissues that are too tight. Even in cases of posterior glenoid deficiency and posterior subluxation, the need for plicating loose posterior tissues is uncommon.

Assuming that the releases discussed above have been made during the surgical approach and glenoid exposure, the time to evaluate soft tissue balance is after the glenoid component has been finally fixed and before the humeral broach has been removed for the final humeral implant placement. A trial humeral head is selected based on preoperative templating, the size of the humeral head removed at surgery, and intraoperative humeral head trialing performed in the earlier portion of the procedure, prior to glenoid exposure. Once the trial head is placed on the broach, the size and humeral head offset are checked by verifying that the humeral head is centered on the humeral metaphysis, that the superior edge of the articular surface of the head meets the humerus at or slightly medial to the supraspinatus tendon–bone junction, and that the distance between the top of the humeral head and the top of the greater tuberosity is approximately 5 to 8 mm.

The humeral head center is, on average, offset posteriorly and medially with respect to the axis of the humeral shaft.[18] Since the stem of the implant or broach is centered within the shaft, a humeral head component with some offset is often required to place the head within the broach or stem and centered on the humeral metaphysis. However, there are occasions where the humeral head offset required

Figure 22-21 In some systems, it is possible to place an offset **(A)** or a centered **(B)** humeral head when needed.

is very little or none. Therefore, if one is using a system with no centered option for the humeral head, a decision must be made with regard to which direction the offset will be placed (i.e., which portion of the metaphysis will be overlapped by the humeral head component). Conversely, if the arthroplasty system has a centered option for the humeral head, it can be placed in this centered position without overlapping any portion of the metaphysis (Fig. 22-21). Alternatively, in either case, the stem can be downsized and cemented off-center within the humeral canal.

With the appropriate humeral head trial fixed to the humeral broach or trial stem in the appropriate position, the humerus is reduced into the glenoid to test for soft tissue tension. In general, the soft tissues are of adequate length if the joint can be put through a normal range of motion passively, except for external rotation, which will obviously be increased because the subscapularis is still detached. There are, however, more specific tests for soft tissue tension or length. If the soft tissues are the correct length, posterior translation of the humerus on the glenoid with the arm at the side and the humerus in neutral rotation should be approximately 50% of the width of the humeral head. Translation of the entire width of the head can also be accepted so long as the humerus returns to the glenoid spontaneously after the posteriorly directed force is removed, and the glenoid is not excessively retroverted. This should also be tested with muscular paralysis reversed, if there is any question. Adequate posterior soft tissue length can also be checked by ensuring that the hand can be brought to touch the opposite shoulder. In addition, proper soft tissue tension should allow inferior translation of one-fourth to one-half the width of the humeral head with the arm at the side in neutral rotation. The final soft tissue tension test is subscapularis length. The subscapularis should come to its projected reattachment site easily with the humerus in 45 degrees of external rotation with the arm at the side. If all of these soft tissue conditions are met, the current implants are selected and inserted.

If the soft tissues are too tight symmetrically, the joint is overstuffed relative to the soft tissue envelope, and there are three possible problems. First, the humeral cut may be wrong, with too much bone remaining. Second, the humeral head size may be too large. Third, the soft tissue releases may be inadequate. The humeral cut and soft tissue releases should be checked and corrected if needed. Inability to reseat the trial stem after the cut has been corrected could be indicative of stem malalignment, which can then be verified with intraoperative radiographs. If the proper humeral cut and adequate soft tissue releases have been verified or corrected and the joint is still too tight, the humeral head size should be decreased. Depending on the arthroplasty system used, the humeral head can be downsized by decreasing the radius of curvature, the humeral neck length, or both. Changing the neck length or head radius without correspondingly changing the other will have an effect on the surface area of the humeral head available for articulation with the glenoid. One should check to be sure that physiologic ranges of motion are possible without a nonarticular portion of the humerus hitting the glenoid surface.

If posterior and inferior translations are inadequate but subscapularis length is appropriate, an imbalance between the anterior and posterior–superior soft tissues exists, and there are two potential explanations: Either the subscapularis is too long or the posterior–superior soft tissues are too short. Again, the humeral bone cut and soft tissue releases should be checked and corrected if necessary. If the imbalance still exists, the humeral head should be downsized and the excessive subscapularis length corrected. This can be done by decreasing the amount of medialization of the attachment site to bone or by overlapping the repair. Alternatively, the excess length can be accepted with the likely resultant weakness, which is usually well tolerated. One other potential explanation of this imbalance is excessive posterior humeral head offset. Under these circumstances, the direction of the humeral head offset can be changed but may result in other unintended consequences, depending on the direction and amount of the change.

If the soft tissues are universally and symmetrically too long, the joint is too loose. Remember that, in general, it is better for a shoulder to be too loose than too tight. However, if the translation is truly excessive, it should be corrected. First, the rotator cuff attachment sites and tuberosities should be checked for inadvertent detachment or fracture. If this has not occurred, it is likely that the head size is too small. This can occur with excessive medialization of the joint line from glenoid reaming, for example. The excess laxity can be addressed by increasing the head size or lateralizing the joint line with a thicker polyethylene glenoid component, if that option is available. This is one argument for testing soft tissue tension before the glenoid has been permanently implanted. If the system used has this option and one is aware that glenoid reaming caused significant medialization of the joint line, a thicker glenoid trial can be used to test the soft tissue prior to permanent glenoid implantation.

When changing humeral head sizes to make up for either excessive joint laxity or tightness, it is important to know whether the system being used has any mismatch between the humeral head and glenoid radii of curvature. In some systems the radii are always equal; in others there is a fixed amount of offset between radii; and in still others the offset varies, depending on which combination of humeral head and glenoid is chosen. One should try to avoid having a humeral head with a larger radius of curvature than the glenoid component and having a radius of curvature of the glenoid that is larger than the humeral radius by more than 10 mm. Although some systems can allow this, a mismatch this large can cause stresses large enough to exceed the yield point of some polyethylenes.[64]

The final situation that can be encountered, although rarely, is excessive posterior translation with either appropriate subscapularis length or relative subscapularis shortening. Under either of these circumstances, the subscapularis should be checked to be sure that it is being released adequately. The two most common areas of continued soft tissue tenodesis are at the inferior border, where the inferior capsule may not have been adequately released from the glenoid, and at the superior border, at the base of the coracoid process. Both of these areas should be released completely, taking care to protect the axillary and musculocutaneous nerves. Release of adhesions on the superficial surface of the subscapularis muscle belly should not be taken farther than the lateral extent of the base of the coracoid to protect the superficially entering nerve supply.[175] In most cases, this will lengthen the subscapularis enough to allow increasing the size of the humeral head to address the posterior laxity.

If the posterior soft tissues are still too loose, there are three options. The first is to increase the humeral head size and accept less external rotation. One should not accept less than 30 degrees of external rotation. The second option is to change the offset of the humeral head posteriorly and accept the resultant changes in head position. In general, this will decrease the greater tuberosity–humeral head distance, which should not be less than 0.5 to 1.0 cm. The final option is to perform a posterior capsular plication through the joint, with the head removed.[122]

RESULTS

In general, results following shoulder arthroplasty are disease specific. The best results are in conditions with an intact or reparable cuff. Among those conditions, the order of decreasing results is nontraumatic avascular necrosis, osteoarthritis, arthritis of instability, and rheumatoid arthritis. In properly selected patients, arthroplasty for primary osteoarthritis or avascular necrosis provides dramatic relief of pain, improvement in function, and patient satisfaction. Approximately 90% of patients report complete or near-complete pain relief.[35,68,69,81,113,114,127,129,132,163] Applying literature estimation of outcome results to a population of exclusively osteoarthritic patients has been difficult in the past because most series have reported results from a mixed disease population. However, several recent case series of patients with osteoarthritis have documented significant functional improvement after arthroplasty for this indication.[55,68,70,132] The degree of postoperative functional improvement is inversely correlated to preoperative function. The degree of preoperative stiffness is correlated with the postoperative range of motion and function.[81] It has also been noted that outcome and patient satisfaction are not significantly different for those patients with repairable rotator cuff tears that received either hemiarthroplasty or total shoulder arthroplasty. The presence of a large tear or fatty infiltration of the rotator cuff is a negative prognosticator.[68,69] Overall, 95% of patients demonstrate a good to excellent outcome (pain relief, functional improvement, and patient satisfaction).[132]

The results of shoulder arthroplasty for osteonecrosis have been less frequently reported than those for osteoarthritis. The general belief is that the results are

among the best of any patients undergoing shoulder arthroplasty because of the integrity of the rotator cuff in most of these patients. This is true, with some provisos. First, assuming all other prognostic factors to be equal, arthroplasty for patients with steroid-induced osteonecrosis have better results than patients with other causes of osteonecrosis.[76] Second, glenoid changes tend to be underestimated at the time of surgery and can be associated with persistent pain and glenoid erosion in patients undergoing hemiarthroplasty.[133] Finally, patients undergoing shoulder arthroplasty may have difficulty in regaining their motion postoperatively and have lower functional scores because of this.[76] The results of arthroplasty may not be as good, relative to primary osteoarthritis, as previously thought; further work is necessary to further delineate the prognosis of patients undergoing shoulder arthroplasty for osteonecrosis.[133,147]

There are few reports specifically outlining the results of arthroplasty in patients with postcapsulorrhaphy arthritis or arthritis of instability.[15,25,72,116–118,152] When compared to other patients requiring shoulder arthroplasty, these patients are younger, predominantly male, and technically more demanding because of severe soft tissue contracture and frequent glenoid bone loss that requires substantial asymmetric reaming and bone grafting. As a result, the pain relief and return of function is not as reliable as in osteoarthritis and osteonecrosis. Moreover, there is a higher early revision rate, presumably because of glenoid-related pain in young patients undergoing hemiarthroplasty.

Inflammatory arthritis (i.e., rheumatoid arthritis) exhibits a spectrum of severity. Consequently, the functional results following arthroplasty are more variable than with osteoarthritis or avascular necrosis.[11,44,57,84,85,89,90,108,119,121,150,159,160,164,169] Patients with rheumatoid arthritis requiring shoulder arthroplasty are typically younger than patients with osteoarthritis and are also predominantly female. The choice between hemiarthroplasty and total shoulder arthroplasty is difficult because of the high incidence of rotator cuff tearing or dysfunction and glenoid erosion. Pain relief is predictable whether hemiarthroplasty, resurfacing arthroplasty, or total shoulder arthroplasty is performed. However, the functional results are less predictable because of rotator cuff deficiency. In addition, progressive proximal humeral migration following shoulder arthroplasty is common because of continued rotator cuff degeneration and superior–central glenoid bone loss.[149,150]

INTRODUCTION

The arthritic shoulder with a massive irreparable rotator cuff tear presents a unique set of surgical challenges distinct form either the massive tear or the arthritic shoulder when each present as separate pathology. Cuff-deficient shoulder arthropathy presents with severe articular and periarticular soft tissue damage. This clinical entity is an end-stage result of several diseases such as rheumatoid arthritis, rotator cuff tear arthropathy, Milwaukee shoulder syndrome, and psoriatic arthritis and posttraumatic problems associated with fracture of the tuberosities and failed prosthetic surgery. Large and massive defects in the rotator cuff tendons lead to a loss in the centering of the humeral head within the glenoid fossa and subsequently result in superior migration of the humeral head. Loss of a fixed center of rotation for the humeral head results in decreased

power of the deltoid. In addition, massive cuff deficiency leads to secondary severe damage to both the intraarticular and other extraarticular soft tissue and bony structures. The result is a painful, dysfunctional shoulder that necessitates, in many cases, a surgical procedure to decrease pain and provide better function. The lack of adequate stability provided by the rotator cuff and the defects in bone stock makes the task of replacing the damaged joint with a stable construct a difficult surgical goal. The aims of this chapter are to review the pathomechanics of this disorder, to evaluate the different treatment options, to discuss the indications for surgical treatment, and to elaborate on the different surgical options. We will establish a decision-making algorithm for the patient with a rotator cuff tear arthropathy based upon current treatment options.

PATHOMECHANICS

The glenohumeral joint lacks significant intrinsic bony stability, and thus relies largely on its soft tissue components for stability. The rotator cuff tendons provide a major contribution to the dynamic stabilization of the glenohumeral joint by creating a compressive force within the concavity of the glenoid fossa.[5,31,34,37,65] By its synchronous net inferior and compressive vector, the rotator cuff opposes the superior displacing effect of the strong deltoid muscle. The rotator cuff functions to keep the humeral head centered in the glenoid fossa throughout the movement of the shoulder.[57,70,71] The coupled compressive and inferiorly directed forces of the infraspinatus and subscapularis muscles has been shown to be a major factor in maintaining glenohumeral stability, while the contribution of supraspinatus is less significant.[35,36] A massive tear, consisting of the supraspinatus and at least one of the other rotator cuff tendons[11] (in most cases the infraspinatus), may render the rotator cuff's anterior and posterior force couple ineffective in both the vertical and the transverse planes. The result is a diminution of joint reaction force and a change in the overall direction of the joint force that leads to the superior destabilization of the glenohumeral joint.[47] In cases where the long head of biceps is still functional, it may oppose, to some extent, the superior migration of the humeral head.[35,36]

Once the proximal pull of the deltoid is left unopposed, the humeral head migrates superiorly toward the coracoacromial arch. The humeral head articulates with the coracoacromial arch superiorly and the superior glenoid rim inferiorly, leading to flattening of the superior part of the humeral head and tuberosities ("femoralization"), rounding and thinning of the coracoacromial arch ("acetabularization"), and destruction of the superior glenoid region (Fig. 23-1). This process was termed by Neer as rotator cuff tear arthropathy. The acromioclavicular joint is also frequently involved in the process, joining its intraarticular space with that of the now joined synovial intraarticular and subacromial bursae spaces. When the humeral head migrates superiorly, its fulcrum for rotation within the glenoid is lost and the deltoid has a smaller mechanical advantage, as a result of its shortened fiber length. The deltoid must therefore generate more force to perform its function.[62] The end result is an incongruous, unstable joint with a higher joint friction and superiorly malpositioned center of rotation.

Figure 23-1 This x-ray image is typical and consists of a superiorly positioned humeral head, and in the end stages of the process an "acetabularized" socket consisting of a thinned sclerotic acromion and the eroded upper glenoid fossa.

CLASSIFICATION

A pathomechanistic and pathomorphologic classification of rotator cuff–deficient arthritis (RCDA) based on the position and stability of the humeral head is presented in Fig. 23-2.[56,63]

The classification is independent of the underlying pathologic conditions and is based on two critical issues for the function of the deltoid muscle: the glenohumeral center of rotation and the degree of anterior–superior instability. Four distinct groups have been formed on the basis of the biomechanics. The four types are distinguished by the degree of superior migration from the center of rotation and the amount of instability of the center of rotation.

Type Ia: Centered stable	Type I b: Centered – Medialized	Type II a: Uncentered – limited stability	Type II b: Uncentered unstable	Relationship of the lever-arms of deltoid and of the upper limb
No superior migration		Superior Translation	Anterior-superior Dislocation	
Acetabularisation of c.a. arch; Femoralisation of humeral head	Medial erosion of the glenoid	Minimum stability by c.a. arch	No stability by c.a. arch	

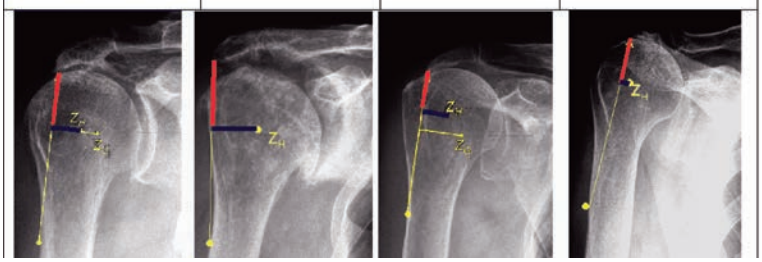

Figure 23-2 A pathomechanistic and pathomorphologic classification of rotator cuff–deficient arthritis, based on the position and stability of the humeral head, is presented.

In the type II cases the humeral head is not centered in the fossa or contained within the coracoacromial arch, and by this definition has an unstable fulcrum.

DIFFERENTIAL DIAGNOSIS

Although sharing a common end result, it is important to recognize the various diseases processes leading to glenohumeral RCDA.

Rheumatoid arthritis (RA) has been the most common cause of RCDA. The frequency of this cause of RCDA has decreased markedly with the use of disease-modifying drugs. Traditionally 48% to 65% of RA patients have significant glenohumeral joint involvement. About 24% of those having glenohumeral arthritis will have a simultaneous rotator cuff tear.[38,59] Superimposed on the aforementioned changes are severe osteopenia, erosions of the *entire* glenoid without osteophyte formation, and medialization of the glenohumeral joint.

Cuff tear arthropathy (CTA) is the extreme end result of a massive rotator cuff tear. The term, coined by Neer in 1983,[43] refers to a primary massive rotator cuff tear that by virtue of mechanical superior instability and nutritional effects leads to a secondary glenohumeral joint destruction.[22] It is believed that between 0% to 25% of massive rotator cuff tears will end up as CTA, but it is difficult, if not impossible, to predict which of the massive tears will result in CTA.

The Milwaukee shoulder syndrome was originally described by McCarty in 1981.[42] This is an uncommon entity affecting shoulders of elderly people, predominantly women. It consists of a massive rotator cuff tear, joint instability, bony destruction, and large blood-stained joint effusion containing *basic calcium phosphate crystals,* detectable protease activity, and minimal inflammatory elements. Its relation to rotator cuff arthropathy is not clear, and it might represent one spectrum of those mentioned above. The role of the basic calcium phosphate crystals in creating this syndrome is still controversial. Whether it is the cause of the articular damage through macrophage spillage of proteases or just the result of the osteoarthritic process is still unknown.[33]

Primary glenohumeral osteoarthritis is the most common reason for shoulder joint replacement; however, it is associated with rotator cuff tears in only 5% of patients, most of which are reparable. It is therefore uncommon for primary osteoarthritis to end up as RCDA.

Posttraumatic conditions can lead to RCDA when the tuberosities are fractures and ununited after traumatic rotator cuff tears or failed rotator cuff surgery.

CLINICAL PICTURE

Patients with arthritic shoulder and irreparable massive cuff deficiency secondary to classic cuff tear arthropathy are primarily elderly people with female gender predominance. When considering other causes of massive cuff deficiency with secondary arthritis, male patients predominate. The patient's main complaints are of severe shoulder pain, limited range of movement, and in some cases recurrent swelling of the shoulder. The pain is constant, aggravated by shoulder motion and felt at the periacromial region and the glenohumeral joint line. On physical examination the examiner can observe wasting of the infraspinatus and supraspinatus muscles, a decrease in active and passive glenohumeral motion, and a crepitus

while moving the patient's shoulder.[33] The x-ray image is typical and consists of a superiorly positioned humeral head and in the end stages of the process an "acetabularized" socket consisting of a thinned sclerotic acromion and the eroded upper glenoid fossa (see Fig. 23-1). Occasionally, the acromioclavicular joint and distal clavicle are also damaged and are thus included in the "socket." Cases of secondary stress fractures of the thinned acromion have also been published.[17]

The combination of the clinical and radiologic information is, in most cases, sufficient to make the proper diagnosis, although other modalities such as computed tomography (CT) may be needed for treatment planning.

TREATMENT

Rotator cuff tear arthropathy combines severe articular damage, bone destruction, osteoporosis, and loss of stabilizing rotator cuff tendons. In contrast to the more common primary degenerative shoulder arthrosis, the inherent instability of the rotator cuff–deficient shoulder necessitates specific consideration. Severe pain and shoulder dysfunction lead many of these patients to seek medical advice. There are several treatment options, and the ideal treatment for any one patient must be individualized to the patient's pathology, functional disability, and treatment goals. These options include nonsurgical treatment and surgical procedures such as humeral head replacement, total shoulder arthroplasty, and even arthrodesis and resection arthroplasty.

TREATMENT OPTIONS

Nonsurgical

Patients with cuff tear arthropathy may retain a surprising degree of function and motion if they have an intact deltoid and acceptable fixed fulcrum mechanics for rotation of the humeral head. Patients with mild symptoms and mild limitation in functional range of motion and activities of daily living should be treated nonsurgically. This includes the use of analgesics and physical therapy to maintain range of motion and to strengthen the deltoid muscle. It has been shown that by strengthening the middle third of the deltoid, some improvement with superior stability control can be gained.[27] The use of repeated steroid injections is discouraged, but an occasional injection may be helpful in managing the most acute symptoms.

In those patients with unremitting pain, significant motion-related pain, and limitation in range of motion and activities of daily living, a surgical intervention should be considered.

Glenohumeral Arthrodesis

The basic concept of fusion is to eradicate pain with elimination of motion. However, there are several drawbacks to its use in this condition:

1. Arthrodesis should ideally be done when there is good function in the opposite shoulder. In as many as 40% of patients with RCDA, the opposite shoulder is involved in a similar process.
2. The involved shoulder is in most cases severely osteopenic, and thus is more prone to failure of internal fixation and subsequent nonunion.
3. Increased scapulothoracic motion needed after glenohumeral arthrodesis exposes the already damaged acromioclavicular joint to excessive motion and therefore pain.
4. Most of the patients involved are elderly patients. Elderly patients have difficulties submitting to the demanding postoperative rehabilitation process necessary after this procedure.[43]

Cofield,[12] in 1979, reported on 12 patients who were an average age of 50 years with rotator cuff tears and who had their shoulder fused. Two of 12 patients developed nonunion and 6 of 12 necessitated a second operation for acromioclavicular pain, nonunion, or proximal migration.

It seems proper to apply Arntz et al.'s[2] and others'[11] recommendations and to consider using arthrodesis in irreparable rotator cuff tears, only in combination with irreparable deficiencies of the deltoid muscle, or in the younger patient with demands for substantial strength at low angles of flexion.

Resection arthroplasty generally results in poor function but is reliable for improvement of pain. Resection arthroplasty yields an unstable, nonfunctional shoulder. In the elderly patient with severe bone loss and massive cuff deficiency often seen with chronic dislocation, resection arthroplasty may be one of the few surgical options to offer the patient pain relief. It should not be entirely abandoned as an option in very selected cases.

Constrained Total Shoulder Arthroplasty

The lack of joint stability led researchers and surgeons in the early 1970s and early 1980s to use constrained designs of total shoulder arthroplasty in cases of rotator cuff tear arthropathy to create a fixed fulcrum for deltoid action (Fig. 23-3). Although initial reports showed good clinical results, longer-term follow-up showed a high percentage of glenoid component loosening and material failure of implants. Post[49] reported that glenoid component radiolucent lines appeared in 30% of primary constrained arthroplasties used in rotator cuff tear arthropathy. Lettin[39] and colleagues reported on 10 of 49 shoulders that developed relatively early glenoid component loosening. It appeared

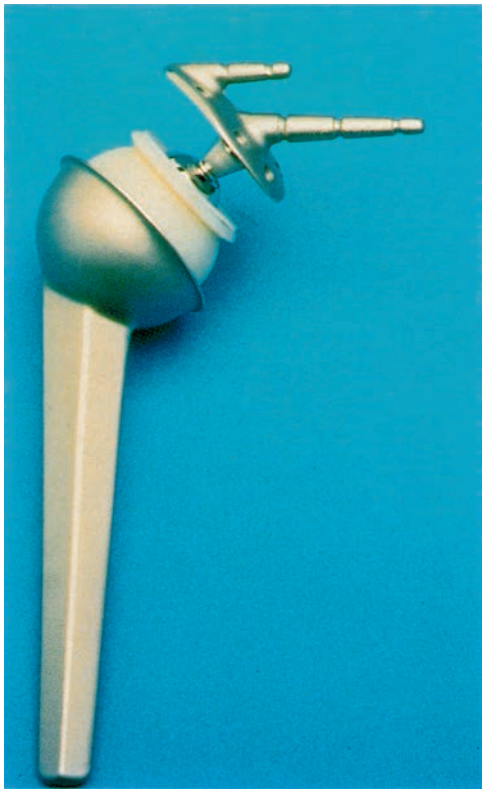

Figure 23-3 Constrained designs of a fixed fulcrum used in the 1970s and early 1980s.

that the inherent constraints in the prosthesis along with a lateral center of rotation transferred strong shear forces to the glenoid component–bone interface. The increased shear forces combined with the osteopenic nature of the bone and the small surface area of the interface led to the glenoid loosening. Given the unacceptable high failure rates, the use of these early types of fully constrained, fixed fulcrum, total shoulder construct for rotator cuff–deficient shoulders was abandoned. The failure of these early designs of constrained arthroplasty resulted from a center of rotation that was lateral to the glenoid component–bone interface.

Semiconstrained Shoulder Arthroplasty

Another prosthetic design used in the early years of shoulder arthroplasty was to enlarge the glenoid component by adding to it a superior hood, which was intended to resist superior migration of the humeral head. Amstutz[1] reported on a subset of 10 hooded glenoid Dana total shoulder arthroplasties performed on patients with massive rotator cuff tears. Pain decreased substantially; however, range of movement did not improve. Two of the 10 patients needed revision surgery. Neer[43] reported on his experience in this type of total shoulder arthroplasty. He used hooded glenoid components in 4 of 11 of the rotator cuff–deficient rheumatoid group and in 8 of 16 of the rotator cuff arthropathy group (Fig. 4). Specific conclusions as to the use of this semiconstrained construct were not made. Recently, Nwakama[44] reported on seven arthritic shoulders with massive rotator cuff tears that underwent total shoulder replacement using a semiconstrained hooded Neer prosthesis. Although pain level was improved in all patients, active motion was actually decreased. Five of six patients had anteroposterior instability and three of six had complete radiolucent lines on radiographic evaluation. Two shoulders necessitated revision surgery for subluxation or glenoid loosening. Orr and colleagues,[45] who analyzed the biomechanical behavior of this construct by using finite element analysis, presented additional support to the relatively high glenoid loosening rate. They found that the addition of superior constraint to the glenoid component generated increased stresses at the glenoid component–bone interfaces, making it more susceptible to early loosening. The lack of active motion improvement combined with early glenoid loosening has discouraged the use of this design.

Unconstrained Shoulder Arthroplasty

Two different types of unconstrained shoulder arthroplasty have been used for RCDA: total shoulder arthroplasty using an anatomic design with no additional built-in constraints and a replacement of the humeral head without use of a glenoid component (hemiarthroplasty).

Unconstrained Total Shoulder Arthroplasty

Neer et al.[43] published in 1982 their experience with prosthetic replacement of 273 shoulders, of which 16 were diagnosed as rotator cuff tear arthropathy. Eight RCDA shoulders received an unconstrained total shoulder prosthesis, while the rest were treated with a semiconstrained (hooded) implant. Eleven patients had a follow-up of more than 24 months. Using Neer's "limited goals rehabilitation" criteria,[43] 10 out 11 patients had successful results. Although 30% of shoulders and 33% of the rotator cuff tear arthropathy shoulders had glenoid lucent lines (less than 1 mm), clinically detected loosening was not found in any of these 273 shoulders. Lohr and Cofield[40] found unconstrained total shoulder replacements to provide better pain relief than hemiarthroplasty in 22 rotator cuff–deficient shoulders. However, a high rate of radiologic and clinical loosening was noted in their patients. Barrett et al.,[4] in a prospective study in 1987, reported on 44 patients who underwent total shoulder arthroplasty. Nine of the patients had a massive tear of the rotator cuff at the time of surgery. Glenoid loosening was found in four patients, all of which had previous massive rotator cuff tear. Three of these patients necessitated surgical revision. It was hypothesized that the unstable shoulder joint causes

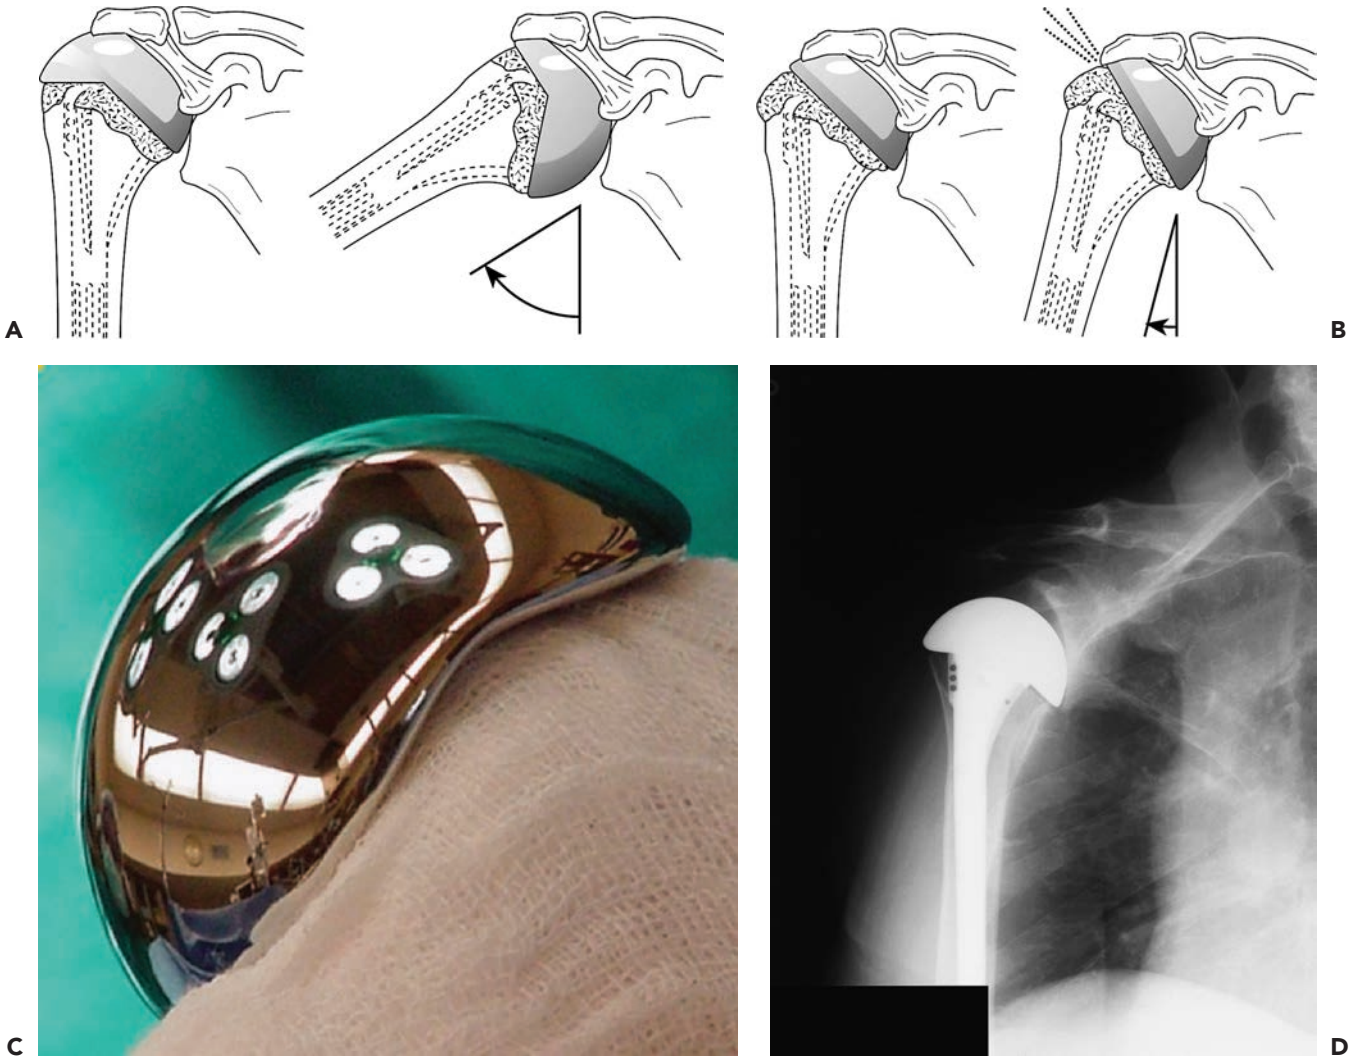

Figure 23-4 Hooded glenoid components.

repeated exaggerated superior translation of the humeral head on the glenoid component, allowing joint compression forces to be put on the superior glenoid margin rather than in the center of the glenoid, leading to loosening. Franklin et al.[26] tried to correlate different clinical and radiographic parameters with glenoid loosening in patients undergoing total shoulder replacement in the presence of massive rotator cuff tear. They found that the amount of superior migration of the humeral head was closely correlated with an increased glenoid loosening rate. They emphasized the eccentric forces applied by the unstable, translated humeral head on the glenoid component resembling the movement of a "rocking horse," leading to the loosening of the glenoid component. Due to these high loosening rates found relatively early in the postoperative course, the use of an unconstrained total shoulder implant has been disfavored.

Humeral Head Replacement

The relatively early loosening of the glenoid component has led surgeons to propose hemiarthroplasty with replacement of only the humeral head as a solution for RCDA shoulders. Using this approach, significant pain reduction in 47% to 86% of patients and significant, yet variable, gain in forward elevation have been reported at an average follow-up of 2 to 5 years.[24,48,51,68,72] Taking into account Neer's limited-goal criteria,[43] successful results have been achieved in 63% to 83% of patients. Pollock et al.[48] found similar pain relief and better forward elevation gains in hemiarthroplasty versus total shoulder replacement in 30 rotator cuff–deficient arthritic shoulders.

The inherent superior instability of hemiarthroplasty in these patients, where no significant soft tissue support is available, has nourished several debates concerning the

implant design and associated procedures needed to stabilize these shoulders.

Humeral Component Size

One of the first solutions to gain better stability was the use of larger humeral head components. The rationale was that a large humeral component can articulate better with the large "acetabulum" (consisting of the superior glenoid and undersurface of coracoacromial arch), therefore creating a relatively stable and more congruent joint. However, potential disadvantages to the use of large humeral components included overstuffing of the joint, which led to increased joint reaction forces, accelerated bone resorption of both the glenoid and the acromion, pain, and eventually further instability.[51] In addition, with the use of a larger humeral head, any attempt to augment or partially repair the deficient rotator cuff became much more difficult. The disadvantages of a large-diameter humeral component and the need for an additional prosthetic contact area with the acromion and coracoacromial arch have led to the use of a specially designed humeral component: the cuff tear arthropathy head (CTA head). This component has an anatomically sized head (lateral offset and radius of curvature) but adds a smooth extension of the articular surface that covers the greater tuberosity, which in RCDA does not have an attached cuff and has an irreparable cuff. This extension of the superior articular surface (Fig. 23-5) articulates with the coracoacromial arch. The CTA design enlarges the joint contact area without increasing the size of the head (lateral offset and radius of curvature) and thereby will not "overstuff" the joint. A recently published study evaluated the results of 60 rotator cuff tear arthropathy shoulders that have undergone humeral hemiarthroplasty using a CTA head prosthesis. None of the patients had an anterosuperior escape of the humeral head on forward flexion prior to surgery. Using Neer's limited-goals criteria, after 2 years of follow up, 89% had a successful result (i.e., significant improvement in range of motion and pain reduction).[63]

Reconstruction and Augmentation of the Rotator Cuff Elements

Pollock,[48] Cantrell and Burkhead,[10] and DiGiovanni[18] have advocated attempts to repair or augment the torn rotator cuff tendons. One of the options suggested is the transfer of the subscapularis tendon to a more superior position as a method for superior stabilization of the humeral head.[43] This option is limited obviously to those patients with a functional, unshortened subscapularis tendon. However, others reported satisfactory results without any attempt to repair or augment the torn supraspinatus and infraspinatus tendons. Williams and Rockwood[68] published satisfactory results with pain relief for 18 of 21 patients using no cuff reconstruction with balancing of the remaining cuff muscles by fine tuning the humeral head component size. Zuckerman et al.,[72] who also did not try to repair or

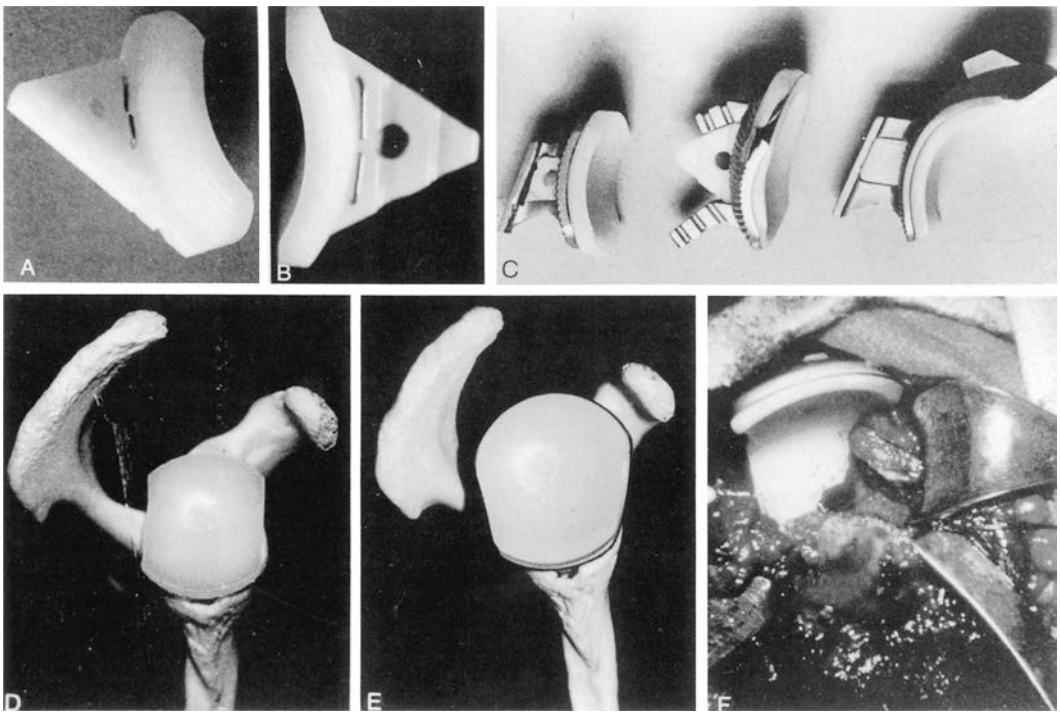

Figure 23-5 This extension of the superior articular surface articulates with the coracoacromial arch.

augment the torn supraspinatus and infraspinatus tendons, published similar results. Sanchez-Sotelo et al.[51] reported on 33 shoulders in 30 patients who received a hemiarthroplasty for the diagnosis of rotator cuff arthropathy. Medium-sized humeral head components were used in most shoulders. Statistically significant correlation was found between attempts to partially repair the rotator cuff tendons and postoperative, clinically significant, anterior instability. The authors explained this association with the creation of a muscle force imbalance by their repair attempts.

Augmentation of Superior Bone Elements

The importance of maintaining the coracoacromial arch in RCDA cannot be overemphasized.[2,51,68,72] The deficiency in superior bony restraints, secondary in most cases to previous surgical decompression of the subacromial space, creates an extremely difficult scenario. Sanchez-Sotelo et al.[51] reported poorer results and increased susceptibility to anterosuperior instability in a subgroup of RCDA patients that had had previous surgical coracoacromial arch decompression. Several solutions have been proposed for restoring these superior bony restraints. Wiley[67] described the use of an autologous tricortical iliac bone graft that was fixed between the coracoid and acromion in cases where the coracoacromial arch was compromised by previous subacromial decompression (Fig. 23-6). Engelbrecht and Heinert[21] introduced another technique in which augmentation of the glenoid rim was achieved by fixing an autologous bone graft to the superior glenoid rim, thus deepening

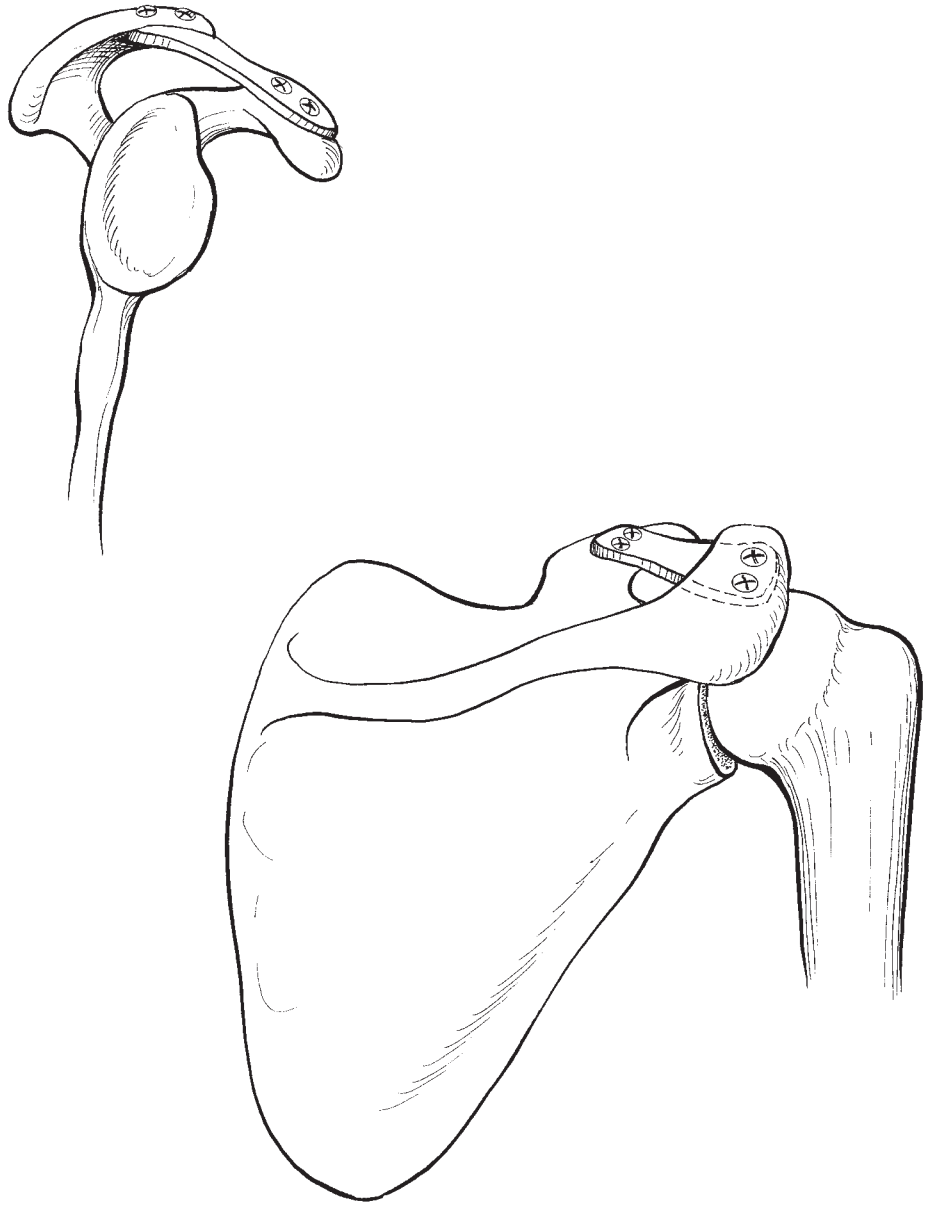

Figure 23-6 Wiley tricortical iliac bone graft that was fixed between the coracoid and acromion. (Reproduced with permission from Wiley AM. Superior humeral dislocation. A complication following decompression and debridement for rotator cuff tears. *Clin Orthop* 1991;Feb(263):135–141.)

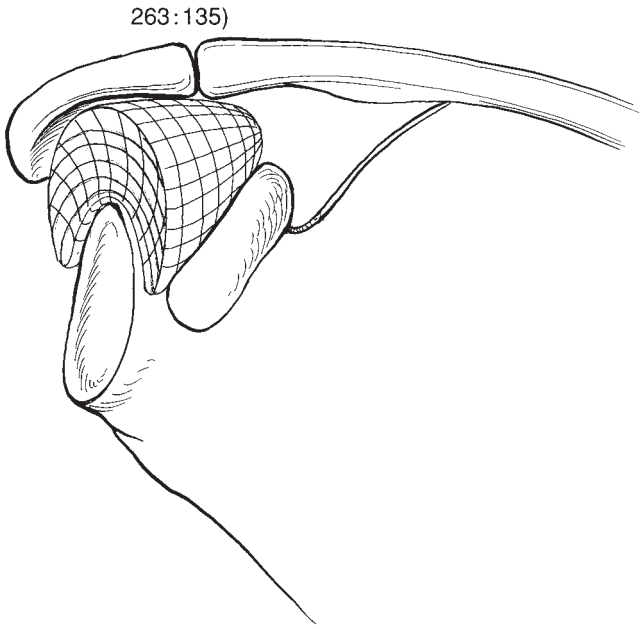

Figure 23-7 Engelbrecht augmentation of the glenoid rim autologous bone graft to the superior glenoid rim, thus deepening and widening the actual articulating surface of the glenoid. In: Kolbel, Helbig, Blauth, eds. *Shoulder replacement.* Berlin: Springer-Verlag, 1987:85–91.)

and widening the actual articulating surface of the glenoid and counteracting superior-directed forces applied by the humeral head (Fig. 23-7).

Bipolar Humeral Prosthesis

Bipolar humeral component design was presented by Swanson et al.[60] in 1975 as a solution for patients with advanced glenohumeral arthritis and poor rotator cuff tissue as part of a total shoulder design. The rational was to decrease prosthetic contact forces by a larger "articular" surface, and by the secondary motion possible within the bipolar humeral prosthesis itself. At a follow-up of 5 years, pain relief was rated good to excellent in 31 of the 35 shoulders operated. Arredondo and Worland[3,69] reported their results using a newer, lower-profile, bipolar design that allows for less bony resection during insertion. At a mean follow-up of 3.1 years (range 2 to 6 years), satisfactory results were found in 92% of their patients using the limited-goals criteria, including both pain relief and improved range of motion. The authors also reported prosthetic birotational motion (head-shell and shell-glenoid motion), which persisted in all shoulders. Vrettos et al.,[64] using the same bipolar prosthesis, reported less favorable results. Six of the seven patients reported moderate to severe pain and were unhappy with the results. No glenohumeral or intrinsic bipolar motion was found in radiographs taken in different angles of abduction. A recent

Figure 23-8 Bipolar hemiarthroplasty concerns of "overstuffing" the shoulder and secondary glenoid wear.

report by Duranthon et al.[19] on 13 RCDA shoulders with a mean follow up of 28 months revealed good pain relief with less than satisfactory range-of-motion improvement. Significant glenoid wear was found in three of the seven shoulders that were observed 2 years after surgery.

To date, bipolar hemiarthroplasty has not gained popularity. The reasons are the concerns of "overstuffing" the shoulder and secondary glenoid wear (Fig. 23-8), rupture of the subscapularis tendon due to the vertical orientation of the component (Fig. 23-9), the effect of polyethylene wear,[33] and the relatively short follow-up reported.

Figure 23-9 Vertical orientation of the bipolar prosthesis.

The inherent superior instability of hemiarthroplasty in RCDA shoulders has been at least partially counteracted using the aforementioned methods with relatively good clinical results. One of the still existing concerns is the durability of this "stability" achieved with the use of hemiarthroplasty in cuff-deficient shoulders. Sanchez-Sotelo et al.[51] reported on 33 shoulders in 30 patients that had a hemiarthroplasty for the diagnosis of rotator cuff arthropathy with an average follow-up of 5 years (range 2 to 11 years). Most shoulders received medium-sized humeral heads. Progressive superior migration and progressive glenoid bone loss were reported in 8 of 33 shoulders and acromial bone loss was reported in 16 of 33 shoulders, leading to acromion fracture in two patients. Poorer results and more severe anterosuperior instability were found in a subgroup of patients that had previous surgical coracoacromial arch decompression.

To summarize, hemiarthroplasty is a good surgical solution for a cuff-deficient arthritic shoulder with a contained humeral head having an intact "acetabularized" coracoacromial arch providing a stable fulcrum for rotation of the humeral head. Hemiarthroplasty is also ideally suited for a cuff-deficient arthritic shoulder with an irreparable rotator cuff but with the remaining cuff and deltoid being sufficient to have active elevation of the shoulder to approximately shoulder height prior to replacement. Hemiarthroplasty, although not a perfect solution, provides good pain relief and moderate range-of-motion gain for most patients, which is relatively long-lasting. Due to the high rates of glenoid component loosening, unconstrained total shoulder replacement should not be considered for rotator cuff–deficient arthritic joints. No study has demonstrated an advantage of rotator cuff partial repair or augmentation in these circumstances over simple débridement. A competent coracoacromial arch is a keystone for successful results and therefore should not be damaged during the surgical procedure. In cases of preexistent coracoacromial deficiency, the use of reversed shoulder prosthesis should be considered. Progressive bone loss and progressive anterosuperior instability could lead to a growing number of unsatisfactory results in long-term follow-up periods (more than 5 years).

In the authors' experience, the ideal surgical technique for hemiarthroplasty for RCDA preserves the coracoacromial arch, deltoid, and remaining cuff without detachment of any of these intact structures. The goals of the surgery are to:

1. Remove all inflamed and pathologic bursae tissues including an abnormal long head of the biceps
2. Remove all humeral osteophytes on the greater tuberosity
3. Replace the head with an anatomically sized humeral head if there is not significant medial glenoid erosion (less than 1 cm) or a larger head if there is significant glenoid bone loss
4. Correct eccentric glenoid bone loss of removal of the high side and create a smooth concave surface for the humeral head in the position that it will articulate
5. Not dissect the coracoacromial arch
6. Not dissect the deltoid origin
7. Not detach any of the remaining intact portion of the rotator cuff

To achieve these goals, a deltopectoral approach is used, keeping the coracoacromial ligament intact. The arm is placed in extension, adduction, and external rotation to dislocate the humeral head from the interval between the deltoid and pectoralis major. All abnormal bursae tissue is removed from around the humeral head and under the coracoacromial arch, taking care to preserve the coracoacromial ligament and remaining attached rotator cuff tendon (Fig. 23-10). A large Darrach is placed into the joint

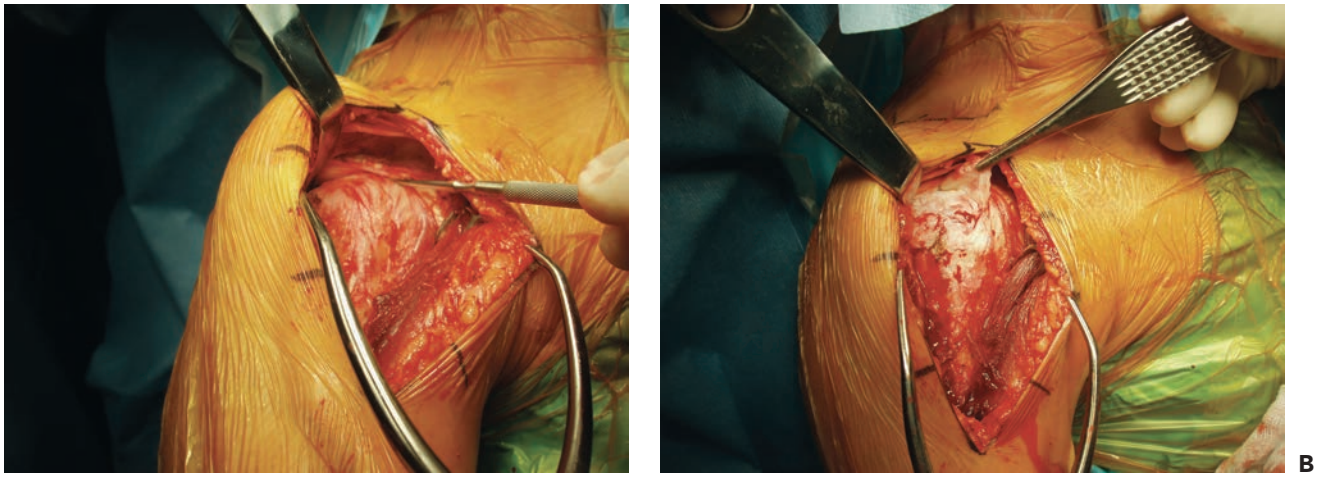

Figure 23-10 **(A)** All abnormal bursae tissue is removed from around the humeral head and under the coracoacromial arch, taking care to preserve the coracoacromial ligament and remaining attached rotator cuff tendon.

through the rotator cuff defect and between the humeral head and the glenoid to further lever the humeral head from the joint (Fig. 23-11). If the long head of the biceps is intact, then it is cut and tenodesed to local soft tissues distal to the bicipital groove. A narrow reverse Homans or bunion-type retractor is placed beneath the remaining intact portion of the anterior and posterior parts of the rotator cuff (Fig. 23-12). This exposes the humeral head from the superior aspect through the existing defect in the humeral head. Using a power saw, a free hand cut is made approximately 5 mm distal to the top of the greater tuberosity and perpendicular to the humeral shaft, thereby cutting off the top of the humeral head, exposing the cancellous bone and lending easy access to the humeral diaphyseal canal (see Fig. 23-12). Using the smallest humeral medullary canal reamers, the canal is broached, and with larger reamers the canal enlarged. A trial broach is then placed into the reamed canal until the collar of the broach

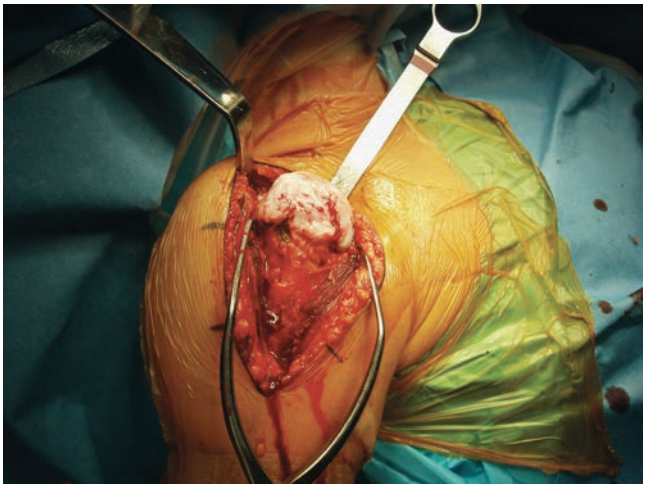

Figure 23-11 A large Darrach is placed into the joint through the rotator cuff defect and between the humeral head and the glenoid to further lever the humeral head from the joint.

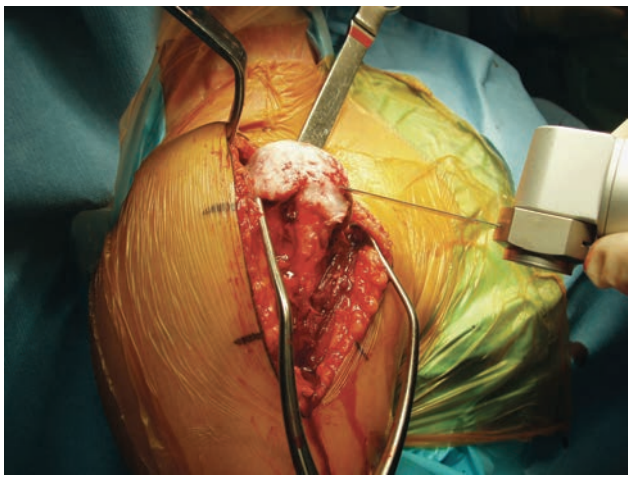
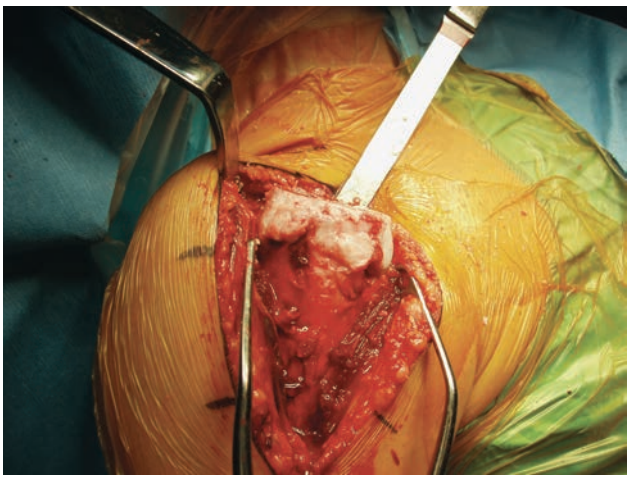
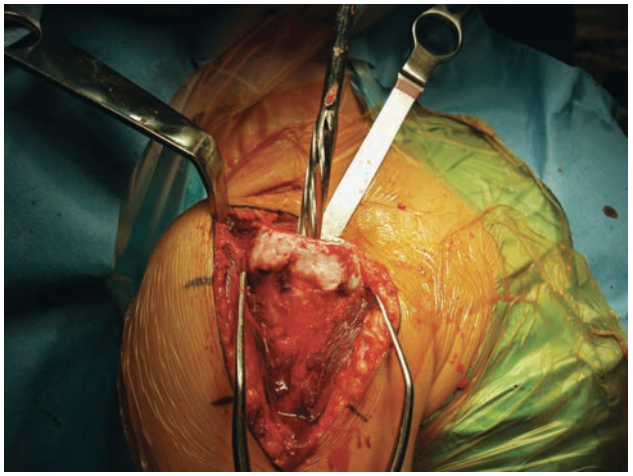


A



B



C

Figure 23-12 A narrow reverse Homans is placed under the remaining rotator cuff to expose the humeral head. **(A–C)** Using a power saw, a free hand cut is made approximately 5 mm distal to the top of the greater tuberosity and perpendicular to the humeral shaft, thereby cutting off the top of the humeral head, exposing the cancellous bone and lending easy access to the humeral diaphyseal canal.

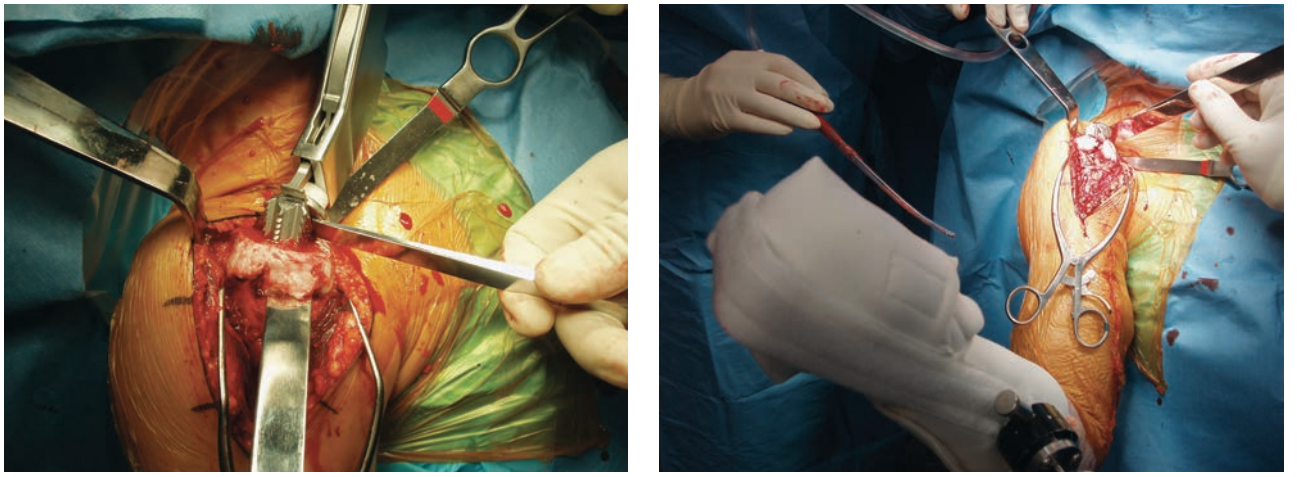


Figure 23-13 A trial broach is placed into the reamed canal until the collar of the broach hits the cut superior surface of the remaining humeral head. The version can be assessed by the plane of the back surface of the collar of the prosthesis and the long axis of the forearm as shown by the two osteotomes. Retroversion is measured from the flat back face of the broach collar to the long axis of the forearm with the elbow at 90 degrees of flexion.

hits the cut superior surface of the remaining humeral head. The broach is rotated to a retroverted position to be approximated 10 degrees more in retroversion than anatomic. Retroversion is measured from the flat back face of the broach collar to the long axis of the forearm with the elbow at 90 degrees of flexion (Fig. 23-13).

Alternatively or additionally, retroversion can be judged by the anatomic neck of the exposed humeral head. The blade of the oscillating power saw is then made parallel to the back surface of the broach collar and the remaining portion of the head is cut at the level of the anatomic neck, taking care to keep the head cut within the joint, thereby preserving the remaining intact cuff and protecting the axillary nerve (Fig. 23-14). The head fragment is removed and the inferior part of the head cut is palpated. Any remaining inferior humeral head osteophyte is removed with a half-inch curved osteotome and/or rongeur. In almost all cases, preoperative passive forward elevation is at least to 120 degrees and an inferior capsular release is not needed, nor is there much osteophyte present on the humeral head in classic CTA. If a capsular release is needed, then it is performed on the glenoid side of the capsule. A Fukuda or similar humeral head retractor is used to retract the humerus and the glenoid is inspected; if it is irregular it can be reamed with a smooth convex reamer or burred by hand to a smooth concave surface. The goal of glenoid preparation is to preserve the thickened cortical-type bone when possible and remove only irregular surfaces and prominent areas of bone that represent the high side of the glenoid when there is eccentric bone loss. All degenerative soft tissue or hypertropic synovium is removed and the joint is irrigated. The proximal humerus is again exposed as previously described. The humerus is then prepared as described by the manufacturer and the broach is inserted. It should be noted that all prosthetic instrument sets are designed for placement of the trials and final implant with a detachment of the subscapularis. When performing the surgery by the method described in this chapter, the instruments may not fit as well and may need to be modified for optimal use. When the trial stem is inserted, the trial heads may be placed and a trial reduction and range of motion with stability testing performed. If a DePuy CTA head is used, the additional cut in the tuberosity is made from the trial head or using the cutting guides

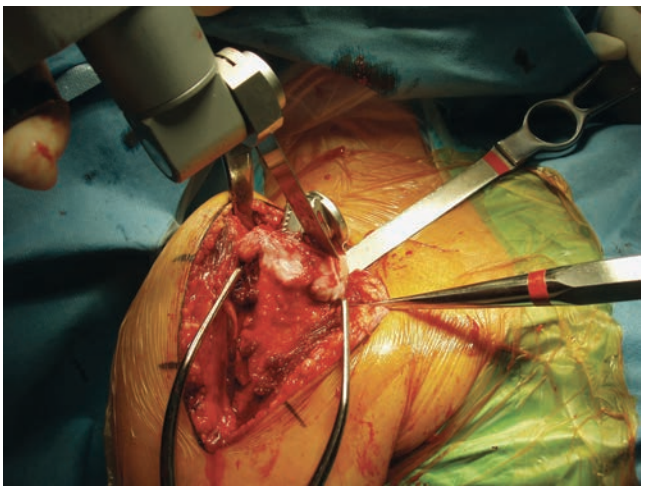

Figure 23-14 The blade of the oscillating power saw blade is made parallel to the back surface of the broach collar and the remaining portion of the head is cut at the level of the anatomic neck, taking care to keep the head cut within the joint, thereby preserving the remaining intact cuff and protecting the axillary nerve.

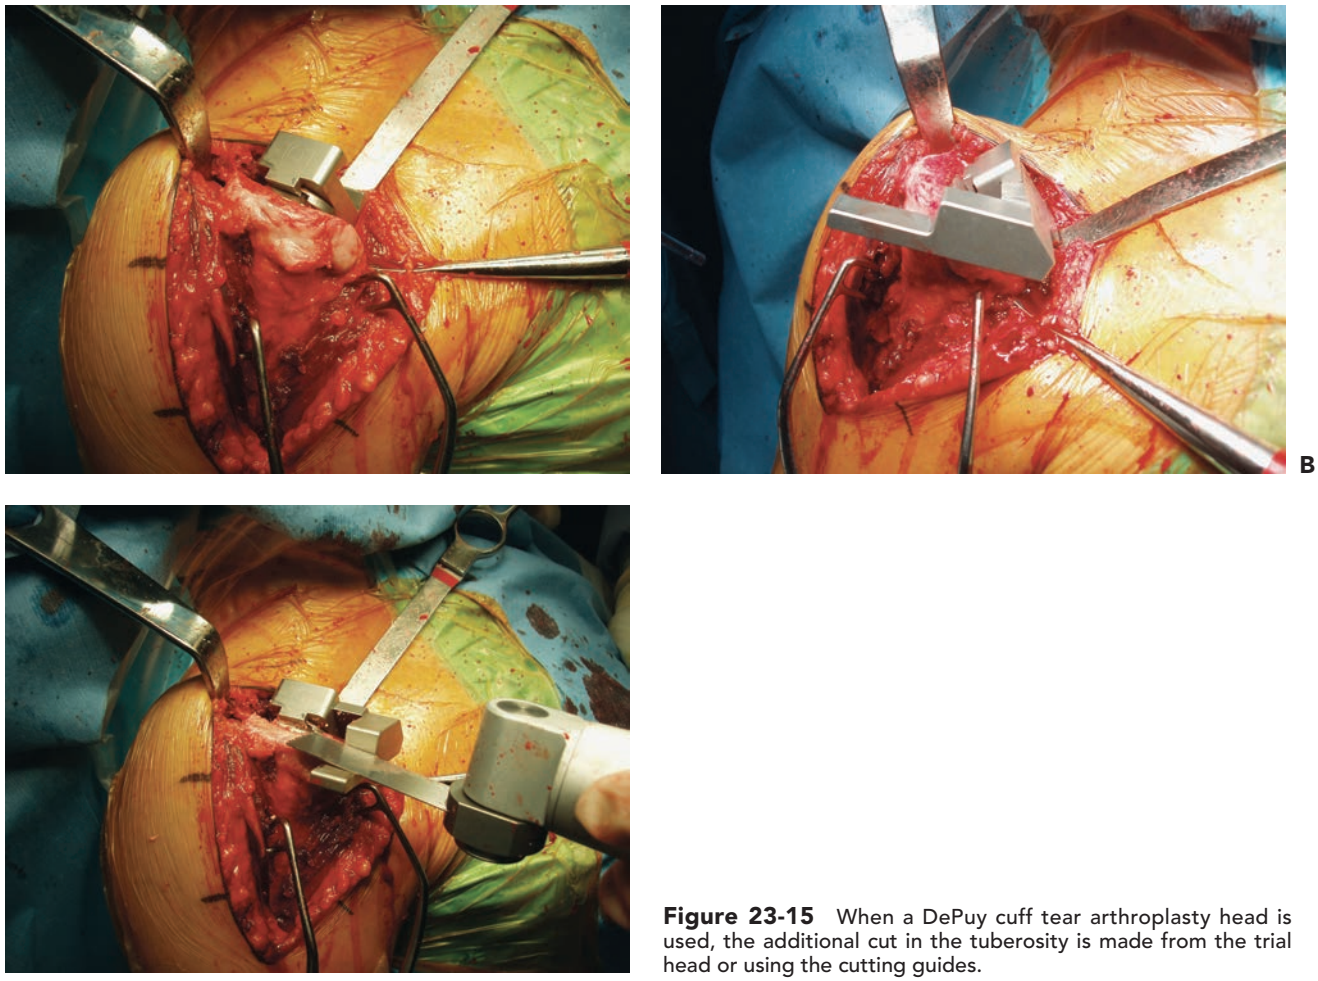

Figure 23-15 When a DePuy cuff tear arthroplasty head is used, the additional cut in the tuberosity is made from the trial head or using the cutting guides.

(Fig. 23-15). After final preparation of the bone cuts and selection of the prosthetic, the final components are assembled and inserted with or without cement depending on the stem design, bone quality, and stability of the stem. Impaction bone grafting can in some cases be performed using either allograft cancellous bone or the patient's resected humeral head in the case of primary replacements. Impaction grafting can increase the stability of the uncemented stem and avoid the use of bone cement in many cases. The final prosthetic should sit directly and precisely on the cut surface of the humerus (Fig. 23-16). With proper surgical technique and rehabilitation, good results can be anticipated in most patients (Fig. 23-17).

Reversed Shoulder Arthroplasty

The term "reversed shoulder" describes a ball-and-socket arthroplasty design where the convex surface is on the glenoid side and the concave surface is on the humeral side. The reverse shoulder systems currently used have a complete conformity of the articular surfaces (equal radii of curvature) and a high degree of constraint (high wall height), thereby enforcing ball-in-socket kinematics by virtue of the design of the prosthetic. The use of reversed shoulder arthroplasty was suggested and tried almost three decades ago.[9,23,46] However, the use of a small glenoid ball with a center of rotation lateral to the glenoid component fixation on the bony glenoid vault in a highly constrained prosthesis resulted in a high rate of prosthetic failure due to loss of glenoid component fixation (Fig. 23-18). Grammont,[29] approximately 15 year ago, renewed the interest in the reversed design construct, especially for use in rotator cuff–deficient arthritic shoulders. In contrast to previous reversed prostheses, Grammont designed a more shallow humeral socket that articulated with a larger radius of curvature hemispherical glenoid component. In this design the center of rotation of the hemisphere was near the component's interface with the bony glenoid. This design produced less interprosthetic constraint, and the small lateral offset (absence of neck) reduced the shear forces at the point of fixation of the glenoid component to the bone, making failure of glenoid fixation minimal. Shifting the glenohumeral center of rotation medially and distally to its original position in the natural shoulder creates a stable

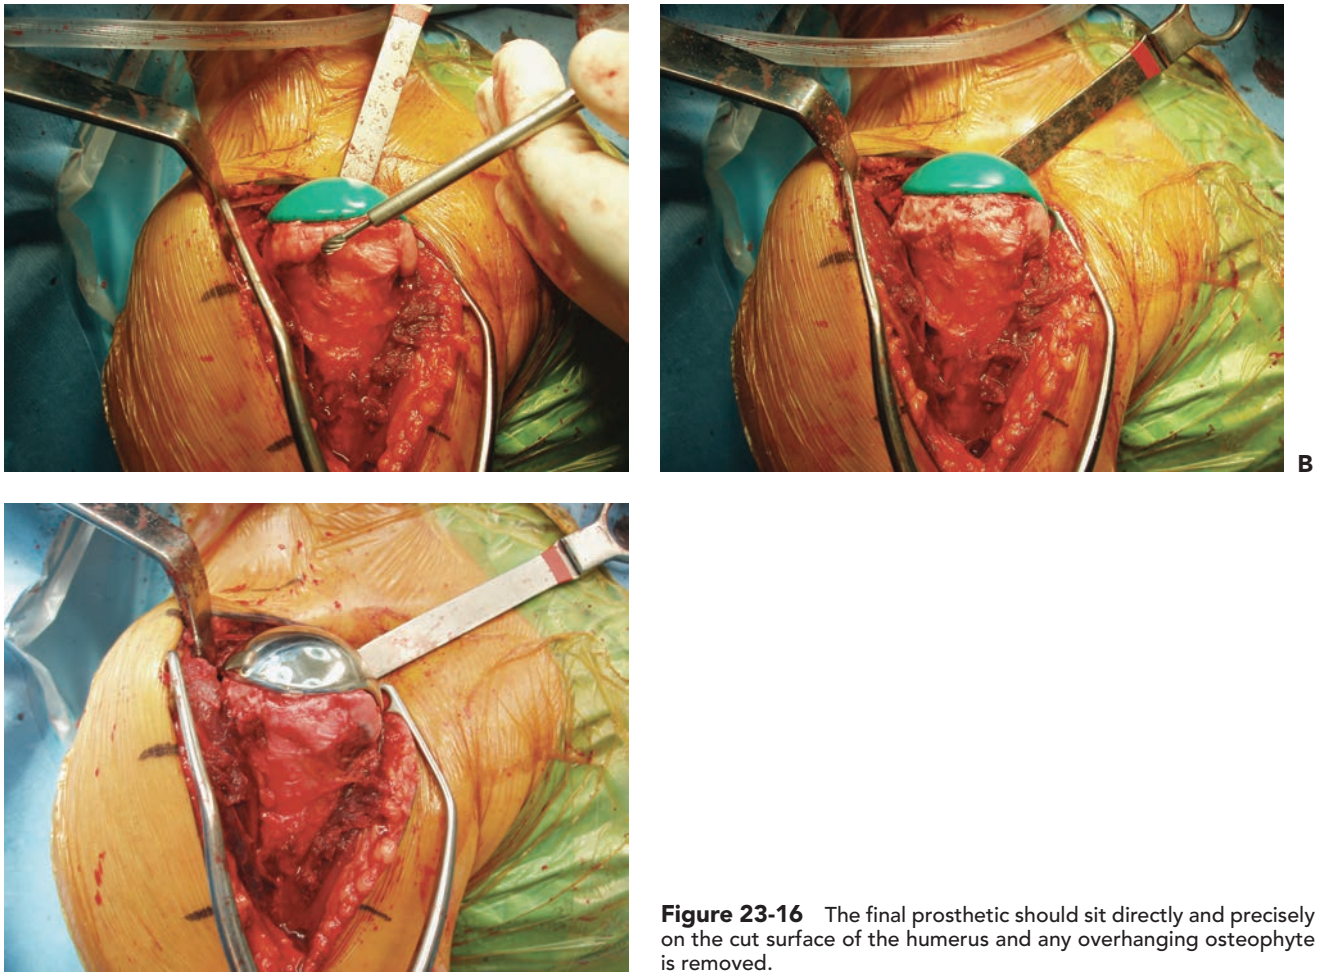

Figure 23-16 The final prosthetic should sit directly and precisely on the cut surface of the humerus and any overhanging osteophyte is removed.

fulcrum and longer moment arm for the deltoid muscle, making it more efficient.[14] The larger spherical glenoid prevents the "rocking horse" effect of the humeral head on the glenoid (Fig. 23-19).

The inherent stability and mechanical advantage of the reversed shoulder prosthesis was compared to the unconstrained shoulder hemiarthroplasty in the absence of functional rotator cuff tendons. Using a computerized model, De Wilde et al.[16] found that the reversed shoulder prosthesis design medializes the rotation center, stretches the deltoid muscle, increases the deltoid lever arm, and results in a significantly more powerful abduction of the shoulder than an anatomic hemiarthroplasty.

The Grammont Delta reverse shoulder prosthesis has been used for almost 13 years in Europe. Several studies have evaluated this prosthesis for the use of rotator cuff–deficient arthritic joint. Bouttens and Nérot[8] reported an average 5-year follow-up on 39 patients with rotator cuff tear arthropathy, Favard et al.[22] on 15 patients with a 25-month follow-up, Sirveaux et al.[58] on 80 shoulders with a 44-month follow-up, Boileau et al.[6] on 21 patients with a 40-month follow-up, and Werner et al.[66] on 58 patients with a 38-month follow-up, demonstrating a significant improvement in pain and significant improvement in active motion. In addition, other surgeons[7,32,50] showed significant pain reduction with no or only minimal pain in most patients and a significant improvement of active forward flexion.

Seebauer et al.[52–55] presented their results with reversed prosthesis Delta3 in 57 patients with RCDA with a mean age of 71 years. Thirty-six patients were available for complete follow-up. The surgical approach used was anterosuperior in 90% and deltopectoral in 10%. After a mean follow-up of 42 months (range 27 to 68), they found that 98% reached Neer's limited-goals criteria. An age- and sex-correlated mean Constant score[13] reached 94% at last follow-up. Nearly all patients reported complete pain relief at rest and for minor activities. Sirveaux et al.[58] retrospectively studied 80 Grammont reversed shoulder prosthesis with a mean follow-up of 44 months. The mean Constant score had increased from 22.6 to 65.6. Ninety-six percent had no or only minimal pain, and the mean active forward elevation increased from 73 to 138 degrees.

Figure 23-17 With proper surgical technique and rehabilitation, good results can be anticipated in most patients.

Figure 23-18 The use of a glenoid ball with a center of rotation lateral to the glenoid component fixation on the bony glenoid vault in a highly constrained prosthesis can result in prosthetic failures due to loss of glenoid component fixation. (From Frankle et al. The reverse shoulder prosthesis for glenohumeral arthritis with severe rotator cuff deficiency. *J Bone Joint Surg* 2005;87A:1702.)

There are, however, several unsolved problems that need to be addressed with the Grammont reverse prosthetic:

1. It is difficult to assess the correct deltoid tensioning during surgery. Undertensioning (using undersized components) may lead to instability of the prosthesis and dislocations in up to 10% of cases[6,58,66] (Fig. 23-20). Overtensioning may lead to restricted range of motion and fatigue fractures of the acromion[6,66] (Fig. 23-21).
2. Inferior scapular notching has been shown to occur in 50% to 96% of cases.[6,7,15,50,58,66] It is a common radiographic finding at early follow-up. Boileau et al.[6] have performed fluoroscopic examinations that showed that scapular notching is a result of impingement of the medial aspect of the polyethylene humeral cup on the scapular neck inferiorly with the arm in the adducted position. It is probably the direct consequence of the absence of a prosthetic neck on the glenoid side and the lowering of the humerus. In many cases (as high as 45%) the notching can involve one or more of the glenoid fixation screws (Figs. 23-22 and 23-23). Werner et al.[66] showed that the notching stabilized in 50% of shoulders in 1 year. They also showed no correlation between notching and the clinical result. However, Sirveaux et al.[58] showed poorer clinical results when significant notching occurred. Due to the relative short follow-up periods in the studies published, the true significance of the notching still unclear.
3. Active external rotation range of motion or strength has not gained from the use of the reversed shoulder prostheses.[6,58,66] There are a couple of explanations: The amount of posterior deltoid that can be used to compensate for the absent external rotators is decreased

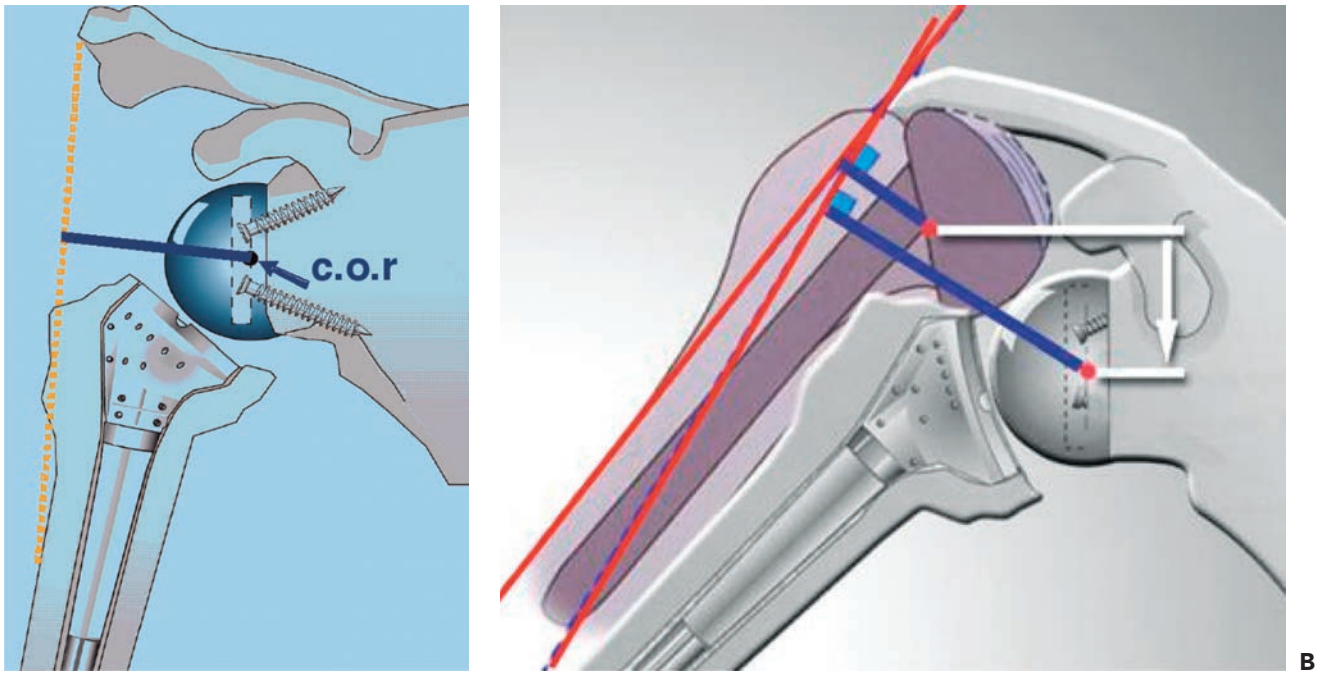

Figure 23-19 Shifting the glenohumeral center of rotation medially and distally to its original position in the natural shoulder creates a stable fulcrum and longer moment arm for the deltoid muscle, making it more efficient.

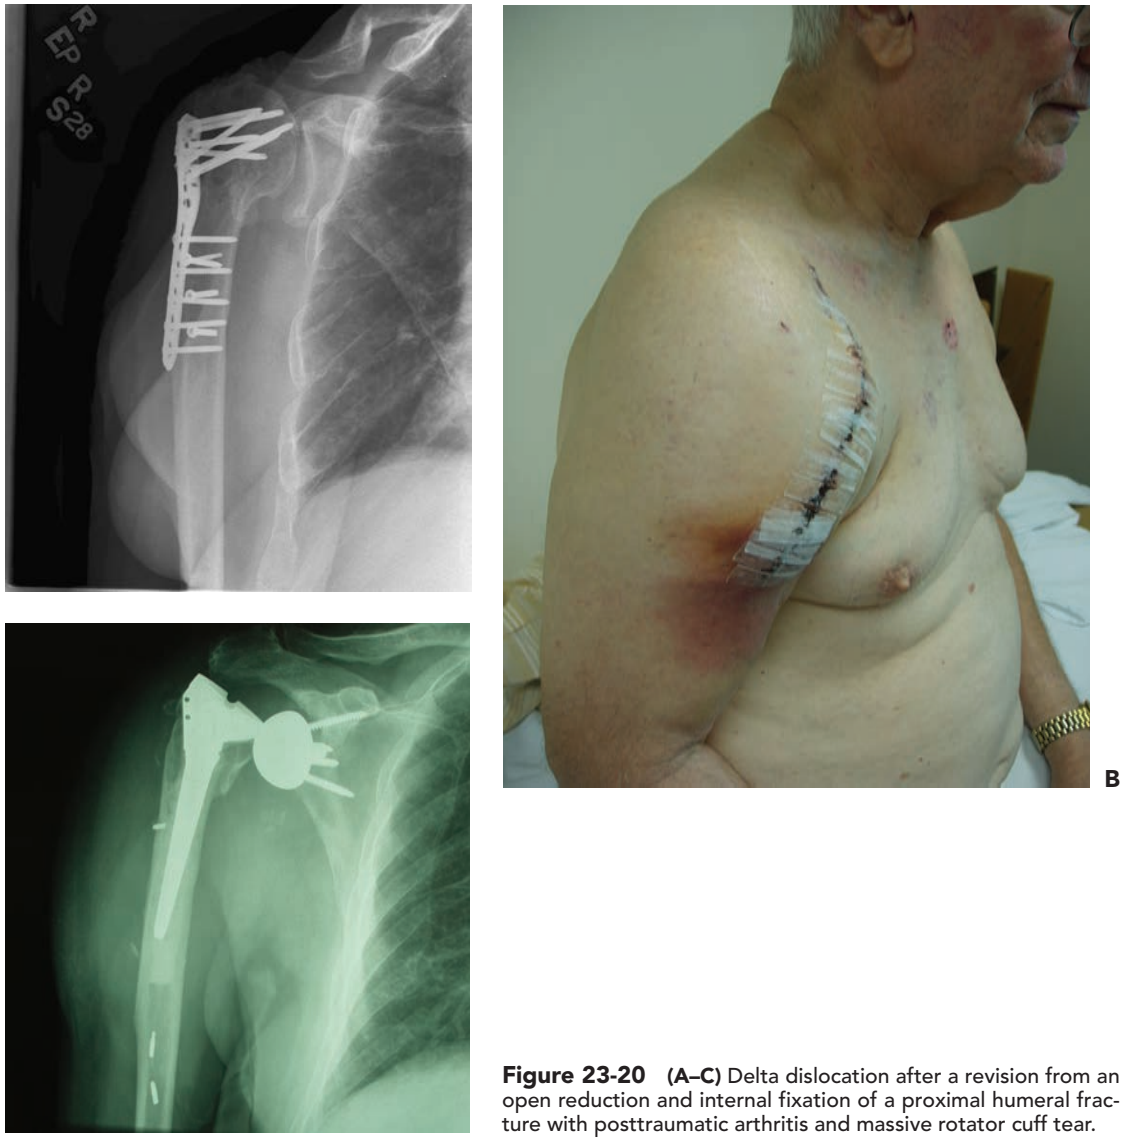

Figure 23-20 **(A–C)** Delta dislocation after a revision from an open reduction and internal fixation of a proximal humeral fracture with posttraumatic arthritis and massive rotator cuff tear.

because of this humeral medialization; and the remaining external rotators (i.e., teres minor) may also be slackened and less efficient because of this humeral medialization. The most important factor in the active external rotation range of motion is the status of the teres minor and any remaining portions of the infraspinatus. The extent of preoperative external rotation strength is an important factor associated with postoperative function and active forward elevation. The active external rotation after a reverse prosthesis is significantly better when the teres minor is intact than when it is absent or has fatty infiltration.[6,7,58,66]

4. There are relatively short follow-up periods. As stated above, most studies of the newer designs are of less than 4 years' follow-up. Larger patient number published studies with longer follow-up periods are necessary to evaluate the rate, progressiveness, and significance of glenoid loosening[20] and glenoid notching.

Other complications reported with the reverse shoulder prosthesis are glenoid and humeral radiolucent lines, glenoid component dissociation, hematoma formation, and infection. Reoperation rate was reported to be as low as 0% and as high as 33% in a recently published study.[66] The reverse shoulder prosthesis by Encore has less notching and a higher incidence of loss of glenoid component failure (12%) due to the presence of a lateral offset to the glenoid component.[25]

The reverse shoulder arthroplasty is a valuable procedure for the treatment of severe dysfunction of the shoulder due to rotator cuff tear arthropathy or in patients with severe humeral bone loss and cuff deficiency. However, because of the relatively high complication rate and the fact that there may be long-term complications that are not yet known, arthroplasty with this implant should be reserved as a salvage procedure for situations in which an acceptable clinical outcome cannot be expected with another treatment modality.

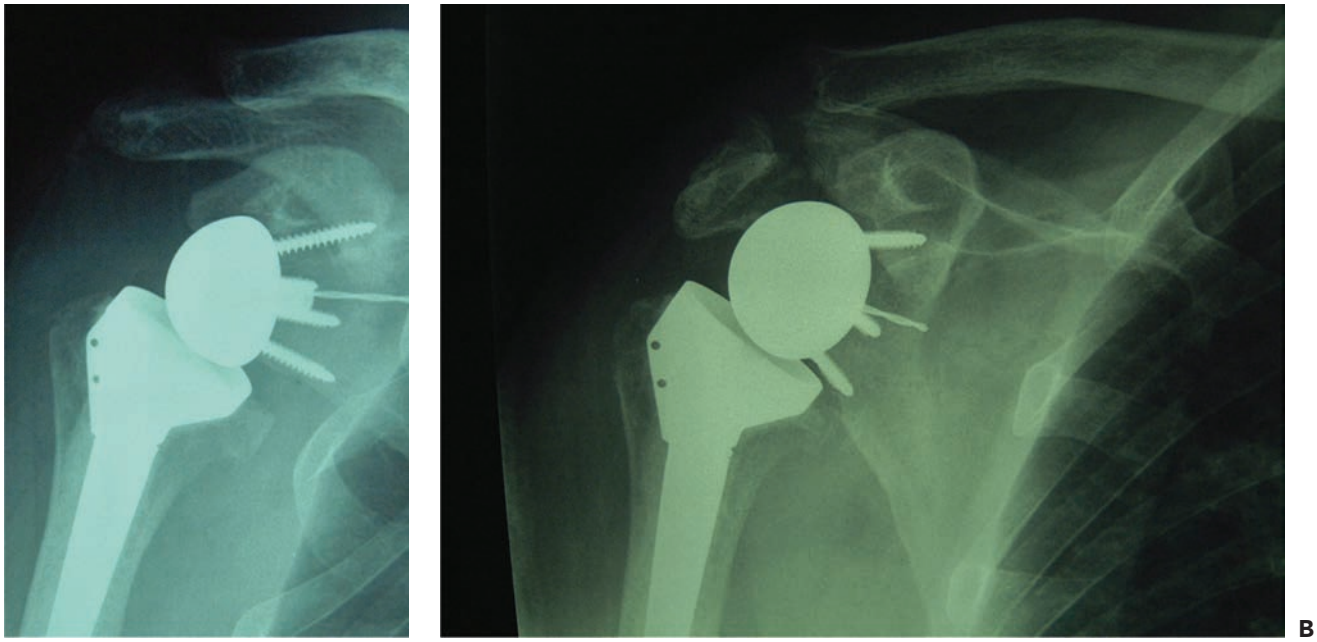

Figure 23-21 **(A,B)** Fatigue fracture of the acromion and the scapula body with a reverse total shoulder arthroplasty.

SURGICAL TECHNIQUE

This prosthesis can be placed using either the superior deltoid splitting approach, which is most popular in Europe and is recommended for the primary arthroplasty for its excellent exposure of the glenoid, or through a standard deltopectoral approach, which is preferred in revision surgery, particularly when removing as stemmed humeral implant. In these cases the deltopectoral approach is more extensile than the superior deltoid splitting approach. An extensile approach may be required to remove a secure humeral stem or other humeral hardware. A deltopectoral approach can be used in primary reverse shoulder replacement. Glenoid exposure is facilitated by absence of a superior and in many cases a posterior rotator cuff. When the subscapularis tendon is detached with a deltopectoral approach, the glenoid exposure is much better than with standard arthroplasty with an intact rotator cuff. In all cases, regardless of the approach used, there needs to be sufficient glenoid bone to allow for secure fixation of the glenoid component.

As the superior approach for the surgical technique using the superior approach for the reversed prosthesis, Delta3 has not been widely described in the English literature and will therefore be described in some detail in this chapter.

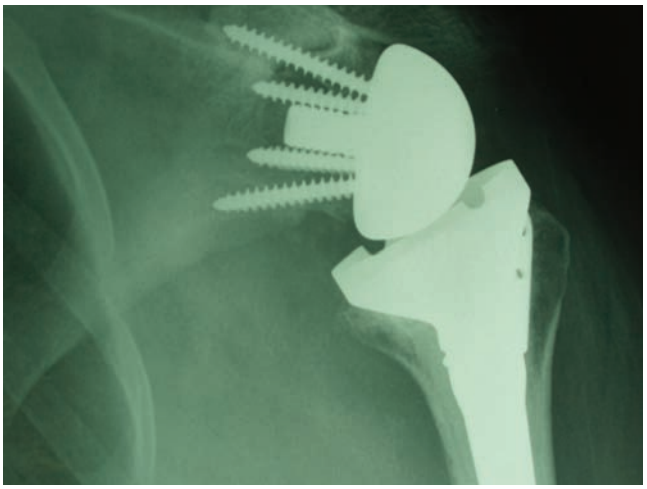

Figure 23-22 Mild inferior scapular notching.

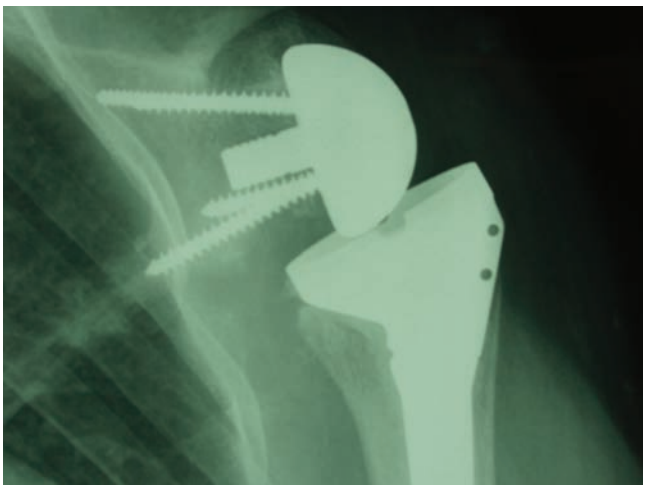

Figure 23-23 Moderate inferior glenoid notching.

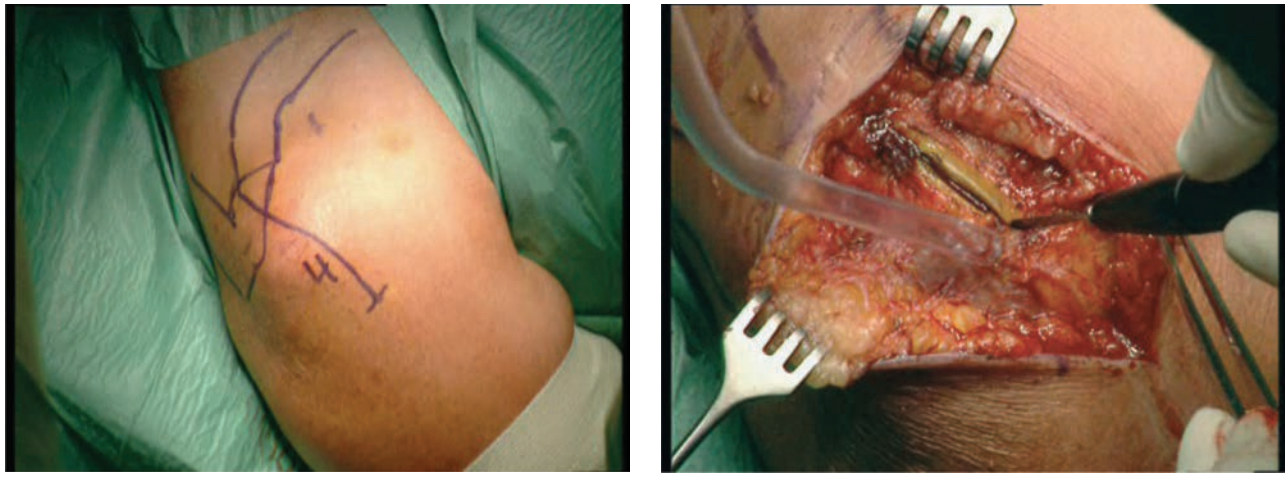

Figure 23-24 **(A,B)** A skin incision is made perpendicular to Langer's lines from the level of the acromioclavicular joint posterior to the joint over the midacromion and over the middle deltoid for a distance of 5 to 6 cm. The anterior deltoid is sharply dissected from the distal 2 cm of the clavicle and the acromion, leaving a tendon and fascia attached to the deltoid muscle for later secure attachment.

Positioning

The patient is positioned in a beach-chair position.

Surgical Exposure

An anterior–superior approach (McKenzie) is generally utilized unless a previous surgery dictates otherwise (deltopectoral, anterolateral).[41] A skin incision is made perpendicular to Langer's lines from the level of the acromioclavicular joint posterior to the joint over the midacromion and over the middle deltoid for a distance of 5 to 6 cm (Fig. 23-24). The anterior deltoid is sharply dissected from the distal 2 cm of the clavicle and the acromion, leaving a tendon and fascia attached to the deltoid muscle for later secure attachment (see Fig. 23-24). The coracoacromial ligament is cut sharply from the acromion and left attached to the undersurface of the deltoid. If there is a prominent acromion or spur, an osteotomy of the acromion is performed to the level of the anterior border of the clavicle. The humeral head is then dislocated superiorly into the wound by extension of the arm, slight external rotation, and axial load at the elbow (Fig. 23-25). The degenerative hypertrophied bursa is removed. Humeral osteophytes are removed with a rongeur.

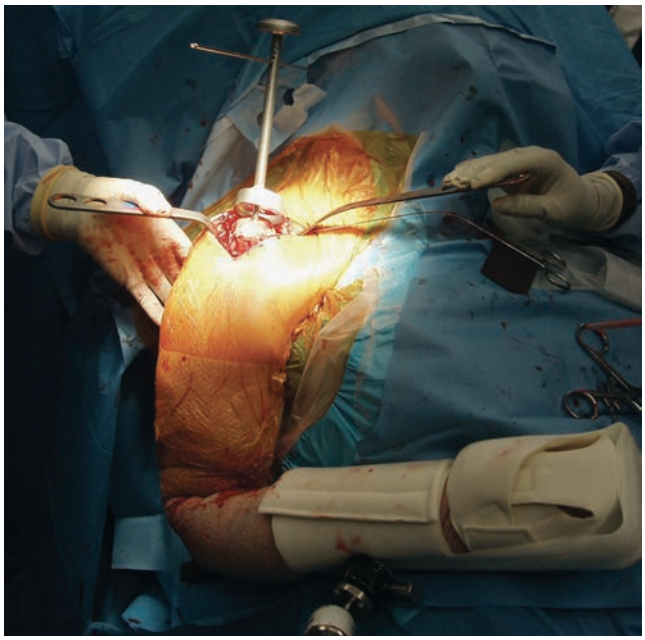

Figure 23-25 The humeral head is dislocated superiorly into the wound by extension of the arm, slight external rotation, and axial load at the elbow.

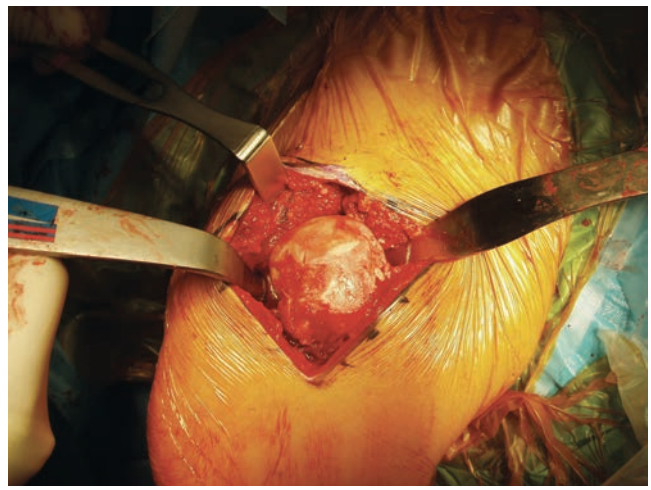

Figure 23-26 Small Homans retractors are placed beneath the intact cuff to expose the humeral head.

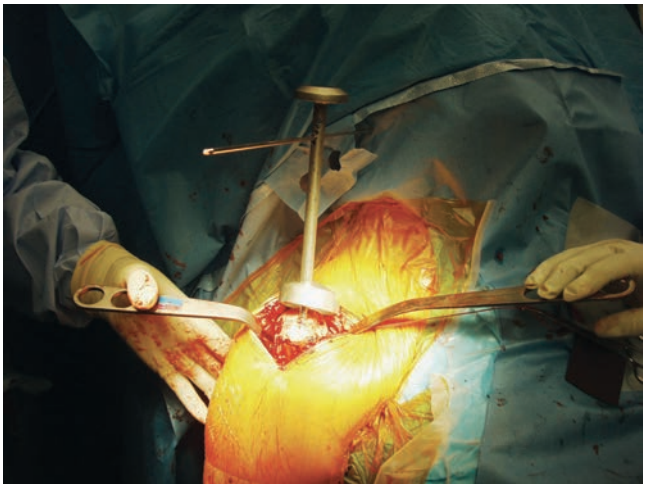

Figure 23-27 The humeral canal is broached with an intramedullary cutting guide and the head is cut in approximately 10 degrees of retroversion.

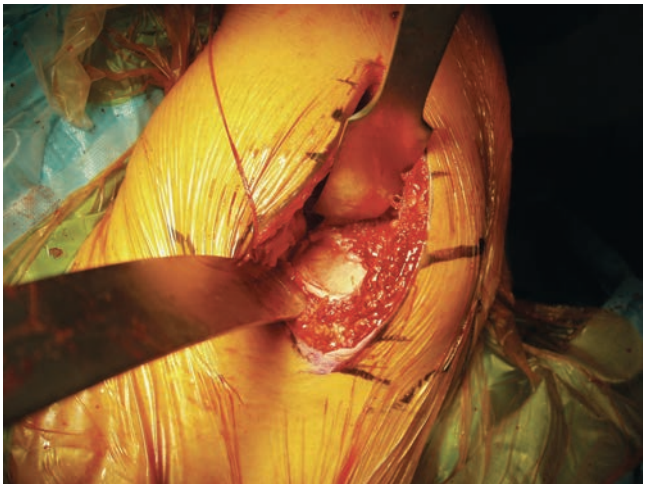

Figure 23-29 A humeral head retractor is placed to expose the glenoid and to be able to palpate the inferior scapula neck.

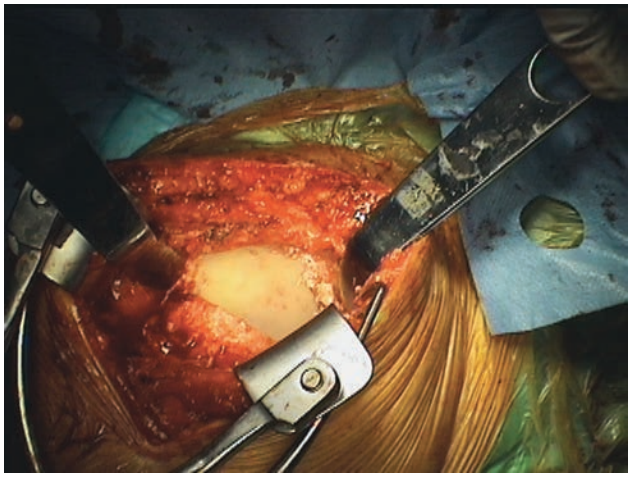
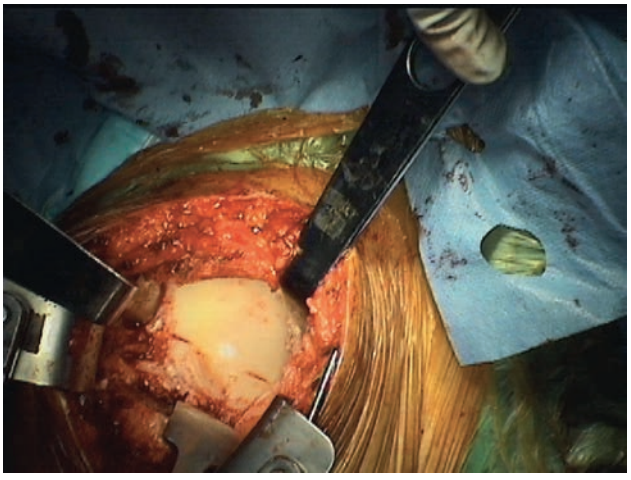
A large Darrach is placed through the cuff defect into the joint and the head is levered away from the glenoid. Any cuff tissues covering the top of the head are removed and care is taken to preserve anterior or posterior cuff tissue when it is present. Small Homans retractors are placed beneath the intact cuff to expose the humeral head (Fig. 23-26). The humeral canal is broached with an intramedullary cutting guide and the head is cut in approximately 10 degrees of retroversion (Fig. 23-27). The height of the head cut should be such that with axial distraction of the humerus, the cut surface of the humeral osteotomy is at the inferiormost portion of the glenoid (Fig. 23-28a). A humeral head retractor is placed to expose the glenoid (Fig. 23-28b). A complete capsulectomy is carried out anteriorly, posteriorly, and inferiorly. It is important to preserve the intact rotator cuff that remains anteriorly and posteriorly and expose the entire glenoid as well as be able to palpate the inferior scapula neck (Fig. 23-29).

Glenoid Reaming

Glenoid reaming is carried out in a slightly anterior and inferior orientation, if allowed by the available glenoid bone stock. This provides more articular contact and stability with the arm in internal rotation, and when the arm is in the adducted position it reduces polyethylene liner contact with the scapula neck, which minimizes inferior glenoid notching (Fig. 23-30). The reaming is preformed for the selected size glenosphere with a goal of inserting the largest component that will be accepted by the soft tissue and bone (glenoid) size. When reaming it is best, when possible, to preserve subchondral bone.

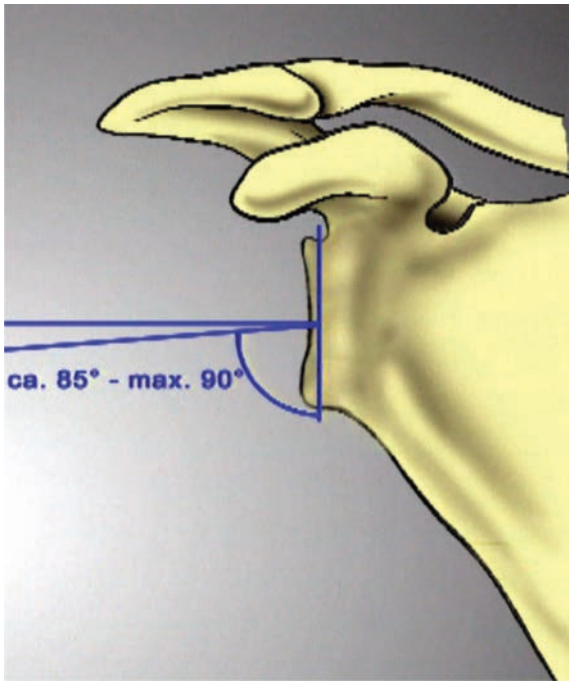
A



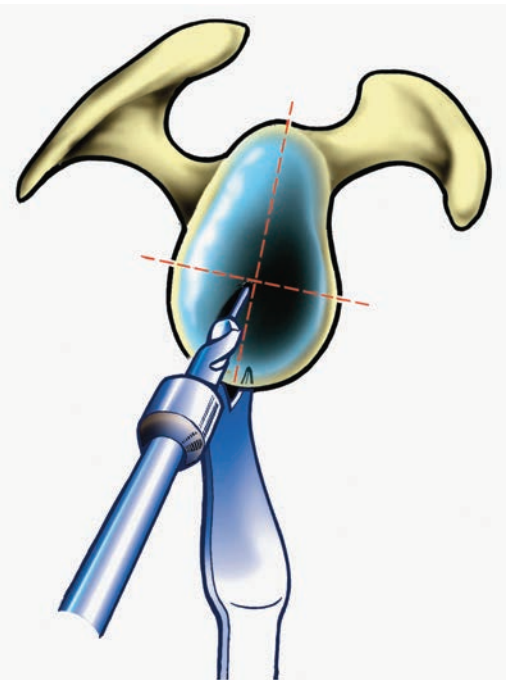


B

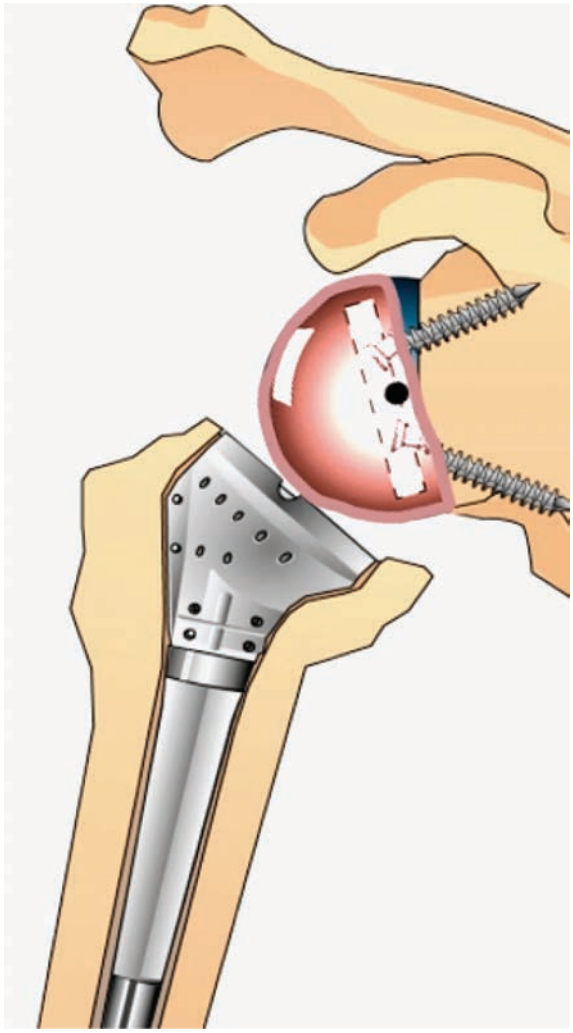
Figure 23-28 **(A,B)** The height of the head cut should be such that with axial distraction of the humerus, the cut surface of the humeral osteotomy is at the inferiormost portion of the glenoid.



A



B



C

Figure 23-30 The glenoid reamer is placed so that the glenosphere is inferior to the glenoid rim and is tilted interiorly.

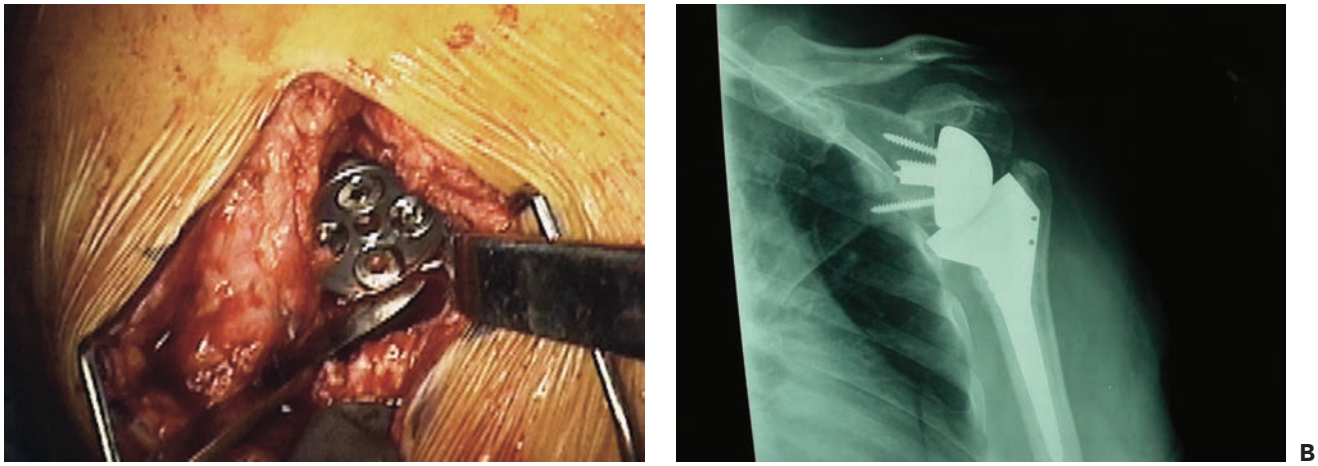


Figure 23-31 **(A,B)** It is important to have the inferior screw in the thick bone of the axillary boarder of the scapula.

Glenoid Assembly

The hydroxy-appitite–coated glenoid base plate ("metaglené") is then connected and secured to the glenoid bone using two divergent locking screws (superior and inferior) and two convergent compression nonlocking screws. It is important to have the inferior screw in the thick bone of the axillary boarder of the scapula (Fig. 23-31). The metaglené is rotated so that the inferior hole in the base plate is in line with the inferior scapula neck and scapula body. This is the first screw to be placed. Orientation of this hole is facilitated by palpation of these bony landmarks, which in turn is facilitated by inferior capsular excision. Currently, two sizes of glenospheres (both fitting onto the same size metaglené) are available (36 and 42 mm in diameter). The size to be used is defined by the diameter of the proximal humerus. When possible, it is preferable to use the larger-diameter glenosphere, which improves stability and range of motion. After secure placement of the definitive metaglené, a trial glenosphere is placed and the humeral shaft is again exposed into the wound as described above.

Humeral Side

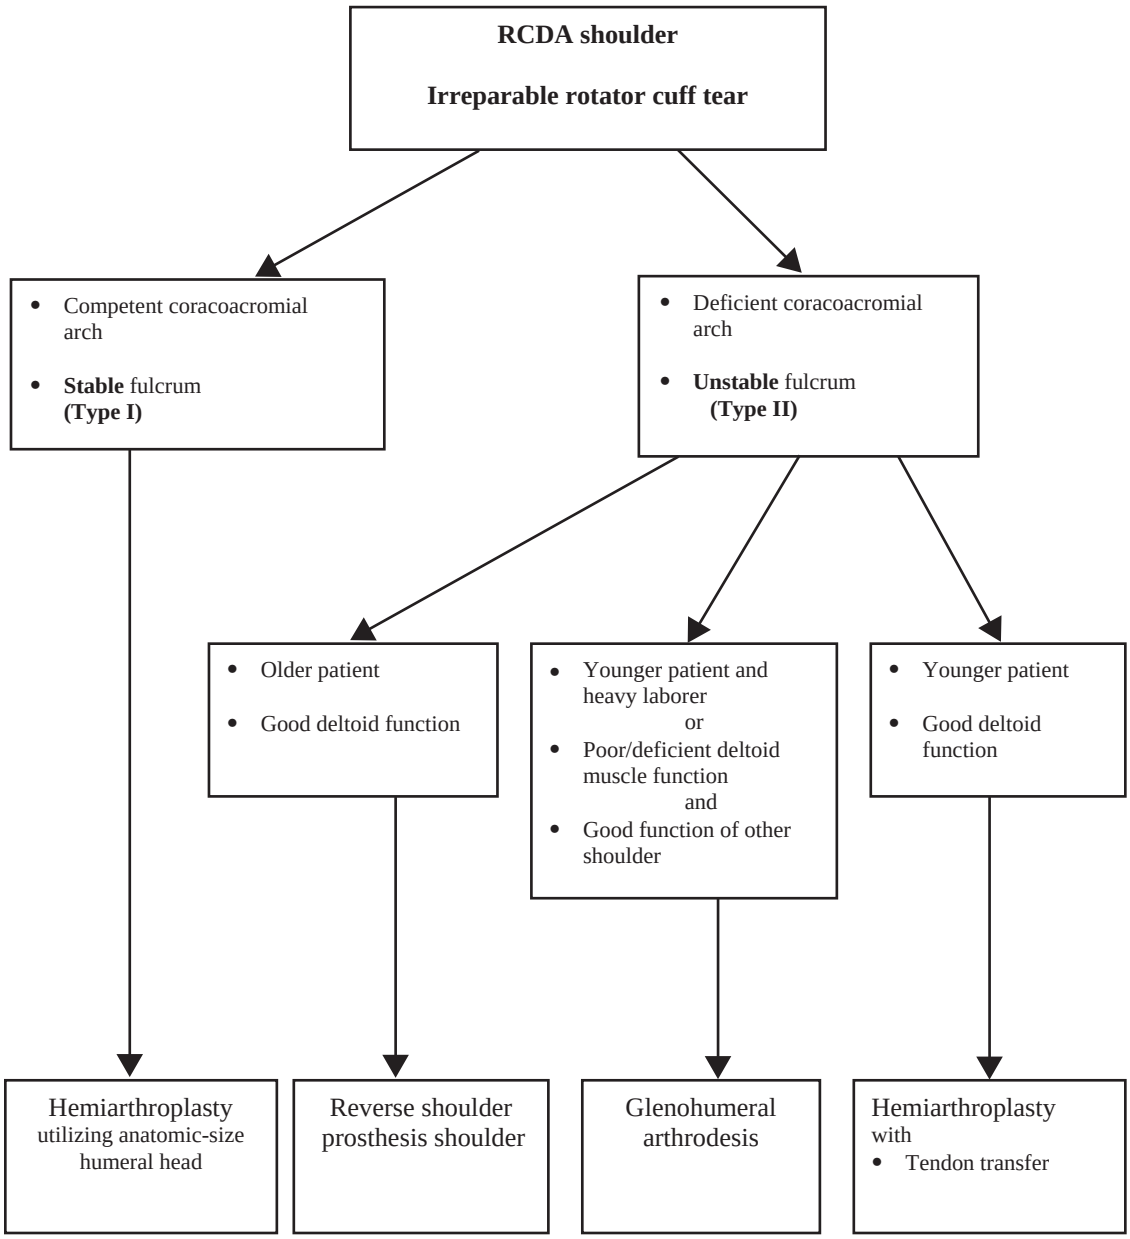
The humeral shaft and the metaphysis are reamed to cortical bone using hand reaming. Using trial components, the stability and range of motion are tested and final prosthetic height and version noted for placement of the final components. The humeral component is cemented. Three thicknesses of polyethylene inserts are available in the standard design. These thicknesses can help adjust for tissue tension at final prosthetic selection. A 9-mm metal extension component that screws into the final (and provisional) implant can also allow for increasing tissue tension after placement of the final component. Ideally, cementing the stem in the proper height is determined by tissue tension of the trial components, which makes routine use of the metal extension piece infrequently necessary. When using the trial component, the tissue tension should be judged with removal of self-retaining retractions with the arm in different positions of flexion and extension and rotation. There should not be any toggle between the components, and in most cases reduction will require firm axial distraction of the humerus to engage the components. Lift-off of the humeral component with the arm in adduction with the arm by the side of the body is not acceptable and requires correction before placement of the final components. When this occurs it is most often due to impingement of the humeral liner on the scapula neck or glenoid rim. If the glenosphere is of the proper size and placement (at or slightly below the inferior glenoid rim with a 10-degree inferior tilt), then this is usually secondary to prominent bony ridge at the glenoid rim or near the glenoid neck, which should be removed with a rongeur or burr. Similarly, if there is component lift-off with internal or external rotation, then removal of any overhanging bone on the glenoid or humeral side is often necessary. Use of the retentive polyethylene component to improve component stability should be avoided, if possible, as it has a greater tendency for notching.

Wound Closure

After thorough irrigation, the deltoid muscle is repaired side to side and with transosseous sutures to the acromion using #2 nonabsorbable braided suture.

Postoperative

Postoperatively, the shoulder is supported with a small abduction pillow for 3 to 4 weeks. Full active assisted



ALGORITHM 23-I
Algorithm for surgical management of rotator cuff–deficient arthritic (RCDA) shoulder.

range-of-motion exercises are immediately started, excluding extension or internal rotation behind the body.

TREATMENT ALGORITHM

Patients with mild symptoms and mild limitation in functional range of motion and activities of daily living should be treated nonsurgically. Painful shoulders with a stable fulcrum should be considered for a hemiarthroplasty. A competent coracoacromial arch is a keystone for successful results, and therefore, should not be damaged during the surgical procedure. Due to the high rates of glenoid component loosening, anatomic (as opposed to reverse shoulder prostheses) total shoulder replacement should not be performed for rotator cuff–deficient arthritic joints. For older patients with a painful, anterosuperiorly unstable shoulder, a reverse shoulder arthroplasty should be considered. For younger patients with an incompetent coracoacromial arch but a good functional deltoid, a combination of hemiarthroplasty and tendon transfer can be considered. For younger heavy laborers and those with a

nonfunctional deltoid muscle, an arthrodesis is a better option than prostheses.

Instability 766
Component Problems 767

While there has been discussion in the literature concerning complications of shoulder arthroplasty, they are often addressed obliquely in the materials presented with only a few articles concentrating on a specific complication. By collating this literature, one can evaluate the types and frequency of complications but is less informed about the nuances of each type of complication and treatment recommendations. Therefore, we have felt it important to not only detail the information in various patient series and display the lesser number of articles addressing a specific complication, but also to present the materials developed over time at our institution that can be analyzed in some depth.

TYPES AND FREQUENCIES OF COMPLICATIONS

Literature

Previously, we identified 22 patient series published since 1980 on unconstrained total shoulder arthroplasty (TSA).[1–22] Combined, these series have reported on 1,183 total shoulder arthroplasties. The authors identified 23 different complications. The total number of complications was 123 for a relative percentage of complications of 10.4%, assuming one complication occurred in each of the shoulders having a complication. Certainly some shoulders had two or more complications, so the number of shoulders having a complication would be somewhat less than 10%. Only rotator cuff tearing, instability, and glenoid loosening occurred in more than 1% of shoulders reported (Table 24-1).

We identified 20 patient series reporting on hemiarthroplasty of the shoulder that have been published since 1980.[5,6,19,21,23–38] These included reports on 498 shoulders. Nineteen different complications were identified and 78 total complications were reported for a relative frequency of complications of 15.7%, assuming only one complication occurred in each shoulder (Table 24-2). Six complications occurred at a frequency of 1% or greater. These included glenohumeral instability, painful glenoid arthritis, humeral tuberosity nonunion, rotator cuff tearing, nerve injury, and infection.

The Mayo Clinic Experience

Total Shoulder Arthroplasty

The relative incidence and type of complications at our institution have changed over time. In 1999, we reported on 419 unconstrained total shoulder arthroplasties performed by the senior author (RHC) between December 1975 and December 1989.[39] The complications were defined according to time of occurrence, with early complications occurring within 90 days of surgery and late

complications occurring after this period of time. Surgical complications were also classified as minor when there was no compromise of outcome and little or no treatment was required. A major complication occurred when the final result was compromised or reoperation was required.

Among these shoulders, 130 (31%) had a major surgical complication, with 95 of these shoulders requiring reoperation (Table 24-3). The most frequent complication requiring reoperation was joint subluxation followed in order of frequency by rotator cuff tearing, glenoid loosening, dislocation, humeral loosening, and infection. One can see that the variety and aggregate number of complications in the early experience with the shoulder arthroplasty was quite high. Therefore, we reviewed the outcome of a more contemporary group of patients to determine whether the complications have changed or the complication rates have lessened over time.

The complications of 431 total shoulder arthroplasties performed in patients by the senior author (RHC) between December 1990 and December 2000 were reviewed.[40] Fifty-three surgical complications occurred in 53 patients. Thirty-two were considered to be major (7.4%), with 17

(3.9%) of these requiring reoperation (Table 24-4). Thirty-two occurred early and 21 occurred late. Rotator cuff tearing was the most common complication encountered. Of the 17 symptomatic cases of rotator cuff tearing, eight patients had a preoperative rotator cuff tear. There were four postoperative subscapularis tears and all four patients experienced anterior instability. When comparing the five main categories of diagnosis (osteoarthritis, rheumatoid arthritis [RA], posttraumatic arthritis, cuff tear arthritis, and osteonecrosis) there was no statistically significant difference ($P = 0.088$) in the complication rates observed in each of these groups—when comparing each of the last four diagnostic categories relative to the primary diagnosis of osteoarthritis. Risk factors for any complication and for specific complications were carefully assessed. The frequency of complications was not affected by age, gender, previous surgery, humeral head size, or whether the humeral component was cemented or uncemented.

When comparing this with the prior study, one can clearly see that the frequency of complications has dramatically decreased as has specifically the number of major complications and the need for reoperation. In addition to the general lessening of complications, there is the noticeable striking diminution of component loosening.

Hemiarthroplasty

We have analyzed our hemiarthroplasties in two groups. The first group includes those with glenohumeral arthritis—either osteoarthritis or RA. Between July 1977 and March 1983, 77 shoulders were so treated in 74 patients.[41] Six patients with six operated shoulders were lost to follow-up and four others died before evaluations were complete. This resulted in 67 shoulders in 64 patients forming the basis of the review. There were 35 shoulders in 35 patients with osteoarthritis and 32 shoulders in 29 patients with RA. Follow-up evaluation averaged 9.3 years and ranged from 2 to 14.1 years. There were three complications: One patient developed a hematoma requiring surgical evacuation; the second had a humeral shaft fracture at the time of surgery, which was treated with internal fixation using a long-stemmed component and cerclage (the fracture healed); and the third complication was a brachial plexus traction injury that recovered without residual symptomatology.

The outcome of humeral head replacements performed for acute proximal humeral head fractures and chronic proximal humeral head fractures between 1979 and 1995 was also reviewed, focusing on complications.[42] Twenty-eight replacements were performed in 26 patients with acute fractures and 55 hemiarthroplasties were performed in 55 patients for problems that arose following initial treatment for a proximal humeral fracture or fracture-dislocation. Again, all patients were included to be sure that every complication was recognized during the follow-up period. In the acute group follow-up averaged 56 months, ranging from 2 to 184 months, while in the chronic group follow-up averaged 57 months, ranging from 5 to 156 months. The complications identified for these acute and chronic fracture groups are displayed in Table 24-5. One is immediately impressed that these are much greater in number and many more types of complications arose when compared with hemiarthroplasty done for the elective treatment for shoulder arthritis.

SPECIFIC TYPES OF COMPLICATIONS

The six significant and most common complications will be individually presented. Material will generally be arranged in the following sequence: the recognition and evaluation of the complication with a classification system if one is applicable, reference to the frequency of the complication as presented in the literature, identification of specific literature for the complication, notation of materials included in pertinent review articles, the experience with this complication at the Mayo Clinic, methods to prevent the complication, and treatment for the complication.

Nerve Injury

Physical examination of the operated upper extremity is the key to diagnosis following surgery. It is quite practical to ask the patient to perform active movement of the hand and wrist and to test for isometric contractions of the elbow flexors and the posterior portion of the deltoid muscle. This usually can be accomplished on the day of surgery; however, interscalene block is now commonly used, making it sometimes necessary to perform the neurologic examination the

day following surgery. Should a nerve injury be identified, the common peripheral nerve injury classification that is defined by Seddon or Sunderland is probably useful in retrospect but has less value in the acute setting.[43,44] Weber et al. developed a post-hip arthroplasty nerve palsy severity scale based on symptoms, physical examination, electromyographic findings, and the compromise of postsurgical rehabilitation,[45] and it is useful as a grading system. This scale, though, as with the more standard classification scheme, is only fully applicable over time, as the nerve injury evolves, and less helpful in the acute setting. Electromyographic testing may be useful after the initial 3 weeks, but as will be explained below, is probably more practical at 4 to 6 weeks, should neurologic recovery not occur in the interim.

In the 22 patient series encompassing 1,183 operated shoulders that were reported since 1980 and defined in Table 24-1, seven nerve injuries (0.6%) were identified following TSA. In the 20 patient series involving 498 shoulders reported since 1980, eight nerve injuries (1.6%) were identified following hemiarthroplasty. The slightly higher frequency following hemiarthroplasty may be attributed to this surgery often occurring in the acute setting where some degree of nerve injury might complicate the initial fracture and yet not be fully defined because of the inability to perform a complete examination before surgery. Only one article has been published on neurologic complications after TSA.[46] These authors identified eight neurologic deficits reported in the literature. Of these five were axillary nerve palsies, only one of which completely resolved and two partially recovered. One musculocutaneous nerve palsy did not resolve. One radial nerve palsy responded completely to removal of cement that had extruded through a humeral defect during revision surgery. The final injury produced ulnar nerve dysesthesias, which resolved.

Nerve injuries have received comment in review articles of shoulder arthroplasty. Miller and Bigliani mentioned that nerve injuries are uncommon, that they most often represent a neurapraxia, and that the axillary nerve is the most likely to be injured.[47] They are of the opinion that if the initial lesion is partial and improving, observation is indicated. If there is a suspicion that the nerve was lacerated at surgery and electromyography at 6 weeks reveals a complete lesion with no improvement at 12 weeks, exploration and surgical repair are suggested. Wirth and Rockwood were able to identify 14 reported nerve injuries following total shoulder replacement.[48] Again, they felt most of the injuries represented a neurapraxia with nonoperative treatment being appropriate. Six lesions involved the axillary nerve, three the ulnar nerve, two the musculocutaneous nerve, and one the median nerve, and two were a more general brachial plexus injury. Resolution was complete in seven, was incomplete in two, and did not occur in one, and in four the extent of recovery was not defined. Importantly, in two shoulders there was a laceration of the axillary nerve occurring in a heavily scarred operative field. Soghikian and Neviaser[49] presented a thorough discussion of complications of hemiarthroplasty, and similarly Muldoon and Cofield[42] presented material on complications of hemiarthroplasty for proximal humeral fractures; in neither of these reviews was nerve injury identified as a complication.

Lynch et al. reported the Mayo Clinic experience with neurologic complications after TSA.[46] Four hundred seventeen arthroplasties were studied. Seventeen patients with 18 operated shoulders had a neurologic deficit after surgery (4.3%). All appeared to be traction injuries; 13 involved the brachial plexus. The upper and middle trunk were involved in six, the upper trunk in three, the lateral

cord in two, the lower trunk in one, and all trunks in one. Interestingly, three were thought to represent the initiation of an idiopathic brachial neuritis. One patient with dysesthesias after earlier radiation therapy had an increase in the level of dysesthesias in the lower trunk and one patient developed median neuropathy at the wrist. The quality of recovery in the first 16 patients was graded as good in 11 and fair in five. Time to recovery was less than 3 months in eight, 3 to 6 months in four, 6 to 12 months in one, and greater than 12 months in three. Numerous patient factors were studied including diagnosis, age, sex, height, weight, use of corticosteroids, the presence of diabetes mellitus, preoperative range of motion, the presence or absence of rotator cuff disease, previous surgery, and the use of interscalene block. None of these was found to be related to a nerve injury. However, exposure through the slightly more demanding deltopectoral approach ($P = 0.003$) and the use of methotrexate in patients with RA ($P < 0.0001$) were statistically associated with the development of a postoperative nerve palsy. Thus, this series of a large number of shoulder arthroplasties defines that brachial plexus stretch injuries are by far the most frequently recognized neurologic deficits following prosthetic shoulder arthroplasty, that when searched for nerve injuries are more common than has been recognized, and thankfully that recovery is the rule, without significant compromise to the arthroplasty per se.

As identified by the above information, prevention of nerve injuries at surgery is usually, but not always, possible. Certainly, locating the axillary nerve at the inferior aspect of the subscapularis and near the posterolateral aspect of the humerus is useful, and careful retraction of the conjoined group is important. Dissection on the undersurface of the superior and posterior aspects of the rotator cuff should not extend more than 1 cm medial to the glenoid rim, to avoid injury to the suprascapular nerve. Positioning of the arm in extension and abduction with external rotation should be limited in extent and time as much as possible. To facilitate all of these protective measures, it is important to have a dry operative field and to be especially cautious when there is distortion of anatomy such as following an old fracture or fracture-dislocation.

Concerning treatment, definition of the injury by careful physical examination is important. If there is weakness of hand, wrist, or elbow function, splinting may be necessary. Swelling should be minimized by elevation and use of compressive dressings. If active motion is not possible for the hand, wrist, or elbow, passive motion should be used. Passive motion of the shoulder should be commenced during the early postoperative period (within the limits determined at surgery) with active assisted motion initiated as the return of strength will allow.

If there is no improvement in neurologic function by 4 to 6 weeks, electromyography with nerve conduction should be performed to determine more precisely the localization and extent of the nerve injury. If the lesions are diffuse and incomplete, one would suspect a brachial plexus stretch–type lesion and conservative measures would continue. If a focal complete nerve injury is identified such as to the axillary nerve, one would be more concerned about a significant adverse intraoperative event. Quite likely in this setting, continued observation would occur. Further examination would be performed at 3 months. If there was no apparent recovery, electromyography would be repeated at that time and more serious consideration would be given to operative intervention to address the isolated nerve lesion. There is an important caveat, however: So few nerve lesions have occurred due to trauma to a specific nerve that it is hard to be concrete about the recommendations for surgical exploration, other than those indications that apply in general to focal peripheral nerve injuries associated with surgical intervention.

Periprosthetic Fractures

Fractures can occur both intraoperatively and postoperatively. Intraoperatively, humeral shaft fractures are most common. Fractures can also involve the proximal humeral metaphysis, the humeral tuberosities, the glenoid, and the coracoid process. Postoperatively, humeral shaft fractures are also most common. Fractures can involve other areas including the acromion process and the coracoid process. The recognition of a fracture intraoperatively may be obvious, but sometimes undisplaced cracks develop in the bone that are only detected on subsequent radiographs. Postoperative humeral shaft fractures have been classified by Wright and Cofield.[50] Type A extends proximally from the tip of the prosthesis and may create stem loosening (Fig. 24-1). A type B fracture is centered at the tip of the stem with minimal to no proximal extension (Fig. 24-2), and the type C fracture involves the humeral shaft distal to the tip of the prosthesis and usually includes fracturing into the distal humeral metaphysis (Fig. 24-3).

All of these fractures following TSA are relatively uncommon, as can be seen from Table 24-1. Intraoperative fractures occur in less than 1% of cases and postoperative fractures occur in less than one-half of 1% of cases. Following humeral head replacement (Table 24-2), intraoperative fractures and postoperative fractures are even less common. However, it is not unusual for a number of arthroplasty series to report one or two humeral shaft fractures, and such is the case with reports by Kelly et al.,[16] Boyd et al.,[51] Barrett et al.,[3] Hawkins et al.,[15] and Faludi and Weiland.[52] The fractures have occurred during varying maneuvers during surgery including exposure, humeral preparation/reaming, and humeral implant insertion. Additionally, three glenoid fractures were described, one by Kelly et al. and two by Hawkins et al. Similarly, a number of these series have described the occasional postoperative fracture including the report of one humeral shaft

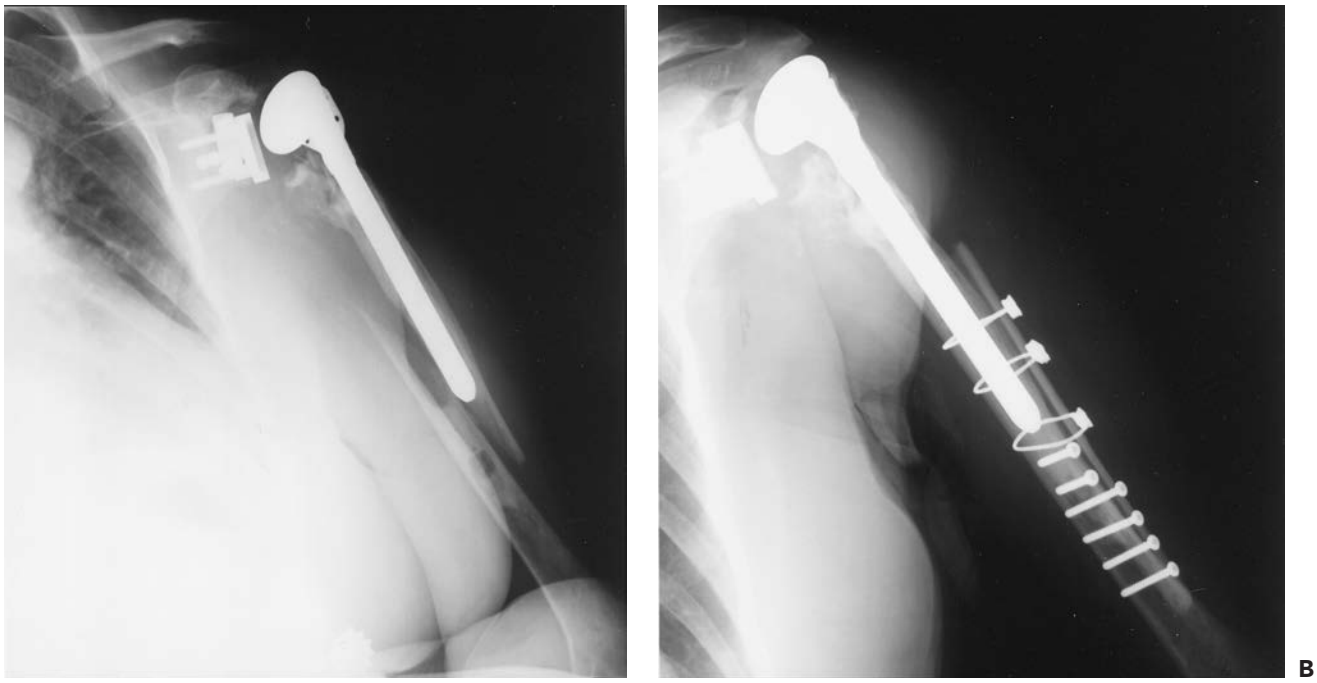

Figure 24-1 **(A)** Example of a type A fracture through the bone and cement mantle. The humeral component was well fixed. The periprosthetic fracture was treated with a cortical strut, cables, and screws. **(B)** Radiograph taken at 4 months demonstrates a healed fracture; however, the strut graft did not appear to be incorporated. (Reproduced with permission from Kumar S, Sperling JW, Haidukewych GH, Cofield RH. Periprosthetic humeral fractures after shoulder arthroplasty. *J Bone Joint Surg* 2004;86A:680–689.)

fracture by Barrett et al.,[3] one humeral shaft fracture by Neer et al.,[18] one humeral shaft fracture by Brenner et al.,[7] three humeral shaft fractures by Post et al.,[53] one humeral shaft fracture by McElwain and English,[54] and one acromial fracture by Arnst et al.[23] and another by Thomas et al.[55] Thus, although fracturing is indeed uncommon, it in fact does occur, and many of the authors reporting on shoulder arthroplasty have experienced this complication at some point in time.

Only a few reports have specifically addressed this problem. Boyd et al. identified seven humeral shaft fractures after shoulder arthroplasty.[56] Treatment was complicated, and five fractures did not unite until surgery was performed. Fractures that were treated operatively healed. In five of the six patients who had union of their fracture, shoulder motion was lost compared to prefracture levels. The authors of this study identified many associated factors including injury to the radial nerve, the high frequency of delayed union or nonunion, the question of mechanical interference with fracture healing by the prosthesis or cement, the advanced age of many patients, the presence of osteopenia or systemic disease, the questionable effectiveness of immobilization, the extensive time to union, and the compromise of function of the shoulder arthroplasty. Because of the small size of the patient group, the many diverse factors that need to be considered, and the variation in outcome, it was difficult for the authors to reach clear recommendations relative to fracture treatment.

Bonutti and Hawkins identified four patients with fracture of the shaft of the humerus.[57] They recognized the historical success with treatment of humeral shaft fractures by conservative means but felt that aggressive treatment was needed for fracture of the shaft of the humerus associated with shoulder arthroplasty. Groh et al. identified 11 fractures adjacent to humeral prostheses.[58] Four fractures extended from the proximal portion of the humeral shaft to beyond the distal tip of the prosthesis, and two occurred immediately proximal to the tip of the prosthesis. Three proximal fractures were managed with an orthosis. The remainder were treated with the combination of a long-stem prosthesis and cerclage wires. All fractures healed and function of the shoulder arthroplasty was maintained.

Campbell et al. identified 16 intraoperative and five postoperative periprosthetic humeral fractures.[59] Fracture outcome was analyzed according to three groups: cast or brace immobilization, intramedullary fixation with a humeral stem plus cerclage wiring, and plate or screw fixation. Stable intramedullary fixation provided superior results in time to union, had less effect on rehabilitation of the shoulder, and demonstrated a trend toward fewer complications. They felt that cast or brace immobilization

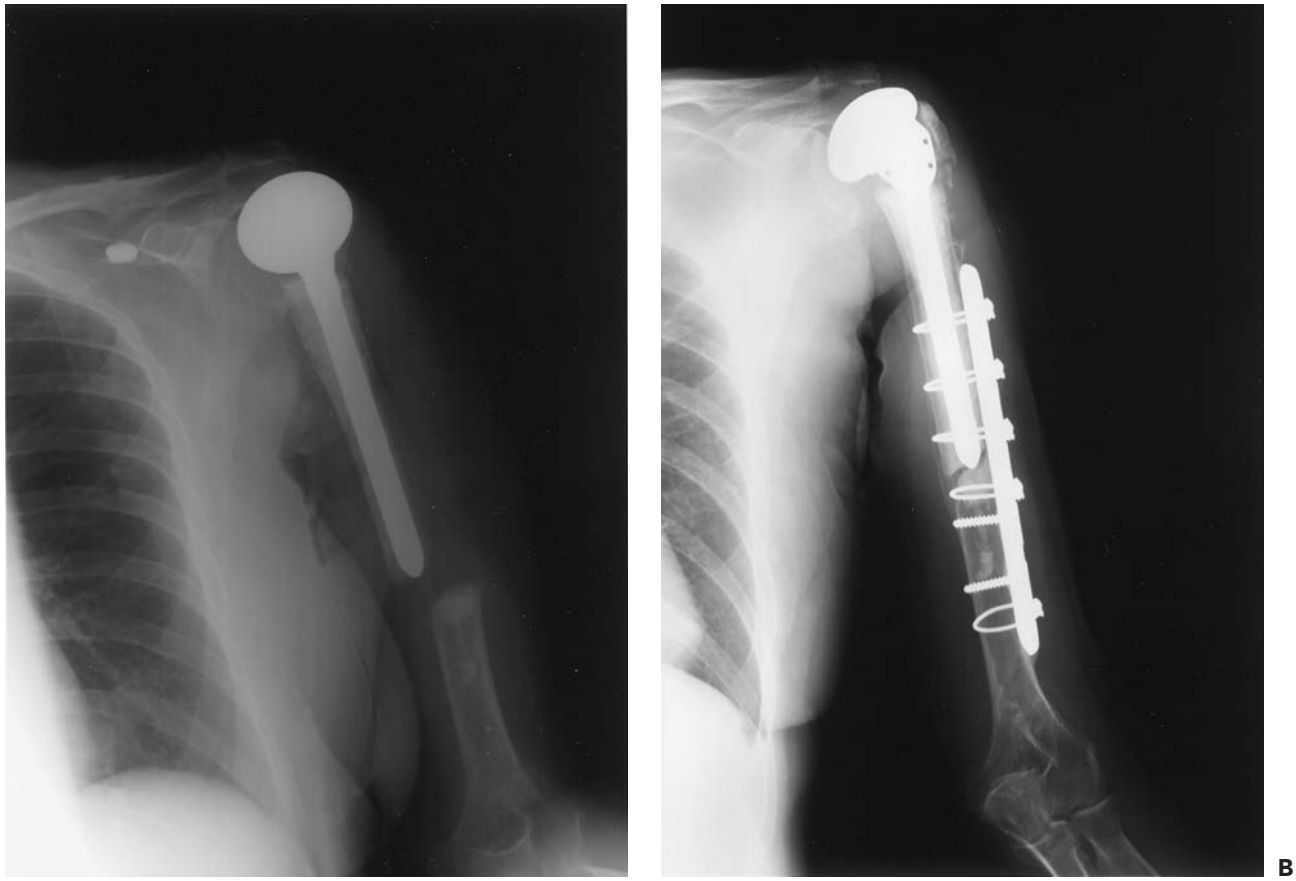

Figure 24-2 **(A)** This patient sustained a type B fracture that subsequently went on to a nonunion with nonoperative treatment. The humeral component was well fixed. Therefore, the patient was treated with open reduction and internal fixation with iliac crest bone graft. **(B)** Radiographs taken 27 months later demonstrate that the fracture healed. (Reproduced with permission from Kumar S, Sperling JW, Haidukewych GH, Cofield RH. Periprosthetic humeral fractures after shoulder arthroplasty. *J Bone Joint Surg* 2004;86A:680–689.)

could be acceptable for postoperative fractures distal to a well-fixed prosthetic stem. The authors noted that more proximal fractures should be fixed with a stem of appropriate length and cerclage wiring.

Three reviews on periprosthetic fractures have been performed at the Mayo Clinic.[50,60,61] Krakauer and Cofield's report included the outcome of intraoperative periprosthetic fractures in total shoulder replacement.[60] Intraoperatively, over an 18-year period, there were nine humeral shaft fractures, five greater tuberosity fractures, two proximal humeral metaphyseal fractures, four glenoid fractures, and two coracoid fractures. Of the intraoperative humeral shaft fractures, stability was achieved with a long-stem implant in six and with cerclage fixation in one. Two fractures were undisplaced and no fixation was performed; healing occurred in one but nonunion developed in the other. Three of the greater tuberosity fractures were sutured. The other two were undisplaced fractures and treated without fixation. One of the sutured greater tuberosities went on to nonunion and compromised active shoulder function. The proximal humeral metaphyseal and coracoid fractures created no adverse effect on arthroplasty outcome. The four glenoid fractures precluded placing an implant, and two of these patients continued to have moderate pain with their hemiarthroplasty.

Between 1976 and 2001, 19 postoperative periprosthetic humerus fractures occurred among 3,091 patients who underwent shoulder arthroplasty at the Mayo Clinic.[61] The outcome of 16 patients who had a complete series of radiographs were included in the study. The mean time from the arthroplasty to the fracture was 49 months (range 1 to 146 months). The indication for the arthroplasty was osteoarthritis in five patients, RA in five patients, failed arthroplasty in two, avascular necrosis in one, posttraumatic arthritis in one, and proximal humeral nonunion in two patients. There were seven patients with severe osteopenia. Twelve fractures occurred at the prosthesis tip, of which six extended proximally (type A) and six did not (type B). There were three fractures distal to the implant and extended into distal humeral metaphysis (type C).

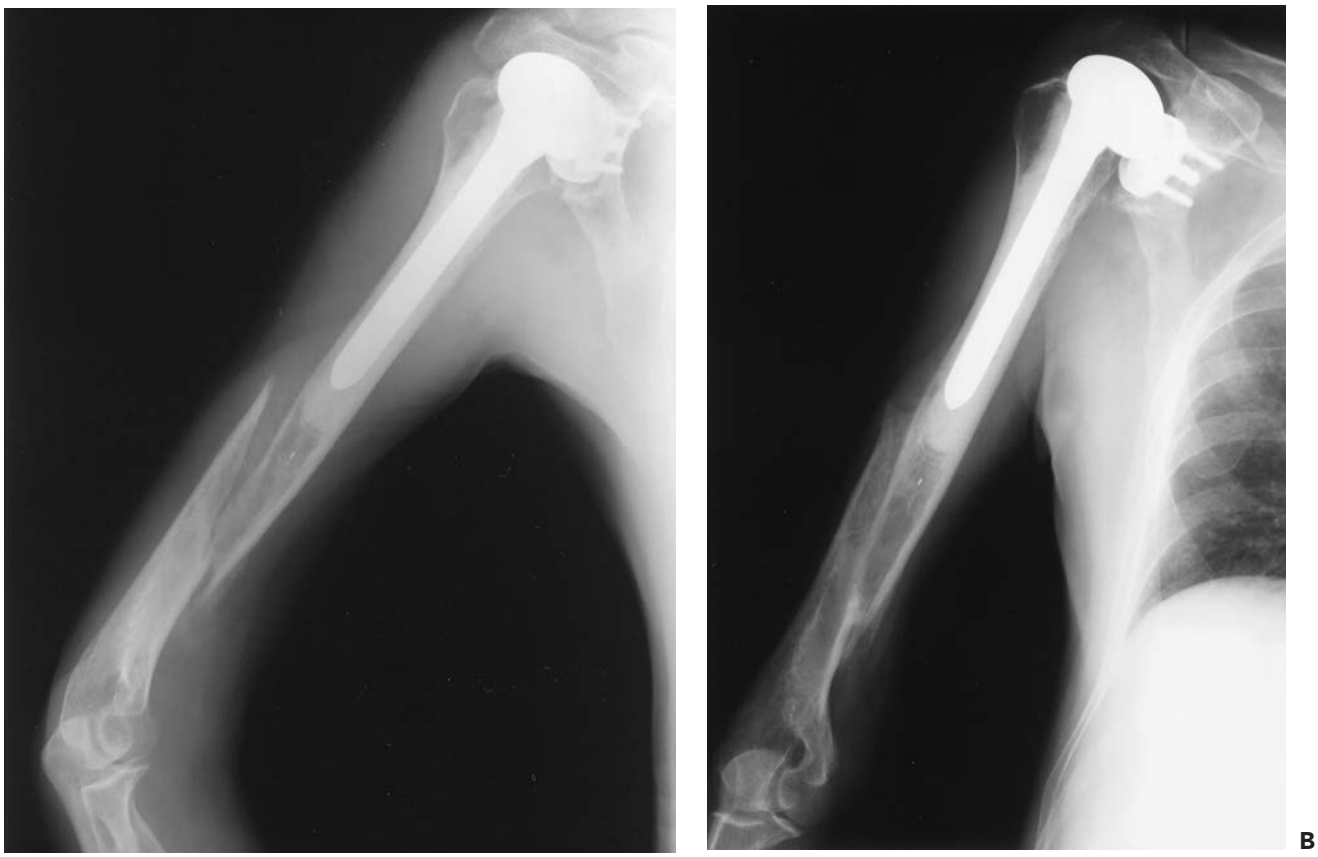

Figure 24-3 Example of a type C periprosthetic fracture **(A)** that was treated nonoperatively and went on to heal in 239 days **(B).** (Reproduced with permission from Kumar S, Sperling JW, Haidukewych GH, Cofield RH. Periprosthetic humeral fractures after shoulder arthroplasty. *J Bone Joint Surg* 2004;86A:680–689.)

One fracture occurred in the proximal metadiaphyseal region due to osteolysis.

There were six fractures that healed with nonoperative treatment at a mean of 180 days. Five of 10 fractures requiring operative management had failed to heal at a mean of 123 days with nonoperative care. The remaining five fractures underwent immediate operative intervention. All of the fractures healed. One patient required multiple procedures including a free fibula transfer. This patient took 1,116 days from the time of first surgery to heal. Except for this case, it took a mean of 230 days after the first surgery for the fractures to heal.

The authors reported that the data from this study did not clearly indicate the need for surgery in the case of a type A fracture. Type B fractures should be treated with surgery. Open reduction and internal fixation should be performed if the component is well fixed. Revision with a long-stem component is recommended if the component is loose. A trial of nonoperative treatment was recommended among those with type C fractures.

The majority of intraoperative fractures can be prevented. As a part of preoperative planning, any stress-risers in the bone should be identified and osteopenia should be noted. One must be careful twisting the humerus during exposure, bone preparation, or seating of the implant. Forces across the humerus or other bones can be diminished by appropriate release of scar and capsular contractures. For patients with extreme osteopenia, one should consider the anteromedial surgical approach with release of the deltoid origin on the clavicle and anterior acromion rather than the deltopectoral approach. This greatly lessens the forces needed for exposure.

Even with the small experience reported by each individual author, the accumulating experience suggests that recommendations for treatment can be made. If an intraoperative humeral shaft fracture occurs, it should almost always be internally fixed; typically this would be with a long-stem humeral implant and wire cerclage. For very distal fractures, plate fixation may be preferred. Similarly, greater tuberosity fractures should almost always be sutured with heavy, nonabsorbable suture or wire. Postoperative humeral fractures may be considered in three categories in the manner of Wright and Cofield. For proximal fractures that involve the implant and are associated with

implant loosening, revision arthroplasty with insertion of the long-stem humeral implant and cerclage fixation should be strongly considered. For those fractures centered around the tip of the implant without a great deal of proximal fracture extension, external support can be undertaken if skeletal alignment is adequate. If skeletal alignment cannot be achieved or delayed union occurs, open reduction and internal fixation (ORIF) with a plate, screws, and cerclage would be indicated. For fractures involving the distal humerus, treatment would be dictated according to the guidelines for distal humeral fractures. This might include external support in the presence of excellent skeletal alignment or ORIF for displaced, unstable fractures.

Infection

Evolution in thinking regarding infections around the prosthetic joint arthroplasty has been directed toward four categories of infections. The first is a positive culture obtained at the time of the arthroplasty, perhaps associated with previous internal fixation. The second is an acute infection developing within 2 to 3 months following the arthroplasty. The third is an apparently acute, probably hematogenous, infection developing quite typically a year or several years following the initial arthroplasty, and the fourth is a chronic infection, sometimes associated with sinus tract formation.

The recognition of a latent, low-grade infection at the time of the arthroplasty can be somewhat difficult. The joint fluid may be slightly opaque. The synovial lining may include scattered areas of mild erythema, small foci of granulation tissue may be present on the eburnated bone surfaces, and the reactive fibrosis may be somewhat softer and slightly more pink than white. However, all these changes may be absent, or if not, quite subtle. A frozen section may show a few foci of polymorphonuclear leukocytes or in fact may show a mild, rather nonspecific low-grade inflammatory response with lymphocytic cells—not atypical of many patients with arthritis. Occasionally in this setting, particularly in individuals who have had previous surgery and internal fixation, it may be prudent to remove the internal fixation to débride any abnormal tissue, to close the wound, and to await cultures before proceeding with the arthroplasty. Judgment in these cases can be extremely difficult, and it seems there are no clear-cut guidelines for these borderline situations.

When infection develops in the acute phase, within the first months following surgery, distinction between a superficial infection and a deep infection can be difficult. The presence of a postoperative hematoma may also cloud the issue. The patient often has the symptoms and signs of an acute infection, but they may be muted. There may be some malaise of varying degree; a fever may or may not be present; the wound can be slightly more swollen than usual, particularly in the presence of a focal hematoma, or the wound may be slightly to markedly red. There may be drainage, or there may not be. The erythrocyte sedimentation rate will be elevated and probably won't be of much diagnostic value. Serum C-reactive protein holds some promise in identifying patients with subacute infections. Similarly, the white blood count can be abnormal in the acute postoperative phase, but abnormalities in the subacute phase will be suggestive of the presence of an infection. Standard radiographs may show gas in the tissues, but this would be unusual. Scintigraphic techniques are probably of little value. Needle aspiration is usually indicated. In the end, débridement with culture of the deep tissues may be the only way to diagnose an infected shoulder arthroplasty in the immediate postoperative period.

An acute, presumably hematogenous infection developing in a previously well-functioning arthroplasty is usually diagnosed clinically, in association with laboratory studies and joint aspiration.

Distinguishing a late, indolent, chronic infection from a mechanical problem can be easily accomplished or may be extraordinarily difficult. Certainly in a patient with a painful arthroplasty, infection should always be considered. The external examination may be normal. The radiographs, however, may show lucencies surrounding the components. In the humerus there may be resorption of bone, particularly in the area of the humeral calcar; laminated periosteal new bone formation; scalloping of the endosteal bone surface; or evident sinus formation through bone. The more chronic and low-grade the infection is, the more likely it is that the laboratory studies will be normal. Scintigraphy can be quite revealing. Usually the technetium-labeled scan will be positive throughout the arthroplasty region if infection is present. However this can also be active in the presence of noninfectious inflammation or mechanical problems. We prefer to supplement that scan with an indium labeled leukocyte scan. This will not always be clearly abnormal, but when positive, it is highly suggestive of infection. Joint aspiration should be performed, and arthrography should not be forgotten. Arthrography can be quite useful at showing irregularities, that is, hypertrophic changes within the synovium, fistula formation from the joint perhaps communicating with a pseudo-bursa, and dye tracking along the interface of the implant or implant and cement with the bone in an irregular fashion. Despite these tests, we have found preoperative studies to be very ineffective in determining the presence of infection.[62]

Referring to Table 24-1, infections reported in the recent total shoulder arthroplasty literature occurred in 0.4% of cases. Infections are reported somewhat more commonly following humeral head replacement. In the recent literature, Table 24-2, infections are reported in 1% of cases. When we reviewed the literature specifically for complications of humeral head replacement for proximal humeral fractures, delayed wound healing or infection occurred in 6 of 203 acutely treated cases and in 3 of 100 shoulders having

delayed treatment for chronic fracture-related problems.[42] Thus, the literature suggests that the infection rate is less than 1% for elective shoulder arthroplasty and may well be several times that for arthroplasty used for the treatment of complex fractures.

There is surprisingly little literature directed specifically toward infections associated with shoulder arthroplasty. Codd and coauthors reported their experience with 16 patients.[63] They recognized, as formulated earlier in this chapter, that there is no single preoperative study that is consistent for the diagnosis of infection, and they suggested relying quite strongly on the operative histology. Interestingly, their group included three patients who had positive cultures while undergoing revision surgery but negative intraoperative histology. These patients were treated with antibiotics, and none of them developed infection following this treatment. Eight patients presented with infection of their arthroplasty, four underwent resection arthroplasty, and four had reimplantation of a prosthesis with antibiotic-containing bone cement. The patients undergoing reimplantation had better shoulder function. In another subgroup, five patients apparently had earlier shoulder infection, which was treated, and then had humeral head replacement at a later date. This report typifies the information on infected shoulder arthroplasties. There is information available, but the numbers of patients are small and one hesitates to be too forceful in recommendations regarding treatment.

Coste et al. reported on the outcome of 49 shoulders with an infected shoulder arthroplasty in a multicenter study.[64] Radiotherapy and previous surgery were found to be significant risk factors for the development of infection. The authors reported that antibiotics or débridement alone were not effective treatments. They recommended in acute infection that immediate revision should be undertaken with extensive débridement and prosthesis exchange with appropriate antibiotic therapy. Jerosch and Schneppenheim reported on their experience with 12 infected shoulder arthroplasties. Among this group, 10 patients presented with late infection. The authors recommended two-stage revision in this group with placement of a temporary spacer.[65]

Three review articles have additional, useful information on the treatment of infection associated with shoulder arthroplasty. Wirth and Rockwood in 1996 reviewed 1,615 total shoulder arthroplasties in 32 scientific reports.[48] Infection was identified as the fifth most common complication. Reported associations included host-related risk factors of diabetes mellitus, RA, systemic lupus erythematosus, previous shoulder operations, remote sites of infection, compromise of the immune system, and the speculation as to whether or not previous steroid injections predispose to infection in this circumstance. The value of preoperative laboratory testing is difficult to ascertain because of inconsistent reporting methods. Suggested treatment options include antibiotic suppression, incision and drainage, removal of the implant with reimplantation, resection arthroplasty, arthrodesis, and amputation. The specific treatment selected depends on the timing of the infection, the pathogen, and the stability of the implant. For early infections with a Gram-positive organism exploration with incision, drainage, and débridement, the use of antibiotics and retention of the prosthesis is recommended. For late infections and those with Gram-negative organisms, removal of the implant, intravenous antibiotics, and then later consideration of reimplantation is suggested.

Miller and Bigliani in 1993 identified four infections in 1,168 reported cases.[47] They commented that the excellent vascularity and abundant soft tissue coverage is one reason for the low rate of infection. There should always be a high suspicion of the possibility of a low-grade infection at the time of revision surgery. One should be particularly wary of infection in an immunocompromised host. Suggested treatment for early infections included débridement, wound closure with drains, an initial broad-spectrum antibiotic with a high sensitivity to Gram-positive organisms, and more specific antibiotics as the culture results become apparent. For delayed infections, removal of the implant is suggested along with the use of intravenous antibiotics and immobilization for 3 months. If the patient is dissatisfied at 1 year, the authors discussed the possibility of performing a fusion if there is no osteomyelitis. It is possible to reinsert a hemiarthroplasty or TSA with antibiotics impregnated in the cement, but osteomyelitis should certainly not be present in this circumstance.

Soghikian and Neviaser in 1993 reviewed complications of humeral head replacement.[49] They recommended that one be quite suspicious of infection in the presence of previous failed ORIF, that perioperative antibiotics be used, that hemostasis be meticulous, and that intraoperative cultures be obtained. When late infection develops, the implant should be removed, there should be antibiotics for a minimum of 6 weeks, and reimplantation should be considered at that time or later.

Sperling et al. reviewed the results of infected shoulder arthroplasties at the Mayo Clinic.[66] Between 1972 and 1994, 2,512 primary shoulder arthroplasties and 222 revision shoulder arthroplasties were performed at the authors' institution. Among these shoulder arthroplasties, 19 primary shoulder arthroplasties and seven revision shoulder arthroplasties were diagnosed with deep periprosthetic infection. Additionally, during this time period, seven primary shoulder arthroplasties and one with a previously revised shoulder arthroplasty were referred for treatment of deep periprosthetic infection. Two shoulders were excluded because of incomplete medical records and with component removal performed elsewhere. The mean time from arthroplasty to the diagnosis of infection was 3.5 years.

The patients were divided into four groups on the basis of treatment. Group I comprised 21 shoulders that underwent

resection arthroplasty. Six of these shoulders had additional episodes of infection. Group II comprised six shoulders that underwent débridement and prosthetic retention. Three shoulders failed this treatment with subsequent reinfection and underwent a resection arthroplasty. Group III comprised two shoulders that had removal of the prosthesis, débridement, and immediate reimplantation. There was one resection arthroplasty 9 months after direct exchange because of reinfection. Group IV comprised three shoulders that had removal of the prosthesis, débridement, and delayed reimplantation. Reinfection did not occur in any of these patients. At the most recent follow-up, patients with a prosthesis had better pain relief and shoulder function than patients treated with resection arthroplasty. The authors concluded that delayed reimplantation may offer the best hope for pain relief, eradication of infection, and shoulder function (Fig. 24-4).

In summary, there are many variables involved with infections surrounding arthroplasties including host factors, the timing and nature of the infection, and the type of organism. For the acute or delayed acute infection, arthrotomy and débridement and the use of intravenous antibiotics should be strongly considered, but this advice must be tempered given the reinfection rate, which is difficult to ascertain from the literature but is moderate, perhaps somewhere between 30% and 60%. In the past, resection arthroplasty was the standard. It is successful for eradication of the infection and usually provides pain relief. Shoulder function is often unsatisfactory if rated on one of the usual shoulder rating systems. Direct exchange of the prosthesis can be considered for lower-grade infections, but the frequency of success is uncertain, due to the limited collective experience with this type of treatment in the shoulder. Delayed reimplantation has been successful for eradication of infection. It is more consistent in offering pain relief and affords better function than resection arthroplasty. The timing to reimplantation is uncertain. The suggested times extend from 6 weeks to 1 year.

Rotator Cuff Tears and Impingement Syndrome

Problems with rotator cuff healing or subsequent rotator cuff tearing following arthroplasty are probably substantially underreported, being identified instead as poorer outcomes and included in the lower portions of result rating scales or detailed in association with instability rather than specifically identified as a rotator cuff stretching or tearing. Certainly, management of the rotator cuff is an important part of shoulder arthroplasty. Preexisting rotator cuff disease and tearing is common. We carefully studied 156 consecutive total shoulder arthroplasties for rotator cuff disease. Overall, 48 (27%) had tears of the rotator cuff present at surgery. Tears did vary in size, being small (less than 1 cm in greatest length) in 10, medium (1 to 3 cm) in 10, large (3 to 5 cm) in seven, and massive (greater than 5 cm) in 21. By disease category, in osteoarthritis there was no tearing in 46 shoulders and the rotator cuff was thin in one and torn in six. In RA there was no tearing in 11 and the rotator cuff was judged to be thin and scarred in 37 and was torn in 18. In old trauma there was no abnormality in six, the rotator cuff was thinned and scarred in two and was torn in three, and in 10 there was tuberosity malunion requiring osteotomy. In rotator cuff tear arthritis the rotator cuff was of course torn in all 14. In other miscellaneous diagnoses there was no rotator cuff tearing in 13 and the rotator cuff was thin and scarred in two and torn in seven. Thus, preexisting rotator cuff disease is an important consideration, may well alter the approach to shoulder arthroplasty, and certainly if tearing is present would predispose the patient to having a complication related to the rotator cuff postoperatively.

The classification of rotator cuff tearing is probably no different with arthroplasty than without arthroplasty. The classification can be by location, tear size, and tear shape. Location identifies the tendon or tendons affected. Size is conveniently recorded in centimeters and is typically measured following the initial débridement before mobilization of the tendons themselves. Many cuff tears are in the impingement area or slightly posterior to this, associated with upward subluxation of the humeral head that may occur in many patients with arthritis. Occasionally longitudinal tears occur in line with the tendon fibers, but most often transverse tears exist. These may be essentially linear or they may include an area defect that has an oval, triangular, or trapezoidal shape, prior to mobilization of the tendon into the defect. Additionally, shoulder arthroplasty has made surgeons acutely aware of the possibility for interstitial tendon tearing, particularly in RA, where the tendons are quite thin and scarred, perhaps one-half to one-quarter of their normal thickness. Certainly if these tendons were examined histologically there would be disruption of tendon fiber continuity; thus, a microscopic rotator cuff tear exists in the absence of a gross full-thickness tear. It has been shown that the outcome of arthroplasty in these patients is strongly influenced by this compromise of rotator cuff function, although stability of the implant can usually be obtained.

The diagnosis of rotator cuff tearing following arthroplasty follows the scheme of diagnosis for rotator cuff tearing in the absence of arthroplasty. Symptomatically there is often an increase in pain, recognition of a loss of active motion, and weakness. Physical examination defines this diminution in active motion relative to passive motion and identifies weakness in the torn cuff components. Additionally, following arthroplasty, rotator cuff tearing may present most dramatically as instability, usually superiorly or anteriorly but occasionally posteriorly. Certainly when instability occurs following shoulder arthroplasty, disruption of the surgical arthrotomy or rotator cuff tearing

Figure 24-4 Example of a 60-year-old man who underwent shoulder arthroplasty for osteoarthritis. He presented 6 years following surgery with increasing pain and erythema. Radiograph demonstrates glenoid component loosening with proximal humeral osteolysis **(A).** He underwent component removal, débridement, and placement of antibiotic impregnated beads **(B).** Two months after component removal, he underwent delayed reimplantation. At the most recent follow-up, 2 years following surgery, he had no pain, 140 degrees of active abduction, and 45 degrees of external rotation **(C).** (Reproduced with permission from Sperling JW, Kozak TKW, Hanssen AD, Cofield RH. Infection after shoulder arthroplasty. *Clin Orthop* 2001;382:206–216.)

should always be suspected. Plain radiographs may show a severe upward subluxation diagnostic of rotator cuff tearing. In the absence of this but with clinical evaluation suggesting rotator cuff tearing, an arthrogram can be performed. With a tendency for fibrosis surrounding implants there is concern that the arthrogram may be false negative; however, practically this seldom seems to be an important issue, with the arthrogram typically defining the rotator cuff tear much as it would in a shoulder without prosthetic arthroplasty. Recently, the technique of performing magnetic resonance imaging (MRI) in a patient with a shoulder arthroplasty has become available.[67] This may be a valuable tool to determine the size of the tear, location of the tear, and degree of fat infiltration of the tendon.

A special note relative to rotator cuff tearing in the postoperative condition relates to healing of the subscapularis. We have recognized that a number of patients following arthroplasty have on physical examination somewhat excessive external rotation and slight weakness in internal rotation. They must in fact have stretched their anterior shoulder capsule and rotator cuff repair or have disrupted it to some degree. In many of these patients there is no patient-identified adverse response with excellent pain relief and motion and maintenance of glenohumeral stability. As such, one cannot assume that disruption of the rotator cuff is the source of pain following shoulder arthroplasty. Other possible sources of pain must also be explored and identified, as apparently rotator cuff tearing can exist following shoulder arthroplasty, and as in the nonarthroplasty state can be minimally symptomatic or asymptomatic.

Although problems with the rotator cuff following arthroplasty are seldom at the forefront of one's thinking when considering complications of shoulder arthroplasty, if one tabulates all the complications of TSA as defined in Table 24-1, rotator cuff tearing is the most common complication in this collection of reported series, having a rate of 1.9%. Following humeral head replacement, rotator cuff tearing occurs in a similar frequency (1.8%) (Table 24-2). Tuberosity problems also occur in fracture patients, with nonunion developing in 1.8% and tuberosity malunion in 0.4% in this group of 20 patient series.

Neer and Kirby, when discussing revision of humeral head and total shoulder arthroplasties, mentioned the possibility of impingement of the rotator cuff in the postoperative state.[68] They said that scar requires release and impingement by the anterior acromion, the coracoacromial ligament requires anterior acromioplasty, and impingement by the acromioclavicular joint requires distal clavicle excision to free the rotator cuff. Miller and Bigliani, in presenting the complications of total shoulder replacement, mentioned a postoperative rotator cuff tear frequency of 3% to 4%.[47] They commented that repair is not always required but recalled the admonition of Franklin et al.'s report[69] that there is an increased frequency of glenoid loosening when there are large rotator cuff tears; this might support repair of a rotator cuff tear in the postarthroplasty patient. Wirth and Rockwood estimateed a 2% frequency of rotator cuff tearing following shoulder arthroplasty and found that both operative and nonoperative treatment have been employed with lack of clear definition of the benefits of one form of treatment over the other.[48]

Arthroscopic acromioplasty has been used for the treatment of impingement following shoulder arthroplasty.[47] Freedman and colleagues reported on the results of six patients who underwent arthroscopic acromioplasty for chronic impingement syndrome following shoulder arthroplasty.[70] The results were excellent or good in five patients and unsatisfactory in one patient.

Probably in no area is the comprehensive approach to shoulder arthroplasty more important than in the prevention of postoperative rotator cuff tearing. Balancing the joint is key to preventing large repair-threatening forces on the arthrotomy site or a repair of a preexisting rotator cuff tear. Component positioning must be carefully performed, the correct size of the component must be selected, unbalanced capsular tightness must be adjusted by appropriate releases or adjustments in component size, and impingement should be eliminated if it exists. Following implantation of the prosthetic parts, the glenohumeral joint should be stable and in fact will usually be stable even prior to the arthrotomy repair. The arthrotomy repair should then be secure. Range of motion of the shoulder should be assessed to define the limits determined by the arthrotomy repair. Sufficient postoperative limb support should be provided, as should careful patient instruction in protecting the limb. The physiotherapy program takes into consideration the limits of motion as defined at the time of surgery and the surgeon's recognition of the rate of soft tissue healing.

There does not seem to be a yes-or-no answer in the recommendations for treatment of rotator cuff tearing following TSA. Certainly, as mentioned above, there are a number of patients who seemingly have compromised their arthrotomy repair, yet are comfortable and have good motion and the arthroplasty is stable. Further surgical treatment would almost certainly not be considered in these patients. Other patients express some weakness of their shoulder following arthroplasty, yet have good pain relief and fair active movement. Again, in many of these older patients surgical repair of their rotator cuff stretching or tearing would not be undertaken. On the other hand, there are some patients who have been doing well with their arthroplasty who have an adverse event or an accident and have a dramatic change in shoulder function, or those who without apparent reason or following an injury develop acute instability of their arthroplasty. In these patients with a rather acute and dramatic change in their arthroplasty with substantial compromise of function, rotator cuff repair would be undertaken. Finally, there are a few patients who

seem to have chronic deterioration of function in their shoulder arthroplasty. Usually this can be attributed to other problems (such as component loosening), but occasionally this is related to a degenerative or impingement-engendered attrition and tearing of the rotator cuff. In these patients, as in patients without shoulder arthroplasty, the situation should be defined and a discussion held with the patient about the benefits and limitations of rotator cuff repair. In this setting, it seems that the benefit/risk ratio is rather close, and typically, continued conservative treatment measures are recommended.

Instability

It is easiest to organize thinking about shoulder instability by utilizing the established categories for shoulder instability in the absence of shoulder arthroplasty. Instability following shoulder arthroplasty does occur acutely. Chronic dislocations can occur and, in fact, so do recurrent dislocations. The instability can be of any degree—mild subluxation or complete dislocation—and it can be in any direction—superiorly, anteriorly, posteriorly, or inferiorly. Perhaps the most common instability situation that occurs following shoulder arthroplasty is some degree of superior humeral subluxation. Boyd et al. commented on this and recognized it in 29 of 131 shoulders (22%) having a Neer prosthesis.[51] In their patient group, even in the presence of this situation, all patients had decreased pain compared to their preoperative state and improved range of motion. This upward subluxation seemed to be caused by a combination of factors and was not due to rotator cuff tearing alone, as they recognized major rotator cuff tears in 21% of patients with a normal glenohumeral relationship and in 24% of patients with this proximal or superior subluxation.

The presence of instability is usually readily recognized by physical examination and radiography. However, there may be associated abnormalities that require more in-depth study including the presence or absence of rotator cuff tearing, component malposition, a component size that is either too large or too small for the soft tissue envelope, or component loosening with a change in component position.

In the literature instability is one of the most common complications seen following TSA, occurring in 1.5% of shoulders (Table 24-1). It may even be the most common complication following humeral head replacement, with 2.8% of the shoulders developing this complication in the 20 series reported since 1980.

There have been two scientific articles directly addressing postoperative instability. Moeckel et al. reported on 10 shoulders developing instability following 236 consecutive arthroplasties.[34] The instability was anterior in seven and posterior in three. They recommended correction of the soft tissue imbalance and prosthetic revision as necessary. With particular reference to disruption of the subscapularis tendon, mobilization and repair of the tendon was recommended, but three of seven continued to have instability and required re-repair supplemented with an allograft of tendo Achilles. This latter technique proved successful in these three shoulders. Wirth and Rockwood reported on 18 shoulders developing instability, 11 posterior, six anterior, and one inferior.[48] For posterior instability, the treatment was directed at restoring appropriate retroversion of the humeral component, performing a posterior capsulorrhaphy, and achieving appropriate position of the glenoid component or in the absence of a glenoid component reaming the glenoid surface to a neutral angle. For anterior instability, component version was again corrected when necessary. The anterior structures were repaired and sometimes reinforced with the pectoralis major tendon. If the coracoacromial ligament could be reconstructed, this was also done. For inferior instability, humeral length was restored.

Several review articles comment on shoulder instability. In Neer and Kirby's 1982 article on revision of humeral head and total shoulder arthroplasties, they recognized loss of humeral height as extremely common following fractures or tumors and, indeed, that it occurred in 18 of 27 failed arthroplasties in this series.[68] At revision surgery the height was restored and comment was made that bone grafting might be needed. Miller and Bigliani identified instability in 1% to 2% of cases.[47] He also recommended restoring humeral length, careful attention to appropriate glenoid positioning when using a glenoid component, or appropriate reaming of the glenoid surface when a glenoid component is not used. At revision surgery it would usually be necessary to correct prosthetic position and to perform soft tissue reconstruction. Wirth and Rockwood's 1996 review of complications of total shoulder replacement noted that anterior instability was associated with dysfunction of the anterior deltoid, malrotation of the humeral component, and disruption of the subscapularis tendon.[48] This latter problem was attributed to poor tissue quality or technique, inappropriately oversized components, or aggressive physical therapy. Superior instability was associated with dynamic muscle dysfunction, attenuation of the supraspinatus muscle–tendon unit, or rotator cuff tearing. This type of instability might be associated with an increased frequency of glenoid loosening. Posterior instability was associated with a retroverted glenoid component, an excessively retroverted humeral component, and soft tissue imbalance. If the glenoid component was not used, posterior instability was associated with posterior glenoid erosion. They recommended being aware of asymmetrical glenoid wear and compensating for this with careful reaming or bone grafting of the glenoid. Also, the surgeon must alter the position of the humeral component to include somewhat less retrotorsion. Treatment for posterior instability would include restoring normal humeral component version, reestablishing proper glenoid compo-

nent version, and addressing soft tissue imbalance, including consideration of posterior capsulorrhaphy. Inferior instability was seemingly always associated with humeral shortening. The treatment was to re-establish humeral length. Soghikain and Neviaser, in reviewing the complications of humeral head replacement, identified superior subluxation as an issue and recommended careful assessment of the rotator cuff during the initial surgery and carefully positioning the height of the humeral component.[49] Adequate postoperative protection is necessary to allow soft tissue healing. Should a postoperative dislocation occur, closed reduction should be performed, followed by immobilization and delayed physiotherapy.

In the original Mayo Clinic series analyzing postoperative surgical complications between 1979 and 1989, subluxation was the most common complication identified (11%). Subluxation was usually a devastating complication. As this complication was the most common one in our patients in the original series and was quite significant, a separate analysis of instability following shoulder arthroplasty was undertaken.

The results of surgical treatment for the unstable shoulder arthroplasty at the Mayo Clinic were recently reviewed.[71] Between 1985 and 1999, 33 shoulders (seven hemiarthroplasties and 26 total shoulder arthroplasties) underwent surgical treatment for instability. There was anterior instability in 19 shoulders and posterior instability in 14 shoulders. The primary arthroplasty had been performed for the treatment of osteoarthritis in 16 shoulders, arthritis of dislocation in six, acute fracture in four, RA in three, and other conditions in four.

Prosthetic instability was attributed to abnormal capsular tension and/or rotator cuff dysfunction in 21 shoulders, malposition of the components in one shoulder, and a combination of both in 11 shoulders. One shoulder was treated with resection of the components. In the remaining 32 shoulders, each of the contributing elements to instability was specifically addressed at the time of revision surgery. Revision surgery was successful in restoring stability in only 9 of the 32 shoulders. Anterior instability had a higher failure rate than posterior instability ($P = 0.04$). Although 11 shoulders had additional surgery to treat recurrent instability, only 14 of the 33 shoulders were stable at the time of the most recent follow-up. Based on a Neer rating system, there were four excellent, six satisfactory, and 23 unsatisfactory results.

The authors noted that soft tissue imbalance was present in most cases of instability following shoulder arthroplasty, and component malpositioning played an additional role in some cases (Fig. 24-5).[72] Unfortunately, more than one-half of the shoulders in the study remained unstable despite attempts at revision. As such, preventing subluxation and dislocation is the key. Identifiable risk factors for postoperative shoulder instability would apparently include an older patient, preexistent rotator cuff disease, preoperative subluxation, or dislocation. Additional factors would include irregular (i.e., asymmetrical) glenoid wear (usually posterior), the use of prosthetic parts that are too small for the surrounding soft tissue envelope, or the use of prosthetic parts that are too large, creating undue stress on the arthrotomy repair with a potential for disruption of the repair early in the postoperative period. Of course, component malposition should be avoided and rotator cuff and capsule repair should be secure with appropriate postoperative external support and a carefully designed therapy program.

The treatment plan includes identifying all factors associated with the instability (involving the bone, the implants, and the soft tissues), and surgery is directed toward addressing all of these abnormalities. Postoperative support should then be ample, and the therapy program would be modified to maintain stability.

Component Problems

Component loosening remains one of the central concerns in shoulder arthroplasty, particularly in regard to the glenoid component. Unfortunately, radiographs about the shoulder can be quite poor and not show the interfaces well, particularly if there is metal backing to the glenoid component, for only slight change in angle of the x-ray beam will obscure interface changes. The 40-degree posterior oblique view is an improvement over the standard anterior–posterior view in assessing the interface between the glenoid implants and the bone of the scapula. We have found fluoroscopically positioned spot views to be most consistent for evaluating not only the glenoid component, but also the humeral component.[73] It is also useful to have a sequence of x-rays because a change in component position may be apparent with a series of films when it is not clearly demonstrated on a film taken at one point in time.

By recognizing the characteristic patient presentation and having high-quality x-rays, over time it is usually possible to diagnose component loosening without needing to resort to more complex studies; however, occasionally these might be necessary and could include arthrography. Arthrography in addition to outlining the rotator cuff tendons will display synovitis, which is often present in situations where component loosening occurs. Also, dye can track between the bone-cement interface. However, the accuracy of this test for the diagnosis of component loosening has not been fully assessed. Shoulder arthroscopy has been suggested as one means to diagnose glenoid loosening.[74]

In the series of total shoulder arthroplasties published since 1980, glenoid loosening was the third most common complication (1.3%), and humeral loosening was recognized to occur in 0.3%. In these series the problem was treated with component revision slightly more than one-half the time and with removal of the loosened glenoid component, generally retaining the humeral head replacement, in

Figure 24-5 **(A)** Preoperative example of a 60-year-old man who sustained a locked posterior fracture dislocation of his shoulder 17 months earlier during a fall. **(B)** Radiographs taken 6 weeks after hemiarthroplasty demonstrate recurrent posterior shoulder instability. **(C)** The patient underwent revision with additional posterior capsular tightening and change in component position. (Reproduced with permission from Sperling JW, Pring M, Antuna SA, Cofield RH. Shoulder arthroplasty for locked posterior dislocation of the shoulder. *J Shoulder Elbow Surg* 2004;13:522–527.)

slightly less than one-half the time. There is little information on the treatment of loose humeral components. One of the authors in this series of reports identified two loose humeral components, but no treatment was undertaken as the patients had no pain. In another series, revision was performed because of symptomatic humeral loosening in one shoulder.

In the recent series on humeral head replacement, humeral loosening was again recognized in less than 1% of shoulders (0.6%). These cases of humeral component loosening were only recognized in a series of isoelastic prostheses and no treatment was mentioned.

Glenoid component loosening has been identified in conjunction with severe incompletely reconstructible rotator cuff tears or following the development of rotator cuff tearing in the postoperative period. Franklin et al.'s seven cases occurring in this setting all exhibited large glenoid bone-cement lucent lines, often in association with a shift in component position.[69] This article was published to remind us of the importance of the rotator cuff in maintaining joint position and in preventing eccentric and excessive component loading and presumably subsequent component loosening.

Review articles are more ample in their discussion of glenoid component loosening. Miller and Bigliani in 1993 described that radiolucent lines were common but that there was apparently no direct correlation to the level of clinical symptoms.[47] They felt that lucent lines may reflect the surgical technique, the quality of the glenoid bone, and changes affected by stress shielding or disuse osteoporosis. Also, they recognized that radiographic technique must be excellent to detect these lucencies in this anatomic region. They felt that loosening could be minimized by careful bone preparation at the time of surgery, fitting the implant

closely to the bone, and using a minimal amount of cement. Humeral loosening was recognized to be rare. Subsidence of the prosthesis can occur in osteoporotic bone, and the use of bone cement to fix the humeral component was suggested. Wirth and Rockwood, in reviewing 32 reports of TSA, identified that loosening represented nearly one-third of all complications and was in fact the most frequent complication reported in those studies they reviewed.[48] They stated that methods to enhance component fixation included concentric spherical reaming of the glenoid surface, preservation of the majority of the subchondral plate, a slight mismatching of the radii of the glenoid and humeral heads, and the consideration of press-fit or tissue ingrowth implants.

Brems evaluated the relationship between lucent lines and revision surgery.[75] In a review of 20 reported series on TSA, there were lucent lines present in 38.6% of all total shoulder arthroplasties at a mean follow-up of 5 years. Among the shoulders with periprosthetic lucency, the rate of revision surgery was 7.7%.

Longer-term follow-up of total shoulder arthroplasties and humeral head replacements is more informative concerning component loosening. Of 113 total shoulder replacements performed at the Mayo Clinic between 1975 and 1981, the probability of implant survival was 93% at 10 years and 87% at 15 years. Seventy-nine of these patients with 89 arthroplasties were available for follow-up an average of 12.2 years following surgery, with a range of follow-up from 5 to 17 years. Seventy-five glenoid components developed bone-cement radiolucencies, and 39 glenoid components (44%) were considered to have radiographic evidence of definite glenoid loosening. This loosening was statistically associated with an increase in pain. Additionally, a change in position of the humeral component occurred in 49% of press-fitted stems but in none of the shoulders with cemented humeral stems. Humeral component loosening was not associated with pain. In this group of patients, glenoid component revision was carried out in four, so although the radiographic frequency of glenoid loosening was quite high, the clinical need for revision surgery remained low even with long-term follow-up. Two humeral components required a revision because of loosening. One humeral component was found to be loose at the time of revision of a loose glenoid component and was revised at that time. A second patient developed humeral component loosening in association with a humeral shaft fracture and revision was undertaken using a long-stemmed humeral component and fracture fixation.

In the series at Mayo of 67 humeral head replacements performed for osteoarthritis or RA, follow-up was possible for an average of 9.3 years. Only one of these prostheses was fixed in place with bone cement. All the remaining Neer implants were press-fitted. Six of the 35 shoulders with osteoarthritis had a lucent zone 1.5 mm or greater surrounding the humeral component, and in three of these there was a change in humeral component position downward in the humeral canal. Three of the 32 shoulders with RA had a 1.5-mm or greater lucent line surrounding the majority of the humeral stem. Nine of the components in rheumatoid patients had a change in component position with the component shifting downward in the humeral canal. In these patients with substantial radiographic changes relative to the humeral component, only one in the osteoarthritic group had severe pain and two in the rheumatoid group had moderate or severe pain. Thus, there was no clear relationship between the development of symptoms and the radiographic appearance of the component. But, of course, it must be clearly noted that the frequency of radiographic changes surrounding these press-fit Neer components was quite high and suggests that fixation with bone cement for this type of implant would be preferred.

Glenoid arthritis has evolved to become the most predominant reason for revision of hemiarthroplasties at our institution (Fig. 24-6).[76,77] Sperling and Cofield reported on the outcome of revision of hemiarthroplasty to TSA for glenoid arthritis at the Mayo Clinic.[78] Between 1983 and 1992, 22 hemiarthroplasties underwent revision for glenoid arthritis. Eighteen shoulders with a minimum 2-year follow-up were reviewed. Thirteen of the hemiarthroplasties were performed at our institution and five were performed elsewhere. There was significant pain relief with revision to TSA. However, 7 of 18 had an unsatisfactory result rating due to limitation of motion or need for an additional procedure.

Given the limitations of the current technology, it may be impossible to fully eliminate glenoid loosening; however, as is outlined in the above series, glenoid loosening that is clinically symptomatic enough to require revision surgery is uncommon, but all attempts to reduce the incidence of component loosening will be quite worthwhile in improving the consistency of shoulder arthroplasty. The surgeon can do little, if anything, to address the bone quality that the individual has; however, the amount of bone in the glenoid is quite small and certainly the bone should be preserved as much as possible during insertion of an implant. This includes preserving much of the subchondral plate of the glenoid and very meticulous removal of only that quantity of bone necessary to insert the implant. Certainly, very little reaming should be performed on the glenoid surface. Only the amount of subchondral plate needed to insert the columns or keel of the component should be removed. Further preparation would include pulsatile water lavage, a thorough drying of the glenoid bone, mixing the bone cement to diminish porosity using a vacuum system or centrifugation, pressurization of the bone cement, impaction of the component into position, and maintaining the stability of the component against the bone until the cement hardens.

The choice of a glenoid component remains controversial. There continues to be significant debate concerning

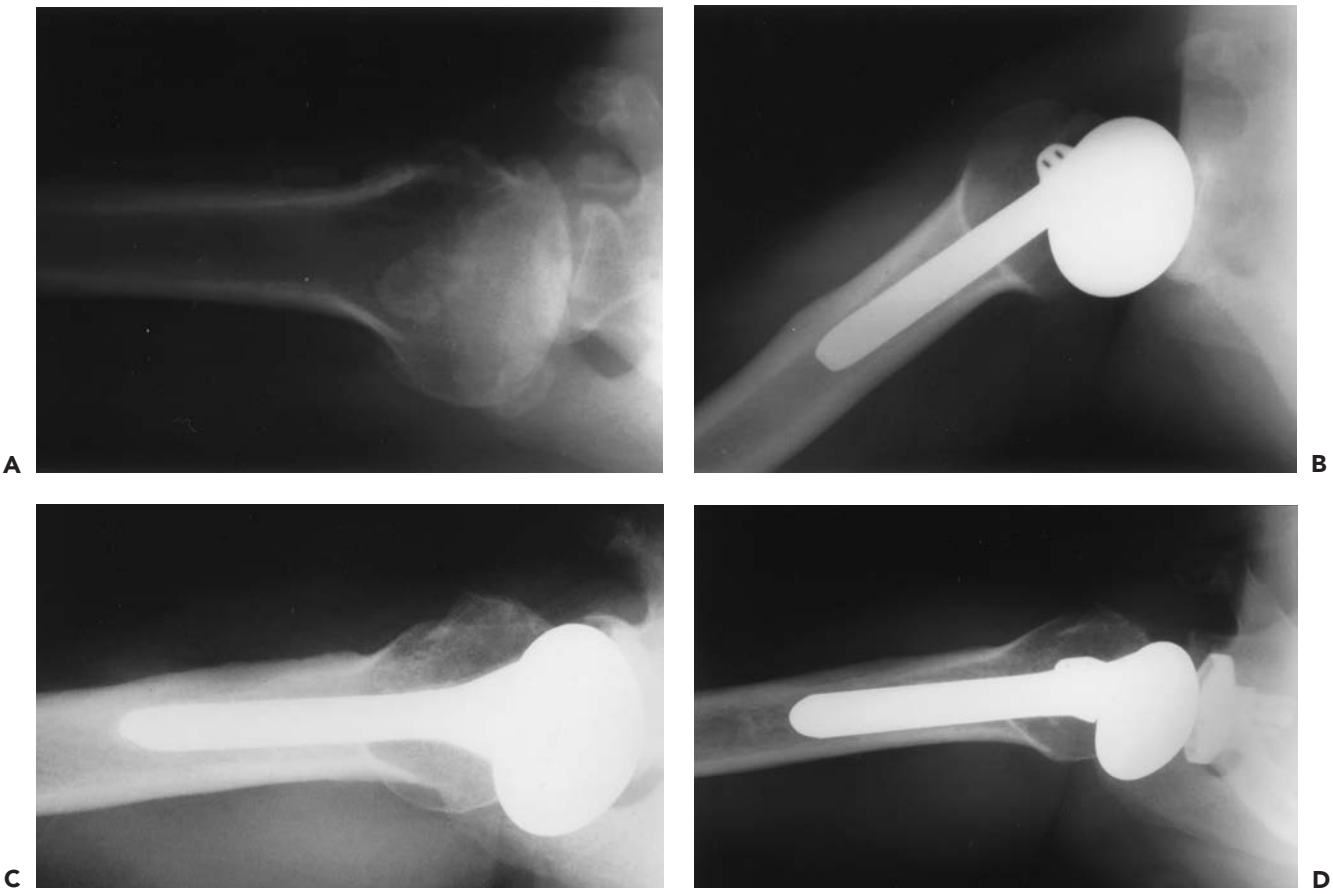

Figure 24-6 **(A)** Example of a 41-year-old man with osteoarthritis. **(B)** Radiograph taken immediately after surgery. **(C)** Radiograph taken 17 years following hemiarthroplasty demonstrates severe glenoid arthritis. **(D)** The patient underwent revision to total shoulder arthroplasty. (Reproduced with permission from Sperling JW, Cofield RH, Rowland CM. Minimum fifteen-year follow-up of Neer hemiarthroplasty and total shoulder arthroplasty in patients aged fifty years or younger. *J Shoulder Elbow Surg* 2004;13:604–613.)

the shape of the glenoid component as well as mismatch between the radius of the glenoid component and humeral head.[79–82] Additionally, the choice of a humeral component also remains controversial and is beyond the scope of this chapter.

Clearly, the joint must be well balanced. Tight capsular structures should be lengthened or divided to lessen unnecessarily high compressive forces across the joint. The rotator cuff should be repaired as best possible and the humeral head should be positioned against the glenoid to eliminate subluxation, as that may create loading of the edge of the glenoid component and subsequent component loosening.

It seems apparent that many glenoid components that have loosened do not require revision surgery. If a patient becomes substantially and continually symptomatic, it is important to exclude other problems as a cause of the symptoms, such as an occult low-grade infection, rotator cuff tearing, or humeral loosening. All of these things, of course, may occur independently or in association with glenoid loosening. Recent data from our institution indicate that satisfactory pain relief is obtained in 86% of patients who have placement of a new glenoid component at the time of revision compared to removal alone in 66%.[83]

Less common complications related to shoulder components include dissociation and component fracture. There have been reports of dissociation of modular humeral head components as well as fatigue fractures of the humeral stem.[84,85] Blevens and colleagues examined the conditions that may affect the Morse-taper interface strength in humeral components. They reported that as little as 0.4 mL of fluid could significantly prevent fixation of the modular head.[86]

INTRODUCTION

Failure of a total shoulder arthroplasty is one of the most difficult problems to surgically manage, and most circumstances result in a complex reconstruction. Case complexity is due to a wide variability and sometimes unpredictability of the pathology, often resulting in severe loss of soft tissue and bone. The literature has few studies devoted to revision shoulder arthroplasty; therefore, most of this chapter will convey the authors' approach based on experience treating the most difficult cases. The first critical decision for the surgeon is deciding which patients need revision surgery and which goals are reasonable for each case. Once the problem is identified, the surgeon will have to

anticipate common problems encountered during revision surgery, which requires meticulous preoperative planning and a thorough understanding of the normal shoulder anatomy. Most importantly, the surgeon should expect to improvise and deal with soft tissues or bone that cannot be restored to normal.

PATIENT COMPLAINTS

The most common presenting complaint of a patient with a failed shoulder arthroplasty is pain, which can occur at rest, with activity, or during sleep (Table 25-1). Loss of function is the next most common symptom that the patient describes, and this can be in the form of stiffness or loss of strength. These complaints are usually described together, but it is important for the surgeon to prioritize the complaints from the patient's perspective to assess patient expectations and better define reasons for pain and functional limitation. It is often useful for the surgeon to define the patient's functional limitations as they relate to stiffness, weakness, and instability. It is also beneficial to define the anatomic reasons for each of these complaints: pain, stiffness, weakness, and instability. Once the anatomic causes are defined it is then recommended to make a mental list of how each of these factors can be reversed or corrected. The ability to correctly define and correct each anatomic factor will define the likelihood and level of success that can be achieved with revision surgery. The most experienced surgeons have the ability to make an accurate assessment of the factors and know their own ability and success rate for reversal of these processes.

Pain can be caused by loose implants, stiffness, infection, implant malposition, instability, implant wear, and impingement. Loss of strength can be caused by rotator cuff tears, muscle atrophy, deltoid insufficiency, and nerve injury. Stiffness can be caused by capsular contracture, malposition of implants, pain, and bony impingement. All three primary symptoms are interrelated, and determining how they are interrelated can be challenging.

Documenting the chronology of the patient's pain, strength, and motion in relation to their postoperative recovery can be helpful. Pain that persists immediately after surgery is consistent with infection and malpositioned implants that overstuff the joint. Stiffness immediately after surgery is consistent with malpositioned implants, persistent capsular contracture, and persistent bone impingement. Stiffness that develops over time after surgery can be due to poor patient compliance with physical therapy and excessive pain that limits full participation in rehabilitation. Loss of strength should not be confused with stiffness. Patients are frequently diagnosed with rotator cuff tears by physical examination because they cannot raise their arms above shoulder level, but if the surgeon takes the time to examine the patient in the supine position, the arm may be limited to only 90 degrees of passive motion. Loss of strength that occurs immediately after surgery may be due to nerve injury or intraoperative muscle injury. More commonly, patients complain of loss of endurance or weakness that occurs secondary to poor muscle rehabilitation or rotator cuff tears. Further investigation with laboratory studies and radiographs will also help diagnose the primary cause of failure.

TABLE 25-1
CAUSES FOR FAILED ARTHROPLASTY

Symptom	Cause
Loss of motion	Bony block malunion
	Prosthetic position
	Prosthetic size
Instability	Incorrect glenoid version
	Glenoid wear
	Rotator cuff deficiency
	Coracoacromial arch deficiency
Weakness	Rotator cuff tear
	Deltoid atrophy
	Neurologic injury
	Loss of tuberosities
Pain	Infection
	Glenoid arthritis
	Stiffness
	Loose components

PHYSICAL EXAMINATION

The physical examination of the failed shoulder arthroplasty should not be different from the examination of a normal shoulder. Careful assessment should include the passive and active arcs of motion; visual inspection of prior incisions and muscle atrophy; strength of the deltoid, external rotators, and subscapularis; and pain-inciting maneuvers. Particular attention should be given to possible superior escape of the humeral head during active elevation of the arm, false-positive belly press test secondary to internal rotation stiffness, anterior deltoid deficiency, and anterior or posterior subluxation of the humeral head that is either static or dynamic.

It is important to remember that patients with pain and limitations of function after prosthetic arthroplasty do not always have a problem with their prosthetic or the surgery initially performed. Patients with well-functioning implants and an anatomic reconstruction (x-ray findings) can have good range of motion, stability, and strength but have problems associated with a painful acromioclavicular joint, subacromial impingement, or rotator cuff or biceps tendon pathology. It is important to consider these diagnoses and evaluate these on physical examination and radiographic studies, particularly when

the joint on examination seems to function well but the patient complains of persistent pain.

DIAGNOSTIC WORKUP

Patients who have a failed shoulder arthroplasty should have a sedimentation rate sent to the laboratory, and if it is elevated an infection should be suspected. In all cases the shoulder should be aspirated to evaluate for an infection. Routine radiographs including a true anteroposterior (AP) radiograph of the shoulder and an axillary lateral of the shoulder should be scrutinized for lucent lines around the implant, version of the humeral and glenoid components, relationship of the humeral head to the glenoid, bone loss, bony impingement from the glenoid or tuberosities, and humerus abnormalities that could interfere with long-stem implants. Comparison to recovery room films or any postoperative films can show obvious changes that could not otherwise be appreciated (Fig. 25-1).

Computed tomography (CT) scans should also be obtained to define the glenoid for possible bone loss that often cannot be appreciated on plain radiographs. Specific instructions for the radiologist should be requested so that the appropriate protocols can be used to subtract the artifact created by metal implants. Also, if the patient's arm cannot be held in neutral rotation during the CT scan, simultaneous images of the humerus epicondyles should be taken for accurate assessment of humeral head version.

Close study of the CT scan during surgery often helps us reconstruct the glenoid with the appropriate version, because we cannot rely on the distorted anatomy during revision surgery.

Finally, a magnetic resonance imaging (MRI) scan should be obtained if there is a suspicion of the significant full-thickness rotator cuff tear. Some may argue that the MRI is not necessary because the best evaluation of the cuff is made intraoperatively, but getting a full preoperative evaluation can help minimize unexpected findings during these complex procedures. Sperling et al. reported their results of a modified MRI protocol for the diagnosis of rotator cuff tendon tears in shoulders with metal prostheses.[5] Twenty-one MRIs were performed with a limited pulse sequence for the evaluation of shoulders before their revision arthroplasties. Of the 11 rotator cuff tears found in the cohort, MRI correctly predicted 10 of them. Subscapularis tears were the most common type of tear found in eight patients. Ten patients did not have a tear at the time of their revision, and MRI predicted that eight of them had an intact cuff. MRI also predicted glenoid wear in eight of the nine hemiarthroplasties in the group.

Bone scans can be used to assess implant loosening, although we rarely obtain this study because the radiographs often show lucent lines around the glenoid implant, and isolated humeral loosening is rare.

Arthroscopy of a total shoulder prosthetic can in some cases give the surgeon a better understanding of the cause of failure or pain. This can be related to glenoid component loosening or failure. Arthroscopy can define biceps tendon damage, rotator cuff damage, and subacromial impingement. In some cases the arthroscopic approach can be used to remove an all polyglenoid component, release or tenodese the long head of the biceps, repair a small to medium rotator cuff tear, perform a subacromial decompression, or remove a symptomatic acromioclavicular joint.

MODES OF FAILURE

To elucidate the common causes of unsatisfactory shoulder arthroplasties, Hasan et al. analyzed 139 consecutive patients who presented to the shoulder service because they were not satisfied with their surgery.[2] Seventy-four percent of the shoulders were stiff, 35% were unstable, and 59% of the

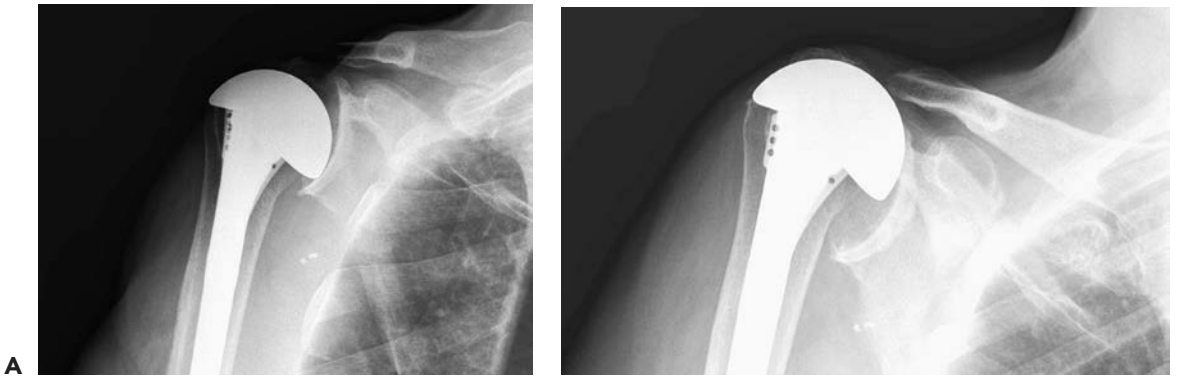

Figure 25-1 **(A)** This x-ray shows a hemiarthroplasty with a cuff tear arthropathy head that is centered in the glenoid. **(B)** One year postoperatively, the head has migrated superiorly in the glenoid. Clinically, the patient has superior escape of the humeral head when he tries to elevate his arm. Patients with superior escape require a reverse shoulder prosthesis to regain active shoulder elevation.

patients with a total shoulder had loose glenoid implants. Implants were malpositioned in 23% of the cohort. In the patients with hemiarthroplasty, 42% had glenoid erosion, and in patients who underwent hemiarthroplasty for a fracture, 43% had nonunion of the tuberosities. The average patient could only perform 2 out of 12 functions on the simple shoulder test. Based on these findings, the authors recommended greater attention to proper implant positioning, postoperative motion, and tuberosity fixation, all of which are directly impacted by the shoulder surgeon.

During the initial evaluation of a failed shoulder arthroplasty, it is often helpful to review the possible modes of failure according to their anatomic origin. The humeral component can cause pain or stiffness because it is loose. Excessive version of the humeral head can cause instability or limit motion or failure of the tuberosity fixation. Incorrect sizing of the humeral head, varus stem positioning, improper stem height, or a combination of all three can lead to an "overstuffed shoulder," resulting in altered shoulder mechanics that cause pain and stiffness. Glenoid loosening can cause pain. Improper glenoid version or excessive glenoid wear can cause instability. Bone loss in either the humerus or glenoid that was present preoperatively could have doomed the implants to failure, and more importantly, will affect the surgical options for revision.

The soft tissue integrity around the shoulder arthroplasty is arguably the most important consideration for the surgeon, even though the bone and implant are so often considered first. Bone defects can often be replaced with bone graft or modified implants with the use of cement, but rotator cuff defects cannot be easily repaired with grafts. Even if the tendon heals appropriately or a tendon graft material is used to deal with a tendon defect, function will not return because the muscle atrophy and fatty fibrous changes are often irreversible. If the rotator cuff cannot be salvaged, then the traditional unconstrained shoulder arthroplasty will not reliably restore shoulder function. A muscle transfer does not restore normal glenohumeral kinematics and a glenoid component should not be replaced because of its propensity to loosen. A constrained reverse total shoulder prosthesis could be used with or without a muscle transfer procedure. A muscle transfer may be indicated in a younger active person if the supraspinatus is not repairable or if there is an additional tear of the infraspinatus and teres minor. A reverse shoulder replacement requires a functioning deltoid and sufficient glenoid bone to allow for secure fixation of the metaglen and glenosphere.

INDICATIONS FOR REVISION

Just as the primary indication for the initial shoulder arthroplasty was pain relief, it should also be the primary reason for performing any revision procedure. Patients should be told to expect less improvement with strength and motion than with pain relief. Our experience has shown that patients who expect to have normal shoulder function after a revision procedure feel unsatisfied with their revision procedure, despite our own satisfaction with the patient's function and radiographs. Also, the surgeon should not have unreasonable expectations of their own surgical ability. Rotator cuff deficiency with muscle atrophy cannot be reversed, proximal bone loss cannot be simply replaced without a strategy to reattach the rotator cuff, and stiffness not caused by bone impingement will likely recur because of patient factors, not surgical technique.

The cause of the failed arthroplasty must be identified and considered surgically correctable (partially correctable) with a low potential of a major complication resulting in increased pain for less function (Fig. 25-2). For instance, a well-fixed humeral implant should not be removed to correct varus positioning to place another unconstrained prosthetic if the resulting proximal bone loss does not allow reattachment of the rotator cuff. Failed shoulder arthroplasties that do not have an identifiable anatomic cause for pain and dysfunction should not undergo revision. The most common indications for

Figure 25-2 This hemiarthroplasty in a rheumatoid patient demonstrates severe medial migration. If glenoid resurfacing is attempted, restoring normal lateral offset should be avoided because the rotator cuff will be too contracted. In revision surgery, soft tissue deficiency may limit reconstructive options more than bone deficiency.

revision unconstrained arthroplasty include loosening of the implants, instability, an unresurfaced glenoid, and implant malpositioning. Revision arthroplasty with a muscle transfer or with a constrained implant is indicated if the patient has superior escape of the humeral head associated with a chronic rotator cuff tear.

MUSCLE TRANSFER OR CONSTRAINED ARTHROPLASTY?

The shoulder surgeon has three surgical treatment options to offer a patient who has a failed shoulder arthroplasty with an unrepairable rotator cuff. First, if the patient's only goal is pain relief and above-shoulder function is not important, then performing a hemiarthroplasty with a cuff tear arthropathy humeral head should provide satisfactory results. A glenoid should not be implanted in these patients because of the high risk of loosening. Second, if the patient would like to regain above-the-shoulder function as well as pain relief, then a muscle transfer will have to be performed to compensate for the rotator cuff deficiency, or a constrained implant can be used. Our experience with the latissimus dorsi transfer for external rotator deficiency has shown better results in younger male patients who do not have superior escape of the humeral head out of the coracoacromial arch during active elevation and the patient should have at least active shoulder elevation to shoulder height. Therefore, in elderly patients, particularly frail women, we avoid muscle transfers in conjunction with revision arthroplasty cases. Third, a constrained reverse total shoulder prosthesis has the advantage of early recovery of above-shoulder motion, compared to muscle transfers. The disadvantages of the constrained prosthesis are the 10% to 20% risk of dislocation, and the inability to externally rotate the arm with elevation in patients without any infraspinatus or teres minor function.

COMMON PROBLEMS TO ANTICIPATE

When there is a possibility that the humeral stem needs to be removed, the surgeon must pay close attention to the design of the proximal portion of the stem. If there is porous coating, or similar surfacing designed to facilitate bone ingrowth, the surgeon should anticipate a difficult removal of the stem, particularly when it is cemented. Often the tuberosities are thin and prone to fracture with excessive torque or aggressive application of the osteotome. A longitudinal osteotomy of the shaft may be necessary, so the surgeon should have a cerclage cable system ready for repair as well as long-stem implants. Also, damage to the tuberosities could preclude reattachment of the rotator cuff, so bone graft and a constrained prosthesis should be available. It is also wise to have a full set of power and hand cement extraction tools. In addition, the surgeon should have a head light and fluoroscopy because they can be helpful to visualize the mid- and distal aspect of the humerus and medullary canal.

Most failed shoulder arthroplasty cases have some form of stiffness, and this may be secondary to bony impingement or soft tissue contracture. If a malpositioned tuberosity or glenoid bone block is identified on the CT scan or at the time of surgery, then an osteotomy will be required if there exists loss of passive range of motion after a complete soft tissue release and if the prosthetic cannot be adapted to compensate for the tuberosity malposition. In all cases the surgeon should expect to perform complete circumferential soft tissue releases and excision of all capsular, subacromial, and subdeltoid scar. The subscapularis should be taken off the lesser tuberosity, except when there is a malunion, which requires an osteotomy or a nonunion of the lesser tuberosity, in which case the subscapularis tendon should be left attached to the mobilized lesser tuberosity fragment. The maximum subscapularis tendon length should be maintained in all revision cases. We do not recommend subscapularis Z-lengthening to improve external rotation because the tendon quality is often insufficient to allow for a secure repair. The incidence of subscapularis insufficiency increases with this technique due to tearing of the tendon and alteration of the moment arm. Separation of the anterior capsule from the tendon should be done at the midsubstance of the tendon or at the glenoid side to avoid thinning of the tendon. Inferior capsular excision will also be necessary, so the surgeon should have the appropriate retractors to isolate and protect the axillary nerve during this portion of the case. Another cause of the severely stiff shoulder is a captured cuff, where the subacromial and subdeltoid scar captures the rotator cuff so that it cannot glide independently of the deltoid and acromion. This subdeltoid subacromial scar can also inhibit dislocation of the prosthesis if it is not excised first.

Careful assessment should be made preoperatively for superior migration and superior escape of the proximal humerus. This abnormality will often cause distortion of the anatomy during the exposure of the case because the insertion of the pectoralis, deltoid, and rotator cuff muscles are more proximal in relation to the coracoid. The constrained prosthesis should also be available if the rotator cuff is deficient.

Preoperative assessment with CT scans should allow the surgeon to determine whether a glenoid implant can be used at the time of the revision. If the bone loss is substantial secondary to longstanding glenoid implant loosening, then the surgeon should have a femoral head allograft available, as well as standard and cannulated screw fixation systems. Medialization of the humerus can often be found with glenoid bone erosion in a hemiarthroplasty. When this is severe, if the surgeon decides

to resurface the glenoid, he or she should avoid completely restoring the normal lateral offset of the humerus, as this will overstuff the joint and lead to certain postoperative stiffness.

Instability is a difficult complication to treat in isolation, and it is even more difficult to treat in the face of glenoid bone loss. The tendency for the inexperienced surgeon is to focus on the bone defects that are obvious on the radiographs. What is often not appreciated is the soft tissue deficiency or redundancy in the direction of the dislocation, which can persist even after the bone loss is restored. The surgeon should anticipate performing capsular plication if posterior instability persists, and this can be done with arthroscopic suture anchors inserted through a posterior portal or with three or four purse-string sutures placed into the posterior capsule from the anterior wound. It is useful to have a mechanical arm holder and a laminar spreader to hold the head away from the glenoid and to expose the posterior capsule. This exposure is often very good due to the redundancy of the posterior capsule.

REVISION EQUIPMENT

Most of the retractors used for primary shoulder arthroplasty are used during the revision cases, with a few exceptions. For removal of the humeral stem, we always order the equipment specific to the stem design. This equipment usually attaches to the stems better than the universal extraction equipment. Thin osteotomes are used to loosen the proximal portion of the stem, and we have saws and a cable system ready in case a longitudinal osteotomy is necessary. Long-stem implants should always be special ordered because they may not come in the standard total shoulder setup, depending on the manufacturer. An assortment of bone tamps may also be used to tap the stem out of the humerus, as well as a set of revision instruments, including ring curettes with long handles, long thin osteotomes, and end-cutting cement removal drills. Anspach or Midas Rex power tools, a headlight, and fluoroscopy equipment should also be available.

Visualization of the entire glenoid, including portions of the body of the scapula, is necessary for bone-grafting cases, and these cases require extensive capsular releases to achieve the proper visualization of the glenoid. We use Fukuda-type retractors with an assortment of designs. The large-diameter Fukuda-type retractors are useful during reaming of the glenoid because they fit well with the circumference of the reamer. Other Fukudas with a thin opening are better for retraction during the exposure of the inferior glenoid. We also use a Gerber retractor to visualize the posterior capsule if a suture plication is necessary (Fig. 25-3).

INCISIONS

Many revision cases have more than one scar from previous surgeries, and they often cross each other at various angles. The incision for the deltopectoral approach has usually been made previously, so the risk of skin necrosis is small when this is the only incision to be used. If the procedure requires better visualization of the posterior glenoid or external rotators, we make a longitudinal incision from the posterior axillary crease to the spine of the scapula. When dual incisions are considered, the patient is positioned in the superior beach-chair position, taking care to get the shoulder far lateral so that the medial border of the scapula is exposed within the surgical field. This is facilitated by using a bean bag, a large bump behind the thorax, or an arthroscopy positioner. When the posterior incision is made, the operating room table is elevated and laterally tilted to the opposite side, and the surgeon sits onto a stool. When incisions are made parallel to one another, we try to have at least 4 cm between the incisions, but when we have had closer or crossing incisions we have rarely had any problems with wound healing in the shoulder.

EXPOSURE

The key to a successful revision shoulder arthroplasty is obtaining generous exposure, with a wide exposure being a primary goal and necessary to avoid compromising the removal of scar and prior implants, repair of the soft tissues, and insertion of the new implant and bone grafts. A wide exposure will result in the least damage to the tissue, as excessive retraction is avoided. If the surgeon is struggling to visualize the posterior attachment of the rotator cuff on the humerus or the posterior glenoid bone defect, insertion of implants will undoubtedly be difficult if not impossible, and ultimately the surgery and result will be compromised. When the initial exposure is compromised, consider extending the incision, releasing and excising more scar tissue, or incising tendons in a way that facilitates repair at the end of the case.

The first step in the exposure for the deltopectoral approach is defining the interval between the deltoid and the pectoralis. The interval will often be scarred from previous surgery, which makes assessment of muscle fiber orientation impossible. The surgeon must find the coracoid proximally and use it to define the interval. We sometimes cut directly down to the conjoined tendon on the coracoid and begin splitting the muscle distal to that point. We also start distal to the prior incision and use virgin tissue planes to find the cephalic vein and the deltoid muscle. We keep the cephalic vein lateral with the deltoid because of the excessive lateral perforators that require ligation if the vein is taken medially. We then work our way to the center of the interval, paying close attention to perforating vessels

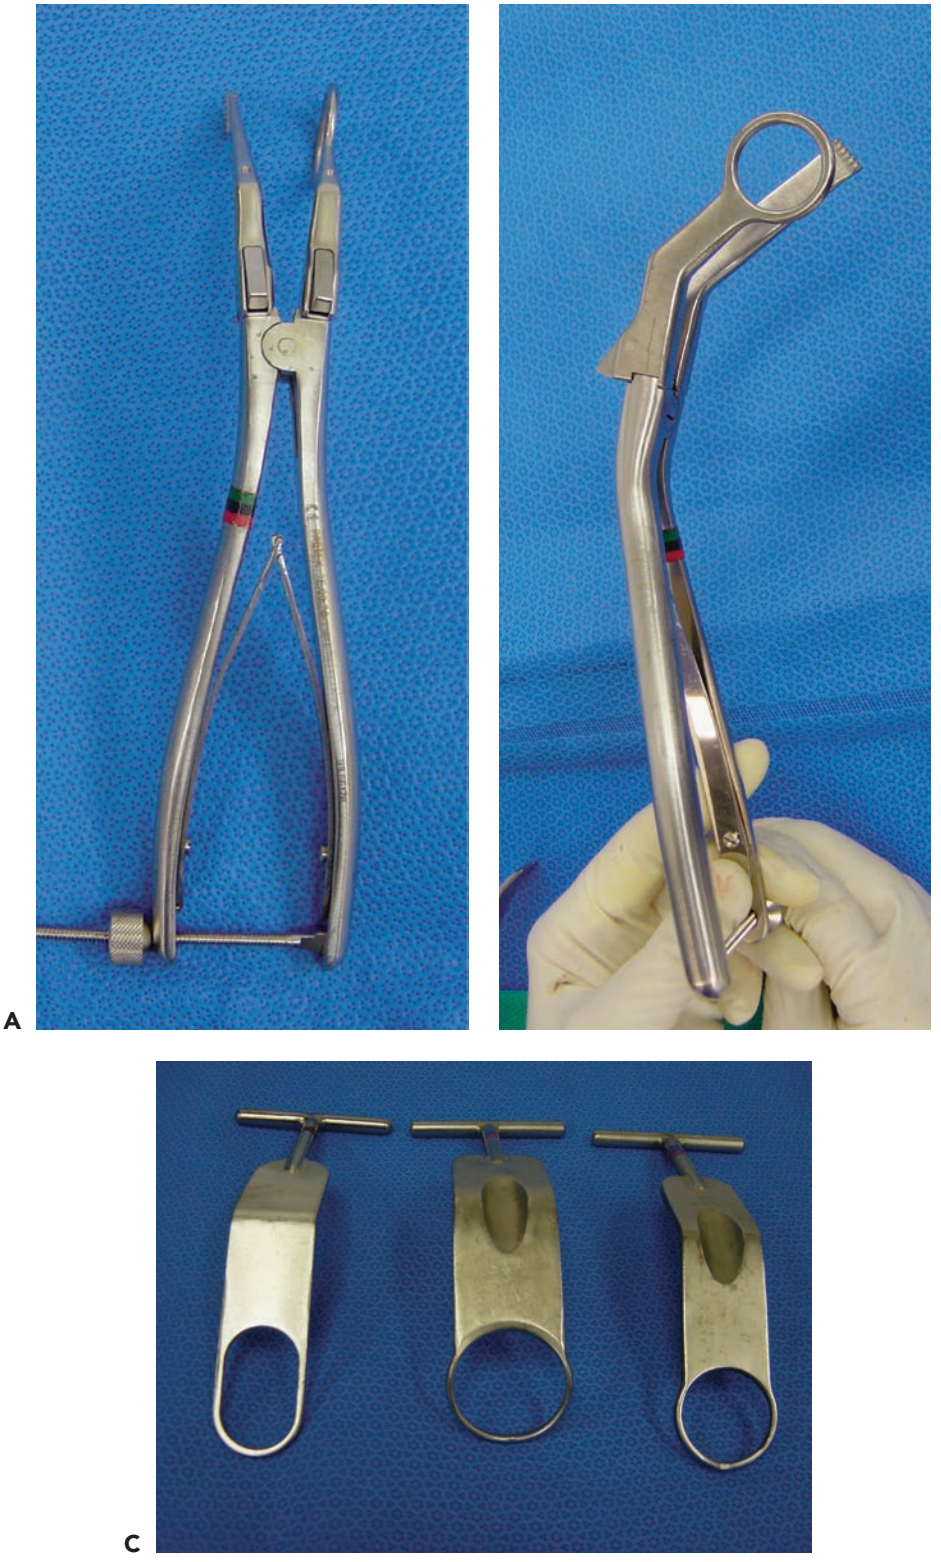

Figure 25-3 **(A–C)** The Gerber retractor is a modified laminar spreader that helps expose the posterior structures of the shoulder. A modified Fukuda retractor can help accommodate large glenoid reamers.

and the cephalic vein, which may be still patent. The most common error at this point of the procedure is not extending the interval proximal enough. The surgeon should be able to easily visualize 1 cm proximal to the coracoid process and should not hesitate to ligate the cephalic vein if it is at risk to rupture. The surgeon should incise the pectoralis tendon 3 to 4 cm distally, leaving a 5-mm cuff attached to the bone for tenodesis of the biceps tendon. Two or three figure-of-eight sutures through the biceps tendon can be placed at this point in the operation, and the tendon can be tenolysed proximally. The rest of the proximal tendon can serve as a landmark for the bicipital groove later in the procedure.

The next step in the exposure is the development of the tissue plane underneath the deltoid laterally. There is usually a perforating vein 2 cm proximal to the deltoid insertion, which the surgeon will tear during careless blunt dissection. Usually the interval is too scarred to allow blunt finger dissection, and sharp dissection is required to elevate the deltoid from the humerus. Do not injure the axillary nerve and accompanying vessels, which lie just distal to the flare of the tuberosities. Once proximal to the shaft, sharp dissection can be done without the fear of damaging vital structures. Scarred bursa should be excised from the rotator cuff, and if the bursa cannot be distinguished from the rotator cuff, the surgeon should incise at the tissue layer just deep to the deltoid muscle fibers up to the acromion. Once this plane is developed, and bent Hohman retractor can be placed over the rotator cuff to hold the deltoid away from the field. In cases where severe scarring limits visualization, a second incision should be made over the interval between the posterior and middle deltoid. This will allow for complete release of scar tissue around the posterior cuff and make possible rotator cuff repair much easier.

Medial exposure should be completed next. The surgeon should sharply incise lateral to the conjoined tendon layer and develop the plane superficial to the subscapularis muscle tendon. This usually requires both blunt and sharp dissection. The brachial plexus may need to be exposed to ensure safe dissection and retraction of the nerves. In some cases safe medial exposure may require osteotomy of the coracoid and distal dissection of the conjoined tendons. Regenerated vessels from the previously ligated anterior circumflex vessels will often course through the scar that needs to be cauterized and incised. Blunt dissection with a Cobb elevator wrapped in a gauze sponge sometimes works well to develop the correct plane and absorb any blood to facilitate visualization. The Kolbel retractor can then be placed under the conjoined tendons for easy visualization of the subscapularis tendon. The dissection should be completed distally to the humeral shaft until the latissimus dorsi tendon is seen. The axillary nerve should be palpated and visualized at this point. It can be visualized if a long right angle retractor is placed inferior and medially.

The subscapularis should be taken off the lesser tuberosity so that the maximum length of the tendon can be preserved. In revision cases, the tendon may be extremely thick because of the excessive capsule scar, or it can be thinned secondary to multiple surgeries and poor healing. We sharply elevate the tendon starting at the biceps groove and keep the capsule and tendon together until we can assess what we have to work with. If the interval cannot be palpated because of scar tissue, we extend the subscapularis takedown proximally until the biceps tendon is seen, and then we incise through the interval scar toward the base of the coracoid. Inferiorly, we incise the tendon approximately three-fourths of its width. At this point, we use a Cobb elevator to sweep away the subscapularis muscle from the capsule beneath. If this cannot be done by blunt dissection, then this interval is created by sharp dissection with a scalpel. The inferior capsule is bluntly cleared with a Cobb and sponge so that it is easily visualized and separated from the axillary nerve. After a blunt retractor is placed between the capsule and axillary nerve, the capsule is incised from its humeral attachment starting proximally and continuing distally to the latissimus dorsi tendon. The capsule is then incised deep around the medial side of the humerus as far as the surgeon can see directly, so that the nerve is not cut by a blind pass of the knife. At this point, the capsule and tendon may still be intimately attached medially, and these two structures are separated sharply with a scalpel. The capsule should be separated from the tendon and released from the glenoid to restore tendon excursion. By this method the entire anterior–inferior capsule is excised. Final release of the subscapularis tendon from the undersurface of the coracoid should completely free the tendon and muscle circumferentially.

At this point, the humeral head can be dislocated. A Hohman retractor is placed between the humeral head and glenoid and is levered inferior to the coracoid to avoid fracture of the process. The Hohman acts as a "shoehorn" to bring the humeral head out of the wound. External rotation and posterior force applied to the head should dislocate the head. If the dislocation cannot be accomplished because the tissue is too tight, additional releases should be performed in the following order: (1) release more inferior and posterior capsule and scar, and (2) then release a small portion of the supraspinatus tendon, leaving room for suture repair at the end of the case. In cases where there is a malunion of the greater tuberosity, adequate exposure of the proximal humerus may require osteotomy of the greater tuberosity. If these releases still do not allow for an atraumatic dislocation of the head, then separation of the modular head can be done in situ. The surgeon holds the proximal humerus laterally with a bone hook and separates the head from the stem with an osteotome or head removal instrument provided by the manufacturer. After the head is removed he or she sharply excises all of the scar

tissue from the posterior and superior aspects of the joint including the glenoid fossa circumferentially, leaving only the posterior and superior cuff intact.

HUMERUS REVISION TECHNIQUES

Maintaining the rotator cuff attachments to the proximal humerus and keeping the tuberosities in continuity with the shaft are the most important goals of revision humeral arthroplasty. If that anatomic relationship cannot be maintained, then an unconstrained arthroplasty will likely result in poor function if the tuberosities cannot be securely fixed in a near anatomic position or do not heal. Care should be taken during the extraction of well-fixed humeral components to avoid levering with osteotomes, as the proximal bone can be quite thin and fragile in the revision setting. Bone overgrowth and scar should be carefully removed from the lateral fin of the prosthesis, as this often impedes easy extraction. Proximal porous coating of the stem stimulates an excellent metal–bone bond, and in our experience, precludes extraction without an osteotomy of the shaft in at least 50% of the cases.

Once the decision is made to perform an osteotomy of the shaft, the incision should be extended distally, and should extend distal to the deltoid insertion and be in the interval between the deltoid and biceps muscles (Fig. 25-4). The shaft should be exposed in line with the biceps groove and the shaft cut longitudinally lateral to the biceps groove to the tip of the prosthetic. We use a power saw to cut through the bone and cement mantle if there is one. A half-inch osteotome is then placed in several locations within the osteotomy site and the sharp edge of the osteotome is placed at the prosthetic cement interval and gently tapped with a mallet to break this bond. When this is completed, the osteotome is placed in the osteotomy and given a quarter turn to wedge open the osteotomy site and break any further bond between the stem and cement. Once the stem is loosened, it can be pulled out with the appropriate extraction device. This technique does not work well for porous-coated stems with bone ingrowth or with cement interdigitation into the porous coating. In these cases thin osteotomes must be used to either cut an interval between the stem and cement through a proximal intramedullary access or through a formal bicortical window that is removed to allow access to the entire anterior face of the stem.

Cement removal can be taken out with power burrs for proximal cement seen within the medullar canal and long thin osteotomes and long power end-cutting drills bits designed for cement removal. In cases where there is no indication of infection, all of the cement does not need to be removed and another stem can be inserted into the previous cement mantel. Leaving the cement in place in noninfected cases may be the best option to avoid multiple fractures or perforations of the thin humeral cortex. In these cases, all loose cement needs to be removed and the inner portions of the cement mantel need to be removed to allow for a stem of sufficient diameter. Distal cement needs to be removed to allow for full seating of the humeral component. Use of fluoroscopy is often helpful to avoid penetration of the cortex, and having the proper drills and equipment is essential. When the humeral shaft is cut in only one cortical surface and then cerclage wired, a long-stem component is not required. If the shaft is unstable and there is a bicortical window or any transverse component to the shaft fracture, then the stem should extend distally two canal diameters beyond the extent of the distalmost fracture line; in most cases, this will mean using a long-stem cemented prosthetic. In patients with short stature, the standard long stems may be too long and the surgeon will need to be prepared to cut the stem in the operating room. This can be done with a diamond high-speed cutting tool (Fig. 25-5).

Cerclage cables can be passed around the shaft to reconstitute the canal, and then the canal can be prepared for the appropriate stem. We prefer to use the 1.6-mm Dall Miles cables. We do not recommend press fitting a stem once the metaphysis has been disrupted. When cementing the stem, care should be taken to avoid the cement extruding from the osteotomy or fracture sites. Wide exposure helps achieve this objective.

GLENOID BONE LOSS

There are three different treatments for glenoid bone loss, including impaction grafting, glenoid sculpting, and bulk allograft. If the defect is contained by a rim of bone, then morselized bone graft can be impacted to fill the defect. There are no scientifically determined guidelines as to when a new glenoid component can be placed into a glenoid with significant bone loss. We use as a general guideline that a glenoid implant can usually be implanted over the graft so long as there is at least 50% of the back surface of the glenoid component in contact with native subchondral bone and 100% of the peripheral rim is intact. If the bone loss in the central part of the glenoid vault is too large, then the current pegs or keel component designs will not allow for stability and a glenoid component of this design should be avoided. In this case, the glenoid is bone grafted and left without an implant (Fig. 25-6). If the patient has pain after the bone graft incorporates (1 year or longer after the surgery), the patient could undergo another procedure for placement of a glenoid or conversion to a reverse shoulder arthroplasty if indicated.

Hill and Norris reported their results of treating 17 glenoid defects with bone grafting in primary total shoulder arthroplasty. All of the patients in the study had a history

Figure 25-4 **(A–C)** A unicortical osteotomy is made with a saw, starting in the biceps groove and extending distally. An osteotome is used to loosen the bond between the prosthesis and the cement before the stem is removed with a bone tamp or slap hammer. **(D–F)** Cables are placed around the shaft and then the canal is prepared for the revision stem using a reamer.

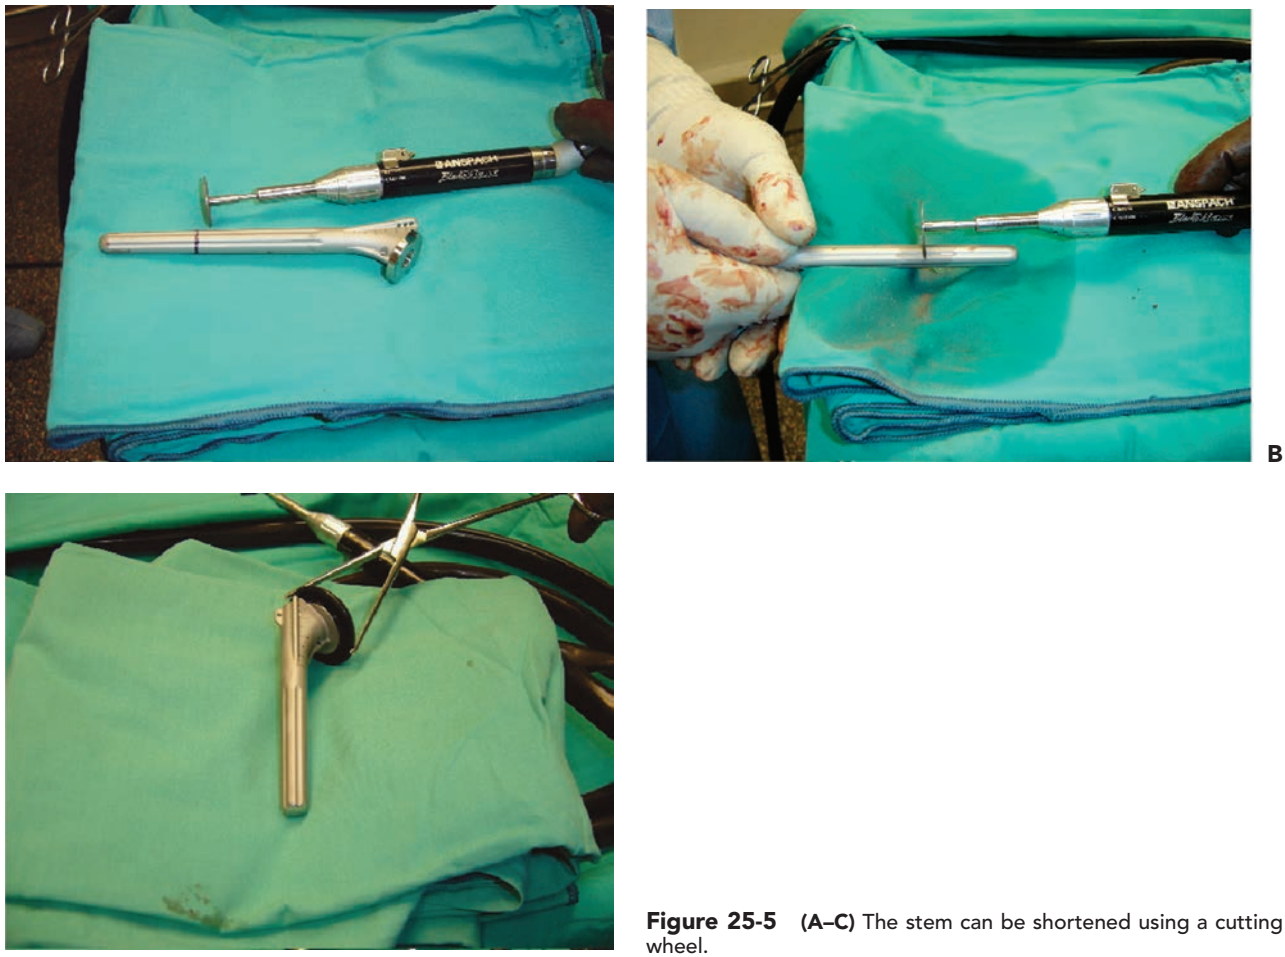

Figure 25-5 **(A–C)** The stem can be shortened using a cutting wheel.

of instability. Twelve of the defects were in the posterior, and five were anterior. The bone graft was taken from the humeral head or from the iliac crest. The average depth of the glenoid defects was 12 mm (range 4 to 15 mm). The average correction of version was 33 degrees. While five total shoulders in the series failed because of persistent instability and rotator cuff tears, only one of the shoulders failed secondary to loosening of the bone graft.[3]

The editor's experience with glenoid bone loss during revision surgery was reviewed. We retrospectively reviewed 32 patients who underwent glenoid revision surgery after total shoulder arthroplasty (TSA). The etiologic factor for glenoid loosening was component malposition (20 patients) or glenohumeral instability (12 patients).

Results were reviewed at a mean follow-up of 4 years (range, 2 to 8 years). Glenoid reimplantation resulted in significant pain relief ($p < 0.0001$), improvement in American Shoulder and Elbow Surgeons (ASES) score ($p < 0.02$), and external rotation (24 to 44 degrees, $p < 0.004$). Revision to a hemiarthroplasty also resulted in significant pain relief ($p < 0.01$) and improvement in ASES score ($p < 0.05$).

For the treatment of glenoid loosening without glenohumeral instability, both reimplantation of a glenoid component and revision to a hemiarthroplasty improved function, satisfaction, and level of pain. Reimplantation of a new glenoid component offered greater improvements in pain ($p < 0.008$) and external rotation (increase of 20 degrees vs. 3 degrees, $p < 0.03$) compared to hemiarthroplasty. For patients with preoperative glenohumeral instability, revision surgery did not improve motion, function, or pain significantly. Risk factors associated with a poor outcome after revision arthroplasty included persistent glenohumeral instability, rotator cuff tears, and malunion of the greater tuberosity.

If a peripheral rim defect is less than 10 mm without significant medial bone loss and there is an intact subchondral bone, then you can normalize version by reaming the high side of the glenoid using a burr and reamer. For peripheral defects that are greater than 1 cm or when reaming the "high side" would result in too much bone loss to allow for placement of a glenoid or would result in humeral instability, then a bulk graft needs to be used. In revision cases this would require allograft materials (femoral head)

Figure 25-6 **(A)** X-ray demonstrates a loose keeled glenoid component surrounded by a large radiolucency, which is usually associated with a large cavitary glenoid defect. **(B)** The glenoid defect is large after the soft tissue is removed. **(C)** Cement is used to make a mold of the defect.

or in primary cases the patient's excised humeral head (if of sufficient size and quality) can be used (Fig. 25-7). In these cases the glenoid defect is made to resemble a step cut with the right angle cut being at the base of the defect. The graft is cut to fit the defect and secured in place with two cannulated small fragment screws inserted percutaneously through a posterior portal. The screws should be inserted below the rim of the graft and at approximately a 45-degree angle to the surface of the graft. The screws should engage the opposite glenoid cortex. The graft should be made larger than needed as it relates to the height of the glenoid surface. The graft and native glenoid is then reamed to be a smooth surface. The newly reamed surface can then be instrumented for either a pegged or keeled component. We make an attempt to use an Anchor peg all polyethylene component to minimize the cement needed for fixation. All

attempts should be made to avoid cement between the graft and the glenoid vault.

Most revision cases, however, have much larger bone defects secondary to persistent instability or long-standing glenoid implant loosening. These large defects often do not resemble the normal anatomy. The glenoid walls are expanded due to bone remodeling, and the defects are irregular in shape. There is variable loss of subchondral bone, the glenoid rim, and the glenoid walls. These three structures define the glenoid vault. We describe a classification of contained and uncontained glenoid bone loss by loss of these three structures. When the subchondral bone is missing, the defect is contained (intact rim and walls). When the rim and/or walls are deficient, then the defect is considered uncontained. In cases of uncontained glenoid bone loss, bulk allograft should be used. If fixed appropriately, the humeral component can articulate with the graft and the patient will have significant pain relief along with shoulder-level function or better if the cuff and tuberosities are intact. If the pain persists, a glenoid component may be implanted at a second procedure, once the bone has consolidated at least 6 months later.

Before implanting a bulk allograft, the extent of the defect should be determined by removal of all soft tissue and loose bone and cement from around the glenoid vault. Retractors should be monitored carefully, because they may lever on the thin walls and fracture the fragile glenoid. Once the defect is completely visualized, we fill the entire defect with bone cement and let it harden. The cement should be inserted just before it hardens to avoid cement extravasation outside the defect. The cement is molded in situ to be the size and shape of the intended bone graft. A screw is put in the middle of the cement to facilitate its removal after it hardens. The hardened cement can now be used as a model to shape the femoral head bone graft so that it will maximize the contact area between the graft and the defect. We fix the bulk allograft with two or three cannulated screws, making sure the screw heads do not protrude on the articular surface of the graft. Finally, a glenoid reamer is used to create a concave surface on the graft with the appropriate version.

TUBEROSITY MALUNION

Just as the integrity and function of the rotator cuff determines the outcome of shoulder arthroplasty, so does the position of the tuberosities in cases with a previous frac-

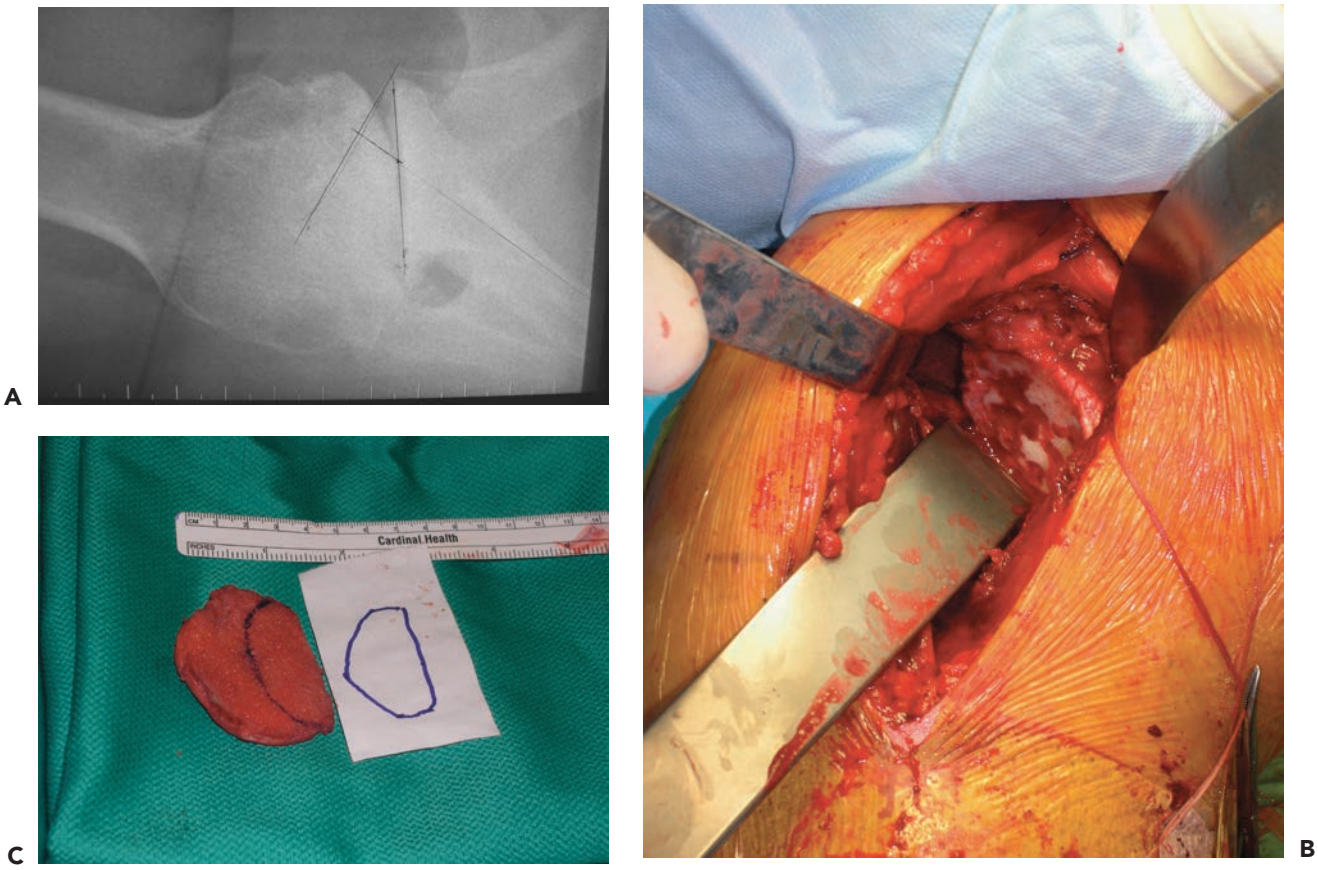

Figure 25-7 **(A)** Lateral x-ray shows significant posterior glenoid wear that requires bone grafting. **(B)** Appearance of the glenoid before preparation.

ture. A study by Boileau et al. evaluated the outcomes of their hemiarthroplasty in patients who had previous proximal humerus fractures.[1] Forty-nine cases had collapse of the humeral head or dislocation of the humeral head without displacement of the tuberosities that required an osteotomy, and 22 cases had malunions of the tuberosities or nonunion of the surgical neck, which required reattachment of the tuberosities to the proximal prosthesis. The adjusted Constant scores were 73% for the nonosteotomy group and 58.5% for the osteotomy group. The active elevation for the nonosteotomy group was 123 degrees, while the osteotomy group did not recover elevation beyond the horizontal (77 degrees). All 11 patients who were dissatisfied with the results of their hemiarthroplasty underwent osteotomy of their tuberosity malunions. The authors recommend avoiding an osteotomy unless it is absolutely necessary. Altering the version, offset, or size of the prosthesis may be enough to overcome the malposition of the tuberosities. Moving the humeral head to accommodate tuberosity malposition may require altering the stem diameter or length and thereby allowing greater flexibility in positioning the head within the confines of the tuberosities. A smaller stem will need to be cemented.

If the tuberosity malunion is too severe and external and internal rotation are limited or if there is abnormal contact of the tuberosities with the glenoid or coracoid or acromion despite altering the position of the humeral prosthesis, then an osteotomy of the tuberosity is indicated (Fig. 25-8). The osteotomy should be performed with a saw to avoid uncontrolled fractures through the proximal humerus. Correct placement of the osteotomy requires complete exposure of both the outer and inner surfaces of the cuff and tuberosity. The osteotomy should be oblique to the humeral shaft to maximize bone contact when it is repositioned onto the new stem and humeral shaft. After the osteotomy is completed, non-absorbable sutures should be placed through the tendon as well as through the bone. A complete posterior and superior capsular release will be required to mobilize the fragment to its new anterior and inferior position. It may be necessary to place the tuberosity in a better than before the osteotomy but not in an anatomic position. In some cases with longstanding posterior nonunion or malunion with

Figure 25-7 (*continued*) **(C–F)** An outline of the glenoid defect is made on paper and then traced over the humeral head that was resected. After the bone graft is cut to the correct size, it is fixed to the glenoid with screws. Then the glenoid and bone graft are reamed and prepared in the usual manner for fixation of the glenoid component. **(G)** Postoperative lateral x-ray shows restoration of the normal glenoid version.

complete capsular excision, there is still contracture of the muscle such that placement of the tuberosity in its normal anatomic positions will lead to severe external rotation contracture. In these cases, we will place the tuberosity as close to its normal position while still allowing the wrist to come within 2 to 3 in. of the abdomen when the elbow is by the patient's trunk. The patients are always placed in a brace for 6 weeks after surgery. Most patients will regain sufficient internal rotation to reach their abdomen within pull off of the tuberosity. Fixation of the tuberosities also includes a circumferential suture that passed through the medial hole of the prosthesis for compression of the tuberosity. The sutures can be passed with a large sharp needle, or if the bone is thin after humeral canal preparation, drill holes can be placed for passage of the sutures. At least one suture should be passed distally to resist superior migration of the greater tuberosity, and at least two sutures should be placed to resist external rotation of the greater tuberosity. If the fins of the prosthesis are exposed, then the sutures should be passed through the fins. The sutures through the tendon are best for resisting tension, and the sutures through the tuberosity bone are best for compression. If after the osteotomy and repositioning of the tuberosity there is minimal bone contact, morselized bone graft should be used to bridge the gap. When the tuberosities and/or cuff are deficient and when after osteotomy there is a high likelihood for nonunion or poor cuff function, then use of the reverse shoulder arthroplasty would be the best option, particularly in patients over the age of 65 years.

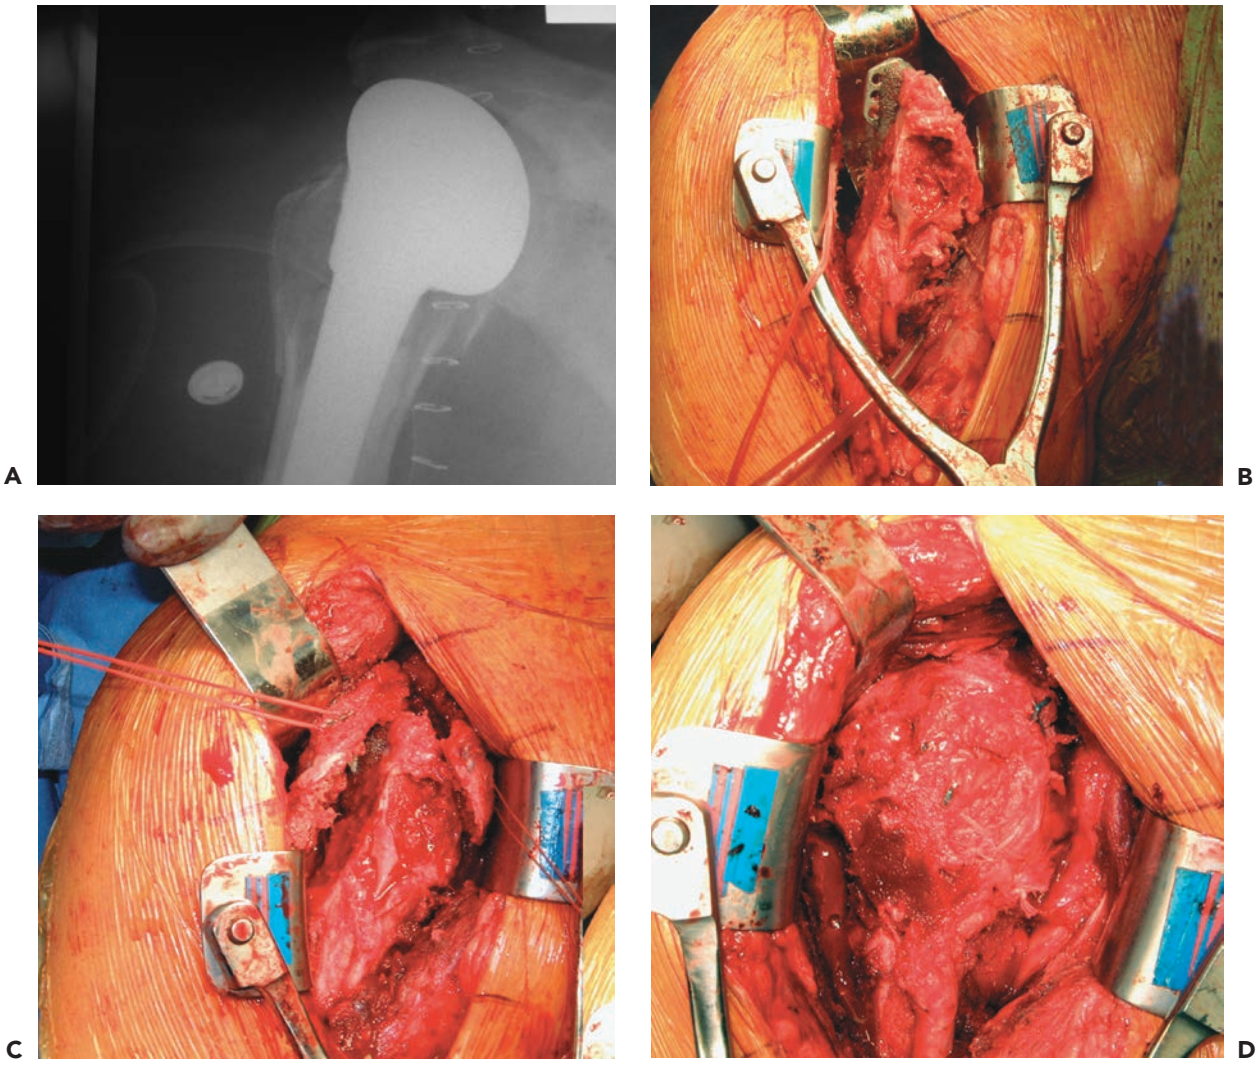

Figure 25-8 **(A)** The greater tuberosity healed 1 cm inferior to its anatomic position. **(B–D)** Intraoperatively, the tuberosity was inferior and posterior to its anatomic position. Release of adhesions was done along the superior and inferior borders of the tendon to allow full excursion with minimum tension. Nonabsorbable sutures were used to attach both tuberosities around the prosthesis.

SEVERE SOFT TISSUE DEFICIENCY AND INSTABILITY

In some patients with severe anterior soft tissue deficiency and anterior instability, a soft tissue reconstruction of the shoulder can be a good option when there is otherwise good bone, deltoid, and superior and posterior cuff function. This circumstance most often occurs with late recognition of a postoperative dehiscence of a subscapularis repair after prosthetic arthroplasty. In these cases, when pain and poor function or prosthetic instability indicate the need for surgery, a soft tissue reconstruction using a long strip of iliotibial band can be used to reconstruct the anterior and inferior capsular tissues. The sternocostal portion of the pectoralis muscle can be transferred either below or above the conjoined tendon to provide some dynamic stabilizer function[4] (Fig. 25-9). As with all revision surgery, balancing the soft tissues, by excision of all contracted tissues both anteriorly and posteriorly, is required to achieve a satisfactory clinical result.

SEVERE SOFT TISSUE AND BONE DEFICIENCY

In some cases after failed arthroplasty there is severe soft tissue loss of both the rotator cuff and deltoid as well as severe glenoid and/or humeral bone loss such that any

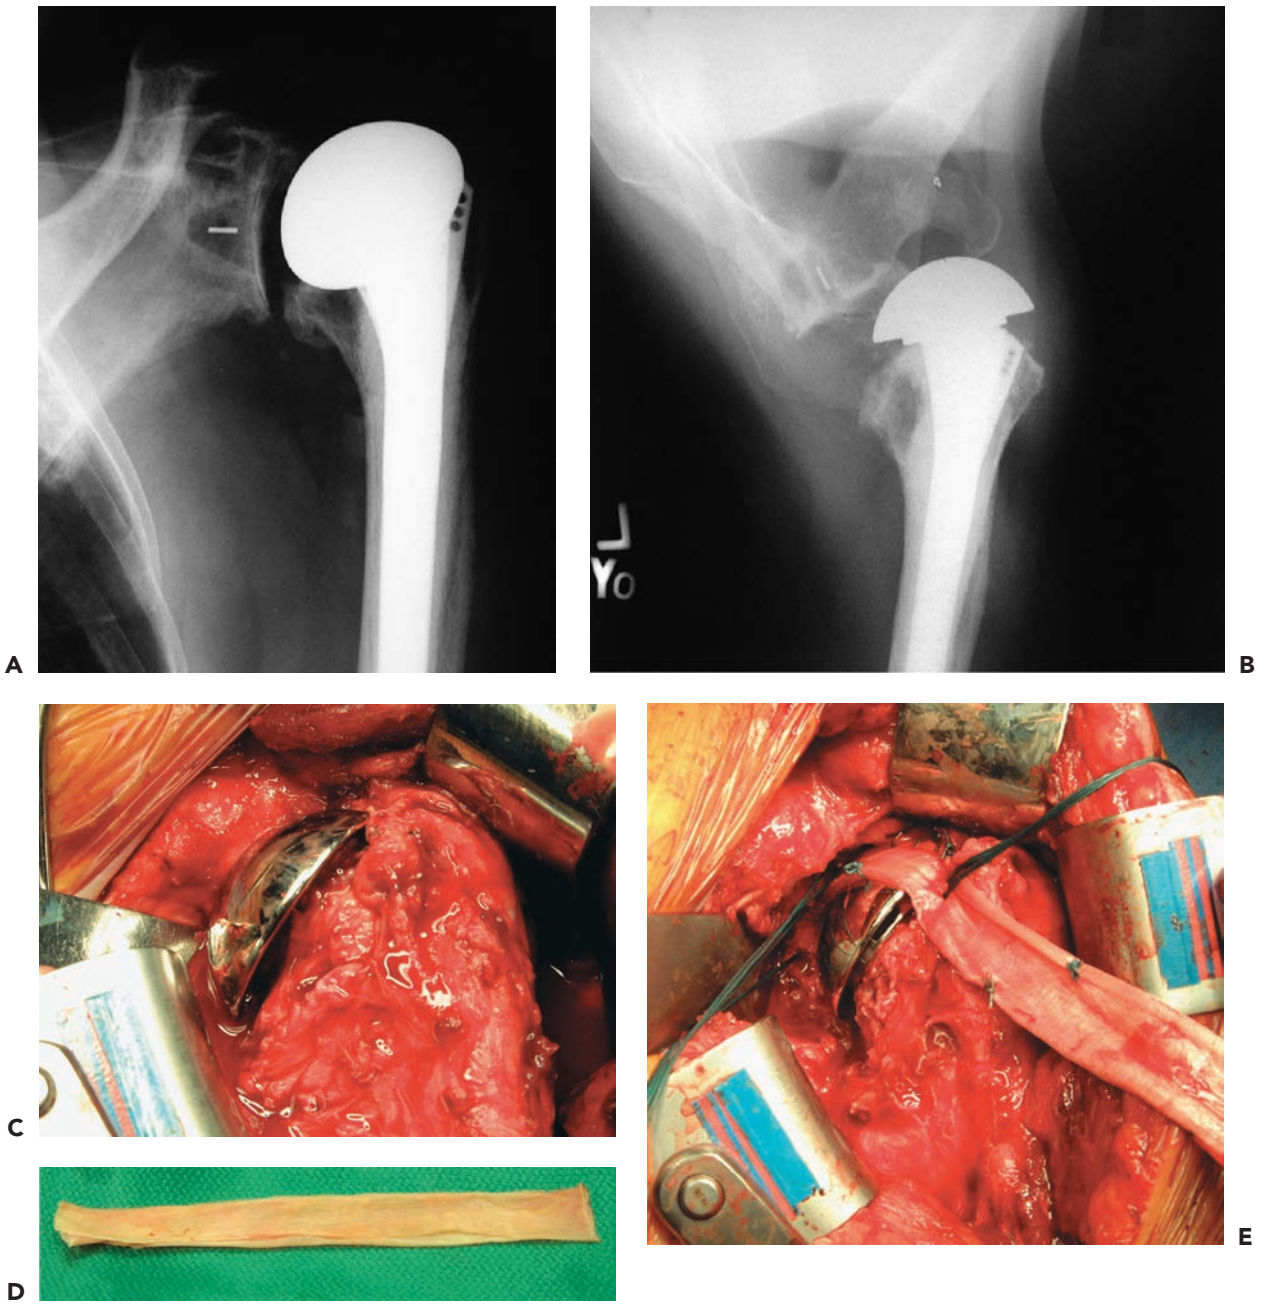

Figure 25-9 **(A,B)** X-rays demonstrate a total shoulder arthroplasty that is unstable anteriorly. **(C)** The subscapularis, a significant active restraint to anterior dislocation, was found detached from the humerus.

prosthetic arthroplasty will be of little value. In these cases either resection arthroplasty or glenohumeral fusion is required. Glenohumeral fusion can be a significant challenge due to both poor soft tissue coverage as well as bone loss. The senior author has converted 11 cases to arthrodesis for failed arthroplasty with severe soft tissue (cuff and deltoid) and bone loss. When there are intact tuberosities, near-normal glenoid bone, and absence of infection (failure of a hemiarthroplasty for arthritis or fracture), then a fusion with structural allograft, plating, and at least 3 months in a spica cast has been successful in relieving pain and getting shoulder-level function in all five cases treated to date. In patients with absence of the tuberosities and/or deficient glenoid bone, a vascularized free fibula autograft is required. In most cases a second or third bone-grafting procedure may be required to achieve

union. Of the six cases treated to date, the senior author has had one persistent nonunion. All the other cases have healed with at least chest-to-shoulder-level function.

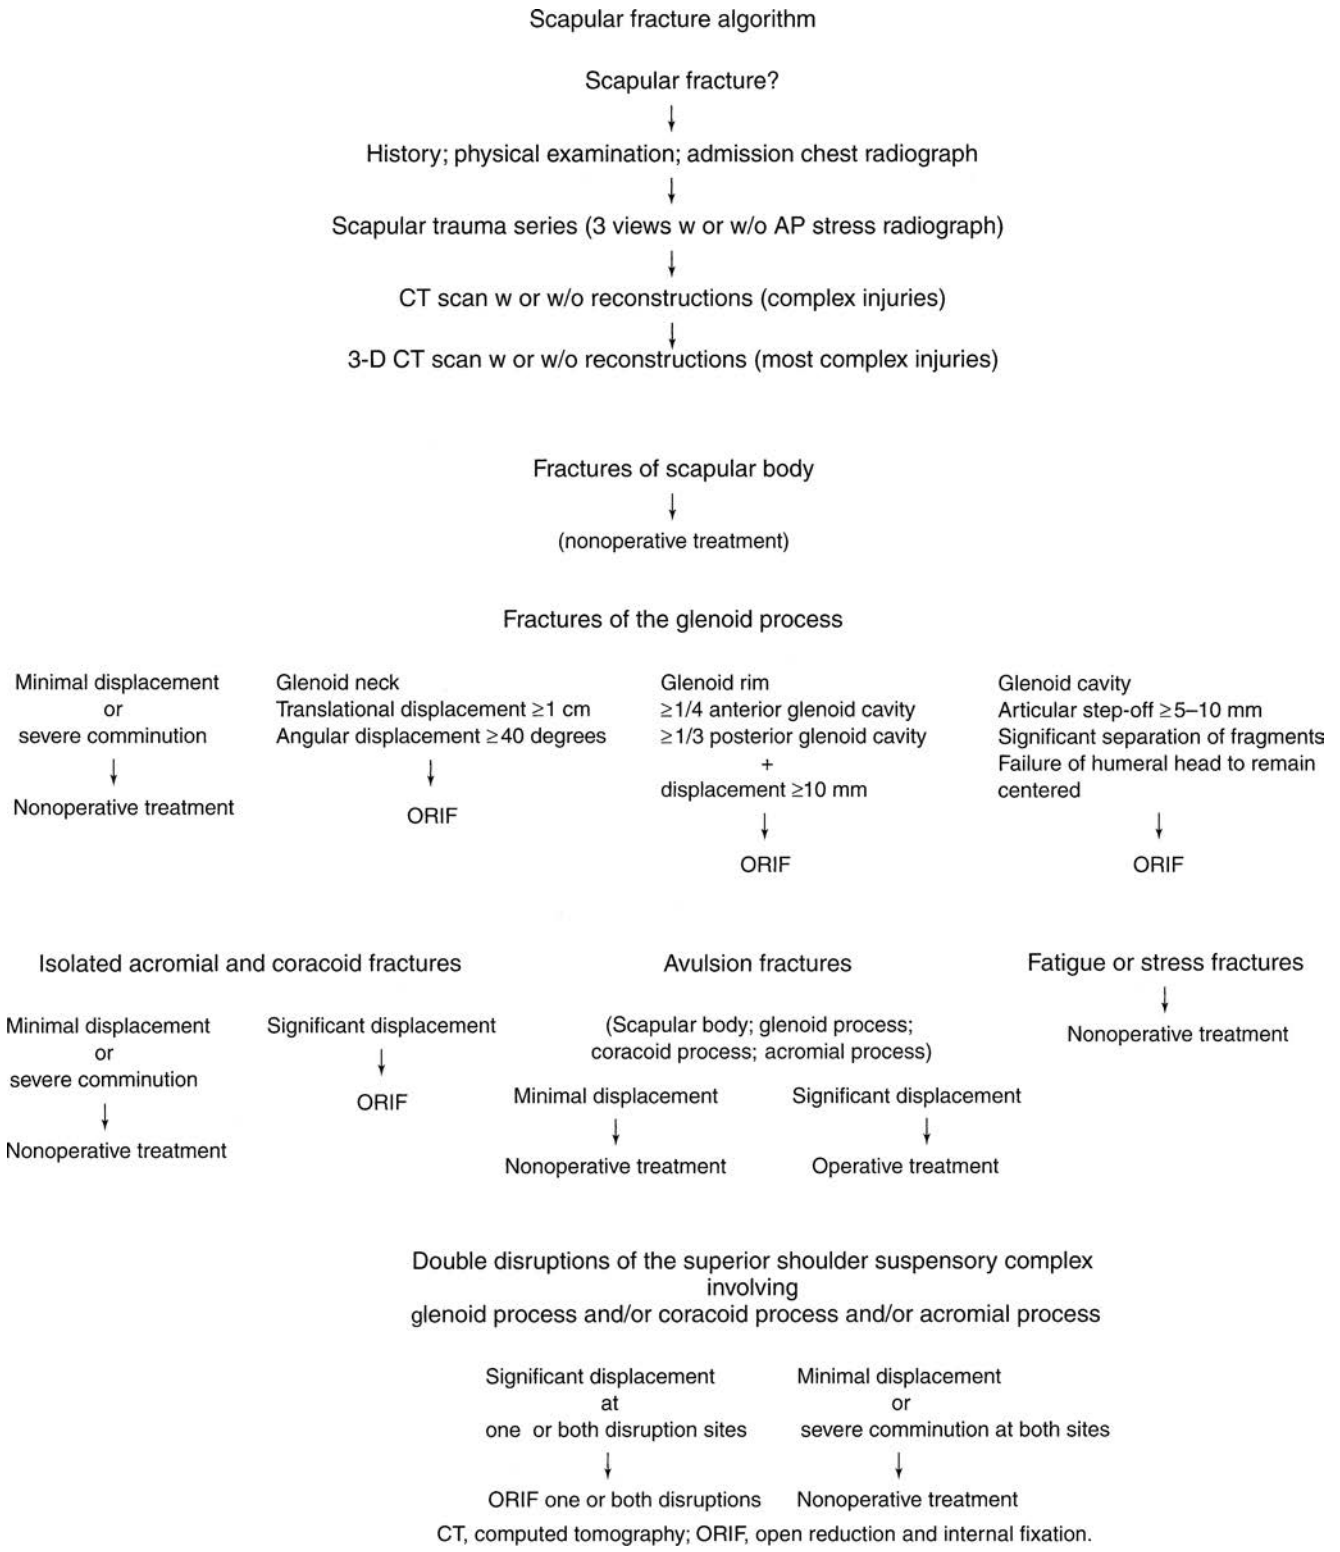
CLASSIFICATION AND INCIDENCE

General Considerations

Fractures of the scapula account for 1% of all fractures, 5% of shoulder fractures, and 3% of injuries to the shoulder girdle. There are two reasons for this relative infrequency: (a) the scapula lies over the posterior chest wall protected by the rib cage and thoracic cavity anteriorly and a thick layer of soft tissues posteriorly, and (b) the relative mobility of the scapula allows for considerable dissipation of traumatic forces. The vast majority of scapular fractures



(90+%) are insignificantly displaced, primarily because of the strong support provided by the surrounding soft tissues, making nonoperative management the treatment of choice for most scapular fractures. As a result, these injuries have received little attention in the literature. Scapular fractures involve a major articulation, however, and when significantly displaced are capable of causing considerable morbidity. Consequently, these injuries deserve more respect and recently have received more consideration in major texts,[11,23,28,32,129,142,143,149,158,169,175,183] general and review articles,[42,51,62,63,68,88,107,125,127,128,145,146,165,168,187,199,202,210] and papers dealing with specific issues.

Scapular fractures are usually the result of high-energy (usually direct but occasionally indirect) trauma. Consequently, they have an 80% to 95% incidence of associated osseous and soft tissue injuries (local and distant) that may be major, multiple, and even life-threatening. These individuals need to be carefully evaluated when they present in the emergency room, and appropriate supportive care must be rendered (see Scapular Fracture Algorithm). As a result, scapular fractures are often diagnosed late or definitive treatment is delayed. This may compromise the patient's final functional result. In addition, if associated injuries involve the shoulder complex, the individual's "scapular fracture" recovery may be compromised still further.

Most scapular fractures involve the body and spine (approximately 50%)[119] (Fig. 26-1). These injuries are often rather alarming radiographically (extensive comminution and displacement are frequently present; Fig. 26-2); however, there is very little enthusiasm in the literature for operative treatment,[72] since bone stock for fixation is at a premium and these injuries seem to heal quite nicely with nonoperative/symptomatic treatment[76]—a good to excellent functional result can be expected. The reason for this positive prognosis probably relates to the fact that (a) the scapulothoracic interval is cushioned by a thick layer of soft tissues, and (b) the mobility of the scapulothoracic articulation compensates for most residual deformities of the scapular body. The literature does mention a fracture of the scapular body with a lateral spike entering the glenohumeral joint as an indication (albeit extremely uncommon) for surgical management.[71] A similar recommendation was made in the case of an individual with a fracture of the scapular body and intrathoracic penetration of the fragments.[18] On rare occasions, a scapular body malunion may result in scapulothoracic pain and crepitus requiring surgical exposure of its ventral surface and removal of the responsible bony prominence(s).[121] Finally, nonunion of a scapular body fracture requiring surgical management has been described.[40,67,93,132]

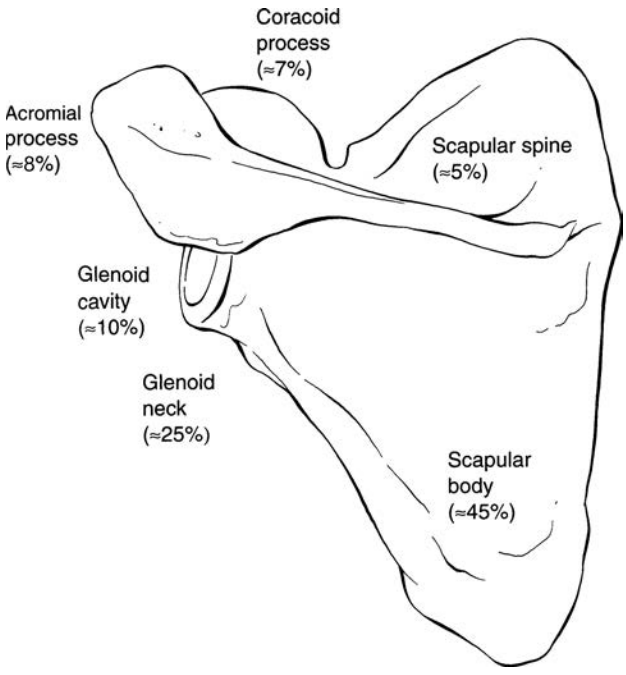


Figure 26-1 Incidence of scapular fractures according to region: the scapular body (≈45%), the scapular spine (≈5%), the glenoid neck (≈25%), the glenoid cavity (≈10%), the acromial process (≈8%), and the coracoid process (≈7%). (D: From Rockwood CA. *Fractures.* Philadelphia: JB Lippincott, 1975:733, with permission.)

The remaining 50% of scapular fractures involve its three processes (see Fig. 26-1). Fractures of the glenoid neck constitute approximately 25% of the total, whereas fractures of the glenoid cavity (the glenoid rim and glenoid fossa) make up approximately 10%. (Fractures of the glenoid process, therefore, account for approximately 35% of all scapular fractures.) Approximately 8% of these injuries involve the acromial process, and approximately 7% involve the coracoid process.[127] (An *acromial fracture* is defined as any fracture that runs from the posterior margin of the scapular spine or acromion to the undersurface of the acromial process all the way to the deepest point of the spinoglenoid interval.)

Diagnosis

The physician's attention is initially drawn to the scapular region by the patient's complaints of pain and abnormal physical findings in the area (swelling, crepitus, ecchymosis, and such). The specific diagnosis of a scapular fracture, however, is ultimately radiographic. These injuries are often initially missed[73] or detected incidentally on the patient's admission chest radiograph (Fig. 26-3). A "scapula trauma series" is then indicated, including true anteroposterior (AP) and lateral views of the scapula as well as a true axillary projection of the glenohumeral joint (Fig. 26-4). The scapula is a complex bony structure. One must be able to visualize and evaluate the scapular body and spine as well as its three processes: the glenoid process, the acromial process, and the coracoid process. The glenoid process is composed of the glenoid neck and the glenoid cavity, which, in turn, is made up of the glenoid fossa and the glenoid rim. Finally, the scapula takes part in three articulations (the acromioclavicular [AC] joint, the glenohumeral joint, and the scapulothoracic articulation), each of which must be carefully evaluated. One should look for associated shoulder girdle injuries, including those involving the clavicle, the proximal humerus, and the sternoclavicular joint.

If an injury to the linkage between the clavicle and the scapula (i.e., a disruption of the coracoclavicular and/or acromioclavicular ligaments) is suspected, a weight-bearing AP film of the shoulder should be obtained (see Fig. 26-4). In some situations, transthoracic lateral and oblique projections of the region may be of value. The scapula trauma series should suffice for most injuries, but if the fracture pattern appears to be complex (multiple fracture lines and significant displacement), computed tomography (CT) scanning is necessary. The superior images allow evaluation of the acromioclavicular joint and the acromial process, while the inferior images show the scapular body and spine and scapulothoracic articulation (Fig. 26-5).

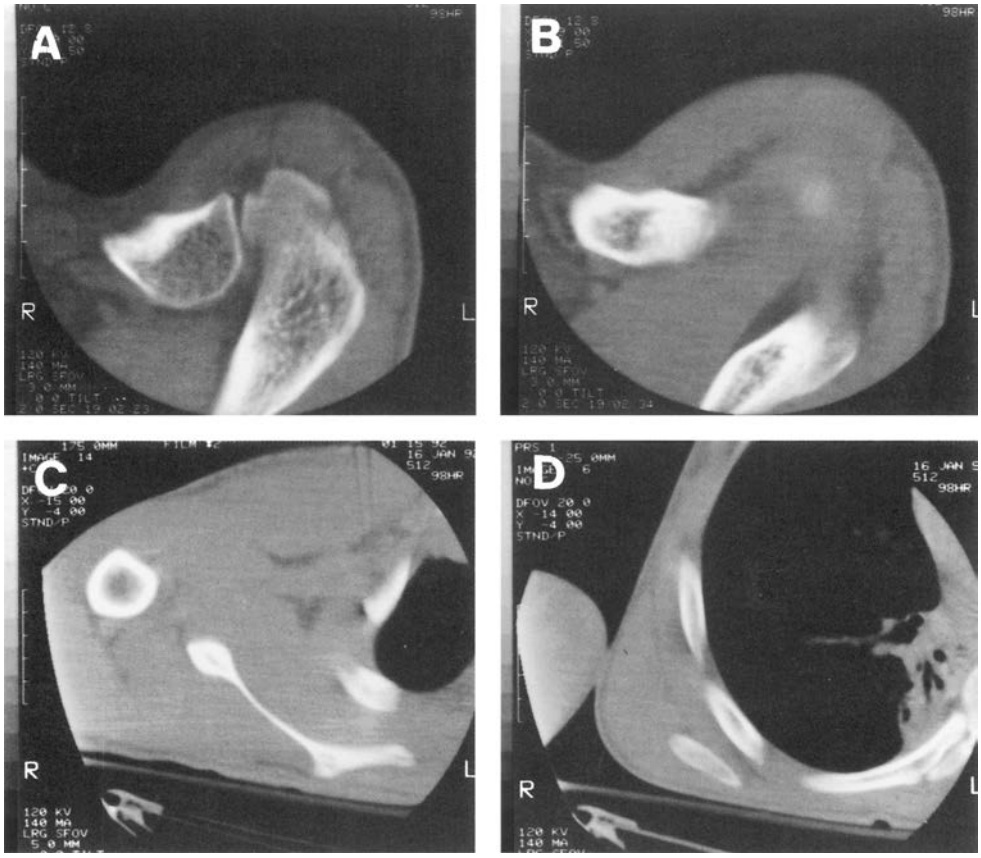

Figure 26-5 Multiple axial computed tomographic images of the scapula: **(A,B)** superior images showing the acromioclavicular joint and the acromion; and **(C,D)** Inferior images showing the scapular body and scapulothoracic articulation.

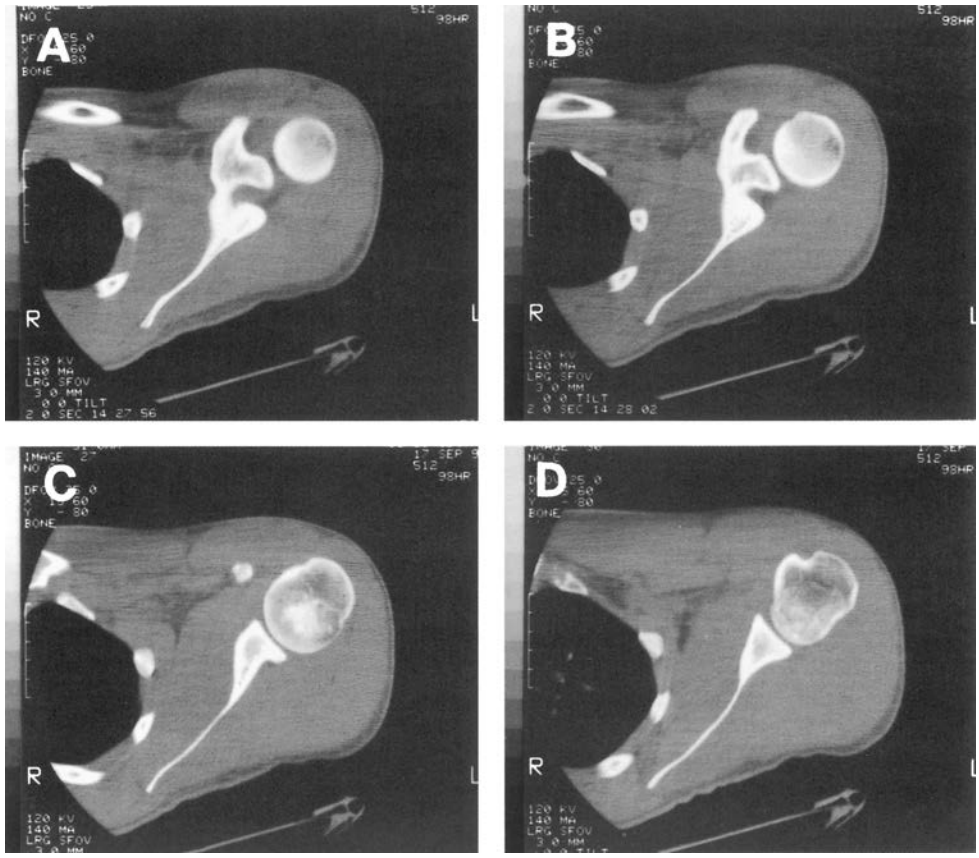

Figure 26-6 Multiple axial computed tomographic images: **(A,B)** most superior; and **(C,D)** most inferior, through the glenohumeral region of the scapula.

The middle images allow one to see the glenoid neck, the glenoid cavity (glenoid rim and glenoid fossa), the coracoid process, and the glenohumeral articulation (Fig. 26-6). In certain clinical situations, reconstructed views can be of great value (Fig. 26-7). Finally, three-dimensional (3-D) scanning can be extremely helpful to the orthopedist trying to evaluate the most complex fracture patterns (Fig. 26-8). Images rotated at 15-degree increments in the horizontal, vertical, and oblique planes can be examined and the most useful projections printed for later reference.

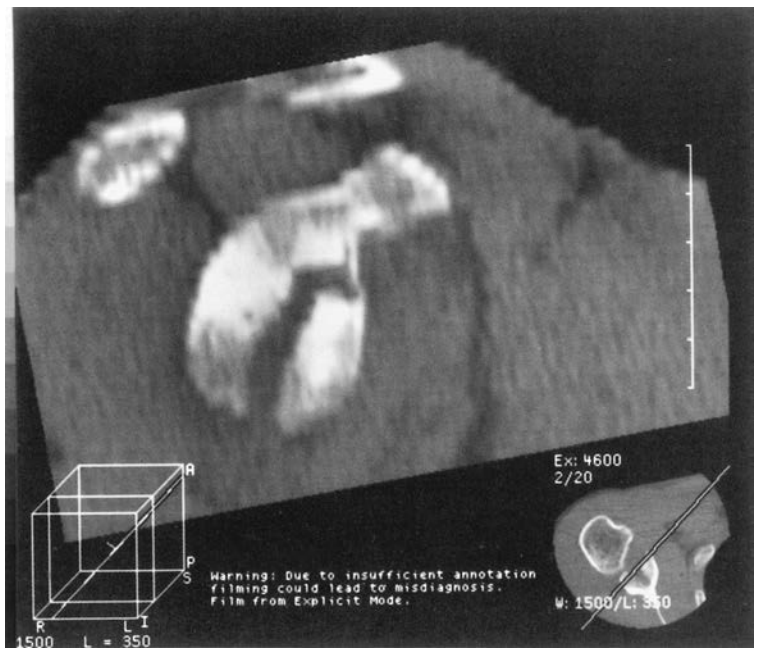

Figure 26-7 A reconstructed computed tomographic image showing the glenoid cavity en face (note the large anteroinferior glenoid rim fragment with severe separation of the articular surface).

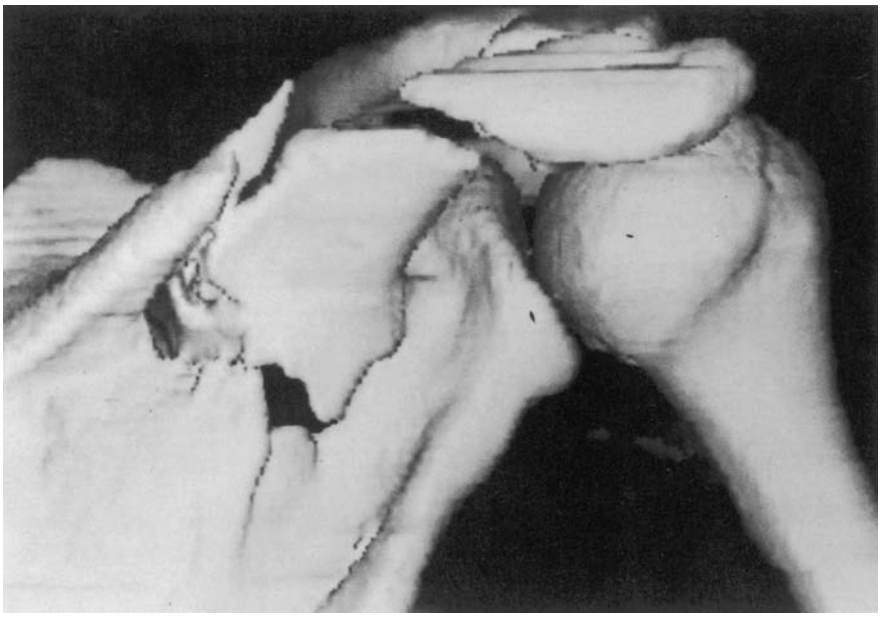

Figure 26-8 A three-dimensional computed tomographic image of an individual who sustained a segmental fracture of the acromion (note the severely displaced intermediate segment).

The proximal humerus can be eliminated for optimal visualization of the glenoid cavity, and other reconstructed images are possible. The exact role, if any, for arthroscopy (both diagnostic and therapeutic) is yet to be defined.

Nonoperative Treatment

Fractures of the scapular body and spine and insignificantly displaced fractures of the glenoid, acromial, and coracoid processes (see sections dealing specifically with injuries to these structures) are managed nonoperatively (Fig. 26-9). The patient's arm is initially placed in a sling and swathe immobilizer for comfort. Local ice packs to the affected area are helpful during the first 48 hours, followed by moist heat thereafter. Analgesic medications are prescribed as needed. Absolute immobilization is generally short term (48 hours), but may continue for up to 14 days, depending on the clinical situation. The patient is then permitted to gradually increase the functional use of his or her upper extremity as symptoms allow and sling and swathe protection is gradually decreased until the 6-week point. Physiotherapy is prescribed during this period and focuses on maintaining and regaining shoulder range of motion. The program begins

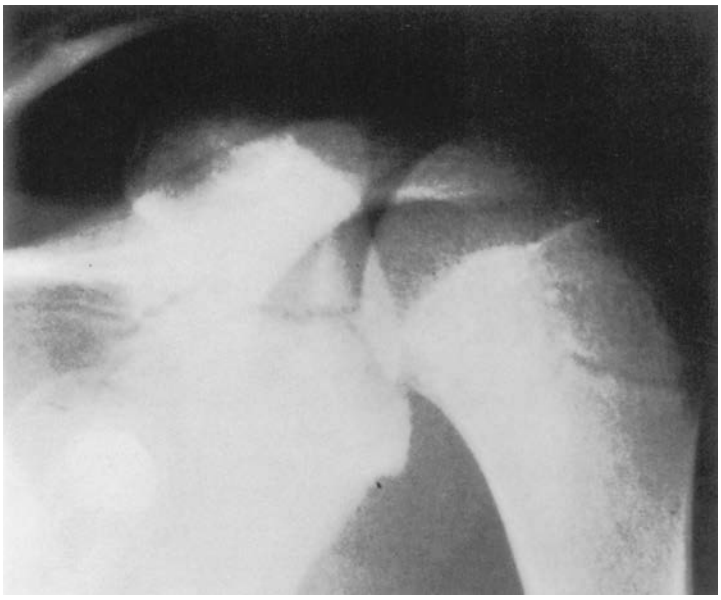

Figure 26-9 An anteroposterior radiograph showing an undisplaced fracture of the scapula involving the glenoid process.

with dependent circular and pendulum movements as well as external rotation to, but not past, neutral, and gradually moves on to progressive stretching techniques in all ranges. Close outpatient follow-up is necessary to monitor and guide the patient's recovery, and x-ray films are obtained at 2-week intervals to ensure that unacceptable displacement does not occur at the fracture site(s). At 6 weeks, osseous union is usually sufficient to discontinue all external protection and encourage functional use of the upper extremity. The rehabilitation program continues until range of motion, strength, and overall function are maximized. Six months to 1 year may be required for full recovery, but a good to excellent result should be readily obtainable.

FRACTURES OF THE GLENOID PROCESS

The glenoid process includes the glenoid neck and the glenoid cavity, which, in turn, is composed of the glenoid rim and the glenoid fossa. Each of these areas may be fractured in a variety of ways. Most investigators agree that if significantly displaced, surgical management is indicated or should at least be considered. Several surgical principles apply.[57,59,61,154]

General Considerations

Surgical Approaches

Depending on the clinical situation, the glenoid process may be approached from three directions or combinations thereof. [65,154] The anterior approach is used for fractures of the anterior glenoid rim and some fractures of the superior aspect of the glenoid fossa. The posterior approach is used for fractures of the posterior rim, most fractures of the glenoid fossa, and fractures of the glenoid neck. The superior approach may be used for (a) fractures of the glenoid fossa with a difficult-to-control superior fragment (in conjunction with either a posterior or an anterior exposure), and (b) fractures of the glenoid neck with a difficult-to-control glenoid fragment (in conjunction with a posterior exposure). Klingman and Roffman described a variation of the posterior approach that they believed allowed open reduction and internal fixation (ORIF) of anterior as well as posterior fragments.[98]

Anterior Approach

For the anterior approach (Fig. 26-10), the patient is placed on the operating room table in the "beach-chair" position. An anterior incision is made in Langer's lines, centered over the glenohumeral joint and running from the superior to the inferior margin of the humeral head. The deltoid muscle is exposed and the deltopectoral interval is dissected over the coracoid process. The conjoined tendon and pectoralis major muscle are retracted medially, whereas the deltoid muscle is retracted laterally with the cephalic vein.

The arm is externally rotated onto a sterile arm support (or a sterile arm positioner can be used) and the subacromial bursa is removed, exposing the subscapularis tendon. (In type III glenoid cavity fractures, opening the rotator interval may allow sufficient exposure.) The tendon is incised 2.5 cm medial to the medial border of the biceps groove and along its superior and inferior borders. It is then dissected off the underlying anterior glenohumeral capsule–glenoid neck periosteum and turned back medially. The anterior gleno-

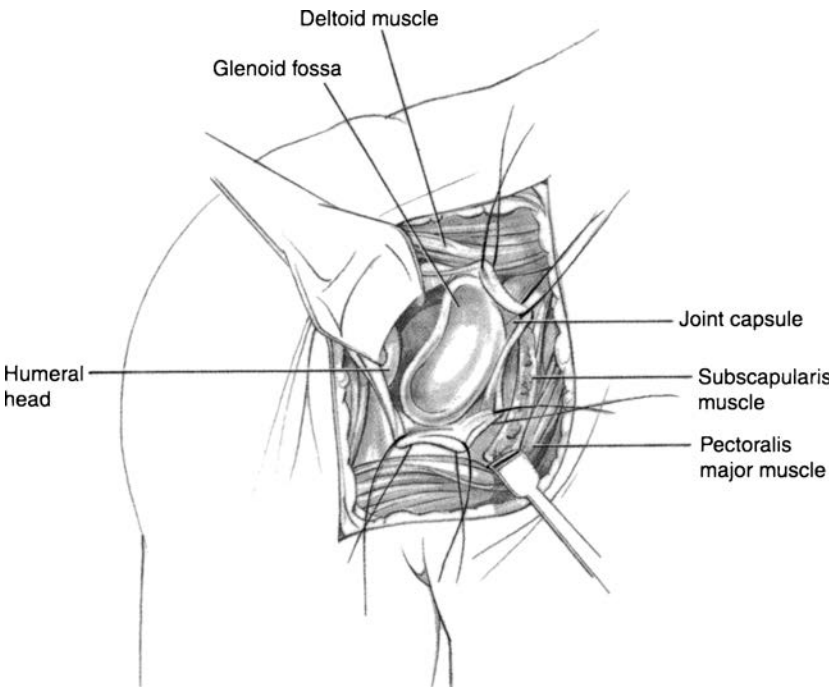

Figure 26-10 Anterior surgical approach to the glenoid cavity.

humeral capsule is incised in the same fashion (5 mm medial to the anatomic neck) and also turned back medially. With a humeral head retractor inserted into the glenohumeral joint (the Fukuda ring retractor is especially useful[46]) and holding the humeral head out of the way, the entire glenoid cavity can be inspected and the surgeon has ready access to its anterior rim. One must take care to avoid injury to the nearby axillary nerve.

Posterior Approach

The patient is placed on the operating room table in the lateral decubitus position, supported by a bean bag. An incision is made over the lateral one-third of the scapular spine, along the posterior aspect of the acromion to its lateral tip, and then distally in the midlateral line for a distance of 2.5 cm. Skin flaps are developed. The deltoid is dissected sharply off the scapular spine and the acromion and then split in the line of its fibers for a distance of not more than 5 cm starting at the lateral tip of the acromion. The deltoid is separated off the underlying infraspinatus and teres minor musculotendinous units and retracted down to, but not below, the inferior margin of the teres minor. (This approach allows maximal exposure; however, a more cosmetic vertical incision from the posterior axillary crease to the scapular spine with superolateral retraction of the undetached posterior deltoid muscle may suffice, especially if access to only the posteroinferior aspect of the glenoid cavity is needed, that is, type Ib and II glenoid cavity fractures.) The infraspinatus tendon is incised 2.5 cm medial to the greater tuberosity and along its superior and inferior borders. It is then dissected off the underlying posterior glenohumeral capsule and turned back medially. The posterior glenohumeral capsule is incised in the same fashion and also turned back medially. (Depending on the particular clinical situation, one may have sufficient exposure by detaching only the lower one-half of the insertion of the infraspinatus tendon and posterior glenohumeral capsule upon the humeral head, making an incision along their inferior border, and retracting the flap thereby created superiorly and medially.[61]) With injuries that involve only the posteroinferior and inferior aspects of the glenoid cavity, one may be able to avoid detaching these structures at all—developing the infraspinatus–teres minor interval and making a linear incision in the capsule may allow adequate access. With a Fukuda retractor inserted into the joint and holding the humeral head out of the way, the entire glenoid cavity can be inspected and the surgeon has ready access to its posterior rim as well as the glenoid neck (Fig. 26-11). The interval between the infraspinatus and teres minor muscles can be developed further and the long head of the triceps detached to gain access to the inferior aspect of the glenoid process and the lateral border of the scapular body (Fig. 26-12). One must take particular care to protect and avoid injury to the nearby suprascapular and axillary nerves.

Superior Approach

The superior approach can be added to either the anterior or the posterior exposure (Figs. 26-13 and 26-14) if a displaced, difficult-to-control or -stabilize superior glenoid fragment or glenoid process fragment is present. Either incision is

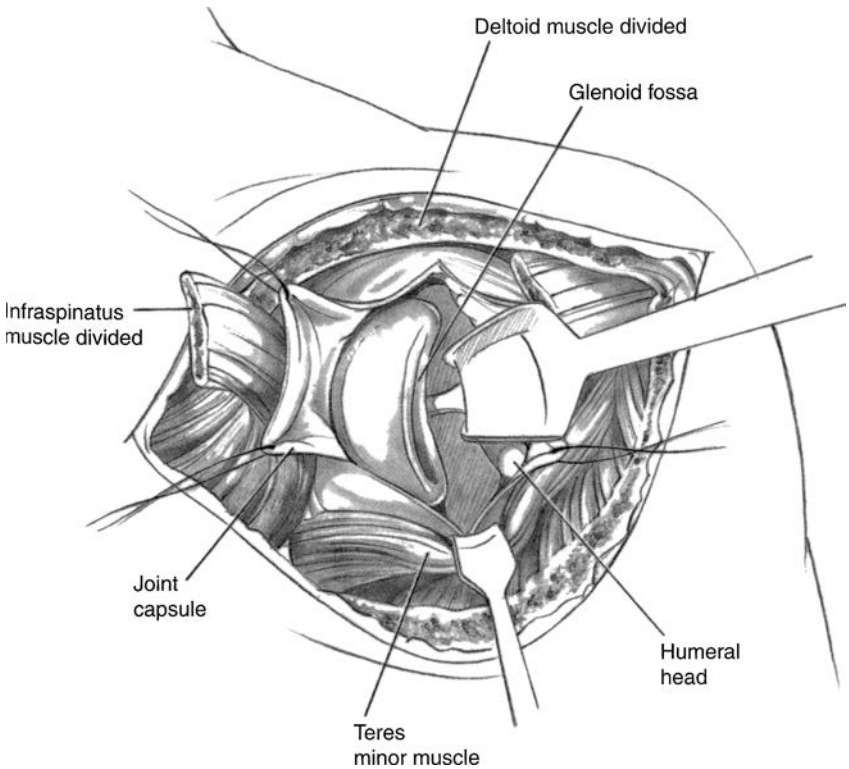

Figure 26-11 Posterior surgical approach to the glenoid cavity: standard exposure.

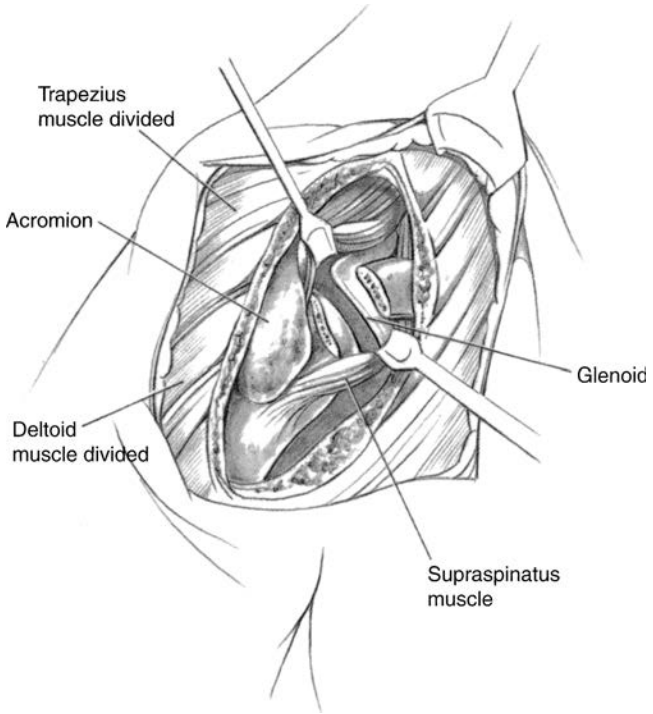

Figure 26-13 Superior surgical approach to the glenoid cavity: soft tissue and bony anatomy.

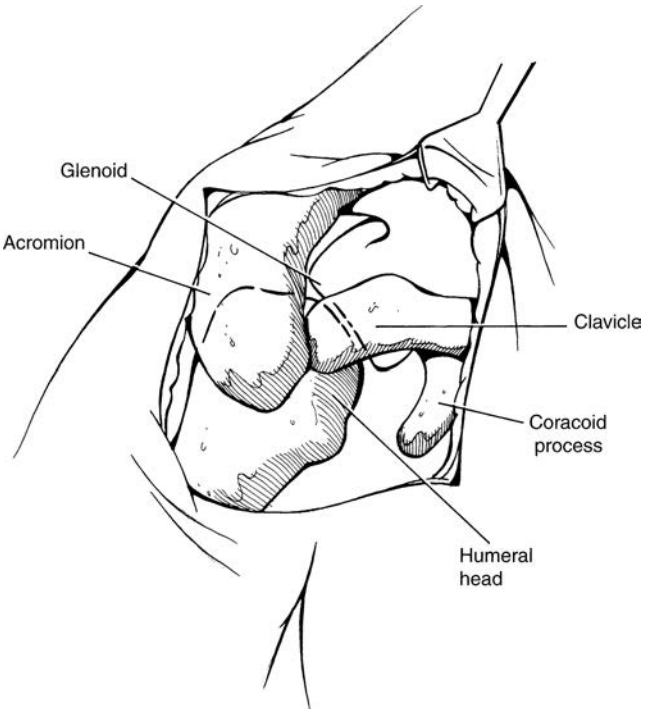

Figure 26-14 Superior surgical approach to the glenoid cavity: bony anatomy.

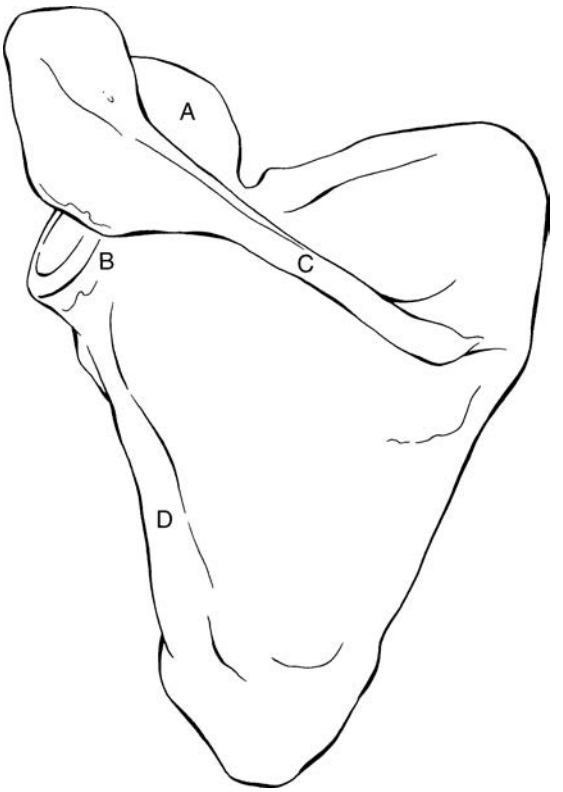

Figure 26-15 Illustration depicting the scapula and areas of sufficient bone stock for internal fixation: **(A)** the coracoid process; **(B)** the glenoid process; **(C)** the scapular spine; and **(D)** the lateral scapular border. (From Goss TP. Fractures of the glenoid cavity [operative principles and techniques]. *Tech Orthop* 1994;8:199, with permission.)

extended over the superior aspect of the shoulder. Soft tissue flaps are developed and retracted, exposing the superior aspect of the distal clavicle, the AC joint, the acromion, and the trapezius muscle. In the interval between the clavicle and the acromion (posteromedial to the acromioclavicular joint), the trapezius muscle and the underlying supraspinatus tendon are split in the line of their fibers, bringing one down upon the superior aspect of the glenoid process (the superior glenoid rim is located posterolaterally) and the base of the coracoid process (located anteromedially). One must take care to protect and avoid injury to the suprascapular nerve and vessels that lie medial to the coracoid process.

Bone Stock

Thick, solid bone for fixation is at a premium because much of the scapula is paper-thin. There are, however, four satisfactory areas: the glenoid neck, the lateral scapular border, the base of the scapular spine, and the coracoid process (Fig. 26-15).

Fixation Devices

A variety of fixation devices are available (Fig. 26-16). The most useful, however, are K-wires, malleable reconstruction plates (Fig. 26-17), and cannulated interfragmentary compression screws (Fig. 26-18). K-wires can be used for temporary as well as permanent fixation. The latter is the case when significantly displaced fracture fragments are too small to allow more substantial fixation, but one must be sure to bend the K-wire at its point of entry to prevent migration. Particularly helpful in the management of glenoid neck fractures are 3.5-mm malleable reconstruction plates, and 3.5- and 4.0-mm cannulated compression screws are especially useful in stabilizing fractures of the glenoid rim and glenoid fossa. These devices may be used

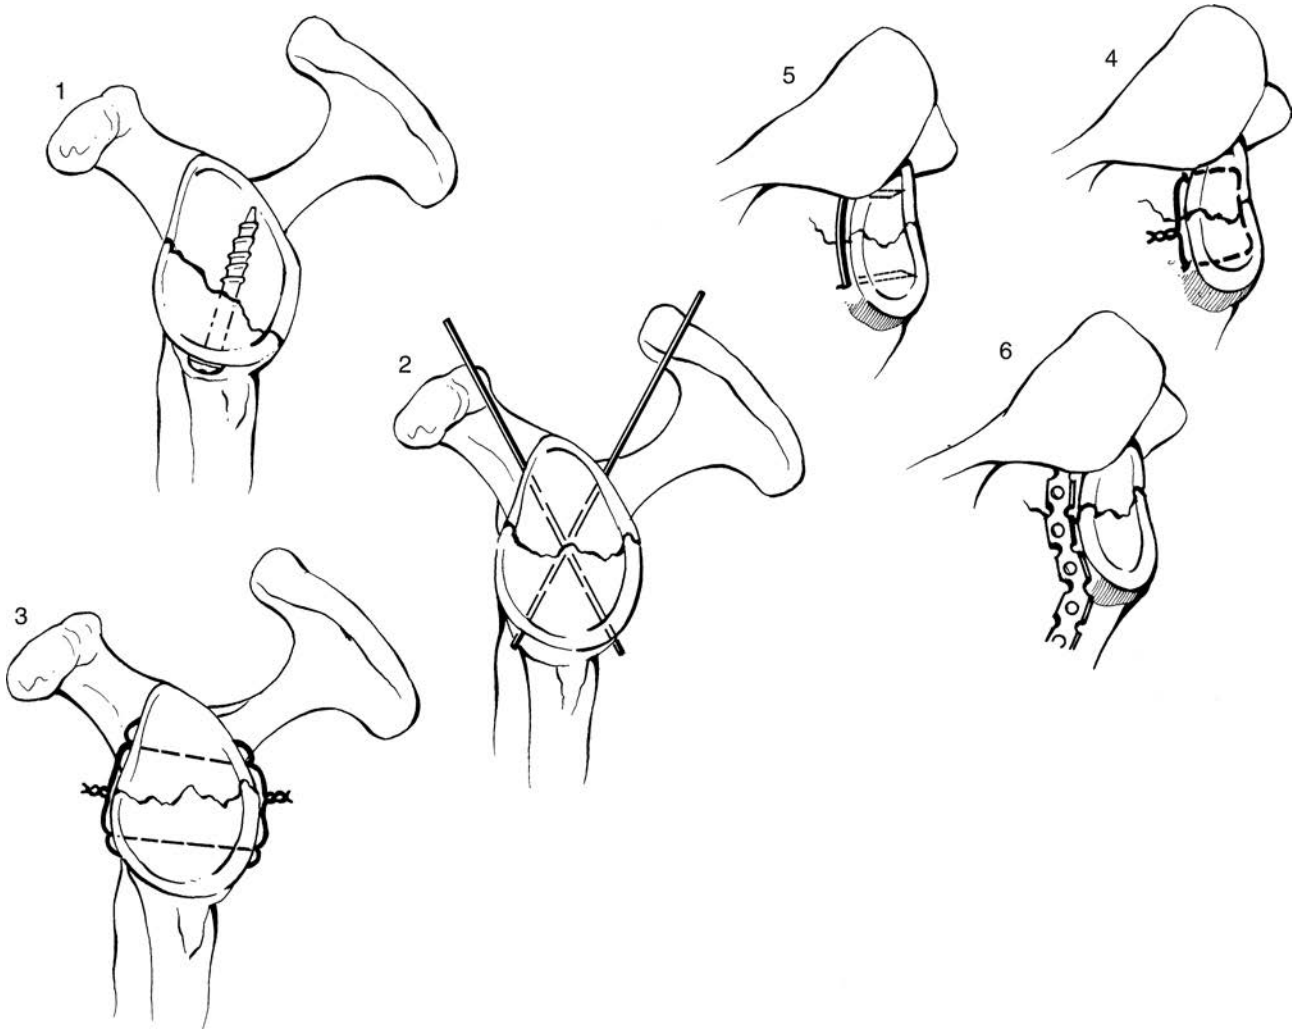

Figure 26-16 Illustrations depicting fixation techniques available for stabilization of fractures of the glenoid cavity: **(1)** an interfragmentary compression screw; **(2)** Kirschner wires; **(3)** a construct using Kirschner wires and cerclage wires or Kirschner wires and cerclage sutures; **(4)** a cerclage wire or suture; **(5)** a staple; and **(6)** a 3.5-mm malleable reconstruction plate.

Glenoid fractures: open reduction and internal fixation. In: Wiss DA, ed. *Master techniques in orthopaedic surgery: fractures.* Philadelphia: Lippincott-Raven, 1998:10, with permission.)

alone or in combination, depending on the clinical situation and taking into account the available bone stock as well as the surgeon's preference and experience. Rigid fixation is desirable, but inability to achieve this goal does not preclude an excellent anatomic and functional result.

Fractures of the Glenoid Cavity

Classification and Incidence

Fractures of the glenoid cavity make up 10% of scapular fractures. The majority (90+%) are insignificantly displaced and managed nonoperatively. Those that are significantly displaced require surgical treatment or at least deserve surgical consideration. Ideberg reviewed over 300 such injuries and proposed the first detailed classification scheme.[85–87] This was subsequently expanded by Goss[58] (Fig. 26-19). Type I fractures involve the glenoid rim: type la, the anterior glenoid rim, and type Ib, the posterior rim. Fractures of the glenoid fossa make up types II to V. Type VI fractures include all comminuted (more than two glenoid cavity fragments) injuries.

Fractures of the Glenoid Rim

Fractures of the glenoid rim occur when the humeral head strikes the periphery of the glenoid cavity with considerable violence (Fig. 26-20). These are fractures distinct from the small avulsion injuries that occur when a dislocating humeral head applies a tensile force on the periarticular soft tissues.[32] Surgical management is indicated if the fracture results in persistent subluxation of the humeral head (failure of the humeral head to lie concentrically within the glenoid cavity) or if the reduction of the fracture or humeral head is unstable. DePalma[32] stated that instability could be expected if the fracture was displaced 10 mm or more and if one-fourth or more of the glenoid cavity anteriorly or one-third or more of the glenoid cavity posteriorly was involved. Hardegger et al.[71] concurred and stated that "operative reduction and fixation of the fragment is indicated to prevent recurrent or permanent dislocation of the shoulder." Guttentag and Rechtine[68] and Butters[23] agreed with these recommendations. Several papers describing operatively managed glenoid rim fractures have also appeared in the literature.[7,105,147,178,194] A true axillary view of the glenohumeral joint, CT images (routine and reconstructed), and, if necessary, 3-D scanning allow one to determine the size and displacement of the rim fragment, whether persistent subluxation of the humeral head is present, and, therefore, whether stability of the glenohumeral articulation is significantly compromised. Surgery, if necessary, is designed to restore articular stability and prevent posttraumatic degenerative joint disease (Fig. 26-21). Type Ia (anterior rim) fractures are approached anteriorly. The displaced fragment is mobilized, reduced anatomically, and fixed in position with cannulated interfragmentary compression screws (ideally two screws are used to provide rotational stability; Fig. 26-22). Type Ib (posterior rim) fractures are approached posteriorly, reduced, and stabilized in the same manner (Fig. 26-23). If the fracture is comminuted and cannot be internally fixed, the fragments are excised. A tricortical graft harvested from the iliac crest is then placed intra-articularly, filling the defect (Fig. 26-24). A simple repair of the periarticular soft tissues to the intact glenoid cavity is an option if the bone defect is less than 20% of the anterior-to-posterior dimension of the glenoid fossa, but restoration of rim contour is preferable.

Fractures of the Glenoid Fossa

Classification, Mechanism, and Surgical Indications

Fractures of the glenoid fossa occur when the humeral head is driven with sufficient force into the center of the glenoid

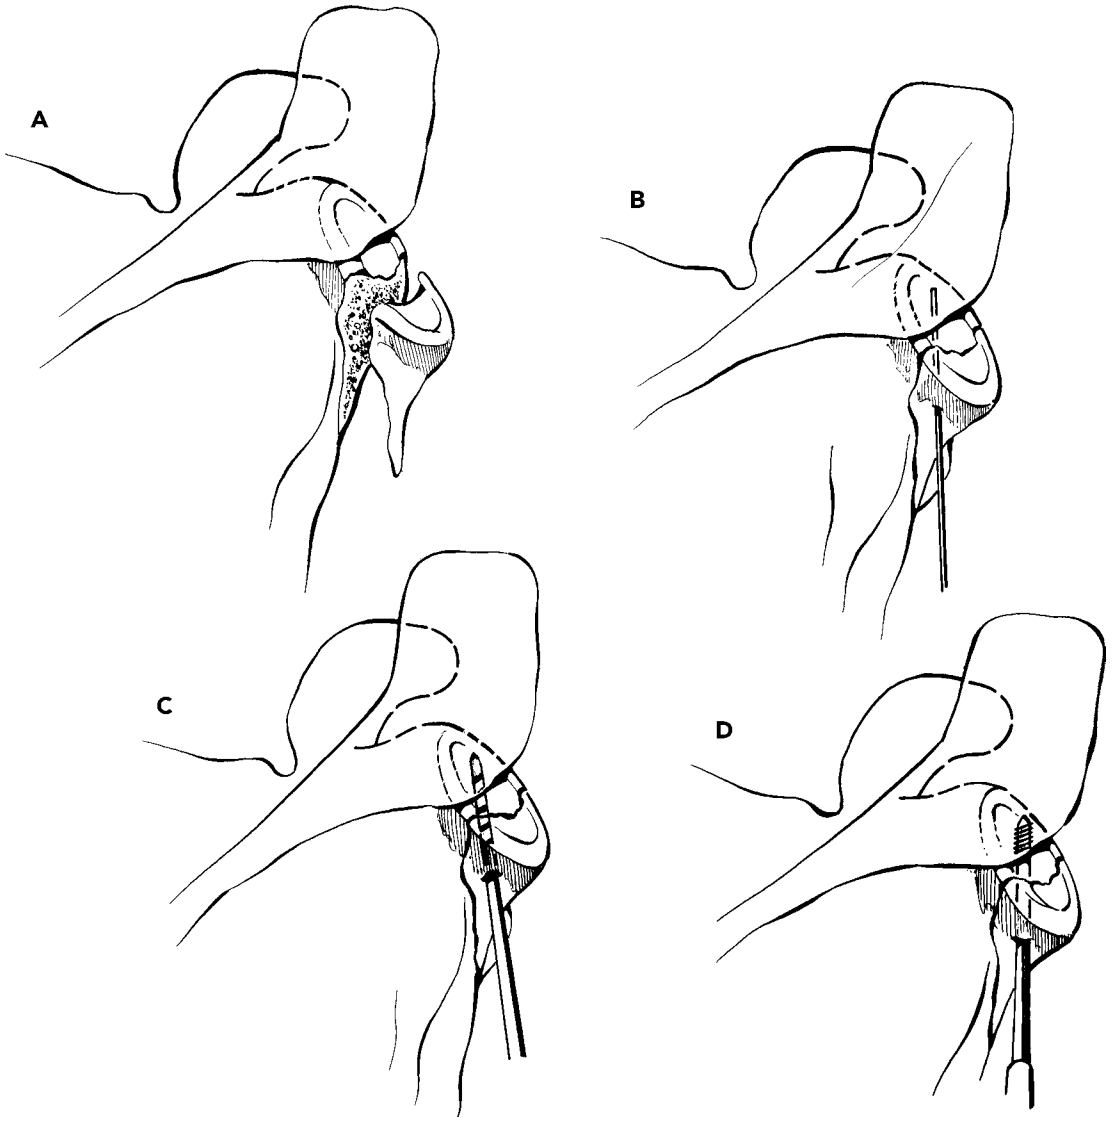

Figure 26-18 Illustrations showing reduction and stabilization of a type II fracture of the glenoid cavity using a cannulated interfragmentary compression screw: **(A)** a fracture of the glenoid cavity with a significantly displaced inferior glenoid fragment; **(B)** reduction of the glenoid fragment and stabilization with a guidewire; **(C)** use of the guidewire to pass a cannulated drill and eventually a cannulated tap; and **(D)** use of the guidewire to place a cannulated interfragmentary compression screw securely fixing the glenoid fragment in position.

concavity. The fracture generally begins as a transverse disruption (or slightly oblique) for several possible reasons: (a) the glenoid cavity is concave so forces tend to be concentrated over its central region; (b) the subchondral trabeculae are transversely oriented so fractures tend to occur in this plane; (c) the glenoid cavity is formed from two ossification centers so the central region may remain a persistently weak area; and (d) the glenoid cavity is narrow superiorly and wide inferiorly with an indentation along its anterior rim—this constitutes a stress riser where fractures are particularly prone to originate before coursing over to the posterior rim (Fig. 26-25). Once this transverse disruption occurs, the fracture may propagate in a variety of directions depending on the exact direction of the humeral head force.

With type II fractures, the humeral head is driven inferiorly, creating an inferior glenoid fragment. Surgery is indicated if there is an articular step-off of 5 mm or more and/or if the fragment displaces inferiorly carrying with it the humeral head, such that the humeral head fails to lie in the center of the glenoid cavity. These injuries can result in posttraumatic degenerative joint disease and/or glenohumeral instability.[56]

Type III fractures occur when the force of the humeral head is directed superiorly, causing the transverse disruption to propagate upward, generally exiting through the superior scapular border in the vicinity of the suprascapular notch. One might question whether this is a fracture of the glenoid cavity or a fracture of the coracoid process,

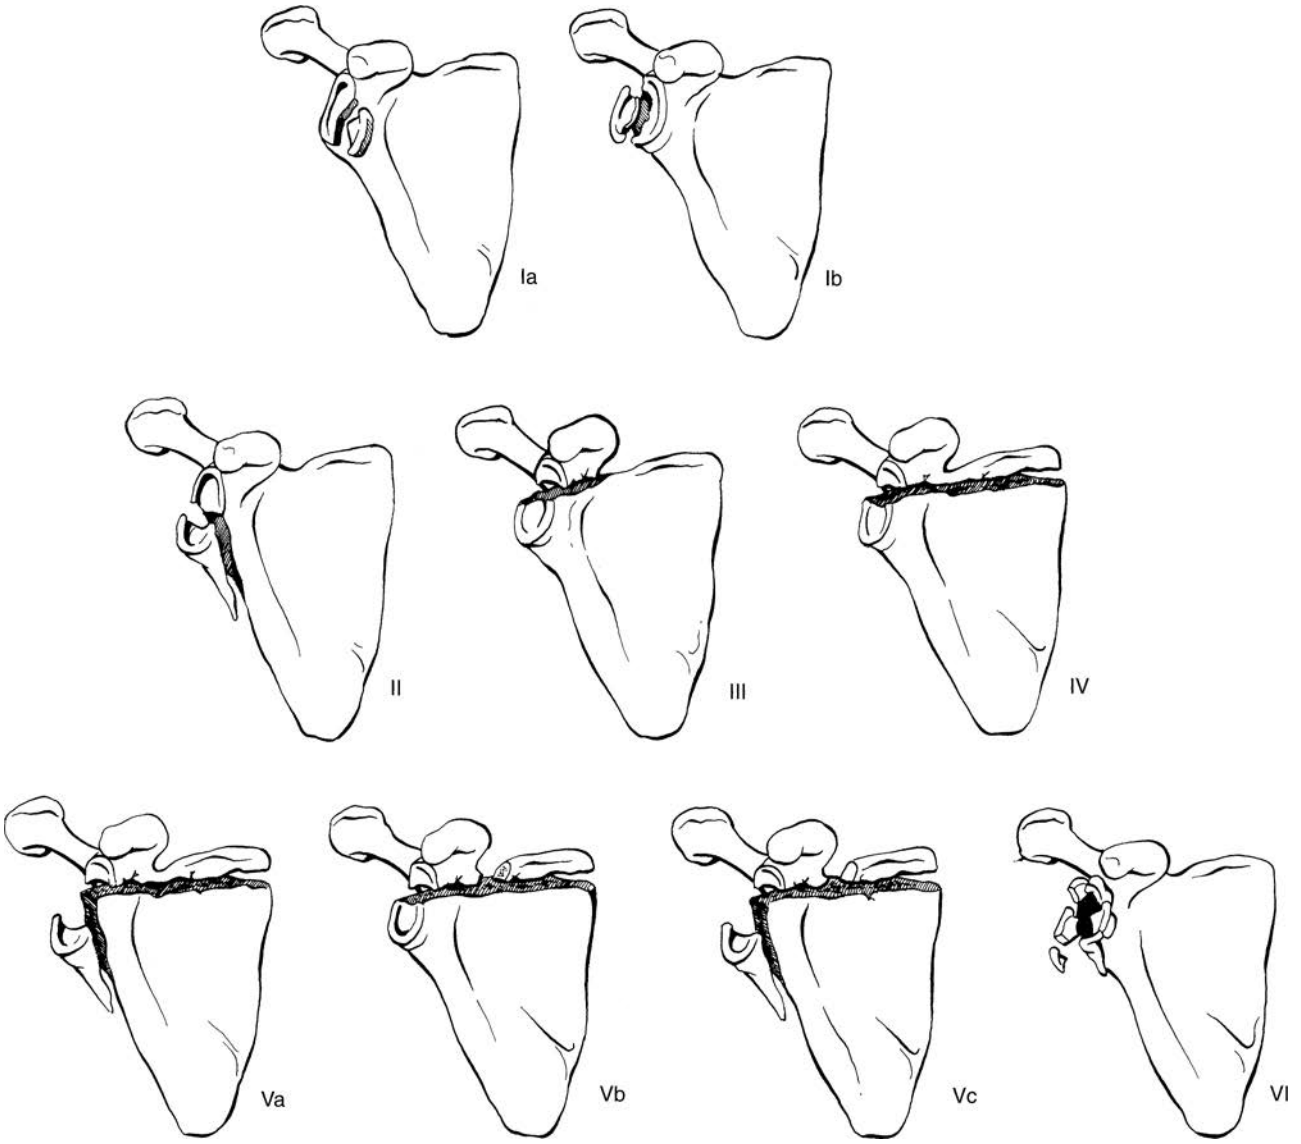

Figure 26-19 Goss-Ideberg classification scheme for fractures of the glenoid cavity.

since the superior third of the glenoid cavity and the base of the coracoid process are formed from the same ossification center (see Fig. 26-26B).[39,122] Regardless, displacement is usually minimal with the fragment lying medially. Consequently, as with fractures of the base of the coracoid process, these injuries are usually treated nonoperatively and heal uneventfully. Any glenoid cavity fracture may be associated with neurovascular damage owing to the proximity of the brachial plexus and axillary vessels as well as the considerable violence involved. Type III as well as type Vb, Vc, and VI injuries, however, are particularly prone, especially if there is an associated disruption of the clavicular–coracoclavicular (CC) ligamentous–coracoid (C-4) linkage or the clavicular–AC joint–acromial strut. Neer and Rockwood considered compression of the adjacent neurovascular structures by these and fractures of the coracoid process an indication for surgery.[143] They and others also described the occurrence of suprascapular nerve paralysis resulting from fractures involving the coracoid process and glenoid neck and extending into the suprascapular notch. (An electromyogram [EMG] was essential for diagnosis, and early exploration was recommended.[28,36,39,180])

Surgical management is considered if there is an articular step-off of 5 mm or more, with the superior fragment displaced laterally, or if there is a severe associated disruption of the superior shoulder suspensory complex[55] (the clavicular–CC ligamentous–coracoid [C-4] linkage or the clavicular–AC joint–acromial strut). These injuries can result in posttraumatic degenerative joint disease and severe functional impairment.

Type IV injuries occur when the humeral head is driven directly into the center of the glenoid fossa.[44] The

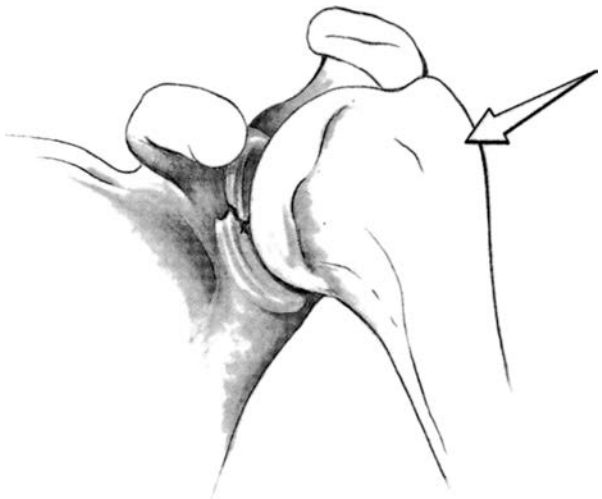

Figure 26-20 Illustration depicting one mechanism of injury responsible for fractures of the glenoid rim: a force applied over the lateral aspect of the proximal humerus (a fall on an outstretched arm driving the humeral head against the periphery of the glenoid cavity with considerable violence could also cause this injury).

Figure 26-21 An axial computed tomographic image of an individual 9 months following a traumatic event. Note the previously undiagnosed displaced type Ia fracture of the glenoid cavity with anterior subluxation of the humeral head and "bone-on-bone" contact (intraoperatively the patient had significant posttraumatic degenerative disease of the glenohumeral joint).

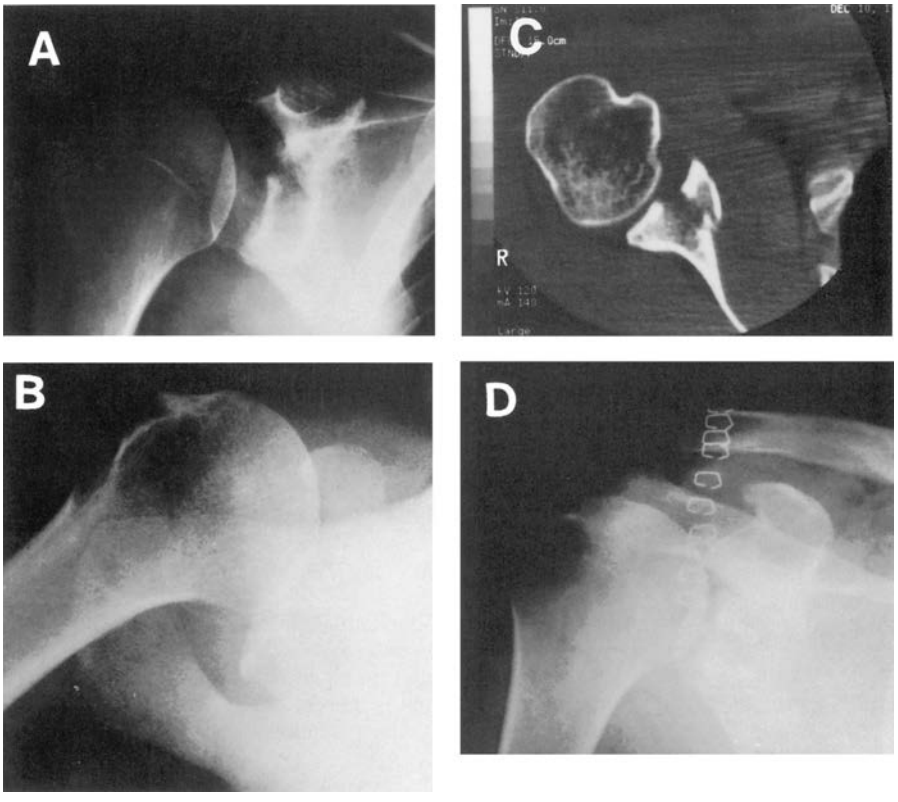

Figure 26-22 Radiographs of a person who sustained a type Ia fracture of the glenoid cavity: **(A)** a preoperative anteroposterior (AP) radiograph showing what appears to be a fracture of the anteroinferior glenoid rim; **(B)** a preoperative axillary radiograph showing what appears to be a fracture of the anterior glenoid rim with anterior subluxation of the humeral head; **(C)** an axial computed tomographic image showing a severely displaced fracture of the anterior glenoid rim; and **(D)** a postoperative AP radiograph showing reduction and stabilization of the anteroinferior glenoid rim fragment with two cannulated interfragmentary screws.

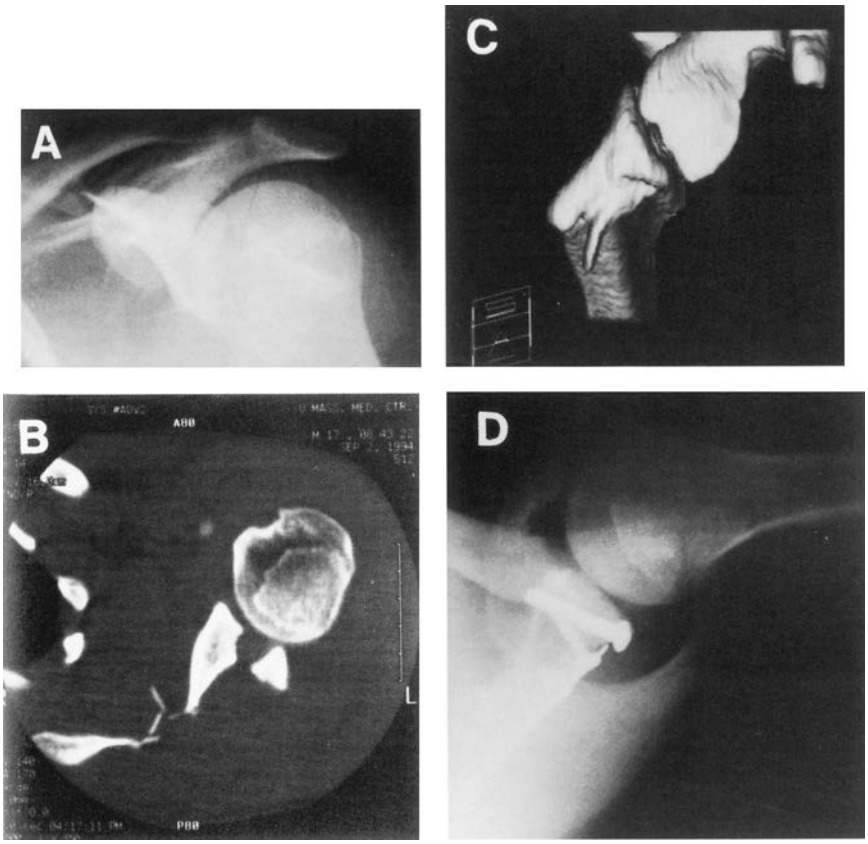

Figure 26-23 Radiographs of an individual who sustained a type Ib fracture of the glenoid cavity: **(A)** a preoperative lateral scapular radiograph showing what appears to be a fracture of the glenoid cavity with significant posterior involvement; **(B)** an axial computed tomographic **(A,B)** image showing a severely displaced fracture of the posterior glenoid rim with posterior subluxation of the humeral head; **(A)** a three-dimensional CT image of the glenoid cavity with the humeral head subtracted showing the severely displaced and rotated posteroinferior glenoid rim fragment; and **(D)** a postoperative axillary radiograph showing anatomic reduction and stabilization of the posterior glenoid rim fragment, with restoration of articular congruity.

fracture created courses transversely across the entire scapula, exiting along its vertebral border. If there is an articular step-off of 5 mm or more, with the superior fragment displaced laterally, or if the superior and inferior fragments are severely separated, open reduction and internal fixation is indicated to avoid symptomatic degenerative joint disease, nonunion at the fracture site (an extremely rare occurrence,[40] but a definite concern in the case shown in Fig. 26-27), and/or instability of the glenohumeral joint.

Type Va, Vb, and Vc fractures are combinations of the types II, III, and IV injuries and are caused by more violent and complex forces. The same clinical concerns and operative indications detailed for the type II, III, and IV fractures apply.

Type VI fractures include all disruptions of the glenoid cavity in which more than two articular fragments are present and are caused by the most violent forces. Operative treatment is contraindicated because exposing these injuries surgically will do little more than disrupt what little soft tissue support remains, rendering the fragments even more unstable and making a bad situation worse. An associated disruption of the superior shoulder suspensory complex may warrant operative correction, however, and this may indirectly improve glenoid articular congruity.

Diagnosis

A true AP projection of the glenohumeral joint, reconstructed CT images in the coronal plane, and even 3-D CT scanning may be necessary to accurately determine whether and to what degree articular incongruity and/or separation is present.[71]

Surgical Management

Type II Fractures

These fractures are approached posteriorly. The infraspinatus–teres minor interval is developed, exposing the displaced inferior glenoid fragment and the lateral scapular border. The fragment is reduced as anatomically as possible and stabilized, generally with two cannulated interfragmentary compression screws passed posteroinferiorly to anterosuperiorly or with a contoured reconstruction plate placed along the posterior aspect of the glenoid process and the lateral scapular border (Fig. 26-28). Excision of the fracture fragment and placement of a bone graft from the iliac crest is an option if severe comminution is present. Associated tears of the labral–capsular–ligamentous complex are repaired if possible, as they are with all fractures of the glenoid cavity. Detachments are corrected with nonabsorbable sutures passed through drill holes or use of suture

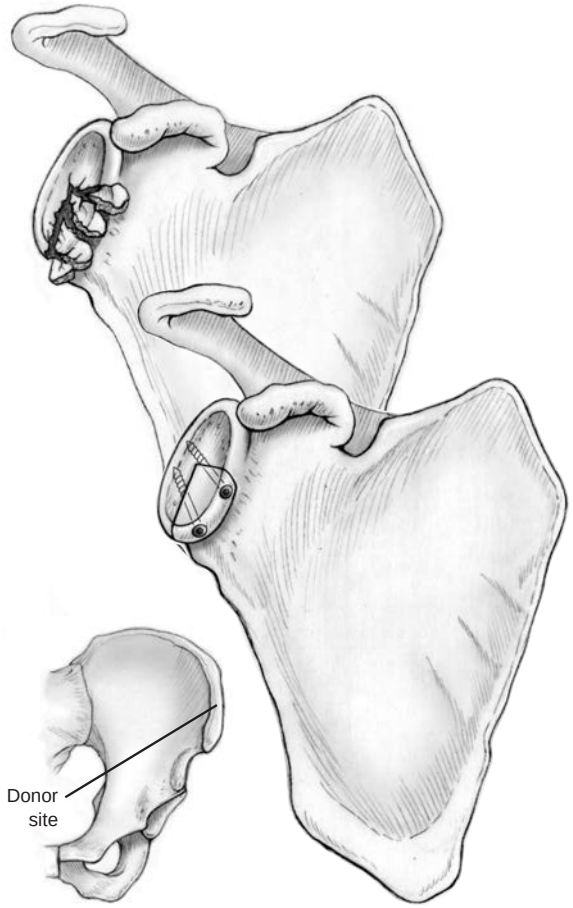

Figure 26-24 Illustration depicting the use of a tricortical graft harvested from the iliac crest to reestablish bony stability in a patient with a severely comminuted type Ia fracture of the glenoid cavity. (Adapted from Goss TP. Fractures of the scapula. In: Rockwood CA, Matsen FA, Wirth MA, Lippitt SB, eds. *The shoulder*, 3rd ed. Philadelphia: Saunders, 2004:413)

anchors, and intrasubstance tears are reapproximated with nonabsorbable sutures placed in a figure-eight fashion.

Type III Fractures

A posterosuperior surgical exposure (or an anterior approach through the rotator interval without taking down the subscapularis musculotendinous unit; see Fig. 26-29) is utilized. A K-wire can be placed into the superior glenoid fragment and then used to manipulate the fragment into satisfactory position relative to the remainder of the glenoid process, thereby restoring articular congruity. The K-wire is then driven across the fracture site and used to place a cannulated interfragmentary compression screw. When there is an associated disruption of the superior shoulder suspensory complex (SSSC), reduction and stabilization of the superior glenoid fragment may restore the integrity of this complex satisfactorily. If not, that injury may need to be addressed as well (Fig. 26-30). Conversely, if the superior glenoid fragment is severely comminuted and difficult to fix, operative restoration of the associated SSSC disruption may improve glenoid articular congruity indirectly and satisfactorily.

Type IV Fractures

These fractures are approached posterosuperiorly. A K-wire is placed into the superior glenoid–scapular segment and then used to manipulate that fragment into position relative to the inferior segment while directly visualizing the reduction via the posterior exposure. The K-wire is then driven across the fracture site and used to place a cannulated interfragmentary compression screw (see Fig. 26-27). A cerclage wire or cerclage sutures passed around the glenoid neck have also been used for fixation. As always, one must take care to avoid injury to adjacent neurovascular structures, in particular the suprascapular nerve and accompanying vessels that pass through the spinoglenoid notch.

Type V Fractures

Type Va fractures are approached, reduced, and stabilized according to the principles described for significantly displaced type II fractures, although a superior approach may need to be added to gain control of the superior glenoscapular fragment. The inferomedial portion of the scapula may be ignored. Type Vb injuries are approached, reduced, and stabilized according to the principles described for significantly displaced type III fractures. The superomedial portion of the scapula may be ignored. If an associated disruption of the superior shoulder suspensory complex is present, it may require operative reduction and stabilization.

Type Vc fractures are exposed by a posterosuperior approach. The superior and inferior glenoid fragments are reduced anatomically and rigidly fixed to each other. Ideally, the fixation is performed with a lag screw, which is generally easier to pass superior to inferior, or with a cerclage wire or suture that is passed through drill holes or suture anchors in the superior and inferior fragments. The glenoid fragment is then reduced and stabilized relative to the scapular body using the principles described for ORIF of glenoid neck fractures. The superomedial and inferomedial portions of the scapula may be ignored. Surgical management of an associated disruption of the superior shoulder suspensory complex is dependent on the exact nature of that injury (Fig. 26-31) (e.g., an associated clavicle fracture may be managed with plate and screw fixation or an intramedullary device).

Type VI Fractures: Management

The upper extremity is initially protected in a sling and swathe bandage, an abduction brace, or even overhead olecranon pin traction—whichever maximizes articular congruity as determined radiographically. Gentle passive circular and rotatory range-of-motion exercises performed by a

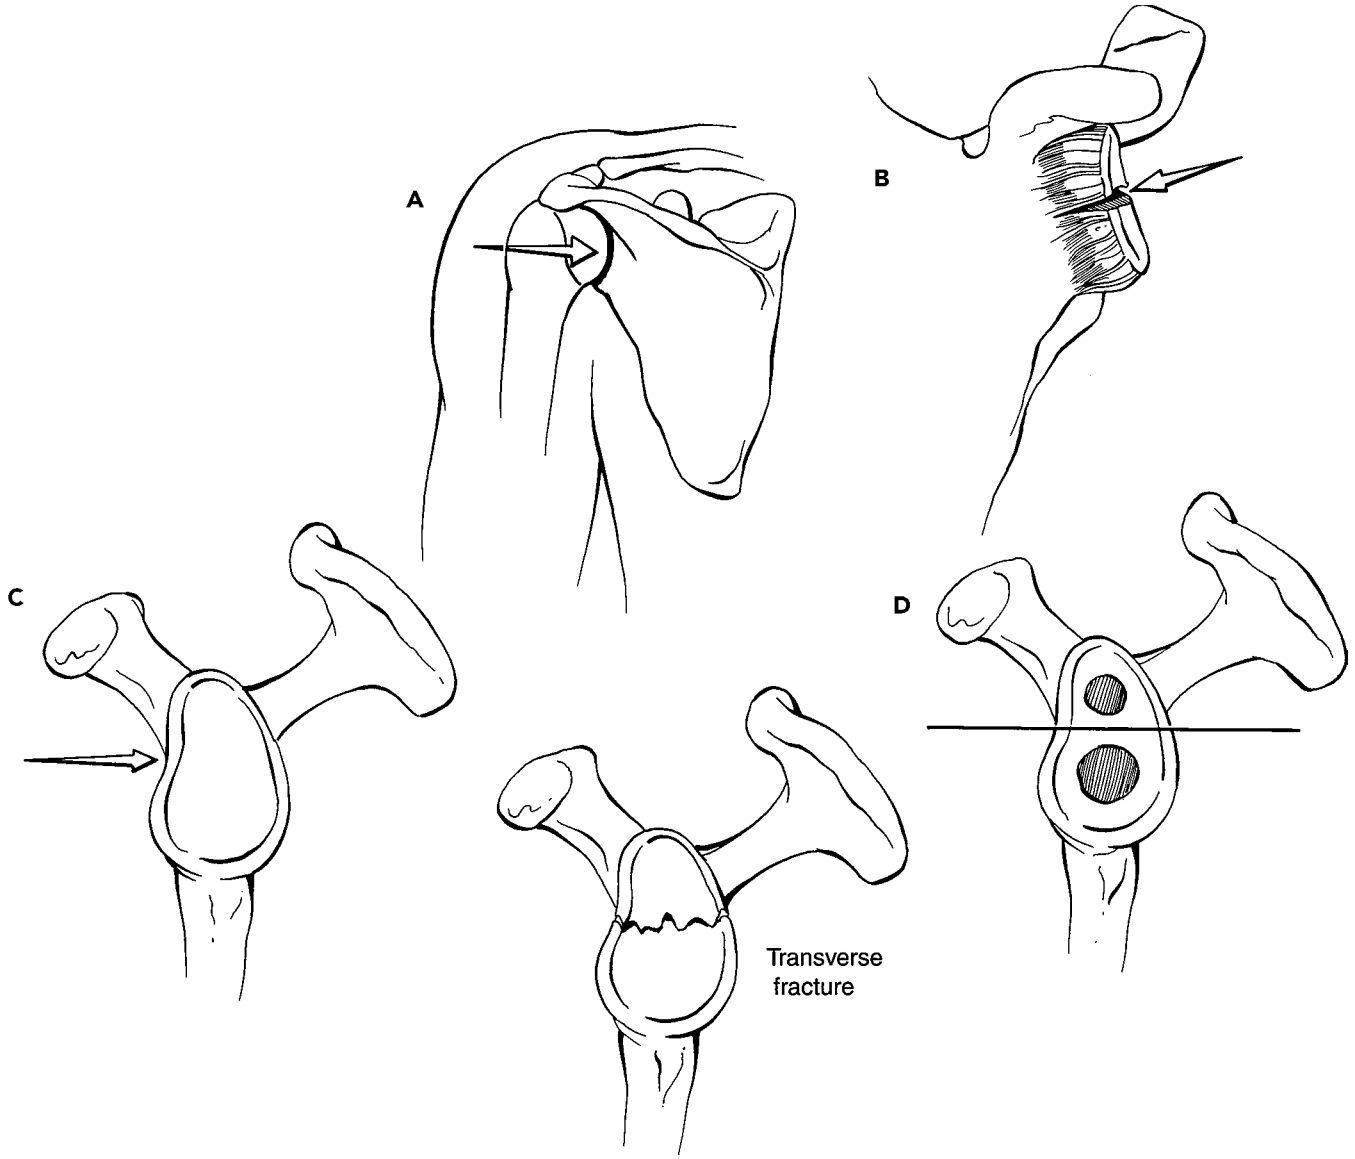

Figure 26-25 Illustrations depicting a transverse disruption of the glenoid cavity and the factors responsible for this orientation: **(A)** the glenoid's concave shape concentrates forces across its central region; **(B)** the subchondral trabeculae are oriented in the transverse plane; **(C)** the "crook" along the anterior rim is a stress riser where fractures tend to originate; **(D)** formed from a superior and an inferior ossification center, the glenoid cavity may have a persistently weak central zone.

therapist and the patient are initiated immediately, in hope that the movement of the humeral head will mold the articular fragments into a maximally congruous position. By 2 weeks, healing is sufficient to allow protection of all such injuries in a sling and swathe immobilizer. Exercises designed to gradually increase range of motion and progressive functional use of the shoulder out of the sling within clearly defined limits are prescribed during the subsequent 4 weeks. At 6 weeks, these fractures are sufficiently healed to allow discontinuation of all external protection. Functional use of the shoulder is encouraged and physiotherapy continues until range of motion and strength are maximized. These injuries obviously have the highest potential for posttraumatic degenerative joint disease and glenohumeral instability.

Results

Bauer et al.[12] reviewed 20 patients treated surgically for significantly displaced fractures of the scapula (6.1-year average follow-up) and reported greater than 70% good or very good results based on a Constant score. They recommended early ORIF for grossly displaced fractures of the glenoid fossa as well as those of the glenoid rim, glenoid neck, and coracoid–acromial processes. Hardegger et al.[71] reported that "if there is significant displacement, conserva-

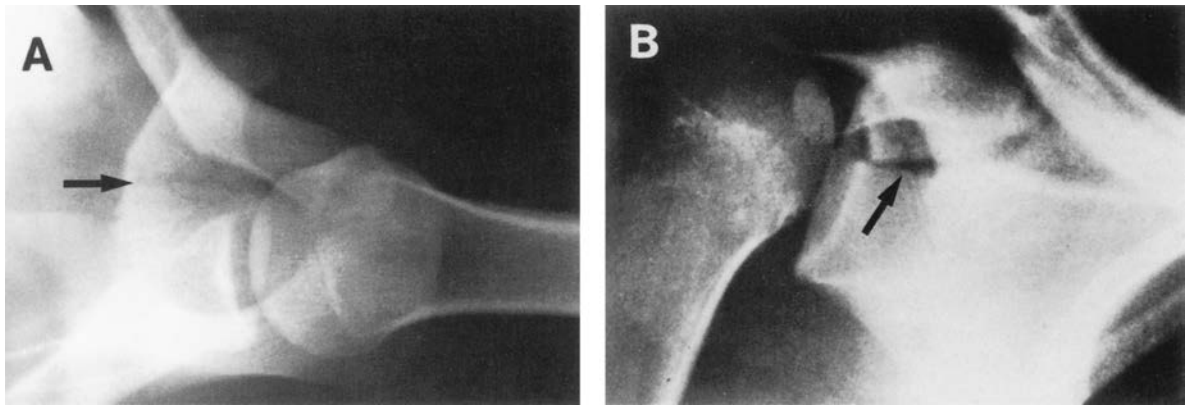

Figure 26-26 Proximal coracoid fractures (two types): **(A)** an axillary radiograph showing an undisplaced fracture of the base of the coracoid process (*arrow*); and **(B)** an anteroposterior radiograph showing a type III fracture of the glenoid cavity (*arrow*) with some medial displacement (from a functional standpoint, this could be considered a very proximal coracoid process fracture).

tive treatment alone cannot restore congruence" and that stiffness and pain may result and "for this reason, open reduction and stabilization are indicated." Kavanagh et al.[94] presented their experience at the Mayo Clinic with 10 displaced intraarticular fractures of the glenoid cavity treated with ORIF. They found ORIF to be "a useful and safe technique" that can "restore excellent function of the shoulder." In their series, the major articular fragments were displaced 4 to 8 mm. They emphasized that it remained uncertain how much incongruity of the glenoid articular surface could be accepted without risking the long-term sequelae of pain, stiffness, and/or traumatic osteoarthritis. Soslowsky et al.[181] found the maximal depth of the glenoid articular cartilage to be 5 mm. Consequently, if displacement at a glenoid fossa fracture site is 5 mm or more, subchondral bone is exposed. Schandelmaier and coauthors reported a series of 22 fractures of the glenoid fossa treated with ORIF. They stated that "if the postoperative courses are uneventful, excellent to good results can be expected."[174] Case reports by Aulicino et al.[8] and Aston and Gregory[7] lend support to the role of surgery in the management of significantly displaced glenoid fossa fractures. Ferraz et al. described a type IV glenoid fossa fracture that progressed to nonunion. When explored surgically, less than

2 years after injury, a 7-mm articular step-off was noted, as well as grade III cartilaginous erosion of the humeral head.[40] Lee and colleagues reported the case of a child who sustained a type II fracture that required ORIF.[111] Ruedi and Chapman[171] stated that "grossly displaced intraarticular fractures of the glenoid that render the joint incongruent and unstable profit from operative reconstruction and internal fixation as incongruities will result in osteoarthritic changes." Rowe[169] has advocated surgical management of severely displaced injuries. Leung et al. reviewed 14 displaced

intraarticular fractures of the glenoid treated with ORIF (30.5-month average follow-up) and reported nine excellent and five good results.[114] On the basis of these reports, it seems reasonable to conclude that there is a definite role for surgery in the treatment of glenoid fossa fractures. An injury with an articular step-off of 5 mm or more should be considered for surgical intervention to restore articular congruity, and displacement of 10 mm or more is an absolute indication to avoid posttraumatic osteoarthritis.

Fractures of the Glenoid Neck

Incidence, Mechanism, and Classification

Fractures of the glenoid neck make up 25% of scapular fractures. It is somewhat surprising that these injuries are not more common, since this portion of the glenoid process is quite narrow. Fractures of the glenoid neck may be caused by (a) a direct blow over the anterior or posterior aspect of the shoulder; (b) a fall on an outstretched arm, with impaction of the humeral head against the glenoid process; or in rare cases, (c) a force applied to the superior aspect of the shoulder complex.

The glenoid neck is that portion of the glenoid process that lies between the scapular body and the glenoid cavity. The coracoid process arises from its superior aspect. Its stability is primarily osseous, specifically its junction medially with the scapular body. Secondary support is provided by its attachment superiorly to the clavicular–AC joint–acromial strut via the clavicular–CC ligamentous–coracoid (C-4) linkage (Fig. 26-32) and the coracoacromial (CA) ligament. Tertiary soft tissue support is provided anteriorly by the subscapularis muscle, superiorly by the supraspinatus muscle, and posteriorly by the infraspinatus and teres minor

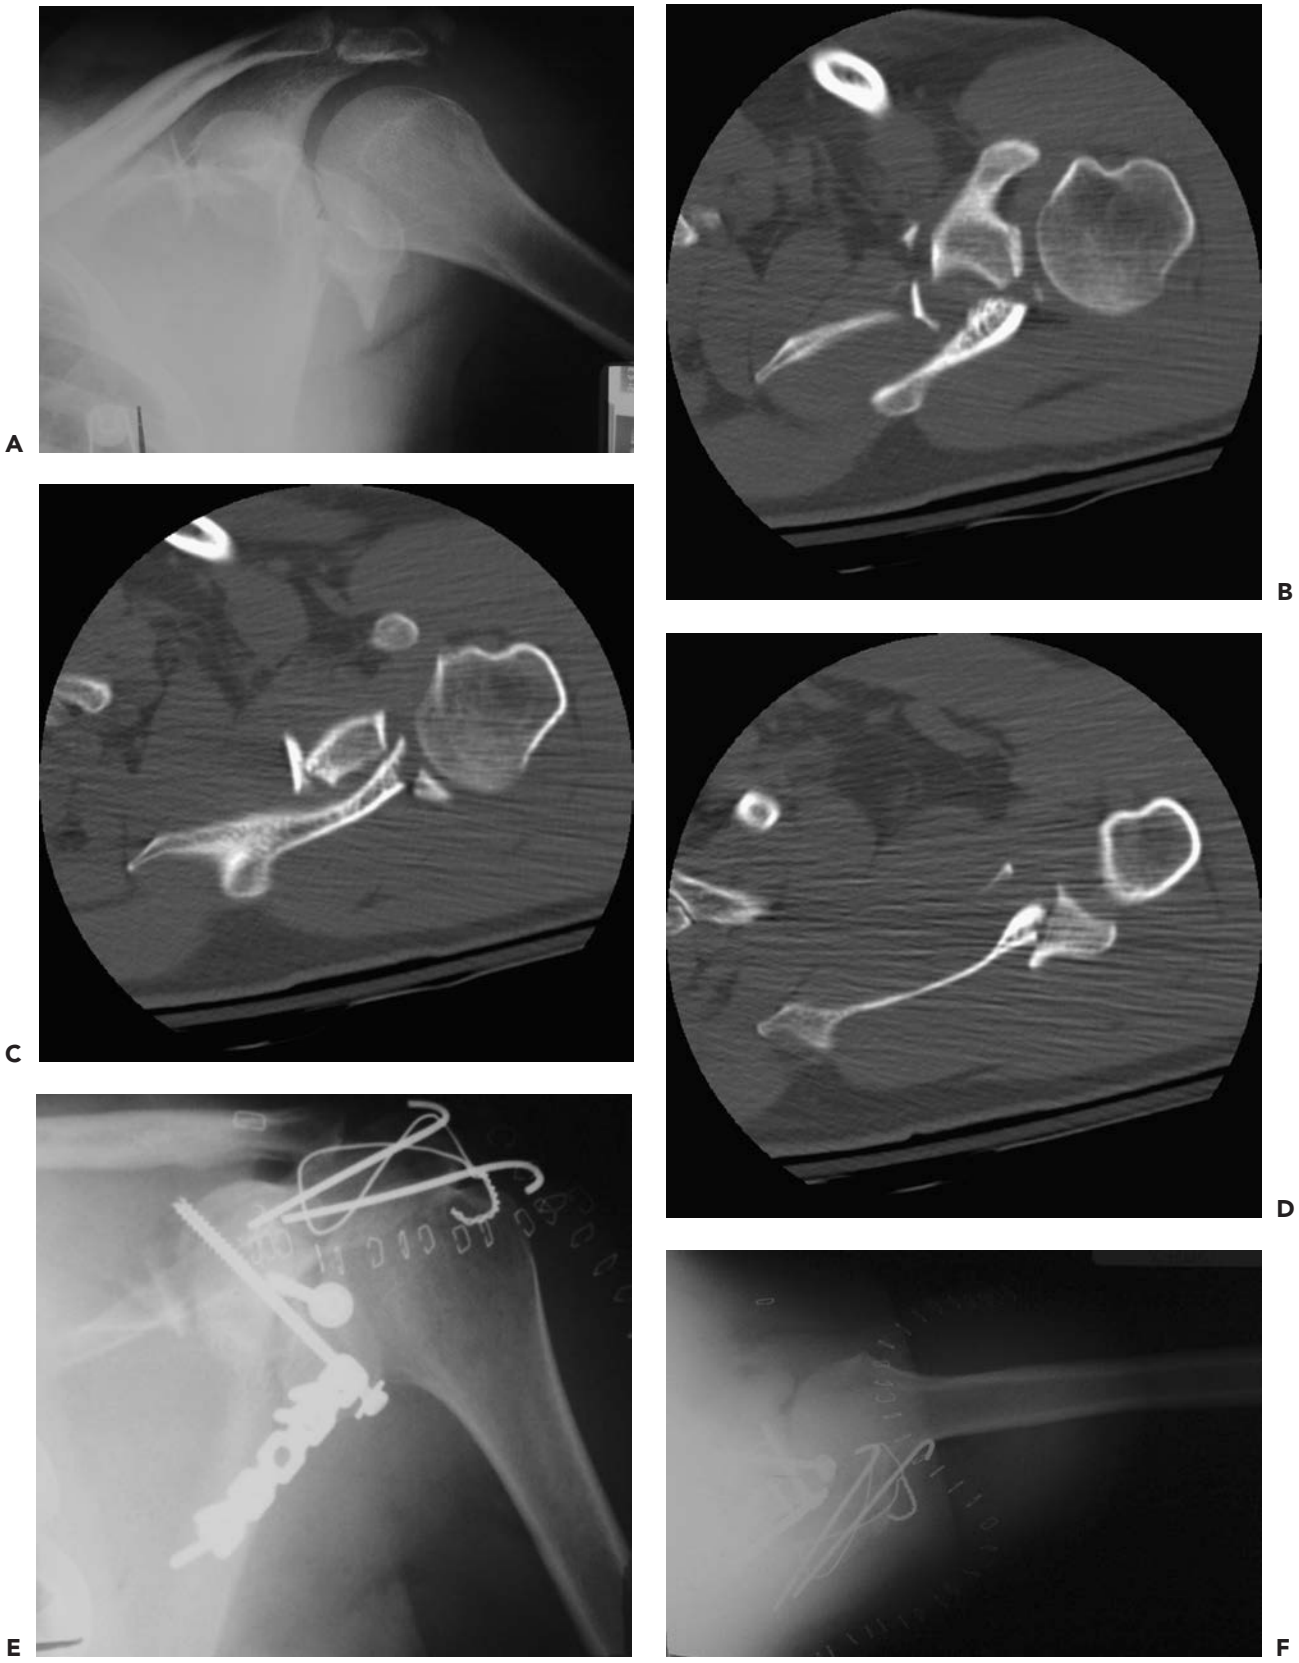

Figure 26-31 Radiographs of a patient involved in a motor vehicle accident who sustained a type Vc fracture of the glenoid cavity: **(A)** anteroposterior (AP) radiograph showing the glenoid cavity fracture; **(B)** axillary computed tomographic (CT) image showing a large anterosuperior glenoid fragment including the coracoid process; **(C)** axillary CT image showing the lateral aspect of the scapular body lying between the two glenoid fragments, abutting the humeral head; **(D)** axillary CT image showing a large posteroinferior cavity fragment; **(E)** postoperative AP and **(F)** axillary radiographs showing the glenoid cavity fragments secured together with cannulated screws and the glenoid unit secured to the scapular body with a malleable reconstruction plate (the acromial fracture was reduced and stabilized with a tension band construct.)

muscles. To be a glenoid neck fracture, the disruption must be complete—exiting along the lateral scapular border and the superior scapular margin, either just lateral or just medial to the coracoid process (Fig. 26-33A,B). Displacement may then occur. If in addition its secondary support is compromised (a coracoid process fracture, a coracoclavicular ligamentous disruption with or without a CA ligamentous injury, a clavicle fracture, an AC joint disruption, or an acromial fracture—that is, a double disruption of the SSSC), there is the potential for severe displacement.[55]

Type I fractures include all insignificantly displaced injuries and constitute 90+% of the total. Management is nonoperative, and a good to excellent functional result can be expected.

Type II fractures include all significantly displaced injuries, and significant displacement is defined as translational displacement of the glenoid fragment greater than or equal to 1 cm or angulatory displacement of the fragment greater than or equal to 40 degrees in either the coronal or the sagittal plane (Fig. 26-34).[60]

One centimeter of translational displacement was chosen by Zdravkovic and Damholt,[207] Nordquvist and Petersson,[148] and Miller and Ada[1,135] as separating major from minor injuries. Bateman[11] believed that this degree of displacement could interfere with abduction. Hardegger et al.[71] pointed out that significant translational displacement changed the normal relations between the glenohumeral articulation and the undersurface of the distal clavicle, AC joint, and acromial process, thereby altering the mechanics

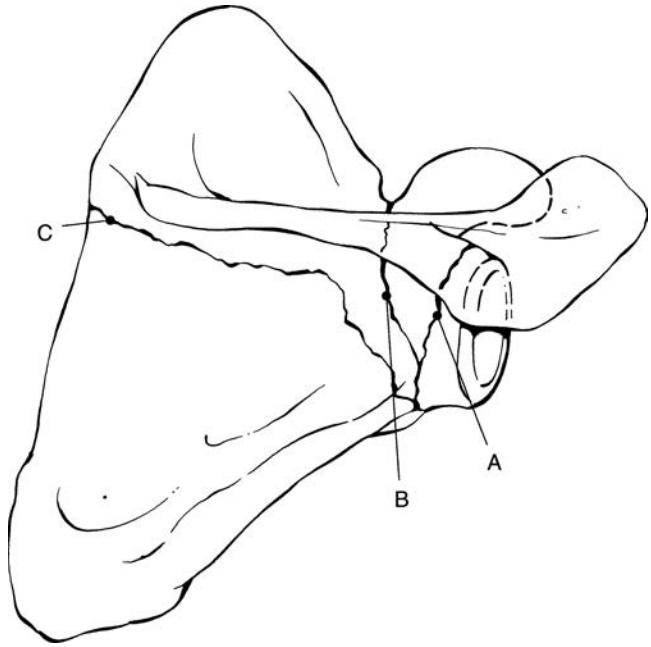

Figure 26-33 Illustration depicting three basic fracture patterns involving the glenoid neck: **(A)** a fracture through the anatomic neck; **(B)** a fracture through the surgical neck; and **(C)** a fracture involving the inferior glenoid neck, which then courses medially to exit through the scapular body (this is managed as a scapular body fracture).

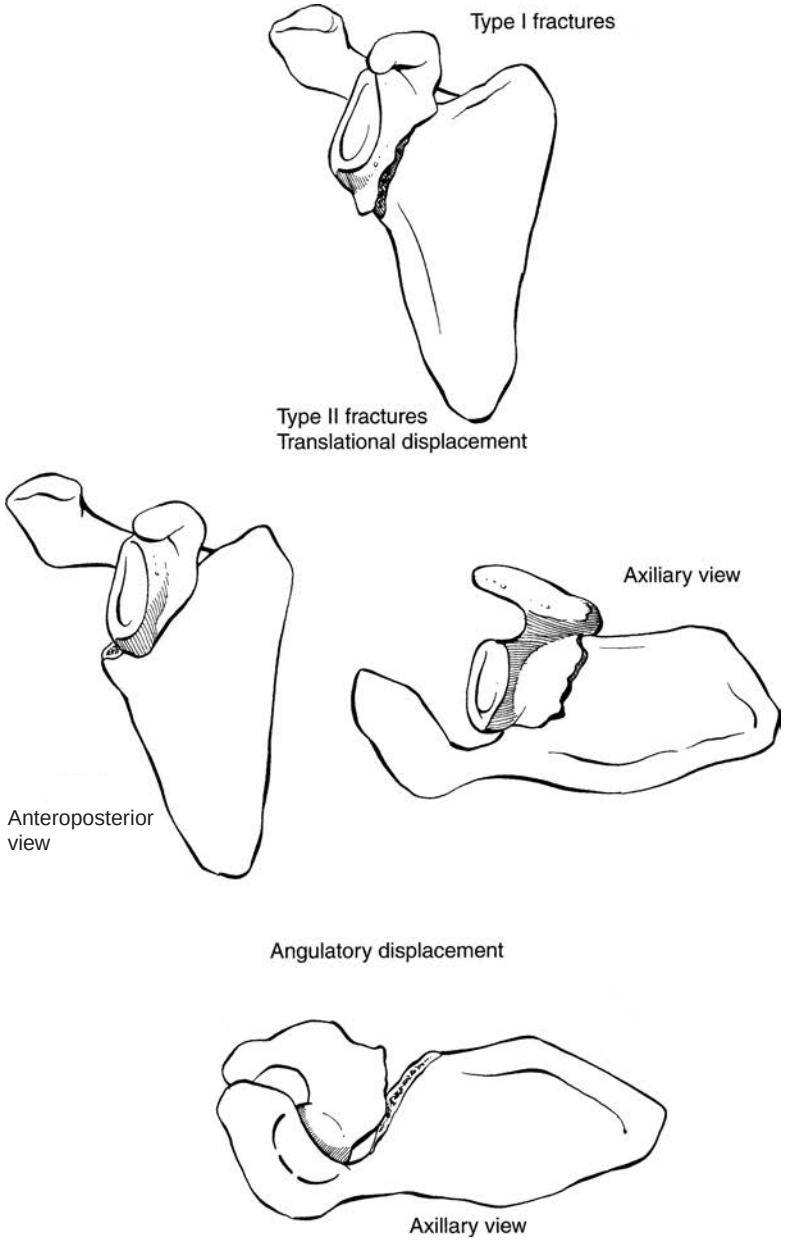

Figure 26-34 Classification scheme for fractures of the glenoid neck.

of nearby musculotendinous units, resulting in a functional imbalance of the shoulder complex as a whole: a "disorganization of the coracoacromial arch." Miller and Ada[1,135] believed that resultant weakness (especially abductor weakness), decreased range of motion, and pain (especially subacromial pain) were largely due to rotator cuff dysfunction. The premise that significant translational displacement of the glenoid process can lead to shoulder discomfort and dysfunction certainly makes sense intuitively—the complex bony relations in the glenohumeral region are clearly altered, as are the mechanics of the musculotendinous structures that pass from the scapula to the proximal humerus (the deltoid muscle and the rotator cuff in particular). The fracture line usually exits the superior scapular border medial to the coracoid process (the surgical neck region). The glenoid fragment is then drawn distally by the weight of the arm and anteromedially by adjacent muscle forces or posteromedially, in which case it is usually forced inferiorly by the scapular spine (Fig. 26-35). Hardegger et al.[71] described a rare case in which the fracture line exited the superior scapular border lateral to the coracoid process (the anatomic neck), allowing the glenoid fragment to be displaced laterally and distally by the pull of the long head of the triceps muscle. Arts and Louette described a similar injury. They believed that such fractures were inherently unstable and in need of ORIF, as opposed to fractures of the surgical neck, which require associated injuries to be rendered unstable and in need of ORIF.[6]

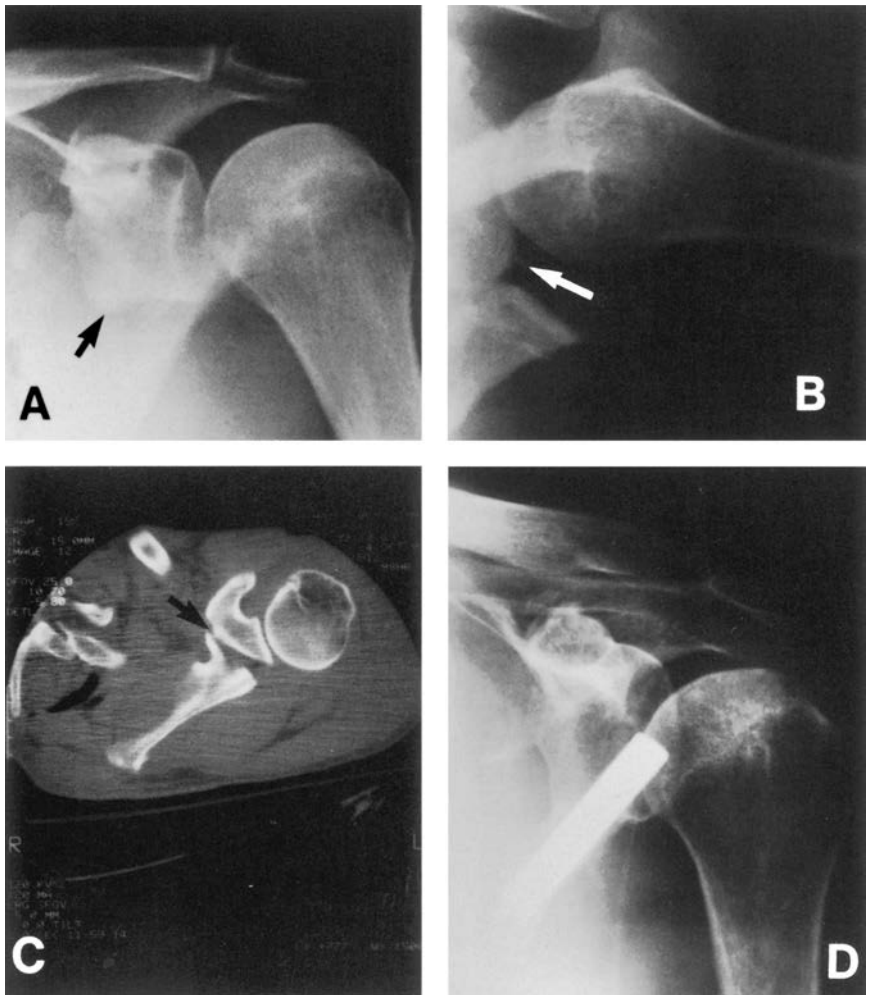

Figure 26-35 Radiographs of a patient who sustained a type II fracture of the glenoid neck with significant translational displacement of the glenoid fragment: **(A,)** a preoperative anteroposterior (AP) radiograph showing the glenoid neck fracture and medial translation of the glenoid fragment; **(B)** a preoperative axillary radiograph revealing that the unstable glenoid fragment is severely displaced anteromedially (the glenohumeral joint is medial to the most lateral aspect of the scapular body), probably owing to an associated disruption of the coracoclavicular ligaments (a violation of the C-4 linkage and, therefore, a double disruption of the superior shoulder suspensory complex) and possibly the coracoacromial ligament; **(C)** a preoperative axial computed tomographic image revealing the glenoid neck fracture to be complete, exiting the superior scapular border medial to the intact coracoid process (a surgical neck fracture); and **(D)** a postoperative AP radiograph showing anatomic reduction and stabilization of the glenoid neck fracture and glenoid fragment.

Bateman[11] and DePalma[32] believed that excessive angulation of the glenoid fragment could result in glenohumeral instability (anterior, posterior, or inferior). Normally, the glenoid cavity faces 15 degrees superiorly and is retroverted 6 degrees relative to the plane of the scapular body. With increasing angulation, the humeral head loses the normal bony support provided by the glenoid cavity (bony instability), which translates into glenohumeral discomfort and dysfunction.[1,11,32,135] Miller and Ada[1,135] felt that angular displacement greater than or equal to 40 degrees in either the coronal or transverse plane was unacceptable (Fig. 26-36). They felt that this degree of displacement adversely altered not only glenohumeral but also other bony relations as well as musculotendinous dynamics, particularly those of the rotator cuff, resulting in pain and overall shoulder dysfunction (diminished range of motion and loss of strength).

Miller and Ada[1,135] retrospectively reviewed 16 displaced glenoid neck fractures (greater than or equal to 1 cm of translational displacement or greater than or equal to 40 degrees of angulation in either the transverse or coronal plane) managed nonoperatively (36-month average follow-up). They found that 20% had decreased range of motion, 50% had pain (75% night pain), 40% had weakness with exertion, and 25% noted "popping." In particular, these patients frequently had shoulder abductor weakness and subacromial pain, due at least in part to rotator cuff dysfunction. They recommended ORIF of glenoid neck fractures with this degree of displacement.

Diagnosis

Diagnosis is ultimately radiographic. Plain radiographs are helpful, but because of the complex bony anatomy in the area, CT scanning is generally necessary to determine whether a glenoid neck fracture is indeed complete, to determine the degree of displacement, if any, and to identify injuries to adjacent bony structures and articulations. One must not confuse these injuries with the more common fractures that course through the inferior glenoid neck and the scapular body (see Fig. 26-33C). CT scanning readily reveals that the latter are not complete disruptions of the glenoid process, since the superior aspect of the glenoid neck is intact. These are essentially fractures of the scapular body and do quite well with nonoperative care

Figure 26-36 A patient who sustained a type II fracture of the glenoid neck with significant angulatory displacement of the glenoid fragment: **(A)** a preoperative anteroposterior (AP) radiograph showing the glenoid neck fracture with severe angulation of the glenoid fragment and a fractured coracoid process—also note the fracture of the scapular body with displacement of the lateral scapular border; **(B)** a preoperative axillary computed tomography projection showing the coracoid process fracture (a violation of the C-4 linkage) that further destabilized the glenoid fragment and allowed severe angulatory displacement to occur (a double disruption of the superior shoulder suspensory complex); **(C)** and **(D)** postoperative AP and axillary radiographs showing the glenoid fragment reduced and stabilized with a contoured reconstruction plate (the coracoid process fracture was allowed to heal spontaneously). (From Goss TP. Fractures of the scapula. In: Rockwood CA, Matsen FA, Wirth MA, Lippitt SB, eds. *The shoulder,* 3rd ed. Philadelphia: Saunders, 2004:413, with permission.)

because the normal relations between the glenohumeral articulation and the distal clavicle–acromion are unaltered (Fig. 26-37).[60] McAdams et al.[124] found that CT scanning did not improve the evaluation of glenoid fractures over plain films but did aid in the identification of associated injuries to the superior shoulder suspensory complex.

Nonoperative Versus Operative Treatment

Imatani,[88] McGahan et al.,[127] and Lindholm and Leven[116] recommended nonsurgical treatment for all glenoid neck fractures, but their studies give few details to justify this conclusion. A long-term follow-up study by Zdravkovic and Damholt[207] included 20 to 30 patients (it is difficult to determine the exact number from the text) with displaced glenoid neck fractures and noted that nonoperative treatment yielded satisfactory results. Nordquvist and Petersson,[148] however, evaluated 37 glenoid neck fractures treated without surgery (10- to 20-year follow-up) and found the functional result to be either fair or poor in 32%. They believed that for some fractures, early ORIF might have improved the result. Although somewhat ambivalent in their recommendations, three studies do mention surgical management as an option in selected cases. Armstrong and Vanderspuy[5] believed that although most of these individuals do well, more aggressive treat-

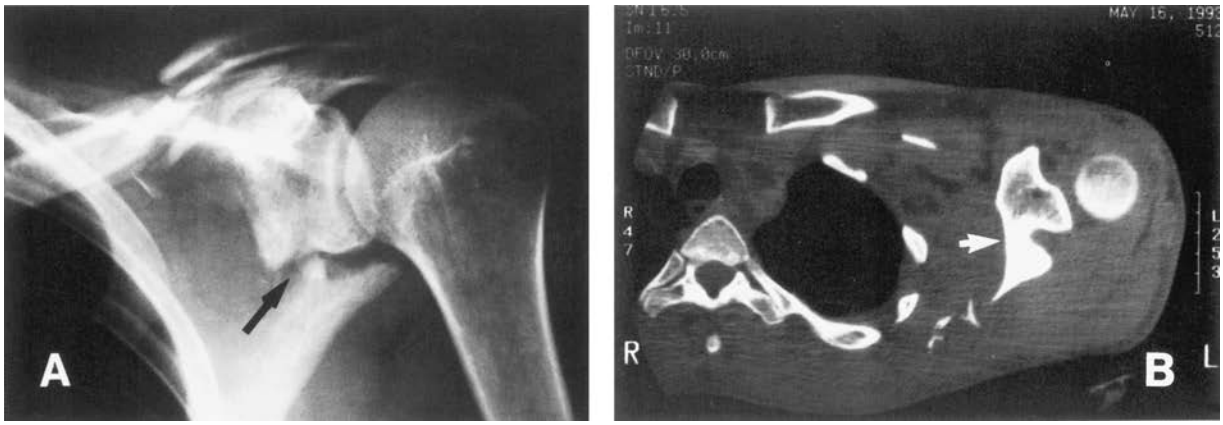

Figure 26-37 Radiographs showing what initially, but erroneously, appeared to be a complete fracture of the glenoid neck: **(A)** An anteroposterior radiograph of the shoulder showing a fracture involving the inferior aspect of the glenoid neck; and **(B)** an axial computed tomographic image showing the superior portion of the glenoid neck to be uninvolved (the fracture exited through the scapular body).

ment including ORIF may be indicated in patients who are young and fit. DeBeer et al.[29] described the operative treatment of a professional cyclist who was able to return to competition at 6 weeks and urged more aggressive treatment in high-demand patients. Wilbur and Evans[199] believed that ORIF might be indicated if the glenoid fragment is markedly displaced or angulated, but did not believe that they had enough information or experience to warrant definitive surgical indications.

Hardegger et al.[71] reported 79% good to excellent results in five displaced glenoid neck fractures treated surgically (6.5-year follow-up). They agreed with Judet,[91] Magerl,[119] Ganz and Noesberger,[48] and Tscherne and Christ[190] that operative management of displaced glenoid neck fractures avoids late disability and yields better results. Gagney et al.[47] found a good result in only 1 of 12 displaced fractures treated nonoperatively. They believed that such injuries "could disorganize the coracoacromial arch," and recommended open reduction. Neer,[142] as well as Rockwood[143] and Butters,[23] presented the recommendations of other investigators, as did a review article by Guttentag and Rechtine.[68] Boerger and Limb reported the case of a patient with a fracture of the glenoid neck and acromial and coracoid processes, a dislocated AC joint, and incomplete paralysis of the infraspinatus muscle treated by ORIF of the acromial and glenoid neck fractures.[19] Clearly, all these investigators agree that the vast majority of glenoid neck fractures can and should be treated without surgery. However, most authors believe that more aggressive treatment, including ORIF, is at the very least a consideration, if not clearly indicated, when the glenoid fragment is severely displaced (i.e., type II injuries). Some might argue with 1 cm of translational displacement being an indication for surgery. However, the decision to proceed becomes easier with increasing degrees of displacement, especially if the glenoid rim lies medial to the lateral margin of the scapular body (see Fig. 26-35). Forty degrees (or certainly more) of angular displacement of the glenoid fragment also seems to be a reasonable indication for operative management.

Surgical Indications and Management

Type II fractures should at the very least be considered for surgical management.

The glenoid process and fracture site are approached posteriorly. The interval between the infraspinatus and teres minor is developed to expose the posteroinferior glenoid neck and lateral scapular border. A superior approach can be added to gain control over the free glenoid fragment. Once a satisfactory reduction has been achieved, temporary fixation can be provided by placing K-wires between the glenoid fragment and the adjacent bony structures (e.g., through the glenoid fragment and into the scapular body; through the acromial process and into the glenoid fragment; and so on). Firm fixation is generally achieved by means of a contoured 3.5-mm malleable reconstruction plate applied along the lateral border of the scapula and the posterior aspect of the glenoid process. Supplemental fixation can be provided by K-wires or lag screws. K-wires providing temporary fixation can be retained or used for the placement of 3.5-mm cannulated lag screws (Fig. 26-38). Conceivably, comminution of the scapular body and spine may be so severe or the size of the glenoid fragment so small as to preclude plate fixation. In these cases, K-wire or lag screw fixation of the reduced glenoid fragment to adjacent intact bony structures (i.e., the acromial process, the distal clavicle, etc.) may be all that can be provided. If a disruption of the clavicular–AC joint–acromial strut is also present, fixation of that injury may indirectly reduce and stabilize the glenoid neck fracture. If significant displacement persists, however, the glenoid neck fracture must also be addressed.[60] Conversely,

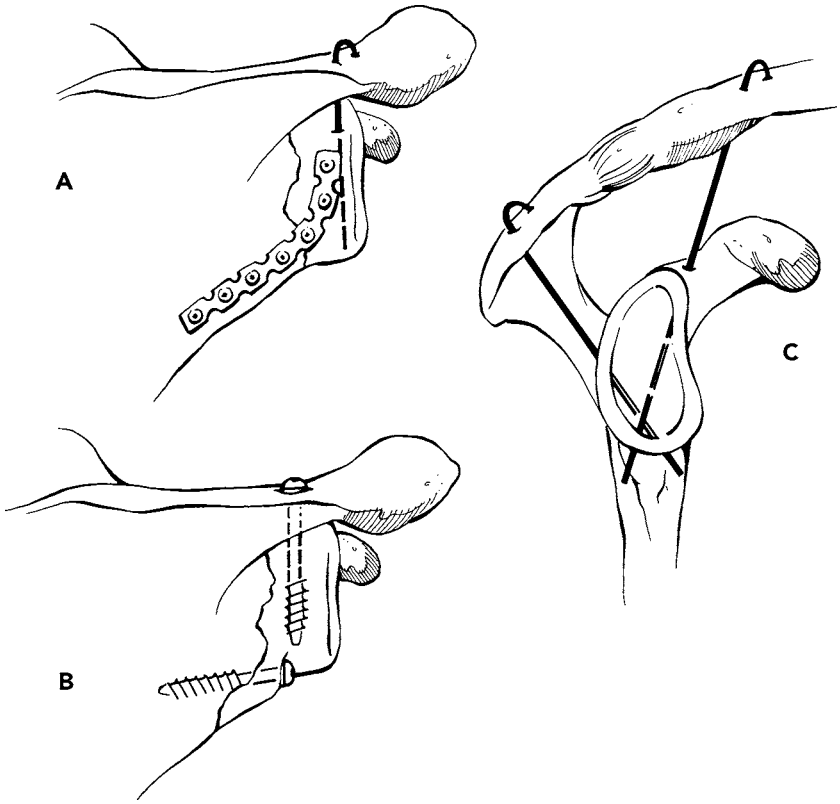

Figure 26-38 Illustrations depicting fixation techniques available for stabilization of glenoid neck fractures: **(A)** stabilization with a 3.5-mm malleable reconstruction plate (note the K-wire running from the acromial process to the glenoid process that can be used for either temporary or permanent fixation); **(B)** stabilization with 3.5-mm cannulated interfragmentary screws; and **(C)** stabilization with K-wires (in this case, K-wires passed from the acromion and clavicle into the glenoid process).

open reduction and internal fixation of the glenoid neck fracture may satisfactorily reduce and stabilize the second disruption. If not, that associated disruption must be addressed.[60] A fracture of the ipsilateral glenoid neck and midshaft clavicle has been termed a "floating shoulder." Disruptions of the clavicular–CC ligamentous–coracoid (C-4) linkage are usually managed indirectly by reducing and stabilizing the glenoid neck fracture and any injuries compromising the integrity of the clavicular–AC joint–acromial strut. Rarely, if the scapular body–spine, acromial process, and distal clavicle are all severely comminuted, overhead olecranon pin traction must be considered or displacement of the glenoid neck fracture must be accepted and managed nonoperatively.

Postoperative Management and Prognosis

The postoperative management of glenoid process fractures depends upon the fixation–stability achieved. Immobilization in a sling and swathe bandage is prescribed during the first 24 to 48 hours following surgery. If fixation is rigid, dependent circular and pendulum movements are then initiated as well as external rotation of the shoulder to, but not past, neutral. During postoperative weeks 3 to 6, progressive range-of-motion exercises in all directions (especially forward flexion, internal rotation up the back, and external rotation) are prescribed, seeking to achieve full range of motion by the end of the 6-week period. The patient is allowed to use his or her arm actively in a progressive manner within clearly defined limits (moving the weight of his or her upper extremity alone when sitting in a protected setting during weeks 3 and 4 and when up and about indoors during weeks 5 and 6). The patient is followed clinically and radiographically every 2 weeks to make sure displacement does not occur at the fracture site and to monitor and update the rehabilitation program. At 6 weeks, healing is sufficient so as to discontinue all external protection and encourage progressive functional use of the extremity. K-wires spanning bones that move relative to each other are removed at this time, as are those passing through soft tissues (K-wires imbedded within a single osseous structure [bent at their entry site to prevent migration] may be left in place). Physiotherapy continues to focus on regaining range of motion as progressive strengthening exercises are added. The patient's rehabilitation program continues until range of motion, strength, and overall function are maximized. Light use of the shoulder is emphasized through postoperative week 12, whereas heavy physical use of the shoulder, including athletic activities, is prohibited until the 4- to 6-month point.

If surgical fixation is less than rigid, the shoulder may need to be protected in a sling and swathe immobilizer, an abduction brace, or even overhead olecranon pin traction for 7, 10, or 14 days (dependent on the clinical situation) before the aforementioned physiotherapy program is prescribed. The patient must be encouraged to work diligently

on his or her rehabilitation program because range of motion and strength can improve, and the end result is often not achieved for approximately 6 months to 1 year after injury. Hard work, perseverance, and dedication on the part of the patient, the physician, and the physical therapist are critical to an optimal functional result.

Although the literature remains somewhat deficient owing to the rarity of these injuries, interest has increased in recent years, resulting in a growing number of case reports and personal series. Although more data are needed, it is reasonable to anticipate a good to excellent functional result if: (a) surgical management restores normal or near-normal glenoid anatomy and articular congruity, as well as glenohumeral stability; (b) the fixation is secure; and (c) a well-structured, closely monitored postoperative rehabilitation program is prescribed.

DOUBLE DISRUPTIONS OF THE SUPERIOR SHOULDER SUSPENSORY COMPLEX

Biomechanics

The SSSC is a bony soft tissue ring at the end of a superior and an inferior bony strut (Fig. 26-39). This ring is composed of the glenoid process, the coracoid process, the coracoclavicular ligament, the distal clavicle, the AC joint, and the acromial process. The superior strut is the middle third of the clavicle, whereas the inferior strut is the junction of the most lateral portion of the scapular body and the most medial portion of the glenoid neck. The complex can be subdivided into three units: (a) the clavicular–AC joint–acromial strut; (b) the three-process–scapular body junction; and (c) the clavicular–CC ligamentous–coracoid (C-4) linkage (Fig. 26-40), with secondary support provided by the CA ligament. The SSSC is an extremely important structure as regards the biomechanics of the shoulder complex: (a) each of its components has its own individual function(s); (b) it serves as a point of attachment for a variety of musculotendinous and ligamentous structures; (c) it allows limited, but very important motion to occur through the coracoclavicular ligament and the AC articulation; and (d) it maintains a normal, stable relationship between the upper extremity and the axial skeleton (the clavicle is the only bony connection between the upper extremity and the axial skeleton and the scapula is "hung" or suspended from the clavicle by the coracoclavicular ligaments and the acromioclavicular articulation).

The "double disruption" concept is a principle that underlies and allows one to understand a variety of difficult-to-treat injuries to the shoulder complex, which have previously been described in isolation, but are actually united by a single biomechanical theme. This "double disruption" concept also has a predictive value for certain injuries that are encountered only rarely.[55]

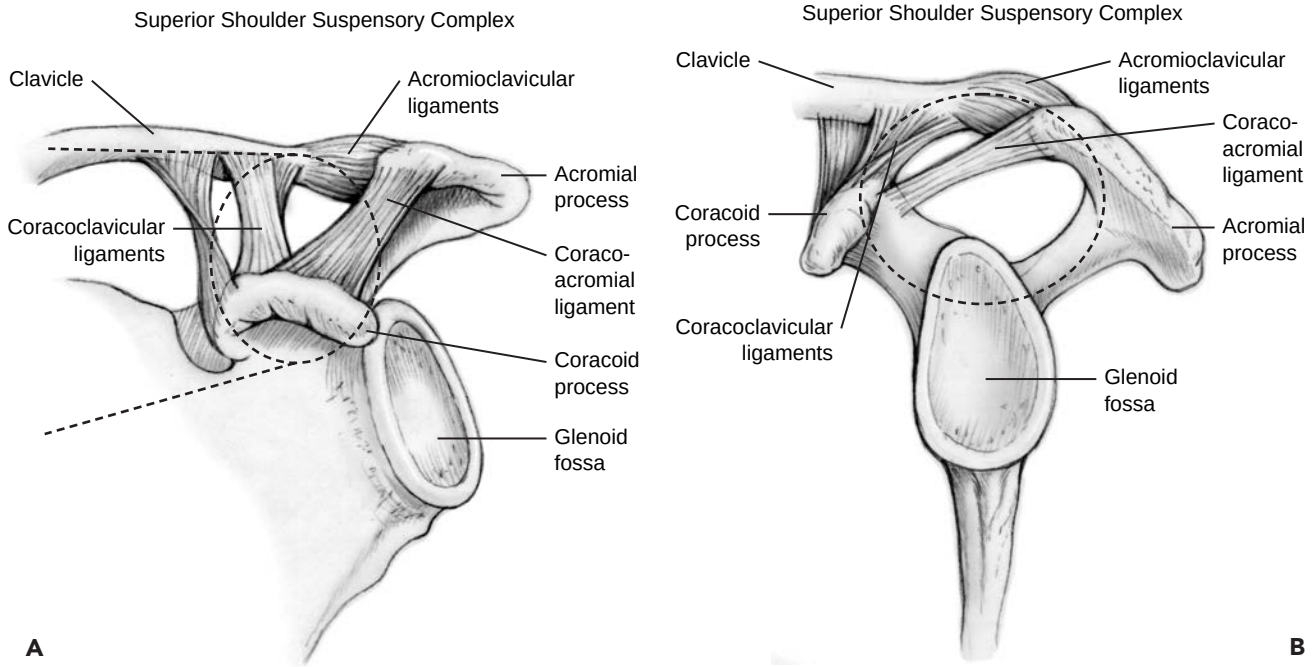

Figure 26-39 Illustrations depicting the superior shoulder suspensory complex: **(A)** an anteroposterior view of the bony–soft tissue ring and the superior and inferior bony struts and **(B)** a lateral view of the bony–soft tissue ring. (Adapted from Goss TP. Fractures of the scapula. In: Rockwood CA, Matsen FA, Wirth MA, Lippitt SB, eds. *The shoulder,* 3rd ed. Philadelphia: Saunders, 2004:413, with permission.)

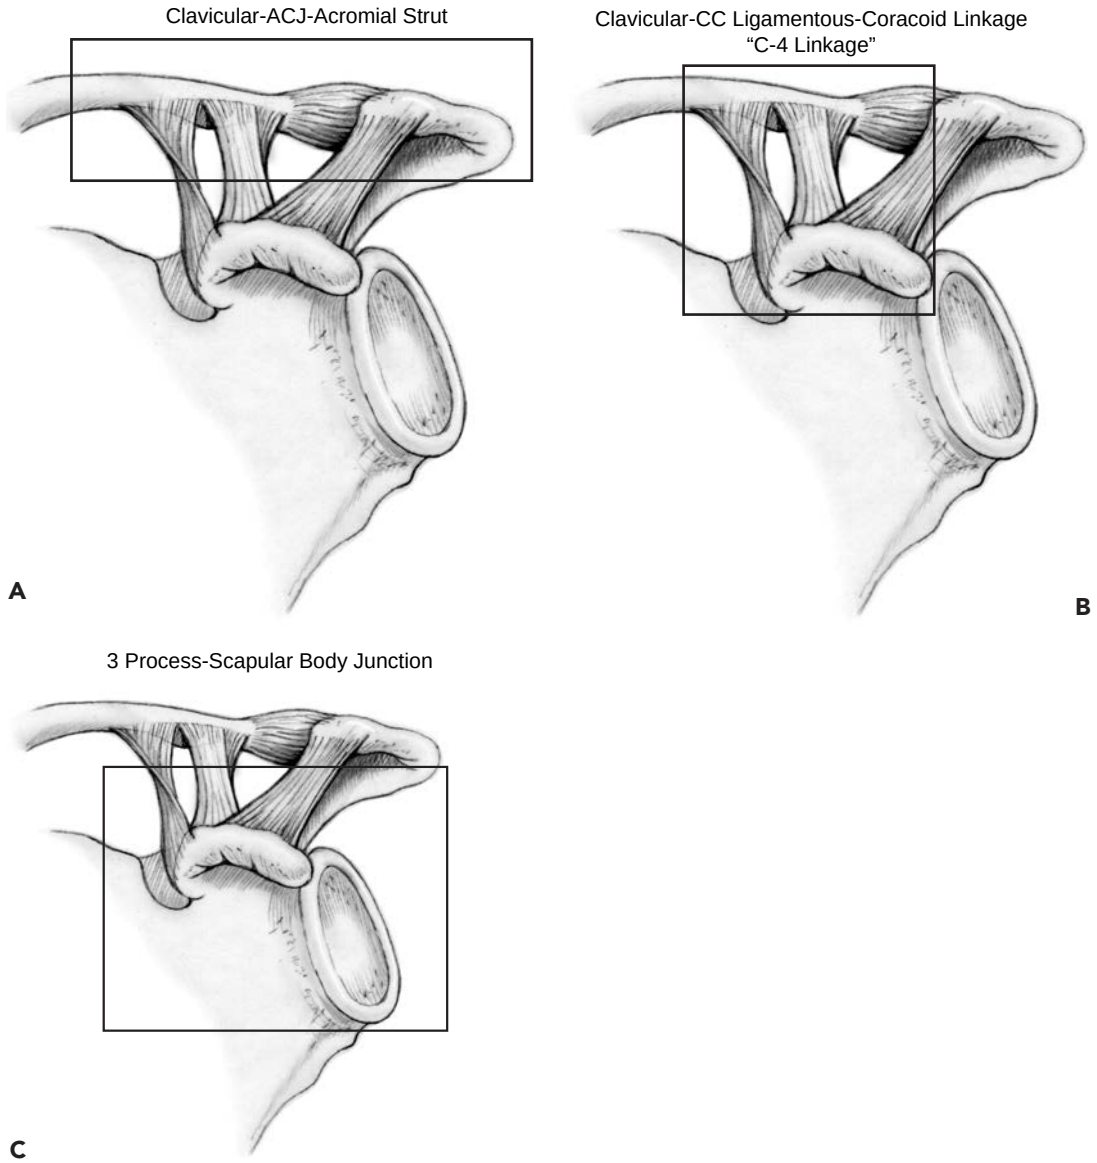

Figure 26-40 The three components of the superior shoulder suspensory complex: **(A)** the clavicular–acromioclavicular joint–acromial strut; **(B)** the clavicular– coracoclavicular ligamentous–coracoid (C-4) linkage; and **(C)** the three process–scapular body junction. (Adapted from Goss TP. Fractures of the scapula. In: Rockwood CA, Matsen FA, Wirth MA, Lippitt SB, eds. *The shoulder,* 3rd ed. Philadelphia: Saunders, 2004:413, with permission.)

Single traumatic disruptions of the SSSC are common (e.g., a type I fracture of the distal clavicle). These are anatomically stable situations because the overall integrity of the complex is not significantly violated and nonoperative management will generally yield a good to excellent functional result.

When the complex is disrupted in two places, however (a "double disruption"), the integrity of the SSSC is clearly compromised, creating a potentially unstable anatomic situation. Significant displacement can occur at either or both sites, resulting in bony healing problems (delayed unions, malunions, and nonunions) as well as adverse long-term functional difficulties (subacromial impingement, decreased strength and muscle fatigue discomfort, neurovascular compromise due to a "drooping" shoulder, and degenerative joint disease) depending on the particular injury.

Double disruptions may take a variety of forms: two fractures of the bony soft tissue ring; two ligamentous disruptions of the ring; a fracture and a ligamentous disruption of the ring; fractures of both bony struts; or a fracture of one strut combined with a ring disruption (either a fracture or a ligamentous disruption; Fig. 26-41). Because the glenoid, acromial, and coracoid processes are all components of the SSSC, many double-disruption injuries involve the scapula. Also, many, if not most, significantly displaced coracoid and acromial fractures are part of a double

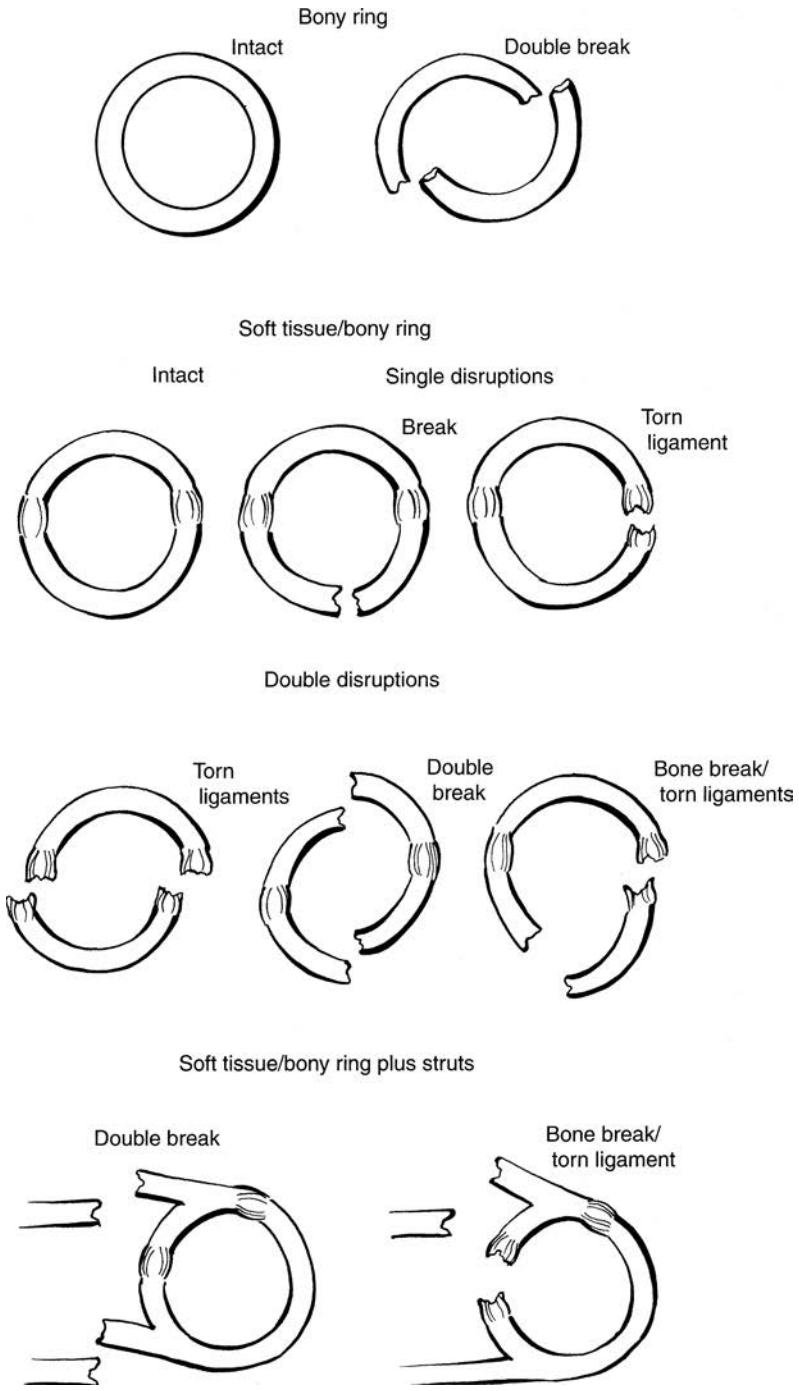

Figure 26-41 Illustrations depicting the many possible traumatic ring–strut disruptions.

disruption. When particularly severe forces are involved, there is the potential for complex injury patterns due to multiple ring and strut disruptions.[20]

Diagnosis

If a single disruption is noted on routine radiographs (a true AP view of the shoulder, a true axillary view of the glenohumeral joint, and a weight-bearing AP of the shoulder to evaluate the integrity of the clavicular–scapular linkage), one should look carefully for a second disruption (CT scanning is often necessary owing to the complex bony anatomy in the area).

Surgical Indications, Management Principles, and Results

If two disruptions are present, one must decide whether displacement at one or both sites is "unacceptable" (a relative term, dependent on the particular clinical situation) and if so, surgical management is generally necessary. Reducing and stabilizing one of the disruptions will frequently

indirectly reduce and stabilize the other disruption satisfactorily (whichever injury is easiest to manage is chosen). If unsuccessful, both disruptions may need to be addressed (see sections dealing with specific injuries). Results, as always, are dependent on the adequacy of the reduction, the quality of the fixation, and the rigor of the postoperative rehabilitation program.

The Floating Shoulder (Ipsilateral Fractures of the Midshaft Clavicle and Glenoid Neck)

Surgical Indications, Techniques, and Results

These injuries represent a double disruption of the SSSC. In isolation, each fracture is generally minimally displaced and managed nonoperatively. In combination, however, each disruption can make the other unstable (i.e., the glenoid neck fracture often allows severe displacement to occur at the clavicular fracture site and vice versa, although to a lesser degree). The situation is rendered even more unstable if an additional disruption of the clavicular–AC joint–acromial strut is present or if the C-4 linkage is violated (Fig. 26-42). Hardegger et al.[71] felt these injuries represented a "functional imbalance" owing to the "altered glenohumeral–acromial relationships." They and Butters[23] recommended surgery to reduce and stabilize the injury. Surgical reduction and stabilization of the clavicular fracture site (most commonly with plate fixation) is advisable if displacement is unacceptable to avoid a nonunion, alleviate tensile forces on the brachial plexus, restore normal anatomic relationships, and ensure restoration of normal shoulder function.[79,104] The glenoid neck fracture will generally reduce and stabilize secondarily; however, if significant displacement persists, it may also require surgical management[78,112] (see Fractures of the Glenoid Neck). Additional injuries to the clavicular–AC joint–acromial strut may require operative treatment, whereas associated injuries of the C-4 linkage will usually heal satisfactorily if the glenoid neck and clavicular fracture

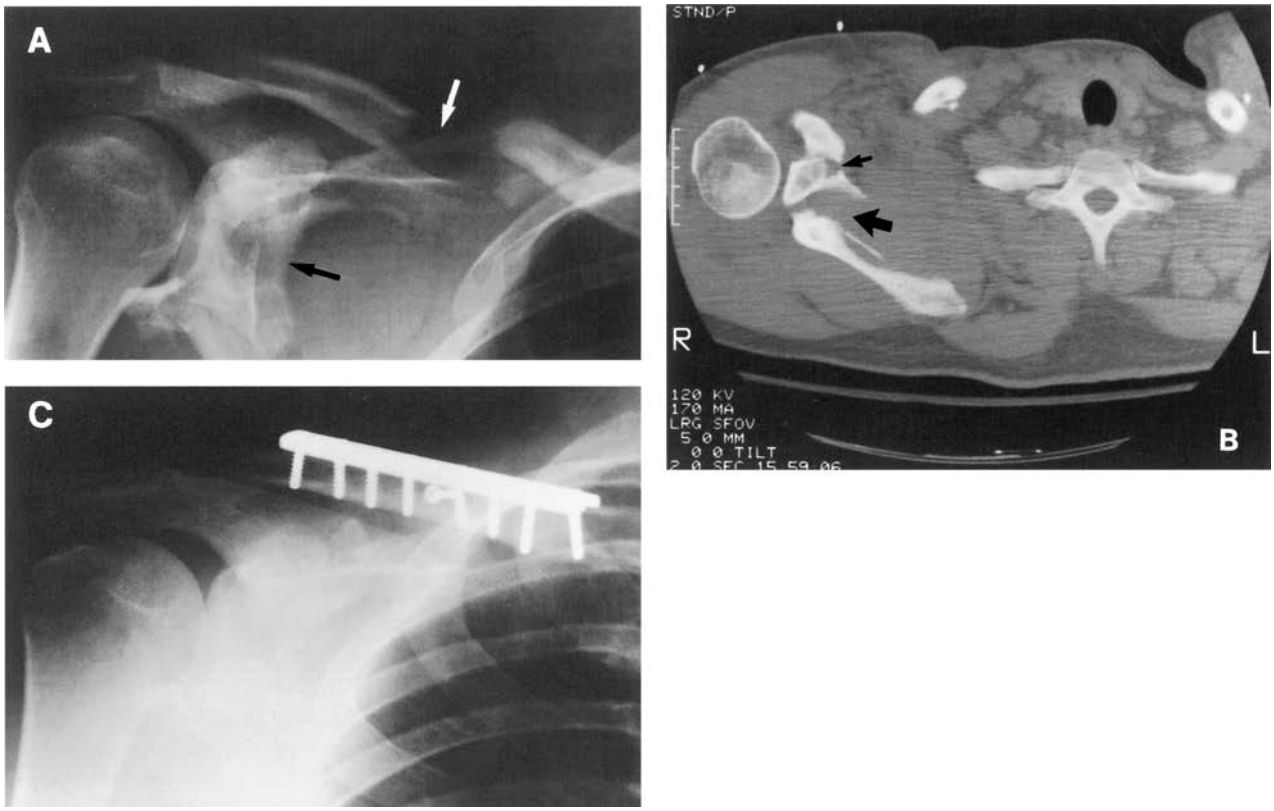

Figure 26-42 Radiographs of an individual who sustained a double disruption of the superior shoulder suspensory complex resulting in a "floating shoulder": **(A)** a preoperative anteroposterior (AP) radiograph showing a fracture of the glenoid neck with medial translation and a severely displaced fracture of the middle third of the clavicle; **(B)** a preoperative axial computed tomographic image showing the glenoid neck fracture to be complete, with the glenoid fragment and the entire superior shoulder suspensory complex rendered particularly unstable by an associated fracture of the coracoid process; and **(C)** a postoperative AP radiograph showing anatomic reduction and stabilization of the clavicle fracture. The glenoid neck fracture was managed nonoperatively, although a strong case could have been made for open reduction and internal fixation in light of its persistent medial translational displacement (the glenoid fragment remained unstable owing to the fractured coracoid process; a double disruption of the superior shoulder suspensory complex was still present).

sites are treated appropriately. Leung and Lam[113] reported on 15 patients treated surgically (average follow-up period 25 months). In 14 of the 15 patients, the fractures healed with a good or excellent functional result. Herscovici et al.[80] reported the results of nine patients with ipsilateral clavicular and glenoid neck fractures (average follow-up period 48.5 months). Seven patients were treated surgically with plate fixation of the clavicular fracture and achieved excellent results. Two patients were treated without surgery and had decreased range of motion as well as "drooping" of the involved shoulder. The authors strongly recommended ORIF of the clavicle to prevent a glenoid neck malunion. Simpson and Jupiter in a review article indicated that these injuries frequently require operative treatment.[177] Rikli et al. expanded this concept somewhat, saying that a fracture of the glenoid neck combined with either a fracture of the clavicle or a disruption of the AC joint or the sternoclavicular (SC) joint results in an "unstable shoulder girdle." They reviewed 13 cases (12 patients) in which the clavicular injury was surgically stabilized and reported excellent results in nearly all.[164]

There has been a great deal of interest recently as regards "floating shoulders," including both clinical and basic science studies. Edwards et al.[37] reported excellent results with conservative treatment of consecutive patients with ipsilateral clavicle and scapular fractures; however, in 5 of the 20 individuals, the scapula fracture did not involve the glenoid neck. Hashiguchi and Ito[74] reported excellent results in five patients with ipsilateral clavicle and glenoid neck fractures in whom fixation of the clavicle alone was performed. Van Noort et al.[193] reported a multicenter study of 46 patients with ipsilateral clavicle and glenoid neck fractures treated both operatively and nonoperatively, with mixed results in both groups. Egol et al.[38] reviewed their results in 19 patients (some treated surgically based on surgeon preference and some treated nonoperatively) and reported good results with each approach. Ramos et al. also reported on a series of patients treated nonoperatively who did quite well.[161] Williams et al. conducted a cadaveric study to determine the stability afforded by specific structures. Using a model with ipsilateral glenoid neck and clavicular fractures, they found that instability of the glenoid segment occurred only with subsequent coracoacromial and coracoclavicular ligamentous sectioning. They concluded that "floating shoulders" only become unstable when there is an associated disruption of the CA and AC ligaments.[200] Perhaps an associated coracoid process fracture would result in instability as well since it serves as a point of attachment for the CA and CC ligaments. Current experience would seem to indicate that (a) the mere presence of a clavicular and a glenoid neck fracture does not demand operative treatment and many/most do well nonoperatively; (b) the more displacement there is at one or both sites, the greater the need for ORIF is; and (c) another disruption of the SSSC may be necessary for significant displacement to occur.

Coracoid Process Fracture as One Component of a Double Disruption of the Superior Shoulder Suspensory Complex

The coracoid process is a vital part of the SSSC serving as one of the bony components of the clavicular–CC ligamentous–coracoid (C-4) linkage that joins the scapula to the clavicular–AC joint–acromial strut. Consequently, if a coracoid process fracture is present and associated with another SSSC injury, the potential adverse consequences of a "double disruption" must be considered and treatment tailored accordingly.[55] Ogawa and coworkers believed that such fractures were usually deep to the CC ligament. They classified them as type I fractures and they thought that they represented a dissociation between the scapula and the clavicle and as such often required ORIF.[152] The following are examples:

A fracture of the coracoid process and a grade III disruption of the AC joint. On occasion, especially in young adults, a force that would otherwise cause a grade III sprain of the AC joint results in an avulsion fracture of the base of the coracoid process or the bony attachment of the CC ligament to the angle of the coracoid process instead of a disruption of the CC ligament (Fig. 26-43). A weight-bearing AP projection of the shoulder complex will show displacement of the distal end of the clavicle above the superior border of the acromion but the CC interval remains normal. Treatment of injuries with a small bony avulsion fracture of the angle of the coracoid process follows the principles developed for grade III AC joint disruptions—specifically, ORIF of the AC joint and coracoid should be considered in young individuals engaged in athletics or heavy manual physical work. Disruptions associated with a fracture of the base of the coracoid process (especially if significantly displaced) should be considered for surgical ORIF of both sites to avoid the adverse long-term effects of a grade III AC separation and a nonunion of the coracoid process. Reports in the literature have described both operative and nonoperative management of these injuries.[15,26,39,69,81,103,110,122,137,159,179,196,208]

Fractures of the ipsilateral coracoid and acromial processes. Isolated fractures of the acromial and coracoid processes (Fig. 26-44) are almost always minimally displaced and, therefore, managed nonoperatively. When they occur together, however, they constitute a "double disruption" of the superior shoulder suspensory complex, a potentially unstable anatomic situation.[25,209] If displacement at either or both sites is unacceptable, surgical management is indicated. ORIF of the acromial fracture may be all that is required, since this will often indirectly reduce and stabilize the coracoid fracture satisfactorily and is technically less difficult than addressing the coracoid injury. If not, however, the coracoid

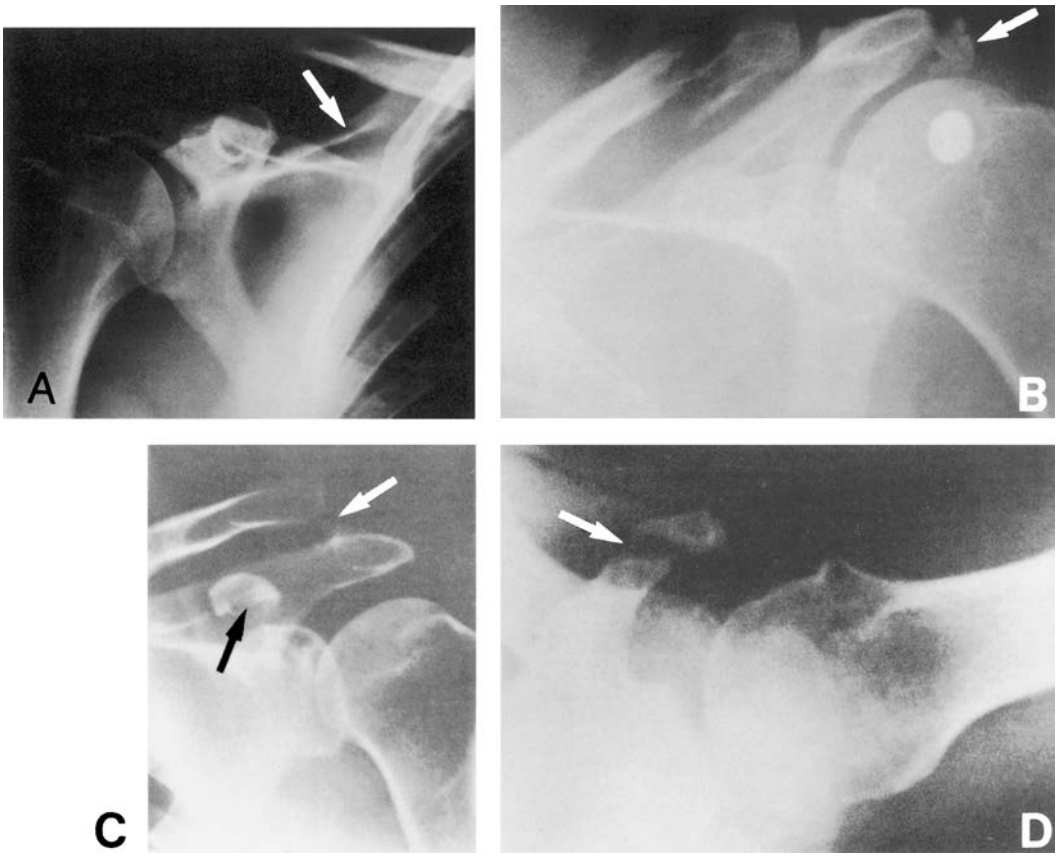

Figure 26-43 Radiographs showing a variety of scapular avulsion fractures: **(A)** a minimally displaced fracture of the superior angle of the scapula (attachment of the levator scapulae; *arrow*); **(B)** a displaced fracture of the lateral margin of the acromial process (origin of the deltoid muscle; *arrow*); **(C)** a type III disruption of the acromioclavicular joint (*white arrow*) with an associated avulsion fracture at the base of the coracoid process; and **(D)** displaced fracture of the tip of the coracoid process (attachment of the conjoined tendon; *arrow*).

fracture may need to be reduced and stabilized as well. Lim and coworkers described such an injury managed with ORIF of both sites.[115]

A fracture of the base of the coracoid process and a fracture of the glenoid neck. A fracture of the glenoid neck can only displace if it is complete (i.e., if the fracture line exits the lateral scapular border and the superior scapular margin adjacent to the coracoid process). Even so, if continuity of the glenoid fragment with the clavicular–AC joint–acromial strut via the C-4 linkage is intact, displacement is usually minimal. If, however, this linkage is disrupted (e.g., a fracture at the base of the coracoid process), significant displacement of the glenoid fragment is particularly likely (translational displacement greater than or equal to 1 cm and/or angular displacement greater than or equal to 40 degrees) and surgical management must be considered.[60] Operative treatment consists of ORIF of the glenoid neck fracture through a posterior or posterosuperior approach. The coracoid fracture will usually heal without direct intervention.

A fracture of the coracoid process and a type I fracture of the distal third of the clavicle (Fig. 26-45). Fractures of the distal third of the clavicle can displace unacceptably if the continuity of the coracoclavicular ligament between the coracoid process and the proximal clavicular segment is disrupted (type II and V fractures[141,142]). The same situation can occur with type I fractures if the coracoid process is fractured. (It would probably make most sense to call all of these injuries type II fractures, that is, situations in which the distal third of the clavicle is fractured, and the linkage between the proximal segment and the scapula [the C-4 linkage] is disrupted.) If displacement at the clavicular fracture site is of such a degree that it makes a delayed union or a nonunion likely, treatment consists of surgical reduction and stabilization of the injury (usually by means of tension band fixation). The coracoid fracture may reduce secondarily and heal uneventfully. If not, the coracoid fracture may also need to be addressed surgically.

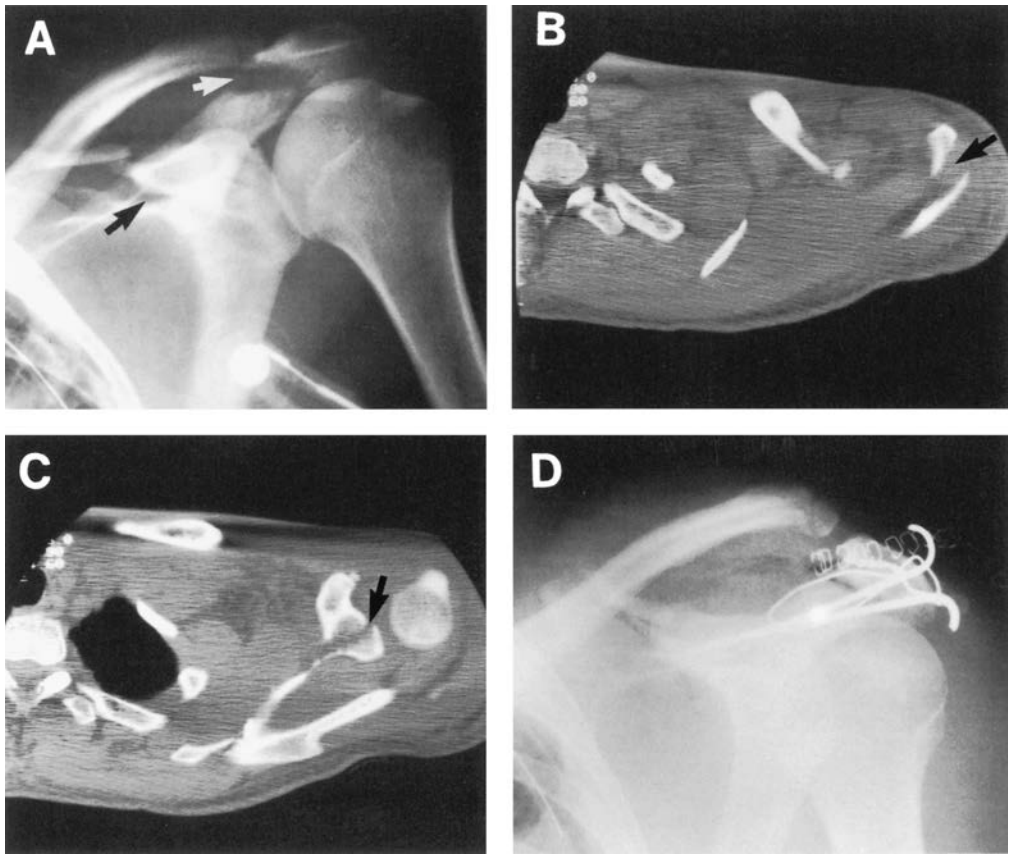

Figure 26-44 A patient who sustained ipsilateral fractures of the coracoid and acromial processes and distal clavicle: **(A)** a preoperative anteroposterior (AP) radiograph of the involved area (*white arrow,* acromial fracture; *black arrow,* coracoid fracture); **(B)** a preoperative axillary computed tomographic (CT) image showing wide separation at the acromial fracture site (*arrow*) owing to the associated coracoid process fracture; **(C)** a preoperative axillary CT image showing the fractured coracoid process (*arrow*); and **(D)** a postoperative AP radiograph of the shoulder showing reduction and stabilization of the acromial fracture using a tension band construct (the coracoid process fracture and distal clavicle fracture were not addressed and healed spontaneously).

Acromial Fracture as One Component of a Double Disruption of the Superior Shoulder Suspensory Complex

Acromial fractures that are significantly displaced are usually the result of the instability created when other fractures or ligamentous disruptions of the SSSC are present.[55] These injuries are generally the result of high-energy trauma and often require surgical intervention. Ogawa and Naniwa divided acromial fractures into two types: type I (lateral to the spinoglenoid notch) and type II (descending into the spinoglenoid notch). They believed that the mechanism of each was different and that type I injuries were more likely to be associated with other injuries to the SSSC (i.e., a "double disruption"), were more likely to be significantly displaced, and were more likely to require ORIF.[151] The following are examples:

Ipsilateral acromial and coracoid process fractures (discussed earlier).

An acromial fracture and a grade III disruption of the acromioclavicular joint. This combination creates a free-floating acromial fragment and can lead to a nonunion as well as the well-described adverse long-term functional consequences associated with AC joint disruptions. One case report describes an individual with an associated axillary nerve deficit.[126] Acutely, isolated grade III AC joint disruptions are usually managed nonoperatively; however, in this situation, if displacement at the acromial fracture site is unacceptable, surgical reduction and stabilization of both injuries is indicated. Kurdy and Shah described a patient treated nonoperatively who realized a "satisfactory" outcome; however, he was 74 years old and an acromial nonunion occurred.[106] Gorczyca and coauthors described an injury that gradually displaced over time and eventually required ORIF.[53] Torrens and colleagues described a combined type VI AC joint disruption and an

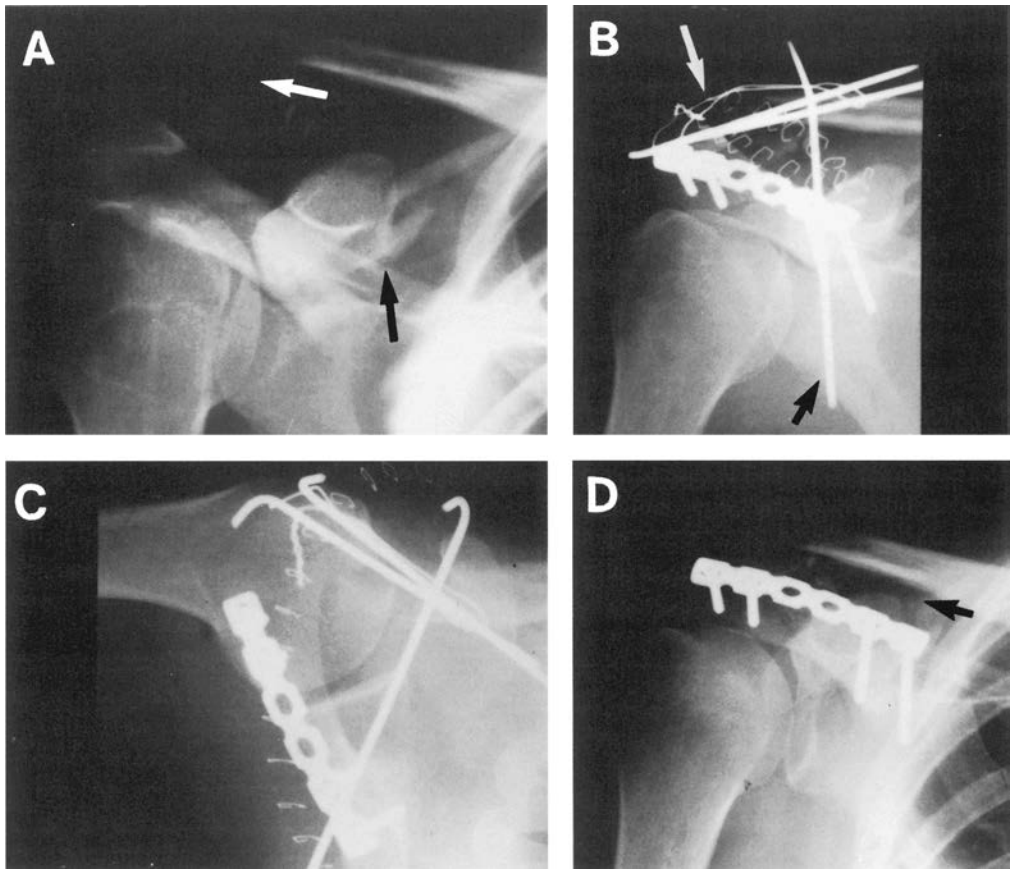

Figure 26-45 A patient who sustained a fracture of the base of the coracoid process, a type I fracture of the distal clavicle, and a nondisplaced fracture of the acromion: **(A)** a preoperative anteroposterior (AP) radiograph showing severe displacement at the distal clavicular fracture site (*white arrow*) and the coracoid fracture (*black arrow*); **(B,C)** postoperative AP and axillary radiographs showing reduction and stabilization of the clavicular fracture using a tension band construct (*white arrow*) and reduction and stabilization of the coracoid process fracture by means of a transfixing K-wire passed into the glenoid process (a cannulated interfragmentary screw would now be used; the acromial fracture was plated, *black arrow*); and **(D)** AP radiograph taken 3 months postoperatively following removal of hardware showing the distal clavicle and coracoid fractures to be healed and the superior shoulder suspensory relationships reestablished (*arrow*).

acromial fracture requiring ORIF of both injury sites.[189]

A segmental fracture of the acromion. As with segmental fractures of other bones, two acromial disruptions create an unstable intermediate segment. If displacement at one or both sites is unacceptable and a nonunion likely, ORIF through a posterolateral approach using plate fixation and/or a tension band construct is performed (Fig. 26-46).

Type III, Vb, and Vc Glenoid Cavity Fractures and Another Disruption of the Superior Shoulder Suspensory Complex

See Fig. 26-30.

ISOLATED FRACTURES OF THE CORACOID PROCESS

Classification and Mechanism of Injury

The coracoid process develops from two constant ossification centers: one at its base, which also forms the upper third of the glenoid process; and one that becomes its main body. In addition, there are at least two inconstant centers: one at its angle where the coracoclavicular ligament attaches and one at its tip where the conjoined tendon is located. The regions at which the centers finally unite are relatively weak, especially in young adults, making fractures more likely to occur when direct or indirect forces are applied.[137,159] The coracoid process, which has been called the "lighthouse of the anterior shoulder," has three basic functions: (a) it serves as a point of attachment

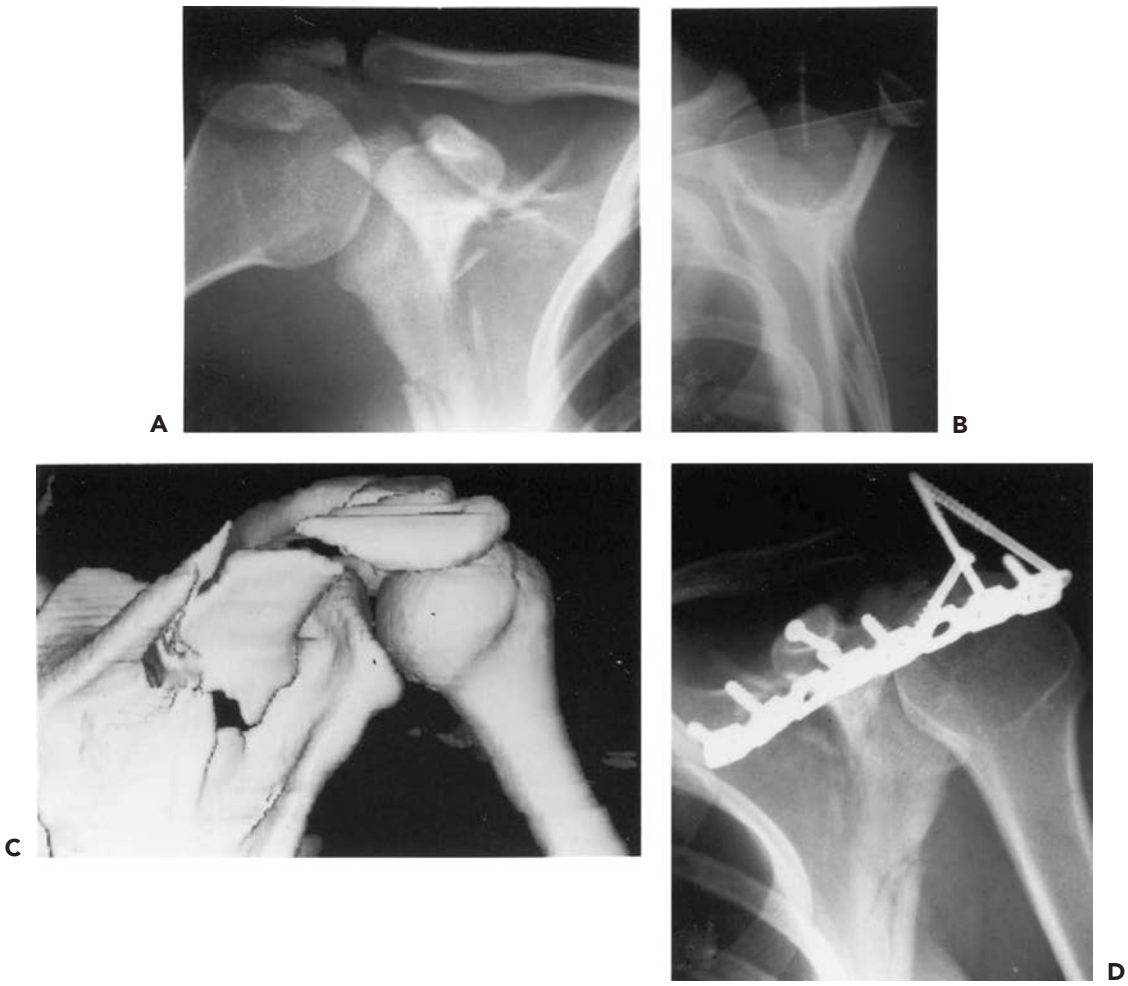

Figure 26-46 Segmental fracture of the acromial process as well as a comminuted fracture of the scapular body: **(A)** preoperative anteroposterior (AP) radiograph; **(B)** preoperative lateral scapular radiograph; **(C)** preoperative three-dimensional computed tomographic radiograph; and **(D)** postoperative AP radiograph showing the acromial fractures reduced and stabilized with a malleable reconstruction plate. (From Goss TP. The scapula: coracoid, acromial, and avulsion fractures. *Am J Orthop* 1996;25:106, with permission.)

for a number of musculotendinous and ligamentous structures (Fig. 26-47), (b) it provides the glenohumeral joint with some anterosuperior stability, and (c) it is an integral part of the SSSC (the scapular–clavicular linkage system), serving as one of the bony components of the clavicular–CC ligamentous–coracoid [C-4] linkage. Coracoid fractures may be caused by a blow from the outside, contact with a dislocating humeral head, or indirect forces applied through the musculotendinous and ligamentous structures at their attachment sites (avulsion fractures fall into this category[27,41,172]). Fatigue fractures have also been described.[21,173] Nontraumatic causes include (a) fractures associated with coracoclavicular tape fixation used in AC joint reconstructions[136] and (b) fractures associated with massive rotator cuff tears. Despite the relative scarcity of isolated coracoid fractures, several types have been described.[39,64] These injuries can be anatomically divided into (a) fractures of the tip of the coracoid (see Fig. 26-43D), (b) fractures between the CC and CA ligaments, and (c) fractures at the base of the coracoid process. Fractures of the coracoid tip are avulsion injuries—the result of an indirect force applied to the conjoined tendon and concentrated over its attachment to the coracoid process (see Fig. 26-43D). Fractures between the CC ligament and the CA ligament may be the result of either a direct or an indirect force.[30] The distal coracoid fragment is usually significantly displaced, drawn distally by the pull of the conjoined tendon and rotated laterally by the tethering effect of the coracoacromial ligament (Fig. 26-48). Fractures of the base of the coracoid process are the most common coracoid fractures. They may be caused by a direct blow from the outside or a dislocating humeral head.[13] Avulsion fractures caused by strong traction forces are also possible.[120,160,167]

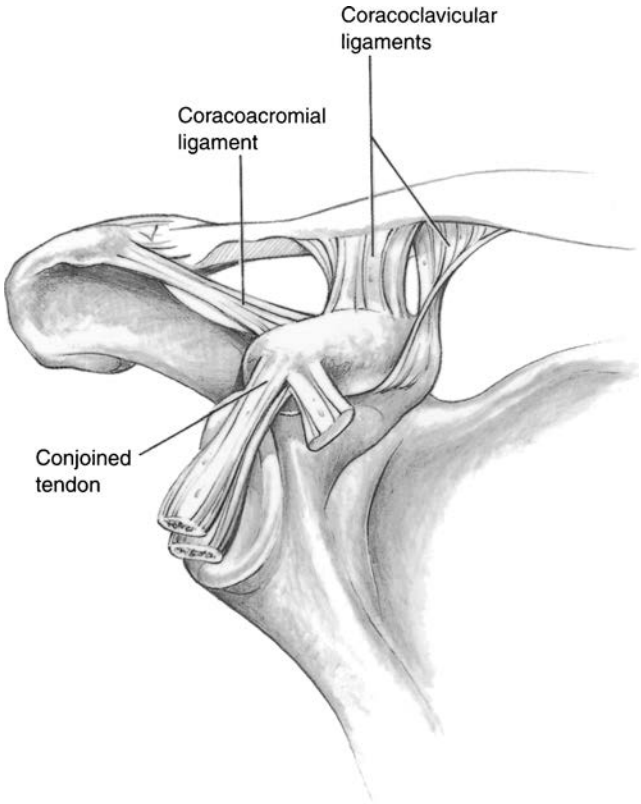

Figure 26-47 Illustration showing the coracoid process as the point of attachment for the conjoined tendon, the coracoacromial ligament, and the coracoclavicular ligament.

Diagnosis

Diagnosis is ultimately radiographic. True AP and axillary projections of the glenohumeral joint will disclose, or at least suggest, the presence of most coracoid fractures. Because of the complex bony anatomy in the area, "tilt"–oblique views,[45,52] or even CT scanning,[99] may be necessary to detect and accurately define some fractures as well as injuries to adjacent bony and articular structures. Accessory ossification centers and epiphyseal lines may complicate the evaluation. A weight-bearing AP view of the shoulder should be obtained if there is concern over the integrity of the scapular–clavicular linkage.

Management

Fractures of the Coracoid Tip

Displacement may be quite marked, but nonsurgical treatment is usually in order.[205,209] ORIF has been advocated in athletes, especially those participating in sports that require optimal upper extremity function, and in persons who perform heavy, manual, physical work. Wong-Chung and Quinlan described a case in which a fractured coracoid tip prevented the closed reduction of an anterior glenohumeral dislocation.[204] Late surgical treatment may be necessary if the displaced bony fragment causes irritation of the surrounding soft tissues.[14] Surgical management (either acute or late if a symptomatic nonunion occurs[49]) takes two forms: (a) ORIF of the bony fragment if sufficiently large and noncomminuted, or (b) excision of the fragment and suture fixation of the conjoined tendon to the remaining coracoid process (Fig. 26-49).

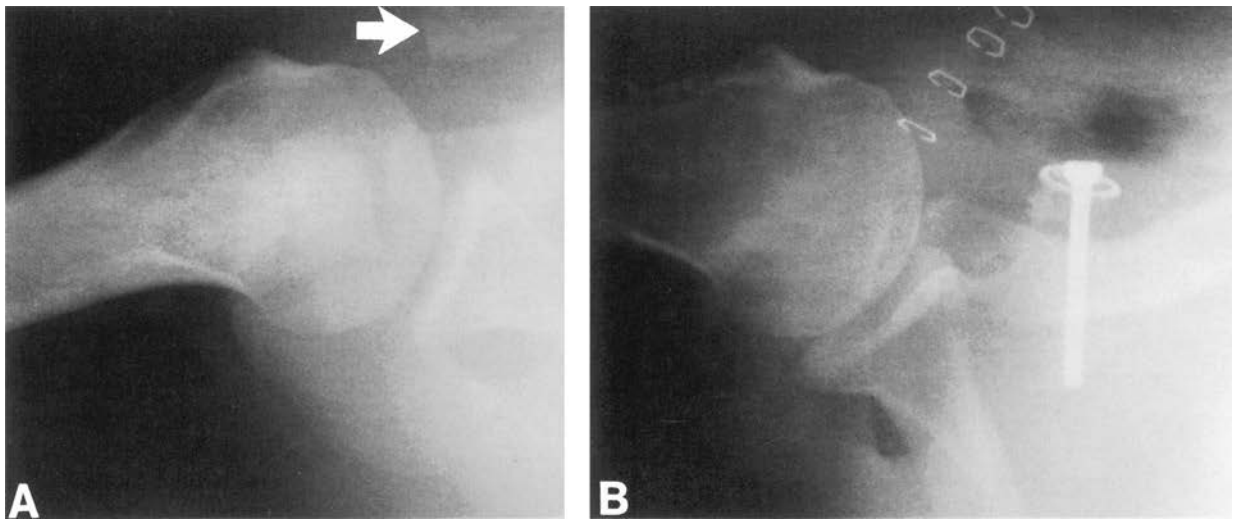

Figure 26-48 A patient who sustained a fracture of the distal coracoid process between the coracoclavicular ligament and the coracoacromial ligament: **(A)** preoperative axillary radiograph showing the significantly displaced distal portion of the coracoid process (*arrow*); and **(B)** postoperative axillary radiograph showing the bony fragment reduced and stabilized using an interfragmentary screw with a ligament washer.

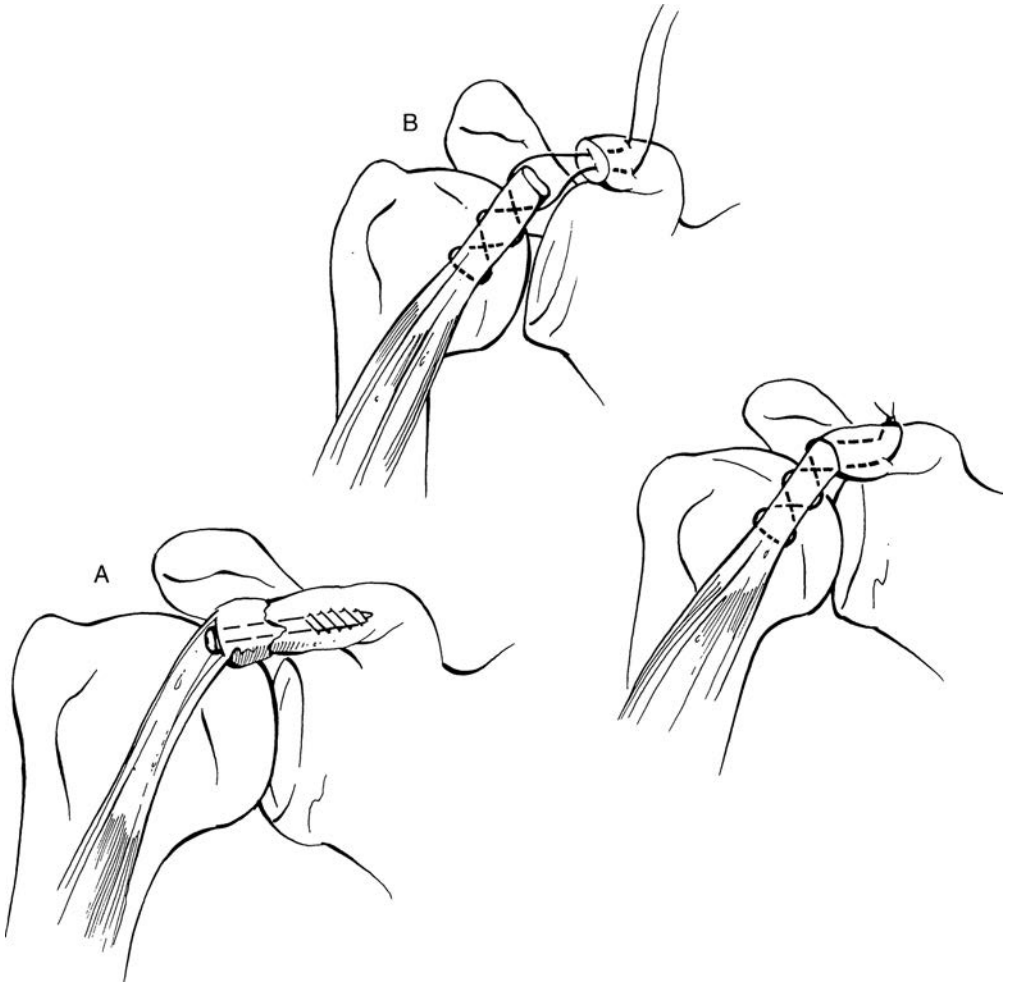

Figure 26-49 Illustrations showing two surgical techniques for managing coracoid process fractures: **(A)** interfragmentary screw fixation (if the fragment is sufficiently large and noncomminuted); and **(B)** excision of the distal fragment (if small and/or comminuted) and suture fixation of the conjoined tendon to the remaining coracoid process.

Fractures Between the Coracoclavicular Ligament and the Coracoacromial Ligament

Initial treatment may be nonsurgical or surgical, following the same reasoning described for significantly displaced avulsion fractures of the coracoid tip. Because the fragment is larger, however, symptomatic irritation of the local soft tissues is more frequent and late surgical management is more likely. The size of the fragment generally makes it amenable to interfragmentary screw fixation. Cannulated 3.5- and 4.0-mm compression screws are particularly useful. As with all coracoid process fractures managed surgically, an anterior deltopectoral interval approach is used, and the rotator interval is opened as need be for optimal exposure of the fracture site (see Fig. 26-29).

Fractures of the Base of the Coracoid Process

These injuries are generally minimally displaced owing to the stabilizing effect of the surrounding soft tissues, in particular the coracoclavicular ligament (see Fig. 26-26). Symptomatic nonsurgical care is usually sufficient and union occurs within 6 weeks.[50,205,209] McLaughlin felt that fibrous union is not uncommon, but is rarely associated with discomfort.[129] If symptomatic, however, bone grafting and compression screw fixation must be considered. This is accomplished by an anterior deltoid-splitting approach, opening the rotator interval for adequate exposure.

ISOLATED FRACTURES OF THE ACROMIAL PROCESS

Classification and Mechanism of Injury

The acromial process is formed from two ossification centers: one for most of its anterior end and one for its posterolateral tip (its base is actually an extension of the scapular body and spine). The acromial process has four

basic functions: (a) it provides one side of the acromioclavicular articulation; (b) it serves as a point of attachment for various musculotendinous and ligamentous structures; (c) it lends posterosuperior stability to the glenohumeral joint; and (d) it is an important component of the SSSC (the scapular–clavicular linkage).

Acromial fractures may be caused by a direct blow from the outside or a force transmitted via the humeral head. Avulsion fractures are the result of purely indirect forces. Even stress and fatigue fractures have been reported.[197] These injuries may be minimally or significantly displaced.

Kuhn et al. proposed a classification scheme that drew some discussion.[101,102,134,186] They emphasized the need for ORIF if an acromial fragment is displaced inferiorly by the pull of the deltoid muscle, compromising the subacromial space, thereby resulting in impingement symptoms and interfering with rotator cuff function.[100]

Diagnosis

Diagnosis is radiographic. True AP and lateral views of the scapula and a true axillary projection of the glenohumeral joint will detect most acromial fractures. The presence of an os acromionale may complicate the evaluation. On occasion, however, CT scanning may be needed to precisely define the injury and disclose involvement of adjacent bony and/or articular structures. A weight-bearing AP projection is obtained if a disruption of the scapular–clavicular linkage is suspected. Arthrography to evaluate the rotator cuff should be considered if the acromial fracture is the result of traumatic superior displacement of the humeral head or chronic superior migration of the humeral head, as seen in longstanding rotator cuff disease (e.g., cuff tear arthropathy with a stress fracture of the acromion). Madhaven et al. described the case of an individual with an acromial fracture associated with an avulsed subscapularis tendon.[118]

Management

Although significantly displaced isolated nonavulsion acromial fractures have been described, the vast majority are nondisplaced or minimally displaced. Symptomatic, nonoperative care will reliably lead to union and a good to excellent functional result. If surgical reduction and stabilization is necessary, a tension band construct is usually chosen for distal disruptions where the acromial process is quite thin, whereas 3.5-mm malleable reconstruction plates are usually chosen for more proximal injuries (Fig. 26-50).[51] Symptomatic acromial nonunion, although uncommon, has been reported in the literature.[54] No more than a small fragment should ever be excised. The presence of a large fragment requires surgical stabilization and bone grafting.[64]

Significantly displaced avulsion fractures may occur wherever musculotendinous or ligamentous structures (the deltoid and trapezius muscles as well as the coracoacromial and acromioclavicular ligaments) attach to the acromion. Two varieties have been described in the literature:

1. An avulsion fracture of the origin of the deltoid muscle.[81] The deltoid is the most important dynamic structure about the glenohumeral joint. Consequently, if a fracture is significantly displaced, surgical reattachment is indicated. This is rather simple and accomplished with multiple nonabsorbable sutures passed in a horizontal mattress fashion through the deltoid and drill holes made along the periphery of the acromial process.

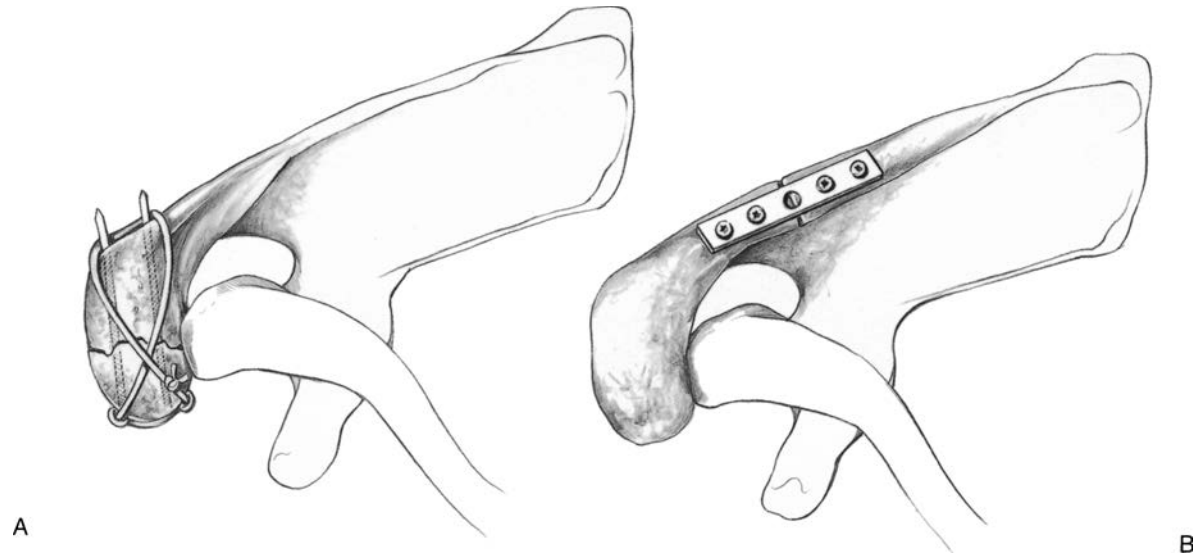

Figure 26-50 Illustrations showing two surgical techniques for managing fractures of the acromial process: **(A)** a tension band construct (most appropriate for fractures through the distal portion of the acromion); and **(B)** plate–screw fixation (most appropriate for proximal fractures).

2. An avulsion fracture through the main body of the acromion.[139,163] Two cases have been described. Both were caused by significant forces transmitted through the surrounding musculature, especially the deltoid. One was treated nonsurgically, whereas the second was managed surgically. Bony union and satisfactory return of function was realized in both.

AVULSION FRACTURES OF THE SCAPULA

Classification and Mechanism of Injury

Most of the scapula is formed by intramembranous ossification, but it also has at least six or seven secondary ossification centers. The scapula has three basic functions: (a) it provides a semistable, yet fairly mobile, platform for the humeral head and the upper extremity to work against; (b) it serves as a point of attachment for a variety of soft tissue structures (musculotendinous and ligamentous; Fig. 26-51); and (c) it takes part in three articulations: the glenohumeral joint, the acromioclavicular joint, and the scapulothoracic articulation. As with other scapular fractures, avulsion injuries are uncommon. By definition, they are caused by indirect forces applied to the surrounding musculotendinous and ligamentous soft tissues and concentrated at their scapular attachment sites. Three mechanisms are possible: (a) severe, uncontrolled muscular contraction caused by electroconvulsive treatment, electric shock, or epileptic seizure;[16,33,77,81,92,96,123,157,176,185,198] (b) strong indirect forces associated with a single traumatic event;[17,31,208] and (c) gradual bony failure caused by lesser but repetitive traumatic events (stress[22] or fatigue[197] fractures). The potential varieties are numerous and many have been described.

Diagnosis

True AP and lateral projections of the scapula and a true axillary view of the glenohumeral joint constitute the diagnostic trauma series. This may be supplemented as need be by CT scanning and a weight-bearing view of the shoulder complex.

Management

Treatment is by and large symptomatic/nonoperative; however, if the fracture is significantly displaced and of functional importance, surgical ORIF must be considered.[64] The following are examples of those injuries that are managed quite successfully nonoperatively:

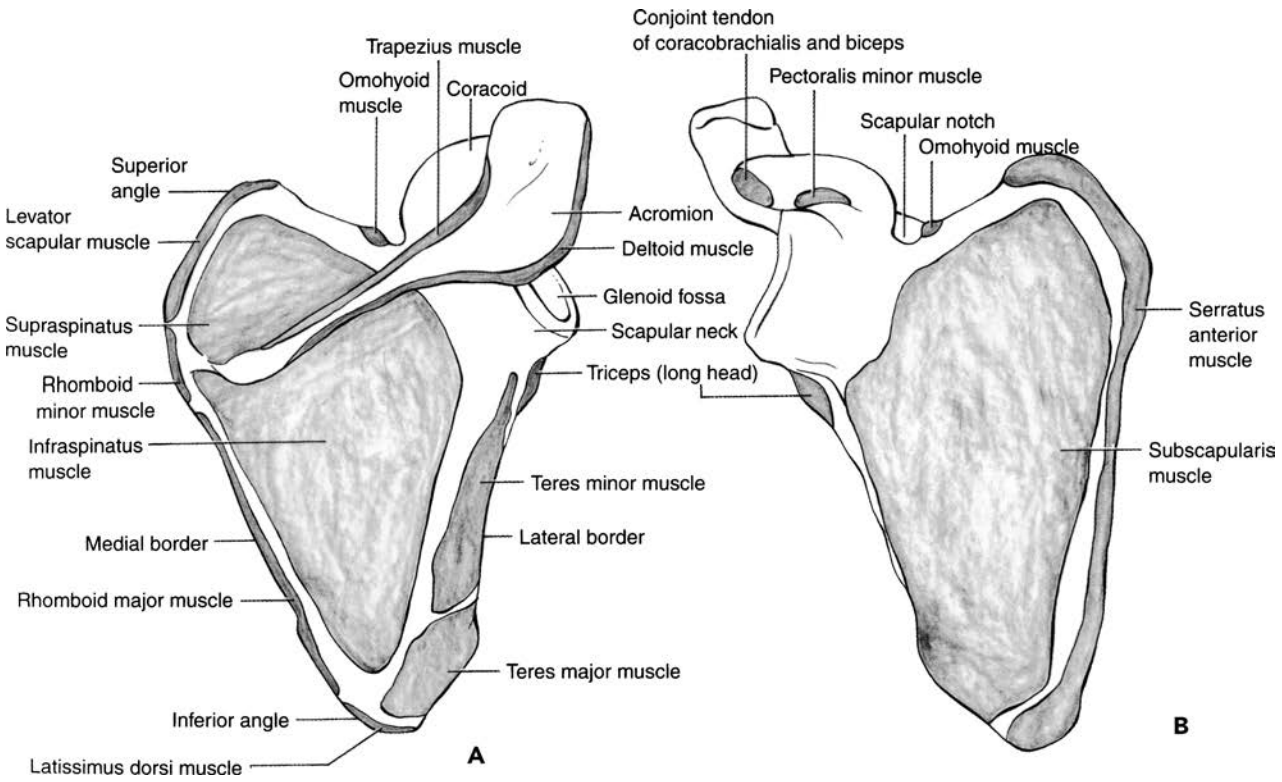

Figure 26-51 Illustrations showing the many scapular musculotendinous and ligamentous attachment sites: **(A)** posterior or dorsal surface of the scapula; and **(B)** anterior or costal surface of the scapula.

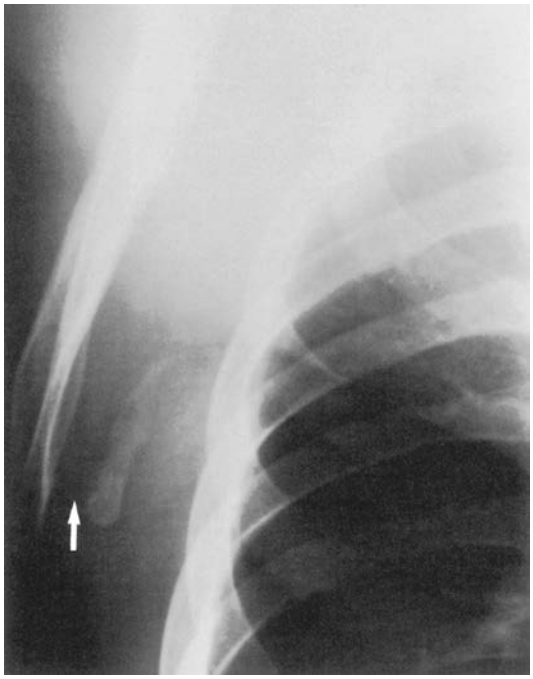

Figure 26-52 A true lateral radiograph of the scapula showing a severely displaced avulsion fracture of the inferior angle (the insertion of a serratus anterior muscle).

- Avulsion fracture of the superior angle of the scapula[54] (insertion of the levator scapulae; see Fig. 26-43A)
- Avulsion fracture of the superior border of the scapula. This injury is often associated with a fracture of the base of the coracoid process and an AC joint disruption.[7,10] Some have attributed the fracture to indirect stresses applied via the omohyoid muscle,[4,89,201] whereas others have considered it an extension of the coracoid fracture.[203]
- Avulsion fracture through the body of the scapula caused by an accidental electric shock[81,185]
- Avulsion fracture of the infraglenoid tubercle (origin of the long head of the triceps) and the lateral border of the scapula (origin of the teres major and minor muscles[81])
- Avulsion fracture of the infraspinatus fossa (origin of the infraspinatus muscle[10] [this must be differentiated from a developmental anomaly [162]])

The following are examples of avulsion fractures that, at the very least, deserve operative consideration:

- Avulsion fracture of the lateral margin of the acromial process (origin of the deltoid muscle;[81] see Fig. 26-43B)
- Avulsion fracture of the distal coracoid process (attachment of the conjoined tendon; see Fig. 26-47)
- Avulsion fracture of the superior angle of the coracoid process (attachment of the coracoclavicular ligament[137]) or the base of the coracoid process in association with a disruption of the acromioclavicular joint (see Fig. 26-43C)
- Avulsion fracture of the inferior angle of the scapula (Fig. 26-52; insertion of the serratus anterior muscle):[24] If significantly displaced, this rare injury causes winging of the scapula and can significantly compromise shoulder function—surgical ORIF is indicated.[75] (This may be the fracture Longabaugh described in 1924.[117])
- Avulsion fracture of the supraglenoid tubercle (origin of the long head of the biceps muscle) indicative of a displaced, possibly symptomatic SLAP lesion[84]
- Avulsion fracture through the body of the acromion: Two cases have been described. Both were caused by a significant force transmitted through the surrounding musculature, especially the deltoid. One was treated nonsurgically whereas the second was managed surgically. Bony union and satisfactory return of function were realized in both.[139,163]

SCAPULOTHORACIC DISSOCIATION

Lateral Dislocation of the Scapula

Scapulothoracic dissociation is a rare traumatic disruption of the scapulothoracic articulation caused by a severe direct force over the shoulder accompanied by traction applied to the upper extremity.[3,34,35,62,82,90,95,109,140,153,170,191] Although the skin remains intact, the scapula is torn away from the posterior chest wall, prompting some to call this injury a "closed traumatic forequarter amputation." Because of the violent forces involved, any of the three bones in the shoulder complex (the clavicle, the scapula, and the proximal humerus) may be fractured, and any of the remaining three articulations (the glenohumeral, AC, and sternoclavicular joints) may be disrupted. Neurovascular injury is common. Disruption of the subclavian and axillary artery (most frequently the former) and a complete or partial disruption of the brachial plexus are well described. In addition, there may be severe damage to the soft tissue supporting structures, especially those that run from the chest wall to the scapula or the chest wall to the humerus. Complete and partial tears of the trapezius, levator scapulae, rhomboids, pectoralis minor, and latissimus dorsi all have been reported. A presumptive diagnosis is based on a history of violent trauma in the presence of massive soft tissue swelling over the shoulder girdle. A pulseless upper extremity, indicating a complete vascular disruption, and a complete or partial neurologic deficit, indicating injury to the brachial plexus, are quite suggestive. Significant lateral displacement of the scapula seen on a nonrotated chest radiograph confirms the diagnosis. As with all rare injuries, awareness of the clinical entity is critical to making the correct diagnosis. Treatment recommendations have focused on care of the accompanying neurovascular injury. If the vascular integrity of the extremity is in question, an

emergency arteriogram is performed followed by surgical repair if necessary. The brachial plexus is explored at the same time. If a neurologic deficit is present, electromyographic testing is performed 3 weeks after injury to determine the extent of damage and to assess the degree of recovery, if any. Cervical myelography can be performed at 6 weeks. If nerve root avulsions or a complete neurologic deficit is present, the prognosis for a functional recovery is poor.[207] Partial plexus injuries, however, have a good prognosis and most patients achieve complete recovery or regain functional use of the extremity. If some portions of the plexus are intact and others are disrupted, neurologic repair is a possibility. Late reconstructive efforts are guided by the degree of neurologic return, and musculotendinous transfers are performed as needed. Care of the surrounding soft tissue supportive structures (musculotendinous and ligamentous) has been nonoperative, consisting of immobilization of the shoulder complex for 6 weeks to allow healing, followed by a closely monitored physical therapy program designed to restore range of motion initially, followed by strength. Magnetic resonance imaging (MRI) of the involved area now offers the ability to visualize important disruptions that may be amenable to surgical repair.

Injury to the sternal–clavicular–acromial linkage (a disruption of the sternoclavicular or AC joint or a fracture of the clavicle) is frequently, if not invariably, present for posterolateral displacement of the scapula to occur. This component of scapulothoracic dissociation has been largely ignored, both in terms of diagnosis and treatment. Of the three possible disruptions, a fracture of the clavicle seems to be the most common. This constitutes a very unstable anatomic situation—the clavicular injury allows maximal displacement of the scapula, whereas the unstable scapulothoracic articulation often leads to significant displacement at the clavicular fracture site. Consequently, surgical ORIF of the clavicle (screw plate fixation for fractures of the middle third and tension band fixation for fractures of the distal third) should be considered (a) to avoid a delayed union or a nonunion; (b) to restore as much stability as possible to the shoulder complex to avoid adverse long-term functional consequences; and (c) to protect the brachial plexus and subclavian and axillary vessels from further injury caused by tensile forces (Fig. 26-53). The upper extremity is protected for 6 weeks while a progressive rehabilitation program is instituted. Uhl and Hospeder described a lesser injury characterized by progressive subluxation of the scapulothoracic articulation and a clavicle fracture (no neurovascular involvement) requiring ORIF of the latter.[192] Similar therapeutic reasoning would apply to scapulothoracic dissociations accompanied by a disruption of the AC or the sternoclavicular joint, although in the latter, metallic fixation devices must be avoided.

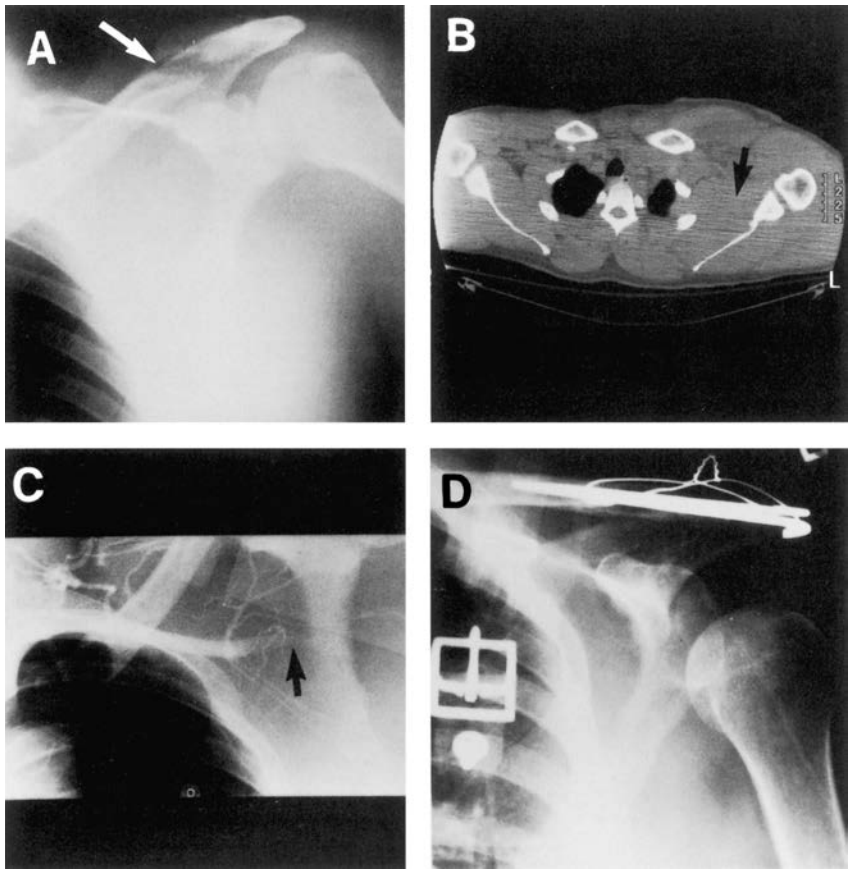

Figure 26-53 A patient who sustained a left scapulothoracic dissociation: **(A)** preoperative anteroposterior (AP) radiograph showing significant lateral displacement of the scapula and a significantly displaced fracture of the distal clavicle; **(B)** computed tomographic image showing significantly increased distance between the left scapula and the rib cage as compared with the opposite (uninjured) side; **(C)** arteriogram showing disruption of the subclavian artery; and **(D)** postoperative AP radiograph showing reduction and stabilization of the distal clavicle fracture (and secondarily the scapulothoracic articulation) by means of a tension band construct.

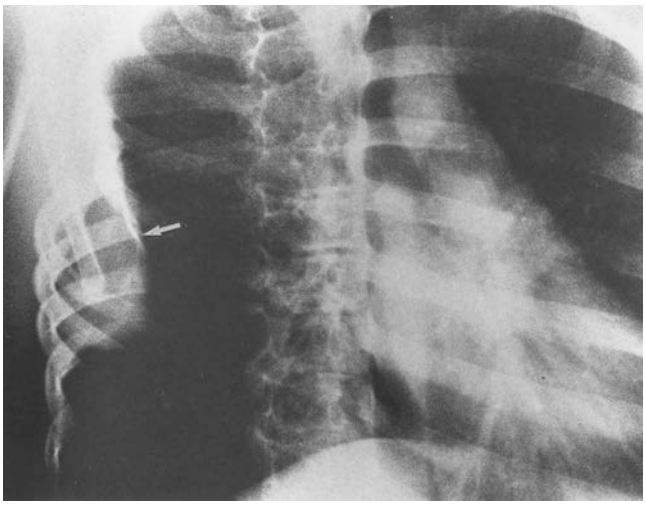

Figure 26-54 A right anterior oblique radiograph taken of a patient who sustained an intrathoracic dislocation of his scapula. (From Nettrour LF, Krufty LE, Mueller RF, et al. Locked scapula: intrathoracic dislocation of the inferior angle. *J Bone Joint Surg Am* 1972;54:413, with permission. Copyright is owned by The Journal of Bone and Joint Surgery, Inc.)

Intrathoracic Dislocation of the Scapula

Intrathoracic dislocation of the scapula is extremely rare. Cases associated with minimal violence and a preexisting factor (generalized laxity or locking osteochondroma) have been described. The scapula becomes locked within the posterior aspect of one of the upper intercostal spaces (Fig. 26-54).[144] A second type is caused by more violent trauma, either a direct blow applied over the posterior aspect of the scapula or a violent outward distractive force applied to the arm. The scapular body is displaced anterolaterally, and its inferior angle becomes lodged between the ribs. The severity of the event usually causes a fracture of the scapula and ribs as well as marked disruption of the periscapular soft tissues.[97] Pell and Whipple described an individual who sustained a fracture of the scapular body with the inferior angle locked within the fourth intercostal space that was managed successfully by closed reduction.[156] The diagnosis may be missed initially because of associated injuries and/or inadequate radiographic projections. Displacement of the scapula may not be readily apparent on routine AP chest radiographs. Tangential views (anterior oblique or lateral scapular projections[144]) or a chest CT may be necessary to establish the diagnosis.

Acute injuries are reduced in a closed fashion under anesthesia by hyperabducting the arm and manually manipulating the scapula (rotating the scapula forward and pushing it backward[32]) while steady traction is applied to the arm. The reduction is usually stable, but securing the scapula to the chest wall with adhesive tape and immobilizing the arm in a sling and swathe are advisable for comfort and soft tissue healing.[97] The dressing and immobilizer are changed at 7 to 10 days and discontinued 2 weeks thereafter. Unprotected and progressive functional use of the shoulder and arm is then permitted and encouraged. In long-standing cases, open reduction with soft tissue detachment may be necessary followed by reconstruction of the periscapular tissues to reestablish stability.[144]

COMPLICATIONS

The most significant complications associated with scapular fractures are those that result from accompanying injuries to adjacent and distant osseous and soft tissue structures. Because of the severe traumatic forces frequently involved, these patients have an average of 3.9 additional injuries, with the most common sites being the ipsilateral shoulder girdle,[87] upper extremity, lung, and chest wall. Twenty-five to 45% of patients have accompanying rib fractures; 15% to 40% have fractures of the clavicle; 15% to 55% have pulmonary injuries[130] (hemopneumothorax, pulmonary contusion, etc.); 12% have humeral fractures; and 5% to 10% sustain injuries to the brachial plexus and peripheral nerves.[34,188] Fractures of the skull are found in approximately 25% of patients, cerebral contusions in 10% to 40%, central neurologic deficits in 5%, tibial and fibular fractures in 11%, major vascular injuries in 11%,[70,182,188] and splenic injuries that result in splenectomy in 8%. Two percent of these patients die. A variety of other cardiothoracic, genitourinary, and gastrointestinal injuries have been described. Stephens et al. reviewed 173 blunt trauma patients (92 with scapular fractures and 81 controls) and concluded that scapular fractures were not a significant marker for greater mortality or neurovascular morbidity.[184] Veysi et al. also showed no increase in mortality; however, they did confirm significantly greater injury severity scores (ISSs) in trauma patients sustaining scapular fractures.[195]

Complications related to the scapular fractures themselves are relatively uncommon. Nonunion, although possible, is quite rare.[25,40,67,93] Malunion can occur in a variety of forms, depending on the particular fracture type. Malunion of a scapular body fracture is generally well tolerated; however, painful scapulothoracic crepitus has been described on occasion. Fractures of the glenoid cavity may result in symptomatic glenohumeral degenerative joint disease. Shoulder instability can occur following significantly displaced fractures of the glenoid neck (angulatory displacement) and fractures of the glenoid rim. Fractures of the glenoid neck with significant translational displacement may give rise to glenohumeral pain and dysfunction related to altered mechanics of the surrounding soft tissues.

Various complications associated with surgical management are possible, for example, infection (both superficial

and deep), intraoperative neurovascular injury, and loss of fixation owing to poor surgical technique. A poorly supervised postoperative physiotherapy–rehabilitation program may lead to unnecessary postoperative shoulder stiffness.

Finally, complications related to poor patient compliance may occur. Examples would include suboptimal shoulder range of motion caused by unwillingness to follow the postoperative physiotherapy program and hardware failure associated with failure to observe postoperative instructions.

ANATOMY

Development

In the newborn infant, the spherical proximal humeral epiphysis contains the primary ossification center and the two secondary centers that will form the greater and lesser tuberosities. The primary ossification center appears within 4 to 6 months of birth, the greater tuberosity at approximately 3 years, and the lesser tuberosity by 5 years. These coalesce between 4 and 7 years and fuse to the shaft between 17 and 20 years, with earlier physeal closure in girls than in boys[44,72,112] (Fig. 27-1).

The physeal plate of the proximal humerus is concave inferiorly and almost spherical, with its apex posterior and medial to its center. This asymmetrical metaphyseal dome and the strong thick attachment of periosteum along the posterior surface explain why anterior, rather than posterior,

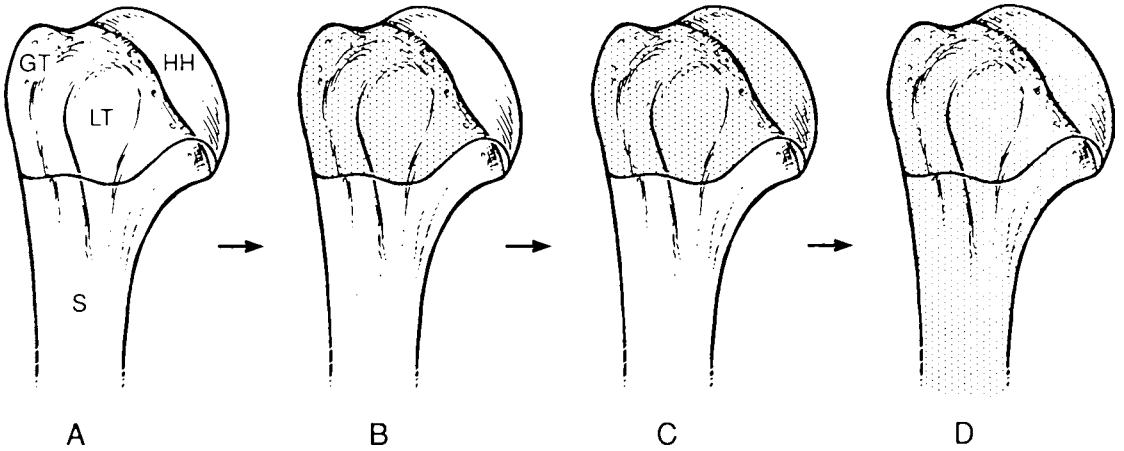

Figure 27-1 **(A)** The humeral head (*HH*) ossification center appears at 4 to 6 months of age, the greater tuberosity (*GT*) at 1 to 3 years of age, the lesser tuberosity (*LT*) at 3 to 5 years of age. **(B)** Coalescence of the GT with the LT occurs at approximately 3 years of age; **(C)** coalescence of the primary ossification center (*HH*) with the greater tuberosity and lesser tuberosity between 4 and 7 years of age; and **(D)** fusion to the shaft between 17 and 20 years of age.

displacement of the metaphysis occurs in fractures (Fig. 27-2). Dameron and Reibel demonstrated, in stillborn infants, that the metaphysis could easily be displaced anteriorly at the epiphyseal plate with the humerus extended and adducted; yet posterior displacement was difficult to achieve.[44] Approximately 80% of humeral growth occurs at the proximal physis, giving this region great remodeling potential following fracture.[49]

Vascular and Neurologic Anatomy

The proximity of the nerves of the brachial plexus and vascular structures to the proximal humerus puts them at risk of injury from proximal humerus fractures and dislocations, as well as during surgical approaches.

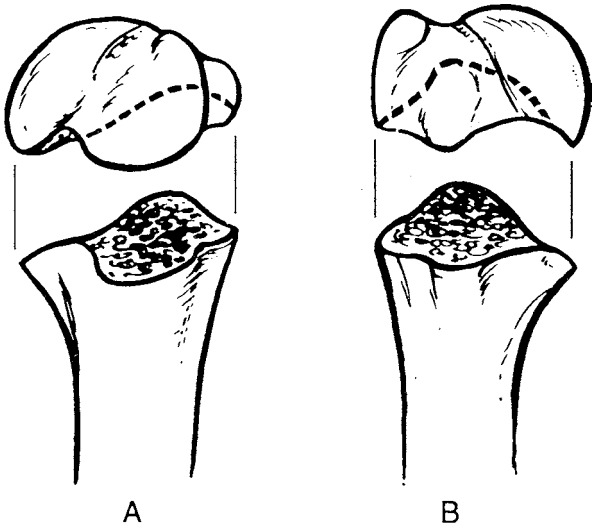

Figure 27-2 **(A)** Lateral and **(B)** anteroposterior view of the proximal humerus, demonstrating the asymmetrical physeal plate and metaphyseal dome with an apex posterior and medial to its center.

Vascular Anatomy

The rich vascular anatomy of the proximal humerus has been further delineated in the recent literature to help explain osteonecrosis of the humeral head. Laing's[93] and Gerber et al.'s[60] studies showed that the anterior lateral branch of the anterior humeral circumflex artery is the primary blood supply to the proximal humerus. The anterior humeral circumflex artery arises from the lateral side of the third division of the axillary artery approximately 1 cm distal to the inferior border of the pectoralis minor muscle (just above the teres major muscle) and courses laterally behind the coracobrachialis to reach the surgical neck of the humerus at the lower border of the subscapularis.[24,60,118] The anterolateral branch sends twigs to the lesser tuberosity, crosses under the biceps tendon, and then arches superiorly adjacent to the lateral side of the intertubercular groove. The vessel then penetrates bone at the cephalad portion of the transition from greater tuberosity to intertubercular groove, staying distal to the position of the old epiphysial plate. The intraosseous portion of this artery has been named the arcuate artery by Laing because of its posteromedial course after entering the humeral head. Multiple branches radiate to supply the subchondral bone of the humeral head[24] (Fig. 27-3).

The importance of both the extra- and intraosseous arterial anastomoses has recently been described. Laing noted abundant *extraosseous* anastomoses between the anterior humeral circumflex artery and posterior humeral circumflex arteries, as well as with the thoracoacromial, subscapular, suprascapular, and profunda brachii arteries.[93] The anterior and posterior circumflex vessels connect with the

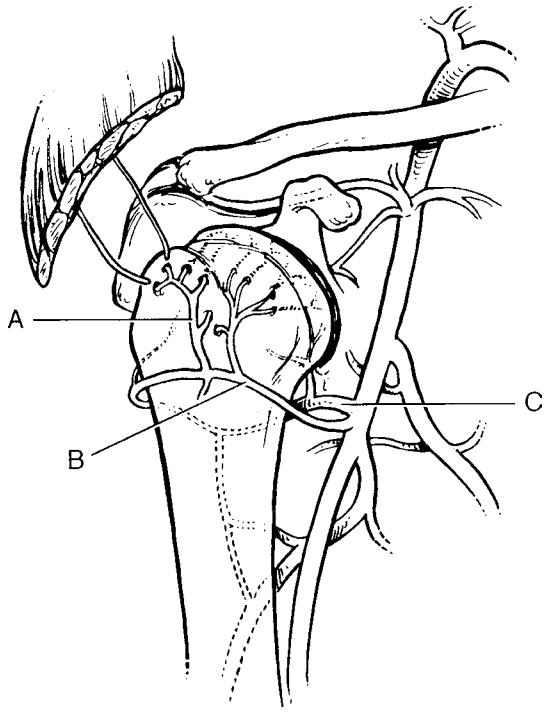

Figure 27-3 The rich vascular anatomy of the proximal humerus: **(A)** The anterior lateral branch of **(B)** the anterior humeral circumflex artery is the primary blood supply. **(C)** The posterior humeral circumflex artery arises close to the anterior humeral circumflex and gives off posterior medial branches to help supply the head.

profunda brachii artery through ascending deltoid vessels. Anastomosis of the profunda brachii artery occurs with the radial (anterior) and medial (posterior) collaterals. This rich collateral circulation about the shoulder can provide adequate circulation to maintain viability of the extremity despite axillary artery disruption after, for example, a dislocation.[53] Gerber et al. also identified abundant extraosseous anastomoses; however, vascularization of the entire humeral head was possible only through the anterior lateral branch of the anterior humeral circumflex artery. Laing noted inconsistent contributions to the humeral head from both the lesser and greater tuberosities.[93] Gerber et al. could not confirm that vessels of the rotator cuff directly vascularized the underlying bone.[60] The posterior humeral circumflex artery arises closely juxtaposed to the anterior humeral circumflex artery and is much larger in diameter.[118] Gerber found that the posteromedial vessels arising from the posterior humeral circumflex artery supplied the posterior portion of the greater tuberosity and a small posterior inferior part of the head. The vessels then formed an anastomosis to the arcuate artery on and within the greater tuberosity and on the joint capsule.[60] Brookes et al. demonstrated that these posteromedial vessels pass beneath the humeral capsular attachment (which at this site extends from 1 cm onto the surgical neck) and run toward the humeral head before entering the bone just below the articular margin.[24]

The study by Brookes et al. emphasized the importance of the *intraosseous* anastomoses and, unlike Gerber et al.'s study, showed that the humeral head could be completely profused after ligation of the anterior humeral circumflex artery at its entry site into the humeral head. They found large metaphyseal arteries that passed through the fused growth plate to anastomose with the arcuate artery in six of the eight normal and control specimens. In addition, significant intraosseous anastomoses occurred between the arcuate artery and the posterior humeral circumflex artery through the posteromedial vessels described in the foregoing and the vessels of the greater and lesser tuberosities.[24]

Knowledge of the vascular anatomy may help predict osteonecrosis of the humeral head. Gerber et al. highlighted the clinical relevance of the intraosseous anastomosis in a case report of a shoulder dislocation with both circumflex arteries interrupted and the extraosseous network compromised. Osteonecrosis did not develop in this patient, suggesting that the *intraosseous* anastomoses are important.[59] A *classic four-part* fracture will lose the blood supply to the head from disruption of the anterior humeral circumflex artery, greater and lesser tuberosities, and any metaphyseal arterial anastomosis. Thus, a high rate of osteonecrosis is expected.[113] Yet, Brookes et al. has shown that perfusion of the humeral head by the arcuate artery may continue if the head fragment includes part of the medial aspect of the upper part of the neck where the posteromedial arteries enter.[24] The so called *four-part valgus-impacted fracture* with limited lateral displacement of the head fragment may retain its vascularity from the posterior medial vessels, thus accounting for the lower incidence of osteonecrosis reported compared with classic four-part fractures.[79] The vascular anatomy also supports the observation that minimally displaced fractures of the anatomic neck, in which the fracture line is at the junction between the articular surface and neck, may be complicated by osteonecrosis as a result of disruption of both the extra- and intraosseous blood supply.[59]

Knowledge of the extensive collateral circulation around the shoulder helps explain the mechanism whereby the viability of the upper extremity can be maintained despite disruption of the axillary artery.

Muscles and Nerves

The proximal humerus is composed of the lesser tuberosity, which is the site of insertion of the subscapularis; the greater tuberosity, which has three facets for insertion of the supraspinatus, infraspinatus, and teres minor; the humeral head; and the shaft. The bicipital groove, a useful surgical landmark, is located between the tuberosities and contains the tendon of the long head of the biceps. The anatomic neck is at the junction of the articular margin of the humeral head and tuberosities, and the surgical neck is the area below the greater and lesser tuberosities.[11,118]

The important muscles and their innervations about the proximal humerus include the subscapularis muscle that arises from the medial two-thirds of the costal surface of the scapula. It is innervated on its costal surface by the upper and lower subscapular nerves. The supraspinatus muscle arises from the medial two-thirds of the bony walls of the supraspinatus fossa of the scapula, and from the dense fascia that covers the muscle. It is innervated from its underside by the suprascapular nerve. This nerve is relatively fixed at its origin from the superior trunk of the brachial plexus and where it passes under the superior transverse scapular ligament. Although rare, a traction injury can occur. The infraspinatus muscle takes its origin from the infraspinatus fossa of the scapula (except its lateral fourth) and from the dense overlying infraspinatus fascia. The suprascapular nerve passes through the notch of the scapular neck and under the inferior transverse scapular ligament to enter the upper part of the infraspinatus muscle.[118]

The teres minor arises from the upper two-thirds of the lateral border of the scapula and from adjacent intermuscular septa. The deltoid takes origin from the lateral third of the clavicle, the anterior and lateral border of the acromion, and the lower lip of the crest of the spine of the scapula. It inserts into the deltoid tuberosity of the humerus. Both of these muscles are supplied by the axillary nerve that arises from the posterior cord of the brachial plexus. An upper branch curves around the posterior surface of the humerus and courses from behind forward on the deep surface of the muscle, approximately 5 cm distal to the lateral border of the acromion, supplying muscular branches throughout its course. A lower branch supplies the teres minor as it ascends onto its lateral and superficial surface.[118] The axillary nerve is relatively fixed at its origin from the posterior cord and as it enters the deltoid. It also passes in close proximity to the inferior capsule, placing it at risk for a traction injury with downward motion of the proximal humerus, as in a dislocation. In fact, it is the most commonly injured nerve, especially from anterior dislocations.[13] This nerve can also be damaged with surgical approaches that split the deltoid fibers beyond 5 cm from the acromial edge or with percutaneous pins inserted from an inferior starting point.[74,97] The pectoralis major muscle has clavicular, sternocostal, and abdominal origins. It is innervated by both the lateral and medial pectoral nerves.[118]

The conjoined tendon is composed of the coracobrachialis and short head of the biceps brachii muscles, which take origin from the coracoid process. They are supplied by the musculocutaneous nerve, which is a branch of the lateral cord of the brachial plexus. This nerve enters the coracobrachialis muscle medially at a mean of 5.6 cm from the coracoid, but may be as close as 3.1 cm.[55] Therefore, retraction during anterior approaches places this nerve at risk for neurapraxia.[74]

The cords of the brachial plexus surround the axillary artery at the level of the humeral neck. Therefore, neurologic injury can result from fractures in this area. These injuries, though uncommon, are encountered more frequently than vascular injuries. Most commonly, they represent either a contusion or mild traction injury with a good prognosis for spontaneous recovery.[173] Electrophysiologic evidence of nerve injury is found in up to 45% of humeral neck fractures and primary dislocations, most commonly involving the axillary nerve, followed by the suprascapular, radial, and musculocutaneous nerves. Older patients and those with clinical evidence of hematomas have more neurologic injuries.[46] Although the neurologic injury does not have the limb-threatening potential of the vascular injury, long-term disabilities are determined by the brachial plexus injury. Although most patients with low-energy injuries recover partially or completely in less than 4 months,[46] permanent motor loss from brachial plexus injury will result in impairment of hand function. Treatment is focused on preservation of hand function, which is more important than shoulder motion.[149]

Muscle Forces

The attachment site of each muscle and the direction of pull are important determinants of fracture deformity and displacement.

The teres minor, infraspinatus, and supraspinatus muscles insert onto the greater tuberosity epiphysis, as does the subscapularis in the area of the lesser tuberosity. When the epiphysis is separated from the metaphysis as in Salter-Harris type I and II fractures, the muscular forces displace it into a position of flexion, abduction, and slight external rotation. The metaphysis often pierces the periosteum anterolateral to the biceps tendon and is pulled anteriorly and medially by the pectoralis major, which attaches to the metaphysis just below its junction with the physeal plate. It is also pulled proximally by the deltoid. The thick posterior periosteum remains intact[44,118] (Fig. 27-4). In the adult, Codman noted that after coalescence of the ossification centers and physeal plate, fractures tend to occur along the lines of the old epiphyseal plate scar, with patterns involving four important segments: the greater and lesser tuberosity, articular surface, and humeral shaft[34] (Fig. 27-5).

Neer emphasized the importance of the muscular attachment sites in determining fracture deformity and displacement[114,115] (Fig. 27-6A). In minimally displaced fractures (one-part), the periosteum, joint capsule, and rotator cuff attachments hold the fracture fragments together.[34] In a displaced surgical neck fracture (two-part), the humeral shaft is displaced forward and medially by the pectoralis major, while the head and attached tuberosities remain in neutral rotation because the rotator cuff is intact and balanced. In displaced fractures of the greater tuberosity

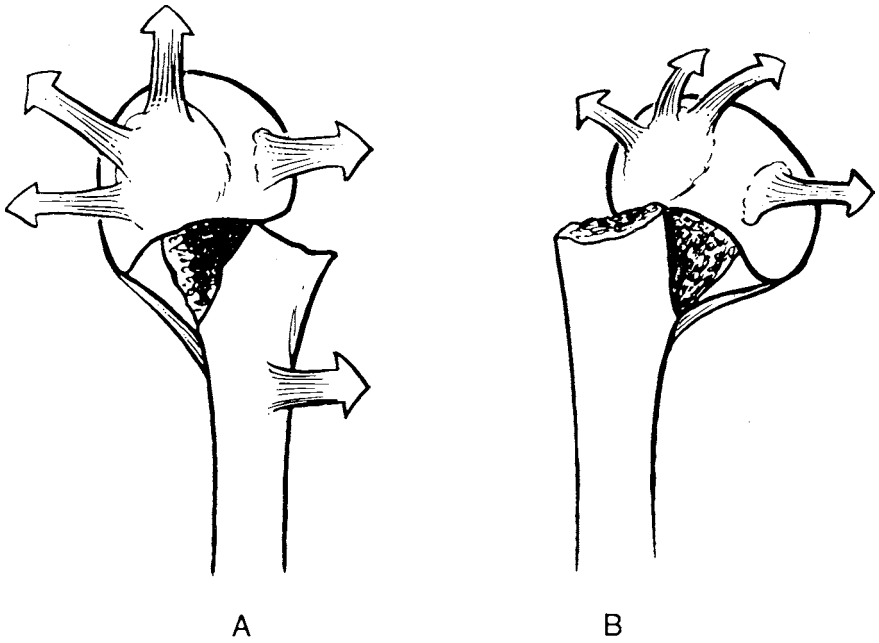

Figure 27-4 **(A)** Lateral and **(B)** anteroposterior view of proximal humerus, showing the muscle forces of the rotator cuff displacing the head and tuberosities into flexion abduction and slight external rotation. The metaphysis is pulled anteriorly and medially by the pectoralis major. The thick periosteum remains intact posteromedially.

(two-part), the supraspinatus and external rotators (infraspinatus and teres minor) actively retract fragments of the greater tuberosity superiorly and posteriorly. The direction may be more superior when the fragment is small and does not include all of the infraspinatus or more posterior with larger fragment size. When a displaced surgical neck component is also present (three-part), unopposed pull of the subscapularis internally rotates the articular segment, causing the articular surface to face posteriorly. This pattern of displacement is accompanied by a longitudinal tear of the rotator cuff (Fig. 27-6B). Similarly, a lesser tuberosity fracture will be displaced (two-part) medially by the subscapularis muscle. When this is accompanied by a displaced surgical neck fracture (three-part), the unopposed pull of the external rotators causes the articular segment to face anteriorly (Fig. 27-6C). Similarly, a longitudinal rotator cuff tear also occurs.

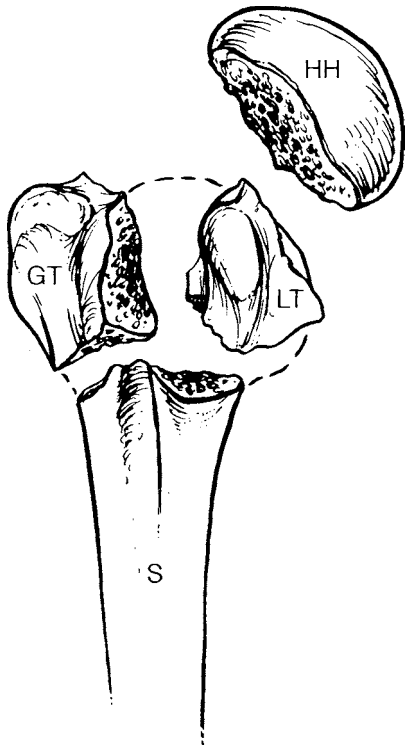

Figure 27-5 Proximal humerus fractures tend to occur along the lines of the old epiphyseal plate scar. The four important segments are the greater tuberosity (*GT*), lesser tuberosity (*LT*), articular surface (*HH*), and shaft (*S*).

If both tuberosities and the surgical neck are displaced (four-part), the greater tuberosity is retracted posteriorly and superiorly by the external rotators; the lesser tuberosity is retracted anteromedially by the subscapularis; and the pectoralis major retracts the shaft medially. The articular segment may be impacted on the upper shaft, displaced laterally, or dislocated anteriorly, posteriorly, or inferiorly. A longitudinal rotator cuff tear occurs between the subscapularis and supraspinatus in the rotator interval area (Fig. 27-6D).

In general, the deforming forces produced by the attached musculature prevent obtaining or maintaining a satisfactory closed reduction. Ultimately, this will determine fracture treatment.

CLASSIFICATION OF PROXIMAL HUMERAL FRACTURES

A classification system for proximal humerus fractures should provide a comprehensive means of describing

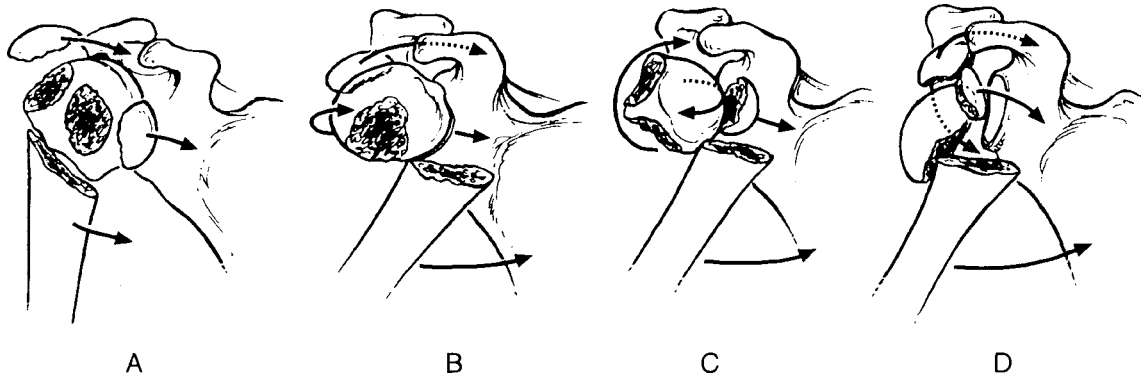

Figure 27-6 **(A)** *Arrows* demonstrating muscle forces on each segment of proximal humerus that determine fracture deformity and displacement. **(B)** Three-part greater tuberosity fracture demonstrates internal rotation of the articular segment and superior and posterior displacement of the greater tuberosity. **(C)** Three-part lesser tuberosity fracture demonstrates external rotation of the articular segment such that it faces anteriorly, and medial displacement of the lesser tuberosity. **(D)** Four-part fracture demonstrating posterior and superior displacement of the greater tuberosity, anterior medial retraction of the lesser tuberosity, and medial displacement of the shaft.

fracture fragment displacement and position, and the presence of dislocation. It should also assist in determining treatment, predicting long-term clinical outcomes, and providing an acceptable level of inter- and intraobserver reliability. And finally, the classification should be based on a standard radiographic evaluation that is easily and reproducibly obtained in the clinical setting.

Pediatric

Aitken classified fractures of the proximal humerus into three types. In his series of 11 cases, all fractures were of the first type: a fracture line through the layer of transitional cartilage and newly formed bone. There were no fractures through the epiphysis or evidence of epiphyseal "crush" injuries.[2]

Salter-Harris defined five types of epiphyseal injuries on the basis of radiologic and pathoanatomic patterns. Type I is a separation through the physis. Type II includes a metaphyseal fragment that is always posteromedial. Type III is a separation through the physis, with an extension of the fracture through the epiphysis and articular surface. Type IV is an intraarticular and transmetaphyseal fracture. Type V is physeal crush injury[136] (Fig. 27-7).

In a more pathophysiologic classification, Shapiro classified fractures of the physis as type A, B, or C. The neonatal epiphyseal separation of the proximal part of the humerus is considered a type A fracture (Salter-Harris I or Salter-Harris II), in which the separate epiphyseal and metaphyseal circulation remains intact and the longitudinal growth of the humerus is not arrested.[143] Neer and Horwitz further graded each fracture according to their initial displacement: grade I less than 5 mm; grade II less than one-third the width of the shaft; grade III up two-thirds of the shaft width; and grade IV more than two-thirds of the width.[112]

Adult

History

The classification of proximal humeral fractures has evolved over the last century parallel to our understanding

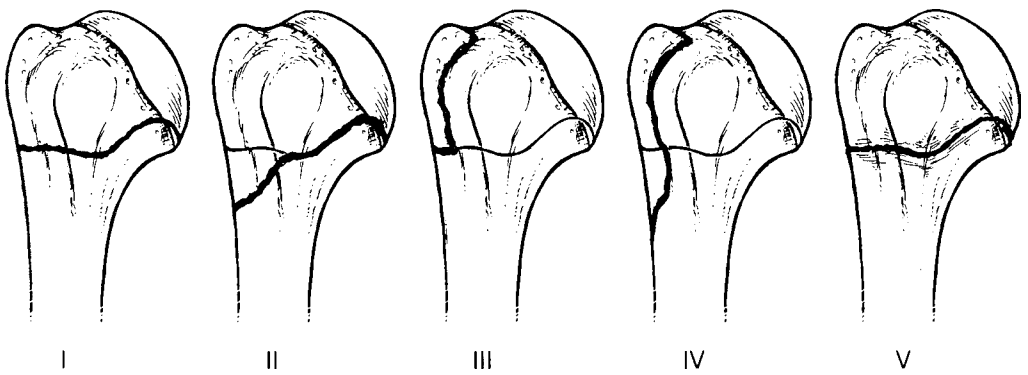

Figure 27-7 The Salter-Harris classification of physeal fractures of the proximal humerus (see text).

of these injuries. Major milestones in this evolution include Kocher's[83] classification that was based upon the different anatomic levels of fracture: anatomic neck, epiphysial region, and surgical neck. The disadvantages of this simplistic system included the lack of attention to important issues, such as the presence of fractures at multiple levels, the degree of fracture displacement, the presence of dislocation, or the mechanism of injury.

Recognizing that classification systems based solely on the anatomic level of fracture did not provide information about mechanism of injury nor assist in the choice of treatment, Watson-Jones[164] proposed a different classification system. He divided proximal humeral fractures into three types: contusion "crack" fractures, impacted adduction fractures, and impacted abduction fractures. He believed that each type was caused by a specific mechanism of injury and required a specific treatment approach. A major disadvantage of this system was that changes in humeral rotation altered the radiographic appearance of the fracture; specifically, the same fracture patterns could appear as an abduction- or adduction-type fracture, depending on the rotational position of the humerus when the x-ray film was obtained.[114] In 1934, Codman presented a classification system based on the epiphyseal regions of the proximal humerus.[34] This system identifies four possible fracture fragments: greater tuberosity, lesser tuberosity, anatomic head, and shaft. His appreciation that fractures occurred along the lines of the epiphyseal scars formed the basis for Neer's development of his classification system.

Neer Classification

Neer[113,114] proposed his classification of proximal humeral fractures in 1970, and since then it has become the most widely used system in clinical practice[13,64,90,106,141,146] (Fig. 27-8). This system is based on the anatomic relations of the four major anatomic segments: articular segment, greater tuberosity, lesser tuberosity, and the proximal shaft, beginning at the level of the surgical neck. Knowledge of the rotator cuff insertions and the effects of the muscular-deforming forces on the four segments is essential to understanding this classification system. Fracture types are based on the presence of displacement of one or more of the four segments. For a segment to be considered displaced, it must be either displaced more than 1 cm or angulated more than 45 degrees from its anatomic position. The number of

Figure 27-9 Anteroposterior view in external rotation **(A)** in internal rotation **(B)** and "Y" scapula view **(C)** of a one-part fracture involving the surgical neck and greater tuberosity. Although there are multiple fracture lines, there is insufficient displacement to characterize them as fragments.

fracture lines is not important in this classification system. For example, one-part fractures, or minimally displaced fractures, are the most common type of proximal humerus fractures and account for up to 85% of all proximal humerus fractures.[75,116,131] Although these fractures may have multiple fracture lines, they are characterized by the fact that none of the four segments fulfills the criteria for displacement. Hence, they are considered one part or minimally displaced (Fig. 27-9A,B).

Displaced fractures include two-part, three-part, and four-part fractures. A two-part fracture is characterized by displacement of one of the four segments, with the remaining three segments either not fractured or not fulfilling the criteria for displacement. Four types of two-part fractures can be encountered (greater tuberosity, lesser tuberosity, anatomic neck, and surgical neck). A three-part fracture is characterized by displacement of two of the segments from the remaining two nondisplaced segments. Two types of three-part fracture patterns are encountered. The more common pattern is characterized by displacement of the greater tuberosity and the shaft, with the lesser tuberosity remaining with the articular segment. The much less commonly encountered pattern is characterized by displacement of the lesser tuberosity and shaft, with the greater tuberosity

remaining with the articular segment. A four-part fracture is characterized by displacement of all four segments.

Neer also categorized fracture–dislocations, which are displaced proximal humerus fractures: two-part, three-part, or four-part, associated with either anterior or posterior dislocation of the articular segment. Therefore, six types of these fracture–dislocation patterns can occur. Neer also described articular surface fractures that were of two types: impression fractures or head-splitting fractures. Impression fractures of the articular surface most often occur in association with chronic dislocations. As such, they can be either anterior or posterior and involve variable amounts of articular surface.[13] Head-splitting fractures are usually associated with other displaced fractures of the proximal humerus in which the disruption or "splitting" of the articular surface is the most significant component.

Reliability of Neer Classification

As noted, the Neer classification is the most widely used classification system for proximal humerus fractures.[90,106,113,114] Recently, there have been several studies that have examined the reliability of the Neer classification.[1,9,21,86,135,146,151] Among four observers of varying expertise who evaluated a series of 100 proximal humerus fractures, Kristiansen et al.[86] found a low level of interobserver reliability using a condensed Neer classification system. The level of expertise was noted to be an important factor on predicting interobserver reliability. However, this study was limited by various factors. First, a complete trauma series was not used; rather, only anteroposterior (AP) and lateral radiographs were examined. Second, a condensed Neer classification was used that consisted of five categories (one-part fractures, two-part fractures, three-part fractures, four-part fractures, and all other fractures and fracture–dislocations), which were somewhat disparate with respect to fracture type, treatment options, and prognosis. And third, intraobserver reliability (reproducibility) was not assessed.

We conducted a study to assess the inter- and intraobserver reliability of the Neer classification system using the radiographs of 50 proximal humerus fractures.[146] Good-quality trauma series radiographs were available for each fracture, consisting of a scapular AP, scapular lateral, and axillary view. The radiographs were reviewed by an orthopedic shoulder specialist, an orthopedic traumatologist, a skeletal radiologist, an orthopedic resident in the fifth year of training, and an orthopedic resident in the second year of training. The radiographs were reviewed on two different occasions 6 months apart. Interobserver reliability was assessed by comparing the fracture classification determined by the five observers. Intraobserver reliability was assessed by comparing the fracture classification determined by each observer for the first and second reviews. Kappa-reliability coefficients were used to adjust the observed proportion of agreement between or among observers by correcting for the proportion of agreement that could have occurred by chance.

All five observers agreed on the final classification in 32% and 30% of cases for the first and second viewings, respectively. Paired comparisons between the five observers showed a mean corrected reliability coefficient of 0.50 (range 0.37 to 0.62) for both testings, which corresponds to a "moderate" level of reliability. An excellent level of reliability (kappa greater than 0.81) was not obtained for paired evaluation. Attending physicians demonstrated slightly higher interobserver reliability than orthopedic residents. Intraobserver reliability ranged from 0.83 (shoulder specialist) to 0.50 (skeletal radiologist) with a mean of 0.65, which corresponds to a "substantial" level of agreement.

Brien et al.[21] also questioned whether the use of plain films is reliable in the Neer classification of complex proximal humerus fractures. They found only fair intraobserver reliability in a 5-year retrospective analysis of 28 fractures with kappa values ranging from 0.37 to 1.00. Surgical neck fractures faired better than tuberosity fractures. The authors admitted to basing diagnosis on incomplete trauma series, with inclusion criteria of only two roentgenograms at 90-degree angles to each other (rather than the preferred three views). Also, there was no standardized radiographic procedure. They suggested that the addition of routine conventional radiographs and computed tomography (CT) scan may increase reliability.

The hypothesis that a better imaging technique may increase the reproducibility of proximal humerus fracture classification was explored by several authors. Bernstein et al.[9] found findings similar to ours for intraobserver reliability (kappa = 0.64) and interobserver reproducibility (kappa = 0.52) when fractures were classified on the basis of radiographs alone. When CT scans were added to plain radiographs, intraobserver reliability increased slightly (kappa = 0.72), but interobserver reproducibility did not improve (kappa = 0.50). They concluded that because even the shoulder experts had difficulty agreeing on which fragments were fractured, new imaging modalities rather than a new classification system may need to be developed.

Brorson et al.[25] assessed the effect of training on the improvement in interobserver variation of the Neer system. The orthopedic medical staff involved in the teaching was provided with a diagram of the Neer classification system and a 45-minute tutorial based on the original reports of the system. This session was repeated again 2 weeks later. They found formal training in the Neer system improved the mean kappa value in specialists from 0.3 to 0.79.

Sjoden et al.[151] investigated 26 proximal humerus fractures with both plain radiographs and CT. Similar to Bernstein, they found that CT scan together with plain radiographs did not make fracture classification more consistent. Sallay et al.[135] conducted a study for which two groups of observers (experts and nonexperts in shoulder surgery) reviewed the plain radiographs and the three-dimensional CT scans of 12 patients with proximal humerus fractures. Both groups of observers displayed suboptimal

reliability for the identification of displaced fracture fragments. The addition of three-dimensional CT scans did not improve the reliability or reproducibility. Unlike our study,[146] Sallay et al.[135] found that experience did not significantly improve the reliability of identifying specific fracture patterns. They recognized the limitations of their retrospective study and the small number of cases and a lack of standardized radiographs. They believed that it was not the classification system that was poor, but more likely the vague criteria for identifying the fractured segments and determining their displacement and angulation.

Burstein has questioned whether classification systems are useful at all.[30] Neer believes that the confusion is due to a bad use of the classification system that he believes is anatomically correct,[37] rather than to a bad classification system. Yet, Rockwood and even Neer stated that even the most experienced surgeon occasionally is in doubt and has to make the final classification at surgery.[30,37,39,117]

The classification of the fracture is critically important to the decision-making process. A fracture classified as minimally displaced by one observer and as a three-part by another may be treated differently by the two observers. Also, the results of treatment for a particular fracture in the literature may be inaccurate because of the difficulties of determining a reliable and reproducible classification.[39]

AO Classification

The AO group has modified the Neer classification, placing more emphasis on the vascular supply to the articular segment of the proximal humerus. Severity of the injury and risk of osteonecrosis forms the basis of the AO classification system (Fig. 27-10). In this system, it is accepted that if either tuberosity and its attached rotator cuff remain in continuity with the articular segment, the vascular supply is probably adequate. Proximal humerus fractures are separated into three types: extraarticular unifocal, extraarticular bifocal, and articular. Each of these types is further subdivided into different groups based on alignment, degree, and direction of the displacement; presence of impaction; and associated dislocation.

Type A fractures are extraarticular and involve one of the tuberosities with or without a concomitant metaphyseal fracture. Group Al fractures are the extraarticular unifocal tuberosity fractures; group A2 fractures are the extraarticular unifocal fractures with an impacted metaphyseal fracture; and group A3 fractures are the extraarticular unifocal fractures with a nonimpacted metaphyseal fracture. Osteonecrosis is unlikely in type A fractures.

Type B fractures are also extraarticular, but involve both tuberosities with a concomitant metaphyseal fracture or glenohumeral dislocation. Group B1 fractures are the extraarticular bifocal fractures associated with an impacted metaphyseal fracture; group B2 fractures are the extraarticular bifocal fractures with a nonimpacted metaphyseal fracture; and group B3 fractures are the extraarticular bifocal fractures with a glenohumeral dislocation. There is a low risk for osteonecrosis in type B fractures.

Type C fractures are extraarticular and involve vascular isolation of the articular segment. Group C1 fractures are

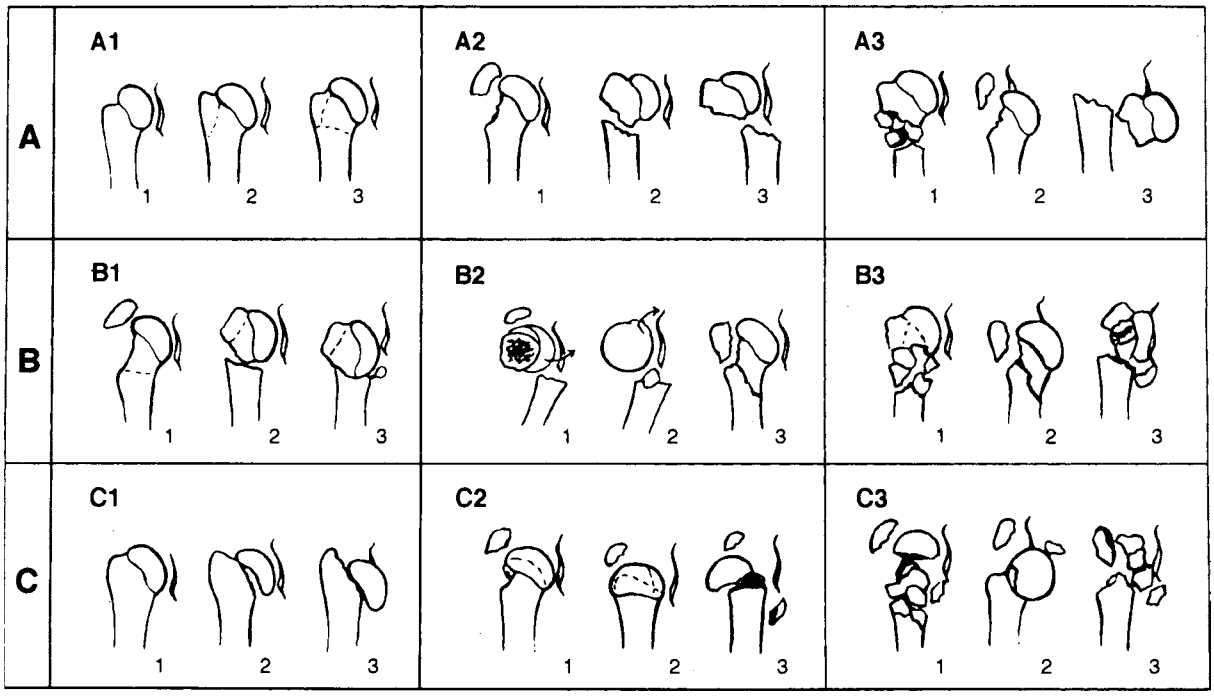

Figure 27-10 The AO classification of proximal humeral fractures (see text).

fractures with slight displacement; group C2 fractures are impacted fractures with marked displacement; and group C3 fractures are associated with a glenohumeral dislocation. There is a high risk of osteonecrosis in this type.

This more complex classification system theoretically should allow development of more detailed guidelines for treatment and prognosis. However, its complexity may actually preclude attaining the widespread utilization that the Neer classification currently commands. Thus far, clinical studies using the AO classification have been quite limited. Recent assessment of its interobserver reliability has not shown it to be significantly better than the Neer system.[78,147] Thus far, no long-term results of treatments based on the AO classification system have been presented. Siebenrock and Gerber's[147] study found that when five experts in shoulder surgery evaluated 95 proximal humerus fractures using simplified versions of both the Neer and AO/Association for the Study of Internal Fixation (ASIF) classification system, there was poor interobserver reliability and acceptable intraobserver reliability for both systems.

Valgus-Impacted

There is a specific type of four-part fracture described that is characterized by a valgus impaction of the humeral head and variable displacement of the tuberosities (Fig. 27-11). This valgus-impacted humeral head fracture pattern does not fit accurately into Neer's classification. The AO classification system classifies these fracture patterns as C2.1- and C2.2-type fractures.[45] However, because of the lower rate of osteonecrosis and the more favorable outcome compared with "classic" four-part fractures, Jakob et al.[79] felt this fracture pattern required special consideration, as will be discussed later.

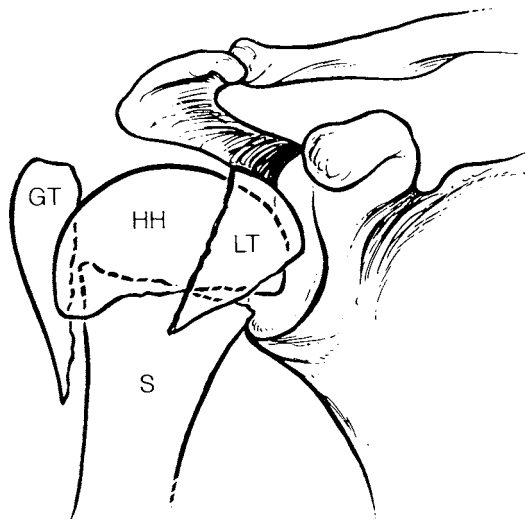

Figure 27-11 Valgus-impacted four-part fracture. The articular segment (*HH*) is impacted and angulated, rather than displaced as in the classic four-part fracture. GT = greater tuberosity; LT = lesser tuberosity; S = the shaft.

Incidence

Proximal humeral fractures account for 4% to 5% of all fractures in adults and less than 1% of children's fractures. Approximately 3% of physeal fractures occur through the proximal humerus.[11,121] Proximal humeral epiphyseal plate fractures can occur any time between birth and physeal closure at approximately 18 years of age. These are most common in adolescents between 10 and 16 years of age (owing to increased sports participation), followed by neonates who sustain birth trauma.[23,44,57,68,172] In patients younger than 17 years of age, Salter-Harris types I and II are most commonly seen with proximal humerus fractures. Salter-Harris type I injuries occur in newborn infants, whereas Salter-Harris type II injuries occur in adolescents.[2,3,44]

Salter-Harris III fractures are rare and usually occur with a dislocation in which the glenoid acts as a wedge to split the epiphysis.[161] Salter-Harris IV fractures are associated with open fractures.[3] No Salter-Harris V fractures have been reported in the literature.[44,138,144] The reason for this fracture distribution can be explained as follows. The proximal humeral epiphysial plate is very active, contributing about 80% of longitudinal humeral growth.[49] It remains open until approximately 19 years of age. The weakest area is distal to proliferating cartilage cells in the "zone of degenerative cartilage," where the cartilage is being converted to bone on the metaphyseal side of the plate.[112] Microscopic studies of fracture specimens in stillborn infants and experimental animals confirm the finding that the fracture through the plate occurs through the hypertrophied cartilage cells adjacent to the zone of provisional calcification, thus avoiding the proliferating cells and causing no harmful effects on growth.[19,44,136] The glenohumeral joint has the most mobility of any joint in the body, which limits the risk for crushing or epiphyseal splitting injuries.[2,112] Lesser tuberosity fractures occur with forced external rotation and abduction, while greater tuberosity fractures occur with dislocations, both being rare injuries.

Proximal humerus fractures account for over 75% of humerus fractures in patients older than age 40. After age 50, women have a much higher incidence than men. An exponential increase occurs after menopause, representing the typical characteristic of an osteoporotic fracture.[5,88,120,131] In patients younger than age 50, high-energy trauma is the most common cause of proximal humerus fractures; after age 50, minimal to moderate trauma is the most common cause.[80] Up to 85% of all proximal humerus fractures are one-part (nondisplaced or minimally displaced) fractures; 15% to 20% of all proximal humerus fractures are classified as displaced. Most two-part fractures are surgical neck fractures, with the majority of these fractures occurring in individuals older than 65 years.[77,165] Although up to 40% of proximal humerus fractures have some involvement of the greater tuberosity,[75,131] isolated two-part displaced greater tuberosity fractures are reported to comprise

less than 2% of all proximal humerus fractures.[77] However, it is believed that this fracture is underdiagnosed and may be more common than the literature suggests.[39] These fractures occur in association with anterior dislocation in 5% to 33% of cases.[62,132,140] Two-part anatomic neck fractures have not been reported to occur in children[44] and constitute only 0.54% of proximal humerus fractures.[77] Isolated lesser tuberosity fractures comprise 0.27% of all proximal humerus fractures and 0.5% of displaced fractures. Two-part lesser tuberosity fracture–dislocations comprise 1.3% of all displaced proximal humerus fractures. Three-part fractures comprise 3% or more of displaced proximal humerus fractures.[77,110,114] Three-part lesser tuberosity fractures occur much less frequently than those of greater tuberosity displacement. Four-part fractures comprise approximately 4% of proximal humerus fractures, and articular surface fractures comprise approximately 3%.[3]

Rating System

There are many different methods currently used to assess shoulder function. To some degree, all shoulder outcome instruments assess pain, function, range of motion, and strength. The problem is that each one emphasizes a different aspect of the shoulder evaluation. Some have a greater emphasis on range of motion, whereas others place more emphasis on pain and still others emphasize function. It is due to these differences that comparing instruments has become difficult if not impossible, and no individual instrument has become universally accepted.

Neer's shoulder grading scale was originally developed to assess shoulder arthroplasty for glenohumeral degenerative joint disease; however, it has been widely used to assess outcome following proximal humerus fractures. Neer used a system based on 100 units: 35 units were assigned for pain, 30 units for function, 25 units for range of motion, and 10 units for anatomy. A score of 89 or higher represents an excellent result; 80 to 88 units is a satisfactory result; 70 to 79 units is an unsatisfactory result; and less than 70 units represents a failure. Each assessment method places varying importance in the areas of pain, range of motion, and function. To facilitate communication between investigators, stimulate multicenter studies, and allow communication of useful and relevant outcome data to physicians, health care organizations, and the general public, a standardized method of assessing shoulder function, regardless of diagnosis, was established by the American Shoulder and Elbow Surgeons (ASES) in 1994.[127] Some of the other scoring systems include the Constant scoring system; the University of California, Los Angeles (UCLA) shoulder rating scale; the Shoulder Severity Index; the Simple Shoulder Test; the Disabilities of the Arm, Shoulder, and Hand Instrument (DASH); and PENN score. It is possible that one assessment system may indicate a good result, whereas another system may indicate a fair or poor result in the same patient. Furthermore, the outcome scores currently used may misrepresent patient perceptions of treatment outcomes. Patients may lack full range of motion and strength—objective measures often emphasized in outcome instruments—yet remain satisfied with a pain-free shoulder and restoration of a functional range of motion.

EVALUATION

Clinical Evaluation

Newborns with an epiphyseal separation of the proximal humerus present with pseudoparalysis with the arm held in extension, swelling at the apex of the shoulder, and occasionally fever. Infection, clavicle fracture, and Erb's palsy are included in the differential diagnosis. Pain with motion of the arm points toward a fracture.[3,22]

In eliciting a history from a patient who has sustained a proximal humerus fracture, determination of the mechanism of injury can be helpful. A child usually gives a history of falling backward onto an outstretched hand with the elbow extended and the wrist dorsiflexed.[3] A loss of consciousness or a history of falls may indicate a cardiac or neurologic cause in the older patient.[42,89]A direct mechanism can occur, such as a blow to the lateral aspect of the shoulder, in both young and older patients. However, in the elderly, the indirect mechanism is much more common and generally involves a fall onto the outstretched arm. In younger patients, this mechanism most commonly results in a dislocation. The indirect mechanism is usually associated with a greater degree of fracture displacement than the direct mechanism. Other indirect causes of proximal humerus fractures are seizures or electroconvulsive therapy without the use of muscle relaxants; both are often associated with posterior dislocations.[89]

The symptoms and signs associated with proximal humerus fractures can be quite variable. However, they most often correlate with the degree of fracture displacement and comminution. Pain, especially with any attempts at shoulder motion, is almost always present. Inspection of the shoulder usually reveals swelling and ecchymosis. The patient should be instructed that over the first 4 to 5 days following injury, the ecchymosis that develops may extend distally into the arm and forearm or even to the chest wall and breast area (Fig. 27-12).

Palpation of the shoulder will usually reveal tenderness about the proximal humerus. Crepitus may be evident with motion of the fracture fragments. The entire upper extremity should be examined. A fall on the outstretched arm can also result in a fracture of another area such as a distal radius fracture. The chest should also be examined, because rib fractures may also occur from a fall.[61,65,124,166]

Figure 27-12 A 72-year-old woman, 2 days following closed reduction of a two-part greater tuberosity fracture–dislocation; the area of ecchymosis has extended to the elbow.

Assessment of fracture stability is an essential part of the examination. The humeral shaft should be gently rotated internally and externally as the proximal portion of the humerus is palpated. If the proximal and distal portions move as a unit, the fracture is stable; however, motion or crepitus is consistent with an unstable or less stable fracture pattern.

Essential to the clinical evaluation of the patient with a proximal humerus fracture is a complete neurovascular examination of the involved upper extremity. Associated axillary artery and brachial plexus injuries have been reported,[69,98,152,154,173] especially with fracture fragments displaced medial to the coracoid process. A 45% incidence of nerve injury has recently been reported.[46] Fracture–dislocations also increase the incidence of neurovascular injury.[123] The most commonly injured peripheral nerve is the axillary nerve.[13] Both sensory and motor testing should be performed to evaluate axillary nerve function. This may be difficult in the setting of acute injury. Therefore, serial examinations should be performed.

Radiographic Evaluation

One of the most important components of the evaluation of proximal humerus fractures is the determination of the position of the fracture fragments and the degree of displacement. Thus, an adequate radiographic evaluation is mandatory.

Trauma Series

The cornerstone of the radiographic evaluation of proximal humerus fractures is the trauma series (Fig. 27-13). The trauma series consists of AP and lateral views of the shoulder, obtained in the plane of the scapula, and an axillary view. Fracture classification and treatment decisions are generally based on these three radiographic views. Each view contributes information obtained from three different perpendicular planes.[2,13,35,66,141] The scapular AP view offers a general overview of the fracture and is usually evaluated first. This view should be made perpendicular to the scapular plane (as differentiated from the plane of the chest), which requires angling the x-ray beam approximately 40 degrees in a mediolateral direction. This compensates for the position of the scapula on the chest wall. It will demonstrate the glenoid in profile as well as the true glenohumeral joint space. In the undislocated shoulder, it shows the humeral head to be clearly separated from the glenoid.

At least one view obtained at 90 degrees to the scapular AP is required for assessment of proximal humerus fractures and fracture–dislocations.[130] This orthogonal view provides important information about angulation and displacement of the fracture fragments[13] and the presence of an associated dislocation.[17,20,104,172] Both the scapular lateral and axillary views are oriented orthogonally to the scapular AP and fulfill the criteria for a second projection. However, the trauma series generally includes all three views.

The scapular lateral, also known as the scapular "Y," can provide important information not evident on a scapular AP view.[49,104,134,172] This view is a true lateral of the scapula, with the x-ray beam passing parallel to the spine of the scapula. This view is taken with the patient standing. It can be obtained with the involved upper extremity immobilized in a sling and does not require any movement of the extremity and, as such, does not add to patient discomfort. The scapular lateral assists in delineating the position of the humeral head relative to the glenoid and is particularly useful in showing posteriorly displaced fragments as well as shaft displacement.

The axillary view also permits assessment of the glenohumeral relation. This is generally obtained with the patient supine. The arm must be positioned in at least 30 degrees of abduction. In the acute setting, positioning is often performed by the physician. The x-ray plate is placed above the shoulder, and the beam is directed to the plate from a caudad position. The axillary view can also be useful in identifying fractures of the glenoid rim, posterior

Figure 27-13 The trauma series of radiographs includes an **(A)** anteroposterior view and **(B)** lateral view in the plane of the scapula, and **(C)** an axillary view.

displacement of the greater tuberosity, medial displacement of the lesser tuberosity, and humeral head articular impression fractures.[42,66,119,130,167]

The relative efficacy of these different views has not been studied extensively. Silfverskiold et al.[148] reported in their prospective study that the scapular lateral view was more sensitive than the axillary view in detecting shoulder dislocations. They did not study fractures specifically. In 92% of their 75 cases, however, the scapular lateral and axillary views resulted in the same diagnosis.

We conducted a study in which the trauma series radiographs of 50 proximal humerus fractures were used to assess the relative contributions of the scapular lateral and axillary radiographs to fracture classification using the Neer system.[145] The radiographs were reviewed by five different orthopedic surgeons with varying levels of experience and

expertise. In the first viewing, radiographs were reviewed and classified in the following sequence:

1. After review of scapular AP view alone
2. After review of scapular AP and lateral views
3. After review of scapular AP, lateral, and axillary views

A second viewing of the same 50 cases was performed 6 months later in a changed sequence:

1. After review of scapular AP view alone
2. After review of scapular AP and axillary views
3. After review of scapular AP, axillary, and scapula lateral views

For the cumulative experience of these five observers, review of the scapular AP and axillary views achieved a final classification in 99% of cases. However, after review of the scapular AP and lateral, the final classification was achieved in only 79% of cases ($P < 0.05$). These results indicate that when combined with the scapular AP radiograph, the axillary view contributes significantly more information than the scapular lateral radiograph in determining fracture classification. Posterior displacement of 1 cm of the greater tuberosity is missed 25% of the time when only AP and lateral scapular views are used alone. Additionally, we also reviewed the accuracy of the axillary projection to determine fracture angulation in experimentally produced surgical neck fractures. We found that it was not reliable projection for assessing the degree of fracture angulation primarily as a result of the variability in arm position (abduction, flexion, or extension) when the radiograph was obtained.[150]

Additional Radiographic Views

If any of these three views of the trauma series is inadequate, it should be repeated. Usually, the fracture can be evaluated and treated based on this set of radiographs. Additional radiographic views may be helpful and have been advocated by others.

The apical oblique view[58] is obtained by directing the x-ray beam through the glenohumeral joint at an angle of 45 degrees to the plane of the chest wall and angled 45 degrees caudally. When compared with the scapular lateral view, it provides additional useful information in the evaluation of proximal humerus fractures and fracture–dislocations, specifically in demonstrating dislocations and posterolateral humeral head compression fractures.[84,128] However, it has not become as widely accepted as the scapular lateral view.

Modified axillary views, such as the Velpeau axillary lateral,[17] the Stripp axillary lateral,[76] and the trauma axillary lateral,[160] have been described. These views permit an axillary lateral to be obtained without removing the injured arm from the sling. The Velpeau axillary lateral is probably the most commonly used, taken with the patient leaning backward approximately 30 degrees over the x-ray table. The x-ray cassette is placed beneath the shoulder on the table, and the x-ray beam passes vertically from superior to inferior through the shoulder joint. Although this view has the benefit of avoiding the need to position the injured extremity, we prefer the standard axillary view because it offers less distortion and bony overlap and thereby provides more useful information.

Other Diagnostic Modalities

Computed tomography scans of proximal humeral fractures and fracture–dislocations may be indicated when the trauma series radiographs are indeterminate. CT scans have been recommended to evaluate the rotation of fragments, the degree of tuberosity displacement, as well as articular impression fractures, head-splitting fractures, and chronic fracture–dislocations.[13,14,31,81,82,92] Castagno et al. reported a small series of 17 patients in whom CT scans of acute proximal humeral fractures demonstrated important information not evident on plain radiographs.[31] Also, spiral CT with three-dimensional and multiplanar reconstructions was reported to provide additional information, compared with standard x-rays, in 10 patients with three- and four-part fractures. However, in this study, standard radiographs did not include an axillary view.[81]

As mentioned earlier in the classification and reliability section, CT does not seem to improve interobserver reliability and fracture classification.[135,151] In our experience, CT scans are most helpful in the evaluation of chronic fracture–dislocations, specifically to identify the size and location of humeral head impression defects and the degree of secondary glenoid changes[146] (Fig. 27-14).

Another imaging modality to consider is magnetic resonance imaging (MRI). MRI provides information about associated soft tissue injuries of the rotator cuff, biceps ten-

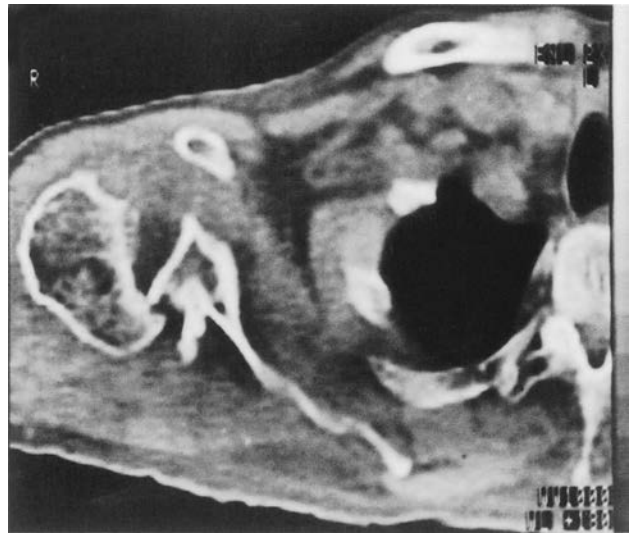

Figure 27-14 Computed tomography scan of the right shoulder in a 56-year-old man with a chronic posterior dislocation of the right shoulder. The image clearly shows the impression fracture of the anteromedial portion of the humeral head, as well as the amount of the articular surface involvement. The calcification about the posterior glenoid neck provides further evidence of the chronic nature of dislocation.

don, and glenoid labrum, which may be helpful in the management of these patients. However, cost benefit issues have to be considered carefully. Thus far, there have been no studies performed to support its routine use.

Vascular Injury and Indications for Arteriogram

The axillary artery lies just anterior and medial to the prox mal humerus.[118] Vascular injury following fracture–dislocation of the humerus is uncommon; it is rare in anterior dislocation without associated fracture; and it is extremely rare in closed humeral neck fractures, despite the fracture's proximity to the artery.[51,94,99,109,113,153,159] Morris et al. identified no vascular injuries associated with proximal humeral fractures in a series of 220 acute arterial injuries.[109] Neer reported on 117 displaced proximal humerus fractures over a 15-year period and found no vascular complications.[113] The literature documents only 16 cases of axillary artery injury from proximal humerus fractures.[94,99,102,103,109,153,159,173]

In pure anterior dislocations, the axillary artery can be damaged in its second part by avulsion of the thoracoacromial trunk or in its third part from avulsion of the subscapular and circumflex humeral vessels (with subsequent linear tears in the artery and intraluminal thrombosis). The mechanism of arterial injury in a pure dislocation is thought to be secondary to tethering of the axillary artery by the subscapular and circumflex arteries, thus accounting for the injuries primarily occurring in the third part.[107] The pectoralis minor muscle may act as a fulcrum that puts the artery on stretch and then pinches the artery with dislocation.[26] The artery may also be fixed to a scarred joint capsule from previous injury or surgery, or atherosclerotic vessels may be present. Both factors increase the risk of vascular injury. Excessive force during reduction may also cause vascular injury.[51]

Although rare, the possibility of axillary arterial injury should be considered in proximal humerus fractures with severe medial displacement of the shaft.[157] The mechanism of arterial injury may be through direct injury by sharp fracture fragments, thrombosis from vessel contusion, or damage from violent stretching or avulsion of the artery with shoulder hyperabduction, especially in fragile atheromatous vessels. Vascular spasm, although exceedingly rare, may occur from kinking.[105]

Although uncommon, when vascular complications do occur, they represent a true emergency.[137] Early recognition and treatment of vascular injuries play an important role in the eventual outcome: If an arterial repair is done in the "golden" period, within 12 hours of injury, a reasonable chance of success can be expected.[168] A careful neurologic and vascular examination is necessary at initial presentation. Axillary arterial injuries are obvious when clinical findings include an expanding hematoma, absent distal pulses in a cold, pale extremity, or the presence of a pulsatile painful mass with a bruit (in a pseudoaneurysm).[168] However, symptoms are often vague and nonspecific, particularly when ischemic changes are progressive. Because of the tremendous collateral circulation around the shoulder, peripheral pulses, initially weak, may return completely over time, despite axillary artery disruption. This may mask an injury and falsely lead the examiner to consider arterial spasm as the cause of the clinical findings. Distal pulses are reported to be palpable in 27% of patients with major arterial injuries about the shoulder.[42] Therefore, a careful assessment of peripheral pulses must be performed.[6] If a patient with a fracture or fracture–dislocation of the shoulder has no pulse, a pulse that comes and goes, or a pulse of lower volume, further investigation is necessary, even if the pulse returns to normal after manipulation or over time.[54] Any suspicion of a vascular injury requires a Doppler examination to determine both the magnitude and quality of the arterial signal. Arteriography should be performed immediately when the Doppler examination or clinical findings suggest arterial compromise.[6,173] Late signs of vascular complications, including false aneurysms and acute ischemia with gangrene, can appear weeks, months, or even years after the initial injury.[6,10,51,54,71,94,99,109,153,155] Thus, angiography is recommended when there is any clinical suspicion of a vascular injury (Fig. 27-15). When an arterial injury occurs in association with a proximal humeral fracture or fracture–dislocation, the fracture should be anatomically reduced and stabilized with internal fixation before vascular repair, to protect the vascular repair so that additional

fracture manipulation will not be necessary after repair.[173] However, it has also been suggested that the order of treatment (reperfusion vs. osteosynthesis) should be dictated by the degree of ischemia.[157]

Treatment of Physeal Fractures

Most proximal humeral physeal fractures can be treated nonoperatively, even when there is significant displacement, because of the great remodeling potential[2,8] (Algorithm 27-1). As a general rule, the younger the patient is, the greater the potential is for remodeling and the greater the initial deformity is that can be accepted. Neer-Horowitz grade I and II fractures do exceptionally well with sling and swath treatment without reduction, because of the remodeling potential of the proximal humeral physis. Neer-Horowitz grade III and grade IV fractures usually require reduction, but may be left with up to 3 cm of shortening or residual angulation because this is often clinically insignificant.

In newborns, most fractures are Salter-Harris type I, for the physeal plate is less resistant to trauma than the bone, joint capsule, and ligaments. If there is marked displacement, a closed reduction can be performed by applying gentle longitudinal traction with the shoulder in 135 degrees of abduction, 30 degrees of forward flexion, and neutral rotation, and directing a posterior force on the shaft.[18] Ultrasound can be used to evaluate the reduction. The prognosis is excellent, even if an anatomic reduction is not fully achieved. If the fracture is stable, the arm can be immobilized against the chest for 5 to 10 days, then used as tolerated. Unstable fractures should be maintained in abduction and external rotation for 3 to 4 days until callous forms.

Salter-Harris type I fractures, and less frequently Salter-Harris type II fractures, occur in children younger than age 5. Closed reduction may be necessary, but up to 70 degrees of angulation with any displacement is acceptable because of the extensive remodeling that is possible in this young age.[112] The arm is held in a sling for 4 days followed by progressive activity.

In the 5- to 11-year age group, metaphyseal fractures are most common because the rapid remodeling in this area results in some degree of weakening. Closed reduction may be necessary, but bayonet apposition with 1 to 2 cm of overlap, 40 to 45 degrees of angulation, or displacement of one-half the width of the shaft are acceptable.[57] Stable fractures are immobilized in a sling and swath; a hanging arm cast is used occasionally in older children. Rarely, a spica cast is used for 2 to 3 weeks in unstable fractures to maintain the arm in the salute position. When callous is evident, the arm is slowly brought down to the side and immobilized in a sling and swath. After 3 to 4 weeks, the fracture should be healed and progressive range of motion exercises are begun. Strengthening of the rotator cuff, trapezius, and deltoid are added as range of motion progresses.[138]

From age 11 until skeletal maturity, there is less remodeling potential than in younger children, so less displacement and angulation is acceptable. The fractures encountered are more frequently Salter-Harris type II, with some Salter-Harris type I fractures. Treatment is by closed reduction with 15 to 20 degrees of angulation and less then 30% displacement considered acceptable. A stable fracture is treated with a sling and swath for 2 to 3 weeks, followed by progressive range-of-motion exercises; an unstable fracture

may need immobilization in a shoulder spica cast with the arm in the salute position.[138]

The indications for operative treatment of physeal fractures of the proximal humerus are not well defined; many factors must be considered. Growth-remaining charts may be of benefit to determine if the patient has sufficient potential to remodel a significantly displaced fracture. The literature supports nonoperative treatment, even for markedly displaced fractures,[2] because the functional outcomes have been satisfactory even in the presence of limitation of motion and persistent deformity.[29] The literature also supports closed reduction and pinning or open reduction and internal fixation in older children with markedly displaced fractures and limited remodeling potential, in whom an acceptable reduction cannot be maintained.[156]

TREATMENT

In this chapter we will focus on the nonoperative management of proximal humerus fractures. For some fracture types it is the preferred treatment approach; for others it will only be acceptable under special circumstances. This will be discussed as each fracture type is reviewed.

The indication for operative versus nonoperative management of adult proximal humerus fractures is determined by numerous factors including the patient's physiologic age, arm dominance, associated injuries, fracture type, degree of fracture displacement, and bone quality. The surgeon's knowledge and skill will greatly affect the functional outcome. He or she must also have the ability to accurately diagnose the fracture, based on an understanding of the relevant anatomy and interpretation of complete radiographs. The patient's general medical condition and ability to undergo major surgery as well as to comply with an intensive rehabilitation program are of paramount importance in developing a management plan.[42]

One-Part Fractures: Adult

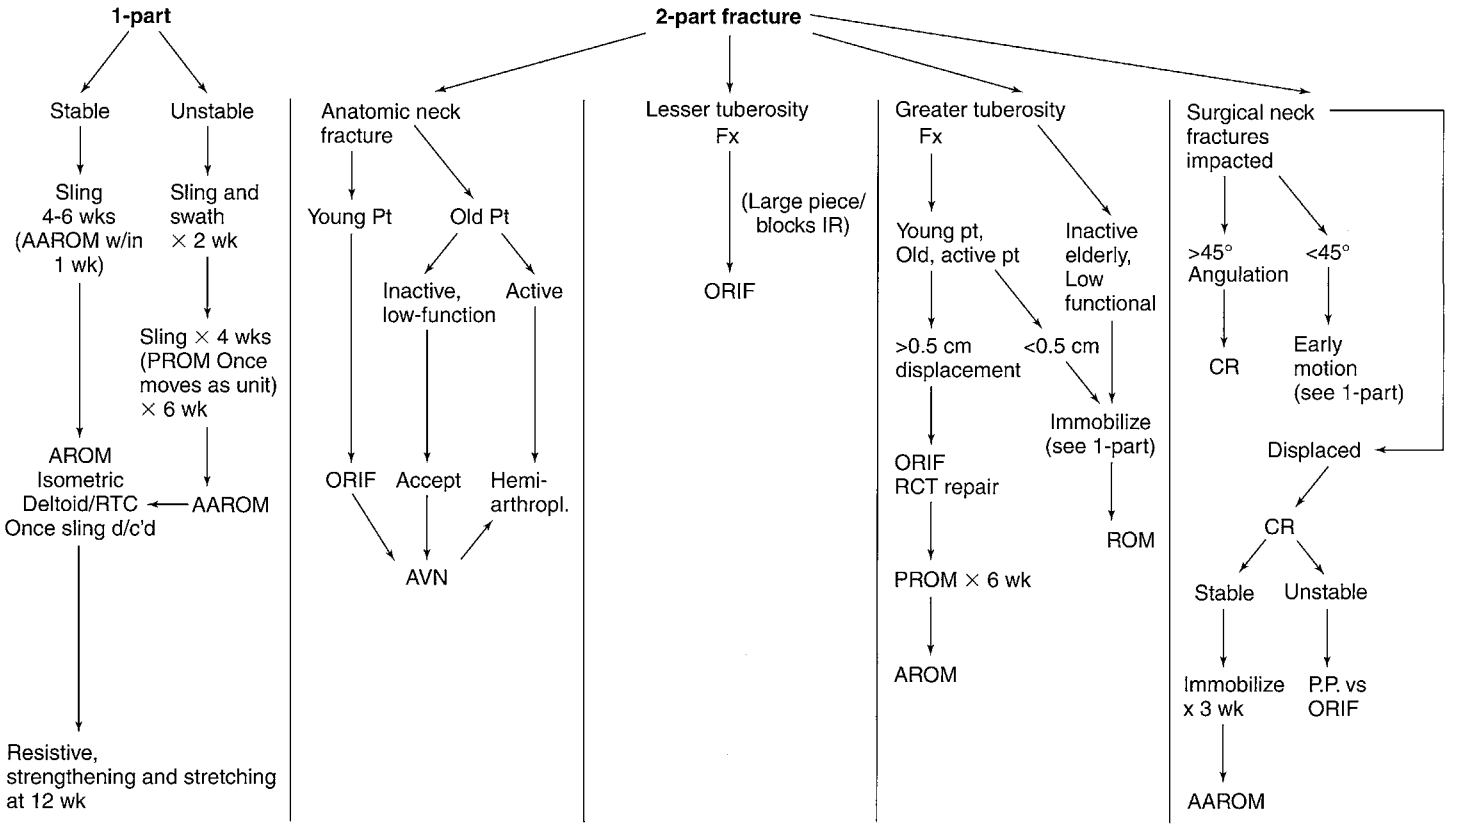
Minimally displaced fractures account for over 80% of all proximal humerus fractures.[114] They are often referred to as "one-part" fractures, based on Neer's four-segment classification. By definition, although there may be many fracture lines, there is no significant displacement of any segment (Algorithm 27-2). However, it is essential to confirm the stability of the fracture. Many of these fractures are impacted and, with rotation of the humerus, the proximal humerus and shaft move together as one unit. This is a stable fracture, and an early range-of-motion program is appropriate. However, some minimally displaced fractures are not impacted, and rotation of the humerus indicates that the proximal segments and shaft do not move as a unit. This fracture is not stable and requires a period of immobilization until sufficient healing has occurred. Once clinical stability is present, as evidenced by movement of the head and the shaft as a unit, range-of-motion exercises can be initiated.

For minimally displaced stable fractures, we prefer immobilization in a simple arm sling. Padding should be placed in the axilla and around the elbow in the sling to prevent skin maceration. Elderly patients must be watched carefully for skin problems, even with use of the simple sling. Swelling and ecchymosis add to the risk of skin problems. When the humerus does not move as a unit, sling and swath immobilization may be preferred. This consists of a standard arm sling with a 6-in. elastic (Ace) bandage used as a swath. The Ace bandage is secured to the sling with safety pins. With a sling and swath of this type, padding should be used in the axilla and around the elbow as described. The swath should be removed two to three times each day to check the skin about the elbow and to allow elbow, wrist, and hand range of motion. In addition, the arm can be gently abducted by gravity to check the skin and axilla.

With minimally displaced fractures that are stable, patients should be started on a range-of-motion program as soon as the initial discomfort subsides. Within 1 week after injury, range of motion therapy should begin, preferably under the supervision of an occupational or physical therapist. This consists of active elbow, wrist, and hand exercises in combination with assisted shoulder range-of-motion exercises. These are begun in the supine position for forward elevation, external rotation, and internal rotation to the chest. Therapy can be supervised in one or two weekly sessions and performed three to five times daily at home by the patient. The patient's arm is maintained in a sling for 4 to 6 weeks. The sling is discontinued when clinical and early radiographic evidence of union is confirmed. At that time, an active range-of-motion program is begun, starting in the supine position, with gradual progression to the sitting position. Isometric deltoid and rotator cuff strengthening exercises are initiated at the same time. When a reasonable range of active shoulder motion is achieved, isotonic resistive exercises for deltoid and rotator cuff muscles are added. Stretching exercises are also added. Approximately 12 weeks after fracture, a more vigorous stretching program is begun.

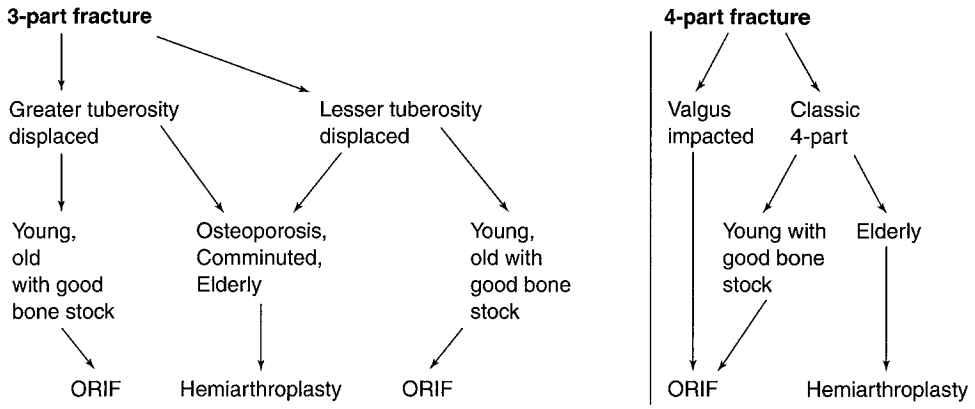
The results of treatment of minimally displaced proximal humerus fractures, using immobilization and early range of motion, have been generally reported as good to excellent.[33,87,90,100,106,114,116,171,172] In our prospective study of patients with one-part stable proximal humerus fractures treated with the aforementioned standardized protocol of short-term immobilization combined with an early range-of-motion program (mean follow-up of 22 months), recovery of range of motion was generally good. Patients regained 87% of forward elevation, 79% of external rotation, and 89% of internal rotation, compared with the opposite shoulder. However, recovery of motion did not necessarily correlate with functional outcomes. Unlike previous studies, we found a high incidence of residual shoulder pain (67%), with a significant number (27%) of patients describing

Adult proximal humerus fracture algorithm



ALGORITHM 27-2

(*continued*)



ALGORITHM 27-2 (*continued*)

the pain as moderate to severe. Moreover, almost 30% of patients required some form of medication for pain relief.

In this series, almost two-thirds (65%) of patients reported some limitation of function, with 42% reporting a significant restriction of overall function. This primarily affected activities of daily living or inability to sleep on the affected side (40%), inability to carry a package at the side (46%), and inability to use the hand over the head (51%).[85]

A similar rehabilitation program is utilized for minimally displaced fractures that do not move as a unit. The shoulder is immobilized until it moves as a unit (clinically stable), although active range of motion of the elbow, wrist, and hand can be initiated immediately. This is usually no longer than 2 to 3 weeks. Gentle assisted range-of-motion exercises of the shoulder are initiated at that time. Range of motion regained with these fractures may be slightly less than with stable, minimally displaced fractures. However, the vast majority of patients regain a good functional range of motion.[172] Overly aggressive early passive range of motion, or active range of motion before healing, increases the risk of healing complications.[42]

Displaced Fractures: Two-Part Fractures

Two-part fractures involve displacement of one of the four segments. Therefore, four different fracture patterns are possible: anatomic neck, greater tuberosity, lesser tuberosity, and surgical neck. Even though surgical neck fractures are the most common fracture pattern, the treatment approach for all four types will be discussed.

Anatomic Neck

A displaced anatomic neck fracture in the absence of tuberosity displacement is quite rare. It may be difficult to recognize on standard radiographic views and a CT scan may be necessary. The problem with this fracture is the high risk of osteonecrosis because of disruption of the intra- and extraosseous blood supply to the humeral head. A true anatomic neck fracture occurs medial to the rotator cuff insertion and, therefore, is devoid of soft tissue or bony attachments. As a result, these fractures are difficult to treat by closed reduction. Open reduction and internal fixation (ORIF) is preferred, with the goal of avoiding prosthetic replacement in young patients. If a displaced anatomic neck fracture occurs in an elderly patient, a choice has to be made between open reduction and internal fixation (and the risk of nonunion, malunion, and osteonecrosis) and primary hemiarthroplasty. Malunion in the absence of osteonecrosis may be compatible with a good functional outcome. However, if osteonecrosis occurs with collapse and articular incongruity resulting in significant pain, then delayed hemiarthroplasty may be necessary. We prefer primary hemiarthroplasty for the active elderly patient whose functional requirements would be better served by early prosthetic replacement and initiation of a rehabilitation program to regain range of motion. If the articular surface is comminuted, then the fracture is similar to a head-splitting fracture, and primary hemiarthroplasty is preferred. Unfortunately, these fractures are so uncommon that the reported experience with either operative or nonoperative management is not sufficient to support broad conclusions.

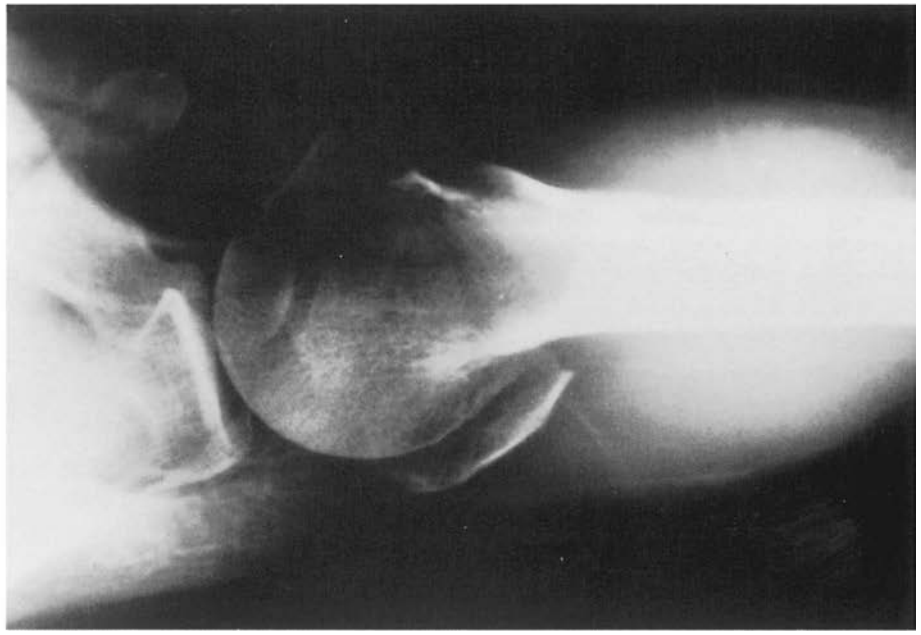
Lesser Tuberosity

Two-part lesser tuberosity fractures in the absence of posterior dislocations are uncommon. When encountered, they may be found in association with nondisplaced surgical neck fractures. The fragment is displaced medially as a result of the pull of the subscapularis muscle. This invariably results in some separation of the anterior portion of the rotator cuff. However, these fractures are of minimal clinical significance unless the fragment is large and includes a significant portion of the articular surface.[111] In this situation, internal rotation may be blocked. It is often difficult to determine the size of the fragment from standard radiographs. A CT scan may be very helpful in this situation. If a large fragment is involved, open reduction and internal fixation is indicated.

Greater Tuberosity

Two-part greater tuberosity fractures are relatively common and can be the source of significant disability. The greater tuberosity fragment is usually displaced superiorly into the subacromial space if the supraspinatus is involved, or posteriorly if the infraspinatus or teres minor is the primary deforming force (Fig. 27-16). The degree and direction of displacement indicate that a longitudinal tear of the rotator cuff is also present. Displaced greater tuberosity fragments will often block abduction or external rotation by impinging on the underside of the acromion or posterior glenoid, respectively. Open reduction and internal fixation of the fragment and repair of the rotator cuff tear is usually the preferred treatment approach.[7,48,114] Although the criterion for displaced fractures is 1 cm, greater tuberosity fractures appear to be different from other proximal humerus fractures. Less than 1-cm displacement may be problematic, particularly when the displacement is superiorly into the subacromial space. Open reduction and internal fixation has been required in 20% of patients when the displacement was between 0.5 and 1 cm.[104] Concomitant subacromial spurs may exacerbate impingement, even when the tuberosity is displaced less than 1 cm. It is important to include posterior as well as superior displacement in the indication for open reduction, for posterior displacement

A



B

Figure 27-16 **(A)** Anteroposterior (AP) and **(B)** an axillary view of a greater tuberosity fracture. Superior displacement into the subacromial space is noted on the AP view, whereas a significant amount of posterior displacement onto the articular surface of the humeral head is best seen on the axillary view.

may also lead to functional deficits, especially in external rotation. Posterior greater tuberosity displacement is best assessed on the axillary radiograph.[56,104]

Surgical Neck

Two-part surgical neck fractures are quite common in the elderly. In these fractures, the shaft may be completely displaced and pulled medially by the deforming force of the pectoralis major, or it may be impacted and angulated at the surgical neck area. Each type of fracture pattern requires a different treatment approach. Treatment depends on fracture stability and the displacement pattern. Posterior angulation is more tolerable than varus or anterior angulation.[42] Impacted fractures with less than a 45-degree angulation may be treated nonoperatively with early motion. Impacted fractures with greater than a 45-degree anterior angulation may limit forward elevation. Therefore, disimpaction, followed by reimpaction to achieve better alignment, should be considered in active patients.

Closed Reduction

When there is complete medial displacement of the shaft, achieving an acceptable functional outcome will require reduction of the fracture. We prefer to perform a closed reduction under anesthesia (regional or general) to obtain better muscle relaxation. The maneuver to achieve closed reduction requires adduction and flexion of the arm across the chest to relax the pull of the pectoralis major. The shaft is then displaced proximally for impaction into the proximal humeral fragment. In thin patients, the proximal fragment can be stabilized manually to enhance impaction. We use fluoroscopy for this maneuver, not only for the initial evaluation of the reduction but, more importantly, to evaluate the stability of the reduction. If the reduction is stable, the arm can be placed in Velpeau-type immobilization (with appropriate padding) with the arm across the chest. Previously, immobilization was continued for approximately 3 weeks; however, more recently we have decreased our time for immobilization to 1 week. Similarly, Hodgson et al.[73] prospectively compared immediate physiotherapy (within 1 week) with delayed physiotherapy (after 3 weeks) in 86 patients with two-part fractures and noted less pain and better shoulder function in the immediate physiotherapy group at 16 weeks. However, by 52 weeks there was no statistical difference between the groups. Radiographs should be repeated during the first week to be certain displacement has not occurred. When there is radiographic evidence of healing or the fracture is stable clinically, an active assisted range-of-motion program can be initiated.

If the fracture can be reduced closed but remains unstable when assessed fluoroscopically, the fracture requires fixation to maintain reduction and allow healing and initiation of range of motion. This can be accomplished via percutaneous pinning or open reduction.

Displaced Fractures: Three-Part Fractures

Two types of three-part fracture patterns can occur. The first type is displacement of the greater tuberosity and shaft, with the lesser tuberosity remaining attached to the articular segment. This pattern occurs more commonly. The second, and less commonly, encountered type of three-part fracture is displacement of the lesser tuberosity and shaft segments, with the greater tuberosity remaining attached to the articular segment.

Treatment options for these fractures include closed reduction, open reduction and internal fixation, or prosthetic replacement. At best, an adequate closed reduction is difficult to achieve, and more difficult to maintain, because the deforming muscular forces cannot be adequately offset by the position of immobilization. The results of closed reduction for three-part fractures have been quite variable.[33,91,97,106,114,171] Neer reported no successful results in 20 three-part fractures treated by closed reduction.[114] However, Young and Wallace reported 76% acceptable results following the nonoperative management of displaced fractures.[171] Unfortunately, they did not specify the number of three-part fractures treated. Leyshon treated 34 patients nonoperatively with 76% satisfactory results.[97] Because of inherent difficulties in performing a prospective randomized study for these uncommon injuries, the orthopedic literature on three-part proximal humerus fractures comprises mainly small series and retrospective reviews.

One exception, however, is the study of Zyto et al.[174] They prospectively followed 37 three-part fractures randomized into treatment with open reduction and internal fixation with tension band versus sling and early motion. Using the Constant score, they concluded that the outcome of operative and nonoperative treatment of three-part fractures of the humerus in elderly patients is similar, with more complications found in the surgically treated group. Criteria to be in the study included injuries not caused by high-energy trauma, at least 30% contact between the humeral head and shaft, and the ability of the patients to cooperate. They did not specify the methods used to classify the fracture patterns or whether interobserver reliability issues were considered. The potential uncertainty of fracture classification among observers makes it difficult to know the specific fracture types being treated. This may explain the wide range of outcomes reported for nonoperative and operative management. Zyto et al. also retrospectively assessed the long-term outcome of nonoperative treatment of three- and four-part fractures in the elderly. They assessed 17 shoulders with a minimum of 10 years of follow-up and found the range of motion to be satisfactory with mean flexion and abduction greater than 90 degrees. They found only four of the patients reported pain, which was described as mild.[175]

Despite some of the favorable results supporting nonoperative treatment, currently operative management is

the treatment of choice for three-part fractures of the proximal humerus.[12,13,40,67,126,139]

Displaced Fractures: Four-Part Fractures

Valgus-impacted

In "classic" four-part fractures, all four segments are displaced and the articular surface is devoid of soft tissue attachments. This results in disruption of the blood supply to the humeral head and a high likelihood of osteonecrosis. There is great variation in the reported incidence of osteonecrosis after these injuries, ranging from 21% to 75%[79,95,97,101,113,158] Neer reported osteonecrosis in six of eight patients with four-part fractures treated with open reduction and internal fixation.[113] Leyson reported osteonecrosis in six of eight patients treated nonoperatively.[97] Lee and Hansen reported a 21% incidence.[95] The variation could be secondary to the inclusion of four-part valgus-impacted fractures, which have a lower rate of osteonecrosis. In this fracture pattern type, the articular segment is impacted and angulated, rather than displaced, and may thus retain its vascularity from the posterior medial vessels traveling within the periosteum.[24,142] Theoretically, this source of blood supply can be interrupted by either a fracture line passing along the edge of the articular surface or through destruction of these vessels by lateral displacement of the articular segment relative to the main distal fragment.[125] Brookes et al. simulated four-part fractures in cadavers and found that perfusion of the humeral head was prevented, unless the head fragment extended distally below the articular surface medially; this allowed some perfusion of the head to persist by the anastomoses of the posterior medial vessels with the arcuate artery.[24]

Reconstruction rather than replacement for the valgus-impacted humeral head fracture has been extensively discussed in the recent literature, because the rate of osteonecrosis following this fracture pattern has been much lower than with the classic four-part fracture.[41] Jakob et al. reported that only 5 out of 19 (26%) valgus-impacted fractures developed osteonecrosis after either treatment by closed (five patients) or open (14 patients) reduction and minimal internal fixation with either AO screws or K-wires. They believed that replacement of the humeral head was not indicated because 74% of these patients had good results after 4 years. However, they also did not advocate nonoperative treatment because of anticipated problems with joint incongruity, impingement from the malpositioned tuberosities, and shoulder stiffness.[79]

In contrast, Court-Brown et al. found nonoperative treatment to be successful in elderly patients with valgus-impacted fractures. In their series, good to excellent results were obtained in 80% of patients treated.[38]

Classic Four-Part Fractures

The results of nonoperative treatment for classic four-part fractures have been consistently unsatisfactory as reported in the literature. Studies that appear to show acceptable results with nonoperative treatment of displaced fractures either have included no true four-part fractures or the classification of the fractures was such that an analysis of four-part fractures was not possible. Compito et al. reviewed 97 fractures from five series of true four-part fractures treated nonoperatively and showed that this resulted in a satisfactory outcome in only 5%.[36]

Misra performed a systematic review of the literature to compare the clinical outcomes of the management of three- and four-part fractures of the proximal humerus by nonoperative methods, internal fixation, external fixation, and arthroplasty. Only 24 reports published between 1969 and 1999 met the eligibility criteria. He found that patients managed nonoperatively had more pain and poorer range of motion than those managed operatively. However, he concluded that the current published data were inadequate for evidence-based decision making for the treatment of complex proximal humeral fractures.[108]

FRACTURE–DISLOCATIONS

Fracture–dislocations of the glenohumeral joint are characterized by a fracture of the proximal humerus in the presence of a complete loss of contact between the articular surfaces of the humeral head and glenoid. These injuries are usually associated with significant disruption of the soft tissues. Such traumatized tissues are prone to develop periarticular scarring and heterotopic bone formation. Repeated forceful attempts at closed reduction will increase the risk and severity of these problems. Therefore, although the first goal of treatment is prompt definitive reduction of the dislocation, multiple manipulations are to be avoided. Excessive force should never be used in the manipulation of fracture–dislocations, because it adds to the amount of soft tissue injury, endangers the adjacent neurovascular structures, and risks displacing previously undisplaced fractures.

Fracture–dislocations are classified by the direction of the dislocation (anterior vs. posterior) and the type of proximal humerus fracture present. The most systematic method to categorize these injuries is the Neer classification of proximal humeral fractures, as described earlier. The category of intraarticular fractures of the humeral head includes not only "head-splitting" fractures, but also the much more common impression fractures frequently associated with dislocations. Posterolateral impression fractures occur in association with anterior dislocations, whereas anterolateral impression fractures occur in cases of posterior dislocation.

Clinical and Radiographic Evaluation

Clinical Evaluation

Fracture–dislocations of the shoulder may occur at any age and by either indirect or direct mechanisms. In general, fracture–dislocations represent higher-energy injuries than simple dislocations or fractures alone. The history may indicate as much. The most common indirect mechanism involves a simple fall onto the outstretched upper extremity. Seizures and electroconvulsive therapy are other potential indirect causes of fracture–dislocations. The direct mechanism of injury involves a direct blow to the proximal humerus, and usually is the result of a fall directly onto the shoulder. As with proximal humerus fractures, patients should be asked about the circumstances surrounding their injury. If a fall was involved, patients should be asked about any head trauma, possible loss of consciousness, other injuries to the ipsilateral upper extremity, any subjective numbness or tingling involving that extremity, or any other focal sites of pain and tenderness. Other important history facts include patient age, occupation, hand dominance, and length of time since the injury.

Common presenting complaints include pain and swelling about the shoulder, especially with attempted motion. On examination, patients will typically exhibit crepitus and severe pain with minimal active or passive range of motion. Ecchymosis generally does not occur until 24 hours or more after the injury, but can occur sooner, usually in elderly patients. Eventually, ecchymosis may involve the entire extremity, as well as the axilla and down along the chest wall.

As with simple dislocations, there will be a change of the normal contour of the shoulder. In anterior fracture–dislocations, there is an anterior prominence in the shoulder, the lateral acromion becomes more prominent, and the coracoid is more difficult to palpate. There is a flattening of the posterior aspect of the joint. Conversely, in cases of posterior fracture–dislocations, the posterior aspect of the shoulder will be full, the anterior aspect of the shoulder hollow, and the coracoid more prominent. These findings can be quite subtle in large, muscular individuals, especially if considerable swelling is present.

Most fracture–dislocations result in the affected arm being held in a very characteristic manner. If anteriorly dislocated, the arm will usually be held in a position of relative abduction and external rotation; there can be a firm, painful block to passive internal rotation as the posterior aspect of the humeral head abuts against the anterior glenoid. Conversely, in posterior dislocations, the arm may be in internal rotation, with a firm, painful block to passive external rotation as the anterior aspect of the humeral head impacts on the posterior rim of the glenoid. The primary exception to these findings occurs when a surgical neck fracture is present, in which case motion in any plane may be possible through the fracture site, rather than at the articulation.

A thorough neurovascular examination of the involved extremity is of paramount importance in cases of glenohumeral fracture–dislocation because of the increased risk of associated vascular or neurologic complications. Vascular injuries, although rare, are devastating when they occur and usually involve injury to atherosclerotic axillary vessels in the elderly. Suspicion of a vascular injury is worked up in a manner similar to that discussed with proximal humerus fractures.

Neurologic injuries are much more common sequelae of fracture–dislocations, with the incidence reported ranging from 2% to 30%.[47,52,63,96,163,170] The axillary nerve is most commonly involved, although the entire brachial plexus or any component thereof may be affected. These injuries almost always represent traction neurapraxias, and most resolve clinically within 5 months.[16,28] However, it is critical that a thorough neurologic examination of the entire extremity be documented, both before and after any attempted manipulations. In evaluation of axillary nerve function, electromyographic (EMG) studies have shown that the commonly used method of testing sensation over the lateral aspect of the shoulder is quite unreliable.[16] A much more reliable method is to test for isometric deltoid motor function, which can be performed even in the context of the acute injury.

Despite the numerous signs and symptoms described in the foregoing, glenohumeral fracture–dislocations may be difficult to diagnose and can be missed by the initial examiner, particularly those involving posterior dislocations.[15,133,169] It is estimated that up to 50% of these injuries are initially misdiagnosed.[32] To avoid this pitfall, it is important to maintain a high level of suspicion for these relatively uncommon injuries, and to obtain a thorough and accurate radiographic evaluation.

Radiographic Evaluation

The plane of the glenohumeral articulation lies approximately 40 degrees anterior to the sagittal plane of the body. This must be taken into account if precise radiographs of this joint are to be obtained. Misdiagnosis of shoulder injuries is often attributed to radiographs being obtained in the plane of the body, rather than in the plane of the scapula centered on the glenohumeral joint. This results in overlapping structures that can be confusing and preclude accurate assessment of the injuries.

The axillary view is essential for evaluating glenoid and humeral articular surfaces, to identify displaced tuberosities, and it is the most sensitive view for detecting glenohumeral dislocations and subluxations. This view is most easily obtained with the patient in the supine position and the affected arm gently abducted to at least 30 degrees. If

possible, the arm can be supported in this position by the patient holding onto an IV pole.[11] If the patient is unable to assist, the arm should be positioned by someone wearing a lead gown.

Although the axillary view is the most difficult of the three views to obtain and requires moving the patient's painful arm, if done carefully, the great majority of patients will be able to tolerate the procedure. For those few patients who are unable to do so, however, the Velpeau axillary view described earlier is a suitable substitute that does not require removing the arm from the sling.[17]

Computed tomography is another imaging modality that can be used in the more complex or comminuted cases. This test provides unparalleled resolution for bony detail and, therefore, provides the most accurate assessment of fragment displacement, amount of articular involvement with a head-splitting or impression fracture (see Fig. 27-14), glenoid rim fractures, and chronic fracture–dislocations.

Although it is not as precise in assessing bony detail as a CT scan, MRI plays a very important role in evaluating traumatic shoulder injuries. It is the test of choice for evaluating soft tissue injuries about the shoulder and so can be used in patients for whom associated glenoid labral or rotator cuff tears are suspected. It can also assess injuries involving the axillary vessels and brachial plexus, and it remains the most sensitive method to detect osteonecrosis, a potential sequela of fracture dislocations.

Associated Injuries

Rotator Cuff Tears

All fracture–dislocations in which either or both tuberosities are significantly displaced will, by necessity, have a longitudinal split in the rotator cuff—often along the rotator interval between the supraspinatus and the subscapularis. In these cases, rotator cuff repair should be performed at the time open reduction and internal fixation is performed. In patients in whom the tuberosities do not fulfill the criteria for "displacement," associated cuff tears are not uncommon as a result of the gradual deterioration that occurs with advancing age. Therefore, the elderly are particularly susceptible to this injury, because their already degenerated cuff tendons are less able to withstand the high-tensile forces generated during dislocation.

Neurologic Injuries

Injury to peripheral nerves and the brachial plexus accompany fracture–dislocation of the shoulder, with a reported incidence of between 2% and 30%. This variability partly reflects age differences of the groups studied, as well as the method of assessing neurologic deficits—physical examination versus EMG. The axillary nerve, which courses anteriorly along the anterior border of the subscapularis, is especially vulnerable to traction injury during an anterior dislocation. It is the most commonly injured nerve in shoulder fracture–dislocations,[47,52,63,96,163,170] and the likelihood of injury increases with the age of the patient, the duration of the dislocation, and the severity of the trauma producing the injury.[122,170] The vast majority of these injuries represent traction neurapraxias and usually resolve spontaneously within 5 months.[16,28] Other isolated nerve injuries to the musculocutaneous, radial, and ulnar nerves are much less common.

When a neurologic injury is suspected, the initial physical examination findings should be carefully documented. An EMG should be obtained 3 weeks following the injury for further documentation. This is a much more sensitive method of assessing a neurologic injury than the physical examination. The difficulties in assessing axillary neuropathy based on physical examinations are twofold. First, dermatomal sensory testing is very unreliable.[170] Second, the high incidence of rotator cuff tears associated with these shoulder injuries confuses the picture somewhat. Clinical findings of weak abduction can be due to rotator cuff tear, axillary neuropathy, or the acute pain associated with the injury.

Vascular Injuries

Fracture–dislocations of the shoulder can, on rare occasions, be associated with vascular injuries—usually involving the axillary artery, its branches, or the axillary vein. These injuries can occur either during the injury itself or during the reduction maneuver. Attempted reductions of chronic dislocations are particularly risky and should be discouraged. Invariably, too many attempts are made and too much force used. Vascular damage most frequently occurs in elderly patients with fragile, atherosclerotic vessels and in patients whose soft tissues (and vessels) may be adherent as a result of previous dislocations or other injuries.[4,43,70] When a vascular injury occurs, it is an emergency and must be addressed immediately. These injuries are associated with a mortality rate of up to 50%.

Different types of arterial damage can occur, including intimal damage followed by thrombosis, avulsion of a large arterial branch, and laceration of the artery itself. As discussed earlier, anatomic studies have shown the axillary artery to be relatively fixed at the lateral border of the pectoralis minor muscle.[27] The artery becomes taut with abduction and external rotation of the arm, and is vulnerable to injury when the humeral head dislocates anteriorly and the pectoralis minor acts as a fulcrum over which the artery is stressed. There is the further risk with fracture–dislocations that the artery can be impaled or lacerated by the fracture fragments. The clinical findings and management of axillary artery injury is as discussed previously.

Impression Fractures of the Humeral Head

All shoulder dislocations impact the humeral head against the glenoid to some extent. An anteriorly dislocated humeral head is compressed against the anterior glenoid by the concomitant muscular contraction, thereby causing an impression fracture of the posterolateral humeral head. This defect, referred to as a Hill-Sachs lesion, can be quite large, especially in cases of chronic dislocation. Posterior dislocations frequently result in impression fractures of the anteromedial portion of the humeral head, referred to as a "reverse Hill-Sachs lesion" (see Fig. 27-14). These impression fractures can be quite large, especially in chronic posterior dislocations. In general, the larger the size of the defect is, the more difficult it is to obtain a successful closed reduction. These impression fractures play a much more prominent role in the treatment of chronic dislocations.

Treatment

Two-Part Fracture–Dislocations: Surgical Neck

Two-part surgical neck fracture–dislocations are very uncommon, but when they occur, the dislocation is almost always anterior.

In general, the approach to these injuries is to first achieve a gentle, closed reduction of the dislocation and then to determine the appropriate treatment for the fracture, based on the evaluation of the postreduction radiographs. Although conscious sedation is usually sufficient, if closed reduction is unsuccessful, general anesthesia should be used to avoid multiple attempts. Closed reduction of the anteriorly dislocated humeral head can often be accomplished with gentle fingertip mobilization of the humeral head while longitudinal traction is applied to the arm. There are a few circumstances in which open reduction is indicated:

1. Vascular injury
2. Open fracture
3. Failed or difficult closed reduction
4. Anterior or posterior dislocation associated with a nondisplaced surgical neck fracture (closed manipulation risks fracture displacement)

Two-Part Fracture–Dislocations: Greater Tuberosity

Greater tuberosity fractures have been reported to occur in up to 33% of anterior shoulder dislocations.[132] This is the most common type of fracture–dislocation. The initial step in treatment of these injuries should always be gentle, closed reduction of the dislocation, followed by a complete set of postreduction radiographs. In many cases, the reduction restores the greater tuberosity fragment to near-anatomic position (Fig. 27-17). When this

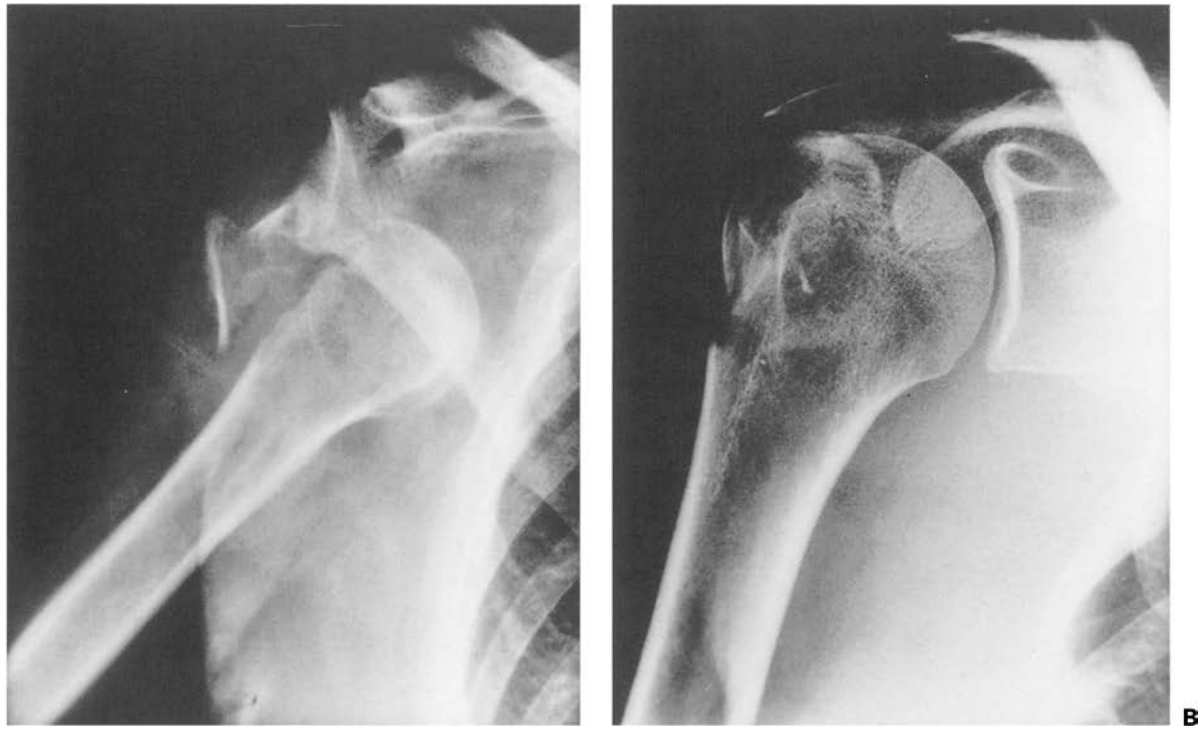


Figure 27-17 A 61-year-old woman who fell onto the outstretched right upper extremity sustaining **(A)** a two-part anterior greater tuberosity fracture dislocation. **(B)** Following closed reduction, there is near-anatomic reduction of the greater tuberosity fragment.

occurs, nonoperative management is preferred, consisting of sling immobilization for approximately 4 weeks. However, passive range-of-motion exercises should be started as soon as discomfort subsides. Frequent follow-up radiographs are essential in the postreduction period to ensure that the tuberosity has not redisplaced with the early motion program.

Management is as with greater tuberosity fractures, discussed earlier. In cases where the greater tuberosity remains displaced by more than 5 mm, operative management is indicated, unless the patient's medical condition or limited functional demands indicate otherwise.[162] Prognostically, dislocations associated with a greater tuberosity fracture rarely go on to become recurrent, because the anterior soft tissues are usually spared, and the joint stability is restored once fracture healing occurs.

Two-Part Fracture–Dislocations: Lesser Tuberosity

Posterior glenohumeral dislocations are sometimes accompanied by lesser tuberosity fractures. This represents an avulsion-type fracture as a result of the strong pull of the attached subscapularis tendon and anterior capsule. When these injuries are acute or recent (within 2 weeks), the first step in treatment should be attempted closed reduction of the dislocation. This can be accomplished with the patient supine, by application of longitudinal traction to the arm while it is held in 90 degrees of forward flexion. The arm should then be gradually adducted across the chest while maintaining traction, in an effort to unlock the head from behind the glenoid. The maneuver can sometimes be facilitated by application of digital pressure on the humeral head from behind or a laterally directed force on the proximal humerus.

Postreduction radiographs should then be obtained to document reduction of the glenohumeral joint, to assess the position of the lesser tuberosity fragment, and to ensure that no other fractures have been displaced by the reduction maneuver. If the reduction is stable and residual tuberosity displacement is less than 1 cm, then the patient should undergo 4 weeks of immobilization in a modified shoulder spica cast or orthosis that maintains the arm at the side in 10 to 15 degrees of external rotation, 10 to 15 of degrees extension, and 10 to 15 degrees of abduction. When residual instability is present or the displacement of a large lesser tuberosity fragment exceeds 1 cm, operative management is indicated. The goals of operative management are to restore stability and anatomically reduce and securely fix the lesser tuberosity fragment. However, the decision to proceed with operative management should be based on a careful assessment of all factors, not the least of which is the patient's own functional expectations.

Three-Part Fracture–Dislocations: Anterior

Three-part anterior fracture–dislocations consist of anterior dislocation of the humeral head with displaced fractures of the surgical neck and greater tuberosity. The lesser tuberosity remains attached to the humeral head and provides some blood supply to the articular surface through the subscapularis and anterior capsule attachments. However, the arcuate artery of Laing, which carries most of the direct blood supply to the head, is at risk with this injury because it penetrates the medial portion of the greater tuberosity, with the resulting risk of osteonecrosis.[60] Open reduction of the dislocation should be performed, for it can be done much more gently, thus reducing the risk of further soft tissue injury. Our preferred treatment for this injury consists of open reduction of the dislocation, followed by fixation of the displaced fragments or proximal humeral replacement.

Three-Part Fracture–Dislocations: Posterior

Three-part posterior fracture–dislocations are characterized by posterior dislocation of the humeral head, with the greater tuberosity attached, in combination with displaced fractures of the surgical neck and lesser tuberosity. Complete radiographs (trauma series) are essential to accurately assess this injury and to avoid overlooking the posterior dislocation.

As with three-part anterior dislocations, nonoperative treatment is not recommended for these injuries. They require open reduction and fracture treatment of the dislocation to be performed as soon as possible after the injury.

Four-Part Fracture–Dislocations

All four-part fracture–dislocations, whether anterior or posterior, are associated with significant disruption of the blood supply to the humeral head. Osteonecrosis of the articular segment is almost inevitable, and for this reason, proximal humeral replacement is the treatment of choice; open reduction and internal fixation is considered only in young patients with good bone quality. Nonoperative treatment is not recommended for this injury pattern.

Summary of Nonoperative Treatment

Most proximal humerus fractures are minimally displaced and therefore can be treated nonoperatively. Two-part surgical neck fractures with less than 45 degrees of angulation and minimally displaced tuberosity fractures that do not impede range of motion can also be treated nonoperatively. Three- and four-part fractures typically should be managed operatively; however, nonoperative treatment may be considered in elderly patients, particularly in those patients with the valgus-impacted pattern.

CONCLUSION 887

INTRODUCTION: DEFINITION OF MINIMALLY INVASIVE FIXATION

Minimally invasive fracture fixation is defined as a technique utilizing indirect percutaneous reduction and fixation under fluoroscopic visualization with hardware (usually pins and/or screws) placed without extensive exposure and soft tissue dissection. Most fractures of the proximal humerus can be treated successfully with nonoperative treatment and early mobilization. Less than 20% of the fractures are displaced and unstable requiring operative stabilization.[11,15,17] There have been numerous controversies over the treatment of these displaced and unstable fractures. Various methods of open reduction and internal fixation have been described and historically have been utilized for the treatment of unstable displaced humerus fractures. Open reduction and internal fixation can potentially increase the risk of avascular necrosis of the humeral head because of damage to the vascular supply to the humeral head secondary to extensive soft tissue stripping at the time of reduction and/or hardware application.[10,11,15,16,40] The primary blood supply to the humeral head is the anterior humeral circumflex artery, which runs along the lateral aspect of the bicipital groove. The blood supply may be compromised at the time of injury and may also be injured during operative treatment. Therefore, increased attention has been given to reducing soft tissue stripping during reduction and plate application. This, in turn, has led to

increased interest in minimally invasive techniques of fracture fixation. The goal is the same for any type of fixation—anatomic reduction and stable fixation.

Recently, there has been a surge of interest in minimally invasive fixation techniques in many different subspecialty areas of orthopedics. The recent trauma literature contains several reports of percutaneous fixation of the femur, tibia, and tibial pilon fractures.[18,27,33] The importance of preserving blood supply and minimizing soft tissue stripping are increasingly recognized. With regard to the treatment of proximal humerus fractures, several techniques have been introduced in the context of minimally invasive fixation. These include flexible intramedullary pins, external fixation, and percutaneous pinning techniques. Zifko et al.[43] introduced 2-mm pins into the humerus from the distal medullary canal about 3 cm proximal to the olecranon fossa in a retrograde fashion. They reported excellent or good clinical results in 58% of patients and a 98% bone union rate. Kristiansen[22] and Kyle and Conner[23] studied outcomes of closed reduction and external fixation of proximal humerus fractures. The former reported excellent or satisfactory results in 68% of his cases and the latter reported satisfactory results in 80% of their cases. External fixation is not indicated in the majority of fractures of the proximal humerus, but it can be a logical alternative in the management of a few selected fractures.[23]

There have been several reports of successful closed reduction and percutaneous pinning during the past two decades.[8,12,14,17,35,36,39] The technique of closed reduction and percutaneous pinning of the proximal humerus fractures was originally described by Böhler, who used the technique for the treatment of the proximal humeral epiphyseal injury in children.[4] The technique has been modified over years and applied to treat the proximal humerus fractures more commonly seen in the older population. The technique was initially used for isolated fractures of the greater tuberosity or surgical neck, and was gradually extended to the management of more complex fracture types (Table 28-1). In selected fractures, closed reduction and percutaneous pinning allows preservation of the intact soft tissue sleeve and periosteal blood supply while obtaining and maintaining a stable reduction. Other potential advantages include a smaller incision, less dissection, and less scarring. A minimally invasive approach minimizes trauma to the rotator cuff and deltoid, and with experience can decrease operative time. While still a difficult and technically demanding procedure, percutaneous pinning of selected proximal humerus fractures shows considerable potential.

TABLE 28-1
FRACTURES AMENABLE TO PERCUTANEOUS PINNING

Two-part	Surgical neck Greater tuberosity *Lesser tuberosities
Three-part	Surgical neck/greater tuberosity *Surgical neck/lesser tuberosity
Four-part	Valgus-impacted

*Without associated posterior dislocation.

INDICATIONS FOR MINIMALLY INVASIVE FIXATION

The technique of closed reduction and percutaneous fixation is difficult and demanding, and careful attention must be paid to appropriate indications and technical considerations. A successful outcome after operative treatment of unstable and displaced proximal humeral fractures, regardless of approach or choice of hardware, depends on a few critical factors: (a) anatomic reduction, (b) stable fixation, (c) careful management of soft tissues, and (d) appropriate rehabilitation. Percutaneous pinning offers an excellent alternative to the open approach in selected fractures (Table 28-2).

Fracture Type

The same principles of anatomic open reduction and stable fixation apply to minimally invasive fracture treatment. Closed reduction of the fracture must be attainable and the reduction must be stable under fluoroscopy after pinning. The fracture must be an acute injury generally less than 14 days old. An intact medial calcar (medial humeral metaphysis just under the articular segment) region is important for stability after reduction and fixation.

Two-Part Fracture of the Surgical Neck

A displaced two-part fracture of the surgical neck is an ideal indication for percutaneous pinning, provided the fracture can be reduced by closed manipulation under anesthesia. In this type of fracture, both tuberosities are attached to the head fragment so that the head stays in a neutral position. Most surgical neck fractures are treated

TABLE 28-2
CONDITIONS FOR SUCCESSFUL PINNING

- Good bone stock
- Intact medial calcar
- Substantial greater tuberosity fragment
- Stable reduction under fluoroscopy after pinning
- Reliable, cooperative patient

nonoperatively. Displacement of 50% or more in an active, healthy individual is an indication for operative treatment. Surgical neck fractures are often easily reduced by the closed method. If closed reduction is not possible, soft tissue such as the long head of the biceps tendon, capsule, or muscle may be interposed between the fragments.[2] In this situation, a limited open reduction is recommended. Even in these cases percutaneous pinning for fracture fixation with minimum hardware can be effective. Comminution of the fracture site, especially the medial calcar (metaphysis) region, is a relative contraindication to closed treatment. A large medial calcar may preclude a stable reduction and the risk of varus displacement is high. An impacted surgical neck fracture is an excellent indication for closed reduction and percutaneous pinning. The impacted anterior fragment should be disimpacted from the shaft to restore the normal neck–shaft angle.

Two-Part Fractures Involving the Greater and Lesser Tuberosities

Traditionally, two-part fractures of the tuberosities have been managed by open reduction and internal fixation.[9,15,29] There have been few attempts to manage these fractures by a closed method.

An isolated greater tuberosity fracture occurs with or without anterior glenohumeral dislocation. Greater tuberosity fractures are usually retracted posteriorly and superiorly, and closed reduction is difficult. However, if this fracture is associated with an anterior dislocation, a closed reduction of the glenohumeral dislocation may successfully reduce the greater tuberosity fracture.[2] Tuberosity fractures with 5 mm[6] or more of displacement are generally considered operative cases. Unlike surgical neck fractures, where displacement is easily tolerated, even minimal displacement of a tuberosity can be problematic. Percutaneous screw fixation of displaced greater tuberosity fractures can be considered if the fragment is substantial enough to allow hardware fixation. If the greater tuberosity fragment is irreducible by closed means or comminuted, open reduction and internal fixation with transosseous and cuff-to-bone suture fixation is required.

Isolated lesser tuberosity fractures are usually associated with posterior dislocations and may also be treated by closed reduction if the articular involvement is minimal. Percutaneous screw fixation can be employed for fixation of the reduced fragment.

Three-Part Fracture

Three-part fractures are often severely displaced and unstable because of the strong deforming forces by attached muscles. They are difficult to treat by closed reduction and minimal fixation methods. However, several authors reported satisfactory results with closed reduction and percutaneous fixation.[1,8,12,14,35,36,39] Closed reduction and percutaneous fixation is a good option for treatment in selected cases, where there is good bone stock without significant comminution. The long head of the biceps tendon may interpose between the fracture fragments, making closed reduction difficult. Sometimes the tendon can be released manually through the small reduction portal. If not, repeated attempts at reduction may cause further comminution and injure the interposed tendon, and a more formal open reduction and internal fixation should be performed.

Four-Part Fracture

Four-part proximal humerus fractures as classified by Neer[1,31,32] are particularly problematic. Historically, they have a very high rate of avascular necrosis following fixation. Because of this, Neer recommended hemiarthroplasty for the treatment of these fractures. However, a subgroup of the four-part proximal humerus fractures, "four-part valgus-impacted fractures," is readily amenable to reduction and fixation. Neer did not specify this fracture in his initial classification system. Similar fractures have been described by several authors[26,28,40] using different names. More recently, the AO/ASIF organization introduced a new classification system, which was essentially an expansion of Neer's original work; in their review, 14% of all documented cases are found to be valgus-impacted injuries and are classified as C2.1 or C2.2 type fractures.[15,26,28] The first authors to deal specifically with this type of fracture were Jakob et al.[17] in 1991.

Valgus-impacted four-part proximal humerus fractures have a unique configuration and a far lower risk of osteonecrosis if treated appropriately. In four-part valgus-impacted fractures, the head is impacted onto the shaft at the surgical neck, such that the articular surface is 90 degrees to the long axis of the shaft. The articular segment faces superiorly, toward the acromion, rather than medially, toward the glenoid. The tuberosities are displaced laterally.[13,17,34,36] (Fig. 28-1). The main source of vascularization for the humeral head, the ascending anterolateral branch of the anterior humeral circumflex artery,[5,10] is interrupted at its point of entry into the humeral head in the area of the intertubercular groove. Other sources of vascularization via both tuberosities and metaphyseal arterial anastomoses are deprived as well. However, perfusion of the humeral head via the intraosseous arcuate artery may continue if the head fragment includes part of the medial aspect of the upper part of the neck. In true valgus-impacted fractures, there is little or no displacement of the medial aspect of the humeral articular surface with respect to the medial aspect of the shaft (see Fig. 28-1). In such cases, the posteromedial arteries from the posterior humeral circumflex artery are still attached to the medial aspect of the articular fragment via the medial soft tissue

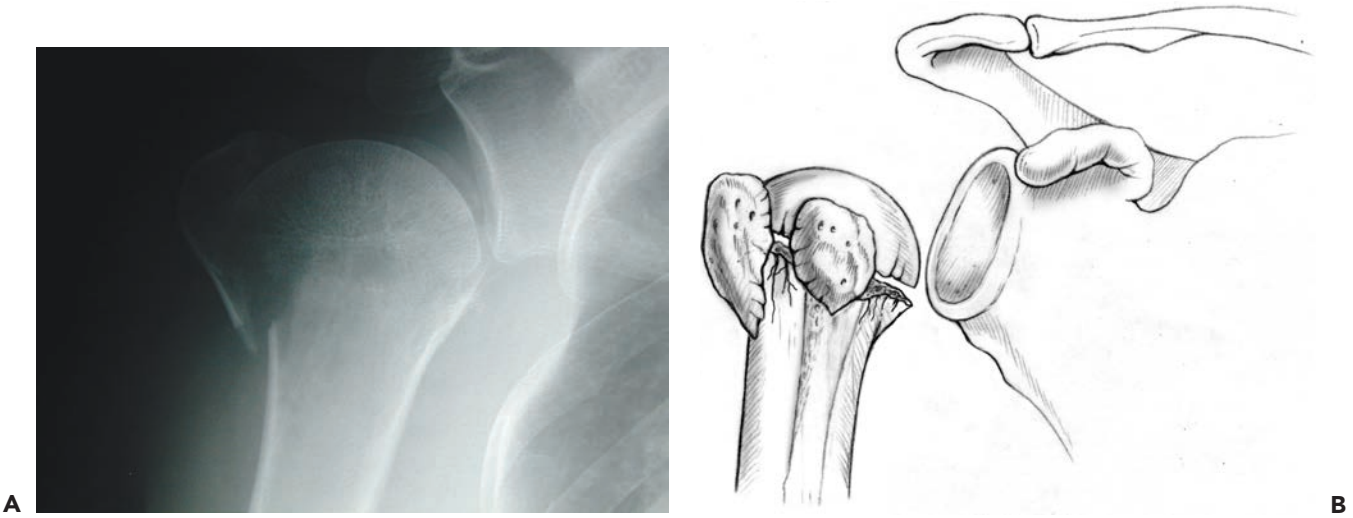

Figure 28-1 **(A)** Valgus-impacted four-part fracture of proximal humerus. The head is impacted onto the shaft at the surgical neck such that the articular segment faces superiorly, toward the acromion, rather than medially, toward the glenoid. The tuberosities are displaced laterally. **(B)** A schematic drawing of valgus-impacted four-part fracture. (Adapted from Resch H, Beck E, Bayley I. Reconstruction of the valgus-impacted humeral head fracture. *J Shoulder Elbow Surg* 1995;4(2):75.)

hinge and thus can supply the articular fragment through the anastomoses with the arcuate artery[5] (Fig. 28-2). Therefore, the prevalence of necrosis of the humeral head (8% to 26%) is much lower than that associated with standard four-part fractures (46% to 75%).[17,25,32,34-36]

In four-part valgus-impacted fractures, a continuous envelope of soft tissue bridging the shaft, tuberosities, glenohumeral joint capsule, and rotator cuff is maintained, even after the high-energy impaction that caused the fracture. This soft tissue envelope substantially contributes to stability after reduction and facilitates anatomic or nearly anatomic reduction of the tuberosities once the head is reduced.[13] However, several anatomic aspects of these unique fractures should be considered before

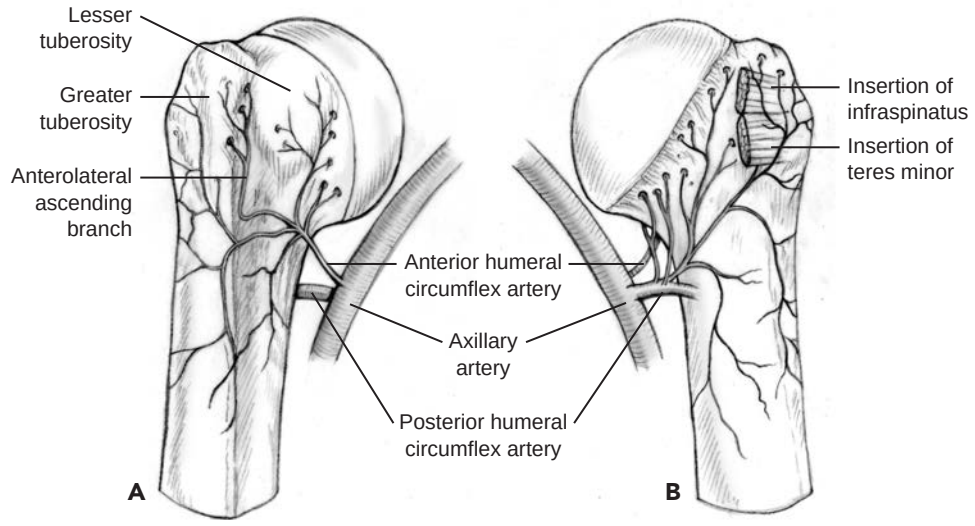

Figure 28-2 Normal blood supply to the humeral head. **(A)** The anterior aspect of the humeral head. The anterior circumflex artery enters the humeral head at the proximal end of the transition from the greater tuberosity to the intertubercular groove. After entering the bone, within the epiphysis, the anterolateral branch gives off the arcuate artery to form numerous intraosseous anastomoses. The arcuate artery vascularizes essentially the entire humeral head. **(B)** The posterior aspect of the humeral head. The posterior circumflex artery has abundant medial branches, which enter the head and anastomose with the arcuate artery from the anterior circumflex artery. (Adapted from Gerber C, Schneeberger AG, Vinh TS. The arterial vascularization of the humeral head. An anatomical study. *J Bone Joint Surg Am* 1990;72(10):1489,1491.)

proceeding to closed treatment. The medial periosteal vessels on the anatomic neck contribute enough blood supply to the humeral head that the incidence of avascular necrosis is low. If the medial periosteal vessels on the anatomic neck are to survive, the fracture line must be located distally to the point at which the vessel enters into the bone. The posteromedial vessels enter the head at the point just distal to the articular cartilage and form an anastomosis with the arcuate artery within the head. If the fracture line is located proximal to the entry point or is combined with comminution on the medial calcar region, the probability of survival of the articular fragment becomes minimal. Another point to consider is that the lateral displacement of the articular segment relative to the shaft compromises the medial periosteal vessel and results in a higher incidence of avascular necrosis. When pronounced lateral displacement of the articular fragment is present in an older patient, primary hemiarthroplasty is inevitable.[34] In young patients, however, closed reduction and percutaneous fixation or open reduction and internal fixation should be attempted first, to avoid hemiarthroplasty in this age group.

Other standard displaced four-part fractures in older patients should be treated with primary hemiarthroplasty because of its high rate of avascular necrosis and instability.[11,32] Resch et al.[36] tried closed reduction and percutaneous fixation in five cases of laterally displaced, nonimpacted four-part fractures. Two of the five required revision to prosthesis; one of the two presented with avascular necrosis. The other three had good results.

Age, Bone, and Soft Tissue

Typical closed reduction and percutaneous fixation employs 2.5-mm pins and/or 4.5-mm cannulated screws. Biomechanically, percutaneous fixation has inherently weaker fixation strength than open reduction and internal fixation with plates or locked intramuscular fixation.[1,21,30,41] Stable fixation with pins and screws requires good bone quality and compliance with a more conservative rehabilitation program. Significant osteopenia or associated conditions risk the postreduction stability and complicate any possible revisions. There are no definite guidelines about age. Chronologic age seems less important compared to physiologic age. Therefore, the patient must be physiologically young with compelling reasons to retain the natural humeral head. The patient must be motivated to undergo this operative procedure and comply with the rehabilitation protocol. The patient should have normal cognitive ability.

Closed reduction and percutaneous fixation is contraindicated in (a) patients with poor bone stock including pathologic fractures; (b) fractures where there is a comminuted proximal shaft fragment, especially in the medial calcar region; (c) displaced four-part fractures (other than the valgus-impacted configuration) in elderly people requiring hemiarthroplasty; (d) some head-split fractures; (e) nonacute fractures (older than 14 days); (f) noncompliant patients or patients unable or unwilling to comply with strict follow-up and rehabilitation limitations; (g) fractures with displaced greater tuberosity fractures that are too comminuted or small for hardware fixation; (h) open fractures which require open irrigation; (i) dirty contaminated deep skin wound over the fracture site; and (j) any medical illness that precludes a surgical intervention.

SURGICAL TECHNIQUE

Preoperative Planning

Patient evaluation begins with a thorough history and physical examination. The mechanism of injury should be noted and all associated injuries completely evaluated. Most proximal humeral fractures are the result of low-energy falls in elderly patients. In the younger population, high-energy injuries are commonly responsible for the fractures. A thorough neurovascular examination should be performed before percutaneous fixation is attempted. The patient's social situation should be assessed to discern whether the patient is likely to comply with rehabilitation and close follow-up. In the case of a dirty contaminated skin wound over the fracture site, the operation must be deferred until the wound heals or other treatment measures are required.

Radiographic evaluation consists of four standard views: a regular anteroposterior (AP) view of the shoulder, a true anteroposterior view (or scapula plane AP) of the shoulder, an axillary view, and a scapular Y-view. The true anteroposterior view of the shoulder with the arm in the neutral rotation is useful to assess the degree of head impaction and tuberosity displacement. The axillary view is helpful in assessing anteroposterior angulation, displacement of tuberosities, presence of articular surface defects, and presence of dislocation. If the patient cannot be positioned for an axillary view, the Velpeau axillary can be used.[3] Clear appreciation of the plane and location of all fracture lines is essential in determining the likelihood of successful percutaneous pinning. If evaluation is incomplete with plain x-rays alone, a computed tomography (CT) scan may be helpful.

The usefulness of CT scans has been a subject of debate. An axial CT scan with 2-mm sections adds detail to evaluation of complex fractures. Additional CT scan images and three-dimensional reconstructions were shown to improve the accuracy of evaluation of proximal humerus fractures.[7] On the other hand, Bernstein et al.[1] reported that the addition of CT scans were associated with a slight increase in intraobserver reliability, but no increase in interobserver

reproducibility. Magnetic resonance imaging (MRI) is not helpful in determining head vascularity after an acute injury and is not indicated.

Closed reduction and percutaneous fixation techniques are based on the assumption that closed reduction and fixation is attainable. Importantly, patients should be prepared beforehand for a situation in which closed reduction and fixation is not possible. The patient should be consented for alternative treatment methods before surgery. The surgeon should be prepared for open reduction and internal fixation or, if necessary, hemiarthroplasty.

Positioning

The patient is positioned to allow unencumbered access to the shoulder, both for easy visualization under fluoroscopy and for easy pin placement (Fig. 28-3). The patient is placed on a radiolucent operating table with the head in a head holder. The procedure can be performed with the patient in the supine position; however, raising the head of the bed 15 to 20 degrees is often helpful for orientation and instrumentation. The thorax is shifted as far lateral as possible to the side of the table to increase radiographic visualization, and stabilized to prevent the patient from falling off the table. The neck should be in a neutral position, and the hips and knees should be flexed. The arm is draped free. Adequate visualization of the shoulder under fluoroscopy should be confirmed before prepping and draping. Alternatively, a complete beach-chair position may also be utilized, although the fluoroscopy must be swung over the top to obtain an axillary view. The x-ray unit is closer to the surgeon's head, however, increasing radiation exposure to the surgeon.[42] A mechanical arm holder is used for positioning the arm during the procedure. The holder can be useful for placing traction on the arm when necessary.

Figure 28-3 Operative setup for closed reduction and percutaneous fixation. The patient is placed in the supine position on the radiolucent operating table. The thorax is shifted to the lateral side of the table and stabilized. The mechanical arm holder is useful for maintaining position of the arm and placing traction on the arm.

The C-arm fluoroscopy is positioned at the head of the bed, parallel to the patient, leaving the area lateral to the shoulder open for access and pin placement. Alternatively, the C-arm can be angled perpendicular to the patient; however, it is much more difficult to get an axillary view with the C-arm in this position. The monitor is placed on the opposite side of the table. We recommend not using an adhesive, plastic drape directly on the skin of the operative site, because it can inadvertently become adherent to the pins during insertion and may be introduced into the wound. The shoulder should be draped to accommodate conversion to an open procedure, should it be necessary.

Fracture Reduction

Bony landmarks are outlined on the skin, especially the acromion. The reduction maneuver may be performed before the sterile prepping and draping (if it can be done entirely by closed means) to assess the feasibility of the closed technique.

Two-Part Fracture of the Surgical Neck

The humeral shaft is typically displaced medially, angulated with the apex anterior and slightly internally rotated because of the pull of the pectoralis major muscle. The head fragment usually remains in a neutral or slightly varus position. Closed reduction is performed by flexing, adducting, and slightly internally rotating the humerus to relax the pectoralis major muscle. Traction is then applied along the long axis of the humerus with a posteriorly directed force applied on the proximal shaft. If the reduction is satisfactory under fluoroscopy, an assistant takes over the position of the reduction and maintains the posteriorly directed force on the shaft. The arm is in slight abduction (20 degrees) in the scapular plane and in neutral rotation.[42]

The fracture fragments can be manipulated through a small "reduction portal." A 1- to 2-cm incision is made off the anterolateral corner of the acromion at the level of the surgical neck. The deltoid is gently and bluntly spread. A blunt instrument can be introduced through this portal, into the fracture, and used to manipulate and/or lever the fragments. Overly aggressive manipulation should be avoided to preserve and protect the osteoporotic bone that often characterizes proximal humerus fractures. This "reduction portal" can be utilized in many of the various fracture configurations.

Two-Part Fracture of the Greater or Lesser Tuberosity

Tuberosity fractures will be discussed in the following section, Three-Part Fracture.

Three-Part Fracture

When a three-part fracture involves the greater tuberosity, the humeral head is internally rotated due to the unopposed pull of the subscapularis. The shaft is displaced medially, internally rotated, and anteriorly angulated by the pectoralis major in the same way as the two-part surgical neck fracture (Fig. 28-4). The closed reduction starts with bringing the arm in flexion, adduction, and internal rotation to relax the pectoralis major. An assistant then applies traction along the line of the humerus with a posteriorly directed force on the proximal shaft. Once satisfactory reduction of the surgical neck is achieved under the C-arm fluoroscopy, traction is released and the arm is brought down to the side and placed in slight abduction. The posteriorly directed force should be maintained until the fracture is fixed with pins. If the rotation of the head fragment is so pronounced that the above measure is not helpful, a Steinmann pin may be drilled into the humeral head for derotation. The reduction is secured by means of two or three terminally threaded 2.5-mm pins drilled from the anterolateral aspect of the shaft to the head in a retrograde fashion. After fixation of the head–shaft interface, the arm is then returned carefully to the neutral rotation.

The greater tuberosity fragment is reduced percutaneously using a hook through the previously described "reduction portal." The hook is placed into the rotator cuff tissue near its insertion to the tuberosity fragment and is used to pull the fragment in an anterior, inferior direction. Alternatively, a puncture incision may be made over the greater tuberosity lateral to the acromion so that a

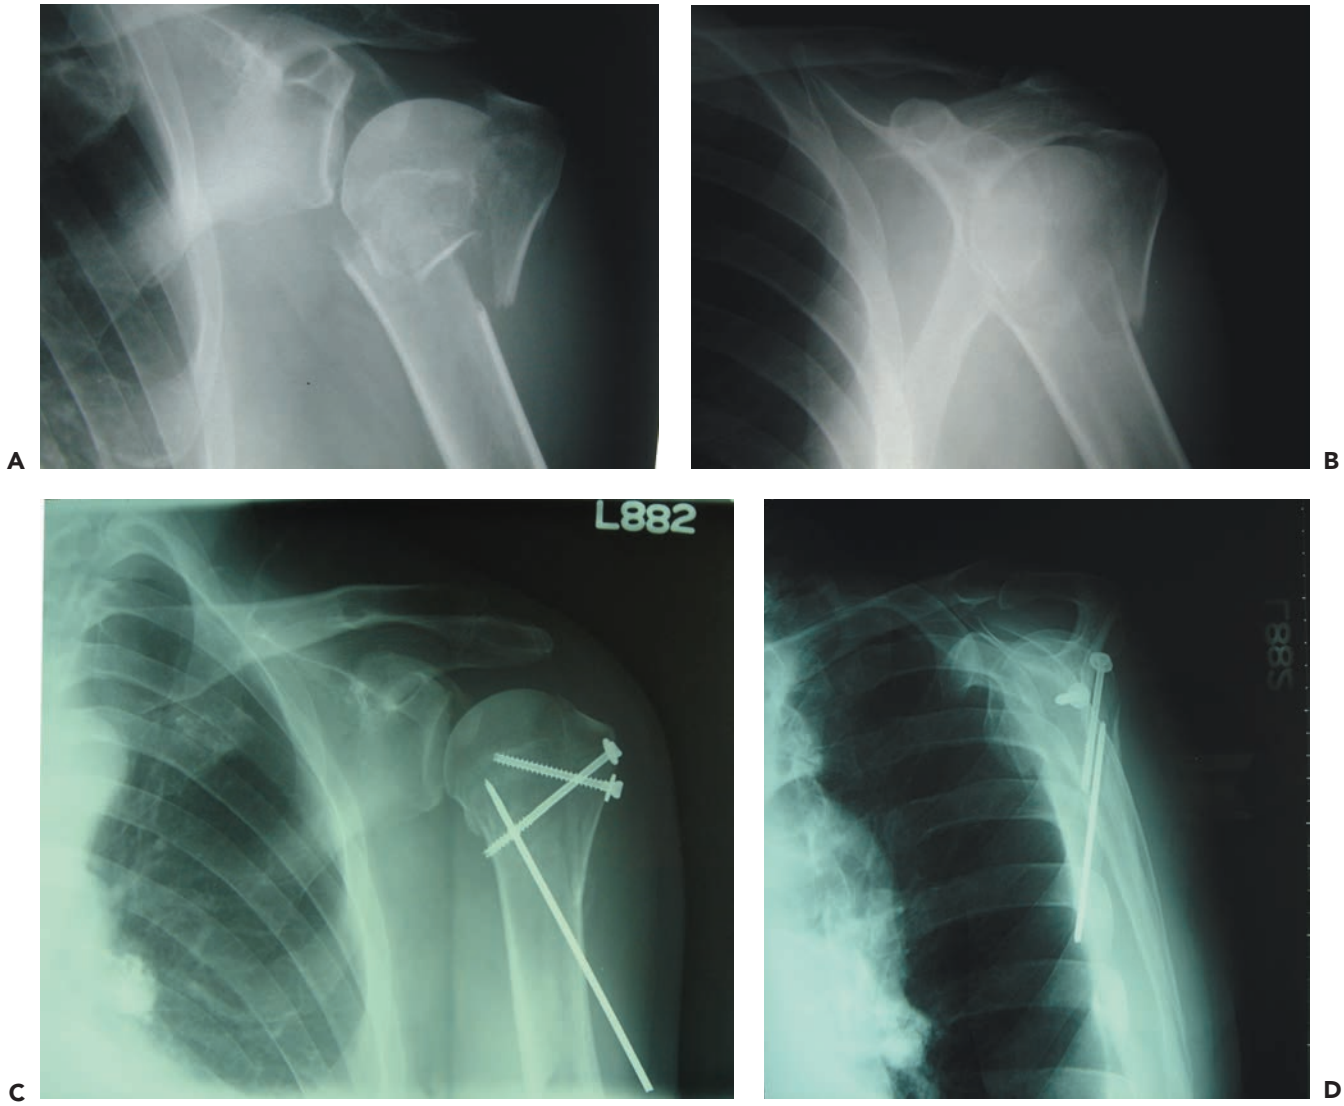

Figure 28-4 Three-part fracture of the proximal humerus involving the greater tuberosity. The humeral head is internally rotated due to the unopposed pull of the subscapularis. The shaft is displaced medially, internally rotated, and anteriorly angulated by the pectoralis major: **(A)** a true anteroposterior view; **(B)** a regular anteroposterior view; **(C,D)** postoperative radiographs.

reduction tool is introduced to pull the greater tuberosity fragment anteroinferiorly. Once reduced, the greater tuberosity should be held temporarily with K-wires or guide pins for 4.5-mm cannulated screws. When the guide pins for 4.5-mm cannulated screws are used, the drilling points will be the final screw insertion sites. Thus, the drilling points should be selected carefully not to cause further fragmentation of the tuberosity. The accuracy of reduction should be verified by at least biplanar fluoroscopic examination.

When the lesser tuberosity is fractured in a three-part fracture, the head fragment is externally rotated, abducted, and anteriorly angulated by the posterosuperior rotator cuff muscles. Thus, the reduction maneuver is composed of external rotation and flexion of the arm and a posteromedially directed force on the proximal shaft with longitudinal traction. Anteroposterior and axillary C-arm fluoroscopy should verify the reduction. A Steinmann pin may also be employed to facilitate the derotation of the head fragment. The reduction should be held in position using multiple terminally threaded 2.5-mm pins as described previously. Then the arm is brought to the side and internally rotated to seat the medially displaced lesser tuberosity on the head–shaft composite. The C-arm is now set for the axillary view. A "reduction portal" distal to the anterolateral corner of the acromion may be created. A hook can be advanced toward the lesser tuberosity, which then can be pulled laterally to its normal position. An axillary fluoroscopic view shows the accuracy of the reduction. Temporary fixation is provided with K-wires or guide pins for 4.5-mm cannulated screws.

A three-part fracture with an impacted head fragment requires a small incision over the fracture site for disimpaction of the head. The detailed technique of reduction is discussed in the following section, Four-Part Valgus-Impacted Fracture.

Four-Part Valgus-Impacted Fracture

The arm is held at the side in neutral rotation. A small 1- to 2-cm incision is made 2 to 3 cm distal to the anterolateral corner of the acromion. Formation of this "reduction portal" facilitates reduction of the fracture percutaneously prior to pin fixation (Fig. 28-5). The reduction portal is positioned distal to the anterolateral corner of the acromion at the level of the surgical neck of the humerus, posterior and lateral to the biceps tendon. The fracture between the greater and lesser tuberosities lies approximately 0.5 to 1 cm posterior to the bicipital groove. Locating the reduction portal over the split between the tuberosities enables elevation of the head fragment by placing the instrument through the fracture line.

After the incision is made, the deltoid is gently and bluntly spread to avoid possible injury to the anterior branch of the axillary nerve in this location. A blunt-tipped elevator or a small bone tamp is placed through the reduc-

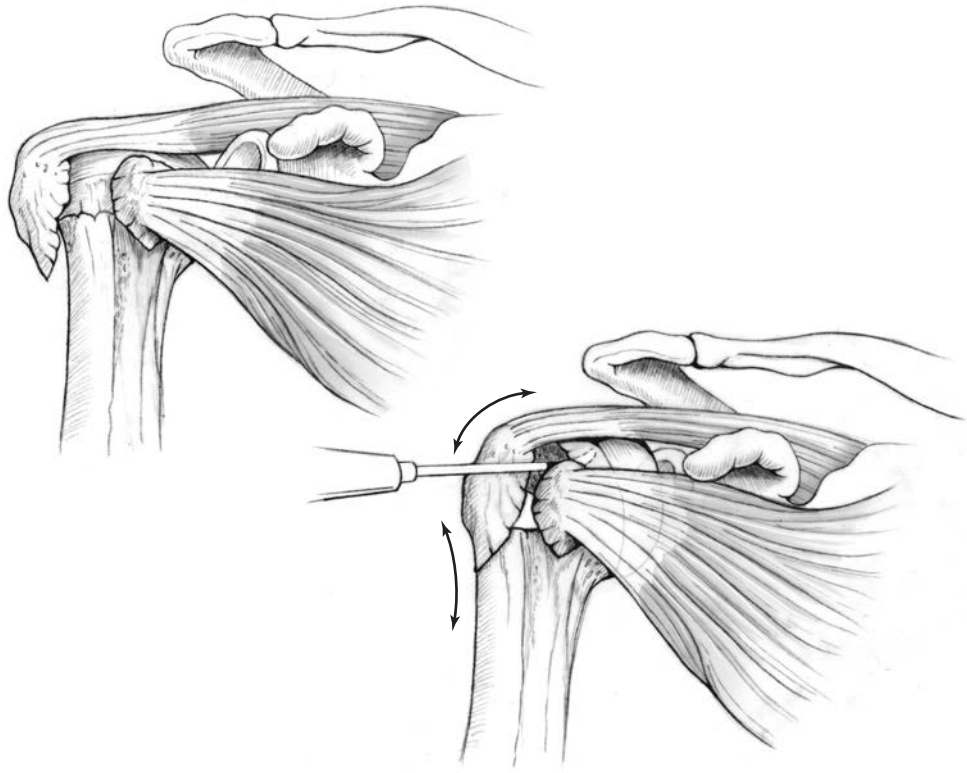
tion portal to lie deep to the lateral margin of the head fragment (Fig. 28-6). The position of the instrument is confirmed with the C-arm fluoroscopy. The elevator or bone tamp is gently tapped with a mallet, elevating the head out of valgus into the reduced position, restoring the normal neck–shaft angle. Characteristically, in a valgus-impacted proximal humerus fracture, once the head fragment is reduced, the intact periosteal sleeve between the fracture fragments causes the tuberosities to fall spontaneously into the reduced position. Occasionally, the lesser tuberosity may still be displaced medially and can require lateral traction via a small hook in the subdeltoid space to



A

The position of the instrument is confirmed with the C-arm fluoroscopy. **(B)** The elevator or bone tamp is gently tapped with a mallet, elevating the head out of valgus into the reduced position, restoring the normal neck–shaft angle. **(C)** When the head is raised, the periosteum on the medial side acts like a hinge, and the greater tuberosity returns to its anatomic position as a result of the inferior pull of the periosteum and the superior pull of the rotator cuff. (Adapted from Resch H, Povacz P, Frohlich R, Wambacher M. Percutaneous fixation of three- and four-part fractures of the proximal humerus. *J Bone Joint Surg Br* 1997;79(2):297.)

bring it into the anatomic position. Final reduction is confirmed with the fluoroscopic images. The pins are then placed under fluoroscopic guidance.

Overzealous impaction with the mallet is a potential pitfall, leading to loss of cancellous bone in the head fragment and potential fracture. Valgus-impacted fractures can be reduced by this closed technique only before healing has taken place. Ideally, surgery is recommended within 2 weeks of injury. Beyond that time point, more aggressive manipulation is required to mobilize the head fragment.

Fixation Technique

For the fixation of the head–shaft fracture plane, we use 2.5- or 2.7-mm terminally threaded pins. Terminally-threaded K-wires or, alternatively, the guidewires from the Synthes (Synthes, Paoli, PA) 7.3-mm cannulated screw set can be used. Fully threaded pins are not used in order to protect the soft tissues. Terminal threads are desirable to minimize the risk of pin migration. Pins are inserted through very small incisions. A scalpel is used to incise only the skin. A curved hemostat or similar instrument is used to dissect down to the periosteum and to mobilize soft tissue to avoid neurovascular injury. A protective sheath such as a drill guide should be used to prevent soft tissue from being caught inadvertently, and it helps guide the pin insertion. Two to three retrograde pins are placed from the shaft into the head fragment. The pins should enter the skin distal to the site where the pins actually enter the bone to obtain the correct angle so that the pins do not cut out posteriorly before gaining fixation in the head fragment. The entry points of the pins should be distal enough to the fracture line not only for adequate purchase of the intact humeral shaft cortex, but also to avoid injury to the anterior branch of the axillary nerve. However, the entry points should also be proximal to the deltoid insertion to avoid injury to the radial nerve. The direction of the pins is generally anterolateral to posteromedial (about 30 degrees) because of the anatomic retroversion of the humeral head. The pins should not be placed directly in the coronal plane, or they will cut out anteriorly. The starting points of the pins should not be too close to one another to avoid a stress riser in the lateral cortex. The pins should be widely spaced across the fracture site and within the head whenever possible. Furthermore, the pins should be multidirectional or multiplanar to maximize the stability of the construct. Two to three pins parallel to one another will act as a single axis of fixation and thus allow rotation. An additional retrograde anterior pin can be employed for further stability. When the anterior pin is placed, it should be kept in mind that the long head of the biceps tendon and the cephalic vein are just a few millimeters away from the pinning point. The pins are stopped within 0.5 to 1 cm of the subchondral bone.

The tuberosities are then secured. Pins or cannulated screws can be selected. We prefer fixation with cannulated screws because the proximal ends of the pins protrude through the deltoid and can cause irreparable damage to the muscle. Pins, if used, must be removed before starting early range-of-motion exercises for this reason. We prefer 4.5-mm cannulated screws to secure the tuberosities. The 4.5-mm screws have substantial guide pins and come in adequate lengths. The guide pins are placed under fluoroscopic guidance through the greater tuberosity, from superolateral to inferomedial, approximately 1 cm distal to the rotator cuff insertion, engaging the medial cortex of the shaft fragment (Fig. 28-7). At this point, care should be taken not to advance the pins past the medial cortex because of the vicinity of the axillary nerve and the posterior humeral circumflex artery. A screw with a washer is used, but one must be careful not to overtighten the screw as this can cause a fracture of the greater tuberosity. Two screws are ideal. The second screw can be a cancellous screw directed into the articular fragment.

Fixation of the lesser tuberosity is debatable in four-part valgus-impacted fractures. Once the humeral head and greater tuberosity are reduced and fixed, the lesser tuberosity is nearly always in the anatomic position. We generally prefer to leave the lesser tuberosity in the reduced position without additional fixation. This has not been found to result in any functional disability postoperatively. If the reduction is incomplete or unstable, a percutaneous cannulated screw (4.5 mm) can be placed from the anterior to posterior direction. Stability of fixation is assessed by gently rotating the arm under fluoroscopy. If there is any concern regarding stability, open reduction and internal fixation should be performed.

After percutaneous fixation, the pins are cut below the skin. The pins should be cut short enough to be buried entirely even after the initial swelling subsides and long enough for easy removal. Cutting the pin below the skin reduces the chance of superficial pin tract infection. All of these small incisions are closed using interrupted nylon suture (Fig. 28-8).

POSTOPERATIVE CONSIDERATIONS

Following the procedure, the affected extremity is immobilized in a sling for approximately 3 weeks. Active range-of-motion exercises of the wrist, elbow, and hand are encouraged. Radiographs are taken 1, 3, and 6 weeks postoperatively to ensure that no pin has migrated and no loss of reduction has occurred. The wound should also be inspected for any wound disruption or pin protrusion through the skin. Usually the pins become more prominent and occasionally protrude through the skin after initial swelling subsides after surgery. The pins should be cut short enough to avoid protrusion through the skin as this occurs. If the fracture reduction is felt to be stable and

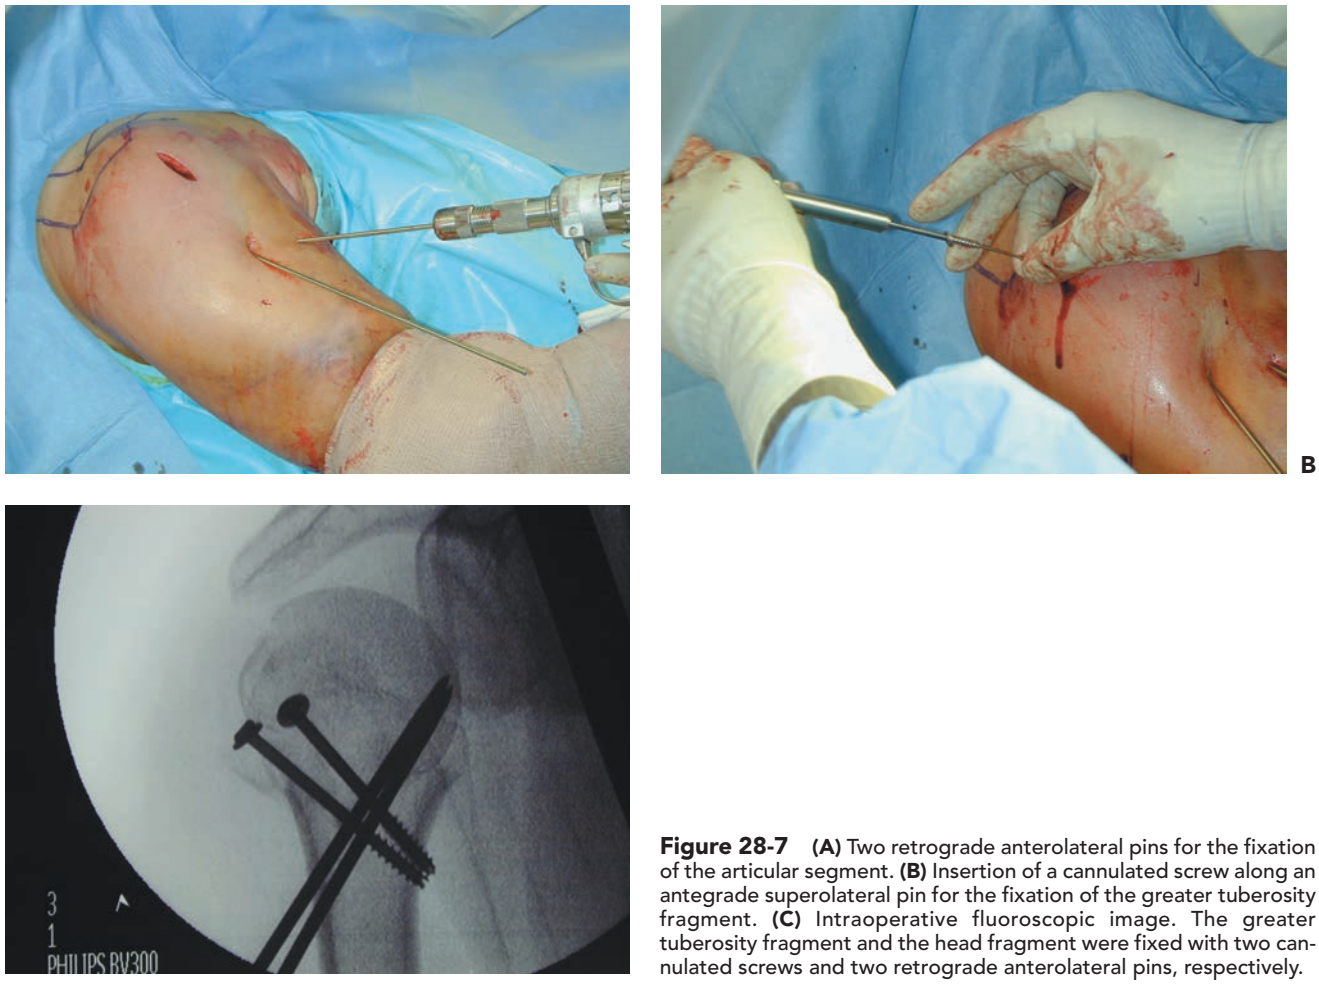

Figure 28-7 **(A)** Two retrograde anterolateral pins for the fixation of the articular segment. **(B)** Insertion of a cannulated screw along an antegrade superolateral pin for the fixation of the greater tuberosity fragment. **(C)** Intraoperative fluoroscopic image. The greater tuberosity fragment and the head fragment were fixed with two cannulated screws and two retrograde anterolateral pins, respectively.

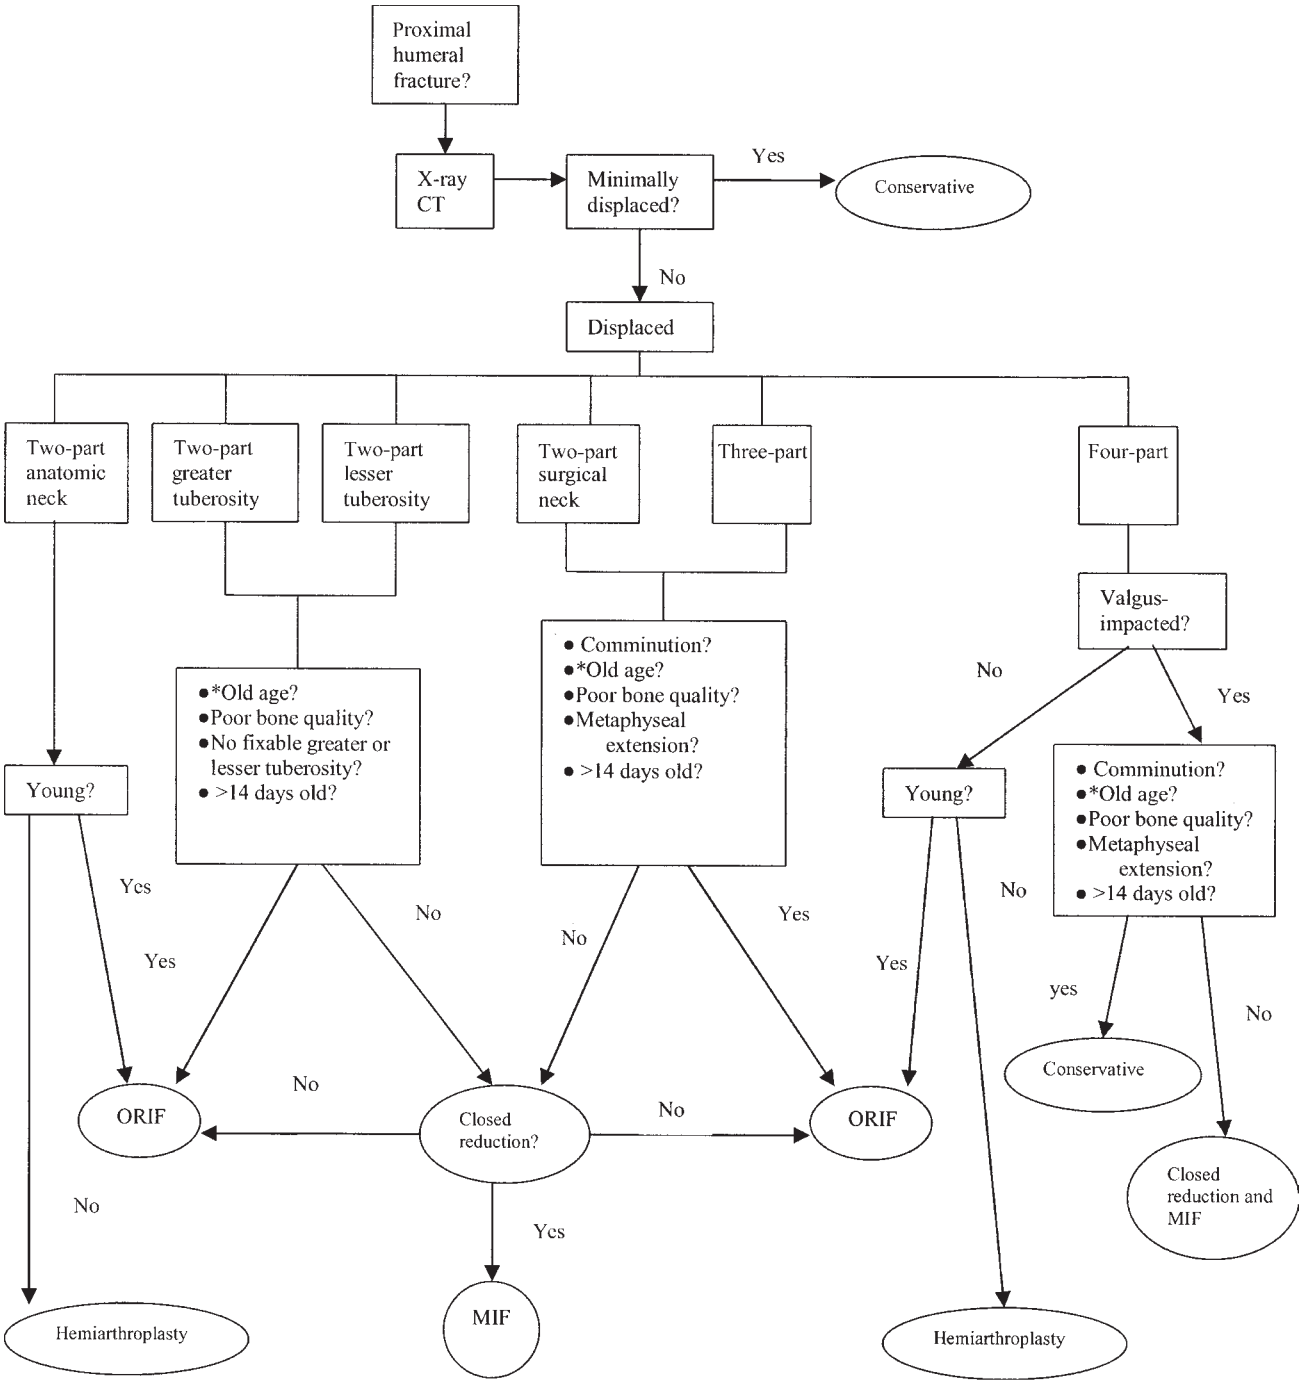
screws have been used for fixing the tuberosities, pendulum exercises may be instituted 2 to 3 weeks postoperatively. If the fracture reduction was not solid at the time of the operation or pins have been used for fixing the tuberosities, exercises should not be started until 3 weeks after the surgery, at which time the pins of the tuberosities are removed. At 3 weeks, the passive forward flexion in the scapular plane and external rotation are started. Active assisted and active range-of-motion exercises are initiated at 6 weeks if there are signs of fracture healing. Progression to light strengthening exercises may start at that point. The pins are removed at 4 to 6 weeks. In a very unstable fracture configuration, it is best to leave the pins in for 6 weeks; however, loosening and migration of pins may necessitate earlier removal. The pins are removed either as an office procedure or in the operating room under local anesthesia, depending on patient and surgeon preference.

RESULTS

In the early report of Kocialkowski and Wallace[19], 22 cases of proximal humerus fractures were treated by closed reduction and percutaneous fixation using smooth K-wires. In their series, two cases were four-part fractures. A poor result by Neer's criteria[31] was seen in 69% of the older age group (older than 50 years), but all patients under 50 years had excellent results. The two four-part fractures developed avascular necrosis. The main complication was pin migration. In the cases studied, only smooth wires were used and they migrated in nine cases (41%). Despite this discouraging early report, many authors have tried to improve fixation methods and treatment guidelines. Several biomechanical studies on the strength of different fixation methods provided better understanding of patient selection and percutaneous fixation technique.[21,30,41]

Jakob et al.[17] presented their results of the treatment of 19 valgus-impacted four-part proximal humerus fractures. Five of these were treated closed. Although they did not specify the results of the five cases, they reported that they obtained satisfactory or excellent results in 74% of the patients with closed or limited open reduction and minimal osteosynthesis; these results are superior to those of conservative treatment. They reported an avascular necrosis rate of 26%, which is a lower incidence than that reported by Neer[32] for four-part fractures.



* Physiologically old (mentally, physically).

Figure 28-8 Treatment algorithm. CT = computed tomography; MIF = minimall invasive fixation; ORIF = open reduction and internal fixation.

Jaberg et al.[14] reported the results of 48 fractures fixed with percutaneous stabilization of unstable fractures of the proximal humerus fractures. In this series, closed reduction was performed and the fractures were stabilized with terminally threaded 2.5-mm AO pins placed in both antegrade and retrograde fashion. This series had 29 fractures of the surgical neck, three of the anatomic neck, eight of three-part fractures, five of four-part fractures, and three fracture–dislocations. Overall, 70% had good or excellent results, 20% fair, and 8% poor. Complete avascular necrosis

with collapse of the humeral head developed in only two patients (one from a two-part anatomic neck fracture and the other from a four-part fracture). However, eight had localized avascular necrosis that resolved over 1 or 2 years. These were thought to represent subtotal avascular necrosis. The fractures united by 6 to 8 weeks postoperatively except in the two cases of avascular necrosis.

Resch et al.[36] published their results of closed reduction and percutaneous fixation of nine three-part fractures and 18 four-part fractures using screws and K-wires. None of the three-part fractures went on to avascular necrosis, and all had good or very good results. There was an 11% incidence of avascular necrosis in the four-part fractures. Among 18 four-part fractures, five had significant lateral displacement of the humeral head. One of these five required revision 1 week after the surgery, and one went on to late avascular necrosis.

Closed reduction and percutaneous fixation of 19 cases of two- and three-part fractures were reported by Chen et al.[8] They used cannulated screws for all the cases except young patients with open physes. Twelve patients had two-part fractures, and six had three-part fractures. By Neer's criteria, overall, 84% had good or excellent results, 10% had fair results, and 5% (one patient) had a poor result. Eleven two-part fractures (84%) and five three-part fractures (83%) had excellent or good results. No significant correlation of fracture type to functional result was noted in their series.

Soete et al.[39] recommended not using the closed reduction and percutaneous fixation technique for four-part fractures because the both of two poor results in their series came from the two four-part fractures. However, these were not the valgus-impacted type.

Herscovici et al.[12] reported their results of closed reduction and percutaneous fixation for 41 proximal humerus fractures. They compared the failure rates of three different percutaneous fixation instruments. There was no failure with using Schanz pins (2.5-mm terminally threaded). There was one (20%) failure with 2.5-mm terminally threaded Dynamic Hip Screw guide pins and 100% failure rate with 2-mm K-wires. There were 21 two-part fractures, 16 three-part fractures, and four four-part fractures. The four-part fractures were not the valgus-impacted type. All patients with four-part fractures did not respond to the fixation and three of them had avascular necrosis develop, irrespective of the type of pin used. In the remaining 33 patients with two- and three-part fractures, a union rate of 94% was observed. One three-part fracture developed avascular necrosis. They recommended against the percutaneous fixation technique for the treatment of four-part fractures, although none of the four-part fractures in their study was the valgus-impacted type.

As previously discussed, the closed reduction and percutaneous fixation technique has been advocated for the treatment of relatively young patients with good bone stock. Recently, Zingg et al.[44] achieved good results in elderly patients (average age 72) with the closed reduction and percutaneous fixation technique. They evaluated the functional and subjective results of 31 patients using the Constant score and Oxford Shoulder Score. Injured shoulders achieved an average function of 82.6%, compared to the uninjured side. The subjective results were very good in 58% of the patients, good in 22%, satisfying in 9%, and poor in 9%. One fracture developed avascular necrosis. They thought the technique was a valuable method for the fixation of the proximal humerus fractures in elderly patients.

COMPLICATIONS

Nerve Injury

The most worrisome potential complication of percutaneous fixation is nerve injury. There is no published incidence of nerve injury after percutaneous fixation, yet most authors commonly expressed their concerns about potential nerve injury. Nerves at risk are primarily the axillary, the musculocutaneous, and to a lesser extent the radial nerve. The axillary nerve courses posteriorly through the quadrangular space and then is divided into the anterior and posterior branches just beneath the inferior capsule of the glenohumeral joint. The anterior branch courses anteriorly on the undersurface of the deltoid and is located approximately 3 to 6 cm distal to the lateral border of the acromion. When making the anterolateral reduction portal, the deltoid should be gently and bluntly spread to avoid any nerve traction. This incision is usually located superior to the zone where the nerve runs; however, one should be cautious during this part of the procedure. The anterior branch of the axillary nerve is also at risk when placing screws through the greater tuberosity, and thus a drill guide can be inserted more superiorly and gently advanced distally to keep the nerve from the path of the drill.

An anatomic study by Rowles and McGrory[38] investigated the spatial relationship between percutaneously inserted pins and neurovascular structures. According to their study, the proximal lateral retrograde pins were located a mean distance of 3 mm from the anterior branch of the axillary nerve. They recommended making the starting point for all lateral pins distal to a point along the lateral aspect of the shaft equal to twice the distance from the top of the humeral head to a line perpendicular to the shaft at the inferiormost margin of the articular cartilage of the humeral head (Fig. 28-9). A safe zone for lateral pins was found between this point and deltoid tuberosity distally. The proximal antegrade greater tuberosity pins were found to have their tips at a mean distance of 7 mm from the posterior humeral circumflex artery and 6 mm from the axillary nerve with the arm in a neutral rotation. These distances decreased with internal rotation and increased with external rotation. The anterior pin was located adjacent to the long head of the biceps tendon, 11 mm from the cephalic vein, and could potentially be near the musculocutaneous nerve. These findings emphasize the importance of

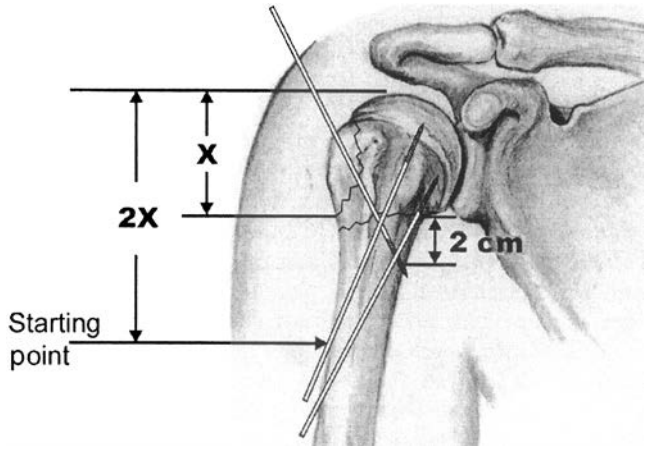


Figure 28-9 Illustration of the proposed starting point for placement of the lateral pins and the end point for the greater tuberosity pins. The starting point for the proximal lateral pin should be at or distal to a point twice the distance from the superior aspect of the humeral head to the inferiormost margin of the humeral head. The greater tuberosity pins should engage the cortex of the humeral neck greater than or equal to 20 mm from the inferiormost aspect of the humeral head. (Reprinted with permission from Rowles DJ, McGrory JE. Percutaneous pinning of the proximal part of the humerus. An anatomic study. *J Bone Joint Surg Am* 2001;83-A(11):1697.)

using a protective sleeve at the time of drilling. The radial nerve will not be injured as long as the retrograde pins are inserted proximal to the deltoid insertion.

Pin Migration

The most common complication is pin migration. Most commonly, the pins back out and become prominent under the skin. Proximal migration into the joint is possible. Percutaneous pinning requires very close follow-up and strict patient compliance. Serious complications of pin migration can be prevented by following patients with radiographs at regular intervals. Sudden increase of pain in either the shoulder or arm may indicate a migrating pin. If the pin is loose, protrudes though the skin, and hinders the rehabilitation, it should be removed. If a pin migrates medially and penetrates the articular cartilage of the head, it should be removed immediately. It is strongly recommended that terminally threaded pins rather than smooth pins be used whenever possible. Moreover, one should be careful not to penetrate the head and back the pin out. This may diminish the mechanical advantage of the terminal threads of the pin and allow loosening.

Loss of Fixation

Loss of fixation may occur with any type of fracture fixation. In some situations, this can be treated with repeat percutaneous fixation. However, if it is felt that the fracture is unstable and further loss of fixation may occur, open reduction and internal fixation is recommended. Loss of fixation has been found to be associated with several factors: the method used for fixation, the severity of the fracture comminution, the bone quality, and patient compliance. According to the study of Wheeler and Colville,[41] the percutaneous pin fixation is unable to maintain rotation loads much greater than rotational loads seen during physiologic loading. They thought percutaneous pin fixation would be unlikely to withstand sudden impact loading and had the potential to fail under activities of daily living. This study suggests a need for more conservative rehabilitation after percutaneous fixation than the traditional open reduction and internal fixation. Patients are encouraged to wear slings for 3 weeks and the activities of daily living are usually delayed until there are signs of fracture healing and the pins are removed. Naidu et al.[30] reported a biomechanical comparison of several different percutaneous fixation constructs. Their study showed that for torsional stability, multiplanar fixation is more important than the number of cortices engaged. On the other hand, bending stiffness increases with the number of cortices purchased. They suggested that a multiplanar pin construct is needed to optimize torsional stiffness, and additional tuberosity pins are needed to augment bending stiffness. A wide pin spread within the fracture can increase stability.

Pin Tract Infection

Superficial infections of the pins have been reported with an incidence of from 0% to 23%.[8,12,14,19,36,39] Jaberg et al.[14] reported four (9%) superficial pin tract infections out of 48 patients, which all resolved with the removal of the pins and local wound care. There was one deep infection in a diabetic patient. In their series, the pins were left through the skin. Because of this risk, we prefer to cut the pins deep to the skin.

Avascular Necrosis of the Humeral Head

The incidence of avascular necrosis after closed reduction and percutaneous fixation of the proximal humerus fracture has been reported to be from 0% to 16%.[8,12,14,39] According to Jaberg et al.,[14] there are two forms of avascular necrosis of the humeral head: complete, with collapse of the humeral head; and subtotal, localized with transient cyst formation and sclerosis of the humeral head. The patients with complete necrosis went on to hemiarthroplasties. The localized necrosis group had moderate pain in the early period. The pain and radiologic changes gradually resolved, showing a slower functional recovery, and all had good or excellent results. This gradual improvement in function and radiographic appearance is thought to result from creeping substitution phenomenon of the humerus head. This localized avascular necrosis of the humeral head was also observed by other authors.[20,24]

Malunion and Nonunion

Residual displacement of the humeral head at the surgical neck is usually well tolerated as long as the tuberosities are well reduced in relation to the humeral head. However, malunited tuberosity fractures are often symptomatic. If the displacement of the malunited greater tuberosity is severe enough to cause impingement in the subacromial space, open surgical intervention is required. Nonunion has almost never been reported.

Rotator Cuff Tear

Recently, Robinson and Page[37] increased concern about rotator cuff tears after four-part valgus-impacted fractures of the proximal humerus. In their study of 29 open reductions and internal fixations augmented with special bone substitute for valgus-impacted fractures, 11 patients had a substantial tear (2.5 cm in length) in the rotator cuff. The tear propagated through the rotator interval longitudinally. They recommended repair of this torn rotator cuff interval. We have not experienced any case complicated by neglected rotator cuff tear and do not know if this repair is necessary.

CONCLUSION

Minimally invasive fracture fixation has considerable potential in the proximal humerus. With the advantages of soft tissue and bone preservation, early results suggest that in selected fracture types, percutaneous pinning is a desirable option. Healing rates are excellent and complications are low. This procedure requires significant technical expertise; however, with an understanding of normal and fracture anatomy, it can be mastered and used to benefit many patients.

INTRODUCTION AND INDICATIONS

The use of a prosthesis in managing fractures of the proximal humerus is ordinarily indicated in patients over 50 with four-part fracture–dislocations, simple four-part fractures, and many three-part fractures when there is osteopenia, comminution, and general debilitation of the patient.[34] In the patient physiologically and/or chronologically less than 50 years of age we would use closed pinning or perform open reduction and internal fixation rather than using a prosthesis. If rigid fixation is not achieved such that we could begin early postoperative range of motion and/or articular surfaces are damaged, then we would use a prosthesis in these cases as well. The less frequently encountered head-splitting fractures and displaced anatomic neck fractures should also be considered for treatment with arthroplasty.

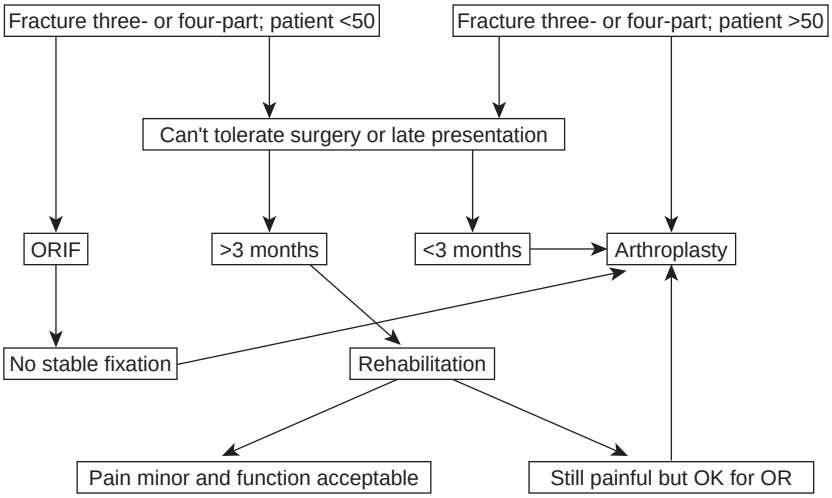
The timing of the reconstruction is important to the outcome. These fractures are best treated in the acute phase (i.e., during the first 7 to 14 days following the fracture). As time passes, the complexity of the intervention increases and the predictability of the outcome decreases.[2] The inferior outcomes when performing late arthroplasty for these injuries are largely related to fixed soft tissue contractures and inability to restore the tuberosities to their anatomic locations.[25] The treatment algorithm illustrates the basic principles of treatment decision making.

Shoulder arthroplasty for the treatment of complex proximal humerus fractures represents a formidable challenge. The surgeon should be honest with him- or herself regarding his or her ability and volume of experience.[17,20,24] The management of a displaced three- and four-part fracture of the proximal humerus is one of the most difficult shoulder problems faced by orthopedic surgeons.

SURGICAL TECHNIQUES

Prosthetic Design Considerations

Since 1991 we have used the DePuy Global Fx modular prosthesis (DePuy [Johnson and Johnson], Warsaw, IN) for



Algorithm 29-I A treatment decision algorithm. ORIF = open reduction and internal fixation.

treatment of complex fractures or fracture–dislocations of the proximal humerus. The use of a modular design has the advantage of allowing the surgeon greater latitude for soft tissue balancing by using various humeral head sizes. The Global Fx prosthesis is different from the Global Advantage prosthesis, which is used to manage patients with arthritis of the shoulder. The key difference is that the proximal body and fins are much smaller and allow for the relocation of the greater and lesser tuberosities around the prosthesis and fixation of the tuberosities to themselves and to the upper shaft of the humerus. The smaller size of the upper body also allows for room for autogenous or bone grafting into any defects between the tuberosities and the shaft of the humerus. The Fx is also available with proximal porous coating of the body for tuberosity healing.

The Global Fx prosthesis utilizes a jig, which allows the surgeon to place, adjust, and then hold the height and retroversion of the prosthesis while the surgeon places the shoulder through a trial range of motion. The various steps of how to use the fracture jig are described in the surgical technique.

Regardless of which system the operating surgeon uses, some additional universal considerations should be noted. First, the relationship of the fins to the version of the prosthesis must be known. Restoring the proper retroversion of the head will affect the anterior fin and lateral fin position, and this reference should be understood for appropriate reduction of the tuberosities. Second, the presence of a medial hole is desirable to allow horizontal stem-to-tuberosity fixation. The cerclage technique and other means of horizontal fixation have been demonstrated to provide increased interfragmentary stability.[1312] The geometry of the proximal body may also play a role in fixation stability as an irregular shape improves the effects of a cerclage compared with a smooth circular design.[35]

Preoperative Planning

Surgeons treating these fractures have only one chance for an optimal outcome because the results of revision surgery are less predictable and generally inferior to primary cases.[2] We emphasize that, if possible, displaced three- and four-part fractures should be managed by an orthopedist who has surgical experience with these injuries.[20] There are contraindications to surgical treatment that include active infection, previous neurologic defects, inability to medically tolerate surgery, and an uncooperative patient. It is not uncommon to have an associated nerve injury with a proximal humerus fracture, and treatment of these patients presents a dilemma. As most of the nerve injuries resolve, we have elected to treat these patients acutely and explore the nerve injury at the time of fracture repair.

It is important to have a lengthy discussion with the patient about the goals of the surgery. Unlike patients with arthritis, these patients generally exhibit near-normal shoulder function prior to fracture. They must understand that surgery will not provide a normal shoulder. With replacement surgery the desired outcome is good pain relief and functional use of the shoulder. One should aim to accomplish four key objectives at the time of surgery: anatomic sizing of the prosthesis, restoration of humeral length, prosthetic retroversion of 20 to 25 degrees, and secure and anatomic tuberosity fixation.

Patient Positioning

The patient is placed in a semi-Fowler or beach-chair position on the operating table (Fig. 29-1A). The standard head rest portion of the table should be removed and replaced with a versatile headrest such as a McConnell (McConnell Orthopedic Mfg. Co., Greenville, TX). This allows free

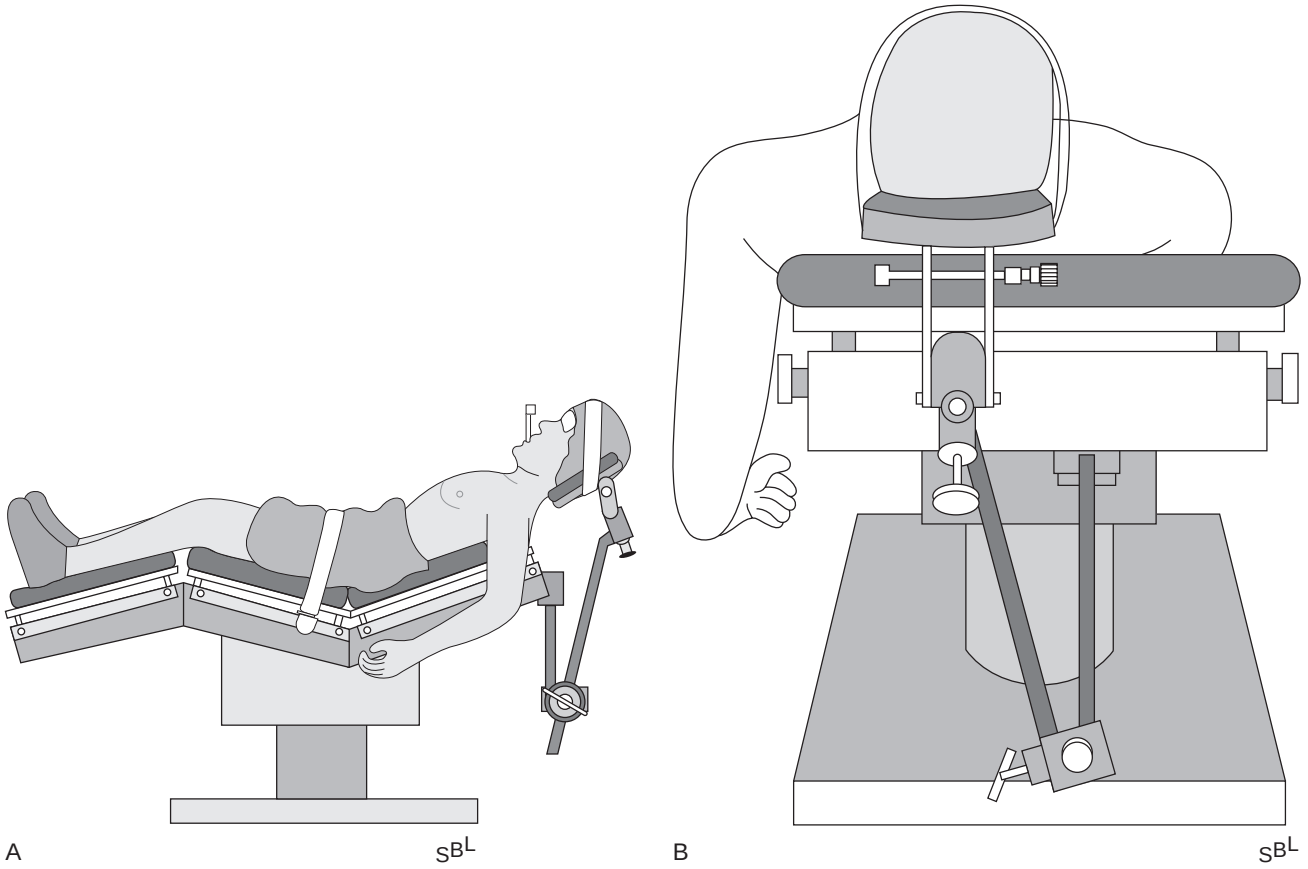


Figure 29-1 **(A)** Patient positioning (side view). **(B)** The involved shoulder should extend over the edge of the table.

access to the superior aspect of the shoulder region. The patient is positioned so that the involved shoulder extends over to the top corner and edge of the table (Fig. 29-1B). The patient's head is secured to the head rest with tape and the anesthesia equipment is draped to isolate it from the sterile field. Caution should be used to ensure that the brachial plexus is not under undue tension when securing the head to the head rest. A kidney post may be helpful to keep the patient's thorax secure on the operating table.

Procedure

An incision running from the clavicle, over the top of the coracoid, and down to the anterior aspect of the arm is utilized (Fig. 29-2). Once the incision has been made, the cephalic vein is located on the deltoid muscle near the deltopectoral interval. The cephalic vein is usually firmly imbedded in the deltoid, and there are many venules from the deltoid into the cephalic vein (Fig. 29-3). For this reason, we recommend that the vein not be sacrificed, but reflected laterally with the deltoid muscle. The deep surface of the deltoid is freed from the underlying tissues, from its origin on the clavicle down to its insertion in the humeral shaft. When the anterior margin of the deltoid has been

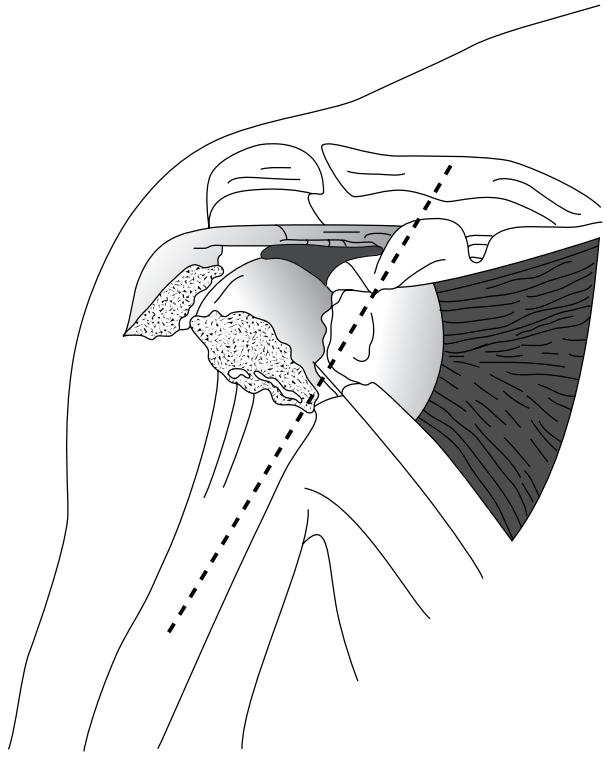

Figure 29-2 Deltopectoral incision.

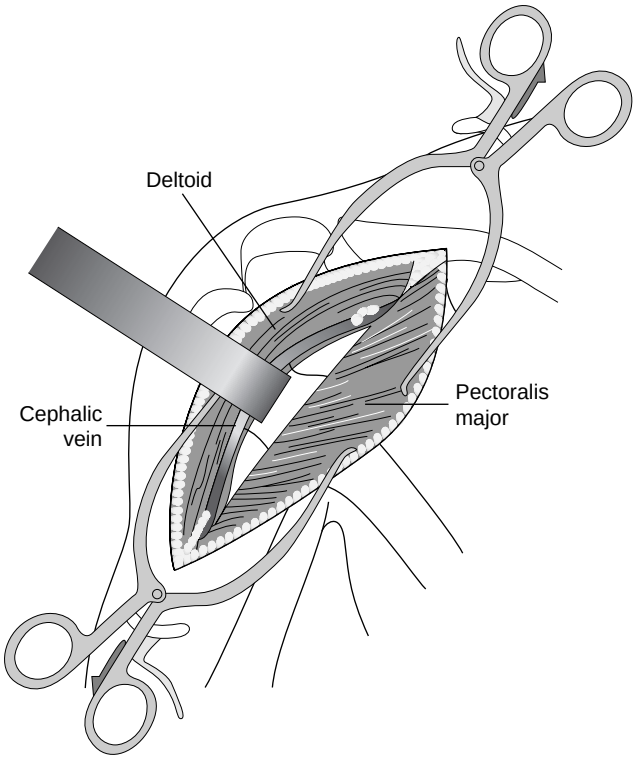

Figure 29-3 Retract the cephalic vein laterally to preserve the venous drainage of the deltoid muscle.

completely freed from its origin to its insertion, especially along its deep surface, the arm is abducted and externally rotated, which allows the deltoid to be gently retracted laterally with one or two Richardson retractors. The deltoid muscle is protected with a moist lap sponge, and the conjoined tendon is retracted medially with a large Richardson retractor.

Release of the insertion of the upper portion of the pectoralis major tendon from the humerus with an electrocautery cutting blade improves exposure of the inferior aspect of the joint. Ordinarily in a complex fracture of the proximal humerus, the circumflex vessels may be disrupted. However, when these vessels are visualized, ligation or cauterization will help control bleeding and improve exposure.

In fracture cases it is especially important to identify and protect the musculocutaneous and axillary nerves. The musculocutaneous nerve is palpated as it comes from the plexus into the posteromedial aspect of the conjoined tendon (Fig. 29-4). Usually, the nerve penetrates the muscle 1 to $1^1/_2$ in. inferior to the tip of the coracoid, but in some instances the nerve has a higher penetration into the conjoined muscle–tendon unit. It is important to remember the location of this nerve when retracting the conjoined tendon. The all-important axillary nerve is located by passing the volar surface of the index finger sown along the anterior surface of the subscapularis muscle. The index finger is hooked anteriorly to identify the axillary nerve (Fig. 29-5). Gentle traction on the lesser tuberosity fragment makes it

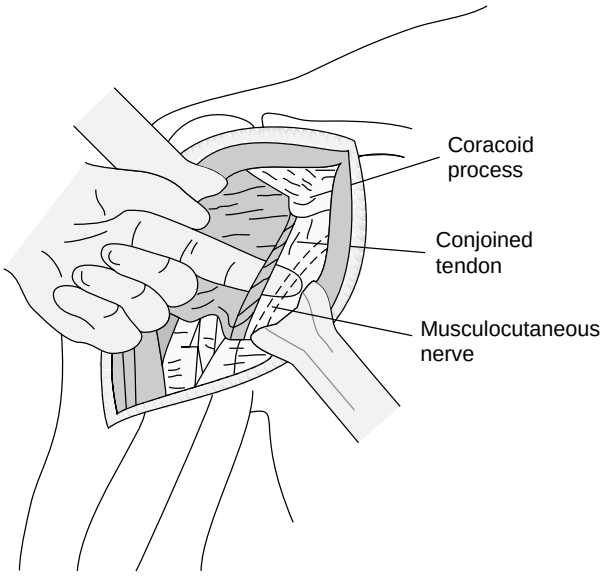

Figure 29-4 Palpate the musculocutaneous nerve beneath the conjoined tendon.

easier to identify the axillary nerve. Occasionally, as with a chronic fracture of the proximal humerus, the nerve will be adherent to the anterior surface of the subscapularis and difficult to locate. When this occurs, an elevator can be passed along the anterior surface of the muscle to create an interval between the muscle and nerve. The axillary nerve is always identified and carefully retracted (when freeing up the lesser tuberosity) to protect it from injury.

The biceps tendon is an excellent landmark to identify the interval between the lesser tuberosity and the greater tuberosity (Fig. 29-6A,B). First a pair of scissors is placed

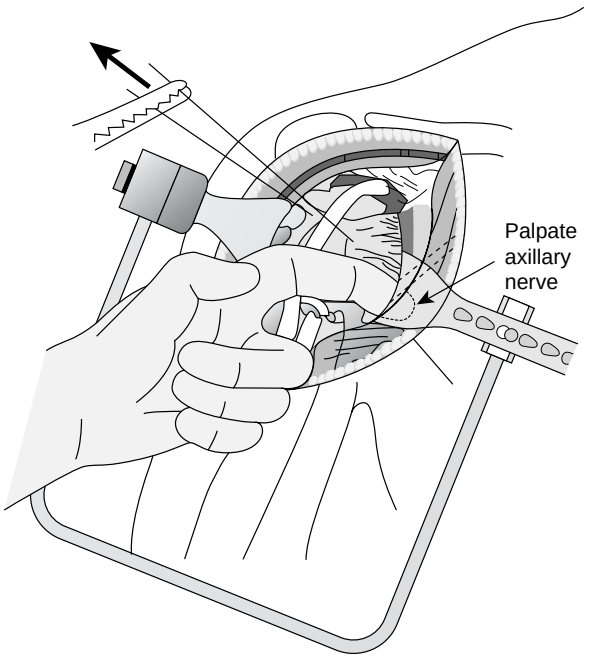

Figure 29-5 Palpate the axillary nerve.

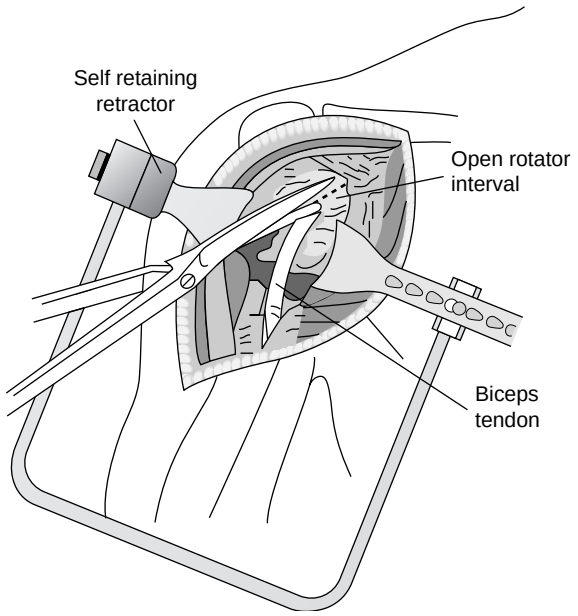

Figure 29-6 Identify the long head of the biceps and release the transverse humeral ligament and rotator interval.

into the sheath of the biceps tendon and used to divide the transverse humeral ligament. Continuing proximally with the scissors, the interval between the subscapularis and the supraspinatus tendons is opened all the way up to the insertion of the biceps tendon into the supraglenoid tubercle. If the biceps tendon has been ruptured, the scissors are placed in the bicipital groove and used to open the interval between the subscapularis and the supraspinatus tendon.

The lesser tuberosity is freed from the underlying humeral head and soft tissues. In similar fashion, the greater tuberosity is carefully identified and mobilized with its attached muscles (Fig. 7A,B). Occasionally the greater tuberosity will be in several fragments. When this occurs, we secure the major fragments together with heavy nonabsorbable sutures so that the majority of the supraspinatus and infraspinatus tendons can be repaired with the fragments at the time of closure. The greater and lesser tuberosity fragments are sufficiently mobilized so that they can be easily repaired around the prosthesis and to each other at the time of closure.

With the tuberosities out of the way, a bone hook or clamp is used to retrieve the humeral head. Once the humeral head has been excised, its dimensions are measured with a template (Fig. 29-8). The humeral head should be transferred to the back table, where an assistant can remove all of the cancellous bone from beneath the articular surface (Fig. 29-9). The autogenous cancellous bone will be used at the time the tuberosities are repaired to the shaft.

At this point, the arm should be extended down off the side of the table, which will deliver the shaft up and out of the wound. Fragments of bone and blood clot are removed from the canal of the humeral shaft. Next the tuberosities are further mobilized so that they will be ready for approximation around the prosthesis, to one another, and to the humeral shaft. The operating surgeon may choose to place the sutures for tuberosity fixation before or after setting the position of the stem. If exposure is limited, it is helpful to place the sutures before the prosthesis.

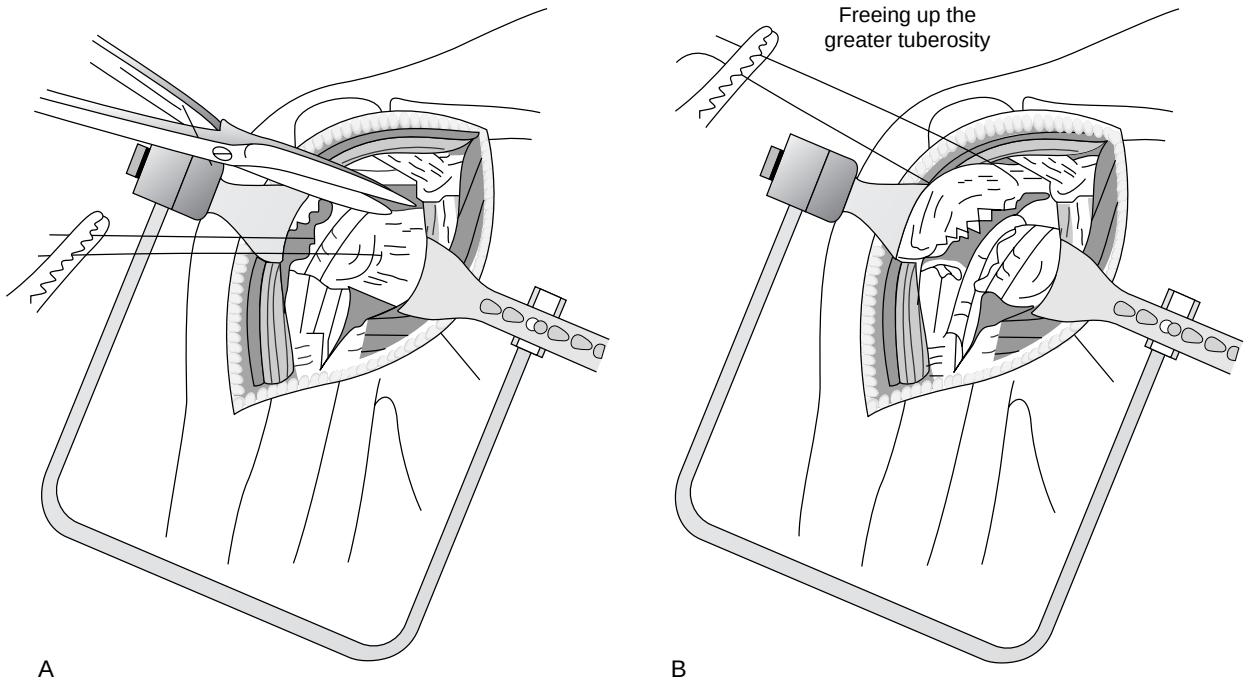

Figure 29-7 **(A)** Freeing the lesser tuberosity. **(B)** Freeing the greater tuberosity.

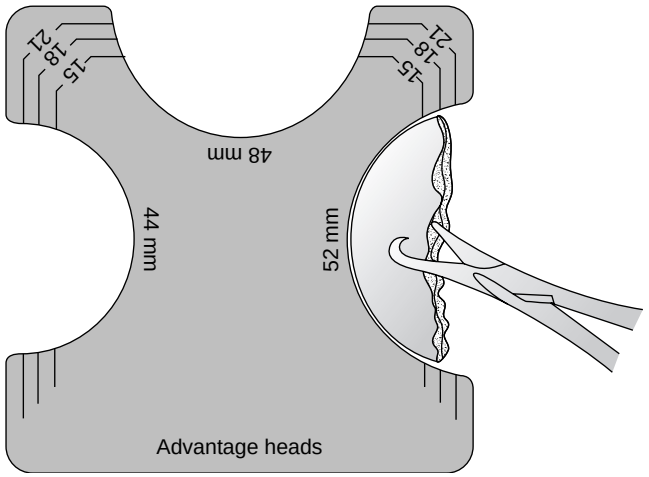

Figure 29-8 Measure the resected humeral head height and diameter with the template to select the head component.

The tuberosity-to-tuberosity fixation is accomplished with heavy nonabsorbable suture placed in a simple or inverted mattress fashion at the insertion of the rotator cuff on the bony tuberosity. The suture fixation at the bone–soft tissue interface is superior to the cancellous bone alone.

Technique without Using the Fx Jig

The proper size humeral head trial is attached to a small humeral broach body and placed into the intramedullary canal. The size of the broach should be small enough to allow the prosthesis to sit down on the upper shaft. In some situations, when trying to determine the correct size trial body, it is important to put in a stem that will fill the shaft of the humerus. If a stem is used that is too big, it will hold the prosthesis too proud. Similarly, a very small stem will allow the prosthesis to sit all the way down to where the collar is sitting on the shaft of the humerus. Usually, by experimenting with different modular trial bodies, it will be noted that the flare of the upper portion of the prosthesis will hold the prosthesis at the near-perfect height. The assistant applies gentle traction to the arm with the forearm held in 0 degrees of rotation. While the assistant maintains traction on the arm, the surgeon uses a tool to lift the collar of the prosthesis so that the head of the prosthesis is at the level of the glenoid fossa (Fig. 29-10). The distance between the top of the shaft of the humerus and the collar of the prosthesis is carefully measured, as it will correspond to the height that the final prosthesis must be cemented to in the proximal humerus. The length of the back surface of the humeral head to the humeral shaft should equal that of the greater tuberosity fragment. Both the trial and final prosthesis have horizontal 5-mm laser marks that can be used to determine the height of the prosthesis up and out of the shaft.

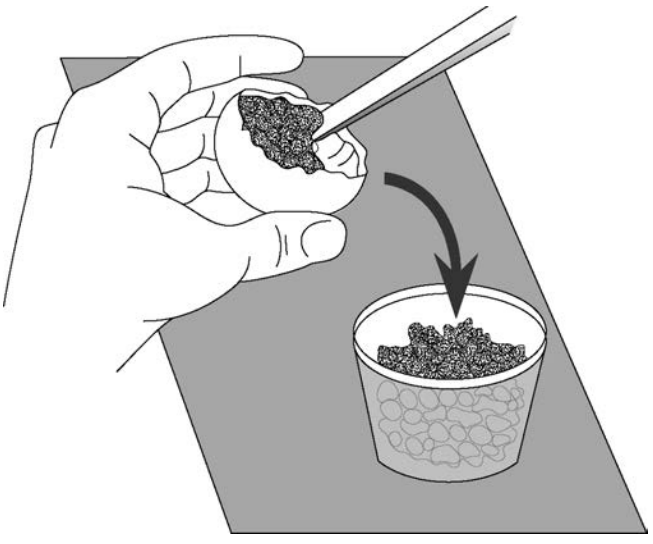

Figure 29-9 Obtain cancellous bone from the resected humeral head for later use as a bone graft.

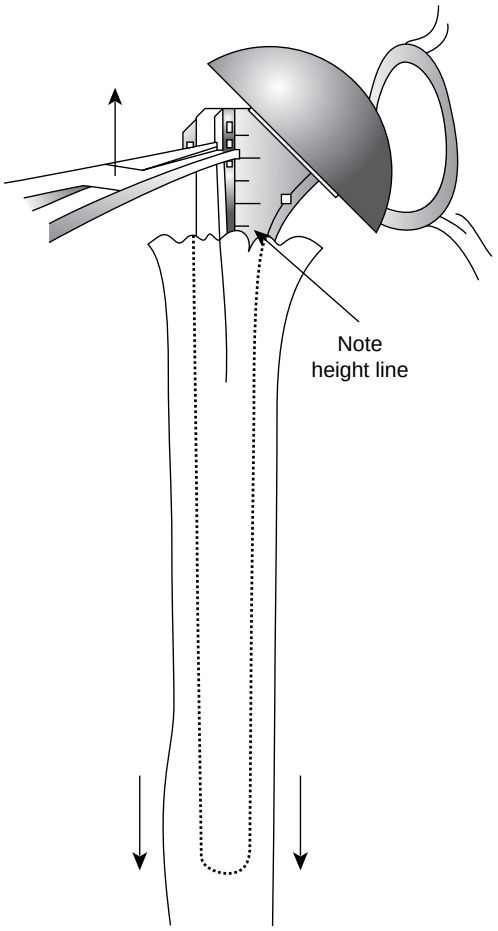

Figure 29-10 Set the height of the component.

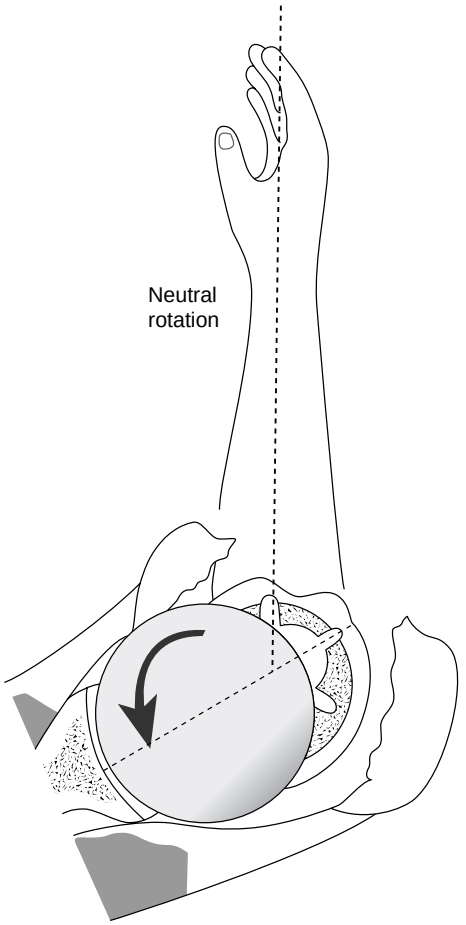

Figure 29-11 Rotate the prosthesis posteriorly to face the glenoid.

The next step will be to determine the proper amount of retrotorsion of the prosthesis. While traction is still being applied to the arm in neutral rotation, the prosthesis is rotated posteriorly until the head of the prosthesis is facing directly into the glenoid fossa. This will correspond to the 20 to 25 degrees of retrotorsion of the head and neck as seen in a normal humerus. A rongeur is used to make a notch in the anterior shaft of the humerus in direct line with the anterior fin of the prosthesis (Fig. 29-11). This will ensure correct retrotorsion of the humeral component when it is cemented into the humeral canal.

Technique When Using the Fx Jig

The Global Fx jig is used to hold the prosthesis at the selected height and retroversion while trialing reduction and range of motion. The surgeon attaches the humeral clamp to the upper shaft of the humerus and then aligns the vertical height gauge to the anterior fin of the trial prosthesis. The fin clamp is attached to the middle hole in the anterior fin (Fig. 29-12). The prosthesis is placed to allow anatomic or near-anatomic reduction of the tuberosities

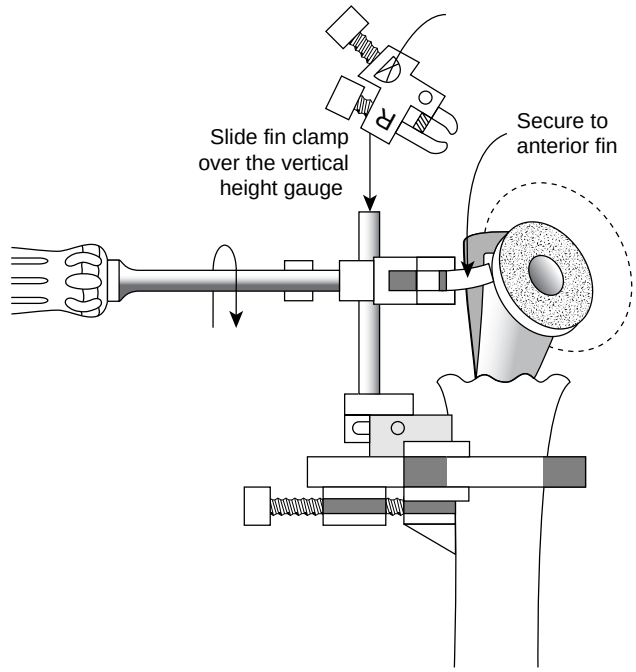

Figure 29-12 Slide the fin clamp over the vertical height gauge.

(Fig. 29-13A). The height is adjusted and noted on the vertical height gauge. It is sometimes helpful to use fluoroscopy to evaluate the height of the prosthesis in relation to the reduced tuberosities and glenoid (Fig. 29-13B). If the jig is aligned perpendicular to the epicondylar axis, this will automatically retrovert the prosthesis 20 to 25 degrees. If more or less retroversion is appropriate, this is accommodated by rotation of the jig on the humeral shaft. The shoulder range of motion can now be tested and minor adjustments made as desired (Fig. 29-14A,B). Proper height of the prosthetic is determined by fitting the greater tuberosity in the interval between the back side of the humeral head to the fractured shaft.

When the proper height and torsion of the trial prosthesis has been determined, two or more drill holes are made in the proximal anterior–medial and proximal anterior–lateral humeral shaft. Heavy nonabsorbable sutures are passed through these holes to secure the tuberosities back to the shaft of the humerus (Fig. 29-15).

Rather than cementing the body of the prosthesis into the humerus and then later attaching the humeral head, it is best to firmly secure the head to the prosthesis prior to implantation. The humeral body is manually supported in the impact stand on the head, then attached to the body with five of six blows from a 1 or 2-lb mallet (Fig. 29-16).

The medullary canal is thoroughly irrigated to remove blood and other debris. A vent tube is inserted down the medullary canal and bone cement is pushed down into the upper humerus with finger pressure (Fig. 29-17). Alternatively, a cement gun can be used but it is not pressurized. A bioabsorbable collagen cement retainer is used. The proper

Figure 29-13 **(A)** Reduce the tuberosities around the positioning jig. **(B)** Intraoperative photograph demonstrating the use of the fracture jig with a trial stem and head. The greater tuberosity is used to help determine the proper height of the prosthetic by using it as an internal "ruler" to determine the proper distance between the back side of the prosthetic head and the proximal fracture of the humeral shaft. The height of the prosthesis is adjusted on the jig until the prosthetic height allows for perfect reduction of the greater tuberosity fragment. **(C)** Use fluoroscopy to confirm tuberosity reduction.

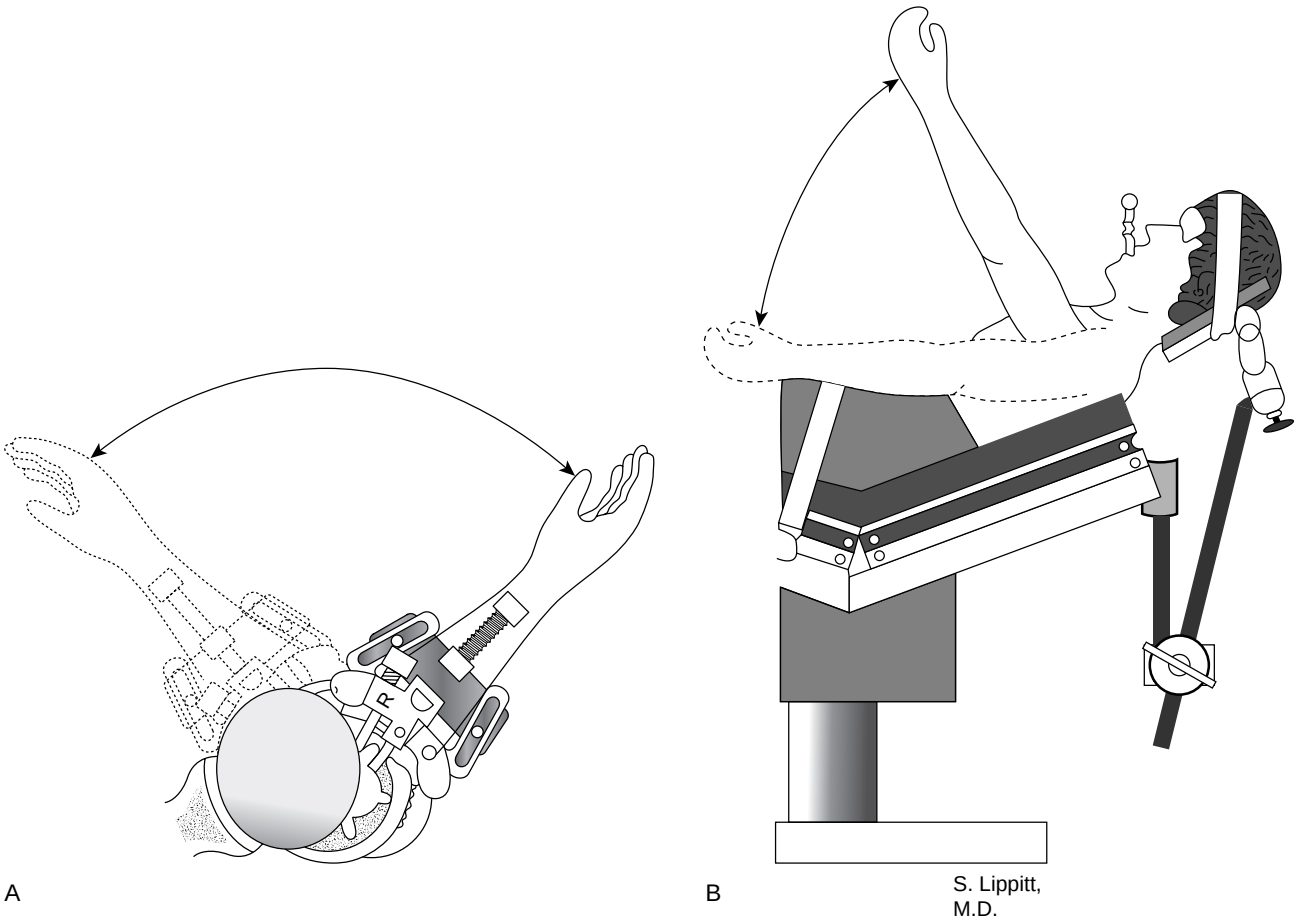

Figure 29-14 **(A)** The positioning jig allows testing of motion and stability in internal and external rotation. **(B)** The positioning jig allows testing of motion in forward elevation.

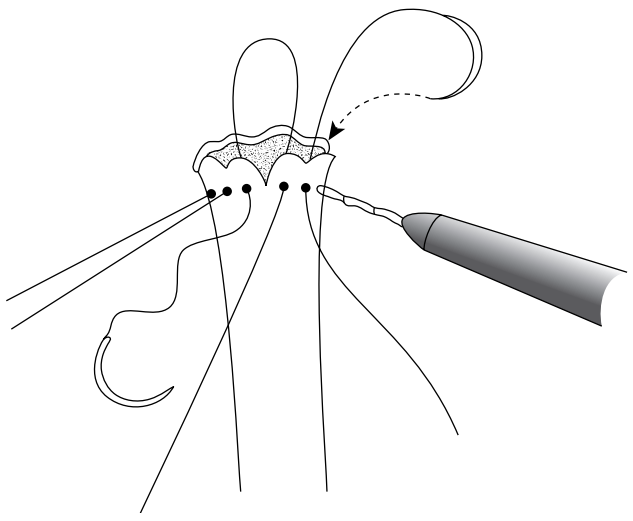

Figure 29-15 Drill holes for suture that will secure the tuberosities to the shaft.

size humeral prosthesis is inserted down into the medullary canal, with the surgeon being sure to maintain the proper retrotorsion by lining up the anterior fin with the previous notch in the anterior shaft of the humerus and by maintaining the proper degree of height out of the shaft or the humerus. Alternatively, the fracture jig can be left in position and used to position and hold the stem while the cement cures (Fig. 29-18).

When the cement has set, the prosthesis is reduced into the glenoid fossa. The cancellous bone graft from the humeral head is placed in the interval between the shaft of the humerus and the collar or neck of the prosthesis (Fig. 29-19). This additional bone graft will help to secure the healing of the tuberosities to the shaft and to each other. The tuberosities are then repaired back to the shaft of the humerus and to each other (Fig. 29-20). The heavy nonabsorbable tapes that were previously placed through the shaft of the humerus are passed through the tuberosities. If necessary, drill holes can be made in the tuberosities for secure fixation. If the tuberosities are fragmented, the sutures can be passed around the fragments and through the tendons, where they will provide firm fixation. If not

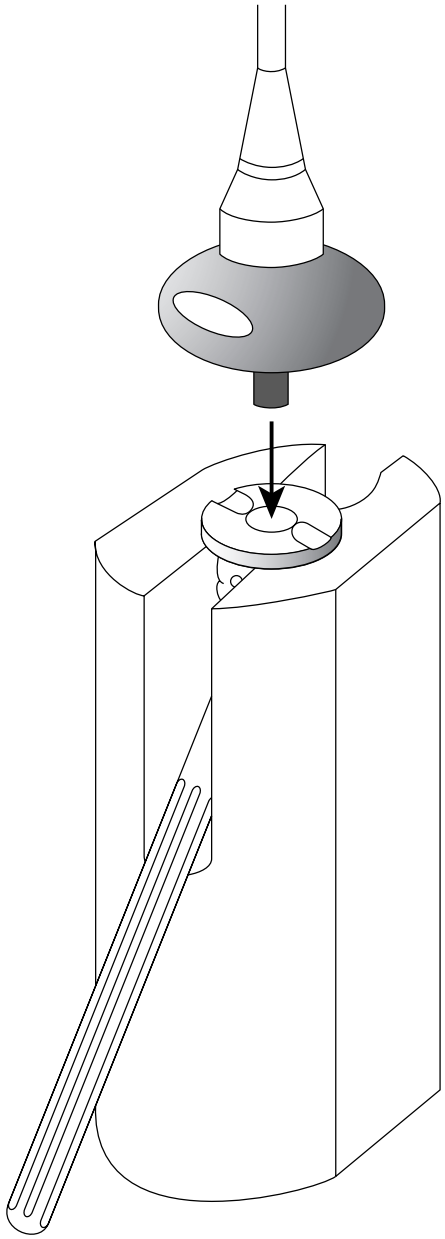

Figure 29-16 The head is secured to the body prior to implantation.

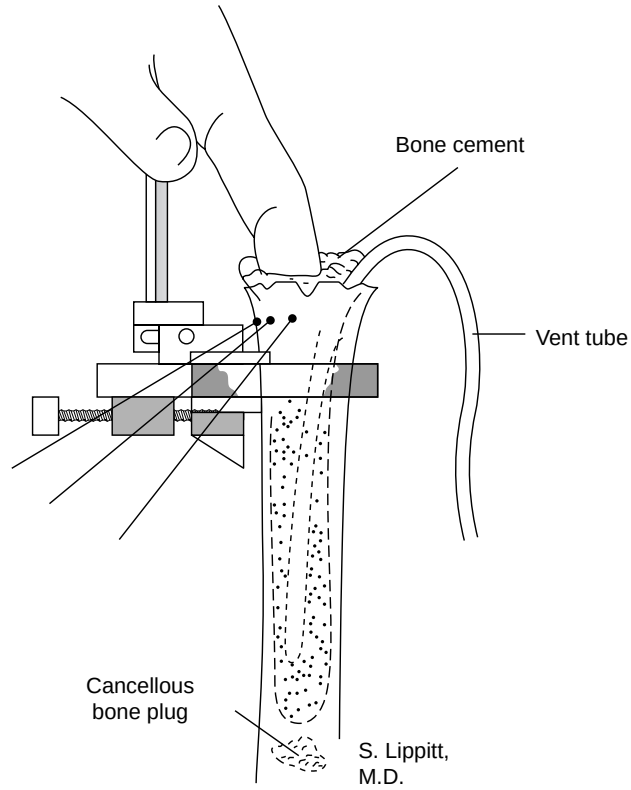

Figure 29-17 Cement is finger pressurized.

already done, nonabsorbable tapes are passed through the greater and lesser tuberosity fragments to secure them to each other. For additional stability, the sutures between the tuberosities can be passed through the holes in the anterior fin of the prosthesis (Fig. 29-21). To aid in repairing the tuberosities to each other, a towel clip is used to hold the tuberosities together while the sutures are tied. The split in the rotator interval is repaired with nonabsorbable sutures. The long head of the biceps that was released can be tenodesed in the interval between the tuberosities.

The wound is thoroughly irrigated with an antibiotic solution and a portable wound evacuation drain unit is placed to prevent the formation of a postoperative hematoma. The soft tissues are infiltrated with 0.25% Marcaine solution, which reduces the immediate postoperative pain and facilitates early passive motion of the shoulder on the same day as surgery. The wound is closed using 2.0 Vicryl in the deep subcutaneous layer and a running subcuticular nylon for the skin. We then obtain portable anteroposterior and axillary views of the shoulder to confirm component positioning before waking the patient (Fig. 29-22A–D).

Postoperative Management

Phase I

We agree with Neer that postoperative management is as important as the surgery itself and believe that early passive flexion and external rotation is the key to achieving satisfactory functional range of motion.[30]

Day 1: On the afternoon of the day of surgery, the sling is removed and the patient has free hand, wrist, and elbow motion. In bed, the patient begins passive forward flexion with the aid of an overhead pulley and passive external rotation with the aid of a stick. At the point the patient feels a good stretch, he or she holds this position for a five count. Each stretch is repeated five times. It is a great psychological benefit for the patient to see his or her arm

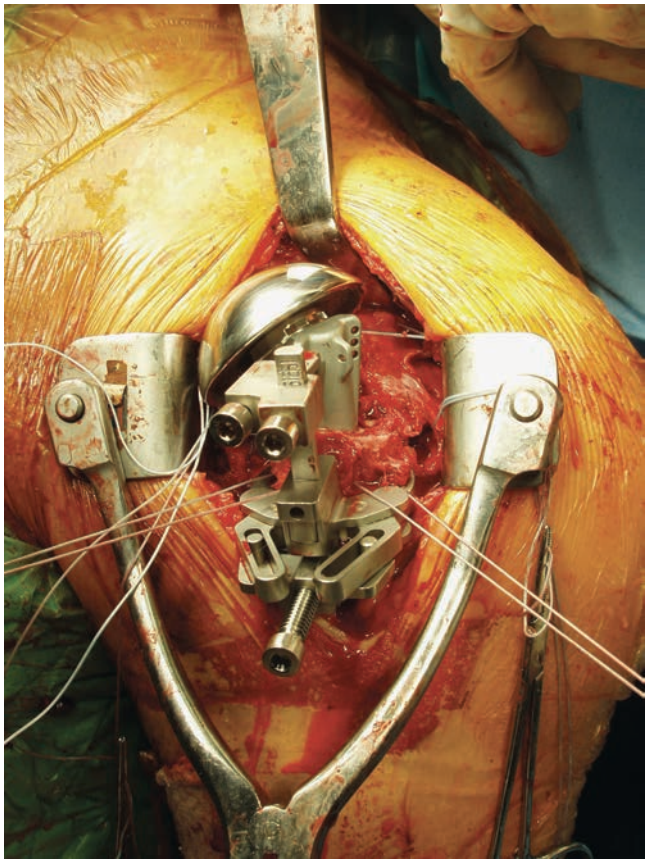

Figure 29-18 Intraoperative photograph of the use of the fracture jig to place the final prosthetic in the same place as the trial prosthetic. Once the cement is cured the jig is removed.

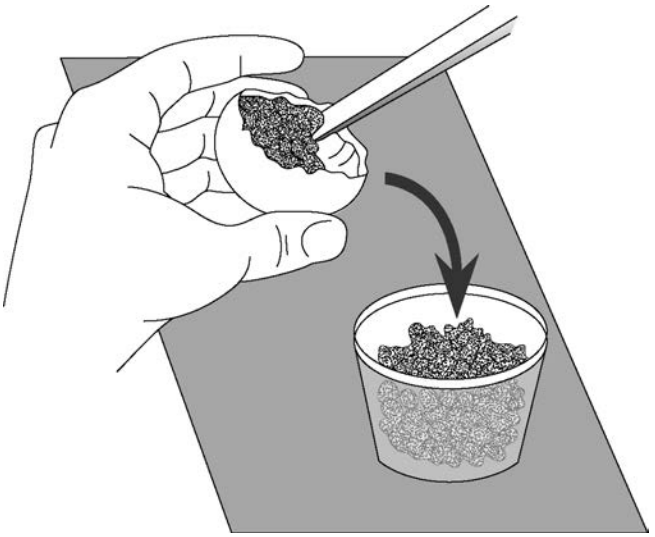

Figure 29-19 Place the cancellous graft around the prosthetic collar and the humeral shaft.

moving before much postoperative pain and swelling set in. Patients are better able to relax physically and mentally as they perform further rehabilitation.

Day 2: On the first postoperative day pendulum exercises are added to the stick and pulley movements to be performed four to six times a day. The patient is helped out of bed and taught not to push off on the operated arm. Independent ambulation and incentive spirometry are encouraged. The patient also begins gentle everyday living activities such as brushing teeth, combing hair, eating, and drinking.

Day 3 to week 6: On postoperative day 2 the patient is ready for discharge home with a pulley kit and stick that will allow him or her to continue the passive motion rehabilitation. By 2 weeks the subcuticular suture is removed and the sling that had been worn in public is discontinued.

Phase II

Usually by 6 to 8 weeks the patient has achieved nice easy passive overhead elevation and is ready to begin resistive exercises. The exercises are designed to strengthen the three parts of the deltoid, rotator cuff, and scapular stabilizer muscles. With the arm at the side, external rotation, internal rotation, abduction, forward flexion, and extension motions are started in a controlled 45-degree arc. Each motion is performed for a five count against resistance provided by a graduated set of Therabands. The resistance is increased when the exercises are done easily without pain, usually at 2- or 3-week intervals.

RESULTS

We treated 28 patients with the above techniques, and at 3.5 years of follow-up (range 1 to 7 years) the overall visual analog scores for shoulder pain, function, the ability to use the arm at work and play, and overall quality of life were 16, 21, 22, and 18, respectively (0 = best and 100 = worst). The patients responded yes to a mean of 66% of Simple Shoulder Test activities. The mean active range of motion was 118 degrees of forward elevation (range 30 to 160 degrees), 28 degrees of external rotation (range 10 to 50 degrees), and internal rotation to T11 (range buttock to T4). The mean preoperative Shoulder Security Index SSI of 35 improved to a mean postoperative value of 80. Those younger than 60 and patients that had not previously been operated on demonstrated a comparatively superior improvement in outcome ($P < 0.05$). Reports in the orthopedic literature demonstrate that when operated on acutely, more than 80%

of patients achieve reliable pain relief and satisfaction[18] (Table 29-1). However, postoperative motion is less predictable. The best results are achieved if technical errors and complications are avoided.[25,36]

Complications

Complications will arise despite meticulous technique and intraoperative caution. Stableforth reported a 6.1% incidence of brachial plexus injuries after fractures of the proximal humerus.[37] This emphasizes the importance of a careful preoperative examination to avoid confusion if a palsy is present in the postoperative period. If nerve injury is suspected either pre- or postoperatively, it should be explained to the patient and carefully followed. Electromyography and nerve conduction studies can follow the progress of the injury. If a palsy is present preoperatively, the continuity of the plexus can be confirmed at surgery. If the palsy appears postoperatively and there is no improvement by 3 months, early exploration may be indicated.

Postoperative infections probably occur less than 1% of the time in shoulder arthroplasty. If the infection is acute and quickly recognized, irrigation, débridement, head exchange, and intravenous antibiotics may arrest the process. If more chronic in nature, infection will necessitate resection of the components and placement of antibiotic-impregnated cement spacer. Based on the bone stock, soft tissue qualities, and risk factors remaining after resolution of the infection, the reconstructive options can be weighed.

Interoperative vascular injury and postoperative venous thrombosis are both very rare with shoulder arthroplasty. The patient's hand and distal pulses should be checked before he or she leaves the operating room, and all bleeding should be identified and controlled. The fracture itself may put the anterior humeral circumflex artery at risk, and the surgeon should confirm that it is not damaged at surgery. With the raw fracture surfaces and hyperemic injury response, postoperative hematoma is not entirely uncommon. If suction drainage is not sufficient to keep the wound decompressed, one should try to aspirate the hematoma and apply a compressive dressing. If aspiration is not successful and tension remains across the surgical wound, we return to the operating theater, evacuate the hematoma, and identify the source of bleeding.

Ectopic bone formation is usually an incidental radiographic finding with no effect on the arthroplasty. It is more common in cases of fracture–dislocation. In some instances the new bone may bridge the glenohumeral joint, resulting in impingement and lost motion. In this unusual case, surgical resection may be indicated to restore a functional range of motion. Traditionally such surgery has been done after radioisotope imaging reveals less activity. However, one may take into consideration early intervention, as the patient will only get stiffer with time.

Clinical success/failure has been correlated with restoration of humeral length, proper version, secured tuberosity fixation, younger age, and early postoperative rehabilitation. Except for patient age, these are factors that are to some degree under the control of the surgeon and patient. Stiffness is one of the most common complications. Contributing factors are initial injury severity, prolonged immobilization, noncompliance with rehabilitation, and nonanatomic prosthetic reconstruction. A stiff shoulder is a painful shoulder and will result in an unsatisfied patient. To avoid any loss of motion due to soft tissue imbalance, the surgeon should as best as possible restore the patient's native geometry. To allow the necessary early rehabilitation, it is paramount to achieve excellent tuberosity fixation. Barring

any surgical limitations, a comprehensive structured rehabilitation program is usually successful for regaining function. If therapy is not working, the patient should be evaluated for tuberosity and humeral component positioning.

Loss of tuberosity fixation is probably the most devastating event to the functional success of the surgery.[22] This can ordinarily be avoided with secure fixation technique and anatomic reduction. If the subscapularis and lesser tuberosity displace in the early postoperative period, it is of utmost importance to make an early diagnosis and a timely repair. Late repairs do not have a great success rate, and we therefore emphasize the need to maximize the chances for success at the first surgical intervention. Tuberosity malreduction will also greatly affect the functional results.[3] Overreduction will put undue tension on the rotator cuff and lead to stiffness, tissue attenuation, cuff tears, and superior migration of the prosthesis. Underreduction will lead to impingement of the greater tuberosity beneath the acromion and/or of the lesser tuberosity beneath the coracoid/conjoined tendon complex.

Malposition of the humeral component is another issue that can be avoided in the operating room by the attentive surgeon. The stem must place the top of the head 5 to 10 mm above the greater tuberosity and in 20 to 40 degrees of retroversion. The head size must restore proper anatomy and offset. This combination will avoid impingement from a high riding tuberosity or loss of motion from the excess soft tissue tension created by a proud or oversized humeral head.

Instability is a problem that may present in two manners. First, if there is failure of the tuberosities and/or rotator cuff, superior migration of the prosthesis may result. With failure of the coracoacromial arch, anterior–superior subluxation or dislocation of the humeral head may result during attempted elevation of the arm. Second, anterior, posterior, or inferior dislocation can result from unrecognized capsular injury or with inadequate and unbalanced tissue tension.

Late Treatment

In some instances a patient is too sick due to massive injury or medical comorbidities to undergo surgery in the acute phase of his or her proximal humerus fracture. In other situations a patient may appear as a result of late referral or late presentation to the health care system. If the patient is elderly or otherwise infirm, then it is best to begin rehabilitation and give him or her a trial of conservative management. Many of these patients will achieve a satisfactory level of function and pain relief. If the patient is younger and more active, we will attempt a prosthetic reconstruction several months postinjury so long as the patient has a clear understanding of the less reliable results.[2532]

There is a subset of these patients that, treated nonoperatively, will continue to have pain with motion and will be severely affected in many aspects of their life. Due to the long duration since the original injury, we frequently are faced with bony malunion, rotator cuff loss, general muscle atrophy in the shoulder girdle, and marked soft tissue contractures. Classically we could offer these patients a choice of an arthrodesis or a resection arthroplasty.[9] Recently, we have addressed this difficult subset of patients with the Delta (reverse) shoulder prosthesis. The criteria of a functioning deltoid and adequate bone stock are essential when employing this prosthesis. This component affords substantial improvement in function and pain relief compared with resection arthroplasty or arthrodesis (Fig. 23A–D).

SUMMARY 939

Fractures of the proximal humerus are relatively common, accounting for approximately 5% of all fractures,[62] and their prevalence can be expected to increase as life expectancy and associated osteoporosis increase. Fortunately, most proximal humerus fractures can be treated nonoperatively with expected good outcomes; initial surgical intervention is required in only 20% of acute fractures.[70] Unfortunately, a small but not insignificant subset of those patients whose initial treatment was either conservative or surgical fails treatment and proceeds to develop either complications from the original injury or complications associated with the management of the injury. The spectrum of such complications of proximal humerus fractures, including neurovascular injuries, avascular necrosis of the humeral head, hardware complications, malunion, and nonunion, can prove extremely problematic and challenging to treat. These patients often have debilitating pain, limitation of range of motion, and loss of function of the shoulder leading to significant disability. Treatment of these complications of fractures of the proximal humerus can prove extremely challenging due to a variety of factors: osteopenic bone, extensive scarring, previous instrumentation, avascular bone, and neurologic injury. This chapter will provide an overview of the

cause, evaluation, and classification of these challenging problems and will include a critical discussion of the treatment options with the goal of providing a simplified treatment algorithm.

COMPLICATIONS OF INJURY

Neurologic Injury

With neurologic injury there are common patterns associated with certain fracture patterns. The incidence of neurologic injury is reported to be between 21% and 50%.[12,24,84] There have been numerous reports that outline the risk of temporary and permanent nerve or vascular injury with fractures and fracture–dislocations of the proximal humerus. The literature is not always clear; some articles quote neurapraxias, without clarifying which ones have resolved spontaneously. Nerve injuries are more common than previously recognized. De Laat et al. evaluated nerve lesions in primary shoulder dislocations and surgical neck fracture–dislocations with a prospective clinical and electromyographic (EMG) study. Electrophysiologic evidence of nerve lesions was found in 45% of the 101 patients evaluated. The most commonly injured nerves were the axillary, suprascapular, radial, and musculocutaneous. These authors stressed the importance of early diagnosis and treatment to prevent lasting impairment in those that involve more than a transient neurapraxia. In three other electrophysiologic studies of surgical neck fractures associated with glenohumeral dislocations, the axillary and other nerves were injured 20% to 30% of the time. Age was a factor; in those older than 50 years, the brachial plexus injury rate was 50%.[12,28,82]

The patient- and fracture-related factors associated with neurologic injury include the elderly and hematoma formation. Most have partial or complete recovery; 5% to 8% have persistent motor loss. The three common shoulder injuries associated with nerve injuries include the anterior shoulder dislocation, the two-part greater tuberosity fracture with an anterior dislocation, and the surgical neck fracture.[15,17] The most common single injury causing a nerve injury in the shoulder is the isolated two-part greater tuberosity fracture with an anterior dislocation.[84] The most common isolated fracture location is the surgical neck. This includes the two-part, three-part, and four-part surgical neck fractures. With a posterior fracture–dislocation, the axillary neurapraxia rate is 31% to 37% of the cases.[12,60] Following a four-part fracture, the nerve injury rate is 6.1%. Of this percentage, only one-third fully recover,[95] whereas following the three- and four-part fractures with a subsequent failed open reduction and internal fixation (ORIF), the permanent nerve injury rate rises to 17.4%, or approximately 8.7 times that of the permanent neurapraxias with the injury before treatment.[77] Thus, an ORIF as an intermediate step before arthroplasty has additional and significant risk. Worse yet, permanent loss of the axillary nerve occurs following blunt trauma in 50% of the cases.[12] Even an isolated anterior dislocation has a 10% to 20% axillary injury rate.[15,64] In summary, the risk increases with advancing patient age, the surgical neck fracture site, an associated dislocation, hematoma formation, blunt trauma, and a failed ORIF.

The diagnosis of nerve injury is more difficult with acute fractures, owing to pain, swelling, and immobilization; later, the physical examination for each motor group is more straightforward.[17,74,104] The major muscle groups to evaluate include the three divisions of the deltoid, the spinati, the internal rotators, trapezius, serratus anterior, rhomboids, and the biceps and triceps. Within the internal rotators, the subscapularis can be isolated with the Gerber lift-off test.[36] The two external rotators, the infraspinatus and the teres minor, can be isolated by palpation and inspection and by the external rotation lag signs before electrical confirmation.[88] These tests are difficult to perform in most patients with the late sequelae of trauma and cannot be performed with an acute injury.

The sensory examination, which has often been used for the evaluation of the deltoid, unfortunately does not necessarily correlate with the motor integrity: EMG studies have documented the unreliability of sensory examination.[8,12] Specifically, the sensation can be intact in the axillary distribution, with disruption of the motor fibers. This has important implications in patient management as well as in the medical–legal exposure. If there is any question about the nerve integrity at any stage in the patient's course, EMG and nerve conduction studies may better delineate the patient's status preoperatively. This permits rational treatment plans (i.e., timing of nerve exploration, followed by decompression, primary or secondary repair or graft, or even in selected cases, muscle transfers). The shift in recent years has been to surgically explore those individuals who have complete loss without any recovery in any one motor group by 3 to 4 months.

The treatment of nerve injuries will depend on the nerves involved, the type of injury, and the age and health of the patient. Nerve recovery is better with younger patients and with less distance from the injury site to the motor end-plate when reinnervation can occur. The prognosis for recovery from a sharp injury is better than from a blunt injury. Certainly, an early exploration and repair are justified with a penetrating injury with complete motor loss in a given motor group. The debatable area is the closed fracture with or without an accompanying dislocation and an associated brachial plexus deficit. The monograph *Traumatic Brachial Plexus Injuries* by Alnot and Narakas is an excellent guide for the complex cases that arise.[1,2]

Vascular Injuries

Vascular injuries are rare with proximal humeral fractures and fracture–dislocations. They are often masked by collateral circulation early on. The incidence of vascular injury is thought to be 0.3% to 3.0% with long bone fractures.[16] Conversely, in those with documented vascular injuries, 10% to 40% had long bone fractures or dislocations; 20% to 42% originally had negative physical findings.

The patient factors associated with vascular injury include the location of the fracture or dislocation, the mechanism of injury, and the age of the patient. More information is available on the association of brachial plexus injuries with vascular injuries. The vascular injuries are less frequently recognized because of the very extensive periscapular collateral circulation.[16] Traffic accidents account for 80%. Two main patterns predominate.[3] In the first and most common pattern, the shoulder is driven down and the head and cervical spine are flexed to the opposite side. This causes a traction injury to the plexus and vascular structures at the base of the neck. In the second, there is an acute narrowing of the costoclavicular space with a crush of the neurovascular structures of the thoracic outlet from a blow to the anterior shoulder girdle. The outlet is narrowed with the arm at the side, or worse when it is abducted. Associated proximal humerus fractures need not even be significantly displaced for a vascular injury to occur at the surgical neck level.[40] Fracture patterns associated with vascular injury usually involve fractures at the surgical neck of the humerus.[61,63,98] The artery at this level forms a "tethered trifurcation" where the anterior and posterior humeral circumflex vessels and subscapular trunks arise from the axillary artery (Fig. 30-1). The vascular injuries are associated with direct trauma, with a dislocated humeral head or a displaced upper humeral shaft. In a three-part greater tuberosity fracture, the circumflex vessels can be caught in the surgical neck site. A thrombus can then develop in the axillary artery.[92] In this case report, intimal damage caused by traction injured the brachial artery and caused it to develop spasm. Thrombus removal alone was insufficient, but circulation was restorable with either a direct repair or by a vein graft. Intimal tears of the axillary artery are described in four other cases at the subscapular and circumflex branches.[43] In two, an anterior dislocation alone occurred. In two, there were three- or four-part fractures with anterior dislocations. Vessel repair restored circulation in all.

The diagnosis of vascular injury often requires a high level of suspicion when ischemia is noted. The physical findings may be subtle, for normal distal pulses may be intact in up to 27% with major arterial injuries about the shoulder. In addition to shoulder pain with the surgical neck fracture level, distal coolness and tingling develop. Palpation of the axillary artery may be precluded by pain, muscle spasm, and swelling. The brachial and radial pulses will be diminished or absent in over 70%. With time, pain on passive extension of the fingers occurs.[40] The six "Ps" to summarize vascular injury are pain, pallor, paralysis, paresthesias, poikilothermia, and pulselessness. In addition, there may be a large or expanding hematoma, pulsatile external bleeding, unexplained hypotension, or a bruit. Usually, a vascular injury accompanies a nerve injury at the same level. These signs and findings are indications for vascular investigation along with imaging. The single-injection trauma angiography is accurate in the operating room setting. If more time is available, then formal angiography can be obtained in the radiographic suite with retrograde femoral arteriogram. In addition, more sophisticated studies include digital subtraction angiography and Doppler arterial pulse volume recordings.

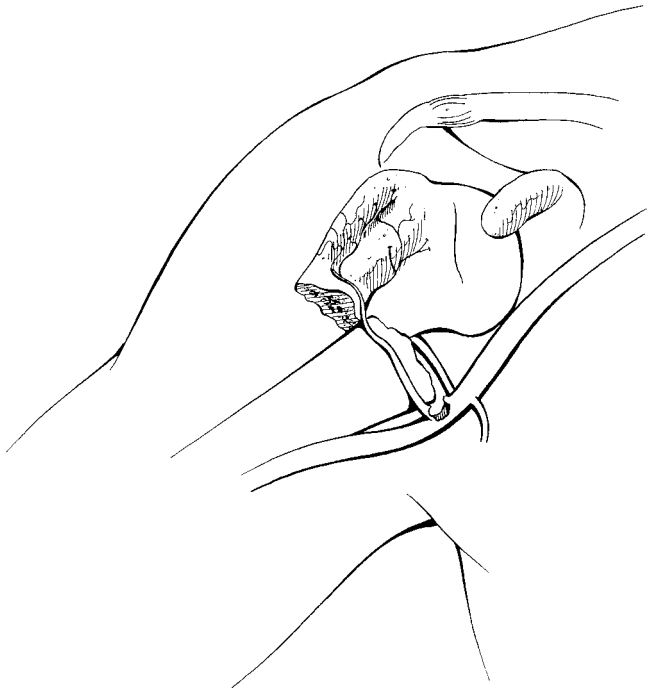

Figure 30-1 A "tethered trifurcation" forms where the anterior and posterior humeral circumflex vessels and subscapular trunks arise from the axillary artery.

Most authors agree that vascular injuries should be repaired. This is done immediately if there is acute ischemia. When performed on a delayed basis, it is to provide better nutrition for associated fracture and nerve healing.[3] At the time of emergency vascular repairs, the nerve repairs are best deferred until later when a good level of transection can be determined for the stretch injuries. The optimal time of nerve repair is 2 weeks to 3 months and may be combined with the elective vascular reconstructions. The one contraindication to a vascular repair is when the distal circulation is good through the collateral

circulation and there is a complete plexus avulsion. Here, no plexus reconstruction is possible.

At the time of acute vascular repairs, the tradition has been to rigidly fix all fractures with plates and screws. More recently, the need for rigid fixation has been debated as more fractures are pinned percutaneously or with limited pin, intramedullary rod, and tension band techniques. This avoids much of the periosteal stripping.[22,23,76] In support of this transition, Sturzenegger et al. noted five times the osteonecrosis rate in treating multifragmented proximal humerus fractures with AO buttress plates as with tension band wiring.[96]

Avascular Necrosis

Osteonecrosis, avascular necrosis, and ischemic necrosis are terms to describe the loss of circulation to the terminal articular surface. This is followed by collapse in most cases. Although rare, it can occur after two-part and minimally displaced fractures (Fig. 30-2). It occasionally occurs with a three-part displaced proximal humeral fracture, but most commonly occurs after four-part fractures or fracture–dislocations. Although the amount of osteoporosis and severity of the trauma may play a role, occlusion of the arcuate artery of Laing in the proximal portion of the biceps groove, which provides vascular supply to the anterior and superior two-thirds of the humeral head, is a major contributing factor.[37,57] This artery is the terminal branch of the ascending branch of the anterior circumflex humeral artery and enters the humeral head near the top of the groove of the long head of the biceps tendon. This point of rigid fixation is vulnerable to displacement of the shaft with fractures, and, especially, with fracture–dislocations. The more segments that are fractured and displaced at the time of a humeral shaft fracture, the greater the increase is in the incidence of injury to this artery. If the articular surface is no longer attached to any tuberosity and the medial soft tissue hinge at the neck of the humeral head is disrupted due to displacement of the shaft and the humeral head (classic four-part fracture), the incidence significantly increases. Neer reported two cases of osteonecrosis out of 33 ORIFs of three-part proximal humeral fractures.[71] Sturzenegger et al. noted six times the incidence of osteonecrosis with use of plates for the proximal humerus as compared with when they used wires and pins to provide what they termed "minimal fixation."[96] Although there are isolated reports without osteonecrosis following ORIF of four-part fractures, many of these have short follow-up. For example, Lee and Hansen reported a case of a vascularization of the humeral head after ORIF of a four-part fracture at 2 years, which then went on to collapse at 3.5 years.[59] In Sturzenegger et al.'s report of ORIF of three- and four-part fractures, three cases developed sympathetic dystrophy with osteonecrosis following hardware complications. Screw penetration into the joint can cause traumatic arthritis. Collapse of the joint makes the use of screws even more problematic.[65,73,96,105] The timing of replacement if this complication occurs is important. The longer one waits, the more likely it is that both sides of the joint will need to be replaced. Either use of the plate that compresses the artery or stripping to place the plate on the fracture sites at the lateral edge of the biceps groove contributes to injury of the artery with subsequent osteonecrosis. Nonunion, malunion, and eventual osteonecrosis are the frequent complications associated with ORIF of displaced four-part fractures.[10,75]

Figure 30-2 Avascular necrosis after a minimally displaced healed proximal humerus fracture.

Another attempt to decrease the incidence of osteonecrosis and extend the indications for ORIF of four-part fractures is a closed pinning and external fixation.[44,52–54] Although this has been a successful technique in Europe, Gerber et al. reported that when absolute anatomic reconstruction is not established, the result will be a failure.[35] There has been a significant increase in the number of nonunions, infections, and axillary nerve palsies following the closed pinning attempts. There is a steep learning curve. As with every new or resurrected technique, a set of complications also emerges.

In those patients in whom posttraumatic arthritis has developed from avascular necrosis, humeral head replacement may suffice. If the glenoid surface is significantly

damaged, and in particular if the concavity of the glenoid is altered with bony erosion at one edge, a total shoulder is preferred. Boileau et al.[13] reported good and predictable outcomes when treating patients with posttraumatic avascular necrosis of the humeral head with prosthetic arthroplasty. In fact, those patients in their series with avascular necrosis had significantly better outcomes than those with nonunions of the surgical neck or proximal humerus malunions. Prosthetic arthroplasty reliably provided pain reduction, restoration of range of motion, and improvement in function in another small series.[25]

MALUNIONS

For symptomatic patients with proximal humerus malunions, realistic nonsurgical options to reduce pain and improve function do not exist, and surgical reconstruction is often necessary. Surgical treatment of proximal humerus malunions proves especially challenging due to associated disruption of normal anatomic relationships, soft tissue scarring and contracture, rotator cuff pathology, postsurgical changes, neurologic impairment, and osteoporosis. This array of concomitant pathology renders the achievement of the operative goals of restoring premorbid functional status and relieving pain exceptionally challenging. The treatment of these complex problems requires thorough preoperative evaluation to determine the causative factors for the malunion and sound understanding and skilled application of the surgical techniques available to treat the entire spectrum of osseous and soft tissue pathology.

Etiology

Proximal humerus malunion results from either inadequate reduction of the displaced fragments or loss of fixation following closed reduction, closed reduction and percutaneous pinning, or ORIF. Although malunions sometimes occur following ORIF, they occur more commonly after nonoperative treatment. The higher incidence of malunion with nonoperative treatment may be secondary to the acceptance or lack of recognition of a significantly displaced fracture. Nonsurgical treatment of a displaced proximal humeral fracture may be a selected option in patients who are poor surgical candidates due to medical illness or have other severe injuries that preclude early surgical treatment of the proximal humeral fracture. Occasionally, a malunion occurs because the treating physician failed to appreciate the extent of displacement either due to lack of experience or inadequate or incomplete imaging studies. The malunion seen after internal fixation usually is secondary to inadequate fragment fixation obtained in the poor cancellous bone of the proximal humerus. This can result in postoperative loss of fracture reduction. It can also occur due to inadequate fragment reduction at the time of surgery.

Other contributing factors in proximal humerus malunions include inadequate immobilization, inadequate length of immobilization, or soft tissue interposition at the fracture site. Excessively aggressive rehabilitation can result in loss of fracture reduction or fixation.

Clinical Evaluation

Eliciting a careful history is essential in the evaluation of a patient with proximal humerus fracture malunion. The history should determine the mechanism of injury and subsequent treatment, with the goal of determining the cause of the malunion. Errors in diagnosis, such as a missed injury, may have occurred. Conditions that contribute to malunion include osteoporotic bone, premature or aggressive rehabilitation, high-energy multitrauma, and inadequate stability of operative fixation and inadequate reduction. Alcohol or steroid use may contribute to the development of humeral head avascular necrosis, which may provide additive joint incongruity to that attributable to the malunion.

The pain or disability associated with a proximal humerus fracture malunion varies considerably and must be addressed in terms of the patient's goals. This assessment is critical. A relatively painless malunion with adequate passive range of motion and strength may not require surgical management, especially in a sedentary patient with limited expectations for upper-extremity function. This is typically seen in the older patient with an isolated surgical neck fracture that heals with a varus malunion but the humeral head remains spherical and without posttraumatic arthritis.

Essential to the clinical evaluation of the patient with a malunion is a complete neurovascular examination of the involved upper extremity. From the initial trauma, there may have occurred associated permanent axillary nerve or brachial plexus injuries, especially if fracture fragments were initially displaced medial to the coracoid process. Axillary nerve injury is often associated with inferior subluxation of the proximal humerus (Fig. 30-3). Possible neurologic injury from previous surgery must also be ascertained. If prior nerve injury is suspected, electromyelographic examination can be helpful in determining the extent of injury and the prognosis for neurologic recovery.

The long head of the biceps tendon interposition can contribute to a malunion of the proximal humerus. Rotator cuff injury may have occurred during the initial trauma and must be addressed at the time of surgery. Iatrogenic injury from previous surgery can include detachment of the origin of the anterior deltoid or deltoid denervation,[39] transection of the long head of the biceps, or subscapularis tendon detachment.

Loss of motion is one of the primary management problems associated with proximal humeral malunion.

Figure 30-3 Anatomic neck malunion in a 64-year-old woman with an associated axillary nerve injury and deltoid paralysis. (Reproduced with permission from Warner JJP, Iannotti JP, Flatow EL, eds. *Complex and revision problems in shoulder surgery,* 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2005.)

Assessment of the degree of loss of passive versus active arcs of motion is necessary and should be considered in terms of the patient's current disability and treatment goals (Fig. 30-4). The progression or improvement of the patient's pain, weakness, and loss of motion must be considered as it relates to the rehabilitation program. If the passive motion is maintained, the rotator cuff is intact, and the surface of the joint is congruent, good function can be present without surgery (Fig. 30-5).

The surgeon should keep in mind the possibility of shoulder sepsis complicating any malunion resulting from prior surgery. If infection is suspected, appropriate hematologic studies are required and aspiration arthrogram is warranted.[25]

Radiographic Evaluation

Plain Radiographs

The most important aspect in the injury evaluation is to determine the position of the fracture fragments. Bone quality and the likelihood of healing must also be assessed. An adequate radiographic evaluation is required and includes an anteroposterior view in the plane of the scapula, axillary lateral, and transscapular lateral views[89] (Fig. 30-6). This series usually provides sufficient information to determine a treatment plan for most patients. Additional radiographic views such as the apical oblique view, which demonstrates posterolateral humeral head compression fractures, and the transscapular lateral view, which may be helpful in the evaluation of superiorly displaced greater tuberosity malunion, can be obtained.

Computed Tomography Scans

Computed tomography (CT) scans of proximal humerus malunions are needed when the plain radiographs are indeterminate. CT scans have been recommended to evaluate the degree of tuberosity displacement and for clearly imaging articular impression fractures, head-splitting fractures, and chronic fracture–dislocations (Fig. 30-7).[9,49,68] Morris et al. reported that CT identified axial malposition of the greater and lesser tuberosity that was not appreciated on plain radiographs in 10 and 18 out of 18 patients, respectively.[68] Additionally, several authors have recommended the utilization of three-dimensional CT reconstructions of the proximal humerus to better comprehend the position of malunited tuberosities (Fig. 30-8).[25,55]

Other Radiographic Modalities

Magnetic resonance imaging (MRI) can demonstrate associated soft tissue problems of the deltoid, rotator cuff, biceps tendon, and glenoid labrum, which can be helpful in the management of patients who may have concomitant osseous and soft tissue pathology (Fig. 30-9). Avascular necrosis can be detected earlier with MRI than with plain films, knowledge of which may affect treatment plans. It should be noted that patients with hardware from prior operative intervention may have signal artifact, which can diminish the quality and utility of the MRI or CT scans.

Classification of Proximal Humerus Malunions

There is presently no universally accepted classification system for proximal humerus malunions that provides a basis for comparing various subsets of malunions and different treatment outcomes. The absence of such a system lends to some difficulty in interpreting the relevant literature and comparing different treatments for specific subsets of malunions or posttraumatic sequelae across all reported cases. A few authors have recognized this shortcoming and have proposed classification systems useful in determining the treatment approach for proximal humerus malunions and evaluating outcomes.

Beredjiklian et al.[7] attempted to provide a method for systematic evaluation of both osseous and soft tissue

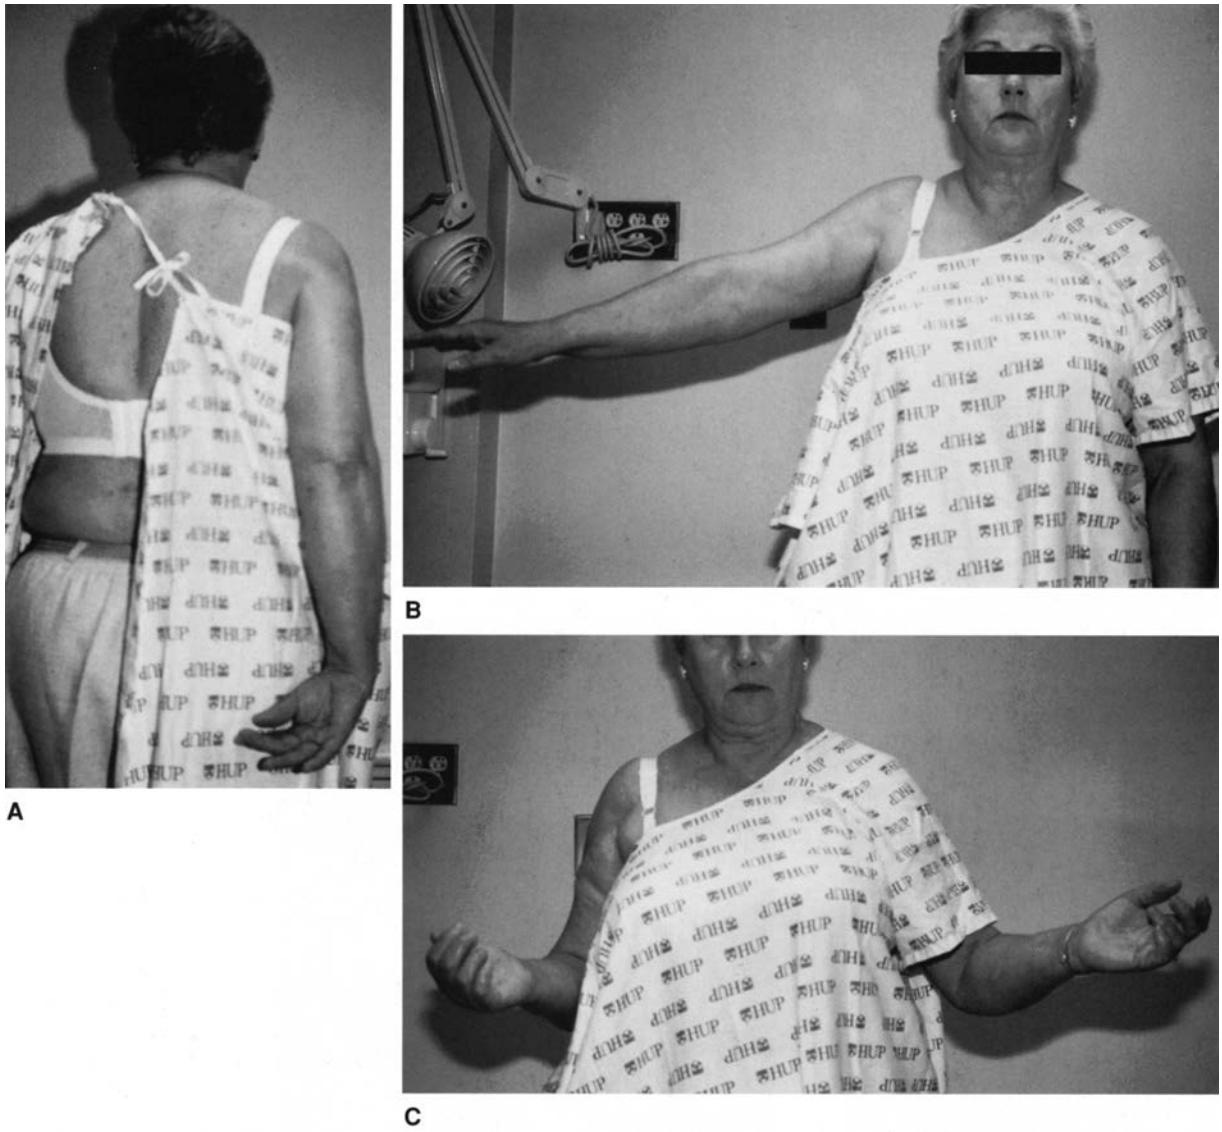

Figure 30-4 **(A)** The patient's functional disability from the marked loss of internal rotation, **(B)** abduction, and **(C)** external rotation, primarily resulting from capsular contracture, necessitating open capsular release. abnormalities. Osseous abnormalities were categorized as malposition of the greater or lesser tuberosity of greater than 1 cm (type I malunion), incongruity or step-off of the articular surface of more than 5 mm (type II malunion), and malalignment of the articular segment by more than 45 degrees of rotation in any plane (type III malunion). Soft tissue abnormalities were classified as soft tissue contracture, rotator cuff tear, and subacromial impingement. Any given patient often has multiple osseous and soft tissue sequelae of their posttraumatic deformity, and this classification system is useful in enabling a holistic awareness of all involved pathology with the aim of treating each component.

In an attempt to simplify the surgical treatment and prognosis in treating the posttraumatic sequelae of the proximal humerus, Boileau et al.[13] proposed a general classification system for proximal humerus fracture sequelae that was not specific for but did include proximal humerus malunions. Intracapsular/impacted fracture sequelae (category 1) included both cephalic collapse and necrosis (type 1) and chronic dislocation or fracture–dislocation (type 2) in which a proximal humerus arthroplasty could be performed without a greater tuberosity osteotomy. Extracapsular/disimpacted fracture sequelae (category 2) included both surgical neck nonunions (type 3) and severe tuberosity malunions (type 4) in which the

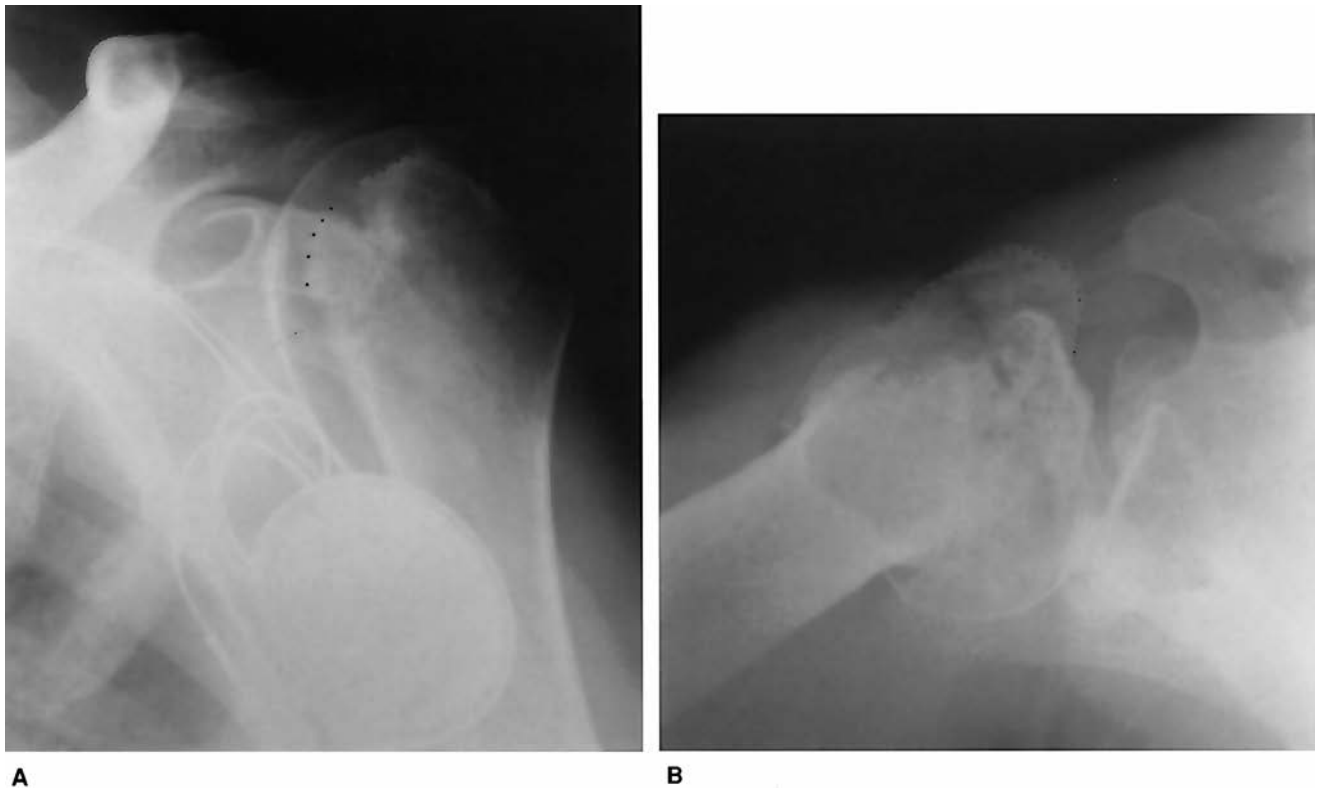

Figure 30-6 A 60-year-old retired but active man sustained a fall that produced pain. **(A)** An anteroposterior and inadequate scapular Y-view did not demonstrate the posterior humeral head dislocation. Malunion of a lesser tuberosity fracture with a posterior dislocation was initially unrecognized because of the lack of an axillary view at the time of the initial injury. **(B)** The axillary view obtained 6 months after injury clearly demonstrates posterior subluxation, malunited tuberosities, and posttraumatic arthritis. The dotted line represents the greater tuberosity. (Reproduced with permission from Warner JJP, Iannotti JP, Flatow EL, eds. *Complex and revision problems in shoulder surgery,* 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2005.)

proximal humerus could not be reconstructed without a greater tuberosity osteotomy. This classification system enabled the prediction of posttraumatic deformities that could be reconstructed with an arthroplasty with a predictably good outcome (category 1) versus those that would yield an unpredictable and likely poor result with arthroplasty (category 2) predicated on the need for greater tuberosity osteotomy and the associated possibility of postoperative displacement, malunion, or nonunion. This series excluded cases in which malunions could be treated with osteotomy and internal fixation without the use of shoulder arthroplasty in treating posttraumatic sequelae.

The most commonly utilized classification of proximal humerus malunions has been a simple modification of Neer's classification of acute proximal humerus fractures.[70] Several authors have utilized this classification and applied it to describe their series of malunions.[5,14,31,77,97] As this is a commonly understood classification system, it will be utilized to structure the following discussion of specific subtypes of proximal humerus malunions.

Specific Fracture Malunions

Two-Part Anatomic Neck Malunion

Isolated anatomic neck fractures are extremely rare, and malunions of this type have not been reported. Subsequent avascular necrosis of the articular surface is a common posttraumatic sequela of this type of fracture. A prosthetic hemiarthroplasty would be selected as the treatment if there is avascular necrosis with head collapse. Theoretically, an anatomic neck malunion could be treated by osteotomy and internal fixation, although risk of subsequent avascular necrosis would be of significant concern.

Two-Part Greater Tuberosity Malunion

Malunion of the greater tuberosity fracture is probably the most common proximal humeral malunion. Greater tuberosity fractures are often retracted superiorly and posteriorly by the deforming forces of the attached

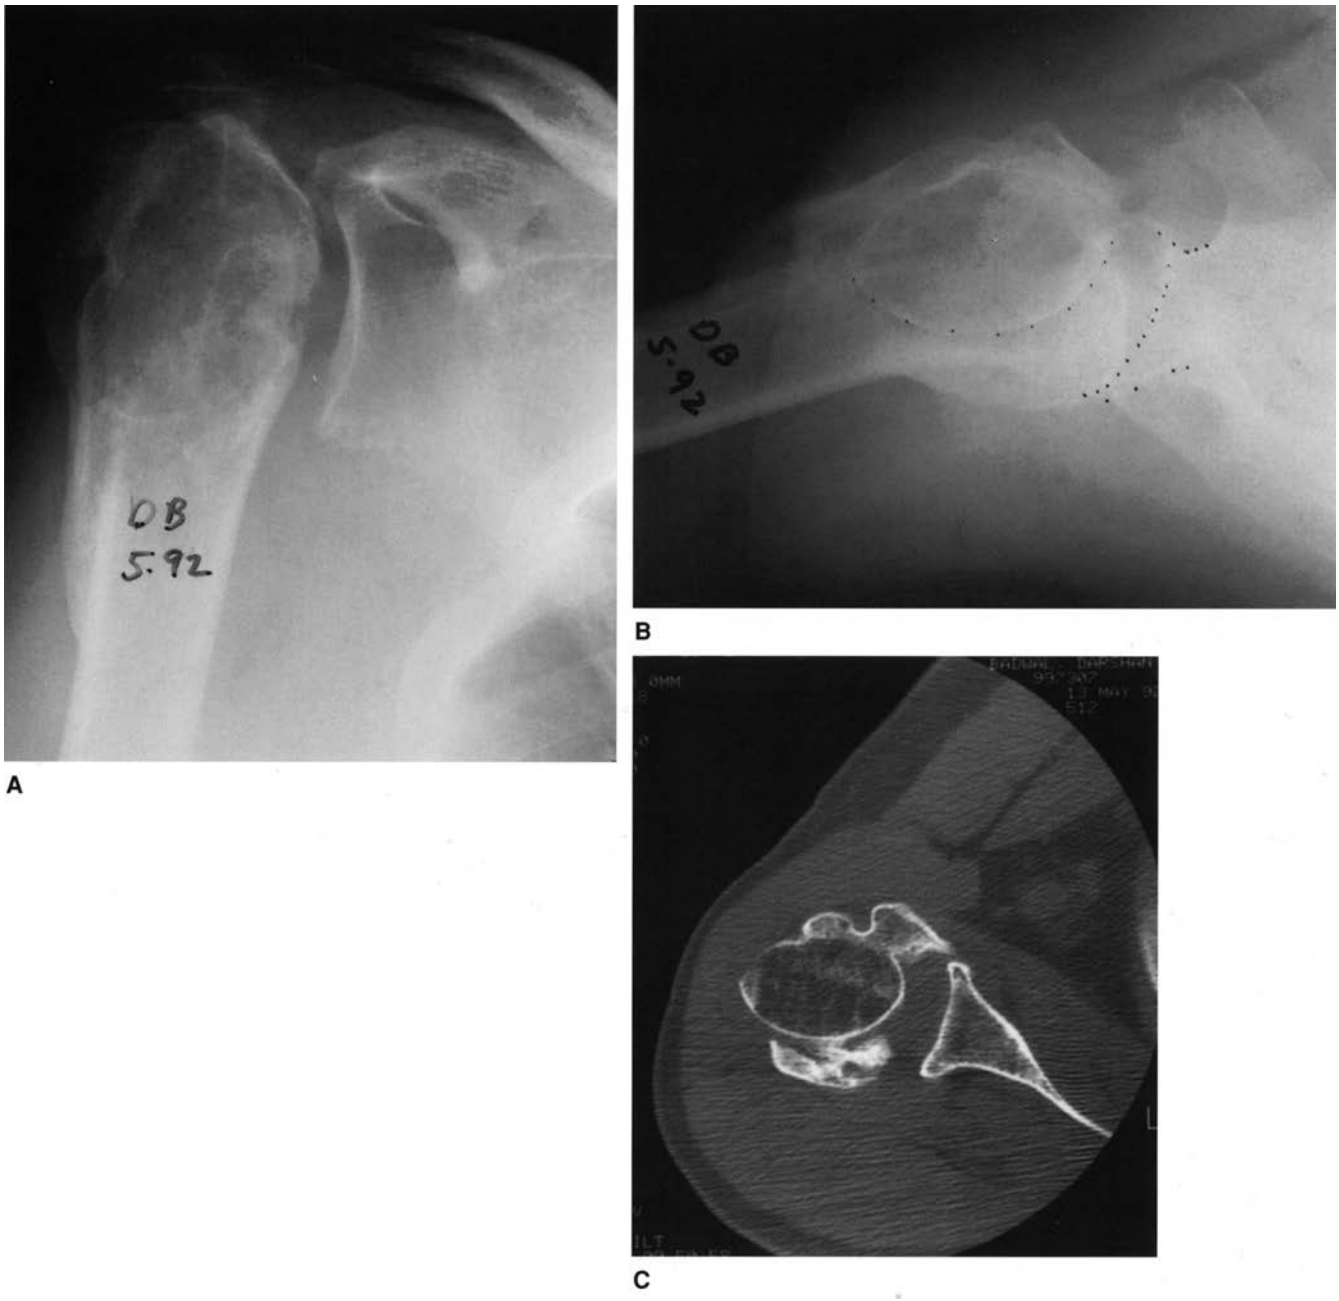

Figure 30-7 A 45-year-old businessman sustained a fall in India that was treated with nonoperative care. He had only mild pain with the activities of daily living and therefore did not consent to surgery. This patient had only 70 degrees of elevation and 0 degrees of external rotation and internal rotation to the buttock. **(A)** Malunion of a four-part fracture is poorly defined on the anteroposterior view. **(B)** The axillary view improves the recognition of the displaced humeral head fragment (widely spaced dotted line), and **(C)** the computed tomography scan best defines the united tuberosities. (Reproduced with permission from Warner JJP, Iannotti JP, Flatow EL, eds. *Complex and revision problems in shoulder surgery,* 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2005.)

supraspinatus, infraspinatus, and teres minor muscles. The articular surface is unaffected by this fracture type and maintains its appropriate relationship with the humeral shaft. Posterior displacement of the greater tuberosity can lead to a rigid, bony block to external rotation, which can be evident on physical examination. In extreme cases, anterior glenohumeral instability can result as the posteriorly displaced greater tuberosity impinges on the posterior glenoid in external rotation.[21] Similarly, superior displacement of the greater tuberosity can block abduction and forward elevation and lead to subacromial impingement as the malunited tuberosity encroaches on the subacromial

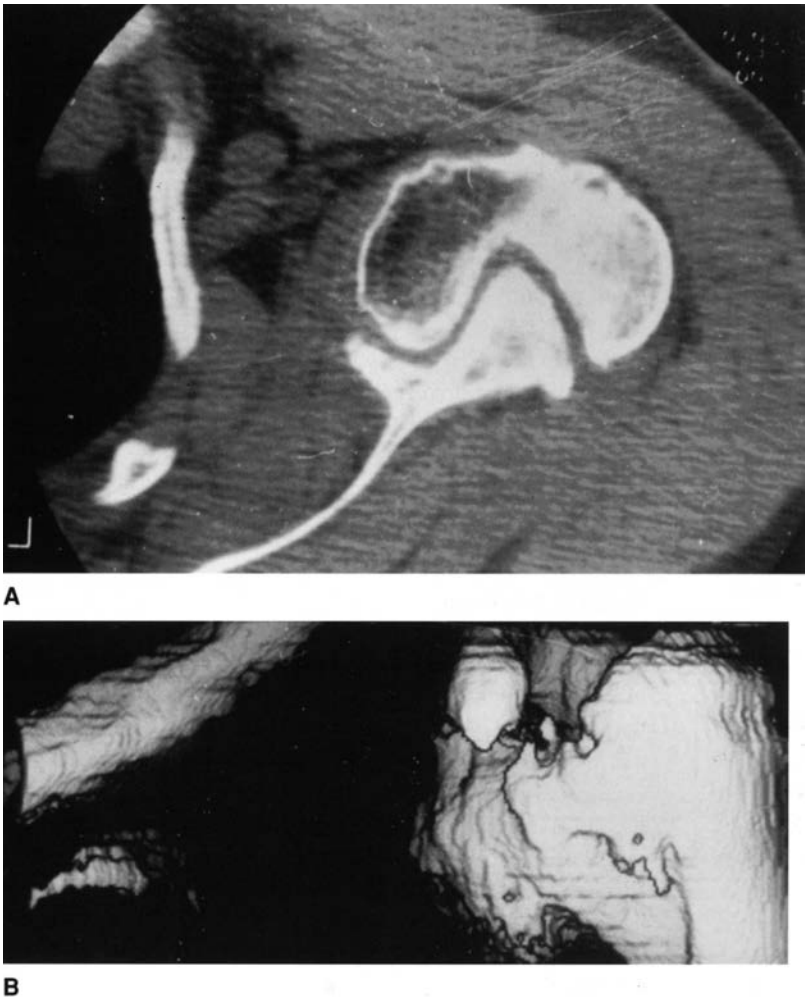

Figure 30-8 A 40-year-old laborer sustained a four-part fracture dislocation that was treated by attempted open reduction and internal fixation 15 years before referral to our center. **(A)** A computed tomography scan and **(B)** three-dimensional reconstruction of this malunited four-part fracture dislocation demonstrate the humeral head in a subcoracoid location and the humeral shaft articulating with the glenoid. This patient performed heavy labor for 15 years with what was essentially a fused "glenohumeral" joint, but pain increased over the years, and he was eventually treated with excision of the malunited head fragment and fusion of the proximal humerus to the glenoid. Successful fusion allowed him to return to heavy labor. (Reproduced with permission from Warner JJP, Iannotti JP, Flatow EL, eds. *Complex and revision problems in shoulder surgery,* 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2005.)

space.[21,48] Tuberosity malposition can result in rotator cuff weakness secondary to the shortened musculotendinous length of the external rotators.[91] Additionally, severe subacromial impingement can lead to rotator cuff attrition or tears. Thus, it is critical to examine the integrity of the rotator cuff through both physical examination and intraoperative evaluation.

Greater tuberosity malunions that heal to the humeral shaft result in less deformity and soft tissue contracture. These malunions are easier to mobilize and reduce to their anatomic site because they move with the humerus when the arm moves and are displaced less. On the other hand, greater tuberosity malunions that heal by fibrous tissue to the posterior part of the humeral head or glenoid neck result in severe shortening of the capsule and attached rotator cuff and can rarely be brought to their anatomic site and still achieve passive internal rotation to the abdomen.

Satisfactory closed reduction of chronically displaced, isolated greater tuberosity fracture is impossible, and malunion of this fracture is best treated by prevention through primary surgical management of the acute fracture. Conversely, fractures associated with an anterior glenohumeral dislocation are often successfully reduced with reduction of the dislocation.[52] Healing of these fractures must be monitored closely when they are treated by closed means because of the tendency for later displacement.[67]

Radiographic Evaluation

Careful radiographic evaluation of the suspected greater tuberosity is required; three high-quality orthogonal views of the shoulder should be obtained.[90] Small fragments isolated to the superior facet of the greater tuberosity often displace superiorly and are more commonly diagnosed on anteroposterior radiographs. Larger fragments containing the superior and posterior portion of the rotator cuff often displace posteriorly behind the humeral head and are more difficult to appreciate on anteroposterior radiographs. The scapular lateral view may be particularly useful in delineating posterior and superior displacement of the greater tuberosity, and the axillary view is particularly useful in determining posterior displacement. Malunion of the greater tuberosity is a result of not obtaining the correct

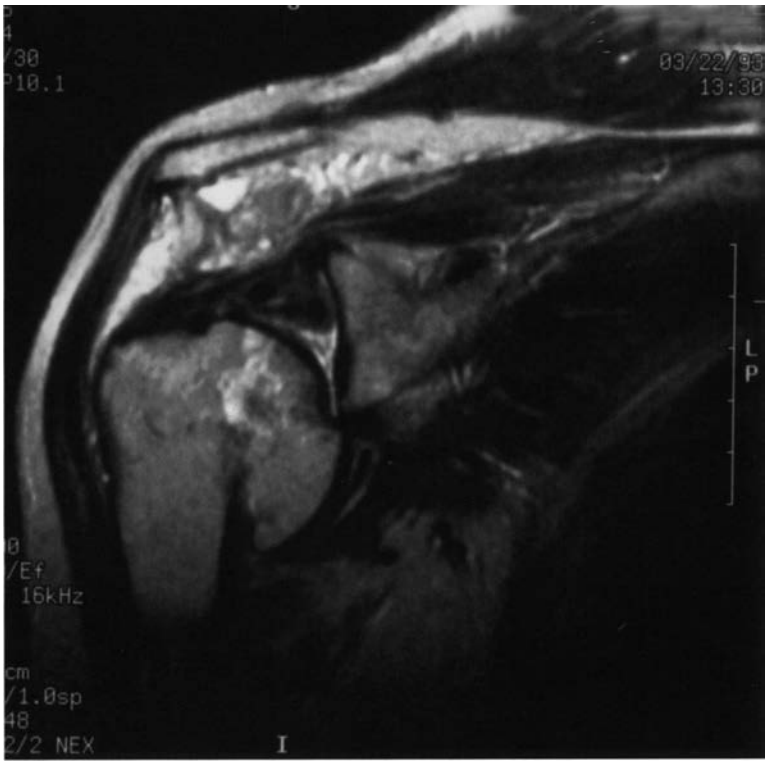

Figure 30-9 Magnetic resonance (MRI) scan demonstrates a posttraumatic arthritis defect in the humeral head, early avascular necrosis, and marked deltoid and supraspinatus atrophy. In this case, the MRI scan is helpful in diagnosing the avascular necrosis, determining the degree of atrophy, and detecting posttraumatic arthritis. (Reproduced with permission from Warner JJP, Iannotti JP, Flatow EL, eds. *Complex and revision problems in shoulder surgery,* 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2005.)

views, obtaining poor-quality views, or not obtaining follow-up x-ray films. In any case, malunion of the greater tuberosity is preventable.

A CT scan of the proximal humerus can be particularly useful in evaluating the greater tuberosity malunion. As stated previously, Morris and associates[68] evidenced that CT scanning enabled accurate evaluation of tuberosity displacement that was inaccurately identified with plain radiographs.

Surgical Indications

The Neer classification of proximal humerus fractures defines 1 cm as the criterion for significant displacement. In the case of greater tuberosity malunion, we think that for most patients the same criterion should be applied to correct the pathologic limitation in motion, rotator cuff weakness, and impingement. In an active patient with malunion of greater than 5 mm in the superior direction, symptoms of subacromial impingement can occur and can warrant surgical intervention.

Surgical Technique

In patients with acceptable passive arcs of shoulder motion, greater tuberosity malunions can be surgically managed with the same techniques used for the acute fracture.[30] For small fragments, up to 3 cm in size, with superior displacement, satisfactory exposure can be achieved with a superior incision within the Langer lines centered on the anterolateral corner of the acromion. The deltoid is detached from the anterior acromion and split a distance of 4 cm from the acromion. Subacromial scar tissue is excised when present. For larger fragments or malunions with posterior displacement, a wider and more extensile exposure is required. In these cases an extended deltopectoral approach is performed.

The greater tuberosity fragment is mobilized by sharp dissection of a fibrous union or by osteotomy of a bony union. The greater tuberosity osteotomy is frequently biplanar,[25] beginning at the anterior callous. Craig described the use of several drill holes prior to osteotomizing the tuberosity to mark the site and minimize fracture and fragmentation.[21] He emphasized that care must be taken during the osteotomy to protect the axillary nerve posteriorly as it emerges from the quadrilateral space. When discrimination between tuberosity and fracture callus is difficult, good-quality radiographs and a CT scan can assist in making this assessment. The donor defect from which the greater tuberosity has been displaced is adjacent to the bicipital groove. It is often filled with fibrous tissue or sclerotic bone and requires débridement and light decortication down to a bed of bleeding bone in preparation for the reduced greater tuberosity. Care should be taken to avoid removing all of the dense, cortical bone so as to preserve adequate bone stock for fixation. With severely posteriorly displaced fragments, excision of the posterior capsule is required to mobilize the greater tuberosity and its attached rotator cuff to allow the greater tuberosity to reach its site of reattachment. The rotator

interval is usually torn, and dissection of the scar in this area is necessary to mobilize the greater tuberosity fracture fragment. The rotator cuff must be brought to length, and any coexistent cuff tear should be repaired first. Temporary traction sutures placed in the rotator cuff insertion allow control of the greater tuberosity fragment to assist in lateral advancement during lysis of adhesions and contracture release. Prior to definitive repair of the rotator interval and fixation of the tuberosity fragment, it is important to inspect the anterior glenoid and labrum through the rotator interval to rule out associated pathology. This is especially true in cases in which the greater tuberosity fracture occurred in the setting of a traumatic anterior glenohumeral dislocation. If a Bankart lesion is identified, some authors advocate repair through the rotator interval prior the bony repair.[21,91] In some cases partial takedown of the subscapularis may be necessary to achieve exposure of the anterior–inferior glenoid. Bankart repair would be recommended in the young, active patient and is usually not required in the older and more sedentary patient. In the senior author's experience only lesions that include a significant bony glenoid component and demonstrate instability prior to surgery are repaired. The vast majority of patients with greater tuberosity fracture associated with an anterior dislocation either do not have a classic soft tissue Bankart lesion or the lesion is minor and does not require repair.

The greater tuberosity fragment can usually be anatomically reduced. In some cases, it cannot be anatomically reduced, in which case the greater tuberosity is returned anteriorly as far as possible and below the top of the humeral head. It is necessary that the patient's arm can be brought passively to the abdomen prior to wound closure. The surgeon may use the supraspinatus, infraspinatus, and teres minor facets of the greater tuberosity as anatomic landmarks for anatomic reduction.

Two to four heavy, nonabsorbable sutures (5-0 or #2 Fiberwire, Arthrex, Naples, FL) are placed vertically in a figure-eight configuration through the greater tuberosity and then through drill holes in the humeral shaft. Horizontal fixation can be achieved by placing intraosseous sutures to the lesser tuberosity area (Fig. 30-10).[79] Incorporation of the sutures in the rotator cuff tendon adjacent to the greater tuberosity fragment is important because the tendon substance is often stronger than that of the osteopenic bone of the tuberosities.

Alternatively, internal fixation of the greater tuberosity with screws and washers could be used in normal bone if the tuberosity fragment is large. In such cases where there is a large fragment of bone with good bone quality, one or two interfragmentary bone screws can be used, but should not be used without the additional use of the suture fixation as described above. Hardware loosening may require later removal.[101] Screw fixation should be avoided in osteopenic bone. Plate fixation is usually not necessary for the management of an isolated greater tuberosity malunion and may lead to subacromial impingement. Wire fixation does not seem to offer any distinct advantage over heavy nonabsorbable suture but does have the disadvantage of material failure and subsequent migration requiring removal.

After reconstruction, the subacromial space is examined with the surgeon's index finger. If it is tight or if a rotator cuff repair was performed, a subacromial decompression is performed to protect the bony and soft tissue repairs.

Passive and active assisted range of motion is begun on the day of surgery, but internal rotation behind the back is avoided for 6 weeks. Active motion is begun at 6 weeks, followed soon by resistance exercises. For cases with severe posterior displacement and difficult mobilization of the fragment, we utilize an abduction orthosis to hold the arm in 0 degrees of rotation, and internal rotation to the abdomen is avoided for the first 4 weeks.

In patients with greater tuberosity malunions and loss of passive arcs of glenohumeral motion, an arthroscopic capsular release without correction of the malunion is usually unsuccessful in achieving acceptable passive arcs of motion with a minimum of 120 degrees of forward elevation. In cases of malunion, there is a significant extracapsular scarring, and therefore we prefer the extended deltopectoral approach with open capsular release at the time that the malunion is corrected. Additionally, for large greater tuberosity fragments with metaphyseal-diaphyseal extension, the axillary nerve limits the extent of a deltoid split, further necessitating the use of a deltopectoral exposure. In cases with internal rotation contracture of greater than 20 degrees, subscapularis coronal plane Z-lengthening is performed. Cases with mild malunion and less severe internal rotation contracture require separation of the subscapularis from the underlying capsule and excision of the capsule and surrounding scar from the subscapularis tendon and muscle. In these cases where osteotomy is not required, an arthroscopic capsular release with excision of extracapsular scar is preferred.

Results

Morris and colleagues[68] reported three greater tuberosity malunions that underwent osteotomy and repositioning. Shoulder elevation and external rotation motion arcs were both improved by 60 degrees. If significant shoulder stiffness and weakness have not yet occurred, the surgeon might expect the good healing rate and functional results that Flatow and coworkers[30] found in their series of acute, displaced greater tuberosity fractures treated by the nonabsorbable suture method of internal fixation.

Eleven of the 39 cases reported by Beredjiklian et al.[7] involved an isolated malunion of the tuberosity (type I malunion). Eight of these patients were treated definitively with an osteotomy of the tuberosity and soft tissue reconstruction, and seven of these reconstructions corrected the bony deformity to within 5 mm of anatomic reduction. Pain relief was significant in all cases and rated as minimal

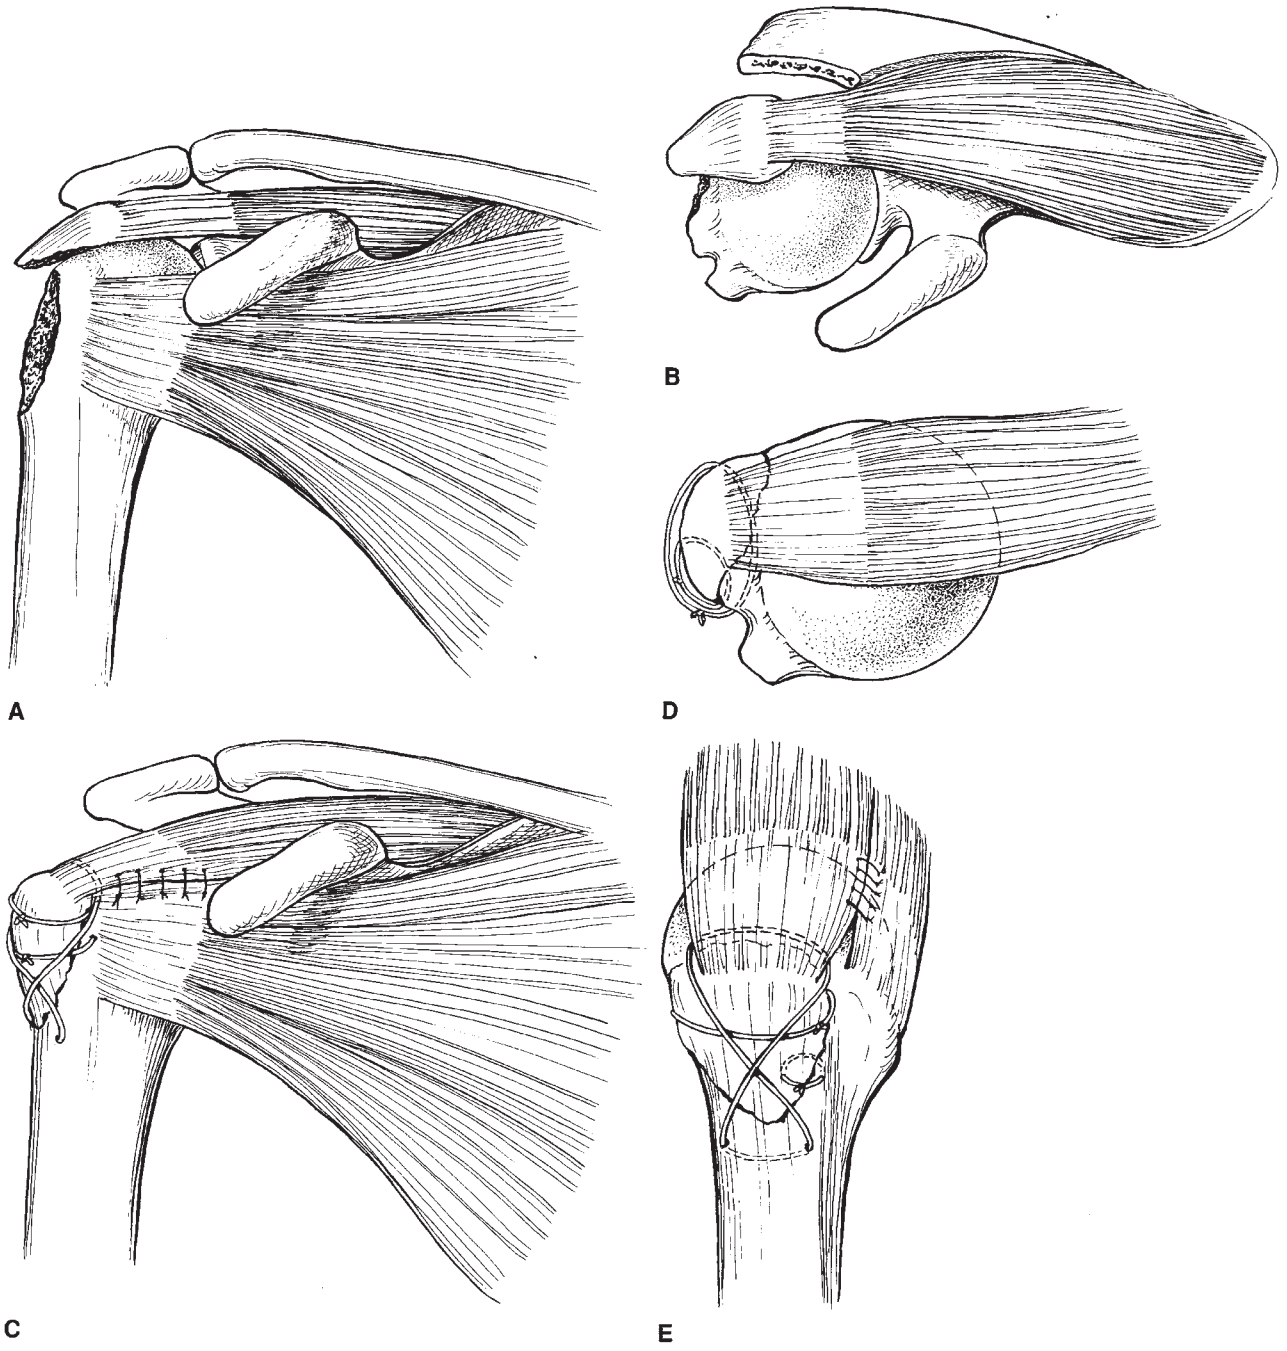

Figure 30-10 **(A,B)** Isolated greater tuberosity fracture with superoposterior displacement. **(C–E)** Reduction of the greater tuberosity and internal fixation using transosseous horizontal sutures and vertical figure-eight sutures. The horizontal sutures between the tuberosities are placed between the bone fragments, which helps to reduce the fragments, and in the rotator cuff tendon insertion sites, which provides the best tissue for maintaining the reduction during the postoperative evaluation. The vertical figure-eight suture also passes through the tendon insertion and then passes through a drill hole 2 cm distal to the metaphyseal fracture line. The vertical suture prevents superior displacement. The rotator interval between the subscapularis and supraspinatus is repaired, significantly improving stability. (Reproduced with permission from Warner JJP, Iannotti JP, Flatow EL, eds. *Complex and revision problems in shoulder surgery,* 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2005.)

or none in 88%. Functional capacity improved in 75% of patients, and, overall, six of eight patients had a satisfactory result. The best outcomes among their 39 cases were seen in the group who had isolated malposition of the greater or lesser tuberosity and had all osseous and soft tissue abnormalities corrected.

Two-Part Lesser Tuberosity Malunion

Two-part lesser tuberosity fractures are rare but often associated with posterior shoulder dislocations. If a malunion fragment is large, it may act as an obstacle to internal rotation and may also involve the articular surface of the humeral head. Associated subscapularis weakness may be seen with significant medial displacement due to altered musculotendinous length.

Radiographic Evaluation

Trauma series radiographs or CT scans can assist in determining size and displacement of the lesser tuberosity fragment. Morris and associates[68] reported that plain radiographs were inadequate in determining lesser tuberosity position when compared with surgical findings and that CT evaluation improved accuracy.

Surgical Technique

A deltopectoral approach can provide access to the lesser tuberosity fragment. Open reduction and internal fixation with anatomic reduction of associated articular involvement can be performed with heavy nonabsorbable sutures. The smaller-sized lesser tuberosity fragment can be excised[56] and the subscapularis tendon repaired directly to the proximal humerus with intraosseous sutures.[9] A chronically retracted fragment may require capsular release to mobilize the fragment. When necessary, we perform this from the inner aspect of the joint in the midcapsule. This approach avoids detachment of the subscapularis.

Surgical Neck Malunion

Isolated surgical neck malunions usually involve anterior angulation and varus deformity secondary to anterior displacement of the shaft by the pectoralis major[27] and abduction of the head by the rotator cuff.[70] This deformity, if severe, can cause limitation of forward flexion and abduction with associated impingement.[19] However, in many cases varus malunion does not result in significant loss in internal rotation and external rotation.

Radiographic Evaluation

Plain radiographic views of the proximal humerus in various degrees of rotation are required to accurately assess angulation. Comparison radiographs of the contralateral shoulder can assist in estimating the degree of deformity and planning the required osteotomy. Beredjiklian et al.[7] provided an excellent description of the method of determining the magnitude of this deformity radiographically.

Surgical Indications

If the surgical neck malunion reveals an increased anterior angulation greater than 45 to 55 degrees, forward elevation will be limited.[9,48] Varus deformity of similar magnitude can cause decreased abduction and forward elevation. These indications were supported by Beredjiklian et al.,[6,7] who classified malalignment of the articular segment of more than 45 degrees with the humeral shaft in any plane as a subtype of proximal humerus malunions requiring intervention.

Surgical Technique

If clinically indicated, osteotomy and internal plate fixation are performed at the malunion site. We prefer the use of a blade plate or a locking proximal humerus plate (Synthes, Paoli, NJ). Open capsular release is usually necessary to restore satisfactory passive arcs of motion and is performed before osteotomy. Bone from the osteotomy can be used for the graft or harvested from the iliac crest. For patients with intraarticular fracture or posttraumatic arthritis/avascular necrosis, hemiarthroplasty is our preferred method of surgical management.

Results

Solonen and Vastamaki[93] described a valgus wedge derotational osteotomy with T-formed AO plate fixation through a deltopectoral approach in seven young patients with preoperative varus angulation ranging from 40 to 60 degrees. Five of the seven patients achieved normal or near-normal results with significantly improved range of motion. Their two poor results were secondary to soft tissue pathology rather than failures in fixation or union of the osteotomy.

Three- and Four-Part Malunions

Three- and four-part malunions are complex problems that can result in severe deformities and significant complications. These posttraumatic sequelae usually require prosthetic replacement. In selected three-part injuries osteotomy of the fracture fragments followed by internal fixation may be attempted if there is no humeral head avascular necrosis or joint incongruity and the bone quality is good.

In three-part malunions either the greater or lesser tuberosity is displaced along with the surgical neck. If the greater tuberosity is left intact, the head will be externally rotated and abducted secondary to the intact superior and posterior portion of the rotator cuff. The shaft will be pulled anteromedially by the pectoralis, and the lesser tuberosity will retract medially. Fractures in which the greater tuberosity is displaced will result in the articular surface being internally rotated by the pull of the subscapularis. The greater tuberosity is posterosuperiorly displaced

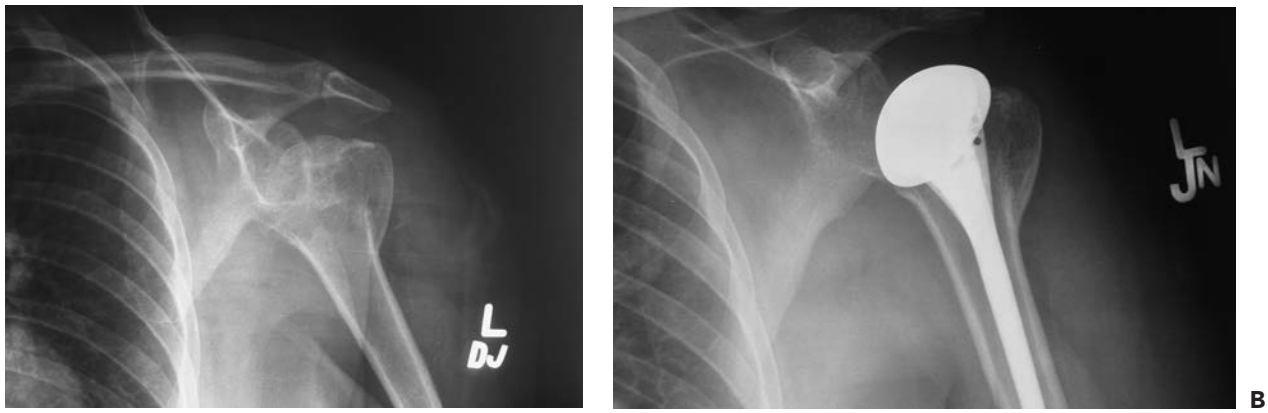

Figure 30-11 A 50-year-old female with posttraumatic arthritis and minimal displacement of the greater tuberosity treated with noncemented hemiarthroplasty without tuberosity osteotomy.

by the intact cuff, and the humeral shaft again is retracted anteromedially. Malunions of this magnitude often lead to severe loss of function, decreased range of motion, and disabling pain. An increased incidence of posttraumatic degenerative arthritis and avascular necrosis of the humeral head is also prevalent.[34]

Four-part malunions are challenging to treat as both tuberosities and the surgical neck are significantly displaced, leading to extreme humeral head distortion. These malunions are associated with significant soft tissue injuries and adhesions, joint incongruity, and an increased incidence of osteonecrosis.[34] Patients with four-part malunions typically have severe pain and disability secondary to restricted range of motion, avascular necrosis, soft tissue injuries, and contractures.

Radiographic Evaluation

Thorough preoperative radiographic studies are required in the treatment of three- and four-part malunions because tuberosity malunion is commonly present. We recommend CT scanning with three-dimensional reconstructions to determine tuberosity position, articular surface congruity, and bone integrity.

Surgical Technique

Most of these types of deformities occur in the elderly, and prosthetic replacement is usually required. The integrity of the glenoid articular surface determines whether humeral hemiarthroplasty or total shoulder arthroplasty is performed, and this determination can be made intraoperatively if preoperative radiographs are indeterminate (see Fig. 30-7).

An extensive deltopectoral approach with preservation of the deltoid origin is our preferred technique. Dissection of subacromial and intraarticular scarring are required to mobilize the rotator cuff and tuberosities, while avoiding neurovascular injury. Capsular contracture always exists, and an extensive capsular excision is required. Rotator cuff mobilization is enhanced by global excision of the capsule. The rotator cuff should be carefully inspected for tears, and these should be repaired.

Tuberosity position must be assessed before surgery and intraoperatively. One centimeter of displacement is a general guideline as the indication for surgical correction of a tuberosity fracture malunion. Greater tuberosity malunion with posterior displacement often blocks external rotation or forward elevation and results in postoperative anterior dislocation. Lesser tuberosity malunion may permit excessive posterior subluxation or block internal rotation because of coracoid impingement.

In some cases of tuberosity malposition, avoiding an osteotomy can be achieved with the use of a small stem that is shifted in the medullary canal to accommodate for tuberosity malposition, and an eccentric humeral head is also helpful to adapt the prosthesis to the malposition (Fig. 30-11). When these measures cannot restore a near-normal relationship between the tuberosities and the humeral head, a tuberosity osteotomy should be performed. Tuberosity reconstruction requires osteotomy with an oscillating saw or osteotome. Large degrees of tuberosity displacement require osteotomy before osteotomy of the humeral head segment. Small displacements can be assessed after osteotomy of the humeral head, and in some cases, tuberosity osteotomy is unnecessary (Fig. 30-12). The bicipital groove is a helpful landmark for tuberosity osteotomy. The osteotomy should produce a tuberosity fragment long enough to ensure contact with the bony humeral shaft on repositioning and large enough so that adequate rotator cuff is attached. The attached rotator cuff may need to be mobilized so as to achieve needed length as described previously.

Tuberosity fixation is achieved by using several heavy nonabsorbable sutures. Two sutures are passed through the middle portion of the tuberosity-to-tendon interface and the anterior flange of the prosthesis. Two more sutures are passed through both tuberosities, one each at the superior

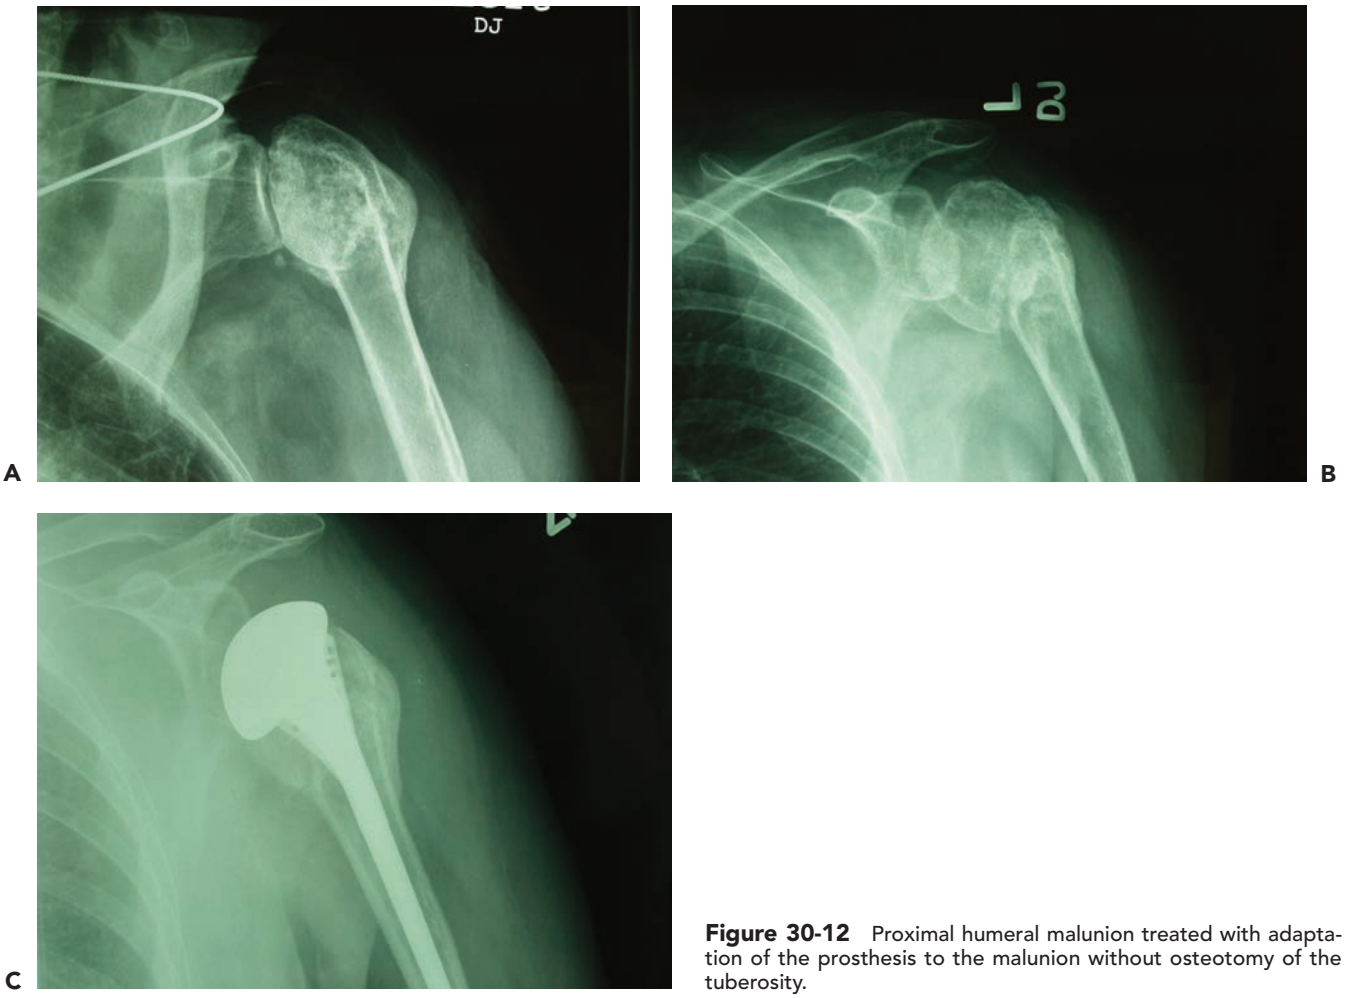

Figure 30-12 Proximal humeral malunion treated with adaptation of the prosthesis to the malunion without osteotomy of the tuberosity.

and inferior ends. Holes are drilled through the lateral and anterior aspect of the proximal humeral shaft. Two sutures are passed through these holes and, in vertical tension band figure-eight fashion, passed through the superior aspect of the tuberosities at the cuff insertion. These two sutures assist in bringing the tuberosities inferior to ensure contact of the tuberosities and the humeral shaft and placement below the top of the prosthetic humeral head. Local bone graft is usually available from the discarded head fragment and is used to increase tuberosity healing. Impingement can be avoided by making certain that the tuberosities are below the superior level of the humeral head.

A modular shoulder arthroplasty system, with a number of head component size options, allows better soft tissue tensioning. Intraoperative prosthetic changes can be made to improve glenohumeral stability and tuberosity position.[25] Humeral shaft bone quality and stability of the humeral component determine whether a cemented or noncemented humeral prosthesis is used.

Postoperative immobilization in a SCOI (Don Joy) brace with slight abduction and neutral rotation for 4 weeks helps protect the tuberosity repair and allows for balanced scarring in both the anterior and posterior aspects of the shoulder. The brace is removed several times a day for pendulum, active assisted, and passive range-of-motion exercises and activities of daily living.

Results

There is a relative paucity of literature regarding the surgical treatment of three- and four-part fracture malunions. The majority of series address the entire spectrum of posttraumatic sequelae of proximal humerus fractures in whole without focusing particular attention on malunions. This leads to a rather confusing body of literature in which comparisons between series are difficult.

In general, the results of prosthetic arthroplasty of three- and four-part malunions are inferior to those of prosthetic treatment of similar acute fractures.[102] Pain relief is usually achieved, but shoulder range of motion and strength are often limited. Patients with these malunions should be prepared for "limited-goals" outcomes following prosthetic replacement.

Tanner and Cofield[97] reported their experience in performing proximal humeral arthroplasty in 49 shoulders

with acute or chronic fractures of the proximal humerus. The chronic fracture group was composed of 27 shoulders with a mean time from initial injury to arthroplasty of 20 months. Sixteen of these 27 shoulders were documented as having malunion with incongruity of the articular surface. All of the patients in the acute fracture group and 25 of 28 shoulders in the chronic fracture group had satisfactory pain relief. Active abduction in the acute and chronic fracture group was 101 and 112 degrees, respectively. Complications were noted to be more frequent in the chronic fracture group and were related to surgical difficulty, extensive tissue scarring, and distortion of anatomy. Note was made that patients with the best function and motion had incurred less surgical insult to the cuff and tuberosity mechanism and did not require a tuberosity osteotomy. Cofield warned that late reconstruction of malunited proximal humerus fractures is "exceedingly complex" and the results in terms of motion and strength are limited; thus, these procedures should be classified as "salvage procedures."[18]

Frich and coworkers[31] found better pain relief in four-part fractures treated with arthroplasty acutely than those treated after a surgical delay, which in their series was of at least 4 months' duration. Of 11 patients in the chronic four-part fracture group treated with prosthetic replacement, only one had a good result, compared with three excellent results and six good results in the 15 patients treated with immediate replacement. There were no good or excellent results for the nine patients with chronic three-part fractures. There was a high incidence of instability for the group with delayed surgery attributed to increased difficulty in soft tissue tensioning, including rotator cuff reconstruction. The authors noted a remarkably limited range of motion in their series of chronic fractures and concluded that "treatment of chronic proximal humerus fractures to a large extent is a soft tissue problem and that the preoperative condition of the soft tissue around the shoulder determines the end result."

Dines et al.[25] reported on a series of 20 shoulder arthroplasties performed for chronic posttraumatic changes of the proximal humerus including malunion, nonunion, impression fractures, and osteonecrosis. Preoperative malunion of the tuberosities or humeral head was noted in 8 of 20 patients, and 12 patients required tuberosity osteotomy at the time of arthroplasty for malunited tuberosities. Fair, good, or excellent results were achieved in 90% of patients. Ninety and seventy-five percent of patients had pain relief at rest and with activity, respectively. Average postoperative motions were forward elevation of 111 degrees, external rotation of 30 degrees, and internal rotation to L2. However, patients requiring tuberosity osteotomy had resultant motion of 15 degrees less forward elevation and 9 degrees less external rotation than those not requiring an osteotomy. Additionally, patients having undergone a tuberosity osteotomy had less improvement in the Hospital for Special Surgery shoulder scoring system than those not requiring an osteotomy (73.6 vs. 82.3, respectively). Thus, avoidance of tuberosity osteotomy is advised whenever feasible. The authors recommended the use of a modular-designed prosthesis to facilitate soft tissue tensioning and tuberosity repair.

In a study of 39 consecutive patients with three- and four-part fractures treated with hemiarthroplasty, Bosch et al.[14] noted that the outcome of primary or secondary hemiarthroplasty was inversely proportional to the time between the injury and the prosthetic replacement. Their series included 17 patients with secondary humeral head replacements greater than 4 weeks postinjury. Limited description of the presence or types of malunions was provided. All patients had satisfactory pain relief, and the only factor found to negatively influence outcome was the length of time from injury to operation.

Seventeen of 23 shoulders with failed treatment of three- and four-part proximal humerus fractures subsequently treated with arthroplasty reviewed by Norris et al.[77] were classified as malunions. All of the shoulders initially treated nonoperatively and 54% of those initially treated surgically had malunion as a complication. Tuberosity osteotomy was required in 57% of cases, and the authors warned that tuberosity osteotomy is a "formidable procedure" with technical difficulty and potential for complications. Pain was satisfactorily relieved in 95% of patients, average forward elevation increased from 68 to 92 degrees, and average external rotation increased from 6 to 27 degrees postoperatively. They concluded that late glenohumeral arthroplasty, albeit technically difficult, is a satisfactory reconstructive procedure when primary treatment of complex proximal humerus fractures is unsuccessful. It was also noted by these authors that results are inferior to those for acute humeral head replacement.

Beredjiklian et al.[6,7] retrospectively reviewed their experience in treating 39 patients with proximal humerus malunions categorized by the presence of osseous and soft tissue abnormalities as previously described. Overall, the result was satisfactory for 69% and unsatisfactory for 31% of patients at an average of 44 months postoperatively. It is notable that 96% of patients with a satisfactory result had operative correction of all osseous and soft tissue abnormalities, whereas 66% of patients with an unsatisfactory result had incomplete operative correction of these abnormalities. Thus, they concluded that operative management of these patients is successful only if all osseous and soft tissue abnormalities are corrected at the time of surgery. Additionally 74% of patients with malunions and joint incongruity treated with prosthetic arthroplasty had a satisfactory result. The rate of complications in their study approached 30% and attests to the technical difficulty in treating proximal humerus malunions.

Sixteen of the 71 shoulders treated with arthroplasty for the posttraumatic sequelae of proximal humerus fractures in Boileau and colleagues'[13] series were characterized as

having severe malunions of the tuberosities. Overall, the results of arthroplasty for this heterogeneous group, including cephalic collapse, locked dislocations, surgical neck nonunions, or severe tuberosity malunions, were encouraging with a significant reduction in pain and improvement in anterior elevation (74 to 102 degrees) and external rotation (0 to 34 degrees). However, the isolated results for those patients requiring tuberosity osteotomy for prosthesis implantation (16 patients with severe malunions of the tuberosity and six patients with surgical neck nonunions) were less favorable. All of the patients in this group had either fair or poor results and did not regain active elevation above 90 degrees (mean active elevation of 82 degrees vs. mean of 123 degrees in patients not requiring osteotomy). The authors concluded that greater tuberosity osteotomy is the most likely reason for poor and unpredictable results after shoulder arthroplasty for the sequelae of proximal humerus fractures and recommended avoiding an osteotomy whenever possible, even if that entails accepting distorted proximal humerus anatomy. Complications occurred in 27% of the cases in this series.

Antuna et al.[5] evaluated the long-term outcome of 50 patients who underwent shoulder arthroplasty as treatment for proximal humeral malunions with a mean of a 9-year follow-up. Shoulder arthroplasty resulted in statistically significant pain relief with significant improvements in postoperative motion: Active elevation improved from 65 to 102 degrees and external rotation improved from 12 to 32 degrees on average. Despite these promising results, 50% of patients in the series had an unsatisfactory result as determined by the Neer result rating with a 20% overall complication rate. Of note, there was statistically significant less postoperative motion in those patients who had undergone previous operative treatment of their initial fracture or who required a tuberosity osteotomy at the time of arthroplasty. Ten of the 24 shoulders that required tuberosity osteotomy had complications including tuberosity nonunion (four), tuberosity malunion (three), and tuberosity resorption (three). These results further attest to the technical difficulty in treating this complex group of patients.

Mansat and colleagues[66] evaluated the efficacy of shoulder arthroplasty for the late sequelae of proximal humerus fractures. Eight of the 28 patients in their series had proximal humerus malunions. Three of these cases required osteotomy of the tuberosities during prosthetic replacement despite the use of a modular prosthesis, and all three of these patients had unsatisfactory results as determined by Constant criteria. The authors noted that patients with malunion or nonunion had the least favorable results when compared to those with simple posttraumatic arthritis or avascular necrosis.

In the case series reported to date, prosthetic reconstruction utilized a standard unconstrained humeral component. The use of the reverse total shoulder should be considered in patients when a tuberosity osteotomy is required, particularly in the older patient. The results of the reverse shoulder have not been published for treatment of severe malunions requiring tuberosity osteotomy, but one would expect better functional results than those reported with unconstrained hemiarthroplasty or total shoulder replacement (Fig. 30-13).

There is also a role for the use of a resurfacing humeral hemiarthroplasty that does not require the use of an intramedullary stem for fixation of the prosthetic. With humeral surface replacement the volume of remaining humeral head after reaming should allow for at least 70% contact with the undersurface of the prosthetic and the bone quality should be sufficient to prevent bone indentation with firm digital pressure after reaming. In addition, the tuberosity should not be malunited or require osteotomy. If these surgical criteria are satisfied, then use of a resurfacing humeral component may allow for greater adaptation of the prosthetic to the proximal anatomy, thereby avoiding osteotomy of the tuberosity, surgical neck, or humeral shaft (Fig. 30-14).

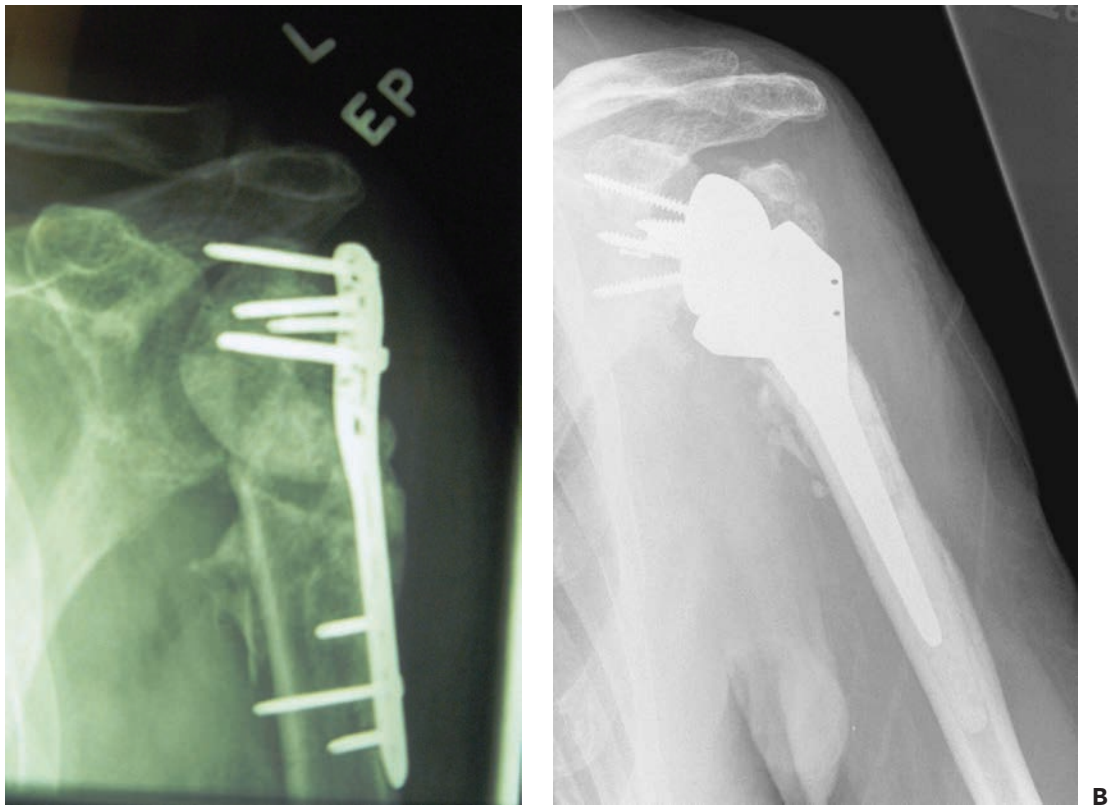
Glenohumeral Surgical Fusion

Glenohumeral fusion of a proximal humerus malunion is indicated only in selected cases. A fusion may be required in the individual with concomitant rotator cuff and deltoid dysfunction.[79] A shoulder infection that cannot be eradicated with hardware removal, irrigation with débridement, and intravenous antibiotics may ultimately require fusion.[38]

Conclusion

Fortunately, proximal humerus malunions are relatively uncommon injuries. However, when present they are painful and severely debilitating with little response to conservative, nonsurgical measures. As evidenced by the significant rate of complications experienced even in the clinical series of accomplished, respected shoulder specialists, these posttraumatic sequelae are among the most challenging and technically difficult disorders that a shoulder surgeon will face. Certainly, the best treatment for any proximal humerus malunion is prevention by adequate treatment of acute fractures. Several authors, citing the increase in complications and worse functional outcomes following late arthroplasty for proximal humerus malunions, warn against making the mistake of assuming that failed primary treatment can simply be corrected with late prosthetic arthroplasty.[14,31,77,79,91,97] Thus, they advocate prompt and proper acute treatment of proximal humerus fractures to avoid the later challenge of treating a malunion.

When faced with a proximal humerus malunion, it is critical to obtain an accurate history and perform a thorough physical examination. Workup should include adequate plain radiographs supplemented with CT scans, three-dimensional CT reconstructions, and MRI scans when uncertainty remains following review of plain films. The ultimate goal of every preoperative evaluation should be



A B

Figure 30-13 The results of the reverse shoulder have not been published for treatment of severe malunions requiring tuberosity osteotomy, but one would expect better functional results than those reported with unconstrained hemiarthroplasty or total shoulder replacement.

maximal understanding of all involved pathology including osseous and soft tissue deformities so that an appropriate surgical plan can be formulated with the aim of treating all components of the posttraumatic pathology. The results for surgical correction of isolated tuberosity malunions are promising and favorable outcomes can be expected. Although results of prosthetic arthroplasty for complex proximal humerus malunions are inferior to acute arthroplasty, results in the literature evidence good potential for pain relief and some improvement in function with the likelihood for limited-goals function. It is essential to counsel patients preoperatively so as to equate postoperative expectations with that which has been evidenced to be attainable.

When it comes to the surgical treatment of proximal humerus malunions, we recommend an approach that addresses all osseous and soft tissue abnormalities present in each posttraumatic shoulder. The treatment algorithm recommended by Beredjiklian and colleagues[6,7] provides a comprehensive, systematic method of evaluating and treating these complex cases in such a manner (Fig. 30-15). It is obvious from the literature that the necessity for a greater tuberosity osteotomy automatically increases the likelihood for complications and decreases the likelihood for favorable, predictable outcomes. Therefore, we recommend avoidance of tuberosity osteotomy during arthroplasty by utilizing a modular prosthetic system and approximating the tuberosity–to–humeral head relationship. Thus, tuberosity osteotomy is avoided unless absolutely necessary for prosthetic implantation. When all osseous and soft tissue abnormalities are addressed surgically with appropriate technique and carefully monitored postoperative rehabilitation, the outcome is satisfactory in most cases. The use of the reverse total shoulder prosthesis in the older patient with severe malunion requiring prosthetic replacement and tuberosity osteotomy may provide better function than that seen with unconstrained arthroplasty.

NONUNIONS

Fractures of the proximal humerus are nondisplaced in the vast majority of cases and typically heal uneventfully with closed treatment. Unfortunately, a small percentage of these fractures, treated nonoperatively or operatively, develop nonunions. Patients that develop this complication are often debilitated with persistent pain and limited function. The technical challenges of previous scarring, poor bone stock, and prior hardware can make these cases extremely challenging, but successful treatment of proximal humerus nonunions resulting in relief of pain and restoration of function can be extremely rewarding.

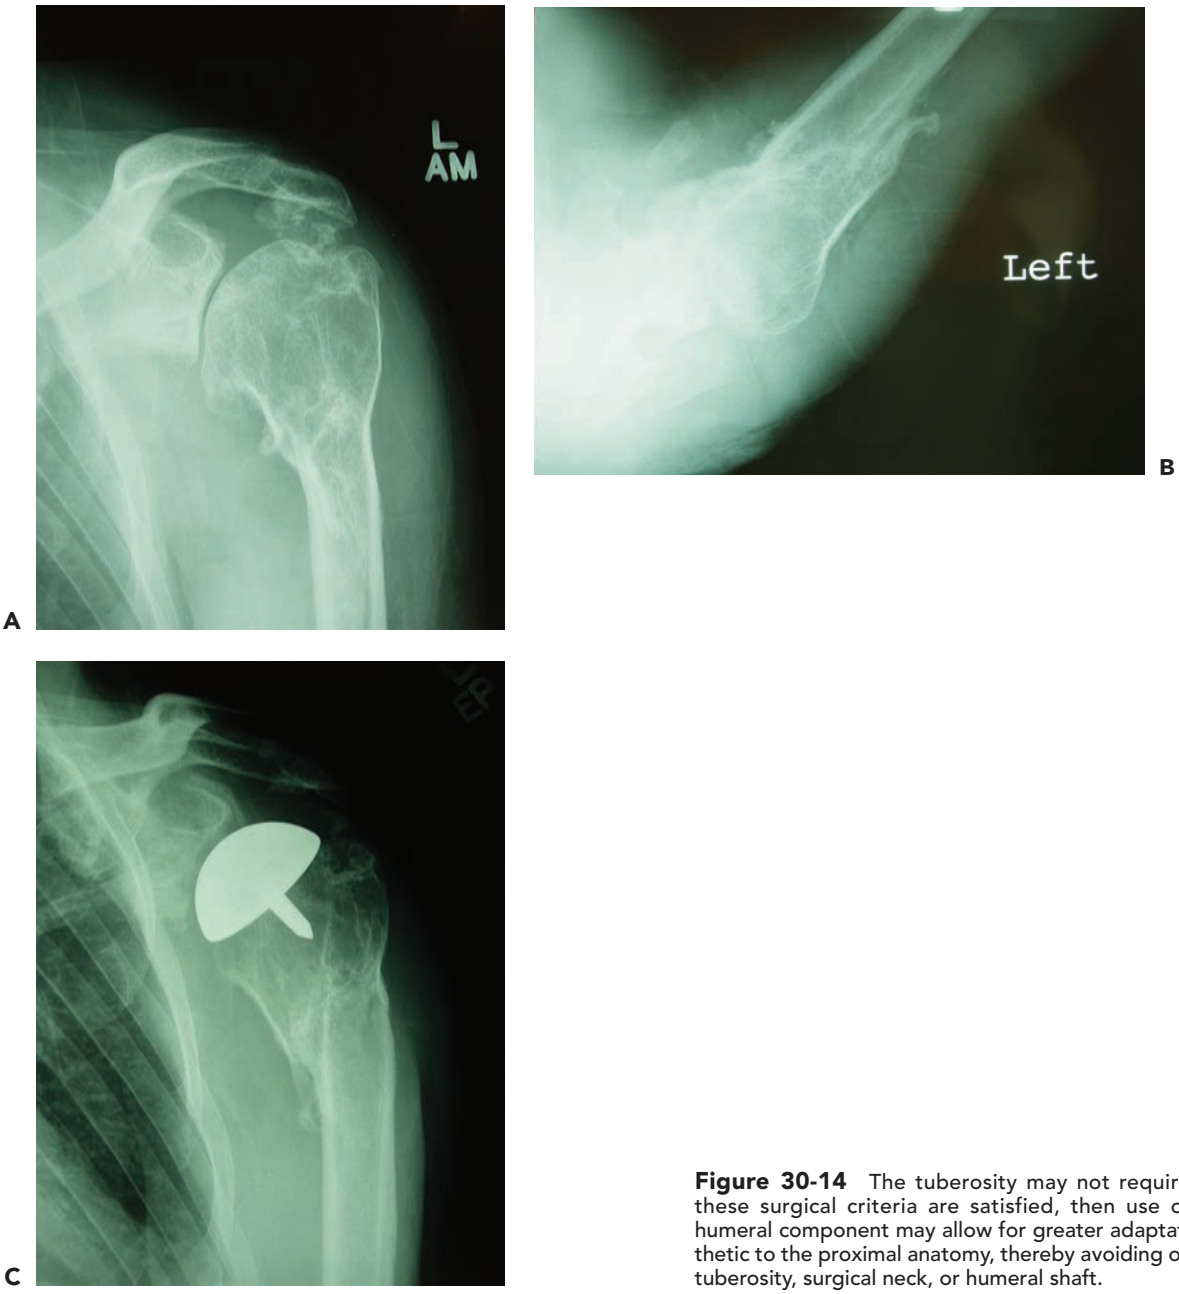


Figure 30-14 The tuberosity may not require osteotomy. If these surgical criteria are satisfied, then use of a resurfacing humeral component may allow for greater adaptation of the prosthetic to the proximal anatomy, thereby avoiding osteotomy of the tuberosity, surgical neck, or humeral shaft.

Etiology

The paucity of literature reporting the incidence of proximal humerus fracture nonunions suggests that they are a rare phenomenon. However, nonunions may be commonly seen after displaced two-part surgical neck fractures or after cases in which inadequate open reduction and internal fixation was used as the primary treatment.[19,103] In fact, up to 23% of surgical neck fractures may go on to nonunion.[72] Other fracture patterns that have a higher incidence of nonunion include those with displaced tuberosities, which are treated closed, and four-part fractures, which are treated either closed or open. Factors contributing to the development of nonunions may be attributed to either patient factors, fracture site factors, sequelae of inappropriate primary fracture treatment, or any combination thereof.

Patient factors that predispose to proximal humerus fracture nonunion include osteoporosis, metabolic bone disease, diabetes, drug or alcohol addiction, nutritional deficiency, smoking, and general noncompliance.[87,100] Each of these comorbidities can significantly impact the healing potential at the initial fracture site, the rate of complications following operative treatment, and the ability of the patient to comply with a postoperative rehabilitation protocol. These factors may have been overlooked or underestimated in the initial decision-making process contributing

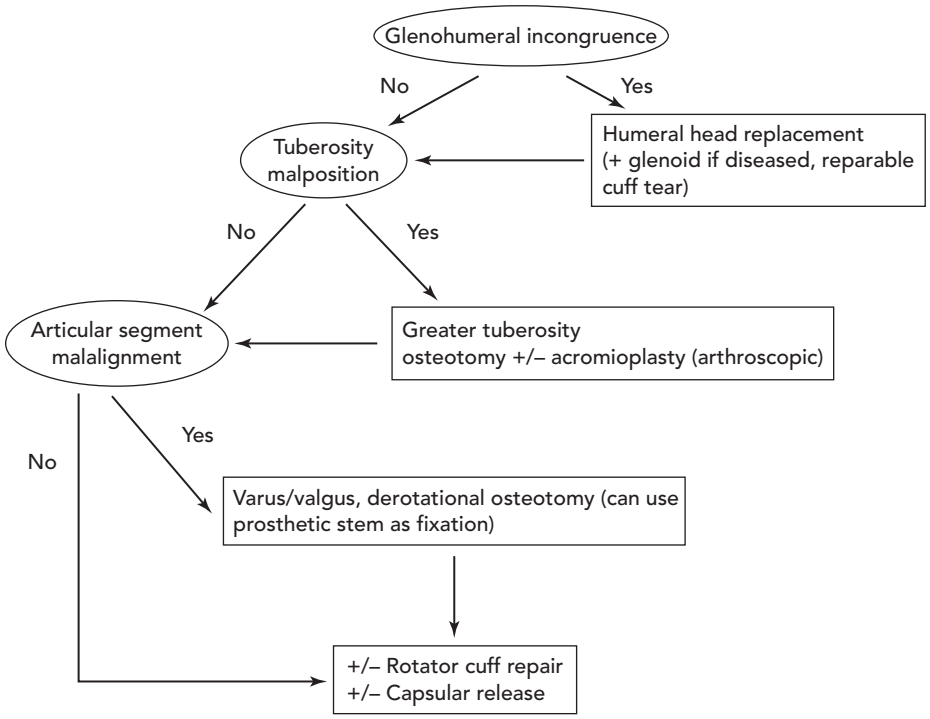

Figure 30-15 Algorithm for the categorization and operative treatment of malunions of the proximal aspect of the humerus. (Modified form Beredjiklian P, Iannotti JP, Norris TR, et al. Operative treatment of malunion of a fracture of the proximal aspect of the humerus. *J Bone Joint Surg Am* 1998;80:1484.)

to the development of the complication. Healy et al.[41] documented in their series of 25 patients with proximal humerus nonunions that the most common associated factor was the presence of one or more significant medical comorbidities in 64% of cases. The results of treatment in this group were unsatisfactory overall, with only four patients having good results. Thus, it is imperative to evaluate patients for these and other coexistent medical comorbidities prior to surgical intervention for treatment of an established nonunion. Glenohumeral joint stiffness, prior to the fracture, has also been identified as a predisposing patient factor to the development of surgical neck nonunions. One small series identified four patients that developed pseudarthroses secondary to preexisting glenohumeral stiffness, either from rheumatoid arthritis or prior glenohumeral fusion.[86] In this situation, humeral motion occurs in the fracture site rather than the glenohumeral joint, leading to nonunion.

Fracture site factors also contribute to the development of nonunions. Soft tissue interposition between the proximal and distal fracture fragments can prevent adequate contact of opposing bone surfaces, impeding callous formation and fracture reduction. The long head of the biceps tendon, the deltoid muscle, or the rotator cuff tendons are potential impediments.[32,69] Additionally, the dense cortical bone in the distal fragment of a surgical neck fracture and the generalized decreased quality of metaphyseal bone in the proximal humerus seen in this elderly population predispose to poor bone healing. Surgical neck fractures are also subject to the deforming forces of surrounding musculotendinous units: The pectoralis major pulls the proximal shaft anteromedially and the rotator cuff tendons rotate and abduct the proximal head or tuberosity fragments. These forces can prevent adequate reduction of the fracture segments and contribute to nonunion. Lastly, synovial fluid from the adjacent joint can dilute the fracture hematoma and inhibit callous formation.

Finally, proximal humerus nonunion can result as the iatrogenic sequela of inadequate primary fracture treatment. Closed treatment can be problematic as the weight of the arm causes distraction across the fracture site, which can be accentuated with the use of a hanging arm cast. Nine of 16 patients with established nonunions in Neer's[71,72] series followed closed treatment, and distraction was implicated as the major cause in each of these cases. Attention to detail is necessary when treating these fractures with immobilization; the arm must be immobilized across the front of the body to neutralize the medial pull of the pectoralis, and the elbow must be kept in front of the midline in the coronal plane to prevent apex anterior angulation and loss of reduction.[32] Inadequate operative treatment can also contribute to nonunion, especially if severe osteopenia is overlooked at the time of initial intervention. Epidemiologic studies have linked proximal humerus fractures with fractures of the distal radius and proximal femur, especially in elderly women.[29,45] This factor should not be overlooked as plate and screw fixation can be problematic in osteopenic bone, leading to inadequate fixation, hardware loosening, fracture site motion, and nonunion. Lastly, premature institution of range-of-motion exercises following closed or open treatment contributes to nonunion. It is imperative that the fracture parts have consolidated and move as a unit prior to the initiation of shoulder motion.

Clinical Evaluation

The degree of pain and functional loss must be carefully assessed with a thorough history and physical examination. Patients typically have little ability to perform basic tasks or activities of daily living due to a flail arm—loss of deltoid and rotator cuff ability to move the arm in space. Pain is variable, but most patients complain of at least moderate rest pain and significant pain with daily activities.[83] Severe pain with more strenuous activities is not uncommon. In rare cases, pain may be minimal and function adequate for a low-demand, sedentary lifestyle justifying benign neglect; this is especially true in the face of significant associated comorbidities and confounding factors.

In cases in which prior operative treatment was attempted, complete review of all records and operative reports is essential, and the potential of an infected nonunion following operative intervention must always be included in one's thought process. This concern warrants further evaluation with a complete blood count, acute phase reactants, aspiration, and culture to screen for sepsis.[25]

Physical examination is often striking in that most shoulder motion occurs at the fracture site rather than the glenohumeral joint.[11,72,78] This may be misinterpreted as falsely adequate passive range of motion, but the patient typically has minimal to no active range of motion of the shoulder (0 to 45 degrees of forward elevation). Severe atrophy of the deltoid, spinati, and periscapular musculature is common, and motor function can be difficult to assess because of the pain, weakness, and mechanical disability of the nonunion. Regardless, it is essential to examine for at least modest firing of the deltoid and rotator cuff musculature to rule out preexisting neurologic dysfunction from the initial injury and/or deltoid dehiscence from any previous surgical intervention. A thorough neurologic examination including motor and sensory function should be performed. If uncertainty exists, an EMG should be obtained to differentiate pain and weakness from neurologic injury. The skin and soft tissues should be examined for integrity as bony prominences from the underlying nonunion can result in overlying skin compromise. Drainage from prior incisions is an ominous herald of an infected nonunion.

Evaluation of the patient's medical comorbidities is also essential. Confounding variables such as severe osteopenia, nutritional deficiency, metabolic bone disease, and medical illnesses with the potential to adversely affect healing must be recognized and investigated. Blood chemistry can provide screening information to assess metabolic bone state, liver function, kidney function, and glucose and fat metabolism. If a medical condition is discovered that affects bone healing, referral to an internist or endocrinologist is warranted.

Radiographic Evaluation

An adequate radiographic evaluation is required and includes an anteroposterior view in the plane of the scapula, an axillary lateral view, and a transscapular lateral view.[89] Radiographs should be critically evaluated for presence of a nonunion, avascular necrosis of the humeral head, posttraumatic arthritis of the glenohumeral joint, and displacement of the tuberosities. A surgical neck nonunion, either hypertrophic or atrophic, is typically obvious; however, additional radiographic views such as the apical oblique view, which demonstrates posterolateral humeral head compression fractures, and the transscapular lateral view, which may be helpful in the evaluation of superiorly displaced greater tuberosity malunion or nonunion, can be obtained. If suspicion of intraarticular extension exists as occurs with a head-splitting fracture, a CT scan can be valuable in delineating this pattern. In addition, a CT scan will clearly define the position of the tuberosities.[68] A significant amount of bone loss at the nonunion site may contribute to shortening of the humerus with associated shortening and dysfunction of the deltoid. A scanogram or plain radiograph of the opposite humerus can be obtained to determine the loss of height that needs to be addressed in the operative treatment.[80]

Classification of Proximal Humerus Nonunions

The classification of proximal humerus nonunions follows Neer's system of classifying acute proximal humerus fractures.[70] This classification is based on a four-part system involving the humeral head, the lesser and greater tuberosities, and the shaft as the four parts. Acutely, when any one of the four major segments are separated more than 1 cm or angulated greater than 45 degrees with respect to another part, the fracture is considered displaced. Unimpacted two-part fractures of the surgical neck are generally associated with a higher incidence of nonunion than other fracture types.[72] Nevertheless, tuberosity nonunions and complex three- and four-part nonunions do occur.

Specific Fracture Nonunions

Tuberosity Nonunion

Plain radiographs in three orthogonal views typically define a tuberosity nonunion. However, CT scanning can be helpful in accurately defining the location and size of united tuberosities.[68] Nonunions of the tuberosities impose significant functional deficits on shoulder function, making the presence of any united tuberosity an indication for surgery. There is typically no role for nonoperative treatment of these nonunions unless the patient has medical contraindications to surgery. Greater tuberosity nonunions function similar to a massive rotator cuff tear, rendering a large portion of the rotator cuff incompetent and leading to significant weakness in external rotation and forward elevation.[21] Associated impingement by a superiorly retracted greater tuberosity can further contribute to pain, rotator cuff

pathology, and disability.[21] Likewise, lesser tuberosity nonunions render incompetence of the subscapularis, a major anterior stabilizer of the shoulder. These patients have weakness in internal rotation as evidenced by the Gerber lift-off test[36] and can have anterior instability. Additionally, a medially displaced lesser tuberosity can cause painful coracoid impingement with limited internal rotation.

Surgical Technique

The surgical technique for repair of a greater tuberosity nonunion is similar to that described in the preceding section on malunions. Repair can be performed through a superolateral incision centered on the anterolateral corner of the acromion for small fragments. As described, the united fragment is débrided of fibrous tissue and scar down to viable bone. Extensive circumferential rotator cuff release is often required to enable reduction of the fragment back into its anatomic bed lateral to the bicipital groove.[21] Concomitant rotator cuff tears should be addressed prior to reduction of the tuberosity fragment. After débridement and preparation of the donor bed, the fragment is secured with two to four heavy, nonabsorbable sutures (#5 Ticron or #2 Fiberwire, Arthrex, Naples, FL) as described. Alternatively, internal fixation of the greater tuberosity with screws and washers could be used in normal bone if the tuberosity fragment is large. When using screw fixation, suture fixation should be used as a supplemental means of fixation to avoid loss of fixation due to fracture of the tuberosity proximal to the screw fixation.

A deltopectoral approach can provide access to the lesser tuberosity fragment. Open reduction and internal fixation with anatomic reduction of associated articular involvement can be performed with heavy nonabsorbable sutures. The smaller-sized lesser tuberosity fragment can be excised[56] and the subscapularis tendon repaired directly to the proximal humerus with intraosseous sutures.[9] A chronically retracted fragment may require capsular release to mobilize the fragment. When necessary, we perform this from the inner aspect of the joint in the midcapsule. This approach avoids detachment of the subscapularis. Our postoperative rehabilitation protocol does not differ from that utilized after the reconstruction of tuberosity malunions.

Surgical Neck Nonunion

Nonunions of the proximal humerus most commonly occur at the surgical neck.[18,19,41,72,80] Patients typically present with pain, disability, and palpable crepitus at the nonunion site. Minimal active motion is present as the rotator cuff attached to the proximal segment has no distal attachment to the upper extremity. The nonunion is usually quite obvious on plain radiographs, although occasionally a CT scan is necessary in differentiating a fibrous union from a nonunion. Osteopenia of the proximal segment and bone loss at the nonunion site are commonly identifiable on plain films. Occasionally, osteopenia and humeral head cavitation, accelerated by the accumulation of joint fluid at the nonunion site, preclude proximal fixation.[72]

The only role for nonoperative treatment is in the medically debilitated patient that would not tolerate surgical intervention or in the patient with medical or social comorbidities that would preclude postoperative compliance. Thus, surgical indications are debilitating pain and loss of function in a cooperative, motivated, and reliable patient. Surgical intervention in these cases can be extremely challenging secondary to extensive capsular contracture, scarring from prior surgical intervention, metadiaphyseal bone loss, distorted anatomy, and osteopenia of the humeral head.[32] Therefore, it is imperative that the patient is counseled preoperatively to enable realistic understanding of these challenges and their relevance to postoperative complications, rehabilitation, and expectations.

Numerous techniques have been described for treating surgical neck nonunions.[4,11,13,20,25,26,32,33,41,47,58,69,77,80,85,87,94] These techniques can be classified into four main groups: intramedullary nails, intramedullary nails with tension bands, open reduction and plate fixation, and arthroplasty. Choice of surgical technique is largely based on the condition of the proximal fragment at the time of intervention. Absolute requirements for any method of open reduction include a viable humeral head with maintained articular surface and adequate bone stock to enable fixation. The presence of avascular necrosis of the humeral head, advanced posttraumatic arthritis, or an osteopenic, cavitary humeral head necessitates hemiarthroplasty.

Surgical Techniques

Intramedullary Nails with and without Tension Bands.

Open reduction and internal fixation with intramedullary nails can occasionally be successfully utilized in surgical neck nonunions (Fig. 30-16). An extended deltopectoral approach is used, avoiding excessive soft tissue detachment from the nonunion fragments. The fibrous tissue and pseudarthroses at the nonunion site is removed, along with any preexisting hardware. The bone ends are decorticated. The nonunion fragments are aligned using the bicipital groove as a reference for proper version. Care is taken not to remove excessive bone to maintain deltoid length. If one fragment has a spike, this may be impaled into the other nonunion fragment, thereby improving fixation and fracture stability. If the humeral shaft can be narrowed and reduced within the cancellous portion of the humeral head, this is done to improve the stability and to increase bone contact (Fig. 30-17).

When Ender intramedullary rods are used, they should be modified by placing a superior hole to the already existing large proximal hole. This preoperative rod modification permits more inferior seating of the rod into the rotator cuff, diminishing the incidence of postoperative subacromial impingement due to hardware. One Ender rod is placed in the greater tuberosity, and one is placed in

Figure 30-16 Intramedullary locking rod to treat a surgical neck nonunion after failed locked plating.

the lesser tuberosity; both are then placed into the distal intramedullary canal of the humeral shaft.

A hole is then drilled in the humeral shaft approximately 2 cm below the nonunion site, and 18-guage wire or 1-mm nonabsorbable suture is passed through the hole in the superior hole of the Enders rods. A figure-eight tension band technique is used. An additional wire or suture may be used at right angles to the first. We do not use tension band wiring alone, preferring the additional longitudinal and torsional stability afforded by the intramedullary fixation.[50]

Depending on the nonunion type (i.e., atrophic, oligotrophic, or hypertrophic), bone quality, and apposition at the nonunion site, bone grafting may be required.[42] We prefer to use cancellous iliac crest autograft packed at the nonunion site. Corticocancellous strips can be used if needed to restore humeral length.[87] We have not used allograft bone for treatment of the atrophic nonunion and prefer autogenous bone when available.

A sling is placed at the time of surgery. The postoperative physical therapy protocol depends on the quality of internal fixation and stability at the nonunion site noticed at surgery. If the surgeon is confident with the surgical repair, passive and active assisted motion of the shoulder can be effected immediately. Careful radiographic evaluation of healing determines when active motion can commence and when the sling is discontinued. As with any shoulder surgery, passive and active range of motion of the elbow, wrist, and hand are started immediately postoperatively.

Results. Neer applied the combination of an intramedullary nail, tension band construct, iliac bone graft, and abbreviated spica cast application successfully in 12 of 13 cases of surgical neck nonunion.[72] He noted that subsequent hardware removal secondary to symptomatic subacromial impingement and release of adhesions was routinely needed for pain-free, functional motion.

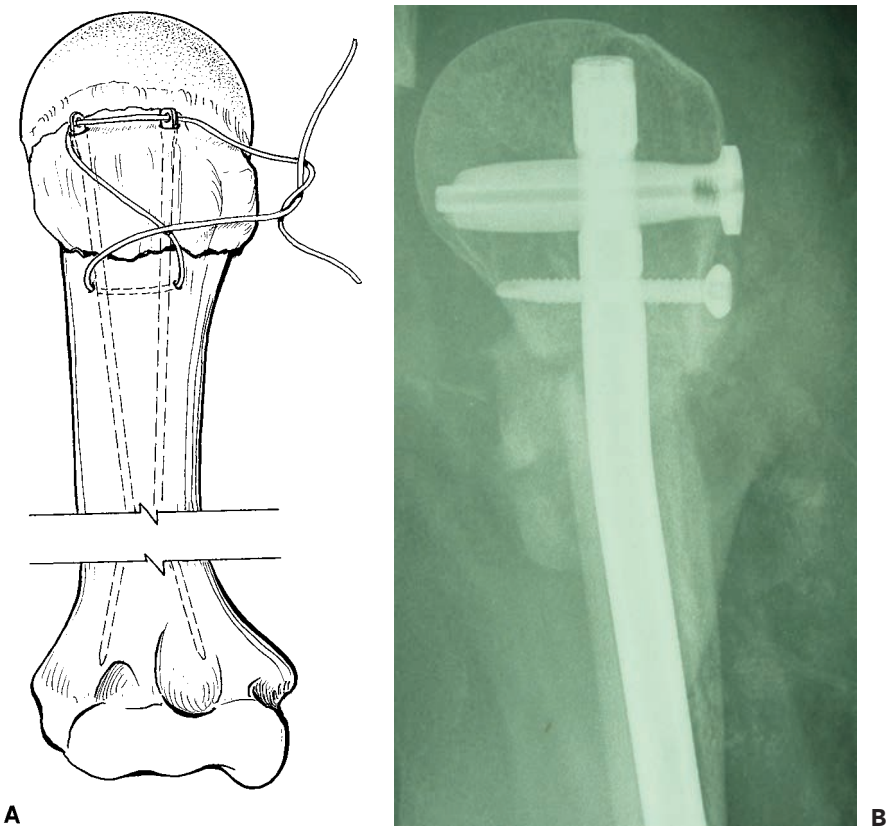
Another series reported on five patients treated with unreamed nails ± a tension band construct.[41] The only patient that evidenced healing at the nonunion was treated with a Rush rod and tension band. All five patients had impingement symptoms secondary to hardware leading to unsatisfactory results.

Nayak et al. reported on successful clinical union in all 10 patients treated with Rush rods, tension banding, and iliac bone grafting.[69] However, two patients evidenced persistent radiographic evidence of nonunion despite good clinical function. Additionally, 80% required reoperation for hardware removal secondary to painful subacromial impingement. The intramedullary rods were not incorporated into the tension band wiring, which may be a critical factor in this failure. Circumflex humeral artery laceration, axillary nerve injury with permanent sequelae, and one cortical perforation with Rush rod insertion were reported complications in this small series.

Norris et al. reported good results using intramedullary rods with a tension band construct.[80] These patients regained excellent motion, and the group did not evidence inferior results to those patients who underwent hemiarthroplasty. The success in this series is likely attributable to the incorporation of the tension band through the proximal holes in the Enders rods, which improves rotational stability and may prevent rod backout into the subacromial space.

These series confirm that intramedullary nails can be successfully utilized in the treatment of surgical neck nonunions, especially when a tension band is incorporated into the construct. However, the high incidence of subacromial mechanical impingement necessitating hardware removal makes this option unfavorable, especially in elderly patients with multiple anesthetic risks. The technical caveat of incorporating the tension band construct through proximal holes in the Enders rods is essential as it provides improved stability and rotational control and may limit backout of the intramedullary device.

Open Reduction and Internal Fixation with Plates. If good-quality bone stock is present and the humeral head fragment is large enough, plate and screw fixation is the procedure of choice. Internal fixation can be performed utilizing



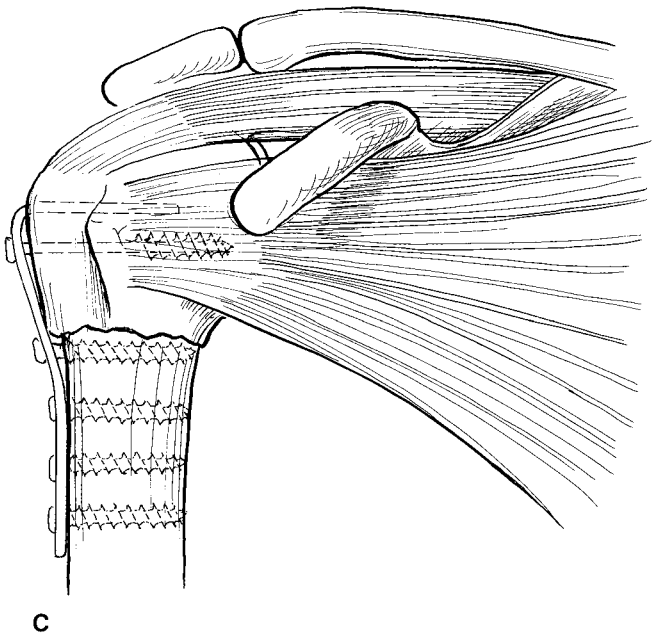


Figure 30-17 **(A-C)** If the humeral shaft can be narrowed and reduced within the cancellous portion of the humeral head, this is done to improve the stability and to increase bone contact. (Reproduced with permission from Warner JJP, Iannotti JP, Gerber C, eds. *Complex and revision problems in shoulder surgery,* 1st ed. Philadelphia: Lippincott-Raven, 1997.)

a variety of plates (T-plates, blade plates, or periarticular locking plates) (Fig. 30-18). The exposure required for plate fixation is greater than that needed for intramedullary rod and tension band fixation, and care must be taken to avoid further devitalization of the nonunion by excessive soft tissue stripping in applying this larger hardware. Humeral head avascular necrosis has been reported with the use of plate fixation of proximal humeral fractures and nonunions, and perhaps the associated increased surgical exposure contributed to this occurrence.[51,99]

The technique for ORIF with plates is performed with the patient in the 30-degree beach-chair position using a standard deltopectoral approach. As the subdeltoid space is dissected, the deltoid muscle is retracted laterally, and the pectoralis major and conjoined tendon are retracted medially. Care should be taken to protect the axillary and musculocutaneous nerves during exposure of this scarred surgical field with potentially distorted anatomy. If preoperative arthrofibrosis exists, arthrolysis of the glenohumeral joint is performed. Arthrolysis of a stiff joint will aid in postoperative rehabilitation and will limit force transmission to the nonunion site.[41] The nonunion site is identified and débrided of all interposing soft tissue, pseudocapsule, and fibrous tissue exposing raw bone ends. If the proximal fragment is small and difficult to control, a 2.5-mm Kirschner wire or the guidewire from a Synthes blade plate set can be useful as a joystick while reducing the nonunion and applying hardware. The wire is drilled into the proximal fragment lateral and posterior to the bicipital groove. Bone contact between the proximal and distal fragments is restored by impaling the diaphyseal fragment into the head of the proximal humerus. Minimal shaping of the distal fragment may facilitate this maneuver. The nonunion site is typically autografted with corticocancellous strips of iliac crest bone graft. As the long head of the biceps tendon is often interposed in the nonunion site, we tenodese the tendon in the area of the intertubercular groove if there is evidence of fraying and tenosynovitis so as to remove it as a source of postoperative pain.

The plate is then applied to the proximal humerus. If a blade plate is used, the guidewire is drilled from the lateral position across the humeral head into subchondral bone. A depth gauge is utilized to determine the appropriate length of the blade and the side plate is contoured to fit the impacted diaphyseal fragment. The rotator interval is incised so that the surgeon has increased exposure and to ensure that the blade of the plate does not violate the articular surface. Screws are placed using standard technique. Several techniques can be added to help prevent failure of the blade in the proximal fragment. As described, impaction of the bone fragments can add stability. Additionally, a cerclage wire or cable can be placed around the proximal shaft and plate to prevent screw pullout. Lastly, a tension band construct can be added by passing 1-mm tapes through the subscapularis and supraspinatus tendons and the proximal plate laterally.

To avoid impingement, care must be taken to avoid placing the plate too proximally. Internal fixation with the humeral head in varus or in excessive internal rotation is another pitfall to avoid with this technique.[99] Alternatively, a locking periarticular proximal humerus plate can be utilized (Synthes, Paoli, NJ).

Postoperative physical therapy follows the same guidelines as described for the intramedullary technique. The protocol may be somewhat accelerated because of the improved bone quality in these usually younger patients.

Results. Vastamaki[99] reported union in all 12 surgical neck nonunions that were internally fixed with an AO T-plate. Nine patients had relief of pain and some improvement in shoulder range of motion and strength. Three patients developed humeral head avascular necrosis.

Healy and coworkers[42] recommended adding a nonabsorbable suture weave through the rotator cuff, and then tying the suture to the T-plate. They felt that this construct reduces the rotator cuff distraction force that pulls the humeral head away from the proximal screw. Sonnabend[94] modified an AO semitubular plate into a blade plate and created two sharp spikes at the proximal end. Combining this technique with bone graft, he achieved union in five of six surgical neck nonunions. He thought there would be a decreased incidence of cutting-out with this construct compared with that of proximal screws. A more inferior position of the plate on the humeral head may be possible with a blade plate than with a T-plate, perhaps reducing the incidence of impingement. Instrum and colleagues,[46] in a cadaveric biomechanical study, revealed comparable fixation strength of these two modes of plate fixation. Palmer and colleagues[81] described the use of a modified 3.5-mm AO dynamic compression plate (DCP) plate with an interlocking screw technique in which screws were placed from the distal plate across the nonunion site and into the proximal fragment through a hole in the intraosseous portion of the 90-degree blade plate. They argued that this technique increases pull-out strength and reduces toggle at the nonunion site.

Galatz et al. recently reported excellent results in 11 of 13 patients treated with open reduction and internal fixation with blade plates or T-plates and bone graft.[32] These elderly patients had significant improvements in pain, motion (24 to 144 degrees of forward elevation), and function. They concluded that open reduction and internal fixation with autogenous bone graft results in excellent outcomes even in patients older than 65 years with significant medical problems.

Humeral Head Hemiarthroplasty Method. Humeral head prosthetic replacement can be necessary in the management of surgical neck nonunions, especially in cases in which internal fixation is precluded because of poor bone quality, small humeral head fragment size, comminution-associated articular surface defects, or head collapse caused

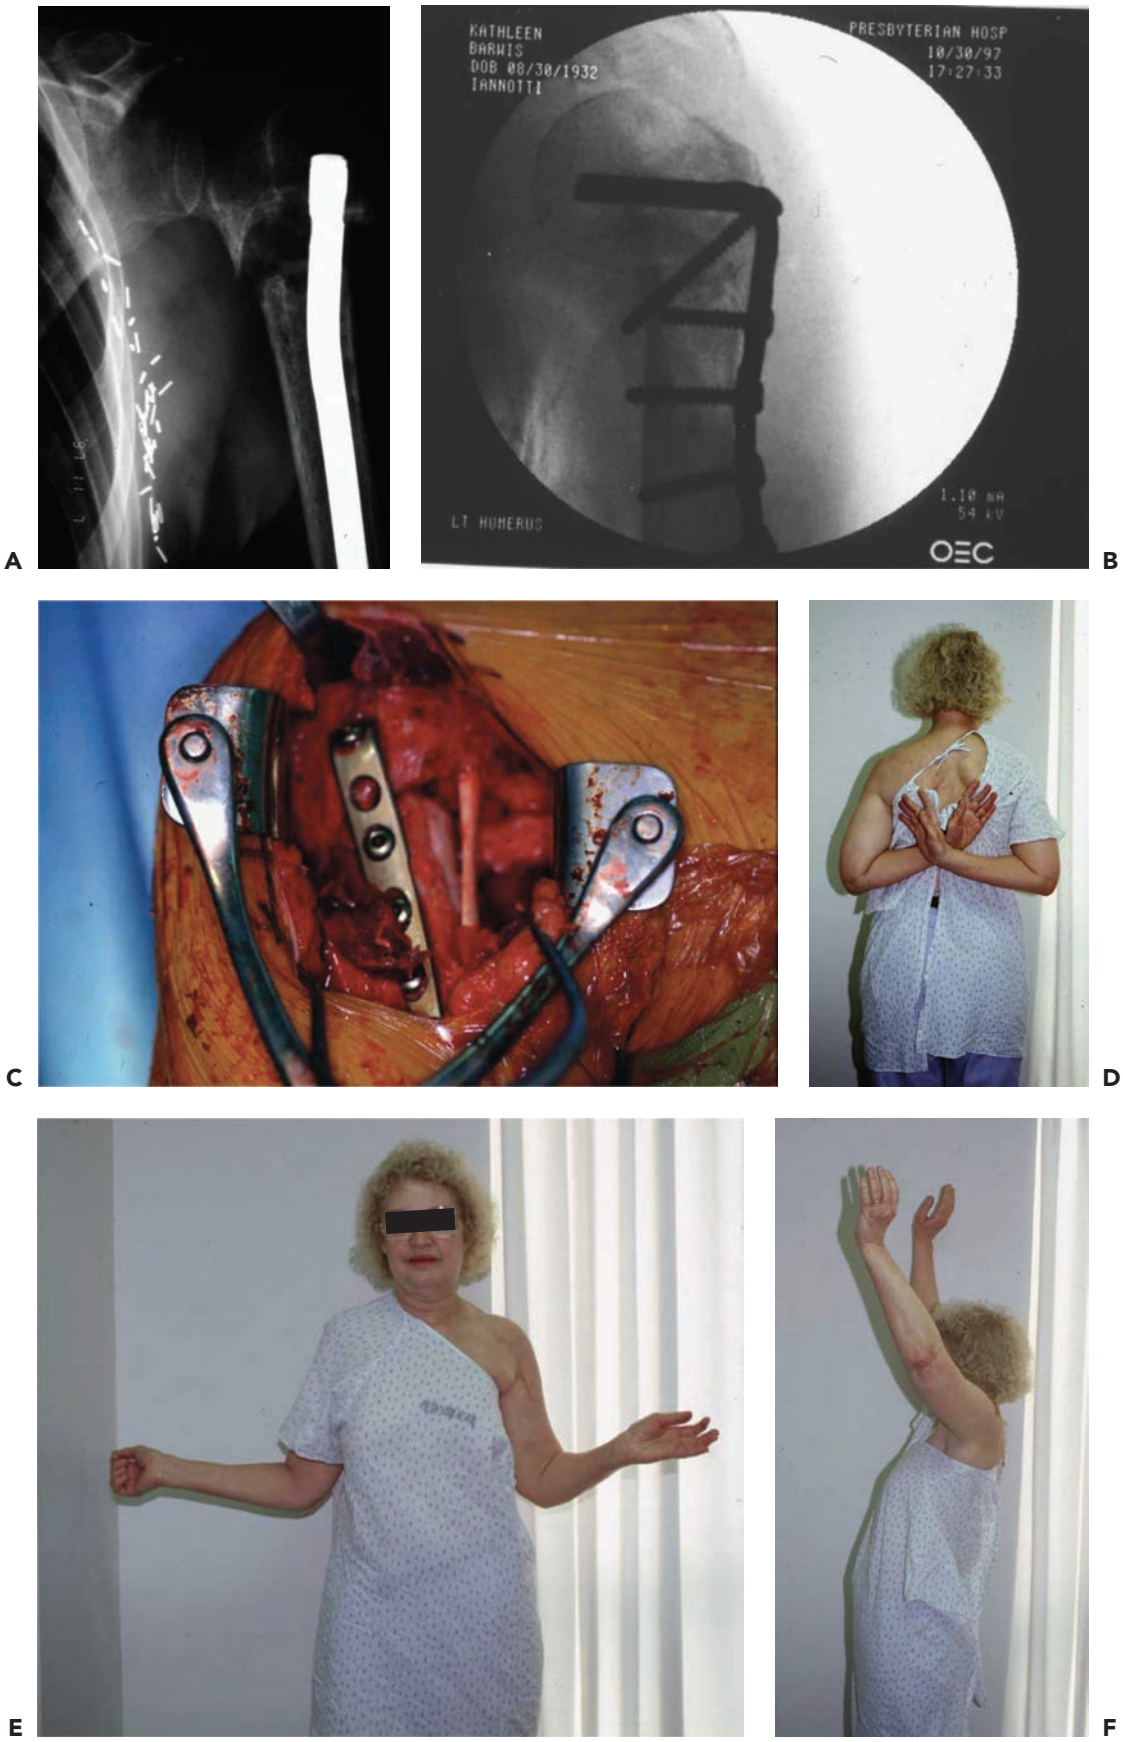

Figure 30-18 Surgical neck nonunion treated with a blade plate and bone graft. It healed with an excellent clinical result in a middle-aged patient.

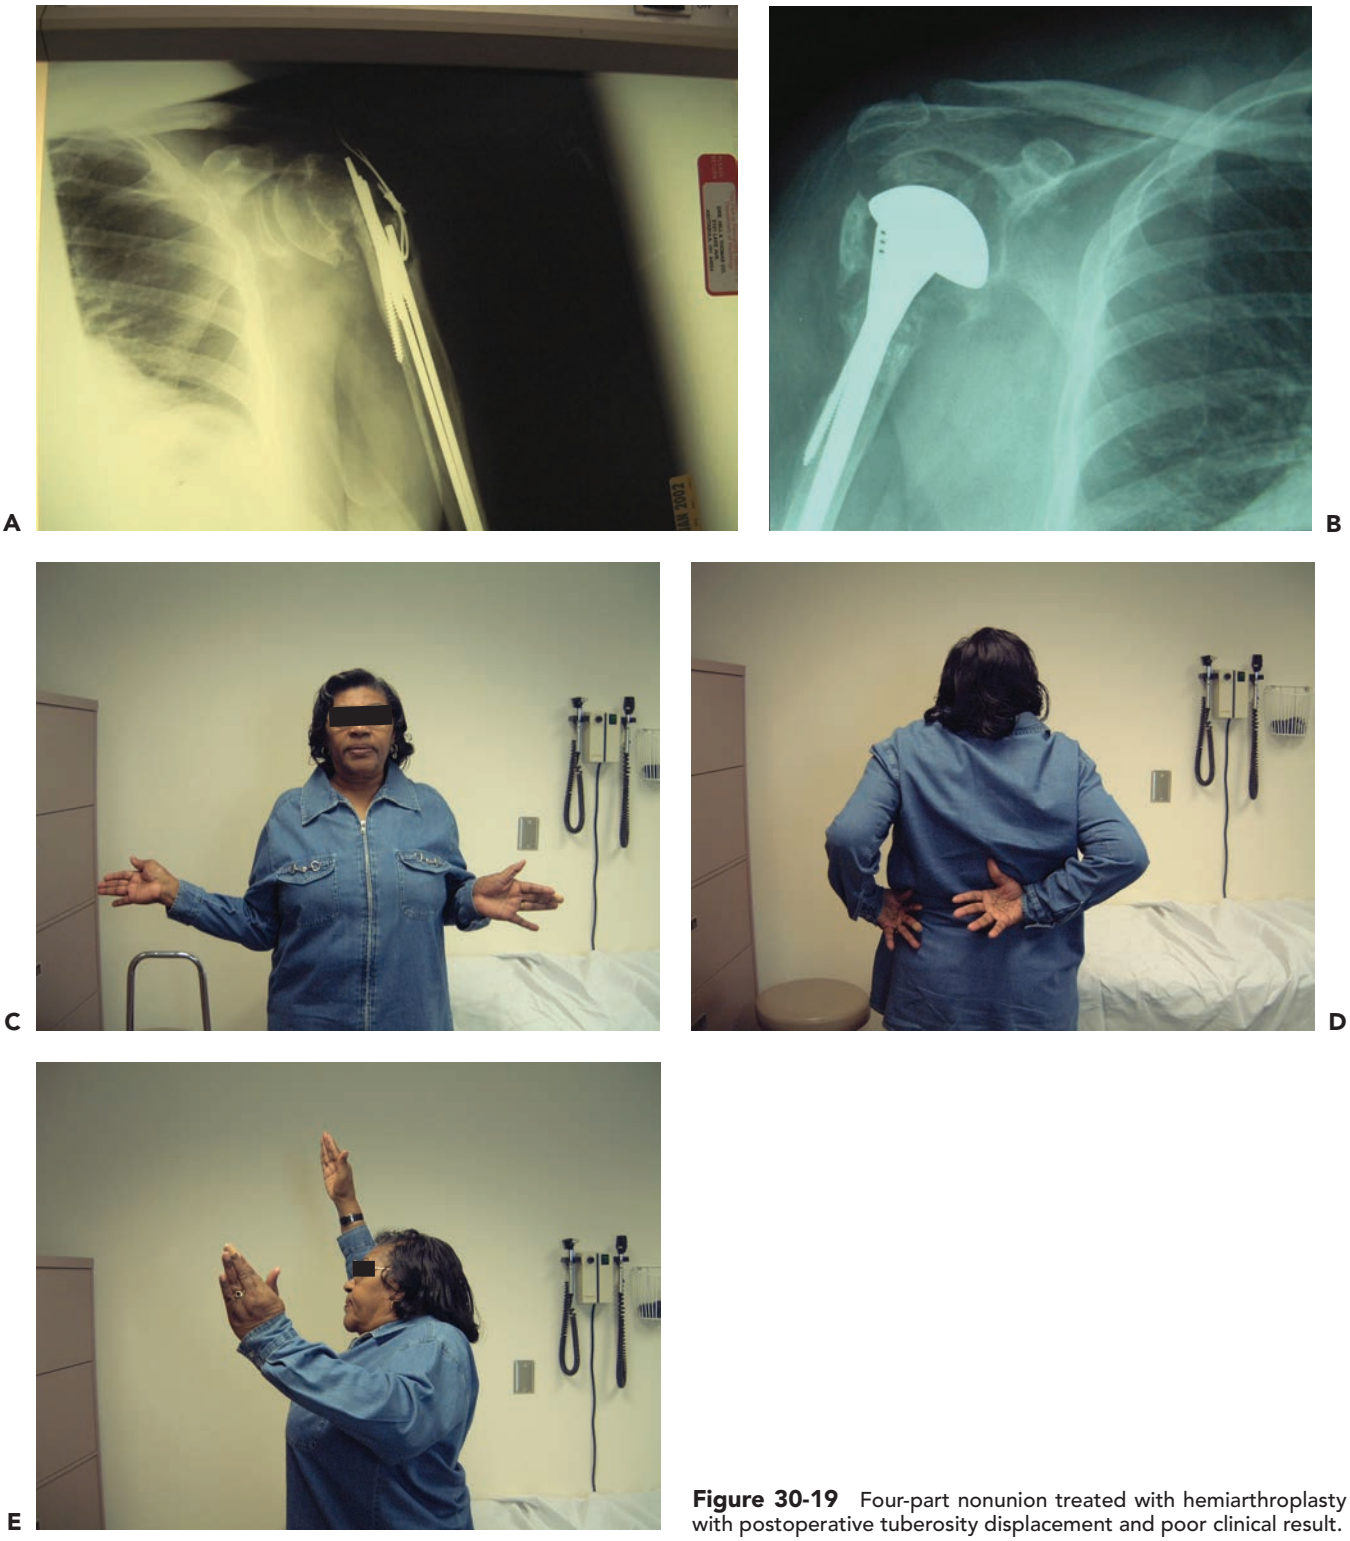

Figure 30-19 Four-part nonunion treated with hemiarthroplasty with postoperative tuberosity displacement and poor clinical result.

by avascular necrosis. In these circumstances the tuberosities are small with poor bone quality, and tuberosity nonunion after prosthetic arthroplasty is common. When tuberosity nonunion occurs, the functional results are often poor (Fig. 30-19). Total shoulder arthroplasty is indicated if concomitant glenoid articular surface defects exist. In these cases the tuberosities are osteotomized and cement fixation is required for stem fixation. Osteotomy of the tuberosities is at the bicipital groove and osteotomy of the articular surface, essentially creating a four-part fracture (Fig. 30-20).

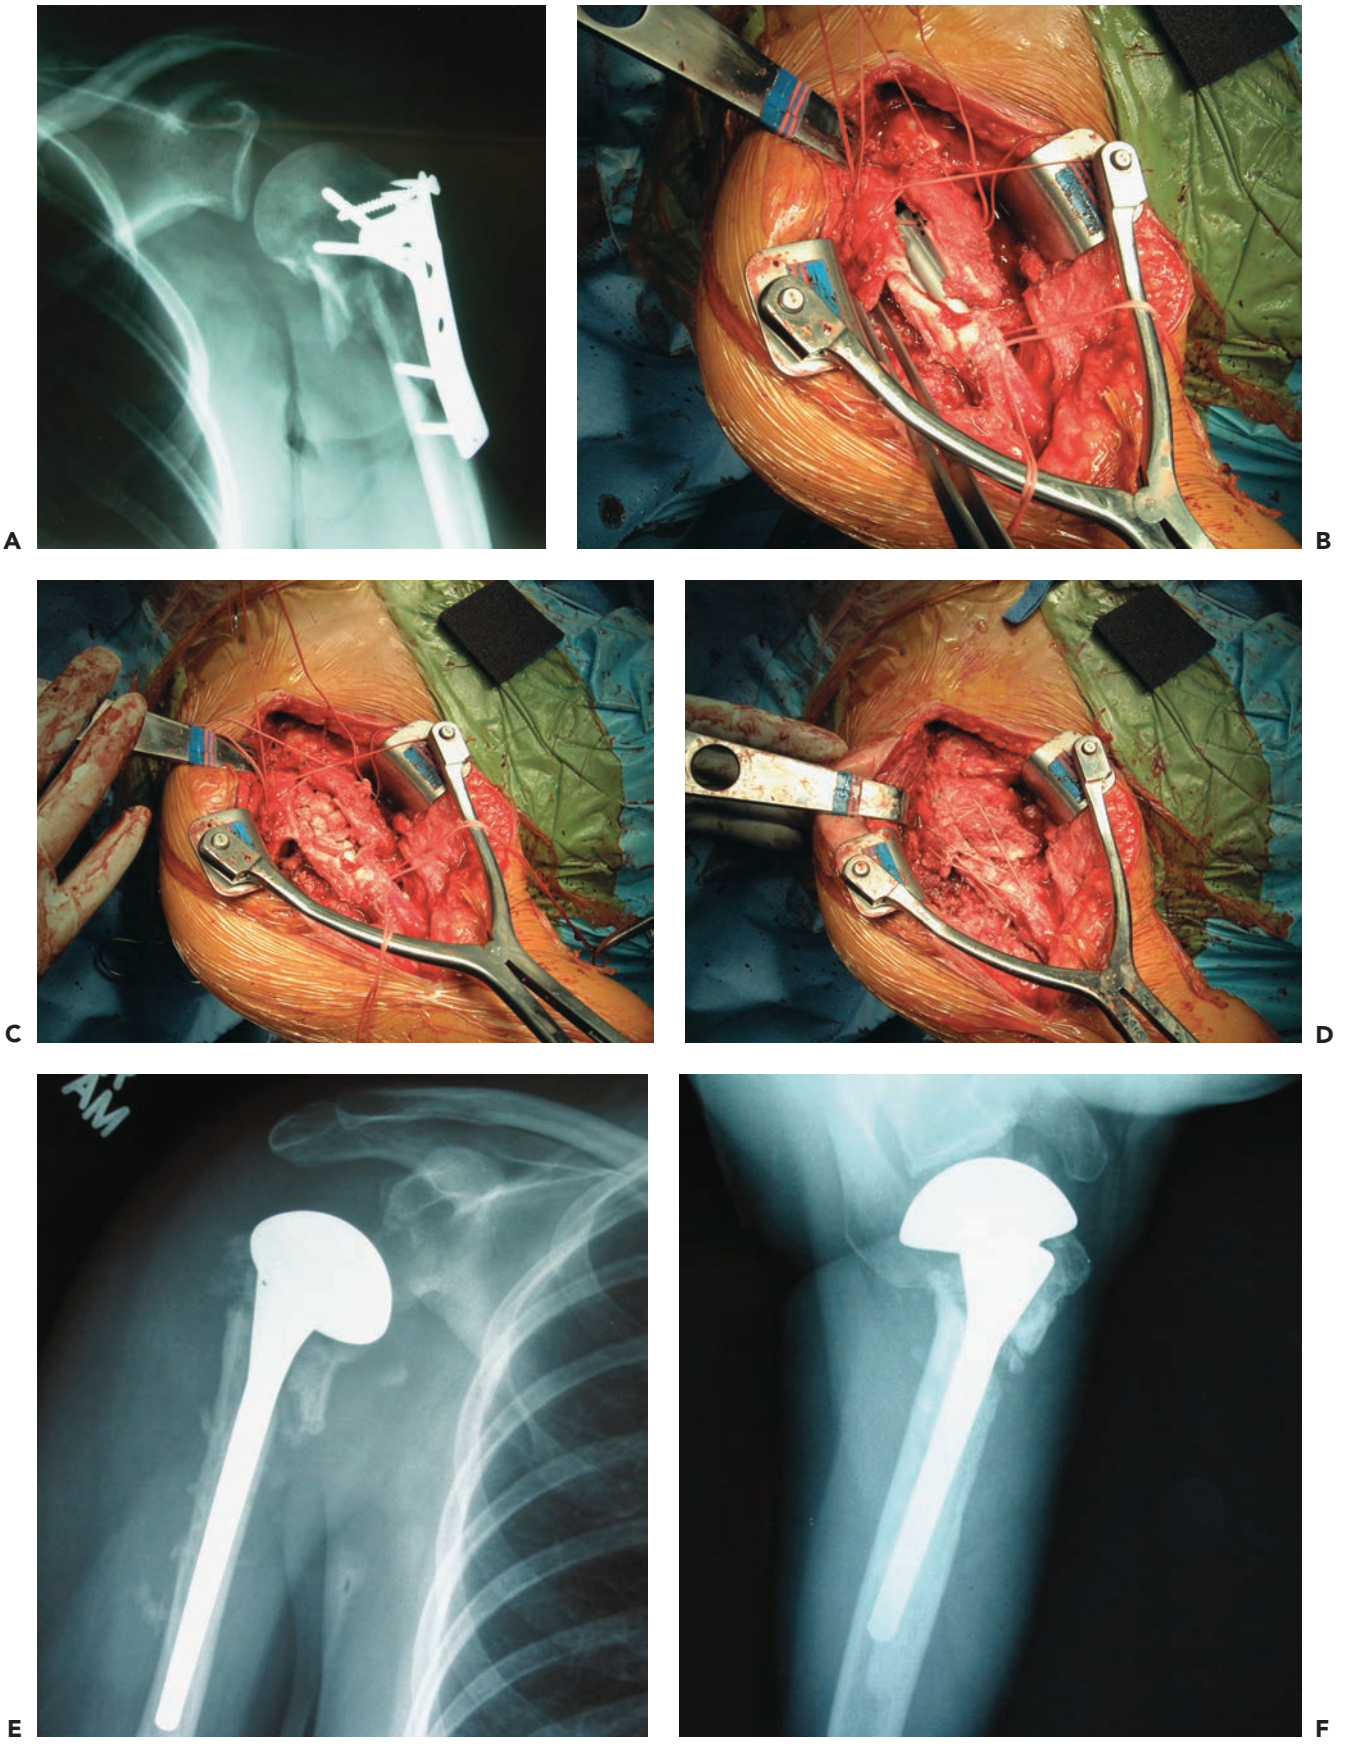

Figure 30-20 Three-part nonunion treated with hemiarthroplasty with good tuberosity healing and good function postoperatively.

Neer advocated the use of iliac crest grafts between the preserved tuberosities to facilitate bony contact and healing of the tuberosities to the shaft and to maintain proper musculotendinous length of the deltoid and rotator cuff musculature.[72] Alternatively, bone graft can be obtained from the humeral head if sufficient. Norris[75] described a technique that can be utilized to avoid splitting the tuberosities individually. A hole can be made in the humeral head through the rotator interval, and the tuberosities can be shish-kebabed as a ring below the prosthetic collar. This technique is desirable as it will improve tuberosity healing and minimize loss of fixation; however, it is technically demanding and fracture of the tuberosity ring can easily occur when passing the prosthetic through the rotator interval into the humeral shaft. We utilize similar surgical technique and postoperative rehabilitation protocol to that described in the preceding section on malunions.

Three-Part and Four-Part Nonunions

The preceding discussion has focused on surgical neck nonunions of the proximal humerus, which are by far the most common. In contrast, three- and four-part nonunions are not very common. Malunions of the tuberosities more commonly accompany surgical neck nonunions than do true associated tuberosity nonunions. Nevertheless, these late sequelae of proximal humerus fractures do occur and warrant discussion.

As in surgical neck nonunions, the critical evaluation of three- and four-part nonunions involves assessment of the quality and vascularity of bone attached to each of the tuberosity fragments and of the integrity of the vascularity and congruity of the articular surface. In those rare cases in which the bone quality is sufficient and the articular cartilage is satisfactory, open reduction and internal fixation with tension suture stabilization of the free tuberosity is preferred. If, however, as is typically the case, the articular segment is incongruous or avascular, prosthetic arthroplasty is the preferred surgical option.[77] Technical themes warranting attention remain the maintenance of humeral length, mobilization of the rotator cuff, and secure fixation of the tuberosities with the addition of autogenous bone graft. Again, our preferred technique for hemiarthroplasty in this setting is discussed in the section on proximal humerus malunions.

In older patients with poor bone quality, a reverse total shoulder replacement is likely to give better clinical results because this prosthetic is less dependent upon healing of the tuberosities (Fig. 30-21).

Results

The results of prosthetic treatment of surgical neck and three- and four-part nonunions will be discussed in this section. There is a relative paucity of literature regarding the prosthetic treatment of proximal humerus fracture nonunions. Most series include small numbers and discuss the entire spectrum of posttraumatic sequelae of proximal humerus fractures in whole without focusing particular attention on specific nonunion type. Thus, a rather confusing body of literature exists in which comparisons between series are difficult. In general, the results of prosthetic arthroplasty for three- and four-part nonunions are inferior to those of prosthetic treatment for similar acute fractures.[14,31,72,77,102] As is true for late prosthetic treatment of malunions, pain relief is usually achieved, but shoulder range of motion, strength, and function are often limited. Accordingly, patients should be prepared for "limited-goals" outcomes following prosthetic replacement. Patients should expect excellent pain relief, but younger, active patients may be disappointed by a lack of overhead motion and strength.

Norris and Turner[78] described four elderly patients with surgical neck nonunions who had satisfactory results in pain relief and function with cemented humeral head hemiarthroplasty using local bone graft. No complications were reported. In another report, however, Norris[77] reported higher complication rates and poorer ultimate shoulder function in the prosthetic treatment of proximal humerus nonunions if a history of prior, failed attempt at open reduction and internal fixation existed. Likewise, Frich and associates[31] evidenced decreased forward elevation and increased pain scores in surgical neck nonunions treated with prosthetic replacement when compared to the results of patients treated with hemiarthroplasty for acute surgical neck fractures.

Nayak and colleagues'[69] series of surgical neck nonunions treated with operative intervention included seven elderly patients treated with hemiarthroplasty. Tuberosity osteotomy was required in all seven of these patients. Those patients treated with prosthetic replacement had better pain relief, but less improvement in range of motion (active forward elevation of 20 degrees improved to 110 degrees) than those treated with internal fixation (20 to 140 degrees). Interestingly, this difference in motion existed despite the presence of mechanical impingement symptoms necessitating hardware removal in 8 of 10 patients treated with intramedullary fixation and tension band construct. Complications including postoperative axillary neuropathy, presumed nonunion of the tuberosities, inferior subluxation of the prosthetic humeral head, and subacromial impingement were reported in the hemiarthroplasty group.

Six patients in Healy and colleagues'[41] review of 25 surgically treated proximal humerus nonunions were treated with hemiarthroplasty and rotator cuff reconstruction. Three patients had good results; two, fair results; and one, a poor result. Although these patients had good pain relief, their shoulder motion and strength was limited; the average range of motion only improved to 72 degrees of total elevation, 30 degrees of external rotation, and internal rotation to the midlumbar spine. Dines et al.'s[25] series of posttraumatic sequelae of proximal humerus fractures treated with hemiarthroplasty included six proximal humerus nonunions. The classification of nonunion type was not included. Active

forward elevation improved from 48 degrees to 120 degrees postoperatively, and all six patients had good or excellent results as determined by the Hospital for Special Surgery (HSS) scoring system. Five of the six patients required tuberosity osteotomies during the hemiarthroplasty.

Antuna and colleagues[4] have published the largest series of proximal humerus nonunions treated with shoulder arthroplasty. All 25 patients in this series had surgical neck nonunions and nine of the patients had three- or four- part nonunions. Shoulder arthroplasty resulted in significant pain relief and improvement in range of motion. Mean active elevation improved from 41 degrees preoperatively to 88 degrees postoperatively. Eleven patients required tuberosity osteotomies at the time of arthroplasty, and 12 patients were reported to have nonunion, resorption, or malunion of the greater tuberosity following arthroplasty; this likely attributes to the lack of above shoulder strength and motion. Additional complications included reoperation for periprosthetic fracture, reoperation for instability, and reflex sympathetic dystrophy. On the basis of a modified Neer result rating system, there was one excellent result, 11 satisfactory results, and 13 unsatisfactory results. Of significant note, the nine patients with a three- or four-part nonunion had significantly less pain relief and were less satisfied with the results of the arthroplasty than were those patients with only a surgical neck nonunion.

Boileau and colleagues'[13] classification of posttraumatic sequelae of proximal humerus fractures included nonunion of the surgical neck (type III). Their series included six cases of surgical neck nonunions, all of which required a greater tuberosity osteotomy to enable prosthetic implantation. In terms of postoperative range of motion and function, these patients did dismally improve in active elevation from 50 degrees preoperatively to only 63 degrees postoperatively. These patients also had less improvement in Constant scores when compared to those patients treated with hemiarthroplasty for avascular necrosis, locked dislocations, or tuberosity malunions. The authors discovered that the most significant factor predictive of poor functional outcome was the need for a tuberosity osteotomy at the time of prosthetic implantation. In fact, all six of these patients requiring tuberosity osteotomy had fair or poor results without active elevation above shoulder level. These results led the authors to conclude that "replacement arthroplasty should be abandoned in the treatment of surgical neck nonunions." Another recent series of posttraumatic sequelae of proximal humerus fractures treated with arthroplasty has also reported that proximal humerus nonunions yield the least favorable results among the spectrum of posttraumatic sequelae treated with shoulder replacement.[66]

Certainly, open reduction and internal fixation is preferred whenever bone stock, articular congruity, and vascularity of the proximal fragment are all satisfactory; however, when these criteria are not fulfilled prosthetic replacement remains the only viable treatment option. Again, these series repeatedly exhibit reliable improvement in pain but limited improvement in strength, motion, or overhead shoulder function. When criteria for open reduction and internal fixation of proximal humerus are not met (i.e., vascularity and quality of proximal bone, position of tuberosities, condition of articular surface, etc.), patients must be prepared for the reality of the challenging nature of this condition and the "limited-goals" expectation of the procedure. As is true for arthroplasty for the treatment of proximal humerus malunions, osteotomy of the tuberosities should be avoided at all costs. The use of a modular replacement system is key in this aspect and, by avoiding complications involved in failed tuberosity union following osteotomy, may improve motion, strength, and function.

Given the poor results of hemiarthroplasty for treatment of proximal humeral nonunion, strong consideration should be given to the use of the reverse total shoulder arthroplasty for these cases when they occur in the older, retired, or sedentary patient. Although results of the reverse shoulder have not been reported to date for specific treatment of these nonunions, it would be expected to yield better functional results than hemiarthroplasty.

SUMMARY

Although the vast majority of proximal humerus fractures that are treated either conservatively or operatively heal uneventfully with good return of function, a small but not insignificant number of patients will suffer debilitating disability from one or more of the sequelae of proximal humerus fractures. In general, the best treatment for these complex and challenging issues is avoidance with appropriate initial therapy as the literature repeatedly evidences superior outcomes for surgical intervention in acute fracture care than in the treatment of these late sequelae. Unfortunately, avoidance of these late complications is not always possible or realistic, especially in the tertiary care, referral setting. Thus, familiarity with the diagnosis, classification, and treatment options for this challenging spectrum of disorders is a mandatory component of the armamentarium of the shoulder surgeon. Comprehensive treatment of all osseous *and* soft tissue pathology in these problematic cases should always be the goal, regardless of surgical technique utilized. In general, preservation of congruency and vascularity of the articular segment of the proximal humerus warrants attempt at open reduction and internal fixation ± arthrolysis and/or rotator cuff reconstruction when warranted. However, in cases in which the articular segment is incongruous, avascular, and unsalvageable, prosthetic arthroplasty remains the only realistic treatment option. It is very clear that the addition of tuberosity osteotomies to any prosthetic replacement markedly diminishes the likelihood of good functional

results. Thus, whenever possible, a modular prosthesis should be utilized to enable implantation of the humeral head component without the requirement for osteotomy of the tuberosities. The use of a surface hemiarthroplasty in selected cases of malunion may allow adaptation of the prosthetic, further avoiding an osteotomy. The reverse shoulder arthroplasty may result in improved functional results in selected patients that require a tuberosity osteotomy.

INTRODUCTION

Fracture of the clavicle is common, and it has long been thought that its inherent reparative capacity will lead to rapid healing despite little more than symptomatic treatment.[273] Deformity has been described more often as a cosmetic concern since function is satisfactory despite malunion.[189,190] It has been suggested by many that primary operative intervention is meddlesome and will result in unnecessary complications.[219,273] However, although the standard of care has long been conservative therapy, operative management of acute clavicle fractures, particularly in polytraumatized patients and in selected cases of young athletes, has proven to be an excellent option.[8,136–141] Despite the proximity of major vascular, nervous, and cardiopulmonary structures, associated injury is uncommon.

This chapter will present to the reader the changing paradigms related to the management of fracture and related complications of the clavicle. A large percentage of clavicular fractures occur in children and heal readily with remodeling of deformity.[231,294] This is not always the case with displaced fractures in adults.

Interest in clavicular nonunion is relatively new[25] and has demonstrated that displaced fractures of the middle portion of the clavicle can in fact be troublesome injuries in adults.[142,188,307,309] Failure of bony union following clavicular injuries can lead to progressive shoulder deformity, pain, impaired function, and neurovascular compromise. Malunion may also contribute to weakness, pain, and neurovascular compromise.[86,87] Data on displaced distal clavicular fractures in adult patients have demonstrated sufficient difficulties with healing to consider primary operative treatment.[62,216–218] A recent investigation focusing on the results

of the treatment of displaced midclavicular fractures in adult patients suggests that this subset of fractures may also be prone to nonunion and delayed union.[307]

ANATOMY

The clavicle is unique among diaphyseal bones in many respects, among them its development, shape, structure, and anatomic relationships. It is the first bone to ossify in the embryo, occurring in the fifth gestational week, and the only long bone to ossify from a mesenchymal anlage (intramembranous ossification). While a number of investigations documenting the histologic evaluation of the embryonic clavicle report that ossification proceeds from two separate centers,[9,71,76,111,187] others assert that a narrow interconnection between these two centers is present from the outset, but may not be seen in any one particular histologic section and will therefore result in sampling error.[92,99,153] Dispute exists as to the cause of congenital pseudoarthrosis of the clavicle, with some suggesting that it is a result of the failure of these two centers to coalesce[150,211] and others believing that pressure from the subclavian artery inhibits ossification, leading to pseudoarthrosis.[180]

Growth in length initially occurs through expansion of the central ossification centers and later by enchondral ossification via epiphyseal growth centers acquired at each end of the bone. The medial (sternal) physis accounts for approximately 80% of the longitudinal growth of the clavicle.[235] Ossification of the sternal epiphysis of the clavicle occurs in the midteenage years and is very difficult to visualize on routine radiography.[69,235] The acromial epiphysis does not ordinarily form a secondary ossification center.[299] Both the sternal and acromial physes can remain open into the third decade of life, particularly the sternal physis, which typically remains open until approximately age 25 years in females and 26 in males.[133,234,235,299] As a result, apparent dislocations of the acromioclavicular or sternoclavicular joints are more likely to be physeal separation injuries in adolescents and young adults.[59,60,200,303]

A number of influences on clavicular length have been investigated. The influence of gender has been clearly shown. In a comparison between African-American males and females and white males, Terry[296] demonstrated that male clavicles are longer than female clavicles. Martin and Saller[193] emphasized that male clavicles in all races are longer than those of females. Dzigora[73] published an average length of 15.6 cm for clavicles of males and 14.3 cm for those of females of Russian ancestry. Investigations looking at body side reveal only the mildest divergence of clavicle length. The left clavicle tends to be longer than the right; this was observed by both Martin and Saller[193] and Dzigora.[73]

The clavicle is named for its S-shaped curvature with one apex anterior medially and another posterior laterally, resembling the musical symbol, clavicula.[205] The larger medial curvature widens the space for passage of neurovascular structures from the neck into the upper extremity via the costoclavicular interval. Men display significantly more angulation of the clavicle than do women.[118,162] The cause for this anatomic phenomenon appears to be the interaction of muscle and bone, since most authors find a positive correlation between increased musculature and clavicular angles. Body side also has significant influence regarding the medial clavicle angle, as confirmed by both Dzigora[73] and Bardeleben.[12] The increased musculature on the right side in right-handed people most likely determines these effects. However, another plausible explanation for clavicular curvature considers the fact that the clavicle is the first bone ossified during embryonic development (the fifth embryonic week) and later the first bone with which the developing thorax and the developing limbs of the upper extremity must conform.[209,250] The theory is that the S-form develops as a result of these interactions. Since the thoracic diameter is well accepted to be larger in males than in females, this would explain gender differences. However, Kummer and Lohscheidt[162] pointed out Pauwels' developmental principles of long bones: They are unable to significantly change the axis of an ossified bone. The axes are finished prior to ossification, in the essential stages of development. Since clavicles ossify early, an essential bone-shape altering factor would have to exist very early in development.

Inman et al. have suggested that the curvature of the lateral third of the clavicle contributes to range of motion of the shoulder girdle by allowing approximately 30 degrees of motion between the scapula and clavicle through the acromioclavicular joint.[126,127,179] According to their description, this motion occurs via inferior translation of the medial portion of the scapula leading to abduction of the scapula through the acromioclavicular joint, a motion that might be thought impossible considering the rigid interrelationship between the clavicle and scapula maintained by the stout coracoclavicular ligaments. However, the lateral curvature and 50-degree rotational motion of the clavicle on its longitudinal axis allow for inferior translation of the attachment of the coracoclavicular ligaments on to the posteriorly directed apex of the lateral clavicle along with the scapula. Inman et al. have likened this to the action of a crankshaft[126,127] (Fig. 31-1).

Others dispute this description, claiming that little motion occurs at the acromioclavicular joint and that the scapula actually rotates along with the clavicle.[48]

The clavicle is made up of very dense trabecular bone lacking a well-defined medullary canal. In cross section the clavicle transitions gradually between a flat lateral aspect, a tubular midportion, and an expanded prismatic medial end.[15,113] (Fig. 31-2)

The average measured diameter of the medullary canal over the course of the clavicle bone is depicted in Fig. 31-2. With its natural S-curve, the clavicle has a double funnel-shaped diameter. At the sternal end, the diameter measures

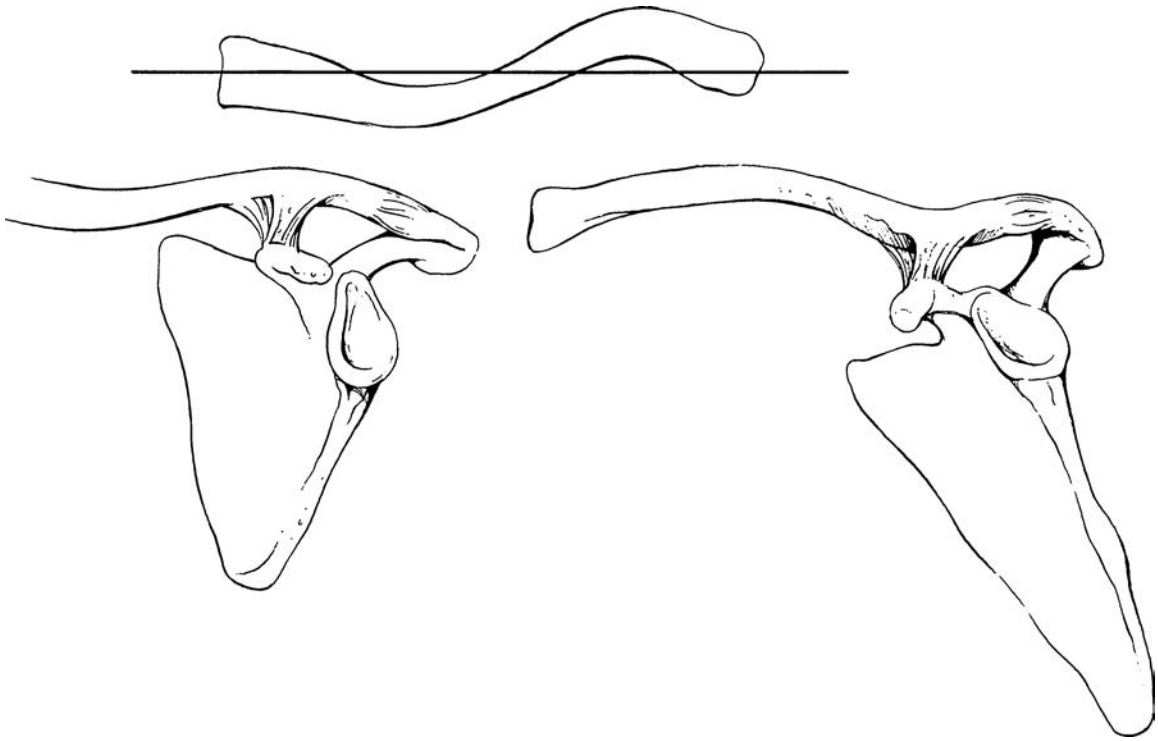

Figure 31-1 There are three axes of clavicular motion: anterior–posterior, superior–inferior, and rotational. According to Inman's description, the 50-degree rotational motion of the clavicle, in combination with the apex posterior curvature of the lateral clavicle, allows for inferior translation of the attachment of the coracoclavicular ligaments on the lateral clavicle. This in turn permits the medial aspect of the scapula to translate inferiorly, with the glenoid abducting through the acromioclavicular joint. This so-called crank-shaft mechanism provides 30 degrees of the total 60-degree contribution of scapulothoracic motion to shoulder abduction. It is important to note that other authors dispute this mechanism.

approximately 18 mm, and decreases in a linear manner to approximately 6.7 mm at the midpoint. Continuing on, the diameter increases in a similar fashion, eventually reaching 15 mm. The narrowest diameter is measured exactly at the meeting point of the medial convexity with the lateral concavity, the most frequent location of clavicle fractures. These peculiarities of the bone's curvature and cross-sectional anatomy as well as its bony structure become important when intramedullary fixation of the clavicle is considered[167] (see Fig. 31-2).

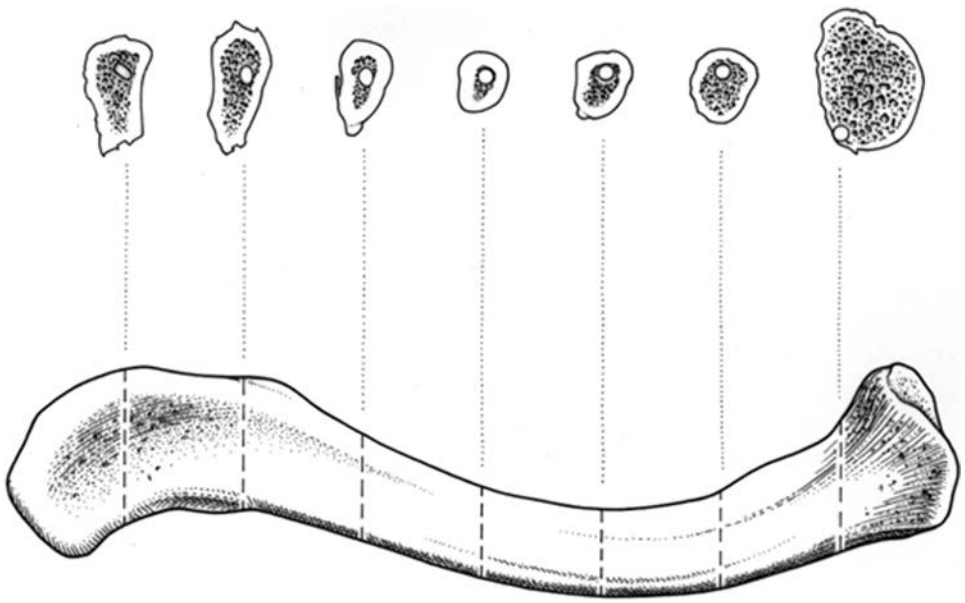

Figure 31-2 The diameter of the medullary canal cross section, the cortical thickness, and the position of the intramedullary nail within the clavicular canal: Contact point and the cortical thickness next to the respective positions become clear. In the medial and lateral portions of the bone are the danger zones for nail perforation, while in the middle third a relative narrowing is present.

The clavicle is subcutaneous throughout its length and makes a prominent aesthetic contribution to the contour of the neck and upper chest. The supraclavicular nerves run obliquely across the clavicle just superior to the platysma muscle and should be identified and protected during operative exposure to offset the development of hyperesthesia or dysesthesia over the chest wall.

The articulation of the clavicle with the trunk is stabilized by the stout costoclavicular and sternoclavicular ligaments. The subclavius muscle may also contribute to stability in this region of the clavicle. The coracoclavicular and acromioclavicular ligaments stabilize the relationship of the distal clavicle with the scapula. The upper portion of the insertion of the trapezius muscle and the anterior portion of the origin of the deltoid further stabilize the lateral clavicle through their attachments to its posterior and anterior aspects, respectively. Fractures in these regions of the clavicle tend to be relatively stable, provided that the described ligamentous and muscular relationships are not disrupted in the traumatic injury.

In displaced fractures and ununited fractures of the clavicle, the most common deformity includes medial–lateral shortening, drooping, adduction, and protraction of the shoulder girdle. The forces contributing to persistence or worsening of deformity following fracture include the weight of the shoulder as transmitted to the distal fragment of the clavicle primarily through the coracoclavicular ligaments as well as the deforming forces of the attached muscles and ligaments. The medial fragment is elevated by the clavicular head of the sternocleidomastoid muscle, which inserts onto the posterior aspect of the medial portion of the clavicle. The pectoralis major contributes to adduction and inward rotation of the shoulder.[121–124]

Bone density correlates strictly with the dynamic and static loading forces applied to a bone.[162,246] In the clavicle, the medial portion of the bone, where increased functional loading is most apparent, displays a clearly higher density. At the intersection of the middle to lateral thirds of the clavicle, there is a significant decrease of bone density. The midportion is the thinnest and narrowest portion of the bone and represents a transitional region, both in curvature and cross-sectional anatomy, making it a mechanically weak area.[113] This, in part, explains the increased frequency of fractures occurring in the middle and lateral thirds of the bone (80% of clavicular fractures occur in the middle third, 10% to 18% occur in the lateral third, and 2% to 10% occur in the medial third). Fractures of the medial third of the clavicle are extremely rare.[27,75,216,218,241,269]

Considering the intimate relationship of the clavicle to the brachial plexus, subclavian artery and vein, and the apex of the lung, it is surprising that injury to these structures in association with fracture of the clavicle is so uncommon. Brachial plexus palsy may develop weeks or years following injury, due to hypertrophic callus with or without malalignment of the fracture fragments leading to compromise of the costoclavicular space.[14,40,52,82,106,124,142,147,159,196,204,264,275,302,312] Narrowing of the costoclavicular space due to malunion or nonunion can also lead to a dynamic narrowing of the thoracic outlet.[13,18,31,51,89,181,210,254,289]

FUNCTION

A review of the comparative anatomy literature reveals that the clavicle has developed from the "os thoracale," a construct of the sternum and clavicle. This "distance-maintainer" between the breastbone and scapula was first observed in fossils of the earliest reptiles, who lived approximately 350 million years ago (Devon). The abilities of the "walking fish," of which the coelacanth is the most well known, were strictly dependent on the development of abduction in the front extremities. Further evidence for the phylogenetically early development of the clavicle is that it ossifies very early during ontogenesis. The functional consequence is, from an evolutionary perspective, the ability to abduct and raise the arms. Conversely, in animals without the ability to abduct the front extremities (i.e., sheep or horses), during ontogenesis the clavicle forms and is even temporarily ossified before completely disappearing by the time of birth.

A clavicle is not beneficial to running and jumping quadruped mammals.[17,18,40,60,179,243,244] In contrast to the quadrupeds, who derive stability and strength from close association of the shoulder girdle with the trunk, in simians the clavicle enhances upper extremity function for swinging through trees. It holds the glenohumeral joint and the upper extremity away from the trunk in all positions. The clavicle enhances overhead activity (combination of shoulder abduction and elevation), particularly in actions requiring power and stability, and resists those tensile forces that become so prominent in activities required by arboreal mammals. It is not surprising then that in cases of clavicle fractures in humans where there is shortening of the sternum–scapula distance, there is a subsequent limitation in shoulder abduction and elevation. The clavicle also serves as a bony framework for muscular attachments, provides protection for the underlying neurovascular structures, transmits the forces of accessory muscles of respiration (e.g., the sternocleidomastoid) to the upper thorax; and contributes to the aesthetics of the base of the neck.[179,209]

It is of interest that children with cleidocranial dysostosis (clavicular aplasia) adapt surprisingly well to an absence of clavicles. However, limitations have been observed with regard to overhead activities requiring strength, stability, and dexterity in cleidocranial dysostosis patients.[14,40,59,60,126,127,190,297] If these congenitally aclavicular children have notable functional deficiencies in comparison with normal children, then one must be concerned about what will happen when the learned coordinated

manipulation of the complex interaction of various muscle groups, ligamentous attachments, and interarticulations of the shoulder girdle is disrupted by sacrificing clavicular continuity in adult patients.[15,72] In fact, some studies have suggested that malunion alone (particularly shortening) can cause pain and inhibit function.[84,85,88]

Because some reports document good function following total or subtotal resection of the clavicle for infection, malignancy, or access to neurovascular structures in small series of patients,[1,55,80,90,108,126,187,310] some authors went so far as to encourage consideration of the clavicle as an expendable or surplus part of the skeleton.[108] Resection of the clavicle has been recommended both in the treatment of clavicular nonunion[36,214] as well as in the treatment of fresh clavicular fractures.[198,249]

It is certainly clear that some patients do very poorly following clavicular resection,[271,286] especially those with trapezial paralysis.[57,142,247,310] We therefore feel strongly that this procedure should be reserved for the unusual situation in which a salvage procedure becomes necessary. The clavicle plays an important functional role in the shoulder girdle, and every effort should be made to preserve or restore normal length and alignment in the treatment of clavicular disorders.

CLASSIFICATION

Surgeons interested in clavicle fractures have long distinguished midclavicular fractures from fractures of the medial or lateral end.[21,117] Following descriptions by Allman,[3] Rowe,[273] and Neer,[216–219] the clavicle has been divided into thirds for purposes of classification. This proves somewhat arbitrary when one considers that the majority of clavicular fractures occur at a distance from the lateralmost aspect of the bone, which falls on a roughly Gaussian distribution between approximately 30% and 60% of the length of the bone.[197] In the majority of reported series, separation of clavicular fractures as occurring in one of the thirds of the bone was most likely based upon interpretation from standard radiographs, rather than precise measurement. This implies that division of the large numbers of clavicular fractures occurring about the middle third–distal third junction as belonging to either the distal third or middle third group is often imprecise and may be arbitrary.

In Neer's defining work on distal clavicular fractures,[216–219] he considered fractures distal to the proximal limit of the trapezoid ligament as distal clavicular fractures and distinguished two types: Type I represents a fracture in which both the trapezoid and conoid ligaments remain intact and are attached to the medial fragment, thereby providing stable reduction of the fracture; a type II fracture consists of a fracture in which the trapezoid ligament remains attached to the distal fragment while the conoid ligament is ruptured and no longer maintains reduction of the medial fragment. In type II fractures, the loss of coracoclavicular ligament restraint on the medial fragment results in wide displacement of the fracture fragments, and in Neer's experience, an increased risk of nonunion[219] (Fig. 31-3).

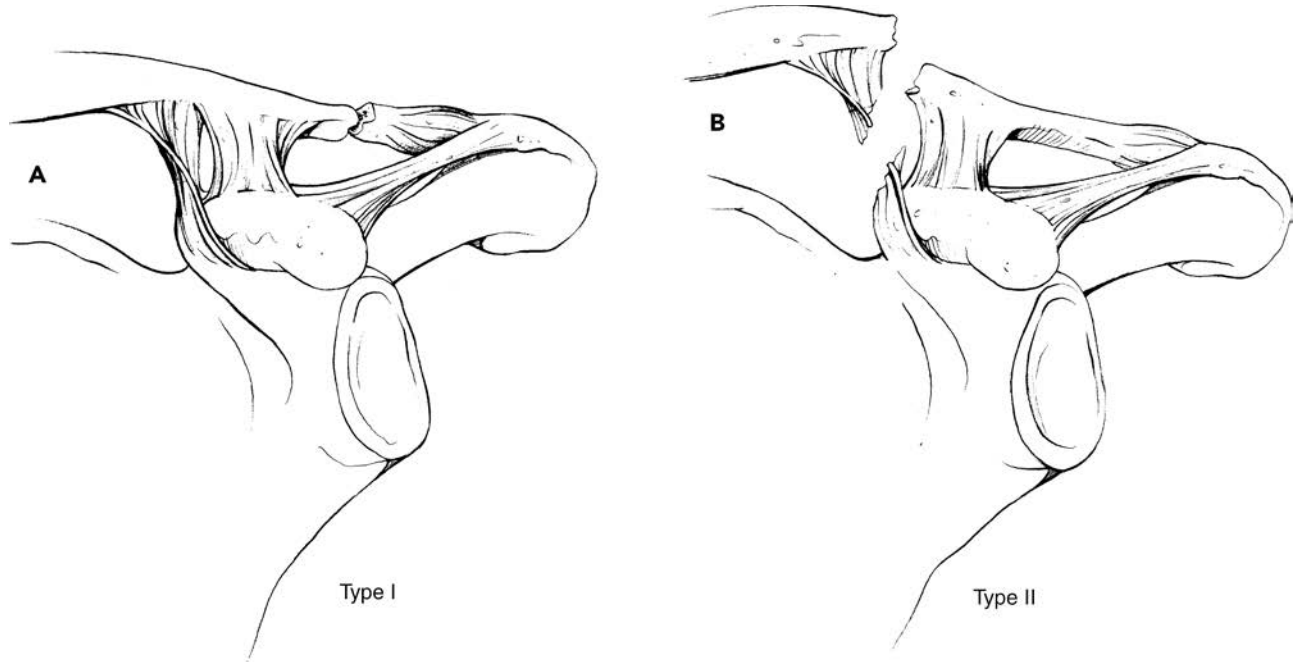

Figure 31-3 When the distal end of the clavicle is fractured, the ligaments may either **(A)** remain intact and serve to maintain apposition of the fracture fragments (type I) or **(B)** rupture, allowing wide displacement of the fragments (type II).

Rockwood subsequently recommended division of type II fractures of the distal clavicle into two subsets: fractures of the distal clavicle in which both the conoid and trapezoid ligaments remain attached to the distal fragment as type IIA and those in which medial fragment instability is a result of disruption of the coracoclavicular ligaments (Neer's original description) as type IIB.[270,272] It is unclear, however, how type IIA fractures differ from more distal midclavicular fractures, especially considering the fact that the most common site of midclavicular fracture is at the junction of the middle and distal thirds.[293] We believe Neer's classification to be more applicable as it serves the role of distinguishing fractures that might potentially be stabilized by ligamentous attachments as either stable (ligaments intact) or unstable (at least partial ligamentous disruption; see Fig. 31-3).

In unusual instances, fractures of the distal clavicle may be unstable in the absence of ligamentous injury. This occurs when both of the coracoclavicular ligaments remain attached to an inferior fracture fragment that lacks attachment to either of the primary medial and lateral fragments.[247]

Neer noted in his initial report that fractures of the distal clavicle are occasionally associated with extension into the acromioclavicular joint, and subsequently distinguished such fractures in his classification system as type III.[216–218] It has been suggested that some injuries diagnosed as type I acromioclavicular joint separation may in fact be intraarticular distal clavicular fractures, and that posttraumatic osteolysis of the distal clavicle[39,130,131,183,262] occurs in part as a result of an undetected intraarticular fracture.[57,217]

In children and adolescents, medial and lateral clavicular injuries most frequently take the form of physeal separation injuries, although metaphyseal fractures also occur.[234,235,303] In distal clavicular physeal injuries and metaphyseal fractures (so-called pseudodislocation of the acromioclavicular joint), the proximal fragment may displace and separate from the surrounding periosteum, while the thin distal clavicular epiphysis, with or without an attached metaphyseal fragment, retains its anatomic relationship to the acromion and the remainder of the shoulder.[90,146,183,184,235,254,304] The acromioclavicular and coracoclavicular ligaments are intact and remain attached to the periosteal sleeve.[234,235,303,309] Analogous patterns of injury occur at the sternal end of the growing clavicle.[36,143,176,258] Since both the medial and lateral physes typically remain open into the third decade of life,[133,234,299] it is important to realize that apparent acromioclavicular or sternoclavicular dislocations in some young adults may actually be physeal separation injuries.[36,54,143,176] As a result, these injuries can, in general, be expected to heal and become stable with nonoperative treatment. They may even remodel somewhat.

Fractures of the sternal end of the clavicle are uncommon and almost without exception treated symptomatically.[3,52,57,84,120,143,172,217,273,314] Craig has subdivided these as minimally displaced (type I), displaced (type II), intraarticular (type III), physeal separation (type IV), and comminuted (type V) fractures. Fractures in this region of the clavicle are so uncommon that the patterns of medial clavicular injury have rarely been described and studied, and it remains unclear how different fracture patterns might influence treatment or prognosis.

Fractures occurring between the medial limit of the coracoclavicular ligaments and the lateral limit of the costoclavicular ligaments represent by far the most common type of clavicular fracture. These fractures have not to this point been subclassified in a universally acceptable manner. Current publications use the Comprehensive Classification of Fractures (CCF) (Fig. 31-4)[47,141,274]: Type A fractures are simple transverse fractures, type B fractures are wedge fractures, and type C fractures are those in which the main fragments are separated by a zone of comminution and have no contact. This classification turns out to be very useful for the decision of which operative procedure should be carried out (plate vs. intramedullary nail). (See section titled Operative Treatment.)

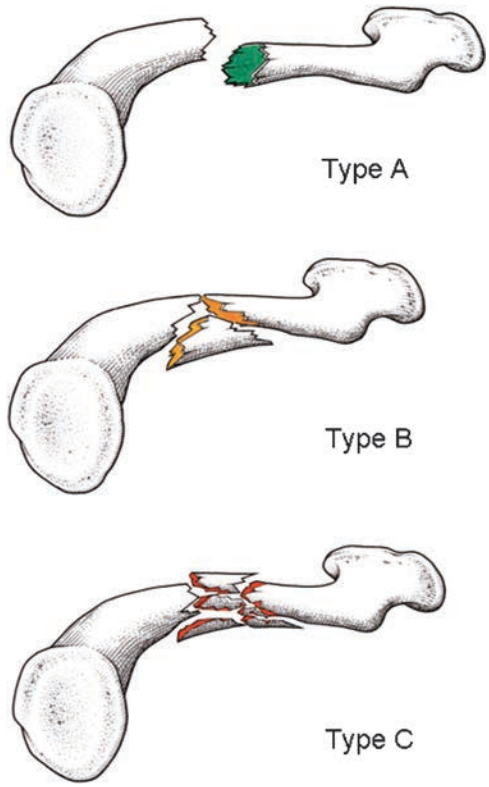

Figure 31-4 Type A fractures are simple transverse fractures, type B fractures are wedge fractures, and type C fractures are those in which the main fragments are separated by a zone of comminution and have no contact. (From Classification, Orthopaedic Trauma Association Committee for Coding and Classification. Fracture and dislocation compendium. *J Orthop Trauma* 1996; 10(5–9):1–154.)

One important element of a midclavicular fracture is the amount of displacement or deformity. Distinguishing *nondisplaced* or minimally displaced fractures (including greenstick and plastic bowing-type[28] fractures in children), which will heal with symptomatic treatment and little concern regarding either cosmesis or function, from *displaced fractures*, which may result in deformity, shoulder dysfunction, and an increased risk of nonunion, has been common practice up to now.[298] However, as seen in Fig. 31-5, the fracture displacement changes depending on body posture. In this particular x-ray, the difference is significant. Therefore, the criterion of fracture displacement is clearly not useful information regarding the choice between operative or conservative management.

Pathologic fractures of the clavicle occur, although they are unusual. Rowe reported fractures through eosinophilic granuloma, Pagetoid bone, and metastatic carcinoma involving the clavicle.[273] Fracture related to enchondroma[25] and arteriovenous malformation[208] have also been reported. Stress fractures of the clavicle have been described following radical neck dissection as a result of the devascularizing dissection and radiation osteitis that complicate the treatment of these tumors.[58,143,239,253,290] Fatigue fracture was also reported in a 12-year-old boy who, while attempting to improve his grades, had apparently been carrying an inordinately large number of books under the arm on the involved side for several months.[148] Stress fracture related to the use of a Dacron graft loop for coracoclavicular ligament reconstruction has also been reported.[70]

MECHANISM

In general, clavicle fractures suffered by adolescents and adults in all regions are the result of moderate or high-energy traumatic injury such as a fall from a height, motor vehicle accident, sport activity, or a blow to the point of the shoulder, and rarely a direct injury to the clavicle. Typical sports concerned include cycling, horseback riding, Alpine skiing, or motorcycling.[154–156,226–228,230,231,233] In children and the elderly, clavicle fractures usually occur following low-energy trauma.[3,52,119,136,137,139–141,228,229,231,273,277,284,287]

It has become clear that the clavicle fails most commonly in compression. Failure in compression is seen following falls onto the shoulder and direct blows to the

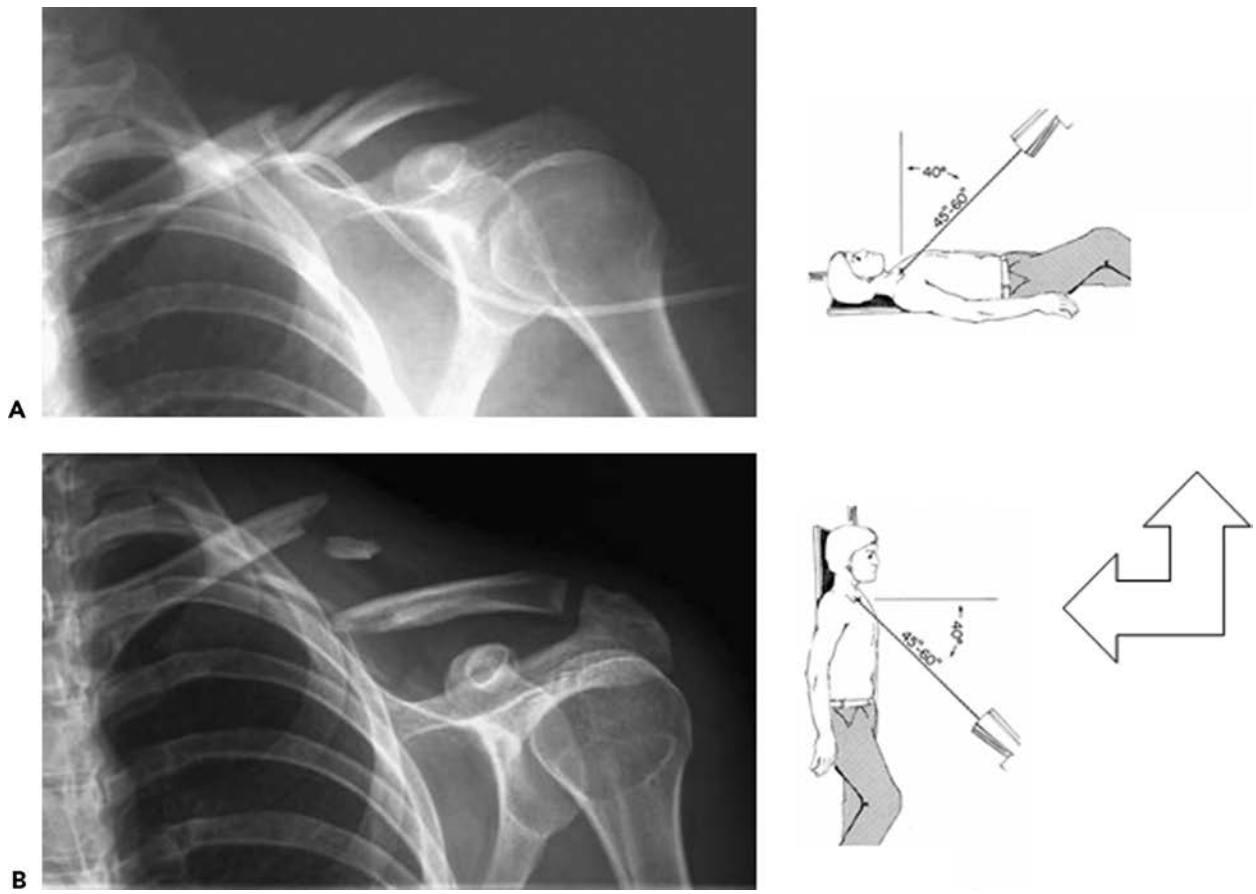

Figure 31-5 X-rays taken of a person with midshaft fracture in reclining **(A)** or standing **(B)** position. The position of the fracture elements changes dramatically depending on muscle tone.

point of the shoulder.[23,95,277,287] A direct blow to the clavicle, seen to occur in some stick-wielding sports such as lacrosse,[284] may also fracture the clavicle. Although a fall onto the outstretched hand has traditionally been considered a common mechanism of midclavicular fracture,[3] recent observations[287] bring this into question.

Stanley et al. studied 122 of 150 consecutive patients presenting to one of two separate hospitals in Sheffield with fractured clavicles. The detailed accounts of their injuries showed that 87% were the result of a fall onto the shoulder, 7% the result of a direct blow to the point of the shoulder, and 6% the result of a fall onto an outstretched hand.[287] Falls on the outstretched hand were the apparent mechanisms of 5 of 79 (6.3%) midclavicular fractures and 2 of 34 (5.9%) distal clavicular fractures, suggesting that direct injury to the shoulder is the most common mechanism of clavicular fracture at all sites. These authors hypothesized that even those patients who recall their injury as a fall onto the outstretched hand may have fallen secondarily onto the shoulder. This second impact may have been the injuring force, suggesting that isolated fall onto the outstretched hand is actually an unusual mechanism of injury.[287]

Neer has stated that distal clavicular fractures tend to be the result of a high-energy, direct blow to the shoulder.[119,216] However, distal clavicular fractures have also been identified in the elderly following lower energy injuries.[231]

EPIDEMIOLOGY

An understanding of the frequency and distribution of clavicular fractures is provided by data collected in Malmo, Sweden. Four percent of all fractures occurring in Malmo in 1987 involved the clavicle. This represented 35% of all fractures in the shoulder region. The overall incidence of clavicle fractures increased from 52 per 100,000 persons per year in 1952 to 64 per 100,000 persons per year in 1987, mostly as a result of an increase in sports-related injury and injuries following a fall.[231]

Seventy-six percent of the fractures occurred in the middle third of the clavicle, a figure that is similar to previous reports.[52,84,217,273] The average age overall in this subgroup was 21 years. However, the average age was 11 years for nondisplaced fractures, 25 years for simple displaced fractures, and 43 years for comminuted fractures.

Twenty-one percent of fractures in Malmo involved the distal clavicle with an average age of 47 years (median also 47 years). This is also comparable with the rate reported in some previous studies[52,58,172] but is double the rate reported in others.[79,119,217,218,273] The incidences of middle and lateral third fractures of the clavicle were comparable for middle-aged adults (approximately 35 to 60 years of age) in the Malmo experience.

Medial clavicular fractures represented only 3% of clavicular fractures.[231] Although many of the published studies report an incidence of 4% to 6%, even 3% is probably an overestimate based on inclusion of many of the more medial midclavicular fractures in this group.[79,119,217,218,273] Taylor measured the distance of 550 fractures from the lateral aspect of the clavicle and found only 0.5% in the medial third of the bone.[292,293] According to the data of Nordqvist et al., the average age of a person sustaining a medial clavicular fracture was 51 years, with a large proportion of fractures occurring in adolescent and young adult males and the elderly. The incidence of both lateral and medial clavicular fractures rose sharply after age 75, suggesting that these areas become substantially more susceptible to fracture when osteoporotic.[229]

EVALUATION

Clavicle fractures resulting from low- to moderate-energy traumatic injuries are easily diagnosed and are associated with few complications. The deformity and swelling associated with the fracture are usually apparent. The location of the fracture along the clavicle can usually be determined by close inspection and palpation, although distinction of fractures of the medial or lateral ends of the clavicle from dislocation of the adjacent joints can be difficult prior to radiographic examination. The patient typically resists all motion of the ipsilateral shoulder, is tender at the fracture site, and holds the arm against the trunk.

Open clavicular fractures are uncommon, even following high-energy traumatic injury, and are usually the result of a direct blow to the clavicle. Tenting of the skin by either one of the major fracture fragments or an intervening fragment of comminuted bone is not uncommon, but a true threat to the integrity of the skin is unusual.[263]

Neurovascular injury,[123] pneumothorax,[67,180,203,312] and hemothorax[167] have been reported in association with fracture of the clavicle, but are uncommon. In contrast to late dysfunction of the brachial plexus following clavicle fracture in which medial cord structures are typically involved, acute injury to the brachial plexus at the time of clavicle fracture usually takes the form of a traction injury to the upper cervical roots. Such root traction injuries usually occur in the setting of high-energy trauma and have a relatively poor prognosis.[17,169,282]

Vascular injuries may not always be apparent. These may consist of an intimal injury or a small puncture wound and can present from weeks to years later in the form of an aneurysm or pseudoaneurysm or thrombosis of the involved vein or artery.

The combination of clavicle fracture and fracture of the first five ribs in severely injured patients is an important indication of high-energy upper thorax trauma. It is not uncommon in such cases that accompanying injuries of

the mediastinal organs (i.e., aortic rupture, heart contusion, pericardial tamponade), the lungs (i.e., hemopneumothorax, lung contusions), and/or cervical and thoracic spine injuries occur.[6,7] The prevalence of pneumothorax in association with fracture of the clavicle is often quoted as being 3%, based on Rowe's study of over 600 fractures at Massachusetts General Hospital.[273] In that study, Rowe did not distinguish between moderate- and high-energy injuries and he did not distinguish isolated fractures from those injuries associated with ipsilateral scapular fracture or dissociation from the thorax, or ipsilateral upper rib injuries.[76,77,120,121,166,169,173,268,306] Again, the presence of these associated injuries indicates an extremely high-energy injury mechanism. Pneumothorax and hemothorax are more common in this situation and are likely to be a result of a more generalized chest wall injury rather than to a direct injury to the apical pleura by the fractured clavicle. Nonetheless, the importance of an evaluation for possible pneumothorax by both physical examination and close inspection of an upright film that includes the ipsilateral upper lung field should be emphasized.[56,185,312] When a clavicle fracture occurs in the setting of a high-energy traumatic injury (such as a motor vehicle accident or a fall from a height), evaluation of life-threatening injury takes precedence and should follow the protocol promoted by the American College of Surgeons.[5] Major vascular disruption can occur in association with fracture of the clavicle, but is extremely rare.[56,64,67–69,107,123,132,195,197,215,236,257,291] Injury to the thoracic duct has also been reported.[20,33] Death following a tear of the subclavian vein with resultant pseudoaneurysm was recorded in the famous case of the death of Sir Robert Peel.[66,164] Arterial thrombosis may occur following intimal injury.[128,168,301] Fracture of the clavicle or dislocation of either the sternoclavicular or acromioclavicular joint in association with lateral scapular translation represents a scapulothoracic dissociation, an injury often associated with severe neurovascular injury.[76,77,102,103,166,240]

Evaluation of the vascular status of the upper extremity should include an assessment of relative temperature and color as compared with the uninvolved extremity. Due to the extensive collateral blood supply to the upper extremity, these factors may appear normal in spite of the presence of a major vascular injury. A difference in peripheral pulses or blood pressure between injured and uninvolved upper extremities may be the only clue that a vascular injury is present. When the limb is threatened or there is persistent unexplained hemorrhage, angiography can help to detect and localize any vascular injury, thereby assisting with definitive management.

Compression[61,83,96,97,106,265] and even thrombosis[177,278,288] of the subclavian vein can occur in the early postinjury period. Pulmonary embolism has been reported in the setting of subclavian vein thrombosis following clavicular fracture.[278,313]

RADIOGRAPHIC EVALUATION

An anteroposterior view in the coronal plane of the clavicle will identify and localize the majority of clavicular fractures. To further gauge the degree and direction of displacement of clavicular fractures, oblique views of the clavicle will be necessary.[260,273] The film should be large enough to evaluate both the acromioclavicular and sternoclavicular joints as well as the remainder of the shoulder girdle and the upper lung fields. Quesada recommended 45-degree caudad and cephalad views, which he felt would facilitate evaluation by providing orthogonal views.[260] Medial clavicular fractures may be difficult to characterize on this view, and computed tomography is often necessary.

Evaluation of distal clavicular fracture displacement in the anteroposterior plane requires a different set of radiographs because cephalad and caudad tilted views are hindered by overlap of the bones of the shoulder, overexposure of the distal clavicle, and frequent failure to accurately depict the degree of displacement. Neer has suggested a stress view (with 10 pounds of weight in each hand) to evaluate the integrity of the coracoclavicular ligaments and 45-degree anterior and posterior oblique views to gauge displacement.[219] However, as we noted, differentiation between displaced and undisplaced fractures may mot be relevant. The position of the fracture elements changes dramatically depending on muscle tone (x-rays taken in standing or reclining positions) and the position of the arm (arm in a sling or free-hanging) (see Fig. 31-5). Instead the shape and number of fragments should be identified.

A radiograph taken with the x-ray source angled with a combination of both anteroposterior and cephalad–caudad obliquity has recently been advocated in the evaluation of midclavicular fractures.[266,305] The so-called apical oblique view (45-degree anterior [plane of the scapula], 20-degree cephalad tilt) may facilitate the diagnosis of minimally displaced fractures (e.g., birth fractures and fractures in children).[305] Ultrasound is also a very sensitive diagnostic tool in the evaluation of birth fractures (Fig. 31-6).[145]

The abduction–lordotic view, taken with the shoulder abducted above 135 degrees and the central ray angled 25-degrees cephalad, proves useful in evaluating the clavicle following internal fixation.[266] The abduction of the shoulder results in rotation of the clavicle on its longitudinal axis, causing the plate to rotate superiorly and thereby exposing the shaft of the clavicle and the fracture site under the plate (Fig. 31-7).

MANAGEMENT OF SPECIFIC INJURIES

Birth Fractures

Fracture of the clavicle is the most common traumatic birth injury. Clavicle fracture must be distinguished from less

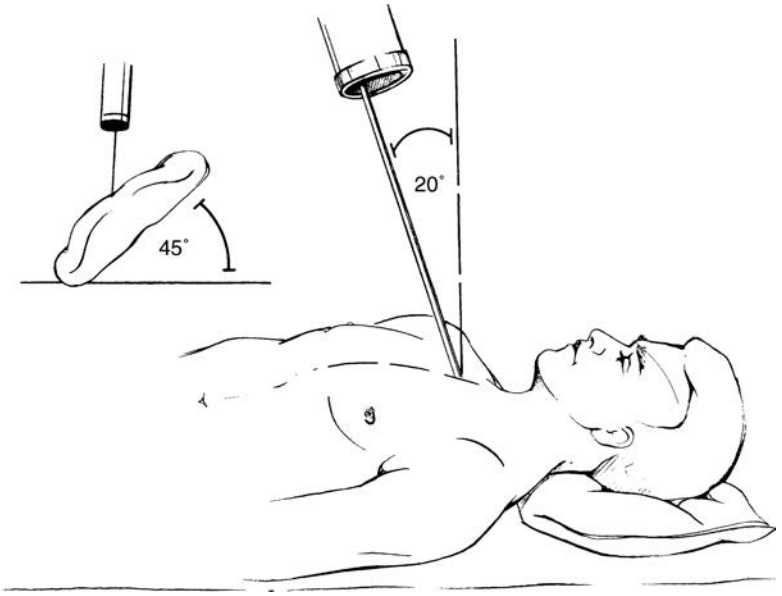

Figure 31-6 The apical oblique view is taken with the involved shoulder angled 45 degrees toward the x-ray source and the x-ray source angled 20 degrees cephalad.

common birth injuries including brachial plexus palsy, fracture–separation of the proximal humeral epiphysis, and fracture of the humeral shaft.[238] High birth weight and shoulder dystocia are clearly associated with an increased risk of all types of traumatic birth injury.[37,45,49,103,104,135,174,238] However, upwards of 75% of neonates with clavicle fractures are the product of a normal labor and delivery and weigh less than 4,000 grams.[42,45,135]

Shoulder dystocia results in a wide separation of the head and shoulder as passage of the shoulder through the birth canal is blocked by the symphysis pubis. This may result in a traction injury to the upper roots of the brachial plexus (Erb's palsy). Fracture of the clavicle may actually protect the brachial plexus by allowing passage of the fetus and decreasing tension on the upper roots.[238] Identification of a clavicle fracture in a neonate that is not moving an upper extremity can be reassuring in that the fracture may explain the findings and generally will heal without long-term sequelae. However, between 1.8% and 5.3%[174,238] of clavicle fractures will have associated brachial plexus injury, and approximately 13% of patients with birth injury to the brachial plexus also have clavicle fractures.[104] Concurrent clavicular fracture apparently does not alter the prognosis of the brachial plexus injury.[4]

The incidence of birth fracture of the clavicle is uncertain as many fractures are asymptomatic and may not be detected. Prospective investigations of consecutive births using either radiography or serial physical examinations have detected birth fracture of the clavicle at an incidence of 1.7% and 2.9%,[135] respectively. The prospective examination of neonates demonstrated that many fractures are not detectable until callus begins to form 1 to 2 weeks following the birth injury. The traditional signs of birth fracture of the clavicle—instability, motion, or crepitus at the fracture site; significant local swelling; and asymmetric Moro reflex—are commonly absent.[135]

Most birth fractures of the clavicle occur during a vertex delivery, although they may also occur with a breech presentation or cesarean section.[238] The anterior shoulder is more commonly involved in most studies. However, in some reviews, the posterior shoulder was more commonly involved [238] and bilateral fracture may also occur. This suggests that both clavicles are subject to compressive forces during delivery as the widest part of the neonate (the shoulders) passes through the birth canal and that either clavicle may fracture, occasionally both.[238]

The level of experience of the obstetrician has been implicated in some studies[49] and found to be unrelated in others.[37] Considering the difficulty making the diagnosis, the benign nature of the injury, and the lack of a clear association with level of experience, the incidence of birth fracture of the clavicle is probably a poor indicator of quality of obstetric care, although it has been used as such.[49,174] It is difficult to assess the risk of forceps delivery because it is now infrequently used and may have simply been associated with more difficult deliveries in prior investigations.[49,174] Most studies demonstrate normal Apgar scores in neonates with birth fracture of the clavicle, indicating that this injury is not associated with postnatal difficulties. On the other hand, at least one study suggests that intrapartum fetal distress may be associated with an increased risk of clavicle fracture as the second stage of labor is iatrogenically shortened by a concerned obstetrician.

Despite a great deal of investigative effort, no reliable risk factors have been determined that distinguish neonates at high risk of birth fracture of the clavicle, and no management recommendations can be made. Recent studies concur that birth fracture of the clavicle may be an

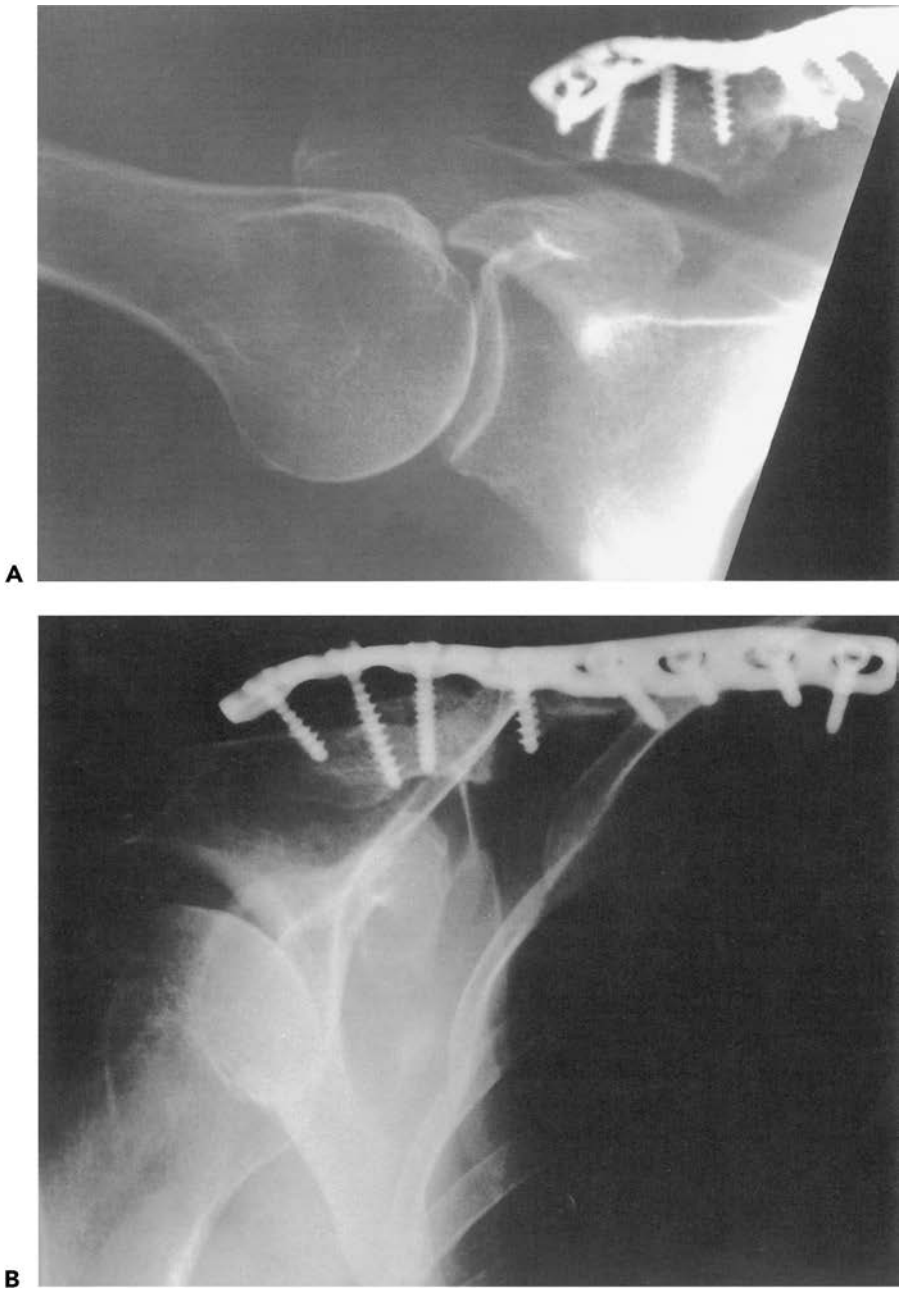

Figure 31-7 The abduction lordotic view **(A)** takes advantage of the rotational motion of the clavicle with abduction of the shoulder to provide an alternative view of the clavicle. This radiographic projection is useful for visualizing the fracture site under the plate, which is often obscured in the routine anteroposterior view **(B).** (From Browner B.D, Jupiter JG, Levine AM, Trafton PG, eds. *Skeletal trauma: fractures, dislocations, ligamentous injuries,* 2nd ed. Philadelphia: WB Saunders, 1998.)

unavoidable, and fortunately inconsequential, complication of normal birth.[45]

Isolated birth fractures of the clavicle heal quickly, remodeling any deformity. Immobilization is probably unnecessary but is commonly used for a brief period to reassure the parents. Careful handling of the infant is the most important measure for reducing discomfort and irritability. If treatment is instituted, a simple, safe method of holding the arm at the side, such as strapping the arm to the trunk with stockinet, a gauze roll, or an elastic bandage with the elbow flexed to 90 degrees and a cotton pad between the arm and trunk, should be used for about a week, after which spontaneous movement should return to the arm indicating that interval healing has increased the stability and decreased the pain associated with the fracture.

Midclavicular Fractures

Nonoperative Treatment

Surviving writings from ancient Greece and Egypt document that for over 5,000 years humans have been concerned primarily with the deformity rather than healing of fractures of the clavicle. In fact, the method of closed reduction of clavicle fractures described in the Edwin Smith papyrus differs little from methods used today.[2,32]

Since that time more than 200 bandaging/strapping techniques have been described.[10,160]

To effect a closed reduction, in most cases the distal fragment must be brought upward, outward, and backward while the medial fragment is depressed. A hematoma block (10 mL of 1% lidocaine injected into the fracture site) can provide adequate anesthesia, but in some cases conscious sedation or general anesthesia may prove necessary. The reduction technique described in the Edwin Smith papyrus,[32] and still commonly used,[261] involves placing a pillow between the shoulder blades of the recumbent patient while the shoulders are spread outward and upward.[32,53,261] Another method for achieving reduction is to bring the shoulders backwards and upwards with the patient in a sitting position while the physician's knee or clenched fist is placed between the shoulder blades to control the position of the trunk.[245,300]

Innumerable devices have been devised in an attempt to effect or maintain closed reduction and thereby minimize the deformity associated with fracture of the clavicle. The majority of these were cumbersome, painful, and even dangerous.[224] Dupuytren in 1839 and Malgaigne in 1859 argued that despite these valiant attempts, deformity of the clavicle was inevitable.[68,69,186] They emphasized the use of the simplest and most comfortable method of treatment, which for Dupuytren consisted of placing the arm on a pillow until healing occurred. It has long been suggested that excellent function can be expected despite residual deformity.[94,95,167,212,245,277] Nonetheless, devices intended for the maintenance of reduction and immobilization of clavicle fractures have remained popular and commonly take the form of either the figure-eight bandage with or without a sling and only on rare occasions a figure-eight plaster (Billington yoke[26]) or a half-shoulder spica cast.[3,245,261,273] Others have followed Dupuytren and Malgaigne in arguing that accurate reduction and immobilization of clavicular fractures is, as stated by Mullick, "neither essential nor possible."[77,78,132,172,212,277] These authors advocate the use of a simple sling for comfort, forgoing any attempts at reduction.

The advantage of the figure-eight bandage is that the arm remains free and can be used to a limited degree. Disadvantages include increased discomfort, the need for frequent readjustment and repeat office visits, and a potential for complications including axillary pressure sores and other skin problems, upper-extremity edema, venous congestion brachial plexus palsy worsening of deformity, and perhaps an increased risk of nonunion.[9,78,94,200,216,255,276,308]

Few investigations have compared treatment with a figure-eight (or reducing) bandage with the use of a simple sling (or supporting bandage).[200] While the details of patient selection and evaluation in these investigations remain unclear based on the data published, these authors found no difference with regard to shoulder function, residual deformity, or time to return to full range of motion and full activity.[9,10,172,200,287]

It is important to emphasize that although the clavicle is one of the most commonly fractured bones, very little in the way of stringent, detailed analysis of clavicular fracture data has been performed. The existing literature regarding nonoperative treatment consists of relatively few series,[52,88,172,277,294] relatively limited studies comparing treatment modalities,[9,200,287] and some technique descriptions,[26,53,115,172,245,300] anecdotal observations,[85,94,224,261] and general reviews.[3,120,121,220–273,257] That conservative management is not always uncomplicated has been reported already by many authors in the past.

Rowe pointed out that injury-related complaints in adults such as pain and injury-caused impediments in the first 3 weeks postinjury are frequently underestimated.[273] On different x-ray series, Mullick showed that the goal of reduction and immobilization in figure-eight bandage was virtually never reached, and that in a few cases displacement actually increased.[212] Petracic et al. proved that with increased tension on the figure-eight sling, venous congestion occurs even before reduction of the fracture.[252] He calls this form of therapy a "symbolic treatment, performed in order to satisfy the patient's need for a decorative bandage." Fowler pointed out in 1968 that figure-eight slings can lead to more problems than the fracture itself due to chafing and pressure in the axilla.[94] In 1982, Piterman reported a painful excoriated axillary wound caused by an overzealously applied figure-eight bandage.[255]

The rates of nonunion with conservative therapy are quoted in the literature with marked variation from 0.3% to 15%.[122,219,273,307] Neer and Rowe reported nonunion rates of under 1% with conservative management of clavicle fractures, however, without differentiating the evaluated patient cohort regarding age and fracture location. Eskola reported a 3% nonunion rate in a predominantly adult population.[85] White et al. reported a 13% nonunion rate and found a correlation with high-energy trauma.[307] Hill et al. assessed nonunion in 15% of his patients and reported a significant correlation with an initial shortening of over 2 cm.[122] Thirty-one percent of their investigated patients were dissatisfied with the outcome of their treatment. In a study of 157 patients, Matis et al. found that half of the cases with clavicular shortening of 1 cm and all cases with clavicular shortening of 2 cm exhibited a significant worsening of shoulder function.[194] A randomized, controlled study investigating whether figure-eight slings really affect healing and function of postclavicular fracture has not yet been completed.

Few reports have attempted to evaluate the relationship between residual deformity and shoulder function.[237] Eskola et al.[85] invited all 118 patients treated for fracture of the clavicle at Helsinki University Central Hospital in 1982 to return for evaluation 2 years following the injury. Among the 89 who presented for the follow-up examination, 24 (27%) had either slight pain on exercise or restricted shoulder movement, with four identified as having

major functional problems. Primary fracture displacement and shortening of the clavicle as compared radiographically with the opposite, uninvolved side at the 2 year follow-up were used as measures of deformity. Among the 15 patients with primary fracture displacement greater than 15 mm at the time of injury, eight (53%) had pain with exercise, whereas only 12 of the remaining 74 patients had pain (16%), a difference found to be statistically significant using chi-squared analysis ($p = 0.02$). Among 47 patients with demonstrable shortening at the final follow-up, 17 (36%) had pain with exercise as compared with 3 of 42 patients (7%) without shortening ($p = 0.02$ by chi-square analysis). Based on these findings, they recommend reduction of deformity associated with displaced clavicular fractures, particularly with regard to shortening. One might question the authors' conclusions based on the simple fact that the more displaced fractures were those associated with higher-energy traumatic injury and might be expected to do worse regardless of residual deformity. The question of which clavicular fractures can be expected to do poorly and why remains uncertain. While the fact that 27% of their patients returning for 2 year follow-up reported problems with pain during exercise or restricted shoulder movement suggests that there may be room for improvement in the treatment of clavicle fractures, we must await more focused and rigidly controlled investigations for data that might alter our approach to treatment (Fig. 31-8).

Operative Treatment

With the development of more rigid implants, there has been some interest in the use of primary operative treatment for clavicle fractures.[149,179,238,242,256,289,315] The good results with open reduction, internal fixation, and bone grafting of clavicular nonunion that have been documented in recent reports also support the contention that internal fixation of the clavicle, when performed properly, should not impede healing.[28,142,188] A number of authors have reported good results using plate fixation of clavicular fractures for open fractures, for fractures with severe angulation that could not be reduced closed, or in multiple traumatic injury, especially in the setting of ipsilateral upper-extremity trauma or bilateral clavicular fracture.[35,149,182,243,289] Kloen et al.[152] favored anteroinferior plating of the clavicle, but biomechanical studies revealed that plates fixed at the superior aspect of the clavicle exhibit significantly greater stability than those on the anterior aspect.[125] Whether the new locking compression plates provide advantages due to biomechanical stability is not yet clear. In particular, scapulothoracic dissociation and the so-called floating shoulder, representing a combination of displaced clavicular and glenoid neck fractures, are felt to be important indications for open reduction and plate and screw fixation of the clavicular fracture.

Khan and Lucas noted no nonunions among 19 patients treated with primary plate fixation.[149] Schwartz and Hocker[289] used 2.7-mm plates and reported nonunion in 3 of 36 patients, which they attributed to using a plate of inadequate length. Poigenfürst et al.'s extensive experience with plate fixation of fresh clavicular fractures identified nonunions in 5 of 122 patients (4.1%) treated operatively.[256] They also related these failures to technical errors including the use of a plate of inadequate length or strength or devitalization of fracture fragments during operative exposure.

External fixation has also been used for fixation of the clavicle. In a study by Schuind et. al.,[280] good results were obtained in 15 fresh midclavicular fractures and in five delayed unions. However, considering the rarity of severe soft tissue injury in this area, the role of external fixation remains unclear.[59]

Within the past few years several publications have described poor outcomes after conservative treatment of severely displaced midclavicular fractures. It has been reported that between 10% and 30% of patients had clinically, radiographically, and subjectively unsatisfactory results because of shoulder shortening,[18,75] nonunion,[49] or impaired function.[49] However, surgical procedures have also been associated with poor cosmetic results and higher incidences of nonunion and refracture when compared with conservative treatment. Therefore, surgery should be done only in specific situations.[16]

The standard treatment in surgical therapy of midclavicular fractures is plate fixation. To avoid breakage of the implant, the plate that is used must be relatively large compared with the bone size. A large incision causing additional soft tissue damage is necessary to position this implant, most commonly a small dynamic compression plate or a small reconstruction plate. Typical complications of plate fixation are infection, hypertrophic scars, implant loosening, nonunion, and refracture after hardware removal.[139,149]

From a biomechanical point of view, intramedullary positioning of the implant is ideal.[259] The diameter of the titanium (Ti) nail Jubel et al.[149] used for intramedullary fixation was small; however, no implant displacement or material breakage occurred. Because of anatomic features of the clavicle, devices for intramedullary fixation need to be flexible. Besides the need for flexibility, the implant needs to be stable enough to neutralize the potential disruptive forces acting on the fracture after stabilization. The implant also has to be small enough to enable its passage through the medullary space, which is narrow, especially in the middle third of the clavicle.[8]

Several authors have described various modifications of intramedullary stabilization.[22,23,29,30,34,38,39] Jubel et al.[136,141] performed a study using elastic stable intramedullary fixation for clavicle fractures (Fig. 31-9). In this study, patients showed significant improvement of shoulder function and

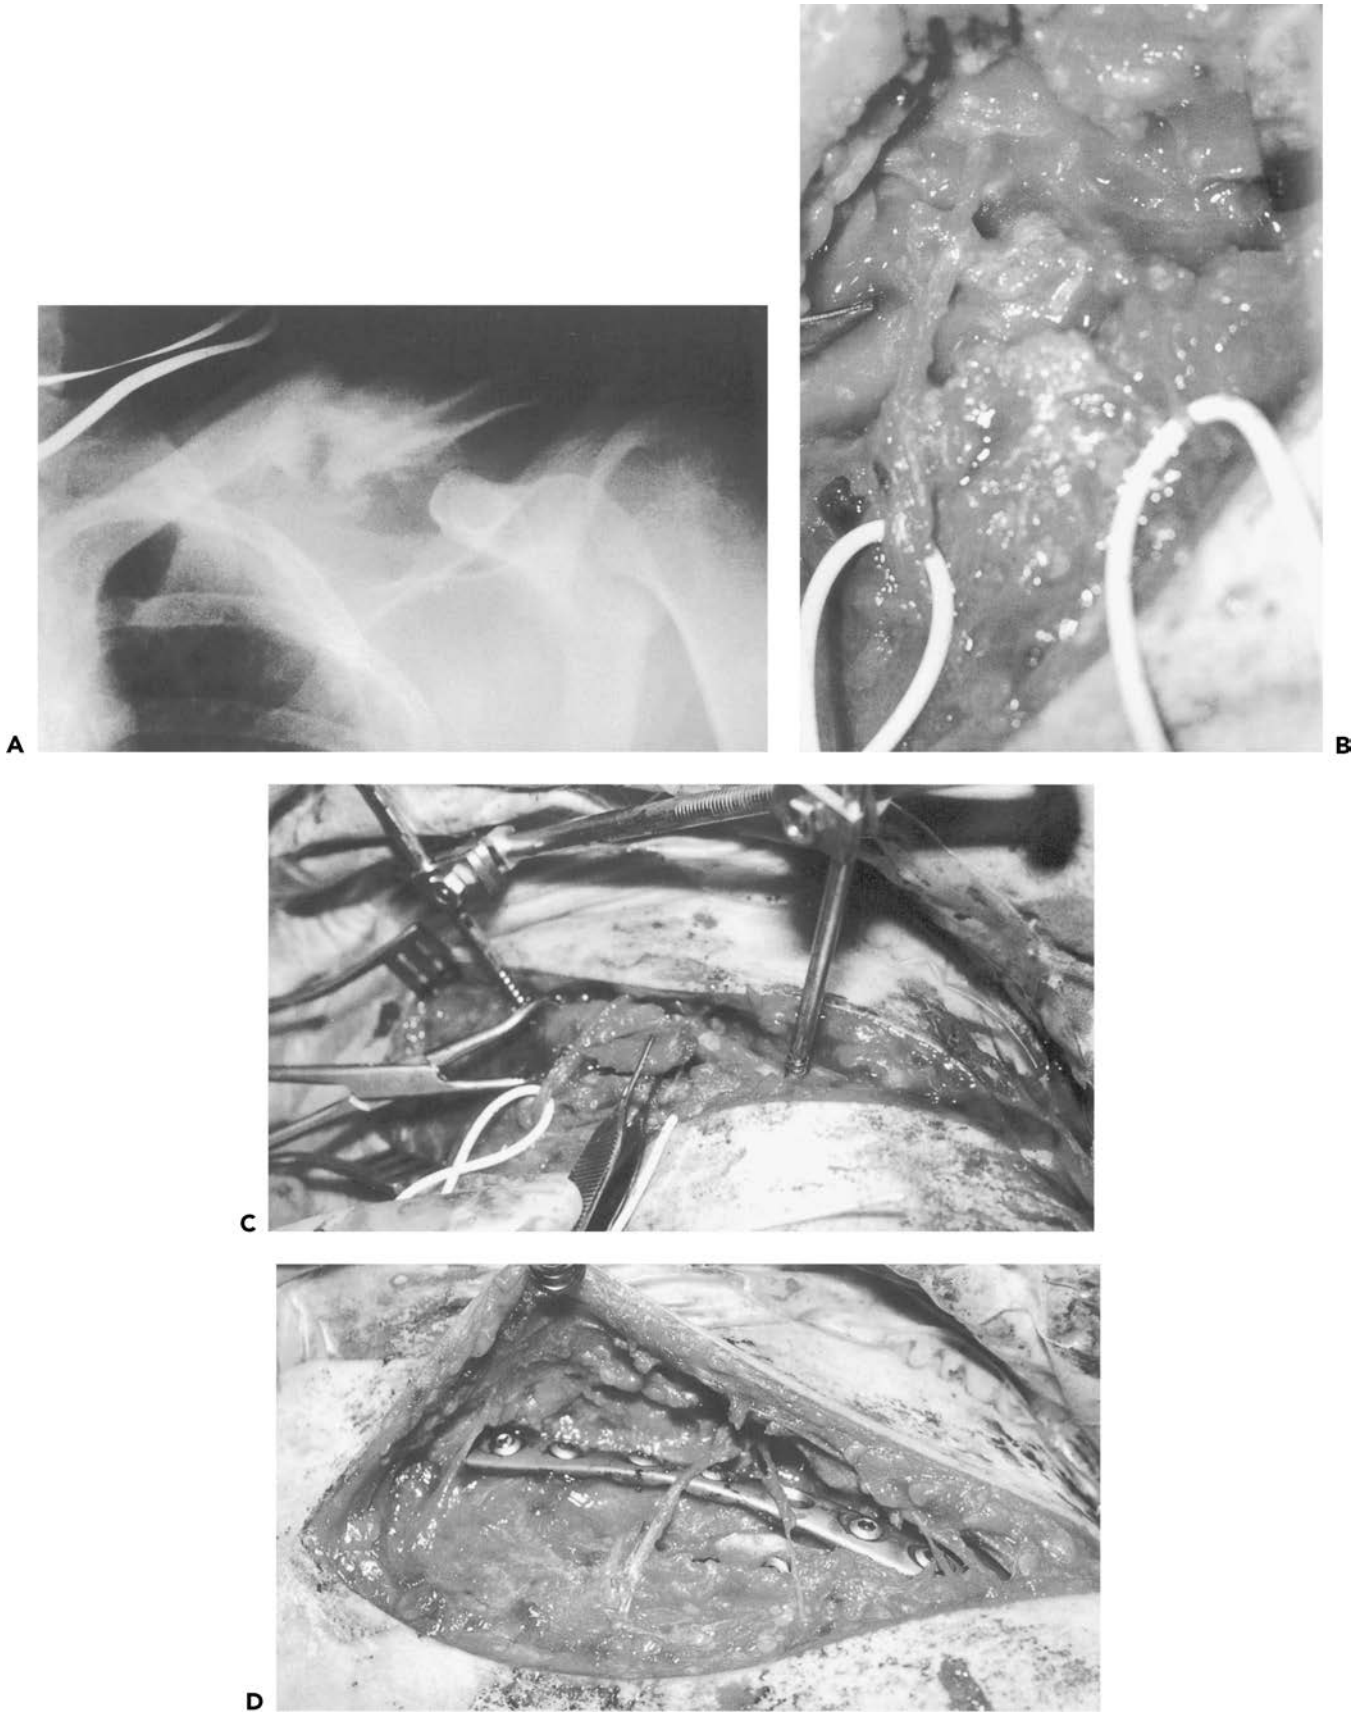

Figure 31-8 A 30-year-old male presented with an ununited fracture of the clavicle associated with excessive callus formation. reduction of pain on day 3 postoperatively, compared to the day prior to surgery. Even patients with bilateral fractures were able to do daily activities without assistance immediately after surgery.

Patients with additional injuries to the lower extremity were able to walk with crutches within the first week after surgery, enabling early mobilization. The original length of the clavicle was restored in all patients but one. Objectively and subjectively, good cosmetic results were achieved using this technique. All patients but one had good biologic fracture healing, so there was no refracture. Because of reduction and stabilization, excessive callus formation, typically seen after conservative treatment, was prevented and the shape of the long bone was restored. The incidence of nonunion was lower compared with the nonunion rate of similar displaced fractures after conservative treatment, plate fixation, or other intramedullary techniques.[17,32,37] These results showed that intramedullary fixation of displaced midclavicular fractures with a flexible Ti nail is a safe, minimally invasive surgical technique, producing excellent functional and cosmetic results compared with plate fixation or conservative treatment. Intramedullary nailing of displaced midclavicular fractures is an alternative treatment to conservative procedures or plate fixation in patients with markedly displaced midclavicular fractures, multiple trauma, fractures of the lower extremities, or associated shoulder girdle injuries.

Author's Preferred Treatment

Nondisplaced and minimally displaced fractures of the midclavicle require little more than symptomatic treatment. This is best achieved with a simple sling, which can be supplemented by a swathe component if necessary for added comfort early in postinjury. The majority of these nondisplaced fractures will be encountered in children who will heal quickly, and although they may not be compliant with sling wear, they usually self-regulate their activity level until healing has progressed and merely require gentler handling during the healing period. The clavicle typically heals sufficiently to discontinue immobilization within 3 to 4 weeks in young children, 4 to 6 weeks in older children, and 6 to 8 weeks in adults. Limitation of activity is usually encouraged for a minimum of 8 weeks following clinical and radiographic union to reduce the risk of refracture.

The optimal treatment of displaced and comminuted fractures of the clavicle is disputed. Wide displacement and soft tissue interposition have been implicated as risk factors for the development of nonunion,[128,142] and at least one study has suggested that residual deformity may alter function.[88] Open reduction and internal fixation of so-called irreducible fractures of the clavicle has been reported with good results.[35,144,149,242,289,315] Our opinion is that displacement should no longer be used as the most important decision criterion for or against surgery. It is an invalid parameter and very difficult radiographically to objectively report (see Diagnosis). The patients themselves should be more involved in making the decision, and should make that decision together with the physician after detailed description of the advantages (pain reduction, immediate sling-free exercise stability) and risks of operative treatment are explained. The physical and vocational activities of the patient must also be considered for this decision.

However, further work is needed to determine the following: (a) What is the percentage of displaced midclavicular fractures that will go on to nonunion, and is it high enough to consider routine operative treatment? and (b) Does the potential loss of function related to persistent deformity justify the risks of routine operative intervention?

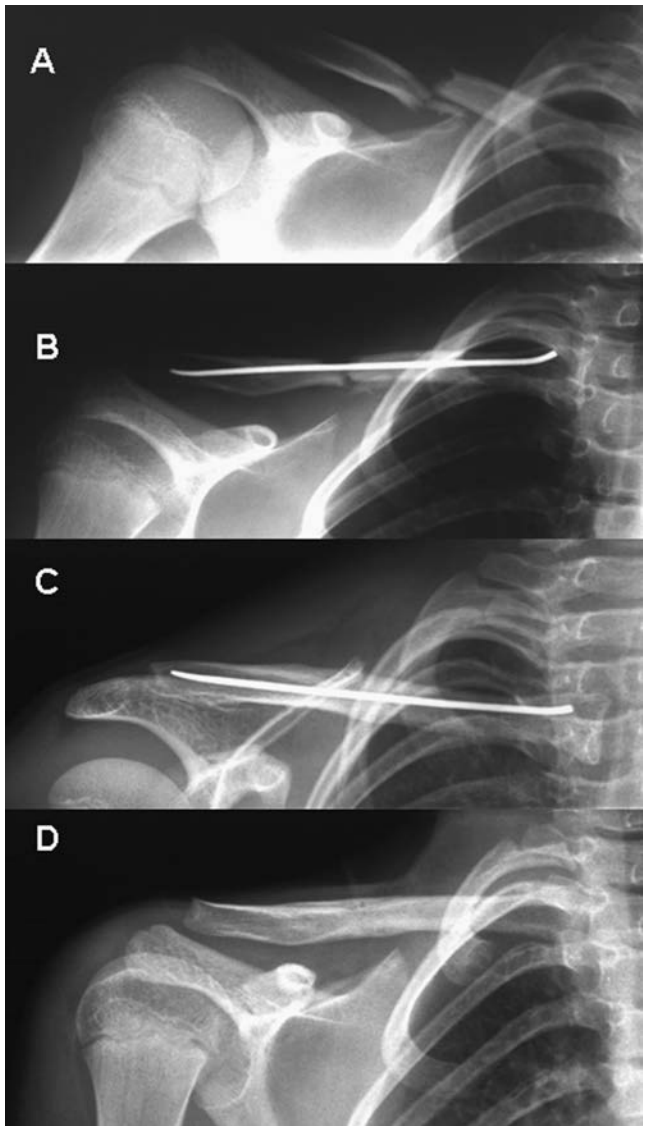

Figure 31-9 A professional 13-year-old motocross driver had a fall during a contest: **(A)** preoperative x-ray; **(B)** postoperative x-ray; **(C)** x-ray 6 weeks after the operation; and **(D)** x-ray after hardware removal. One week after the operation, he resumed the training on his motocross. In the second postoperative week, he participated again in a contest and, in the third week, became German Champion in his division. The definitive indications for primary surgical intervention that we would consider are uncommon and include open fracture, scapulothoracic dissociation,[76,77,166] so-called floating shoulder injuries,[102,120,121,268] and associated major vascular injury in which an open approach will be necessary for vascular repair. While isolated fractures of the sternal end or middle third of the clavicle do well with nonoperative treatment, complex clavicular injuries involving dislocation or epiphyseal separation at one end of the clavicle in combination with a fracture of the middle third would probably benefit from open reduction and internal fixation.[81,112,165,170,297,311] Likewise, the rehabilitation of associated ipsilateral upper-extremity trauma may be facilitated by operative fixation of the clavicle. In the absence of these indications, nonoperative treatment remains our preference.

It is often stated that when the skin is threatened by pressure from a prominent clavicular fracture fragment, then closed reduction and internal fixation should be considered. Actually, it is extremely rare that the skin will be perforated from within.[263] However, in the head-injured patient, operative stabilization may be required.

The merits of open or closed reduction and operative fixation in the setting of neurovascular compromise are also unclear. Certainly, when an open approach for vascular repair is required, internal fixation of the clavicle should be performed, but fortunately acute neurovascular injury is rare in association with clavicular fracture.[96] The most frequent vascular disturbance encountered is venous congestion of the arm, which, in the absence of deep venous thrombosis, aneurysm, or pseudoaneurysm, can be treated expectantly.

Acute injury to the brachial plexus is extremely uncommon following fracture of the clavicle, and when present, is more likely to be the result of a traction injury to the upper roots of the brachial plexus. What may prove to be an indication for operative intervention is a plexopathy, which develops in relation to abundant callus in a malaligned fracture presenting at a time remote from the injury. In these instances, open realignment, reduction of callus bulk, and internal fixation of the fracture should be considered (Fig. 31-10).[302]

When performing closed or open reduction and internal fixation of the clavicle, we prefer minimally invasive intramedullary nailing with a 2.0- to 3.5-mm titanium nail (Prevot nail) for closed clavicular fractures (CCF) type A and B, and fixation with plate and screws for CCF type C fractures. Given the fact that intramedullary fixation of the clavicle is technically difficult owing to the curvature, high density, and small intramedullary canal of the bone, it is remarkable that good results with this technique have been observed.[28,41,136,137,139–141]

Our technique for internal intramedullary fixation of the clavicle is as follows: Patients are positioned on a radiolucent operating table in the supine position. A skin incision of 1 to 2 cm is made just above the sternal end of the clavicle. Approximately 1 cm distal to the sternoclavicular joint, a hole is drilled into the ventral cortex of the medial end of the clavicle with a 2.5-mm drill and widened using an awl. The Ti nail, 2.0 to 3.5 mm, is fixed in a universal chuck with a T-handle. With oscillating movements of the surgeon's hand the unreamed Ti nail is advanced until it reaches the fracture site. To ensure correct placement of the nail, fluoroscopic control is used for reduction and insertion of the nail into the lateral fragment. If closed reduction fails, an accessory incision of 3 to 4 cm is made above

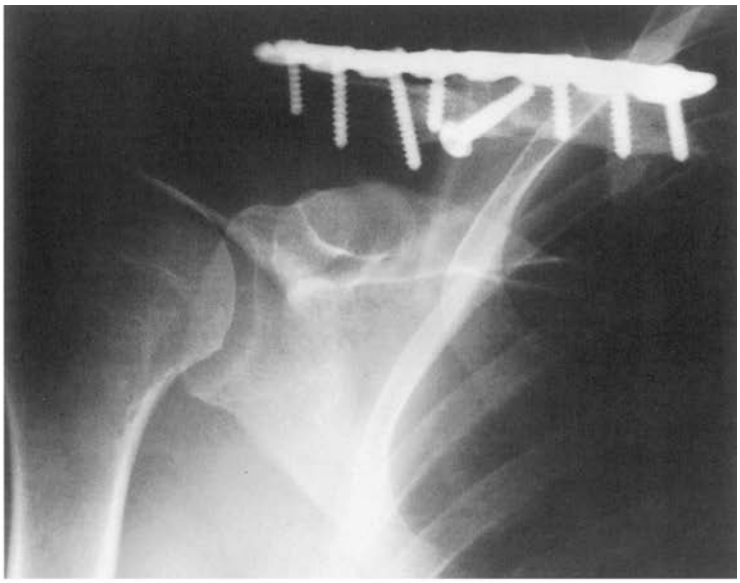
Figure 31-10 Operative technique for plate fixation of the clavicle. **(A)** The patient is positioned in the beach-chair position. **(B)** Incision of the skin is chosen to respect the relaxed skin tension lines. **(C)** The supraclavicular nerves are identified under loupe magnification and protected. Schantz screws are placed medial and lateral to the fracture site. **(D)** A small distractor is used to restore the length and alignment of the clavicle. When comminution results in a bony defect after anatomic reduction, an autogenous iliac crest autograft is applied. **(E)** The clavicle is stabilized using a 3.5-mm limited contact dynamic compression plate.



F

G

Figure 31-10 (*continued*) **(F)** When the fracture pattern allows, an interfragmentary lag screw is used to obtain compression between the fracture fragments. **(G)** Hypertrophy of the scar is uncommon. (From Browner, Jupiter, Levine, Trafton, eds. *Skeletal trauma: fractures, dislocations, ligamentous injuries,* 2nd ed. Philadelphia: WB Saunders, 1998.)

the fracture site to enable direct manipulation of the fragments. Additional fragments are maintained in their positions, maintaining soft tissue connections. The protruding end of the nail is cut off at the site of its insertion.

For postoperative treatment, patients are instructed to mobilize the affected extremity. Postoperative immobilization is not performed. Physical therapy is prescribed for patients with multiple trauma or accessory injuries.

Our technique for internal plate fixation of the clavicle is as follows:[142,178] We apply a 3.5-mm limited contact dynamic compression plate (LCDC Plate, Synthes, Paoli, Pa.) or the locking compression plate (LC Plate, Synthes, Paoli, Pa.) to the anterior or superior aspect of the clavicle. A minimum of three screws should be placed in each major fragment. When the fracture pattern allows, an interfragmentary screw will greatly enhance the stability of the construct. In the presence of fracture comminution or gaps in the cortex opposite the plate, we recommend the addition of a small amount of autogenous iliac crest cancellous bone graft.

We prefer to close the wound over a suction drain, ensuring meticulous hemostasis. If the skin condition allows, wound closure is accomplished in an atraumatic fashion with a subcuticular suture. These measures will reduce the incidence of wound hematoma and promote cosmetic wound healing.

Our current practice, provided we are confident with the security of fixation, is to use a sling for patient comfort during the initial 7 to 10 postoperative days. The sling may be removed for short periods of passive shoulder pendulum and overhead elbow-flexion range-of-motion exercises without resistance, which are continued until fracture union has been demonstrated, which usually occurs between 6 and 8 weeks postoperatively. Thereafter, progressive strengthening exercises are permitted, and full overhead activities are gradually resumed. A return to all occupational duties and recreational pursuits is usually possible by 3 months after operative treatment.

In most cases, plate removal is unnecessary; on occasion, however, hardware may cause skin problems due to its prominence. In those instances, we remove the plate, provided a minimum of 12 to 18 months have elapsed since the injury and the cortex under the plate has reconstituted as viewed from an apical lordotic projection.

Distal Clavicular Fractures

Fractures of the distal clavicle with little or no displacement are treated symptomatically with a sling. While some cases of nonunion following such fractures have been reported,[227,263] the chance of this occurrence is extremely low.

Displaced distal clavicular fractures, on the other hand, are recognized as the only general type of clavicle fracture for which routine primary operative treatment should be considered. This is based on the work of Neer[216,218] and others[79,228] who have found that between 22% and 33% of these fractures will fail to unite following nonoperative treatment. An additional 45% to 67% will require more than 3 months to heal the fracture.

A number of surgeons have reported healing in 100% of operatively treated displaced lateral clavicle fractures within 6 to 10 weeks after surgery, with few associated complications. The period of disability in these cases was shortened, with a relatively rapid return to full shoulder mobility and function.[79,100,218,228] Other authors have reported acceptable results with nonoperative treatment,[204,205,269] stating that those few nonunions that become symptomatic can be treated with a reconstructive procedure at a time remote from the injury if necessary.

Neer recommended stabilization of displaced distal clavicular fractures using two Kirschner wires to control rotation. The wires are first passed into the distal fragment from proximal to distal through the fracture site, crossing the acromioclavicular joint and exiting the acromion and the skin on the lateral aspect of the shoulder. The protruding part of the wires is then engaged and advanced proximally across the fracture site and into the medial fragment. The wires are then bent to decrease the risk of migration, and are cut beneath the skin. Shoulder motion must be restricted to prevent pin breakage and migration. Others have used a single wire,[119,247,273] threaded wires,[119] or screws,[220,222,223] and some have made a point of avoiding the acromioclavicular joint. Caution was urged in a recent report by Kona et al., who noted high rates of both nonunion and infection with transacromial wire techniques.[158]

Alternative techniques for operative fixation of distal clavicular fractures include coracoclavicular screw fixation[11] or transfer of the coracoid to the clavicle.[43,110] A combination of coracoclavicular ligament reconstruction and wire fixation of the fracture fragments,[44,175] a transacromial Knowles pin fixation,[91] or a hook plate fixation[74,93,105,207,273] have also been described. The AO/ASIF group has recommended using a tension band wire construct with two Kirschner wires, which enter on the superior aspect of the clavicle, avoiding the acromioclavicular joint.[118,281] In addition, they also suggest consideration of a small plate, either a small T-shaped plate or a hook plate, and occasionally direct one of the screws into the coracoid as described by Bosworth.[11,29] A specially designed plate that is contoured so that its distal limit curves under the acromion through the acromioclavicular joint has also been utilized.[116,274]

We prefer to use a tension band wire technique. The distal clavicle and acromion are exposed through an incision in the relaxed tension lines of the skin with the development of thick flaps. Provisional fracture reduction can be held with a transacromial Kirschner wire. Definitive fixation consists of two stout smooth Kirschner wires passed through the outer edge of the acromion and crossing obliquely across the acromioclavicular joint and fracture to purchase in the solid cortex of the dorsal clavicle medial to the fracture. An 18-gauge wire is then looped through a drill hole medial to the fracture and around the tips of the wires, which are bent 180 degrees, turned downward, and impacted into the acromion (Fig. 31-11)

If a tear in either the trapezoid or conoid ligaments is identified, an attempt is made to perform a suture repair. The wound is closed over a suction drain. The postoperative management differs from that for midclavicular fractures in that patients are maintained in a sling for a minimum of 4 to 6 weeks.

Medial Clavicular Fractures

Little exists in the literature about fractures of the medial clavicle. These fractures are very uncommon and most surgeons have limited experience with them. The literature offers little more than case reports, the majority of which describe medial physeal separation injuries. While some authors recommend open reduction and internal fixation, the majority advocate nonoperative treatment initially with resection of the medial clavicle if symptoms persist.[3,136,143,176,258] Considering the risks attendant with implant insertion and migration in this region, we rarely consider operative treatment. The generally good results of nonoperative treatment are related to the

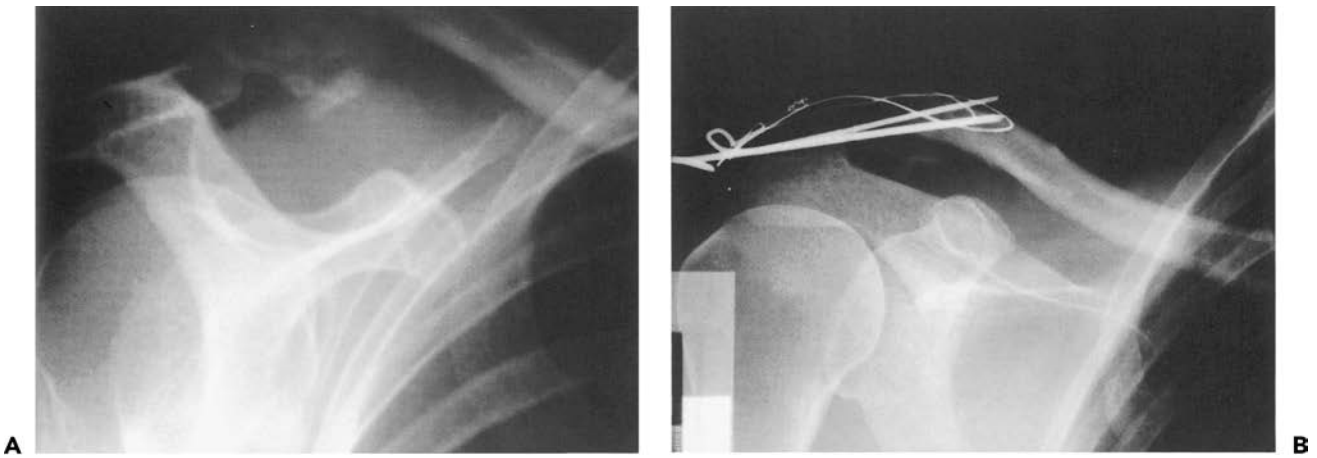


Figure 31-11 **(A)** A 55-year-old female sustained a comminuted type II fracture of the distal clavicle in a motor vehicle accident. **(B)** Fixation was achieved using two transacromial Kirschner wires exiting through the thick dorsal cortex of the medial fragment in combination with a tension band wire. (From Browner, Jupiter, Levine, Trafton, eds. *Skeletal trauma: fractures, dislocations, ligamentous injuries,* 2nd ed. Philadelphia: WB Saunders, 1998.)

fact that fractures of the sternal end of the clavicle are often physeal separations that heal with stability and may even remodel somewhat. Displaced fractures must be evaluated with computed tomography scanning to be certain that posterior displacement of the fragments does not present a threat to neurovascular structures at the base of the neck.

Floating Shoulder

Floating shoulder is an unstable combination of fractures that involves the scapular neck and the ipsilateral midclavicle, and it requires surgical treatment. According to Herscovici et al.,[120] floating shoulder is a rare injury with an incidence of approximately 0.1% in all patients with fractures. They also reported that functional disorders sometimes remain when only the fracture of the clavicle is diagnosed, the fracture of the scapula is missed, and conservative treatment is performed. Floating shoulder is an unstable injury that is likely to displace as a result of muscle strength and upper-limb weight, and for which surgical treatment is considered to be appropriate. If the patient is treated conservatively, where sufficient reduction and maintenance of reduction are difficult to assess, nonunion and/or malunion will occur, breaking down the suspension mechanism of the clavicle and leading to a drooping shoulder. Leung et al.[173] reported that open reduction and plate fixation procedures are necessary for both fractures of the scapula and the clavicle. On the other hand, Herscovici et al.[120,127] reported that, if the clavicle is fixed by open reduction, an unstable fracture becomes stable, resulting in bony union for both fractures; therefore, plate fixation of only the clavicle is sufficient to correct a floating shoulder.[114]

COMPLICATIONS

Nonunion and Malunion

The percentage of nonoperatively treated clavicular fractures that fail to heal within 6 months of injury has been reported variously as 0% (of 342 patients),[277] 0.1%,[216] 0.47%,[120] 0.8%,[239] 0.9%,[144] and 2.2%.[84,88] White et al. reported that they had encountered eight nonunions (8%) and 18 delayed unions (16%) among 112 adult fractures of the clavicle proximal to the coracoid, the majority occurring as a result of a high-energy traumatic injury.[307] Proposed risk factors for nonunion based on series of patients presenting with nonunion include the severity of the initial trauma,[24,95,134,276,309] fracture comminution, and refracture. Jupiter and Leffert,[142] as well as others,[188,202] found that the degree of fracture fragment displacement was the most important risk factor for nonunion. These risk factors often are interrelated and reflect more severe soft tissue injury, decreased stability, and limited apposition of fracture fragments. The role of soft tissue interposition remains unclear.[129,188] The fact that midclavicular nonunion is far more common than distal clavicular nonunion has been ascribed to the fact that midclavicular fractures are far more common overall. Primary operative treatment of fractures of the clavicle has been associated with a risk of nonunion (3.7% according to Rowe[273] and 4.6% according to Neer[219]). While contemporary series report high union rates with internal fixation of fresh clavicular fractures,[35,79,315] they identify improper technique including utilization of too small or too short a plate and excessive soft tissue stripping as reasons for operative failures[256,281] (Fig. 31-12).

On occasion a clavicular nonunion may be asymptomatic and discovered incidentally on a chest radiograph.[134]

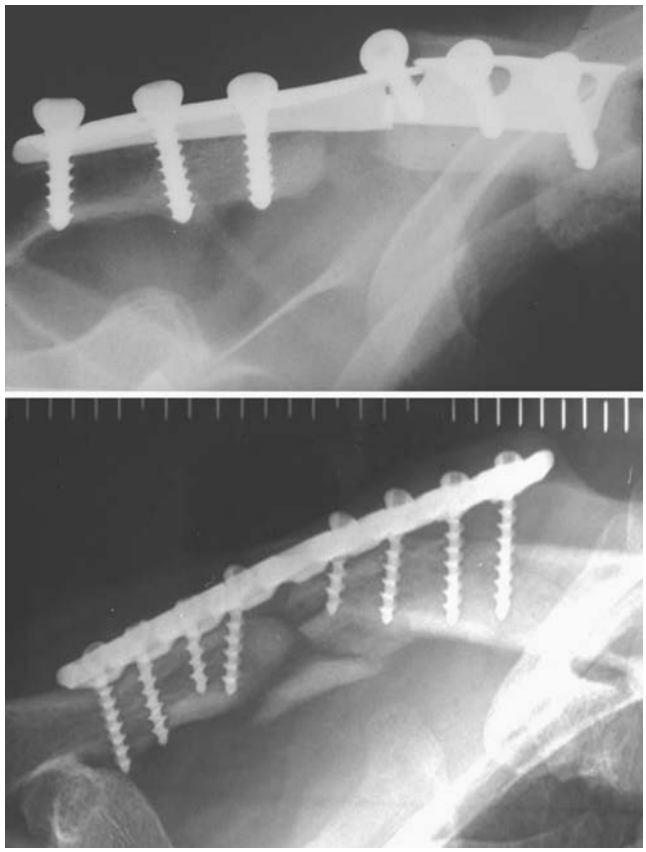

Figure 31-12 Implant loosening and nonunion are typically related to inadequate plate size and length. (With kind permission from Prof. Klaus Emil Rehm and Dr. Axel Jubel.)

Prior to more reliable means of internal fixation, some authors[134,309] recommended against operative intervention. In fact, patients presenting with an ununited clavicle are more likely than not to have specific complaints regarding increasing deformity, consisting of adduction, shortening, and protraction of the shoulder girdle. Altered shoulder function occurs as a result of the deformity, pain, or local compression of the underlying brachial plexus or vascular structures.[142,285] Occasionally patients will present decades after the original injury requesting treatment.[142,309] Unfortunately, this may be partly due to the fact that these patients had been advised previously that nothing operative could or ought to be done (Fig. 31-13).

The neurovascular problems that may accompany clavicular nonunion include thoracic outlet syndrome,[13,19,31,51,89,210,254,289] subclavian artery or vein compression[62,159] or thrombosis,[62,106,312,313] and brachial plexus palsy.[40,65,142] The prevalence of neurovascular dysfunction in patients presenting with clavicular nonunion has varied widely in reported series from as few as 6% to as many as 52% of patients.[134,142,157,309]

In the treatment of clavicular nonunions, we prefer to distinguish between reconstructive procedures in which the goals of both relief of pain and neurovascular compression as well as enhanced function are sought via restoration of the length, alignment, and continuity of the clavicle; and salvage procedures in which the clavicle is either resected, contoured, or avoided altogether (i.e., first rib resection[61]) with the limited goal of relieving symptoms. Although treatment of clavicular nonunion with electrical stimulation has been attempted,[34,50,51,63] there are few indications for its use. Symptomatic clavicular nonunion typically has elements of both shoulder deformity and dysfunction as well as neurovascular compromise that are not addressed by electrical treatment,[213] and the union rates do not approach those obtained by open reduction and internal fixation with provision of an autogenous bone graft.

With the advent of improved techniques of stable fixation, the results of reconstructive procedures have improved to the point that salvage operations are now largely of historical interest.[202,285] The only situation in which we would consider partial resection of the clavicle is in a chronically infected clavicle in a medically compromised patient or in a very distal clavicular nonunion. A small distal clavicular fragment can be resected and the coracoclavicular ligaments securely attached to the outer end of the medial fragment.[285]

The treatment of clavicular nonunion has evolved from the screw fixation of tibial or iliac crest bone grafts used by early authors,[16,98,276] to intramedullary fixation,[111,134,181] which seems to be a good alternative technique to plating,[28,41] to plate and screw fixation.[105,142,157,192] One of us treated 29 hypertrophic malunions of the clavicle with intramedullary nailing (as described above; study is currently being published). Twenty-five cases required an additional incision over the fracture to cannulate the medullary canal with a 3.5-mm drill. The bone shavings produced from debulking the callus, with or without additional cancellous bone graft, facilitated bony healing. In all cases, however, the patient was additionally informed and consented for plate fixation with cancellous bone grafting, since it is often decided intraoperatively that conventional plate fixation is necessary. Our preference for plate fixation and our operative technique and rehabilitation protocol are described previously under Author's Preferred Treatment. A few points regarding the treatment of midclavicular nonunions deserve further discussion.

In hypertrophic nonunions, the exuberant callus can be resected and saved for use as bone graft, making harvest of an iliac crest graft unnecessary in some cases. The nonunion site does not require débridement, as the fibrocartilage will progress to union following stable internal fixation. If the fracture line is oblique, it is sometimes possible to secure the fragments using an interfragmentary screw in addition to the superiorly placed plate.

Atrophic nonunions present sclerotic ends with interposed fibrous tissue while pseudoarthroses will have a false synovial-lined cavity. Resection of the ends of the

Figure 31-13 A 56-year-old woman presented with complaints of increasing shoulder pain, stiffness, and deformity after injuring her clavicle at age 14. **(A)** An anteroposterior radiograph demonstrated an ununited fracture of the clavicle with widely displaced, atrophic fragments. **(B)** The supraclavicular nerves were identified under loupe magnification and protected throughout the operative procedure. **(C)** A distractor was used to restore the anatomic length and alignment of the clavicle and a tricortical bone graft from the iliac crest was used to bridge the residual bony defect. **(D)** One of the screws through the plate transfixes the bone graft. (From Browner, Jupiter, Levine, Trafton, eds. *Skeletal trauma: fractures, dislocations, ligamentous injuries,* 2nd ed. Philadelphia: WB Saunders, 1998.)

fracture fragments and the intervening tissue is required in both situations. In this situation a small distractor often proves invaluable in helping to control the fragments as well as to attain the desired length and alignment. A sculptured tricortical iliac-crest bone graft will be useful to ensure restoration of length and alignment and to promote healing.

We harvest the iliac graft from the crest through an oblique incision along the midpoint of the ilium. The crest is exposed subperiosteally and a tricortical section, measuring one and one-half times the anticipated size of the final graft, is removed with either osteotomes or a small oscillating saw. The graft is then sculptured to create large cancellous pegs at each end, which plug into the medullary canals of the clavicular fragments (Fig. 31-14).

This interdigitation increases the stability of the construct and facilitates plate fixation. The graft is positioned so that the dorsal cortical margin of the iliac crest lies on the inferior surface of the clavicle, affording the advantages of better purchase of a screw as well as more resistance to bending forces at the nonunion site. Additional cancellous graft from the iliac crest is compacted into the medullary canals of each fragment prior to the final impaction of the corticocancellous segmental graft.

A 3.5-mm limited contact dynamic compression plate (Synthes, Paoli, Pa.) is then applied with a minimum of three screws in each major fragment and a single screw transfixing the graft. Compression is applied to both surfaces of the graft to enhance its incorporation. The wound is closed with a subcuticular suture over suction drainage.

Malunion has traditionally been considered primarily a cosmetic concern.[224] However, it is not surprising that some reports exist of difficulties in shoulder function in patients with overriding of clavicular fragments.[84,85,88] In addition, compression of underlying neurovascular structures has been reported in association with malaligned clavicle fractures due to narrowing of the costoclavicular space and compression of the brachial plexus and subclavian artery or vein. Malunited fractures typically may give rise to neurovascular symptoms weeks or months following the injury due to proliferative callus.[13,50,51,89,264]

The senior author (JBJ) has treated four patients with malunited clavicular fractures for deformity associated with ipsilateral glenohumeral dysfunction either alone or in combination with scapulothoracic dysfunction (unpublished series). The malunion was osteotomized through the plane of deformity, realigned using a small distractor, and secured with a plate and screws. In each case, function was improved and the outcome deemed satisfactory (Fig. 31-15).

Some patients are unhappy with the appearance of their healed clavicular fractures due to a prominent bump at the apex of the deformity. These patients should be advised that an operation to smooth the contour of the deformity would essentially trade a bump for a scar. There is a risk that the scar could be hypertrophic and more unsightly than the bump. Furthermore, the removal of bone places the clavicle at an increased risk for refracture.

Neurovascular Complications

Acute neurovascular complications are rare and typically occur in association with scapulothoracic dissociation[56,123,215] or are unrelated to the clavicular fracture (e.g., brachial plexus traction injury).[123,169] Neurovascular dysfunction as a result of narrowing of the thoracic outlet can occur within the first 2 months of injury when the fracture is malaligned or many months or even years later as a result of hypertrophic callus in the setting of nonunion.

Further mention should be made here of thrombosis and pseudoaneurysm of the subclavian or axillary artery or subclavian vein presenting at a time remote from the injury. Cases of axillary or subclavian artery thrombosis presenting late with symptoms of atrophy and cold intolerance of the involved upper extremity most likely represent missed acute intimal injury,[123,128,283] but may also result from compression in a narrowed costoclavicular space.[295] Cerebral embolism has been reported following subclavian artery thrombosis in this setting.[312]

True aneurysms of the subclavian artery may occur as poststenotic aneurysms when the costoclavicular space is narrowed.[64,395] Displaced clavicular fracture fragments may very rarely cause a small perforation injury of the subclavian artery. Occasionally a pseudoaneurysm develops that may present months to years later with brachial plexus dysfunction due to compression.

Neurovascular symptoms related to compression by hypertrophic nonunion have been mistaken for sympathetically maintained pain (shoulder–hand syndrome) in the past. Damage to the supraclavicular nerves can cause anterior chest wall pain.[259]

Complications of Operative Treatment

Despite the proximity of important anatomic structures beneath the clavicle, intraoperative complications are rare. Eskola et al. reported tearing of the subclavian vein, pneumothorax, air embolism, and brachial plexus palsy all in a single patient during dissection of a clavicular nonunion.[84,151] On the other hand, wires and pins show a remarkable ability to migrate once inserted[182] and may ultimately be found in the abdominal aorta,[213] ascending aorta,[225] and pericardium causing fatal tamponade[46]; the pulmonary artery[174]; the mediastinum[38]; the heart[248]; the lung[199,207,267] (sometimes the opposite lung[267]); or the spinal canal.[232] A patient presenting to Kremens and Glauser[161] brought in a Steinman pin that he reported having expectorated 1 month following fixation of his medial clavicular fracture.

(From Browner, Jupiter, Levine, Trafton, eds. *Skeletal trauma: fractures, dislocations, ligamentous injuries*, 2nd ed. Philadelphia: WB Saunders, 1998.)

Poigenfürst et al. documented superficial infections in 9 (7.4%) and deep infections in 2 (1.6%) of 122 patients undergoing plate fixation of fresh clavicular fractures,[256] but other authors have had little trouble with infections following plate fixation.[35,141,142,188,242] Many authors cite hypertrophic scar formation as one of the potential complications of operative treatment of clavicular fractures,[147] particularly the proponents of intramedullary fixation who advocate a more oblique incision in alignment with Langer's lines.[220,222,223] We have had no particular problem with cosmetically displeasing scars.

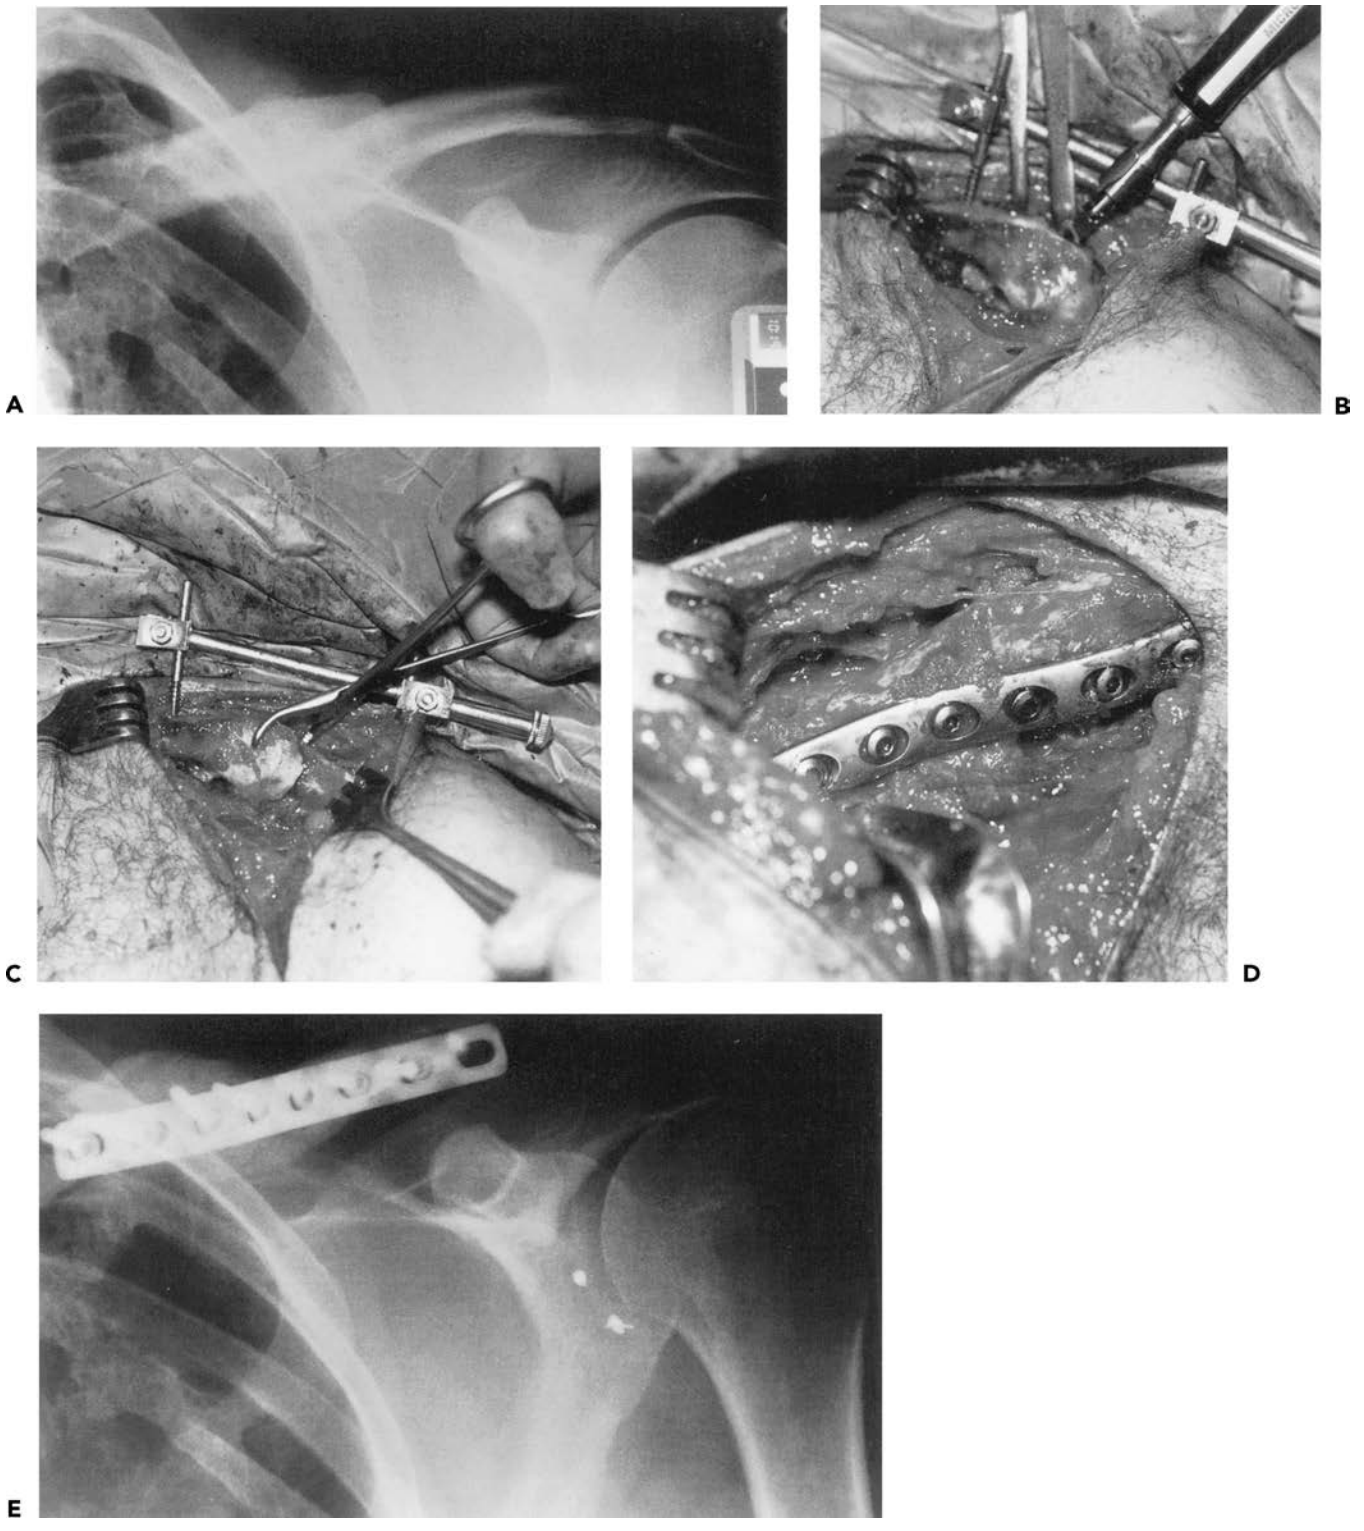

Figure 31-15 A 35-year-old male presented with complaints of restricted shoulder motion, weakness, and discomfort after healing of his fractured clavicle with 2 cm of shortening. **(A)** Anteroposterior radiograph demonstrating malunion of the clavicle. **(B)** An oscillating saw is used to create a long oblique osteotomy of the clavicle. **(C)** A distractor is used to restore length and alignment. **(D)** Fracture reduction forceps help maintain alignment while an anterior plate incorporating an interfragmentary screw is applied. **(E)** Radiograph demonstrates stable plate fixation with restoration of clavicular length. (From Browner, Jupiter, Levine, Trafton, eds. *Skeletal trauma: fractures, dislocations, ligamentous injuries*, 2nd ed. Philadelphia: WB Saunders, 1998.)

Refracture

Repeat fracture of the clavicle usually occurs upon premature resumption of full activity, in particular contact sports activity. The typically vigorous healing response of the clavicle results in a rapid decrease in pain and return of shoulder function so that overenthusiastic patients will often ignore their physician's admonition to avoid contact sports for at least 2 to 3 months or longer following healing of the fracture. Refracture following plate removal is unusual if the plate remains in place a minimum of 12 to 18 months following healing of the fracture.[256,285]

Failed Internal Fixation

The standard method of fixation for the clavicle is plate fixation. The particular problem with this technique is that the tension-held side of the clavicle, and thus the optimal position for the plate, changes with each direction of stress and rotation of the arm. Tensile forces against the implant cannot be prevented using plate fixation. To avoid plate breakage, a very large plate in proportion to the size of the bone must be chosen. However, using a typical narrow 3.5-mm LCDC plate or 3.5-mm reconstruction plate, the desired screw anchoring is not always possible. Typical complications after plate fixation include implant fracture, implant loosening, malunion, and refracture after removing the hardware. In cases of implant breakage or loosening, normally refixation is indicated if the fracture is not yet consolidated and the soft tissues allow for another procedure.

Fractures are not expected to heal independently when implants break or loosen. The goals of refixation are to achieve more proportionate stability of the fracture to avoid nonunion and to restore the clavicular length.

For refixation, a 3.5- mm LCDC plate, a 3.5-mm LC plate, or a corresponding reconstruction plate should be chosen; a one-third tubular plate is not appropriate. At least six, and preferably eight, cortical screws should be inserted into each major fragment. Particularly in cases of screw loosening, the fixed-angle plates should be used since in such cases (as well as in cases of poor bone quality), better bony anchoring can be achieved. However, if an adequate position cannot be found using a straight plate despite bending, the molded reconstruction plate is better. Because of the osteoporosis present in refixation procedures of the clavicle, titanium implants should be used exclusively (due to biocompatibility). Intramedullary support in the form of elastic titanium nails is an alternative to refixation with a plate for simple (two-fragment) fractures. After refixation procedures, elevation and abduction of the affected arm should be limited to 90 degrees for a period of 6 weeks to limit the rotation of the clavicle on the longitudinal axis.

In cases of implant fracture or loosening in combination with soft tissue infection or wound-healing disturbances, therapeutic measures should be taken in stepwise fashion. The first procedure should be simple implant removal. Once the soft tissues have revitalized, bony refixation is indicated. However, in such cases it should be explained to the patient that operative refixation may be delayed posthardware removal and postinfection recovery, in anticipation of spontaneous healing. In the case of bony consolidation, potential outcomes should be estimated as for nonoperative management. If bony healing does not occur spontaneously, the nonunion can always be treated operatively.

The development of nonunion after plate fixation, when the plate remains intact, is always the expression of a biologic (cellular), as opposed to mechanical, problem. Operative therapy for such cases requires placement of a corticocancellous bone strut graft from the iliac crest to be anchored ventrally across the fracture site with minifragment screws. (See section on Nonunion and Malunion.) This should be performed after the nonunion tissue has been débrided. If the plate is found to be loosened intraoperatively, the refixation should be performed according to the principles described previously with a 3.5-mm plate.

In cases of loose implants with radiographic evidence of delayed union or nonunion, we believe ultrasonic therapy is indicated prior to performing further operative measures.

Implant fractures, implant loosening, and nonunion postlateral clavicle fractures are usually evidence of a combination of mechanical and cellular problems. The local cellular problem is solved by débriding the nonunion tissue and attaching a corticocancellous iliac crest strut graft that can be fixed to the medial and lateral fragments with mini- or small-fragment screws. (See Nonunion and Malunion.) If there is sufficient bony anchoring for the lateral fragment, the mechanical problem can be solved by using a fixed-angle small fragment plate for refixation. The medial fracture fragment should additionally be fixed to the coracoid with a 1.5-mm Polydioxanonacid (PDS) cord figure-eight suture. If the lateral fragment is too short for good anchoring, we stabilize the fracture using a titanium nail introduced over the acromion, which enters the medullary canal of the clavicle from lateral (Fig. 31-16) or using two plates fixed from the dorsal and anterior aspect (Fig. 31-17).

As a last resort for chronic pain secondary to lateral malunion, there remains the option to resect the lateral third of the clavicle. The problem with sternal-end clavicular fractures is normally the short medial fragment. In these cases, implant loosening and subsequent fracture can occur as a result of insufficient anchoring. For refixation, we choose a fixed-angle 2.7-mm minifragment plate in L- or T-form. With such a plate, it is normally possible to anchor two to three screws in the medial fragment. Additionally, the lateral fragment is fixed near the sternum to the second or third rib with a 1.5-mm PDS-cord figure-eight suture.

Figure 31-16 If the lateral fragment is too short for good anchoring, we stabilize the fracture using a titanium nail introduced over the acromion. The medial fracture fragment should additionally be fixed to the coracoid with a 1.5-mm PDS-cord figure-eight suture. (With kind permission from Prof. Klaus Emil Rehm and Dr. Axel Jubel.)

When refracture of the clavicle occurs after implant removal, indications for refixation depend on the complaints of the patient and the conditions of the local soft tissue. Again, this appears to come from a (preoperatively present) cellular problem. It can therefore, in principle, be treated like the case of a nonunion. Alternatively, with suitable fracture forms, intramedullary stabilization can be performed. Intramedullary fixation is performed with the goal of avoiding further compromise of the periclavicular soft tissue.

In fractures with a large wedge fragment or a comminuted zone (CCF type C), intramedullary fixation is not indicated. Possible complications postintramedullary stabilization of the clavicle are lateral perforation, painful protrusion of the medial nail end, implant displacement, and nonunion. In cases of painful, moderately prominent medial nail ends, a so-called pseudobursa can develop in a period of 4 to 6 weeks postfixation. Only in such a case, where a pseudobursa develops and the patient continues to complain of pain, or in the case of a very long nail end with impending skin perforation should a nail-shortening procedure (under local anesthesia) be performed.

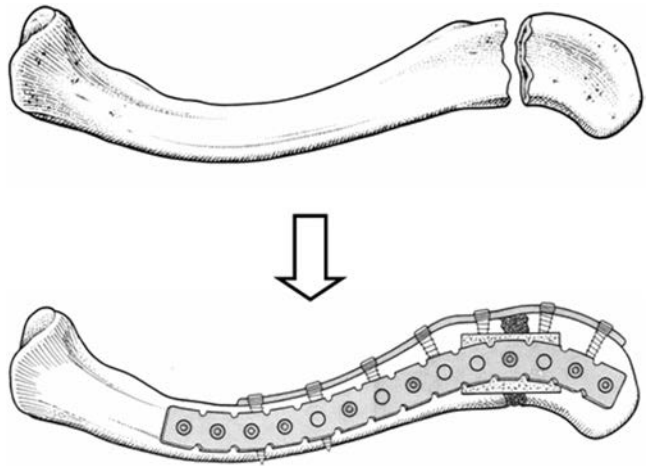

Figure 31-17 Another option in the case of a small lateral fragment is the use of two limited contact plates in combination with a bone graft.

Lateral perforation alone is not a problem, and does not require a corrective procedure. Only cases where lateral displacement of the implant occurs during the course of healing require therapy. Premature removal of the implant should be performed from the lateral side. Indications for refixation should depend on the further course and complaints of the patient; however, only seldom is reoperation necessary, since healing results are similar to those after conservative management. When indications for refixation exist such as increased displacement, absence of bony healing, and/or increased subjective complaints from the patient, it should be performed as described previously with a plate.

INTRODUCTION

The acromioclavicular joint is a diarthrodial joint formed by the distal clavicle and the medial facet of the acromion. This joint stabilizes the scapula and upper extremity to the clavicle via a complex of ligaments and the fascia of two muscles. As orthopedic surgeons we are frequently presented with patients suffering traumatic or degenerative conditions of this joint. Traumatic injuries of the acromioclavicular joint frequently occur in persons participating in contact and collision sports such as football, hockey, and rugby or those suffering a fall onto the shoulder.[28,34,96,114] Degenerative conditions evolve as a consequence of daily life but can also be provoked by repetitive use in sports such as baseball and weightlifting. Treatment of injuries to the acromioclavicular joint continues to be a topic of active discussion. Injuries that may be inconsequential to

the average person may restrict the activity of the competing athlete. A complete understanding of the relevant anatomy, biomechanics, and diagnosis of injuries to the acromioclavicular joint helps suggest a logical approach to treatment and restoration of shoulder function. This chapter should provide the reader with a working knowledge of the pertinent anatomy and biomechanics of this joint, along with recognition of injury, classification, nonoperative management, and current standards of operative treatment.

BONE AND LIGAMENT ANATOMY

An understanding of the anatomy and biomechanics of the acromioclavicular joint is essential to treating patients with acromioclavicular pathology (Fig. 32-1). Knowledge of the exact locations of insertion of the acromioclavicular ligaments along with the conoid and trapezoid ligament is important prior to operative resection of the distal clavicle. Comprehensive knowledge of the bony and ligamentous anatomy of this joint will also give us a better understanding of newer and better operative techniques to recreate anatomy of the acromioclavicular joint than are currently in our armamentarium.

The acromioclavicular joint is a diarthrodial joint involving the medial facet of the acromion and the distal clavicle. Its articular surfaces are covered with hyaline cartilage until age 17 when it acquires the characteristics of fibrocartilage on its acromial surface and at age 23 on its clavicular surface.[111] DePalma noted that before the age of 3 to 5 years only a fibrocartilaginous bridge exists between the acromion and the clavicle and not a true joint cavity.[32] Along with the sternoclavicular joint, the acromioclavicular joint provides a bony link of the shoulder to the axial skeleton. The inclination of the joint is variable in both the sagittal and coronal planes.[92] The most common type of inclination is with the clavicle overriding the acromion. The least common inclination is with the clavicle underriding the acromion.[112] Pitchford and Cahill felt that acromioclavicular joints with a more vertical orientation were more susceptible to osteolysis because higher forces were concentrated across the clavicle.[89] A fibrocartilaginous disc of varying size and shape is present in the joint.[33] Degenerative changes of the disc increase in frequency with age.

The presence of a coracoclavicular joint is uncommon but varies from the presence of a well-developed diarthrodial articulation to the presence of articular facets and synovial structures within the coracoclavicular ligaments.[52] A bony bar may form in place of the coracoclavicular ligaments, the

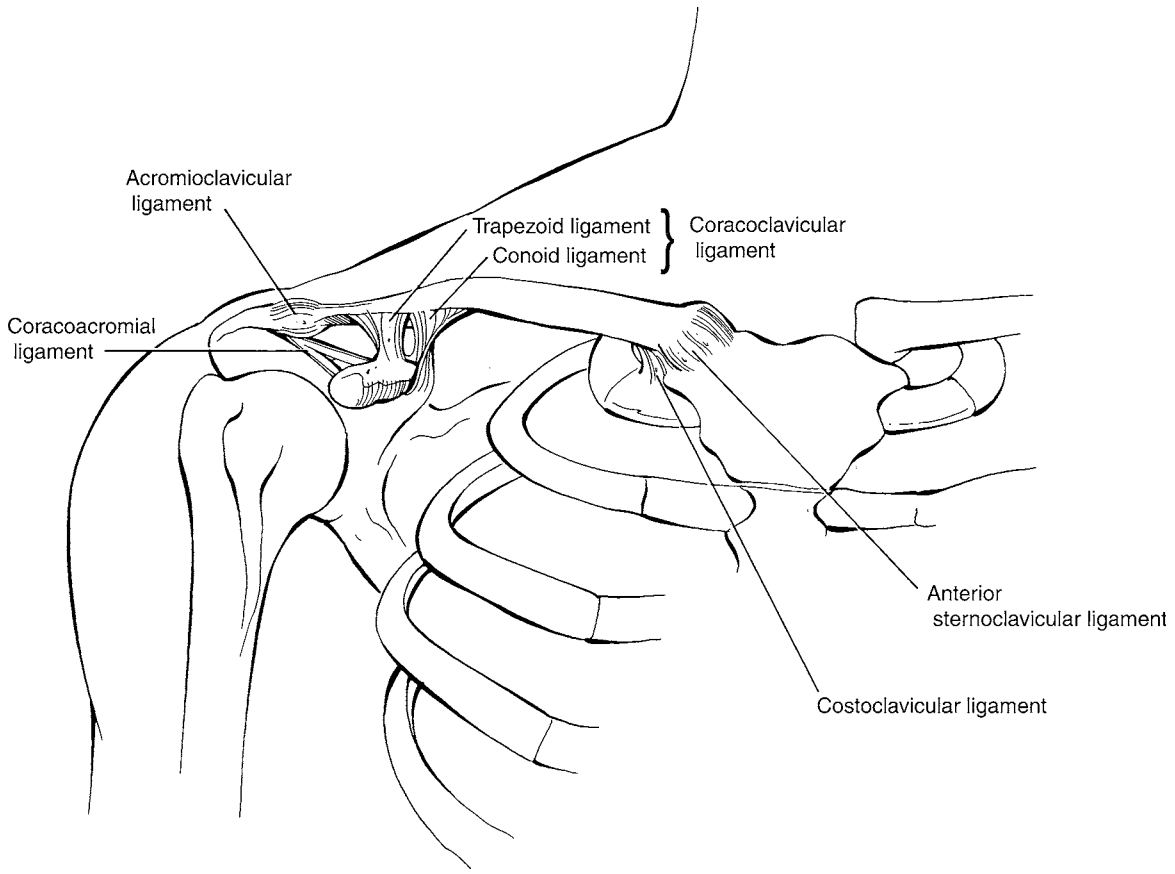

Figure 32-1 Ligamentous anatomy of the acromioclavicular joint.

so-called "coracoclavicular bar."[98] This connection may be complete or incomplete. Coracoclavicular articulations have also been linked to compression of the subclavian artery and brachial plexus, along with early degenerative changes of the acromioclavicular and sternoclavicular joints.[98,120]

The primary stabilizers of the acromioclavicular joints are the ligaments that surround the joint. A thin capsule surrounds the joint and is stabilized by anterior and posterior as well as superior and inferior ligaments. The superior acromioclavicular ligament is the most robust of the ligaments and is reinforced by fascial attachments of the deltoid and trapezial muscles.[97] The inferior ligament in many cases is nonexistant.[91] The insertion points of the superior acromioclavicular ligament on the acromion and clavicle were determined by Wright and led to the conclusion that resection of bone as little as 2.6 mm of the distal clavicle in men and 2.3 mm in women performed arthroscopically could violate the ligament.

Vertical stability (superoinferior) is provided by the coracoclavicular ligaments (conoid and trapezoid). These ligaments pass from the inferior surface of the clavicle to the base of the coracoid process of the scapula. The trapezoid ligament is the most lateral of the two. It is a broad, thin, quadrilateral-shaped ligament running obliquely from the superior surface of the coracoid process to the oblique ridge on the inferior surface of the clavicle. The conoid ligament is more conical in form, with its base directed superiorly. Its apex attaches to a rough impression at the base of the coracoid process medial to the trapezoid ligament. It attaches by its base to the coracoid tuberosity on the inferior surface of the clavicle and a line proceeding medial for 1 cm on this bone. These ligaments are the primary stabilizers of the acromioclavicular joint and constitute the primary supports by which the scapula is suspended from the clavicle. Division of the acromioclavicular ligaments and joint capsule, along with detachment of the trapezius and deltoid, allows less than 50% subluxation superiorly. Posterior dislocation, though, is possible.[112] Complete superior dislocation of the acromioclavicular joint will occur only after complete division of the coracoclavicular ligaments has also occurred.

The conoid ligament is the primary stabilizer with superior displacements. Salter found that there was considerable variation in the length and width of the conoid and trapezoid ligaments.[97] He also found that a bursa can exist between the ligaments. Recent literature also found variation in the insertional distances (from the acromioclavicular joint) of these ligaments. There was found to be a significant gender-related difference in the insertional distances of either the trapezoid or conoid ligaments. Resection of less than 11 mm should not violate the trapezoid ligament and resection less than 24 mm should not violate the conoid ligament in either gender.

In children, the clavicle is surrounded by a thick periosteal tube that extends all the way to the acromioclavicular joint. A secondary ossification center is present at the distal clavicle and fuses with the clavicle at about the age of 19.[26] Because of the variation in anatomy compared with adults, children are more prone to fracture and pseudodislocations than true dislocation of the acromioclavicular joint.[39,85]

An ossification center appears in the body of the coracoid at approximately 1 year of age. Another combined ossification center for the base of the coracoid and upper forth of the glenoid occurs close to age 10.[26] These centers fuse to the scapula at about age 15. Near puberty, the acromion forms two to five ossification centers that fuse at about age 22. Failure to fuse the acromial ossification center leads to an os acromiale.

BIOMECHANICS

Acromioclavicular joint motion occurs as the arm abducts and forward flexes. While the clavicle rotates upward 50 degrees with overhead motion, only 5 to 8 degrees occurs at the acromioclavicular joint due to synchronous scapuloclavicular motion. Observations by Inman et al. indicated that the clavicle rotates as the arm is elevated.[54] This was always felt to imply that motion (rotation) must be present at the acromioclavicular joint for overhead motion to occur. This finding was contradicted by observations by other authors, who found little motion restriction after acromioclavicular joint fusions or fixations.[42,93] Rockwood, in a classic study in which percutaneous pins were implanted in volunteers, found little motion between the acromion and clavicle.[93] His findings led him to conclude that there was synchronous movement of the scapula and clavicle. Thus, while the clavicle rotates the scapula rotates with it, and therefore, minimal rotation (5 to 8 degrees) is required between the two. Hence, most scapulothoracic motion must occur at the sternoclavicular articulation. Clinically, fusion of the acromioclavicular joint will lead to minimal dysfunction.

Stability of the acromioclavicular joint is rendered by the ligamentous complex. Testing of strength to failure at the Biomechanics lab at the Mayo Clinic demonstrated the acromioclavicular capsule/ligament complex to be the strongest and stiffest, followed by the conoid ligament and finally the trapezoid ligament.[60] Fukuda et al. used 12 fresh frozen specimens and studied ligamentous contribution to joint constraint by performing load displacement tests, along with sequential cutting of the ligaments.[44] The contributions of the different ligaments to constraint changed not only with direction of loading, but also with amount of loading and displacement. With small amounts of load and induced displacement, the acromioclavicular ligament contributed more restraining force to superior displacement. With larger loads and displacement, the coracoclavicular (conoid) ligaments were major restraints. The acromioclavicular ligaments (superior and posterior) acted as the primary constraint to posterior clavicular displacement and posterior axial rotation at all loads. For axial compression

loading of the acromioclavicular joint, the trapezoid muscle was the major restraint. Debski et al. confirmed these observations by noting 100% displacement in the anterior and posterior direction after resection of the acromioclavicular ligaments.[30] Other authors have shown that the inferior acromioclavicular ligament only contributes about 50% of the restraint to force as the superior ligament.[18,31,61] This work implies that, to achieve normal physiologic function of this joint, preservation or reconstruction of both stabilizing groups of ligaments is important. Surgical procedures that excise the distal clavicle may not make this possible. Posterior abutment of the resected distal clavicle against the base of the acromion may be a cause of failure after open distal clavicle resection.[14,24,42] Traditionally, large amounts (1 to 2 cm) of resection of the clavicle were recommended. Acromioclavicular resection of even 1 cm would potentially compromise anteroposterior stability of the distal clavicle by loss of capsular insertion. Resection of less bone (5 mm), along with preservation of part of the acromioclavicular ligament, either superior or posterior or inferior, will ensure that no bone-to-bone abutment occurs. This can be accomplished either through an open or arthroscopic approach.[7,18,43]

The impact of the deltoid and trapezius muscle and fascia on stabilizing the acromioclavicular joint is unknown. The fascia of these muscles blends with the superior acromioclavicular ligament and adds stability to the joint, but the contribution has not been elucidated.[11] Most surgeons recognize the importance of this fascia and imbricate the fascia over the acromioclavicular joint to reinforce its stability during reconstruction.[17,94] These muscles may also contribute to generation of forces across the acromioclavicular joint and the genesis of osteolysis during weightlifting activities.[20]

CLASSIFICATION OF ACROMIOCLAVICULAR JOINT DISLOCATIONS

Injuries to the acromioclavicular joint can be classified according to findings on physical examination and anteroposterior (AP) and axillary radiographs. The amount of damage to the acromioclavicular and coracoclavicular ligaments, as well as the deltoid and trapezius attachments, determines the current classification.

Injuries of the acromioclavicular joint most commonly occur as a result of direct trauma. Typically, a fall onto the superior aspect of the shoulder with the arm in adduction occurs, as with a fall off a bike or a horse. Another mechanism of injury is a laterally based force directed to the shoulder, as in a hockey player hitting the boards. If the upper extremity is not used to absorb the force, the area of impact is distributed across the acromioclavicular joint. Because of significant stability of the sternoclavicular joint, the energy of impact is distributed to the acromioclavicular and coracoclavicular ligaments or the clavicle itself.[10,82] The direction and magnitude of the forces determine the severity of injury and the structures injured. With an acromioclavicular injury, the force is initially distributed to the acromioclavicular ligaments. If the magnitude of force is severe, injury progresses to the coracoclavicular ligaments along with the deltoid and trapezial fascia. Fractures of the distal one-third of the clavicle occur rarely, but should be recognized. These fractures may or may not be associated with coracoclavicular ligament disruption.

Injuries to the acromioclavicular joint by indirect injury have also been described. Force is typically directed superiorly by the humeral head upward into the acromion. This may occur with a fall on an elbow or outstretched arm. With this mechanism, injury is primarily to the acromioclavicular joint as the coracoclavicular ligaments are relaxed with upward movement of the scapula relative to the clavicle.

The mechanism of injury for the most severe dislocation, type VI, is felt to be a severe force directed onto the superior surface of the distal clavicle along with abduction of the arm and retraction of the clavicle.[48,72,87]

Classically, injuries to the acromioclavicular joint were classified as either types I, II, or III.[3,110] Rockwood added three other types of injury to the acromioclavicular joint and expanded the classification to the current six types. Recent magnetic resonance imaging of the coracoclavicular ligaments after injury and in a cadaver has questioned the validity of the Rockwood classification system to accurately determine pathoanatomy.[6] Keeping with convention and until another classification defining the pathology is validated, we will use the Rockwood classification, as described below:

Rockwood Classification

Type I injury (Fig. 32-2)
Sprain of the acromioclavicular ligaments alone

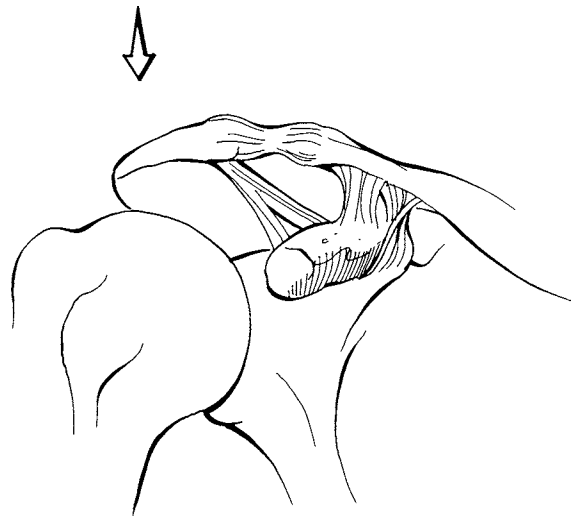

Figure 32-2 Type I Injury.

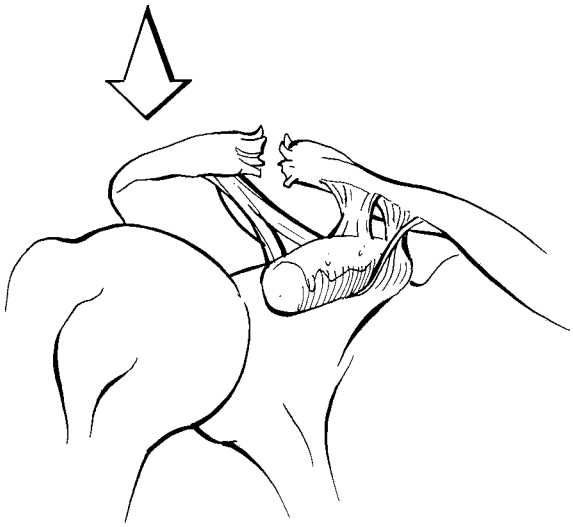

Figure 32-3 Type II Injury.

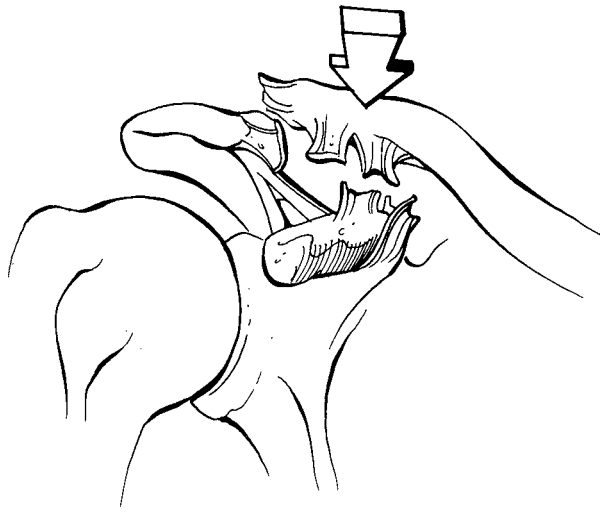

Figure 32-5 Type IV Injury.

Type II injury (Fig. 32-3)
- Acromioclavicular ligament and joint capsule disrupted
- Coracoclavicular ligaments intact
- Up to 50% vertical subluxation of the clavicle

Type III injury (Fig. 32-4)
- Acromioclavicular ligament and capsule disrupted
- Coracoclavicular ligaments disrupted
- Dislocation of acromioclavicular joint, with the clavicle displaced superiorly, and loss of contact between the clavicle and acromion

Type IV injury (Fig. 32-5)
- Acromioclavicular ligament and capsule disrupted
- Coracoclavicular ligaments disrupted
- Acromioclavicular joint dislocation with clavicle displaced posteriorly into or through the trapezius muscle (posterior displacement confirmed by axillary radiograph)

Type V injury (Fig. 32-6)
- Acromioclavicular ligament and capsule disrupted
- Coracoclavicular ligament disrupted
- Complete detachment of deltoid and trapezius fascia from the distal clavicle
- Acromioclavicular joint dislocated with extreme superior elevation of the clavicle (100% to 300% of normal)

Type VI injury (Fig. 32-7)
- Acromioclavicular ligament and capsule disrupted
- Coracoclavicular ligaments disrupted
- Acromioclavicular joint disrupted with the clavicle displaced inferior to the acromion or coracoid process

Various type III equivalent injuries have been described, primarily in children. Children younger than 15 years typically do not sustain true dislocations of the acromioclavicular

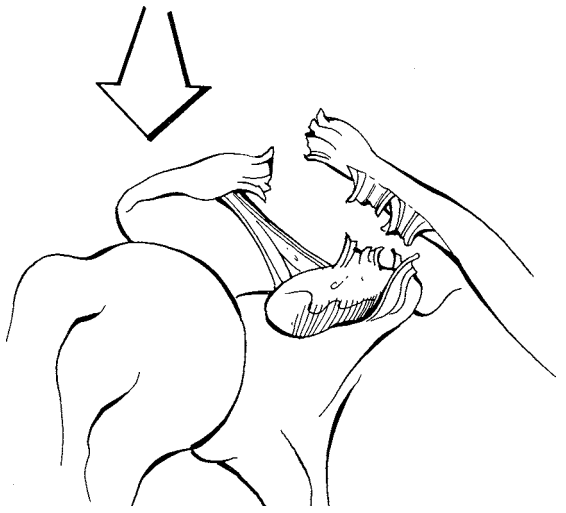

Figure 32-4 Type III Injury.

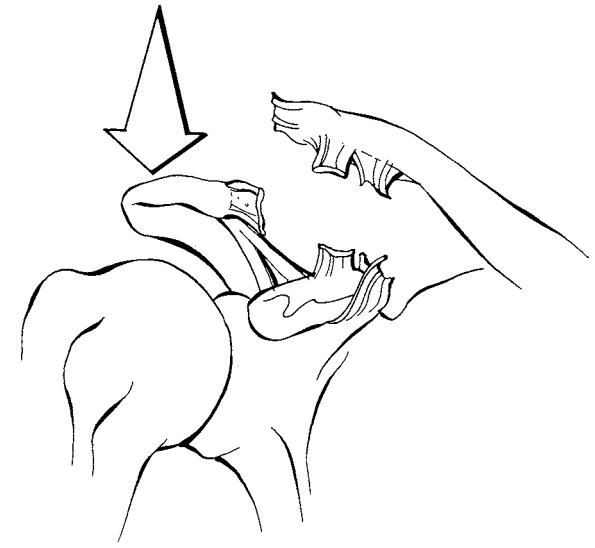

Figure 32-6 Type V Injury.

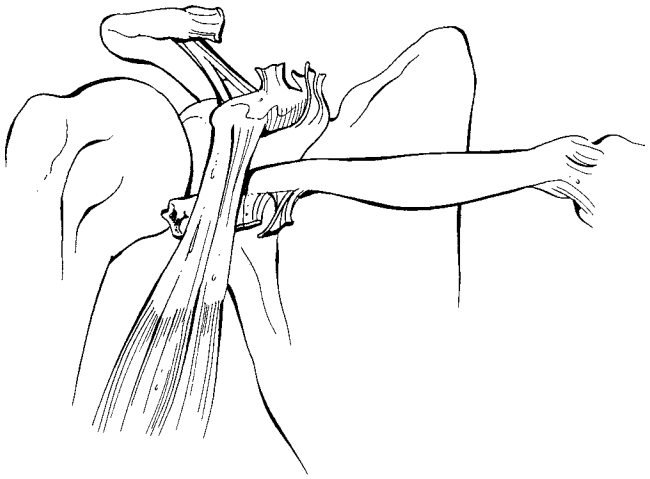

Figure 32-7 Type VI Injury.

joint, but rather, fractures of the clavicle.[26] Disruption of the periosteal sleeve of the clavicle allows the bone to displace superiorly without disruption of the coracoclavicular ligaments (Fig. 32-8). Thus, in children the classification of acromioclavicular injuries is based on the position of the clavicle with injury to the periosteal sleeve with intact ligaments.

Classification of Acromioclavicular Joint Injuries in Children

Type I injury
- Sprain of acromioclavicular ligaments
- Periosteal sleeve intact

Type II injury
- Partial disruption of periosteal sleeve
- Slight widening of acromioclavicular joint

Type III injury
- Periosteal tube disrupted with instability of the distal clavicle
- Superior displacement 25% to 100% of distal clavicle on AP radiograph

Type IV injury
- Periosteal tube disrupted
- Deltoid and trapezial detachment
- Clavicle displaced posteriorly through or into trapezius viewed on axillary radiograph

Type V injury
- Periosteal tube disrupted
- Deltoid and trapezial detachment
- Clavicle displaced subcutaneously greater than 100% of normal

Type VI
- Inferior displacement of clavicle beneath the coracoid process

Fractures of the coracoid, if through the common growth plate with the upper glenoid fossa, may mimic an acromioclavicular injury, but the coracoclavicular interspace remains intact.[63] Fracture of the base or tip of the coracoid combined with acromioclavicular ligament disruption is an atypical form of injury to this area. An axillary view will best demonstrate a fracture of the coracoid.[12,74,108] This injury should be suspected in acromioclavicular injuries in the first three decades of life.

RADIOGRAPHY

Standard anteroposterior radiography of the shoulder joint overpenetrates the acromioclavicular joint and makes

Figure 32-8 Periosteal sleeve disruption of the clavicle in a child allows super migration of the bone without disruption of the coracoclavicular ligaments.

Figure 32-9 Alexander scapular lateral view with complete acromioclavicular joint dislocation.

interpretation difficult. An anteroposterior acromioclavicular joint radiograph and a 15-degree cephalic-tilt view are recommended to evaluate the acromioclavicular joint.[123] The superior tilt of the Zanca view makes sure the spine of the scapula is not superimposed on the acromioclavicular joint. Thus, subtle fractures of the distal clavicle will not be missed. Axillary lateral-view radiographs are also useful to evaluate the position of the clavicle relative to the acromion. This is particularly useful in the evaluation of type IV acromioclavicular joint injures.

Alexander described the scapular lateral radiograph as a technique to evaluate acromioclavicular joint injuries (Fig. 32-9).[1] In this view, a comparison superolateral radiograph is taken with the shoulders protracted forward. In the normal shoulder, the integrity of the acromioclavicular joint is maintained. With an acromioclavicular dislocation, the distal clavicle is displaced superiorly to the acromion.

Stress or weighted radiographs have been recommended in the past to differentiate type II from type III acromioclavicular injuries. These radiographs, with the patient seated or standing with weights (15 lb) strapped to the wrists, will accentuate the difference between the normal and injured shoulder (Fig. 32-10). Typically, a large 14 × 17-in. cassette is used to visualize both shoulders on the single plate. A comparison of the coracoclavicular space between the normal and injured shoulder is made. In large individuals, two separate plates may be required. A difference of 25% to 40% increase in space is felt to be significant for full disruption of the coracoclavicular ligaments.[9,93] It is important to have the patient relaxed or muscle forces may lift the arm superiorly and reduce the injured joint, distorting the interpretation. The same may occur if the patient is asked to hold the weights in his or her hands. The importance of these views is dependent on their use as a prognostic factor in treatment of these injuries. With the tendency to nonsurgical treatment of type III injuries, stress radiographic differentiation between type II and III injuries becomes clinically irrelevant. Others have noted low clinical yield as a reason to discourage use of stress radiographs.[15]

Our current recommendation for routine assessment of the acromioclavicular joint radiographically is an anteroposterior or Zanca view, along with an axillary view.

Computed Tomography

Computed tomography may be the best test to evaluate arthritic changes of the acromioclavicular joint including joint space narrowing, erosions, and subchondral cysts.[38] It is also ideal for demonstration of clavicular fractures, particularly those involving the distal clavicle (type II) and

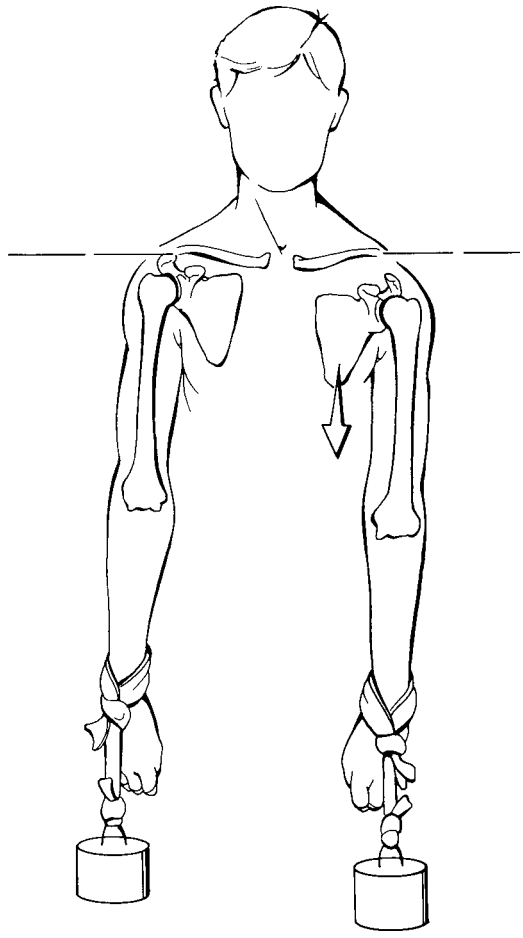

Figure 32-10 Weighted X-Ray technique.

Figure 32-11 Type IIA distal clavicle fracture.

acromioclavicular joint (Figs. 32-11 and 32-12). A benefit is its ability to be well tolerated by the multiply injured trauma patient. Its shortcoming is in its ability to show soft tissue changes including ligamentous, capsular, and synovial abnormalities. While it needs to be kept in our armamentarium, its price may make it an impractical examination for most acromioclavicular pathology.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is an important modality for assessment of soft tissue and bony abnormalities about the shoulder. The coronal plane best demonstrates the acromioclavicular joint.[100] Osteophyte formation and its secondary impact on the rotator cuff, along with bone edema of the distal clavicle and acromion, may be best evaluated by MRI. Stress-induced changes of osteolysis may be best seen on MRI as well as soft tissue swelling, prominence of the joint capsule, joint space widening, cortical thinning or irregularity, subchondral cystic change, and osseous fragmentation.[29,122]

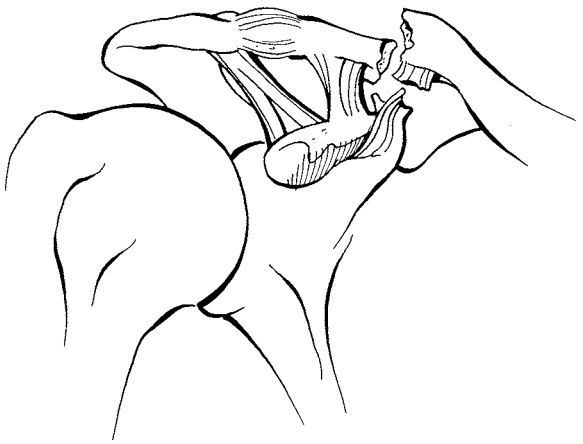

Figure 32-12 Type IIB distal clavicle fracture may mimic acromioclavicular joint disruption.

TRAUMATIC LESIONS—ACROMIOCLAVICULAR DISLOCATIONS

Injuries to the acromioclavicular joint should be suspected in anyone with trauma to the shoulder and a history demonstrating the typical mechanism of injury (Fig. 32-13). Not infrequently, the patient will present with a significant abrasion over the superior aspect of the shoulder secondary to the fall. Inspection will demonstrate swelling or prominence of the distal clavicle. It is important to remember that the prominence of the distal clavicle is actually accountable to the downward sag of the shoulder and arm, not upward displacement of the clavicle.

Initial discomfort of the injury may cause the patient to tense his or her shoulder musculature or cradle his or her arm and make the prominence of the clavicle less noticeable. As the initial swelling subsides, the deformity and prominence of the clavicle become more noticeable. Palpation will typically reveal local tenderness. In type I injuries, the only finding may be localized tenderness. Direction of instability will be difficult to discern initially because of the patient's discomfort. With time, the swelling and pain will subside and make detection of the instability easier. As

Figure 32-13 Acromioclavicular joint injuries typically are the result of a fall on the superior aspect of the shoulder.

the patient becomes more comfortable, anteroposterior and superoinferior translation of the distal clavicle can be assessed. Depending on the severity of the injury, motion of the shoulder joint is typically restricted most in abduction or cross-body adduction. With lesser injuries (type I), pain may be produced only with resisted abduction or cross-body adduction and direct palpation of the acromioclavicular joint. Rotation of the humerus with the arm at the side is generally comfortable with these injuries and can be used to detect associated injuries of the glenohumeral joint.

Type I Injury—Assessment

Because type I injury is the least severe of the injuries, generally there is mild to moderate pain and swelling. Athletes will frequently continue to participate in the athletic activity that caused the injury. Arm movements typically are comfortable except for cross-body adduction. The only obvious abnormality is tenderness to palpation.

Typically, these radiographs are essentially normal when compared with the involved shoulder. Radiographs years later may display degenerative changes at the acromioclavicular joint.

Type II Injury—Assessment

The patient will display moderate to severe pain over the acromioclavicular joint. If seen before swelling occurs, slight prominence of the clavicle is noted, best indicated by running a finger over the clavicle to the acromioclavicular joint. Anteroposterior motion of the distal clavicle can be noted when grasping the clavicle and stabilizing the shoulder. Pain may be present over the costoclavicular interspace.

Radiographic findings display slight widening of the acromioclavicular joint when compared with the normal side. Even with stress radiographs, the coracoclavicular space is maintained.

Type III Injury—Assessment

In type III injury, moderate to significant pain is usually present. Initially the prominence of the distal clavicle may be diminished by the patient cradling the arm upward to relieve pressure and discomfort on the injured joint (Fig. 32-14). Abduction of the arm or cross-body adduction increases the discomfort. With palpation, the distal clavicle feels unstable both anteroposteriorly and superoinferiorly. Typically, the patient is tender at the acromioclavicular joint as well as the coracoclavicular interspace.

The joint is totally displaced on the anteroposterior radiograph compared with normal. The axillary view fails to demonstrate anteroposterior displacement of the distal clavicle. If total acromioclavicular displacement is noted on the anteroposterior radiograph but the coracoclavicular interspace is maintained, one should suspect a fracture of the coracoid process. This can best be demonstrated by a Stryker notch view.[51,93] With this view, the patient lies supine with the cassette under the involved shoulder. The hand is placed on top of the head. The radiographic beam is tilted 10 degrees cephalad and centered over the coracoid process.

Figure 32-14 Type III injury. Prominence of the distal clavicle accountable to the downward sag of the shoulder.

Type IV Injury—Assessment

Typically, the patient is in more pain than with the more common type III injury. Palpation along the clavicle will demonstrate posterior displacement of the distal clavicle through the trapezius muscle. The clavicle does not have the "free-floating" feel of the type III injury. Once swelling subsides, observation from above and behind the patient will demonstrate posterior displacement of the clavicle in a thin patient (Fig. 32-15). Motion of the shoulder is much more painful than in the type III injury.

The anteroposterior view may show displacement of both the acromioclavicular joint and the coracoclavicular interspace. On the axillary view, posterior displacement of the distal clavicle in relation to the acromion is most pronounced. A computed tomography (CT) scan may be warranted in heavy individuals or in those with multiple injuries that make the axillary lateral radiograph difficult. The CT scan may also be used in persons for whom there is a suspicion of associated glenoid fractures.

Type V Injury—Assessment

This injury presents with findings very similar to the type III, but with more displacement of the clavicle. This generally

Figure 32-15 Type IV injury. Clavicle and acromion outlined with distal clavicle buttonholed through trapezius.

has more of the "ear tickler" presentation, owing to the more extensive injury to the deltoid and trapezial fascia (Fig. 32-16). Typically, the patient is in more pain than with a type III injury. The skin is severely tented and it appears that the clavicle may protrude through it.

These injuries display gross displacement of the acromioclavicular and coracoclavicular space on radiographs. The coracoclavicular space may be two to three times wider than normal.

Type VI Injury—Assessment

With this injury, the superior aspect of the shoulder appears flatter because of the downward displacement of the clavicle. The acromion is more prominent and palpable with a stepdown or depression over the distal clavicle. This rare injury may also present with neurologic changes because of proximity to the upper roots of the brachial plexus. Because of the severity of the injury, associated injuries should be suspected, including fractures of the ribs and pneumothorax, and sternoclavicular injuries.

On the anteroposterior view, the clavicle will be displaced inferior to the acromion or coracoid. Because of the magnitude of force required to produce this injury, associated fractures of the ribs or scapula should be sought.

Treatment

Although the treatment of type III acromioclavicular joint injuries remains controversial, prospective studies comparing nonoperative and surgical treatment of these injuries have yielded similar results.[5,22,99,107] Thus, the pendulum of care has swung to the initial nonoperative care of these patients. Not all patients, however, do well with conservative care. Guidelines for care at this time are not fixed and are frequently dictated by the patient's desires and goals as well as the surgeon's experience. Some authors who generally favor the conservative treatment of these injuries may recommend surgical repair in patients involved in heavy labor or overhead sports.[5,22,35,107,115,117] One study, though, demonstrated little effect on athletic strength or performance with acromioclavicular dislocation.[109] Questions still remain whether complete dislocation of the acromioclavicular joint affects performance of the overhead laborer or throwing athlete, or whether surgical procedures can fully restore normal anatomy and function.

Treatment Options and Indications

Type I—Acute

Type I sprains of the acromioclavicular joint are treated nonoperatively by all. Analgesic medication and a sling are used per patient's comfort. Cryotherapy, for periods of no longer than 15 to 20 minutes, is used to reduce swelling. Local wound care may be necessary to treat the abrasions that are frequently seen with these injuries. Early active motion and exercise to promote return to activity are recommended. Most active individuals, along with athletes, will return to their desired activity in 2 to 14 days. Athletes involved in contact sports, such as football, can add cutout pads or modify their shoulder pads to reduce contact to the joint.

Type I—Chronic

Degenerative changes at the acromioclavicular joint in athletes are frequently the result of old type I and II acromioclavicular joint sprains. Damage to the meniscus and articular cartilage with an acute injury can lead to degenerative changes later in life (Figs. 32-17 and 32-18). Pain caused by degenerative changes at the acromioclavicular joint secondary to type I sprains can be treated with mild analgesics, nonsteroidal antiinflammatory medications, or intraarticular injections of corticosteroid preparations. Those who do not respond to conservative care may require resection of the distal clavicle to provide relief of symptoms. This can be performed with the use of an open or, today, more commonly an arthroscopic approach.[42,46,47,50,76,106] The technique used depends on the surgeon's preference and experience. A potential advantage to the arthroscopic technique is the requirement for less resection of the distal clavicle (5 to 7 mm) because of the preservation of the capsular ligament.[42] Return to activity and athletic competition after

Figure 32-16 **(A,B)** Clinical photograph, and **(C)** AP nonstress radiograph of the shoulder demonstrates the typical appearance of a Type V acromioclavicular separation.

Figure 32-17 Radiograph of acromioclavicular joint at time of Type I injury.

Figure 32-18 Radiograph of acromioclavicular joint 10 years after Type I injury. Note irregularity of distal clavicle.

clavicle resection is dictated by wound healing and restoration of motion, strength, and comfort.

Type II—Acute

Acute type II injuries are treated in a manner similar to the type I acute sprains: a sling, analgesic use, and icing per the patient's comfort. The potential for intraarticular damage and degenerative damage may be enhanced by the increase in sagittal plane motion of the acromioclavicular joint. Some physicians may use a sling or harness for longer periods to preclude conversion to a type III injury. Return to activity is predicted by restoration of motion, comfort, and strength. For athletes, Gladstone and colleagues recommend a four-phase rehabilitation program, as described below[34,49]:

Phase 1: Use ice, immobilization, and analgesics. Begin active assisted range-of-motion exercises, particularly internal and external shoulder rotation at low levels of abduction and forward flexion (30 to 40 degrees). Advance to phase 2 when the patient has 75% of full motion, minimal pain and tenderness on palpation of the acromioclavicular joint, and manual muscle grade of 4 or 5 of anterior and middle deltoid and upper trapezius.

Phase 2: The goals of this phase are to restore full and painless range of motion and increased strength. Rotation is continued but at greater degrees of abduction and forward flexion. Strengthening is continued for the deltoid, trapezius, and rotator cuff. Bench and military press is restricted. Advance to phase 3 when the patient has nonpainful range of motion, is nontender to palpation, and has strength 75% of normal side.

Phase 3: The goal of this phase is to restore strength to the entire shoulder girdle. Exercises emphasized include shoulder flexion, abduction, shrugs, and bench press. Progress to phase 4 when patient has full range of motion, painless motion, and nontender, normal clinical examination and isokinetic test data with close to 100% strength.

Phase 4: Progress with sports-specific exercises and throwing.

Type II—Chronic

In patients with pain and degenerative change of the acromioclavicular joint, the treatment recommended is similar to type I injuries. Analgesic medication, nonsteroidal antiinflammatory medications, and injection with corticosteroid medications seldom offer long-term relief. An evaluation of patients after isolated resection of the distal clavicle has noted some poor results attributed to abutment of the posterior clavicle on the acromion. Symptomatic type II acromioclavicular joint injuries can be treated as type III injuries, with resection of the distal clavicle along with reconstruction of the ligamentous structures. Typically reconstruction involves transferring the coracoid ligament to the resected clavicle.[113] This enhances superior–inferior stability of the joint, but provides little anteroposterior stability. Recently, techniques that recreate both the acromioclavicular and coracoclavicular ligaments with either autogenous graft (semitendinosis) or allograft have been suggested.[31,34,56] Work by Lee et al. in a cadaver model showed that shoulder extension produced forces across the coracoclavicular ligaments that exceeded the ultimate tensile strength of a Weaver-Dunn reconstruction.[67]

Type III Injuries (Fig. 32-19)

The trend in the treatment of these injuries remains a more conservative approach. A distinct advantage of surgical treatment over conservative care has never been clearly demonstrated. When comparing operative and nonoperative techniques pain, range of motion and persistent symptoms are very similar.[34,66,88] When considering a surgical approach to treatment, the surgeon must ask himself or herself whether today's surgical options truly restore the anatomy and function of the acromioclavicular joint. The

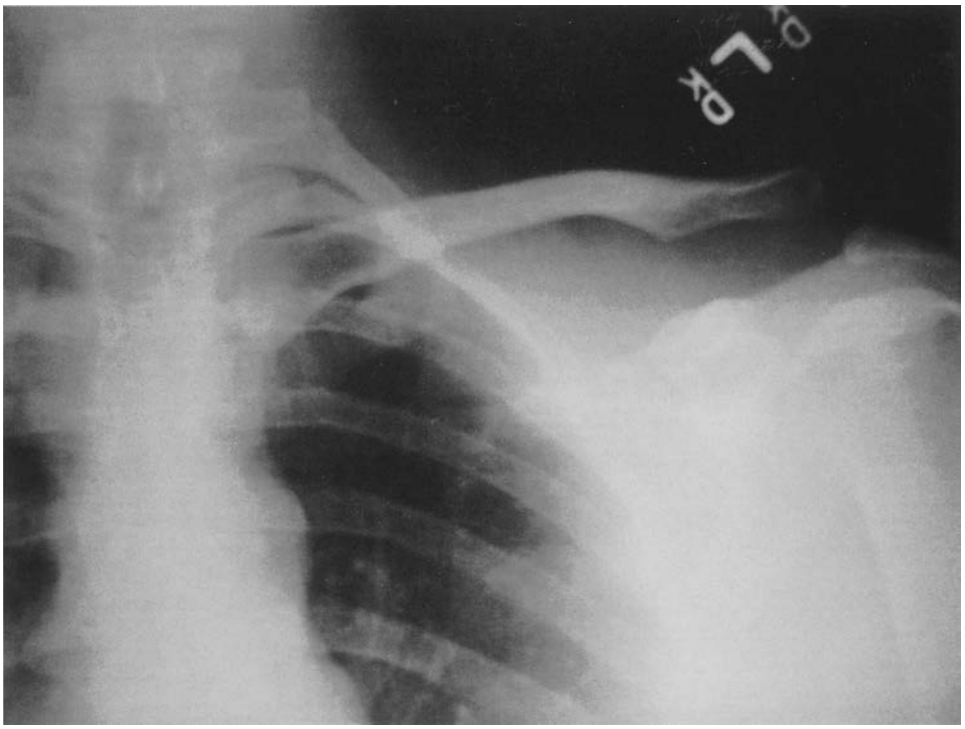

Figure 32-19 Complete displacement of the acromioclavicular joint.

authors have conducted an informal survey of physicians involved in the care of professional athletes involved in the sports of football, hockey, and baseball and found that the majority favor a nonoperative approach to the management of these injuries. However, these physicians would consider operative reduction for the throwing athlete's dominant extremity, particularly the baseball pitcher. Quarterbacks throw with a less specific motion and generally do not fall into the same consideration. A recent prospective study by Schlegel found little difference in the outcomes of type III injuries, compared to normals, treated only using a sling for comfort and active range of motion without formal physical therapy when looking at eventual strength and comfort.[99] This study did not look specifically at athletes.

For those electing a surgical reconstruction, the timing of the repair may be an issue. One consideration is to delay the operation to see if the patient remains symptomatic. Even the newer surgical reconstructions can be performed as a delayed procedure. Weinstein et al., however, noted a trend toward better results when the surgery was performed in the first 3 weeks after injury.[115] Others have found no significant difference between early and late ligamentous reconstruction.[35] Whether the surgeon's preference is operative or nonoperative, there are certainly those patients that will require surgical reconstructions after the failure of conservative care.

Nonoperative care of type III acromioclavicular joint injuries is similar to that for type I and II sprains. Analgesia, icing, and a sling for comfort are also used. Because of the pain and deformity, it is unlikely that the individual will return to heavy labor or athletic activity as soon as after a type I or II injury. Professional football or hockey players, though, will frequently return to their sport within a few days to weeks.

Correction of the deformity by a brace or cast has fallen out of favor and become mostly of historical interest. Kenny Howard, a trainer at Auburn University, along with Dr. Jack Hughston, developed a brace for this purpose (Fig. 32-20).[3] This device, known as a Kenny Howard brace (Fig. 32-21), combines a sling with a strap over the distal clavicle that applies downward pressure on the clavicle while providing a superior force on the humerus. To be effective, the brace must be worn continuously for 6 to 8 weeks while healing occurs. Any displacement of the brace during this period will lead to loss of reduction and subsequent failure. The brace can be quite cumbersome to wear and even painful. Skin maceration and breakdown is a risk, and there is even a report of an athlete who sustained an anterior interosseous nerve compression while using the sling.[84]

Our approach to the treatment of type III acromioclavicular injuries is to treat these injuries nonoperatively, with surgical stabilization being considered only if an athlete or laborer places significant demands on the upper extremity. If conservative treatment fails, stabilization is considered later in those who continue to note symptoms with activity. Excellent results can be obtained with late reconstruction.

Various surgical options have been described and are being expanded upon. They will be detailed later in this chapter. These options include arthroscopic and open reconstructions. The open options include dynamic muscle transfers, primary acromioclavicular joint fixation,

Figure 32-20 Axillary radiograph demonstrating posterior displacement of the distal clavicle in relationship to the acromion.

primary coracoclavicular ligament fixation, excision of the distal clavicle with or without coracoclavicular ligament reconstruction, and reconstruction of both the acromioclavicular and coracoclavicular ligaments with autogenous or allograft tissue. Many of these options include augmentation of the reconstructions with soft tissue grafts or artificial tapes or sutures.

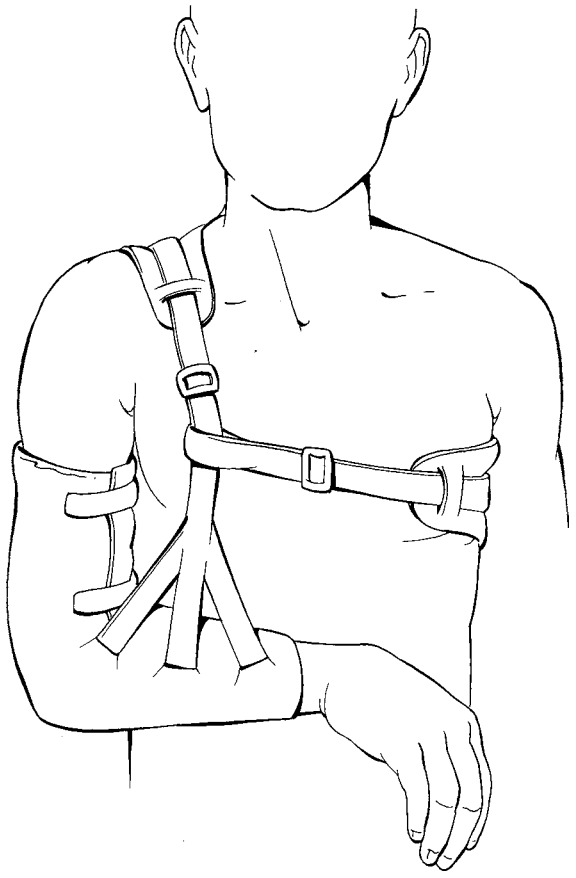

Figure 32-21 Kenny Howard brace.

Type IV Injuries

We agree with most authors that posterior displacement of the clavicle through the trapezius will lead to discomfort with motion. Thus, these injuries should be treated with the goal of reducing the deformity. Options include an attempt at closed reduction to displace the clavicle from its buttonholed position in the trapezius, and converting the injury to a type III and then treating it conservatively. The most common recommendation would be open reduction and fixation by one of the surgical options outlined with type III injuries. Our recommendation would be to reduce the joint operatively because the displacement involves significant stripping of the deltotrapezial fascia. Meticulous closing of the deltotrapezial fascia over the repair augments the procedure.

Type V Injuries (Fig. 32-22)

We feel that many type V injuries are actually treated as type III injuries and may do quite well with conservative care. Most authors feel that these injuries imply a greater amount of damage to the ligamentous structures. Type V injuries may require operative reduction because of the significant stripping of deltotrapezial fascia and potential compromise of the overlying skin. These injuries are probably best treated with a reconstruction that addresses the coracoclavicular ligament, acromioclavicular ligament, and deltotrapezial fascia disruption. We favor a procedure that excises the distal clavicle because of concern for later degenerative changes at the acromioclavicular joint and the potential for discomfort or rotator cuff impingement. Excision of the distal clavicle has not been shown to compromise muscle strength.[109]

Type VI Injuries

The potential for closed reduction of such an injury is remote. These are rare injuries that require open reduction and stabilization. Excision of the distal clavicle will aid in the reduction of the acromioclavicular joint.[48]

Figure 32-22 Type V injury. Note gross displacement of acromioclavicular and coracoclavicular spine.

Injuries in Children

Type I, II, and III injuries in children are treated similarly to those in adults. Use of a sling, ice, and mild analgesics are all that are required. These injuries can be expected to go on and heal without sequelae.[37,53] Markedly displaced type IV, V, and VI injuries should be treated surgically. Replacement of the clavicle into its periosteal sleeve, suturing the sleeve closed, and then fixation with a coracoclavicular lag screw or transacromial fixation are generally recommended.[26,85] After 4 to 6 weeks the fixation will have to be removed before starting rehabilitation.

Type II Equivalent Injuries

A fractured coracoid along with an acromioclavicular dislocation is an exceedingly rare injury. It is easy to overlook the coracoid fracture, particularly in light of the more obvious acromioclavicular joint disruption. Most occur in the second or third decade of life. Review of the literature would indicate that these injuries do well when treated conservatively or surgically. Thus, we would recommend a conservative approach and avoid potential complications of surgery.[12,55]

Surgical Treatment of Acute Acromioclavicular Joint Dislocation

A variety of surgical approaches have been described to manage these injuries and restore the anatomic relations of the acromioclavicular joint.[5,35,40,56,62,65,103,107,115] The question remains whether these techniques are effective at restoring normal functional anatomy and, therefore, offer a distinct advantage over a conservative approach.

Surgical Options

Many different operative procedures have been described to repair and stabilize acute acromioclavicular dislocations (types III, IV, V, and VI). Some can be performed arthroscopically or via an open surgical technique. The most popular options include dynamic muscle transfers, primary acromioclavicular joint stabilization, primary coracoclavicular and extraarticular stabilization, excision of the distal clavicle with coracoclavicular ligament reconstruction, or more recently reconstruction of both the acromioclavicular ligaments and coracoclavicular with autogenous or allograft tissue. The goal of each of these procedures is to reduce the joint and create an environment for soft tissue healing and stabilization of the distal clavicle.

Dynamic Muscle Transfers

The clavicle may be stabilized by transfer of the tip of the coracoid process and its attached tendons of the coracobrachialis and short head of the biceps to the undersurface of the clavicle.[13,41,104] Theoretically, this transferred tendon acts as a dynamic depressor of the clavicle and holds the acromioclavicular joint reduced. Ferris et al. reviewed 20 patients managed with a dynamic transfer and found nearly half with continued aching at the acromioclavicular joint.[41] These results are most likely due to the lack of distal clavicle stability and excessive motion. Possible complications of this surgical procedure include the risks of nonunion or injury to the musculocutaneous nerve.

Primary Acromioclavicular Joint Stabilization

The dislocated acromioclavicular joint can be stabilized by transfixing it with Kirschner wires or Steinmann pins or screws (Fig. 32-23). This treatment typically has been performed in conjunction with repair of the acromioclavicular or coracoclavicular ligaments.[95] Technically, transfixion of this joint is demanding because of the thin acromion and the curved nature of the clavicle. Other concerns include the necessity for hardware removal and the risk of pin breakage and migration.[71] In addition, surgical trauma to the meniscus and articular cartilage may occur and lead to the subsequent development of degenerative arthritis of the acromioclavicular joint.[107] There has been recent interest in the use of bioabsorbable materials to transfix the acromioclavicular joint. The potential advantage of these materials is that they provide fixation of the joint, without the necessity of a second procedure for hardware removal.

Recent studies have advocated the use of a specialized hook plate to stabilize the acromioclavicular joint.[40,103,119] Described in the 1980s, the plate provides stability to the

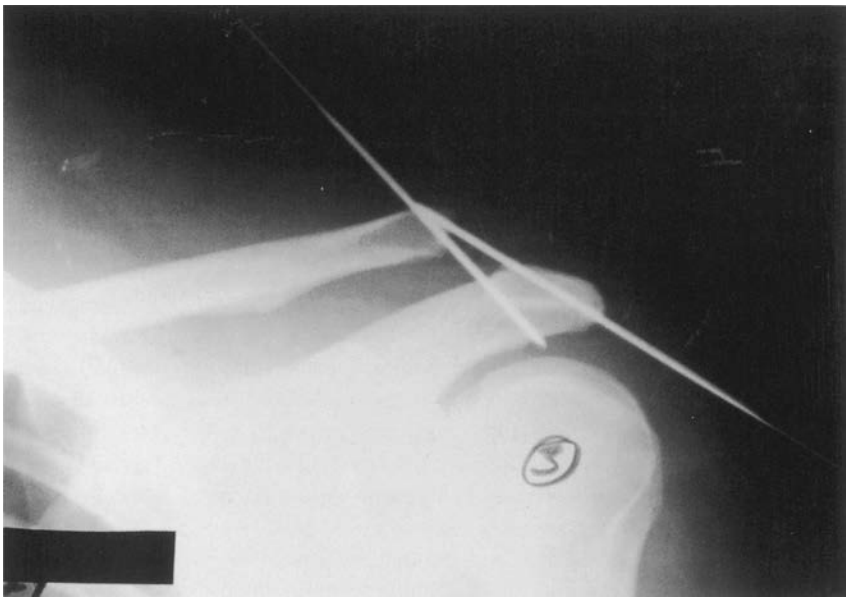

Figure 32-23 Fixation failure: Transfixion of acromioclavicular joint is demanding due to the thin acromion and curvature of the clavicle.

acromioclavicular joint but is a technically demanding procedure with a high complication rate that may make it impractical. It also requires a secondary removal at a later date. Studies of small groups of patients showed high incidence of infection and wound healing problems (up to 28%) with the plate such that common usage of this plate should not be undertaken.

Primary Coracoclavicular and Extraarticular Stabilization

Stabilization of the distal clavicle can be achieved by securing the clavicle to the coracoid process of the scapula. Bosworth described a technique in which he placed a screw through the clavicle into the base of the coracoid (Fig. 32-24).[16] Initially, the screw was placed percutaneously and the acromioclavicular joint was not explored or débrided. The Bosworth screw technique is often accompanied now by joint exploration and repair of the coracoclavicular ligaments.[58,59] Repair of the deltotrapezius fascia is also accomplished during this procedure. Screw removal is typically considered between 8 and 10 weeks postoperatively. Ossification between the coracoid and the clavicle occurs with some frequency and has not generally caused a problem with shoulder motion.[58]

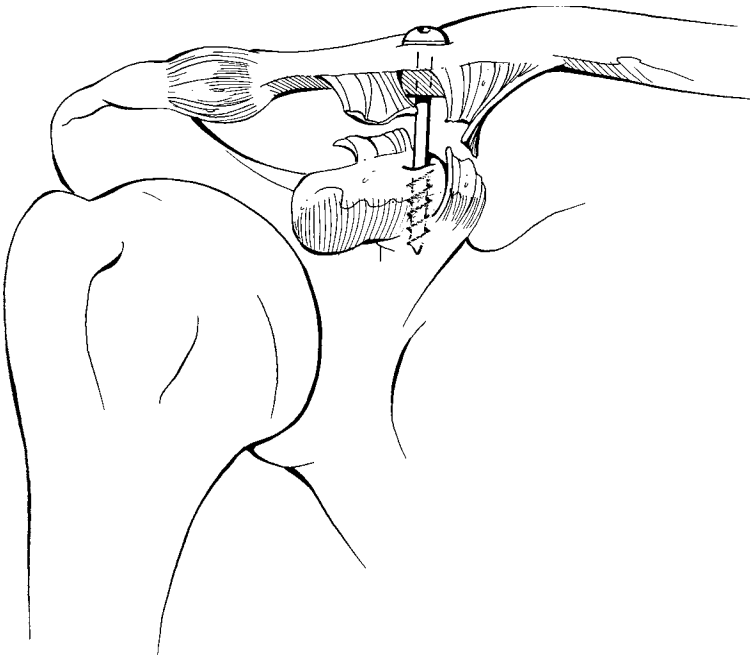

Figure 32-24 Screw fixation of clavicle to base of coracoid.

Other forms of extraarticular stabilization eliminate the need for screw removal. Cerclage fixation of the clavicle to the coracoid has been accomplished using wire,[2,9] Dacron graft, or other synthetic tape[57,78,86]; braided bioabsorbable suture; or, more recently, autologous or allograft hamstring tendon.[56] Typically, coracoclavicular fixation is accompanied by repair of the coracoclavicular ligaments, acromioclavicular joint, and deltotrapezius fascia. Use of nonabsorbable Dacron tape has been associated with erosion through the clavicle, failure of fixation,[27,45] and late infection.[79]

Accurate reduction of the acromioclavicular joint is difficult, but critical, particularly when the distal clavicle is not excised. Morrison and Lemos documented the need to accurately determine the subcoracoid and transclavicular positions of the fixation device.[75] They determined that the loop should be placed at the base of the coracoid and then inserted through a hole at the junction of the anterior and middle third of the clavicle. They felt that if the loop is posterior or goes around the clavicle, it tends to displace the clavicle anteriorly.

Excision of the Distal Clavicle and Coracoacromial Ligament Reconstruction

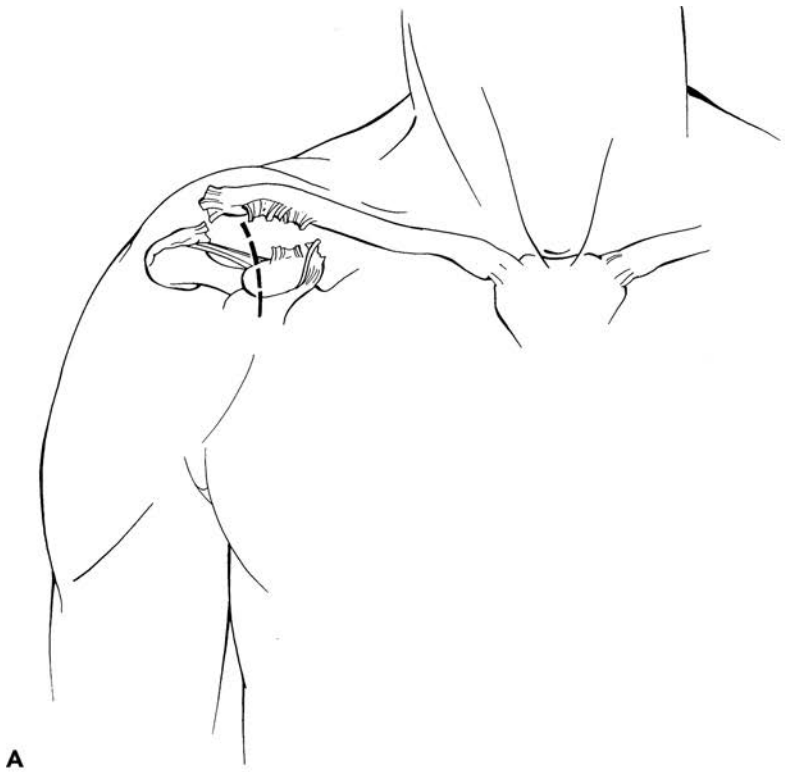
In 1972, Weaver and Dunn described a technique they used to treat acute and chronic acromioclavicular joint dislocations.[113] The surgical procedure involved excision of the distal clavicle, followed by transfer of the coracoacromial ligament to the resected end of the distal clavicle. Many variations and modifications of this procedure have been used when reconstruction of the joint is performed.[19,35,115] The decision of whether to preserve or excise the distal portion of the clavicle is based on concern over the ability to completely reduce the acromioclavicular joint and the possibility for development of degenerative arthritis. In evaluating acromioclavicular joint and coracoclavicular ligament repair, Smith and Stewart found no difference in symptoms, strength, or function, but did find a higher incidence of degenerative changes when the distal clavicle was not excised.[105] Symptomatic degeneration of the acromioclavicular joint has been effectively managed by excision of the distal clavicle.

Recent concern that this reconstruction only addresses the coracoclavicular ligaments has led to techniques that address both the coracoclavicular ligaments and their individual components (trapezoid and conoid) along with the acromioclavicular ligaments. Recently, Krishnan et al. presented their results with a technique undertaken in nine patients with type V dislocations.[62] The technique involves (a) distal clavicle resection; (b) intramedullary transfer of the coracoacromial ligament; (c) coracoclavicular reconstruction using an absorbable suture braid and ipsilateral semitendinosis graft through a drill hole in the clavicle and figure-eight around the coracoid; and (d) acromioclavicular joint superior capsular reconstruction with a remaining semitendinosis graft fixed with transosseous sutures to the acromion and posterior clavicle. All patients before the surgery demonstrated symptomatic posterior translation of the distal clavicle relative to the acromion. All patients did well at 22 months based on the American Shoulder and Elbow Surgeons (ASES) score, pain, and function. No patients demonstrated symptomatic posterior translation of the clavicle at follow-up.

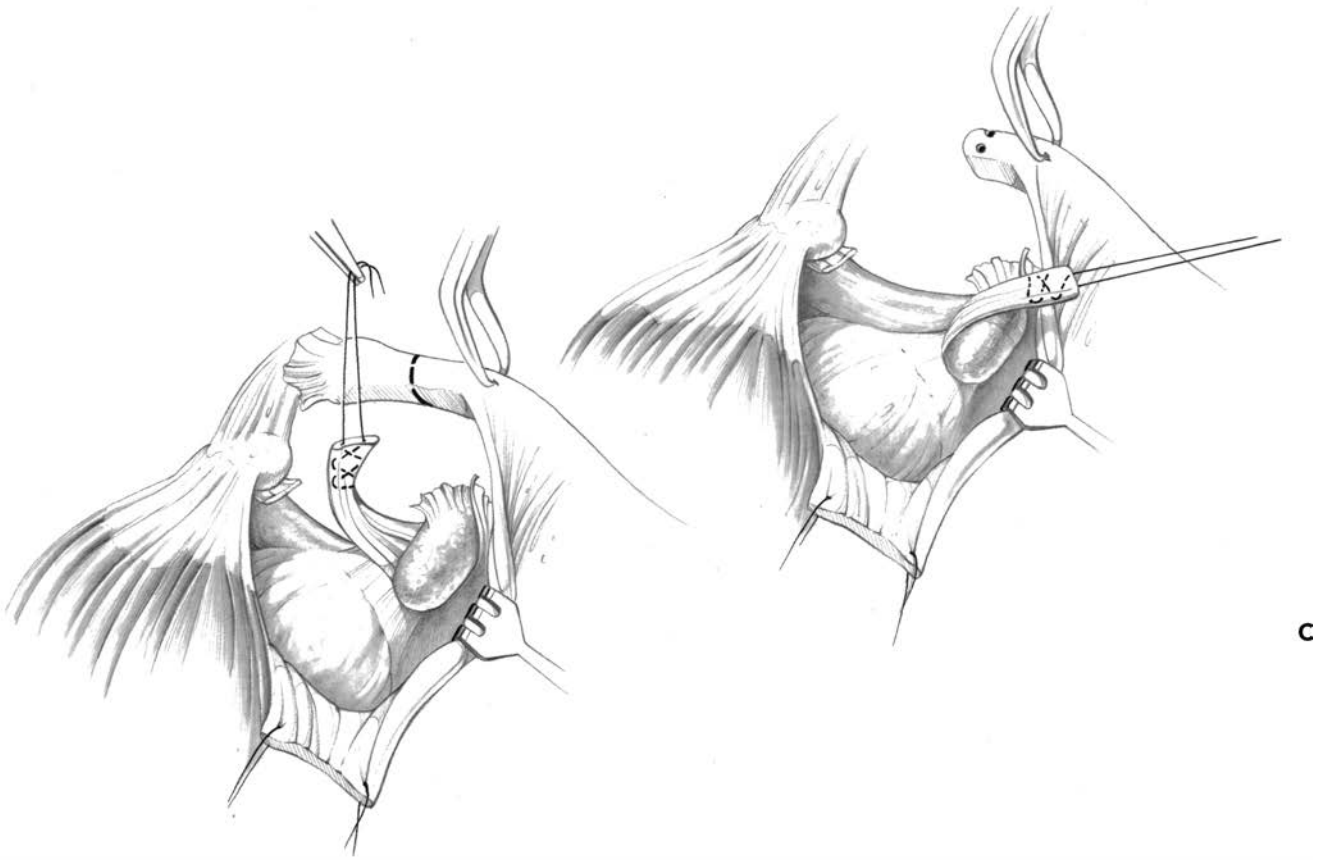
Open Technique

Our preference for reconstructing a disruption of the acromioclavicular joint is to address the pathology as completely as possible. This entails stabilizing the resected distal clavicle by transferring the coracoacromial ligament to it and supporting the repair using a braided absorbable suture along with an autogenous or allograft semitendinosis tendon. We also believe that an attempt should be made to reconstruct the acromioclavicular ligaments utilizing the semitendinosis graft. If possible, we also repair the coracoclavicular ligaments and the deltotrapezial fascia. In our opinion, the only significant surgical variable in the acute injury is deciding whether to preserve or excise the distal clavicle. We prefer its excision because of the difficulty in obtaining a perfect reduction of the acromioclavicular joint. We are concerned that the injury or incomplete reduction may lead to the development of degenerative arthritis. Pain also may occur from the degenerated joint or from inferior projecting spurs that cause mechanical impingement on the rotator cuff. No significant deficits in muscle strength were observed in athletes who have undergone excision of the distal clavicle.[109] Therefore, it may be advantageous from both a short- and long-term perspective to excise the distal clavicle as part of the reconstructive procedure.

Patients are positioned in the beach-chair position with most of the scapula and shoulder draped free. The shoulder is approached through a vertical incision from the coracoid to the posterior border of the clavicle (Fig. 32-25a). The incision passes approximately 2 cm medial to the acromioclavicular joint. The incision is planned and subcutaneous tissue undermined laterally so that the distal clavicle and anterior acromion can be reached. Next, the deltotrapezius fascia is incised along the clavicle using the Bovie electrocautery. In type IV and V acromioclavicular joint dislocations, the deltotrapezius fascia may be disrupted, and this opening should be extended as necessary. The dissection should be performed to carefully maintain a deltoid flap for later repair. As the incision in the fascia is carried laterally to the acromion, care is taken to dissect beneath the deltoid to expose the coracoacromial ligament. Once the coracoacromial ligament is completely defined, it is released from the undersurface of the acromion, with care to maximize its length. We place two independent no. 2 nonabsorbable sutures, usually Fiberwire, in the ligament to secure it to the distal clavicle.



A



B

C

Figure 32-25 **A-G:** Surgical steps as outlined in this chapter: **(A)** The vertical skin incision extends approximately three inches from the coracoid process to the posterior aspect of the clavicle. It passes about 2 cm medial to the acromioclavicular joint. **(B)** The deltoid and trapezius fasciae are carefully maintained as flaps. The coracoacromial ligament is dissected and released from the undersurface of the acromion. Two sutures are placed in the ligament in order to secure it to the clavicle. **(C)** The distal 1-1.5 cm of the clavicle is excised and the intramedullary canal is curetted open. Two drill holes are placed along the cut end of the clavicle from the superior surface into the canal.

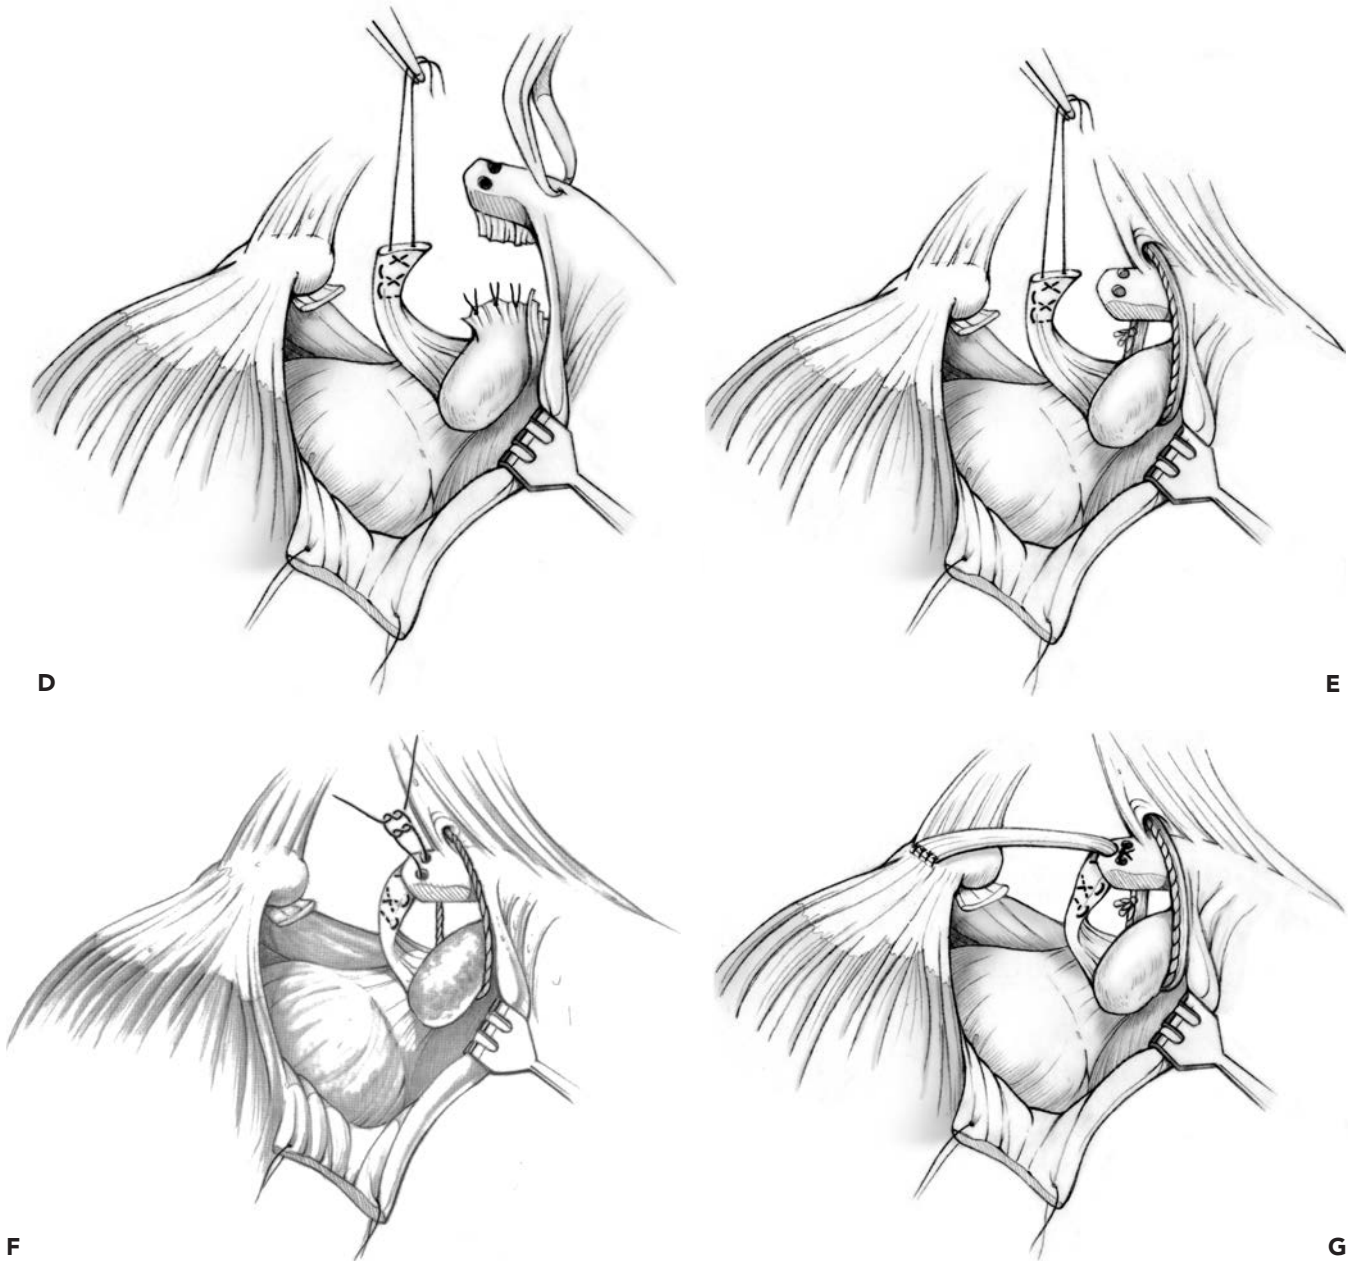


Figure 32-25 (*continued*) **(D)** The coracoclavicular ligaments are identified and tagging sutures are placed. **(E)** Braided PDS sutures are placed beneath the base of the coracoid process and through drill holes in the clavicle. Semitendiosis tendon is used along with PDS suture. Knots are tied inferior to the clavicle. **(F)** The coracoclavicular loop of suture is tied first. Second, the sutures from the coracoacromial ligament are tied. Finally, the coracoclavicular ligaments are repaired. **(G)** A piece of the semitendinosis tendon is used to reconstruct the superior acromioclavicular capsule.

Typically, one suture is placed in a Bunnell fashion and the other using a Kessler-type stitch. If the coracoacromial ligament is felt to be insufficient, we add an 8- to 10-mm strip of the conjoined tendon and turn it superiorly.

At this point, the distal clavicle is exposed subperiosteally from beneath the trapezius muscle and fascia. We excise the distal 1 to 1.5 cm of the clavicle using a sagittal saw. A curette is used to hollow out the intramedullary aspect of the clavicle. A 1.6-mm drill bit is used to create two drill holes along the superior surface of the cut end of the clavicle entering into the intramedullary canal. Looped passing sutures are then passed through each of these holes, which are used later to facilitate passage of the sutures placed in the coracoacromial ligament. Care is taken to place the holes back from the cut end of the clavicle and provide a secure bony bridge between drill holes.

After the coracoacromial ligament is prepared for transfer, we dissect the torn coracoclavicular ligaments and reconstruct them as much as possible. Although most disruption occurs in the midsubstance, avulsion from the bone is occasionally encountered. These injuries are more easily sutured and repaired back to bone. Typically, we place tagging-type sutures, as these are tied in the final step of the procedure before closing the deltotrapezial fascia.

The third stage of the procedure involves placing a loop of absorbable suture beneath the coracoid and over or through drill holes in the clavicle. We currently also augment this reinforcing suture with a strand of autogenous or allograft semitendinosis tendon placed through drill holes in the clavicle and looped in a figure-eight fashion around the coracoid. The superior surface of the coracoid is palpated and its medial and lateral aspects are defined. We use a combination of a right-angled clamp and curved Satinsky vascular to carefully dissect beneath and around the coracoid process. Once the end of the clamp is visualized, we grasp the looped end of a suture and pull it around the coracoid process. The position of the clavicle directly superior to the coracoid is now identified. This area of the clavicle is usually still covered by adherent trapezius muscle. Two drill holes wide enough to pass a loop of semitendinosus tendon are drilled in the clavicle just over the coracoid process and are made in the anterior third of the clavicle. A looped suture is passed through the holes and held with a hemostat.

The looped sutures around the coracoid and through the anterior third of the clavicle are used to pass the suture of choice along with the hamstring tendon for final fixation. We have not used nonabsorbable suture or tape, owing to concerns over risks of infection and erosion through the clavicle. If available, a 5-mm tape of polydioxanonsulfate (PDS) is used; otherwise, strands of readily available no.1 PDS are braided together. We usually braid three strands of PDS together, use two of these braids, and tie them independently. With the advent of using a hamstring tendon to secure the repair, probably only one braid of PDS is necessary. Beginning with these coracoclavicular sutures and the hamstring augmentation, the first part of the repair is secured. The knots are tied so that they end up inferior to the clavicle and do not interfere with closure of the deltotrapezial fascia. The hamstring augmentation is secured to itself with nonabsorbable sutures. Secondly, the two coracoacromial ligament sutures are passed through the drill holes in the distal clavicle and tied independently. Next, the coracoclavicular ligaments are repaired as completely as possible. The next part of the repair involves using a strip of semitendinosus tendon to reconstruct the superior acromioclavicular capsule. This reconstruction can use transosseous sutures on the acromion and the superior sutures used to tie the coracoacromial ligament into its osseous tunnel. Finally, the deltotrapezial fascia is carefully repaired over the clavicle. This not only covers the different parts of this reconstruction, but also reinforces and supports the repair.

Postoperatively, the arm is supported in a sling for 4 weeks. Motion exercises, including pendulums and gentle active elevation, are begun at 2 weeks. Progressive range-of-motion and strengthening exercises are not begun until 6 weeks after surgery. Heavy weightlifting, pushing, pulling, and other stressful activities are delayed until 3 months, and contact sports are allowed at 5 to 6 months.

Results

A careful review of the literature fails to demonstrate a clear choice from among the many different procedures, modification, and combinations that have been described. While most procedures give satisfactory results, there definitely seems to be a trend toward the more physiologic procedures that address both sets of ligaments (coracoclavicular and acromioclavicular). There are few comparison studies, as most authors report the results of a given procedure. Kennedy has reported on a modification of the Bosworth technique that includes a débridement of the acromioclavicular joint and repair of the trapezius and deltoid fascia.[58] He found that even when a bony bridge developed between the clavicle and the coracoid process, function and range of motion were maintained. Acromioclavicular and coracoclavicular fixation have been compared in several studies.[8,64,105,107] Coracoclavicular fixation has generally been favored because of its lower complication rate and overall superior results. In addition, a higher degree of late degenerative arthritis has been noted with acromioclavicular fixation.[105,107]

Weaver and Dunn described their procedure and results in 12 patients with acute type III acromioclavicular injuries.[113] Rausching et al. reported similar good results using this procedure, based on joint stability, pain, and function.[90] Browne et al. reviewed a group of patients with coracoclavicular fixation, with and without resection of the distal clavicle, and failed to demonstrate an advantage to distal clavicle excision.[19] Smith and Stewart also looked at the effect of distal clavicle excision in patients treated with acromioclavicular fixation and coracoclavicular ligament repair.[105] They observed good results except for a higher incidence of degenerative acromioclavicular joint changes when the distal clavicle was excised.

Recently, studies have indicated that the classic Weaver-Dunn procedure may not support some of the forces required during motion of the upper extremity. Lee employed a cadaveric model to demonstrate that shoulder extension produced forces across the coracoclavicular ligaments that exceeded the tensile strength of the classic Weaver-Dunn procedure. Thus, the current trend is reconstructive procedures that augment the coracoclavicular reconstruction with hamstring tendon and also address the acromioclavicular ligaments and capsule. Krishnan et al.[62] recently reported their results with the new reconstructive procedure that addresses both sets of ligaments. In nine

patients with symptomatic type V joint dislocations, the final ASES score was 96, active anterior elevation averaged 163 degrees, external rotation was 58 degrees, and internal rotation was T10. No patient demonstrated posterior translation of the clavicle asymmetric to the normal side. Pain averaged 0.4 (0 = no pain; 10 = worst pain) and satisfaction averaged 9.6 (10 = totally satisfied) in these patients.

Arthroscopic Treatment of Acute and Chronic Acromioclavicular Joint Dislocation

All arthroscopic procedures for stabilization of an acromioclavicular joint dislocation are evolving but have not yet become widely used. An arthroscopic technique permits minimally invasive access to the acromioclavicular joint without detachment of the deltoid or trapezius. The postoperative recovery is proposed to be faster, although this has not been tested in a comparative trial. Wolf[118] was the first to develop an arthroscopic technique using a drill guide to place a transcoracoid–transclavicular loop of suture material to stabilize the distal clavicle and reproduce the coracoclavicular ligaments to form an artificial ligament. This arthroscopic technique is combined with a mini-open technique for distal clavicle resection and tying the suture material.

All-Arthroscopic Acromioclavicular Joint Stabilization Technique

The procedure is performed with the patient in the beach-chair position under interscalene block with the arm maintained by an arm holder. Four portals are used: the standard posterior for the glenohumeral joint, the lateral portal as used for acromioplasty, an anterolateral at the anterior corner of the acromion, and the anterior portal for the distal clavicle resection.

After viewing the glenohumeral joint to define and treat other pathologic lesions, the arthroscope is placed into the subacromial space using the posterior portal. The subacromial bursa is removed to obtain clear visualization of all of the subacromial structures to include the coracoacromial ligament and its associated artery (acromial branch of the thoracoacromial artery), the torn coracoclavicular ligaments, and both the more lateral and anterior trapezoid and the more medial and posterior conoid ligament. The coracoacromial ligament is carefully dissected from surrounding tissue, and the artery is cauterized from the deltoid muscle.

Sutures—Inferior Attachment

The arthroscope is then placed in the lateral portal and instrumentation is used through the anterior, anterolateral, and posterior portals. The coracoacromial ligament is dissected from the deltoid and followed to the base of the coracoid. An Orthocord (Mitek), a Fiberwire (Arthrex), or an Ultrabraid (Smith and Nephew) suture is shuttled through the ligament beginning very close to its origin on the coracoid process. Alternatively, both braids are then passed several times through the coracoacromial ligament until its insertion on the acromion keeps the artery outside the loops (Fig. 32-26). Suture management is performed by PDS shuttle with a Spectrum (Linvatec) device, or direct passage by a Clever Hook (Mitek) may be used from the combined anterior, anterolateral, and posterior portal. The coracoacromial ligament is sharply dissected from the acromion undersurface. The sutures are retrieved posteriorly to keep the coracoacromial ligament close on the rotator cuff and away from the burr when a subacromial decompression is performed to facilitate a lateral view of the acromioclavicular joint and distal clavicle. A resection of the distal clavicle is performed.[18] The access to the distal clavicle can be difficult as it is dislocated superiorly and is better exposed by pushing down the clavicle while pushing up at the elbow. A resection of 5 to 7 mm of the distal clavicle is important to prevent painful bone-to-bone contact when the clavicle is reduced and held at the level of the acromion. When reduction looks difficult to maintain, one or two double-loaded suture anchors are placed through the anterior portal at the base of the coracoid where the coracoacromial ligament was attached and the sutures are retrieved posteriorly and later passed through drill holes in the distal clavicle.

Sutures—Superior Transosseous Management

Two-millimeter drill holes are made, using a percutaneous technique, in the lateral clavicle from superior to inferior about 5 mm apart, at the insertion of the native coracoacromial ligament.

Before passing the coracoacromial ligament sutures through the drill holes, the right length of the coracoacromial ligament is assessed by bringing the free end of the looped ligament with a grasper to the clavicle undersurface, while the assistant lifts up the arm to reduce the acromioclavicular joint dislocation. If the length is not perfect, additional looping of suture in the coracoacromial ligament or release of a loop is necessary. The number of holes drilled in the clavicle is based on the number of suture anchors in the coracoid. Two to three sutures can be passed through one drill hole.

A suture shuttle is placed through the drill holes in the clavicle using a 16-gauge spinal needle loaded with a looped #0 PDS suture (Fig. 32-27). Alternatively, a Hewson suture passer can be used. A grasper is used to retrieve the PDS suture loop, and the more lateral coracoacromial ligament suture is pulled out through the anterior portal. The coracoacromial ligament suture and the shuttle loop are passed through the drill hole by pulling out the needle and its attached suture at the same time. The same procedure is performed for the second coracoacromial ligament suture. Sutures on the anchors are passed using the same technique.

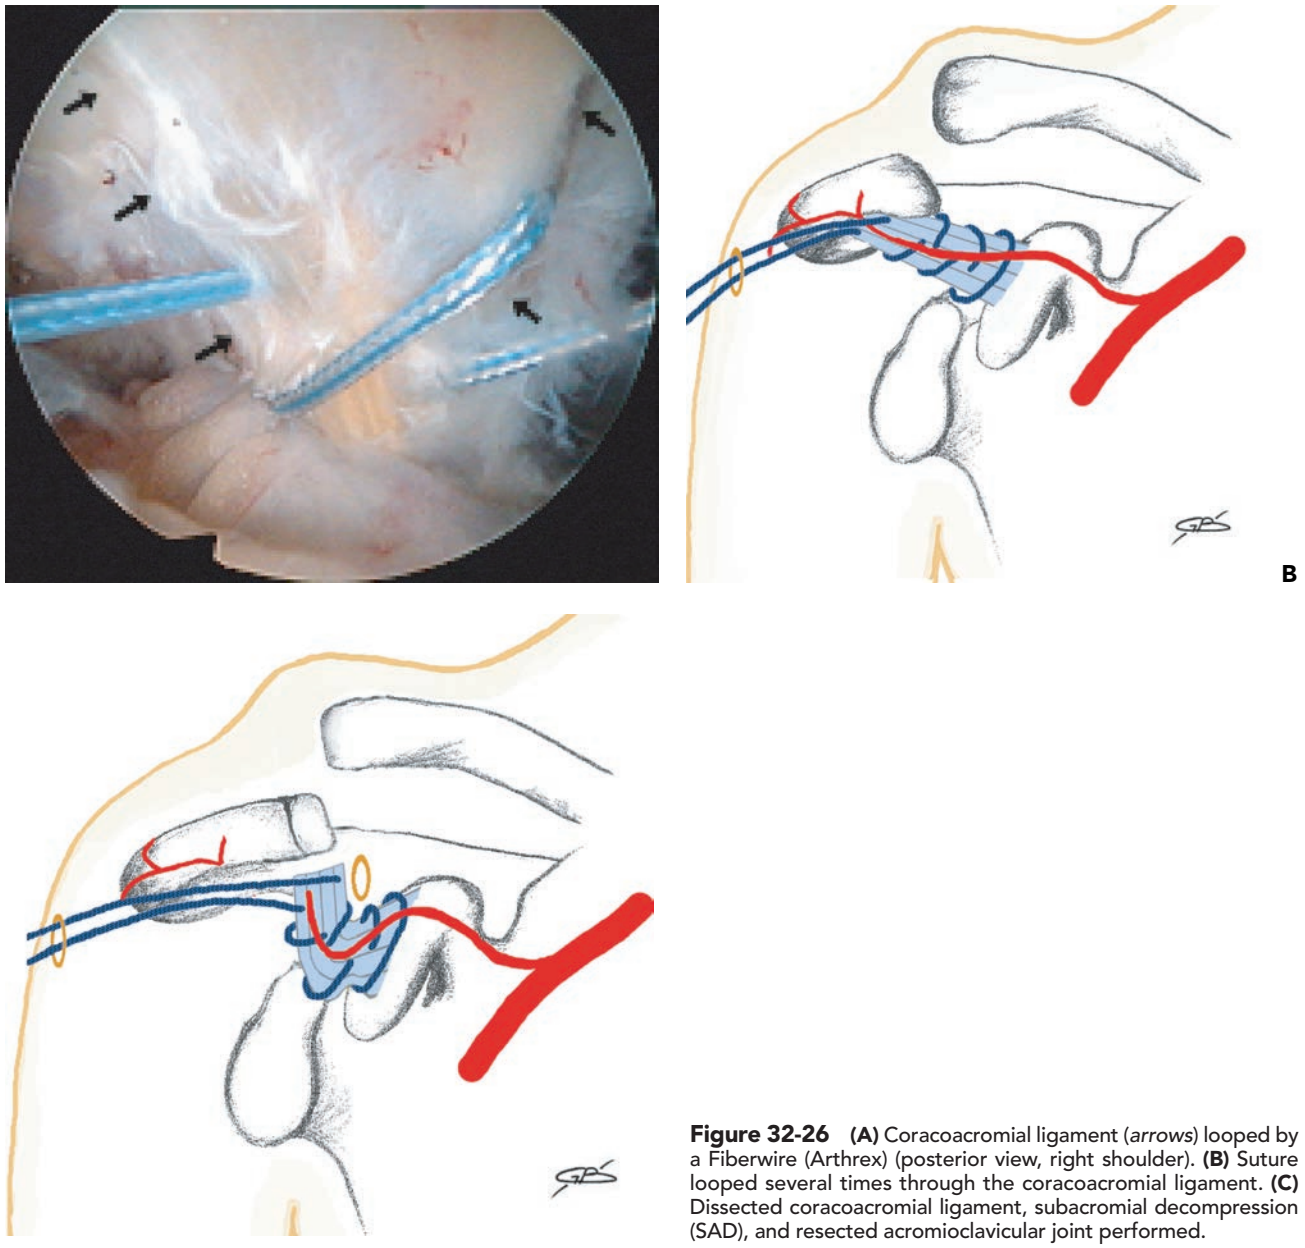

Figure 32-26 **(A)** Coracoacromial ligament (*arrows*) looped by a Fiberwire (Arthrex) (posterior view, right shoulder). **(B)** Suture looped several times through the coracoacromial ligament. **(C)** Dissected coracoacromial ligament, subacromial decompression (SAD), and resected acromioclavicular joint performed.

Final Fixation

If the final length and position of the coracoacromial ligament is good, then the knot is tied without creating another portal. Both sutures are retrieved between the clavicle and the subcutaneous tissue (Fig. 32-28). The traction on the arm is released to reduce the acromioclavicular joint by the assistant lifting the upper arm and pushing on the lateral clavicle at the same time.

The subcutaneous knot is tied blindly by successive half loops under slight overreduction of the acromioclavicular joint to compensate for the loss of reduction during the healing period. As knot tying cannot be visualized in this region, experience with knot tying is required to secure this knot. Alternately, this knot can be tied by direct visualization by making a small incision over the clavicle. Once the knot is tied, the sutures are cut with a blind cutting device and the portals are closed with absorbable sutures.

For an extra-secure reduction of the clavicle, a suture anchor in the base of the coracoid is necessary to maintain the reduced acromioclavicular joint. When this is used, the sutures are passed as described and tied first.

Postoperatively, a sling is used for 6 weeks; x-rays are performed in the recovery room and then 6 weeks after surgery. Motion is limited during the first 6 weeks with forward flexion and abduction up to 90 degrees; after 6 weeks the patients may start to move in the full range of motion, but without heavy lifting for the first 3 months.

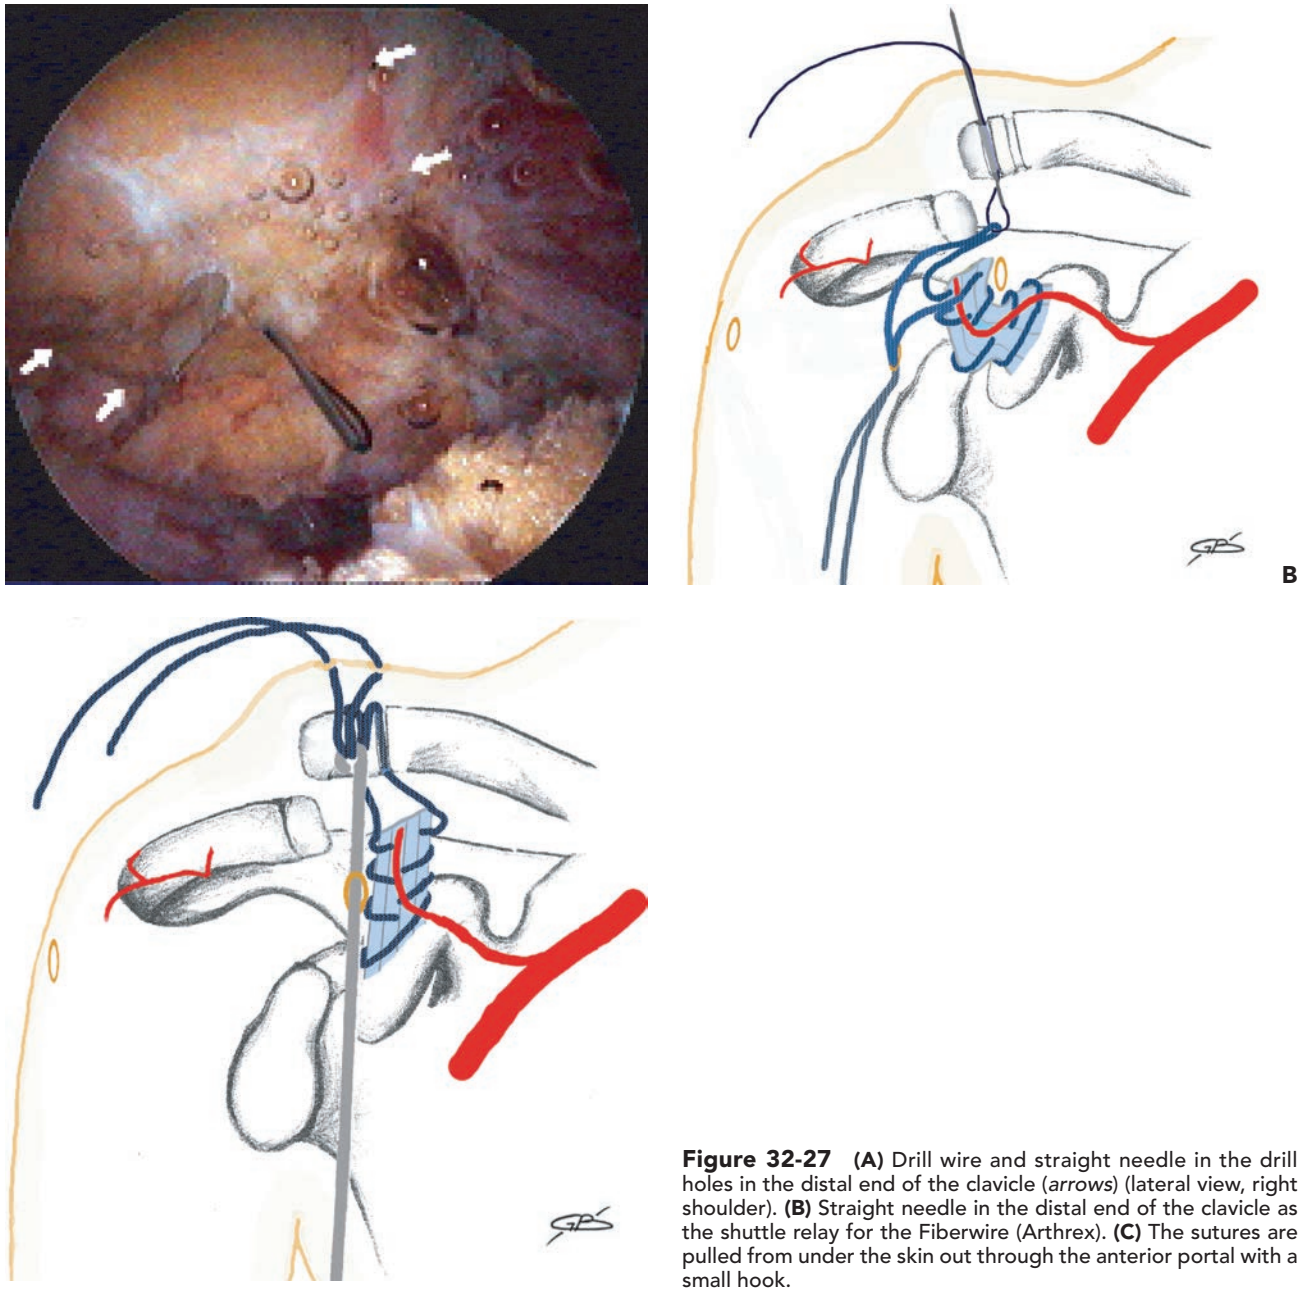

Figure 32-27 **(A)** Drill wire and straight needle in the drill holes in the distal end of the clavicle (*arrows*) (lateral view, right shoulder). **(B)** Straight needle in the distal end of the clavicle as the shuttle relay for the Fiberwire (Arthrex). **(C)** The sutures are pulled from under the skin out through the anterior portal with a small hook.

Results

An unpublished clinical experience with these techniques by one of the authors (LL) is a series of 14 cases from May 2002 to May 2003 with the technique described for transfer of the coracoacromial ligament and also temporary supplemental fixation with K-wires across the acromioclavicular joint. In only three cases was a full reduction maintained and in nine cases a partial reduction was maintained. A more recent technique of coracoacromial ligament transfer was performed in 20 cases with additional suture fixation using two double-loaded suture anchors placed in the base of the coracoid and passing the sutures between base of the coracoid and transosseous clavicle tunnels. In these cases K-wires across the acromioclavicular joint were not used. With this newer technique there was only one case of complete loss of fixation in a patient that did not follow postoperative instructions, two cases with partial loss of reduction with a good clinical result, and 17 cases without loss of reduction and an excellent clinical result. Further study and use of this technique by other surgeons will help clarify the perceived benefits over more traditional open surgical techniques, which have provided very reliable and reproducible results.

OSTEOLYSIS OF THE CLAVICLE

Osteolysis of the distal clavicle is felt to be related to repetitive activities such as weightlifting.[4,20,124] While an uncommon condition, it is felt to be increasing because of the popularity of weight training and the increasing awareness of physical fitness. Repetitive stress to the subchondral bone leads to subchondral fatigue fractures and a hypervascular response leading to resorption of bone. Some of the hallmarks of this condition are demineralization, osteopenia, subchondral cyst formation, and distal clavicle erosion.[77,101] The patient typically presents with pain over the acromioclavicular joint related to overhead activities. The pain may radiate to the neck and trapezius and down the arm and deltoid. Pain may be elicited by daily activities but is usually most pronounced with overhead athletic activity, particularly motions that bring the arm across the chest (adduction). Weightlifting activities such as the bench press, dips, and pushups exacerbate the pain.[20,101] Associated symptoms of popping, grinding, or catching are sometimes noted.

Physical examination of the extremity will typically find point tenderness over the acromioclavicular joint along with prominence of the distal clavicle. Maneuvers such as reaching across the body will elicit pain localized to the acromioclavicular joint. Motion is infrequently restricted. Impingement maneuvers may be positive if the rotator cuff is secondarily affected.

Radiographic evaluation of the shoulder will infrequently visualize the acromioclavicular joint adequately. The typical standard views of the shoulder overpenetrate the acromioclavicular joint and do not allow adequate assessment. For better visualization, the technique should be modified to underpenetrate one-third of joint. The Zanca view, an AP view with the beam tilted cephalad 15 degrees to better visualize the acromioclavicular joint without overlapping the spine of the clavicle, is helpful. Radiographic findings of osteolysis of the distal clavicle include distal clavicle osteopenia, cystic changes, and loss of subchondral bone detail. Later changes may include changes along the medial aspect of the acromion and widening of the acromioclavicular joint.

Occasionally, a bone scan may be helpful to further evaluate acromioclavicular joint pathology in light of relatively normal radiographs, particularly with osteolysis. Cahill believes that technetium-99m-labeled phosphate scintigraphy is the most diagnostic test in the evaluation of osteolysis.[20] Uptake of tracer is noted not only in the distal clavicle, but also in the adjacent acromion.

MRI may be a more practical test in the evaluation of the acromioclavicular joint since it allows excellent evaluation of the adjacent soft tissues including the rotator cuff, which is frequently secondarily involved. Edema in the distal clavicle on MRI has a high correlation with the presence of symptoms.[102]

Initial treatment of the acromioclavicular joint with osteolysis is nonoperative. Options include activity modification, cryotherapy, nonsteroidal and analgesic medications, occasional corticosteroid injections, and physical therapy. Most nonoperative treatments may require an extended period of time and require significant restrictions of an athletic endeavor to be effective. Many of

today's athletes will not tolerate the significant time and restriction of nonoperative treatments. Operative resection of the acromioclavicular joint may be required in patients with persistent pain and loss of function who do not respond to nonoperative modalities or in those who do not wish to modify their activities. Worcester and Green[121] found 100% success with joint resection in patients who responded to acromioclavicular joint injection.

Degenerative Lesions of the Acromioclavicular Joint

Patients who have degenerative or posttraumatic arthropathy of the acromioclavicular joint most commonly present with pain similar to osteolysis. The pain may be localized to the top of the shoulder and the area of the acromioclavicular joint, but it may also be referred to the area of the upper arm. Unlike osteolysis, typical impingement-type symptoms occur with abduction and overhead positions. Weight lifts, including bench press, incline press, and abduction exercises, frequently generate symptoms. Pain also occurs with cross-body arm positions. Patients often have night pain and pain when lying on the involved side. A history of previous injury to the shoulder and the patient's diagnosis, treatment, and recovery should be elicited. Some patients notice prominence of the acromioclavicular joint and may have clicking or catching in the area. Patients with acromioclavicular joint arthropathy may be symptomatic from motion of the arthritic joint, or outlet impingement from inferior projecting spurs may cause typical rotator cuff–type symptoms. A careful physical examination and radiographic evaluation are useful to determine the degree of acromioclavicular joint involvement and subacromial impingement.

A thorough examination is performed to evaluate the shoulder for all possible pathologies. Visual inspection may reveal asymmetry and a prominence of the acromioclavicular joint. There is asymmetrical point tenderness over the joint, which may be accentuated by horizontal cross-body adduction. This test is sensitive, but not specific, as it may elicit pain in patients with impingement from subacromial pathology. Acromioclavicular joint stability is assessed by grasping the distal clavicle between the thumb and index finger and translating the clavicle anteroposterior and superoinferior while the other hand stabilizes the acromion. Glenohumeral stability is also evaluated with typical apprehension, relocation, and translation tests. A careful neurologic examination should determine whether there is any possible brachial plexus involvement. Selective injection of lidocaine into the acromioclavicular joint frequently helps confirm that the joint is the cause of the symptoms. Response to injection of the subacromial space may also provide useful information on the presence of rotator cuff impingement.

A complete radiographic evaluation of the acromioclavicular joint includes standard AP and coracoacromial outlet ("Y") views. The outlet view is critical to accurately assess the anatomy of the anterior acromion and the degree of outlet impingement. Because the acromioclavicular joint is frequently difficult to assess on standard AP views, an underpenetrated view or Zanca view is warranted. An axillary view helps evaluate the anteroposterior position of the distal clavicle and the presence of an os acromion. MRI has supplanted use of the bone scan in determining the amount of acromioclavicular degeneration and the effect it may have impinging on the rotator cuff.

Patients who have pain primarily from a degenerated acromioclavicular joint have the best chance of responding to conservative management. Those who have symptoms that appear to be secondary to the effect of narrowing of the subacromial space from acromioclavicular joint spurring may have more refractory pain. We begin all patients who have no contraindications on a regime of nonsteroidal antiinflammatory medications. They are counseled to avoid provocative activities or arm positions and instructed in range-of-motion and stretching exercises to minimize capsular contractures. An intraarticular injection of lidocaine and steroid into the acromioclavicular joint may provide significant and sustained symptom relief. When subacromial impingement is also apparent, we will inject the subacromial space for diagnostic and therapeutic benefit. Only rarely have we used more than a total of three intraarticular acromioclavicular joint injections.

When patients have persistent pain and loss of function and activity levels despite attempts at conservative treatment, they may consider operative intervention. Excision of the distal clavicle is the procedure of choice. Similarly, patients with impingement from pathology at the acromioclavicular joint will benefit from surgical management. In these patients, excision of the distal clavicle is combined with an acromioplasty to decompress the coracoacromial outlet. Early surgical treatment may be preferred for symptomatic patients that have a complete tear of the rotator cuff.

Acromioclavicular joint resection and acromioplasty can be performed either open or by using arthroscopic techniques. The open procedure is straightforward and familiar to most surgeons. The amount of bone to be removed can be measured and predictably resected. In the absence of diagnostic errors, the results of surgery are reproducible and well documented. One disadvantage of open surgery is that it requires detachment of some portion of the deltoid from the trapezius to expose the clavicle. Access to the anterior acromion for an acromioplasty requires even greater dissection of the deltoid. This amount of soft tissue trauma accounts for the fairly significant amount of early postoperative pain that is experienced with this procedure. Historically, 1 to 2 cm of distal clavicle has been resected. Disruption of the acromioclavicular ligaments has raised some concerns about the problem of

postoperative horizontal instability of the clavicle.[14] Cosmetic issues are generally of lesser concern.

Arthroscopic excision of the distal clavicle has evolved as a popular yet technically demanding procedure. It can be used for isolated acromioclavicular joint arthrosis or in conjunction with an acromioplasty when impingement anatomy is present. Other than the difficulty in obtaining precise and reproducible bone resection, arthroscopic techniques offer advantages to open surgery. There is no significant trauma to the deltoid, less postoperative pain, and minimal scarring. In addition, no protection is necessary for the deltoid postoperatively (as opposed to open surgery). The recommended amount of distal clavicle resection has been determined to be only 5 mm to 1 cm.[42,43,81,83] Less bone resection and preservation of the acromioclavicular ligaments should diminish concerns over horizontal instability of the clavicle.

Complications of Surgery

Complications related to acromioclavicular injuries may occur as a result of the injury or related to its treatment, including surgery. Symptomatic degenerative changes occur with mild degrees of acromioclavicular injury.[25] Osteolysis of the distal clavicle may occur not only related to repetitive use, but also as a posttraumatic condition.[70,77] Ossification in the coracoclavicular interval may occur after coracoclavicular ligament injury or following surgical repair or stabilization. Its presence does not appear to affect outcome or results.[73,116] Some patients with chronic displaced acromioclavicular joint injuries complain of arm weakness, paresthesias, or other vague symptoms suggestive of traction on the brachial plexus. These thoracic outlet–type symptoms may be related to inferior position of the shoulder girdle relative to the thorax.

The surgical treatment of these injuries is associated with a significant number of possible problems. Most common may be the persistence or recurrence of a mild prominence or deformity that is often asymptomatic. Fixation failure with complete recurrence often will require a revision procedure.[68,75] The use of hardware has been associated with breakage, migration, and fixation failure.[21] Kirschner wires and Steinmann pins have migrated from the acromioclavicular joint to dangerous locations, such as the lung,[36,71] spinal cord,[80] and neck.[69] Fixation across the acromioclavicular joint may also precipitate arthritic changes of this joint. Erosion of the clavicle by wire or nonabsorbable suture used in coracoclavicular fixation has also been observed with some frequency.[57,78,86] This may lead to fracture of the clavicle or coracoid process. We have also seen infections related to the use of nonabsorbable augmentation tapes sometimes years after the initial surgery.[79,82]

Neurovascular injuries have been reported in relation to surgical treatment of these injuries, primarily because of the close proximity of the brachial plexus along with the subclavian artery and vein. Transfer of the short head of the biceps to the clavicle to provide dynamic stability has been associated with musculocutaneous injury.[23,68]

Resection of too much bone on the distal clavicle may produce instability of the clavicle in the anteroposterior plane that can be associated with symptoms.[14] Open techniques of distal clavicle resection commonly removed 2 to 3 cm of bone and has the potential to compromise the acromioclavicular ligaments, capsule, and deltotrapezial fascia attachments. Recurrent symptoms after clavicle resection were shown to correlate with the amount of anteroposterior translation of the distal clavicle.

No matter what method of treatment for these injuries is subscribed, the goals should remain the same: return to full preinjury or preoperative range of motion, with restoration of painless strength and function.
