To my son, Matthew, and my father, Frank, for their never-ending support. To my colleague and best friend, Jerry Williams.

—Joseph P. Iannotti

To all of my teachers, especially Charles A. Rockwood, Jr., M.D., for their wisdom and patience. To my friend and trusted colleague, Joseph Iannotti M.D., Ph.D., without whom my professional journey would be incomplete. To my family, especially my wife, Robin, and my children, Mark and Alexis, for the love and support we share with each other.

—Gerald R. Williams, Jr.

Preface xiii

VOLUME 1

PART I: ROTATOR CUFF DISEASE AND TENDON RUPTURES 1

1 **Anatomy, Biomechanics, and Pathophysiology of Rotator Cuff Disease 3**
David L. Glaser, Jerry S. Sher, Eric T. Ricchetti, Gerald R. Williams, Jr., and Louis J. Soslowsky

2 **Diagnosis, Patient Selection, and Clinical Decision Making 39**
Allen Deutsch, Matthew L. Ramsey, and Joseph P. Iannotti

3 **Management of Rotator Cuff Disease: Intact and Repairable Cuff 53**
Joseph P. Iannotti, Michael J. Codsi, Laurent Lafosse, and Evan L. Flatow

4 **Management of Irreparable Rotator Cuff Tears: The Role of Tendon Transfer 101**
John G. Costouros, Christian Gerber, and Jon J.P. Warner

5 **Complications of Rotator Cuff Surgery 147**
Brian D. Cameron, Gerald R. Williams, Jr., and Joseph P. Iannotti

6 **Calcifying Tendinitis 185**
Shawn P. Hennigan and Anthony A. Romeo

7 **Disorders of the Biceps Tendon 217**
Ken Yamaguchi, Jay Keener, and Leesa M. Galatz

8 **Traumatic Muscle Ruptures 261**
Donald F. D'Alessandro, Patrick M. Connor, and Marshall A. Kuremsky

PART II: GLENOHUMERAL INSTABILITY 279

9 **Anatomy, Biomechanics, and Pathophysiology of Glenohumeral Instability 281**
Brian J. Cole, Clifford G. Rios, Augustus D. Mazzocca, and Jon J.P. Warner

10 **Biomechanics and Pathologic Lesions in the Overhead Athlete 313**
Patrick J. McMahon, Thay Q. Lee, and James E. Tibone

11 **Diagnosis of Glenohumeral Instability 339**
Jerry S. Sher, Jonathan C. Levy, Joseph P. Iannotti, and Gerald R. Williams, Jr.

12 **Anterior and Anteroinferior Instability: Open and Arthroscopic Management 369**
Anthony Miniaci, David E. Haynes, Gerald R. Williams, Jr., and Joseph P. Iannotti

13 **Posterior Instability: Open and Arthroscopic Management 401**
Matthew L. Ramsey and Jeffrey S. Abrams

14 **Multidirectional Instability: Open and Arthroscopic Management 433**
John J. Brems and Felix H. Savoie, III

15 **Chronic Dislocations 461**
Sean M. Griggs, G. Brian Holloway, Gerald R. Williams, Jr., and Joseph P. Iannotti

16 **Complications of Instability Surgery 487**
Mark D. Lazarus and Michael Walsh

PART III: FROZEN SHOULDER 539

17 **Diagnosis and Management of the Stiff Shoulder 541**
Frances Cuomo and G. Brian Holloway

PART IV: GLENOHUMERAL JOINT ARTHRITIS AND RELATED DISORDERS 561

18 **Pathophysiology, Classification, and Pathoanatomy of Glenohumeral Arthritis and Related Disorders 563**
David N. Collins

19 **Biomechanics of the Glenohumeral Joint: Influence on Shoulder Arthroplasty 633**
Gerald R. Williams, Jr., and Joseph P. Iannotti

20 **Alternatives to Replacement Arthroplasty for Glenohumeral Arthritis 655**
Sumant G. Krishnan, David C. Harkins, and Wayne Z. Burkhead, Jr.

21 **Glenohumeral Arthrodesis 675**
Robin R. Richards

VOLUME 2

22 **Unconstrained Prosthetic Arthroplasty for Glenohumeral Arthritis with an Intact or Repairable Rotator Cuff: Indications, Techniques, and Results 697**
Gerald R. Williams, Jr. and Joseph P. Iannotti

23 **Cuff Deficiency Arthropathy: Unconstrained and Constrained Shoulder Arthroplasty 727**
Ori Safran, Ludwig Seebauer, and Joseph P. Iannotti

24 **Complications of Shoulder Arthroplasty 753**
John W. Sperling and Robert H. Cofield

25 **Techniques for Revision Arthroplasty: Management of Bone and Soft Tissue Loss 773**
Michael J. Codsi and Joseph P. Iannotti

PART V: FRACTURES 791

26 **Fractures of the Scapula: Diagnosis and Treatment 793**
Thomas P. Goss and Brett D. Owens

27 **Fractures of the Proximal Humerus: Classification, Diagnosis, and Nonoperative Management 841**
Joseph D. Zuckerman and Deenesh T. Sahajpal

28 **Minimally Invasive Techniques for Proximal Humeral Fractures 873**
Leesa M. Galatz and Hyun Min Kim

29 **Hemiarthroplasty for Proximal Humerus Fractures 889**
Michael A. Wirth, Zachary R. Leitze, and Charles A. Rockwood, Jr.

30 **Malunions, Nonunions, and Other Complications of Proximal Humerus Fractures 907**
Todd F. Ritzman and Joseph P. Iannotti

31 **Fractures of the Clavicle 943**
Jonas Andermahr, David C. Ring, and Jesse B. Jupiter

PART VI: ACROMIOCLAVICULAR AND STERNOCLAVICULAR JOINTS 977

32 **Disorders of the Acromioclavicular Joint: Pathophysiology, Diagnosis, and Management 979**
Gordon W. Nuber and Laurent Lafosse

33 **Disorders of the Sternoclavicular Joint: Pathophysiology, Diagnosis, and Management 1007**
Edwin E. Spencer, Jr., Michael A. Wirth, and Charles A. Rockwood, Jr.

PART VII: NEUROMUSCULAR AND SCAPULOTHORACIC DISORDERS 1055

34 **The Scapulothoracic Articulation: Anatomy, Biomechanics, Pathophysiology, and Management 1057**
John E. Kuhn

35 **Injuries of the Brachial Plexus 1087**
Scott H. Kozin

36 **Suprascapular and Axillary Nerve Injuries 1135**
Young W. Kwon and Stephen A. Hunt

PART VIII: NEOPLASIA AND INFECTION 1155

37 **Tumors of the Shoulder Girdle 1157**
Martin M. Malawer, James C. Wittig, and Kristen Kellar Graney

38 **Sepsis of the Shoulder Girdle 1201**
Wudbhav N. Sankar and John L. Esterhai, Jr.

PART IX: REHABILITATION AND OUTCOME MEASURES 1233

39 **General Techniques of Shoulder Rehabilitation 1235**
Martin J. Kelley, Brian G. Leggin, and Kenneth J. Rogers

40 **Disease-Specific Methods of Rehabilitation 1265**
Brian G. Leggin and Martin J. Kelley

41 **Measurement of Shoulder Outcomes 1295**
Brian G. Leggin, Joseph P. Iannotti, and Gerald R. Williams, Jr.

PART X: PAIN MANAGEMENT 1317

42 **Medical Management of Chronic Shoulder Pain 1319**
Samer N. Narouze and Nagy A. Mekhail

43 **Anesthesia for Shoulder Surgery 1347**
Michael P. Smith, Robert Helfand, and John E. Tetzlaff

New York, New York

Preface

Like the first edition of *Disorders of the Shoulder: Diagnosis and Management*, the second edition is intended to be a valuable reference text for any student of shoulder disorders—including shoulder, hand, and sports medicine subspecialists, orthopedic generalists with a subspecialty interest in shoulder disorders, orthopedic residents and fellows, and rehabilitation professionals. The contributing authors are experts in shoulder surgery from around the world, many of whom have trained with us over the last 15 years. In addition, we have authored or coauthored many of the chapters in the second edition and have contributed many figures to others, with the goal of producing a comprehensive text with a cohesive philosophy for diagnosis and treatment. The multidisciplinary aspect of shoulder disorders remains a common theme, with extensive coverage of supportive fields, including anesthesia, pain management, and rehabilitation.

Some of the best attributes of the first edition have been combined with new ideas to enhance the second edition. Treatment algorithms remain an important defining element, as we believe a logical, protocol-driven approach to common shoulder problems is valuable. Separate chapters on complications of surgical management of common shoulder disorders have been maintained. Basic science principles important to the pathogenesis and treatment of shoulder disorders continue to be emphasized, with a strong effort to correlate the basic science information with clinical practice. Treatment recommendations are grounded in peer-reviewed evidence and clinical experience, with concise, clinically relevant bibliographies.

The depth of certain chapters has been expanded to correspond to recent changes in clinical practice. Discussion of minimally invasive and arthroscopic surgery for a wide spectrum of rotator cuff pathology and instability problems has been added. Material on complex and revision surgery for joint replacement, rotator cuff repair, muscle transfer, and complex instability surgery has been updated. The chapters on scapular disorders and brachial plexus injuries contain new information on pathogenesis and treatment. Principles of tissue engineering that may be relevant in the future management of rotator cuff disorders are outlined in the chapter on anatomy, pathogenesis, and biomechanics of rotator cuff disease. Finally, reverse shoulder arthroplasty for arthritis and cuff deficiency and bone-sparing humeral resurfacing arthroplasty are new topics in the second edition.

One of the challenges of any comprehensive medical text is to stay current with the evolution of clinical practice. The field of shoulder surgery is evolving more rapidly than most orthopedic subspecialties. This is both a curse and a blessing. It is impossible to match the unrelenting pace of discovery in the diagnosis and management of shoulder disorders. However, it is a privilege to try—a privilege made possible by the interest of you, the readers. We hope the second edition meets your expectations and piques your interest enough to justify the creation of a third edition.

Rotator Cuff Disease and Tendon Ruptures

I

1 Anatomy, Biomechanics, and Pathophysiology of Rotator Cuff Disease

ROTATOR CUFF AND RELATED ANATOMY

Normal Anatomy of the Rotator Cuff

Four muscle–tendon units make up the rotator cuff: the supraspinatus, infraspinatus, subscapularis, and teres minor. The shoulder comprises a complex of four articulations including the glenohumeral joint, scapulothoracic joint, sternoclavicular joint, and acromioclavicular joint that, under normal conditions, move in synchrony, affording smooth, unhindered motion of the arm. An intricate relation exists between the osseous elements and the surrounding muscles and ligaments. The tissues of the shoulder can be grouped into four separate and contiguous layers that alternate between muscular and fibrous elements.[56] Layer 1, the most superficial level, includes the deltoid and pectoralis major muscles. Layer 2 is a continuous fascial layer that extends circumferentially from anterior to posterior and incorporates the clavipectoral and posterior scapular fascia. Layer 3, again a muscular layer, includes the rotator cuff, and layer 4, the deepest level, comprises the fibrous capsular elements. This classification can contribute to a better understanding of the shoulder's complex anatomy and safeguard against deviation from internervous planes during surgical procedures (Fig. 1-1).

The four muscles that compose the rotator cuff take their origin from the body of the scapula and envelope the humeral head as they insert along the tuberosities of the proximal humerus.[66] The musculotendinous cuff is firmly adherent to the underlying glenohumeral capsule and provides circumferential reinforcement except at the rotator interval and axillary recess. The *rotator interval* is a triangular area that is made up of fibrous elements and bordered by the upper margin of the subscapularis tendon and anterior aspect of the supraspinatus.[73] Within the interval lie the coracohumeral ligament, the biceps tendon, and the superior

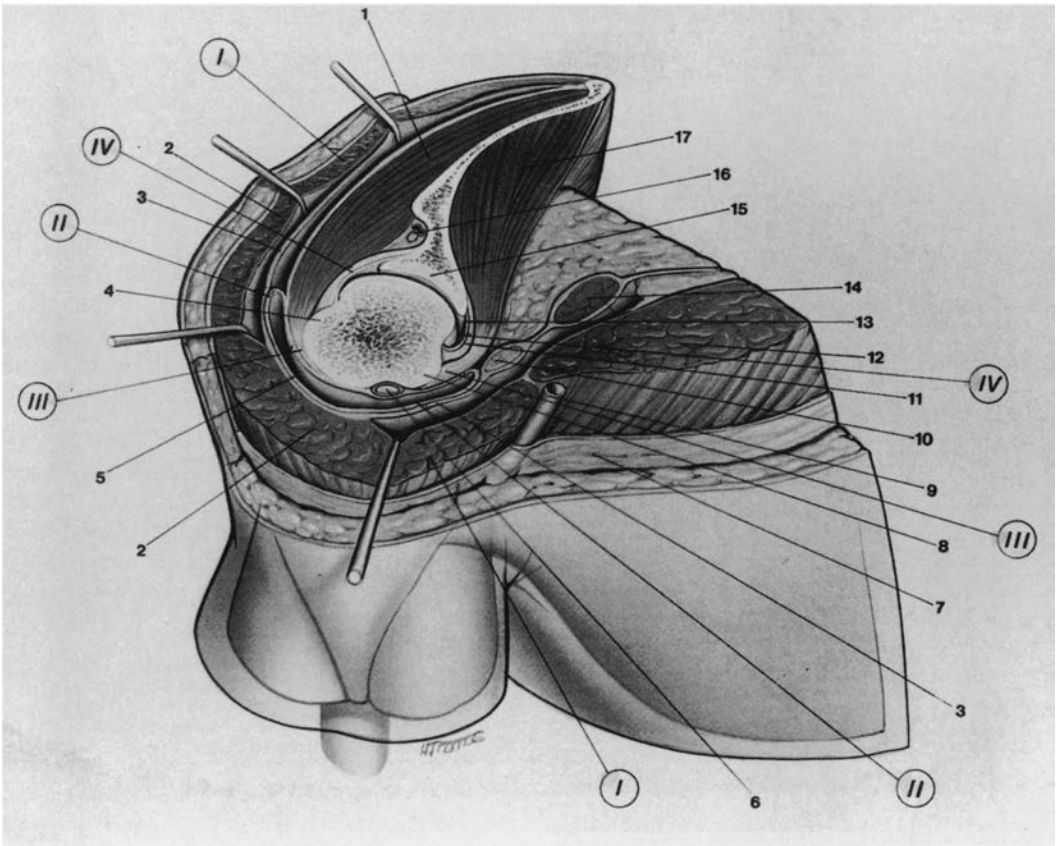

Figure 1-1 Supporting layers of the glenohumeral joint: **Layer I:** Deltoid (2) and pectoralis major muscles (12); **Layer II:** Clavipectoral fascia (3), conjoined tendon (10), coracoacromial ligament, posterior scapular fascia (3), and superficial bursal tissue (5); **Layer III:** Deep layer of subdeltoid bursa, rotator cuff (1,17); **Layer IV:** Glenohumeral joint capsule (11), synovium (13), coracohumeral ligament. (From Cooper DE, O'Brien SJ, Warren RF. Supporting layers of the glenohumeral joint. An antomic study. *Clin Orthop* 1993;289:144–155, with permission.)

glenohumeral ligament. The coracohumeral ligament is seen superficially, whereas the superior glenohumeral ligament reflects around the biceps tendon and serves as an internal pulley at the floor of this space.[127] The coracohumeral and superior glenohumeral ligaments take origin from the lateral base of the coracoid and superior labrum, respectively[99,173] (Fig. 1-2). In one report, through gross anatomic study, variability was observed at the insertion of the coracohumeral ligament. Seventy-four percent of specimens demonstrated a predominant insertion into the rotator interval; in the remainder, the principal attachment was to the supraspinatus tendon.[173] Multiple functions have been attributed to the coracohumeral ligament, and most notably, they include limitation of external rotation in the adducted arm and restraint against inferior translation.[18,107,109,186–188] The intraarticular boundaries of this space can be easily visualized arthroscopically and are marked by the glenoid rim, the upper subscapularis tendon, and the intraarticular portion of the biceps tendon (Fig. 1-3). The *axillary recess,* which also lacks muscular or tendinous coverage by the rotator cuff, demonstrates capsular redundancy at the inferior aspect of the joint. This tissue laxity affords normal arm abduction, whereby patulousness or contracture can mediate joint instability or restriction of motion.

The four rotator cuff muscles are often considered as distinct separate musculotendinous units that directly overlie the joint capsule and insert onto the proximal humerus. Clark and Harryman[48] performed gross anatomic and histologic studies in cadaveric specimens to better define the relation between the rotator cuff tendons and their underlying capsular elements. The fibers of the rotator cuff tendons interdigitate and fuse, forming a common insertion on the tuberosities of the humerus.[158] Fibers from both the subscapularis and infraspinatus interdigitate with respective fibers of the supraspinatus. Microscopically, the rotator cuff complex is stratified into five distinct layers that also receive reinforcement from the coracohumeral ligament and is contiguous with the glenohumeral capsule (Fig. 1-4).

The Subscapularis Muscle

Anteriorly, the *subscapularis* muscle takes its origin along the costal surface of the scapula and inserts onto the lesser

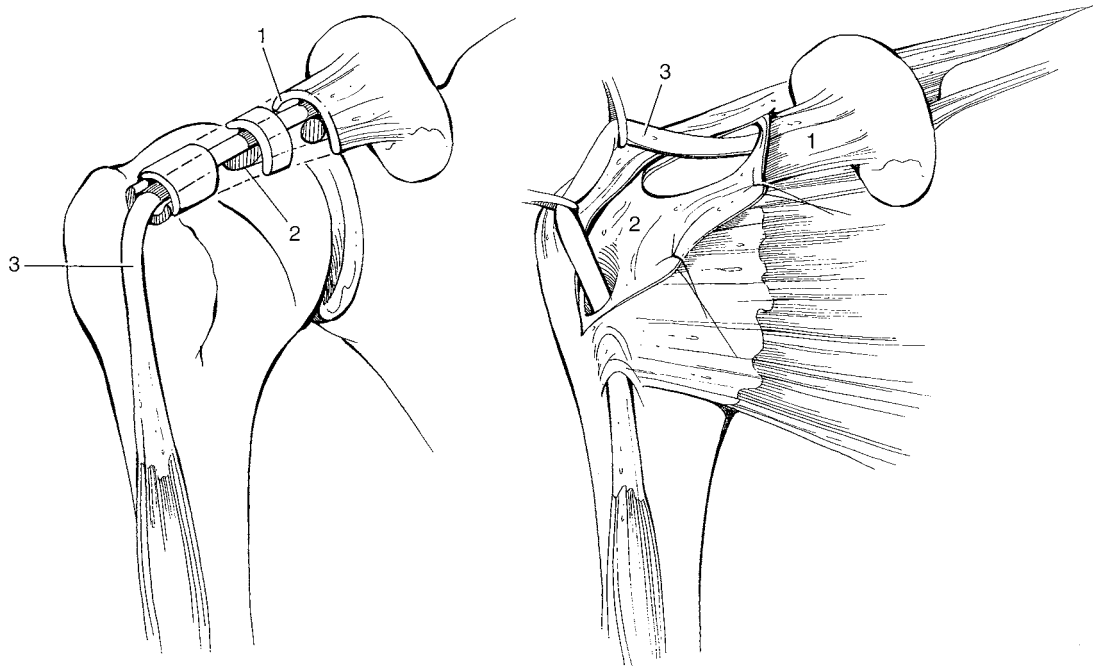

Figure 1-2 Anatomy of the rotator interval. Coracohumeral ligament (1); superior glenohumoral ligament (2); biceps tendon (3). (From Walch G, Laurent NJ, Levigne C, Renaud E. Tears of the supraspinatus tendon associated with "hidden" lesions of the rotator interval. *J Shoulder Elbow Surg* 1994;3:353–360, with permission.)

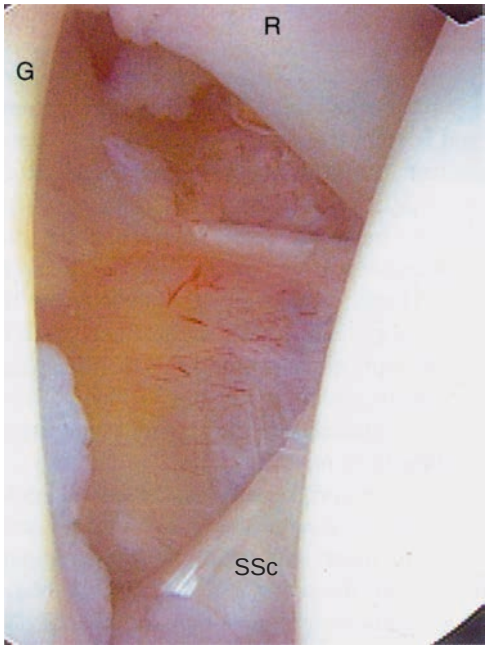

Figure 1-3 Region of rotator interval as viewed arthroscopically. Safe portal of entry lies between the biceps tendon (*R*), upper border of subscapularis tendon (*SSc*), and glenoid rim (*G*).

tuberosity of the humerus[26,159] (Fig. 1-5). It is the largest and most powerful of the rotator cuff muscles with its origin occuping greater than 90% of the anterior scapular surface. As the multipennate muscle funnels laterally toward its insertion, it has a dual innervation from both the upper and lower subscapular nerves that arise from the posterior cord of the brachial plexus. The upper subscapular nerve innervates a greater portion of the muscle. Although commonly considered to be an internal rotator of the shoulder, its contribution to arm abduction and humeral head depression has also been emphasized.[116,184,185,219] The subscapularis bursa lies between the subscapularis tendon and neck of the scapula. It is found just inferior to the coracoid process and protects the tendon as it courses along the scapular neck and coracoid.[159] The bursa communicates with the glenohumeral joint capsule and can harbor intraarticular loose bodies (Fig. 1-6). Zlatkin and colleagues[267] described three areas of capsular insertion along the anterior glenoid neck. A type I capsule is inserted adjacent to the anterior glenoid labrum, whereas types II and III are inserted progressively more medial on the scapular neck. This categorization likely reflects the variation in morphology and size of the subscapular bursa, which can be readily identified on coronal magnetic resonance images (MRIs). While a predisposition to anterior glenohumeral instability in patients with a medial capsular insertion has been suggested, no controlled studies elucidating this issue have yet been conducted.

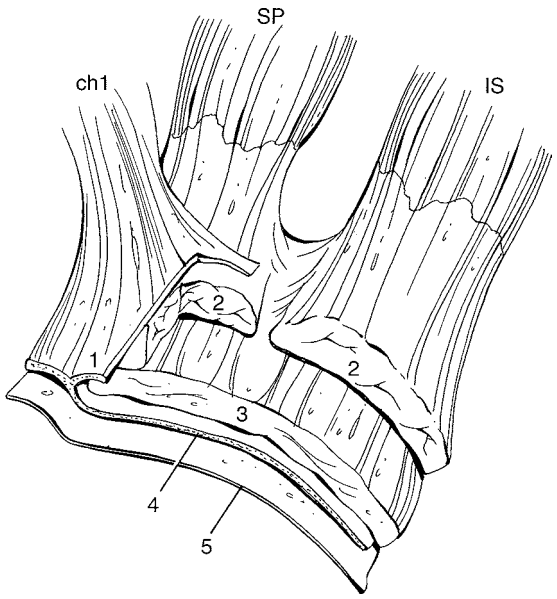

Figure 1-4 Schematic diagram of the supraspinatus and infraspinatus tendinous insertions. Five discrete layers are identified. The orientation of the fascicles in the numbered layers is indicated by the lines on their upper surfaces. *Layer 1* is composed of superficial fibers that overlie the cuff tendons and extend from the coracoid process to the greater tuberosity. These fibers form an extension of the coracohumeral ligament (*chl*). *Layers 2* and *3* contain the fibers of the supraspinatus (*SP*) and the infraspinatus (*IS*) tendons. The fibers in layer 2 are oriented parallel to the axes of the supraspinatus and infraspinatus tendons. The fibers of layer 3 are smaller and are obliquely oriented with respect to the fibers of layer 2. Within layer 3, the fibers of the supraspinatus tendon fan out and intermingle with the fibers of the adjacent infraspinatus and subscapularis tendons. This intermingling between the infraspinatus and supraspinatus creates the variation in alignment of the fibers observed in layer 3. In *layer 4*, the fibers make up the deep extension of the coracohumeral ligament. These fibers branch off the main body of the ligament at the anterior border of supraspinatus tendon and then course between the tendon and capsule as far as the junction between the infraspinatus and supraspinatus. *Layer 5* is the true joint capsule of the shoulder, which forms a continuous fibrous cylinder extending from the glenoid labrum to the neck of the humerus. The synovial lining of the capsule is in direct contact with the articular surface of the humeral head. The orientation of the fibers within the capsule is quite variable and not identified in this diagram. (From Clark JM, Harryman DT. Tendons, ligaments, and capsule of the rotator cuff. *J Bone Joint Surg Am* 1992;74:713–725, with permission.)

The Infraspinatus and Teres Minor Muscles

The *infraspinatus* and *teres minor* muscles make up the posterior portion of the rotator cuff. The infraspinatus is triangular and is often inseparable from the teres minor. They take origin from the infraspinatus fossa and dorsolateral border of the scapula, respectively, and insert onto the greater tuberosity of the humerus.[159] The suprascapular nerve innervates the infraspinatus, and the axillary nerve supplies the teres minor. These muscles externally rotate the humerus and stabilize the glenohumeral joint in concert with the subscapularis and supraspinatus muscles. The infraspinatus has a pennate muscle architecture with a central raphe that should not be confused with the intermuscular interval between it and the teres minor.

The Supraspinatus Muscle

The *supraspinatus* originates from the suprascapular fossa and inserts along the greater tuberosity of the humerus.[249] It receives its innervation from the suprascapular nerve, which arises from the upper trunk of the brachial plexus. This muscle contributes to glenohumeral compression during active shoulder motion and assists the deltoid in effecting humeral abduction.[52,53,114] The supraspinatus is situated between the humeral articular surface and the acromial arch, where it is protected by a synovial cavity on either side. The subacromial and subdeltoid bursae are found superficial to the tendon and separate it from the deltoid muscle. The bursa varies in size and extends laterally from the subacromial space to the proximal humeral metaphysis (Fig. 1-7).

The *suprascapular nerve* arises from the upper trunk of the brachial plexus and courses through the suprascapular notch just medial to the base of the coracoid process. It supplies the supraspinatus muscle before passing through the spinoglenoid notch, where it finally provides neural innervation to the infraspinatus (Fig. 1-8). Warner and associates[255] have highlighted the path and variational anatomy of the suprascapular nerve as it enters the posterior aspect of the shoulder. Eighty-four percent of 31 specimens revealed one or two branches of the nerve to the supraspinatus muscle. In 84% of specimens, the first branch originated either under the transverse scapular ligament or 1 mm distal to it. In 3%, the first motor branch originated proximal to the ligament and passed superficial to it. The infraspinatus muscle revealed three to four branches in approximately one-half of the specimens. Bigliani and coworkers[21] measured the distance of the nerve from fixed scapular landmarks and observed that it lay an average of 1.8 cm (range 1.4 to 2.5 cm) from the midposterior glenoid rim to the base of the scapular spine. The distance of the nerve from the supraglenoid tubercle to the base of the scapular spine measured an average of 2.5 cm (range 1.9 to 3.2 cm). These observations emphasize the caution required for surgical management of shoulder disorders such as mobilization of a torn and retracted rotator cuff, arthroscopic portal placement, transglenoid drilling, and neurolysis of an entrapped suprascapular nerve.

The Deltoid Muscle

Superficial to the subacromial and subdeltoid bursae lies the *deltoid* muscle. It is composed of three heads (anterior, middle, and posterior) that vary in structure and function. The muscle has an extensive origin, arising from the distal

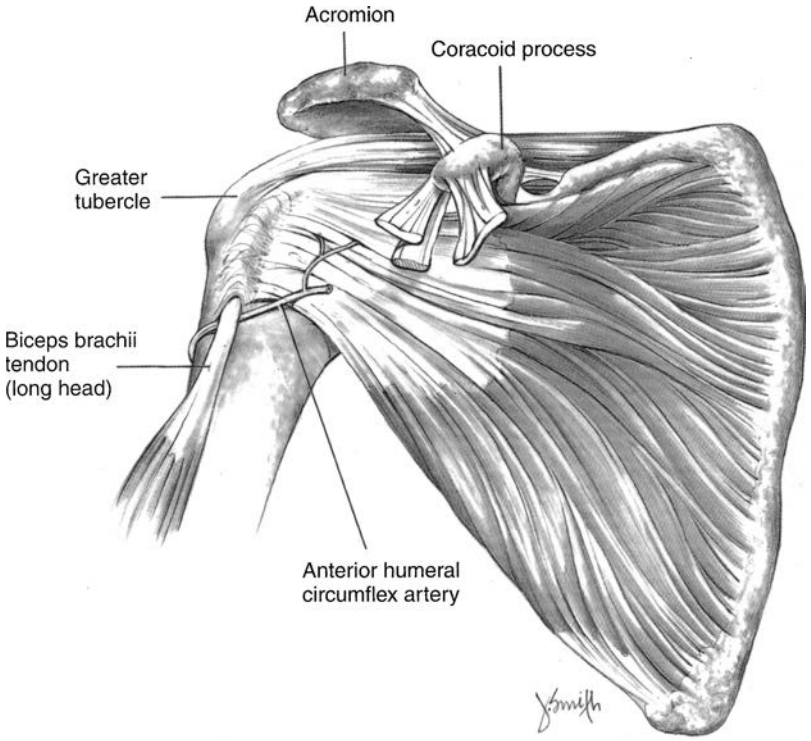

Figure 1-5 Anatomic course of the subscapularis muscle.

one-third of the clavicle, the acromion, and the lateral one-third of the scapular spine. It converges distally to insert on the deltoid tuberosity of the middiaphysis of the humerus (Fig. 1-9). Its broad origin, which is derived from the mobile scapula and clavicle, affords the deltoid a mechanical advantage by allowing the muscle to maintain its resting length at various arm positions. Furthermore, the bipennate structure of the large middle head contributes to abduction strength through contraction of its fibers at an angle to the line of pull, which also serves to maintain muscle fiber resting length and improve efficiency. In contrast, muscles with a parallel fiber arrangement, such as the anterior and posterior deltoid, by virtue of their structural configuration, result in considerably decreased strength during contraction.[60]

Differences in activity of the three portions of the deltoid relative to arm position have been observed through electromyographic analysis. The anterior and middle heads remain active at all angles of abduction and in multiple

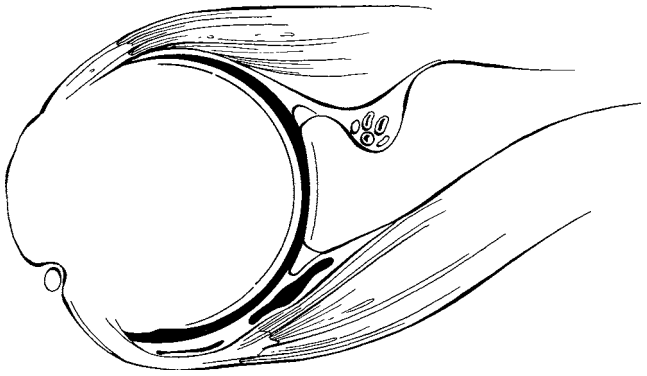

Figure 1-6 The subscapularis bursa. Note its subcoracoid location between the glenoid neck and subscapularis muscle belly.

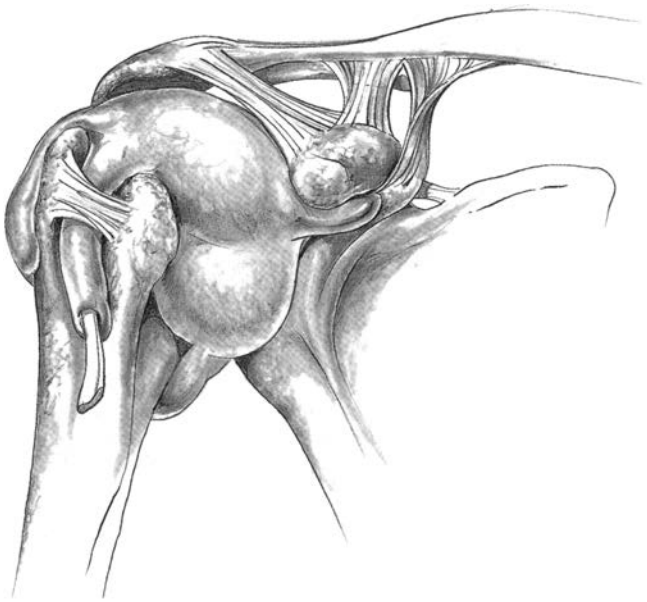

Figure 1-7 The subacromial and subdeltoid bursae.

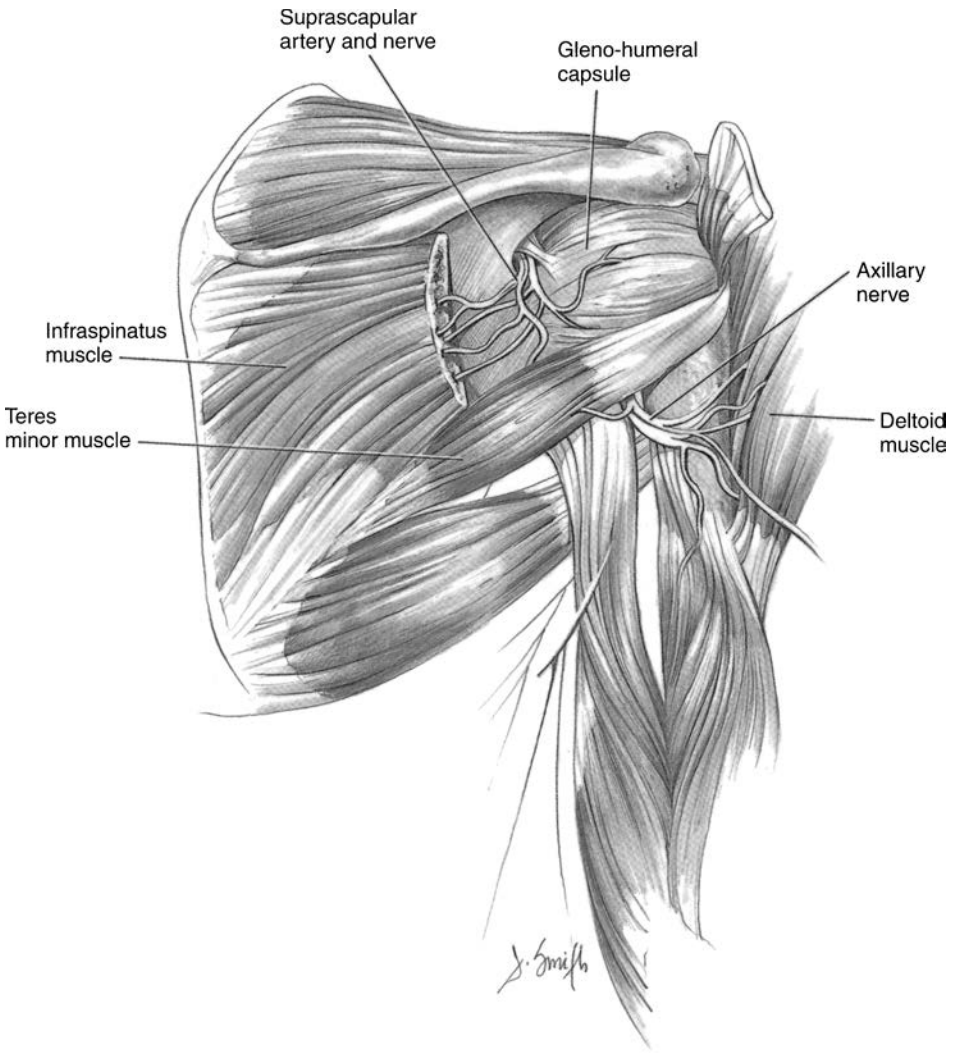

Figure 1-8 Anatomic course of the suprascapular nerve.

planes (coronal, scapular, and parasagittal), whereas the posterior deltoid, also an important shoulder extensor, contributes to elevation when the arm is above 110 degrees.[221] Moreover, when the arm is in abduction, the posterior deltoid functions as a secondary external rotator, for which its clinical importance is increased in patients with massive rotator cuff tears extending into the infraspinatus and teres minor tendons.

Neural innervation is afforded by the *axillary nerve,* which takes a circuitous path before entering the deltoid muscle. It arises from the posterior cord of the brachial plexus and courses across the inferolateral border of the subscapularis. It passes inferior to the glenohumeral axillary recess and exits the quadrangular space, along with the posterior humeral circumflex artery, where it divides into two trunks. The posterior trunk splits and innervates the teres minor and posterior deltoid before terminating as the superior lateral cutaneous nerve. The anterior trunk winds around the humerus and innervates the remaining deltoid muscle. It becomes subfascial and intramuscular at a point between the anterior and middle heads[35] (Fig. 1-10). Burkhead and colleagues[35] observed that the axillary nerve can occupy a position as close as 3.1 cm from the lateral tip of the acromion and that in 20% of specimens it was less than the generally accepted 5-cm distance.[1]

Vascular Supply to the Rotator Cuff

Multiple vessels contribute to the vascularity of the rotator cuff. The anterior and posterior humeral circumflex arteries both supply the superior, as well as the anterior and posterior portions of the cuff, respectively. The suprascapular artery also supplies the superior cuff, and in the majority of persons the acromial branch of the thoracoacromial artery will nourish the supraspinatus. Additional contributions may include branches of the subscapular and the suprahumeral branches of the axillary artery. Osseous vessels emanating from the tuberosities of the proximal humerus have also been included in the vascular makeup of the rotator cuff[5,43,83,145,161,208] (Fig. 1-11).

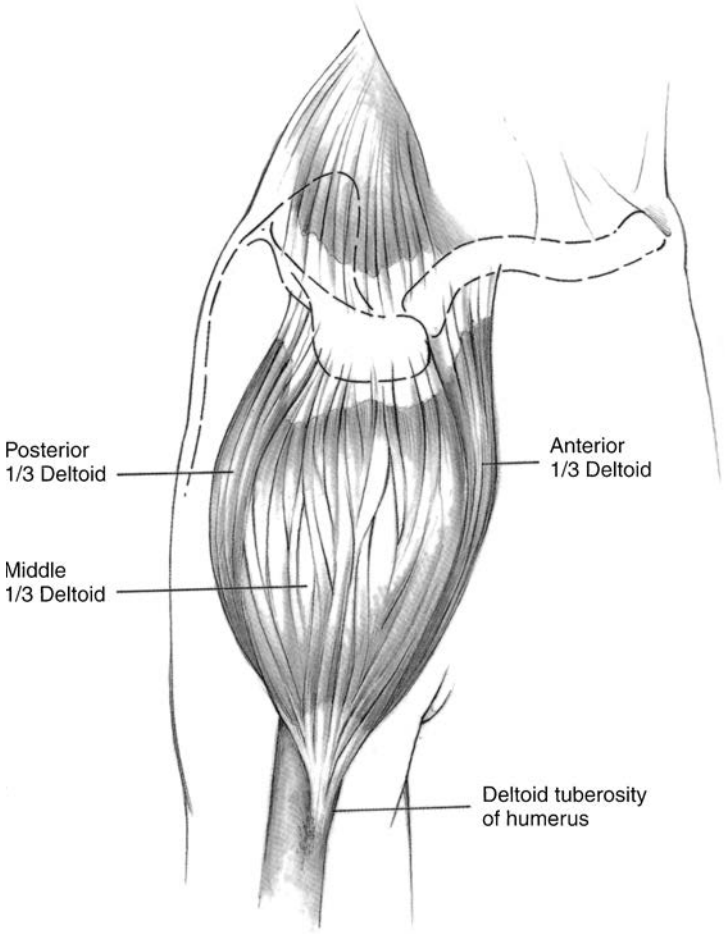

Figure 1-9 The deltoid muscle.

ROTATOR CUFF FUNCTION

The complex interaction of the rotator cuff and surrounding muscles is largely responsible for the shoulder's considerable range of motion and the preservation of glenohumeral joint stability. Although debate continues over a few functions of the rotator cuff, the preponderance of data support its role as a dynamic stabilizer, providing humeral depression, humeral rotation, abduction, and joint compression. Its role in "dynamization" or tensioning of the glenohumeral ligaments in the midranges of motion remains unclear and will require validation with further study. Furthermore, the rotator cuff has an integral part in maintaining force couples in multiple planes, whereby its absence could potentially result in abnormal kinematics, an unstable fulcrum, and abnormal humeral head excursion.

The rotator cuff comprises a group of muscles that are considerably smaller in size and cross-sectional area when compared with the more superficial structures, such as the deltoid, pectoralis major, latissimus dorsi, and trapezius. In addition, because they lie deep in the shoulder and in close proximity to the center of rotation of the glenohumeral joint, these muscles are collectively unable to generate the same degree of torque as the larger and more superficial structures. In part, the relatively shorter lever arm, or distance of the muscle from the center of rotation, accounts for observable differences in generated force. Consequently, given its anatomic architecture, maintenance of a stable glenohumeral fulcrum during active arm motion is one function that is both important and well suited to the rotator cuff (Fig. 1-12).

A normal-functioning rotator cuff achieves dynamic stability through multiple mechanisms. It acts through direct joint compression as well as through asymmetric contraction and "steering" of the humeral head into the glenoid during active motion.[19,94,142,180,192,212,261,263] Compression is achieved through the perpendicular vector of pull by the humeral head into the glenoid that serves to minimize tendencies toward joint subluxation.[142,180] Multiple forces pass across the shoulder during active motion to achieve a desired arm position. Force couples across the shoulder remain integral to maintaining normal function, especially when placed in a perspective of the minimally constrained

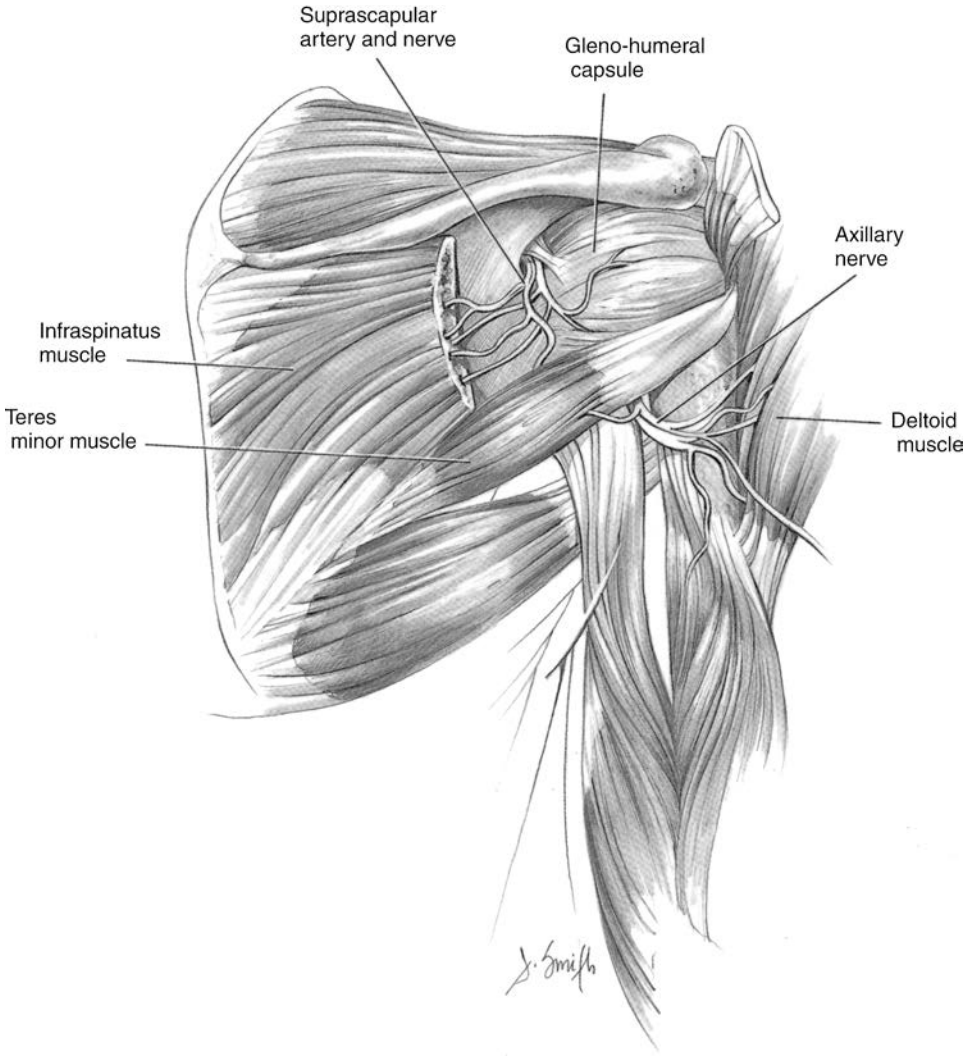

Figure 1-10 Anatomic course of the axillary nerve.

design of the glenohumeral joint. Force couples in various planes exist that can be defined as the action of two opposing muscle groups required to achieve a given movement. Inman and associates[116] initially described force couples involving the glenohumeral joint. They noted that the deltoid muscle acts to pull the humeral head in a cephalad direction, while the subscapularis, infraspinatus, and teres minor act as a functional unit counteracting the deltoid and effecting depression of the humeral head.

Other biomechanical studies have highlighted the role of the infraspinatus and subscapularis in maintenance of normal glenohumeral kinematics.[32,218] In one cadaveric investigation, the isolated absence of an applied supraspinatus force appeared to have no appreciable difference on humeral head migration when measured radiographically in the anteroposterior plane. Absence of force generated by the infraspinatus, teres minor, and subscapularis, on the other hand, resulted in an increase in superior humeral translation because the deltoid was unopposed.[218] Burkhart[32] expanded on the importance of force couples in preserving normal kinematics in patients with rotator cuff tears. He noted that balanced forces in both the coronal and transverse planes afforded normal glenohumeral motion patterns as long as anterior and posterior portions of the cuff were preserved beyond a critical threshold (Fig. 1-13). The location, as opposed to size of the tendon tear, was suggested to be a more significant determinant in resultant glenohumeral kinematics.

The rotator cuff contributes strength to the arm. Howell and coworkers[114] noted that, after selective blockade of the suprascapular and axillary nerves in normal volunteers, the supraspinatus and deltoid muscles contribute equally to measured torque in abduction. These findings are comparable with other reports on selective blocking of the axillary nerve in which it was noted that approximately 60% of the strength in abduction was attributable to the deltoid muscle.[52,53] Compromise of rotator cuff or deltoid function in such individuals could be expected to result in a

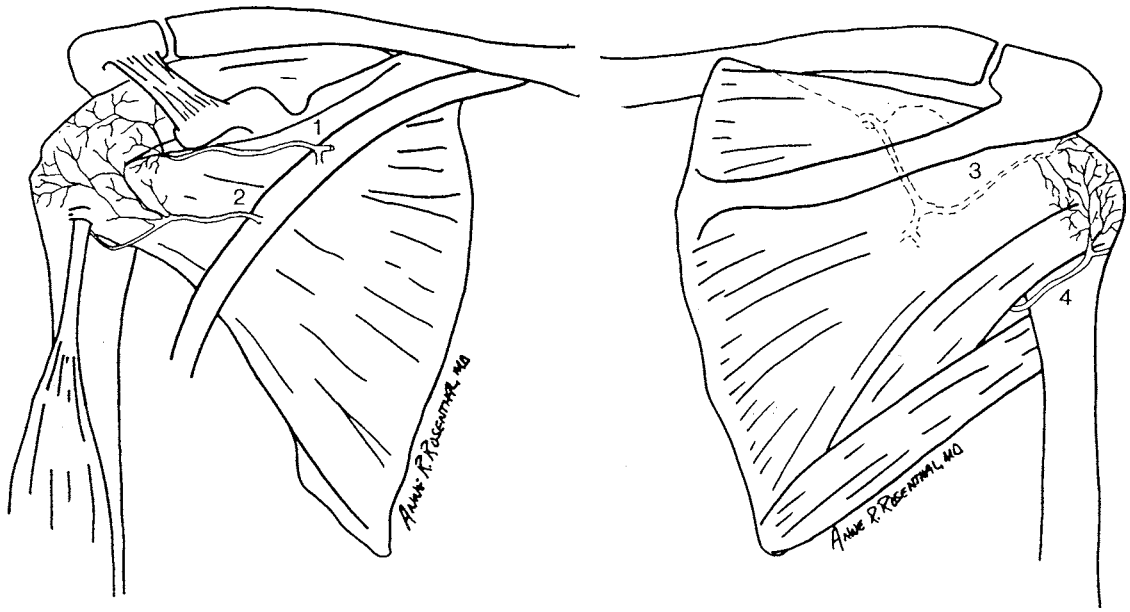

Figure 1-11 Vascular supply to the rotator cuff. 1 = suprahumeral branch; 2 = anterior humeral circumflex artery; 3 = suprascapular artery; 4 = posterior humeral circumflex artery. Expression and enzymatic activity of MMP-2 during healing process of the acute supraspinatus tendon tear in rabbits. *J Orthop Res* 2002; 20(5):927–933, with permission.)

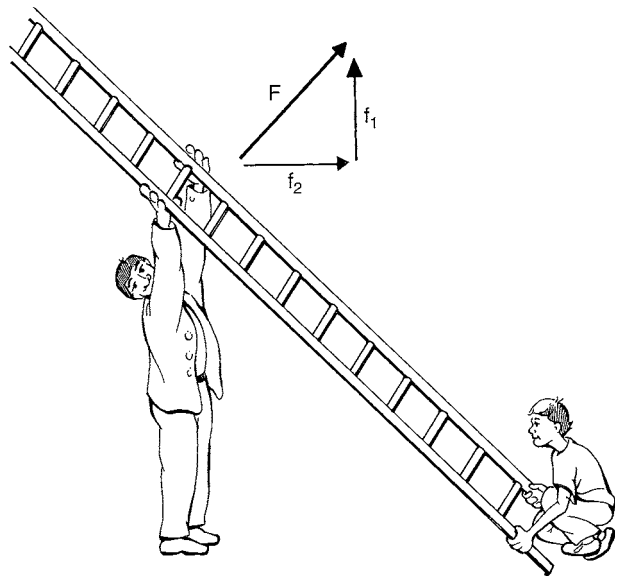

Figure 1-12 The shoulder muscles can be grouped as either primary movers or primary stabilizers. This situation is somewhat analagous to that of a large man and a small boy teaming up to lift a ladder. Typically, the stronger one will lift or move the ladder, while the weaker one will hold it from sliding or lifting off the ground (stabilizer). There is a point at which the force generated by the stronger one can overpower the resistance of the weaker one and stability is lost. (From O'Driscoll SW. Atraumatic instability: pathology and pathogenesis. In: Matsen FA, Fu FH, Hawkins RJ, eds. *The shoulder: a balance of mobility and stability.* Rosemont, IL: American Academy of Orthopaedic Surgeons, 1993: 305–316, with permission.)

progressive loss of muscle force with arm elevation and in early fatigability. The infraspinatus has also been implicated as a contributor to arm elevation. Otis and associates[185] reported decreases in abduction and external rotation torque of up to 45% and 75%, respectively, after selective paralysis of the infraspinatus muscle. These findings contrast with one electromyographic (EMG) study that demonstrated silent electrical activity in the infraspinatus when it was elevated to 120 degrees.[198]

In an effort to clarify the collective role of the infraspinatus, teres minor, and subscapularis, Sharkey and coworkers,[219] in a biomechanical cadaveric investigation, evaluated the contribution of these muscles to force in abduction. Because the tendons of the subscapularis and infraspinatus insert both above and below the humeral center of rotation, it is conceivable that portions of these muscles may act as arm abductors as well as humeral head depressors. Their data suggested that the combined contractions of these muscles contribute to arm abduction and that the magnitude of their contribution was similar to that of the supraspinatus. Otis and colleagues[184] provided further indirect evidence of the functional relation of the rotator cuff and deltoid to humeral elevation. By calculation of changes in moment arms and measurement of muscular excursion in cadaveric specimens, they demonstrated that both the infraspinatus and subscapularis contribute to abduction. Changes in rotation further affected the capacity of either muscle to augment elevation in the scapular plane. Internal and

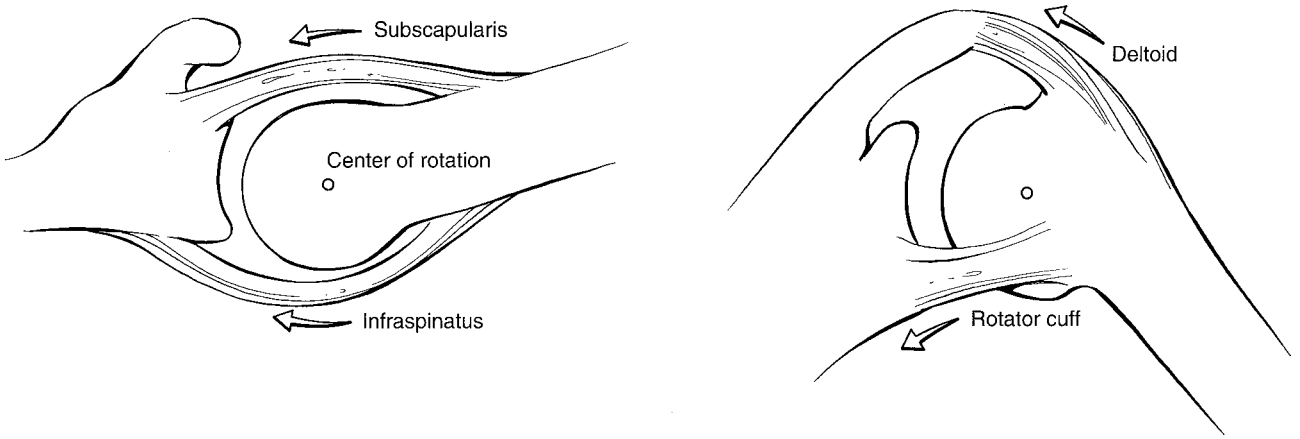

Figure 1-13 Force couples of the shoulder. **Left:** The transverse plane force couple balances the opposing forces of the anterior and posterior cuff. **Right:** The coronal plane force couple consists of the deltoid counterpoised against the inferior portion of the rotator cuff. external rotation enhanced the ability of the upper portions of the infraspinatus and subscapularis, respectively, to abduct the arm. The data help to partly explain how a supraspinatus defect may not necessarily limit functional abduction of the arm.

ROTATOR CUFF DISEASE

Rotator cuff disease is characterized by specific signs, symptoms, and altered anatomy. It has many causes, which will be covered later in this chapter. Clinically patients can present with complaints of pain, weakness, or a combination of both. Radiographically, cystic changes may be seen along the superior aspect of the greater tuberosity with sclerosis or erosion on the undersurface of the acromion from pathologic contact. Cystic changes can also be seen (more easily with MRI) in the lesser tuberosity from coracoid impingement. MRI is useful in defining the extent of the rotator cuff disease and is very sensitive and specific.

Cuff tendonitis, tendinosis, calcific tendonitis, and partial- and full-thickness rotator cuff tears are common manifestations of the disease.

Rotator Cuff Tears

Tears of the rotator cuff typically involve the supraspinatus tendon and, to a variable degree, they will often include the posterior cuff. The subscapularis tendon, although less frequently involved, may be easily overlooked if not considered during diagnostic evaluation.

A universally accepted classification scheme for rotator cuff disease does not exist, making studies evaluating the results of surgical treatment difficult to compare. However, important parameters to consider when describing rotator cuff lesions include the duration, depth, and size of a tear, as well as the condition of the muscle and the tendon. Tears may be acute which typically present with the sudden onset of pain and dysfunction after a traumatic event. Chronic tears are present for longer than 3 months and may be associated with a variable degree of weakness and discomfort. Some patients may have a previously documented chronic rotator cuff tear and develop an acute extension of the lesion after a traumatic insult.

The depth of a tear will differentiate partial- from full-thickness lesions. Moreover, partial-thickness tears can be present on either the articular or bursal surface, or they may be intrasubstance. The thickness of the lesion may also vary until it extends through the entire tendon, at which point the subacromial space communicates with the glenohumeral joint. Gradation of partial-thickness lesions has been described; however, difficulty lies in the definition and accurate assessment of such lesions. For example, fraying of the tendon observed during an operation may be considered as a partial tear by some surgeons and not by others. Moreover, the incidence of such lesions in relation to symptoms and the results of treatment are not easily determined because of variability in imaging capabilities, interpretation, and lack of uniformity in classification.

Full-thickness tears may be described as small (less than 2 cm in diameter), medium (2 to 4 cm), large (4 to 5 cm), or massive (more than 5 cm). Additionally, a torn rotator cuff may be retracted, deficient, attenuated, or friable at the time of surgical assessment. The muscle can be best assessed with the aid of quality MRI scans on which cross-sectional area, degree of fatty infiltration, and alterations in overall muscle signal intensity can be determined. MRI investigation looked into the correlation of supraspinatus muscle atrophy in association with rotator cuff tears and residual function using EMG analysis. As the supraspinatus

became more atrophic, the EMG function of the muscle decreased.[163] Although these observations suggest a decrease in function in conjunction with MRI-evident supraspinatus atrophy, the influence of these findings on outcome after surgical repair of the rotator cuff will require further study.

Tears involving the rotator interval, although less common, have also been described.[135,253] Surgical exploration of this interval in 116 patients with supposed isolated tears of the supraspinatus tendon revealed occult lesions of the coracohumeral ligament, superior glenohumeral ligament, and upper border of the subscapularis in 19 cases. Treatment consisted of a rotator cuff repair and reconstruction of the rotator interval complex.[253] Although these lesions can be difficult to diagnose, their association with pain or dysfunction and the optimal method for their treatment remain undetermined.

Glenohumeral abnormalities have also been associated with tears of the rotator cuff. A prospective series of 100 patients with full-thickness tears who underwent a diagnostic arthroscopy revealed glenohumeral abnormalities in 74% overall. Common observations included lesions of the anterior labrum in 62%, intraarticular biceps tendon tears in 16%, and articular cartilage abnormalities in 28%.[157] Clearly, such lesions are being detected with increased frequency with the more widespread application of arthroscopic techniques.

Tearing of the rotator cuff may also result from differences in the mechanical properties of the bursal and articular surfaces of the tendon. Nakajima and coworkers[164] performed histologic and biomechanical analyses of the rotator cuff tendon in 20 autopsy specimens. The bursal layer demonstrated distinct tendon bundles that were more resistant to applied tensile loads. In contrast, tendon fibers of the articular surface were thinner, variable in their architectural arrangement, and more susceptible to tearing under tension. Fukuda and colleagues[77] histologically studied intratendinous tears of the rotator cuff in surgical specimens and implicated shear between the bursal and joint layers in the pathogenesis of observed lesions. Although such investigations provide further insight into potential underlying causes of rotator cuff tears, it is unlikely that one mechanism can explain the different types of tendon abnormalities. Additional study will be required to help define the causes of the disparate lesions observed.

Etiology and Pathogenesis of Rotator Cuff Disease

Multiple etiologic factors have been associated with the development of rotator cuff disease (Table 1-1). Tendon degeneration, vascular factors, impingement, trauma, glenohumeral instability, scapulothoracic dysfunction, and congenital abnormalities all appear to contribute, in some combination, to the formation and progression of rotator cuff lesions. Recognition of such processes will lead to an increased ability to effectively diagnose and treat patients who present with symptoms related to the rotator cuff. Controversy continues to exist concerning the pathogenesis of rotator cuff disease. The heterogeneity of the disorder, as well as the notion that rotator cuff disease may not actually represent a continuum of the same process but rather is a compilation of independent disorders, may partly explain the differing viewpoints on its origin.

Age-Related Degeneration or Senescence

In early anatomic investigations, Codman and Akerson[50] had suggested that degenerative processes, in association with trauma, were responsible for the genesis of rotator cuff tears. He noted that tendinous defects within the supraspinatus were commonly found 1 cm medial to its insertion on the greater tuberosity. The frequency of his findings increased with age. Subsequently, other anatomic investigations provided further evidence of degenerative changes about the shoulder with advancing age.[49,50,57,61,62,95,100,129,183,258]

Senescent changes of the rotator cuff likely occur in a manner similar to that of other joints in the body.[46,61,156] Through anatomic studies, DePalma[61,62] detailed these changes in the glenohumeral joint and rotator cuff. Observations included tearing of the cuff tendon and synovium, which became more pronounced with each successive decade of life. Moreover, DePalma and others[61,62,100,129,168,198] noted that partial-thickness tears typically begin to occur between 40 and 60 years of age and are also more frequent in older persons. Brewer[27] studied the rotator cuff in autopsy specimens and observed age-related changes, including a loss of cellularity, disorganization, and fragmentation, that led to dissolution of the cuff in older subjects. It is difficult to determine whether degenerative processes are directly responsible for observed lesions or whether they predispose the rotator cuff to tearing through alternative mechanisms. Additionally, although cadaveric age-related rotator cuff findings suggest that partial-thickness lesions develop into full-thickness tears, sufficient data in support of this concept are lacking.

Vascular Factors

The relation between the microvascular blood supply of the rotator cuff and tendon degeneration remains a subject of debate. Conflicting reports describing the vascularity of the supraspinatus tendon exist; however, in many investigations, the methods employed were limited. Moreover, although vascular-mediated mechanisms have been suggested as an important factor in the genesis of rotator cuff disease, studies have been unable to sufficiently attribute hypovascularity as a direct cause for observed tears of the rotator cuff.

TABLE 1-1
FACTORS CONTRIBUTING TO PATHOGENESIS OF ROTATOR CUFF DISEASE

Traumatic factors
Rotator cuff
Acute high-velocity trauma (acute partial- or full-thickness tears)
Repetitive low-velocity microtrauma (overuse, athletic, or work-related syndromes)
Supraspinatus outlet
Acromioclavicular separation
Coracoid nonunion or malunion
Greater tuberosity malunion
Acromial malunion or nonunion
Degenerative factors
Proliferative and degenerative changes of the acromion, coracoacromial ligament, acromioclavicular joint, or greater tuberosity
Intrinsic degenerative changes of the rotator cuff
Dystrophic calcification
Developmental factors
Os acromiale
Coracoid malformation
Type II or type III acromial morphology
Low-lying acromioscapular angle
Capsuloligamentous factors
Instability
Traumatic, unidirectional
Atraumatic, multidirectional
Capsular contracture
Tight posterior capsule
Scapulothoracic neuromuscular dysfunction
Chronic cervical spondylosis
Serratus anterior palsy (long thoracic nerve injury)
Trapezius nerve palsy (spinal accessory nerve injury)
Scapulofascial muscular dystrophy
Scapulohumeral neuromuscular dysfunction
Entrapment syndromes
Axillary nerve
Suprascapular nerve
Inflammatory disease
Calcific tendonitis or bursitis
Rheumatoid arthritis
Crystal-induced arthropathy
Iatrogenic or acquired disorders
Hardware placement
Foreign materials
Inferior placement of the humeral prosthesis
Corticosteroid-induced tendonopathy

From Iannotti JP, ed. *Rotator cuff disorders: evaluation and treatment. American Academy of Orthopaedic Surgeons Monograph Series.* Park Ridge, IL: American Academy of Orthopaedic Surgeons, 1991:2, with permission.

Mayer[151] initially dismissed the view that tendons were avascular and showed that they receive a vascular supply from three sources: muscular, osseous, and direct tendinous sites. Codman[49,50] subsequently proposed that a critical portion existed within the distal rotator cuff tendon predisposing it to degeneration and calcification. He suggested a vascular or ischemic mechanism, which, in association with trauma, leads to tearing of the rotator cuff. McMaster[154] further supported this concept and showed that when normal musculotendinous specimens were placed under mechanical loads, the muscle became the initial point of failure. However, if the tendon was compromised secondary to an interrupted blood supply and repeated stress, it then became the initial site of failure while the integrity of the muscle was preserved.

Several investigators have observed a decrease in vascularity of the rotator cuff tendon. Notably, Lindblom[141] performed histologic analysis of 12 cadaveric shoulders and demonstrated a region of hypovascularity of the rotator cuff tendon near its insertion to the greater tuberosity. Rothman and Parke[208] also confirmed a region of relative hypovascularity within the distal rotator cuff tendon after arterial latex injection into 72 cadaveric shoulders. They noted consistent vascular patterns, which were independent of age, in their specimens; however, they felt that their methods were not sufficiently accurate to reflect age-related changes. Brooks and colleagues[28] performed postmortem quantitative histologic evaluations of the rotator cuff that showed a decrease in vessel number, size, and percentage of tendon occupied by vessels in both the distal supraspinatus and infraspinatus tendons. Because the hypovascular zone was not isolated to just the supraspinatus tendon, the authors concluded that other factors must be important in the pathogenesis of rotator cuff disease. This was further confirmed by the difference in observed frequency of tears of the supraspinatus and infraspinatus tendons.

In contrast, other reports failed to show similar decreases in vascularity of the rotator cuff tendon. Moseley and Goldie[161] performed microinjection studies on 72 cadaver shoulders and demonstrated a "watershed" area or zone of anastomoses between osseous and tendinous vessels supplying the rotator cuff tendon. They termed this region the "critical zone," which was 1 cm proximal to the rotator cuff insertion and was previously noted by Codman[49,50] to be the frequent site of rotator cuff tendon failure. Their findings were also independent of age.

Rathbun and Macnab[202] used both microangiographic and histologic techniques to evaluate the tendon vascularity of the rotator cuff in cadavers. They showed adequate vascularity when injections were performed on the abducted arm, but in the adducted arm the vessels were "wrung out" and no longer perfused. They hypothesized that the critical zone was subject to a transient hypovascularity that was mediated by position of the arm.

More recently, a vascular study in 18 anatomic specimens revealed differential vascularity between the bursal and articular surfaces of the rotator cuff. The bursal surface was observed to be well vascularized, whereas the articular surface demonstrated a sparse arteriolar pattern.[145] The authors concluded that deficient tendon vascularity differentially predisposed the articular surface of the rotator cuff to degenerative changes and failure.

Intraoperative laser Doppler flowtometry has also been used to assess rotator cuff tendon vascularity in symptomatic patients. One investigation was aimed at clarifying the discrepancy between surgical findings of increased vascularity in patients with impingement syndrome and previous cadaveric reports demonstrating a hypovascular zone within the supraspinatus tendon. The patients with tendinitis and intact tendons always demonstrated increased vascularity in the area of greatest mechanical impingement, or the critical zone. Increased vascularity was also observed at the tendon margins of those patients with partial-thickness tears. Patients with complete tendon tears had variable degrees of vascularity at the tendon edges. The authors concluded that impingement generates a hypervascular response that results in the resorption of injured tendon fibers by neovascular tissue and mediates the progression of rotator cuff disease.[233] These findings also corroborate an earlier cadaveric investigation in which an increase in the number of blood vessels was observed in areas of degenerative tendon. These vessels invaded degenerative tendons through ingrowth of granulation tissue from both the bursal and synovial joint surfaces; this was never observed in normal tendons. Interestingly, in normal tendons, the number of arterioles was noted to decrease with age.[258]

Despite the findings of earlier microinjection studies, many of the conclusions are limited by the inherent shortcomings of the methods used. Lack of small-vessel perfusion in a cadaveric specimen may not satisfactorily reflect vascular characteristics in vivo. Moreover, microinjection studies that do not use histologic techniques may not afford adequate assessment of tissue vascularity, for capillary networks cannot be identified. In addition, postmortem investigations lack the clinical correlation necessary to attribute specific findings to clinical symptoms. With further study, use of in vivo methods, and employment of microscopic tissue evaluation, some of the limitations of earlier reports can be overcome and may permit a more detailed assessment of tendon vascularity in relation to clinical findings.

Impingement and the Coracoacromial Arch

Impingement

Neer[166,167] initially popularized the concept of impingement syndrome, noting that the rotator cuff was potentially

subject to repeated mechanical insult by the coracoacromial arch during elevation of the arm. His observations highlighted the anterior functional arc of shoulder motion, with resultant impingement of the rotator cuff by proliferative spurs and excrescences extending from the anterior third of the acromion and coracoacromial ligament. This was in contrast with impingement by the lateral acromion, as had been generally accepted.[10,223] He subsequently described three stages of the impingement syndrome that exist as a continuum, ultimately leading to tears of the rotator cuff. Stage I, characterized by subacromial edema and hemorrhage, was typical in symptomatic patients younger than 25 years of age. Stage II included fibrosis and tendinitis and was more common in persons 25 to 40 years old. With continued progression, stage III, or rotator cuff failure, would result and was characterized by partial or complete tendon tears typically in persons older than 40 years of age. He attributed 95% of all rotator cuff lesions to primary mechanical impingement.

Some biomechanical investigations have validated Neer's observations implicating the anterior acromion as a source of impingement.[36,69,75,148,165,166] Burns and Whipple[36] studied the anatomic sites of tendon compression against the coracoacromial arch. In the neutral arm position, the supraspinatus and intertubercular portion of the biceps tendon lies inferolateral to the coracoacromial ligament and anterior to the acromion. Arm elevation in the scapular plane resulted in contact of the supraspinatus and the anterior acromion and coracoacromial ligament. Biceps tendon impingement, on the other hand, occurred predominantly against the lateral free edge of the coracoacromial ligament. Flatow and colleagues,[75] using stereophotogrammetry to evaluate subacromial contact areas with arm elevation, noted a progressive decrease in the acromiohumeral interval with scapular plane abduction. The humerus and acromion were at their closest proximity between elevations of 60 and 120 degrees. Moreover, contact and proximity were observed to begin at the anterolateral aspect of the acromion at 0 degrees elevation and shift medially with progressive arm elevation. Only the anterior aspect of the acromion demonstrated the potential for subacromial contact. Additionally, acromiohumeral distances were decreased in shoulders with a hooked acromion morphology. In a subsequent investigation, Bigliani and colleagues[20] studied the effect of anterior acromioplasty on subacromial contact in seven cadaveric specimens. Their data suggested that flattening of the anterior third of the acromion was required to eliminate impingement. Although inherent limitations in a cadaveric model exist, they did note that flattening of just the anterior ridge of the acromion, rather than the anterior third, was insufficient to eliminate impingement in 50% of specimens.

Jobe and associates[124,125] popularized the concept of secondary mechanical impingement in throwing athletes. They noted that rotator cuff lesions are the end result of a continuum that progresses from instability, subluxation, impingement, and tension overload of the cuff, with resultant tearing. Repeated mechanical stresses cause failure of the glenohumeral static restraints and place increased demands on the dynamic stabilizers. The rotator cuff eventually fatigues, resulting in abnormal translation of the humeral head and secondary impingement. If left untreated, the impingement can progress and cause tearing of the cuff. The ability to distinguish between primary and secondary impingement, as described by Neer and Jobe, respectively, is paramount to effectively treating patients affected with these disorders. Although satisfactory results have been reported for subacromial decompression in patients with primary impingement, the same does not hold true for individuals with the secondary type.[3,70,81,93,102,108,196,216,229,235,239,250] Rather, treatment in this group requires attention to the underlying instability.

Coracoacromial Arch

The coracoacromial arch marks the superior boundary of the subacromial space. It comprises the coracoid process, the coracoacromial ligament, and the acromion (see Fig. 1-7). Mechanical forces about the coracoacromial arch, while not fully understood, have also been linked to the development of rotator cuff disease.[77,110,164,224]

The Acromion

The shape of the acromion exhibits variability among individuals. In an anatomic study of 140 cadaveric shoulders, Bigliani et al.[22] identified three predominant acromial forms when assessed in the sagittal plane (Fig. 1-14). A type I acromion had a flat undersurface and was present in 17% of cases. A type II acromion revealed a curved undersurface and was found in 43% of specimens. A hooked acromion, or type III, although present in 39% of cases, was found in 70% of shoulders with observed tears of the rotator cuff. A follow-up clinical study, using supraspinatus outlet radiographs to assess acromial morphology and arthrograms to determine rotator cuff integrity, affirmed the association between a "hooked" acromion and the presence of rotator cuff tears in patients presenting with various shoulder complaints.[160]

Despite the potential value of correlating specific acromial forms with lesions of the rotator cuff, other investigators have been unable to demonstrate comparable findings and have questioned the reliability of radiographic acromial morphology assessment in the sagittal plane.[13,16,72,96,120,268] Moreover, even though a flat acromion could be readily detected by most clinicians, confusion has arisen with regard to discernment of the curved (type II) and hooked (type III) patterns. Jacobson and colleagues[120] studied 126 supraspinatus outlet radiographs in an attempt to determine the reliability of detecting acromion

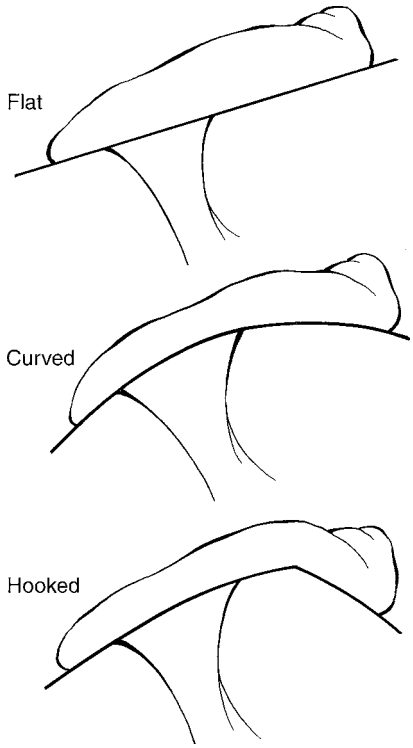

Figure 1-14 Acromion morphology: **type I:** flat; **type II:** curved; **type III:** hooked. (Adapted with permission from Bigliani LU, Morrison DS, April EW. The morphology of the acromion and rotator cuff impingement. *Orthop Trans* 1986;10:288.)

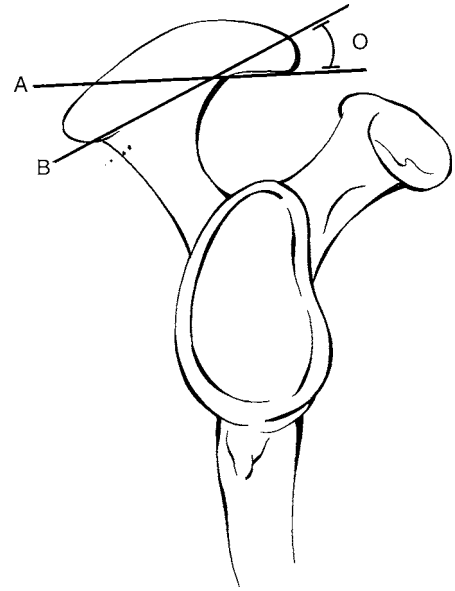

Figure 1-15 Depiction of acromial angle. (From Toivonen DA, Tuite MJ, Orwin JF. Acromial structure and tears of the rotator cuff. *J Shoulder Elbow Surg* 1995;4:376–383, with permission.)

morphology. Inter- and intraobserver reliability coefficients of 0.516 and 0.888 were demonstrated, respectively. The data suggest that observers were each consistent in using a given set of classification criteria, but that these criteria differed among examiners. Furthermore, they also reflect the qualitative component of acromion morphology assessment and the potential difficulties in comparison of published studies. Some of the observed differences may best be explained by the potential for acromion architecture to exist as a continuum, ranging from a flat to a hooked configuration, with varying degrees of curvature within the extremes.

In an effort to objectively quantitate and standardize the classification of acromion morphology, Toivonen and coworkers[243] devised the measurement of an "acromial angle." This angle was formed between two lines drawn along the undersurface of the anterior third and posterior two-thirds of the acromion (Fig. 1-15). The authors reported reproducible methods and demonstrated a significant association between increasing acromial angle and rotator cuff tears. The types I, II, and III acromion had acromial angles of 0 to 12, 13 to 27, and greater than 27 degrees, respectively. Moreover, their findings were consistent with those of Bigliani et al.[22] in that 89% of type III acromions were associated with tears of the rotator cuff.

Kitay and associates[132] called into question the use of supraspinatus outlet radiographs alone in evaluating acromial morphologic condition. Analysis of anteroposterior, axillary, 30-degree caudal tilt and supraspinatus outlet views in 23 surgically treated patients with impingement syndrome revealed the greatest interobserver reliability for the 30-degree caudal tilt view (0.84; Fig. 1-16). The caudal tilt x-ray film reflected the acromial spur in its combined anterior and inferior projections, whereas the outlet view provided information on the inferior projection of the spur. The combined use of these two radiographs was believed to be the best predictor of intraoperative acromial spur size.

The effect of age on acromial morphologic condition has not been sufficiently studied, leaving many questions unanswered about the potential for developmental alterations in acromial shape. Nicholson and coworkers[178] attempted to address this issue by quantifying osseous dimensions of the acromion and evaluating the relation between morphologic condition and age. Analysis of 420 scapulae in different age groups revealed no trends toward the alteration of acromial morphology. Although age did correlate with an increase in frequency of anterior acromial spur formation, it did not significantly change the dimensions of the acromion or alter morphology when assessed using supraspinatus outlet radiographs. The data suggest that the acromion's morphologic condition functions both independently and in association with age-related degenerative processes in the development of rotator cuff disease.

Figure 1-16 Thirty-degree caudal tilt radiograph depicting anterior–inferior projection of an acromial spur. The *solid line* designates the anterior cortical margin of the distal clavicle.

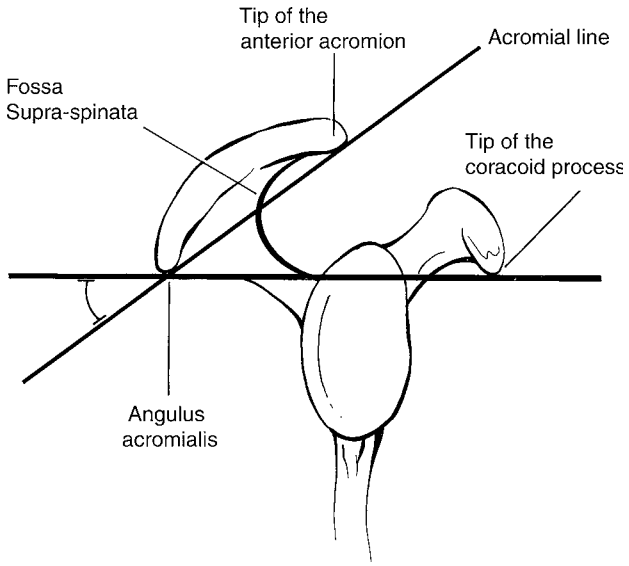

Figure 1-17 Acromial slope (tilt). This angle reflects the pitch of the acromion and is formed by a line across the posterior acromion and coracoid tip and along the undersurface of the acromion. (From Aoki M, Ishii S, Usui M. Clinical application for measuring the slope of the acromion. In: Post M, Morrey B, Hawkins R, eds. *Surgery of the shoulder.* St Louis: Mosby-Year Book, 1990: 200–203, with permission.)

Neer and Poppen[169,172] suggested that both the slope of the acromion and acromioclavicular joint spurs can compromise the integrity of the rotator cuff through impingement mechanisms. Aoki and coworkers[8,9] measured acromial slope and found a decreased angle in patients with impingement syndrome when compared with normal controls. Qualitatively, this parameter refers to the pitch of the acromion in the sagittal plane. A more horizontal acromion would have a lower pitch and a corresponding low angle (Fig. 1-17). This lower pitch can result in a reduced area of the supraspinatus outlet, thereby creating the potential for rotator cuff compromise.[268]

Zuckerman and colleagues[268] studied the spatial anatomy of the coracoacromial arch and supraspinatus outlet as they relate to full-thickness tears of the rotator cuff. In an anatomic investigation of 140 shoulders, they demonstrated a significant association between rotator cuff tears and measured parameters, including a reduced supraspinatus outlet area, lower acromial tilt, and larger anterior projection of the acromion. These findings support the contention that elements other than sagittal plane acromial morphology can be important factors leading to disorders of the rotator cuff. Their work was further supported by Edelson and Taitz,[67] who, in an anatomic study of 200 scapulas, observed that acromial slope, length, and height were most closely associated with osseous degenerative changes of the coracoacromial arch. Although such factors have also been implicated in the pathogenesis of rotator cuff disease, standard acromioplasty may not adequately address these elements and may explain failed surgical treatment in specific cases.

Attention to acromial morphology in other planes has also become an area of increasing interest. Banas and colleagues[13] described the "lateral acromion angle" after retrospectively reviewing 100 shoulder MRI scans in symptomatic patients. This angle is formed by a line along the undersurface of the acromion, as viewed in the coronal plane, and a second line joining the most superior and inferior margins of the glenoid (Fig. 1-18). As the lateral acromion angle decreased, a statistically significant increase in rotator cuff disease was observed. This parameter was felt to be an independent predictor of rotator cuff disease and further highlights the importance of acromial morphology assessment in multiple planes.

Ozaki and coworkers[189] looked at the relation between anatomic changes of the acromion undersurface and pathologic findings within the rotator cuff. Histologic and radiographic evaluation demonstrated an association between bursal-side partial rotator cuff tears and abnormalities of the acromion undersurface. Changes on the acromion correlated with the severity of the bursal tear, and the prevalence increased with advancing age. Interestingly, shoulders that demonstrated joint surface partial tears revealed an intact acromion undersurface. Their data further support the contention that rotator cuff tears represent a degenerative age-related process and that acromial abnormalities reflect secondary changes resulting from a bursal surface cuff tear. Whether precarious tendon vascularity or mechanical insult by the overlying coracoacromial arch also mediate this process remains undetermined;

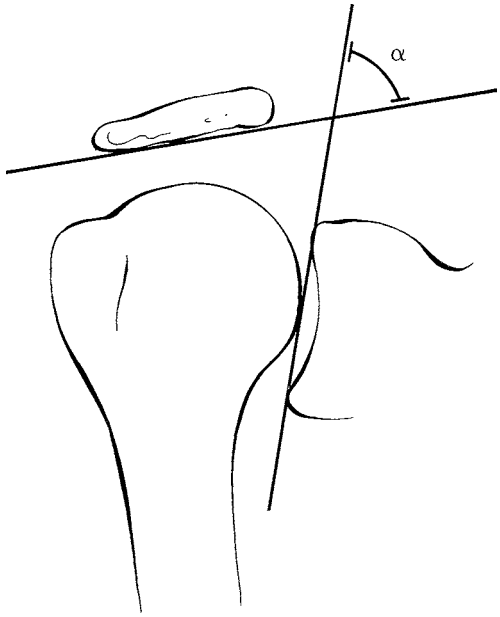

Figure 1-18 Lateral acromion angle. This angle is formed by the intersection of a line along the undersurface of the acromion in the coronal plane and a second line connecting the superior and inferior margins of the glenoid. (From Banas MP, Miller RJ, Totterman S. Relationship between the lateral acromion angle and rotator cuff disease. *J Shoulder Elbow Surg* 1995;4:454–461, with permission.)

however, it seems conceivable that both factors play a contributing role.

The Coracoacromial Ligament

The contribution of the coracoacromial ligament alone in the impingement syndrome has been investigated. It has been suggested that thickening of this ligament may predispose some patients to shoulder impingement. Uhtoff and coworkers[245] performed histologic analysis of the coracoacromial ligament in 17 patients with painful arc syndrome. Although they observed diffuse degenerative changes within the ligament, excessive proliferation of fibrous tissue could not be identified. Impingement in these patients was thought to occur as a result of expansion of the volume of the rotator cuff tendon or bursa, rather than the ligament itself. They highlighted the concept that any process that causes a decrease in the volume of the supraspinatus outlet can result in impingement syndrome. The coracoacromial ligament was believed to be one component of an unyielding tunnel that becomes too restrictive for its expanded contents.

While commonly described as having an inverted "Y" configuration, other morphologic types have been noted.[113,213] Holt and Allibone[113] performed an anatomic and histologic analysis of the coracoacromial ligament in 50 shoulders and noted variable forms among individuals. They observed three predominant variants and described them as "quadrangular, Y-shaped or broadbanded" (Fig. 1-19). The quadrangular and Y forms demonstrated a frequency of 48% and 42%, respectively. In the Y type, the two limbs take origin from the medial and lateral aspects of the coracoid. As they project superolaterally to insert onto the undersurface of the acromion, the bands fuse and form the anterior soft tissue boundary of the coracoacromial arch (Fig. 1-20).

Biomechanical and geometric testing of the coracoacromial ligament has demonstrated that the lateral band was both shorter in length and smaller in cross-sectional area in shoulders with rotator cuff tears. Although histologically there were no structural differences in the ligament between normally formed shoulders and those with rotator cuff tears, there was evidence of decreased mechanical properties in the latter. The reduction in mechanical integrity of the ligament was thought to reflect the multiple directional loads imposed on this structure in shoulders with rotator cuff tears.[224] One additional investigation employing scanning electron micrographs in eight cadaveric shoulders demonstrated that observed degenerative changes of the rotator cuff were characteristic of alterations resulting from frictional and rubbing mechanisms. Observations support the contention that degenerative changes already present in the cuff, irrespective of cause, can be aggravated by proposed frictional or abrading type forces.[110] Additional reports have suggested that increases in measured subacromial pressures in patients with impingement syndrome may mediate the development and progression of rotator cuff disorders.[121,222,262]

In contrast with its implicated role in the pathogenesis of impingement syndrome, the coracoacromial ligament has been shown to function as a dynamic brace that lends support to the acromion and coracoid during loads imposed by the surrounding musculature. Putz and colleagues[201] used strain gauges to measure distortion of the coracoid and acromion after resection of the coracoacromial ligament in eight cadavers. With applied loads, significantly more distortion of the acromion was observed. Soslowski and associates[228] have noted that the coracoacromial arch acts as a buffer against superior translations when the humeral head is not centered in the glenoid. This may occur during normal obligate translation of the joint with humeral rotation and also in patients with glenohumeral instability. Furthermore, its role as a secondary restraint to anterosuperior migration of the humeral head in patients with large rotator cuff deficiencies has also been emphasized.[11,74,97,228,257] Salter and coworkers[213] have suggested that the coracoacromial ligament provides mechanical support to the acromioclavicular joint. Gross and microscopic anatomic evaluation revealed that fibers at its insertion under the anterior acromion were contiguous with the inferior acromioclavicular joint capsule.

Although such studies have provided quantitative analysis of the coracoacromial arch in relation to shoulder function,

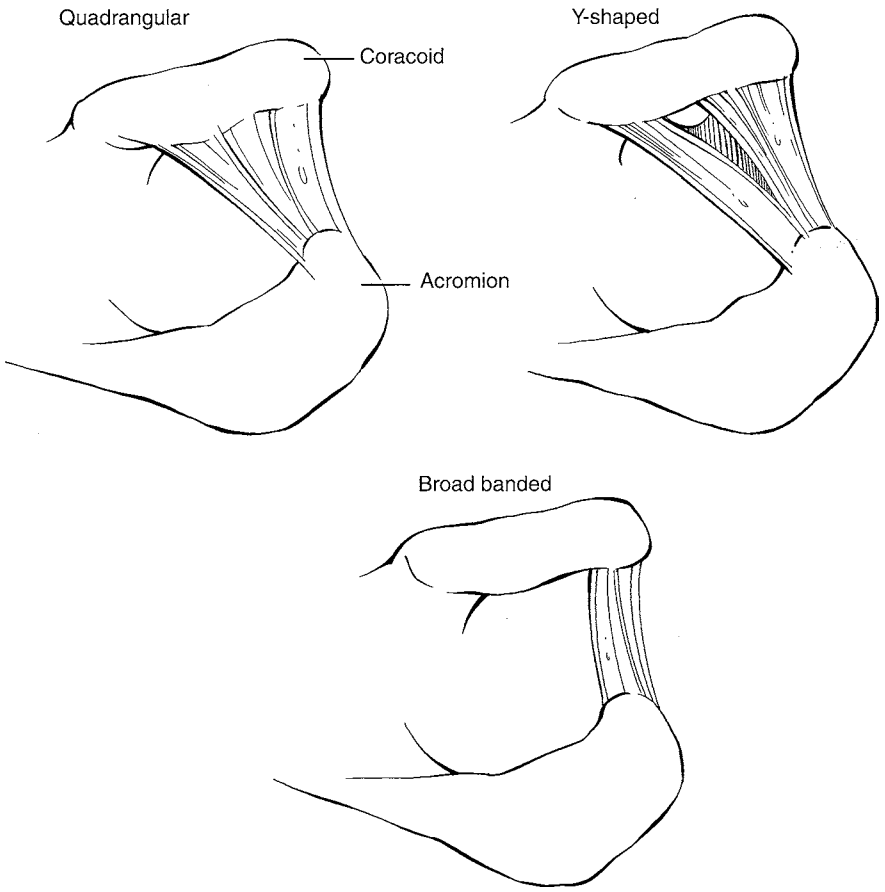

Figure 1-19 Anatomic variants of the coracoacromial ligament. (From Holt EM, Allibone RO. Anatomic variants of the coracoacromial ligament. *J Shoulder Elbow Surg* 1995;4: 370–375, with permission.)

additional investigations are needed to further clarify subacromial stresses and contact areas in multiple planes of motion and in different pathologic states. Increased understanding of these issues may enhance our ability to effectively evaluate and treat patients with rotator cuff disease.[128]

Others have noted that coracoacromial ligament division alone may be sufficient for adequate decompression of the subacromial space in selected patients.[126,256] One report highlighted sectioning of the ligament in a subgroup of persons with clinical findings of impingement

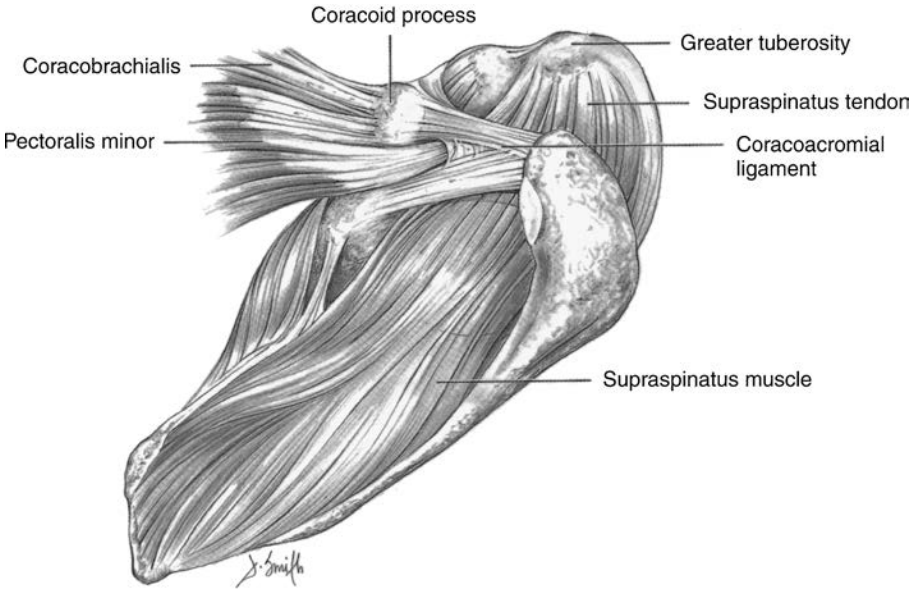

Figure 1-20 The coracoacromial arch. Note the Y configuration of the coracoacromial ligament.

syndrome despite an absence of degenerative spur formation and the presence of a flat-appearing acromion.[126] Although satisfactory results were reported for most patients, the role of coracoacromial ligament division alone in such patients has not been sufficiently studied. Furthermore, although this structure has been implicated in the pathogenesis of rotator cuff disease, recent emphasis has focused on its important functional role as a secondary passive restraint to anterosuperior migration of the humeral head in cuff-deficient patients.[74,97,257] Questions on the benefits of limited subacromial decompression remain unanswered and continue to be an area of active investigation.

Subacromial Spurs

The distinction between native acromion morphology and developmental subacromial osseous excrescences has not always been clear.[36,47,181,189] Although a strong association between degenerative subacromial hypertrophic spur formation and full-thickness tears of the rotator cuff exists, a causal relation remains difficult to prove.[22,50,78,137,156,160,166,168,181,183,189,206] Proponents of intrinsic pathogenic mechanisms support the contention that subacromial spurs represent secondary changes occurring as a result of existing tears of the rotator cuff.[189] Conversely, others have suggested that observed lesions of the rotator cuff occur because of mechanical insult by inferiorly projecting subacromial bony excrescences.[166,168] The formation of such spurs has been suggested to occur as a result of repeated tension exerted on the coracoacromial ligament.[106,181]

Despite controversy over the initial lesion, subacromial spurs appear to have a role in the development and progression of commonly observed rotator cuff tears. One histologic evaluation of bursal side rotator cuff tears in surgical specimens revealed variable-thickness tears of the supraspinatus corresponding with areas of impingement of the overlying acromion and coracoacromial ligaments. Also observed were avascular regions of the proximal edge of the torn tendon. The combination of findings led the authors to conclude that multiple causes, including both intrinsic and extrinsic causes, were responsible for the observed abnormalities.[78]

Coracoid and Acromioclavicular Osteophyte Impingement

Alternative sources of impingement have been implicated in the development of rotator cuff disease. Distally pointing acromioclavicular osteophytes, the coracoid process, and the posterosuperior aspect of the glenoid can contribute to shoulder pain and rotator cuff lesions in certain patients.[59,64,84,85,98,123,133,143,166,168,169,172,190,194,217,234,242,252,254] Petersson and Gentz[194] studied the relation between distally pointing acromioclavicular osteophytes and ruptures of the supraspinatus tendon. By using radiographic analysis in patients with arthrographically confirmed rotator cuff tears and anatomic dissections in cadaveric subjects, they were able to demonstrate a strong association between ruptures of the supraspinatus tendon and periarticular osteophytes. Although acromial excrescences were also observed, their frequency in subjects with rotator cuff ruptures was less than that of acromioclavicular bone spurs. Seeger and coworkers[217] reviewed MRI scans in 107 patients with painful shoulders. Bony and soft tissue abnormalities clinically described in impingement syndrome were evident in 53 persons. In these cases, the supraspinatus was noted to be compressed by either osseous spurs, hypertrophic capsular tissue of the acromioclavicular joint, or a low-lying acromion.

Whereas abnormalities of the acromioclavicular joint have been associated with rotator cuff disorders, acromioclavicular joint arthrosis has also been observed in 65% of asymptomatic persons with and without tears of the rotator cuff.[220] These findings suggest that acromioclavicular joint abnormalities on imaging studies alone may not be a reliable predictor of disease in the absence of correlative symptomatology. Moreover, treatment of such periarticular abnormalities based on imaging studies alone, such as excision of small inferior acromioclavicular osteophytes during subacromial decompression, may convert a painless condition to a symptomatic joint in certain patients.[134] However, patients with clinical evidence of the impingement syndrome and symptomatic arthritis of the acromioclavicular joint have been treated successfully with combined subacromial decompression and distal clavicle resection.[147]

Coracoid Impingement

Impingement of the rotator cuff between the humeral head and coracoid process can also occur with certain arm positions in some patients.[64,84,85,98,133,190] Gerber and coworkers[84] recognized the subcoracoid space (region between the tip of the coracoid process and humeral head or lesser tuberosity) as a source of shoulder pain and reported on idiopathic, iatrogenic, and traumatic causes of abnormalities affecting either the coracoid, glenoid, or humeral head. In all types, anterior shoulder pain was reproduced with either internal rotation of the arm in 90 degrees of abduction or adduction with the shoulder flexed to 90 degrees. Computed tomography scans of 47 shoulders in normal volunteers highlighted dimensional parameters of the subcoracoid space and suggested variational anatomic features that may predispose certain individuals to coracoid impingement. The subcoracoid space was confirmed as not being a free space, but rather a region just sufficient to accommodate gliding of the soft tissues between the coracoid process and humeral head. The distance between the coracoid and humerus decreased with the arm in forward

flexion and internal rotation, especially in those persons with a coracoid projecting far laterally and close to the scapular neck. Moreover, the soft tissues in the space became folded with the arm in this position. Alterations in the coracohumeral relation (e.g., osteotomy or fracture) as studied in cadaveric controls highlighted the potential for impingement with the arm in a flexed and internally rotated position.[85] Although this entity remains an uncommon form of impingement and often a difficult diagnosis, satisfactory results have been reported with surgical treatment in selected patients.[64,84]

Internal Glenoid Impingement

Arthroscopic evaluations of throwing athletes who have the painful arc syndrome have demonstrated impingement of the deep surface of the rotator cuff against the posterosuperior glenoid rim with the arm in 90 to 150 degrees of abduction and maximal external rotation.[59,122,123,143,155,242,252,254] It has been suggested that abduction and external rotation of the arm can entrap a portion of the supraspinatus tendon between the humeral head and glenoid in susceptible persons. Increased glenohumeral external rotation, decreased humeral retroversion, scapulothoracic dysfunction, and poor throwing technique all have been implicated in the development of this disorder. Associated findings include partial-thickness tearing of the undersurface of the infraspinatus and supraspinatus tendon, degenerative lesions of the posterosuperior glenoid labrum, and osteochondral impression fractures of the humeral head. Patients will typically complain of posterior shoulder pain that is elicited by overhead activity. Although these observations help emphasize alternative sources of shoulder impingement, further study is needed to better define this entity, its pathomechanics, and optimal treatment.

Acute Trauma and Rotator Cuff Tears

Most symptomatic rotator cuff tears are a result of an acute injury in the setting of some preexisting rototar cuff disease. Traumatic insults to the shoulder can result in tearing of the rotator cuff tendon. Neviaser and coworkers[177] reported on a series of 30 patients who had a concurrent rupture of the rotator cuff with an anterior dislocation of the glenohumeral joint. All patients were older than 40 years of age and were unable to sufficiently elevate the arm in the postinjury period. The supraspinatus was torn in most of the patients, with variable degrees of infraspinatus involvement. All patients with recurrent anterior instability had disruption of the subscapularis tendon. These individuals were satisfactorily treated with primary repair of the tendon without reconstruction of the capsulolabral complex. Similar findings were noted in other reports that also included disruption of the infraspinatus and teres minor tendons in a patient with recurrent posterior dislocations.[118,175,176,203]

Ruptures of the rotator cuff can occur in 14% to 63% of patients after an acute anterior or inferior dislocation.[112,149,195,203,241] The incidence increases in older persons and has been reported in 63% of patients older than 50 years of age.[203] Presumption that the rotator cuff tear is a result of the dislocation is based on negative patient accounts of shoulder pain or dysfunction before occurrence of the traumatic event.[175,176] However, it is conceivable that a tear may have been present before the injury and was extended or exacerbated after the dislocation. This may parallel patients who demonstrate acute extensions of a chronic, preexisting rotator cuff tear in the absence of instability. Although the chronicity of a potential preexisting rotator cuff lesion is sometimes difficult to determine, its influence on the prognosis and treatment should be considered. In such instances, surgical reconstruction of the rotator cuff may be more challenging than anticipated owing to the chronic component of the injury.

Fractures of the greater tuberosity, with or without a glenohumeral dislocation, can also result in tears of the rotator cuff. Neer[167] reported that a displaced greater tuberosity fracture results in an obligate longitudinal cuff tear at the region of the rotator interval. Posterior dislocations can result in a fracture of the lesser tuberosity, with disruption of the subscapularis. Interestingly, recurrent instability after fracture dislocations of the greater tuberosity is rare and is reported to range from 1% to 4%.[153,209,211]

Other forms of traumatic rotator cuff lesions include small partial-thickness tears of the supraspinatus or subscapularis in young, repetitive overhead athletes. Sports such as tennis, swimming, and baseball may predispose certain persons to rotator cuff tears through repeated mechanical stresses. One proposed mechanism suggests that fatigue of the scapular stabilizers results from repeated throwing, causing the humeral head and rotator cuff to abut against the acromion during arm elevation. The scapula is thought to "lag" behind the humerus, becoming unable to abduct sufficiently. Patients with neural impairments causing weakness of the trapezius or serratus anterior muscles can also develop secondary impingement through similar mechanisms. Loss of the suspensory mechanism of the scapula, such as in traumatic disruption of the acromioclavicular and coracoclavicular ligaments, may result in comparable rotator cuff abnormalities. In such cases, rotator cuff impingement occurs secondary to abnormal functional mechanics of the scapula.

Congenital Abnormalities: Os Acromiale

An association between an unfused acromial epiphysis, or "os acromiale," and tears of the rotator cuff has also been described.[162,170,179] The acromion has three centers of ossification that typically unite with the scapular spine by age 12

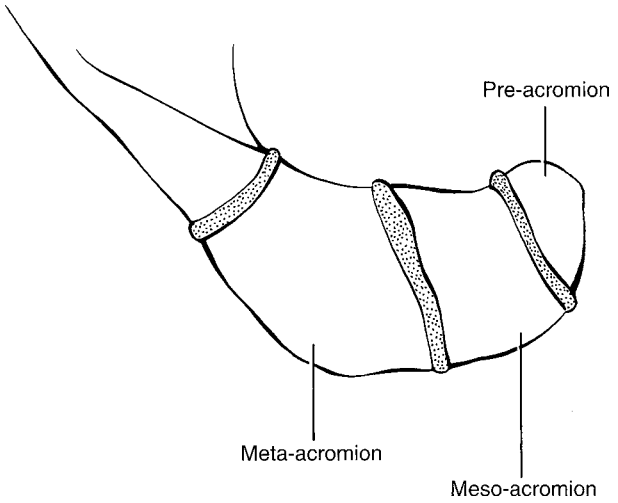

Figure 1-21 Three ossification centers of the acromion. (From Liberson F. Os acromiale: a contested anomaly. *J Bone Joint Surg* 1937;683–689, with permission.)

and with each other by ages 15 to 18[76,138,174, 232] (Fig. 1-21). These three centers are designated as the preacromion, mesoacromion, and metaacromion. The prevalence of os acromiale has been reported to range from 1% to 15%, with a 62% frequency of bilateral involvement.[68,99,138,178] Abnormal motion at the synostosis or synchondrosis is thought to decrease the capacity of the subacromial space and contribute to mechanical insult of the underlying rotator cuff.

An os acromiale can be identified on an axillary radiograph and should not be mistaken for a fracture of the acromion. Failure to recognize this entity can potentially compromise the results of treatment. Consensus on the optimal management is lacking and has ranged from conservative treatment to excision versus internal fixation and bone grafting.[33,115,136,162,179] Norris and associates[179] evaluated a group of 29 patients with os acromiale and suggested bone grafting in patients in whom the os was considered to be unstable. Standard acromioplasty was believed to be satisfactory in patients with a stable synostosis. Arthroscopic subacromial decompression alone has been reported to yield poor results in some patients, for symptoms were noted to recur within 1 year of surgery.[115] Whereas smaller fragments may be amenable to excision in symptomatic patients, no controlled studies exist comparing excision with internal fixation and bone grafting for meso os acromiale. Because the acromion serves as the origin for the deltoid, potential compromise of this important muscle should be considered during surgical management of affected patients.

The finding of an os acromiale may be incidental and not necessarily correlate with a patient's symptoms. Normal shoulder function has been noted in patients with an os acromiale.[33,138] Burkhart[33] reported on a high-performance tennis player who had competed without pain or dysfunction for 15 years before evaluation. Furthermore, clinical experience has demonstrated that many patients who present with shoulder pain and have an os acromiale had been asymptomatic for many years before clinical presentation. Often, a traumatic event has been presumed to precipitate symptoms surrounding the os acromiale. If the prevalence of this anomaly is estimated at 1% to 15% of the general population, then it seems likely that many individuals with an os acromiale never develop symptoms given the frequency of cases seen in a clinical shoulder practice.

NATURAL HISTORY

The rotator cuff is subject to substantial forces because it maintains the humeral head within the shallow glenoid. It is situated in a potentially tight subacromial space and undergoes senescent structural changes commonly observed in other joints of the body.[46,61,156] When the cuff fails, spontaneous healing of the torn tendon is not expected to occur, and multiple factors may be responsible. Its fibers are under tension and typically retract on tearing. In full-thickness lesions, only bursal tissue may bridge the area of tendon loss. Histologic evaluation of partial tears in surgical specimens has also demonstrated patterns of incomplete healing. Observations included neovascular tissue at the distal margin of the defect and relative avascularity of the proximal stump. Although the potential for a reparative process was felt to exist, there was no evidence of closure of the defect in any of the specimens. The findings were suggestive of a futile attempt at healing.[78] Other investigators have noted that resorption of tendon fibers by neovascular tissue can occur.[233,258] This may potentially weaken surrounding intact fibers placed under increased loads as a result of a tear. Because the torn cuff is bathed in synovial fluid, factors responsible for normal healing and formation of fibrin clots may be disrupted. Moreover, tearing may further impair the blood supply to a relatively dysvascular tendon.

The prevalence of rotator cuff tears in the general population can be extrapolated from both cadaveric and MRI studies. The frequency of complete and partial rotator cuff tears ranges from 5% to 39% and 13% to 3%, respectively.[50,79,100,129,130,168,189,194,220,258] Although anatomic studies have reported an increase in pathologic findings about the cuff with advancing age, they are limited by an inability to sufficiently correlate findings with symptomatology. Given the prevalence of rotator cuff tears in cadaveric studies alone, it remains unclear whether observed findings could be considered part of the normal aging process.

A prospective investigation was conducted to determine the prevalence of rotator cuff tears in an entirely asymptomatic population by using shoulder MRI scans in 96 normal volunteers. Overall, complete and partial-thickness

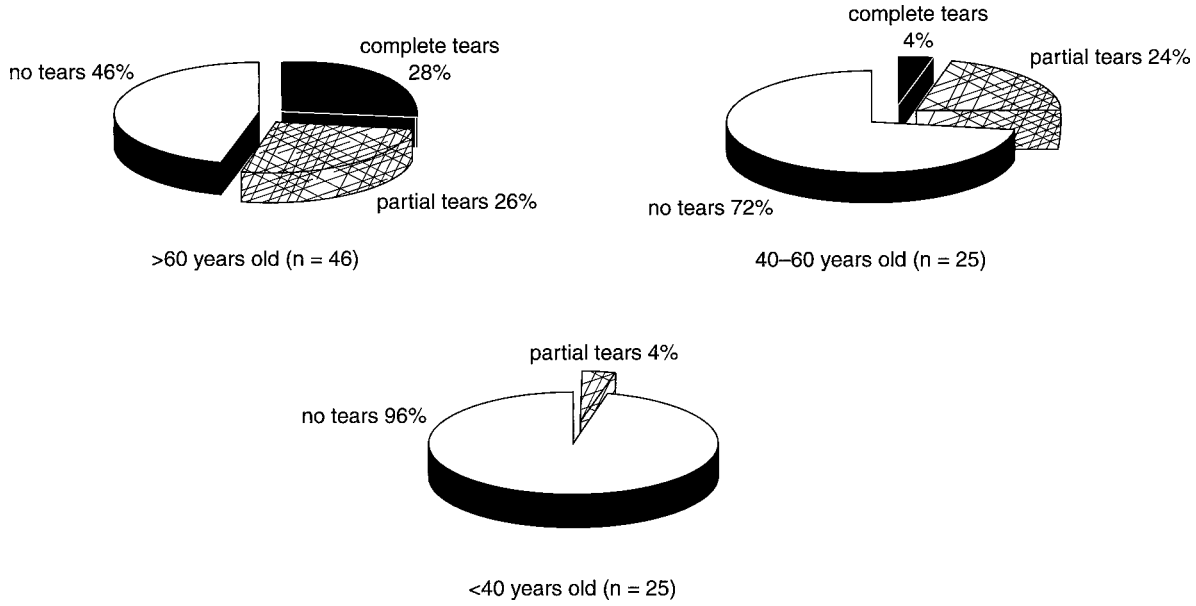

Figure 1-22 Prevalence of magnetic resonance imaging–evident rotator cuff tears in (*left*) asymptomatic volunteers older than 60 years of age, (*right*) those 40 to 60 years, and (*bottom*) those younger than 40 years. (Adapted with permission from Sher JS, Uribe JW, Posada A, Murphy BJ, Zlatkin MB. Abnormal findings on magnetic resonance images of asymptomatic shoulders. *J Bone Joint Surg Am* 1995;77:10–15.)

tears were found in 14% and 20% of individuals, respectively. In persons older than 60 years of age, the prevalence of complete and partial tears was 28% and 26%, respectively[220] (Fig. 1-22). The results provided in vivo evidence that asymptomatic individuals with rotator cuff tears can exhibit normal shoulder function. Moreover, they emphasized the dangers of basing operative decisions on MRI scans alone. The high prevalence of cuff tears in an asymptomatic population and their direct correlation with age support the contention that some rotator cuff tears occur as part of a normal age-related process.

The question of why some patients with rotator cuff tears develop symptoms and others do not remains an area of interest. Both prior reports and clinical observation affirm that many patients with cuff tears may not demonstrate significant pain or dysfunction.[25,29,152,210,214] Clearly, some individuals with symptomatic tears respond well to conservative treatment despite the persistence of a tendon defect. Yamaguchi et al. examined longitudinally the natural history of asymptomatic rotator cuff tears over a 5-year period to assess the risk factors for symptoms and tear progression. They found that 51% (23 shoulders) became symptomatic over a mean of 2.8 years and returned on their own. Of the remaining patients who returned for evaluation, only nine were asymptomatic. Of these nine, two asymptomatic tears had cuff tear progression.[265]

Other authors have documented good functional results, in the short term, in patients who had undergone débridement, rather than repair of a torn rotator cuff. Furthermore, satisfactory pain relief was predictably achieved despite lack of closure of the tendon tear.[30,136,182,205,207,269] As such lesions do not typically heal, it would seem conceivable that factors other than the tendon defect itself must contribute to the generation of symptoms. Fukuda and associates[77] suggested that subacromial bursal inflammation, as evidenced in surgical histologic specimens of partial-thickness rotator cuff tears, mediates symptoms in affected patients. They noted that the degree of inflammation likely correlates with the patient's level of symptoms. Others have suggested additional sources of shoulder pain that potentially include synovitis, intraarticular pathology, and mechanical factors.[34,69,166,168]

Alterations in normal glenohumeral kinematics have also been considered in the development of symptoms, but equally important, may be individual differences in scapular mechanics, compensatory action of surrounding muscles, and variable tolerances to pain. Multiple studies have shown abnormal superior migration of the humeral head during active arm elevation in shoulders with rotator cuff tears and the impingement syndrome.[32,63,144,197,218,264] In normal shoulders, on the other hand, the geometric center of the humeral head remains centered on the glenoid during active arm elevation.[4,197,218] Abnormal glenohumeral patterns of motion have thus been suggested to play a role in mediating pain. Burkhart[32] emphasized the concept of an anatomically deficient, but biomechanically intact, rotator cuff. Fluoroscopy was used to assess kinematics of the glenohumeral joint in patients with massive tears of the rotator cuff. Normal patterns were demonstrated, provided sufficient anterior and posterior cuff were present to preserve the normal

transverse plane force couple. Location rather than size of the tear was felt to have a more important role in preserving normal glenohumeral motion. Another biomechanical study evaluating glenohumeral motion in artificially created tendon defects highlighted the potential for normal kinematics, provided only a portion of the cuff was violated. Lesions of the supraspinatus did not alter normal motion patterns, whereas defects involving both the supra- and infraspinatus demonstrated an increase in humeral cephalad migration.[144]

An investigation attempted to address the relation between glenohumeral kinematics and symptoms in patients with rotator cuff tears. Computer-enhanced radiographic measurements were obtained during arm elevation in patients with known tears of the rotator cuff. An asymptomatic and a symptomatic population were studied, which revealed progressive superior humeral head translation in both groups when compared with normal controls.[264] These data demonstrate that loss of glenohumeral kinematics, as measured in the coronal plane, does not correlate with the presence of symptoms. More likely, symptoms are the result of multiple factors that may not necessarily be independent of one another.

The fate of the many types of cuff lesions cannot always be predicted. It is difficult to conclude that all rotator cuff lesions fall within a continuum progressing from tendinitis to full-thickness tears, because conclusive evidence supporting this concept is lacking. Rather, it seems more plausible that the types of pathology observed reflect the multifactorial cause and pathogenetic mechanisms so far identified. Moreover, we cannot definitively determine that partial tears heal, for evidence to the contrary exists.[78] The significance of bursal and joint surface partial lesions in relation to symptoms and their pathogenesis also remains uncertain.

The natural history of patients with symptomatic full-thickness rotator cuff tears is variable. Moreover, our ability to reliably predict a given patient's course is limited and may partly reflect insufficient knowledge about its pathogenesis. Clinical experience has demonstrated that patients with similar-appearing lesions may have differences in symptoms, function, and response to treatment. Cofield[51] noted that conservative management of patients with chronic painful rotator cuff tears will likely result in a successful outcome less than 50% of the time. Others have noted similar findings after nonoperative treatment and reported gradual deterioration of shoulder function with time in some patients.[117,214,259] Neer and coworkers[171] estimated that cuff tear arthropathy will develop in 4% of patients with complete rotator cuff tears. If the tear was not sufficiently large or became sealed off by bursal tissue, then development of cuff-related arthropathy was less likely. The surgical recommendations for patients with symptomatic complete tears are generally individualized and based on the duration of symptoms, severity of pain, degree of dysfunction, and functional goals. Although satisfactory results can usually be achieved with surgical treatment in many patients, isolating those individuals likely to achieve similar outcomes with nonsurgical management continues to be a challenge. The heterogeneity, lack of uniform classification, nonuniformity in treatment strategies, and existence of similar lesions in normal asymptomatic persons make it difficult to predict the likely outcome of these patients. The use of appropriate animal models and execution of large longitudinal follow-up studies can help further identify prognostic criteria for rotator cuff lesions.

Given the evidence to date, it seems likely that the rotator cuff has some degree of reserve that affords functional use of the arm in cases of limited tendon deficiencies. Moreover, location rather than size of a tear may be more important in the development of symptoms; however, this issue requires elucidation with further study. Factors such as synovitis, subacromial bursitis, and intra-articular abnormalities may contribute to pain and dysfunction, but further basic science and clinical research can help define and isolate specific causes of pain in affected patients. Enhancement of our ability to identify individuals with cuff lesions prone to progression and dysfunction will afford the development of optimal treatment approaches individualized to a given patient's clinical findings.

ANIMAL MODELS OF THE ROTATOR CUFF

Animal models have been developed to test hypotheses related to the pathogenesis of rotator cuff disease. Such models are necessary to test hypotheses in a repeatable and controllable manor. Criteria for selecting an animal model of rotator cuff disease include animal size, anatomic relationship to humans, intrasynovial versus extrasynovial tendon location, intraarticular versus extraarticular tendon location, ease of tendon manipulation, ease of measurement of tissue properties, and animal availability and affordability. Anatomic similarity to the human shoulder includes evaluation of the shoulder musculature and associated bony anatomy (acromion, coracoid, clavicle, humerus), particularly the relationship between the supraspinatus tendon and the acromion or other structures immediately superior to the tendon, as well as articulations (glenohumeral, subacromial, acromioclavicular) and planes of motion.[226]

In designing any animal model, the clinical question being investigated will dictate the appropriateness of the selected model.[42] Therefore, while one animal may be ideal to study one aspect of rotator cuff disease, another species may be more appropriate for another area of rotator cuff pathology. As a result, multiple animal models of

the rotator cuff have arisen to assess different areas of rotator cuff pathology, such as intrinsic tendon degeneration, tendon injuries or tears, and subsequent tendon healing or surgical repair. These include rat, rabbit, avian, canine, goat, and sheep models (Table 1-2).

Soslowsky et al.[225,226] developed a rat model for studying multiple aspects of rotator cuff disease. The initial study evaluated 33 animal species as potential models. Gross anatomic dissections, radiographic assessments, and activity monitoring demonstrated that the rat was the only animal of the 33 with anatomic and functional relationships comparable to the human shoulder. In particular, the rat was the only animal with an acromion immediately positioned over the supraspinatus tendon, as in humans. The tendon passes repetitively under the acromion when the rat is ambulating, which may parallel repetitive over-

TABLE 1-2
COMPARISON OF COMMON ANIMAL MODELS FOR ROTATOR CUFF DISEASE

Species	Positives	Negatives
Rat (supraspinatus–infraspinatus tendon)	1. Acromial arch complex immediately positioned over supraspinatus tendon 2. Supraspinatus tendon passes repetitively under acromion during ambulation—may parallel repetitive overhead activities in humans 3. Controllable, reproducible alterations in tendon with potentially similar histologic, biologic, and biomechanical changes to human rotator cuff disease 4. Infraspinatus tendon long: covered entirely by acromion making ideal for use as impingement model	1. Quadruped: weight-bearing upper extremity 2. Acromial arch complex differences: acromion, AC ligament, clavicle, and coracoid in rat vs. acromion, CA ligament, and coracoid in humans 3. Small size: problem for experimental manipulations, such as creating tears or surgical repair, and applicability of techniques to humans 4. Supraspinatus tendon short: acromion covers muscle rather than tendon
Rabbit (supraspinatus tendon)	1. Supraspinatus tendon–bone insertion at the greater tuberosity identical to tendon–bone interface in humans: four zones of transition (tendon proper, nonmineralized fibrocartilage, mineralized fibrocartilage, and bone) 2. Delayed and immediate tendon repair models	1. Quadruped: weight-bearing upper extremity 2. Shoulder anatomy not as similar to human as rat model 3. Small size: problem for experimental manipulations, such as creating tears or surgical repair, and applicability of techniques to humans
Sheep (infraspinatus tendon)	1. Tendon dimensions, properties similar to the human supraspinatus tendon 2. Larger size allows evaluation of clinically applicable surgical techniques of rotator cuff repair 3. Delayed and immediate tendon repair models	1. Quadruped: weight-bearing upper extremity 2. Tendon heals spontaneously after detached: need to actively prevent healing to study effect of a delayed repair 3. Complex limb immobilization, partial weight-bearing protocol postinjury and repair to allow surgical repair healing
Canine/beagle (infraspinatus tendon)	1. Larger size allows evaluation of clinically applicable surgical techniques of rotator cuff repair	1. Quadruped: weight-bearing upper extremity 2. Shoulder anatomy not as similar to human as rat model
Chicken (supracoracoid tendon)	1. Non–weight-bearing, hanging shoulder joint as in human 2. Anatomic similarity: bursa-like structure superior to tendon, joint capsule inferiorly	1. Lack of an acromion, other structural differences: prevent creation of insertional tendon injury, tendon–to–bone repair 2. Small size: problem for experimental manipulations, such as creating tears or surgical repair, and applicability of techniques to humans

AC, acromioclavicular; CA, coracoacromial.

head activities in humans. While certain species of nonhuman primates also satisfied the selection criteria, they were eliminated because of questions of practicality of use due to expense and management issues.

This rat model was initially used to examine both intrinsic (degeneration) and extrinsic (compression) mechanisms of rotator cuff disease.[40] An intratendinous injection of bacterial collagenase was used to simulate intrinsic tendon degeneration, while an Achilles tendon allograft placed immediately underneath the acromion was used to simulate an extrinsic mechanism of subacromial impingement by decreasing the subacromial space. Both alterations resulted in controllable and reproducible injuries in the supraspinatus tendon, with a tissue response bearing significant similarity to a state of tendinosis seen in adult human tendon.[226] This rat model has subsequently been used to study numerous other areas of rotator cuff pathology, including the role of repetitive overuse activity of the supraspinatus tendon in tendinosis through the use of a rat treadmill running protocol,[40,193] the healing response of rotator cuff tears by creation of a defect or complete detachment of the supraspinatus tendon,[17,41,90,91,237] and the healing response of rotator cuff tears after surgical repair by complete detachment and repair of the supraspinatus tendon.[236,238] In addition to separately studying the intrinsic, extrinsic, and overuse injury models as factors in the development of rotator cuff tendinosis, the effect of a combination of these mechanisms in the development of rotator cuff tendinosis has been investigated.[227] These numerous studies demonstrate that controllable and reproducible alterations in the supraspinatus tendon can be made in this model, with potentially similar histologic, biologic, and biomechanical changes to human rotator cuff disease.

Despite its many benefits, the rat model does show some limitations. Rats have been noted to have high healing potential. One potential explanation is based on the size of the tissue. Considering that a rat supraspinatus tendon is only about 4 to 6 mm in width, and taking into account that cell size in rats and human are the same, rats may possess similar healing potential if the same actual size tear is made in a physiologically similar human (relative age). The rat is a quadruped, using its arms for ambulation and, thus, weight bearing. Human shoulders do bear significant loads, but it is unclear how similar the human situation is to the rat model. Anatomically, the rat acromial arch complex differs slightly from humans, consisting of the acromion, acromioclavicular ligament, clavicle, and coracoid, compared to the acromion, coracoacromial ligament, and coracoid in humans. Finally, the small size of the animal limits its use in certain experimental manipulations. For example, evaluating surgical techniques of human rotator cuff repair, such as tendon grasping or tendon-to-bone fixation, are best studied in animals with tendon size and dimensions more similar to the human rotator cuff.

Variations in the rat rotator cuff model have been attempted by others. Intrinsic tendon degeneration has also been modeled through the use of an injection of carrageenan, a polysaccharide.[240] Schneeberger et al.[215] created a rat model of subacromial impingement using the infraspinatus tendon. The authors felt that the supraspinatus tendon was not ideal to study subacromial impingement because the tendon is short in rats and the medial side of the acromion covers the supraspinatus muscle rather than the tendon. In contrast, the infraspinatus tendon is long in the rat and is found in close contact with the undersurface of the acromion across its entire tendon width. To create subacromial impingement, one or two bony plates, approximately 2 $\times$ 2 mm in size, were harvested from the scapular spine and placed on the undersurface of the acromion. Fixation was achieved with one absorbable suture stitch placed through two 0.4-mm drill holes made in the bony plate(s) and the acromion. One or two plates could be fixed to the acromion to vary the degree of impingement. This impingement model reproducibly led to bursal-sided infraspinatus tears of variable thickness, with no evidence of articular-sided or intratendinous tears noted. However, the bony plates displaced from the subacromial space in 31% of the rats.[215]

Several authors have investigated rabbit models of rotator cuff disease. Bjorkenheim et al.[23,24] examined healing properties of a supraspinatus defect in a rabbit model, including the use of intraarticular pressure readings in the glenohumeral joint to follow healing response. A triangular-shaped defect in the supraspinatus tendon was made near its insertion to the greater tuberosity, and subsequently it was shown that tissue resistance to hydrodynamic pressure in the glenohumeral joint was a reliable method of assessing the strength of the healing defect.[24] Uhthoff et al. also examined healing of a supraspinatus defect in an acute repair rabbit model.[247,248] In one study, the tendon was surgically exposed and transected near its insertion at the greater tuberosity. A bony trough at the greater tuberosity was immediately burred to expose cancellous bone, and the tendon edge was repaired back to the trough. Two weeks after repair, the cellularity of the cancellous bone underlying the bony trough and the thickness of the subacromial bursa were significantly increased, while the cellularity of the supraspinatus tendon stump was significantly decreased.[247] Changes in vascularity paralleled these changes in cellularity. The findings suggest that the underlying bone and subacromial bursa contribute to the early phases of tendon healing following surgical repair, while the tendon stump does not.

This rabbit supraspinatus detachment model has also been used to investigate healing response in nonrepaired tendon, as well as tendon undergoing delayed

repair.[44,150,246] In the delayed repair model, following supraspinatus detachment, the proximal tendon stump was wrapped in polyvinylidine fluoride membrane to prevent spontaneous reattachment. After 6 or 12 weeks, the tendon was reattached to the greater tuberosity. The supraspinatus tendon was successfully repaired using this model, but repair and healing did not reverse muscle and fatty changes that had developed while the tendon was detached. Reattachment of the supraspinatus tendon at 6 weeks did not reverse muscle atrophy or fat accumulation in the ensuing 6 weeks, but it did prevent an increase in fat accumulation when compared with later reattachment at 12 weeks.[150,246]

The rabbit model of rotator cuff disease has many of the same advantages and disadvantages of the rat model. The rabbit shoulder anatomy is less similar to human anatomy than the rat,[226] but the rabbit has been chosen by many investigators because the supraspinatus tendon–bone insertion at the greater tuberosity is identical to the tendon–bone interface in humans with four zones of transition: tendon proper, nonmineralized fibrocartilage, mineralized fibrocartilage, and bone.[247] Like the rat, the rabbit has four-legged ambulation and, thus, bears weight on its upper extremities. Although larger than the rat, the rabbit is still small in size and may also be less applicable for use in certain investigations.

Larger-size animals have also been used as rotator cuff models, particularly to evaluate surgical repair of rotator cuff tears, and include the sheep,[55,86–88] the goat,[230] and the beagle or other canines.[6,7,131] All of these large animal models have focused on the infraspinatus tendon, with the sheep most extensively studied. Without a suitable animal model for in vivo testing of rotator cuff repair techniques, Gerber et al. attempted to develop such a model in sheep.[86–88] An initial cadaveric study demonstrated that the sheep infraspinatus tendon has similar size, shape, and mechanical properties to the human supraspinatus tendon and is almost indistinguishable on histologic examination, making it an ideal animal model for evaluating surgical techniques of rotator cuff repair applicable to humans. Multiple suturing methods for tendon grasping and tendon-to-bone repair were tested with this sheep cadaveric model, and the modified Mason-Allen stitch was found to have the highest tensile strength and cause the least tendon strangulation.[87]

An attempt was made to repeat this in vitro study in an in vivo sheep model while also testing bone augmentation techniques at the repair site. To best simulate properties of long-standing rotator cuff tears, development of a chronic injury model with delayed tendon repair was attempted.[88] Infraspinatus tendon transection was made at the greater tuberosity insertion, with delayed repair at 4 to 6 weeks postinjury to replicate properties of chronic tears, including tendon atrophy, retraction, shortening, and greater tuberosity osteoporosis. Osteoporosis was created by decortication of the greater tuberosity, leaving exposed cancellous bone at the insertion site. Problems were encountered in the pilot studies of this model, however, and it was abandoned for an immediate-repair model. The difficulties with the model included complex limb immobilization and weight-bearing protocols postinjury and postrepair. The tendon repairs could not withstand full weight bearing on the extremity, and it became necessary to cement a rubber ball to the hoof of the operated limb to protect weight bearing and protect the surgical repair. These weight-bearing issues again highlight the problem of developing an animal model of rotator cuff disease in a quadruped. Most significantly, however, after 4 to 6 weeks of infraspinatus detachment, the tendon–bone junction was covered in such extensive scar that normal tendon and scar tissue were indistinguishable. As a result, repair sutures were frequently placed in peritendinous scar tissue rather than tendon, producing a high failure rate of tendon repair (12 of 15 animals). Even after abandoning this chronic model for an immediate-repair protocol, a reasonable success rate of surgical repair (8 of 10 sheep) was achieved only after tendon was repaired under no tension and weight bearing was protected postoperatively for 5 weeks.[88]

With recognition of the aggressive spontaneous healing response in the infraspinatus tendon following detachment, the delayed repair sheep model was reattempted using techniques to actively prevent healing of the tendon edge until the time of delayed repair. Gerber et al.[86] modified the surgical protocol by releasing the tendon at the time of injury with a greater tuberosity osteotomy, leaving a 2×1.5 cm fragment of greater tuberosity attached to the tendon edge to allow for better localization and fixation of the tendon at the time of delayed repair. In addition, the end of the infraspinatus tendon was covered in a 5 cm–long silicone rubber tube to prevent spontaneous healing prior to delayed repair. These modifications were successful, and delayed repairs were performed between 40 and 42 weeks posttendon release to mimic repair of a chronic rotator cuff tear. Indeed, at the time of repair, the detached tendon was found to have many properties that mimic a chronically torn rotator cuff, including significant retraction, muscle atrophy, and fatty infiltration.[86]

Coleman et al.[55] also developed a chronic rotator cuff repair model with the sheep infraspinatus tendon and utilized another technique to actively prevent healing of the tendon edge until the time of delayed repair. The infraspinatus tendon was detached from its insertion at the greater tuberosity and then repaired at different time points: immediate repair to simulate an acute tear model; 6-week delayed repair to simulate a chronic, repairable tear model; and 18-week delayed repair to simulate a chronic, irreparable tear model. Active healing or scarring prior to

surgical repair was prevented in the delayed repair groups by wrapping the tendon end in a Gore-Tex dura substitute, shown to inhibit scar formation.[15] Protected weight bearing for 5 weeks postoperatively was also utilized in this model by affixing a rubber ball to the hoof of the surgically repaired extremity. This protocol resulted in successful surgical repair of tendon back to bone in both delayed repair groups, with the detached tendon edge easily identifiable at the time of repair. The 18-week irreparable tear group showed twice as much tendon retraction as the 6-week repairable tear group at the time of repair and required a polylactic acid patch to span the tendon–bone gap and allow tendon reattachment. In addition, the earlier repair of tendon (6 weeks vs. 18 weeks) was found to result in more rapid recovery of infraspinatus muscle function and tendon elasticity.[55]

Unlike the other quadruped animal models, Kobayashi et al.[133] attempted to develop a rotator cuff model in a species with a non–weight-bearing, hanging shoulder joint as in the human, and chose the avian shoulder. Despite the lack of an acromion, the avian supracoracoid tendon has considerable anatomic similarity to the human rotator cuff tendon, including a bursa-like structure superior to it and the joint capsule inferiorly. An acute injury and repair model was examined, with a long transverse full-thickness laceration, approximately 60% of tendon width, created in the chicken supracoracoid tendon. This injury was made proximal to the insertion site, unlike in other models due to anatomic differences, and then immediately repaired with a single simple stitch. Analysis with histology and in situ hybridization found that peritendon cells of the bursal side of the tendon played a significant role in the repair process, which then progressed to the articular side of the tendon. Several limitations in this model relate to the differences in avian and human shoulder anatomy. In addition to the lack of an acromion, other structural differences prevented evaluation of an insertional injury and tendon-to-bone repair process.

Canine models, such as the beagle, have also been used to study the role of synthetic materials, such as a polylactic acid patch, in irreparable rotator cuff tears. As with the sheep, the beagle rotator cuff model utilizes the infraspinatus tendon. A polytetrafluoroethylene (PTFE) graft was tested in an acute injury and repair model by first detaching the infraspinatus and then removing 1 cm of tendon at the insertion edge to create an irreparable defect.[131] The injuries were immediately repaired, with the PTFE felt graft sutured to the tendon edge and to a bone trough created in the greater tuberosity to span the irreparable defect and bring tendon back to bone. All reconstructed infraspinatus tendons healed. A poly-L-lactic acid (PLLA) felt graft was also tested with this same model. All but two of the tendons healed back to bone using this graft. PTFE and/or PLLA grafts may become clinically useful bioabsorbable materials for rotator cuff reconstruction.

A well-chosen animal model and well-designed experimental protocol can be powerful tools with which to test hypotheses related to pathogenesis or potential mechanisms of rotator cuff disease. Essential to this statement is appropriately matching the animal model to the condition being studied. In general, larger animals, such as sheep, are necessary to closely model and evaluate surgical techniques used clinically. Smaller animals are more practical in terms of expense, care, and handling, but their size can make tissue access and analysis more difficult at times. With research focusing more and more on tissue engineering techniques and gene therapy as novel approaches to the treatment of musculoskeletal diseases such as rotator cuff pathology, animal models will be essential for rigorously testing hypotheses related to such therapies.

ROTATOR CUFF TISSUE ENGINEERING

Basic Principles of Tissue Engineering Design

The goals of tissue engineering are to increase the healing response of the body to insults to regenerate tissues efficiently and to produce new tissues that are comparable to healthy tissue in strength and function. In the case of tendon, this goal translates to a restoration of load-bearing function with a decreased risk of recurrent failure. The rotator cuff is a musculotendonous complex that is likely to benefit from the development of tissue engineering models for tendon repair.[251]

To maximize success of a tissue engineering approach for the treatment of rotator cuff disorders, there are three key steps to accomplish. Step 1 is the identification of the targets and intended goals. To accomplish step 1, there needs to be an understanding of events involved with the rotator cuff disease process, with a focus on the identification of therapeutic targets. This includes defining the temporal, spatial, cellular, and molecular events involved with cuff degeneration of repair as well as the origin of the responding cells. Step 2 is defining biomechanical properties and testing protocols. This will allow for the ability to quantitatively evaluate the properties of the engineered tissue. This assessment demands established standards of successful biomechanical restoration.[101,103,104,119] Step 3 is choosing the engineering strategy best suited to achieve desired effect.[37,80] Engineered tissue can be created by altering the responding cells, augmenting the healing signals, blocking the inhibitor pathways, or creating de novo tissue in a bioreactor, while functional tissue engineering uses stem cells placed on a scaffold that can be manipulated with signaling molecules in the correct biomechanical environment to form a tendon. Choosing the strategy best suited for your intended goal is paramount for a successful program.[251]

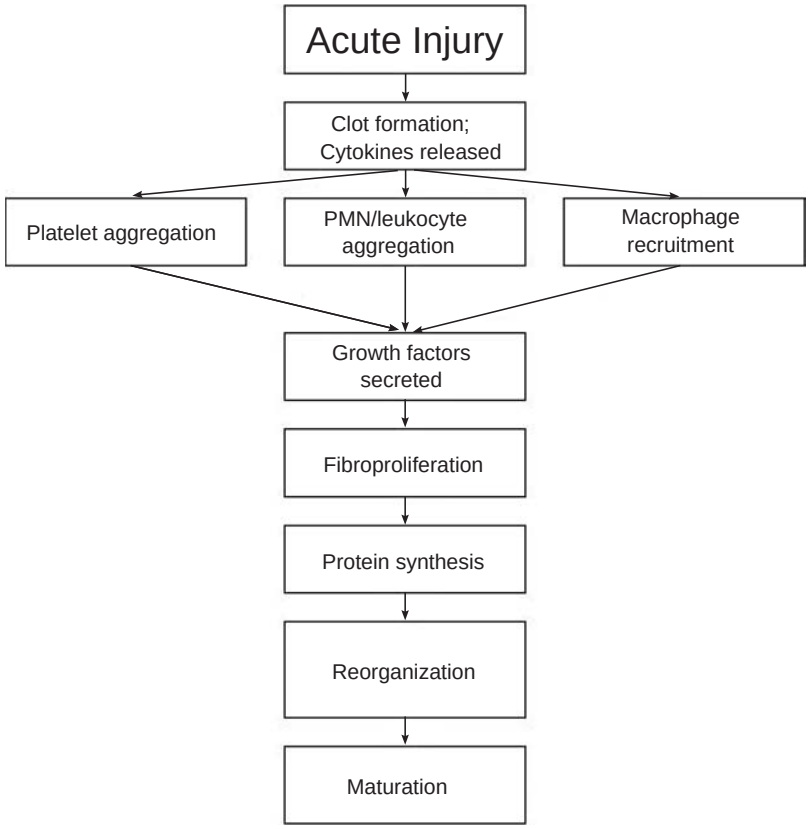

Figure 1-23 Sequence of biologic and mechanical events in the healing process in tendon following acute injury. PMN, polymorphonuclear. (From Van Kleunen JP, Soslowsky LJ, Glaser DL. Tissue engineering of rotator cuff tendons. In: Wnet G, Bowlin G, eds. Encyclopedia of Biomaterials and Biomedical Engineering, 2004:1622–1628, with permission.)

Step 1: Cellular and Molecular Events Involved in Cuff Degeneration and Repair

Pathologic responses to a loaded environment may be a result of lower metabolic activity in tendon associated with an inability to react to changes in load. An increase in the proportion of collagen III, increased fibril diameter, reduced collagen turnover, increased mature crosslinking, decreased proteoglycan and water content, and reduced cellularity have been found to occur with aging. These changes produce a less compliant tissue that is more susceptible to injury and inadequately prepared to heal efficiently following pathologic events. All of these changes can be addressed with tissue engineering.[14,105,204]

Injury may be precipitated by direct events or may be purely a result of chronic degeneration. Initially following insult, the tissue surrounding the tendonous injury undergoes a hemorrhagic response that triggers the inflammatory pathway. Secretion of growth factors, including platelet-derived growth factor (PDGF), transforming growth factor-α and -β (TGF-α, TGF-β), basic fibroblast growth factor (bFGF), and epidermal growth factor (EGF), accompanies this response to direct the attraction and proliferation of fibroblasts and to stimulate collagen and protein synthesis. Fibroblasts play the central role in healing and remodeling tendon at the site of injury. This process takes considerable time, and even at maturation, the biomechanical properties of healed tissue are inferior to those of uninjured tendon due to a complicated system including a proportional decrease in the amount of collagen I and an increase in the amount of collagen III (Fig. 1-23). Again, these cytokines can be targets for tissue engineering.[260]

Specific targeting of the cellular pathways involved in tendon healing has been impossible because the identity of the stem cell population that contributes cells to the healing tissue remains unknown. Both extrinsic and intrinsic sources of cells have been described and no certain answer has been elucidated.[82,199] Glaser et al. recently investigated the heritage of cells involved in the healing tendon. The objective of this study was to examine the specific ancestry of cells that participate in tendon healing including myoblasts, activated satellite cells, differentiated skeletal muscle cells, vascular and nonvascular smooth muscle cells, pericytes, endothelial cells of developing and mature blood vessels, and bone marrow–derived cells. This study suggested that smooth muscle cells from mature or immature vessels or from pericytes are a major source of responding cells in the fibroproliferative stage of tendon healing and that cells of endothelial origin respond to a tendon injury by participating in neovascularization, but do not contribute to fibroproliferation. Despite the

hypothesized role satellite cells play in healing, activated satellite cells do not have a major role in healing tendon injuries. Cells of bone marrow origin contributed to the inflammatory process. However, bone marrow–derived cells did not contribute to the fibroproliferative response or develop into tendon cells. This study helped to elucidate the origins of cells involved in the various steps of the healing process.[92,140]

Step 2: Defining the Standards of a Rotator Cuff Tendon

Before a tissue engineering model can be created, defining standards for the engineered tissue is an initial step and guides the remaining developmental process. The ability of an engineered tissue to withstand forces approximating those experienced during a healthy state helps to define this goal. Biomechanical properties for a given tissue must be understood and prioritized. Stress and strain parameters should be measured in both normal and repaired tissue. Biomechanical analyses have identified principle tensile units in each component of the rotator cuff that define the mechanical parameters that result in failure. The anterior third of the supraspinatus, midsuperior and inferior portions of the infraspinatus, and superior and midsuperior portions of the subscapularis tendons have been identified as these primary units (Table 1-3).[103,104,119]

Step 3: Common Tissue Engineering Strategies

To achieve these goals, attempts at tissue engineering in rotator cuff tendons have taken several directions. Several of these studies have demonstrated promise as potential means of augmenting the healing response in damaged tendon. Unfortunately, no studies have combined all of these techniques in one system. In this section, we will describe several models of tissue engineering that have demonstrated improvements in tendon healing. Rehabilitation is a mechanical therapy that aims to improve tendon healing through the application of regulated mechanical stresses on the healing tendon. Cell therapy focuses upon the implantation of stem cells, or other pluripotent cells, into a site of tendon healing. These cells may serve a role in regenerating tissue and producing growth factors important in the healing process. Small intestine submucosa is an acellular biologic scaffold that has come under recent examination as an organized matrix for the direction of connective tissue healing. Gene therapy is a broad field of study that is based on the incorporation of genetic material into host tissue to augment the healing process from a

TABLE 1-3
TENSILE PROPERTIES MEASURED IN HUMAN ROTATOR CUFF TENDONS

genetic biochemical level. The proposed mechanisms by which each of these models serves to augment tendon healing will be discussed, in addition to their appropriate roles in the repair of the rotator cuff.

Cell Therapy

Mesenchymal stem cells (MSCs) and other stem cells are pluripotent cells isolated from various sources that have not yet differentiated into a specific cell line. These cells have the potential to develop into a wide variety of tissues including bone, cartilage, tendon, fat, marrow stromal cells, and muscle. Studies examining the transplantation of allogeneic and xenogeneic stem cells into human tissue both in vitro and in vivo have shown that these cells maintain their pluripotency following transplantation and undergo site-specific differentiation.[139,200] In this manner stem cells transplanted into a region of damaged tendon may differentiate into endothelial cells, osteoblasts, and fibroblasts to act as a biologic patch and to further augment the healing process through the increased production of collagen and proteoglycan.

While the potential for improved healing is substantial in this model of tissue engineering, many challenges exist that must be met to develop a functional application of cell therapy to tendon repair. An adequate source of stem cells must exist for a substantial transplantation of stem cells to be a reality. Autogenous donation is ideal in terms of delivering an immunologically low-risk population of cells, but the collection process may incur other morbidities. Allogeneic and xenogeneic sources may be easier to develop but carry the risk of potential rejection or disease transmission.[38] Once a reliable population of stem cells is isolated, a delivery vehicle must be selected that will protect the cells but will also allow them to function normally following transplantation. Once both of these needs are met, a technique must be developed to combine the stem cells with the carrier in vitro and deliver them in vivo. This composite must be provided in such a way that makes its use feasible, safe, and efficacious.[38]

Early studies in animal models and in humans have demonstrated successful implementation, survival, and differentiation of MSCs in tendon, but more work is required to fully elucidate the recipient response to donor cells and to determine optimal conditions for successful implementation of the technique.[12,111,191,266] Standardization of a safe, effective delivery system will facilitate the potential use of cell therapy as an adjunct to tendon repair.

Gene Transfer

Gene transfer therapy is a model that seeks to directly induce greater healing ability in the cells already in existence around a site of injury. Several growth factors have been implicated in the healing response of tendon, including TGF-β, TGF-α, bFGF, PDGF, insulin-like growth factor (IGF)-I, and EGF.[2,45,65,105,231] The goals of gene transfer, with regard to tendon healing, are to up-regulate the synthesis of these growth factors and to suppress production of endogenous proteins that may inhibit efficient, organized remodeling of damaged tendon.

For transfer to occur to host cells, an appropriate vector must be developed that will successfully deliver genetic material to the desired target and allow implementation into the host's genome. Viruses, liposomes, and gene guns are all methods of delivery that have demonstrated potential use for this purpose.[37,58,244,260] Successful delivery and implementation of genetic material into the host's genome will lead to synthesis of the proteins encoded by the delivered gene or to down-regulation in the production of an unwanted protein from a separate path. The advantages of this model of tissue engineering are that it induces a significant, local production of a substance that augments healing and that it is not complicated by morbidities associated with insertion of donor tissue. The disadvantages are those most commonly associated with the vectors used for gene delivery. The production of certain viral vectors is a difficult process with a frequently low yield. Several viral strains carry a risk of mutagenesis that may interfere with the intended genetic result. Some strains of virus, adenovirus the most notable, are capable of stimulating an inflammatory response and secondarily immunogenic rejection in the host. Gene guns, which involve particle bombardment of genetic material into host tissue, require specialized equipment that significantly increases the costs of production and utilization. Liposomes and naked DNA, while less immunogenic than other vectors, are not as successful as other methods in transfecting host cells. Because of these limitations, vector development remains an extremely active component of gene transfer research.[71]

While the use of gene transfer is in its early stages, some studies have demonstrated successful incorporation of marker genes into tendon and ligament.[89,146,224] Promising studies have explored the transfer of antagonists to FAK, a protein kinase linked to adhesion formation, and of genes encoding PDGF.[71,260] Future studies will continue to examine the insertion of genes to augment the production of growth factors involved in the healing processes of tendon or of antagonists to inhibit the production of proteins found to interfere with organized remodeling.

CONCLUSION 50

INTRODUCTION

It is crucial to properly diagnose the extent of the rotator cuff pathology to direct clinical decision making. Historical factors, including the mechanism of injury and the presence or absence of a traumatic cause, can help determine the severity of the injury and whether the injury is acute or degenerative in nature. Patient age and activity level can guide the discussion of surgical goals and patient expectations. Diagnostic imaging aids in determining tear characteristics, such as tendon involvement, tear size, tear retraction, and muscle atrophy. These factors help to formulate and implement a treatment algorithm (Table 2-1).

EVALUATION

Clinical History

Patients with rotator cuff problems will typically complain of pain or weakness or both. Many patients cannot recall an injury, and in others, symptoms may have begun after a trivial trauma (e.g., catching their balance by holding onto a railing). However, more-severe injuries may play a role, especially when a cuff tear occurs in association with a dislocation in an older patient. The pain is usually described as anterior, down the anterior humeral region, or lateral, down to the deltoid tuberosity. Pain in the back of the shoulder or trapezius or that which radiates down past the elbow into the hands is more consistent with a cervical radiculopathy, although there are exceptions. Pain from rotator cuff pathology is usually increased with use of the arm, particularly for overhead activities, and is often most severe at night, frequently interrupting sleep.

Because splinting from pain may simulate weakness, lack of strength does not always indicate a large tear unless a subacromial anesthetic injection has been given first. Furthermore, patients with massive tears may still

TABLE 2-1
ALGORITHM FOR SURGICAL DECISION MAKING

Pathology		Treatment
Subacromial bursitis/ tendonitis	⇒	Arthroscopic subacromial bursectomy
If prominent/worn coracoacromial ligament	⇒	Arthroscopic coracoacromial ligament excision
If prominent acromion, bone spur, <50% thickness partial rotator cuff tear	⇒	Arthroscopic acromioplasty, cuff débridement
If >50% thickness partial rotator cuff tear, small or medium full-thickness rotator cuff tear	⇒	All-arthroscopic or arthroscopically assisted ("mini-open") rotator cuff repair
Large or massive rotator cuff tear	⇒	All-arthroscopic or open rotator cuff repair, coracoacromial ligament preservation Possible muscle transfer in selected patients

have remarkably good motion and function. However, it is more common for patients with large or massive tears to report weakness and fatigue with overhead use and difficulty in raising their arm. If the onset of weakness is sudden after an injury, especially one causing a glenohumeral dislocation, then not only a rotator cuff injury needs to be suspected, but also a neurologic injury (most commonly suprascapular or axillary nerve) should be ruled out.

Physical Examination

Inspection and Palpation

In the presence of a rotator cuff tear, crepitus on passive motion can be palpated by placing a hand over the superior aspect of the shoulder. Visual inspection for shoulder symmetry will not reveal variations between shoulders in the presence of acute rotator cuff tears. However, in the presence of long-standing cuff tears, atrophy of the supraspinatus or infraspinatus will often be present. Asymmetry of the biceps muscle belly may be a clue to a partial recession or dislocation of the tendon of the long head of the biceps.[37] A complete rupture, not infrequently, is seen with large cuff tears and can be identified by deformity of the long head of the biceps.

Range of Motion

Range of motion of the shoulder should be performed actively and passively and compared with the asymptomatic side.[1] Patients with less active than passive range of motion may indicate the presence of a rotator cuff tear. This limitation of active range of motion may be caused either by weakness or pain (Fig. 2-1). Subacromial injections with 1% lidocaine (Xylocaine) can be used to help distinguish between the two. If there is limited range of motion, but no difference between active and passive, then adhesive capsulitis or arthritis should be suspected. It is surprisingly infrequent for patients with rotator cuff tears to have decreased passive range of motion, although this can occur. Patients with rotator cuff tears most commonly exhibit posterior capsular stiffness with a loss of the ability to reach up the back or adduct across the body. Loss of

Figure 2-1 **(A)** This patient with a massive cuff tear has full passive elevation when assisted with the other arm. **(B)** Active elevation, however, is severely impaired.

internal rotation can be measured with the arm in abduction and compared to the opposite asymptomatic shoulder. This method of measurement is very accurate particularly when the examiner holds the top of the shoulder to detect and restrict scapula rotation. Excessive passive external rotation in the injured shoulder compared to the opposite side is a good indicator of a full-thickness complete or near complete tear of the subscapularis. These signs should be systematically evaluated in all patients suspected of having a rotator cuff tear.

Strength

Strength of the shoulder should be examined in elevation, abduction, external rotation, and internal rotation. Patients with rotator cuff tears may exhibit weakness or pain on resistance to muscle testing. Isometric strength testing can be used to attempt to isolate specific cuff muscles. The supraspinatus can be tested with the arm internally rotated and elevated 90 degrees in the plane of the scapula, the infraspinatus with the arm at the side in neutral rotation and varying degrees of external rotation with the elbow flexed 90 degrees, and the subscapularis with the elbow flexed 90 degrees and the hand behind the waist or against the abdomen. A handheld or wall-mounted dynamometer has been demonstrated to be a reliable and discriminatory means for assessing strength of the rotator cuff in symptomatic individuals.[20] Patients with partial-thickness tears usually demonstrate more pain on muscle testing than individuals with full-thickness lesions. For large or massive tears, strength may be reduced when compared with the contralateral side. Weakness of external rotation is a common finding, particularly when the infraspinatus is involved in the tear. Patients with large or massive tears involving the infraspinatus will often be unable to maintain their arm in external rotation.

Hertel and coworkers[21] have quantified these findings by describing external rotation and internal rotation "lag signs," which measure the difference between passive and active terminal rotation. If the patient sits with the arm at the side and the elbow bent 90 degrees, the arm may be fully externally rotated passively, but once the arm is let go it will "fall off" into internal rotation[4] (Fig. 2-2A–C). The similar inability to actively externally rotate the abducted arm has been termed the "signe de clairon," since it puts the arm in the position used to blow a bugle[13] (Fig. 2-2D). This pathologic sign usually indicates a massive tear with involvement of the lower head of the infraspinatus and teres minor tendons. The degree of apparent weakness of external rotation in the abduction position may be measured differently if the arm is placed in the plane of the scapula versus the coronal plane. When the arm is in the coronal plane the posterior deltoid can act as a weak external rotator, giving the impression of greater external rotation strength of the rotator cuff. As the arm is brought into the plane of the scapula or sagittal plane, the external rotation effect of the posterior deltoid is diminished.

Weakness of terminal internal rotation indicates involvement of the subscapularis. Internal rotation strength can be evaluated with the "lift-off" test[14] (Fig. 2-3A–C). Patients are asked to reach behind their back and place their hand on the trunk. The test is considered positive if the patients are unable to lift and maintain their hand away from their trunk. The position of the arm for the "lift-off" test in maximum internal rotation may be difficult to accomplish for a patient with a large rotator cuff tear.[12] Another method to test the strength of the subscapularis is to have the patients place their hands on their abdomen, internally rotate their shoulders, bringing their elbows in front of their torso, and then push their hands into their abdomen (Fig. 2-3D). When the subscapularis is deficient the patient's elbow will fall back behind the coronal plane of the body or the patient will not be able to initiate active internal rotation with the palm flat on the abdomen. With mild weakness of the subscapularis the patient will not be able to compress the abdomen with terminal internal rotation and will attempt to use the posterior deltoid to achieve abdominal compression, resulting in pull-back of the arm. When the shoulder is weak in internal rotation, the patient will also compensate for his or her inability to bring the elbow forward by bringing the palm of the hand off the abdomen. In all cases a true positive test must allow for passive internal rotation to achieve these maneuvers. When there is a tight posterior capsule preventing passive internal rotation to the coronal plane, then these tests for subscapularis function are not reliable.

Provocative Testing

Provocative tests are used to elicit symptoms of impingement by maneuvering the biceps and rotator cuff under the coracoacromial arch. The Neer impingement test entails elevation with the arm internally rotated,[34] whereas Hawkins' test for impingement is elevation to 90 degrees, adduction across the chest, and internal rotation[18] (Fig. 2-4). Both of these tests bring the biceps, rotator cuff, and greater tuberosity directly under the coracoacromial arch. However, these maneuvers may also cause pain in other shoulder conditions such as stiffness, calcium deposits, and arthritis. In patients with classic impingement syndrome, pain will not only be produced by these impingement maneuvers, but should be nearly completely eliminated following a subacromial injection of 10 mL of 1% lidocaine. A subacromial lidocaine injection has been found to be helpful in differentiating weakness secondary to a rotator cuff tear from weakness that is due to pain inhibition.[3]

Posterior internal glenoid impingement can result in partial tears of the supraspinatus and anterior half of the infraspinatus when abnormal contact exists between these

Figure 2-2 **(A)** This patient with a massive tear involving the posterior cuff can be passively externally rotated. **(B)** When the arm is let go it "falls off" into internal rotation, demonstrating severe weakness. **(C)** One year after rotator cuff repair he has regained active external rotation, although his strength is not full. **(D)** "Signe de clarion": Right arm must be elevated higher than left to reach mouth since active external rotation is impaired.

tissues and the posterior superior glenoid. This type of impingement occurs when the arm is brought into the extremes of external rotation and abduction (cocking arm position of throwing or anterior apprehension position). In these cases placing the arm in this position will cause pain in the posterior glenohumeral joint line. With a slight change in arm position, either bringing the arm in less external rotation or less coronal plane extension or placing a posterior directed force along the anterior aspect of the shoulder (relocation test), the pain is substantially diminished. These maneuvers are helpful in the diagnosis of posterior glenoid impingement. Anterior internal glenoid impingement occurs when the undersurface of the subscapularis, the medial biceps pulley complex, and the biceps tendon contact the anterior superior aspects of the glenoid labrum and rim. In these cases cross-body adduction and internal rotation and resisted forward flexion with the arm in this position will differentially illicit a greater amount of pain compared to the same cross-body adduction with external rotation (O'Brien's sign). With both posterior and anterior glenoid impingement, superior labral tears (SLAP lesions) can occur and are part of this pathology and symptoms complex. Subcoracoid impingement may also occur with cross-body adduction and internal rotation.

The acromioclavicular (AC) joint is often a source of pain; it should be inspected for prominence and palpated for tenderness. Maneuvers to elicit signs of impingement can also exacerbate pain from the AC joint. AC joint pain is often increased with internal rotation and cross-body adduction. Pain with these maneuvers should be at the top of the shoulder and should not be confused with posterior or lateral arm pain, which is more commonly associated with rotator cuff disease or posterior capsular tightness.

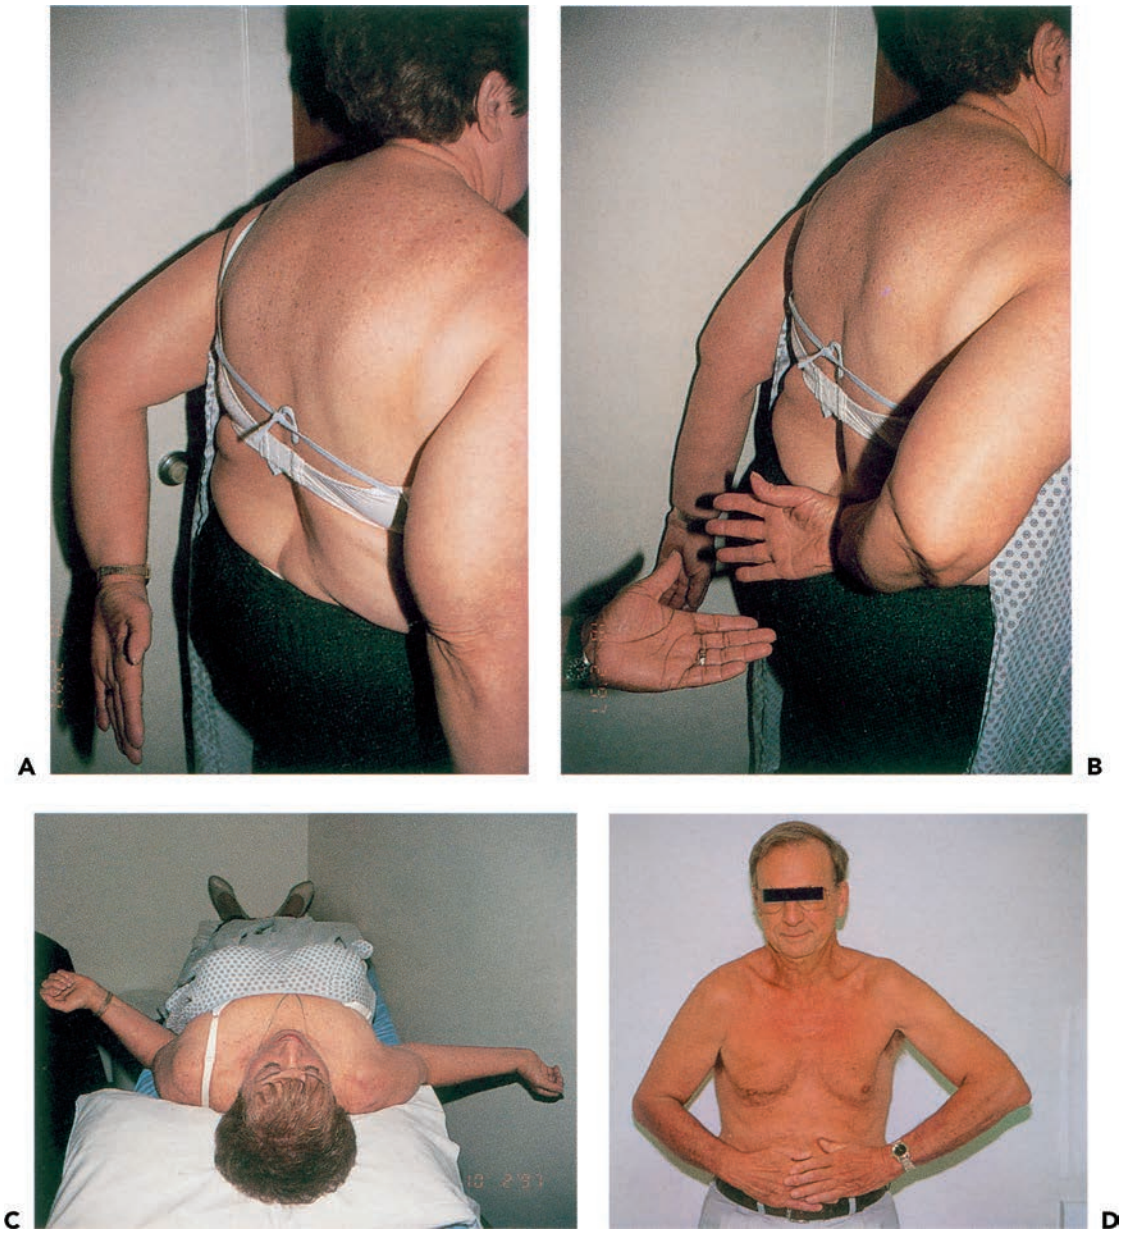

Figure 2-3 **(A)** The lift-off test is used to evaluate the integrity of the subscapularis tendon.[16] Although originally it was described as asking the patient to lift her hand off the small of her back, it can be more sensitive if the examiner holds the hand to maximally internal rotate the arm and then lets go. This patient is able to maintain maximal internal rotation with her left shoulder. **(B)** Her right shoulder, which has an isolated subscapularis tear, has an internal rotation lag because she cannot maintain maximal internal rotation. **(C)** Her right shoulder has increased external rotation, another finding in subscapularis ruptures. **(D)** Abdominal compression test: The right elbow falls back when the patient tries to compress his abdomen.

When there is uncertainty about the source of shoulder pain, serial injections, first into the subacromial space followed by an injection into the AC joint, can be performed and patient responses recorded. It is not uncommon for patients to have prominent, arthritic AC joints that are asymptomatic. Resection of the distal clavicle should be performed when the AC joint itself is tender and painful. Finally, instability testing should be performed in those patients, especially throwing athletes, in whom the relative contributions of instability and rotator cuff pathology are uncertain. Instability and partial cuff tears, particularly those associated with posterior internal glenoid impingement, are not an uncommon combination of overlapping pathologies in the younger athletic patient population.

IMAGING

Radiographs

Plain radiographs are used to determine the bony morphology of the acromion and to evaluate the position of the humeral head relative to the glenoid fossa and acromion. Plain radiographs are also important to rule out other sources of shoulder pain such as calcific tendinitis, glenohumeral osteoarthritis, or destructive bone lesions. Patients with rotator cuff pathology are evaluated with five views of the shoulder. Anteroposterior (AP) views in the plane of the scapula in neutral, internal, and external rotation are obtained to visualize the glenohumeral joint and greater and lesser tuberosities, and to bring small calcium deposits into relief. The AP view may also reveal an excrescence or cysts on the greater tuberosity, suggestive of rotator cuff disease. A double-density sign within the acromion on a standard anteroposterior radiograph of the shoulder has been described as highly suggestive of an os acromiale.[27] The os acromiale is best seen on a well-performed axillary view (Fig. 2-5), but can be also seen on magnetic resonance imaging (MRI) (Fig. 2-6). The acromiohumeral interval can also be assessed on the AP views and, if less than 7 mm, may be an indication of a torn or nonfunctioning rotator cuff.[47]

On the axillary view, the glenohumeral joint and tuberosities can be inspected. The acromion is usually well visualized on the axillary view and can be evaluated for the presence of an os acromiale, or unfused anterior acromial epiphysis. The most common type of os acromiale is a meso type and is seen at the level of the posterior margin of the clavicle (see Fig. 2-5). The axillary view is also useful to look for subtle joint space narrowing seen in early arthritis.

Finally, a supraspinatus outlet view will show the subacromial space and the coracoacromial arch. To obtain this view, a lateral x-ray film of the scapula is obtained while the x-ray beam is angled downward 10 degrees.[6,36] The supraspinatus outlet view will reveal any spurs encroaching on the subacromial space from the AC joint or anteroinferior acromion (Fig. 2-7). It is also the view used to determine the acromial morphology (Fig. 2-8).

Tendon Imaging

Arthrography is an extremely accurate method for the detection of full-thickness rotator cuff tears (Fig. 2-9). However, it is an invasive procedure that does not give accurate information on tear size or the condition of the rotator cuff muscles. Also, partial-thickness tears are less reliably assessed.

In recent years, high-resolution dynamic shoulder ultrasound has gained popularity as a noninvasive, accurate method to evaluate the rotator cuff (Fig. 2-10).[10,22,23,29,31,32,39,42,45,50]

The advantages of this technique are that it is noninvasive, is less expensive than MRI, uses no radiation, can be

performed in the clinic setting, allows for dynamic examination, and can be performed on both shoulders without undue time or cost. Ultrasonography and MRI have been demonstrated to have comparable accuracy for identifying full-thickness and partial-thickness rotator cuff tears.[29,39,42,45]

Improvements in the quality, portability, and cost have led orthopaedic surgeons to incorporate dynamic ultrasound in the clinic setting.[23,50] This approach may allow for a more efficient management of rotator cuff pathology. It is quick, inexpensive, safe, and tolerated by claustrophobics. However, accuracy is operator-dependant;[22,29,32] therefore, ultrasound has not replaced MRI as the imaging modality of choice in most clinics or centers to assess the rotator cuff. In addition, MRI remains a more accurate method to detect muscle atrophy and associated intraarticular pathology, including glenoid labrum tears and glenohumeral ligament injuries.

Figure 2-7 Supraspinatus outlet view demonstrates a prominent anterior acromion in a 31-year-old former college outfielder. This can be a clue that despite the patient's young age, extrinsic impingement may be involved.

MRI is the imaging study of choice to assess the rotator cuff in many centers. The accuracy in detecting full-thickness cuff tears has been reported between 93% and 100% (Figs. 2-11 and 2-12). Partial-thickness tears are less accurately detected and are more dependent on the

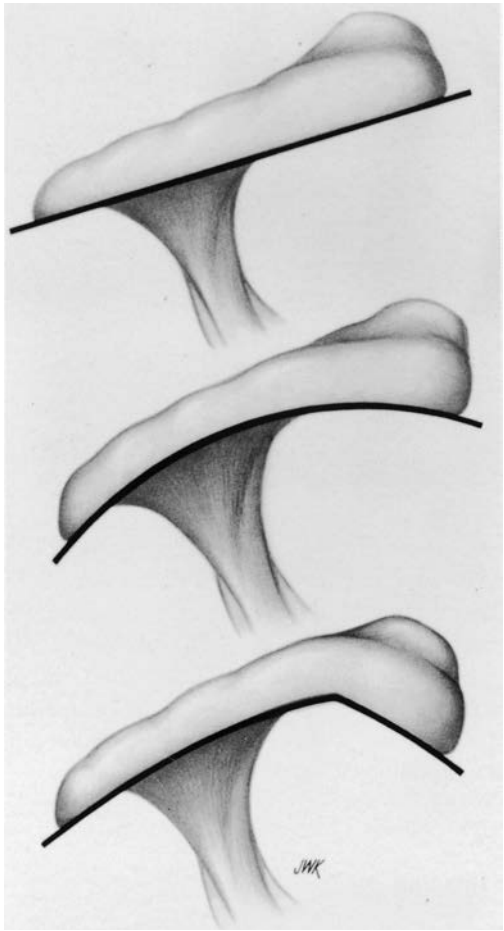

Figure 2-8 Acromion morphology as described by Bigliani et al.[6]: *type I* flat, *type II* curved, and *type III* hooked.

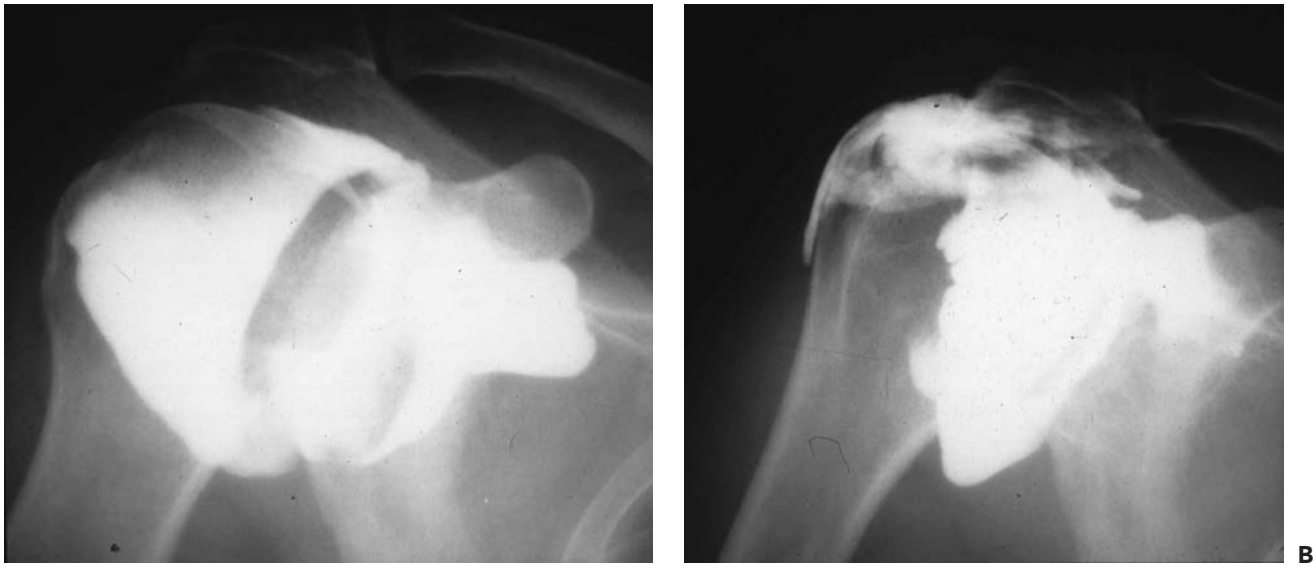

Figure 2-9 **(A)** Normal and **(B)** abnormal single contract arthrogram demonstrating a full-thickness tear of the rotator cuff.

technique used[12] (Fig. 2-13). The main advantage of MRI, however, is the wealth of information gained. The quality of the rotator cuff muscles, size of the tear, amount of retraction, involvement of the biceps tendon, and partial-thickness cuff tears can clearly be determined (Figs. 2-11, 2-12, 2-13, and 2-14). Because many surgeons use different approaches depending on tear size and muscle quality, this information is of value. Even when the approach will not change, many patients wish realistic projections of time in the hospital, postoperative restrictions, and length of rehabilitation to prepare themselves. Finally, some patients base their decision whether to undergo an operation at all on what functional gains can reliably be expected, and an MRI scan of cuff muscle atrophy can help the surgeon give an accurate prognosis. The degree of muscle atrophy has been found to correlate with functional result after rotator cuff repair, with worse function associated with greater atrophy.[15,16,26]

In the experience of the authors, a two-tendon tear with moderate to severe atrophy with retraction medial to the midlevel of the humeral head is often not repairable, and when repairable has a very high rate of incomplete healing or not healing at all of the repaired tendon. In these cases when the patient still has reasonable active elevation and

lower functional demands, a more limited-goals arthroscopic débridement surgery or an arthroscopic repair may be a better option and more extensive open procedure. On the other hand, when these MRI findings exist and there is poor function in a more youthful and active patient, a muscle transfer surgery should be discussed when an open surgical repair is planned. When the tear is found to be not fully repairable, or if fully repairable under some tension and with a thin tendon, a primary muscle transfer is recommended.

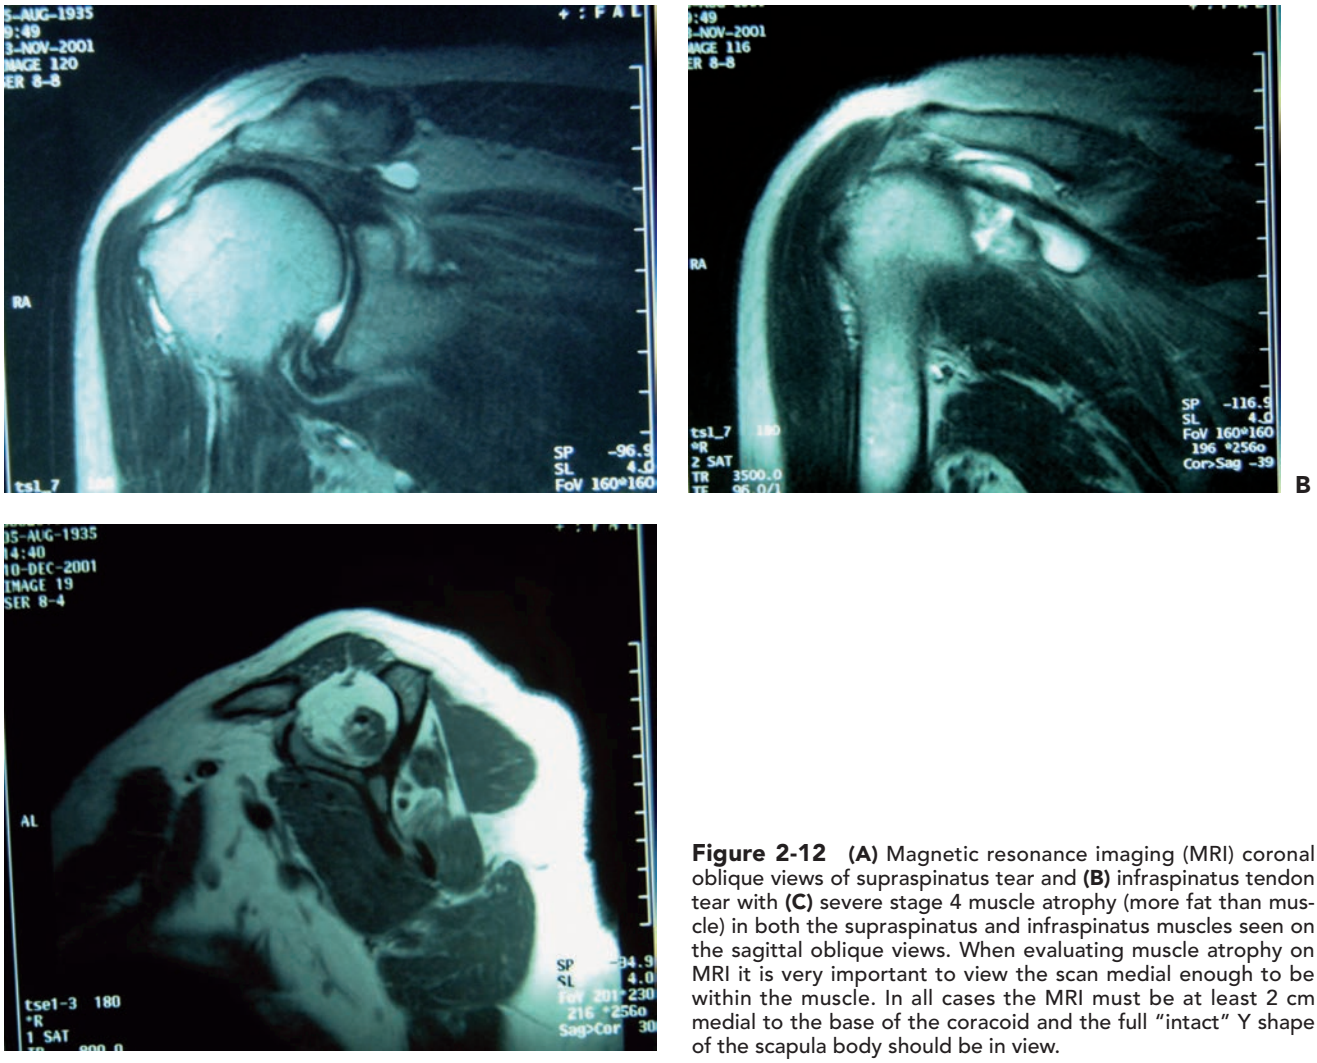
The main disadvantages of MRI are its cost, patient tolerance, the inability to utilize it in patients with a pacemaker, metal in the eye, aneurysm clips, and the difficulties posed to patients with claustrophobia.

The use of arthrogram in conjunction with MRI can increase the sensitivity of detecting full-thickness rotator cuff tears in the postoperative setting. However, the routine use of MRI arthrogram for diagnosis in the primary setting may not be justified because of its invasive nature and in this setting does not significantly improve the accuracy of a well-performed MRI.

The decision regarding whether to utilize dynamic ultrasound versus MRI should be based on the experience of the examiner with both imaging techniques, the importance of gaining additional clinical information regarding muscle atrophy and lesions of the glenoid labrum, patient tolerance, and cost.

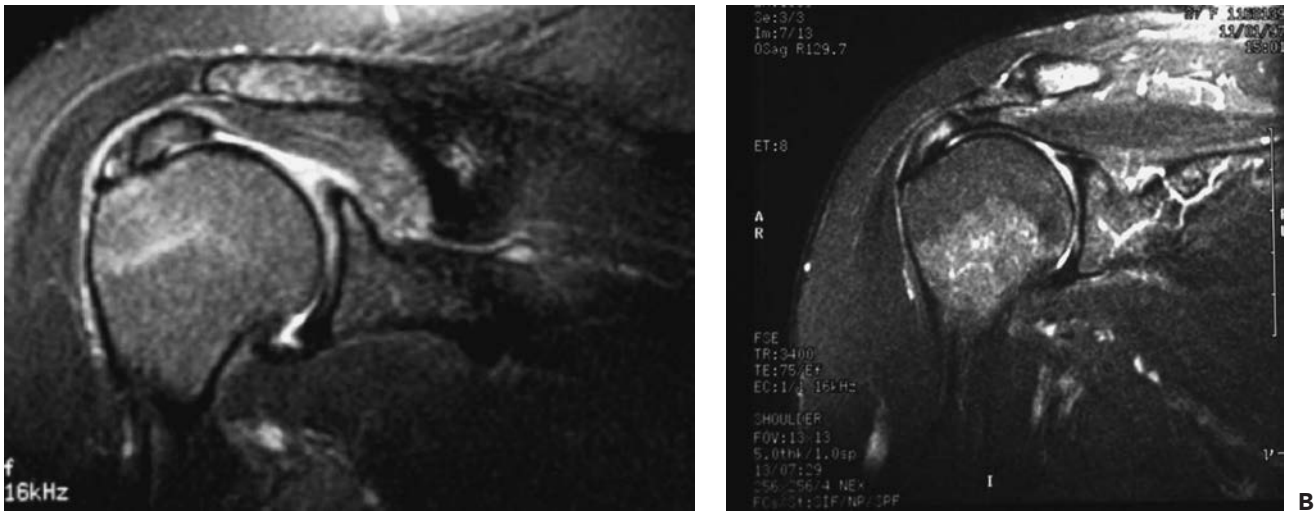
NONOPERATIVE TREATMENT

Rotator cuff pathology is a common cause of shoulder pain, with a reported incidence of rotator cuff tears ranging from 5% to 40%, with an increased incidence in older patients.[11,17,26,28,34,38,41,48] Clearly not all patients with rotator cuff tears are disabled by this condition. McLaughlin noted approximately 25% of cadavers studied had a rotator cuff tear and hypothesized that not all of



A B C

Figure 2-12 **(A)** Magnetic resonance imaging (MRI) coronal oblique views of supraspinatus tear and **(B)** infraspinatus tendon tear with **(C)** severe stage 4 muscle atrophy (more fat than muscle) in both the supraspinatus and infraspinatus muscles seen on the sagittal oblique views. When evaluating muscle atrophy on MRI it is very important to view the scan medial enough to be within the muscle. In all cases the MRI must be at least 2 cm medial to the base of the coracoid and the full "intact" Y shape of the scapula body should be in view.



A B

Figure 2-13 **(A,B)** Magnetic resonance imaging coronal oblique views showing a high-grade partial-thickness rotator cuff tear.

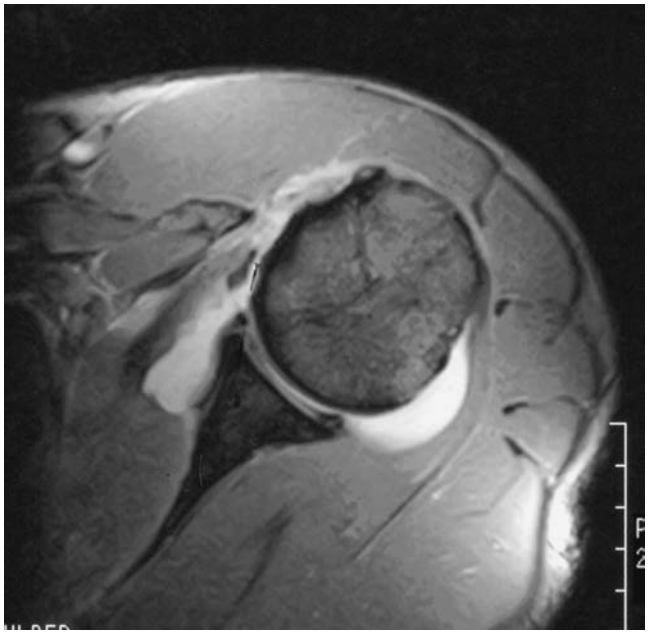


Figure 2-14 Axial magnetic resonance image showing an acute full-thickness tear of the subscapularis with a dislocated biceps tendon. Whenever there is subluxation or dislocation of the biceps there should be a strong suspicion for a partial- for full-thickness tear of the subscapularis. Both abnormalities are best viewed on the axial T2 weighted images.

these had been symptomatic in life,[30] as has been shown in more recent MRI studies of asymptomatic patients.[40] The aim of nonoperative treatment, then, is to help a patient with symptomatic rotator cuff disease become asymptomatic.

A review of the literature suggests that nonoperative treatment of rotator cuff tears is successful in 33% to 92% of cases[7,8,19,24,43,44,48] with most studies reporting a satisfactory result in approximately 50% of patients. Boker and coworkers[7] reported on 53 patients with documented rotator cuff tears undergoing nonoperative treatment at an average follow-up of longer than 7 years. Seventy-five percent of patients had satisfactory pain relief, particularly those presenting after an acute injury. Patients with long-standing pain (over 6 months) did not respond well to nonoperative therapy. Wirth and coworkers[49] reported on 60 patients with documented rotator cuff tears, and at a minimum of 2 years follow-up, only 62% of patients had a satisfactory result. Furthermore, only 4% of the patients were rated as excellent.

Authors' Preferred Treatment

In the authors' experience the patient that is most suitable and responsive to nonoperative management are those patients with chronic attritional rotator cuff tears that are limited to one to one and a half tendons. The onset of these patients' symptoms is not associated with a significant traumatic event. Generally these patients are over the age of 60 and are less active than their younger or more active counterparts. Patients particularly suited for nonoperative management have pain as the primary reason for functional weakness and will often be able to actively elevate their arm to at least shoulder height after a lidocaine injection to the subacromial space. In patients that are active with higher functional demands, regardless of age, and a documented acute full-thickness cuff tear, greater than 2 cm without atrophy on MRI and a clear history of trauma are best treated with earlier (less than 3 months from injury) surgical intervention.

Our own approach would be to recommend nonoperative treatment for patients with rotator cuff disease who present with pain without dramatic or progressive weakness. Treatment would be instituted after a history, physical examination, and plain radiographs. Unless there was diagnostic confusion, we would not image the cuff initially, but rather would consider an MRI later if this approach had failed, once surgery was being considered. Patients with weakness, especially if the onset was sudden after an injury, are imaged more expeditiously.

Patients are taught a home exercise program and sent to physical therapy for supervision and education.[24,33] Also instituted is a course of oral nonsteroidal antiinflammatory medications, heat application, and modification of activities to eliminate offending motions. Initial exercises aim at eliminating any subtle stiffness (especially posterior capsular tightness, which can exacerbate impingement) and strengthening the rotator cuff, initially in nonimpingement arcs of motion, and parascapular muscles. The patient's progress is monitored after 4 to 6 weeks. If adequate progress has not been made, a subacromial injection may be considered, especially if pain is limiting the patient's ability to perform exercises. We prefer a mixture of 3 mL of lidocaine (1%), 3 mL of bupivacaine (0.25%), and a depot corticosteroid (usually 8 mg of dexamethasone acetate in 1 mL). This can be very helpful,[6] even though pathologic studies have shown that true inflammation is rarely present in degenerative rotator cuff disease.[52] This injection is occasionally repeated after a few months, but repeated injections are not used.

For patients with pain as their chief complaint, rather than weakness, and who fulfill the criteria noted previously, this type of program is continued for 4 to 6 months before an MRI is obtained and surgical options are discussed. When weakness is prominent or progressive and fulfills the criteria noted previously, this process is accelerated and MRI or ultrasonographic imaging may be performed at the time of the initial evaluation. A common presentation is that of sudden loss of strength after a relatively trivial injury. Because splinting from pain (e.g., from hemorrhagic bursitis) can simulate weakness, we would generally start with a therapy program if the lag signs are minimally positive or negative and the apparent weakness is improved with a lidocaine

injection to the subacromial space. However, if there has not been dramatic improvement after a few weeks, an MRI is obtained. If a cuff tear is found of sufficient size to explain the weakness, timely repair is considered,[2] for it is likely that this is an acute tear, or at least an acute extension of a prior small, more chronic tear. In these cases the MRI will often show an inconsistency between the size of the tear and the muscle atrophy (e.g., the tear involves the supraspinatus and infraspinatus but only the supraspinatus as significant atrophy, suggesting that the infraspinatus tear is more recent, representing an acute extension of the chronic tear). If the tear size seems inconsistent with the physical findings, other causes of weakness, especially a nerve injury, should be considered. Occasionally an older patient will present with dramatic weakness after a dislocation, and both a cuff tear and a brachial plexopathy will be present, and their relative contributions to the patient's weakness may be unclear. However, because waiting for the nerve lesion to resolve would likely allow irreversible atrophy of the cuff muscles to develop, it seems prudent to recommend early cuff repair in most of these patients.

SURGICAL MANAGEMENT

Surgical Indications

The presence of a rotator cuff tear is not necessarily an indication for surgery. As previously mentioned, MRI and cadaver studies have shown asymptomatic patients to have cuff tears.[40] The indications for surgical repair of rotator cuff tears are, therefore, the presence of pain or functional deficits that interfere with activities and have not responded to conservative measures. Most surgeons would continue nonoperative treatment for at least 3 to 4 months before considering repair; when weakness is prominent or progressive, more timely repair may be considered.

More recently, a more proactive approach has been advocated in patients with full-thickness rotator cuff tears. (This is particularly the case in younger patients who put greater functional demands on their shoulders and who desire restoration of full shoulder strength.) The rationale for early repair stems from the fact that nonoperative management can lead to tear progression and irreversible changes to the muscle–tendon unit, including muscular atrophy, tendon retraction, and tissue thinning. A natural history study demonstrated that symptoms can develop in patients with previously asymptomatic rotator cuff tears. There was a risk for tear size progression over time with a significant increase in pain and decrease in the ability to perform activities of daily living.[49] Bassett and Cofield reported that in patients who have an acute injury and a full-thickness rotator cuff tear, repair within the first 3 weeks resulted in the best surgical outcome.[2]

Another indication for early repair is an acute subscapularis rupture. Patients older than 40 years who sustain a shoulder dislocation are at increased risk for rotator cuff tear.[37] These patients should be examined for subscapularis injury. If the patient exhibits internal rotation weakness, increased passive range of external rotation compared to the opposite arm, or a positive lift-off sign or abdominal compression test, he or she should be imaged to rule out a subscapularis injury. After the subscapularis ruptures, it can retract medially under the brachial plexus. It is easier to dissect the subscapularis, and an arthroscopic repair may be more feasible during the first several weeks after rupture. Scarring of the tendon to the anterior joint capsule and axillary nerve makes late repair technically more challenging and increases the risk of nerve injury.

Surgical treatment should also be considered in patients with large or massive tears that are symptomatic despite conservative management. While these tears are at greatest risk for structural failure of the repair, an attempt at rotator cuff repair can decrease pain and improve function and strength.[25] In cases of tears that involve two or more rotator cuff tendons, healing of the anterior and posterior cuff musculature can restore a balanced force couple and help reestablish the ability to raise the extremity.

CONCLUSION

Accurate diagnosis of rotator cuff pathology is essential to formulate a treatment algorithm. The mechanism and chronicity of injury and physical examination findings aid in determining the severity of the injury. Imaging studies can assess the specific tendon involvement and identify prognostic factors for success of operative or nonoperative treatment. An accurate diagnosis can assist in the determination of the best surgical or nonsurgical approach and guide rehabilitation.

ROLE OF BIOLOGIC ENHANCEMENT OF ROTATOR CUFF REPAIR 80

INTRODUCTION

In the 19th century the cause of chronic shoulder pain was poorly understood, and most cases were lumped together and vaguely ascribed to "periarthritis."[64] In a series of papers beginning in 1904, Codman shifted attention away from the glenohumeral joint and toward the subdeltoid bursa and its contents, especially the supraspinatus tendon.[37–50] In 1911 he reported his first repair, performed in 1909, of a full-thickness supraspinatus tear.[44] Although scattered reports of procedures that included repair of the tendons of the short rotators have been identified in the older literature,[29,177] Codman's reports and lectures eloquently presented the clinical and pathologic findings of rotator cuff injuries and influenced a generation of orthopedic surgeons on the importance of these disorders. The field was further advanced by McLaughlin, who published a series of practical reports on the treatment of rotator cuff tears over a 30-year period.[140–143]

Codman emphasized the role of trauma in causing rotator cuff tears, and disputed Meyer's theory of attrition.[48,146] Other authors recognized that the acromion could pinch underlying structures and advocated complete or lateral acromionectomy[6,103,216] for a variety of painful conditions, usually when the cuff was intact. Neer's report in 1972 described the impingement syndrome and its role in rotator cuff disease.[154] He identified the anteroinferior acromion as the principal area of pathology, and advocated anterior acromioplasty to enlarge the subacromial space and decompress the rotator cuff.[154,155] Neer argued that total acromionectomy was unnecessary, and in fact, was deleterious to shoulder function.[158] He thus advocated a reshaping (without removal) of the anteroinferior acromion, preservation of the deltoid, and mobilization and repair of the tendons. These

principles led to a revolution in rotator cuff surgery. The results of rotator cuff repairs had been unpredictable and often disappointing before 1970, with unsatisfactory results reported in as many as 26% to 46% of patients.[11,23,44,48,49,60,94,112,221] More recent experience, using techniques that follow the principles established by Neer, have documented predictably satisfactory results for pain relief and function.[1,10,16,35,51,53,54,69,76,110,149,155–157,165,173,179,183,184]

The advent of arthroscopy has had a dramatic effect on the evaluation and treatment of rotator cuff pathology.[30,70,71,72] The combination of the arthroscope's ability to routinely visualize the glenohumeral joint as well as the undersurface of the rotator cuff tendon and the information gained from the widespread use of magnetic resonance imaging (MRI) has uncovered a bewildering array of "lesions." Diagnostic accuracy has been improved and the new information has led to a better understanding of the pathogenesis of rotator cuff injuries, the frequency of asymptomatic lesions, and the causes of pain in the absence of a full-thickness rotator cuff tear. Clear value has been demonstrated for the therapeutic value of arthroscopic techniques.[87,226] Arthroscopic anterior acromioplasty, arthroscopic rotator cuff repair, and arthroscopic-assisted "mini-open" repair are new tools available to the orthopedic surgeon for the care of rotator cuff disorders.

The anatomy, biomechanics, pathoetiology, and classification of rotator cuff tears are discussed in Chapter 1. Chapter 2 discusses the diagnosis of rotator cuff tears, so these areas will be mentioned only when necessary to place surgical principles in context. This chapter will focus on the reparable (or intact) cuff tendon. The management of irreparable tears will be discussed in Chapter 4, as will biceps lesions in Chapter 7, complications of cuff repairs in Chapter 5, and arthritis with cuff deficiency in Chapter 23.

NONOPERATIVE TREATMENT

Rotator cuff pathology is a common cause of shoulder pain, with a reported incidence of rotator cuff tears ranging from 5% to 40%, with an increased incidence in older patients.[62,99,125,133,155,178,201,222] Clearly not all patients with rotator cuff tears are disabled by this condition. McLaughlin noted approximately 25% of cadavers studied had a rotator cuff tear and hypothesized that not all of these had been symptomatic in life,[141] as has been shown in more recent MRI studies of asymptomatic patients.[198] The aim of nonoperative treatment, then, is to help a patient with symptomatic rotator cuff disease become asymptomatic.

A review of the literature suggests that nonoperative treatment of rotator cuff tears is successful in 33% to 92% of cases,[19,21,24,91,96,99,174,175,187] with most studies reporting a satisfactory result in approximately 50% of patients. Boker and coworkers[21] reported on 53 patients with documented rotator cuff tears undergoing nonoperative treatment at an average follow-up of longer than 7 years. Seventy-five percent of patients had satisfactory pain relief, particularly those presenting after an acute injury. Patients with long-standing pain (over 6 months) did not respond well to nonoperative therapy. Wirth and coworkers[222] reported on 60 patients with documented rotator cuff tears, and at a minimum of 2 years follow-up, only 62% of patients had a satisfactory result. Furthermore, only 4% of the patients were rated as excellent.

Bartolozzi et al. reported on 136 patients treated with nonoperative modalities with an average 1.5-year follow-up.[9] Seventy percent of the patients had excellent or good results. Prognostic factors for success included tear size less than 1 cm and symptom duration less than a year. Goldberg et al. treated 46 patients with a full-thickness tear with nonoperative modalities.[96] After an average follow-up of 2.5 years, 59% of the patients experienced an improvement in their symptoms, 30% of patients got worse, and 5% stayed the same. The ability to sleep on the affected side and the ability to place the hand behind the head were significantly improved.

Authors' Preferred Treatment

Our own approach would be to recommend nonoperative treatment for patients with rotator cuff disease who present with pain without dramatic or progressive weakness. Ideally patients treated nonoperatively have chronic tears limited to the supraspinatus tendon or have irreparable tears with at least shoulder-level active elevation and lower demands for lifting and reaching activities of more than a few pounds above shoulder level. Treatment would be instituted after a history, physical examination, and plain radiographs. Unless there was diagnostic confusion, we would not image the cuff initially, but rather consider an MRI later if this approach had failed, once surgery was being considered. Patients with weakness, especially if the onset was sudden after an injury, are imaged more expeditiously. In these cases an acute full-thickness tear is suspected and in most healthy patients a repair of the acute tear is preferred over prolonged nonoperative treatment, which in some cases may result in a much more difficult repair, less likelihood for healing, and sometimes an irreparable tear.

Patients are taught a home exercise program and are sent to physical therapy for supervision and education.[121,152] Also instituted is a course of oral nonsteroidal antiinflammatory drugs, heat application, and modification of activities to eliminate offending motions. Initial exercises aim at eliminating any subtle stiffness (especially posterior capsular tightness, which can exacerbate impingement) and strengthening the rotator cuff and parascapular muscles. The patient's progress is monitored after 4 to 6 weeks. If adequate progress has not been made, a subacromial injection may be considered, especially if pain is limiting the patient's ability to perform exercises. We prefer a mixture of 3 mL of lidocaine (1%), 3 mL of bupivacaine (0.25%), and a depot corticosteroid (usually

8 mg of dexamethasone acetate in 1 mL). This can be very helpful,[19] even though pathologic studies have shown that true inflammation is rarely present in degenerative rotator cuff disease.[213] This injection may be repeated after 2 to 3 months, if the initial injection was helpful, but more than two injections a year are discouraged.

For patients with pain who still have good functional use of the arm with minimal weakness, this type of program is continued for 4 to 6 months before an MRI is obtained and surgical options are discussed. When weakness is prominent or progressive, this process is accelerated. A common presentation is that of sudden loss of strength after a relatively trivial injury. Because splinting from pain (e.g., from hemorrhagic bursitis) can simulate weakness, we would generally start with a therapy program. However, if there has not been dramatic improvement after a few weeks, an MRI is obtained. If a cuff tear is found of sufficient size to explain the weakness, timely repair is considered,[10] for it is likely that this is an acute tear, or at least an acute extension of a prior small tear. If the tear size seems inconsistent with the physical findings, other causes of weakness, especially a nerve injury, should be considered. Occasionally an older patient will present with dramatic weakness after a dislocation, and both a cuff tear and a brachial plexopathy will be present, and their relative contributions to the patient's weakness may be unclear. However, because waiting for the nerve lesion to resolve would likely allow irreversible atrophy of the cuff muscles to develop, it seems prudent to recommend early cuff repair in most of these patients.

SURGICAL MANAGEMENT

Surgical Indications

The presence of a rotator cuff tear is not necessarily an indication for surgery. As previously mentioned, MRI and cadaver studies have shown asymptomatic patients to have cuff tears.[198] The indications for surgical repair of a chronic rotator cuff tear are the presence of pain or significant functional deficits that have not responded to 2 or 3 months of conservative measures. In a younger and active (work, sports, or hobbies) patient, an acute full-thickness tear is an indication for early surgery without any trial of nonoperative treatment. Bassett and Cofield reported that in patients who had an acute injury and a full-thickness rotator cuff tear, repair within the first 3 weeks resulted in the best surgical outcome.[10] Specific indications should be tailored to the pathology and individual patient factors.

Surgery for Subacromial Impingement, Cuff Intact

Subacromial impingement results from irritating contact between the rotator cuff and biceps tendon and the coracoacromial arch. The various causes of this syndrome, as well as the pathomechanics involved, are reviewed in Chapter 1. Whether or not impingement is thought to be primary or secondary in a particular patient, if a prominent anterior acromion is felt to be contributing to pain and tendon injury at the time that surgery is considered, then an acromioplasty is considered. Open acromioplasty[154] has been an effective procedure, with long-term satisfactory results ranging from 80% to 90% in most series.[102,108,155,183]

In 1985 Ellman introduced the technique of arthroscopic subacromial decompression.[66] His preliminary findings were that the results of arthroscopic subacromial decompressions are comparable with open decompressions. In a follow-up study,[67] he demonstrated an 88% satisfactory outcome for arthroscopic subacromial decompression. Similarly, in a prospective, randomized study, Sachs and associates[194] found that patients having an arthroscopic acromioplasty did better in the first 3 months following surgery than did patients undergoing an open procedure. After 3 months the two groups were equal. Long-term follow-up showed no difference between the two procedures, with an overall success rate of 90%. These findings are consistent with other reports in the literature.[3,71,71,86,175,192,193,205]

Open Acromioplasty

Open acromioplasty should follow the principles as described by Neer.[154] The area of greatest impingement is along the undersurface anterior and lateral portions of the acromion. An anterior–inferior acromioplasty as described by Neer is therefore the preferred technique. In this technique, the anterior deltoid is sharply dissected from the anterior acromion with the underlying coracoacromial ligament (CAL). It is important to preserve the CAL length so that when the deltoid is reattached to the acromion the CAL is sutured back to the anterior acromion margin. The principle of an anterior–inferior acromioplasty is to preserve the normal anterior–posterior dimension of the acromion. When a large acquired osteophyte is formed within the CAL, this abnormal portion is removed but the natural anterior–posterior dimension of the acromion is preserved. Preserving the normal acromion dimension and suturing the CAL back to or near the anterior acromion is believed to decrease the incidence of superior escape of the humeral head, which can occur when there is a large or massive rotator cuff defect and loss of the depression and containment function of the rotator cuff. It should also be understood that some patients with rotator cuff tears (full thickness or partial thickness) do not have acquired spurs, nor do they need acromioplasty.

Arthroscopic Acromioplasty

Arthroscopy may be performed in either the lateral or beach-chair position. The beach-chair position allows for

scalene anesthesia (awake patients do not tolerate the lateral position well), provides a standard anatomic orientation (same as open cases), facilitates conversion to an open procedure, and avoids the risks of fixed traction.[202] The torso is angled approximately 60 degrees from the horizontal plane.[182,226] A head rest that allows access to the superior and posterior aspects of the shoulder is used. The arm is draped free, allowing shoulder rotation, extension, and elevation. Two small towels are placed under the scapula to elevate the shoulder off the table.

Regional interscalene anesthesia avoids the morbidity of general anesthesia, allows improved relaxation, and facilitates outpatient surgery.[25,180] There is a misperception among some surgeons that patients are loath to undergo a scalene block. Although it is true that patients often express unease with being awake during surgery, they generally become highly accepting when reassured that they will be as sedated as they wish, especially if reminded about the risks of general anesthesia.

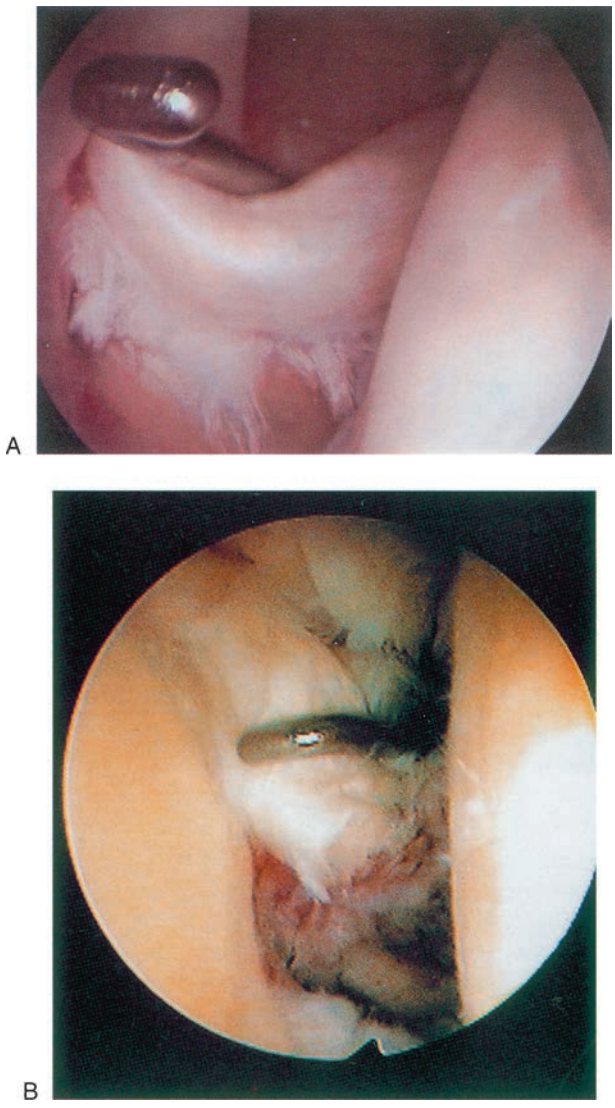

Figure 3-1 **(A)** Partial biceps tear seen on glenohumeral arthroscopy as the biceps is pulled down into the joint. This will be débrided. **(B)** Proximal stump of a torn biceps tendon. This will be resected back to the base.

Surgical Technique for Arthroscopic Acromioplasty

We prefer to perform routine decompressions arthroscopically in all patients when there is a significant subacromial impingement lesion and an intact or partial-thickness cuff tear. The procedure begins with glenohumeral joint inspection. Any inflamed synovium should be débrided and glenohumeral pathology addressed as indicated[57] (Fig. 3-1). Attention is then focused on the undersurface of the rotator cuff, and any irritation or tears evaluated.

Once the glenohumeral joint has been examined, the subacromial space is entered with the arthroscope.

Typically a thick bursitis is encountered, and this is removed with a 5.5-mm full-radius soft tissue motorized shaver. Once there is good visualization of the subacromial space, the undersurface of the acromion and CAL are inspected. Although there may be a synovitic or inflamed appearance to the ligament, the usual finding is hypertrophy of the ligament, with a degenerative, attritional lesion of the anteroinferior acromion, including frayed fibers hanging down (Fig. 3-2). In young, athletic patients there may be no bone abnormalities, but just scarring of the bursa and thickening of the coracoacromial ligament.[8] In these patients, a soft tissue decompression with débridement without release of the ligament, combined with

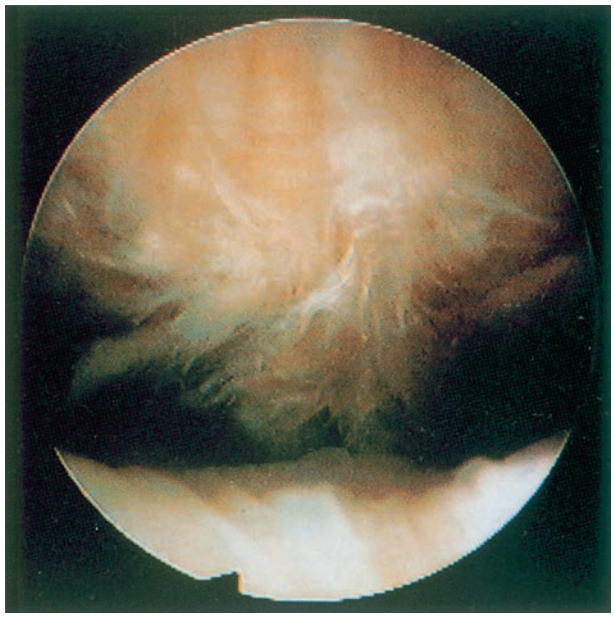

Figure 3-2 Attritional lesion of the anteroinferior acromion at the insertion of the coracoacromial ligament.

renewed rehabilitation to treat any subtle underlying instability, may be helpful.

In older patients with a more degenerative profile, the ligament is removed only from the undersurface of the acromion to visualize the acromion and its anterior margin, and an acromioplasty performed. The CAL is sequentially removed from the undersurface of the acromion using electrocautery and then freed at its margins laterally and medially. It is important to visualize the entire acromion to the junction between the anterior two-thirds and posterior one-third of its anteroposterior dimension, from the acromioclavicular (AC) joint to the lateral margin to perform an adequate acromioplasty. We routinely use the electrocautery to expose the anterolateral and lateral aspect of the acromion to better appreciate the acromial morphology and spur size. Bipolar cautery devices are the best device for this part of the procedure.

The bony acromioplasty is performed with a 5.0– to 6.0-mm tapered burr. The thickness and morphology of the acromion as well as the size of any bone spur will dictate the amount of bone removed in an individual patient. A popular technique for determining the amount of bone removal is the "cutting-block" technique[33] (Fig. 3-3). In this method the burr is brought in from the posterior portal, applied to the posterior acromion, and then advanced to plane down the anterior acromion, thereby flattening the entire acromion. This approach aims to convert the acromion to a type I after Bigliani et al.[18] However, this may remove an excessive amount of bone if the burr is brought into the subacromial space at an acute angle to the posterior surface of the acromion. In the past, the coracoacromial arch has been often thought of as a purely harmful structure, causing impingement and good for little else. Indeed, in 1984, Rockwood advocated the routine removal of the CAL at the time of any shoulder operation.[187] This encouraged, in past years, a "more is better" approach to bone removal at acromioplasty. However, contact by the acromion on the underlying rotator cuff and humerus in normal shoulders has a passive, stabilizing function.[77,79,130,151,167,215,220] In a later study simulating different amounts of bone removal at acromioplasty, smoothing the anterior third of the acromial undersurface removed all focused contact on the supraspinatus insertion, which was termed "impingement." Total flattening of the acromion was found to be not only unnecessary to relieve impingement, but also this technique destroyed much of the broad contact between the bone and rotator cuff, which was likely important for stability of the humeral head in a superior direction.[75]

Figure 3-3 Cutting block technique for arthroscopic acromioplasty. The burr is entering from posterior and the remaining acromion bone is at the anterior margin.

In addition to removing excessive bone, the arthroscopic cutting block technique may risk injuring the deltoid origin, especially in curved acromions in which a line drawn up against the posterior acromial undersurface essentially transects the anterior acromion. Indeed, some surgeons who purport to use this technique will depart from it when they notice a thin, curved acromion. We prefer to aim for opening up the subacromial space by resculpting the anteroinferior acromion so that it curves gently away from the underlying humerus and cuff. The amount of bone removal may be estimated from the preoperative outlet view and measured intraoperatively by comparison with the known diameter of an instrument (Fig. 3-4). The transition to the posterior acromion is then smoothed. All debris is removed, and the bursal space is irrigated. After decompression, the instruments are removed and portals are closed with absorbable suture. The patient is placed in a removable sling for 1 to 2 days for initial comfort. Postoperative motion exercises are generally started immediately, and progressed as tolerated.

The major advantage of arthroscopic over open decompression is that deltoid detachment is avoided.[2] Use of the arthroscope also allows inspection of the glenohumeral joint, as well as the undersurface of the rotator cuff, and any pathology encountered can then be addressed. Finally, arthroscopic decompressions are less invasive and are routinely performed on an outpatient basis. In most clinical practices it is rare to perform an acromioplasty as an isolated procedure as in the vast majority of cases there is cuff damage requiring débridement or repair.

Acromioclavicular Joint Resection

AC joint resection is performed when there is significant tenderness over the AC joint on preoperative examination, pain over the AC joint with activities, and anatomic evidence of arthritic changes on preoperative radiographs. The techniques for open or arthroscopic distal clavicle resection are detailed in Chapter 32. The authors prefer the arthroscopic approach for AC joint resection; it is performed after the acromioplasty in three steps:

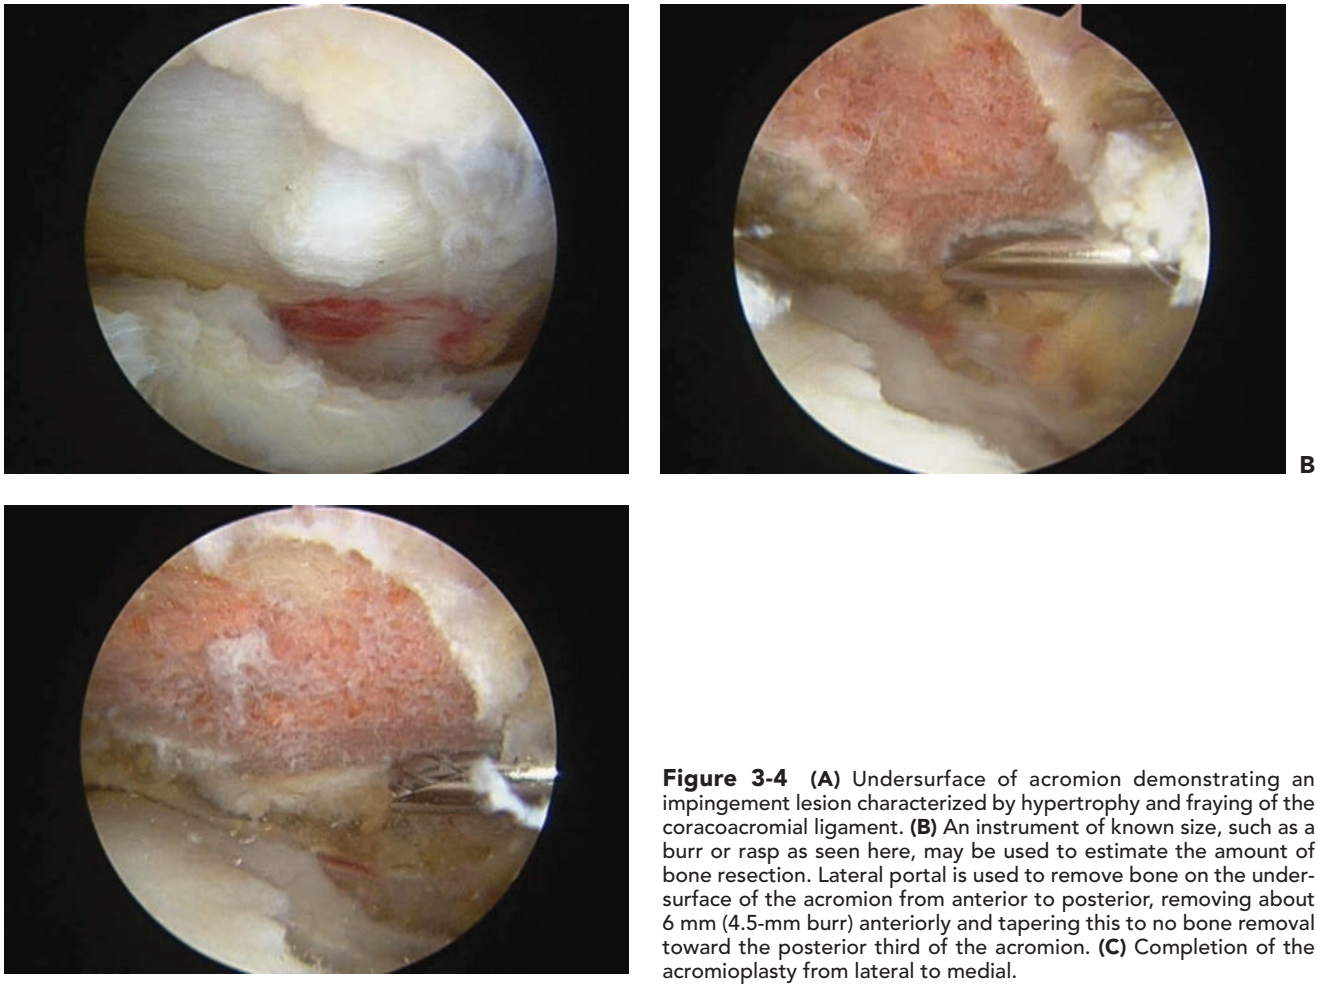

Figure 3-4 **(A)** Undersurface of acromion demonstrating an impingement lesion characterized by hypertrophy and fraying of the coracoacromial ligament. **(B)** An instrument of known size, such as a burr or rasp as seen here, may be used to estimate the amount of bone resection. Lateral portal is used to remove bone on the undersurface of the acromion from anterior to posterior, removing about 6 mm (4.5-mm burr) anteriorly and tapering this to no bone removal toward the posterior third of the acromion. **(C)** Completion of the acromioplasty from lateral to medial.

- First, using the posterolateral portal for visualization, the soft tissue and medial portion of the acromial facet of the AC joint is removed, thereby exposing the distal clavicle. The inferior osteophyte of the distal clavicle is removed.
- An anterior–superior portal is placed in the AC joint to introduce the burr. Bone is removed from both the acromion and clavicle with visualization from the lateral portal. Special care must be taken to remove the posterior and superior clavicle spur while preserving the attachment to the posterior and superior AC capsular ligaments.
- Finally the modified posterior portal is inspected to check the anterior clavicle, ensuring that the superior AC ligament is intact (Fig. 3-5).

Surgery for Partial-Thickness Rotator Cuff Tears

The literature remains unclear and somewhat confusing on the treatment of partial-thickness rotator cuff tears. Recommendations range from conservative therapy to open rotator cuff débridement and repair. Prior to arthroscopic surgery, excision and repair of significant partial cuff tears seemed logical and added little morbidity to an open procedure.[82,157] However, after the advent of arthroscopic acromioplasty, but before techniques of arthroscopic tendon repair had been developed, simple débridement with or without decompression became more widely used for partial tears and even many full-thickness tears.[58,68,72,117] Later, as data accumulated that indicated poor results after this procedure,[18,217] primary excision of the damaged tendon followed by primary tendon repair came back into vogue. This procedure became more popular thanks to the development of mini-open and arthroscopic techniques, because it avoids conversion to a full open procedure.[73] Currently, recommendations for the operative management of partial tears vary between investigators. Essentially, there are three surgical options: débridement alone, decompression and débridement, and excision of damaged tendon with primary repair (usually along with decompression). Let us examine each of these in turn.

Andrews reported good success with débridement,[4] but his population was young and athletic. It is likely that

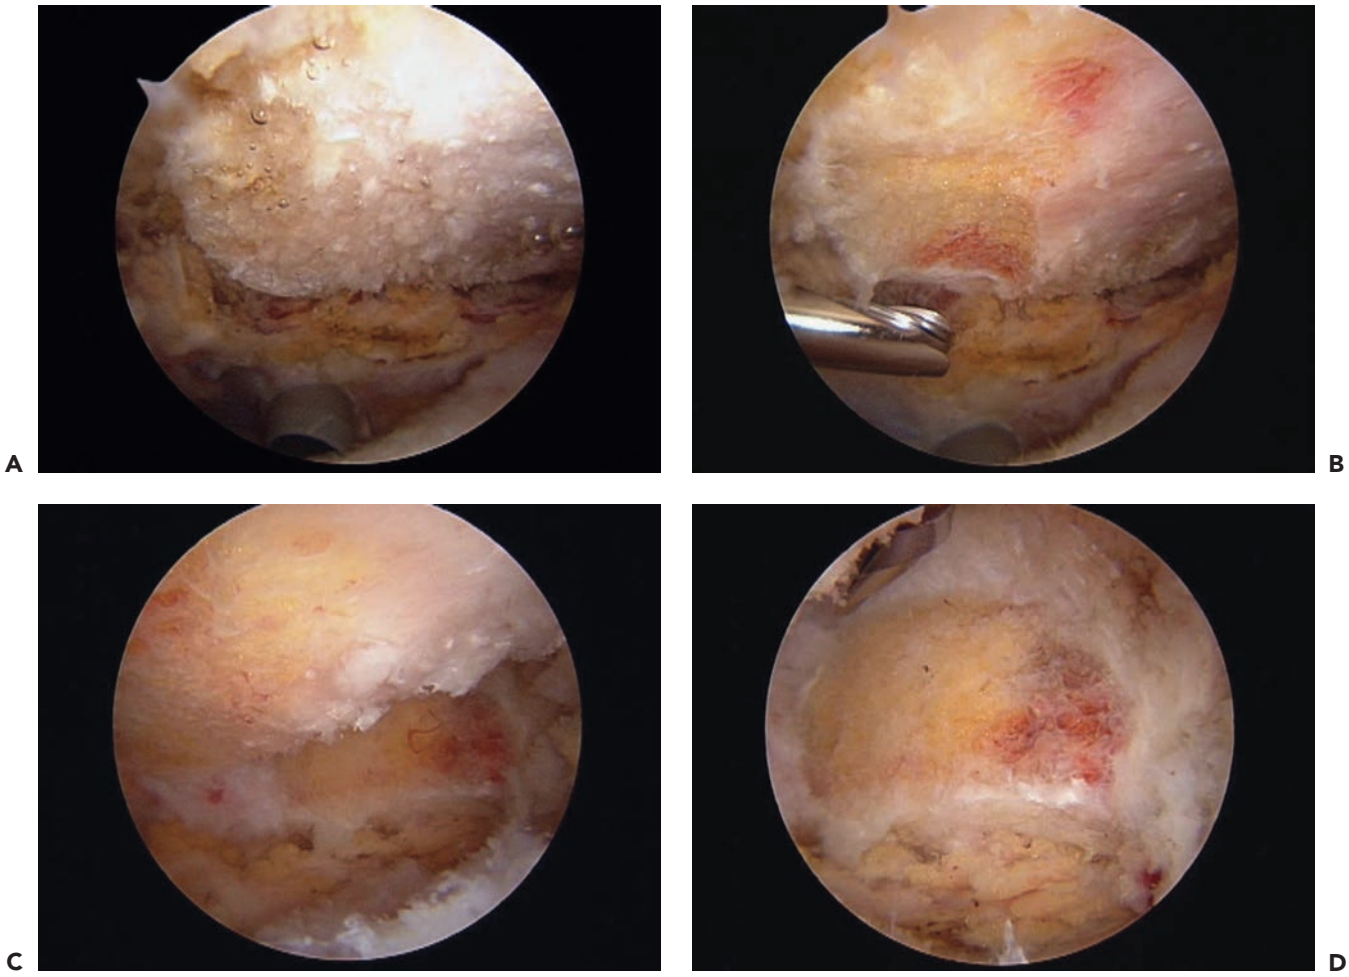

Figure 3-5 **(A)** Arthroscopic view of acromion after removal of soft tissues and coracoacromial ligament. **(B)** Lateral removal of bone (acromioplasty). **(C)** Completed acromioplasty and distal clavicle resection. **(D)** Distal clavicle resected with 360-degree view of the resected clavicle showing complete resection with intact superior and posterior acromioclavicular capsule. overuse and tensile failure were involved, rather than any acromial abnormalities. Snyder and coworkers[205] reported their results on arthroscopic cuff débridement with or without subacromial decompression. They had 85% satisfactory results, with similar results between those patients having a decompression and those not having a decompression. However, patients were not randomized for decompression, but were selected on clinical criteria, likely correctly identifying patients in whom impingement was prominent. Arroyo and coworkers noted that young, overhead athletes frequently develop subacromial scarring and bursitis owing to overuse and instability, and that soft tissue cleanout of the subacromial space may be helpful.[8] Altchek and Carson studied 50 throwing athletes with anterior shoulder pain, which was refractory to nonoperative treatment,[2] and found that most had fraying of the articular surface of the cuff. Débridement of this area, combined with débridement of bursitis and CAL hypertrophy when noted, was associated with favorable results in 80% of cases.[2]

The role of internal impingement, in which the cuff undersurface abuts the glenoid rim in abduction and external rotation,[122,123,213] also adds complexity to decision making. This mechanism and other causes of cuff failure are discussed in Chapters 1 and 2. When deep-surface cuff partial tears are associated with internal impingement, most surgeons have employed simple débridement;[73] however, little data are available on the effectiveness of this approach. In some cases, anterior subluxation has been thought to play a role, and capsulorrhaphy recommended.[123] Indeed, one author has suggested that derotational humeral osteotomy be considered.[213] In any event, this group of younger patients, who are often involved in throwing sports, is a different group from that of older patients with degenerative tendon failure.

In some patients, simple débridement has been far less satisfactory. Ogilivie-Harris treated 57 partial tears with

arthroscopic débridement alone, and found that only half achieved satisfactory results.[169] In this group, acromioplasty appears to improve results.[24,68,86,170,226] Arthroscopic decompression has also been effective. Gartsman noted that 33 of 40 patients (83%) with partial-thickness tears had major improvements in their shoulders at an average of 29 months after arthroscopic acromioplasty.[86] However, not all patients do well with this approach. Altchek and coworkers noted that the results of débridement and decompression of partial tears were not as favorable as those from decompression in shoulders with intact cuffs.[3] But which subgroups of partial tears need more than decompression?

Weber felt that the degree of tendon involvement was important.[217] He reported inferior results in patients undergoing débridement and decompression of partial cuff tears that involved more than half the tendon's thickness, as compared with a mini-open approach in which the damaged tendon was excised and healthy tissue repaired side to side.[217] Interestingly, his recommendations are the same as those of Neer et al.[157] (done open), although less aggressive than Fukuda and coworkers, who performed excision of damaged tissue on most partial tears[82] and achieved a 92% success rate. Further study is needed to make definitive recommendations for treatment.

Authors' Preferred Treatment

We treat minor degrees of tendon injury in a young, athletic patient with rehabilitation. If that fails, arthroscopy is considered. This population will often have subtle degrees of instability, but if cuff and bursal pathology are the dominant findings and anteroinferior labral detachment is not found, then we would not perform a capsulorrhaphy. We would débride the partial tear and any labral fraying, and then inspect the bursa. If there is bursitis and CAL hypertrophy, then we would débride those areas, performing in effect a soft tissue subacromial decompression.

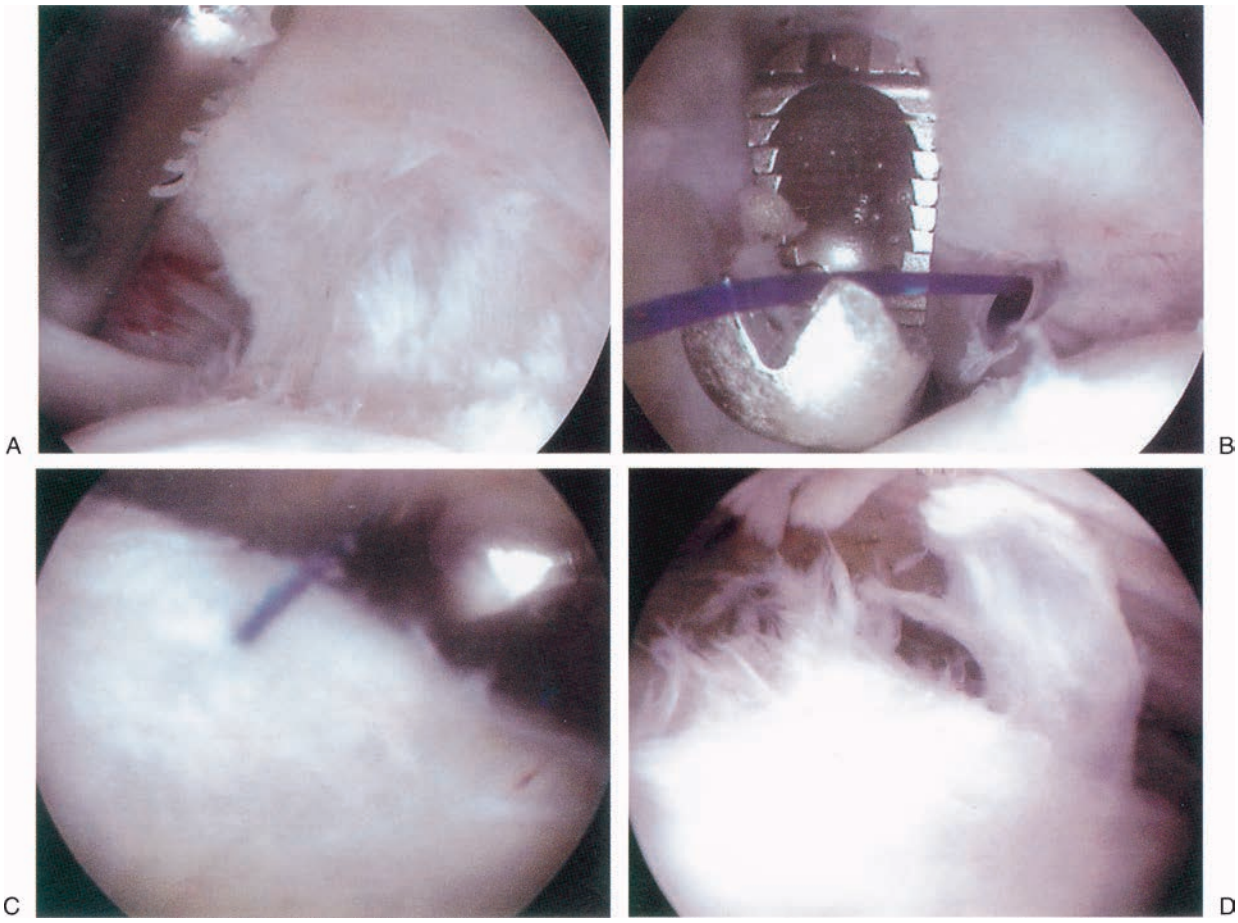

Figure 3-6 Partial-thickness tears of the rotator cuff can be treated with débridement if the tear is less than 50% of the thickness of the tendon. **(A)** Arthroscopic view from the posterior glenohumeral portal of an articular-sided partial-thickness tear of the supraspinatus. **(B)** An absorbable suture is placed through the tendon with a spinal needle to allow bursal-sided inspection. **(C)** Subacromial view of the bursal side of the tendon showing that the tear does not extend to the bursal surface. **(D)** Subacromial view of a different patient who has a partial bursal-sided tear.

For older patients with degenerative partial cuff tears who fail nonoperative treatment, we will perform a shoulder arthroscopy to determine the depth and size of the tear. If the tear is less than 50% in thickness, then we will perform an arthroscopic cuff débridement followed by an anterior acromioplasty with CAL excision (Fig. 3-6). The retracted edge of the "rim-rent" can be bulky, and may cause the tendon to buckle and jam in the subacromial space. Débridement includes trimming this edge to decrease its bulk. A colored absorbable (in case a piece breaks off) suture is passed through the partial tear with a spinal needle to aid in identifying the corresponding bursal surface of the tendon later. This will help to avoid missing a full-thickness perforation and to find cases in which the tendon is thinned from both sides. If the tear involves more than 50% of the tendon's thickness in an active patient, we will perform the arthroscopic anterior acromioplasty and arthroscopic rotator cuff repair.

SURGICAL TECHNIQUE

Partial Tear

Partial Bursal Surface Tear: Guy Rope technique

The guy rope technique is currently used only for partial superficial tears. A posterior subacromial portal and a lateral instrumentation portal are used. The greater tuberosity is abraded and a hole is drilled as lateral as possible into the border of the greater tuberosity. A metallic screw anchor loaded with a double suture is placed laterally through the strong cortical bone of the great tuberosity

Through an anterior portal a pig-tail suture passer (Linvatec) equipped with a 45-degree curved hook (left-rotated for a right shoulder and vice versa) is loaded with a single strand of PDS #0. The instrument is passed through the cuff from the superficial to the deep layer and then back again, twisting the hook, resulting in a U-suture (Fig. 3-7A). The

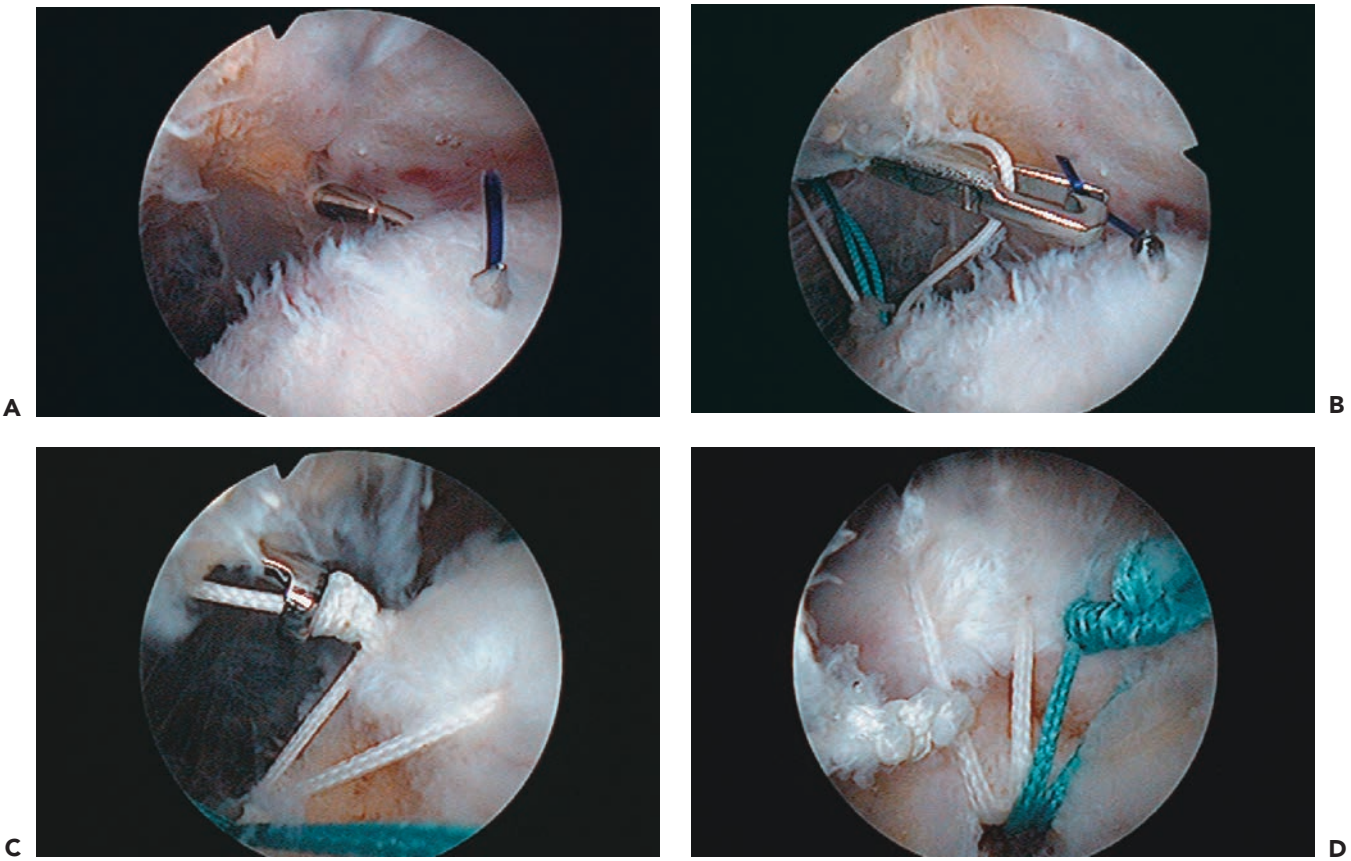

Figure 3-7 Superficial cuff tear: Guy rope suture. **(A)** Placement of PDS suture for suture relay (double pass of suture through the tendon). **(B)** After placing the anchor lateral in the greater tuberosity, one permanent suture is taken with the PDS and passed from superficial to deep within the tendon. **(C)** The same limb of the suture is passed from the acromial to articular surface and then back to the acromial surface of the tendon and the knot is tied. Both sutures are passed in this manner. **(D)** The final repair has a double grasp of the suture in the tendon (mattress suture) but the suture is passing over the top of the tendon. This method allows for greater surface area of contact between the tendon and greater tuberosity than what would be achieved with a mattress suture where both limbs of the suture are tied over the top of the tendon and both limbs contact bone from the deep side of the tendon.

PDS end is grasped at the same time as one of the two sutures is loaded on the anchor by a forceps and pulled out through the lateral portal. The PDS is used as a shuttle relay for passing the nonabsorbable suture. (Fig. 3-7B,C). Alternatively the sutures can be passed directly with suture punch instruments or grasped directly with a tissue penetrator. A sliding knot on the anterior strand of the thread is pushed on the cuff and pulled laterally to the anchor to bring the tendon to the greater tuberosity. Then the knot is secured by changing traction on the threads, and two additional half loops are pushed along the posterior thread. The second suture is passed through the tendon in the same way to obtain a double suture technique (Fig. 3-7D).

Intratendinous Tear

Only an acromioplasty is performed for this lesion because it is thought that relief of the impingement prevents further tendon damage.

Partial Articular Surface Tear

Articular surface partial tears most often affect the supraspinatus, and they can be associated with secondary biceps tendon instability when the tendon tear is located at the level of the posterior biceps pulley. This lesion is best visualized with internal rotation of the shoulder as the biceps tendon subluxates over the lateral wall of its groove (Fig. 3-8A,B).

The aim of the supraspinatus repair is to rebuild the juxtacartilaginous tendon's insertion. To reattach the supraspinatus, after cleaning the bursa and acromioplasty, the repair is managed by the intraarticular visualization "inside out" technique. A small anterosuperior portal close to the anterior corner of the acromion is placed near the rotator interval at the anterior part of the supraspinatus above the biceps groove. A 5-mm incision is made in the cuff in the midportion of the partial cuff tear. All anchors and instruments can be placed through this cuff defect, and then this defect is closed with suture at the end of the repair. In this way the intact superficial bursal surface portion of the cuff remains intact and the footprint of the cuff is reestablished medially at the margin of the articular cartilage. A metal anchor is inserted in the previously abraded area of the tuberosity, close to the cartilage and to the posterior border of the biceps groove (Fig. 3-8C).

Two techniques are possible to pass the four sutures through the tendon. A suture passer can be introduced by the lateral portal used for the acromioplasty, perforating the cuff from outside to inside, and either a PDS suture can be used as a suture relay or the suture on the anchor can be passed directly (Fig. 3-8D–G). The four threads are successively passed and pulled through the tendon. Visualization of the knot may be done on subacromial space, but secure tension is necessary to ensure good application of the cuff over the bone (Fig. 3-8H).

It is important to avoid strangulation of the biceps with the suture fixation. When the biceps pulley reconstruction is not secure or anatomic or when biceps degenerative changes are visible, then a tenodesis of the biceps is performed.

Full-Thickness Rotator Cuff Tears

History

Codman performed his first cuff repair in 1909,[44] and in 1934 he noted that 20 of 31 patients followed after repair of full-thickness rotator cuff tears obtained a good result.[48] Four years later Outland and Shepherd published a series of 12 rotator cuff repairs; satisfactory results were obtained in 67%.[171] McLaughlin, using a transacromial approach, reported 94% pain relief and 100% return to manual labor in 32 patients after cuff repair.[140] In the 1950s and 1960s, overall satisfactory results after cuff tendon repair were seen in 77% of Moseley's cases,[153] 74% of Godsil and Linscheid's cases,[94] 60% of Heikel's cases,[112] and 66% of Debeyre et al.'s cases.[60]

In 1972, Neer advocated routine anterior acromioplasty at the time of rotator cuff repair.[154] Of 20 patients with full-thickness tears treated by acromioplasty and repair, 19 (95%) achieved satisfactory results (patient satisfied, no significant pain, less than 20 degrees of limitation of elevation, and at least 75% of normal strength). In this and in other writings,[154,156–158] Neer argued for certain principles in rotator cuff surgery:

1. Reshaping rather than removing the acromion, avoiding procedures that damage the deltoid origin
2. Restoring motion
3. Releasing, mobilizing, and repairing the torn tendons
4. Surgeon-directed individualized rehabilitation

Although most modern surgeons have employed an approach similar to Neer's, there have been exceptions. Repair of the tendons without acromioplasty has been advocated,[95,168,200] as has acromioplasty without tendon repair.[189] Some have even continued to advocate acromionectomy.[23] Nevertheless, decompression and repair remains the most common treatment for full-thickness tears requiring surgery. With recent advancements in arthroscopy, many authors are advocating arthroscopic repair of rotator cuff tears. Preliminary results appear to be promising and equal to those for mini-open repairs.[87,203,210] Arthroscopic repair follows the same principles as those for open repairs, including subacromial decompression, cuff mobilization, and repair of the tendon back to the tuberosity. Technically, this can be very challenging, particularly on the upslope of an individual surgeon's learning curve.

Principles of Open Rotator Cuff Repair

Approach

Although stiffness is surprisingly infrequent in shoulders with large cuff tears, it can occur.[157] Even if superior structures may be released during an open repair, the inferior capsule and axillary recess are difficult to reach through an open anterosuperior approach. Consequently, stiff shoulders are gently manipulated at the beginning of the procedure.

A variety of surgical approaches for cuff repair have been reported.[138] Norwood et al. have described a posterior approach,[168] whereas Leffert and Rowe preferred an anterior, deltopectoral exposure,[131] also advocated by Gerber et al. for subscapularis ruptures.[91] Most authors, however, have employed an anterosuperior approach through a split or takedown of the proximal deltoid.[138] In an attempt to visualize large tears with retraction, takedown of the anterior or lateral deltoid origin has been used, as have acromion-splitting approaches. However, Codman,[48] after trying various techniques, came to prefer a deltoid split combined with rotation of the head beneath the split to expose the involved area of the cuff. Diamond, in 1964, described an extensile approach for acromionectomy in which a deltoid split was taken up over the acromion, which was then exposed subperiosteally.[63] Neviaser et al. employed a split taken into the AC joint with subperiosteal reflection of the flaps to expose the tear, made easier because the distal clavicle was routinely resected.[165] However, exposure of a retracted posterior tear may be difficult with an anterior split, occasionally even requiring a supplemental posterior incision.[157] For this reason Bigliani et al. have shifted the split posteriorly by beginning it at the anterolateral corner of the acromion; this affords excellent posterior exposure[16,56] (Fig. 3-9).

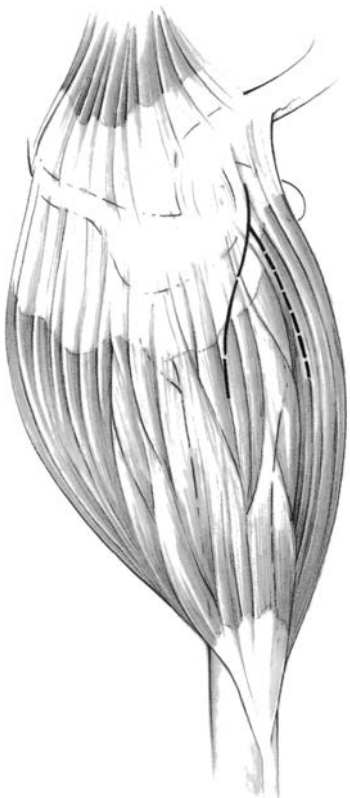

Figure 3-9 The posterior curve of the deltoid incision allows the exposure to be centered over the greater tuberosity for better access to the cuff. The dotted line demonstrates the less desirable anterior exposure provided by the older and more anterior type of deltoid incision. (From Bennett WF. Arthroscopic repair of massive rotator cuff tears: a prospective cohort with 2- to 4-year follow-up. *Arthroscopy* 2003;19(4):380–390, with permission.)

Decompression

Traditionally, decompression at the time of cuff repair has consisted of anterior acromioplasty, resection of the coracoacromial ligament, and, if needed, resection of downward-projecting acromioclavicular osteophytes.[154] It has become increasingly appreciated that the coracoacromial arch has a normal buffering role in passively resisting superior humeral translation,[75,77,79,130,151,167,215,220] especially when the dynamic stabilizing function of the cuff muscles has been lost. Wiley reported that anterosuperior subluxation could result from decompression without repair of massive cuff tears,[220] but we have noticed this also after decompression and repair when the repair fails or the muscles, although reattached, are too atrophied to generate the force necessary to center the head. Indeed, Watson, noting that his cases of cuff repair did better when the coracoacromial ligament was incised rather than resected, conjectured that coracoacromial ligament "removal may allow the strong deltoid muscle to pull the humeral head proximally," stretching and potentially damaging the cuff repair.[215]

Preservation of the coracoacromial arch for stability has been employed at the time of arthroplasty for cases of end-stage rheumatoid arthritis and cuff-tear arthropathy.[7,181] In 1991, one of us (ELF) began to preserve the coracoacromial ligament when repairing massive tears, and reported on the initial experience a few years later.[80] This has not appeared to result in postoperative impingement or inadequate pain relief. Whether this should be used for all tears or only large ones, and if the latter, what size cutoff there should be, remains unanswered.

Tendon Mobilization and Repair: Open Technique

The aim of tendon mobilization is not only to allow repair, but to free the cuff muscle–tendon units so they can glide, and to prevent postoperative stiffness.[156,157] It is unfortunate that the cuff literature has emphasized concepts such as "coverage of the head," as if cuff repair were a plastic surgery procedure. No hand surgeon would sew a graft into an old, scarred flexor tendon laceration and say that he or she had "covered" the proximal interphalangeal joint. The goal should be to restore the cuff's dynamic function as best possible. Therefore, the tendons must not only be repaired, but also freed from adhesions to surrounding structures so that the muscle–tendon unit can glide and function. Also, passive shoulder motion may be normal, despite extensive cuff scarring, because the capsule is detached from the humerus along with the cuff tendons, so motion occurs "through the tear." If the tendons (and the attached capsule) are repaired without being adequately released, a stiff shoulder may result, and stretching exercises will improve motion only by pulling out the repair.

Arthroscopic techniques have progressed to the point where experts report that the same tendon releases traditionally performed open may be accomplished arthroscopically.[81,87] A possible exception may be chronic subscapularis tears, which may have extraarticular adhesions (especially including the axillary nerve). More recently, the techniques for arthroscopic repair of subacute and chronic subscapularis tendon tears are reported to be safe and successful.

Repair of the tendon is performed with the arm at the side. Performing the repair with the arm in abduction and then placing the patient in an airplane splint will usually lead to pullout of the repair when the brace is discontinued.[163] However, protection of a repair of a large tear (performed with the arm at the side) with a brace was employed by Neer,[157] and has been more recently advocated by Gerber.[93] Recently developed braces are more comfortable than earlier models, are less likely to rotate into extension, and allow for more intermediate positions, rather than wide abduction and external rotation. It is our impression from clinical experience that bracing, or use of an abduction pillow, for at least 4 weeks after repair of chronic posterior-superior two-tendon cuff tears results in better healing. During this time it is still important and necessary to begin passive range-of-motion exercises.

Traditionally, many surgeons preferred repairing the tendon to a trough in bone.[142] Many techniques have been reported in which the tendon edge is pulled into a deep cancellous trough with mattress sutures. Several factors have contributed to a trend away from cancellous troughs. First, use of mattress sutures often allows some mobility of the free edge of the tendon, or at least some discontinuity between the repair and the tuberosity. We have preferred simple or Mason-Allen sutures that hold the tendon edge flat against the tuberosity and present a smooth surface. Second, concern for the holding power of sutures in osseous tunnels, and especially for the pullout strength of suture anchors, has prompted a desire to preserve the cortical bone at the articular–tuberosity junction. Finally, doubts have been raised as to whether, in fact, cancellous bone is a better healing bed for tendon than cortical bone—a recent study in sheep found no difference in repair strength.[206] Most surgeons freshen the bone at the articular–tuberosity junction to remove nonhealing bursal tissue and scar, but do not necessarily expose the cancellous bone. We believe that removing the degenerative soft tissue is important; then removal of some bone without creating a trough or exposing the cancellous bone of the greater tuberosity yields a bone area that will allow healing and preserve the mechanical strength of the cortical bone.

Numerous suture techniques have been described. An influential study recently suggested that modified Mason-Allen sutures provided the best holding power in a weak tendon while minimizing strangulation.[92] However, simple sutures elongate least under load, and thus gap less in a strong tendon. The most accepted arthroscopic techniques involve placing suture anchors, threading the sutures through the edge of the torn tendon, and then arthroscopically tying knots to secure the repair. Alternatively, a

transfixing implant such as a tack or staple may be used, or a suture anchor with attached suture may be threaded directly through the tendon edge.

Deltoid Repair

In open surgery the deltoid must be securely repaired; indeed, some of the worst complications in cuff surgery involve damage to or detachment of the deltoid. The deltoid may be repaired back to bone, a cuff of soft tissue, or both. Some surgeons detach a portion of the deltoid with a sliver of acromial bone, so that it can be repaired bone to bone. When repairing the deltoid after open cuff repair, it is necessary to use heavy (#2) nonabsorbable suture to the deltotrapezius fascia and through the acromion bone.

The major advantage of arthroscopic repair is believed to be the preservation of the deltoid origin. However, Rockwood and Lyons have suggested that subperiosteal elevation of the deltoid, as is performed with arthroscopic acromioplasty, may detach a large proportion of the Sharpey fibers of the deltoid origin, causing substantial weakening.[189] Indeed, with the advent of mini-open cuff repair, surgeons have been able to examine the deltoid after an arthroscopic acromioplasty, and many have noted (anecdotally) occasional thin areas or even frank detachment of the anterior fibers. It is therefore important when performing an arthroscopic acromioplasty to keep the anterior and superior attachments of the deltoid to the acromion.

Rehabilitation

Passive motion begun early after repair is used by most rotator cuff surgeons, and active motion is generally deferred until tendon healing can be expected. The limits of motion must be based on the surgeon's impressions of the security of the repair and the quality of the tissues. These factors are highly variable. Stiffness is unusual after repair of massive tears, because most of the capsule was off with the tendon and both are often thin and insubstantial. Pulling out of the repair is the more likely complication, so slow, gradual, passive motion is generally the core of the postoperative program. Conversely, patients with small tears, with thick, robust tendon (and attached capsule), not infrequently may become stiff after repair, whereas repair dehiscence is far less frequent than after repair of massive tears.[105] For these patients, a more aggressive mobilization program is used. In any event, the program must be directed by the surgeon who performed the repair, and progress must be closely monitored.

Mini-Open Approach for Full-Thickness Rotator Cuff Tears

Arthroscopic approaches generally involve three bursal portals: anterior, lateral, and posterior. Whereas a decompression and, if indicated, a distal clavicle resection involve visualizing the anteroinferior and anteromedial acromion, the cuff tear and tuberosity are generally quite lateral to the acromion, and the lateral portal must not be placed too high. Mini-open approaches are considered to be those that employ only a split of the deltoid, without any takedown of the origin. The actual skin incision may range from a 3-cm portal extension in the skin creases[182] to a fairly large longitudinal incision.[176]

In an arthroscopic-assisted approach, the initial procedure is the same as with an arthroscopic repair, usually including an arthroscopic subacromial decompression. Then a small incision is used to directly repair the tear through a deltoid split without detachment. This approach is especially useful for small and medium cuff tears. Although some authors have made quite large skin incisions and still called it a "mini-open" approach, if only a deltoid split is used, most surgeons have kept the incision small and in the skin creases. We have preferred a "portal-extension" approach in which the anterolateral portal is extended to a length of 3 cm, anterior to posterior[182,226] (Fig. 3-10). Flaps are elevated, and the deltoid is split in the direction of its fibers to just posterior to the anterolateral corner of the acromion. The deltoid split should be no longer than 5 cm from the acromion and should incorporate the small defect from the arthroscopic portal. None of the deltoid is detached from the acromion. A stay suture is then placed in the deltoid to prevent propagation of the split and possible damage to the axillary nerve. By maneuvering the arm, the entire extent of the tear can be seen. This approach can provide adequate exposure of the supraspinatus and the upper portions of the infraspinatus tendons, but access to the subscapularis and lower portions of the teres minor is difficult.

When a mini-open approach is performed, it is best suited for the small (less than 1 cm) and medium cuff tears (1 to 3cm). In these size tears retraction of the tendon should be limited to the midhumeral head. In many cases use of a mini-open technique for tendon repair can be a useful method of advancing to a full arthroscopic repair. The steps of the arthroscopic-assisted mini-open procedure are as follows: (1) diagnostic arthroscopy of the glenohumeral joint; (2) diagnostic arthroscopy of the subacromial space; (3) arthroscopic bursectomy, removal of soft tissue undersurface of the acromion, and acromioplasty; (4) cuff tendon edged débridement and tendon mobilization; (5) decortication of the greater tuberosity; (6) placement of bone suture anchors; (7) passage of sutures into the tendon; and (8) knot tying. These surgical steps involved can be performed with an arthroscopic technique, and when the procedure becomes more difficult for the skill level of the surgeon, it can be safely and effectively converted to the mini-open technique to complete the procedure.

When this procedure is performed, we generally recommend limiting this technique to isolated supraspinatus tears because the releases for large, retracted tears seem

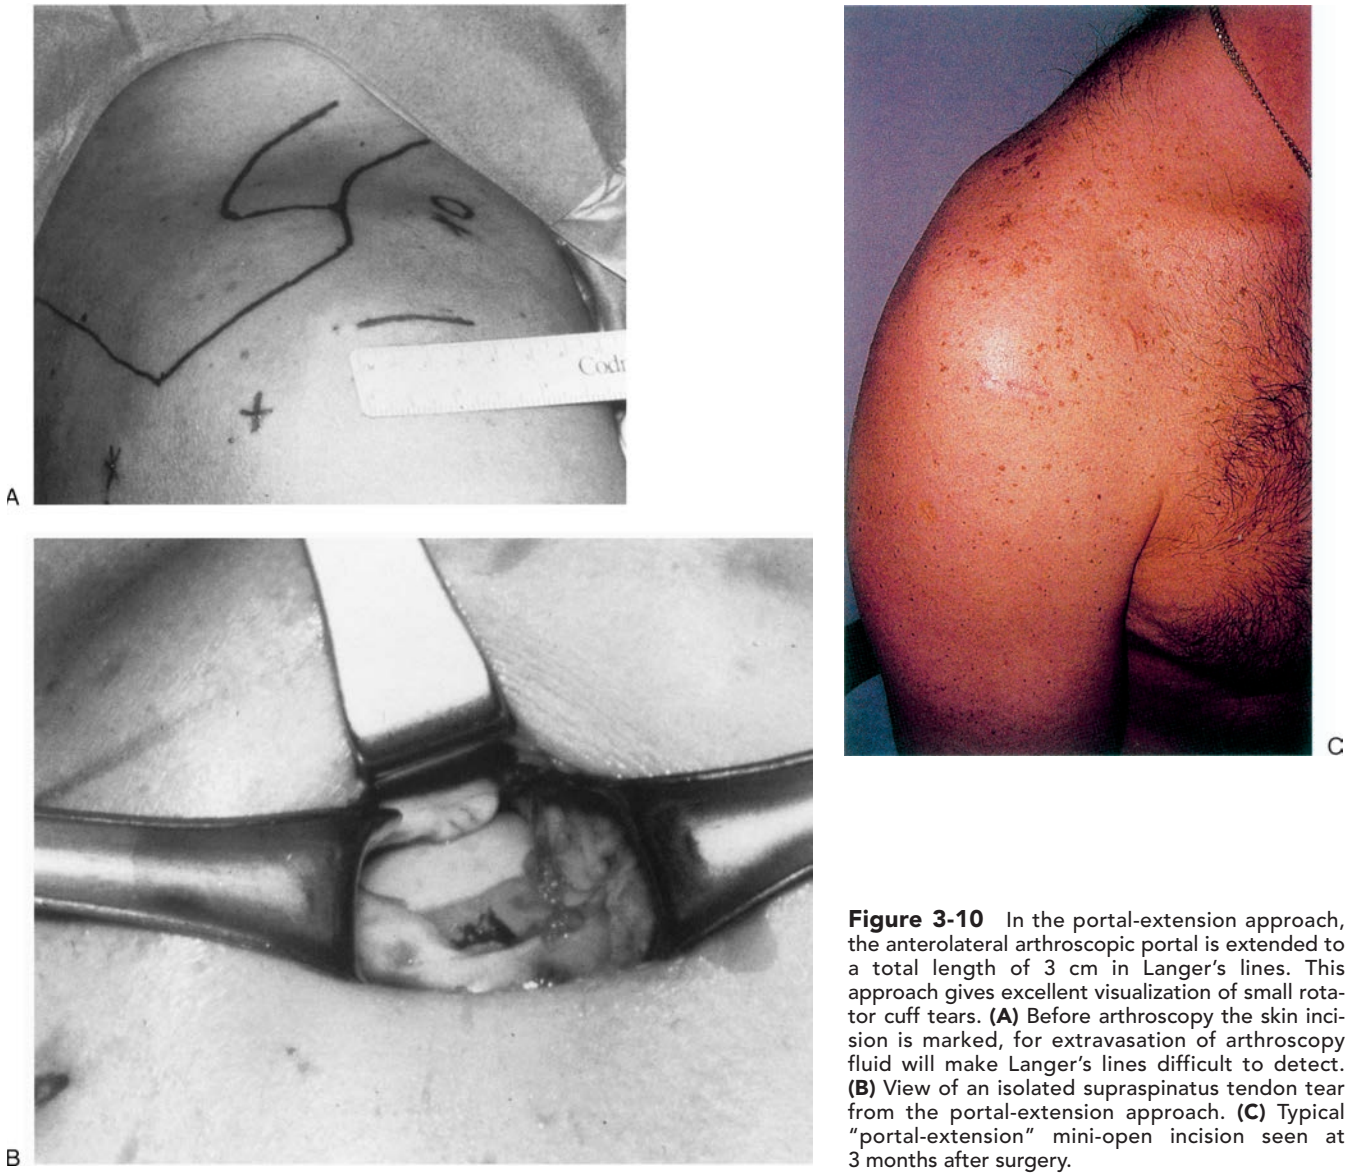

Figure 3-10 In the portal-extension approach, the anterolateral arthroscopic portal is extended to a total length of 3 cm in Langer's lines. This approach gives excellent visualization of small rotator cuff tears. **(A)** Before arthroscopy the skin incision is marked, for extravasation of arthroscopy fluid will make Langer's lines difficult to detect. **(B)** View of an isolated supraspinatus tendon tear from the portal-extension approach. **(C)** Typical "portal-extension" mini-open incision seen at 3 months after surgery.

more reliably and more rapidly performed using a full open or arthroscopic technique. Also, the limited exposure of the mini-open technique does not allow for adequate visualization of the tear configuration for placement of anchors, tendon-to-tendon repair, or tying of the sutures compared to a full open or all arthroscopic technique. With limited exposure excessive retraction of the deltoid may result in increased morbidity, which includes deltoid injury, detachment of the deltoid origin, and increased postoperative pain. Although the mini-open technique is useful for the smaller tears, it is also true that these smaller tears with minimal retraction are easily treated by full arthroscopic techniques. We currently view the value of the mini-open technique as an option for a surgeon to transition from a full open to a full arthroscopic cuff repair.

Technique for Standard Full Open Superior Approach for Posterior Superior Cuff Tears

Many skin incisions can be used to gain access to the rotator cuff, but in our experience the most versatile and cosmetic incision (6 to 10 cm) is one extending from the middle of the acromion anteriorly to approximately 2 cm lateral to the coracoid in the lines of Langer (Fig. 3-11). This incision can be moved medially if access to the AC joint is necessary or laterally if a large tear is anticipated and the AC joint does not need to be addressed. We use this approach for all large and massive tears.

Following the skin incision, subcutaneous flaps are raised. A 3- to 5-cm deltoid split is made from the anterolateral corner of the acromion distally in the direction of the deltoid fibers for tears limited to the supraspinatus

Figure 3-11 Skin incision in Langer's lines at the superoanterior aspect of the shoulder extending from the lateral aspect of the anterior third of the acromion inferiorly to the lateral aspect of the coracoid.

tendon. A stay suture is placed at the end of the split to avoid extension of the split and possible damage to the axillary nerve, which generally lies 5 to 6 cm from the tip of the lateral acromion. For massive posterior tears, the deltoid split is made more posteriorly, starting at the middle of the acromion to allow for greater exposure of the back of the cuff.[16] The deltoid origin is then elevated over the anterior acromion to the anterior aspect of the acromioclavicular joint, traveling 2 to 3 mm posterior to the anterior edge of the acromion. The dissection is then continued around the anterior edge of the acromion underneath the anteroinferior acromion, so that the entire coracoacromial ligament is subperiosteally elevated and stays as one flap with the anterior deltoid (Fig. 3-12). This keeps a thick flap of tissue with the anterior deltoid, allowing secure repair to the acromion with transosseous sutures.

Once the coracoacromial ligament is detached, there is excellent exposure of the anterior acromion and any spurs that may have developed. An acromioplasty is then performed. A 1-in. wide sharp osteotome or an oscillating micropower saw is used to remove the anteroinferior aspect of the acromion from the AC joint to the lateral edge of the acromion. The amount of bone removal depends on the thickness of the acromion, the degree of anteroinferior acromial prominence, and the size of any spurs. The emphasis should be on contouring a smooth undersurface of the acromion. Rongeurs, rasps, and a burr are used to obtain a perfectly smooth surface. The wedge of bone excised should, however, consist of the full width of the acromion from the medial to the lateral border. If the AC joint is tender preoperatively, a distal clavicle excision will be performed. This is performed from the undersurface using either a rongeur or a burr. The superior and posterior AC ligaments are left intact for distal clavicle stability. If the AC joint is not tender preoperatively, then the AC joint is left undisturbed, even if it is arthritic. If it is felt that inferior AC osteophytes are contributing to impingement, then they are removed, and the undersurface of the AC joint is smoothed. Some surgeons have found a high incidence of postoperative AC pain after such undersurface trimmings, and have suggested that perhaps it is better to either leave the joint unviolated or to completely resect the distal clavicle. However, this has not been our experience.

Once the acromioplasty is performed, the bursa is removed for easy rotator cuff visualization. Mobilization of the rotator cuff is the first step in repairing the tendon. Stay sutures are placed in the retracted rotator cuff tendon, beginning anteriorly and working posteriorly, which can be used for traction while mobilizing the tendon. Clamps (which might crush the tissue) are not employed. To mobilize the tendon, all adhesions are freed, beginning on the bursal side, bluntly separating the tendons from the undersurface of the acromion and deltoid. After complete bursal surface release and exposure, the posterior tissues are assessed to determine the full extent of the cuff tear. Usually a portion of the posterior cuff remains attached to the humeral head (Fig. 3-13).

Releases are performed systematically. First the tendon edges are freshened to remove nonsticking bursal tissue and to stimulate healing, and to remove a tapered edge to yield a thick edge that will hold sutures. This generally means removing 1 to 2 mm of tissue; resection of tendon edges to bleeding tissue is not advocated, as, despite a white, nonbleeding appearance, the edges of cuff tears are, in fact, usually well vascularized. The plane between the cuff tendons and the overlying acromion and deltoid is bluntly developed. The retracted tendons are often scarred to the coracoid base, with fixed shortening of the coracohumeral ligament.[160] This ligament is divided (Fig. 3-14), and the coracoid base is freed anteriorly, laterally, and posteriorly, but not medially (to avoid injury to the suprascapular nerve).

As the tendons retract, the capsule may shorten until the tendons are tenodesed to the glenoid rim. To release them, the capsule is divided external to the labrum. Care must be taken to avoid going more than 1 cm medial to the glenoid rim, lest injury to the suprascapular nerve ensue. The use of a self-retaining laminar-type device placed between the humeral head and acromion, to sublux the humeral head inferiorly, can be extremely helpful in performing these releases (Fig. 3-15).

The tendons commonly retract variable amounts. A frequent pattern is that the supraspinatus is retracted medially, whereas the subscapularis is out to length. In such a situation the anterior margin of the supraspinatus, being

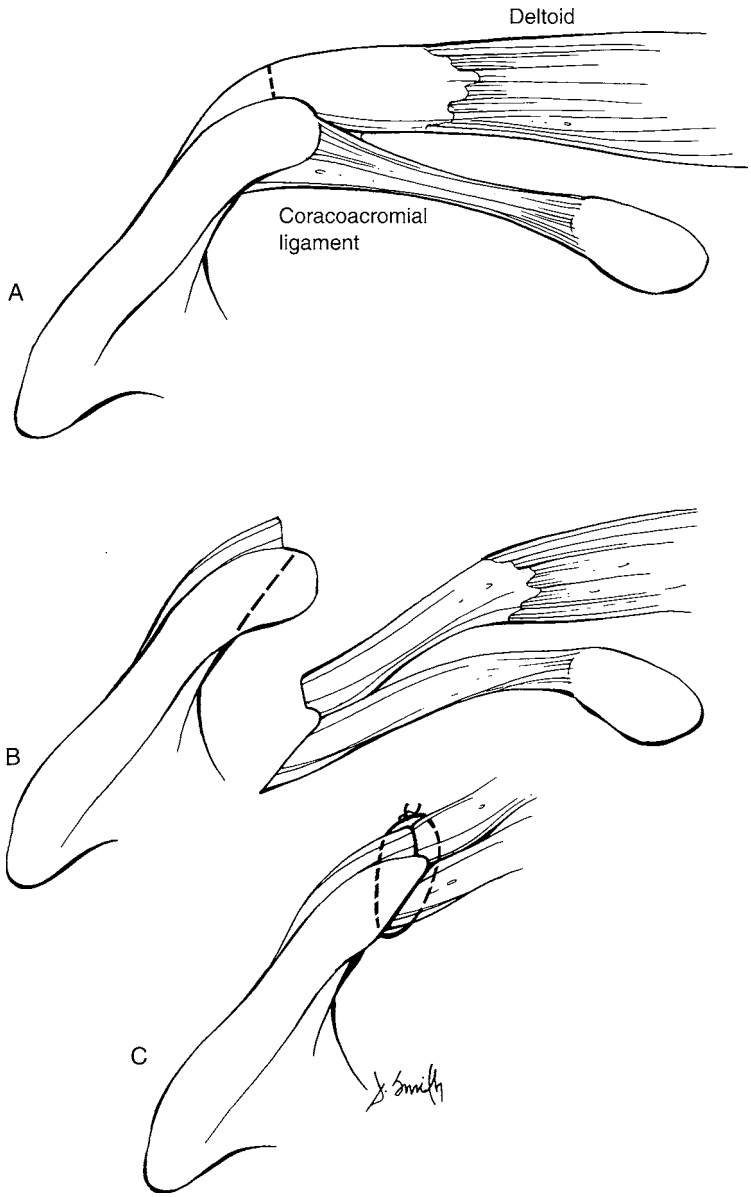

Figure 3-12 **(A)** An incision is made just behind the anterior acromion. **(B)** This is then skived under the acromion to elevate the deltoid and coracoacromial ligament as one flap. The dotted line shows the amount of the acromioplasty. **(C)** The coracoacromial ligament is repaired with transosseous sutures.

medially retracted, is scarred to the medial aspect of the subscapularis. To realign it, an "interval release (slide)"[16] may be helpful. The interval between the supraspinatus and subscapularis is divided to the coracoid base (Fig. 3-16). If there is differential retraction between the supraspinatus and infraspinatus posteriorly, it can also be useful to free the interval between these two tendons (Fig. 3-17). Not only do interval releases allow realignment of retracted tendons, but they also function as "relaxing incisions"[215] so that the tendons, scarred into a circle with the attached capsule at the glenoid rim, may be brought out over the larger-diameter humeral head.

Next the articular surface of the tendon is mobilized. Usually, when the tendon is retracted, the capsule shortens, so that the tendon is essentially tenodesed to the glenoid rim. This may be released by incising the capsule external to the labrum (Fig. 3-18). Care must be taken to avoid injury to the suprascapular nerve at the base of the scapular spine or to the biceps tendon origin. Once the undersurface is freed, the excursions of the tendons are assessed.

If the biceps tendon is intact and gliding in its groove, it is preserved. It is often enlarged and may have minor degrees of fraying. If a significant portion of the biceps tendon is damaged, or if it is subluxed out of its groove (usually in association with a tear or the upper portion of the subscapularis), it is detached from the glenoid and either tenodesed or incorporated into the repair.[31,157]

Intact muscles are generally not rerouted, and tendon transfers for cuff repair are described in Chapter 4. By using the techniques of tissue mobilization described previously,

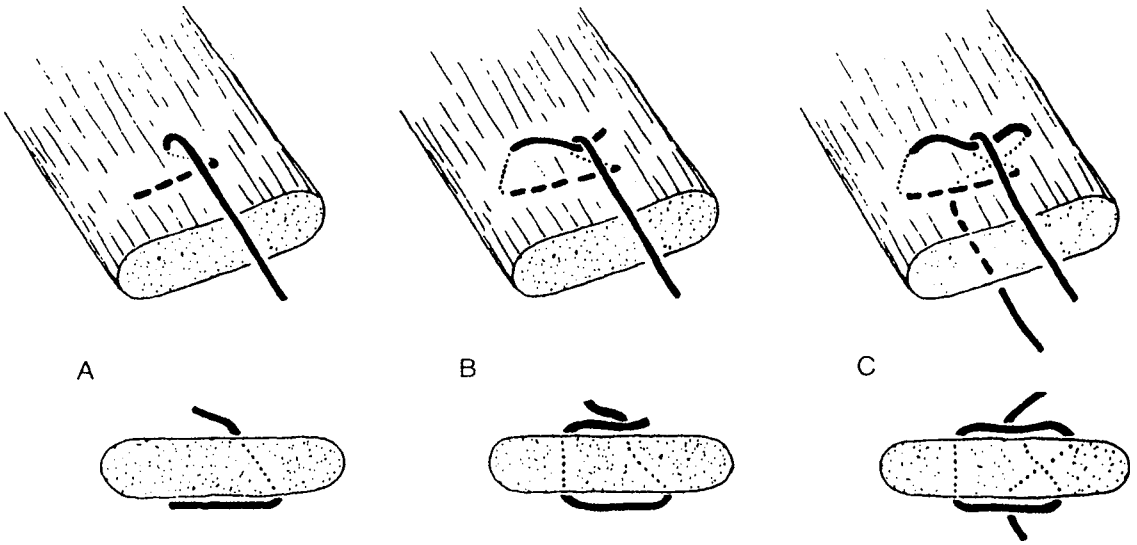

Figure 3-13 Schematic illustration of the Mason-Allen stitch used in rotator cuff repair. **(A)** The stitch is passed obliquely from the superior tendon surface to the inferior tendon surface. **(B)** The suture is then passed directly through the tendon from the inferior surface to the superior surface. **(C)** Finally, the suture is passed in front of the stitch placed in panel A, and brought obliquely through the tendon such that it passes just behind the transverse suture lines present on the inferior tendon surface. This illustration assumes that the suture is now going to be passed through the bone. If the suture has already been passed through a bone tunnel, the steps are inverted (the suture first enters through the inferior surface of the tendon). (From Flatow EL, Weinstein DM, Duralde XA, Compito CA, Pollock RG, Bigliani LU. Coracoacromial ligament preservation in rotator cuff surgery. *J Shoulder Elbow Surg* 1994;3:73, with permission.)

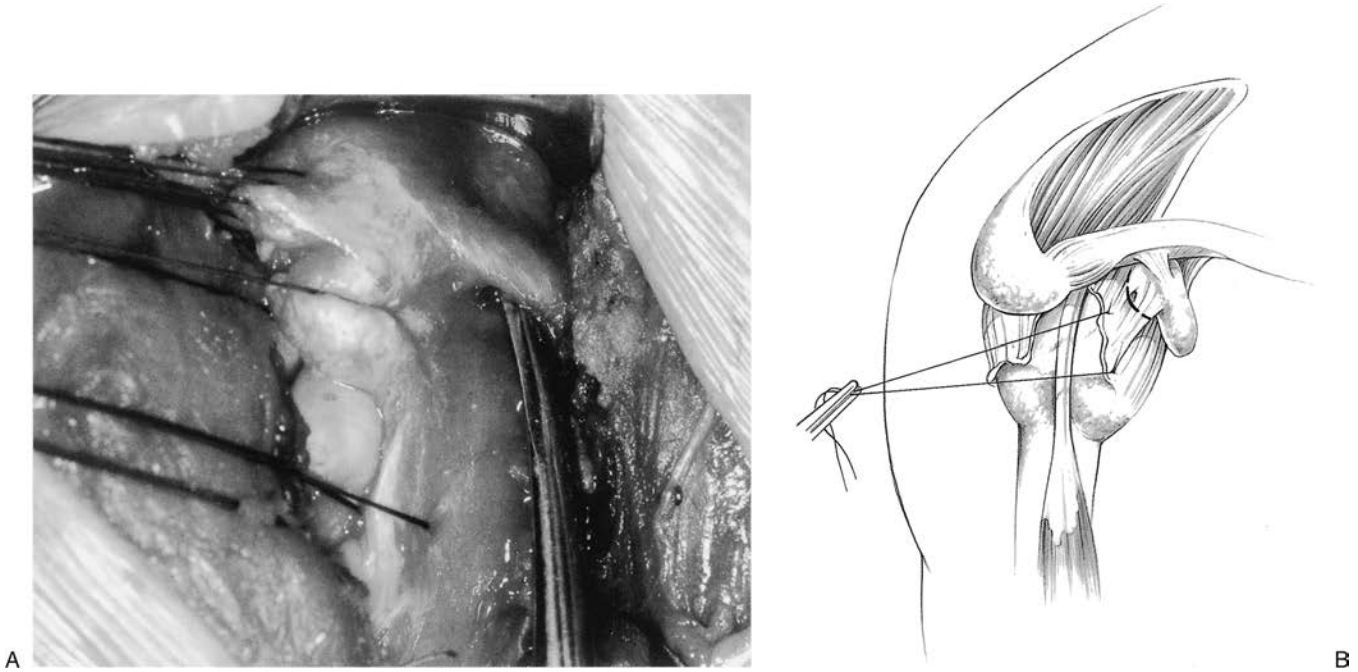

Figure 3-14 **(A)** The coracohumeral ligament (at end of instrument) is contracted, tethering the retracted tear edge to the coracoid. **(B)** This ligament must be divided (*dotted line*) and the coracoid base freed to mobilize the tendon. (From Lazarus MD, Yung S-W, Sidles JA, Harryman DT. Anterosuperior humeral displacement: limitation by the coracoacromial arch. American Academy of Orthopaedic Surgeons, 62nd Annual Meeting, Orlando, Florida, February 1995, with permission.)

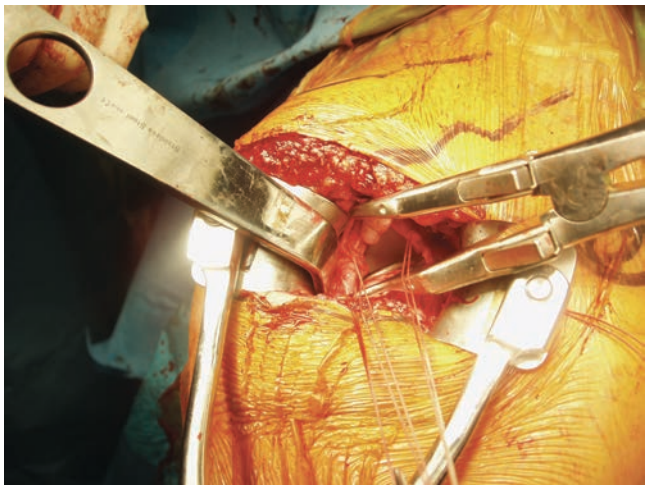

Figure 3-15 Lamina spreader-type device designed by Christian Gerber to subluxate the humeral head from the glenoid to gain access to the superficial and deep portion of the rotator cuff and capsule and to see within the joint.

tendon repair may be achieved in all but a few rare situations. These repairs may sometimes be imperfect, reattaching an atrophied muscle by thin, poor-quality tendon tissue. However, reattachment gives the muscle–tendon units a better chance for functional recovery than leaving them disinserted. If there is significant loss of cuff tissue and full repair is not possible, the anterior and posterior cuff are mobilized cephalad as much as is possible to gain a better fulcrum for head depression.[27]

The greater tuberosity is prepared for tendon repair by removing all soft tissue and smoothing irregular bony prominences with a rongeur or curette. A deep trough is not used, for it requires more tendon mobilization and has not been shown to be necessary to promote tendon-to-bone healing. There are many ways to make a tunnel in bone for passing sutures. Among the techniques that we find useful include the use of a set of reusable curved awls (Link America, Denville, NJ), disposable suture passing set (Linventec), or a custom power tool such as a Curvetec. An inexpensive method is the use of a heavy cutting needle on a heavy needle passer that can be loaded with suture directly and passed through the bone of the greater tuberosity. The tendon is then repaired to the greater tuberosity, with the arm at the side in a neutral position. A combination of simple and Mason-Allen stitches are used at the tendon edge. In all methods the bone holes should remain small and separated by about 1 cm of bone and should be at least 2 cm from the top of the greater tuberosity. Adhering to these principles will minimize the sutures cutting through the bone. When the bone is very weak, use of a bone augmentation device (plate or plastic button) can be used beneath the sutures and the knots tied over the device (Fig. 3-19).

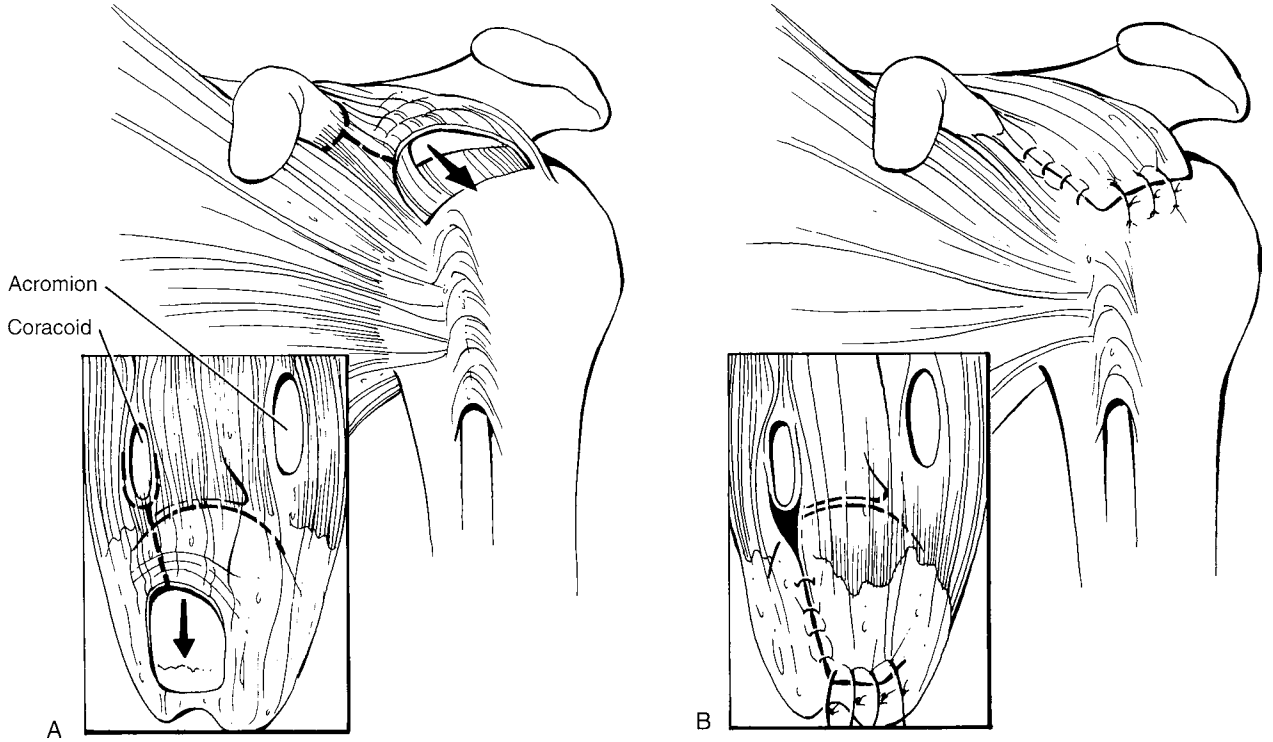

Figure 3-16 **(A)** If there is differential retraction, release of the rotator interval (*dotted line*) can allow realignment of the supraspinatus tendon (*arrow*). **(B)** After the tendon is repaired to the bone, the interval is sutured. (Redrawn from Calvert P, Packer N, Stoker D, et al. Arthrography of the shoulder after operative repair of the torn rotator cuff. *J Bone Joint Surg Br* 1986;68:147–150.)

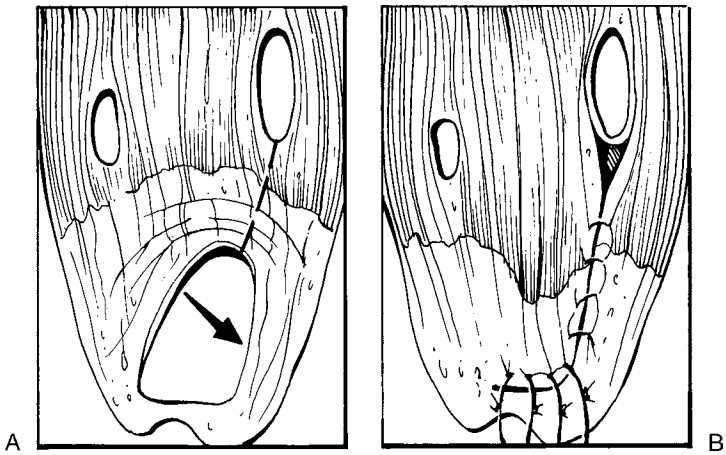

Figure 3-17 **(A)** If the tear is retracted with the greatest differential retraction between the posterior supraspinatus and the infraspinatus, a posterior interval release (*dotted line*) is performed, separating these two tendons so that the supraspinatus tendon may be mobilized (*arrows*). **(B)** After the tendon is repaired to bone the interval is repaired with sutures. (Redrawn from Calvert P, Packer N, Stoker D, et al. Arthrography of the shoulder after operative repair of the torn rotator cuff. *J Bone Joint Surg Br* 1986;68:147–150.)

We still prefer transosseous sutures over metallic suture anchors in open cuff surgery because of the variable strength of the tuberosity bone in these often elderly cuff-disease patients (unlike the uniformly hard bone of the anterior glenoid in instability patients or in younger patients with smaller tears and better bone for arthroscopic cuff repair). Also, the attached sutures tend to hold loose anchors in the superior joint, where articular damage may result (Fig. 3-20). However, technical improvements, including plastic anchors, resorbable anchors, and better fixation techniques, may make implants more attractive in the future.

Following repair of the rotator cuff, the deltoid is repaired, which is as important as the rotator cuff repair itself. A heavy no. 2 nonabsorbable suture is used to reattach the deltoid back to the anterior acromion. An anatomic repair can be achieved by passing one suture through the AC joint capsule and then two sutures through the bone of the acromion. A Mason-Allen suture[92] technique (see Fig. 3-13) is used to hold the deltoid fibers securely. The deltoid split is closed in a side-to-side fashion with simple buried knots. The coracoacromial ligament is repaired together with the anterior deltoid flap to the anterior acromion. This provides a buttress that may provide restraint from superior migration or anterosuperior instability of the humeral head.

Depending on the quality of tissue and repair, postoperative rehabilitation is tailored to the security of the repair and the quality of the tissues. Braces that hold the arm in wide abduction and external rotation are not used. However, occasionally, the posterior cuff is repaired with some tension, and a brace to hold the arm in slight abduction

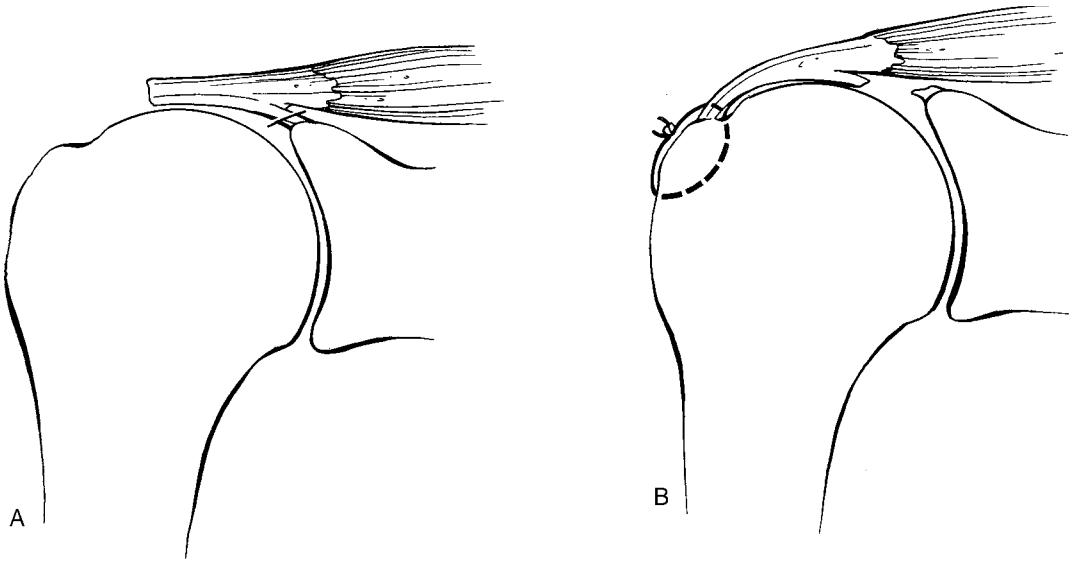

Figure 3-18 **(A)** If the retracted tendon is tethered to the glenoid rim by a shortened, fibrotic capsule, the capsule should be incised (*dotted line*). **(B)** This allows mobilization and repair of the tendon.

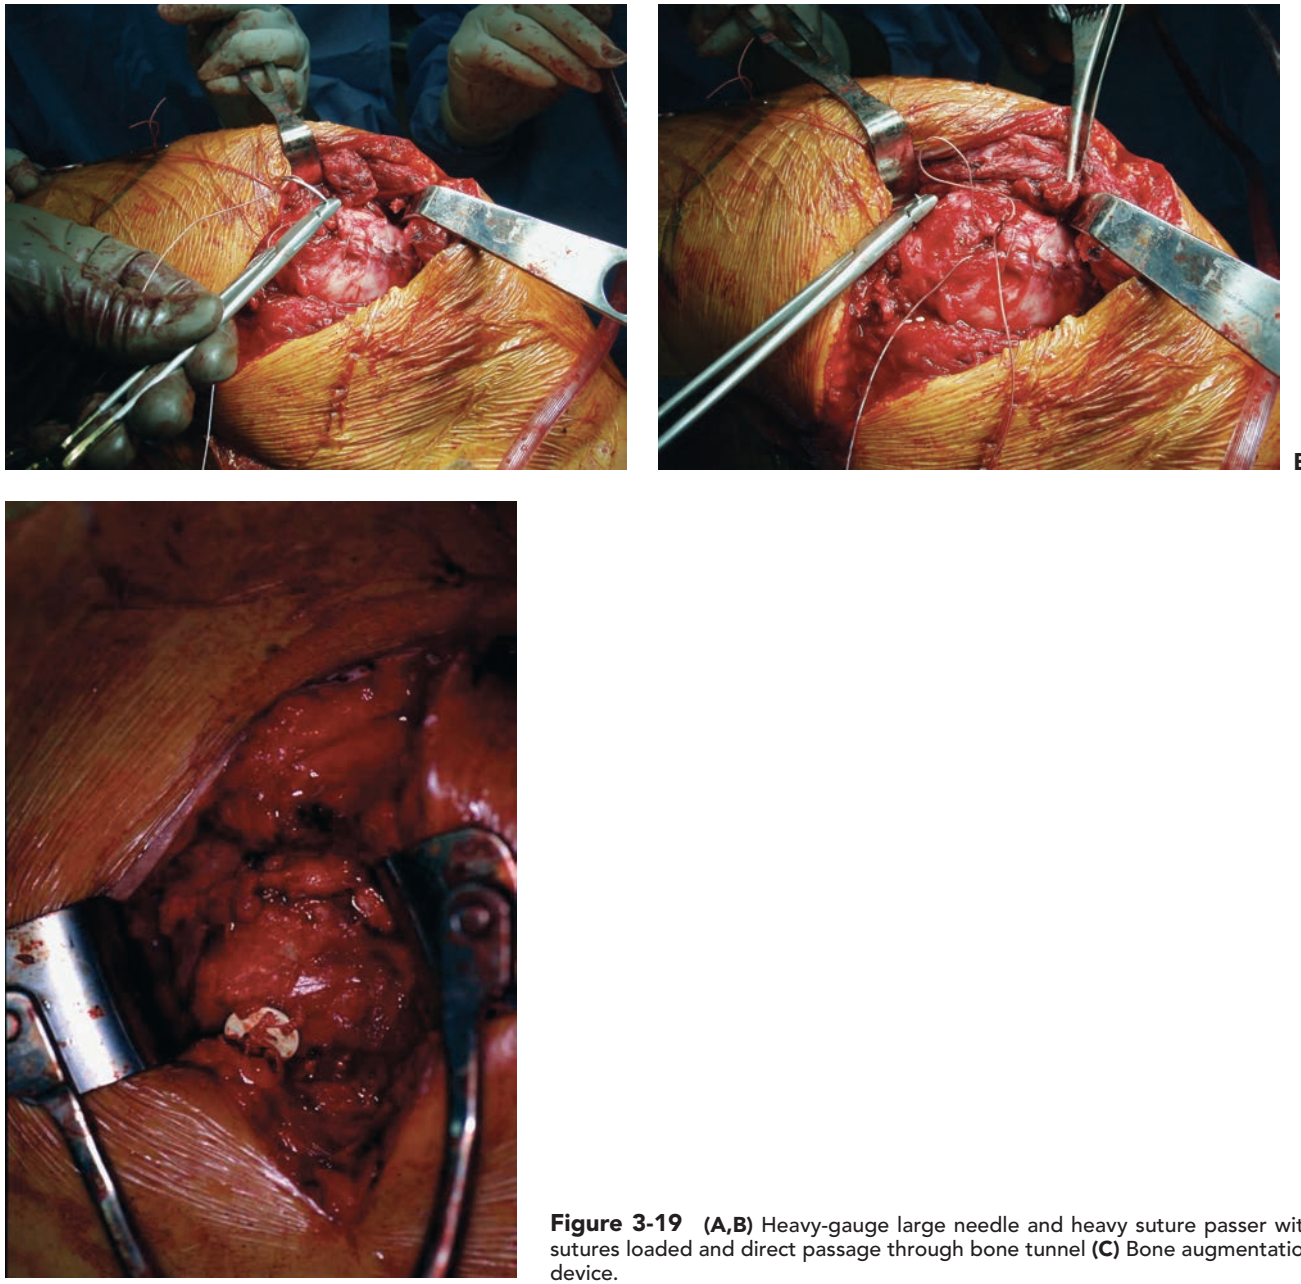

Figure 3-19 **(A,B)** Heavy-gauge large needle and heavy suture passer with sutures loaded and direct passage through bone tunnel **(C)** Bone augmentation device.

and neutral rotation may be used; this avoids the sling position of internal rotation across the body. Passive motion is still begun immediately, with the therapist or a trained family member raising the arm in the scapular plane above the brace.

Postoperative Care for Open Repair

A physician-directed rehabilitation program is usually begun on the first postoperative day. For very massive tears with poor tissue, only pendulum and passive elevation in the scapular plane by the surgeon, the therapist, or a trained family member are used for the first 6 weeks. Pulley elevation is not used owing to the significant active cuff recruitment that results.[139] Elevation is allowed to a level determined at the time of repair, usually between 120 and 140 degrees. Assistive exercises are begun at 6 weeks, but active elevation and light resistive exercises are not allowed until 3 months after repair of these massive tears. Patients after repair of medium and large tears with good tissue begin an assistive program immediately, and active exercises (progressing slowly to light resistive) are added between 6 and 8 weeks postoperatively.

The use of a standard sling versus a small pillow sling versus an abduction brace or large pillow for large posterior-superior two-tendon rotator cuff tears remains controversial. In cases with two-tendon tear involvement

Figure 3-20 This metal anchor has pulled out of the soft bone of the tuberosity. Because it is attached to sutures on the cuff edge, it has stayed adjacent to the articular surface.

(supraspinatus and infraspinatus tendon tears) one of the authors (JPI) will routinely use an abduction brace for the first 4 weeks after surgery. The brace is removed a few times each day for washing, dressing, eating, and doing the exercises noted previously. The patient will otherwise wear the brace during the first 4 weeks after surgery for about 18 to 20 hours each day. Thereafter, the patient is protected in a sling for an additional 2 weeks. Smaller tears treated by either open or arthroscopic means are treated with a sling for 4 weeks after surgery with the same mobilization protocol. The rationale for this different method of postoperative care is based on the increased tissue tension present in large tears with muscle atrophy and fibrous tissue formation within the muscle. This increased tissue tension results in greater tension at the repair site, particularly with the arm by the side. In addition, one of the authors (JPI) believes the use of a brace significantly decreases the patient's overall activity level. With this combination of factors, we believe our results of tendon healing are improved compared to sling immobilization alone.

A study by Reilly et al. showed that supraspinatus tendon tension was reduced by 34 N when the arm was abducted 30 degrees.[186] Tendons repaired in a cadaver that were subjected to 34 N of force over 24 hours gapped an average of 9 mm. Davidson and Rivenburgh showed that the repair tension in 67 rotator cuff repairs correlated with lower Constant scores if it was greater than 8 lb at the time of the repair.[59] Hersche and Gerber measured the tension in a normal supraspinatus tendon with the arm at the side and compared it to the tension in a chronically torn tendon repair with the arm at the side.[115] The normal tendon generated 25 N of force, compared to 59 N of passive tension in the pathologic tendon.

Technique for Anterior Deltopectoral Approach for Isolated Subscapularis and Anterior-Superior Cuff Tears

A deltopectoral approach is considered a preferred technique over a superior approach for open repair for full-thickness tears of a majority of the subscapularis tendon, particularly when the tendon is retracted and the tear is more than 2 months from injury (Fig. 3-21). In these cases the retracted tendon can be more easily and safely found and mobilized. In these cases the axillary nerve should be localized and retracted. After initial exposure there is often a fibrous tissue covering the humeral head and joint, which needs to be excised to expose the joint and find the torn tendon. This tissue can be quite thick and in some cases may seem to be an intact tendon, but when the humerus is rotated this tissue can be seen not to move with the humeral head or lesser tuberosity (Fig. 3-22). With a chronic tear, the retracted tendon is often scarred in a retracted position requiring release of the scarred and contracted coracohumeral ligament and anterior capsule.

After the tendon is mobilized, suture fixation to the decorticated lesser tuberosity is accomplished by suture anchors or with bone tunnels. Mobilization of the tendon

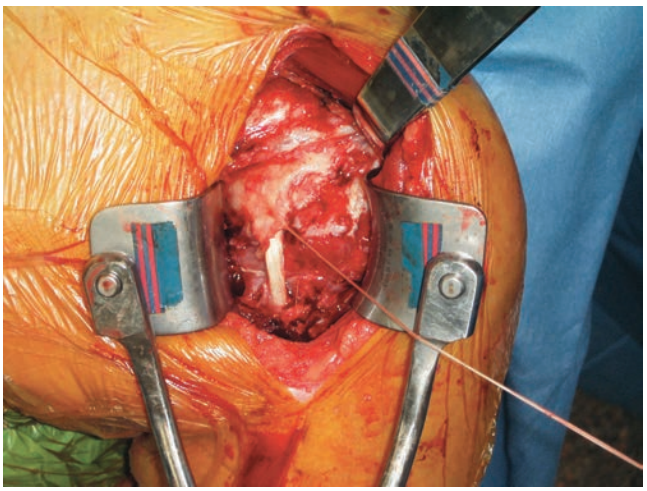

Figure 3-21 Deltopectoral approach for subscapularis tendon tear. This provides excellent exposure and adds a greater margin of safety to the axillary nerve when mobilizing the retracted tendon.

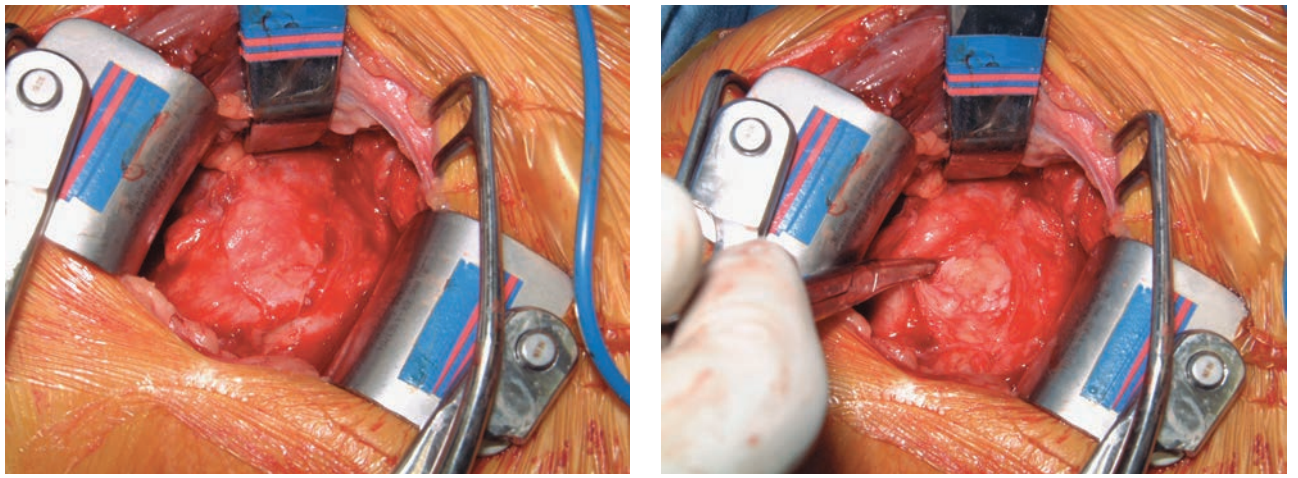

Figure 3-22 **(A)** The thickened bursae over the torn subscapularis can at times make the initial exposure of the tendon seem as if it were intact. **(B)** It is necessary to incise and then excise this tissue to identify and repair the tendon.

should be sufficient to allow the tendon to be repaired to bone with at least 0 degrees of external rotation.

Postoperative rehabilitation should include use of a gunslinger-type brace or small abduction pillow. It is advisable to have the arm in neutral rotation rather than in full internal rotation. Scarring in a full internal rotation (sling) can make rehabilitation to achieve external rotation difficult.

In some patients with massive tears of the subscapularis, supraspinatus, and portions or all of the infraspinatus, there is a need to combine the deltopectoral and superior approaches.

Technique for Arthroscopic Repair of Full-Thickness Tears

Five standard portals are most commonly used (Fig. 3-23) for a full arthroscopic cuff repair. The first is the posterior portal for the evaluation of the glenohumeral joint (Fig. 3-23, portal a). A second posterosuperior portal placed at the posterolateral angle of the acromion and is used for the subacromial space (Fig. 3-23, portal b). Two instrumentation portals are initially localized using a spinal needle working from outside in. One is a portal near the midlateral acromion and another portal is more anterior near the coracoacromial ligament (Fig. 3-23, portal c and d). The fifth approach is anterosuperior at the anterolateral corner of the acromion (Fig. 3-23, portal e).

Diagnostic Arthroscopy

A systematic assessment of the glenohumeral and subacromial space is done both statically and dynamically to assess tissue quality and mobility of the tendon tissue. After a complete visualization, the degree of cuff retraction and mobilization to the insertion site is tested. In many cases the tendon will be under tension when pulled to the greater tuberosity or will not be able to reach the greater tuberosity with the arm adducted to the side of the body. In these cases a periglenoid capsular and subacromial release of bursae, scar, and adhesions is performed so that the tendon can be easily pulled to the tuberosity with the arm by the patient's side. The release is essential to perform the repair without excessive tension. Mobilization is performed from medial to lateral for U-shaped tears (Fig. 3-24A–C) or by reducing with traction on the tendon combined with humeral rotation in L-shaped tears (Fig. 24D,E). Special attention is given

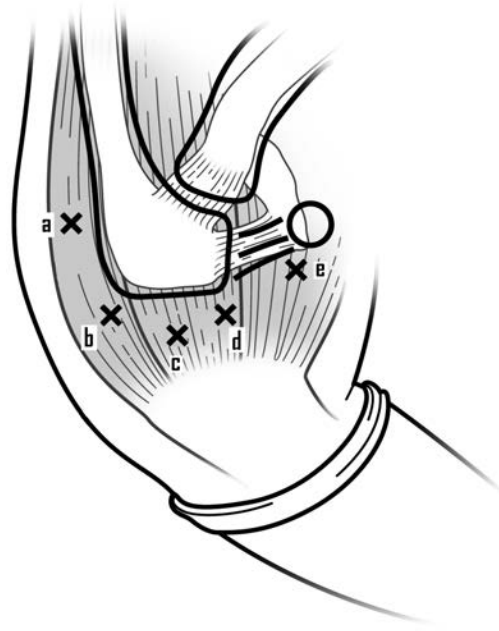

Figure 3-23 Arthroscopic portals for repair of full-thickness rotator cuff tears.

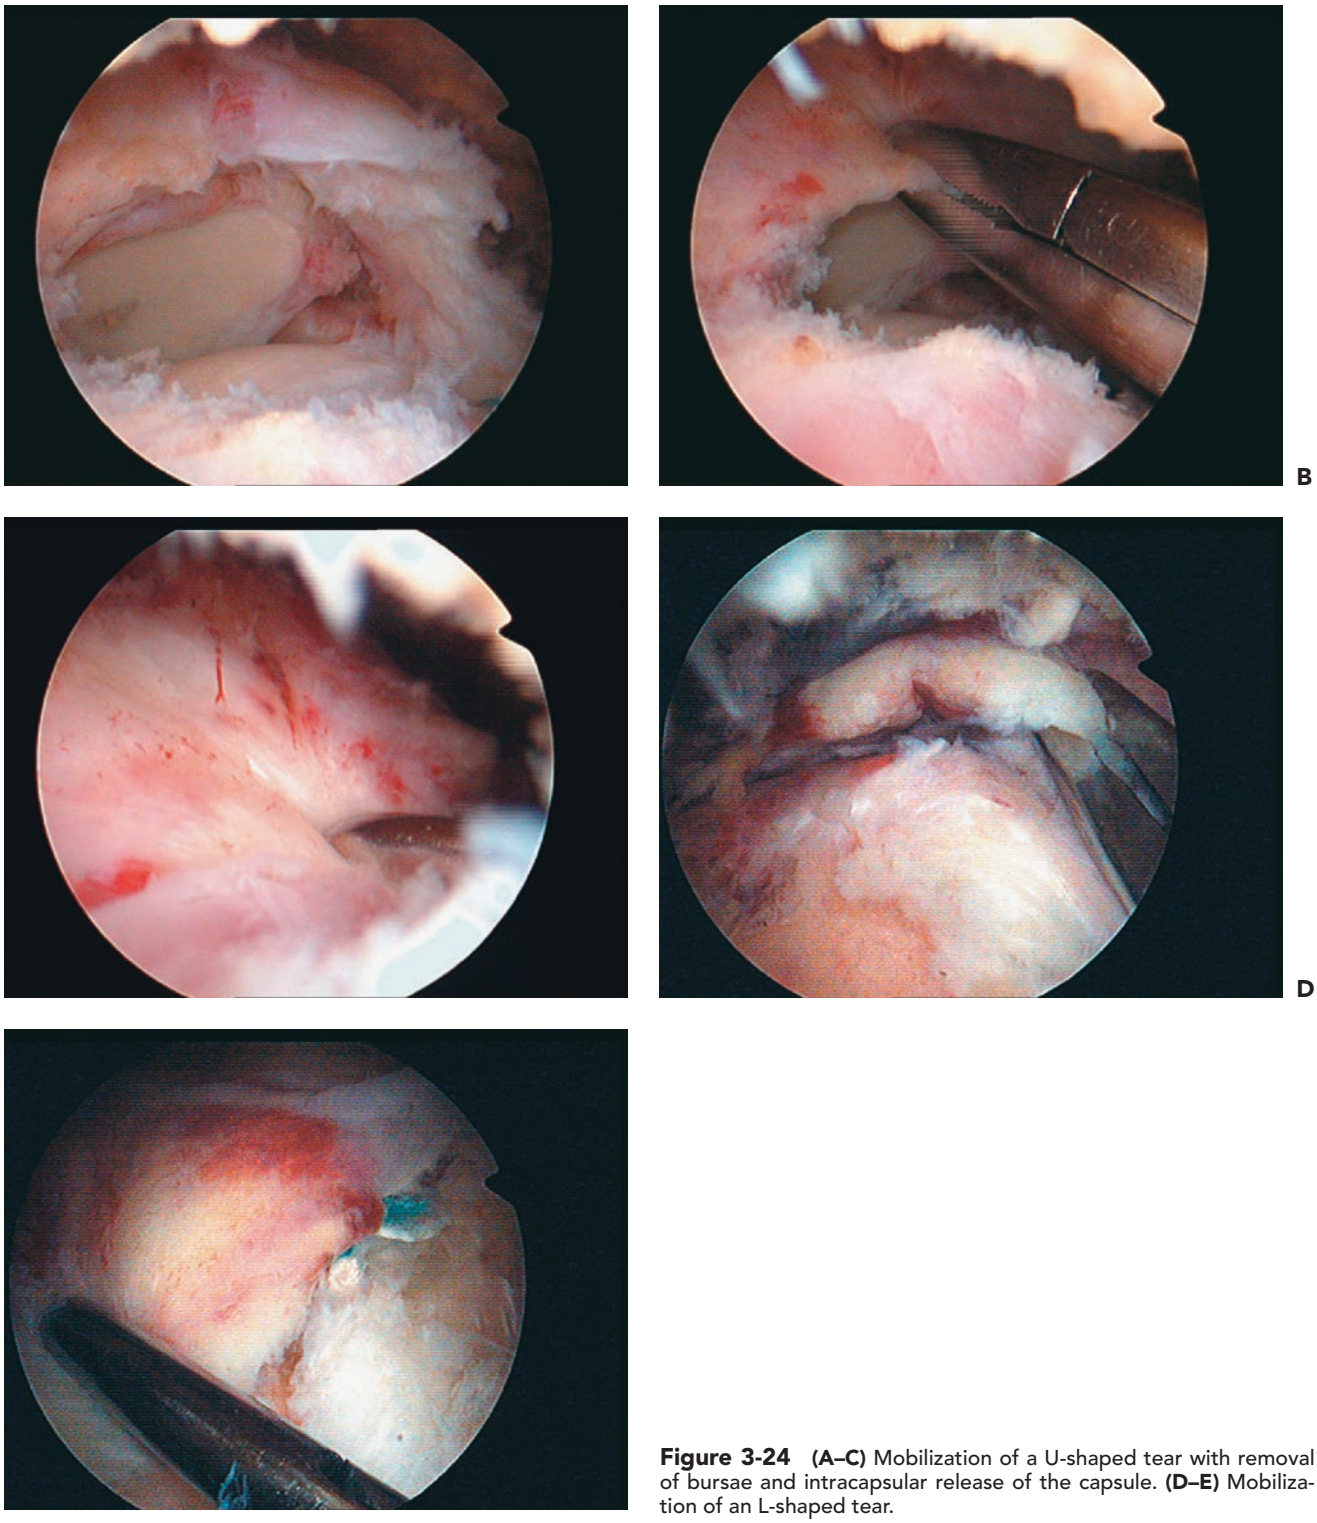

Figure 3-24 **(A–C)** Mobilization of a U-shaped tear with removal of bursae and intracapsular release of the capsule. **(D–E)** Mobilization of an L-shaped tear.

when delamination occurs to repair both deep and superficial leaves of the tear; this is more commonly seen in massive posterior cuff tear.

The stability of the origin of the long head of the biceps tendon is evaluated with a probe. Its stability within the groove is inspected and with internal and external rotation of the arm to check the anterior and posterior pulley. Instability may require repair, tenodesis, or tendon release.

Based on cuff tear size, the ability to mobilize the cuff to the tuberosity and the biceps tendon, and muscle quality, the plan for further treatment is made intraoperatively.

Acromioplasty is systematically performed in addition to the tendon repair, except for massive, partially repairable ruptures where the coracoacromial arch is the last structural element to keep superior stability and avoid anterior-superior escape of the humeral head. If lack of space impedes the exposure or the passage of the instruments, acromioplasty is performed prior to repair of the tendon; otherwise it is done after repair so as to avoid this as a source of bleeding during the repair. The coracoacromial ligament is released with an electrocautery; a burr is used to remove bone form the acromion starting at the anterior lateral corner and proceeding medial to the AC joint to achieve a flat type I acromion (Figs. 3-4 and 3-5).

Mobilization of the Tendon Tear

For large retracted tears the intraarticular capsular and subacromial release is essential to mobilize the tear and decrease the traction on the repair. We used to do it with a bipolar electrocautery device.

For posterosuperior cuff tears, the coracoacromial ligament is released from the base of the coracoid at the anterosuperior edge of the glenoid rim with intraarticular assessment. The capsule is released above the labrum from the anterior-superior to posterior-superior quadrants. Released bursal side scar tissue is removed medially until the cuff muscle is seen.

Special care must be given to the subscapularis release for massive retracted tendons as it usually requires visualization of the axillary nerve and the medial plexus with the axillary artery (Fig. 3-25). This can be a dangerous part of the surgery that should not be done without advanced expertise.

Tendon Fixation

Anchors: The type of fixation depends on the bone quality and influences the technique used for anchor insertion. The use of push-in anchors (vs. thread-in anchors) enables the surgeon to pass a suture through the cuff first and then load the anchor with the suture and place the anchor in bone. When using screw-in anchors or anchors with two preloaded sutures, an anchor-in first technique is required.

Location: Location of the fixation is done according to the lesion, but whenever possible, restoring the normal footprint of the rotator cuff is performed by adding a double row of anchors. One row restores the lateral tendon attachment and the other the medial cartilaginous attachment.

Suture: Suture type #2 or #3 is always a braided nonabsorbable. Absorbable sutures break before tendon healing. Different techniques to pass the braided suture through the tendon using different devices must be available:

- A two-step technique uses a suture passer (Linvatec) equipped with a 45-degree curved hook (left rotated mostly used for a right shoulder and vice versa), loaded with a simple PDS #0 pushed through the hook (Fig. 3-26). The PDS is grasped by a forceps and can be pulled out through the same or a different portal. The PDS is easily used as a shuttle relay for passing a nonabsorbable suture, which is already fixed to an anchor. This avoids any twist or soft tissue interposition when many sutures are used.
- Direct braided suture passing is done in two ways:
  1. An instrument loaded with the suture is grasped by a second retriever (Fig. 3-27); the instrument from a second instrument portal is used to grasp the suture. Alternatively, the same instrument can be used in the same portal by a straight-shaped (Fig. 3-28) or a curve-shaped instrument (Fig. 3-29) once the tendon is perforated. A special shuttle instrument allows for this to be done in one step (Fig. 3-30). The difficulty is in releasing the suture from the instrument without pulling it out of the tendon and grasping it with the same instrument. Lastly, a disposable instrument can pierce the tendon and with a retractable wire can grasp the suture passing this through the tendon (Fig. 3-31).
  2. A suture is retrieved by using a perforating grasper already passed through the tendon. The difficulty with this technique is in anticipating the position of the retriever and preparing to bring the suture to the retriever (Fig. 3-32).

Whatever device or technique is used, the key of the tendon perforation is the access and the direction of the device to perforate the tendon as perpendicular as possible to the direction of the fibers. An in-line device must come from the top or the bottom of the tendon; a curved device should come perpendicular to the tendon (from either the anterior or posterior portal for the supraspinatus tendon),

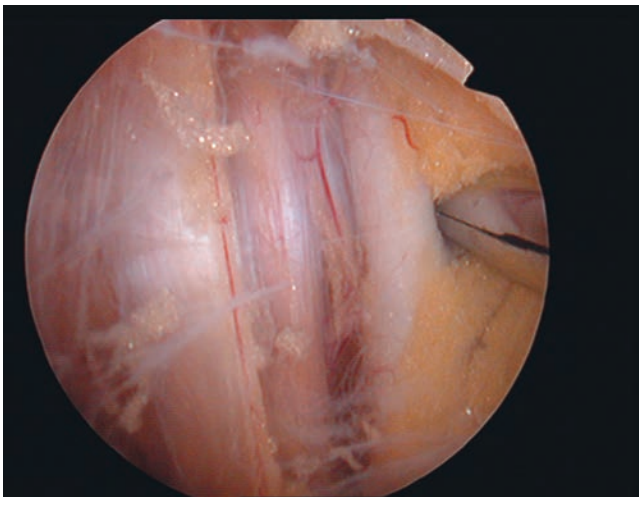

Figure 3-25 Arthroscopic view of the brachial plexus, which often is required for arthroscopic mobilization of a retracted chronic subscapularis tear.

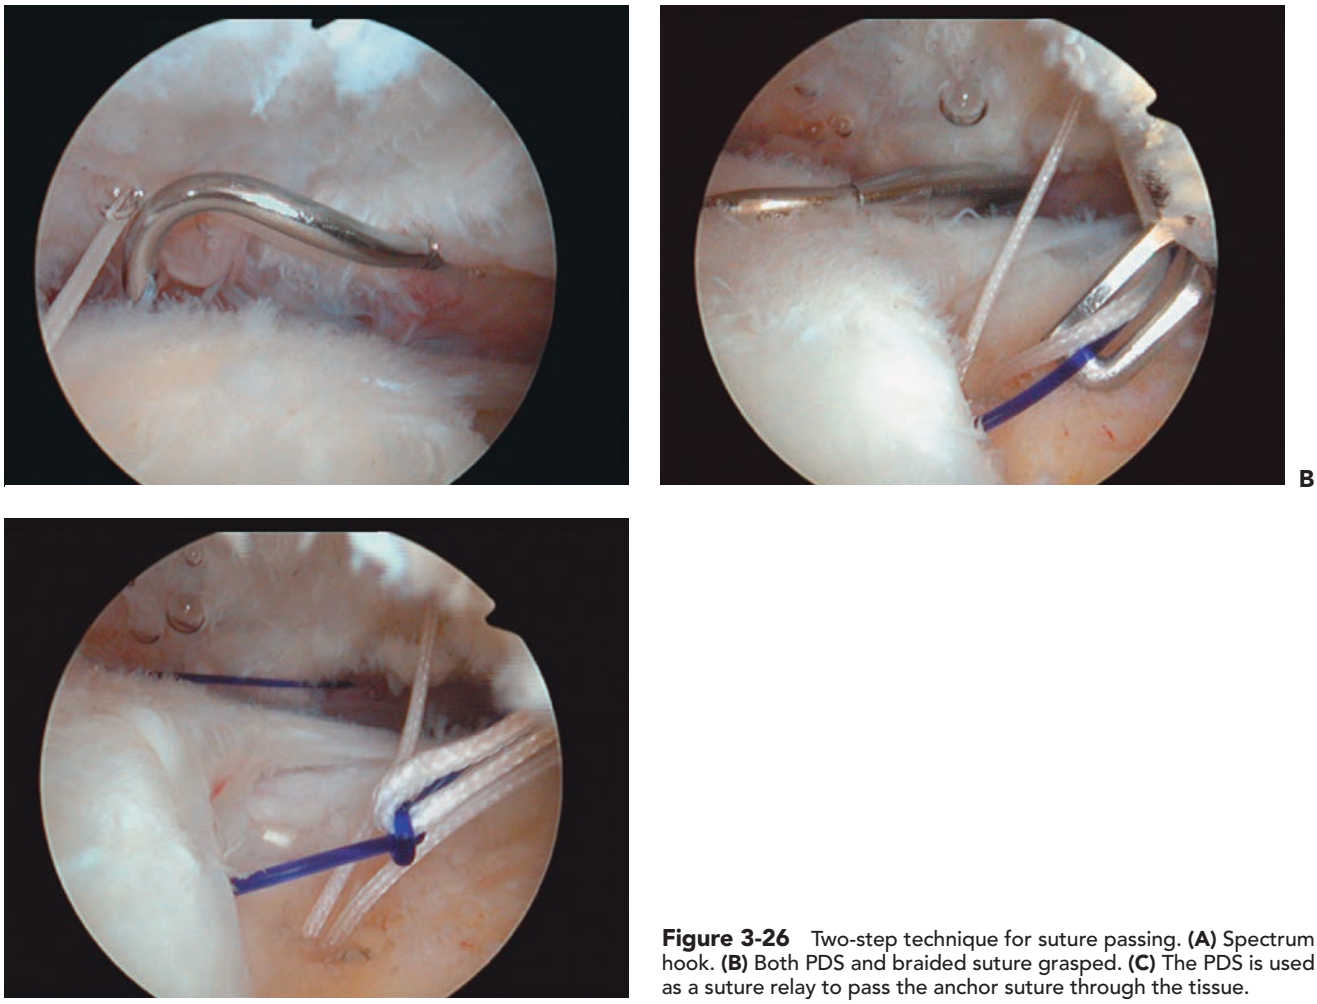

Figure 3-26 Two-step technique for suture passing. **(A)** Spectrum hook. **(B)** Both PDS and braided suture grasped. **(C)** The PDS is used as a suture relay to pass the anchor suture through the tissue.

except for the Express Sew (Arthrex), which has a different shaped needle that can perforate the side of the tendon.

Different Stitches: A few different stitches are possible (Fig. 3-33):

- Simple stitch
- U shape by perforating the cuff from the superficial to the deep layer and back by twisting the perforating hook in one pass of the instrument, to realize a guy rope attachment (see Fig. 3-7)
- A mattress suture by performing successive passage of the suture through the cuff

Side-to-Side Suture: A "lasso" technique was developed by one of us (LL; Fig. 3-34). The aim is to have increasing hold and approximation of the tissue as the suture is pulled and the knots tightened. Once a double braided suture is passed through the two tendons or two edges of the same tendon, then one of the free ends of the same suture is passed through the loop located on the other side. The suture through the loop is tied to the other side of the suture. When the suture is pulled through the loop it gives a perfect method for tightening the suture on the tendons.

Full-Thickness Tears

With a full-thickness tear, reattachment of the tendons establishes an anatomic footprint of the tendon using two rows of suture, one row medially at the cartilage–bone interface and the other row on the lateral aspect of the great tuberosity (Fig. 3-35).

Tears Isolated to the Supraspinatus (Small and Medium-Sized Tears)

After removal of the bursal scar and mobilization of the tendon, the repair starts with medial fixation. The anchor is passed through an accessory small portal (about 2 to 3 mm) situated at the lateral border of the acromion to reach the greater tuberosity as perpendicularly as possible (Fig. 3-36). The repair is done with visualization of the biceps tendon as described for a partial deep cuff tear, or from subacromial if the biceps is torn or fixed to the groove (tenodesis). Bone suture fixation is done with an anchor through the anterosuperior portal. The sutures need to be passed with a mattress

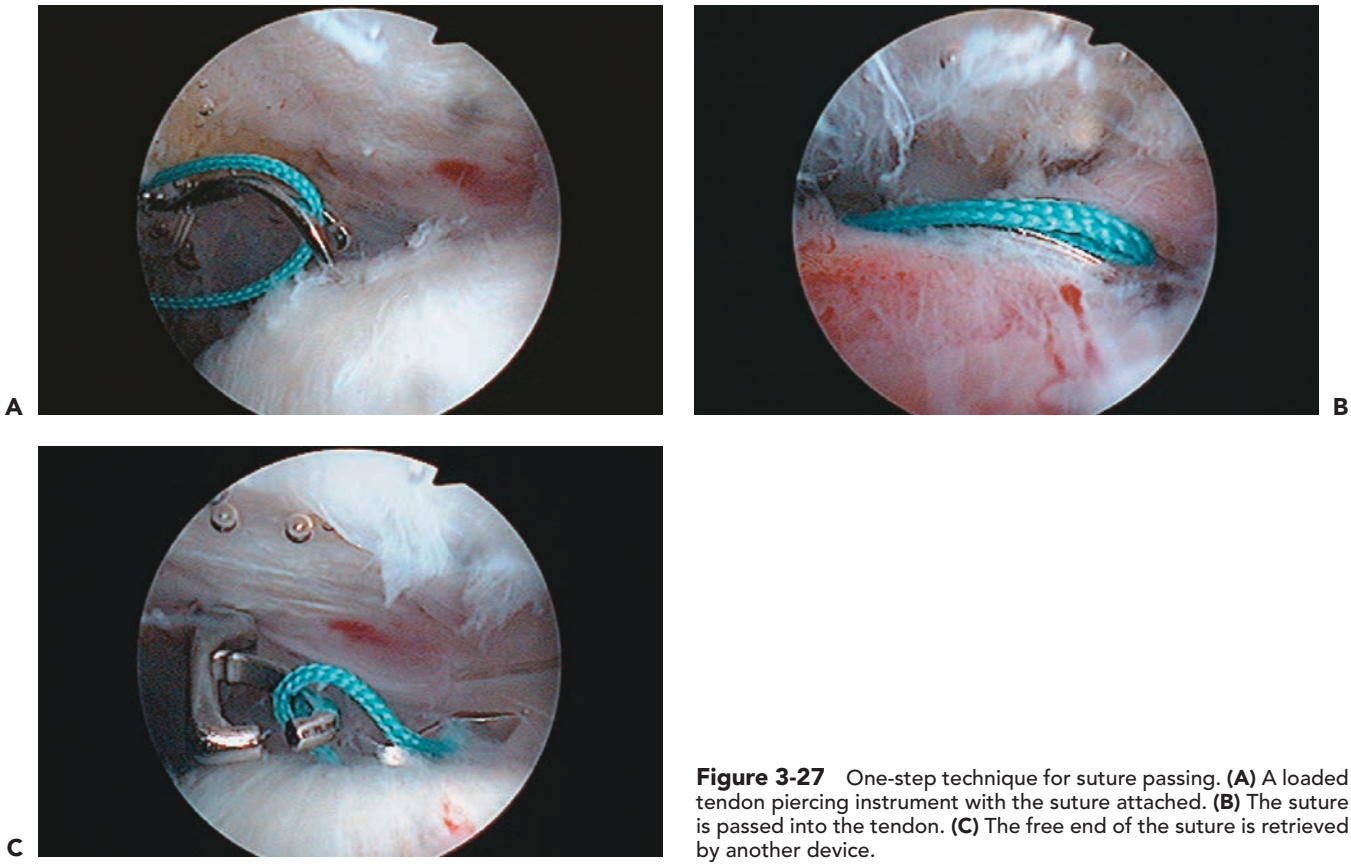

Figure 3-27 One-step technique for suture passing. **(A)** A loaded tendon piercing instrument with the suture attached. **(B)** The suture is passed into the tendon. **(C)** The free end of the suture is retrieved by another device.

technique approximately 15 mm from the edge of the tendon and each limb of the suture approximately 5 mm from one another. There are many ways to pass these sutures, as described previously in this chapter. These sutures are not tied at this point but pulled through an anterior portal to keep them out of the surgical field.

A second anchor is then placed laterally and the sutures passed as a simple stitch or a U stitch for a guy rope technique as described previously. The Spectrum instrument is often used for a U stitch and a grasper may be used for a simple stitch. Knots are tied first with the lateral fixation followed by the medial sutures.

Extension into the Infraspinatus Tendon

Tears that extend into the infraspinatus tendon are often L shaped. These tears require a reverse approach for the tendon-to-bone reinsertion. The arm is placed closer to the side of the body. The visualization is through the anterolateral portal. The tendon is pulled from posterior to anterior and to a lesser degree from medial to lateral. The first anchors are placed at the posterolateral border of the greater tuberosity following the same principles of a supraspinatus repair but using two posterior portals for the instruments. In cases of a laminated tear, the deeper-flap one is fixed first to the medial part of the tuberosity (Fig. 3-37). Before tendon fixation to bone, a tendon-to-tendon suture repair is necessary between the split in the infraspinatus tear to close the "L" portion of the tear. The side-to-side sutures between the supra- and infraspinatus are performed after the tendon to bone to perform an anatomic repair with lateral view and both anterior and posterior portal for instrumentation.

Subscapularis Tendon Tears

Tear of the Upper Third. Subluxation or dislocation of the long head of the biceps tendon (LHB) is often associated with this pathology. When the LHB is in its normal position in the groove, then one needs to be careful neither to create instability by damaging the medial pulley nor to create an impingement between the LHB and the knots tied for subscapularis fixation. The entire operation is performed in the anterior portal and a lateral portal, or alternatively located at the rotator interval near the LHB. The scope is placed near the bicipital groove and is oriented inferior. To expose the subscapularis, the arm must be positioned with more flexion than usual. After abrasion of the lesser tuberosity, an anchor is inserted just in front of the biceps groove and the braided suture is passed through the subscapularis tendon in the same manner as used for the other tendon repairs (Fig. 3-38). The suture retriever may be passed through the canula or the anterosuperior portal

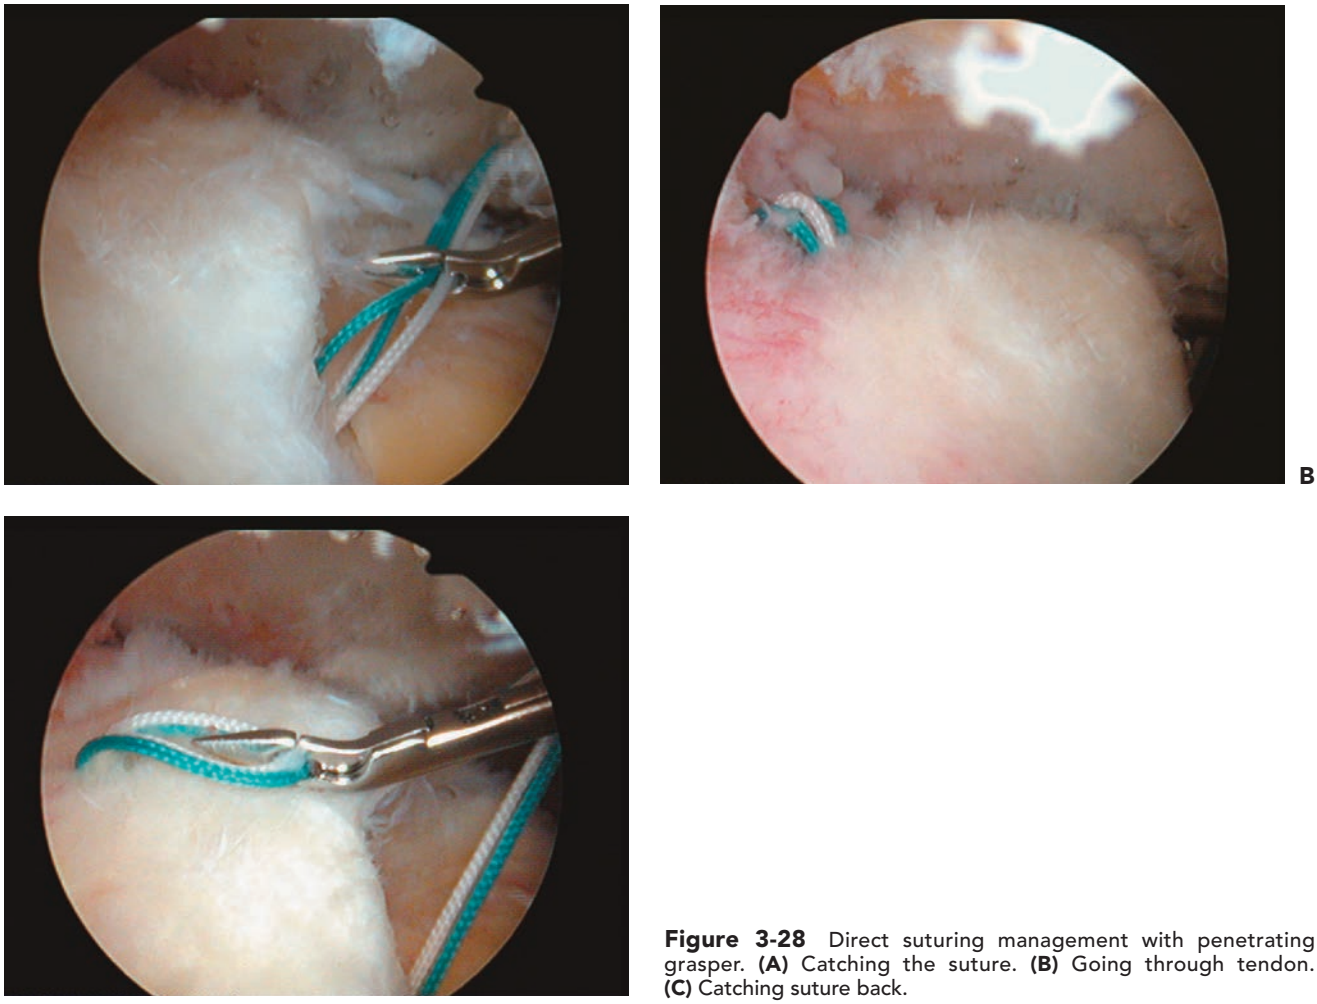

Figure 3-28 Direct suturing management with penetrating grasper. **(A)** Catching the suture. **(B)** Going through tendon. **(C)** Catching suture back.

based on the location of the tendon. A U and simple suture are used on an anchor with a double suture. While pulling at the strands, the knot is tightened and the arm is internally rotating to help reduce the tear.

ROLE OF BIOLOGIC ENHANCEMENT OF ROTATOR CUFF REPAIR

Rotator cuff tears fail to heal in 5% to 90% of cases depending upon the size of the tear, chronicity of the tear, degree of muscle atrophy, amount of fibrofatty degeneration, and method of repair. There is a growing interest in methods to enhance the biologic potential of rotator cuff tendon repair through the use of naturally occurring extracellular matrices (ECMs). Several of the currently available and Food and Drug Administration–approved products are listed in Table 3-1. ECMs are naturally occurring three-dimensional constructs that are harvested from human or animal tissues and are often processed by the manufacturer to remove most of the cellular components. The goal for removal of the cells is to decrease the antigenicity of the material. Cell removal involves different, often patented and proprietary processes that can include saline and mild acidic washes and in some cases the use of enzymes to remove DNA and RNA. The degree and consistency of cell removal varies among the graft materials available for clinical use today. The second major differences in these graft materials is the use of cross-linking agents. Cross-linking of collagen will result in a marked decrease in the ability of the host to resorb the matrix and in these cases the material is a permanent implant.

The purpose of the use of most of the ECM grafts is to apply an absorbable three-dimensional matrix that contains growth factors and an environment that promotes host cell infiltration and subsequent production of neotendon matrices. Over a period of time (6 to 12 weeks), the graft material is absorbed, assuming that the material is not cross-linked. During this time period the graft material loses its mechanical properties, and in most cases it is not sufficient to act as a mechanical tendon substitute of the repair site. Moreover, the decrease in the graft material properties occurs in a time frame that is shorter than the

time it takes to produce a strong new tendon host matrix either within the primary tendon-to-bone repair site or within the graft material. For these reasons the absorbable graft materials available today should not be used primarily as a mechanical augmentation device but rather for their biologic properties. The primary repair, quality of the tissues, and postoperative rehabilitation should be mechanically sufficient to allow for optimal healing. Under these circumstances chronic two-tendon tears of the supraspinatus and infraspinatus tendon will fail to heal in 30% of cases when repaired by open surgery, using bone reinforcement, with #2 nonabsorbable sutures and a Mason-Allen suture technique and an abduction brace or pillow for 4 to 6 weeks after surgery.[93] If these ECM grafts are to have a potential biologic benefit in these types of tears, it is likely to be apparent only when the mechanical environment of the repair is sufficient to allow an intact repair in the first 6 weeks after repair.

For smaller tears with less tension at the repair site and better quality of the tissue, the healing rate without biologic enhancement is 85% or greater with open or arthroscopic repair, use of a sling, and early mobilization of the shoulder. In these cases the use of a graft may improve the results of surgery under these surgical and postoperative conditions.

There continues to be rapid progress and advances in this area of tendon repair augmentation and careful prospective randomized clinical trials are needed of the currently available products as well as those that will be developed in the future. All clinicians using these materials are at this point advised to have a thorough understanding of the products' properties and evidence-based data to support their safety and efficacy in each specific clinical application.

Results

The long-term results of rotator cuff repair have been evaluated. Wolfgang[224] in 1974 reported on 65 full-thickness rotator cuff repairs that were first evaluated at 9.8 months and then at 8.2 years postoperatively. In addition to cuff repair, 55% of the shoulders in this series underwent

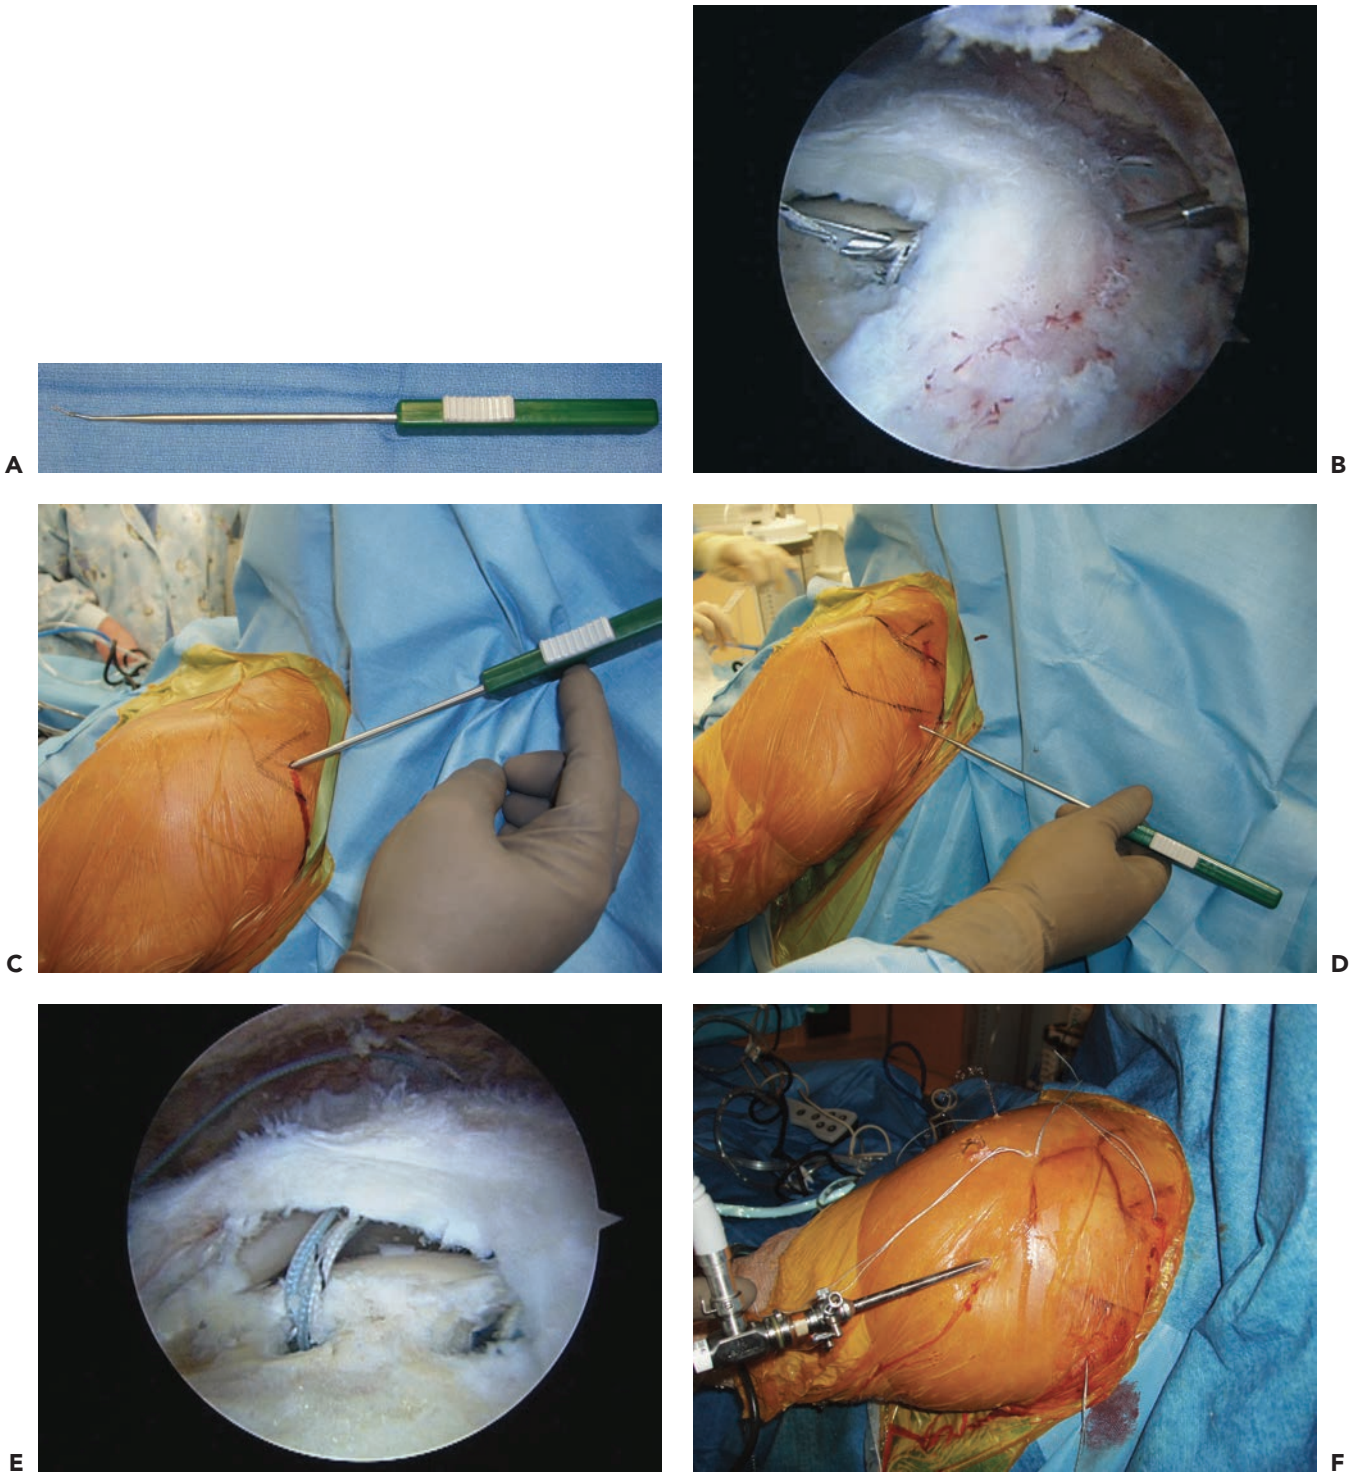

Figure 3-31 **(A,B)** An alternative device has a retractable wire loop that comes from the end of the instrument. lateral acromionectomy. Sixty-nine percent of the shoulders in this series demonstrated good to excellent results at 9.8 months; 46 of these patients were again evaluated at an average of 8.2 years postoperatively, and 74% of these had good to excellent results at that time. Petersson[178] in a different study in 1981 also demonstrated that the results of rotator cuff repair do not deteriorate over time. Of 66 original surgical patients in the study, 43 shoulders were available for reexamination at an average of 14 years after the original procedure. These results were compared with the

results obtained in these same patients only 6 months after their original procedures. A good result was judged to be a shoulder with more than 150 degrees of elevation, as well as being devoid of pain. At 6 months postoperatively, 63% of the shoulders were rated as good, and at 14 years postoperatively, 58% were judged to have good results.

Samilson and Binder[195] in 1975 evaluated the results obtained in 33 shoulders with full-thickness tears undergoing surgical repair. The coracoacromial ligament was excised in all cases, and an anterior acromioplasty was performed in 21% of the shoulders in addition to the tendon repair. After average follow-up of 23 months, 84% of these shoulders were rated as having good or excellent results; 76% of the patients returned to work and 70% of the shoulders demonstrated increased strength in external rotation postoperatively.

By 1985, the techniques of rotator cuff repair became more standardized for surgeon acceptance of the importance of physical therapy, anterior acromioplasty, and the preservation of the deltoid muscle origin. Hawkins and coworkers[110] reviewed 100 consecutive rotator cuff repairs at a mean of 4.2 years postoperatively. Repair of the tendon and anterior acromioplasty were employed in all surgical procedures. Postoperatively, 86% of these 100 patients had no or slight pain. The average active abduction postoperatively was 125 degrees (compared to 81 degrees preoperatively). Of the patients in Hawkins' series, 78% could use their affected arm above the shoulder level either normally or with minimal compromise postoperatively, compared with 16% of patients being able to do this preoperatively. Postoperative strength in external rotation of the shoulder was considered to be normal in 42%, compared with 22% of shoulders preoperatively. All but six of the patients (94%) considered themselves to be improved after rotator cuff surgery. Although a statistically significant improvement in strength of the shoulder was demonstrated

postoperatively, the authors of this study were of the opinion that the improvement in function was primarily related to relief of pain.

Ellman and coworkers[69] reviewed 50 rotator cuff repairs after an average follow-up duration of 3.5 years. A full-thickness tear was present in 49 of the shoulders (98%). Anterior acromioplasty was performed in 48 of the shoulders (96%), and in 20 of these same 48 shoulders, distal clavicle excision was also performed. These authors rated their results according to the criteria of Neer.[154] They obtained a satisfactory result in 84% of the shoulders when pain, function, and strength of forward flexion were evaluated. Forty-nine of the patients (98%) were satisfied with their result.

A large series of rotator cuff repairs was reviewed by Neer and coworkers[157] in 1988. These authors analyzed 245 shoulders with tears of the cuff necessitating repair, and 243 of these (99%) also underwent anterior acromioplasty. Follow-up averaged 5.5 years and results were graded as "excellent" (essentially normal shoulder), "satisfactory" (no significant pain, active elevation above horizontal, and patient pleased with result) or "unsatisfactory." Excellent or satisfactory results were obtained in 92% and excellent results were obtained in 78% of these shoulders.

When using these principles for rotator cuff repair, Cofield, in a review of the literature, found an average of 85% of patients had satisfactory results, with reports up to 100%.[51] The Shoulder Service at New York Orthopaedic Hospital for rotator cuff repairs in 486 patients found 96% had satisfactory pain relief and 80% had substantial functional improvement.[179]

Recently, Cofield and coworkers[53] examined 81 shoulders following rotator cuff repair at an average of 7.5 years following surgery. Anterior acromioplasty and repair of the tendon defect were performed on all of the shoulders at surgery. Ninety-three percent obtained satisfactory pain relief and 94% of the patients were of the opinion that they were much better after surgery; 83% returned to work. Overall, 65% had excellent results and 79% had either excellent or satisfactory results.

Cofield[51] reviewed many different series of rotator cuff repairs and averaged the results as described by the various authors. Overall, pain relief occurred in 87% of shoulders, and patient satisfaction averaged 77%.

Factors appearing to influence the outcome of rotator cuff repair appear to be the size of the tear, patient age, and preoperative function. Hattrup evaluated patient age relative to outcome following rotator cuff repair.[106] He was able to show that patients older than the age of 65 years tended to have poorer results as well as larger cuff tears. Cofield and coworkers found that tear size is the single most important factor influencing long-term results.[53] Pollock and coworkers[179] also found that cuff tear size directly correlated with final outcome. Satisfactory results were obtained in 95% of small, 94% of medium, 88% of large, and 84% of massive tears. Others have also found that results for surgical repair of massive tears are inferior to those for smaller tears.[17,53,56,61,97,101,104,131,156,163,173] Harryman and coworkers suggested a reason why larger tears did less well: The repair was less likely to remain intact.[104] Increased preoperative tear size, poorer tissue quality, increased difficulty of tendon mobilization, and the presence of a rupture of the tendon of the long head of the biceps, together, adversely affected outcome.

Numerous studies have found other factors that affect the outcomes of rotator cuff surgery. A study of 30 diabetic patients with rotator cuff repairs revealed a 10% rate of infection and 7% rate of failure compared to a group of matched controls, which had only one failure and no infections.[35] Another study evaluated the effects of smoking in a group of 95 patients compared to a control group of 125 nonsmokers.[137] The mean postoperative University of California, Los Angeles (UCLA) score for the smokers was 25 and for the nonsmokers was 32. Tear size and worker's compensation status were not found to correlate with outcomes in the study. Age is another variable that may affect the outcome of rotator cuff repair, but this has not been consistently found in many case series. The number of excellent and good results for patients older than 62 ranges from 44% to 87% in three cases series designed specifically to evaluate the effects of age on rotator cuff repair outcomes.[100,129,225]

Concomitant acromioplasty has been the standard of care for many years, until recent reports showed data that question the effectiveness of this treatment for patients undergoing rotator cuff repair. Goldberg et al. reported their results of open rotator cuff repair in a series of 27 patients with small and large tears.[95] None of the patients had concomitant acromioplasty. The Simple Shoulder Test (SST)

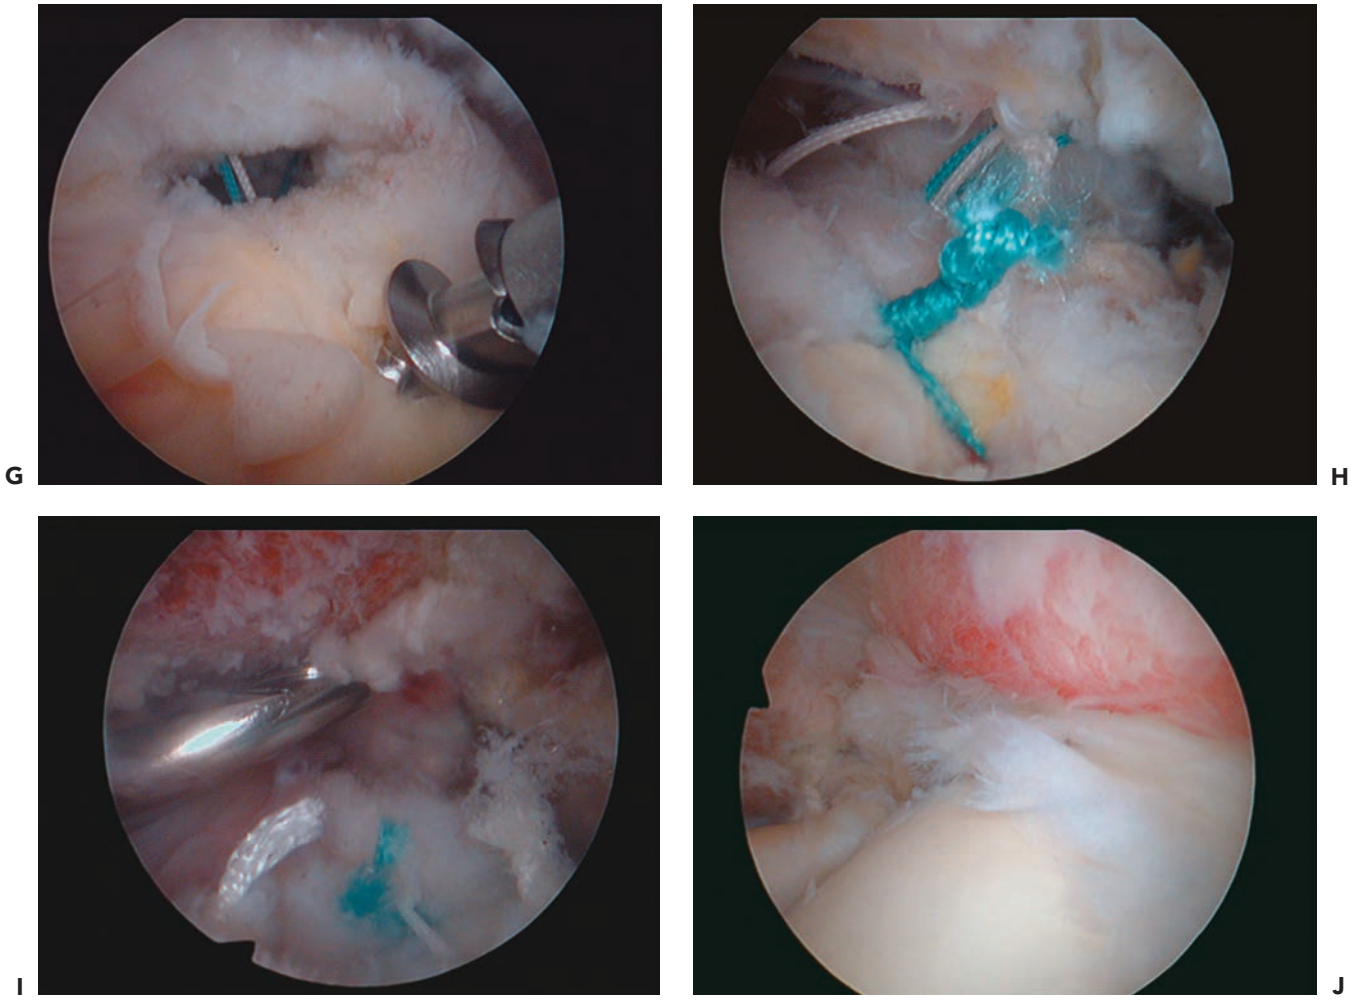

Figure 3-36 (*continued*)

scores improved from 6 to 10 after an average follow-up of 4 years. Gartsman and O'Connor reported their results of a randomized study comparing the treatment of rotator cuff repairs with either a concomitant acromioplasty or no acromioplasty.[89] All patients in the study had a type II acromion, and all the rotator cuff tears involved only the supraspinatus tendon. After a minimum 1-year follow-up, the mean American Shoulder and Elbow Surgeons (ASES) score for the acromioplasty group was 91.5, and for the nonacromioplasty group was 89.2, which was not statistically significant. Tear size, patient age, and preoperative ASES scores were the same in both groups.

Many techniques have been described for the management of massive rotator cuff tears, including débridement,[5,110,145,150,189,227] partial repair,[27] mobilization and repair of cuff tissue,[16,51,56,60,69,110,140,142,154,156,157] tendon transfer,[31,52,90,119,156,161,164] implantation of fascia,[12] allografts,[162] and the placement of synthetic material.[172] Mobilization and transposition of existing rotator cuff tissue has generally yielded better results than implantation of fascia, allografts, synthetic material,[16,51,56,76] or cuff débridement.[5,110,145,150,220,227]

Ellman and coworkers[69] were able to show a correlation between a poor result and preoperative strength and active range of motion. If patients had grade three-fifths strength or less or were unable to abduct their shoulder beyond 100 degrees, there was an increased risk of a poor result. When patients have an unsatisfactory result, it is usually associated with poor function and not pain relief. This is supported by Bigliani et al.[16] and Hawkins et al.,[110] who found that there was good pain relief for repairs of massive tears, but functional improvement was less predictable.

Finally, the final outcome of rotator cuff repair may not necessarily be directly related to complete healing of the tendon. Calvert and coworkers[32] demonstrated good function, pain relief, and satisfaction despite having a documented dye leak at follow-up shoulder arthrography. Packer and coworkers had similar findings[173] and suggest a "water-tight closure" of a cuff defect is not necessary. Likewise, Harryman and coworkers[104] found up to 50% of their

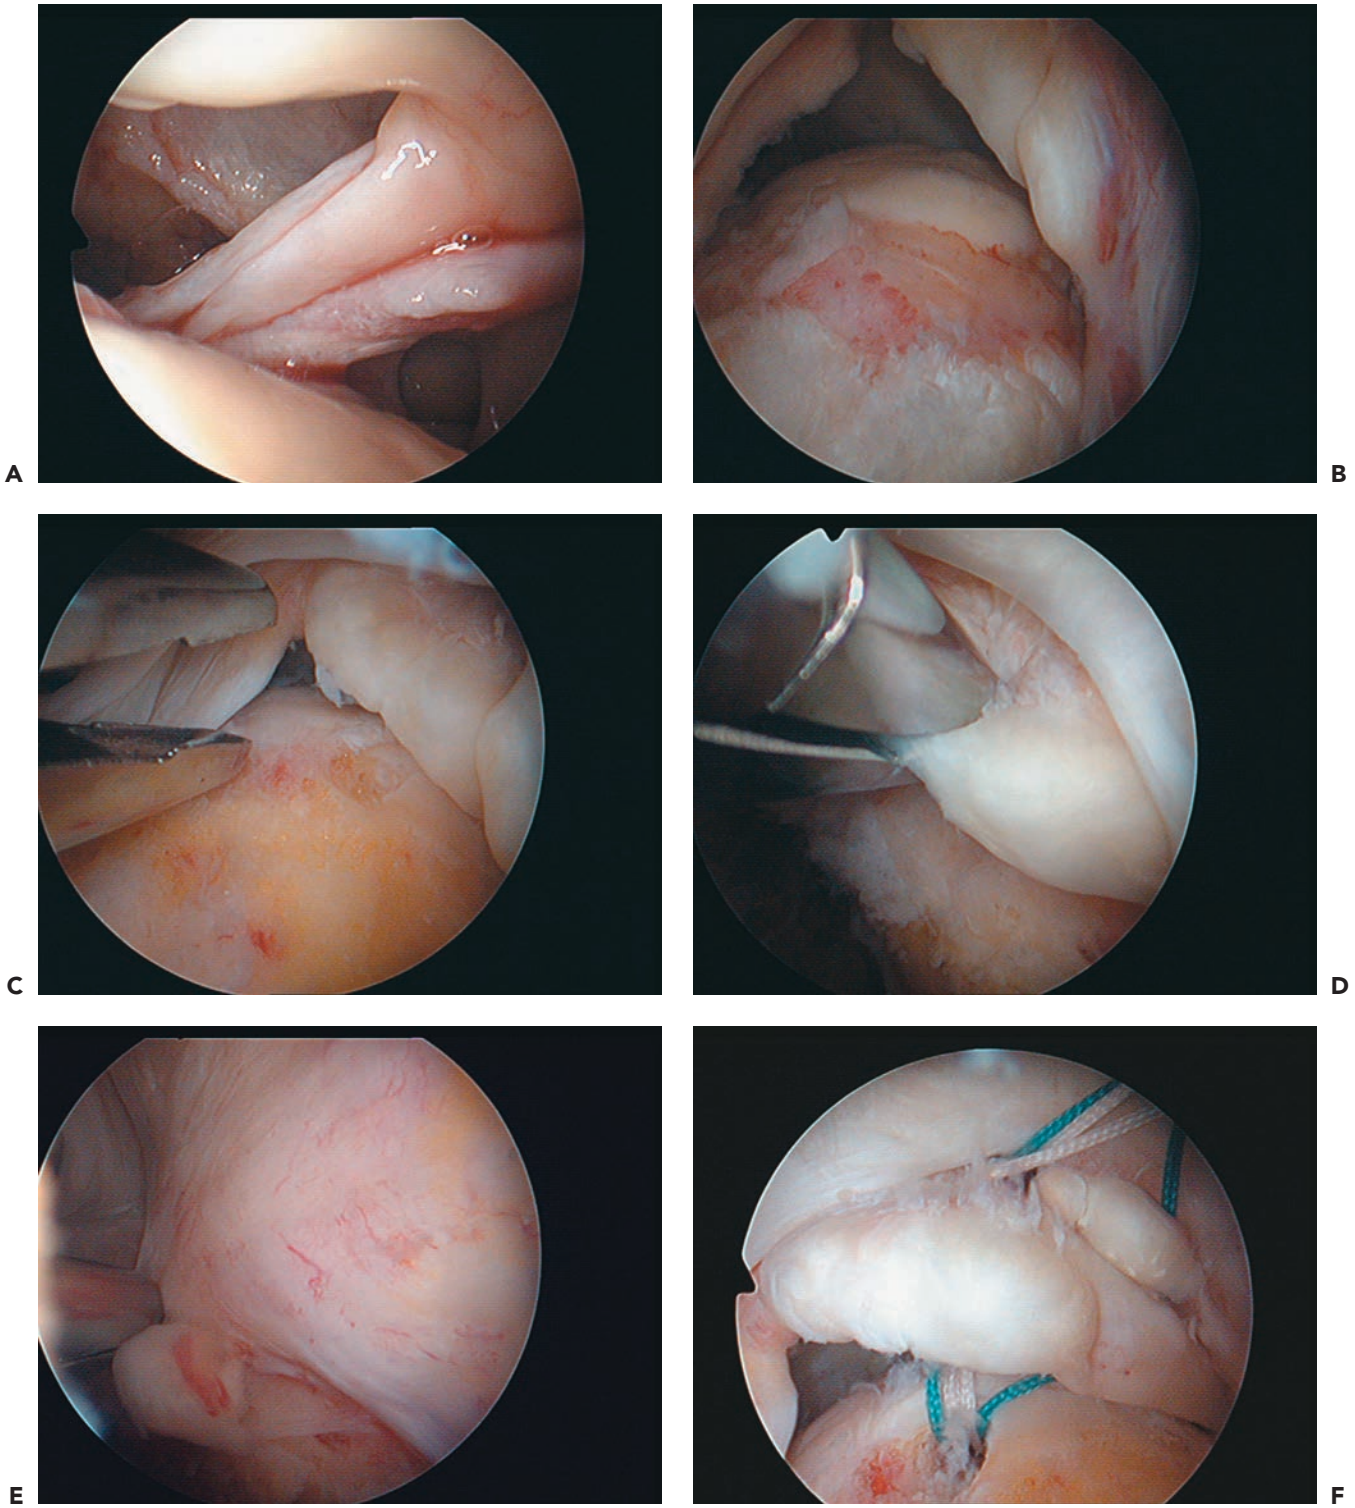

Figure 3-37 Infraspinatus delamination tear. **(A)** Air arthroscopy (articular side) showing the delamination of the cuff tear. **(B)** V-shaped tear from the bursal surface showing the delamination having a deep articular surface tear **(C,D)** that requires repair to the medial footprint of the greater tuberosity **(E–G)** and a superficial surface tear requiring repair to the lateral aspect of the greater tuberosity **(H–L).**

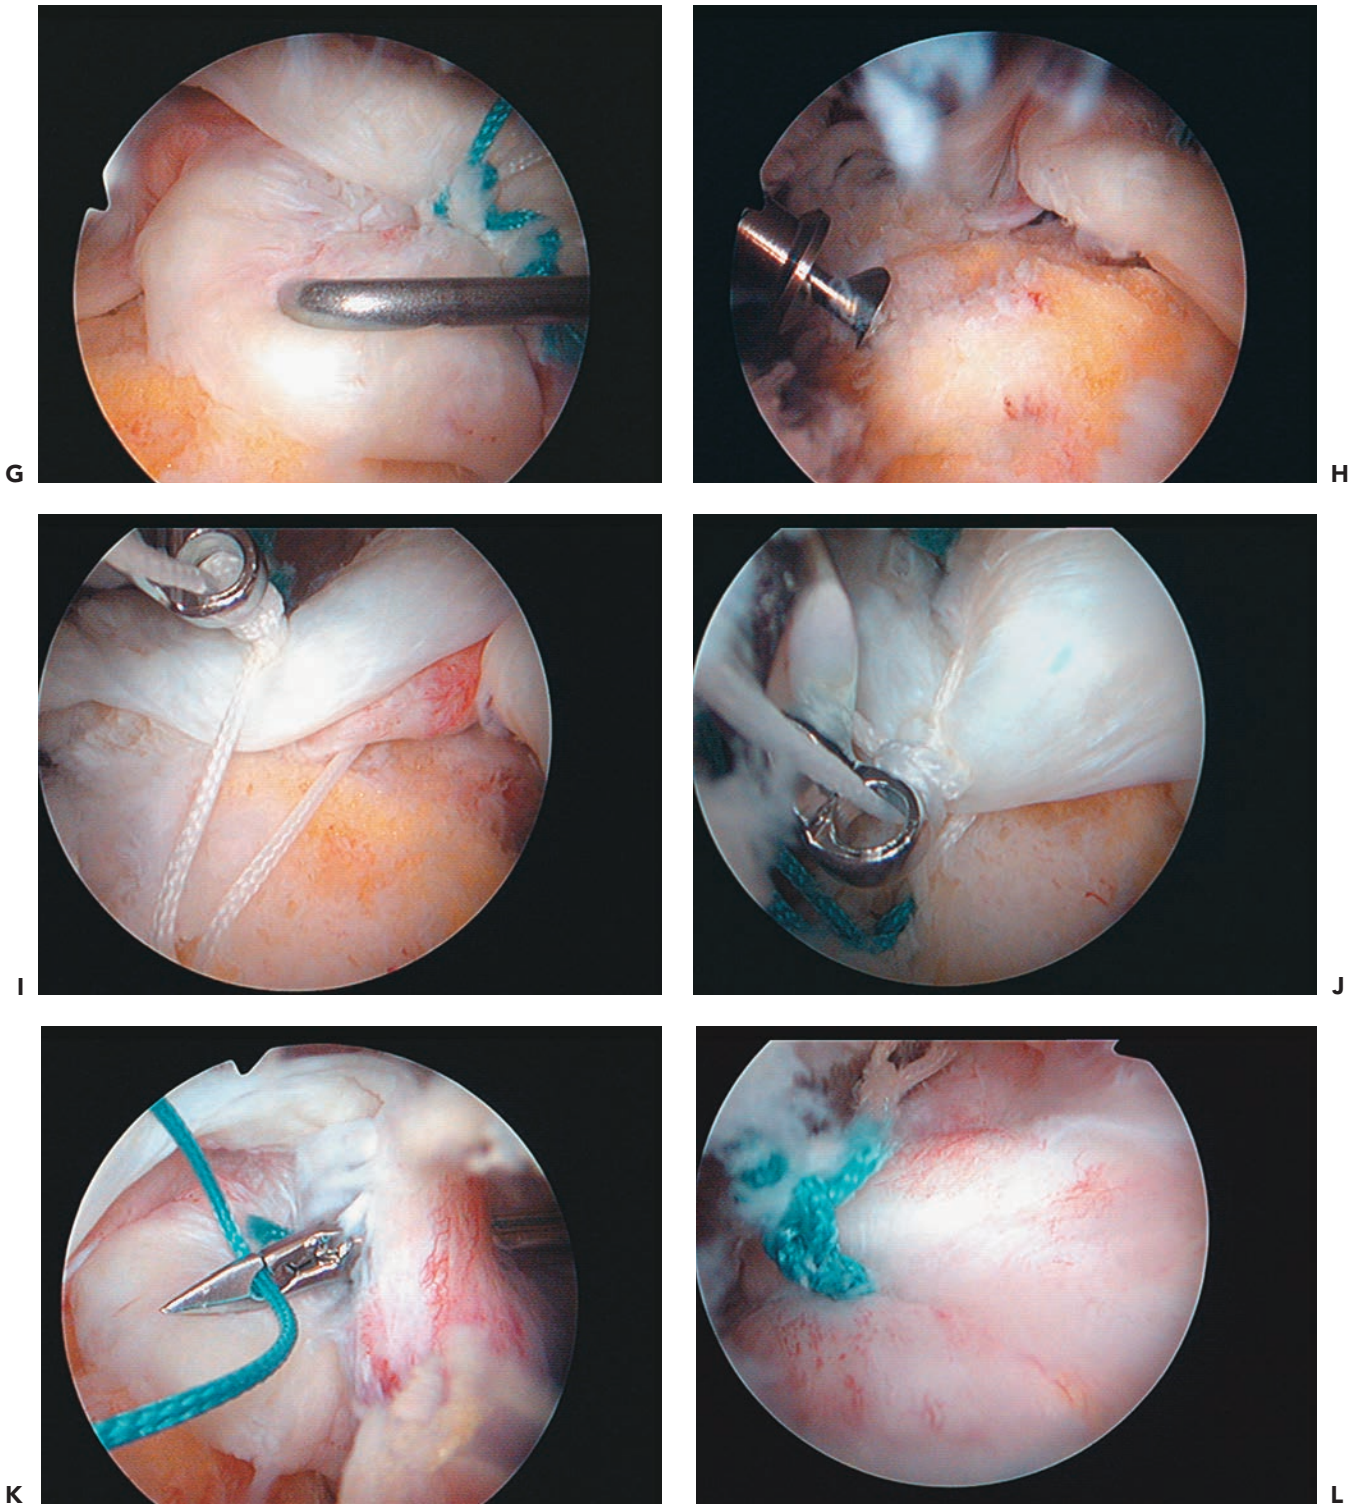

Figure 3-37 (*continued*)

cuff repairs had a postoperative defect. This did not adversely influence patient satisfaction or pain relief, but it did affect shoulder strength. Indeed, in their study the most important factor affecting strength and function at follow-up was a maintained tendon repair. This, combined with the poor results reported for decompression without repair of cuff tears,[145] has led to an increased emphasis on the technical adequacy of tendon repair, including the use of stronger sutures, tendon or bone augmentation, and postoperative bracing.[92,207]

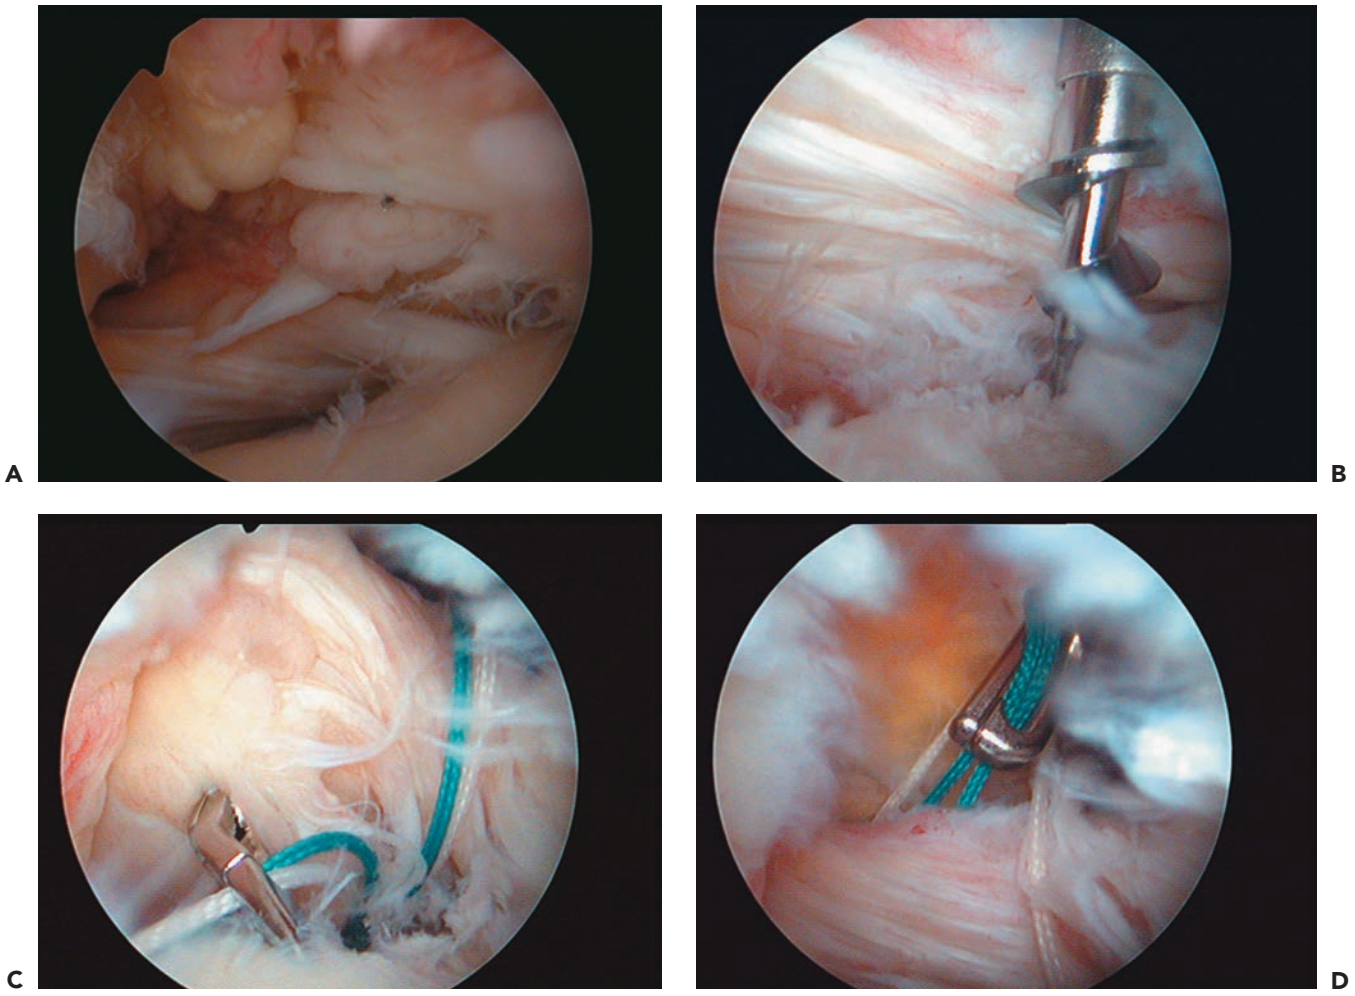

Figure 3-38 **(A)** Upper portion of subscapularis has a 1-cm tear of the rolled edge of the tendon. **(B)** The anchor is placed just medial to the bicipital groove. **(C)** The tendon is pierced and the sutures grasped and pulled through the tendon. **(D–G)** The sutures are retrieved and tied.

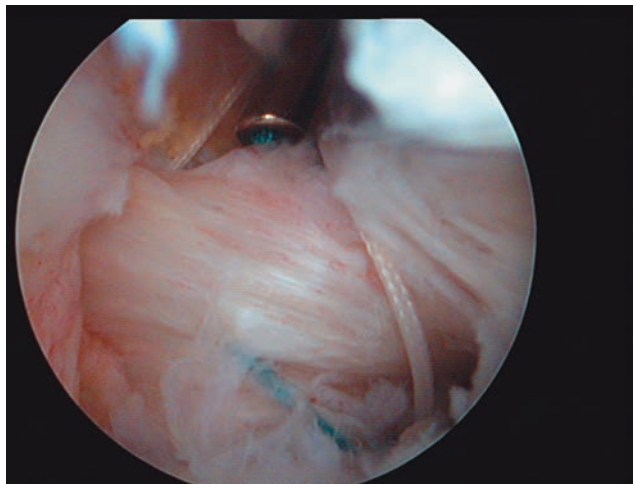
A particularly careful and well-documented study[120] found 88% good or excellent results after cuff repair, and good correlation between patient satisfaction and objective measures such as the Constant score.[118,119]

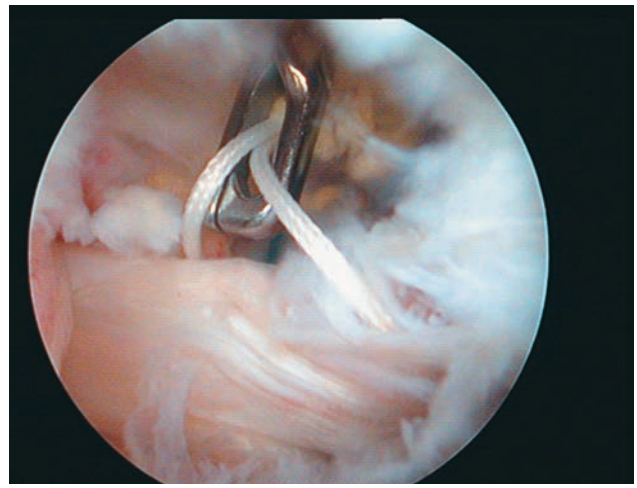
Gerber et al. reported their results of open repair of 29 massive rotator cuff tears after a minimum 2-year follow-up.[93] The tendons were repaired with a modified Mason-Allen suture technique fixed to the humerus through a thin titanium plate for cortical bone augmentation. The Constant score improved from 49% to 85% of the normal shoulder, and forward flexion improved from 92 to 142 degrees. Patients with two-tendon tears had better motion, less pain, and higher Constant scores than patients with three-tendon tears. Postoperative MRI revealed retears in 34% of patients, and the patients with failed repairs had significantly lower Constant scores, more pain, and less active motion. Muscle atrophy could be reversed in the supraspinatus muscle if the repair did not fail, but atrophy could not be reversed in the other muscles of the rotator cuff. Fatty degeneration increased in all muscles regardless of the repair integrity.

For the purpose of finding an association between repair integrity and outcome, Klepps et al. reported their results of open repair of 32 medium and large rotator cuff tears.[126] After a minimum 1-year follow-up, the UCLA shoulder score was 31 for tears less than 3 mm and 29 for tears greater than 3 mm, which was not significantly different. The retear rate by MRI at 1 year was 31%, and patients with failed repairs had lower UCLA scores and worse pain scores.

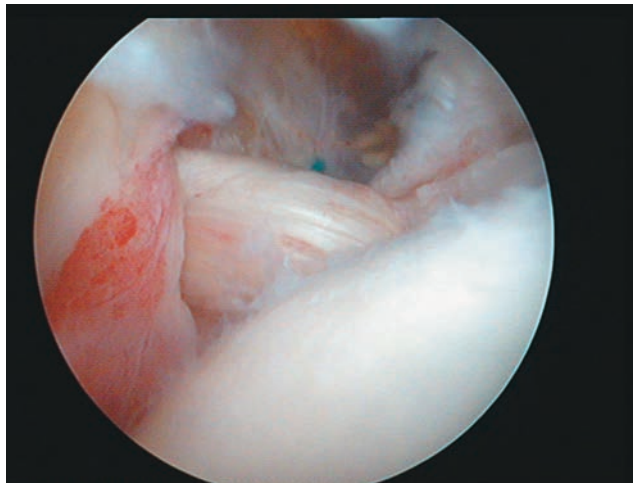
In 1999, Rokito et al. reported their results of open repair of 30 large and massive rotator cuff tears after a minimum 4-year follow-up.[190] All of the patients were satisfied with the procedure, and the average UCLA score improved from 12 to 31. The mean peak torque in flexion, abduction, and external rotation was 80%, 73%, and 91%,



E



F



G

Figure 3-38 (*continued*)

respectively, of the normal shoulder. This study suggests that the results of open repair are durable after many years, and that patients may require more time to regain their maximum shoulder strength. In the same year, Romeo et al. reported their results of open repair of 72 full-thickness rotator cuff tears after a minimum follow-up of 2 years.[191] Twenty-one tears were massive tears, but they were all repairable. Seventy-six percent of the patients had minimal pain, were able to perform activities of daily living, had 75% of normal strength, and lost less than 20 degrees of forward flexion. Patients with massive cuff tears had an average UCLA score of 81 compared to patients with a smaller tear, who had a score of 91; women with an associated biceps tendon rupture had an average UCLA score of 65 compared to women without a biceps rupture, who had a score of 95.

In a study with the longest follow-up after rotator cuff surgery, Galatz et al. reported their results of 33 open repairs after 10 years of follow-up.[84] The raw Constant scores were the same at 2- and 10-year follow-up, but after the scores were normalized for expected age-related activity level, the Constant scores were even greater after 10-year than after 2-year follow-up. Twelve patients continued to work at their same occupation, and only two patients retired because of problems with their shoulder. The patients' subjective evaluation of the procedure did not change after 10 years (Table 3-2).

The results of arthroscopic acromioplasty with a mini-open rotator cuff repair are good. Levy and coworkers reported 80% satisfactory result.[132] Of their patients 96% were satisfied with the procedure. We have recently reported our experience with mini-open rotator cuff repairs following an arthroscopic acromioplasty.[182] All 30 of our patients had an excellent result at an average of 25 months of follow-up. All the tears in this study group were either small or medium.

The short-term benefits of mini-open repair were reported by Hata et al.[105] The authors compared their results of mini-open repair to a cohort of patients who were treated earlier with a classic open repair. No massive tears were included in the study. At 3- and 6-month follow-up, the mini-open group had 12 degrees more forward flexion,

TABLE 3-2
RECENT CLINICAL STUDIES (LAST 5 YEARS) REPORTING RESULTS OF OPEN ROTATOR CUFF REPAIR

Author	Year	Number of Patients	Outcomes	Minimum Follow-up	Number of Massive Tears	Failed Repairs
Rokito et al.[190]	1999	30	UCLA 31 Excellent + good results 76%	4 years	13 (43%)	
Romeo et al.[191]	1999	72	Satisfactory 76% Constant score Massive 68 Others 82	2 years	21 (29%)	
Knudsen et al.[127]	1999	31	Constant score Intact cuff 75 Cuff defect 62	1 year	0	32%
Gerber et al.[93]	2000	29	Normalized Constant 89%	2 years	29 (100%)	34%
Galatz et al.[84]	2001	33	Excellent + good 91%	10 years	11 (33%)

Klepps et al.[126]	2004	32	Constant 80	1 year	13 (40%)	31%
Duralde and Bair[65]	2005	24	Excellent + good 67%	2 years	24 (100%)	

but at 1-year follow-up, motion and strength were the same. The average UCLA score was 33 at 1-year follow-up.

Reports by Hersch and Sgaglione showed that excellent results can be achieved in up to 90% of patients when the mini-open approach is used.[114] The authors also cited the added benefit of arthroscopic visualization of the glenohumeral joint to diagnose concomitant biceps, articular, or AC joint pathology. What is lacking from these recent studies are significant numbers of patients with massive rotator cuff tears who have been shown to have worse results after classic open repairs.

Entirely arthroscopic repair is still in evolution, but early results have been variable depending on cuff tear size, location of the tear, and chronicity.[87,135,218] The results seen with arthroscopic repair have been consistent with those seen with open repair when comparing patient and anatomic factors that affect outcome. Weber compared 39 entirely arthroscopic repairs with 101 arthroscopic-assisted mini-open repairs; he found lower early morbidity, but also a higher complication rate, including three loose anchors (8%), in the arthroscopic group.[218] After 6 weeks, the outcomes were identical. Three recent series contained 137 patients followed for at least 1 year after arthroscopic cuff repair;[20,197,210] overall, 88% achieved good or excellent results.

Numerous studies have shown that arthroscopic repair of full-thickness rotator cuff tears provides excellent or good results in 85% to 95% of patients after a minimum 2-year follow-up. The strengths of these studies include the use of validated outcome scores, uniform surgeon experiences, and large patient numbers. One major deficiency in the arthroscopic literature is the small number of massive rotator cuff repairs, which has been shown in previous studies to adversely affect functional outcome scores. Many studies that include all sizes of cuff tears will report that statistical analysis did not find any correlation between outcome scores and tear size, even though the number of massive tears in the study is small. Data analysis in each of these studies may be misleading with regard to tear size and outcome because of the lack of statistical power, not because the association does not exist when using arthroscopic repair techniques. Another confounding variable that is not reported in any of the arthroscopic studies is muscle atrophy or fatty infiltration, which has been shown by Gerber et al. to play a significant role in the outcome of open rotator cuff repairs.[93] So while most reports show that the average rotator cuff tear can be treated successfully with arthroscopic techniques, questions remain regarding the best approach to use for the treatment of massive rotator cuff tears with muscle atrophy.

In 1998, Gartsman et al. reported their results of arthroscopic treatment of 73 rotator cuff tears after a minimum 2-year follow-up.[88] Six patients had massive tears. The

Constant score improved from an average of 41 to 89, and 83% of patients had an excellent or a good result. Burkhart et al. treated 59 patients with arthroscopic rotator cuff repair directly to bone or with margin convergence alone.[28] This series included 13 massive cuff tears. Excellent and good results were found in 95% of patients according to the Constant score. The average score for massive tears was 29.9, while the average score for all others was 31.6.

Only one study to date has reported the results of the integrity of arthroscopically repaired rotator cuffs. Galatz et al. repaired 18 rotator cuff tears that were all larger than 2 cm and evaluated their patients with ultrasound 1 year after the repair.[85] Seventeen of the 18 patients had recurrent tears, yet the average ASES score improved from 48 to 80, and all of the patients were satisfied with the procedure (Table 3-3).

The personal experience of one of the authors (LL) with 116 shoulders in 115 patients operated on for full-thickness rotator cuff tears from 1998 to 2001 was evaluated.[20] In this series, there were 63 (55%) men and 52 (45%) women with a median age of 57 years (range 36 to 80 years). There were 13 anterosuperior lesions (six large subscapularis tears) and 40 superior, 36 posterosuperior, and 27 massive rotator cuff tears.

The patients were evaluated pre- and postoperatively according to the criteria of the Constant and Murley Score (CMS).[4] Preoperatively, all patients had a standard set of radiographs, arthrograms, and arthro-CT scans; postoperatively all had standard radiographs, 89 patients had an arthrograms, and 17 of these had an additional CT scan. Pre- and postoperative images were measured for humeral head–acromion distance, arthrographic signs of retear, tear retraction, and, when CT scan was available, fatty degeneration of the muscles according to the criteria of Goutallier et al.[99]

Average follow-up was 26 months (24 to 60 months). There were no infections for frozen shoulder. Revision surgery was performed for retear, biceps problems, and captured cuff problems.

The CMS increased from 40.3 for that of a normal shoulder preoperatively to 80.1 postoperatively. All parameters of CMS were improved. The postoperative scores correlated with the high patient satisfaction. The greatest improvement was with anterosuperior tears, with an average increase of 43.6%. The average increase for superior lesions was 41.1%, for the posterosuperior lesions 39.5%, and for the massive lesions only 36.4%.

The best improvement in pain was found in the posterosuperior lesions, the greatest improvement in activities of daily living were with superior lesions, and the best outcome in mobility and strength were with anterosuperior lesions. The influence of the intraoperative state of the LHB and its treatment were not studied in the anterosuperior lesion. Eighty-seven of the 116 patients had a postoperative arthrogram or arthro-CT. Forty-two (48.3%) were watertight and 45 (51.7%) had a positive arthrogram. The presence of complete healing based upon the presence of a leak on arthrogram was different among the different lesions.

A negative arthrogram is clearly a complete healing of the tendon but a leak of contrast can be correlated with a recurrent tear or to a nonwatertight repair; however, in some shoulders this may still represent partial healing or almost complete healing in a case when the rotator interval was not closed. Our arthrogram data are difficult to evaluate because of incomplete recording of the intraoperative estimate of the cuff repair or the nature of the rotator interval closure.

Correlation between clinical results and postoperative arthrograms demonstrate that patients with a leak of contrast (51.7%) had a greater gain in all CMS variables than those with a watertight cuff, but both patient groups had similar absolute postoperative Constant scores. This further supports our opinion that a leak on a postoperative arthrogram is not always correlated to a clinically significant recurrent tear. Conversely, a poor clinical result, in

TABLE 3-3
REVIEW OF RECENT LITERATURE ON THE RESULTS OF ARTHROSCOPIC ROTATOR CUFF REPAIR

Author	Year	Patients	Outcome	Massive Tears
Gartsman et al.[88]	1998	73	Excellent + Good 83%	6 (8%)
Tauro[211]	1998	43	Excellent + Good 64%	0
Burkhart et al.[28]	2001	59	Excellent + Good 95%	13 (22%)
Murray et al.[144]	2002	48	Excellent + Good 96%	0
Bennett[13]	2003	24	ASES 83 Constant 73	0
Bennett[14]	2003	37	ASES 77 Constant 74	37 (100%)

Wolf et al.[223]	2004	95	Excellent + Good 94%	0

which recurrent surgery was necessary, was always correlated with a massive leak of contrast on arthrogram and a massive retraction at the second surgery. In some cases revision surgery was required for persistent untreated biceps pathology or a cuff capture due to adhesions, and in these cases there was a negative arthrogram.

CONCLUSIONS 141

INTRODUCTION

Irreparable tendon tears of the rotator cuff are found in a small proportion of patients who undergo operative treatment, as approximately 95% of all tears are reparable by

conventional methods.[131] Open and arthroscopic repair techniques have been shown to consistently improve pain and function in 90% of selected patients, although structural integrity of the repair following surgery may not correlate with positive outcomes.[4,10,30,31,35,37–39,60,62,76,83,108,110,132] The variability in clinical outcome regardless of the integrity of the repair may be more a reflection of the unclear natural history of this disease rather than the response to treatment.[4,35,44,60,72,76,83] It is clear, however, that larger tears carry a much greater risk of failure following surgery and are associated with worse clinical outcomes.[44] Furthermore, recent studies have shown that simple débridement of massive tears are not associated with a high degree of satisfaction in the younger or active patient.[101]

While the prevalence of irreparable tendon tears is quite low, they can profoundly impact the functional capacity of patients and can be associated with significant pain. Numerous tendon transfers have been proposed in the treatment of irreparable rotator cuff tears. These transfers have included the pectoralis major,[36,42,45,70,73,111,133,138] latissimus dorsi,[2,43,45,52,66,94,130,131,134] supraspinatus,[26,59] subscapularis,[23,74] trapezius,[92] teres major,[21] long head of the triceps,[61,87,120] and teres minor.[98] Interpositional materials have also been recommended as a possible treatment and have included allografts,[97] fascial autografts,[7] synthetic materials,[95,102] the lateral deltoid,[3] the long head of the biceps tendon,[58] and xenograft.[115] The variability in the published results of these techniques demonstrates a lack of consensus on the optimal treatment of massive, irreparable rotator cuff tears. Moreover, most reports are based on anecdotal experience or retrospective review. Thus, inherent biases and confounding variables make it difficult to draw any meaningful conclusions about the best method of treatment. For these reasons, the prognosis after an attempted reconstruction using these techniques remains unclear.

The criteria that enable one to distinguish patients with irreparable rotator cuff tears who are candidates for tendon transfer from those who are better served by other methods or skillful neglect will be discussed. The following chapter will also focus on the treatment of irreparable anterosuperior and posterosuperior rotator cuff tears using techniques that have shown consistency in clinical practice and validation in the literature.

In some patients, although there is a massive irreparable cuff tear, there is sufficient rotator cuff and deltoid function to allow the patient to have sufficient strength and elevation to serve their functional needs. In most cases these individuals are over the age of 70 years, are retired, and their primary complaint is pain. In some cases these patients maintain weak over-shoulder-level elevation. When weakness is not a primary complaint and pain is of primary concern, a limited-goals arthroscopic débridement of the bursae, release of a damaged biceps tendon, and débridement of a painful and symptomatic acromioclavicular arthritis can provide sufficient improvement of pain to result in improved patient function and patient satisfaction. In these cases a muscle transfer may help with functioning but may not be required for the patient's needs. This is particularly a consideration in the older patient with low functional demands.

DEFINITION OF AN IRREPARABLE TEAR

The definition of an "irreparable" rotator cuff tendon tear has evolved in recent years based on increasing scientific evidence that substantiates the critical interplay of tendon reparability with muscle and tendon quality.[46,47,55,56] It is becoming accepted that tendon size is a less important determinant of reparability and outcome as is the degree of tendinous and muscular degeneration, fatty infiltration, and cranial migration of the humeral head.[30,55,88,126,137] The poor correlation in published reports between tear size and functional outcome has confirmed this concept.[9,13,22,113]

Irreparable tears that may be indicated for a latissimus muscle transfer are defined as those involving at least two rotator cuff tendons (supraspinatus and infraspinatus) with retraction that is not amenable to mobilization and repair to the anatomic footprint with the arm in less than 60 degrees of abduction.[52] Mobilization may include release of the coracohumeral ligament, interval slide, and circumferential capsulotomy.

We currently believe that the determination that a rotator cuff tendon tear is irreparable can be made by preoperative evaluation without the need to attempt surgical mobilization. This contention is based on an understanding of the biomechanical and structural changes that accompany a chronic, massive tear of the rotator cuff.

Preoperative criteria that enable the surgeon to determine whether a rotator cuff tendon tear is irreparable are both clinical and radiographic. The relevant clinical factors include profound weakness of internal or external rotation in combination with a marked "lag sign."[64] The weakness is usually such that, in the case of a posterosuperior tear, the patient cannot raise his or her arm against gravity (Fig. 4-1). In an irreparable tear of the subscapularis, some patients maintain the ability to raise their arm overhead, although they have profound internal rotation weakness.[133]

In the case of an irreparable posterosuperior tear, the patient will have a lag between passive and active external rotation. In these cases, the patient's arm will fall into internal rotation when the examiner releases it from maximal passive external rotation (Fig. 4-2). When the arm is at the side in adduction, this degree of lag is consistent with an irreparable tear of the infraspinatus (Fig. 4-3).

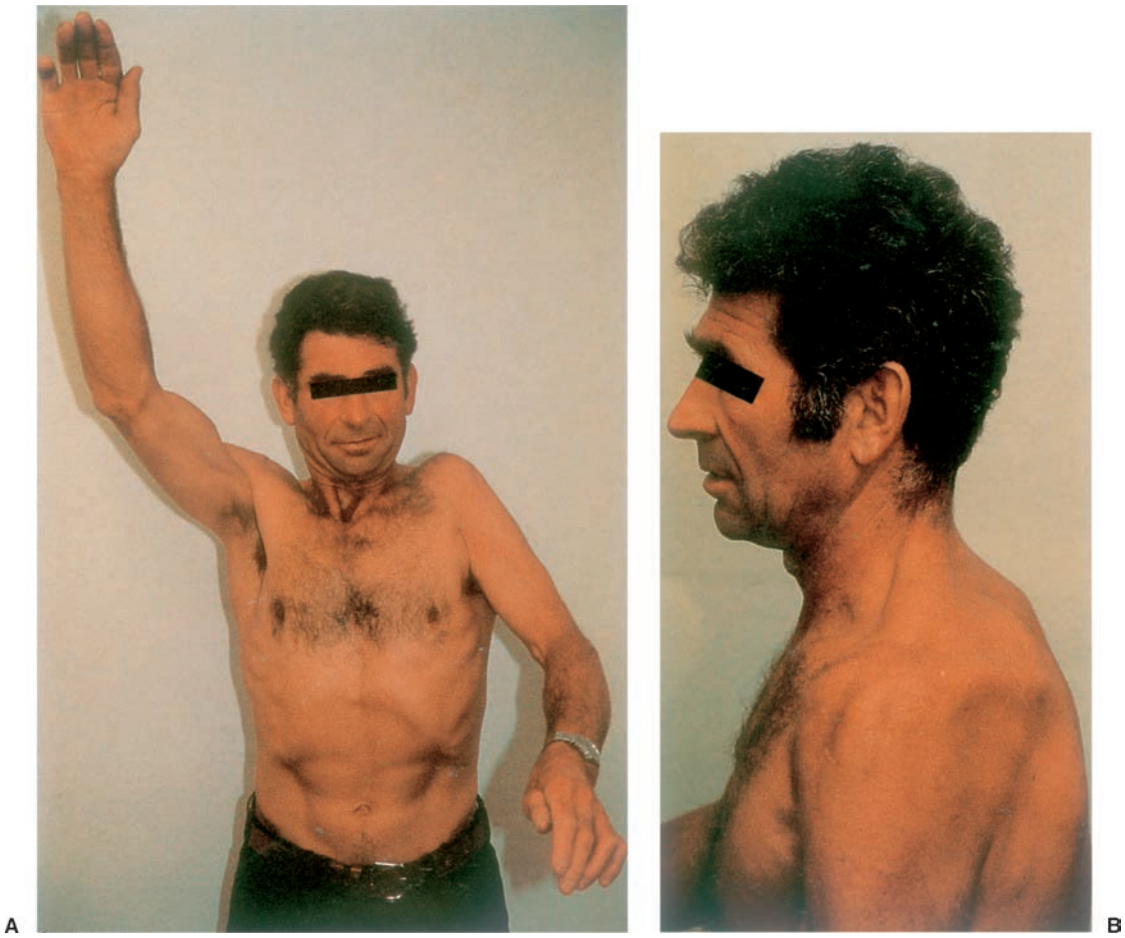

Figure 4-1 A 52-year-old mason with a traumatic posterosuperior rotator cuff injury. At examination, he showed **(A)** the inability to raise the arm against gravity, or pseudoparalysis, with **(B)** clinical evidence of severe atrophy of the supraspinatus and infraspinatus muscles.

Figure 4-2 A 59-year-old man with a chronic, massive tear of the posterosuperior rotator cuff. Demonstration of the external rotation lag sign **(A,B)** with the arm at 90 degrees of abduction, which demonstrates disruption of the infraspinatus and teres minor.

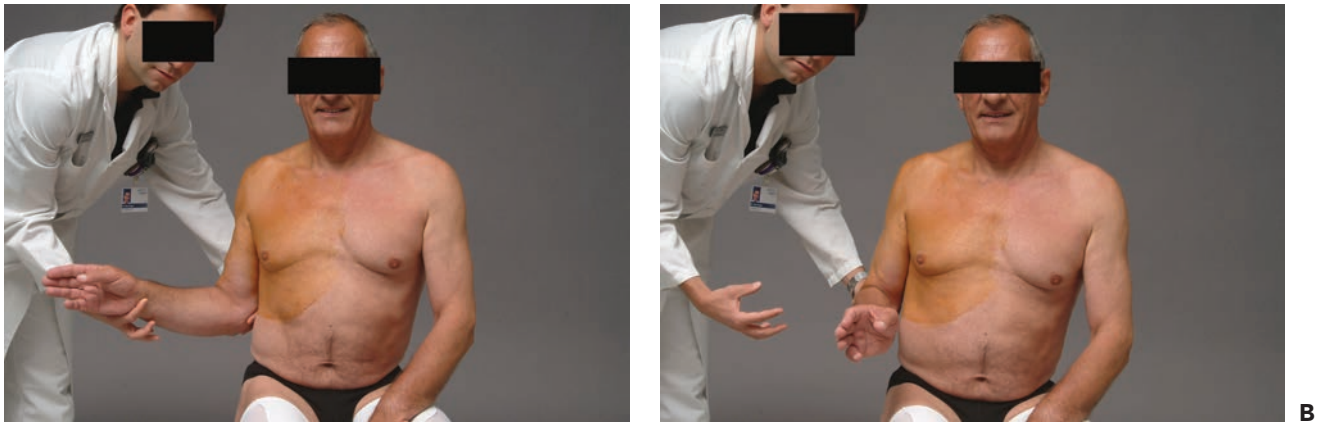

Figure 4-3 With the arm in adduction, a lag between maximal passive and active external rotation **(A,B)** is pathognomonic for a tear of the infraspinatus.

When the patient's arm is abducted and held in maximal passive external rotation position, the patient may be able to actively maintain this position if the teres minor is intact.

Anterosuperior rotator cuff tears in which the subscapularis is completely torn, with or without a concomitant supraspinatus tear, typically display positive lag signs in internal rotation. The "lift-off" sign is the inability to lift the hand off the lower back, while the "belly-press" sign is the inability to maintain the hand against the abdomen without the elbow moving backward when resistance is applied against internal rotation (Fig. 4-4).[46,47,64] Each of these maneuvers tests the function of the subscapularis at terminal internal rotation.[46,47,64]

Other clinical findings that suggest an irreparable massive tear are superior displacement of the humeral head combined with anterior or posterior translation. In cases of massive posterosuperior tears, the humeral head may display proximal migration in combination with excessive scapular motion. In contrast, patients with massive anterosuperior tears will exhibit superior migration of the humeral head with anterior translation when attempting abduction (Fig. 4-5).

The radiographic parameters suggesting an irreparable tear include static superior subluxation with an acromiohumeral interval less than 5 mm on an anteroposterior radiograph[8,15,30,72] and static anterior subluxation in the case of a chronic subscapularis rupture.

Magnetic resonance imaging (MRI) and computed tomography (CT) scans that demonstrate profound muscle atrophy with a Goutallier stage of 3 or greater also suggest a tear with poor-quality tissue that will consistently fail to heal with surgery (Fig. 4-6).[44,55,56,72,131,135]

Although most irreparable tears tend to be "massive tears" of the posterosuperior cuff, irreparable and massive tears are certainly not synonymous. The characterization of a cuff tear as irreparable is based not only on size, but also on tissue quality, degree of retraction, and, in some cases, the skill and experience of the surgeon.[52] Despite the fact that tendinous tissue can be sewn together either with arthroscopic or open methods, the incidence of disruption of large and massive tears is very high.[9,27,72,84,130,142]

The definition of a "massive tear" continues to be controversial. The most commonly accepted definition of a massive tear in North America is defined by Cofield as one with a maximum diameter of 5 cm or greater.[22] Others, including Gerber,[44,64,72,99] have claimed that this, perhaps, is not an ideal definition as absolute size may be variable among patients and inconsistently reported before or after débridement of nonviable edges during surgery (Fig. 4-7). For this reason, we support a definition of "massive tears" as those involving disinsertion of two or more rotator cuff tendons.[107,111]

In Neer's series of 340 rotator cuff tears operated on over a 13-year period, 145 (43%) were classified as massive.[96] Ellman and associates reported that 9 of 54 (17%) rotator cuff repairs involved massive tears.[30] Harryman et al. reported that 28 of 105 (27%) surgically treated tears were massive.[60] Warner reported that 146 of 407 (36%) rotator cuff repairs involved massive tears, and that 19 of 407 (5%) involved combined supraspinatus and subscapularis tears.[130] Despite the fact that the definition of massive tears was variable in these studies, they do provide a rough estimate of their frequency in a referral shoulder specialist practice. It is very likely that the percentage of all tears that undergo surgery that are massive tears is substantially less in the general surgical population.

Posterosuperior tears are the most common configuration of massive tear and, by definition, involve the supraspinatus and infraspinatus tendons.[131] Less commonly but not infrequently, the subscapularis and supraspinatus are involved with a unique epidemiology, etiology, and prognosis that has been highlighted relatively recently and is gaining appreciation in the literature.[44,47,138]

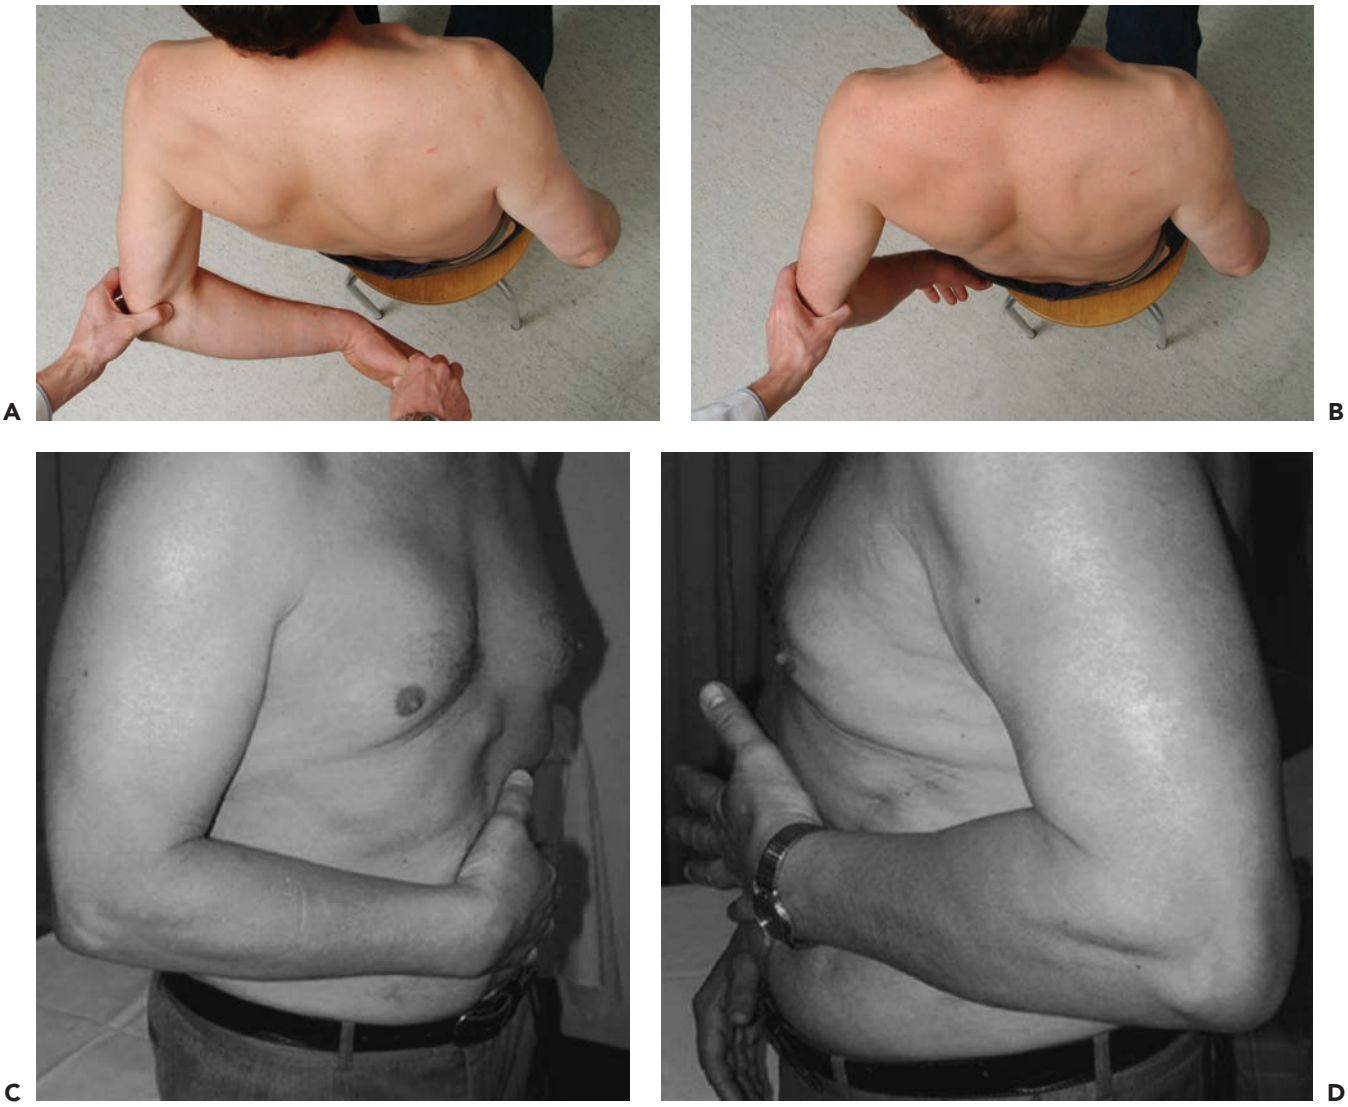

Figure 4-4 The lift-off and belly-press tests are used to test the integrity of the subscapularis tendon. In the lift-off test the patient is asked to lift his or her hand off the lower back. It has been found to be more sensitive and specific if there is the presence of an internal rotation lag sign after the clinician releases the hand from maximal internal rotation with the arm off the back **(A,B)**. In the belly press sign **(C,D)**, the patient exerts an internal rotation force on the belly, with the elbow forward and anterior to the midline of the trunk. If the subscapularis is ruptured, the patient is unable to keep his or her hand on the stomach with resisted internal rotation, and the elbow will fall back posteriorly. (Reprinted with permission from Gerber A, Clavert P, Millett PJ, Holovacs TF, Warner JJP. Split pectoralis major transfer and teres major tendon transfers for reconstruction of irreparable tears of the subscapularis. *Tech Shoulder Elbow Surg* 2004;5:5–12.)

PATHOANATOMY AND PATHOMECHANICS

The role of the rotator cuff muscles and of the deltoid have been studied clinically and experimentally in great detail.[15,25,53,65,68,75,89] The force generated by an individual rotator cuff muscle is largely determined by its physiologic cross-sectional area (PCSA) (Table 4-1).[65,75,82,122,124] The moment is the product of the force and the distance from the center of rotation to a perpendicular line drawn along a muscle's line of action (Table 4-2).[5,6,11] As Tables 4-1 and 4-2 indicate, the supraspinatus is relatively weak given its small PCSA, smaller size, and closer insertion to the axis of rotation. Furthermore, its relative contribution is decreased with increasing abduction. Keating et al. have shown[75] that the supraspinatus, for example, makes a small (15%) contribution to the overall abduction moment arm of the shoulder compared to the subscapularis (52%) and to the combined effort of the infraspinatus and teres minor (33%).

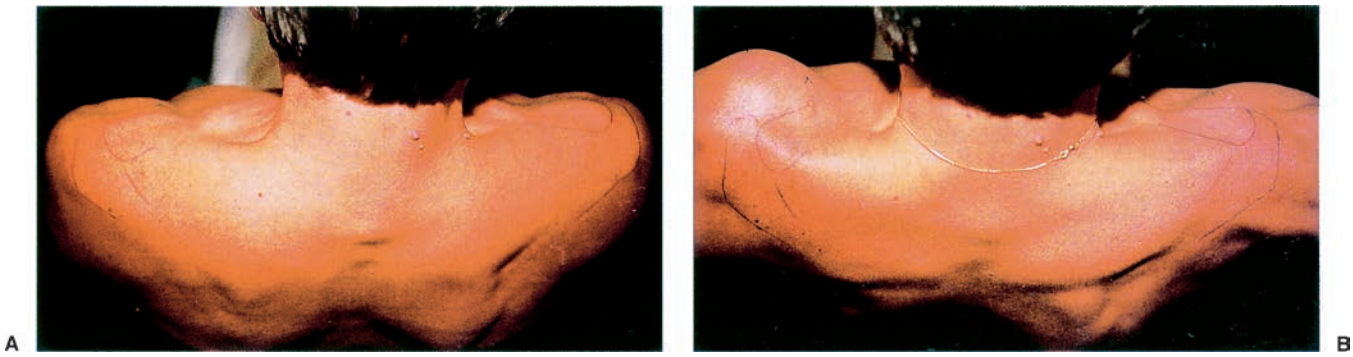

Figure 4-5 Dynamic anterosuperior subluxation indicates major injury to the supraspinatus and subscapularis. The clinical diagnosis is made if **(A)** the patient has normal contour of both shoulders at rest and **(B)** subluxates his or her shoulder anterosuperiorly while resisting abduction. The condition of anterosuperior subluxation can be precipitated by open or arthroscopic subacromial decompression, with release of the coracoacromial ligament. If anterosuperior subluxation becomes static, clinically or radiographically, successful restoration of overhead elevation by direct surgical repair is exceedingly rare, and subacromial decompression is detrimental.

The excursion of the rotator cuff tendons is relatively small (range 0.5 to 4.0 cm) during scapular abduction. In contrast, the deltoid muscle has an excursion of 6.5 cm (Table 4-3).[90] The rotator cuff muscles are therefore important stabilizers of the humeral head that provide a fixed fulcrum of rotation that is primarily generated by the deltoid during abduction.[90] Disruption of the supraspinatus with either the infraspinatus or subscapularis disrupts this balance and can result in loss of efficiency of the deltoid during abduction.[8,81,122,137]

Clinical[13,18–20] and experimental[122] data show that the shoulder may remain well compensated even though there is a structural lesion of the rotator cuff. Extension posteriorly may result in cranial migration[125,126] and extension anteriorly may lead to loss of elevation and allow anterosuperior subluxation.[13,43,100] Even in some cases of massive rotator cuff tear, however, biomechanical decompensation does not occur, and the exact reasons for this remain unclear. It is likely that the remaining muscles have sufficient force to maintain an anterior–posterior force couple, which keeps the humeral head centered and allows for a fixed fulcrum for deltoid contraction to raise the arm.[14,15,18,19] Equally confounding is the observation that some patients with relatively small tears may have poor function (Fig. 4-8).[13,15,18,20]

Muscle Atrophy and Fatty Degeneration

Goutallier et al. (59) were the first to emphasize the correlation of overall shoulder function with the degree of fatty degeneration and muscle atrophy that was evident radiographically in selected muscles of the rotator cuff. He recently validated a global fatty infiltration index (GFDI) consisting of the degree of fatty infiltration of the supraspinatus, infraspinatus, and subscapularis divided by three. He has shown that a value of 2 or greater is predictive of tear recurrence following surgery.[57] Of 220 patients who underwent rotator cuff repair, the highest percentage of recurrent tears was noted in the posterosuperior tears (56%). While Goutallier used CT to assess and grade muscle atrophy and fatty infiltration, the use of MRI has been investigated by others who have shown good to excellent inter- and intraobserver reliability, but poor correlation between MRI and CT.[32] More recently, Pfirrmann and

TABLE 4-1
PHYSIOLOGICAL CROSS-SECTIONAL AREAS FOR ROTATOR CUFF MUSCLES (IN % OF TOTAL CUFF)

Muscle	Bassett[6]	Keating[75]	Herzberg[65]
Subscapularis	46	52	51
Supraspinatus	16	15	16
Infraspinatus	38	33	33

TABLE 4-2
ROTATIONAL POTENTIAL OF ROTATOR CUFF (PERCENTAGE)

Muscle	Bassett[6] arm 90 abd + 90 er[a]	Keating[75] arm at side[a]
Subscapularis	42 (2.8 cm)	52 (2.3 cm)
Supraspinatus	13 (2.1 cm)	14 (2.0 cm)
Infraspinatus + teres minor	45 (3.1 cm)	32 (2.2 cm)

[a] Number in parentheses are average movement of the arms.

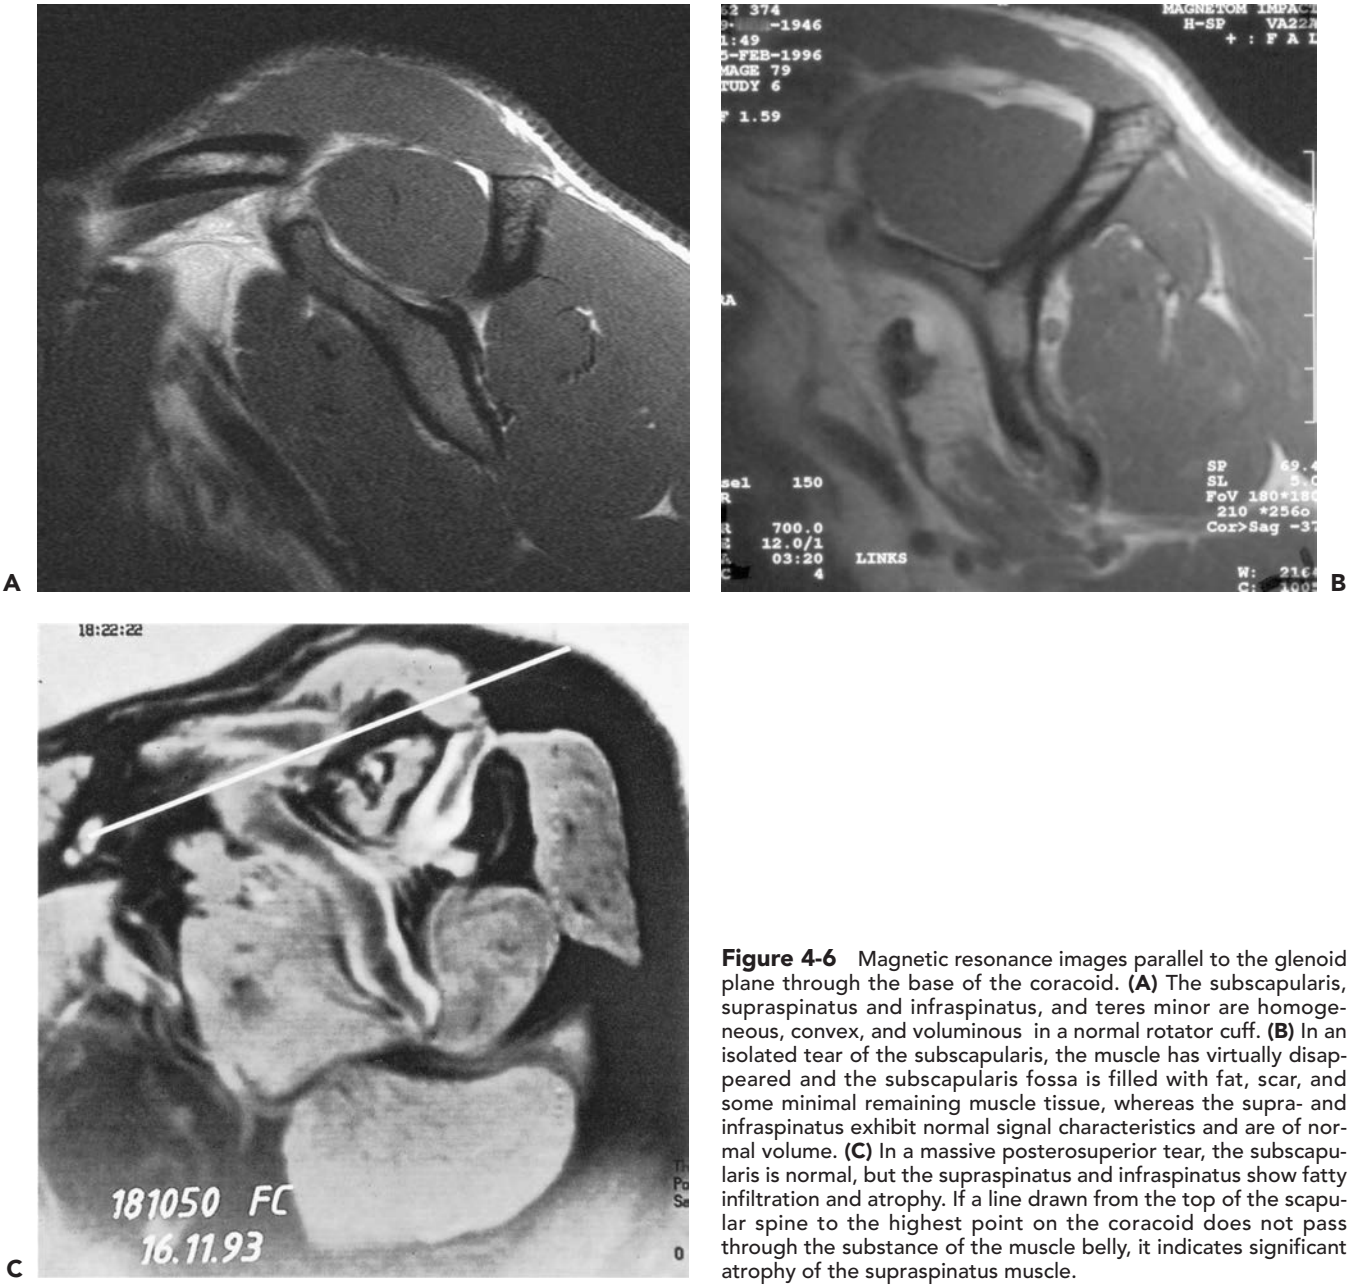

Figure 4-6 Magnetic resonance images parallel to the glenoid plane through the base of the coracoid. **(A)** The subscapularis, supraspinatus and infraspinatus, and teres minor are homogeneous, convex, and voluminous in a normal rotator cuff. **(B)** In an isolated tear of the subscapularis, the muscle has virtually disappeared and the subscapularis fossa is filled with fat, scar, and some minimal remaining muscle tissue, whereas the supra- and infraspinatus exhibit normal signal characteristics and are of normal volume. **(C)** In a massive posterosuperior tear, the subscapularis is normal, but the supraspinatus and infraspinatus show fatty infiltration and atrophy. If a line drawn from the top of the scapular spine to the highest point on the coracoid does not pass through the substance of the muscle belly, it indicates significant atrophy of the supraspinatus muscle.

coworkers[109] used MRI techniques to measure fat content in the rotator cuff muscles, and this method promises to be the most accurate means of characterizing muscle health in patients with massive rotator cuff tears.

Recent experiments have attempted to elucidate the pathogenesis of fatty infiltration of muscle following a rotator cuff tear. Gerber and coworkers showed that fatty infiltration in a sheep model of rotator cuff tears is a necessary consequence following macroarchitectural change rather than a degenerative process.[91] As the tendon tears and the muscle retracts, the pennation angle of the muscle decreases, enabling the space in between individual muscle fibers to become replaced with fat (Fig. 4-9). The structural changes that occur in this manner within the muscle unit are associated with significant changes in their structural behavior. Specifically, the muscle present in a chronically retracted tear with fatty infiltration is characterized by increased passive tension during tensile loading that creates a pathologic stress–strain behavior that compromises stability and healing of tendon-to-bone repairs.[63] In other words, as the muscle retracts and becomes filled with fat, it becomes stiffer and less compliant. Further work by Gerber following repair of chronically retracted tears indicates that there is no improvement in vascularization, intramuscular pressure, and individual muscle fiber composition.[49] Thus, in a chronic, massive rotator cuff tear, once muscle retraction

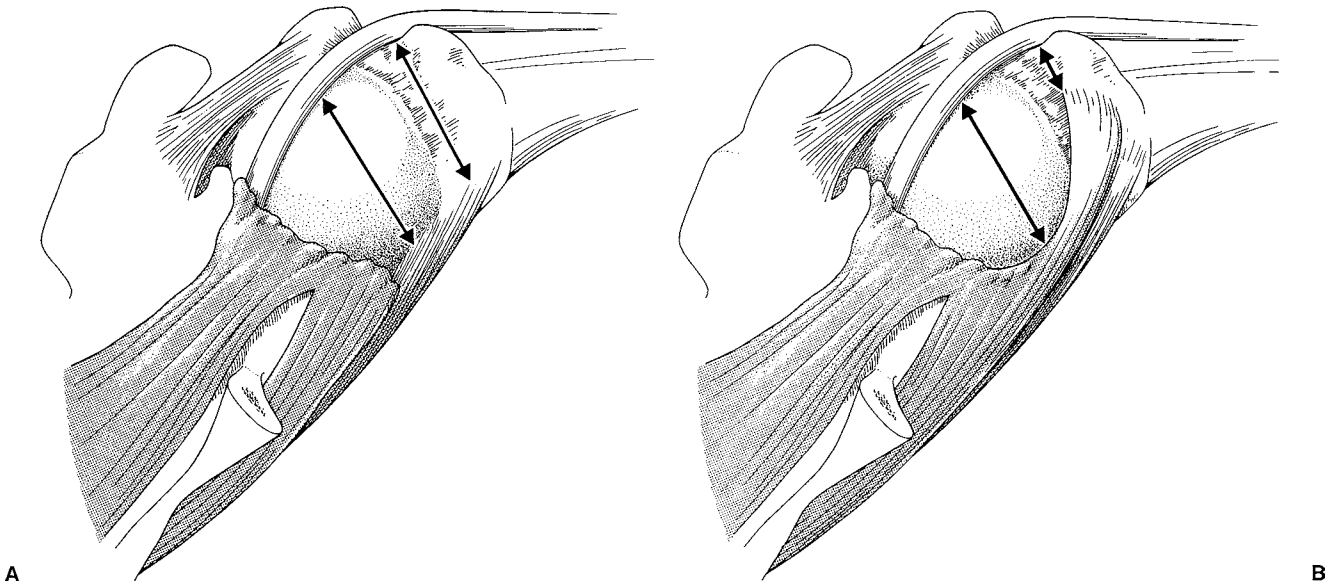

Figure 4-7 If the rotator cuff is measured in centimeters, this should be done by measuring the distance of retraction of the cuff tendons from their insertion to the greater or lesser tuberosity. This will also document **(A)** that two tendons are torn. If the size of the tear is measured from the top of the humeral head, a relatively small tear **(B)** can be mistaken for a massive tear due to buttonholing of the proximal humerus through the defect.

occurs and atrophy and fatty infiltration ensue, the associated increase in interstitial connective tissue alters the structural properties of the muscle itself. In these cases, direct repair of the tendon to bone becomes impossible.[49]

In support of this conclusion is the observations of Warner and colleagues that there is a correlation between the MRI appearance of atrophy and fatty degeneration and overall shoulder function and biomechanics (Fig. 4-10).[135] Others have correlated the degree of fatty infiltration with quality of muscle and tendon tissue.[49,51,91]

The role of the long head of the biceps in superior stability of the humerus has been a subject for debate.[67,79,125,127,128,139,141,150] We agree with the observations of Walch et al.[127] that the degenerated biceps in the setting of a massive rotator cuff tear may be a significant pain generator and should be routinely tenotomized. Thus, we always perform a biceps tenotomy or tenodesis if the patient has any symptoms of biceps irritation or if there is significant degeneration observed in the tendon at the time of surgery.

Figure 4-10 **(A,B)** A 72-year-old man with a massive, irreparable posterosuperior rotator cuff tear is able to maintain good flexion due to maintenance of a good anterior–posterior force couple and a well-functioning deltoid. **(C)** However, he displays a significant loss of active external rotation. **(D)** Oblique sagittal plane magnetic resonance imaging demonstrates severe fatty degeneration of the supraspinatus and infraspinatus muscles.

THE MECHANICAL BASIS OF TENDON TRANSFER FOR RECONSTRUCTION OF THE ROTATOR CUFF

The requirements for safe and effective tendon transfer for rotator cuff deficiency have been described by several investigators.[11,65,117] First, two types of muscle have to be distinguished if tendon transfer surgery is to be considered. One type consists of short, strong muscles with short amplitudes that are less able to generate tension; the other consists of relatively long muscles with large amplitudes that are more able to generate tension. Shiino,[117] Herzberg et al.,[65] and Wang et al.[129] emphasized the anatomic and physiologic requirements for muscle transfer including a constant vascular pedicle, adequate muscle length, sufficient cross-sectional area, and an acceptable deficit following harvest. These data are extremely useful to define optimal transfer for compensation of a functional deficit of the rotator cuff (Fig. 4-11).

The subscapularis functions as an intrinsic internal rotator and head depressor. It provides a posteriorly directed force on the humeral head while internally rotating and abducting the humerus. Herzberg described in elegant studies that the subscapularis and infraspinatus act in synergy to facilitate abduction and active elevation, whereas the subscapularis in isolation dramatically inhibits these motions.[17,65]

The supraspinatus is a relatively weak muscle whose contribution to shoulder motion decreases with increasing abduction (14% overall).[5,75] Again, the tendon excursion of the deltoid is much greater and responsible for a larger proportion of simple plane abduction.[45]

A series of recent biomechanical studies have attempted to determine why certain tendon transfers are mechanically more effective than others for the treatment of massive rotator cuff tears. In a simulated biomechanical model, Magermans and coworkers compared the effectiveness of latissimus dorsi, teres major, or a combination of these two units to the insertions of either teres minor, infraspinatus, supraspinatus, or subscapularis.[86] They concluded that a transfer of the teres major to the supraspinatus insertion produced the best functional outcome with respect to moment arm, muscle length, and muscle force. They suggested that this difference is largely attributed to the greater physiologic cross-sectional area of the teres major compared to the latissimus dorsi muscle (6.08 cm^2 vs. 5.62 cm^2, respectively), relative muscle length (86.4% vs. 80.5%), and moment arm (2.0 cm vs. 1.8 cm).[94] Our practical experience, however, has favored the latissimus transfer because the teres major is often bulky and has an extremely short tendon that is difficult to grasp, prone to pullout, and often does not reach farther than the infraspinatus insertion once it is mobilized. It needs to be further recognized that both the latissimus dorsi and teres major are internal rotators of the humeral head and are normally antagonistic to the external rotation function of the posterior rotator cuff.

INDICATIONS FOR TENDON TRANSFER

Posterosuperior Tears

The indications for tendon transfer for posterosuperior defects are summarized in Table 4-4. The indications for tendon transfer have been established based on a number of clinical studies and clinical observations.[2,43,52,94] In general, these procedures are indicated in individuals who have refractory pain and weakness, but an otherwise normal joint, in the setting of an irreparable rotator cuff tear.

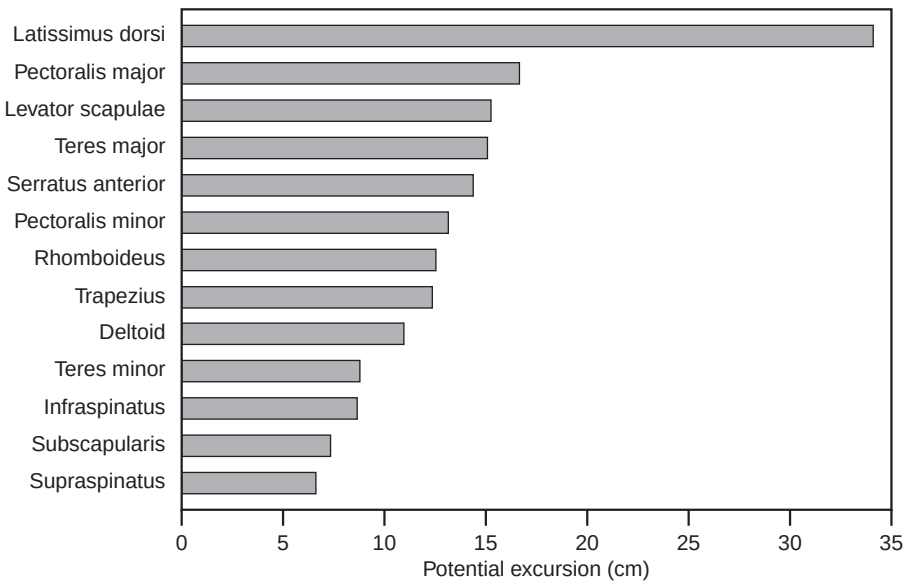

Figure 4-11 Distribution of potential excursion in 13 shoulder girdle muscles studied. Each muscle is presented as a whole without division into bellies. (Reproduced with permission from Herzberg G, Urien JP, Dimnet J. Potential excursion and relative tension of muscles in the shoulder girdle: relevance to tendon transfers. *J Shoulder Elbow Surg* 1999;8 :430–437.)

TABLE 4-4
SURGICAL INDICATIONS FOR LATISSIMUS DORSI TRANSFER IN POSTEROSUPERIOR DEFECTS

- Chronic supraspinatus/infraspinatus and/or teres minor tear or failed prior repair with retraction that is not amenable to surgical mobilization
- Isolated supraspinatus/infraspinatus and/or teres minor tear that is mobile but has a high likelihood of failure (fatty degeneration III or IV, acromiohumeral distance <5 mm on true anteroposterior radiograph)
- No evidence of static posterior subluxation on the axillary lateral radiograph
- Fatty degeneration of the supraspinatus or infraspinatus muscles of grade III or IV on magnetic resonance imaging or computed tomography scan

In the case of a posterosuperior tear that is irreparable, the degree of weakness is crucial in the decision of whether a tendon transfer is an appropriate treatment. If the patient has mild to moderate weakness, a latissimus transfer can be expected to give sufficient force to elevate the arm against gravity above shoulder level. We determine this by assisting the patient in forward flexion. If the degree of assistance required to elevate the arm overhead is minimal, then a latissimus transfer is indicated. If, however, the patient requires a great deal of assistance to raise the arm, and when the examiner releases the arm the patient cannot maintain it overhead, then a latissimus transfer is not likely to effectively restore the patient's ability to raise the arm overhead. We describe this patient as having a pseudoparalysis (see Fig. 4-1).

Contraindications to latissimus dorsi tendon transfer include associated anterosuperior tears that involve the subscapularis, cases of static anterior subluxation, advanced arthritis, or in the setting of axillary nerve injury or infection.

Anterosuperior Tears

The indications for pectoralis major transfer in anterosuperior defects are summarized in Table 4-5. In the case of an anterosuperior tear that is irreparable, many patients are able to raise their arm overhead, and certainly in this circumstance a pectoralis major transfer is indicated. If, however, there is static anterosuperior subluxation and inability of the patient to raise his or her arm overhead, a pectoralis major transfer will not restore effective elevation of the arm and the patient will probably remain symptomatic. In these cases, a reverse shoulder prosthesis may be the only option for restoration of function and alleviation of pain.

Of course, all considerations for treatment must be catered to an individual patient's disability and expectations for pain relief and functional recovery. Comorbid conditions including diabetes, cardiovascular disease, pulmonary disease, uncontrolled seizure disorder, or immunosuppression may have a negative impact on the patient's potential for recovery and ability to adhere to a rigorous postoperative rehabilitation regimen.

Contraindications to pectoralis major transfer in our experience exist in the setting of associated irreparable posterosuperior tears, cases of static superior subluxation, advanced osteoarthritis, or ongoing infection or axillary nerve injury. These contraindications are not yet clearly substantiated in the literature.

TABLE 4-5
SURGICAL INDICATIONS FOR PECTORALIS MAJOR TRANSFER IN ANTEROSUPERIOR DEFECTS

- Chronic subscapularis tear or failed subscapularis repair
- Isolated subscapularis tear or combined subscapularis/supraspinatus tear if the supraspinatus is reparable (mobile, fatty degeneration II or less, acromiohumeral distance >5 mm on true anteroposterior radiograph)
- No evidence of static anterior subluxation on the axillary lateral radiograph
- Subscapularis tear with retraction to the glenoid on preoperative imaging that is not mobile to the anatomic footprint at the time of surgery despite surgical releases
- Fatty degeneration of the subscapularis muscle of grade III or IV on magnetic resonance imaging or computed tomography scan

The important factors in the history and clinical examination that enable the surgeon to make the diagnosis of an anterosuperior, posterosuperior, or combined anteroposterosuperior rotator cuff tear are discussed in Chapter 2 and will not be described in this chapter.

Radiographic evaluation in all patients consists of a true anteroposterior plain radiograph with the arm in neutral rotation. This enables the assessment of the acromiohumeral distance (Fig. 4-12). Even more accurate is the LeClerq view, which is performed with resisted abduction.[8] The axillary lateral radiograph allows one to determine the presence of static anterior subluxation and the stage of glenohumeral arthritis (Fig. 4-12).[114] Further imaging includes either a CT or an MRI with intraarticular contrast. MRI is the currently preferred method for assessment of tear quality, size, and degree of retraction, fatty degeneration, and muscle atrophy.[33,55]

SURGICAL TREATMENT OF ANTEROSUPERIOR DEFECTS

Historical treatment options for management of irreparable tears of the subscapularis have consisted of transfer of the acromial portion of the trapezius, the pectoralis minor, and the pectoralis major. Relevant to the success of these transfers is an understanding of their amplitudes and relative strengths as described earlier.

Despite the poor amplitude and strength characteristics of the trapezius, Patte et al.,[106] Patte and Debeyre,[105] Goutallier et al.,[54] and Yamanaka and Mikasa[140] reported good results utilizing this transfer for isolated insufficiency of the subscapularis. The tendon of the acromial portion of the trapezius is released with a small bony fragment, the musculotendinous unit is mobilized, the distal clavicle is resected, and the transfer is performed through the acromioclavicular joint to the lesser tuberosity (Fig. 4-13). Goutallier et al. reported their results in 25 cases as good to excellent pain relief and "acceptable" functional improvement. Unfortunately, absolute recovery of function, strength, and range of motion was not reported.

Recent experience by Resch[111,112] and others[36,69,70,73,77] has demonstrated that the pectoralis major appears to be the most reliable alternative for managing an irreparable tear of the subscapularis. Our own experience[42,44–47,70,73,93,111,112,131,133] supports this conclusion. The biomechanics of this transfer, however, are not ideal as the pectoralis major, once transferred, is unable to recreate the vector of the subscapularis, which produces a posteriorly directed force on the humeral head. Presently, there is no transfer that restores the strength and amplitude of the subscapularis optimally, although surgical techniques that route the tendon underneath the conjoined tendon have attempted to mimic the true course and force vector of the native musculotendinous unit.[36,77,78,111,112]

Figure 4-12 True anteroposterior (AP) and axillary lateral radiograph of the glenohumeral joint. The true AP view of the glenohumeral joint allows for assessment of the acromiohumeral distance and static superior subluxation, while the axillary lateral view is used to assess for static anterior or posterior subluxation.

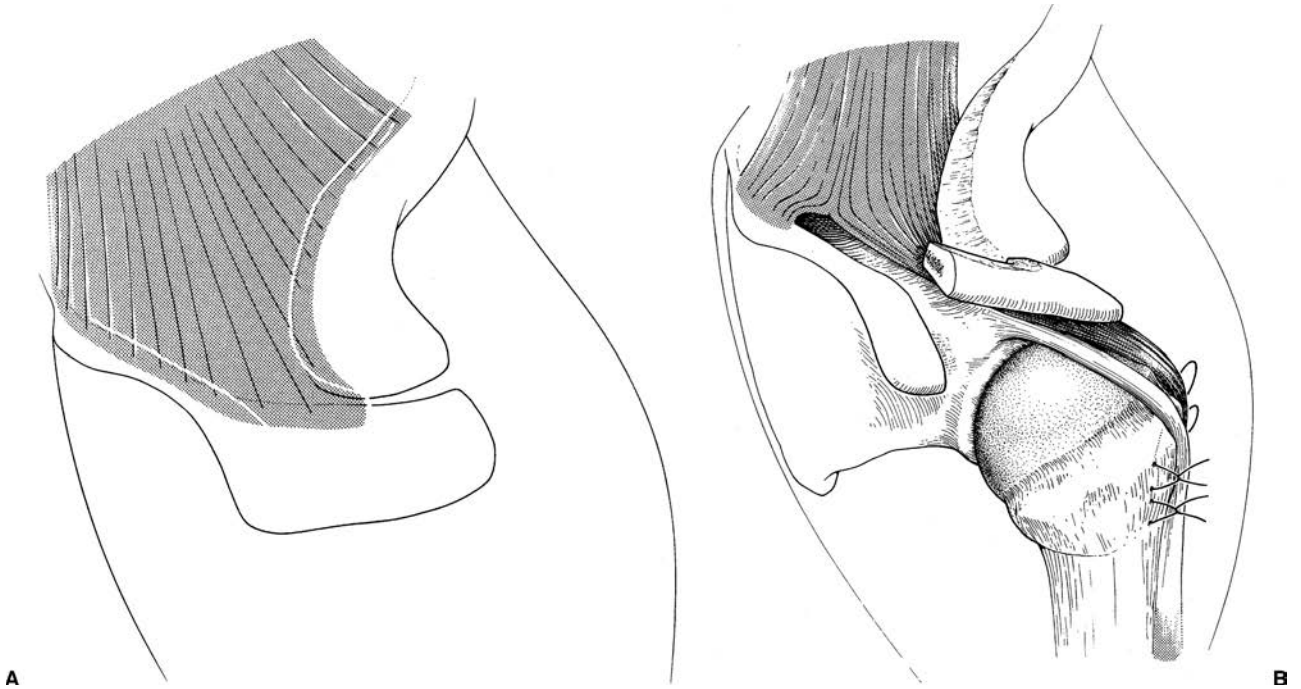

Figure 4-13 Technique of trapezius transfer for subscapularis deficiency. **(A)** The trapezius is elevated with a piece of the underlying acromion. **(B)** After elevation of the musculotendinous unit, it is either passed through the enlarged acromioclavicular joint or through the split acromion and reinserted at the lesser tuberosity. If a frontal split of the acromion has been used, this is closed with simple transosseous sutures.

Results of Pectoralis Major Transfer

Wirth and Rockwood were the first to describe the technique of pectoralis major transfer for irreparable tears of the subscapularis.[138] They reported on 13 shoulders found to have irreparable injury to the subscapularis at the time of surgery for recurrent anterior instability. Seven patients were treated with pectoralis major transfer, five with transfer of the pectoralis minor, and one with transfer of both muscles. They noted satisfactory results in 10 patients, all of whom displayed active contraction of the muscle transfer, and unsatisfactory results in three patients at a mean follow-up of 5 years after surgery.

The pectoralis major transfer has also been reported by others[24,45,93,111,112,133] in the setting of an irreparable anterosuperior rotator cuff tear with associated advanced tissue degeneration and fatty infiltration.[28,34,46,55] Gerber reported on a series of 28 patients with chronic irreparable subscapularis tears treated with pectoralis major transfer.[73] At an average 32-month follow-up, the mean relative Constant scores increased from 47% to 70%, with statistically significant improvements in pain, active elevation, and abduction strength. The outcomes were clearly less favorable if the subscapularis tear was associated with a concomitant irreparable supraspinatus tear (Constant score 49% vs. 79%). In addition, patients having undergone pectoralis major transfer were clearly inferior to those following direct repair of reparable subscapularis tears.

Resch reported on his experience using a modification of the procedure described above in which he transfers the superior two-thirds of the pectoralis muscle underneath the conjoined tendon (Fig. 4-14).[112] This modification was made in an effort to reproduce the normal course of the subscapularis tendon beneath the short head of the biceps and coracobrachialis muscle. Four of the 12 patients had concomitant tearing of the supraspinatus muscle. At an average follow-up of 28 months, 9 of 12 patients were graded as excellent/good, 3 as fair, and none as poor. All patients reported pain improvement, and the average Constant scores increased from 20 to 63.[112]

Warner and colleagues reported on another modification of the procedure, which involves transfer of the inferior, sternal portion of the pectoralis major tendon beneath the clavicular head of the muscle and superficial to the conjoined tendon (Fig. 4-15).[42,93] They felt that this would help avoid the risk of injury to the musculocutaneous nerve that can occur with transfer underneath the conjoined tendon. Furthermore, they also observed that in some cases of severe scarring after prior surgery, safe dissection underneath the conjoined tendon was problematic. They reported on 20 cases, 9 of which were combined transfer of the teres major and pectoralis major. The rationale for use of the teres major was that it would provide a greater stabilizing force than the sternal head of the pectoralis major alone. The combined transfer was used for

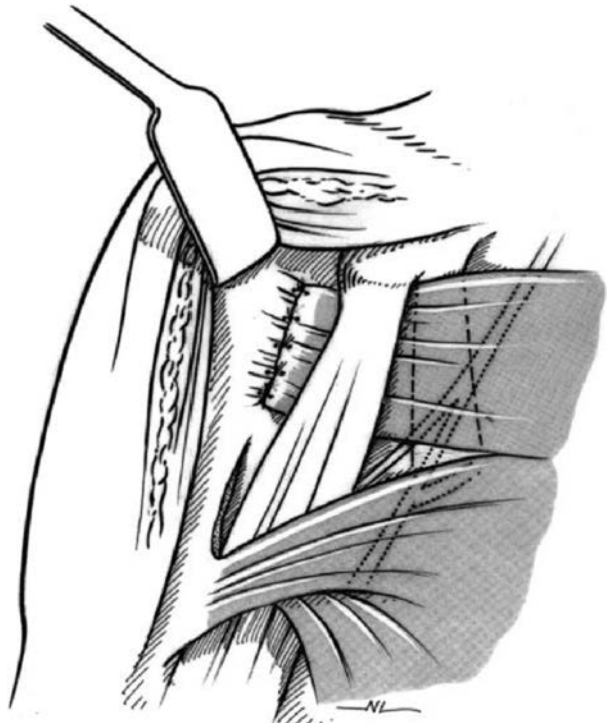

Figure 4-14 Technique of subcoracoid pectoralis major transfer of the superior half of the tendon to the lesser tuberosity for an isolated rupture of the subscapularis. (Reproduced with permission from Resch H, Povacz P, Ritter E, Aschauer E. Pectoralis major tendon transfer for irreparable rupture of the subscapularis and supraspinatus tendon. *Tech Shoulder Elbow Surg* 2002 ;3:167–173.)

patients with complete absence of the subscapularis tendon, whereas the isolated sternal head of the pectoralis was used for patients where the lower muscle fibers of the subscapularis remained intact. For the 11 patients that underwent isolated transfer of the sternal head of the pectoralis major, the mean American Shoulder and Elbow Surgeons (ASES) score improved from 42 to 61 points at an average follow-up of 38 months postoperatively. For patients who underwent the combined pectoralis/teres major transfer for a complete irreparable tear, the mean ASES score increased from 34 to 55 points. The majority of patients in both groups noted substantial pain relief.[42]

Other anatomic and cadaveric studies have attempted to determine the optimal route of transfer for the pectoralis major tendon to optimize the force vector.[36,77,78] Yamaguchi and colleagues recommended dissection of the musculocutaneous nerve from the overlying conjoined tendon and passage of the tendon of the pectoralis major beneath the conjoined tendon but superficial to the nerve. The decision to transfer the superior one-half or the entire tendon is based on the degree of subscapularis atrophy and the age of the patient, with elderly patients and those with significant atrophy generally undergoing transfer of the entire tendon (Fig. 4-16).[77,78] The transfer is attached to the greater tuberosity of the humerus. Two of their 14 patients who underwent this procedure suffered transient musculocutaneous neurapraxia. Nine of their 14 patients were satisfied with the procedure, with significant improvements in pain scores (visual analog scale [VAS] score from 7 to 3) and active flexion (28 to 61 degrees).[77,78] Clinical studies have failed to demonstrate a clear advantage among these different modifications.

SURGICAL TREATMENT OF POSTEROSUPERIOR DEFECTS

An isolated supraspinatus tear is rarely irreparable. Herzberg et al.[65] showed that isolated contraction of the supraspinatus leads to anterolateral elevation of approximately 60 degrees and external rotation of 20 degrees. Furthermore, its efficiency is substantially greater when it is activated simultaneously with the lateral deltoid.

The supraspinatus advancement, first described by Debeyre et al.,[26] is a technique that is more of a muscle "slide" rather than a transfer. Nonetheless, it has been deemed effective in the treatment of isolated irreparable tears of the supraspinatus. It is performed by releasing the muscle belly of the supraspinatus to allow lateral advancement of the tendon, being cognizant to avoid injury to the suprascapular neurovascular pedicle.[136] Although their success led them to extend this methodology to the treatment of the rare irreparable infraspinatus tear,[104,107] this technique remains largely historical, as others have not been able to validate its usefulness.

Cofield described a partial subscapularis transfer that utilizes the superior two-thirds of the tendon to replace an irreparable supraspinatus tear.[23] This rotational flap has been effective in his hands for medium-sized tears,[23] but unfortunately, much less effective in the treatment of massive tears.[74] Karas and Giachello showed that patients who undergo transfer of the subscapularis for an irreparable supraspinatus tear actually had worse function after the procedure.[74] It is our experience that the function of the subscapularis is of critical importance to overall shoulder function such that transfer of the superior two-thirds, which is usually inherently partially injured, is usually not advised. This concept, to protect and preserve the subscapularis, is supported by clinical and basic science observations that patients with massive tendon tears but a preserved anterior–posterior force couple can still elevate their arms and maintain the humeral head centered on the glenoid.[15–19,122,123]

Takagishi[121] described the trapezius transfer for isolated irreparable tears of the supraspinatus, which appears structurally well suited based on amplitude and strength. The technique involves transfer of the acromial portion of the tendon to the greater tuberosity. In a slight modification, Yamanaka and Mikasa[140] used an acromial-split technique rather than a distal clavicle resection and reported on seven cases with no excellent results.

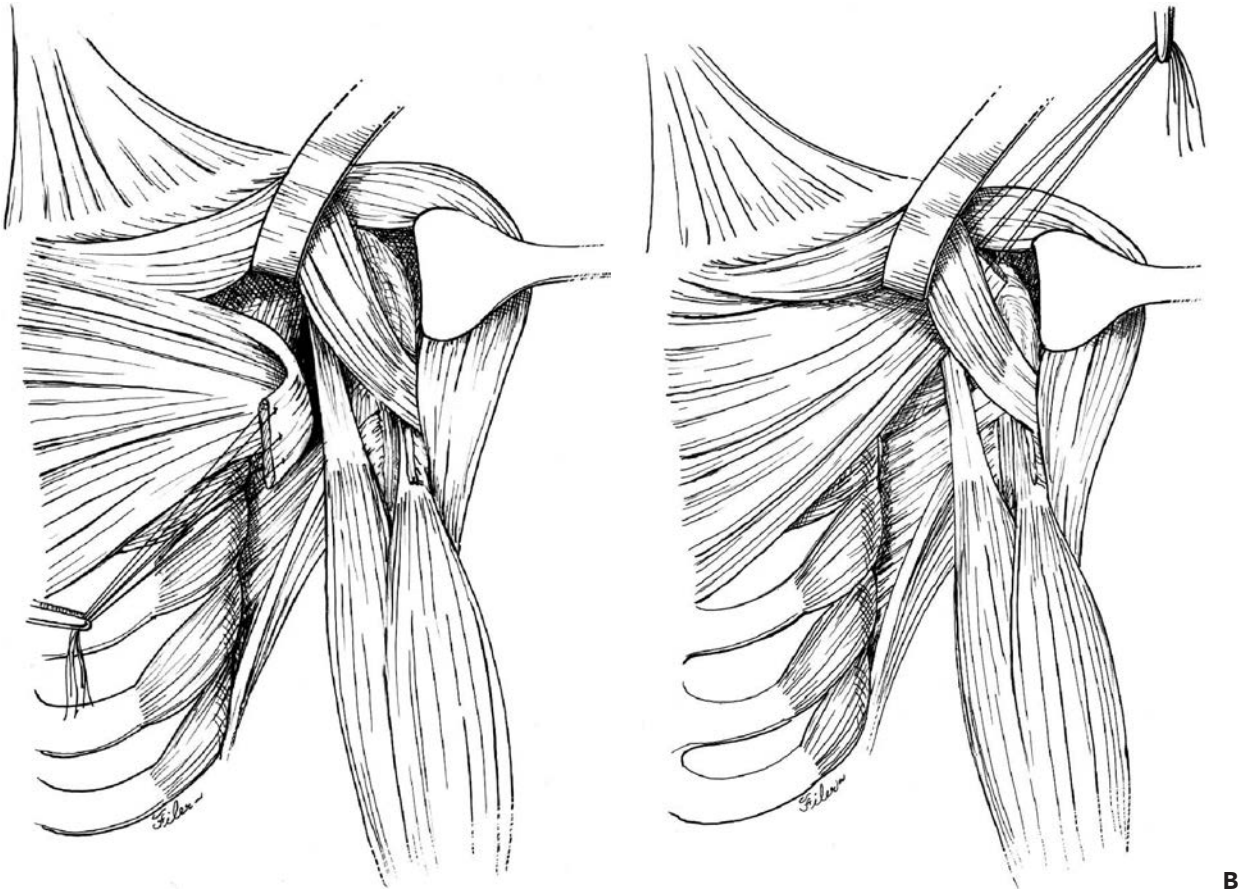

Figure 4-15 The sternal head of the pectoralis major tendon is **(A)** detached and **(B)** passed beneath the clavicular head prior to transfer to the lesser tuberosity. (Reprinted with permission from Gerber A, Clavert P, Millett PJ, Holovacs TF, Warner JJP. Split pectoralis major transfer and teres major tendon transfers for reconstruction of irreparable tears of the subscapularis. *Tech Shoulder Elbow Surg* 2004;5:5–12.)

Apoil and Augereau[3] recommended the lateral deltoid transfer based on the original description by Takagishi[121] (Fig. 4-17). This technique involves the release of an approximately 2.5-cm-wide strip of the anterolateral deltoid from the acromion, which is transferred to the supraspinatus stump or the superior aspect of the glenoid. They noted excellent results, which have been duplicated by Gazielly in 25% of his series of 20 patients who underwent this procedure.[40] A prospective study by Le Huec et al. yielded satisfactory pain relief and high patient satisfaction, but no gain in strength.[80] More recently, Gedouin et al. reported on 41 patients with a minimum 5-year follow-up who underwent the deltoid transfer for irreparable rotator cuff tears.[41] In his series, 92% of patients were satisfied with the procedure, and average Constant scores improved by 25 points (from 37 to 62 points).[41] Active flexion improved from 113 to 148 degrees with associated improvement in strength (flexion force from 1.3 to 2.9 kg).[41] Despite the experience of these surgeons, our concern is that the critical importance of a functional deltoid, especially if further treatment of rotator cuff arthropathy is undertaken using the reverse shoulder prosthesis, obviates the perceived advantage of a deltoid transfer (Fig. 4-18).

The infraspinatus is rarely irreparable in isolated cases as it usually exists in combination with an irreparable supraspinatus. The infraspinatus functions in active elevation as well as external rotation. The infraspinatus advancement has been described earlier and has provided favorable results for some surgeons (Fig. 4-19). However, this has not been reproduced in the hands of others.

Based on the work of Herzberg et al.,[65] the latissimus dorsi possesses the proper structural and physiologic characteristics for treatment of infraspinatus tears in isolation or with coexistent supraspinatus tears, and thus it has been our preferred method of treatment in such cases for the past 15 years. In his studies of the mechanical effects of latissimus transfer to multiple areas, Herzberg also confirmed that the ideal insertion site is at the tip of the greater tuberosity or at the supraspinatus footprint.

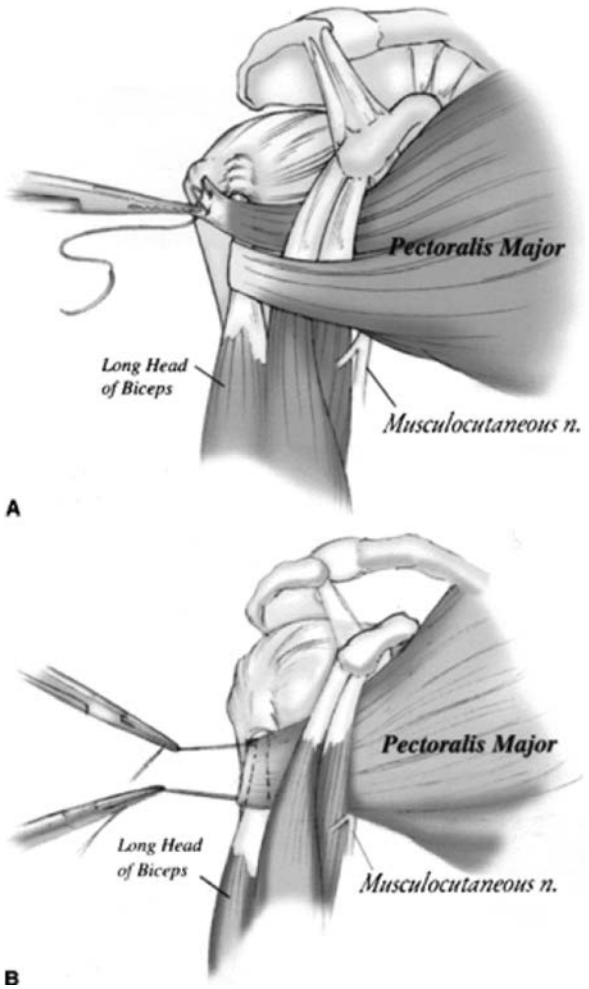

Figure 4-16 Subcoracoid pectoralis major transfer superficial to the musculocutaneous nerve. **(A)** Split transfer. **(B)** Complete transfer. Subcoracoid pectoralis major transfer: a salvage procedure for irreparable subscapularis deficiency. *Tech Shoulder Elbow Surg* 2001;2:85–91.)

Results of Muscle Transfer for Posterosuperior Defects

Gerber et al. were the first to report on successful management of massive irreparable posterosuperior tears using a latissimus dorsi tendon transfer in 1988.[52] He noted that these patients gained an average of 50 degrees of active elevation and 13 degrees of active external rotation following this procedure. He demonstrated that preexisting injury of the subscapularis and inability to repair that tendon was associated with poor recovery of function.[43,44]

Recently, Gerber et al. reviewed their mid- to long-term clinical and radiographic outcome of patients who underwent latissimus dorsi transfer at an average follow-up of 53 months (range 24 to 126 months).[48] Thirteen of these patients had a deficient subscapularis. The age- and gender-matched Constant score improved from 55% to 73%, with significant improvements in pain, flexion, external rotation, and strength in abduction. It was again noted that patients with a dysfunctional subscapularis did significantly more poorly in all parameters tested.

One explanation for inferior results in combined anterosuperior defects has been proposed by Burkhart, who emphasized the importance of a balanced force couple and fulcrum in the shoulder.[15,17] Others have confirmed this concept in biomechanical studies.[85,122]

The effectiveness of latissimus dorsi transfer has also been compared in primary versus revision surgery. Warner and Parsons[134] found significantly higher functional gains postoperatively in primary surgery compared to revision surgery. At a mean follow-up of 19 months, patients who underwent latissimus dorsi transfer as a salvage procedure had a higher rate of rupture of the transfer (44% vs. 17%) as well as significantly worse Constant scores (55% vs. 70%).[134]

Aoki and coworkers[2] reported on 12 cases of latissimus dorsi transfer for irreparable rotator cuff tears at an average follow-up of 3 years. They noted excellent results in 4 of 12, good results in 4 of 12, and poor results in 3 of 12, and were able to correlate electromyelography (EMG) activity of the muscle during active motion in 9 of 12 cases.[2] Active flexion improved from 99 to 135 degrees on average, with associated improvements in strength in external rotation. They concluded this technique to be an effective salvage procedure in restoring function and decreasing pain in irreparable tears.

Irlenbusch and colleagues performed a latissimus dorsi transfer in 22 patients, 7 of whom were for failed prior open rotator cuff repair surgeries at an average 9 months follow-up.[66] Average Constant scores improved from 43 to 67 versus 33 to 62 in revision cases. Poor results were associated with concomitant rupture of the subscapularis or deltoid insufficiency. Pain improved significantly in all patients.

Celli et al. reported on the results of isolated teres major transfer for irreparable infraspinatus tears.[21] Although isolated tears of the infraspinatus are exceedingly rare, they reported on six patients, all of whom were satisfied with the procedure. Average Constant scores improved from 40 to 62, and active external rotation improved by 35 degrees in abduction and 25 degrees in adduction.

Malkani and colleagues recently reported on transfer of the long head of the triceps in the treatment of irreparable tears of the supraspinatus and infraspinatus.[87] In a review of 19 shoulders in 18 patients who underwent this surgical procedure at a minimum of 2 years follow-up, 100% of patients were satisfied with their outcome, with average overall improvement in their University of California Los Angeles (UCLA) score from 9.7 to 28.8.

SURGICAL TREATMENT OF COMBINED ANTERO- AND POSTEROSUPERIOR DEFECTS

The only report in the literature of combined latissimus and pectoralis major transfer for anteroposterosuperior

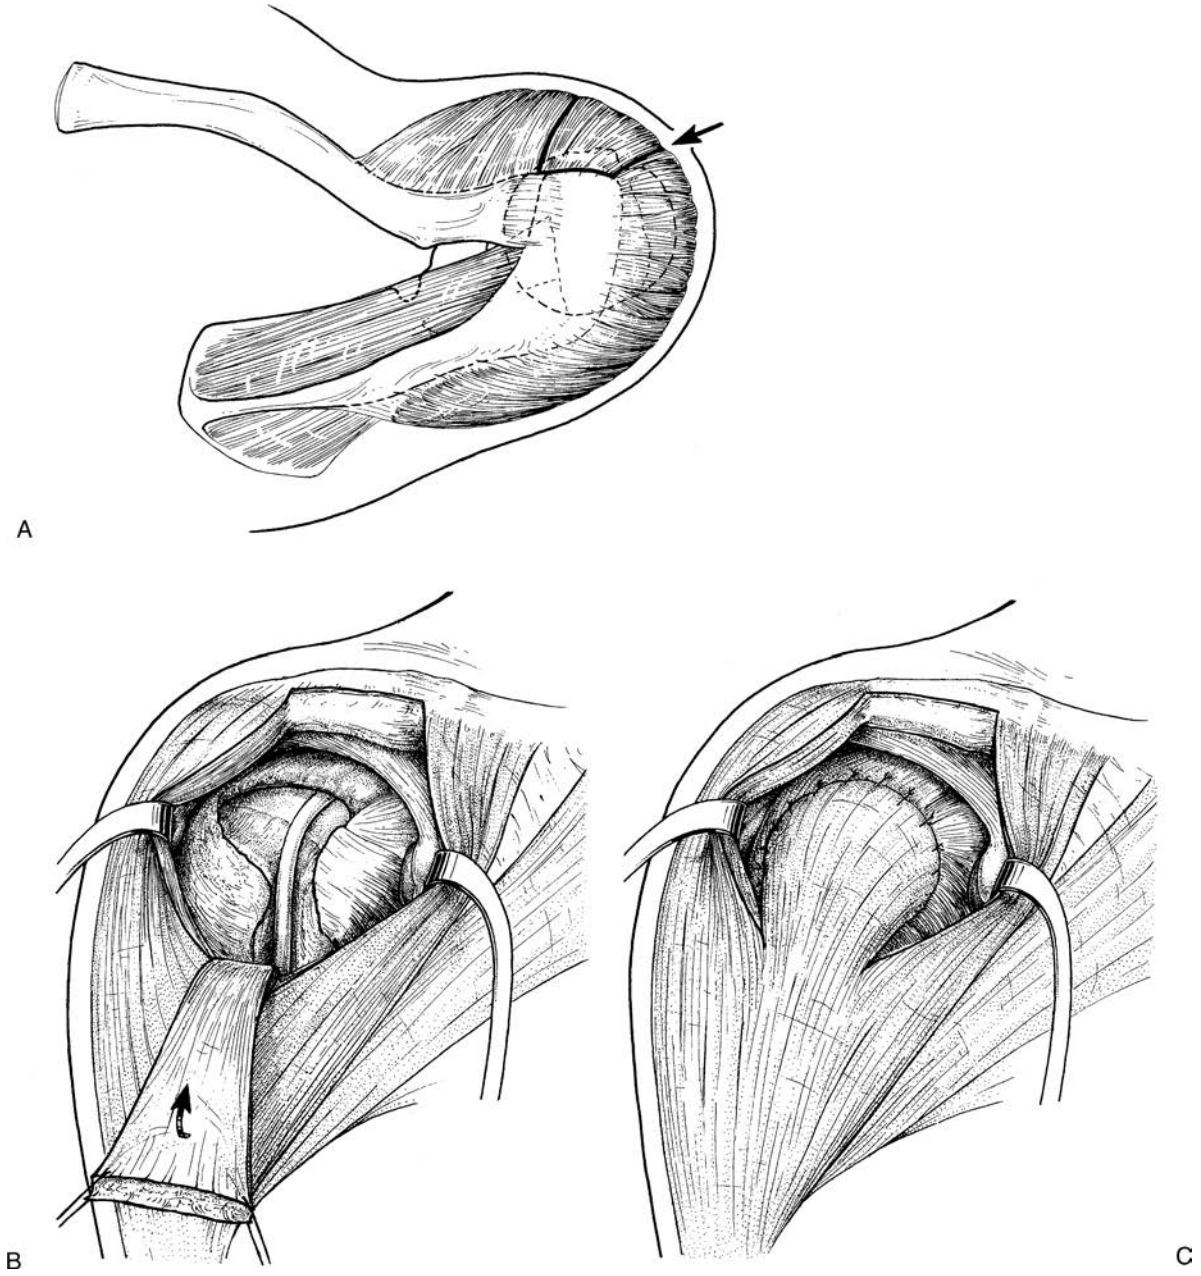

Figure 4-17 Deltoid flap technique. **(A)** An anterolateral strip of approximately 2.5 cm is tailored through a superolateral approach. **(B)** The tear is identified and débrided. **(C)** The deltoid flap is sutured to the stump of the supraspinatus, infraspinatus, subscapularis, or superior labrum depending on the pathology that is present.

rotator cuff defects was presented by Aldridge and colleagues.[1] They retrospectively reported on 11 consecutive patients treated in this fashion with a minimum 2-year follow-up. They noted an improvement in active elevation of 42 to 86 degrees and of active external rotation from 0 to 13 degrees. Five out of 11 patients showed a significant improvement in pain, strength, and function, while four showed no improvement. Standardized outcome instruments showed statistically significant improvements, with the average Constant score improving from 21 to 36, and the average UCLA score from 13 to 19.

Our experience has been that combined anterior and posterior transfers are generally not successful owing to the requirements for different postoperative therapy programs and the major weakness that cannot be restored with the mechanical advantage of these combined transfers. Thus, we do not advocate this approach.

Figure 4-18 Deltoid injury. **(A)** 52-year-old patient with right deltoid injury following open rotator cuff repair. **(B)** A 64-year-old woman who was treated with a lateral deltoid transfer for an irreparable supraspinatus tear. Her right shoulder shows a residual deltoid injury postoperatively.

TREATMENT ALGORITHM: ANTEROSUPERIOR TEARS (FIG. 4-20)

In patients with an isolated irreparable tear of the subscapularis tendon, pectoralis major transfer is likely to provide a reliable method of pain relief and functional recovery. The combination of a supraspinatus tear may also be treated with a pectoralis major transfer, with or without an associated teres major transfer, as long as there is no fixed anterosuperior displacement of the humerus from the glenoid. In patients with chronic anterosuperior tears who have static superior and anterior subluxation of the humeral head, a pectoralis major transfer will not recenter the humeral head and it will not give reliable recovery of function. In these cases a reverse shoulder prosthesis may be the only solution for restoration of function. This method of treatment is described elsewhere in this text (Chapter 23).

TREATMENT ALGORITHM: POSTEROSUPERIOR TEARS (FIG. 4-21)

In patients with an irreparable tear of the supraspinatus and infraspinatus who also have marked weakness of external rotation, a latissimus dorsi tendon transfer is a reliable method of treatment. However, the degree of weakness must not be greater than mild to moderate. Again, our method for determining this is based on the degree of assistance required to enable the patient to elevate his or her arm overhead. If the patient is completely unable to initiate any muscle force to assist the examiner in raising his or her arm, and if the arm then falls back down when the examiner removes his or her hand, the patient is considered to have a pseudoparalysis of the shoulder. In such cases, the magnitude of force provided by a latissimus dorsi that is transferred to the greater tuberosity will be insufficient to elevate the arm. In most of these patients the humeral head shows static superior displacement with an acromiohumeral distance less than 5 mm. These individuals are best managed using a reverse shoulder prosthesis.

TECHNIQUES OF MUSCLE TRANSFER

Latissimus Dorsi Transfer for Irreparable Posterosuperior Rotator Cuff Tear

Dr. Warner's Technique in Lateral Decubitus

The patient is placed into a lateral decubitus position on a long bean bag that is contoured around the patient. An articulated hydraulic arm holder (Spider Arm Positioner, Tenet Medical Engineering, Calgary, Alberta, Canada) is used on the contralateral side of the operative table, and this permits placement of the arm in the proper position for tendon harvesting as well as setting the tension of the tendon transfer during fixation. This positioning allows the surgeon to perform the procedure with one assistant provided the arm holder is available (Fig. 4-22).

An anterosuperior approach is utilized and the deltoid is split directly off the lateral acromion. The deltoid is then elevated using electrocautery in the subperiosteal plane off the anterior and posterior acromion so that this sleeve is in continuity with the deltoid and trapezius fascia. By making this vertical split directly laterally, we are able to expose the humerus from the teres minor to the subscapularis (Fig. 4-23). Furthermore, the dissection is performed parallel to the muscle fibers of the deltoid, which we believe protects the deltoid from disruption when it is repaired.

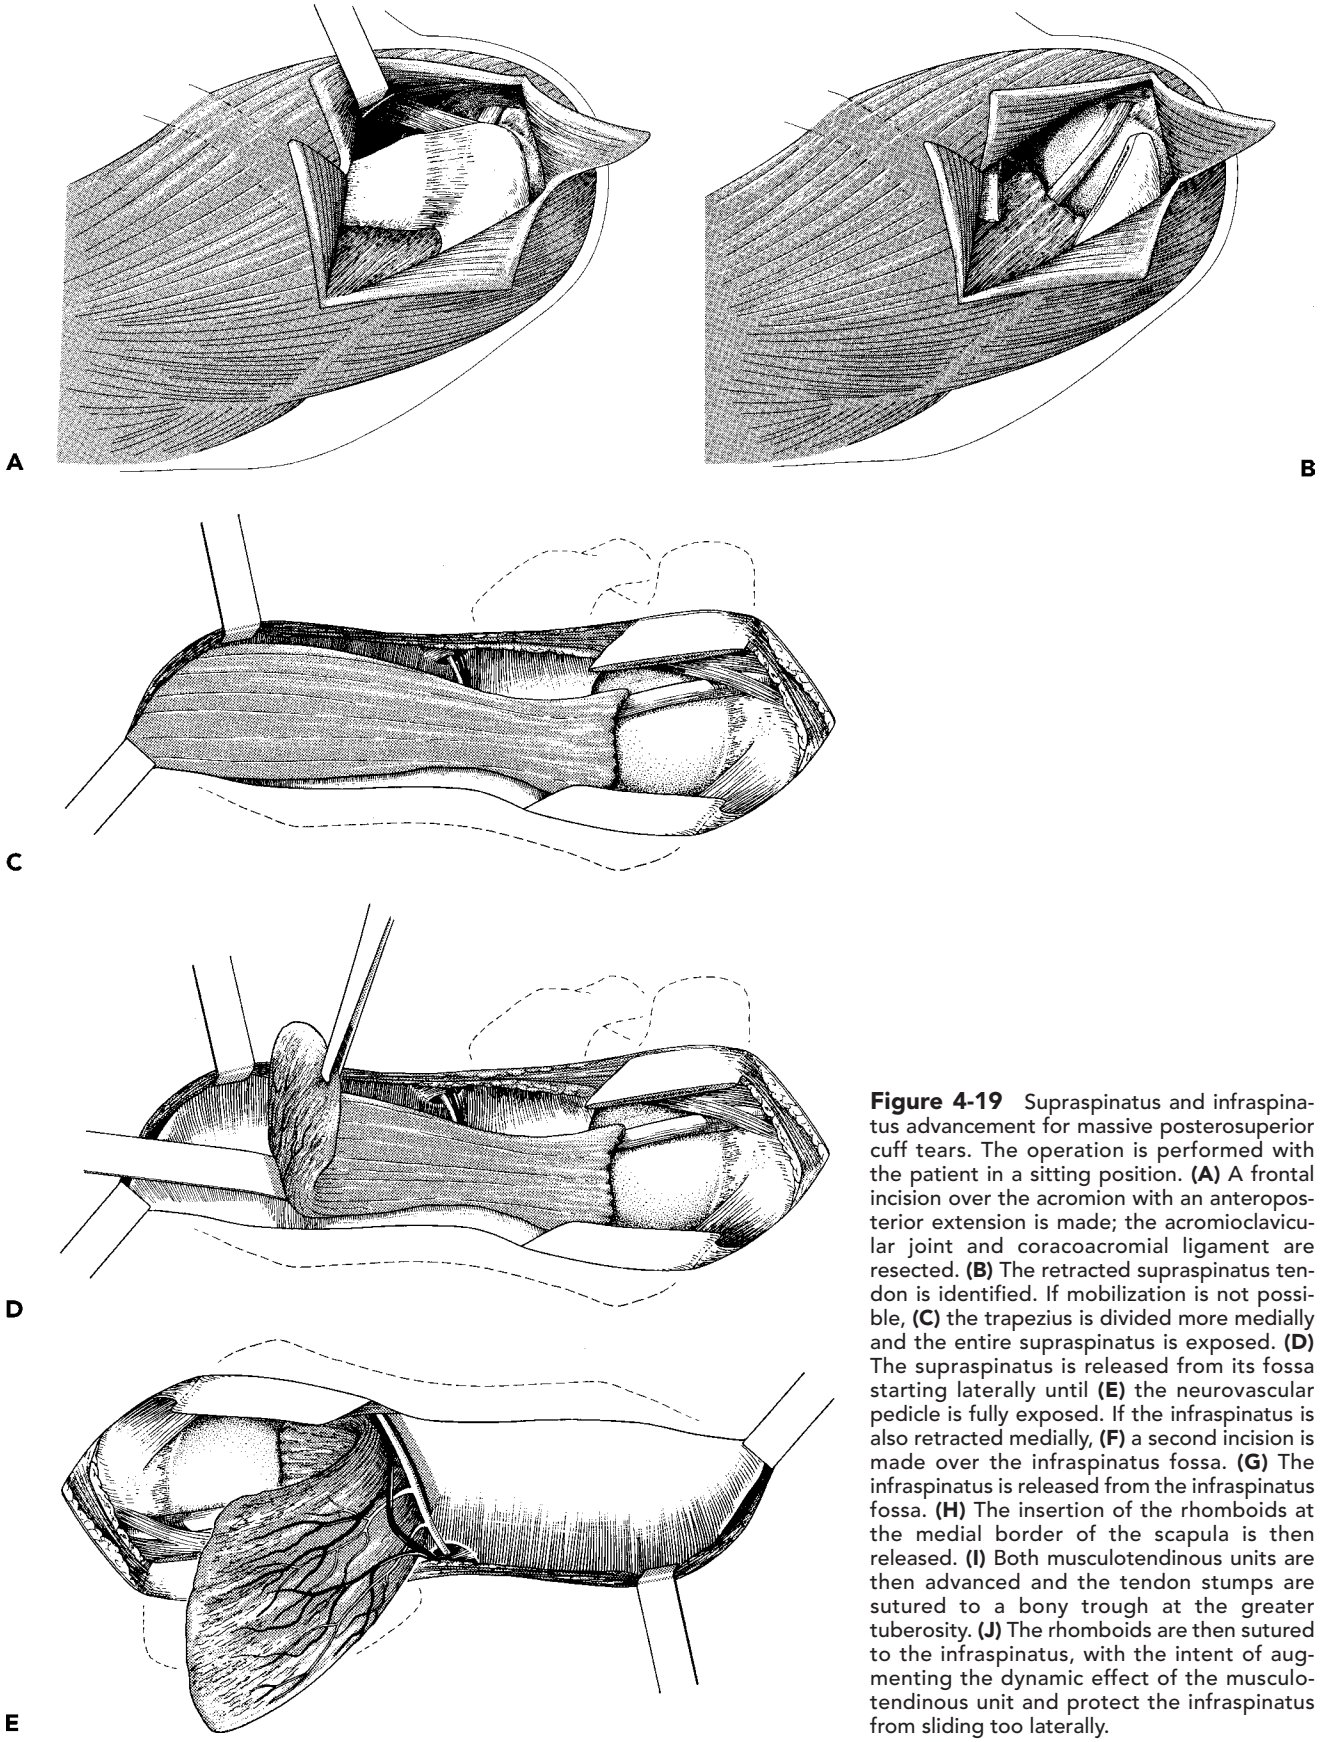

Figure 4-19 Supraspinatus and infraspinatus advancement for massive posterosuperior cuff tears. The operation is performed with the patient in a sitting position. **(A)** A frontal incision over the acromion with an anteroposterior extension is made; the acromioclavicular joint and coracoacromial ligament are resected. **(B)** The retracted supraspinatus tendon is identified. If mobilization is not possible, **(C)** the trapezius is divided more medially and the entire supraspinatus is exposed. **(D)** The supraspinatus is released from its fossa starting laterally until **(E)** the neurovascular pedicle is fully exposed. If the infraspinatus is also retracted medially, **(F)** a second incision is made over the infraspinatus fossa. **(G)** The infraspinatus is released from the infraspinatus fossa. **(H)** The insertion of the rhomboids at the medial border of the scapula is then released. **(I)** Both musculotendinous units are then advanced and the tendon stumps are sutured to a bony trough at the greater tuberosity. **(J)** The rhomboids are then sutured to the infraspinatus, with the intent of augmenting the dynamic effect of the musculotendinous unit and protect the infraspinatus from sliding too laterally.

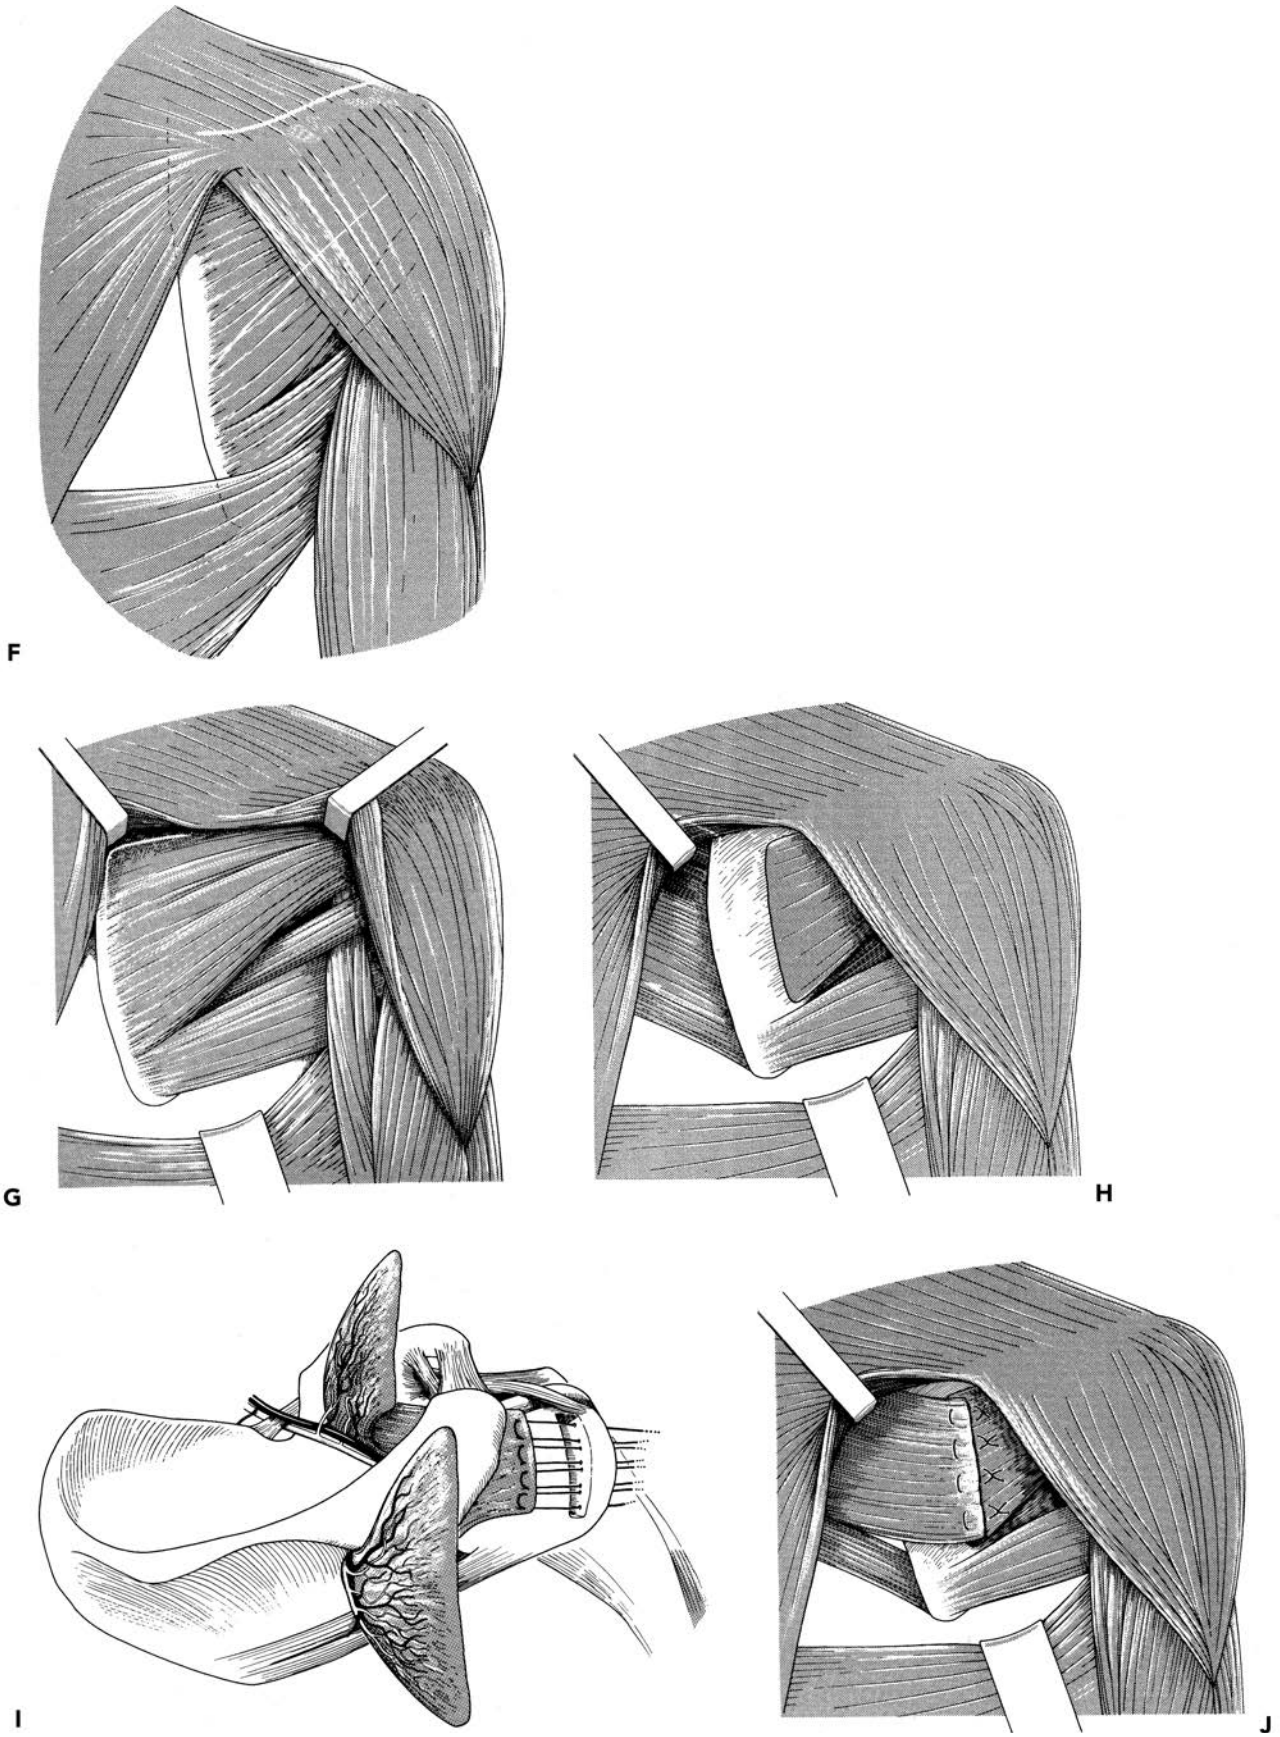

Figure 4-19 (*continued*)

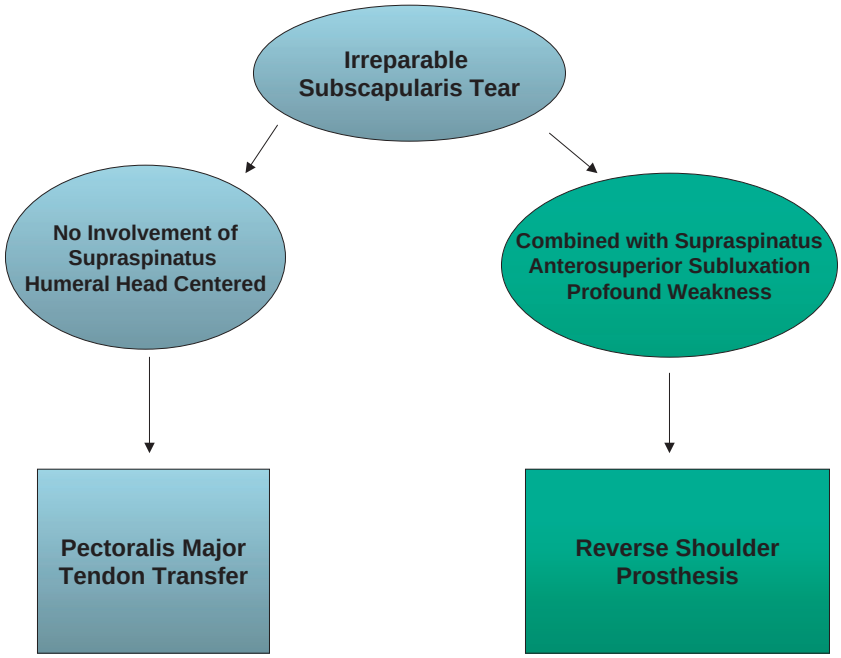

Figure 4-20 Algorithm for the treatment of anterosuperior rotator cuff tears.

If the coracoacromial ligament has not been disrupted by prior surgery, we are careful to define it and avoid its detachment as it is an important restraint to superior displacement of the humeral head in patients with a massive rotator cuff tear. More often than not, however, an acromioplasty and resection of the coracoacromial ligament has already been performed. In cases where there has been no acromioplasty, we perform a modified acromioplasty using a small saw and remove only the undersurface of the acromion from lateral to anterior, being careful not to detach the origin of the coracoacromial ligament.

Adhesions often exist between the acromion and the rotator cuff and between the rotator cuff and the deltoid. Internal rotation of the arm will expose the posterior rotator cuff, while external rotation will expose the anterior rotator cuff. Adhesions are sharply released in this interval.

If the supraspinatus and infraspinatus tendon remnants are discernible, they are mobilized as much as possible, and sutures are placed through them to be used to secure the latissimus dorsi along its medial edge following the transfer.

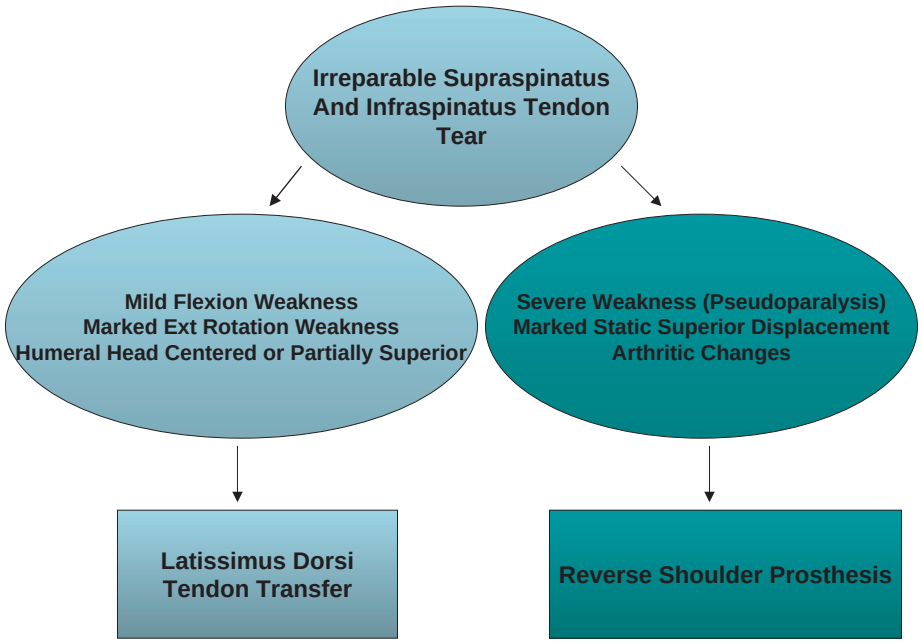

Figure 4-21 Algorithm for the treatment of posterosuperior rotator cuff tears

Figure 4-22 Patient positioning in the lateral decubitus position for latissimus dorsi tendon transfer using an articulated hydraulic arm holder (Spider Arm Positioner, Tenet Medical Engineering, Calgary, Alberta, Canada).

Once it is defined, the remnant of the infraspinatus or teres minor is secured with several sutures of nonabsorbable, braided material (#2 Ethibond, Ethicon, Johnson & Johnson, Westwood, MA). The upper insertion of the subscapularis is also defined and sutures are placed through it as well.

The biceps, if present, is usually degenerated in these individuals, and in such cases it is tenodesed within the bicipital groove using a bone anchor (TwinFix, Smith & Nephew Endoscopy, Andover, MA).

Next, the greater tuberosity is débrided clear of soft tissue and remnant of the stump of the torn tendon. A rongeur is used to abrade the bone, but a bone trough is not created. We prefer to use suture anchors to fix the tendon transfer, as these can be placed at points along the greater tuberosity to secure the latissimus tendon directly into the "footprint" of the supraspinatus and infraspinatus. Usually three or four screw-in anchors appropriate for tuberosity fixation are placed into the greater tuberosity.

The latissimus dorsi is harvested only after all of the above preparatory steps have been performed. Exposure of the latissimus dorsi is facilitated by placing the patient's arm into flexion, adduction, and internal rotation. The articulated hydraulic arm holder can maintain the arm in this position during tendon dissection. It is helpful at this stage of the procedure for the assistant to stand on the side opposite the surgeon, as this facilitates retraction and exposure of the tendon insertion during the dissection.

An L-shaped incision is made along the anterior belly of the latissimus muscle and then along the posterior axillary line. Curving the incision laterally at its proximal portion will make exposure of the tendon insertion easier (Fig. 4-24A). During the dissection, the muscles of the latissimus (most anterior muscle on the chest wall), teres major, long head of the triceps, and posterior deltoid are defined. The latissimus is dissected first from its attachments to the anterior chest wall, followed by identification of the interval between it and the teres major (Fig. 4-24B). This interval can be variable and difficult to define because in some patients, the two muscles may seem to be conjoined. However, careful dissection and retraction, which places each under tension, will allow clear dissection of the latissimus muscle from the teres major.

As the dissection proceeds toward the insertion of the latissimus dorsi tendon, several fascial bands may be encountered that course anteriorly. If the surgeon palpates the insertion of the tendon on the humerus, the correct plane of dissection can be clarified. Maintenance of the arm in internal rotation will make this step easier.

The tendon insertion is then isolated and the latissimus is detached from the humerus sharply. A traction suture in a whipstitch configuration facilitates dissection of the muscle toward its origin until the thoracodorsal neurovascular pedicle is identified (Fig. 4-24C). This structure courses on

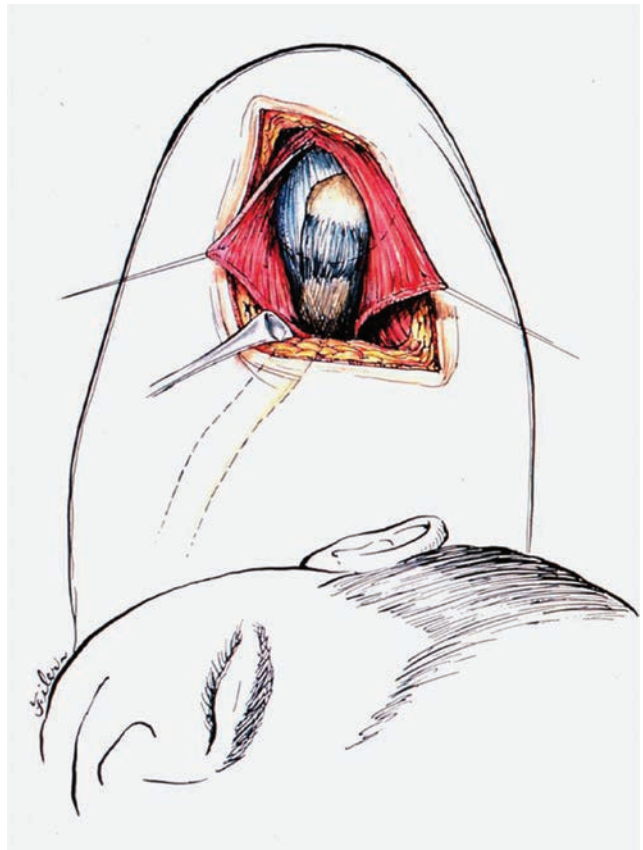

Figure 4-23 Anterosuperior approach to the rotator cuff utilizing a deltoid split directly off the lateral acromion. The deltoid is elevated using electrocautery in the subperiosteal plane off the anterior and posterior acromion so that this sleeve is in continuity with the deltoid and trapezius fascia.

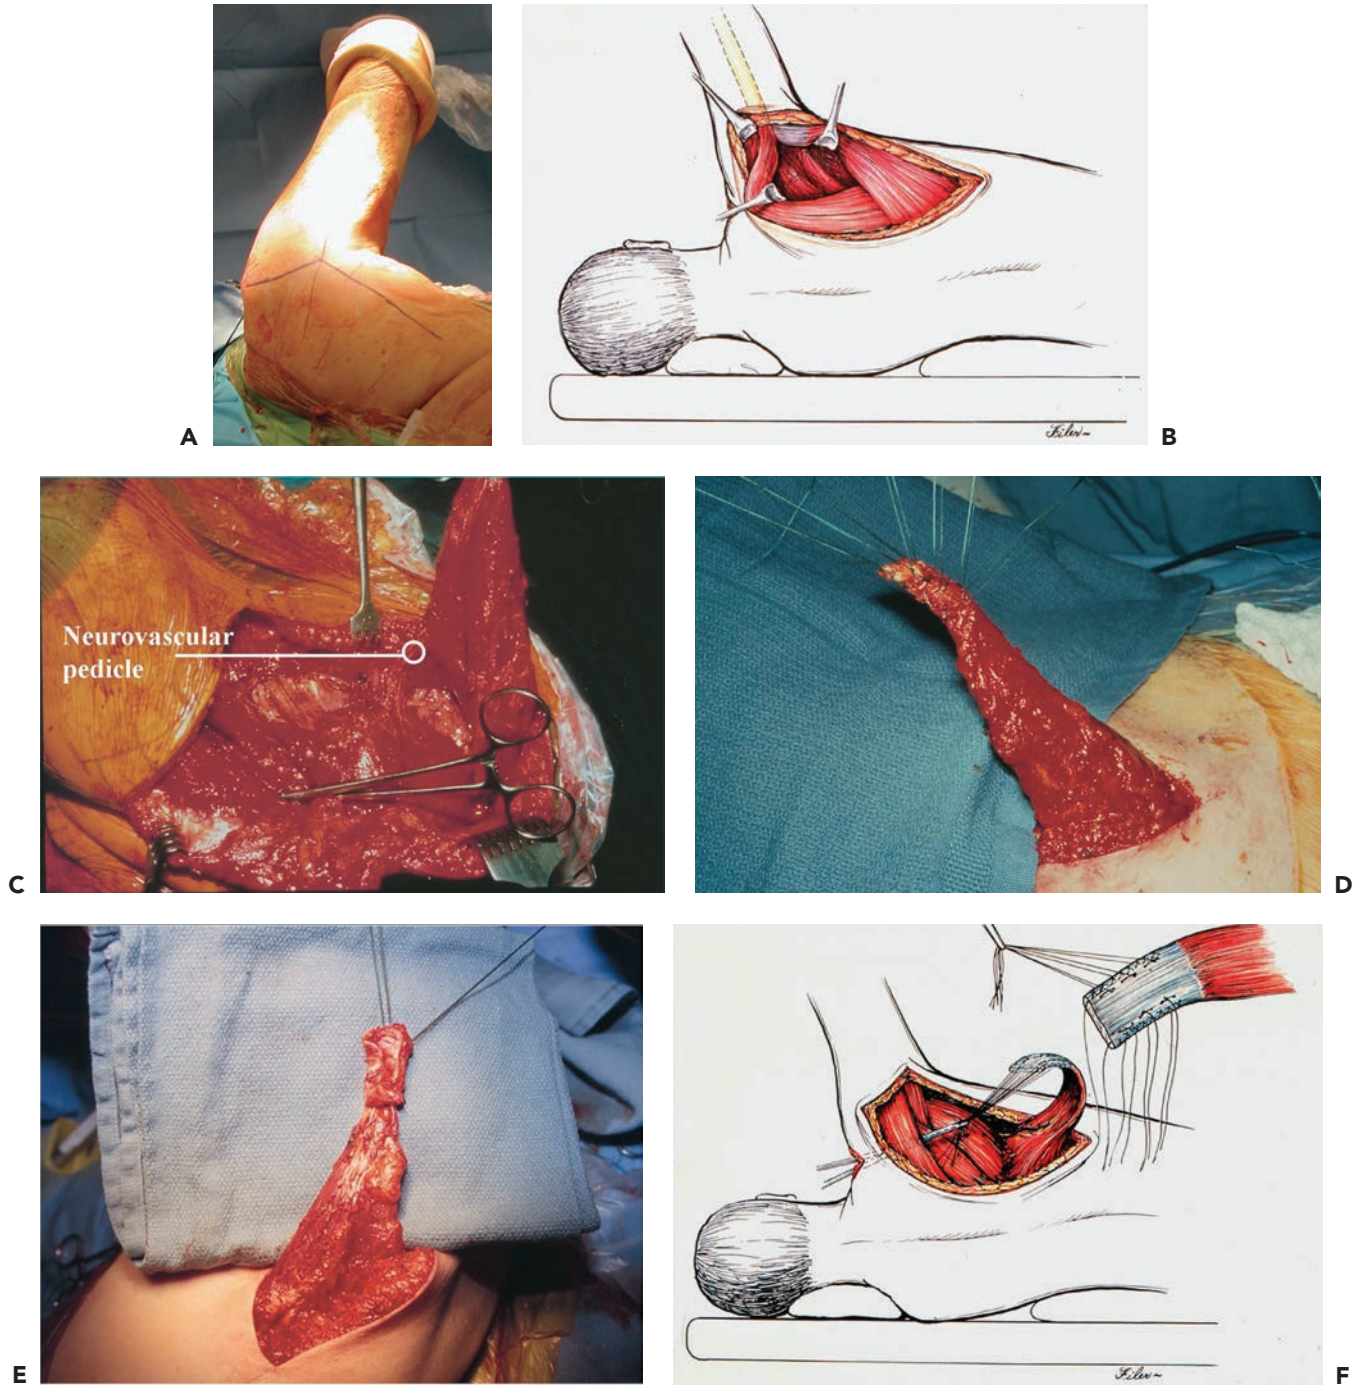

Figure 4-24 Technique of latissimus dorsi tendon transfer (JPW). **(A)** Skin incision follows anterior border of latissimus and curves along posterior axillary line. **(B)** Identification of teres major (superior)–latissimus dorsi (inferior) interval. **(C)** Thoracodorsal neurovascular pedicle. **(D)** During mobilization of musculotendinous unit, the tendon is tagged with a nonabsorbable suture in a Krakow configuration to facilitate traction and later transfer. **(E)** Fascia lata augmentation of latissimus tendon. **(F,G)** Transfer of tendon beneath through interval, defined by inferior border of posterior head of deltoid and teres minor into subacromial space. **(H)** Definitive fixation of tendon transfer using bone anchors or transosseous tunnels.

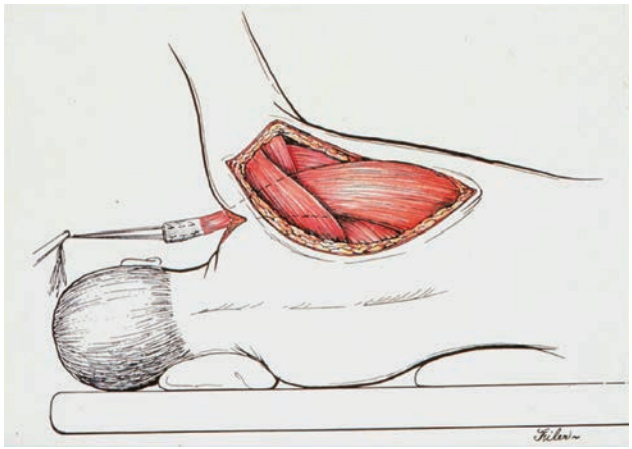
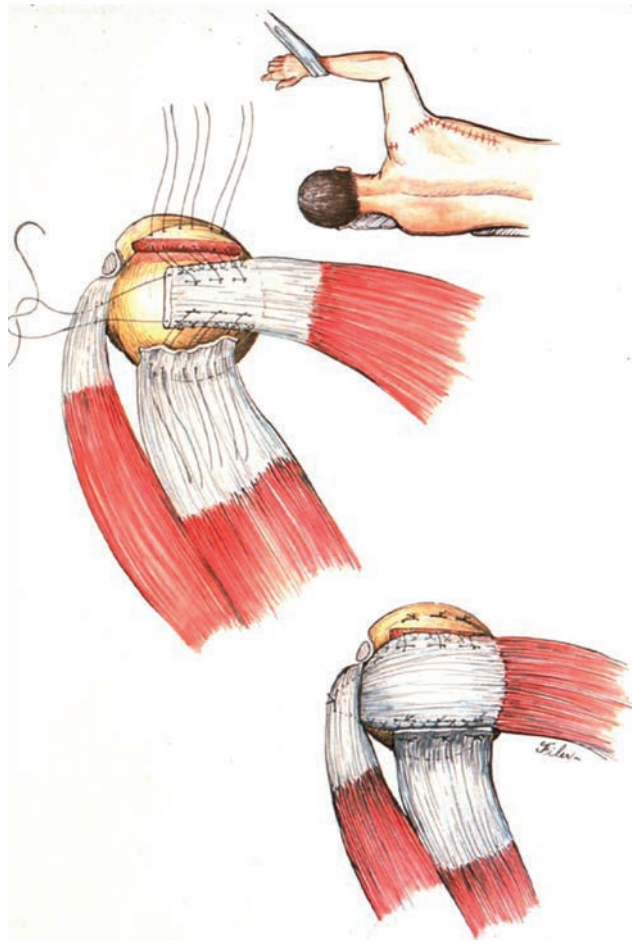
the chest wall and can be clearly defined if tension is maintained on the tendon by an assistant. We place sutures on either edge of the tendon to facilitate this step (Fig. 4-24D).

The extent of tendon release and mobilization of the musculotendinous unit is determined by the surgeon intraoperatively such that it can be pulled to the level of the posterior acromion. This will ensure sufficient length for the transfer over the greater tuberosity. We usually release the tendon from attachments to the chest wall all the way to the inferior edge of the scapula. While the neurovascular



G



H

Figure 4-24 (*continued*)

pedicle is identified, its dissection and release is never necessary to gain mobility for the transfer.

Before transferring the tendon, we prefer to augment it with fascia lata from the ipsilateral thigh. Based on our initial experience, the tendon in many patients is quite diminutive and some patients had late rupture of the transfer. For this reason, we started to use the fascia lata to augment the tendon (Fig. 4-24E). A strip of fascia lata is typically 2 to 3 cm wide by 6 to 8 cm long. The defect in the fascia is then closed.

The fascia lata is secured to the latissimus tendon from the musculotendinous junction to the end of the tendon. While length of the tendon is almost never a problem, it is possible to lengthen the tendon with the graft. We use braided nonabsorbable suture (#2 Ethibond, Ethicon, Westwood, MA) along the length of the tendon and the graft.

The interval underneath the deltoid and superficial to the teres minor is then dissected from posterior, and a curved clamp is placed underneath the acromion so that it comes into this interval (Fig. 4-24F,G). This interval is then sharply and bluntly dissected to ensure that free and unrestricted excursion of the tendon transfer is possible.

A clamp is then passed from the anterosuperior incision beneath the acromion and deltoid to grasp the sutures in the latissimus tendon for the transfer. The arm is then placed in a position to tension the tendon transfer. This is approximately 45 degrees of abduction and 45 degrees of external rotation. Then tendon is fixed to the posterior rotator cuff and over the greater tuberosity using the previously placed bone anchors. Finally, it is fixed to the subscapularis, and the sutures in the remnants of the supraspinatus and infraspinatus are sewn into the medial edge of the tendon (Fig. 4-24H). The deltoid is then repaired to the acromion with transosseous sutures and the deltoid split is closed in a side-to-side fashion. After placing a sterile dressing, the shoulder is placed into a prefabricated abduction orthosis to maintain arm position and to protect the graft from excessive tension (SOBER Abductor, Pharmap, Crolles, France) (Fig. 4-25).

Postoperative Care

Phase I (first 6 weeks) consists of continuous wearing of the brace and passive motion by the therapist bringing the arm into abduction and external rotation. Adduction and internal rotation are not permitted. This ensures that the

Figure 4-25 Abduction brace for postoperative protection of tendon transfer (SOBER Abductor, Pharmap, Crolles, France).

tendon moves in its new soft tissue tunnel and will not become tethered while it heals.

Phase II (second 6 weeks) consists of removal of the brace and then active assisted range-of-motion as well as continued passive range-of-motion exercises. The patient is permitted to use the arm for daily living activities, and water therapy may be commenced to facilitate return of passive motion arcs.

Phase III (12 weeks to 16 weeks) consists of ongoing active assisted motion and initiation of biofeedback program. A cutaneous biofeedback device is used by the patient (Myotrac, Thought Technology, Ltd., Montreal, Québec, Canada). The patient is then instructed by the therapist in the methods of training the latissimus transfer to become an active elevator and external rotator of the shoulder. The biofeedback unit is applied over the latissimus muscle. The first maneuver that the patient is instructed to perform is the "J-maneuver." The patient's shoulder is placed in approximately 90 degrees of flexion and the patient is instructed to pull downward and across the body. This will cause the latissimus to contract while the biofeedback unit gives the patient audiovisual feedback. During sustained contraction of the latissimus muscle, the patient then attempts to raise the arm into flexion, so as to trace the letter "J" with the hand. This maneuver sustains contraction of the latissimus muscle during elevation of the arm (Fig. 4-26).

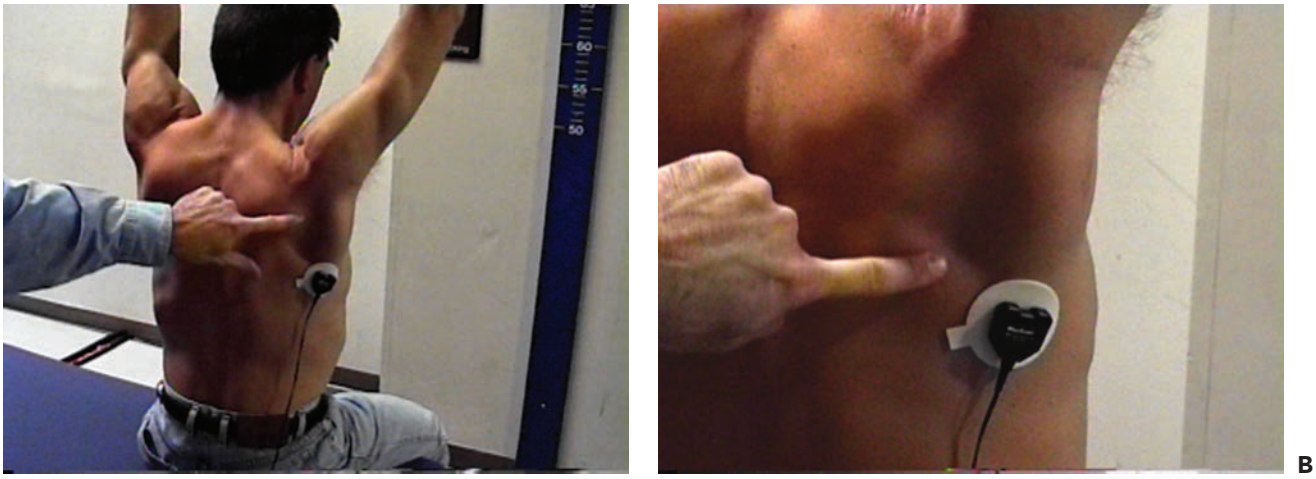
Once the patient is able to initiate and maintain contraction of the latissimus with the "J-maneuver," he or she is instructed to attempt contraction of the latissimus with external rotation. This can be facilitated by having the patient lie on his or her opposite side while pulling downward, followed by active external rotation.

In phase IV (16 weeks), biofeedback continues as long as necessary, and it may take up to 1 year for patients to successfully train the tendon transfer to actively assist in arm elevation and external rotation. Strengthening is begun when the patient achieves latissimus contraction during elevation, and we try to limit this to elastic bands rather than free weights.

Dr. Gerber's Technique in Beach Chair

Surgery is performed under general anesthesia combined with patient-controlled interscalene analgesia (PCIA), which facilitates early passive mobilization postoperatively. The patient is placed in a beach-chair position in such a manner that sufficient access to the entire scapula and latissimus dorsi muscle belly is possible using a full-length beanbag. A mechanical arm holder is not used during the operation.

The bony landmarks of the shoulder are palpated and outlined, including the acromion, acromioclavicular joint, coracoid process, and clavicle.



A B

Figure 4-26 Biofeedback training of latissimus muscle following tendon transfer involves use of a biofeedback unit (Myotrac, Thought Technology, Ltd., Montreal, Québec, Canada) and the J-maneuver.

An anterosuperior approach to the rotator cuff is performed through a 12-cm incision parallel to Langer's lines over the lateral one-third of the acromion (Fig. 4-27A). In general, this incision begins at the posterolateral edge of the acromion and ends anteriorly 2 to 3 cm lateral to the coracoid process. The anterolateral deltoid is detached from its origin with a thin wafer of bone using a flexible 1/2-in. osteotome to allow for preferential bone-to-bone healing following repair of the deltoid at the completion of the procedure (Fig. 4-27B–D). The deltoid is split no more than 5 cm from its origin at the junction of the anterior and middle raphe to avoid possible injury to the axillary nerve.

The subacromial bursa is resected sharply, and minimal anterior acromioplasty is performed, as well as distal clavicle resection if needed. A subacromial retractor (Sulzer Medica, Winterthur, Switzerland) (Fig. 4-28) is placed to allow visualization of the entire rotator cuff, from the teres minor to the subscapularis. The long head of the biceps is routinely tenodesed into the bicipital groove using a nonabsorbable anchor, as it is frequently degenerated in the setting of a massive tear and may persist as a significant pain generator following surgery.

Mobilization of the supraspinatus and infraspinatus tendons is then performed, beginning on the bursal surface and proceeding to the articular surface, followed by placement of traction sutures using nonabsorbable, braided suture (#2 Ethibond, Ethicon, Johnson & Johnson, Westwood, MA) in a modified Mason-Allen configuration (Fig. 4-29). Mobilization may include release of the coracohumeral ligament, interval slide, and circumferential capsulotomy. Release of the articular side of the posterosuperior cuff does not extend beyond 1.5 cm medial to the glenoid rim to avoid inadvertent injury to the suprascapular nerve.[136]

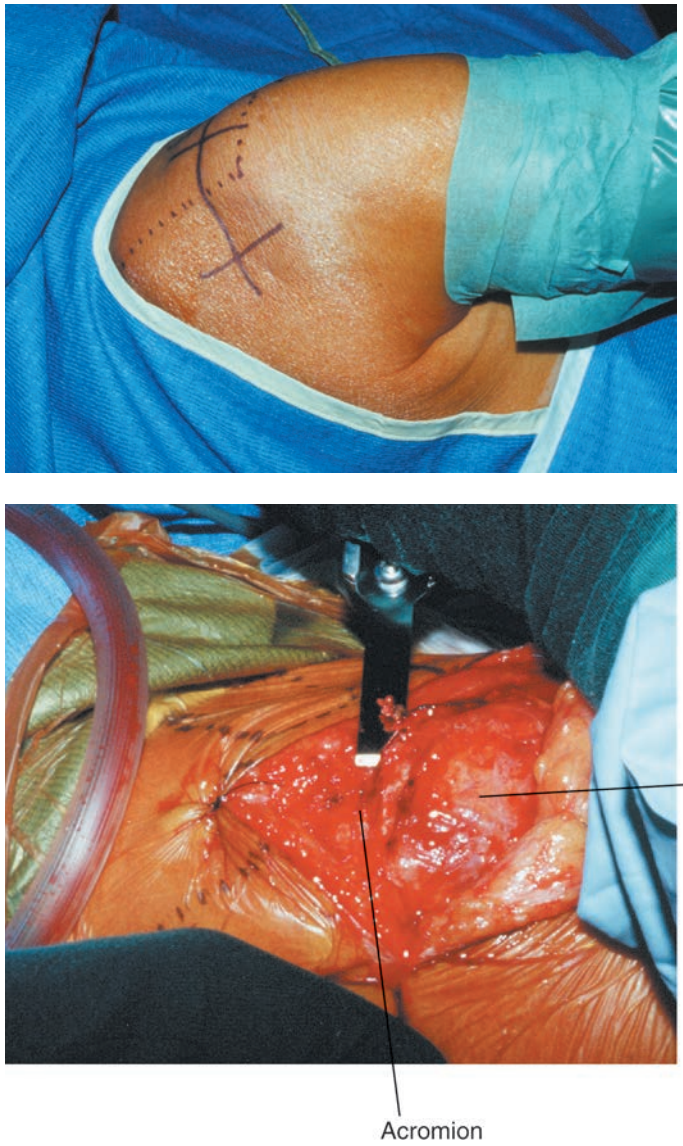


Figure 4-27 Anterosuperior exposure. **(A)** The incision is parallel to Langer's lines over the lateral one-third of the acromion beginning at the posterolateral edge of the acromion and extending anteriorly to 2 to 3 cm lateral to the coracoid process. **(B)** Deltoid exposure with middle deltoid detachment using ½-in. straight osteotome from anterolateral acromion. **(C,D)** Middle deltoid detachment enables exposure underlying humeral head and rotator cuff. (Reprinted with permission from Holovacs TF, Espinosa N, Gerber C. Latissimus dorsi transfers in rotator cuff reconstruction. In: Craig EV, Thompson RC, eds. *Master techniques in orthopaedic surgery: the shoulder*. Philadelphia: Lippincott Williams & Wilkins, 2004.)

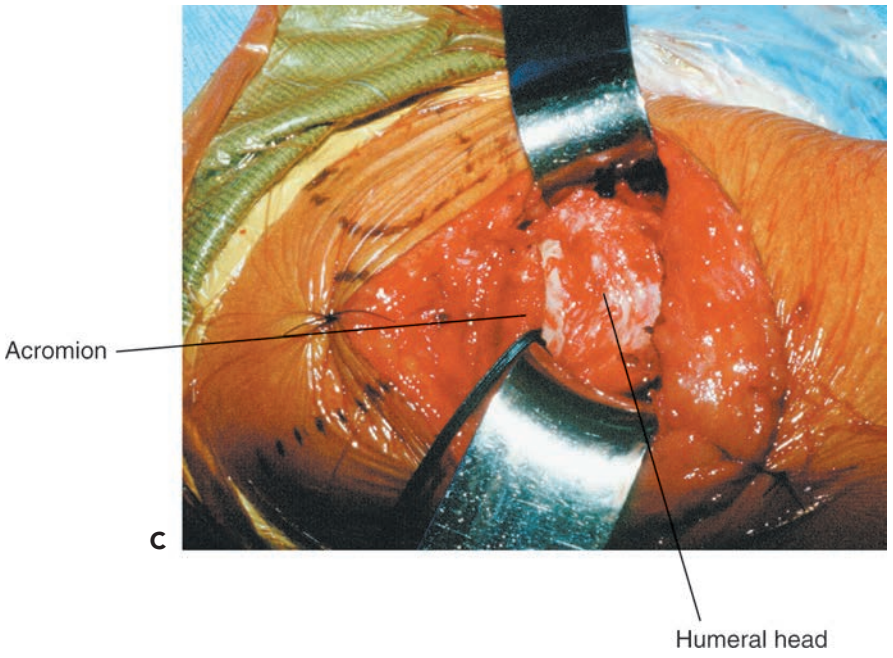
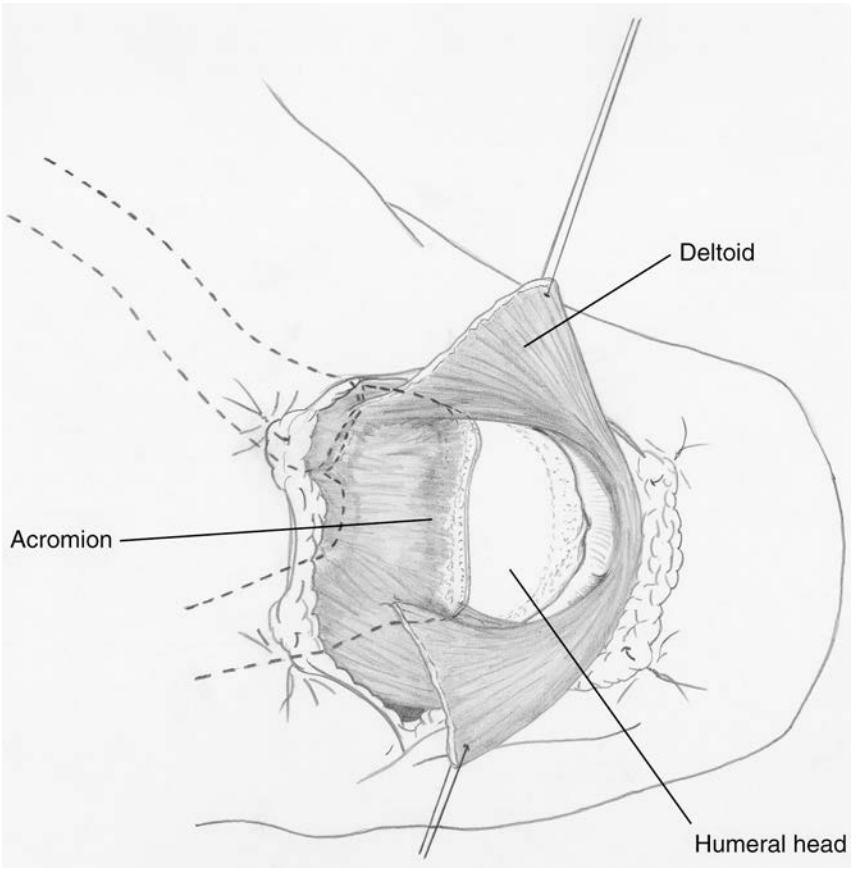


C



D

Figure 4-27 (*continued*)

Attention is then directed to harvest of the latissimus dorsi tendon. With the arm fully elevated, adducted, and internally rotated using a second assistant, the anterior border of the latissimus dorsi muscle is palpated. An approximately 25-cm incision is made from the anterior border of the latissimus dorsi muscle, which curves to the posterolateral upper humerus about 4 cm distally and does not traverse the axilla (Fig. 4-30A). Sharp dissection is used to raise subcutaneous flaps just superficial to the underlying fascia over the posterior deltoid, long head of the tri-

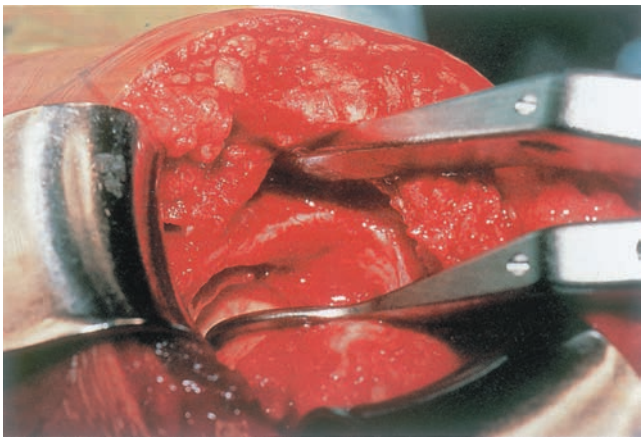


Figure 4-28 Subacromial retractor used during anterosuperior exposure (Sulzer Medica, Winterthur, Switzerland). This device has a ring that is used to retract the humeral head inferiorly and a straight limb analogous to a lamina spreader that distracts the acromion superiorly to enlarge the subacromial space. This greatly facilitates identification and mobilization of a retracted rotator cuff tendon.

ceps, teres major, and latissimus dorsi. The anterior latissimus is dissected off the chest wall fascia, beginning at the level of the muscle belly and proceeding proximally toward the insertion of the tendon on the proximal humerus (Fig. 4-30B). The radial nerve crosses over the humerus immediately distal to the insertion of the latissimus tendon on the humerus, while the circumflex vessels and axillary nerve are located just proximal to the tendon.

The interval between the superior border of the latissimus and the inferior border of the teres major is often difficult to distinguish, but can be more easily identified at the more proximal portion of either muscle. The latissimus tendon is released from its insertion using a long-handled no. 15 scalpel, and tagged with two no. 3 Ethibond sutures in a Krakow configuration (Fig. 4-30C–E). As traction is applied on the muscle, dissection can continue distally to achieve sufficient excursion of the musculotendinous unit to reach the superolateral aspect of the greater tuberosity (Fig. 4-30F). The thoracodorsal neurovascular pedicle does not necessarily need to be identified, but can be found as it enters the muscle approximately 10 cm distal to the musculotendinous junction.

The interval between the inferior border of the posterior deltoid and underlying teres minor is identified and developed using a combination of sharp and blunt dissection. A curved Mayo clamp is passed from the previous anterosuperior exposure into this interval (Fig. 4-30F). It is extremely important to adequately develop this potential space to allow for free and unrestricted excursion of the tendon transfer with the proximal humerus. The latissimus dorsi tendon is then transferred to the superolateral humerus (Fig. 4-30G).

The tagged end of the latissimus is sutured to the superior border of the subscapularis through bone tunnels passing through the lesser tuberosity (Fig. 4-30H). The previously mobilized supraspinatus and infraspinatus tendons are either repaired to a bony trough at their anatomic insertion through bone tunnels (if sufficient mobilization is possible) prior to transfer of the latissimus, or more often, repaired to the medial border of the tendon transfer. The lateral border of the tendon transfer is repaired through bone tunnels passing through the greater tuberosity and exiting laterally over a titanium cortical bone augmentation device, which prevents cutting of the sutures through the bone (Stratec/Synthes, Paoli, PA) (Fig. 4-31).

Suction drains are routinely placed in both the inferior and anterosuperior wounds deep to fascia. The deltoid split is reapproximated with a running 0-PDS monofilament suture (Ethicon, Johnson and Johnson, Westwood, MA). The osteotomy of the anterolateral middle deltoid is repaired with #2 fiberwire (Arthrex, Naples, FL) passed through drill holes in the lateral acromion. The superficial fascia of the deltoid split is reinforced with a running 2-0 PDS monofilament suture (Ethicon, Somerville, NJ).

Sterile dressings are applied, which are watertight to enable early aquatherapy postoperatively. Prior to transfer off the table, the patient is placed into an abduction brace (SOBER Abductor, Pharmap, Crolles, France) at 45 degrees of abduction and 45 degrees of external rotation, and the

brace is worn continuously for 6 weeks following surgery (Fig. 4-25).

Postoperative Care

Passive range-of-motion exercises with the arm maintained in 45 degrees of external rotation and isometric contraction of the deltoid are initiated on postoperative day 1. Passive motion is important not only with respect to tendon healing,[29,32,118,119] but also to maintain glenohumeral motion and prevent adhesion of the tendon transfer to surrounding soft tissues. Aquatherapy is also initiated at this time on a routine basis. The splint is discontinued after 6 weeks, at which time active external rotation and abduction are initiated, as well as passive internal rotation. The patient is allowed to begin performing gentle activities of daily living at this time. Strengthening exercises are not allowed until 3 months after surgery and are continued for 6 to 9 months. It may take up to 12 months for complete retraining of the transferred latissimus dorsi to occur (Fig. 4-32).

Pectoralis Major Transfer for Anterosuperior Rotator Cuff Defect

Dr. Warner's Technique for Pectoralis Major Transfer

The patient is placed in the beach-chair position such that free access to the shoulder is possible (Tmax Beach Chair,

Figure 4-30 (*continued*)

Tenet Medical Engineering, Calgary, Alberta, Canada). An articulated hydraulic arm holder (Spider Arm Positioner, Tenet Medical Engineering, Calgary, Alberta, Canada) is used on the ipsilateral side of the operating table to facilitate proper arm positioning during exposure and tendon harvest and to enable proper tensioning of the tendon transfer (Fig. 4-33). A combined regional and general anesthetic is administered, and antibiotic prophylaxis is given in all cases prior to surgery.

An extended deltopectoral approach is performed to expose the inferior border of the pectoralis major tendon as well as the latissimus dorsi tendon. If, based on preoperative imaging or clinical examination, there exists suspicion of a supra- or infraspinatus tear, dissection is extended over the superior rotator cuff as previously described for the latissimus transfer. Repair of these structures, if warranted and feasible, is performed at this time.

The interval between the deltoid and the pectoralis major is developed. All subdeltoid adhesions are released. The subdeltoid bursa as well as any scar tissue overlying the lesser tuberosity is removed. Of note, scar tissue overlying the lesser tuberosity may be mistaken for native subscapularis tendon, which, in reality, has retracted medially beneath the conjoined tendon.

The biceps tendon usually shows signs of degeneration in the context of a subscapularis tear, or if intact, is usually unstable and medially subluxated or dislocated. For these reasons or to exclude this nidus as a possible pain generator postoperatively, the biceps is routinely tenodesed. The authors differ in their preferred methods of biceps tenodesis.

The subscapularis is then mobilized with the assistance of braided traction sutures (#2 Ethibond, Ethicon, Johnson & Johnson, Westwood, MA) that are placed through good-quality tissue in the retracted lateral edge of the subscapularis. The circumflex vessels are identified and controlled with suture ligature, and the axillary nerve is routinely identified and protected prior to mobilization of the retracted tendon. If the subscapularis is deemed irreparable following these measures, the decision is made to perform the pectoralis transfer. If only a portion of the subscapularis is reparable, most often the inferior one-third, this should be performed prior to pectoralis transfer as this may improve anterior stability of the humeral head (Fig. 4-34).

The sternal and clavicular heads of the pectoralis major tendon are identified at their humeral insertion (Fig. 4-35A,B). The tendon of the sternal head is invariably inferior and deep to the clavicular head, and the interval between these two portions can be easily developed at their insertion. The sternal head is detached (Fig. 4-35C) and tagged with braided nonabsorbable sutures in a modified Mason-Allen configuration. Medial dissection to facilitate transfer of the sternal head should not exceed 10 cm to avoid risk of denervation of the lateral pectoral nerve. Following dissection, the sternal head is passed beneath the clavicular head, superficial to the conjoined tendon, and anchored to the lesser tuberosity using either transosseous sutures or bone anchors in such a way that approximately 30 degrees of external rotation is possible (Fig. 4-35D). One of the authors (CG) uses a thin, seven-hole titanium plate (Stratec-Synthes, Oberdorf, Switzerland) to augment suture fixation at the inferolateral greater tuberosity.[53] The rotator interval is then closed by suturing the inferior edge of the supraspinatus to the superior border of the pectoralis transfer.

In the presence of a complete rupture of the subscapularis tendon in combination with a supraspinatus tear, a combined transfer of the teres major is performed in combination with the sternal head of the pectoralis major tendon (Fig. 4-36). In brief, the insertion of the latissimus dorsi tendon is identified and detached with a small cuff of tendon remaining on the humerus to enable later repair

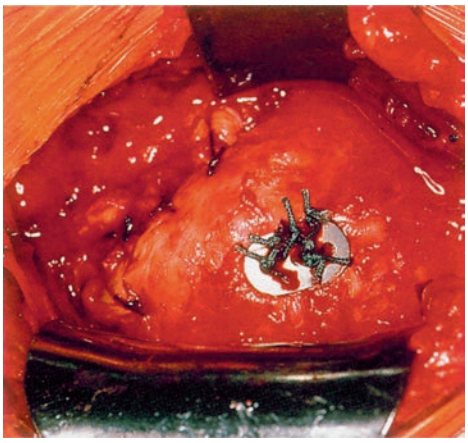

Figure 4-31 Direct repair of the lateral border of the tendon transfer is achieved with transosseous sutures, which are augmented using a titanium cortical bone augmentation device (Stratec/Synthes, Paoli, PA).

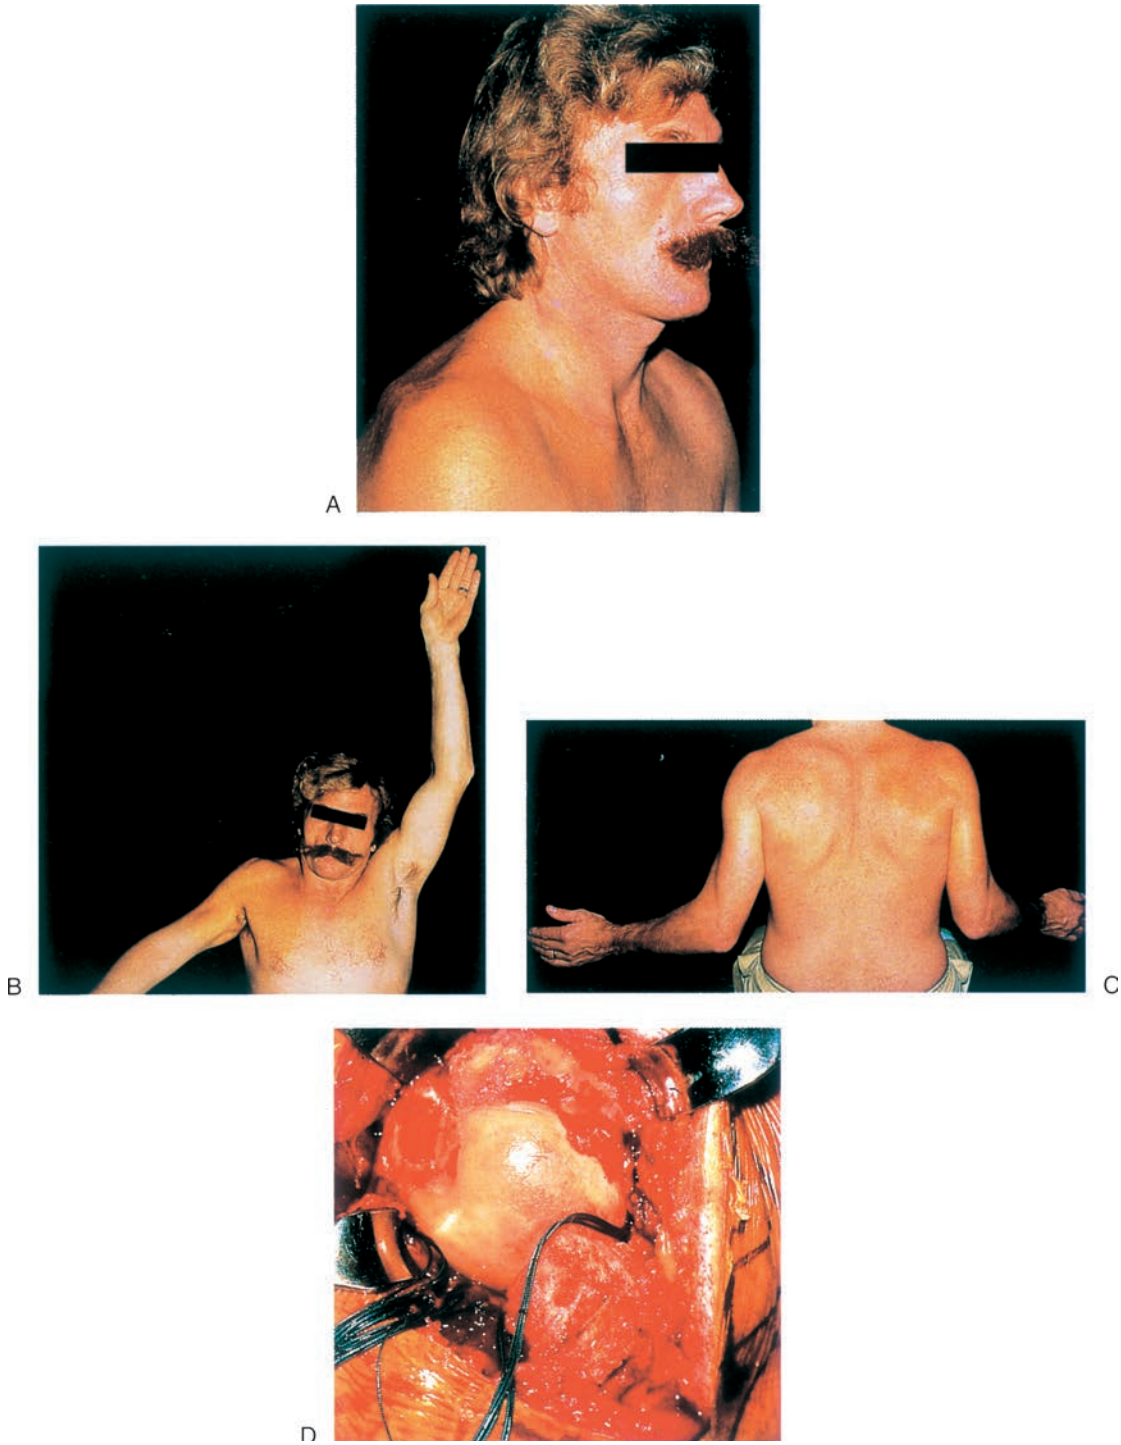

Figure 4-32 **(A)** A young patient with a massive tear and severe atrophy of the supra- and infraspinatus. **(B,C)** He has pseudoparalysis to scapular plane abduction and external rotation. **(D)** Intraoperatively, the residual supra- and infraspinatus tears are not reparable, and a latissimus dorsi tendon transfer is performed. **(E, F)** At 2 years postoperatively, the patient has recovered elevation and external rotation and is pain-free. **(G,H)** At 10 years postoperatively he maintains flexion and external rotation and is working as a truck driver.

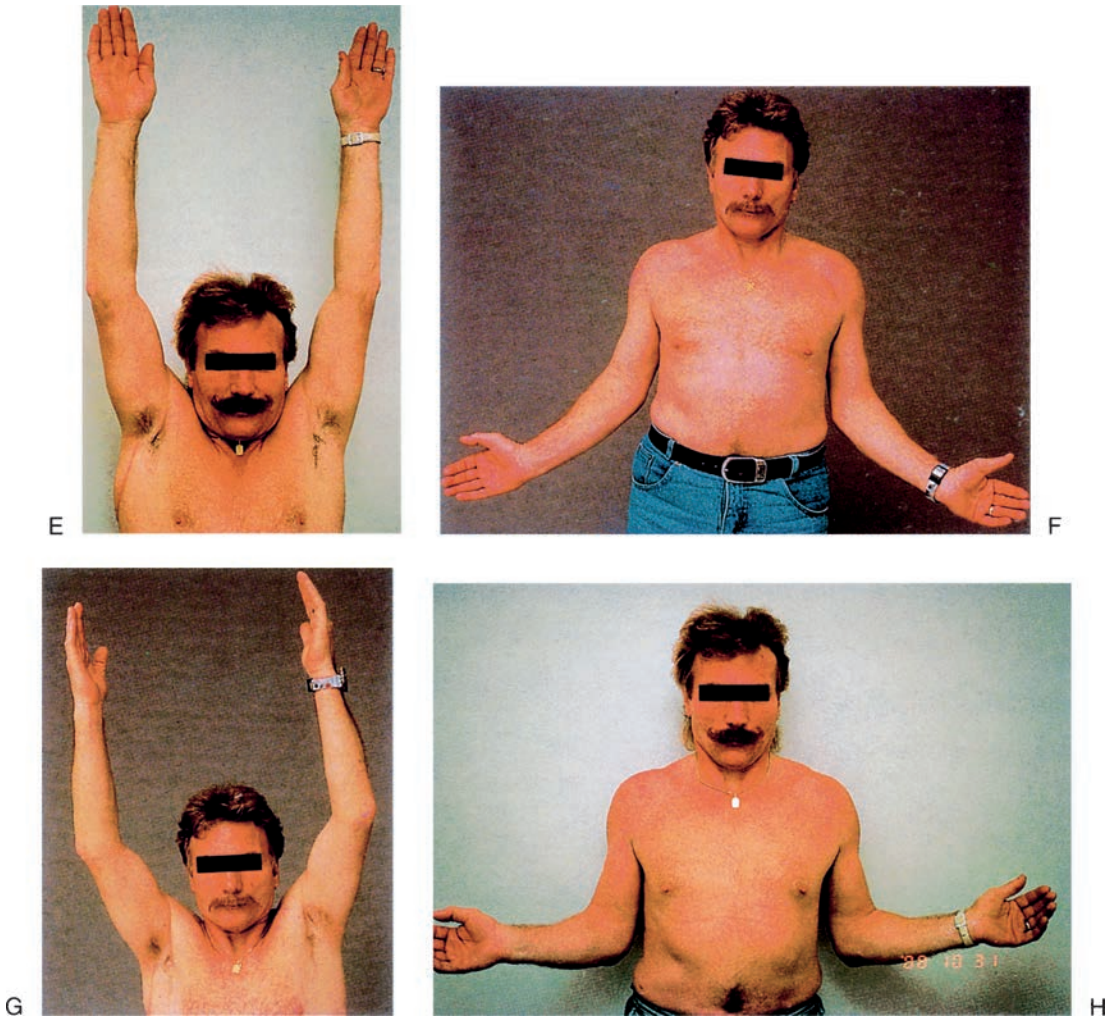

Figure 4-32 (*continued*)

(Fig. 4-36A). This procedure is facilitated with the arm in maximal external rotation. The interval between the teres major and latissimus is identified and developed laterally, with special care taken to avoid injury to the axillary nerve, which usually runs along the superior border of the teres major. Once the upper and lower borders of the teres major are released, the insertion is detached and tagged with nonabsorbable #2 suture (Fig. 4-36B). Care must be taken not to exceed 7 cm of medial dissection from the insertion in order to preserve the neurovascular pedicle supplying the muscle. The latissimus tendon is then repaired back to the stump left behind previously at the humeral insertion. The teres major and sternal head of the pectoralis major tendon are then passed beneath the clavicular head of the pectoralis major (Fig. 4-36C) and reattached to the lesser tuberosity using bone anchors (Fig. 4-36D).

Postoperative Care

Phase I (first 6 weeks) consists of continuous wearing of an abduction brace (UltraSlingII, Donjoy, Carlsbad, CA) and passive motion by the therapist, which brings the arm into adduction and internal rotation. Abduction and external rotation are not permitted. These measures ensure that the transferred tendon is able to move in a controlled fashion without compromising the integrity of the repair. The benefits of passive motion on tendon healing have been previously described.[29,32,118,119]

Phase II (second 6 weeks) consists of removal of the brace and active assisted range-of-motion as well as continued passive range-of-motion exercises. The patient is permitted to use the arm for activities of daily living at this time. Aquatherapy may be commenced to facilitate return of passive motion arcs.

Phase III (12 weeks to 16 weeks) consists of ongoing active assisted motion as well as gentle strengthening exercises using elastic bands. Phase IV (16 weeks) consists of strengthening exercises using free weights. Return to work or sports is not expected until 6 months after surgery. Completion of rehabilitation may take as long as 12 to 18 months.

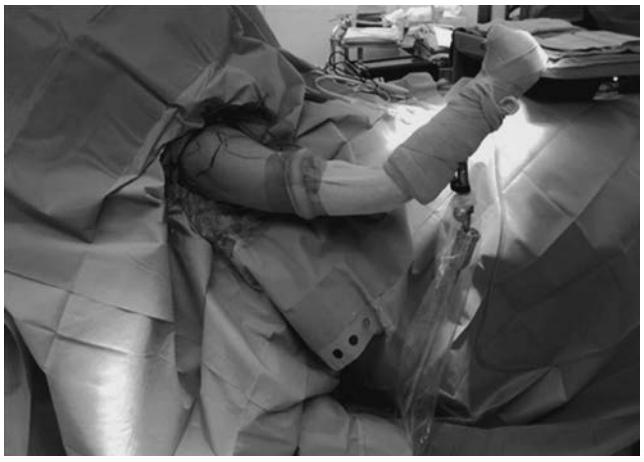

Figure 4-33 Beach-chair position for pectoralis major tendon transfer. An articulated hydraulic arm holder (Spider Arm Holder, Tenet Medical Engineering, Calgary, Canada) is used on the ipsilateral side of the operating table to facilitate proper arm positioning during exposure and tendon harvest as well as to enable proper tensioning of the tendon transfer. (Reprinted with permission from Gerber A, Clavert P, Millett PJ, Holovacs TF, Warner JJP. Split pectoralis major transfer and teres major tendon transfers for reconstruction of irreparable tears of the subscapularis. *Tech Shoulder Elbow Surg* 2004;5:5–12.)

Dr. Gerber's Technique for Pectoralis Transfer

Surgery is performed under general anesthesia combined with PCIA, which facilitates early passive mobilization postoperatively. The patient is placed in a beach-chair position using a full-length beanbag sufficiently lateral on the table to enable free access to the shoulder. A mechanical arm holder is not used during the operation.

An extended deltopectoral approach is made sharply through an approximately 12- to 15-cm incision (Fig. 4-37A). Extensive scar tissue, if present from previous surgery, is débrided as needed. The cephalic vein is generally retracted laterally with the deltoid, while the underlying conjoined tendon is gently retracted medially. Distal dissection is continued until exposure of the entire pectoralis major tendon insertion is identified. With the arm in gentle abduction and internal rotation, the subdeltoid adhesions are released sharply from the humerus followed by placement of a deltoid retractor.

At this point, the superior rotator cuff is assessed, and the proximal incision is extended to a superolateral approach if rotator cuff reconstruction is warranted.

In patients with subscapularis tears, the biceps tendon is frequently degenerated or subluxated, and for this reason, it is either tenotomized or tenodesed in the bicipital groove with an appropriate bone anchor (Super Anchor, Mitek, Ethicon, Johnson & Johnson, Westwood, MA) depending on the age and cosmetic demands of the patient.

The anterior humeral circumflex vessels are then identified and usually ligated or cauterized. The axillary nerve is routinely visualized by dissecting between the lower border of the subscapularis and circumflex vessels, and a vessel loop is placed around the nerve throughout the entire procedure. An attempt is then made to repair the subscapularis musculotendinous unit following mobilization and release from the rotator interval, the base of the coracoid, the brachial plexus, and the subscapularis fossa. The residual tendinous tissue is grasped with braided nonabsorbable suture (#2 Ethibond, Ethicon, Johnson & Johnson, Westwood, MA) with use of a modified Mason-Allen technique. Both strands of one suture are passed through the lesser tuberosity transosseously, into the medullary canal, and out through the greater tuberosity with the arm in neutral rotation. As described for latissimus transfer, a cortical augmentation plate is used to strengthen the repair (Stratec-Synthes, Paoli, PA). If only a partial repair of the subscapularis is possible, usually the inferior portion, this should be performed in addition to a pectoralis transfer (Fig. 4-37B).

The upper and lower borders of the pectoralis major tendon are identified at the tendon's insertion on the humerus (Fig. 4-37B). The entire tendinous insertion is released to maximize the length of tendon that is harvested from superior to inferior and tagged with three braided #3 Ethibond sutures (Ethicon, Johnson & Johnson, Westwood, MA) in a modified Mason-Allen configuration (Fig. 4-37C,D). The musculotendinous unit is then mobilized sufficiently to enable passage superficial to the conjoined

Figure 4-37 (*continued*)

tendon and just medial to the greater tuberosity (Fig. 4-37E). The pectoralis tendon transfer is not repaired to the lesser tuberosity for two reasons: (1) to not disrupt a possible prior repair of residual, native subscapularis tendon, and (2) to place the pectoralis major unit under adequate tension. The transfer is repaired transosseously into a bony trough that is prepared with a high-speed burr, and fixed over a cortical augmentation device (Fig. 4-37F,G).

Following the transfer, the upper portion of the pectoralis major is sutured to the inferior border of the supraspinatus with a running 0-PDS monofilament suture (Ethicon, Johnson & Johnson, Westwood, MA), constituting a partial lateral rotator interval closure.[71]

Closure is always performed over a suction drain that is removed 2 days following surgery.

Postoperative Care

Patients who have undergone an isolated repair of the subscapularis tendon with or without pectoralis major tendon transfer wear a sling for 6 weeks postoperatively. Patients with combined repairs of the subscapularis and supraspinatus are placed into an abduction brace in 45 degrees of abduction for 6 weeks (SOBER Abductor, Pharmap, Crolles, France).

Immediately after surgery, passive range-of-motion exercises are initiated under the supervision of a physical

Figure 4-38 A 54-year-old banker who suffered a complete, irreparable tear of the subscapularis following an injury playing tennis. Preoperatively, he suffered from significant pain and displayed positive lift-off and belly-press signs. Following pectoralis major tendon transfer and partial repair of the inferior portion of the subscapularis tendon, **(A)** he noted significant improvement in pain with an associated decrease in passive and active external rotation, which is common following this procedure. **(B)** Postoperative photograph of a different patient who has undergone pectoralis major transfer of the right shoulder displays an elevated anterior axillary fold, which invariably occurs using this technique. (Reprinted with permission from Jost B, Gerber C. Pectoralis major transfer for subscapularis insufficiency. *Tech Shoulder Elbow Surg* 2004;5:157–164.)

therapist within a range found to be safe at the time of surgery, generally with restricted passive external rotation beyond 10 degrees and no restrictions to forward elevation and internal rotation. Aquatherapy is a standard part of the postoperative regimen, beginning on postoperative day 2. Active range-of-motion exercises are permitted 6 weeks following surgery, and strengthening is allowed at 3 months postoperatively (Fig. 4-38).

Complications

The primary complications that have been reported with tendon transfer for irreparable rotator cuff tears include infection, nerve injury, and rupture of the tendon transfer.

If one reviews all published series on pectoralis major transfer for irreparable anterosuperior rotator cuff tears, the overall complication rate is 10%.[36,42,70,73,77,111,112,138] The most frequent complication was rupture of the tendon transfer, which occurred in 6% of all cases. Treatment of documented tendon rupture consists of immediate revision and repair of the transfer. Infection occurred in 2% of all cases, which is comparable to that found in revision shoulder surgery.

Another, more subtle complication of pectoralis major transfer can include subcoracoid impingement due to static and/or dynamic anterior subluxation of the humeral head following the transfer.[73] The only report of this phenomenon was reported by Jost and Gerber in 3% of their 30 transfers.[70] There have also been reports of transient musculocutaneous nerve injury following subcoracoid transfer of the pectoralis major tendon in 4% of such cases.[36,42,77,111,112]

In cases of latissimus transfer, injury to the axillary nerve may occur during passage of the tendon transfer beneath the deltoid. In these cases, electrodiagnostic studies are helpful in making a diagnosis and a decision of whether to surgically explore and repair the nerve if needed. Furthermore, as described earlier, revision cases are associated with a higher risk of rupture of the tendon transfer and require immediate revision.[134] In rare cases, deltoid dehiscence can occur and should be approached with immediate reconstruction, as delayed repair is associated with significantly worse outcomes.[116]

In Gerber's review of 69 cases of latissimus transfer with an average follow-up of 53 months, no infections were noted, but three patients experienced transient postoperative dysesthesias that resolved spontaneously in 6 months. Two patients required a second surgery for acromioclavicular joint excision. One patient was successfully revised for a postoperative deltoid disinsertion.[48]

CONCLUSIONS

The indications and techniques for tendon transfer in the setting of irreparable rotator cuff tears continue to evolve. An increased understanding of the natural history of irreparable and massive rotator cuff tears as well as the underlying biochemical mechanisms that instigate fatty infiltration, muscle atrophy, and tendon degeneration is helping to guide treatment decisions. Currently, the treatment of irreparable anterosuperior defects with pectoralis major transfer and its modifications results in improved pain and function in a large proportion of patients. The use of latissimus dorsi tendon transfer for the treatment of posterosuperior, irreparable lesions has proven to be an effective method of treatment and is time tested. The

management of combined antero- and posterosuperior defects continues to be a difficult problem, although some recent literature has suggested the benefits of combined pectoralis with latissimus dorsi tendon transfer. The most important element for success is proper patient selection as well as compliance with a strict postoperative rehabilitation regimen. Future studies and surgical advancements will enable the surgeon to better define the indications for tendon transfer based on a more thorough knowledge of response to treatment using these methods.

CONCLUSIONS AND TREATMENT ALGORITHM 178

INTRODUCTION

Rotator cuff pathology represents the most common source of shoulder pain, and acromioplasty the most common surgical procedure of the shoulder. Age-old debates persist regarding intrinsic and extrinsic causes of rotator cuff

TABLE 5-1
CAUSES OF PERSISTENT SHOULDER PAIN AFTER ROTATOR CUFF SURGERY

- Extrinsic shoulder pathology
  - Brachial plexopathy
  - Cervical radiculopathy
  - Long thoracic neuropathy

disease. However, most authors agree that rotator cuff surgery is generally successful. Rotator cuff surgery is routinely performed in the outpatient setting[43] and generally consists of an anterior acromioplasty, rotator cuff repair, or a combination of both. Recently, debate about the need for acromioplasty has resurfaced. The literature is replete with articles describing the diagnosis and treatment of rotator cuff pathology, espousing new techniques and technology. It is interesting, then, that there is a relative paucity of data regarding complications of such common surgical practices. There are a number of causes of persistent shoulder pain following rotator cuff surgery that are either intrinsic or extrinsic to the shoulder girdle (Table 5-1). Persistent shoulder pain and poor results are not necessarily complications of surgery, just as complications do not always equate to a poor result or persistent pain. The complications discussed in this chapter, although not all-inclusive, are directly related to the surgical procedure and relate to preoperative, intraoperative, and postoperative etiologic factors. These complications include acromial fracture, persistent subacromial impingement, heterotopic ossification, postoperative stiffness, infection, suprascapular nerve injury, axillary nerve injury, deltoid detachment, recurrent rotator cuff tear, and anterosuperior humeral head subluxation.

Complications following rotator cuff surgery are probably underreported or underappreciated. Although several authors have studied the results of operative treatment of failed rotator cuff repairs,[12,49,156] Mansat and colleagues have published the most definitive study regarding complications following rotator cuff repair (Table 5-2).[131] In their series of 116 rotator cuff repairs, the combined medical and surgical complication rate was 38% (44 shoulders). While the surgical complication rate was 33% (38 shoulders), complications that affected the final surgical outcome occurred in 16% of patients (23 complications in 19 shoulders). Complications included failure of tendon healing (17), frozen shoulder (3), deep infection (2), and anterosuperior humeral head dislocation (1). Failure of tendon healing was inferred clinically by an inability to actively flex the arm farther than 120 degrees in the absence of stiffness. The actual rate of recurrent tearing may have been higher if postoperative imaging studies had been obtained. In Mansat et al.'s extensive literature review, as well as their reported study, the rate of revision surgery was approximately 3.5%.

There have been no recent studies specifically addressing the incidence of surgical complications following rotator cuff repair. Most of the studies describe surgical results following reoperation for a particular complication, and the authors are not able to offer knowledge of the true incidence of surgical complications. To a certain extent, each complication has its own incidence and associated etiologic factors. These will be discussed individually in the following sections.

The evaluation of patients with persistent pain and dysfunction following rotator cuff surgery requires a thorough knowledge of the potential postsurgical complications. The most important diagnostic components are history

and physical examination. In addition to obtaining a history from the patient, clinical records and imaging studies from prior surgeries should be reviewed whenever possible. Potential adjunctive studies may include magnetic resonance imaging, ultrasonography, arthrography, computed tomography, scintography, and electrodiagnostic tests. The history, physical findings, and relevance of various adjunctive tests vary according to the complication(s) present.

The treatment options for patients with complications following rotator cuff surgery vary according to the specific complication. Furthermore, multiple complications may coexist in the same patient and, therefore, require combined treatment strategies. In general, the results following treatment of complications of rotator cuff surgery are inferior to the results that would have been obtained following uncomplicated primary rotator cuff surgery. However, when patients are selected carefully and the complications treated appropriately, the symptoms associated with their complications can often be improved.

ACROMIAL STRESS FRACTURE

Etiology and Prevention

Acromial fracture has been reported in association with both open and arthroscopic acromioplasty.[135,138,165] Although the reported incidence of fractures is quite low, the overall incidence is unknown and may be underreported or undetected. Etiologic risk factors that have been identified include osteopenia and overzealous bone resection. The higher prevalence of fracture during arthroscopic acromioplasty is probably related to technical error. The technique of arthroscopic acromioplasty is difficult to master and carries with it a significant learning curve.[4,35,52,121,165] Three-dimensional perception of the direction and depth of bone resection is often difficult to appreciate arthroscopically, when visualizing in a two-dimensional field. This holds true even for experienced surgeons.

It has been stated anecdotally in the literature that removal of greater than 50% of the acromial thickness increases the likelihood of fracture.[138] With this in mind, the risk of acromial stress fracture following arthroscopic acromioplasty can be mitigated by maintaining as much of the thickness of the acromion as possible while still removing the subacromial spur. There is no predetermined amount of bone to resect among all patients with subacromial impingement. Rather, the amount of bone resection will vary depending on the size of the spur as well as the size of the acromion (i.e., patient). Several studies suggest that the amount of bone resection required to relieve abnormal subacromial contact may be rather small.[56,114] There probably exists an optimal range of bone resection that will both relieve impingement and minimize the risk of postoperative acromial fracture. Bone resections on either side of that range may result in poorer results due to either acromial stress fracture or persistent impingement.

Preoperative radiographic assessment of acromial morphology (shape and thickness) should be used to provide an estimate of the amount of bone to be removed intraoperatively. Although the interobserver reliability of the commonly used classification system of acromial morphology (types I, II, and III) has been called into question,[227] the supraspinatus outlet view has been advocated by many authors as the best view to evaluate subacromial spurring.[143,147,148,153] Others have favored a standing anteroposterior (AP) view with 30-degree caudal tilt to assess the anterior prominence of the acromion.[42,180] Since the acromial spur occurs in two planes (anterior and inferior), use of both the outlet and 30-degree caudal tilt views is recommended to provide sufficient preoperative information regarding spur size and acromial thickness. Determination of acromial thickness should also be measured at the junction of the middle and anterior thirds of the acromion, which indicates the true thickness of the acromion. This measurement can then be subtracted from the measured thickness of the spur to provide an estimate of the desired bone resection.

Although Neer cautioned against shortening of the anterior acromion, subsequent authors have noted the importance of the anterior prominence in the impingement syndrome. Rockwood and Lyons[180] formally described the two-step acromioplasty in which any portion of the acromion projecting anterior to the clavicle is removed, followed by removal of the inferior aspect of the acromion. This may be performed with either an osteotome or oscillating saw, followed by feathering of any residual ridge with a burr or nasal rasp. Some authors recommend using only the burr.[138] These techniques are reliable and reproducible with few reported acromial fractures in the literature.[138]

Arthroscopic acromioplasty may be performed via anterior or posterior approaches.[4,35,52,187] While overzealous bone resection may occur during either technique, the mechanism differs depending on which operative portal is used. Techniques that solely use the posterior portal for acromial resection use the undersurface of the posterior acromion as a template to progressively flatten the acromion from posterior to anterior.[35,187] A drawback of this technique is the inability to visualize the thickness of the acromion. This can be overcome by performing the acromioplasty in two stages. Through an anterolateral portal, a full-thickness resection of a small portion of the anterior acromion, determined by extending a line laterally from the anterior cortical border of the clavicle, is performed. The coracoacromial ligament is subperiosteally elevated from the anterior aspect of the acromion, and the hood of the burr is turned toward the deltoid fascia to maintain an intact deltoid origin. This is followed by the posterior cutting block technique, while visualizing the

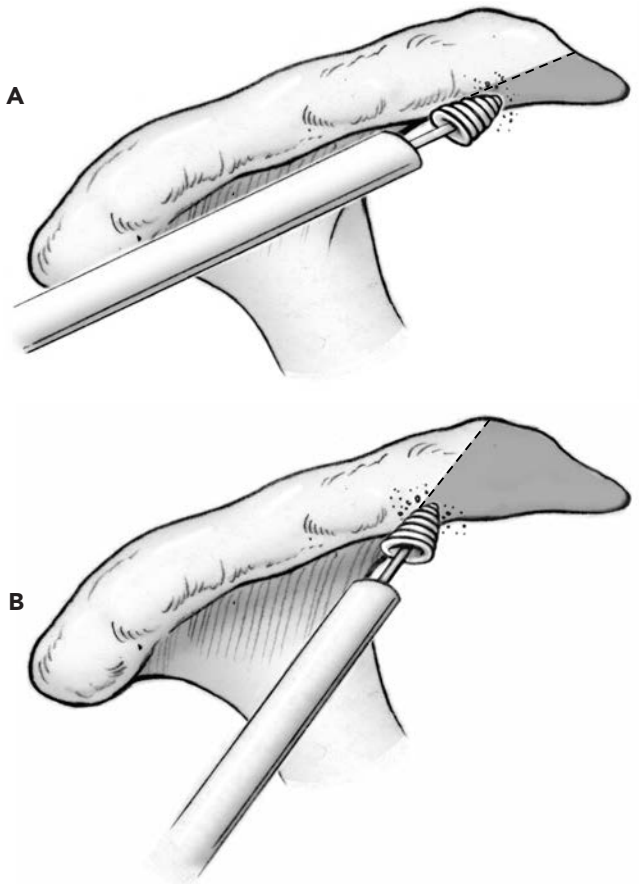

Figure 5-1 **(A)** Arthroscopic acromioplasty via a posterior approach should maintain the burr parallel to the undersurface of the acromion to produce a flat acromial surface, while maintaining maximal thickness. **(B)** If the burr meets the acromion in a convergent manner, the acromion may be amputated or excessively thinned, leaving it prone to stress fracture.

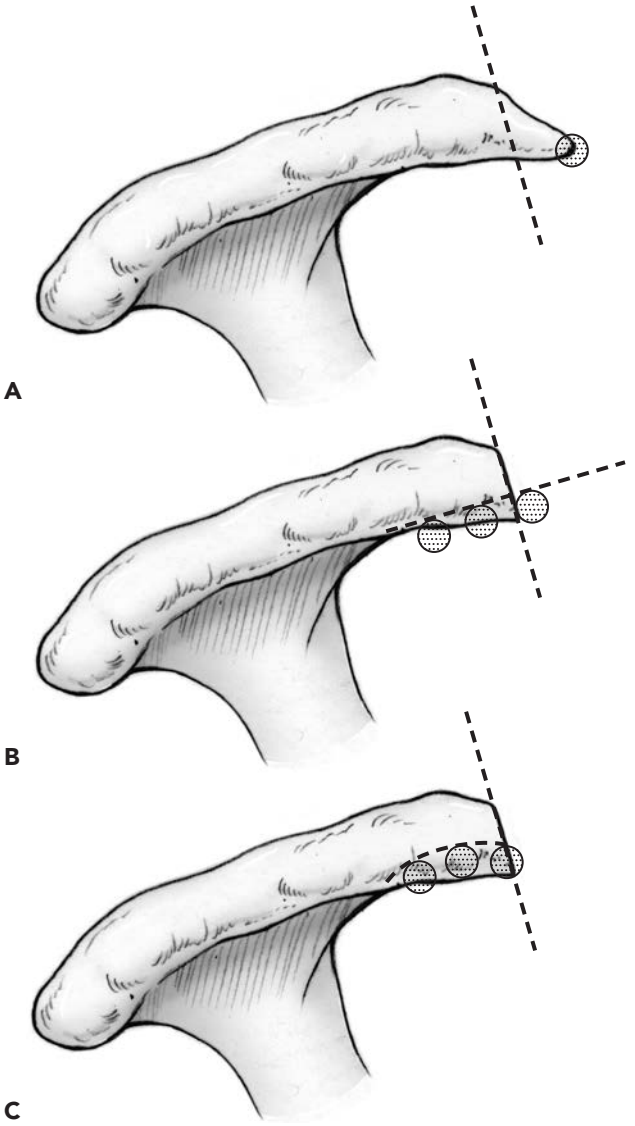

Figure 5-2 Arthroscopic techniques that use an anterolateral portal for bone resection may also result in inappropriate bone resection. **(A)** The initial step involves resection of a small portion of the anterior acromion. **(B)** The remaining acromion is then beveled from anterior to posterior to produce a flat undersurface. **(C)** When the resection is not tapered from anterior to posterior, a dome-shaped acromion will result, which is prone to stress fracture.

thickness of the acromion through the anterolateral portal. The most common error occurs when the surgeon fails to keep the burr parallel to the undersurface of the acromion. When the posterior acromion and arthroscopic burr are convergent, rather than parallel, the anterior acromion may be excessively thinned or amputated (Fig. 5-1). This problem may occur if the surgeon has placed the posterior portal too low, or may be related to an inferior prominence of the posterior acromion. The surgeon can compensate by replacing the instrument through a separate, more parallel portal, or by adjusting the angle or amount of resection accordingly. Under-resection can be easily addressed by making a second pass of the burr while over-resection is not a correctable error. The known diameter of the burr is used to properly measure the depth of the bone resection as well as the thickness of the residual anterior acromion, so that approximately 50% of the thickness remains following acromioplasty.

Acromial resection through a midlateral or anterolateral portal requires that the burr sweep from anterior to posterior. The amount of bone resection, or depth of penetration of the burr, is greatest at the anterior acromial margin and is progressively tapered to zero at the posterior border of the acromioclavicular joint. Failure to taper the resection depth will result in a thinner, dome-shaped acromion that may be prone to stress fracture (Fig. 5-2). Care should also be taken to preserve at least 50% of the thickness of the acromion. We try to accomplish this by performing the acromioplasty in two stages. The first stage is performed as described above. This is followed by beveling of the acromion from anterior to posterior, starting laterally and progressively working toward the medial acromial facet.

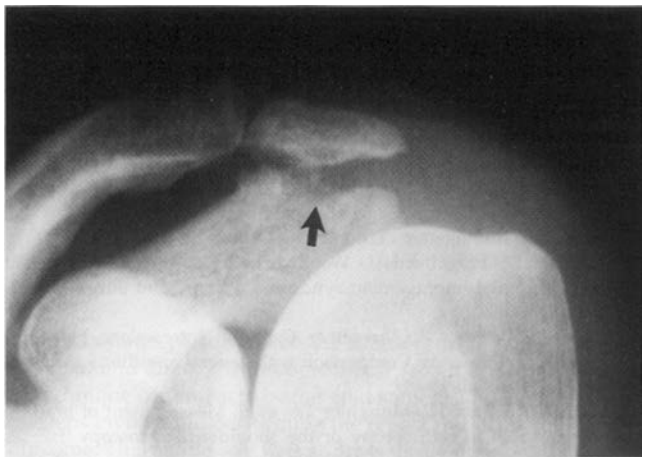

Figure 5-3 Mesacromiale iatrogenesis. (Courtesy of Mark Lazarus, MD.)

Evaluation

Although acromial fracture following anterior acromioplasty occurs either intraoperatively or within the first several months following surgery, there is often a delay in diagnosis due to a low index of suspicion. While the inciting event may be rather minor, the patient will often report a sudden, marked increase in pain, associated with swelling. There will be marked point tenderness over the dorsal aspect of the acromion, corresponding to the fracture site. This typically occurs at the junction of the anterior and middle thirds of the acromion, in line with the posterior border of the clavicle and acromioclavicular joint. The diagnosis is confirmed with routine radiography including an axillary view, a supraspinatus outlet view, and an anteroposterior view with 30-degree caudal tilt (Fig. 5-3).[42,153,180] If these studies are not sufficient, magnetic resonance imaging will confirm the diagnosis.

Treatment

Nonoperative treatment of patients with acromial stress fracture following anterior acromioplasty is generally unsuccessful. Patients frequently develop a painful nonunion as a result of micromotion from deltoid contracture. This is similar to patients with a painful os acromiale. Surgical treatment options include excision, open reduction and internal fixation, and bone grafting.[135,167] The anterior fragment, which has already been partially resected, is often thin and irregular. Under these circumstances, it is usually difficult or impossible to perform adequate internal fixation of the fragment, and excision is preferred. Open excision requires detachment of the deltoid, which is prone to postoperative dehiscence. Careful arthroscopic excision of the fragment may be less likely to lead to dehiscence of the deltoid if the deltotrapezial aponeurosis is left intact at the time of surgery. Open reduction, internal fixation, and possible bone grafting is preferred when the fragment is large enough.

Arthroscopic excision is delayed for 6 to 12 weeks following the initial surgery to allow the fracture and soft tissue envelope to recover from the hemorrhagic stage of the acute injury. The resulting healed fibrous tissue surrounding the fracture site is theoretically less likely to fail after the nonunited anterior fragment has been excised. Arthroscopic excision is performed in a manner analogous to excision of a painful preacromion or mesacromion.[223] The subacromial space is viewed through the posterior portal and the burr is placed through an accessory anterolateral portal. The soft tissue on the undersurface of the acromion is removed using an electrocautery or radiofrequency device, and any remaining coracoacromial ligament is subperiosteally elevated from the anterior aspect of the fragment. The fragment is then removed using a hooded arthroscopic burr, sweeping from the anterior lip of the nonunited fragment to the nonunion site (Fig. 5-4). The resection begins laterally and proceeds medially. Eventually, all that remains is a thin dorsal cortex that can be carefully peeled away from its fascial envelope, leaving an intact sleeve of deltotrapezial aponeurosis that is in continuity with the remaining acromion and the anterior deltoid. If the surgeon feels that he or she risks disruption of the fascia, it is more advisable to leave a small amount of the dorsal periosteum than to penetrate the fascial layer.

Excision of fragments that are larger than a typical meso os acromiale may result in unacceptable deltoid weakness. If the fracture line is posterior to the posterior aspect of the acromioclavicular joint, open reduction and internal fixation should be strongly considered.

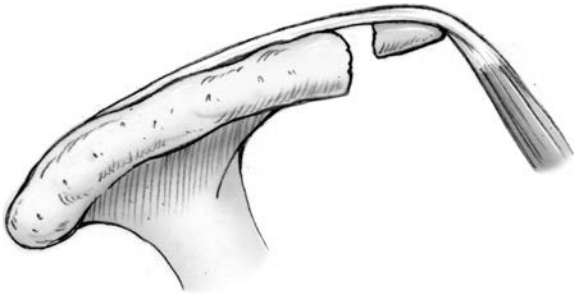
Postoperatively, it is important to emphasize full passive motion exercises, beginning on the day of surgery. An overhead pulley is added at 4 weeks. Active assisted motion is allowed 6 weeks postoperatively. A therapy regimen that is too aggressive risks disruption of the thin deltotrapezial aponeurosis. Subsequent rotator cuff and scapular strengthening exercises are initiated 8 to 12 weeks following surgery.

Results following treatment of postoperative acromial stress fracture have been sparsely reported. Excision of the anterior acromion does shorten the anteroposterior dimension of the acromion, thereby compromising the deltoid lever arm. This may potentially lead to weakness in forward elevation, fatigue in overhead activity, and inconsistent pain relief.[135] However, if the deltoid remains intact, an excellent result is possible.

PERSISTENT SUBACROMIAL IMPINGEMENT

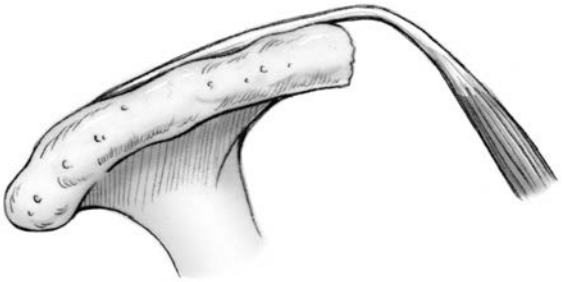
Etiology and Prevention

The objective of anterior acromioplasty is to establish a tunnel beneath the anterior acromion and the acromioclavicular

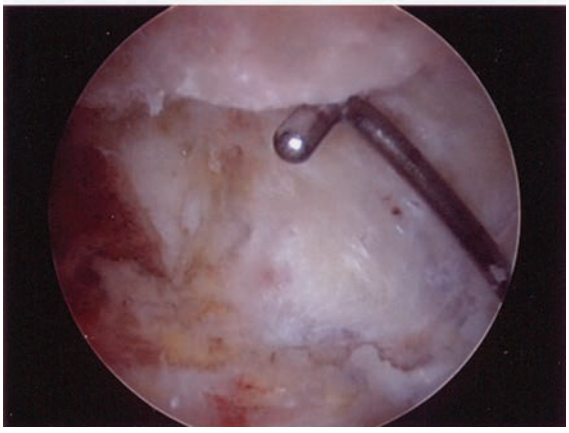


B

A

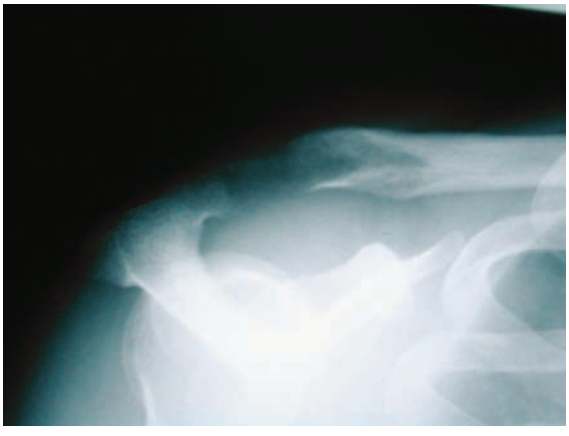


D



C

F



E

Figure 5-4 **(A)** The ununited anterior acromial fragment lies within the anterior deltoid aponeurosis and extends to the posterior border of the acromioclavicular joint. **(B)** Arthroscopic excision begins at the anterior edge of the anterior fragment and extends posteriorly toward the nonunion site, progressing from lateral to medial. **(C,D,E)** Complete excision leaves the deltotrapezial aponeurosis on the dorsal surface of the acromion in continuity with the anterior and middle deltoid. **(F)** Atraumatic excision maintains a normal deltoid contour.

joint, thereby enlarging the supraspinatus outlet and freeing the supraspinatus tendon. Persistent impingement following rotator cuff surgery, therefore, is the result of inadequate supraspinatus outlet decompression. This has been reported in association with residual anterior spurring,[58,161,182] inferiorly projecting acromioclavicular osteophytes,[148] and persistence or regrowth of the coracoacromial ligament.[148,161,182] Persistent impingement has been reported in 18% to 79% of patients with failed acromioplasty.[58,94,161,182] The true incidence of inadequate outlet decompression or persistent impingement following acromioplasty is unknown. Those who do not believe in acromioplasty in the management of rotator cuff disease undoubtedly also doubt the role of persistent impingement as a cause of persistent pain following rotator cuff surgery.

Debate continues regarding surgical indications, technique, and the optimal amount of acromial resection required to relieve supraspinatus outlet narrowing.[63,72,164] It is believed that Sir Reginald Watson-Jones performed the first lateral acromial excision for the treatment of supraspinatus tendon lesions.[6,216] Although several early authors advocated lateral or radical acromionectomy in cases of chronic supraspinatus syndrome,[6,21,83,137] these procedures are associated with significant complications[151] and have been largely abandoned. In 1972, Neer described the impingement syndrome, noting a characteristic ridge of proliferative spurs and excrescences on the undersurface of the anterior acromion.[148] He recommended anterior acromioplasty with removal of a wedge of bone, including the anterior edge and lateral portion of the undersurface of the acromion. While Neer cautioned against shortening of the normal anterior acromion,[147] it is clear that the intended purpose of his procedure was not only to flatten the undersurface of the acromion, but also to remove any anterior projection of the acromial spur.[147–149] Since the transition from the normal acromion to anterior spur is not always apparent, Rockwood and Lyons[180] selected an imaginary line extending laterally from the anterior cortical border of the clavicle and recommended removal of any acromial projection extending past this line. The likelihood of persistent impingement related to residual acromial spurring is minimized when the resection produces a smooth inferior acromial surface, with an anterior edge that approximates the anterior cortical border of the clavicle.[149,180]

The causal relationship between acromial morphology and rotator cuff disease remains elusive. Radiographic, histologic, and cadaveric studies indicate that acromial spurs are actually traction enthesophytes, a response to tension rather than compression.[36,163,196] The shape of the acromion changes with increasing age and in the presence of rotator cuff tearing.[159] While the correlation between type III acromions and the incidence of rotator cuff tears has been called into question, there appears to be a relationship between type III acromions and rotator cuff tear size.[103] Cadaveric studies clearly reveal that contact between the undersurface of the coracoacromial arch and the rotator cuff is a normal phenomenon.[56] Animal studies have demonstrated that abnormal subacromial pressure or prominences will induce an impingement lesion or bursal-sided tearing, but does not seem to result in the articular-sided and intratendinous lesions that are most often seen in clinical practice and microscopic studies.[188,192] Some authors have advocated a subacromial smoothing to remove an area of arch prominence that may create point pressures on the bursal side of the rotator cuff, rather than a nonanatomic flattening of the undersurface of the acromion. The current trend in the literature seems to be toward a more conservative acromioplasty, and in some cases, no acromioplasty.[23,63,72] Therefore, the significance of residual subacromial spurring in the persistence of pain following rotator cuff surgery is difficult to confirm. Practically speaking, if persistent postoperative pain is relieved with subacromial injection and other causes of persistent pain, such as stiffness, have been eliminated, removal of any residual subacromial prominence is reasonable.

Inferiorly projecting acromioclavicular osteophytes may represent a source of persistent impingement pain.[147] This problem is prevented by identifying, and addressing, acromioclavicular pathology at the time of the original surgery.[47] Distal clavicle excision is appropriate in patients who have symptoms related to the acromioclavicular joint. Coplaning of the medial acromial facet and inferior surface of the distal clavicle theoretically removes contact pressure on the rotator cuff, and is based on preoperative imaging studies, intraoperative palpation, and arthroscopic visualization. Technical points that are worth mentioning include preservation of the superior and posterior acromioclavicular ligaments when performing the distal clavicle excision and minimal disruption of the joint when performing distal clavicle coplaning. The inferior acromioclavicular ligament should be preserved in patients without preexisting osteoarthritis, since disruption may lead to a subtle but painful instability. The interested reader is referred to Chapter 32 for a detailed discussion of acromioclavicular joint abnormalities.

Persistence or regeneration of the coracoacromial ligament has been described in the literature and may represent a cause of persistent impingement following subacromial decompression.[84,123,147,161,182] Since the persistent coracoacromial ligament is often associated with a persistent acromial spur,[182] it is difficult to attribute the importance of the ligament to the patient's symptoms. It is important to remember that contact between the rotator cuff and coracoacromial ligament occurs in normal shoulders. In addition, preservation of an intact coracoacromial arch has been increasingly emphasized as a humeral head containment mechanism in rotator cuff–deficient shoulders.[57,122,219] Codman emphasized the importance of

the coracoacromial arch, stating that "evidently, the coracoacromial ligament has an important duty and should not be thoughtlessly divided at any operation." Among patients with an intact or small repairable cuff, resection of a small portion of the ligament is not likely to result in clinically significant anterosuperior subluxation. However, excision of the coracoacromial ligament in patients with an irreparable cuff tear or a large tear that is difficult to repair may increase the risk of postoperative anterosuperior escape of the humeral head.[219] Currently, most authors consider preservation of the coracoacromial ligament and direct repair to the acromion at the time of open repair of large rotator cuff tears. During arthroscopic acromioplasty, we will subperiosteally elevate the ligament from the anterior aspect of the acromion to remove the spur and will allow the origin of the ligament to regenerate.

Evaluation

The diagnosis of persistent subacromial impingement following rotator cuff surgery is made when physical findings associated with subacromial impingement are present, those findings improve substantially following a subacromial injection of local anesthetic (positive impingement test), and there is radiographic evidence of continued supraspinatus outlet narrowing.[42,148,153,180] Patients may complain of night pain and difficulty with overhead activities, and often note little or no postoperative improvement. The impingement sign and reinforcement tests (Hawkins, Jobe) elicit pain and may be associated with subacromial crepitus.[92,93,95,148]

Preoperative range of motion should be carefully evaluated to detect the presence of capsular contracture. Posterior capsular contracture is manifest by decreased internal rotation of the arm in the abducted position (90 degrees of elevation in the scapular plane). This finding is commonly associated with the impingement syndrome and may contribute to continued subacromial impingement following rotator cuff surgery.[132–134]

Supraspinatus outlet views and 30-degree caudal tilt radiographs[17,42,180] should demonstrate evidence of supraspinatus outlet narrowing (Fig. 5-5 and 5-6). Some patients whose postoperative radiographs reveal little or no evidence of continued anatomic narrowing of the supraspinatus outlet may have continued pain and physical findings suggestive of subacromial impingement. Presumably, their persistent symptoms are on the basis of a persistent coracoacromial ligament, subacromial scarring, or some other less obvious problem such as early glenohumeral arthritis. A diagnostic subacromial injection of lidocaine is often very helpful in localizing pain to the subacromial space (assuming the cuff is intact) and is used routinely as a confirmatory test in patients with suspected continued subacromial impingement following rotator cuff surgery.[90]

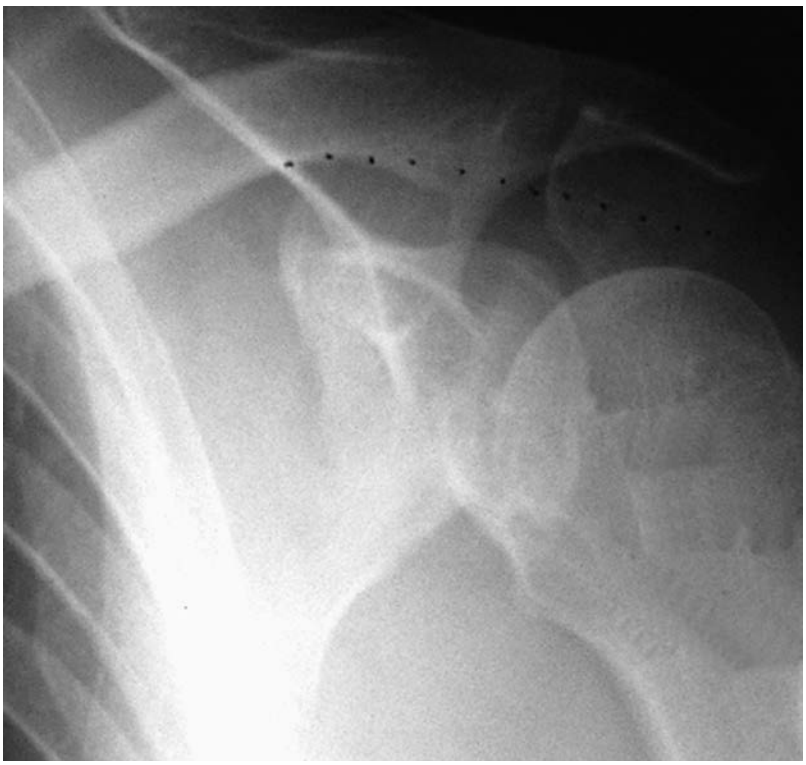


Figure 5-5 A standing anteroposterior radiograph with 30-degree caudal tilt in a patient with persistent pain following previous arthroscopic acromioplasty. Note the persistence of an anterior acromial spur.

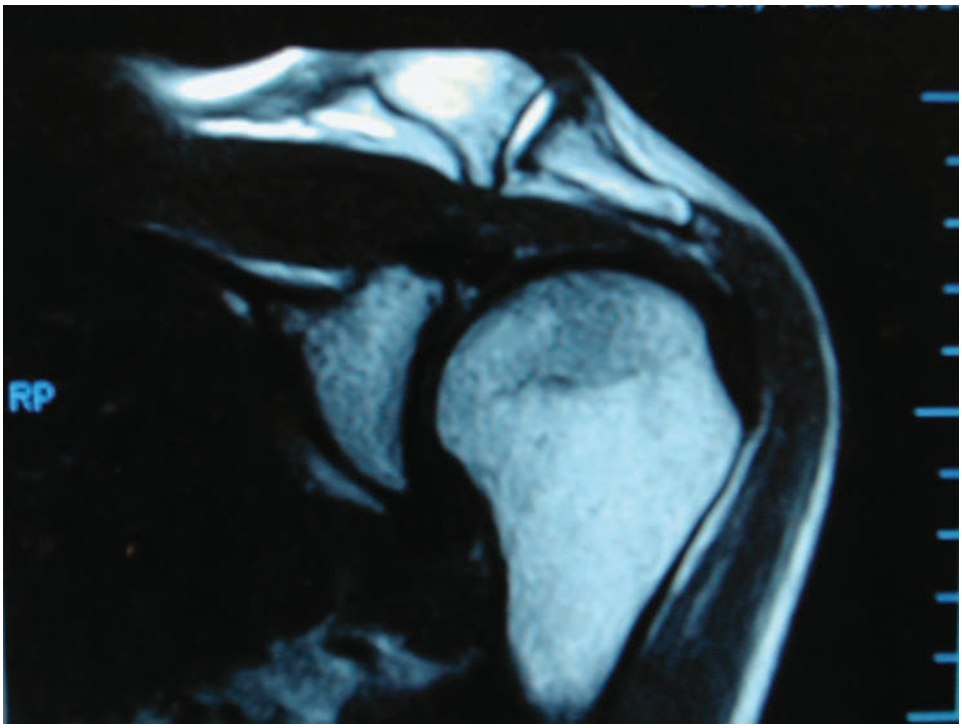

Figure 5-6 A coronal magnetic resonance imaging scan reveals persistent subacromial impingement from an inferior distal clavicular osteophyte.

Treatment

Persistent supraspinatus outlet narrowing from residual acromial spurs, persistent coracoacromial ligament, or inferior acromioclavicular osteophytes may be managed by repeat arthroscopic or open subacromial decompression.[58,90,162,182] The surgical techniques and postoperative rehabilitation for revision acromioplasty do not differ significantly from the analogous primary procedure in a nonoperated shoulder (Fig. 5-7). These techniques are extensively described in Chapters 3 and 39, regarding primary rotator cuff repair and rehabilitation.

The overall results of revision subacromial decompression are inferior to those achieved following primary subacromial decompression.[58,90,161,182] This holds true for both open and arthroscopic procedures. Satisfactory results have been reported in 10% to 75% of patients undergoing revision subacromial decompression.[58,90,161,182] Although some authors advocate open techniques for revision acromioplasty, it is not clear that this offers a more favorable result than arthroscopic surgery. Factors associated with inferior results include open workman's compensation claims and factors associated with secondary gain,[90] postoperative subacromial scarring, unrealistic patient expectations, and unrecognized concomitant pathology. The importance of strict patient selection on the basis of continued radiographic supraspinatus narrowing and positive subacromial injection tests cannot be overemphasized.

HETEROTOPIC OSSIFICATION

Etiology and Prevention

Heterotopic ossification is a poorly understood condition featuring the formation of bone in periarticular regions. Although the pathogenesis is unclear, ectopic bone formation in general is most often related to burns, brain injury, or spinal cord injury. In the shoulder, heterotopic ossification has also been noted following acromial surgery and distal clavicle excision.[6,10,11,83,121,222] The reported incidence of heterotopic ossification following anterior acromioplasty varies between 3% and 30%, and is associated with poorer postoperative results.[6,10,11,83,121,222] While Berg and Ciullo[10,11] noted no significant difference between open and arthroscopic methods, Lazarus and collegues[121] reported a much higher incidence of heterotopic bone formation following arthroscopic acromioplasty (30%) as compared to open acromioplasty (10%).

The etiology of heterotopic ossification following acromioplasty is probably multifactorial. Neer[149] warned against the use of a power burr or handheld rasp because he felt that it would disseminate morselized bone throughout the subacromial space. Some authors who exclusively use the power burr during open acromioplasty have not noted any problems with heterotopic ossification. Lazarus et al.[121] proposed that the use of an arthroscopic burr and pressurized pump forces bone particles into the soft tissues,

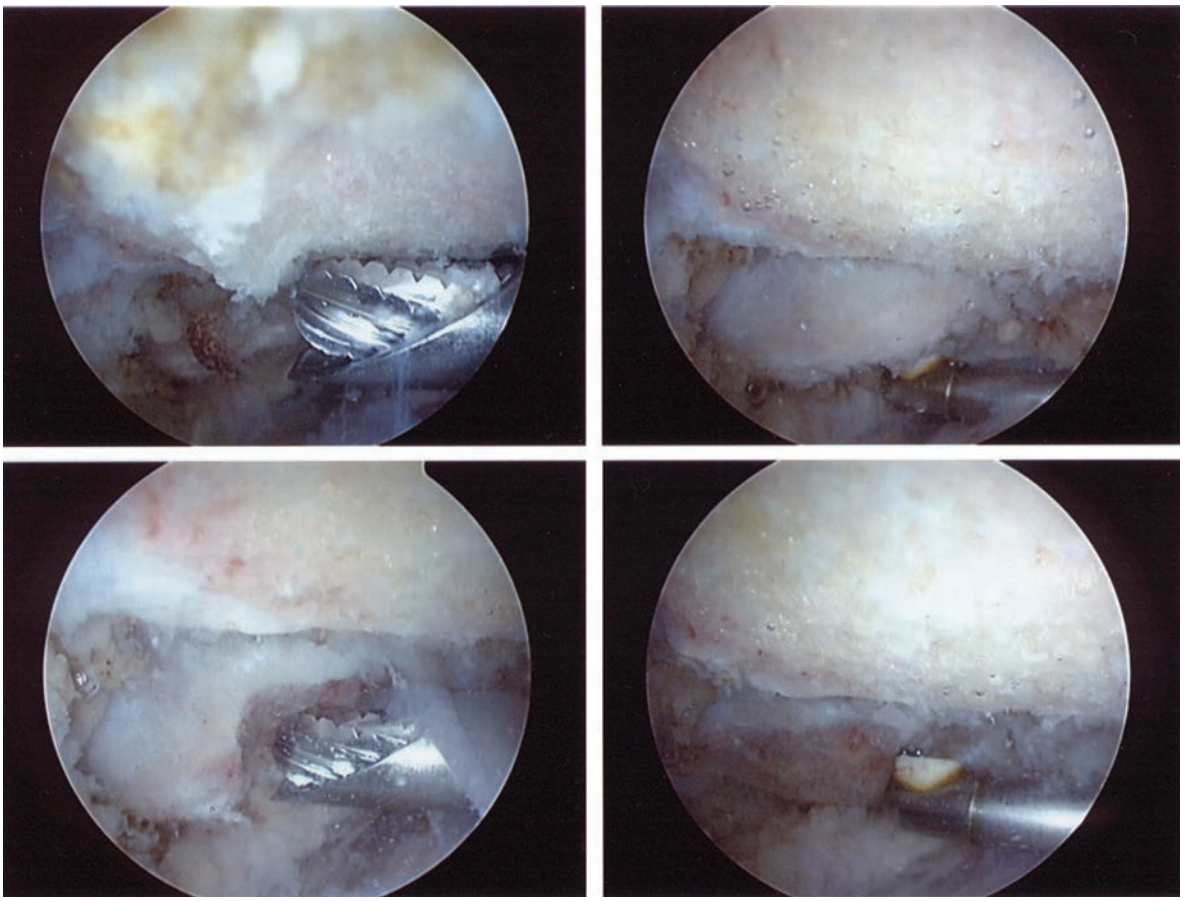

Figure 5-7 A conservative acromioplasty is performed along with resection of the inferior clavicular osteophyte.

increasing the risk of heterotopic bone formation following arthroscopic acromioplasty. However, since immediate postoperative radiographs were not taken, they may have mistaken inadequate bone resection with the formation of heterotopic bone. Berg and Ciullo[10] obtained radiographs within 8 weeks of surgery, noting no evidence of heterotopic bone. The overall incidence of heterotopic ossification in their series was 3.2%, and these authors noted a strong association between postoperative heterotopic ossification and a history of chronic pulmonary disease.[10]

While complete prevention of postoperative heterotopic ossification following open or arthroscopic acromioplasty would be preferable to its treatment, this may not be possible. However, some technical considerations may mitigate the occurrence of this complication. The use of an osteotome during open acromioplasty may produce less bone particulate debris than a power burr or handheld rasp.[149] When the latter instruments are used, copious irrigation is recommended to reduce the amount of bone debris that has been created. During arthroscopic acromioplasty, frequent use of the suction attachment on the burr will minimize the spread of bone particles into the subacromial space. The subacromial space should be carefully inspected at the completion of the procedure, and any visible bone should be removed using the suction. Berg and Ciullo[10] have recommended prophylactic treatment with indomethacin or radiation among patients with a history of ankylosing spondylitis, hypertrophic pulmonary osteoarthropathy, chronic pulmonary disease, smoking, or hypertrophic arthritis.

Evaluation

Recurrent pain attributable to heterotopic ossification will usually develop within 3 to 6 months following surgery. Heterotopic ossification most commonly occurs in the subacromial space, within the acromioclavicular interval, or at the deltoid attachment site. The impingement sign, impingement test, and impingement reinforcement tests are frequently positive,[92,93,148] and passive arcs of motion are usually not significantly limited.[10,121] Severe periarticular heterotopic ossification occurs rarely and is associated with a dramatic loss of passive glenohumeral motion, resembling a frozen shoulder. Erythema and warmth may be present, mimicking infection. Occult infection may provoke the development of ectopic bone and should be carefully investigated.

Figure 5-8 **(A)** Anteroposterior and **(B)** axillary radiographs of a patient with severe glenohumeral motion loss associated with extensive subacromial and pericapsular heterotopic ossification following repair of a supraspinatus tendon rupture. **(C)** Computed tomography reveals anterior and posterior extension of the heterotopic bone.

The classification system of Booker and colleagues has not been extensively applied to the condition in the shoulder. Radiographic analysis, including anteroposterior, axillary, supraspinatus outlet, Zanca, and 30-degree caudal tilt views, will facilitate the diagnosis.[42,153,180] Computed tomography may be helpful in identifying multiple sites of heterotopic bone and may assist in preoperative planning (Fig. 5-8).

Treatment

Once the process of heterotopic ossification has begun, it is doubtful whether any of the available preventative measures can affect the outcome. Experience with this problem about the shoulder is limited and recommendations are based on the reported experience and treatment of heterotopic bone formation about other joints. A major concern relates to the timing of surgical intervention, with some authors indicating that the arbitrary 12- to 18-month delay may be unnecessary.[136,177] They suggest that the heterotopic bone associated with a central nervous system injury behaves differently than that seen in postoperative patients.[178] Surgical treatment is performed as early as 3 to 4 months, at which time the heterotopic bone often has a well-defined margin and trabecular pattern on standard radiographs.[177] It does not appear to be necessary to wait for the radionucleotide bone scan or serum alkaline phosphatase level to normalize.[136] Early excision of heterotopic bone in the elbow has offered significant benefits and yielded favorable results.[136] Advantages include the ability to more easily peel away immature bone from the tissue planes as well as accelerated functional recovery. Early

restoration of motion may provide beneficial effects to the articular cartilage, and may help prevent secondary soft tissue contracture and muscular atrophy, hopefully maximizing functional recovery.[136,178]

The treatment of heterotopic ossification following rotator cuff surgery is based on the location and severity of the process. Prior to removal, the precise distribution of bone, the optimal surgical approaches, and the potential anatomic hazards should be reviewed. Isolated deposits within the subacromial space may be débrided by open or arthroscopic methods. Open débridement requires detachment of the deltoid but may be associated with a lower recurrence rate and allow a more thorough excision than arthroscopic débridement.[121] Extensive pericapsular ossification requires an open approach, which is directed toward the location of the largest amount of bone. It usually occurs anteriorly and is accessed through a deltopectoral approach. When possible, excision is preferred through a muscle splitting rather than muscle detaching approach. Anterior and inferior pericapsular bone is excised through a subscapularis splitting incision. When this is not possible, the subscapularis is divided 1 to 2 cm medial to its insertion and reflected medially to expose the heterotopic bone. Heterotopic bone within the superior capsule and supraspinatus can then be excised by sharply dividing the interval between the supraspinatus and the superior capsule. Posterior heterotopic bone may require a second, more posterior incision for adequate exposure. Single low-dose radiation or a 6-week course of indomethicin[10] is administered postoperatively to prevent recurrence.

FROZEN SHOULDER

Etiology and Prevention

The literature currently lacks a standardized definition of frozen shoulder in the postoperative setting. Therefore, the incidence of postoperative stiffness following rotator cuff surgery is unknown. However, there is generalized agreement that the hallmark of postoperative capsular contracture involves a commensurate decrease in both active and passive arcs of motion, which can involve one or more planes of motion. This motion loss is asymmetric in comparison to the contralateral, uninvolved shoulder. In our clinical practice, we have defined this as a 20-degree loss of passive motion in any plane as compared to the opposite side. Symptomatic loss of motion following rotator cuff surgery may be attributed to a variety of etiologies including preexisting medical conditions, surgical technique, and postoperative rehabilitation. The likelihood of developing postoperative stiffness is highest in patients who exhibit significant capsular contracture preoperatively.[149] Patients with comorbid conditions known to be associated with adhesive capsulitis, including diabetes mellitus and hypothyroidism,[155,213] are also at increased risk of developing postoperative stiffness.

Frozen shoulder that occurs following rotator cuff surgery is caused by a combination of capsular contracture and extracapsular scarring. Capsular involvement may be localized or generalized. Localized posterior capsular contracture is commonly associated with the subacromial impingement syndrome and rotator cuff disease.[132–134] Failure to address this through preoperative stretching, or intraoperative capsular release, will result in persistent postoperative stiffness, pain, and dysfunction. Generalized capsular contracture develops when there exists an element of preoperative generalized adhesive capsulitis, following prolonged postoperative immobilization, or in association with predisposing factors such as diabetes mellitus, hypothyroidism, or occult glenohumeral arthritis.

Extracapsular adhesions may develop in the humeroscapular motion interface following rotator cuff surgery, interfering with normal shoulder function and motion.[186] During normal shoulder motion, the upper proximal humerus and rotator cuff slide beneath the smooth undersurface of the coracoacromial arch, deltoid, coracoid process, and conjoined tendons. Postoperative adhesions may form in this interface, especially between the raw cancellous undersurface of the acromion and the rotator cuff.[142,149] The subdeltoid and subacromial adhesions capture the deltoid and humeral head, altering the normal biomechanics of the glenohumeral joint. Subdeltoid adhesions may effectively tenodese the deltoid, requiring a greater effort from the supraspinatus tendon to achieve shoulder abduction. Iatrogenic tightening of the rotator cuff interval and overadvancement of the rotator cuff tendon are examples of operative techniques that may lead to loss of motion by capturing the shoulder.[210]

In general, rotator cuff surgery should be avoided in patients with evidence of a generalized frozen shoulder.[132,148,149,180] Capsular contracture should be addressed through preoperative capsular stretching exercises. In cases of recalcitrant stiffness, consideration may be given to closed manipulation or arthroscopic release,[169,213] prior to performing rotator cuff surgery. An alternative approach in smaller rotator cuff tears associated with stiffness is to combine capsular release with cuff repair. Under this scenario, rehabilitation should be directed primarily at the frozen shoulder, realizing that there might be a greater chance of cuff rerupture.

Evaluation

A careful history of the patient with suspected postoperative frozen shoulder may reveal the presence of predisposing risk factors. Since the hallmark of frozen shoulder is a symmetric decrease in both active and passive arcs of motion,[154,155,158,213,214] motion should be evaluated in all

planes and compared to the contralateral, normal shoulder. While this can be performed in the sitting or supine positions, some patients are better able to relax in the supine position with gravity eliminated.

The clinical manifestation of capsular contracture depends on which portion of the capsule is affected. An isolated rotator interval contracture will limit external rotation with the arm at the side, while having less of an effect on rotational motion with the arm at 90 degrees of scapular elevation.[89] Posterior capsular contracture will result in decreased terminal elevation, cross-body adduction, internal rotation behind the back, and decreased internal rotation with the arm at 90 degrees of elevation in the scapular plane.[132] Generalized capsular contracture will result in a global loss of motion.

Patients with acute synovial inflammation may be particularly difficult to examine. This obstacle may be mitigated with an intraarticular injection of lidocaine (with or without cortisone). The injection may be both diagnostic and therapeutic, and should facilitate the examination. Other patients with secondary gain may demonstrate subjective complaints out of proportion to their expected objective findings. While examination under anesthesia represents a reliable method of determining the presence or absence of true capsular contracture, some simple measures may be applied to the conscious patient. When passive supine external rotation at the side equals, or approximates, the opposite side, no superior capsular contracture is present. The arm is then brought to 90 degrees in the scapular plane and passive internal and external rotation is measured. No inferior capsular contracture exists when this arc approximates the opposite side. If the arm cannot be passively forward elevated beyond 90 degrees under these circumstances, the cause is likely to be voluntary guarding, rather than contracture.

Radiographic evaluation of patients with frozen shoulder is usually normal, although it should be performed to exclude the presence of pericapsular heterotopic ossification or glenohumeral arthritis. While arthrography has been recommended in the past, it is not necessary to make the correct diagnosis of frozen shoulder. Magnetic resonance imaging does not assist in making the diagnosis of frozen shoulder, but may be indicated when the patient has regained full motion and continues to complain of persistent pain.

Treatment

Some loss of motion following repair of a large rotator cuff tear may be inevitable due to loss of tendon tissue during local transplantation of the tendon. The acceptable amount of passive motion loss associated with acceptable results has not been defined in the literature, but some patients are obviously not bothered by painless loss of motion, provided that function and strength are improved. Symptomatic motion loss following surgery is frequently related to dense adhesions in the humeroscapular motion interface,[142] as well as capsular contracture.[213,214] Nonsurgical joint mobilization techniques are continued for 3 to 6 months, provided that the patient continues to demonstrate improvement. The judicious use of intraarticular steroid injections will usually provide significant pain relief and facilitate participation in the therapy program. However, when postoperative stiffness occurs following rotator cuff repair, the merits of intraarticular steroid placement must be balanced against the possibility of delayed tendon healing and tendon damage.[19,203,218]

Closed manipulation alone is often unsuccessful in patients with postoperative shoulder stiffness, but may be attempted. Arthroscopic capsular release has been shown to be a successful technique in regaining motion in shoulders that are recalcitrant to nonsurgical measures or closed manipulation.[87,214] The technique is somewhat of a misnomer in that the authors address both the capsular and extracapsular sources of shoulder stiffness at the time of surgery.[210,214] The arthroscopic sheath and blunt obturator are placed into the subacromial space through a posterior or posterolateral portal. An attempt is made to pass the sheath lateral to the tuberosity and into the lateral subdeltoid recess. If this is unsuccessful, the arthroscope is placed and an accessory anterolateral portal is established, through which an arthroscopic resector or radiofrequency device is placed. The dense adhesions in the humeroscapular interface are then resected with careful attention directed at avoiding damage to the rotator cuff, deltoid, or axillary nerve. The resection is complete when the arthroscope can pass freely from the subacromial space, over the greater tuberosity, into the lateral subdeltoid recess (Fig. 5-9). Adhesions between the coracohumeral ligament and underlying rotator cuff are débrided to the level of the coracoid process, and any anterior adhesions between the subscapularis and deltoid are also débrided.

The arthroscope is then placed into the glenohumeral joint through the standard posterior portal. Release of the capsular structures is then performed according to the preoperative evaluation. These techniques are described extensively in Chapter 17 on the diagnosis and management of the stiff shoulder. Open releases are indicated in patients who have failed arthroscopic release or have had iatrogenic tightening of tendinous structures.

Several authors have reported excellent recovery of motion following arthroscopic treatment of postoperative stiffness. However, despite improvements in motion, pain relief and functional improvement are generally less favorable than in patients with idiopathic frozen shoulder and patients who did not develop postoperative stiffness.[67,105,214] Therefore, caution should be exercised in predicting the outcome of arthroscopic release among patients with postoperative frozen shoulder, and patients should be counseled regarding the possibility of persistent pain despite the successful return of motion.

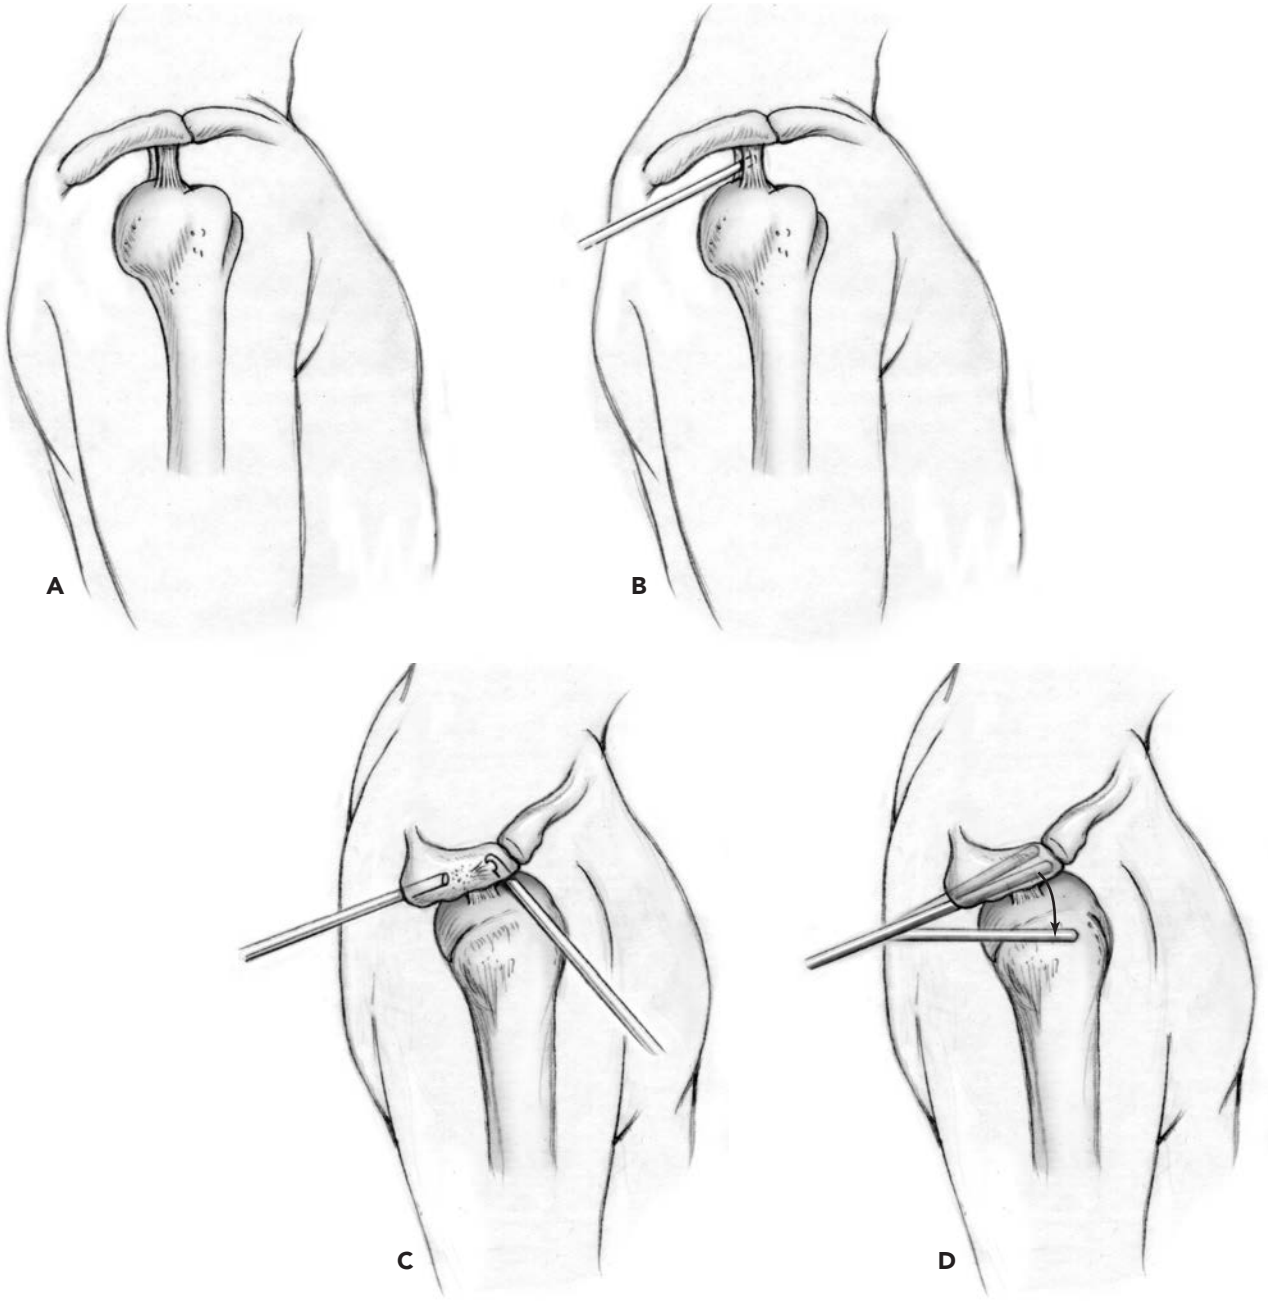

Figure 5-9 Frozen shoulder following previous rotator cuff surgery is often characterized by dense adhesions between the undersurface of the acromion and the superficial surface of the rotator cuff **(A).** A blunt obturator placed into the subacromial space is prevented from moving over the humeral head into the subdeltoid bursa by the adhesions **(B).** After the adhesions have been resected and the subacromial space has been reestablished **(C),** the blunt obturator can easily pass from the subacromial space into the lateral subdeltoid recess and back again **(D).**

INFECTION

Etiology and Prevention

Deep infection following rotator cuff surgery is relatively uncommon, but represents a potentially devastating complication in terms of functional outcome. The incidence of infection following shoulder arthroscopy has been reported to be approximately 0.4%,[7,13,199] while that of open and mini-open rotator cuff repair has been reported to range between 0.27% and 1.9%.[98,131,195] Risk factors may include patient age, preexisting medical conditions such as hypothyroidism and diabetes mellitus, local irradiation, smoking and alcohol intake, instrument sterilization problems, and

increased operative times.[37,141] It is not clear whether steroid injections administered prior to surgery may increase the risk of infection.[102] A low index of suspicion, related to the infrequency of this complication, often leads to a delay in diagnosis.[97,141] Deceptively innocuous-looking wound problems may mask soft tissue loss, rotator cuff and deltoid dehiscence, and osteomyelitis. Extensive soft tissue destruction and a delay in diagnosis are both associated with a worse prognosis. While aggressive surgical débridement, combined with soft tissue coverage and intravenous antibiotics, will usually control the infection, permanent functional deficits frequently persist.[97,141] Obviously, prevention of this complication is preferred to treatment.[48,189]

The use of preoperative antibiotic prophylaxis is strongly recommended in the prevention of postoperative infection.[48,85,220] Although overuse of antibiotics is directly related to the development of resistant bacterial strains, the treatment costs and clinical morbidity associated with an infection following rotator cuff repair support the use of prophylactic antibiotics. The most commonly reported offending pathogens are *Staphylococcus aureus*, coagulase-negative *Staphylococcus*, and *Propionibacter acnes* species.[98,120,141] Due to their typical susceptibilities, the most common prophylactic antibiotic is a first-generation cephalosporin such as cefazolin.[189] With the emergence of methicillin-resistant *Staphylococcus aureus* as a community-acquired pathogen, Bactrim DS may be added to the prophylactic preoperative regimen when placement of an implant is planned.

Since most of the infecting organisms are present in normal skin flora, careful skin scrubbing, preparation, and draping may prevent contamination. Axillary hair should either be shaved prior to Betadine scrubbing or sealed off from the operative site during draping. Impermeable drapes and stockings should be used during arthroscopic procedures. Arthroscopic instruments should be either autoclaved or soaked in warm 2% glutaraldehyde for 20 minutes.[189] Operating time and operating room traffic should be minimized. Intraoperative conversion from arthroscopic to open methods may be associated with an increased risk of infection. Herrera and colleagues[98] reported a 1.9% infection rate (seven patients) following arthroscopic subacromial decompression and mini-open rotator cuff repairs. They were able to reduce this rate to zero by changing surgical gloves, applying a second preparation of Betadine, and placing a new extremity drape at the time of mini-open repair.

Evaluation

Shoulder infections are rarely diagnosed acutely. This is often the consequence of subtle physical findings and a low index of suspicion.[97,141] Following arthroscopic procedures, infection is usually manifest by a low-grade fever, as well as erythema and prolonged drainage from one or more of the portal sites.[120] Patients will complain of progressively increasing pain and a change in the nature of the drainage from a thin, serous fluid to a thick, yellow exudate. A white blood cell count obtained in the early postoperative period may remain within the normal range. While the diagnosis is confirmed by a positive culture aspirate from the portal site or subacromial space, a negative culture does not exclude the possibility of an infection, especially if antibiotics were administered prophylactically at the time of surgery or in the postoperative period.

The clinical symptoms of infection following open rotator cuff surgery may vary from pain, swelling, and erythema to wound dehiscence, drainage, general malaise, fever, and leukocytosis.[141] Untreated infections may develop a draining sinus or synovial-cutaneous fistula.[207] Patients who present to their postoperative visit (7 to 10 days) with an erythematous wound and the appearance of a subcutaneous hematoma should be suspected of having a deltoid detachment, deep wound infection, or both. Hematoma formation is a reasonable diagnosis when the fluid collection occurs within the first 24 to 48 hours following surgery and is not accompanied by erythema. Aspiration of a hematoma should produce organizing clot, while the expression of serosanguineous fluid is more likely to represent an infection. The diagnosis of infection is confirmed by a positive culture of the aspirate. It should be emphasized that the growth of *Propionibacter* species is not necessarily a contaminant and must be considered an infecting organism.[98,141]

Routine radiographs may reveal soft tissue swelling. The presence of subacromial air at 7 to 10 days postoperatively may indicate the presence of a gas-forming organism. Magnetic resonance imaging during the immediate postoperative period will be of limited value due to postoperative artifact. In addition, the presence of deltoid or rotator cuff deficiency will be identified at the time of surgical débridement of the infection. In the chronic setting, magnetic resonance imaging as well as scintigraphy may be of value in identifying the presence of osteomyelitis.

Treatment

Deep infection following rotator cuff surgery is uncommon, with relatively few reports in the literature addressing the management of this complication.[97] The most important factors in effectively treating deep infections are a high index of suspicion, early diagnosis, and aggressive surgical treatment.[98,141] There is a tendency to treat patients with postoperative wound problems (such as mild erythema, drainage, or late hematoma formation) with oral antibiotics. While these methods may occasionally be successful, the preferred management of a deep, postoperative wound infection is surgical drainage and débridement.

Early infection (within 4 weeks of surgery) following arthroscopic acromioplasty may be adequately treated by arthroscopic irrigation and débridement. The subacromial

space should be aggressively débrided prior to entering the glenohumeral joint. The subacromial space often contains loculations of infected tissue, which may be débrided with an aggressive arthroscopic resector. Copious amounts of irrigant should then be allowed to flow through the subacromial space to decrease the bacterial load. Once the subacromial space has been adequately débrided and irrigated, the arthroscope is placed in the glenohumeral joint, and the joint is irrigated with 3 to 6 L of antibiotic-impregnated irrigant. It is helpful to establish an outflow portal to facilitate flow of the fluid through the joint. One drawback of the arthroscopic approach is difficulty in adequately débriding the biceps tendon sheath. The biceps tendon should be grasped intraarticularly and pulled into the joint to break up any infected adhesions in the tendon sheath.

Open irrigation and débridement is preferred for infections following open or mini-open rotator cuff surgery, allowing inspection of the deltoid repair as well as direct access to the biceps tendon sheath. Serial débridements may be required.[98] If the deltoid repair is intact, the deltoid is split in line with the previous split, and the subacromial space is inspected. If the rotator cuff is intact, and the loculations within the subacromial space can be adequately débrided, the procedure is performed without detachment of the deltoid repair.

When the deltoid repair has failed, or the subacromial space cannot be adequately débrided, the deltoid is released and retracted anteriorly to access the subacromial space. Once the necrotic debris has been removed and the subacromial space has been irrigated, the rotator cuff is inspected. If the rotator cuff repair is intact, the rotator cuff and sutures are left in place. Small incisions are then made in the rotator interval and biceps tendon sheath to permit irrigation of the glenohumeral joint.

When the rotator cuff repair is disrupted, the necrotic tendon edges are débrided and all visible suture and suture-anchoring material is removed.[120] The revision rotator cuff repair is delayed until the time of the final irrigation and débridement, or until the infection has cleared (6 weeks). However, if the tendon defect is particularly large, consideration should be given to early repair at the time of initial or secondary débridements. In all cases, the deltoid should be securely repaired to the bone of the acromion at the time of the final débridement. Unrepairable rotator cuff defects may be associated with persistent synoviocutaneous fistula formation. I (BDC) have had anecdotal success in treating such cases with aggressive débridement, sinus tract excision, deltoid repair, partial rotator cuff repair, and placement of a patch graft (Restore Patch, Depuy Orthopedics, Inc. Warsaw, IN). Other authors have described muscle transfers to "seal off" the joint.

Antibiotics are withheld until intraoperative cultures have been obtained. Broad-spectrum antibiotic coverage for skin organisms such as *Staphylococcus aureus* and *Propionibacter acnes* is then administered. This usually includes vancomycin or a first-generation cephalosporin such as cefazolin. The antibiotics are changed appropriately as indicated by the culture sensitivities. The duration of antibiotic coverage is individualized, but generally includes 1 to 4 weeks of intravenous treatment, followed by 1 to 4 weeks of oral treatment. If there is any suspicion of osteomyelitis, antibiotic treatment may continue for 6 weeks.

Neglected infections following rotator cuff surgery often result in a long interval (i.e., months) between the index procedure and subsequent surgical intervention.[97,141] These late or chronic infections often present with draining sinus tracts, synoviocutaneous fistulas, severe soft tissue loss, or exposed bone (humeral head or distal clavicle). Complete eradication of the infection requires radical débridement of all necrotic debris, excision of synovial tracts, removal of all retained suture or suture-anchoring devices, and aggressive débridement of any affected bone. Multiple débridements are often necessary, and the rotator cuff is left unrepaired until the infection has been successfully cleared. Vascularized rotational myocutaneous flaps from the latissimus dorsi or pectoralis major muscles may be required to facilitate wound closure and restore the soft tissue envelope.[86,97,141] Intraoperative specimens of fluid, soft tissue, and bone shavings should be sent for aerobic, anaerobic, fungus, and acid-fast bacillus culture. Parenteral antibiotics are continued for at least 6 weeks following débridement.

Postoperative rehabilitation includes immediate passive mobilization in all cases. In patients who require a revision deltoid or rotator cuff repair, an abduction brace is used to protect the repair for 3 to 4 weeks. The brace is removed only to allow passive motion exercises several times daily. Active assisted range of motion is allowed 6 weeks postoperatively and strengthening is initiated 8 to 12 weeks following surgery.

Patients with an intact rotator cuff and deltoid at the time of débridement are placed in a postoperative sling. If the index and revision surgeries were performed arthroscopically, and did not include a rotator cuff repair, active motion and strengthening are allowed according to the patient's symptoms. If either surgery included a rotator cuff or deltoid repair, passive motion exercises are performed for 6 weeks. Thereafter, active motion and strengthening exercises are added.

Postoperative wound infection following rotator cuff surgery clearly has a negative effect on overall outcome.[97,120,141] The clinical results are directly related to timely intervention, with a delay in treatment resulting in the worst outcome. All patients, regardless of rotator cuff or deltoid integrity, seem to have more pain than their counterparts who have not been infected. The pain is usually not disabling, nor is it usually severe enough to require analgesics. Early intervention will frequently facilitate a successful deltoid and rotator cuff repair. Most patients who ultimately possess an intact deltoid and rotator cuff demonstrate good overhead function. Even patients with

an intact deltoid and a small rotator cuff defect may possess overhead function, although they may demonstrate some degree of fatigue. Overall, the clinical outcome of this complication is not as poor as those reported for spontaneous septic arthritis of the shoulder in adults.[65,116]

DELTOID DETACHMENT

Etiology and Prevention

Detachment of the deltoid origin represents a potentially devastating complication of rotator cuff surgery.[12,49,80,151,156,197] To our knowledge, it has only been reported following open and mini-open rotator cuff surgery, but in our clinical practice we have seen deltoid detachment occur as a result of arthroscopic rotator cuff surgery. Postoperative deltoid detachment may occur as the result of poor intraoperative technique, overzealous acromial excision, postoperative infection, and inappropriate postoperative physiotherapy.[80,151,156,197] Poor prognostic factors include lateral acromionectomy, involvement of the middle deltoid, and a recurrent or massive rotator cuff tear.[12,151,197]

Anatomic and histologic studies clearly indicate a direct attachment of the tendon to the anterior and lateral acromion, rendering the release of deltoid fibers inevitable during any method of acromioplasty.[112] Arthroscopic acromioplasty, which removes 4 or 6 mm of bone, will release 43% and 72% of the deltoid origin, respectively.[206] Although some detachment of the anterior deltoid fibers occurs during arthroscopic acromioplasty, functional compromise has not been shown in clinical studies. Several authors have described arthroscopic excision of a mesoacromion. This procedure releases all of the anterior and lateral tendinous attachments of the deltoid and emphasizes preservation of the superior deltoid fascia. Again, functional compromise has not borne out in these clinical studies. Other authors have shown regrowth of the coracoacromial ligament following subperiosteal release of the ligament during arthroscopic acromioplasty. Fibrous reattachment of the released deltoid fibers has not been studied but remains an area of further investigation.

The fibers of the middle deltoid are arranged perpendicular to the acromion, while those of the anterior deltoid arise obliquely from the anterior acromion. Conservative deltoid splitting approaches exploit this interval by dividing the tendinous raphe between the middle and anterior thirds of the deltoid (Fig. 5-10). This may result in fewer deltoid detachments and less tendinous retraction when deltoid detachment does occur.[132,138,198] Deltoid releasing approaches should extend onto the dorsal surface of the acromion to ensure a strong distal musculocutaneous cuff of tissue for reattachment to bone.[180] While all attempts should be made to avoid disruption of the middle deltoid,

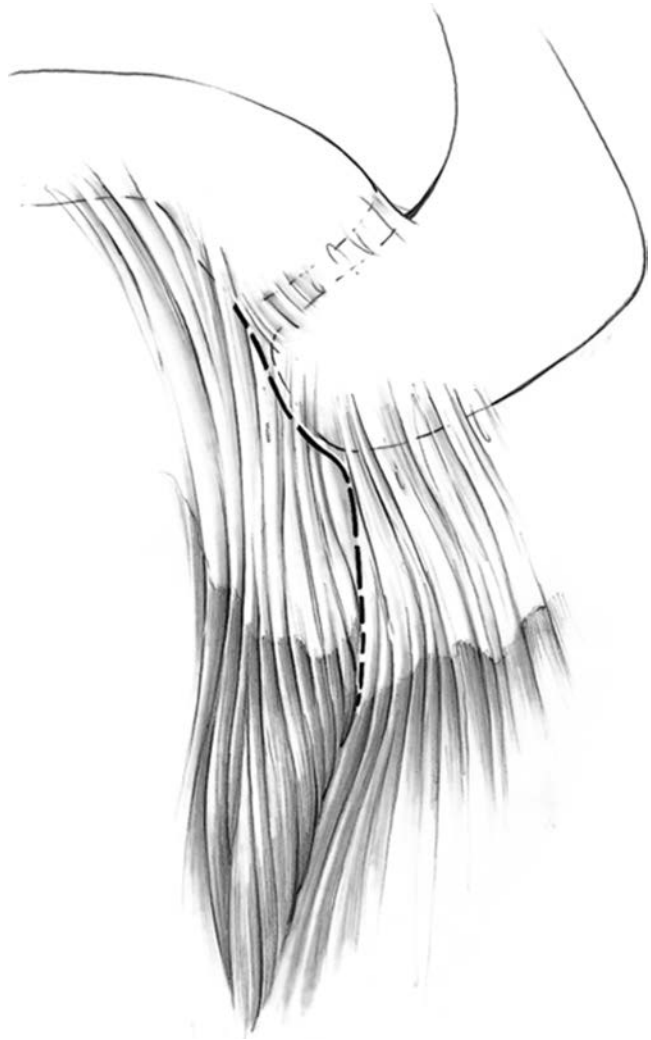

Figure 5-10 The anterior deltoid fibers arise obliquely from the anterior acromion, and the middle deltoid fibers arise perpendicularly from the lateral acromion. Incisions that exploit this interval may be less likely to result in postoperative deltoid detachment and retraction.

this may not be possible when attempting to repair a large or massive rotator cuff tear that extends into the infraspinatus or teres minor tendons.[14] We have not found detachment of the middle deltoid to be necessary during open rotator cuff repair. However, if more posterior exposure than is attainable without middle deltoid detachment is required, the middle deltoid should be released and reattached in a similar fashion to the anterior deltoid origin. Repair of the deltoid origin includes identifying and incorporating the deep deltoid fascia, which has a tendency to retract distally when released. The deltoid split should be closed with tendon-to-tendon sutures, and the deltoid origin should be repaired to bone or to an adequate soft-tissue cuff using nonabsorbable sutures.

Deltoid detachment that occurs in the setting of prior lateral or radical acromionectomy represents an extremely

disabling and often irretrievable condition.[12,151,180,197] While good results have been described following radical acromionectomy and acromion excision,[6,21,83,137] these procedures are clearly not required to relieve impingement,[56,148] and fortunately have been largely abandoned.

As with any repaired tendon, the deltoid should be protected postoperatively. Acromioplasty by any method theoretically weakens the deltoid origin[112,206] and the degree of postoperative protection is dependent on the surgical procedure as well as the quality of repair. Following arthroscopic acromioplasty, we allow activities of daily living immediately, but restrict lifting to the weight of the arm for 2 to 4 weeks. Following open acromioplasty, the deltoid repair is protected, allowing only pendulum and passive motion exercises for 6 weeks.

Evaluation

While failure of the deltoid repair occurs early in the postoperative period, there is often a long delay prior to diagnosis or intervention.[197] The clinical presentation is variable and depends on the size and location of the deltoid defect, the status of the coracoacromial arch, the amount of remaining acromion, and the status of the rotator cuff. Most cases are heralded by a sudden onset of increased pain and localized swelling or hematoma formation over the anterior acromion. All patients who present with a sudden onset of pain and localized swelling or hematoma formation over the acromion within the first couple of weeks following rotator cuff surgery should be suspected as having a deltoid detachment, infection, or both.

Physical examination will reveal the presence of a visible and palpable defect at the detachment site, with the deltoid retracted distally (Fig. 5-11). Since the fibers of the middle deltoid attach to the acromion perpendicular to their line of action, postoperative detachment of the middle deltoid results in a greater degree of distal retraction than detachment of the anterior deltoid. The findings associated with a small detachment may be subtle and the examiner can verify the diagnosis by having the patient gently abduct or forward elevate the arm against resistance while palpating the border of the acromion with the other hand. When the rotator cuff is intact and there is no capsular contracture, overhead elevation is often preserved in all but the largest deltoid detachments. Patients with concomitant rotator cuff deficits, especially in the presence of a deficient coracoacromial arch, may present with severely compromised overhead function.[12,49,80,156,197,219]

Figure 5-11 Postoperative deltoid detachment is characterized by distal retraction of the detached deltoid, which can easily be recognized as a mass or prominence in the anterior or lateral arm.

Routine radiographic evaluation should include anteroposterior, axillary, supraspinatus outlet, and 30-degree caudal-tilt views[42,153,180] to assess the amount of remaining acromial bone. Magnetic resonance imaging will reveal the deltoid detachment, but is most valuable in assessing the integrity of the rotator cuff (Fig. 5-12). If a concomitant deep wound infection is suspected, aspiration of the subacromial space or glenohumeral joint will provide a specimen for culture.

Treatment

Detachment of the deltoid following rotator cuff surgery is best managed by early detection and prompt deltoid repair. While small (1 to 1.5 cm) detachments may not be symptomatic or clinically relevant, they should be closely monitored for propagation of the defect or functional impairment. Larger deltoid detachments should be repaired as soon as they are recognized. When the detachments are detected early (within 4 to 6 weeks), the deltoid can usually be easily repaired. Firm repair to the bone of the acromion as well as the deltotrapezial fascia is recommended. The rotator cuff should also be carefully inspected for evidence of a recurrent tear, which should be repaired at the time of deltoid repair.

Deltoid detachments are frequently overlooked in the immediate postoperative period and may persist for prolonged periods of time.[80,197] Sher and collegues[197] reported on a series of deltoid detachments that were undetected for an average of 17 months. Mobilization and repair of the chronically retracted deltoid is extremely difficult, especially when it involves a significant portion of the middle deltoid. Full-thickness skin flaps are created and the skin is undermined to identify the intact portions of the deltoid as well as the retracted margins of the deltoid. Invariably, a thin layer of scar tissue occupies the interval between the retracted deltoid and the acromion. Incision of the scar tissue should begin at the anterolateral border of the acromion and extend distally toward the border of the normal deltoid. The subdeltoid adhesions should be carefully released with a combination of blunt and sharp dissection to establish the humeroscapular interface. Digital palpation of the deep and superficial surfaces will identify the

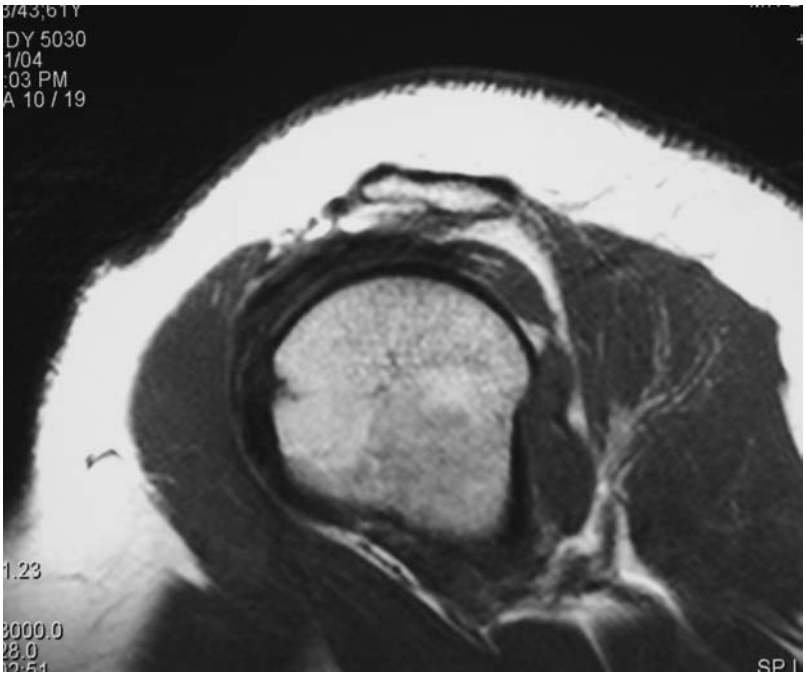

Figure 5-12 Sagittal magnetic resonance imaging scan of a postoperative deltoid detachment.

thicker area of the intact portions of the normal deltoid. Once the intact portions of the anterior and middle deltoid have been identified, the intervening scar tissue can be released from the acromion (Fig. 13A). The split at the anterolateral acromion can then be extended to the level of the axillary nerve, which is easily palpated on the deep surface of the deltoid fibers. A circumferential release of the retracted portions of the deltoid can then be performed to mobilize the muscle proximally toward the acromion (Fig. 5-13B). The retracted portions of the middle and anterior deltoid are then convergently mobilized toward the anterolateral border of the acromion, creating a V–Y repair configuration (Fig. 5-13C,D). The intervening scar tissue is then excised and sutures are placed in the corners of the anterior and middle deltoid that are to be approximated to the anterolateral border of the acromion. It is important to incorporate the deep deltoid fibers to facilitate a full-thickness repair. The acromion is then lightly decorticated and the anterior and middle portions of the deltoid are then sutured to the acromion through drill holes using heavy, nonabsorbable sutures. It may be helpful to retain a small portion of the scar tissue, which can be sutured to the deltotrapezial fascia, allowing reinforcement of the repair. The remaining split in the deltoid is then closed using interrupted absorbable sutures (Fig. 5-13E).

When primary repair is not possible, a rotational deltoidplasty may be performed by transposing a portion of the adjacent intact deltoid into the defect,[197] attaching it to the acromion. The new defect in the deltoid is then closed in a side-to-side fashion. As the complexity of the required reconstruction escalates, the expected results deteriorate.

Postoperatively, the deltoid reconstruction or repair is protected for 3 to 6 weeks in an abduction orthosis. Passive motion exercises are initiated within the first week, followed by active motion and strengthening at 6 and 12 weeks, respectively.

Reported results for surgical treatment of deltoid detachment are sparse and generally carry a poor prognosis.[12,156,197] Sher and collegues[197] reported 67% unsatisfactory results among 24 patients who were followed for deltoid repair or reconstruction following postoperative deltoid detachment. The poorest results occurred in patients with an associated large rotator cuff tear who demonstrated weakness in external rotation, prior acromionectomy, and a large residual deltoid defect. Predictive variables for a favorable result include an intact or repairable rotator cuff, early recognition and treatment, little or no middle deltoid involvement, and no acromial insufficiency.[197]

AXILLARY NERVE INJURY

Etiology and Prevention

Axillary nerve injury represents the most common single nerve injury to the shoulder.[166] The course of the axillary nerve makes it vulnerable during any operative procedure involving the inferior aspect of the shoulder. Injury by direct laceration or overzealous traction may occur during any of the operative approaches, denervating the entire deltoid distal (anterior) to the point of injury.[22,31,147–149] This usually results in substantial disability.[80]

Figure 5-13 (*continued*).

The nerve courses posterior to the coracoid process and crosses the inferolateral border of the subscapularis, 3 to 5 mm medial to the myotendinous junction. Throughout its course it rests an average of 2.5 mm from the inferior glenohumeral ligament, passing within 12.4 mm of the glenoid rim at the 6 o'clock position.[173] At this point, the posterior branch separates from the main anterior circumflex branch and lies closest to the capsule and glenoid. The superior–lateral brachial cutaneous nerve and the nerve to the teres minor always originate from the posterior branch.[8] This anatomic relationship is of note because loss of sensation over the deltoid may indicate loss of teres minor function. After passing through the quadrangular space, the axillary nerve courses from posterior to anterior along the deep surface of the deltoid, which it innervates.[22,31,127] The posterior deltoid is variably innervated by both the anterior and posterior branches of the axillary nerve, with the nerves consistently entering the muscle directly inferior to the posterolateral corner of the acromion.[8]

The distance from the lateral edge of the acromion to the axillary nerve is generally thought to be about 5 cm,[127] but is subject to variation depending on the size of the arm (i.e., patient). Burkhead and collegues[31] have shown the axillary nerve to lie as close as 3.5 cm from the edge of the acromion in a cadaver specimen, and have shown that the distance decreases as much as 30% with increasing abduction of the humerus.

Axillary nerve injury during the superior, deltoid splitting approach can be avoided by limiting the extent of the deltoid split to 3 cm or less.[31] When more distal exposure is required, the axillary nerve can be easily palpated on the deep surface of the deltoid, and protected (Fig. 5-14). Neer recommended placing a suture at the apex of the deltoid split to prevent distal propagation and inadvertent nerve injury during retraction of the deltoid during rotator cuff repair.[147–149] During the anterior approach for subscapularis repair, the axillary nerve should be identified at the inferior border of the subscapularis muscle and may be gently protected with a blunt retractor. External rotation of the arm will also relax the nerve when performing the intraarticular capsular releases required to mobilize the tendon. Posterior approaches for latissimus dorsi or teres major transfer should maintain the subdeltoid dissection medial to the posterolateral border of the acromion to avoid denervating the posterior deltoid.[8] Arthroscopic approaches should avoid excessively inferior placement of any of the portals[166] and pay careful attention to avoiding excessive fluid extravasation into the arm. Arthroscopic capsular releases should be performed with the knowledge that the axillary nerve is in close proximity to the inferior glenohumeral ligament.[173] Abduction, external rotation, and perpendicular traction may increase the zone of safety during arthroscopic capsular releases near the 5 to 7 o'clock positions.[208]

Figure 5-13 The interval between the detached deltoid and the acromion will be traversed by a thin layer of scar tissue. The scar tissue is released from the margins of the acromion, and is then incised distally **(A).** Digital palpation of the anterior and posterior flaps will reveal the junction of the thick retracted deltoid edge and the thinner scar tissue **(B).** Palpation of the axillary nerve defines the distal extent of the longitudinal split. The respective distances from the intact portions of the middle and anterior deltoid to the anterolateral corner of the acromion are measured. Sutures are placed within the fibrous, retracted edges of the deltoid at the points corresponding to the previously measured distances **(C).** These two sutures are then passed through drill holes in the anterolateral corner so that they come to rest adjacent to one another **(D).** The remaining portions of the deltoid are also reattached to the acromion through drill holes **(E).**

Figure 5-14 Digital palpation of the deep surface of the deltoid can be used to identify the axillary nerve so that the deltoid split does not extend distal enough to cause injury to the nerve.

Evaluation

The clinical features associated with axillary nerve injury vary according to the location of the injury. In some cases, the location of the previous skin incision will suggest an axillary nerve injury. The initial presentation usually includes weakness in shoulder abduction and elevation. However, deltoid weakness may be masked by a strong and competent rotator cuff. Numbness and paresthesias in the lateral arm will be present when the injury is proximal to the superior lateral brachial cutaneous nerve.[8] Since the sensory nerve usually arises proximal to the common zone of injury and the cutaneous distribution of the axillary nerve and associated cutaneous nerves overlap substantially, the absence of sensory deficits is often unreliable in making the diagnosis. Generally, a characteristic pattern of deltoid atrophy will develop distal (anterior) to the site of injury (Fig. 5-15).[22,31,32,51,119,124,127] Other causes of atrophy should be excluded at the time of physical examination. The absence of a palpable defect at the border of the acromion will help to differentiate a nerve injury from a deltoid detachment. Disuse atrophy will affect all portions of the deltoid, mimicking the atrophy seen with a proximal nerve injury. However, disuse atrophy should not present with associated sensory deficits.

Deltoid dysfunction in a suspected proximal nerve lesion may be assessed clinically by performing the deltoid lag test.[101] Since no other muscle can compensate for the posterior part of the deltoid in a position of maximal shoulder extension, testing in this plane is highly specific for the deltoid and, consequently, axillary nerve function. With the patient seated, the physician places the arm into full extension and asks the patient to actively maintain this posture. If the deltoid is weak, the arm will drop. The suspected

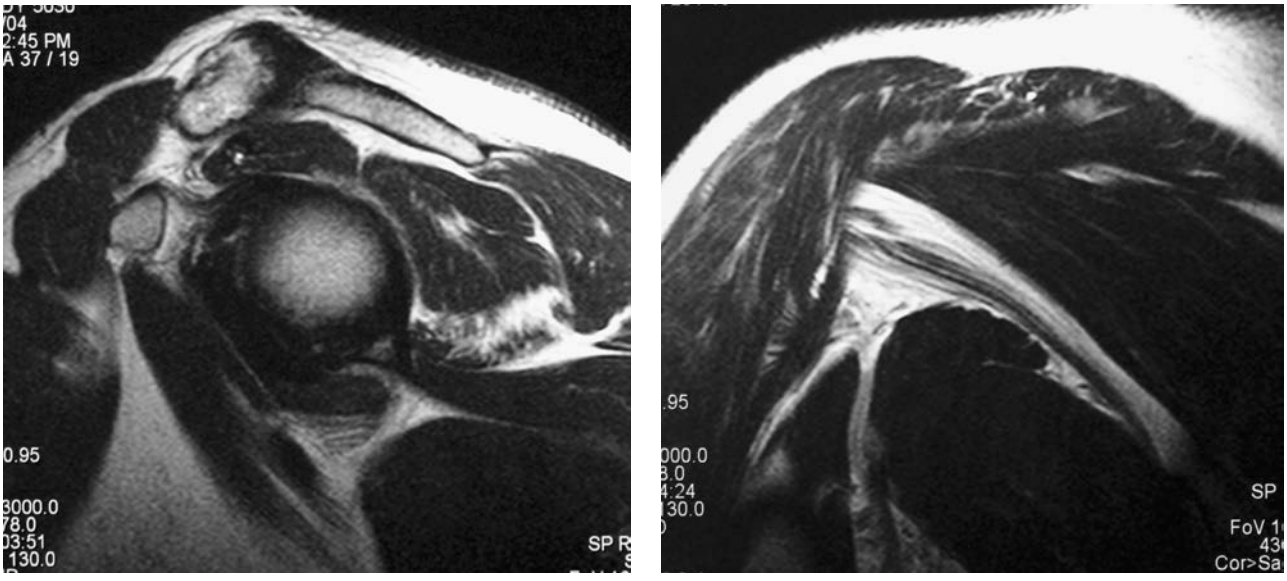

Figure 5-15 Axillary nerve injury during rotator cuff surgery is the result of direct incision of the nerve or traction neuropathy. Fatty atrophy is seen within the teres minor muscle.

diagnosis of an axillary nerve injury is confirmed by electromyography. All three portions of the deltoid should be tested to ensure that a false-negative study is not produced from isolated testing of an intact portion of the deltoid. Experienced electromyographers may be able to provide an opinion on the type of nerve injury (i.e., whether the nerve is likely to be in continuity). Serial electrophysiologic studies may be used to follow progressive regeneration of the nerve. Magnetic resonance imaging is helpful in determining the integrity and reparability of the rotator cuff.

Treatment

Treatment of an axillary nerve injury depends on the degree of functional impairment, as well as the status of the rotator cuff and coracoacromial arch. When the injury is proximal or posterior, exploration may be considered if there is no clinical or electrophysiological recovery by 3 to 6 months following injury. However, the nerve injury typically occurs at the level of the anterolateral acromion, whereby the caliber of the nerve and terminal branches often precludes neurolysis, nerve repair, or grafting. Therefore, available treatment options include activity modification and rehabilitation, muscle transfers, and arthrodesis. Although active abduction may be limited after acute injury, most patients with an intact rotator cuff are able to compensate for the loss of deltoid function with time and are willing to pursue nonoperative treatment. Some authors have reported excellent functional shoulder recovery among patients with an isolated axillary nerve injury, despite a complete paralysis of the deltoid muscle.

Management of an axillary nerve injury in the presence of a recurrent rotator cuff tear depends on the size and reparability of the rotator cuff defect and on the integrity of the coracoacromial arch. When the rotator cuff defect is small or reparable, consideration is given to bipolar latissimus transfer.[110] Alternatively, Leffert has described rotational deltoidplasty with excision of the denervated portion of the muscle to restore anterior deltoid function. These procedures are not performed, however, until the revision rotator cuff repair has been performed and the subsequent final results have been evaluated. The location of the axillary nerve injury may spare enough of the middle deltoid that affected patients are willing to live with the axillary nerve injury if the repeat rotator cuff surgery has been successful.

Axillary nerve injury in association with a massive or irreparable rotator cuff tear is usually not a correctable problem. When coracoacromial arch insufficiency is added to this clinical vignette, the shoulder is nearly flail. The likelihood of restoring normal function to any portion of this triad is abysmal, leaving the patient with a choice between acceptance of the deficits or arthrodesis. Patients considering arthrodesis should fully comprehend that they will lose all rotational motion of the shoulder, even with the arm at the side. The potential pain relief and stability provided by arthrodesis may not justify the loss of this last remaining function of the shoulder.

SUPRASCAPULAR NERVE INJURY

Etiology and Prevention

Numerous studies exist describing the course of the suprascapular nerve, as well as pathologic entities associated with it. Interestingly, iatrogenic injury to the suprascapular nerve during rotator cuff surgery has been reported only a handful times in the literature.[76,226] It is usually the result of aggressive lateral mobilization of a large or massive chronically retracted rotator cuff tear. The nerve either becomes kinked along the lateral margin of the suprascapular notch or is directly injured by surgical dissection, which extends too far medial to the glenoid rim. All of the above reported cases were confirmed using electrodiagnostic studies. Since postoperative electrodiagnostic studies are not routinely performed, the true incidence of suprascapular nerve injury may be higher than reported.

While suprascapular neuropathies of the shoulder can present with concomitant rotator cuff tears, the clinical presentation may be confusing, and the rotator cuff tear may mask a neuropathy.[209] Clinical examination alone will not differentiate between rotator cuff tears and suprascapular neuropathy. Since the clinical manifestation of suprascapular nerve entrapment is pain and associated external rotation weakness, the significance of the neuropathy may be lost in the presence of a rotator cuff tear. It is more likely that an electromyography study is obtained following rotator cuff repair to determine the cause of persistent pain or weakness. However, if a nerve injury is uncovered at this point, it is not possible to elucidate whether it occurred iatrogenically or was present preoperatively.

Postoperative suprascapular neuropathy may actually represent a failure in diagnosis, with the injury having been present preoperatively. A recent study by Vad[209] and colleagues utilized preoperative electromyography to show a 28% incidence of neurologic injury occurring in the presence of large rotator cuff tears with associated atrophy. Albritton and colleagues[2] have shown in a cadaveric study that 2 to 3 cm of medial retraction of the supraspinatus tendon will change the course of the suprascapular nerve and place it under tension. They postulate that supraspinatus and infraspinatus atrophy, following isolated supraspinatus tears and massive tears, may be associated with suprascapular nerve injury. Lateral mobilization of the muscle during rotator cuff repair may actually be beneficial in relieving tension on the nerve and may assist in reversal of muscle atrophy in the supraspinatus. The infraspinatus muscle appears to be less resistant to nerve injury.

The course of the suprascapular nerve predictably leaves the superior trunk of the brachial plexus and reaches the

dorsal surface of the scapula by passing through the suprascapular notch, beneath the transverse scapular ligament.[16,211] Two motor branches typically innervate the supraspinatus muscle, with the first motor branch being the larger of the two and originating under or just distal to the ligament. The nerve continues through the spinoglenoid notch, where three to four motor branches innervate the infraspinatus muscle. The inferior transverse scapular ligament appears to be a variable structure under which the nerve may become compressed.[108] Superiorly, the nerve is 2.5 to 3 cm medial to the supraglenoid tubercle, whereas the branches to the infraspinatus lie 1 to 2 cm medial to the midportion of the posterior glenoid rim.[16,211]

The anatomy of the suprascapular nerve leaves it vulnerable to either direct or indirect injury.[16,211] Capsular releases passing medial to the above described "safe zone" risk direct injury to the nerve. Limiting the amount of medial dissection through the capsulotomy may avoid injury to the nerve branches. Indirect injury occurs when traction is placed on the nerve branches during lateral mobilization of the rotator cuff tendon. Since the nerve occupies a relatively fixed position on the floor of the supraspinatus fossa and at the notch, lateral advancement of the tendon risks tethering the nerve as it crosses through the notch while the motor branches pivot around the pedicle of the nerve.[211] Cadaveric dissections demonstrated tethering of the nerve and its branches when the tendon was advanced laterally further than 1 cm using conventional repair techniques.[78,211] Warner and colleagues have shown that this safe zone may increase to 3 cm when the muscle is released from its respective fossa and allowed to advance laterally with the tendon.[211]

The clinical relevance of cadaverically derived safe zones for advancement is not entirely clear. Warner and colleagues[211] obtained their data using cadavers without retracted rotator cuff tears. Lateral advancement of greater than 1 cm may be safely performed when a large, acutely retracted musculotendinous unit is restored to its original, premorbid length. Conversely, it may not be possible to gain even a centimeter of length in a chronically retracted musculotendinous unit without placing significant tension on the neurovascular pedicle. In general, the concept of limiting the amount of lateral advancement of a chronic, retracted rotator cuff tear during repair is valid, although the clinical safe limit for advancement is not entirely known.

Evaluation

Determining the cause of persistent pain and external rotation weakness following rotator cuff repair may be difficult. A protracted recovery may be expected in association with surgical repairs of large, chronically retracted rotator cuff tears.[64,107,184] The additional effects of an associated nerve injury may be difficult to quantify. However, the presence of significant external rotation weakness with the arm at the side and at 90 degrees of abduction should alert the surgeon to the possibility of either a recurrent rotator cuff tear or a suprascapular nerve injury. Preoperative and surgical records should be reviewed to determine the integrity of the rotator cuff. If the rotator cuff was intact at the time of surgery, a suprascapular nerve entrapment or nerve injury should be suspected. Similarly, when the size of a preoperative rotator cuff defect is not sufficient to explain the amount of atrophy or external rotation weakness, the diagnosis of nerve injury is entertained. Under these circumstances, electrodiagnostic testing is indicated. In all cases of suspected suprascapular nerve injury, testing should be included for the possibility of superimposed cervical radiculopathy. If these studies indicate that the suprascapular nerve and the brachial plexus are normal, then magnetic resonance imaging is performed to identify a persistent or recurrent rotator cuff tear.

Preoperative magnetic resonance studies may supply the clinician with valuable information regarding the suprascapular nerve.[109] Studies depicting atrophy of the supraspinatus and infraspinatus muscle bellies, in the presence of a supraspinatus tear and an intact infraspinatus, should indicate the possibility of a preoperative suprascapular nerve entrapment (Fig. 5-16). The presence of a ganglion cyst in the suprascapular or spinoglenoid notches may also cause entrapment of the nerve at its respective location.[168]

Treatment

Treatment options for a suprascapular neuropathy include observation and rehabilitation, nerve exploration and decompression, and muscle transfers.[45] Management depends on the degree of functional impairment, the age and activity level of the patient, and the status of the supraspinatus and infraspinatus muscles. Since most injuries represent a traction neurapraxia or axonotmesis, nonoperative treatment should be considered in all patients with a suprascapular nerve injury. Activity modification to avoid additional trauma and irritation of the nerve is balanced with a scapular and rotator cuff conditioning program to maximize muscular function while the nerve is healing. While some patients may improve, the overall success rate of nonoperative treatment is not known. Failure to follow an appropriate rehabilitation program and continued high-demand activities may actually lead to worsening of symptoms.[45] Even when the nerve does not completely recover, many patients are willing to modify their activities and accept the limitations associated with the suprascapular nerve injury.

The presence of a suprascapular nerve lesion in association with a retracted tear involving the supra- and infraspinatus may represent a special situation. As mentioned above, retraction of the supra- and infraspinatus changes

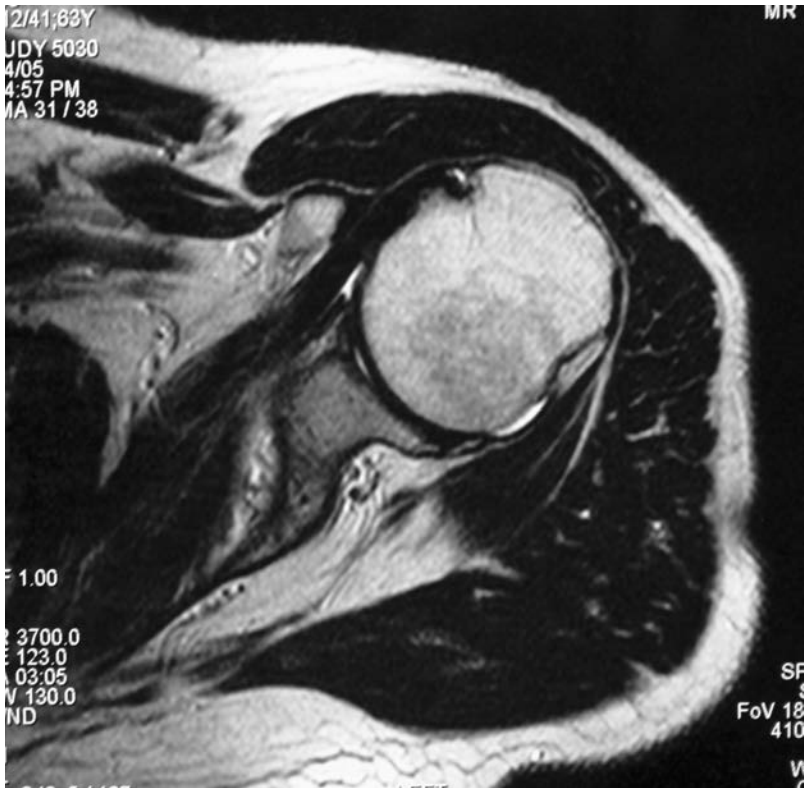

Figure 5-16 Preoperative magnetic resonance imaging scan of a patient with suprascapular neuropathy reveals severe increased signal in the infraspinatus muscle in the presence of an intact tendon.

the course of the nerve and may actually cause the nerve to be tented over the scapular spine. Therefore, repairing the tendon may relieve the tension on the nerve. This phenomenon may be an indication for relatively early cuff repair to facilitate nerve recovery.

Operative intervention may be considered in the young or active patient who presents with suprascapular neuropathy following mobilization and repair of a chronic, retracted rotator cuff tear. Nerve exploration and decompression is indicated when there exists significant functional impairment, no electromyographic or clinical improvement has been shown over a 6-month period, the rotator cuff repair is intact, and the supraspinatus and infraspinatus muscles have not undergone significant fatty degeneration. In a proximal lesion, decompression of the nerve is performed at the suprascapular notch and includes division of the transverse scapular ligament with lateral enlargement of the notch as necessary.[5,172,174] With isolated involvement of the infraspinatus, the nerve should be approached on both sides of the scapular spine. When present, the spinoglenoid ligament should be released. The spinoglenoid notch should not be deepened further than 1 cm to avoid creating a stress riser at the base of the acromion.

Tendon transfers are considered in patients who have either failed decompression of the nerve or are not candidates for nerve decompression. However, it is highly unlikely that a patient with an intact rotator cuff repair will have significant enough functional impairment related to the suprascapular neuropathy to warrant tendon transfers to augment posterior rotator cuff function. In this rare circumstance, tendon transfers are performed as described for irreparable posterior rotator cuff insufficiency in Chapter 4.

Postoperative suprascapular neuropathy, which occurs in conjunction with an intact rotator cuff, probably represents a failure in preoperative diagnosis. This situation should be treated as a primary suprascapular neuropathy.

RECURRENT ROTATOR CUFF TEAR

Etiology and Prevention

Since Codman's initial treatise on the surgical treatment of rotator cuff tears in 1911,[39] improved operative techniques have been responsible for a high success rate, with enduring patient satisfaction.[1,40,62,96,185] However, recurrent or persistent rotator cuff defects have been reported to occur in 20% to 90% of cases,[18,34,60,64,74,88,118,126,202] with the risk of recurrence increasing relative to the size of the initial tear. The failure rates between arthroscopic and open repairs appear to be equal when the tear is small and involves minimal retraction of the musculotendinous unit. The incidence of failure is highest among elderly patients with chronic and retracted tears involving two or three tendons. Arthroscopic and open repairs under these conditions

represent the highest retear rate, with early reports suggesting that arthroscopic repair may be associated with higher recurrence rates.[18,60] Associated risk factors for recurrent tears include advanced age, tear size, fatty degeneration, chronicity and atrophy, poor tendon quality, poor bone quality, inappropriate rehabilitation, inadequate subacromial decompression, smoking, steroid injections, and diabetes.[15,49,64,74,88,126,156,202] Persistent defects are not necessarily the sine qua non for failure, since the presence of a persistent rotator cuff defect is compatible with a good postoperative result following rotator cuff repair.[34,64,88,118,126] This process of converting a symptomatic tear into an asymptomatic retear is not entirely clear, although it may involve adequate subacromial decompression,[24,25,164,181] débridement, biceps tenotomy, partial healing of the rotator cuff, and adequate postoperative rehabilitation. The quality of functional results, however, depends on the size of the persistent defect, associated atrophy of the rotator cuff muscles, integrity of the deltoid and the coracoacromial arch, and functional demands of the patient.[53,88,107,148,181,219] Patients with persistent rotator cuff defects will be capable of overhead function when the deltoid is intact and the anterior and posterior portions of the rotator cuff are intact and balanced.[24,25,28,148,181] However, they will generally complain of fatigue with overhead activities and limitation in activities that require vigorous or sustained overhead strength, as compared to patients with an intact rotator cuff.[64,88] Therefore, the goal of rotator cuff repair is long-term restoration of a functional, healed musculotendinous unit. While this may not always be attainable in primary rotator cuff repair, the development of recurrent rotator cuff tears may be mitigated through a combination of careful preoperative patient selection, meticulous surgical technique, and attention to appropriate postoperative protection and rehabilitation.

With the understanding that the correlation between postoperative subjective and functional results and anatomic results (i.e., rotator cuff integrity) is variable,[64,88,126] outcome studies have begun to focus on patient satisfaction in terms of patient-derived subjective assessments of symptoms and function.[104,140,160,183] While it is true that, on average, postoperative shoulder performance scores are better in patients with intact rotator cuff repairs than in those with reruptures, even patients with rerupture often have improved pain and function. Preoperative and surgical variables that are associated with poorer patient satisfaction include age less than 55 years; smoking; débridement of massive, irreparable rotator cuff tears; chronic or unrepairable subscapularis tears; and patients with larger or massive supraspinatus and infraspinatus tears.[40,69,91,104,107,130,160,185,200,215,217] Objective postoperative variables that are associated with poorer patient satisfaction include diminished and weakened forward elevation, impingement signs, and acromioclavicular joint pain and tenderness. Subjective variables associated with poorer patient satisfaction include persistent pain, functional impairment, and work disability.[160,217]

Preoperative variables exist that will have a bearing on the ability to obtain long-term tendon-to-bone healing. In the presence of an acute rotator cuff tear, the biologic potential for healing appears greater when the repair is performed within 3 weeks of injury.[9] In long-standing tears or delayed repairs, muscle atrophy and fatty infiltration may develop, which are variably reversible[190] and appear to have a negative effect on the outcome following rotator cuff repair.[74,75] There appears to exist a direct relationship between tear size and degree of atrophy.[202,225] These changes may be graded using computed tomography scanning or magnetic resonance imaging and increase with elapsed time from the tendon rupture.[59] Additionally, chronic retraction and scarring of the musculotendinous unit may preclude the surgeon from obtaining an adequate tendon-to-bone repair. Therefore, in the presence of an acute or acute-on-chronic rotator cuff tear with retraction of the tendon, early repair is more likely to result in long-term tendon-to-bone healing as compared to late repair. This potential advantage should be considered in the context of appropriate patient selection criteria such as age, physical demands, comorbidities (diabetes, smoking), and motivation (willingness to comply with rehabilitation), prior to recommending surgical intervention.

The surgical principles that most likely reduce postoperative recurrent tears or persistent defects include adequate mobilization of the tendon to the greater tuberosity, preparation of the tendon and bone interfaces, and secure fixation of the tendon to bone. These principles hold true for all repair methods. The superficial surface should be free from the overlying deltoid, acromion, subdeltoid bursa, scapular spine, coracoid, and the trapezius muscle. Capsular releases are frequently required to release the tenodesis effect of the underlying capsule.[228] Interval releases may also be required to allow full excursion of the contracted tendon.[14,148–150] A thorough understanding of the various tear configurations will enable the surgeon to perform the proper releases, repair longitudinal tears in a convergent manner, and repair the tendon to bone with minimal tension. A repair that has been overly tensioned will eventually fail.[30] Inability to adequately mobilize the tendon may be due to substantial intramuscular scarring and the development of fatty atrophy. Tendon convergence and advancement methods are discussed extensively in Chapter 3, while the management of the irreparable rotator cuff tear is discussed in Chapter 4.

Débridement of the greater tuberosity, along with abrasion of the cortical surface at the proposed site of tendon attachment, may enhance tendon healing. While open rotator cuff techniques often include the creation of a shallow cancellous trough, most arthroscopic techniques repair the tendon to the cortical surface of the greater tuberosity. The rates of tendon healing between a shallow

cancellous groove or trough, and a cortical bone surface appear to be equal.[201] Complete removal of the cortical surface of the humeral attachment site in long-standing rotator cuff tears will often reveal a virtually hollow greater tuberosity and should be avoided.[139] While excessive débridement of the tendon edges is not necessary or advisable, excision of the friable, necrotic edges will reveal a healthy tendon edge for suture placement.[73] Rotator cuff repair failures frequently occur when the suture pulls through the tendon.[46] Tendon grasping suture techniques such as the Mason-Allen technique provide excellent pullout strength and presumably a more durable repair during open rotator cuff surgery, as compared to simple or mattress sutures.[70,193] The holding strength of arthroscopically tied horizontal mattress sutures appears to be higher than that of the Mason-Allen suture. The massive cuff stitch, which includes a horizontal mattress stitch that is reinforced with a vertical loop, may act in a similar manner to the Mason-Allen suture technique.[128] Despite these data, there is no evidence to show that tendon grasping suturing techniques produce any higher healing rates than multiple simple sutures; many surgeons still prefer multiple simple sutures over mattress or other tendon grasping techniques.

Strength of fixation is related to the pullout strength of anchoring devices, knot stability, suture elongation, the number of bone anchors, quality of bone and rotator cuff tissue, passive tension, and physiologic cyclic loading; the interested reader is directed to Chapter 3 on rotator cuff repair. While the holding strength that is required for successful tendon-to-bone healing is unknown, data exist supporting both the use of open transosseous techniques as well as arthroscopic fixation using bone anchors.[38,175] The advent of improved suture anchoring devices has led to their widespread acceptance and use in rotator cuff repair procedures. Advantages include the ease of use, decreased operating time, and decreased surgical exposure and morbidity. Suture anchors can provide equivalent fixation strength to transosseous tunnels, and under cyclic loading conditions may be somewhat better.[26,38,175] While most arthroscopic rotator cuff repair failures occur at the tendon–suture interface, anchors may subside without actually pulling out of the bone, leading to gap formation, poor tendon-to-bone healing, and rotator cuff repair failure (knot loosening or loop elongation will also contribute to failure). Pullout strength varies according to the anchoring device and bone quality of the humeral head.[139] Tingart and colleagues[204] have shown that the higher bone mineral density in the proximal–medial and proximal–anterior regions of the greater tuberosity (i.e., closer to the articular surface) is associated with increased pullout strength of suture anchors. While suture anchors may represent an attractive option in young patients with high bone density, caution should be exercised among patients with poor bone quality such as postmenopausal women, smokers, and elderly patients, as these devices may not provide adequate pullout strength.[193] Osteoporosis of the proximal humerus will also develop in the presence of a chronic rotator cuff tear, regardless of age.[139] Under these circumstances, passing sutures through bone tunnels and tying the sutures over a lateral bone bridge may provide superior strength.[70,193] This may be augmented with a thin plate or button to provide additional resistance to pullout of the sutures.[33]

Proper postoperative protection and rehabilitation play an important role in preventing postoperative recurrent or persistent rotator cuff defects. While the clinical importance of early passive motion of the shoulder following rotator cuff repair is well established,[111,117,149,150,152,180] the positions of extreme extension, adduction, and internal rotation should be avoided in the early postoperative period to minimize tension on the repair.[228] Arm position in this extreme range may not pose a problem with smaller tears. However, in larger posterior–superior tears, passive forward elevation exercises should be combined with slight abduction of the arm (15 to 30 degrees) to offset the effects of flexion. A protective orthosis may be placed with the arm at the side in a small amount of abduction to decrease passive tension and reduce bone–tendon gap formation.[176] Chronic or massive tears may require the use of a larger abduction pillow or orthosis, depending on the amount of tension that is observed at the time of surgery.[99] It should be emphasized that an abduction orthosis, which is placed to relieve tension, is unlikely to induce healing in the presence of an overtensioned repair. Tension overload will predispose to failure of the repaired fibers under physiologic cyclic loading conditions.[26,30] Active motion exercises should be instituted between 6 and 8 weeks postoperatively,[111,117,149,150,152,180] avoiding resisted vigorous strengthening and isokinetic exercises until 3 months following repair. The initiation of early active motion and the use of weights in the early postoperative period have been associated with failure of the tendon repair.[156]

Evaluation

Since the risk of recurrent rotator cuff tears is highest among elderly patients with chronic tears involving two or more tendons,[88] the index of suspicion for this complication should be high when these patients complain of persistent pain and functional impairment. Physical findings vary according to the size and location of the tear, the integrity of the coracoacromial arch, and the presence of soft tissue contracture. Lack of both active and passive elevation is more likely to represent capsular contracture rather than residual rotator cuff insufficiency. It is extremely difficult, if not impossible, to determine the presence and clinical relevance of recurrent rotator cuff tears in a stiff shoulder. Once the soft tissue contracture has been excluded or corrected, the physical findings associated with a recurrent rotator cuff tear will become more apparent.

Symptomatic patients will have subacromial crepitance and weakness on isolated muscle testing, and will often demonstrate a positive "lag sign" on physical examination.[100] When pain appears to be a limiting factor during strength testing, a subacromial lidocaine injection will usually alleviate a significant amount of associated pain and increase the reliability of the examination. Recurrent defects in the posterior–superior portion of the rotator cuff (supraspinatus and upper infraspinatus tendons) generally demonstrate weakness of arm abduction and weakness of external rotation with the arm at the side. This external rotation weakness generally improves when the arm is brought into 90 degrees of elevation in the scapular plane. Conversely, a tear extending to the posterior–inferior portion of the rotator cuff (inferior infraspinatus and teres minor tendons) will usually demonstrate external rotation weakness with the arm at the side as well as in 90 degrees of elevation in the scapular plane. External rotation lag signs refer to the inability of the patient to actively maintain maximal external rotation of the arm when it has been passively placed in this position by the examiner. Positive external rotation lag signs with the arm at the side, or with the arm at 90 degrees of elevation in the scapular plane, indicate recurrent defects in the posterior–superior and posterior–inferior rotator cuff, respectively. External rotation lag signs at any level of abduction are not particularly reliable in the detection of weakness associated with an isolated supraspinatus tear.[106] Abduction of the arm in the scapular plane with the elbow extended and the humerus internally rotated is generally accepted to represent supraspinatus function.[100,111] Therefore, weakness in this position may indicate a recurrent or persistent tear of the supraspinatus.

Subscapularis insufficiency results in increased passive external rotation of the shoulder, as well as weakness of terminal internal rotation. Detection of a recurrent defect requires careful isolation of the muscle from other internal rotators of the shoulder girdle.[79] The internal rotation lag sign[100] represents the inability of the patient to maintain the dorsum of the hand away from the midlumbar spine after it has been passively placed in this position of maximal internal rotation by the examiner. Similarly, the lift-off test[69] is sensitive for detecting subscapularis insufficiency and describes the inability of the patient to actively lift the dorsum of the hand away from the lumbar spine. These tests require full passive internal rotation to place the arm in the appropriate position. In the presence of posterior capsular contracture, the abdominal compression test appears to be as specific as the lift-off test in determining subscapularis insufficiency.[205] A positive test occurs when the patient is unable to maintain the flexed elbow anterior to the coronal plane of the body while simultaneously maintaining the palm of the hand compressed against the abdomen. Scapular protraction is often difficult to control and will interfere with the performance of this test. When this occurs, it may be easier to control scapular protraction with the patient in the supine position.

The suspected diagnosis of a recurrent rotator cuff tear may be confirmed with ultrasonography, arthrography, or magnetic resonance imaging.[34,64,81,88,129,162] The presence of postsurgical artifact will interfere with the interpretation of imaging studies, and the diagnostic criteria for a full-thickness recurrent tear are more stringent than that for a shoulder that has not undergone surgery. Magnetic resonance arthrography may offer the most information including tear size, muscle atrophy and fatty infiltration, and concomitant biceps and labral pathology. While the clinical relevance of minor tendon signal abnormalities is uncertain (Fig. 5-17A),[144] a well-defined tendon gap that is traversed by fluid is a reliable indicator of a persistent or recurrent rotator cuff defect (Fig. 5-17B).[81,118,162,202]

Treatment

The treatment options for recurrent or persistent rotator cuff defects are the same as those for primary rotator cuff tears. They include rehabilitation and activity modification, débridement, revision repair or partial repair, tendon augmentation (utilizing allograft, autograft, or xenograft), and distant tendon transfer.[14,24,25,49,66,82,181] Specific treatment recommendations are dependent on patient age, activity level, motivation, tear size, functional impairment, and tissue quality. The mere presence of a recurrent tear of the rotator cuff is not by itself an indication for repair. Revision rotator cuff repair is much more challenging than primary rotator cuff repair, especially in the setting of deltoid detachment or coracoacromial arch insufficiency. Rehabilitation of the remaining portions of the rotator cuff, deltoid, and scapular stabilizers is a reasonable initial approach for many patients with a recurrent defect, and may eliminate the need for further surgical intervention. Postoperative stiffness from subacromial scarring or capsular contracture should also be identified and corrected prior to considering revision rotator cuff surgery, especially in patients with large recurrent defects. Among patients with capsular contracture and irreparable rotator cuff insufficiency, arthroscopic capsular release may improve their function sufficiently that they are able to tolerate the residual rotator cuff insufficiency and avoid a complicated reconstructive procedure.

Revision rotator cuff surgery may be considered when nonoperative treatment has failed. Early surgical intervention is considered in patients who are markedly symptomatic following a traumatic, inciting event, which results in an early retear of the rotator cuff repair. This is especially true when the patient's original surgery was performed to repair an acute, large tear and the original repair was felt to be of good quality. Symptomatic patients who demonstrate weakness upon isolated muscle testing, have positive lag signs, and whose imaging studies reveal a recurrent tear

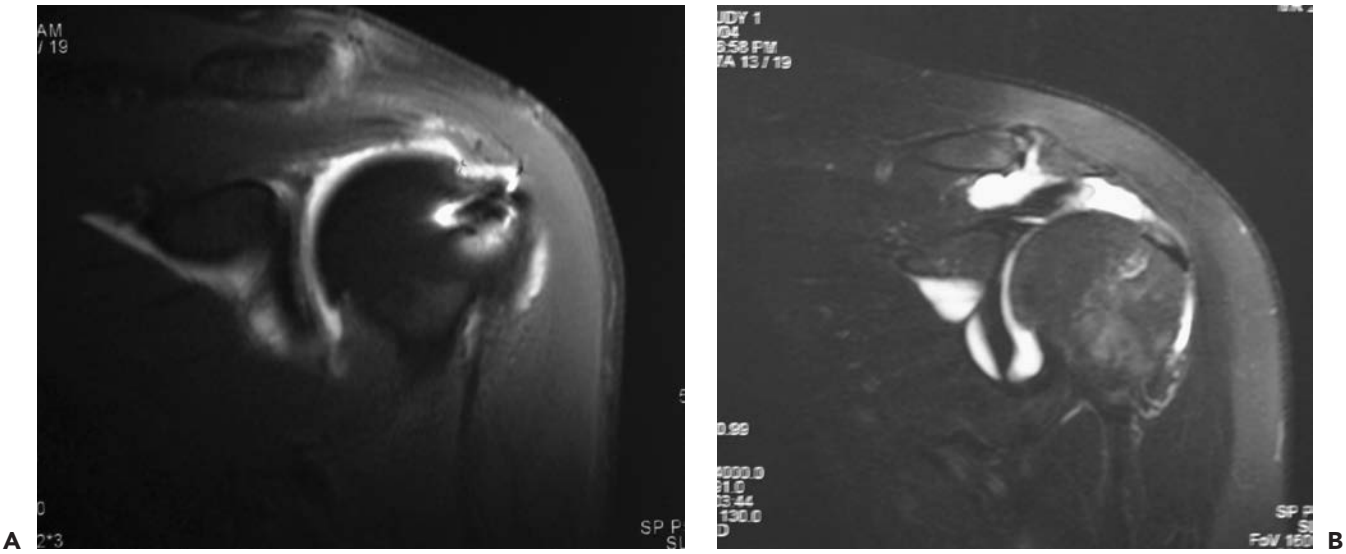

Figure 5-17 Criteria for the diagnosis of a recurrent full-thickness defect must be stringent to avoid false-positive results secondary to postsurgical artifact. **(A)** Subtle signal intensity abnormalities seen on magnetic resonance arthrography may represent scarring rather than a recurrent defect. **(B)** A well-defined tendon gap filled with fluid that communicates to the subacromial space, however, is a reliable sign of a persistent or recurrent rotator cuff tear.

that is commensurate with the physical findings are candidates for revision rotator cuff repair. The surgical principles of tendon mobilization and tendon-to-bone fixation are the same as that for primary rotator cuff repair. When the entire defect is not reparable, partial repair may decrease strain at the margins of the tear and result in improved function.[25,29] A decision must then be made regarding tendon augmentation, tendon transfer, or leaving a residual defect. The anterior and posterior portions of the rotator cuff should not be transposed superiorly to close the defect. In the presence of intact anterior and posterior force couples, a residual superior defect may be commensurate with intact overhead function, especially if this ability was intact preoperatively.[24,28] A patch graft represents a potential treatment option to augment the defect between the anterior and posterior cuff tendons, acting to resist inferior displacement of the tendons and therefore maintaining a more favorable orientation of the force couples.[145] However, its effectiveness appears to decline with increasing tear size.[194] Most patches are currently only approved for augmentation of a repair and not for spanning of large, irreparable defects. Latissimus dorsi transfer[66,71,212] may be considered for irreparable posterior cuff insufficiency, while pectoralis major or teres major transfer may be considered for anterior cuff insufficiency.[3,221] The coracoacromial ligament should be preserved in all cases and repaired to the acromion.

The reported results following revision rotator cuff repair are conflicting, with most authors describing disappointing results in about 50% of patients.[15,49,217] A satisfactory outcome is most dependent on an adequate subacromial decompression, repair of the rotator cuff with tendon-to-bone sutures, avoidance of weights in the early postoperative period, and an intact and functioning deltoid.[156]

ANTEROSUPERIOR HUMERAL HEAD SUBLUXATION

Etiology and Prevention

Normal shoulder kinematics in the presence of an intact rotator cuff, functioning deltoid, and intact coracoacromial arch will maintain the geometric center of the humeral head within 2 to 3 mm of the center of the glenoid during active elevation of the arm.[56,113,115,170] Although the greater tuberosity may contact the anterior acromion and coracoacromial ligament with elevation above 60 degrees,[56] the compressive force of the normal rotator cuff will actively center the humeral head into the glenoid fossa during deltoid muscle contraction and serves as the primary restraint to anterosuperior translation of the humeral head.[113,125] Under normal loading conditions, the static coracoacromial arch plays a limited role as a secondary passive restraint to anterosuperior subluxation, but assumes a crucial role in the presence of a dysfunctional rotator cuff.[57] In the presence of small rotator cuff tears, there are usually sufficient forces anteriorly and posteriorly to compensate for the loss of function that accompanies the tear. Although glenohumeral kinematics are altered,[224] the remaining rotator cuff muscles continue to serve as the primary restraint to superior translation, and

the coracoacromial arch probably plays a more important role as a passive restraint. When rotator cuff tears become too large or are "unbalanced," the remaining rotator cuff muscles are unable to compensate for the loss of joint compressive forces.[27] In these "uncompensated" rotator cuff tears, the humeral joint reaction force is not directed into the glenoid. Rather, the muscle imbalance between a dysfunctional rotator cuff and a strong deltoid directs the humeral head anterosuperiorly, and the intact coracoacromial arch becomes the only restraint to further anterosuperior subluxation. In the setting of uncompensated rotator cuff dysfunction, coracoacromial insufficiency from prior surgery will severely compromise overhead function.[219] The incidence of this complication following rotator cuff repair is unknown, but when it occurs, the results are devastating and have historically been unsalvageable.[54,57,219] Patients who have poor preoperative function will often indicate that it is worse following surgery that results in anterosuperior humeral head subluxation. Their pain and dysfunction is often intolerable, even with activity modification and analgesics.[54,219]

Prevention of anterosuperior humeral head subluxation involves preservation of the coracoacromial arch during acromioplasty and rotator cuff repair, particularly in the presence of a large rotator cuff tear or a decreased preoperative acromiohumeral interval. While the indications for coracoacromial ligament preservation and repair continue to evolve,[55] this generally includes patients with two and three tendon tears, in whom the risk of a recurrent rotator cuff defect is sufficiently high to justify restoration of the coracoacromial arch. To facilitate repair of the ligament to bone, the anterior length of the acromion should be preserved while smoothing the undersurface of the acromion.[24,28,147,148] Some authors have advocated rotator cuff repair without performing an acromioplasty to avoid disrupting the integrity of the coracoacromial arch.[23,63,72] Clearly, partial excision of the coracoacromial ligament during acromioplasty has met with good results among patients with small rotator cuff tears, suggesting that repair of the coracoacromial ligament is not required in all rotator cuff repairs.[14,88,96,148,150,157,180,181] Although there may be a growing trend toward coracoacromial ligament preservation during both open and arthroscopic acromioplasty, there is currently little data in the literature to support routine repair of the ligament in small tears.

The operating surgeon should proceed cautiously when evaluating patients with marginal overhead function and complete obliteration of the acromiohumeral interval, as these patients are at high risk for deteriorating function following subacromial decompression and rotator cuff repair. If surgical intervention is contemplated in these patients, imaging studies such as magnetic resonance imaging and ultrasound will provide critical information regarding reparability of the rotator cuff. In the setting of an irreparable rotator cuff tear, a more conservative deltoid sparing open approach or arthroscopic decompression may be considered. Arthroscopic subacromial decompression usually requires subperiosteal release of a portion of the coracoacromial ligament, although the most medial portion or the acromial attachment can often be preserved. Studies indicate that the coracoacromial ligament may regenerate or heal, provided that the anterior length of the acromion is preserved.[84,123] Conservative arthroscopic decompression with biceps tenotomy may represent a reasonable alternative to conventional arthroscopic acromioplasty in patients with massive rotator cuff tears, and preserves the coracoacromial arch.[191]

The coracoacromial ligament can be released and repaired in one of two ways during open subacromial decompression. First, the deltoid insertion, subacromial bursa, and coracoacromial ligament can be released in a single layer and reattached to the acromion at the completion of the procedure. Alternatively, the interval between the deltoid attachment and the coracoacromial ligament can be dissected, releasing the deltoid from the anterior acromion. The underlying ligament and bursa can then be subperiosteally released from the undersurface of the acromion to maximize the length of the ligament. The bursal roof and ligament are then immediately sutured to the deep deltoid fascia and ultimately repaired to the anterior acromion as a single layer (Fig. 5-18). Tuberoplasty, as described by Fenlin and colleagues, represents an alternative to conventional open acromioplasty in patients with massive rotator cuff tears and may assist in preserving the coracoacromial arch.

Evaluation

The manifestations of anterosuperior humeral head subluxation are often apparent on clinical examination. With the arm at the side, the humeral head rests within the glenoid cavity. However, when the patient attempts to actively elevate the arm, the humeral head will rise out of the glenoid into a subcutaneous position anterior to the acromion. Full passive forward elevation is usually possible unless the anterosuperior subluxation is chronic and fixed. Due to the massive rotator cuff tear, the patient will be unable to raise the arm overhead and will demonstrate weakness in external rotation with the arm at the side and with the arm at 90 degrees of elevation in the scapular plane. Although the subscapularis may be involved, some inferior fibers may remain intact, leading to negative abdominal compression and lift-off tests. However, internal rotation strength will often be weak and the internal rotation lag sign may be present.[69,100] This complication is often also accompanied by deltoid insufficiency,[219] consisting of thinning, detachment, or atrophy associated with denervation.[61]

Radiographic studies are obtained to evaluate acromial bone loss and humeral head morphology and include

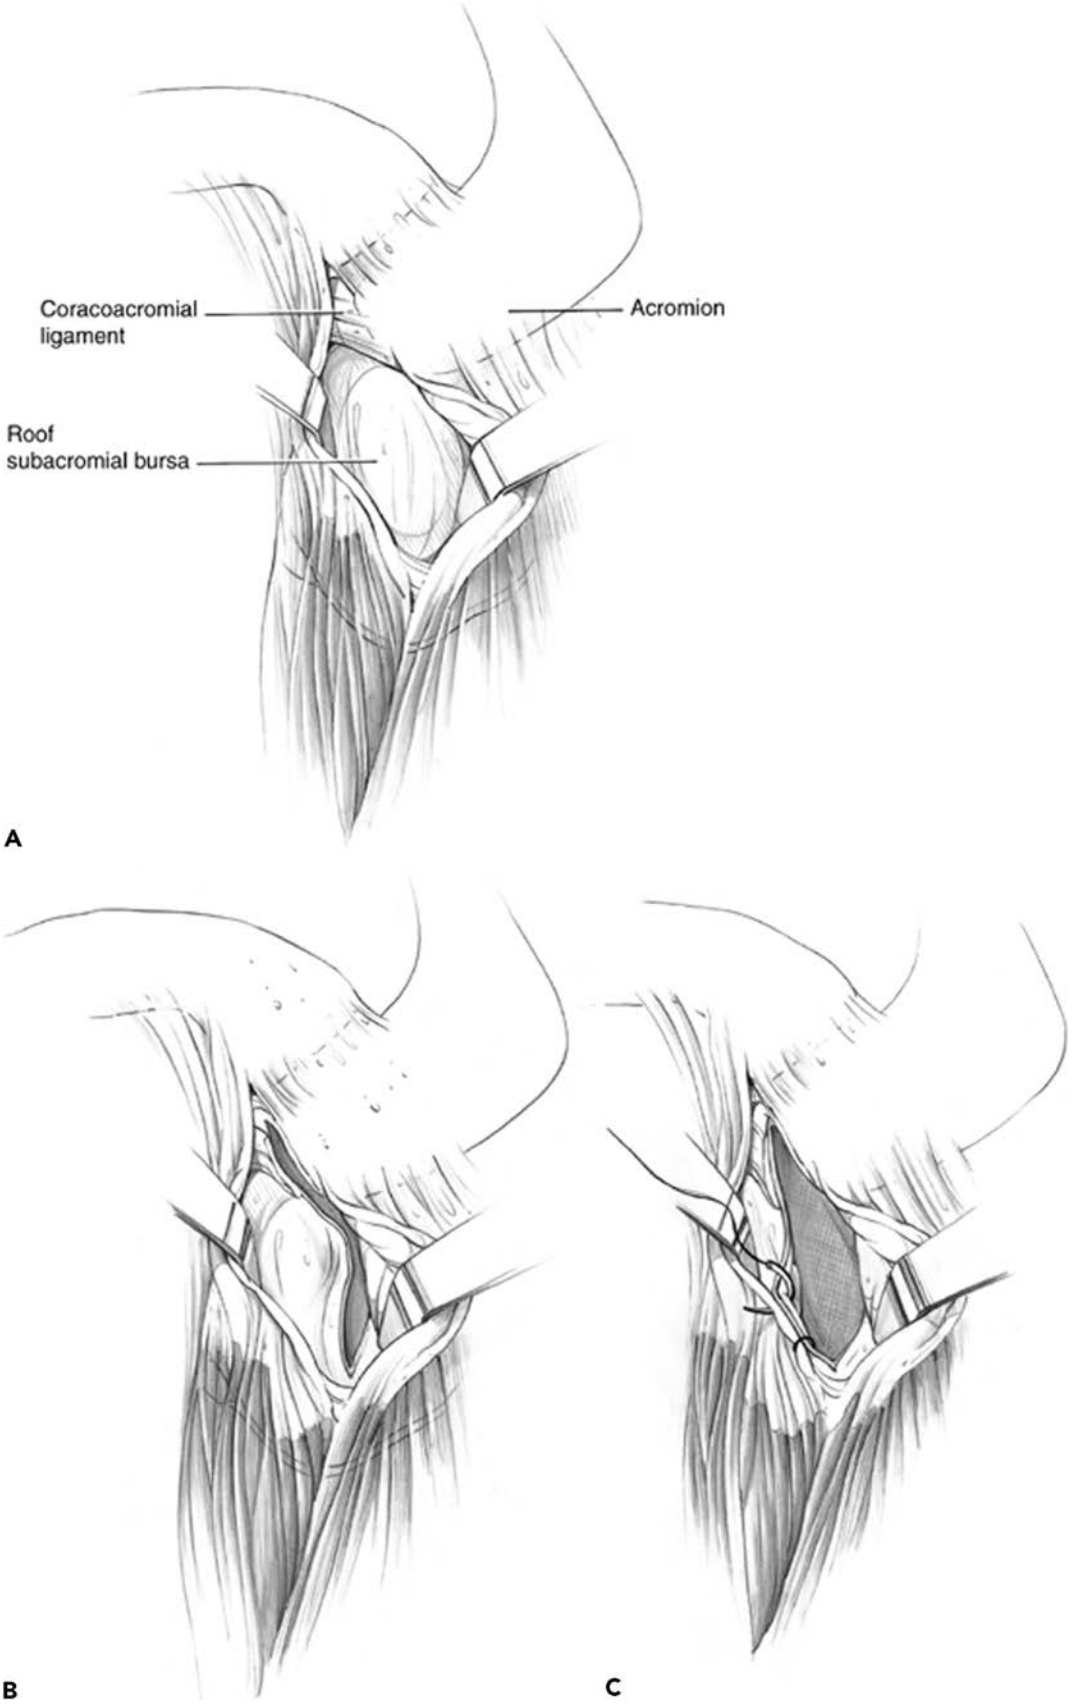

Figure 5-18 The coracoacromial ligament may be preserved during open rotator cuff surgery by reflecting the anterior deltoid in one layer, leaving the roof of the subacromial bursa and coracoacromial ligament attached to the acromion. **(B)** The roof of the bursa is then incised in line with the deltoid split, and the acromial attachment of the anterior portion of the bursal roof and the coracoacromial ligament are released from the anterior acromion. **(C)** The superior edge of the bursal roof and the acromial attachment of the coracoacromial ligament are sutured to the deep surface of the anterior deltoid fascia.

anteroposterior, axillary, 30-degree caudal tilt, and supraspinatus outlet views. Acromial bone loss is best appreciated on the 30-degree caudal tilt and axillary views, while the anteroposterior view will reveal humeral head articular changes associated with rotator cuff tear arthropathy, and static humeral anterosuperior subluxation. Magnetic resonance imaging is not required to confirm the diagnosis of anterior subluxation or recurrent rotator cuff tear, but will provide prognostic information regarding atrophy and fatty infiltration of the rotator cuff musculature. It will also facilitate treatment decisions regarding muscle transfer by indicating which muscles are still intact.[66,68]

Treatment

Surgical treatment of anterosuperior subluxation is at best a salvage procedure and consists of motion sparing and motion sacrificing options. Tendon transfers, coracoacromial arch reconstruction, and constrained arthroplasty are directed at preserving motion,[54,66,77,219,221] while arthrodesis is directed at relieving pain at the cost of glenohumeral motion.[41] A nonprosthetic motion sparing approach requires that the rotator cuff tear, coracoacromial insufficiency, or both be addressed. Since the rotator cuff tear is usually not repairable, reconstruction options to restore a balanced anterior and posterior force couple include partial repair, tendon transfers, or a combination of both. When the subscapularis is intact, latissimus dorsi transfer is performed to augment the posterior–superior force couple.[66] This transfer will not restore a balanced rotator cuff in the presence of subscapularis insufficiency and is therefore not indicated in this setting. Galatz and colleagues[61] have demonstrated success in treating anterosuperior subluxation that occurs in the setting of massive rotator cuff tear with subscapularis insufficiency. They described a dynamic transfer of the pectoralis major beneath the conjoined tendon to offset the loss of the subscapularis and the deltoid. Combined latissimus dorsi and pectoralis major transfers in the treatment of both anterior and posterior rotator cuff insufficiencies has been described,[3] but little data exist regarding this procedure in the treatment of anterosuperior subluxation. Coracoacromial ligament reconstruction has been described using either bone graft or autologous fascia lata.[54,219] Experience with either technique is relatively limited and the results uncertain. Flatow and colleagues[54] have combined soft tissue coracoacromial ligament reconstruction with appropriate tendon transfers to restore both dynamic and static restraints to anterosuperior subluxation. Patients were apparently not particularly ebullient regarding their results.

Although previous experience with constrained arthroplasty has met with disastrous results,[44,50,171] a new generation of inverse constrained prostheses have gained renewed interest in Europe, and more recently in the United States.[20,77,179] Indicated for anterosuperior subluxation or chronic pseudoparalysis, this reverse ball-and-socket joint appears to improve the moment arm of the intact deltoid, often allowing elevation above the horizontal plane. When this is combined with appropriate tendon transfers, patients may regain the ability to perform overhead functions and gain restoration of external rotation. Although technically demanding, this may prove to be a defining treatment option for patients with anterosuperior humeral head subluxation.

Arthrodesis will usually improve pain and increase stability and strength. It is reserved for patients with extreme pain who are willing to sacrifice glenohumeral rotation.[146] Although some patients with anterosuperior subluxation may be content to use the involved extremity as a helping hand with the arm at the side, others will perceive loss of glenohumeral rotation as a decrease in function. Patients should be carefully counseled regarding these limitations prior to recommending arthrodesis.

CONCLUSIONS AND TREATMENT ALGORITHM

Rotator cuff surgery is generally safe and efficacious. However, when complications occur, they are frequently accompanied by recurrent symptoms that may be worse than the original preoperative complaints that prompted the patient to seek medical attention in the first place. Reported results of surgical treatment of these complications are inconsistent and the incidence probably underreported. Surgical treatment of complications of rotator cuff surgery is demanding and requires both a motivated patient and a knowledgeable surgeon. It is impossible to establish rigid patient selection criteria and treatment protocols for all types and combinations of complications of rotator cuff surgery. However, adoption of a systematic approach that is based on known anatomic observations and sound surgical principles affords the best opportunity for a successful outcome. One algorithmic approach to the management of patients with complications following rotator cuff surgery is depicted in Fig. 5-19.

Several principles involved in the development of this algorithm deserve emphasis. First, the presence of significant stiffness interferes with the interpretation and clinical significance of any associated complications. Frequently, patients with documented recurrent rotator cuff defects will present with an inability to either actively or passively elevate their arm further than 90 degrees. If these patients had normal arcs of motion prior to their index procedure, restoration of normal or near-normal passive motion will frequently be accompanied by significant gains in active elevation. The patient may be satisfied with his or her shoulder function after simple arthroscopic capsular release and be willing to forego more complicated surgical procedures, particularly if his or her recurrent rotator cuff defect is irreparable.

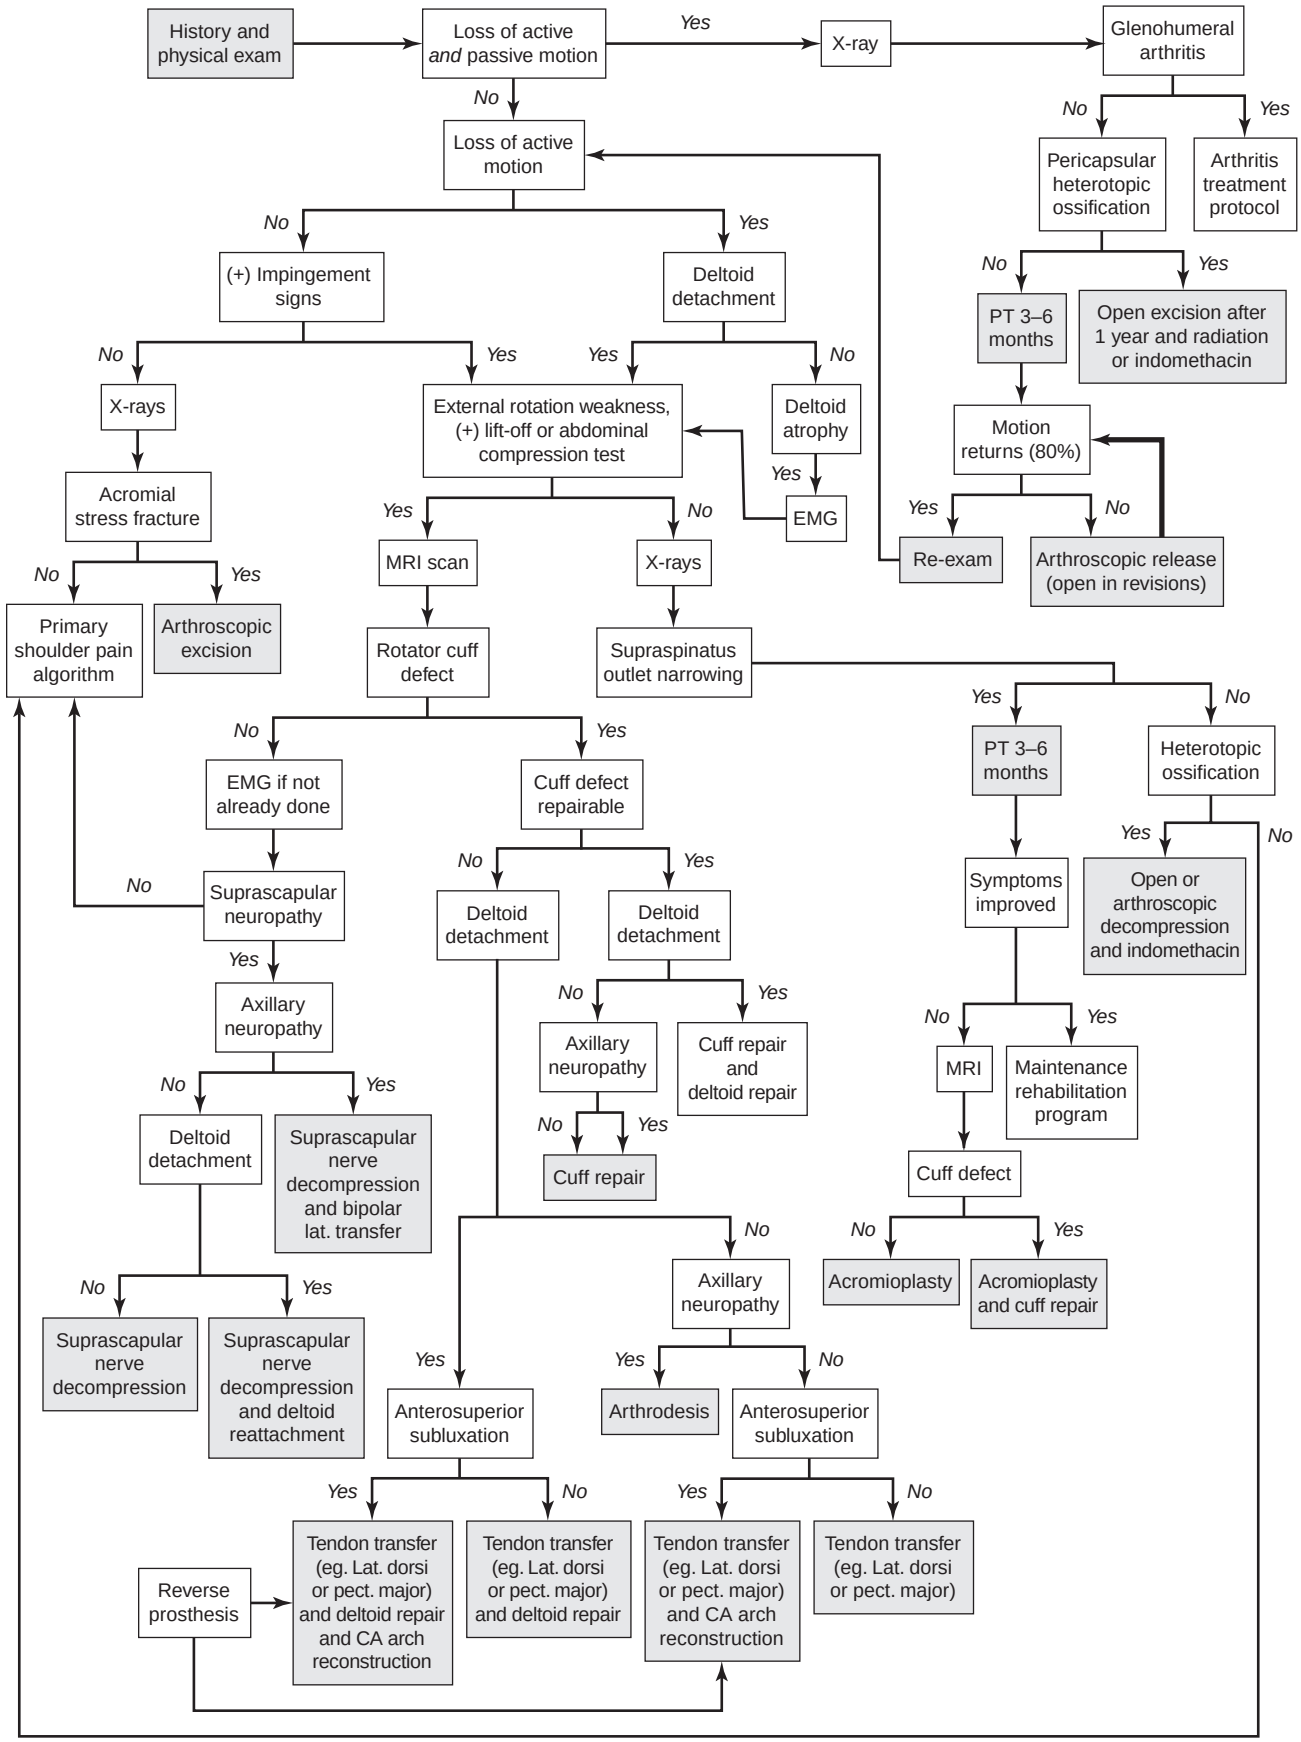

Figure 5-19 Treatment algorithm for the management of complications following rotator cuff surgery.

Loss of active elevation in the presence of normal or near-normal passive motion may indicate deltoid insufficiency, rotator cuff insufficiency, or both. Furthermore, the presence of pain and voluntary guarding will interfere with the interpretation of physical findings. This is particularly true for strength assessment of various portions of the rotator cuff. Subacromial lidocaine injections may decrease pain and improve the reliability of strength and functional assessments of the rotator cuff, and is frequently utilized in the diagnosis of patients with continued pain and dysfunction following rotator cuff surgery.

Ultimately, the final outcome among patients who have developed postoperative complications following rotator cuff surgery is affected by multiple factors. Assuming that the original diagnosis was correct, the goals of revision surgery are to reestablish passive motion; to restore a balanced anteroposterior force couple by rotator cuff repair, partial repair, or tendon transfer; and to preserve or restore deltoid function. The importance of coracoacromial arch preservation, especially among patients with massive rotator cuff tears, cannot be overemphasized. While the results of coracoacromial arch reconstruction have been disappointing, inverse prosthetic replacement, with or without tendon transfer, may represent a reasonable salvage procedure. Clearly, when reviewing the results following complications of rotator cuff surgery, the most efficacious method of ensuring patient satisfaction is prevention.

SUMMARY 212

PATHOPHYSIOLOGY

Introduction

Calcifying tendinitis of the rotator cuff is a disease of unknown cause that is characterized by multifocal, cell-mediated calcium deposition in viable tissue. These deposits normally undergo spontaneous resorption followed by subsequent healing of the tendon. The clinical presentation is variable; patients may have little or no symptoms during the formative phase, or they may have acute symptoms during the resorptive phase.

Definition and Classification

Calcifying tendinitis of the rotator cuff tendons differs from dystrophic calcification or other rotator cuff tendinopathies in several ways. First, calcifying tendinitis occurs in vascularized, viable soft tissue, whereas tendinopathies tend to occur in dysvascular, nonviable soft tissues. Next, calcifying tendinitis is a disease that proceeds toward resolution. Degenerative tendinopathies tend to worsen over time. It is unusual to see other signs of degenerative changes in calcifying tendinitis, whereas they are commonplace in dystrophic calcification and tendinopathies. Another difference between calcifying tendinitis and dystrophic calcification is in the radiographic location and appearance of the calcification. In dystrophic calcification, the calcifying deposits tend to occur at the insertion site of the tendon into the bone and are commonly stippled in appearance. In calcifying tendinitis, the calcification tends to occur 1 to 2 cm proximal to the insertion site of the tendon, and within the midsubstance of the tendon (Fig. 6-1).

Duplay first recognized the subacromial bursa as a source of shoulder pain in 1871.[28a] He coined the term "scapulohumeral periarthritis." In 1907, Painter described subacromial calcium deposits, and felt that these deposits were the primary source of pathology.[101] There were later descriptions by Bergemann and Steida in 1908, who also believed that the subacromial bursa was the primary site of pathology.[10] In fact, this was the opinion of many authors at the beginning of this century. Codman, in 1909, was one of the first to demonstrate that the calcium deposits were located in the tendons of the rotator cuff, and not in the subacromial bursa.[21] In 1912, Wrede was

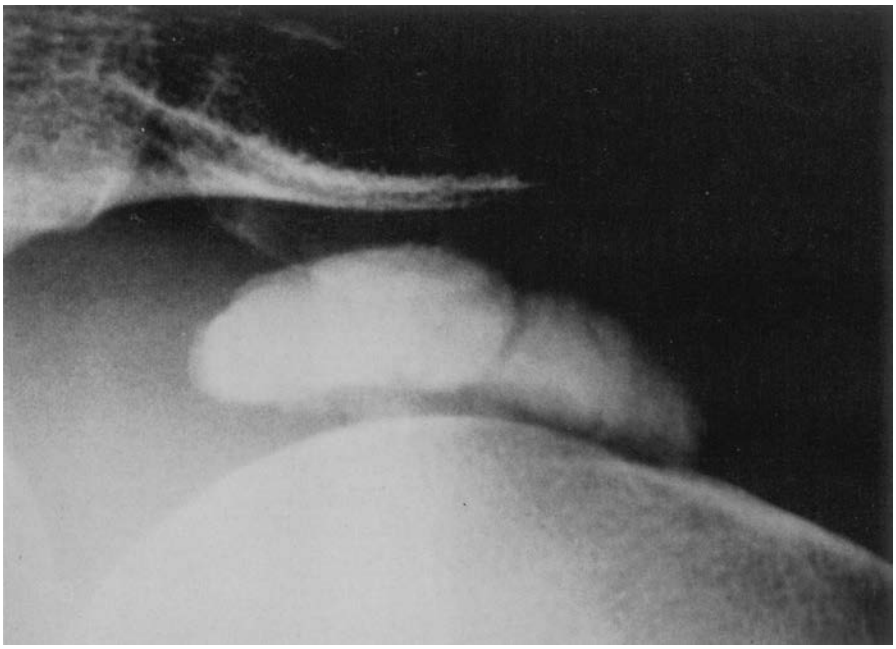

Figure 6-1 The typical location of the calcific mass is within the midsubstance of the tendon, not at its insertion site. Calcifying tendinitis most commonly affects the supraspinatus tendon. (Courtesy of Dr. Gilles Walch.)

credited with the first histologic description of the disease of calcifying tendinitis. He identified the presence of chondrocytes among tenocytes within the tendon.[149] The intratendinous location of the calcified deposits was later confirmed by other authors, such as Schaer in 1936,[126] Sandstrom in 1938,[123] and McLaughlin in 1946.[81] These authors all believed that calcifying tendinitis was the result of a degenerative process. Bateman observed that calcium deposits occurred close to the site of tendon attachment that is now known as the "critical zone," an area that may have diminished vascularity. He thought that "abnormal aging of collagen fibers initiated the calcification mechanism."[8] This belief persisted despite the observation in 1937 by Sandstrom and Wahlgren that calcification occurs in viable, not necrotic, tissue.[124] Moseley, in 1963, stated that "at operation, I have noted that the tendon was well vascularized around the area of deposit and therefore disagree with the idea that the calcium salts were precipitated in an area of previous disease with resultant ischemia."[92]

DeSeze and Welfling in 1970 coined the term "tendinites calcifiantes," denoting an evolutionary process of calcifying tendinitis tending toward spontaneous healing.[26] This differs in many ways from degenerative tendinopathy and now appears to be the description of choice for calcifying tendinitis. Uhthoff, in 1975, elucidated the pathogenesis of calcification, correlating histologic findings with clinical symptoms.[135]

Codman, in his classic text, pointed out that disease in the supraspinatus tendon tended to appear in a specific area of the tendon about "half inch proximal to the insertion degenerative of the tendon." He called this area the "critical portion."[21] This area was later renamed by Moseley and Goldie as the "critical zone."[93] Multiple studies of vascularity of the rotator cuff tendon by microangiographic techniques have been performed. The critical zone is a watershed area within the supraspinatus tendon, with its blood supply coming from the proximal muscular portion of the supraspinatus as well as from the osseotendinous junction. This may account for a relative decrease in perfusion. This was supported by studies performed by Rothman and Parke.[120] However, Moseley and Goldie thought that this area had a rich anastomosis.[93]

Rathbun and Macnab, in 1970, performed cadaveric studies to study the vascularity of the supraspinatus tendon.[112] They found that the perfusion to the critical zone in the supraspinatus tendon was largely dependent on the arm position. The critical zone was subject to a "wring-out" phenomenon, from pressure on the tendon exerted by the humeral head with the humerus in the adducted position.

Terminology

The terminology surrounding calcifying tendinitis has also evolved along with a better understanding of the pathogenesis. In 1907, Painter first used the term "calcifying bursitis."[101] This was later used by Bergemann and Steida in 1908,[10] and again by Steida in 1908.[133] In 1937, Sandstrom coined the term "peritendinitis calcarea."[124] The first appearance of the term "calcifying tendinitis" appeared in the North American literature in 1952 by Plenk.[108] DeSeze and Welfling coined the term "tendinite calcifiante" in 1970.[26] In 1979, Dieppe referred to this condition as calcified peritendinitis.[27] The term "tendinitis" is preferred over

tendinosis because of the acute nature of symptoms and the tendency toward complete resolution. "Tendinosis" is more appropriately used for conditions of a degenerative nature in which symptoms are chronic and tend toward a gradual deterioration over time.

Classification

There are many classification schemes created for calcifying tendinitis of the rotator cuff, some based on clinical presentation and others based on radiologic findings. DePalma and Kruper divided calcifying tendinitis into three categories based on the presenting symptoms: acute, subacute, and chronic.[25] Bosworth classified calcifying tendinitis by the radiographic size of the deposits.[15]

Patte and Goutallier described two forms of calcifying tendinitis: localized and diffuse. Localized deposits were discrete, dense, and homogeneous in density, and they had a tendency to heal spontaneously. In contrast, the diffuse form tended to appear "fluffy" on radiograph, was heterogenous in density, and tended to heal more slowly. Patients with the diffuse type were believed to have a higher likelihood of clinical symptoms.[102]

Uhthoff and Sarkar proposed that calcifying tendinitis is a dynamic disease that progresses through a complete cycle in most patients. Calcifying tendinitis has two distinct pathologic phases: the formative phase and the resorptive phase. Contained within these two phases are three distinct stages of calcification: the precalcifying stage, the calcifying stage, and the postcalcifying stage[142] (Fig. 6-2).

Other causes of calcification about the shoulder are numerous, including arteriosclerosis of brachial and axillary vessels, calcified soft tissue or bony neoplasms, patients with chronic renal failure, heterotopic ossification following acromioplasty and distal clavicle resection, subdeltoid calcifying bursitis in rheumatoid arthritis, and chronic acromioclavicular separation with calcification of the coracoclavicular ligament, as well as in diabetes.[1,2,9,11,27,41,47,59,78,79,89,107,126] Other distinct causes of calcification about the shoulder include the "Milwaukee" shoulder. This is characterized by massive calcifications in association with a complete rotator cuff tear, severe glenohumeral arthritis, acromioclavicular arthritis, or some combination thereof. Dystrophic calcifications are seen at the torn ends of the rotator cuff tendon after a complete tear.

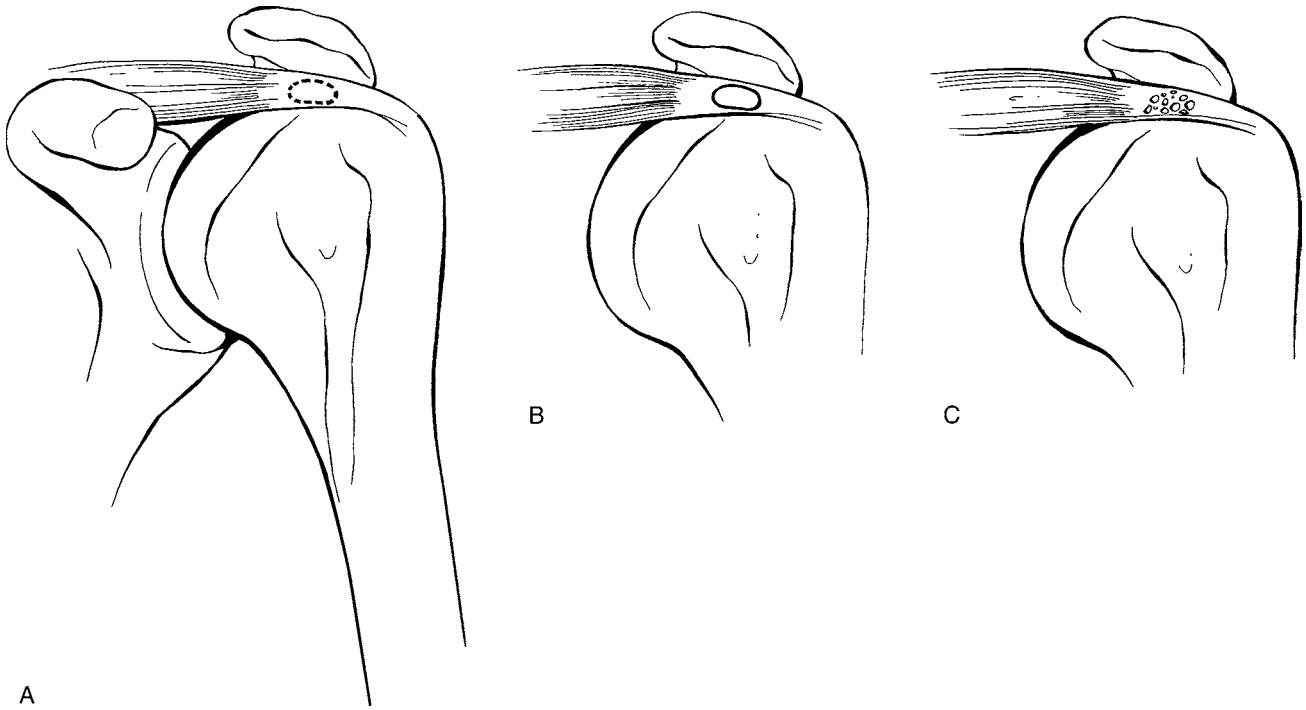

Figure 6-2 The calcification of the rotator cuff tendon progresses through three distinct stages: **(A)** The precalcific stage demonstrates a metaplasia of the tenocytes into chondrocytes. Degenerative changes of the tendon are absent. The signal for this metaplasia is unknown. **(B)** The calcifying stage begins with the formative phase, with small foci of calcium deposits that can coalesce into a large homogeneous deposit. The absence of a vascular response distinguishes this calcification process from endochondral ossification. **(C)** The postcalcific stage begins with resorption of the calcific deposit and ends with reconstitution of the normal tendon.

Pathogenesis

Considerable controversy still exists over the cause of calcifying tendinitis. Codman initially proposed that calcifying tendinitis is a degenerative process of the rotator cuff tendon. He believed that the fibers of the tendon degenerate, become necrotic, and then develop dystrophic calcification.[21] Other authors accepted this concept. In 1946, McLaughlin pointed out that the earliest lesion in rotator cuff tendon calcification is a focal hyalinization of fibers that eventually become fibrillated, detached from the tendon, and wound up into rice-like bodies that undergo calcification.[81] This theory was further supported by an experimental study performed by Macnab. He was able to show that interruption of the vascular supply to the Achilles tendon in rabbits can produce the hyalinization of the tendon fibers, followed by calcification.[72] Brewer has shown that as the supraspinatus tendon ages, its vascularity diminishes. By about the fourth or fifth decade, many fascicles in the tendon have thinned and fibrillated. The natural senescence of rotator cuff tendons with decreased vascularity is suggested as a contributing factor to the pathogenesis of calcifying tendinitis.[17]

In contrast, Uhthoff et al. have pointed out that there are various aspects of calcifying tendinitis that are not consistent with a degenerative process.[135,138] In calcifying tendinitis, the calcification occurs in apparently viable tissue. Degenerative calcification occurs in nonviable or poorly vascularized tissue. The peak incidence of calcifying tendinitis is in the fourth and fifth decades in most studies. The incidence of calcifying tendinitis is rare in the sixth decade. Calcifying tendinitis has not been reported in patients who were older than the age of 71. This would include autopsy findings on patients older than 71, including those with a previous history of calcifying tendinitis. These well-documented characteristics of calcifying tendinitis support the concept that this distinct clinical entity is a reparative process progressing through a predictable disease cycle.

Uhthoff and Sarkar have divided the typical cycle of calcifying tendinitis into three distinct stages: precalcific, calcifying, and postcalcific. The precalcific stage is marked histologically by metaplasia of the tenocytes into chondrocytes. This is accompanied by increased proteoglycan formation. The cause for the initiation of this process is unknown. Codman suggested that hypoxia may play a role in initiating this process,[21] but other catalysts may include microtrauma, disuse, hormonal factors, or dietary factors. The formative phase marks the beginning of the calcification, the hallmark of which is calcium deposition, primarily into matrix vesicles within the chondrocytes. Histologic examinations reveal that, during the formative phase, the surrounding tissue is relatively avascular and is marked by the absence of vessels. This process of calcification is distinctly different from endochondral bone formation, which is marked by the presence of blood vessels at the time of calcification. Generally, the foci of calcium deposits coalesce to form large deposits until a very dense homogeneous and typically well-delineated calcium deposit is formed. Clinical symptoms are often absent. However, when clinical symptoms accompany the formative stage, the findings are typically similar to patients with mild to moderate subacromial impingement.[76] The lack of hyperalgesia and the ability to use the shoulder for many activities may not lead to medical evaluation and confirmation of the diagnosis. Intermittent worsening of the symptoms, including diffuse pain, difficulty with overhead activities, and rest pain, defines the clinical picture of "chronic" calcifying tendinitis. At this stage, plain radiographs for the evaluation of nonspecific shoulder pain may detect a calcific deposit within the rotator cuff tendon, most typically the supraspinatus tendon.[39] During the formative phase, the calcium deposit exists primarily as a chalky deposit that is well demarcated within the tendon. The duration of the formative phase is variable, and it may last for many years.

The proliferation of blood vessels at the periphery of the calcium deposit heralds the phase of resorption. With the vascularization process, cellular infiltration occurs with macrophages, mononuclear giant cells, and fibroblasts initially seen at the periphery of the calcific deposit. These cells mediate an aggressive inflammatory process, releasing various cellular mediators and enzymes that break up the calcium deposit and phagocytose the calcium. With the vascular and cellular infiltration comes an obligate increase in the intratendinous pressure, largely as a result of the edema, which causes the classic acute hyperalgesia of calcifying tendinitis. The pressure may be so great that the deposit ruptures into the subacromial bursa, or into the area external to the subacromial bursa in the subacromial space. Roentgenographically, the calcium deposit now appears poorly delineated and fluffy. Concomitant with the inflammatory response, fibroblasts lay down collagen in the cavity left behind by the resolving calcium deposit. As the collagen matures and the resorptive process proceeds to conclusion, the fibers line themselves along the axis of the tendon, allowing return of the tendon structure, and eventual tendon function.

The postcalcific stage is marked by fibroblasts laying down collagen, primarily type III, which later remodels into type I collagen. This final stage completes the natural cycle of calcifying tendinitis. There is speculation, but no firm evidence, that the healed tendon may be more susceptible to degenerative tearing over time (Fig. 6-3).

Incidence

The incidence of calcifying tendinitis varies with diagnostic techniques, the patient population being studied, and the geographic location. At a recent meeting, North American

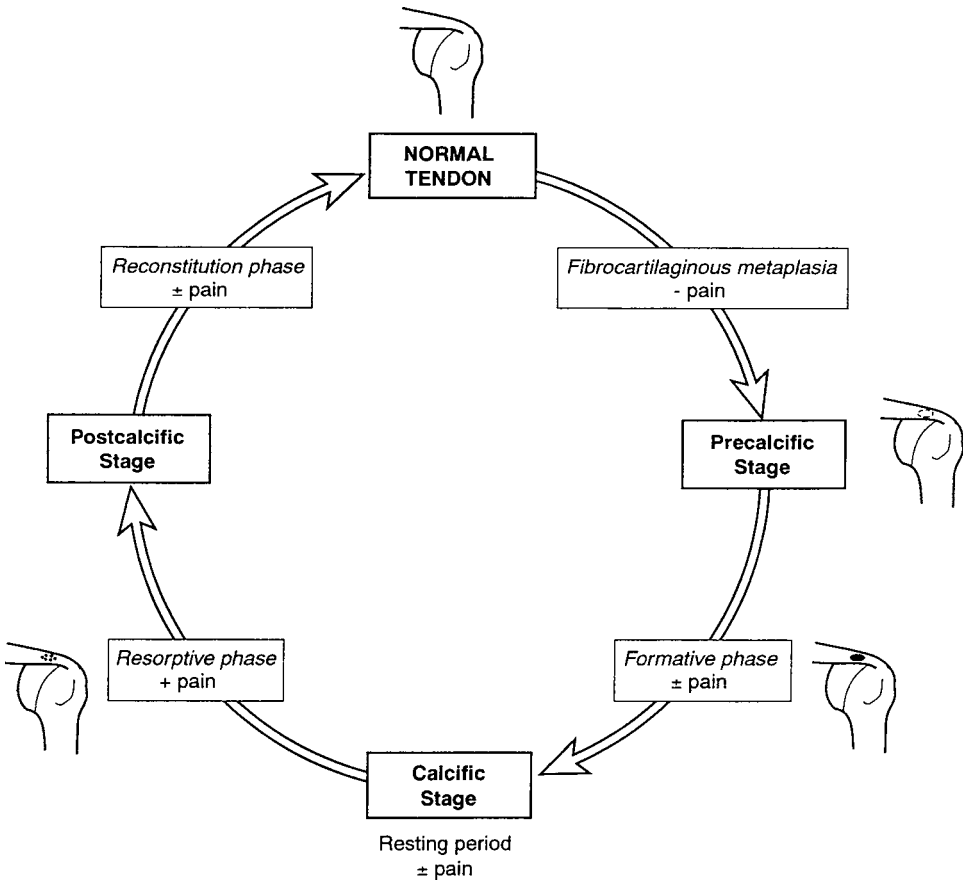

Figure 6-3 Summary of the natural cycle of calcifying tendinitis.

shoulder surgeons reported an overall decrease in incidence of calcifying tendinitis.[142] In fact, Neer commented that surgical treatment of calcifying tendinitis was one of the most common procedures performed at his teaching hospital when he was a resident.[96] However, surgical treatment and the diagnosis of this disorder has become less common owing to factors that are not understood. The reported incidence of calcifying tendinitis seen by European and Japanese surgeons has not significantly changed during the same time period.

Bosworth reported a 2.7% incidence of calcifying tendinitis among 6,061 asymptomatic office workers.[14] In a report from France, Welfling et al. reported an incidence of 7.5% of the disorder among 200 asymptomatic shoulders. However, in 925 symptomatic shoulders, there was a 6.8% incidence.[146] Ruttimann reported a 20% incidence in 100 asymptomatic shoulders.[122] Regional variation suggests that hereditary and dietary factors may play a role in the predisposition toward calcifying tendinitis.

Most authors report that the highest incidence of calcifying tendinitis occurs between the ages of 40 and 50 years. Thirty-six percent of the patients in the study by DePalma and Kruper[25] fell into this age category, as did 42% of the patients in a report by Uhthoff and Sarkar.[137] Welfling et al., on the other hand, reported the highest incidence between the ages of 31 and 40 years. No patient was older than the age of 71 years.[146] Nutton and Stothard reported a case of a 3-year-old child with acute calcific supraspinatus tendinitis.[99] Recently, Hsu et al., reporting on their patient population from Taiwan,[53] reported that 69% of the patients in their study were older than 60 years of age, the first report to suggest that calcifying tendinitis may have a distinct clinical variant in an Asian population, with its onset in an older-aged group.[53] Furthermore, the significant incidence of associated rotator cuff tears in Hsu et al.'s study is in distinct contrast with other studies of calcifying tendinitis.

The calcifying deposits are most commonly located in the supraspinatus tendon. Plenk reported an 82% incidence in the supraspinatus tendon.[108] In Bosworth's report, the supraspinatus was involved in 51% of his patients, the infraspinatus in 44.5% (Fig. 6-4), the teres minor in 23.3%, and the subscapularis in 3% (Fig. 6-5).[14] DePalma and Kruper reported that the supraspinatus was involved in 74% of their cases.[25] Hsu et al. reported a similar 70.7% involvement of the supraspinatus, with 26.8% involving the infraspinatus.[53]

There is still some controversy over the role of the subacromial bursa in calcifying tendinitis. It is commonly believed, however, that the subacromial bursa is not a

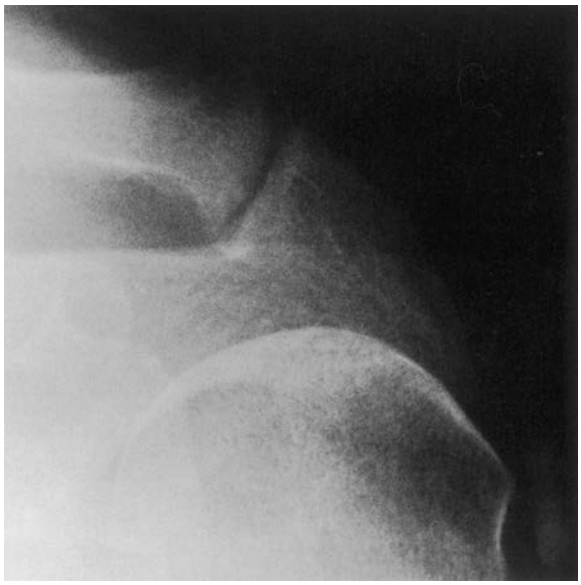

Figure 6-4 Calcifying tendinitis involving the infraspinatus tendon, which occurs in approximately one-third of patients with calcifying tendinitis. (Courtesy of Dr. Gilles Walch.)

factor in the chronic phase of this disorder. This belief is supported by Carnett, who noted that bursitis forms a minor and infrequent feature of chronic calcifying tendinitis.[19] Ishii et al. noted bursal reactions in subacromial bursal specimens removed at the time of surgery from 63 patients, 6 of whom had calcifying tendinitis. Their findings clearly showed that the strongest bursal reaction was present with a rotator cuff tendon tear, and was weakest in calcifying tendinitis.[55] Pedersen and Key looked at the pathology of calcareous tendinitis and subdeltoid bursitis, and found that at surgery the bursa was thin and translucent, light pink, and without evidence of acute inflammation. They did note some free calcium material in several instances. However, in each of these cases, there was also roentgenographic evidence of rupture of the calcium deposit into the bursa. As they stated, "unless there was free material in the wall of the bursa, this was not the site of gross inflammatory change."[104] Sarkar and Uhthoff stated that "it has been known for a long time that calcification of rotator cuff tendons occurs primarily in the tendon substance and not in the bursa."[125] Thus, it appears the bursa may become involved secondarily from either impingement, with subsequent inflammation of the bursa, or from rupture of the calcifying deposit into the bursa, with secondary inflammation.

In the gender of the patients, most authors agree that there is a higher incidence among females than males. Uhthoff and Sarkar reported a 57% incidence of female involvement,[137] while Bosworth reported a 76.7% incidence.[14] Welfling et al.[146] reported that 62% of his patients with calcifying tendinitis were female, and 64% of the patients in the study by Lippmann were female.[67] DePalma and Kruper also reported that 60.3% of their patients were female.[25] However, Hsu and his collaborators reported only a 26% incidence of female patients, again drawing attention to the distinct difference in their Asian patient population and possibly the clinical condition they have reported.[53]

Calcifying tendinitis may be related to certain occupations or activities. DePalma and Kruper reported that 41% of their patients were housewives and 27% were executives

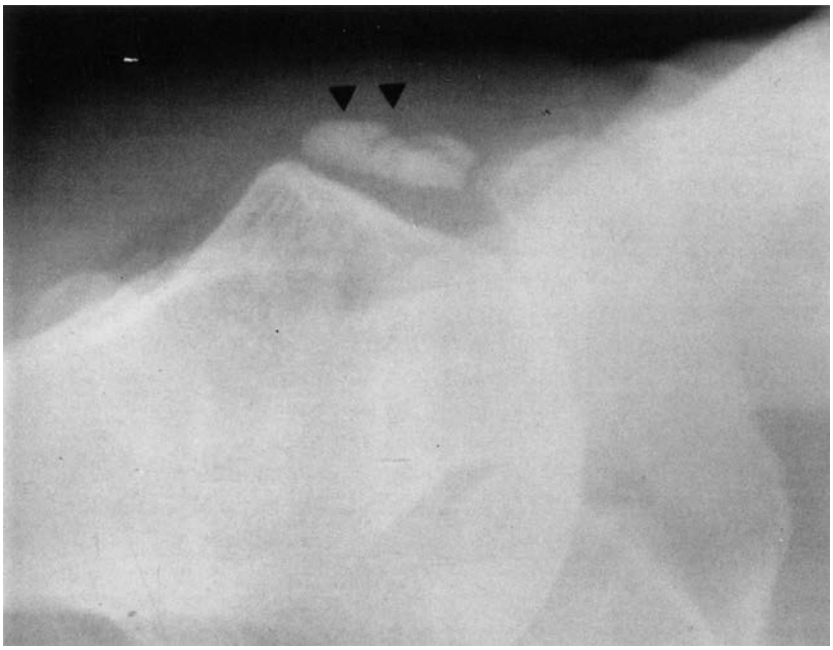

Figure 6-5 Calcifying tendinitis involving the subscapularis tendon. Because the deposit is superimposed on the humerus with an anteroposterior radiograph, this rare situation can be easily missed if an axillary lateral radiograph is not obtained. (Courtesy of Dr. Gilles Walch.)

and salespersons.[25] Uhthoff and Sarkar reported that 43% of their patients were housewives and 44% were clerical workers.[137] It appears that heavy laborers suffer less from calcifying tendinitis than do sedentary workers or workers who primarily perform nonstrenuous tasks with their elbow at their side. There does not appear to be a direct relation between trauma and calcifying tendinitis.

The incidence of bilateral involvement increases with the length of follow-up. Welfling et al. reported an incidence of 24.3% of bilateral calcifying tendinitis of the shoulder.[146] DePalma and Kruper reported a 13% incidence of bilateral calcifying tendinitis,[25] and Uhthoff and Sarkar reported a 17% incidence.[137]

In some instances, calcifying tendinitis appears to be part of a systemic disease.[107] This is supported by the incidence of calcifications occurring at other sites, most notably around the hip. No other study has suggested a similar incidence of hip involvement. Welfling et al. reported that 62.5% of his patients with calcifying tendinitis of the shoulder had simultaneous calcifications around the hip, whereas in the control group, only 4% had calcifications about the hip.[146] Gschwend et al. were unable to prove an association with diabetes or gout.[45] However, other authors feel that there is an increase in the incidence of calcifications in many areas of the body in patients with diabetes, including the shoulder region.[59,78] Abnormalities in calcium or phosphate metabolism have not been reported as part of the clinical syndrome of calcifying tendinitis, although they are clearly evident with other conditions leading to soft tissue calcifications, such as renal osteodystrophy.[2] There have also been attempts to correlate HLA-A1 presence with calcifying tendinitis, although the role for HLA testing in diagnosis or management of patients is unclear.[130]

Clinical Presentation

The clinical presentation is highly variable. An understanding of the pathogenesis of calcifying tendinitis allows the clinician to make proper diagnostic as well as management decisions. The formative phase of calcification is frequently subclinical or even asymptomatic. It is often discovered serendipitously. As Baer observed during surgery, large deposits may lead to an impingement syndrome.[5] In contrast, the resorptive phase, which occurs later in the cycle of calcifying tendinitis, is commonly characterized by acute symptoms. The pain seen at this stage is related to the increase in intratendinous pressure from the vascular proliferation, influx in inflammatory cells, edema, and swelling. As tendon volume increases, the unyielding dimensions of the subacromial space may add additional pressure to the involved tendon, leading to evidence of secondary impingement.[135]

Bursitis has been suggested as a source of pain. However, during surgery, bursal reaction is minimal and is localized to a focal area with hyperemia. It is usually not severe enough to cause a bursal thickening. The rupture of the calcific material into the bursa may cause a crystalline-type bursitis. However, DeSeze and Welfling reported 12 patients who had rupture of the calcified deposit into the bursa, only eight of whom showed symptoms.[26]

Many authors have stressed the typical subclinical nature of the formative phase. Codman noted that the "usual history is not acute pain in the beginning."[21] Gschwend et al. observed that the calcification is often asymptomatic at the beginning, but its disappearance is marked with acute pain.[45] Wilson stated that many patients know about the calcium deposit for months to years before an acute attack.[147] Rowe broke down the clinical course of patients with calcifying tendinitis into the silent phase, the impingement phase, and the acute phase.[121] Pinals and Short,[107] Booth and Marvel,[13] Simon,[131] Re and Karzel,[113] and Bosworth[15] provided similar descriptions.

Most authors discuss two primary clinical phases—acute and chronic—with some variation. The subacute or chronic phases are characterized by mild symptoms, whereas the acute phase has more severe symptoms.[33,38,146] DePalma and Kruper divided the clinical presentation of patients into three groups, based on the duration of symptoms. The acute cases had severe shoulder pain for less than 4 weeks duration, the subacute cases had more mild symptoms lasting anywhere between 1 and 6 months, and the chronic cases were those in which patients had mild symptoms present for more than 6 months.[25] Jones observed that the onset of pain in patients with calcification of the supraspinatus tendon was very sudden and severe and usually not precipitated by injury. He stated that "there is inability to rest or sleep and sometimes patients have become mentally strange after several days of such pain."[57] He was most likely describing the presentation of hyperalgesia related to the resorption phase of calcifying tendinitis. Lapidus coined the term "dormant" deposits with which patients may be without symptoms, except for occasional aches and pains. He suggested that rupture of the tendinous tissue into the floor of the bursa, with extrusion of the calcifying material, was the cause of the developing acute symptoms.[64] Moseley described calcifying tendinitis in terms of four distinct phases: a silent phase, a mechanical phase, followed by rupture of the calcified material into the subbursal space, and finally intrabursal rupture of the calcific deposit.[91] Lippmann described a phase of increment and a phase of disruption. The phase of increment correlates with very mild symptomatology. Radiographic appearance is discrete and homogeneous in density. The phase of disruption, however, is marked by severe pain and a radiographic appearance that is heterogeneous and fluffy.[67] As implied from these various clinical classification schemes, the pathologic stages of calcifying tendinitis correlate with the clinical presentation, with mild symptoms common with the formative stage, but severe symptoms being typical of the onset of the resorptive phase.

The intensity of the pain may be very severe with the acute clinical phase. Initially, rupture of the calcified deposit into the bursa was presumed to be the cause of these symptoms. However, DeSeze and Welfling documented acute symptoms in only 8 of 12 patients who had roentgenographic evidence of rupture of the calcium deposit into the bursa. They postulated that the acute symptoms appear to be related to the increase in intratendinous pressure caused by vascular proliferation, inflammatory cell accumulation, and edema. Their explanation is supported by the common intraoperative observation that the calcium deposit literally spurts from the tendon when the tendon is incised during the acute clinical phase.[26]

Calcifying tendinitis should be understood as a continuum, not two distinct subgroups of a disease. Uhthoff and Sarkar stress that "the calcifying deposit must first be formed and thereafter be removed before the tendon is reconstituted." In their experience, the process of formation is usually without symptoms. Serendipitous roentgenographic discovery is common. However, during the stage of resorption, symptoms are usually severe, corresponding to the acute phase in other classification schemes. Once the resorptive phase has resolved, the tendon reconstitutes its fibrous architecture in this self-healing condition, completing the cycle of calcifying tendinitis.[137]

The duration of symptoms correlates with their acuity. The more acute the symptoms are, the shorter the duration of symptoms is. Simon reported a definite relation between the intensity of symptoms and duration. The acute symptoms last up to 2 weeks; subacute 3 to 8 weeks; and chronic more than 3 months.[131] DePalma and Kruper stated that the acute symptoms last less than 1 month, subacute between 1 and 6 months, and chronic longer than 6 months.[25] Booth and Marvel stated that "acute calcifying tendinitis is a self-limited process with a natural history of 6 to 14 days."[13] According to Carnett, the chronic cases "ran a self-limiting course and irrespective of treatment, the patient made a complete recovery at varying periods from a few months up to 3 years."[19] Codman believed that few cases were exceedingly acute, and that most cases of calcifying tendinitis ran a subacute course over months to years.[21] In Howorth' s series, the duration of symptoms in his patients with calcifying tendinitis was 2 days to 20 years, with an average of 2 years. Only 24 patients out of a consecutive series of 100 patients had symptoms of less than 1 month's duration. Nearly all of the others came in because of intermittent exacerbations of pain.[52] Pendergrass and Hodes made the observation that acute symptoms subside in less than 2 weeks, even in the absence of treatment.[105] The importance of the relation between the acuity of symptoms and their resolution becomes paramount when discussing intervention and the "success" of treatment because it appears that most patients presenting with acute hyperalgesia will improve even without treatment.

The location of pain is typically referred to the insertion of the deltoid in over half of the patients. This referral pattern, common with supraspinatus tendinopathy, reflects the frequent involvement of the supraspinatus tendon with calcifying tendinitis. Less commonly, the pain radiates toward the neck. Most patients give a history of difficulty with overhead tasks, inability to sleep on the affected shoulder, or increasing pain during the night that often prevents sleep. Other complaints may include shoulder stiffness, less strength with the arm away from their side, or mechanical complaints, such as "snapping" or "catching" of the shoulder.

Physical Examination

Physical examination characteristics are dependent on the phase of presentation. With the subacute or chronic phase, examination findings often mimic subacromial impingement, with mild decreases in range of motion and a "positive" impingement sign.[76] Kessel and Watson described the "painful arc of motion," with symptoms of pain elicited with motion of the arm between 70 and 110 degrees of elevation. The painful arc most commonly relates to subacromial pathology.[62] Patients may have a sensation of painful catching caused by a localized impingement of the calcified mass on the coracoacromial arch. The chronic phase of calcifying tendinitis may also present with supraspinatus and infraspinatus atrophy.

During the acute phase, pain is frequently intense, with patients often stating that they have never felt more severe pain. The severe pain leads to guarding against any motion, for they fear the examination may worsen their symptoms. Even if they allow motion, the glenohumeral motion and even the scapulothoracic motion may be severely limited by muscular spasm. Strength testing is prohibited by the pain. Provocative tests, such as the impingement sign, are impossible because of the loss of motion. This "pseudoadhesive capsulitis" is distinguished from idiopathic frozen shoulder by the severity of the pain, by the acute and rapid onset of the pain, and by the radiographic findings. The severity of the pain and the shoulder examination findings may also be confused with acute brachial plexitis (Parsonage-Turner syndrome), but is distinguished by the lack of pure neurologic findings and sparing of the elbow, wrist, and hand function.

Imaging Studies for Calcifying Tendinitis

The calcium deposits are localized to an area within a tendon that is approximately 1 to 2 cm from its insertion site on the tuberosity of the humerus.[21] The pattern of the deposit may be characteristic for the stage of calcifying tendinitis; therefore, a full understanding of the pathogenesis is essential to proper radiologic interpretation.

When a diagnosis of calcifying tendinitis is suspected, radiographs of the shoulder are mandatory. Radiographs can make or confirm the diagnosis, suggest the pathologic phase, and permit radiographic follow-up. Calcifying tendinitis can be suggested by the clinical features discussed, including the age of the patient, the pattern of symptoms, and examination findings. Furthermore, in patients presenting with findings suggestive of subacromial abnormality, a careful review of the radiographs is important. Harbin pointed out that a diagnosis of bursitis was frequently made in cases of calcifying tendinitis because of the failure to recognize the calcification on roentgenograms.[48]

Although many radiographic views of the shoulder may be helpful for specific conditions, routine radiographs must include a true anteroposterior view of the shoulder and an axillary lateral one.[77] Other views are directed by the history and the findings on clinical examination. Although many cases of calcifying tendinitis will be detected with a true anteroposterior view of the glenohumeral joint, additional anteroposterior films, with the shoulder in internal as well as external rotation, are recommended to see the tuberosities and the tendon insertions in multiple profiles. Anteroposterior radiographs with the humerus in neutral rotation show the greater tuberosity in profile, thereby bringing any calcium deposits within the supraspinatus tendon into view. Calcifications within the subscapularis tendon are detected with an anteroposterior view of the humerus in external rotation. With the humerus in internal rotation, precise localization of calcium deposits in both the infraspinatus and teres minor can be made based on their relative location on the greater tuberosity. If calcification is present in the middle one-third of the greater tuberosity, the infraspinatus tendon is likely involved. If the distal one-third of the greater tuberosity is involved, the teres minor is involved. These calcifications are frequently missed on standard anteroposterior radiographs owing to superimposition of the calcification over the proximal humerus (Fig. 6-6). In addition, calcifications within the long head of the biceps are frequently seen adjacent to the upper portion of the glenoid, and the position of these deposits is unchanged by external or internal rotation of the humerus. Calcifications in the region of the lower portion of the glenoid may represent involvement of the short head of the biceps or the triceps. Rupture of the calcium into the subacromial bursa may give a "skullcap appearance."[131] A supraspinatus outlet view is helpful in determining whether a deposit is in the supraspinatus or infraspinatus and whether it is encroaching on the coracoacromial arch (Fig. 6-7).

In 1934, Codman reported the presence of a pyramidal shadow in the region of the subacromial bursa just above the tip of the greater tuberosity and stated that this represented calcification within the region of the subacromial bursa. However, on exploration during surgery, he noted no bursal involvement. The calcium deposit was completely contained within the tendon of the rotator cuff.[21]

Figure 6-6 Calcifying tendinitis involving the infraspinatus or teres minor can be readily seen on an anteroposterior radiograph of the shoulder with the humerus held in internal rotation.

Bosworth believed that routine use of fluoroscopy was more accurate than routine roentgenographic examination, with concern that radiographs commonly missed calcifications that were superimposed over the humeral head or the acromion.[15] He claimed that "regardless of whether

Figure 6-7 A supraspinatus outlet view confirms the involvement of the supraspinatus tendon. Localizing the calcific deposit is essential for successful needling or surgical decompression of the lesion.

or not roentgenograms are taken, fluoroscopy should never be omitted as an essential part of the exam." He also pointed out that many calcified deposits are "discovered accidentally," with nothing being done about it. Howorth also felt that fluoroscopy may be useful to localize the calcium deposition.[52] Fluoroscopy may help with visualization of the calcific deposit, but its value over routine radiographs in determining treatment is unknown. He felt that his technique was a more sensitive way to detect the calcifications than even surgical exploration.

Bosworth reported a classification scheme based on the size of the calcium deposit. Small deposits, up to 0.5 mm in diameter, were of little or no clinical significance; medium-sized deposits, 0.5 to 1.5 mm in diameter, were of moderate clinical significance; and the larger deposits, of more than 1.5 mm in diameter, were most likely to cause clinical symptoms.[15] Patte and Goutallier described a classification scheme that divided the radiographic appearance of calcifying tendinitis into a localized form and a diffuse form. The localized form was characterized by round or oval, homogeneously dense calcifications that were close to the bursal wall. These tended to heal spontaneously. The diffuse form was thought to be situated deeper than the localized form, close to the bony insertion of the tendons. The density was heterogeneous, and these were considered to cause more pain and to take longer to resolve.[102] Most authors feel that the classifications by both Bosworth and by Patte and Goutallier are not of much clinical value.

The French Society of Arthroscopy has classified rotator cuff calcifications into four categories (Fig. 6-8).[88] Type A is a homogeneous calcification, with well-defined limits, and represents approximately 20% of the patients presenting in a large multicenter review. Type B is heterogeneous calcification that is fragmented, but with well-defined limits and was seen in 45% of the patients. Type C calcification is a heterogeneous calcification, with poorly defined limits, sometimes with a punctate appearance; 30% of the patients present with this finding on radiographs. Type D calcification is a dystrophic pattern at the insertion of the rotator cuff. This pattern clearly represents a degenerative process and should not be confused with calcifying tendinitis (Fig. 6-9). With types A and B, the calcifications, at surgery, have a pasty consistency 50% of the time. Type C is diffuse, and a well-organized calcific deposit may not be present. This classification has relevance to the stage of calcifying tendinitis, the radiographic appearance, and implications for intervention.

Other authors have attempted to correlate the appearance of the calcified deposit on roentgenogram with the clinical phase of calcifying tendinitis. DePalma and Kruper described two radiologic types. Type I was amorphous, "fluffy" and "fleecy" in appearance, and heterogeneous, with a poorly defined periphery. This pattern was usually encountered in acute phases. Occasionally, they noted a contiguous overlying crescent-like streak that they believed represented rupture of the calcified deposit into the subacromial bursa. Type II had a well-defined outline and was homogeneous in density. This appearance was common in the subacute or chronic phase of calcifying tendinitis.[25] DeSeze and Welfling[26] and McKendry et al.[80] were also able to correlate clinical symptoms with the radiographic appearance of the calcium deposit. Friedman could not find a correlation between the size of the particles and the severity of symptoms.[33]

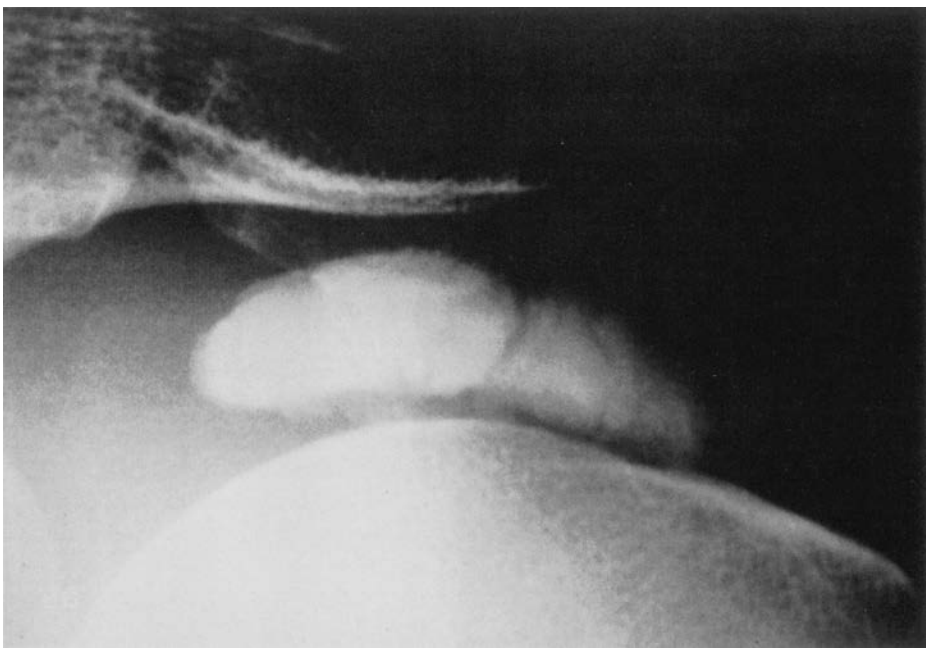

Figure 6-8 The French Society of Arthroscopy has classified rotator cuff calcifications into four categories: *type A:* homogeneous, well-defined limits; *type B:* heterogeneous, fragmented, well-defined limits; *type C:* heterogeneous, poorly defined limits; *type D:* dystrophic pattern. A type B calcification is seen in approximately 45% of the patients in their multicenter evaluation. Fifty percent of patients with this pattern will have a pasty consistency to the calcific material at the time of surgery. (Courtesy of Dr. Gilles Watch.)

Pulich emphasized that tendinous calcifications differ from capsular or bursal calcifications because the calcific deposit of calcifying tendinitis is contained within the tendons of the rotator cuff and remains confined to the points of insertion of the tendon. Bursal or capsular calcifications eventually conform to the cavity within which they are contained.[111]

Uhthoff et al. do not believe that all cases end with rupture of the calcified deposit into the subacromial bursa.[138] When this did not occur in their patients, symptoms tended to be more prolonged and recurring. Furthermore, they demonstrated a strong correlation between the clinical symptoms, radiographic appearance, and intraoperative findings in 41 patients undergoing surgery for calcifying tendinitis.[80] Of the 41 patients, 31 had chronic or subacute symptoms, and 10 had acute symptoms. Twenty-four of 31 patients with chronic symptoms had roentgenograms consistent with the formative phase of calcifying tendinitis. Intraoperatively, the calcified deposit appeared chalk-like in 29 of the 31 patients. Of the 10 patients with acute symptoms, eight had x-ray films consistent with the resorptive phase; nine patients also had a toothpaste-like consistency of the calcified deposit.

Other radiographic concerns include coexisting conditions. Some authors have raised the question of concomitant presence of a rotator cuff tear with calcifying tendinitis. Although McLaughlin and Asherman stated that the presence of calcifying tendinitis is strong evidence against a rotator cuff tear,[83] other authors, including Hsu and his colleagues, believe that one should commonly consider the possibility of coexisting calcifying tendinitis and rotator cuff tear.[53] However, their study contrasts with many of the tenets concerning calcifying tendinitis that are confirmed in previous studies, and suggests that the report by Hsu et al. is discussing a subset of calcifying tendinitis, a completely different condition, or a variation of calcifying tendinitis unique to his Taiwanese patient population. Also, many patients were older than the age of 60, at which an increased incidence of rotator cuff tears would be expected in a control population without calcifying tendinitis. However, others have suggested an increased incidence of rotator cuff tears with calcifying tendinitis. Kernwein observed that, in patients older than the age of 40 years with calcifying tendinitis, there was a 90% probability that an arthrogram would reveal rotator cuff tear.[61] This report has not been supported by others.[39] Wolfgang observed that 23% of the patients that had a rotator cuff tendon repair also had calcifying tendinitis.[148]

Jim et al. looked at the coexistence of calcifying tendinitis and rotator cuff tendon tears prospectively in their Taiwanese patient population. In 81 patients with calcifying tendinitis, an arthrogram was performed to look for concomitant rotator cuff tear. Twenty-two arthrograms were positive. Small amounts of calcifications were statistically more likely to be associated with rotator cuff tear in this population. They concluded that calcifying tendinitis with rotator cuff tendon tear is not uncommon, especially in older patients.[56]

Confounding this issue, Loew et al. correlated the presence of calcifying tendinitis with subacromial impingement findings. They looked at 75 patients with calcifying tendinitis, and prospectively performed roentgenographic studies as well as magnetic resonance imaging (MRI) of these patients to identify additional findings of subacromial

impingement. They found degenerative tendon changes in 11% of the 75 patients, and a type III acromion in 16% of these patients. Their conclusion was that there was little correlation between calcifying tendinitis and additional findings of subacromial impingement.[70]

The role of computed tomography (CT) and MRI in calcifying tendinitis is still unclear. CT may help localize the calcific deposit, but is unlikely to add additional information that will influence treatment. On MRI, the T1-weighted images show calcifications as decreased signal intensity, whereas T2-weighted images may show perifocal increased uptake around the deposit, largely from edema during the resorptive phase.[51,54] A cautious interpretation of the MRI findings is important because the decreased signal intensity, combined with the relatively thin dimensions of the cuff lateral to the calcific deposit, may be interpreted as a large rotator cuff tear. This false MRI interpretation, when combined with a limited physical examination secondary to pain, may lead to a more aggressive surgical approach than is indicated by the true pathology. Re and Karzel stated that routine use of CT and MRI are probably unnecessary if adequate roentgenograms are obtained.[113] However, if evaluation of coexisting pathology is the intent, MRI is the most effective specialized radiographic study.[51,54] An arthrogram will also provide additional information on the integrity of the rotator cuff.

Maier prospectively studied 65 shoulders with chronic calcific tendinitis treated with extracorporeal shock wave therapy, and was able to correlate preoperative gadolinium-enhanced MRI findings to outcomes. Patients underwent preoperative and postoperative radiographic analysis, as well as Constant scoring. Preoperative MRI findings included the presence or absence of contrast enhancement of the synovia, the calcific deposit, and the subacromial bursa. Among the 16 patients that lacked contrast enhancement around the deposit, 15 patients had satisfactory outcome, compared to 44 patients with positive contrast enhancement, with 57% satisfactory outcome. Similar outcomes were observed among those shoulders that lacked contrast enhancement in both the synovia as well as the bursa. However, there was no significant correlation between size or morphology of the calcific deposit. The authors concluded that the absence of contrast enhancement, especially around the deposit, is a strong predictive parameter of a positive clinical outcome.[73]

Ultrasound has also been used for evaluation of calcific deposits. Hartig and Huth demonstrated that ultrasonography was more sensitive than plain radiographs for detecting calcific deposits in the rotator cuff tendons.[50] In 217 cases of calcifying tendinitis, ultrasound detected 100% of the lesions, while plain radiographs demonstrated 90%. Ultrasound has the added benefit of not exposing the patient to unnecessary radiation. Unfortunately, ultrasonography is highly dependent on technicians and radiologists with significant experience in evaluating shoulder conditions.

Natural History

Calcifying tendinitis proceeds through a cycle of calcification, resorption, and then tendon reconstitution in most cases (see Fig. 6-3). The self-healing nature of calcifying tendinitis has been emphasized. Carnett pointed out the "tendency for the hyperacute pain to ease up after a few days or within two weeks." He also stated that "in many chronic cases, the condition ran a self-limiting course and irrespective of treatment, the patient made complete recovery at varying periods from a few months up to 3 years."[19] Unfortunately, not all cases of calcifying tendinitis resolve expediently and without sequelae.

Codman questioned the ability of the involved rotator cuff tendon to completely heal and reconstitute its normal integrity. He stated that "although it is the rule that cases of calcified deposits recover with no known sequelae, I am more and more inclined to think that they must result in some atrophy of the tendon, whether they are absorbed naturally or are removed."[21]

Howorth noted that the calcareous deposits often change in size and density over a period of months or years, but may in fact change over a few days. He also noted that calcium deposits within the tendons commonly persist for many years unless there is spontaneous or surgical drainage. Rupture of the deposit into the subacromial bursa not only results in a change in the location and density of the calcified material, but also usually is followed by immediate relief of symptoms and absorption of the calcified material.[52]

McLaughlin, in 1946, reported that 90 patients who had calcified deposits discovered incidentally by roentgenograms returned at a later date with pain, presumably owing to irritation by the calcified deposit. Acutely painful lesions frequently had a portion of the calcified deposit in contact with the bursal floor and occasionally within the subacromial bursa itself. He suggested that if the lesion was left untreated it could produce constant mild pain for as long as 15 years. However, these calcified deposits were rarely found in unselected cadavers older than 66 years, which indicated that "most if not all deposits are limited by some spontaneous mechanism prior to the sixth decade."[81]

Lippmann observed that the phase of interval symptoms abides by no time schedule, and has been observed to persist for as long as 12 years. He noted that a close inverse relation between the severity of pain and its duration exists, but rarely does the painful absorption of calcium persist for longer than 3 weeks.[67] Moseley outlined a detailed natural history of calcified deposits in the rotator cuff. He described an initial "silent phase," which was characterized by minimal clinical signs and symptoms. The "mechanical phase" was characterized by impingement-type symptoms. These patients tended to have a painful arc of motion. The "subbursal rupture" phase is a result of partial evacuation of the calcified deposit. As such, symptoms

in this phase of the disease tend to recur. The final phase, which he called "intrabursal rupture," is characterized by complete drainage of the calcified deposit under the floor of the bursa and secondarily into the bursa. Clinical symptoms were most severe with this phase, corresponding to resorption of the calcific deposit. He believed that the calcified deposit had to be completely eliminated before the patient was free of symptoms.[91]

Lapidus and Guidotti reported on "a number of cases of spontaneous recovery in the patients who came under observation days following the onset of the acute symptoms." They also noted complete disappearance of the deposit radiographically in those same patients.[65] Ghormley observed that although the tendency for complete resolution was the rule, some cases would go on to "heterotopic ossification."[38] This concept has not been supported by others.

Uhthoff and Sarkar have conclusively demonstrated that calcifying tendinitis is an active, cell-mediated process that tends to progress toward spontaneous resolution, including tendon reconstitution. The roentgenographic appearance, the clinical symptomatology, and the histologic and gross appearance can be reasonably predicted by knowing any one of the aforementioned features and by understanding the cyclic nature of this disorder.

Other authors have suggested that because the success of intervention is high and rapidly resolves the clinical symptoms, patients should not have to wait for the expected resolution of their condition. Codman felt that if he personally developed calcifying tendinitis, he would rather have surgical treatment than wait for the condition to resolve on its own.

Harbin also suggested that "conservative treatment in the acute cases seems to be unwise." He recommended that "since the operative treatment is so simple, offers so little danger, and promises complete relief in practically 90% of the cases, one should have little hesitancy in urging it in all cases in which the condition has persisted over a period of months without relief by the more conservative measures."[48]

Harmon reported that the natural course of calcifying tendinitis could be favorably influenced by treatment properly applied relative to the time in the cycle of the disease. He too recommended removal of large to medium-sized deposits within the rotator cuff tendons. This was based on his observations that few quiescent or mildly symptomatic deposits disappear spontaneously. However, in the acute and hyperacute deposits, these tended to disappear in 7 to 14 days with conservative treatment.[49] DePalma and Kruper believed that the natural history of calcifying tendinitis could usually be favorably altered by the treatment chosen. They reported on the results of a long-term follow-up study of shoulder joints treated for calcifying tendinitis, surgically as well as conservatively. They observed that 84% of the patients treated conservatively had favorable short-term results. However, long-term results revealed that only 61% were favorable. In contrast, surgical management produced 96% favorable results. They noted that the convalescence period was longer when the calcifying tendinitis was treated surgically.[25]

Most recently, Kempf et al. noted that although the natural evolution of this calcifying tendinitis is favorable, the cyclic natural history described by Uhthoff may in fact be blocked at any stage of the disease.[60] Even though many studies have demonstrated that conservative treatment of these deposits can be successful in most of these patients, a study by Noel and Brantus encourages a cautious posture for prognosis because only 50% of their 124 cases treated without surgery demonstrated favorable results.[97]

TREATMENT

The treatment of calcifying tendinitis has tended to vary according to the expertise and experience of the treating physician. There have been a variety of treatment methods proposed, all of which have had some success in the treatment of calcifying tendinitis. An understanding of the pathophysiology of calcifying tendinitis is essential when determining the correct intervention. Uhthoff and Loehr's explanation of the three pathophysiologic stages of calcifying tendinitis created a framework in which to establish an appropriate treatment algorithm.[142]

Determining the correct stage of calcifying tendinitis includes a careful history, physical examination, and appropriate plain radiographs. Acute calcifying tendinitis is severely painful, with patients splinting their upper extremity against any movement. Narcotic medications may be required to control pain and allow sleep at night. Patients often demand intervention because of the severity of their symptoms and the effect on their daily activities, even if they understand that their condition may actually be resolving. Because acute symptoms are associated with the resorption phase, which is frequently measured in days or weeks, treatment at this stage is likely to be associated with a favorable result, even though the treatment may have had no direct effect on the natural history of the patient's condition. With chronic symptoms secondary to calcifying tendinitis, intermittent worsening of symptoms may lead to patient dissatisfaction. The goal of intervention should be to establish a treatment plan that can accelerate the natural history of this condition or encourage the resolution of symptoms without significant risk to the patient.

Nonoperative Treatment

Virtually all patients with calcifying tendinitis are successfully treated with nonoperative management. Gschwend and colleagues estimated that more than 90% of patients are adequately treated with conservative management.[45]

Litchman et al. reported that they were able to treat 99 of 100 patients with calcifying tendinitis without surgical intervention.[68] Treatment options include analgesics, nonsteroidal antiinflammatory medications, physical therapy, infiltrations, needling or barbotage with or without aspiration, extracorporeal shock wave treatment, and antiinflammatory radiotherapy.[6,16,41,45,49,69,74,94,103,105,106,118]

On initial presentation, patient complaints are most commonly related to pain. Nonsteroidal antiinflammatory medications are often prescribed. Their efficacy for the treatment of chronic or acute calcifying tendinitis and their effect on the natural history is unknown. During the acute hyperalgesia of the resorption phase, narcotic medication may be indicated for the relief of severe pain that interferes with sleep and daily activities.

Many authors recommend physical therapy for the treatment of patients with calcifying tendinitis, especially those patients presenting with mild pain and chronic symptoms.[14,32,38,45,67,81,92] The primary focus of physiotherapy is to reestablish normal shoulder motion. Some authors have suggested that therapy is necessary to prevent an idiopathic frozen shoulder. However, there is no evidence to confirm that calcifying tendinitis leads to a generalized contracture of the glenohumeral joint capsule, which is the hallmark of a frozen shoulder.[77] Restriction in motion is more likely to be secondary to pain, muscular spasm, and an increased volume of the rotator cuff within the confines of the coracoacromial space. Because the coracoacromial arch is congruent with the normal rotator cuff tendon and proximal humerus, a change in the volume of the rotator cuff tendon from a calcific deposit or the combined effects of the deposit and factors involved in the resorptive phase are likely to lead to mechanical irritation. This mechanical irritation will lead to decreased volitional movement of the shoulder to avoid discomfort. The primary focus of therapy is mobilization, avoiding the stiffness that accompanies inactivity and pain so that once the calcifying tendinitis has improved, there is no long-term restriction on shoulder motion. Exercises initially include pendulum exercise and gentle passive range of motion. As the symptoms improve, stretching of the shoulder can be accomplished with passive to active motion, including forward elevation, external rotation, internal rotation, and horizontal adduction.

Physical modalities, such as ultrasonography, infrared heat, and iontophoresis, have been used to treat calcifying tendinitis.[44] However, there is no evidence that any of these physical modalities have a beneficial effect on the resolution of the calcifying tendinitis, either in the acute or chronic clinical phase. Griffin and Karselis have observed that ultrasonography was unable to mobilize the calcium crystals or to stimulate the resorption of the calcium deposit.[44] However, ultrasonography did provide short-term pain relief.

Needling or Puncture Aspiration

Some form of needling of the calcific deposit has been commonly recommended for the treatment of calcifying tendinitis. The methods of needling or puncture aspiration have been varied and include the placement of a needle within the calcific deposit to decompress the pressure at the site of the calcifying tendinitis; an injection of a local anesthetic alone; an injection of a local anesthetic with needling of the deposit, followed by a cortisone injection; an injection of cortisone alone in the subacromial space; and a needle aspiration-irrigation to decompress and remove the calcific deposit. There are some data to support each of these techniques. Much of the confusion arises from the treatment of calcifying tendinitis during the resorption stage. Because the acute symptoms are commonly associated with an expedient resolution of the condition, any treatment at this time is likely to be "successful." In fact, the treatment goal during the acute hyperalgesic clinical phase, corresponding to the stage of resorption, should be primarily directed toward improving patient comfort, with a secondary goal of avoiding any intervention that may inhibit the tendon restoration. Because each method may be effective, the single best treatment must also take into account the cost to the patient both in terms of potential risks as well as the costs related to the expense of the procedure.

Several authors have recommended needling or barbotage of the calcific deposit (Fig. 6-10). In Codman's treatise on rotator cuff disorders,[21] he refers to Flint's 1913 publication describing aspiration of the calcific deposit. After reading Flint's publication, Codman tried the aspiration and felt at the time of the aspiration that he actually punctured the deposit, which allowed the contents to leak into the bursa and relieve the patient's pain. He stated this was not Flint's exact plan, but was his achievement nonetheless. Barbotage can be accomplished either with a blind approach, as described by DePalma and Kruper,[25] or may be done with a more sophisticated measure of localizing the lesion using either fluoroscopic control or ultrasound.

Patterson and Darrach recommended needling of the calcification in conjunction with an injection of local anesthetic in the subacromial space.[103] Friedman demonstrated the ability to achieve pain relief in 85% of patients treated with this method.[33] However, in 11 out of 70 shoulders, the method failed to relieve the acute pain. Furthermore, Friedman noted that the amount of actual calcium removed did not appear to be important to the outcome of the needling of the calcified deposit. He concluded that piercing the calcium deposit was essential, whether or not the calcium was removed by aspiration or irrigation.

In DePalma and Kruper's report, a 1% solution of a local anesthetic was used to anesthetize the area of the subacromial space.[25] After needling the deposit and attempting to remove as much of the calcific mass as possible,

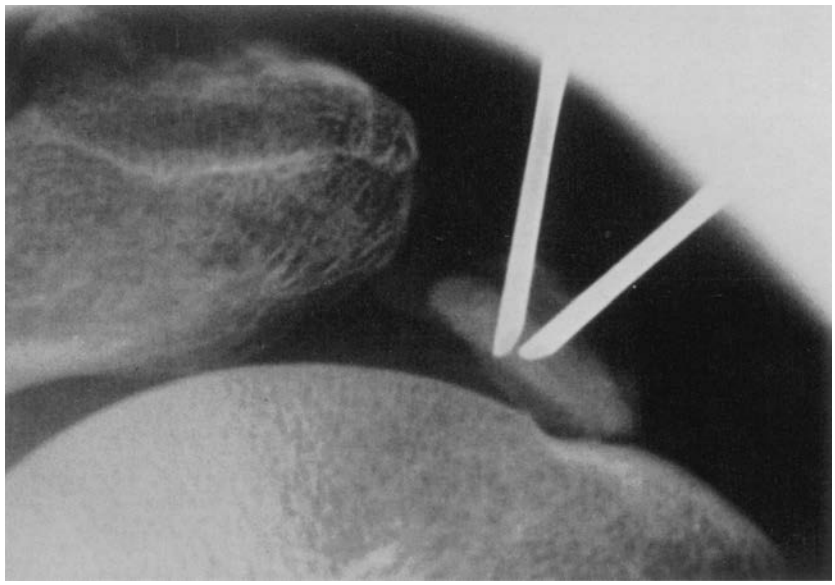

Figure 6-10 Needling of the calcific deposit decompresses the lesion, decreases the pressure in the tendon, and subsequently alleviates the symptoms of calcifying tendinitis. Needling can be performed "blind" in the office, or by using specialized techniques, such as fluoroscopy, to accurately localize the deposit. A second needle can be inserted into the area of the deposit for additional decompression or lavage. (Courtesy of Dr. Gilles Walch.)

multiple punctures were then placed with the 18-gauge needle into the rotator cuff tendon. It was suggested that this would cause an active hyperemia, enhancing dissolution and absorption of remaining calcific material. After completion of the needling, 10 mL of hydrocortisone was injected at the site of needling. One hundred fifty-four shoulders were evaluated for calcifying tendinitis, 86 of these treated by conservative methods. Ninety-four of the shoulders were reevaluated at follow-up, with 41 of the shoulders being treated by multiple puncture of the deposit. Only 23 of the 41 shoulders treated conservatively were reexamined, with 13 having a good result, five having a fair result, and five having a poor result. In other patients contacted by questionnaire, 18 shoulders in total, 12 were rated as good, four fair, and two poor. It was their opinion that conservative management provides satisfactory short-term results in most cases.

Key recommended needling in acute cases when a single large deposit is seen on radiographs.[63] After needling and aspirating the deposit, multiple punctures were performed. He suggested needling under local anesthesia for patients who would best be treated by operative removal but did not want to undergo an operation. Key felt that it was not a reliable form of treatment, and he recommended surgery for those patients who did not respond to physical therapy and physical modalities.

Lapidus presented 16 cases of patients presenting with acute symptoms.[64] He found that treatment by infiltration with a local anesthetic and injection of saline into the calcified deposit caused relief of symptoms and disappearance of calcification soon afterward and, therefore, injection therapy was beneficial. It was clear that his treatment occurred at the time of resorption and it was likely that resolution of the calcium would occur without the injection. Moutounet and his colleagues discussed the radiologic localization of the calcific deposit with subsequent needling.[94] After needling the deposit, corticosteroid was injected into the area of the deposit. They concluded that direct puncture of the calcification shortens the natural history of both acute and chronic calcifying tendinitis and accelerates resorption in 50% of the cases. With the addition of a small amount of cortisone, pain was relieved, and 80% good and very good results were achieved.

Clement also described a method of needling of the calcific deposit.[20] After spraying the skin with ethyl chloride, a no. 22 needle containing lidocaine and methylprednisolone was used to inject the solution into the subacromial space. Once the local anesthetic had become effective, the calcific deposit was needled repeatedly. Clement recommended 15 to 20 times. This was done without any type of radiologic localization of the calcific deposit. Clement mentioned that the acute pain subsided within 24 hours. Within a few days, the patients were referred to the therapist for ultrasonic treatment. He concluded that the pain was relieved with needling and injection and that the absorption of calcium was improved with ultrasonic treatments. There was no control group to evaluate whether the ultrasonic treatment had any effect in addition to the needling. In his series, there were no recurrences.

Farin et al. described a more sophisticated technique using ultrasonic-guided needling and aspiration, as well as lavage of the calcific deposits.[31] The technique of ultrasonographic localization was described, and two case reports were provided. The goal was direct needling of the deposit, followed by aspiration and lavage to remove as much of the calcific material as possible (Fig. 6-11). Within

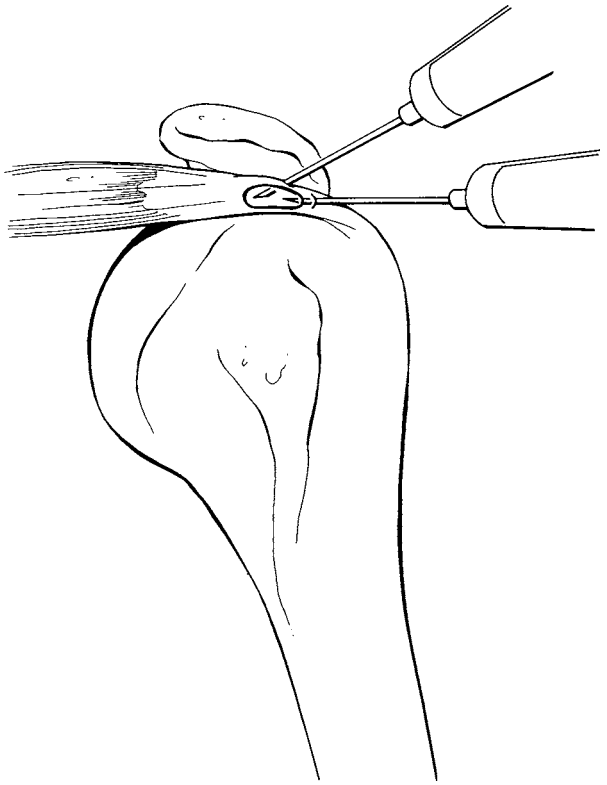

Figure 6-11 Needling and lavage can be effective if the deposit is localized. Sophisticated imaging techniques, such as fluoroscopy or ultrasound, permit accurate localization and direct penetration of the calcific deposit.

a few days of the treatment, both patients had a substantial reduction in their discomfort and were started on physical therapy programs. Bradley et al. reported 11 cases with radiographically evident calcific deposits. By using an ultrasound guidance technique, the deposit was needled and aspirated. Six of 11 patients had "relief" on the same day, four additional patients were pain-free after 2 weeks, and the remaining patient, who had no change in symptoms, had a supraspinatus tear seen on the ultrasonographic examination.[16]

Although needling of the deposit with adjunctive use of a local anesthetic is widely accepted, the addition of corticosteroid to the local treatment has been controversial. Harmon, discussing the treatment for calcific rotator cuff tendinitis in 609 shoulders, performed 263 needlings after local injection of hydrocortisone Meticorten anesthetic drugs.[49] A total quantity of 20 to 40 mL suspension with one-half 1% lidocaine and one-half hydrocortisone, 25 mg (or prednisolone 25 or 50 mg/10 mL) was used. This was blindly injected into multiple sites just proximal to the greater tuberosity, which was determined by the patient examination and radiographs. The results were considered excellent by this method alone, with the disappearance in 14 days or less after the last injection. However, approximately 54% of this group required two or more injections to alleviate the symptoms. Furthermore, there was no difference in those shoulders that were injected and needled with lidocaine alone or with the lidocaine and corticosteroid suspension. Subjectively, there did appear to be decreased muscle spasm and periarticular stiffening with the corticosteroid suspension.

Friedman noted that patients who had corticosteroid injected at the time of the calcium needling appeared to have less pain after the anesthetic effect of procaine (Novocaine) had worn off.[33] However, he emphasized that the decompression of the calcific deposit was far more important than the local effect of hydrocortisone. Those deposits that had been definitely pierced or aspirated had results that were similar whether or not corticosteroid had been used. It did not appear that corticosteroids had any negative effect, nor did they appear to have any effect on the reduction in the size or the disappearance of the calcium deposit.

Lapidus recommended anesthetizing the shoulder with a local anesthetic followed by multiple punctures through the calcified deposit.[64] At the completion of the multiple puncture, an injection of corticosteroid is performed. In his series of 248 cases, 83 patients received a corticosteroid injection. It is unclear as to what criteria were used to decide on which patient received a corticosteroid injection. Of the 83 patients who did receive the injection, 19 (23%) actually had aspiration of the calcific deposit. Lapidus stated that "practically all" of the patients were promptly relieved, and it was unclear whether the cortisone affected the final result. Murnaghan and McIntosh treated 27 patients with local anesthetic and 24 patients with corticosteroid and was unable to demonstrate a difference in the results.[95]

Gschwend found that corticosteroid injections were short acting, and their effect was on symptoms alone.[45] Moseley felt that steroids injected into tense deposits may cause extensive necrosis and, therefore, recommended that if steroids and a local anesthetic are to be injected, it must be only into the subacromial space and bursa.[92]

Neer believed that cortisone injections do have a role in the treatment of patients with calcifying tendinitis.[96] When patients had pain and stiffness that could not be effectively treated with physiotherapy, he recommended a limited number of local steroid injections to reduce inflammation and resume exercises. When the resorptive phase had begun and pain was severe, he recommended an injection of lidocaine followed by needling, and then completed with an injection of corticosteroids. In those deposits that had occurred during the formative stage, again, injections, including cortisone injections, were recommended. Neer noted that when he was a resident, the most frequent shoulder operation in his hospital was excision of calcium. However, he believed that treatment using parenteral nonsteroidal antiinflammatory medications and corticosteroids reduced the surgical excision of calcium to a rare procedure.

Other authors have expressed concern over the injection of corticosteroid and the disruption of the normal tendon-

healing process, or tendon reconstitution. Lippman believed that corticosteroids could inhibit the resorptive phase and possibly return the calcifying tendinitis back to its static or resting phase.[67] Uhthoff and Sarkar have also stated that there is no indication for an injection of cortisone when treating the acute clinical or resorptive phase of calcifying tendinitis.[141]

In conclusion, an injection of corticosteroids is primarily effective as a long-acting pain reliever, possibly because of the resolution of the associated inflammatory process of the resorptive phase. Cortisone does not appear to have any benefit on the resolution of the calcific deposit. However, despite theoretical concerns, there is no evidence that an injection of corticosteroids into the subacromial space following needling of the calcific deposit has any adverse effects.

Radiotherapy

Radiation or x-ray therapy has been advocated for the treatment of calcifying tendinitis of the shoulder.[6,100,105,108] Treatments have varied from a single large dose of radiation to small doses on a repetitive basis. Improvement in symptoms has been reported in 70% to 100% of patients. Radiotherapy was initially proposed in Europe and later used in the United States. Plenk evaluated the effect of radiation therapy in 21 patients, with an additional 17 patients as a control group.[108] In the control group, the patients were set up exactly as the study group, only a lead shutter was placed in front of the x-ray tube housing to prevent any radiation of the shoulder. Remarkably, a definite improvement or complete relief of pain within 6 weeks after therapy was discovered in 15 of the treated patients and 15 of the control patients. It was Plenk's opinion that "calcifying tendinitis of the shoulder is essentially a self-limiting disease." He argued that there was no benefit from radiation therapy, and stressed the importance of understanding the natural history of calcifying tendinitis.

Recently, Ollagnier and coworkers reported on a group of 44 patients receiving what they termed "antiinflammatory radiotherapy."[100] All patients were treated with a dose of radiotherapy ranging from 600 to 1,200 R, divided between five and nine sessions. With a mean follow-up of longer than 2 years, 68% of the patients were satisfied or very satisfied with the treatment. However, when the treatment was broken down into the various stages of calcifying tendinitis, it was clear that patients presenting with the formative stage of calcifying tendinitis had equivocal results, with 6 out of the 14 patients not a part of the satisfied group. In those patients in the resorption phase or demonstrating heterogeneous pattern to the calcific deposit, six out of the eight were in the satisfied group. The author speculated that antiinflammatory radiation therapy was effective and that it is "at least as efficient as needle aspiration or lithotripsy."

Baird reported on 18 cases of calcifying tendinitis:[6] Nine patients were in the acute phase, five patients in the subacute phase, and four patients in the chronic phase. He suggested that only one exposure was required to relieve the pain completely and restore normal function for patients in the acute phase and some patients in the subacute phase. No serious adverse effects were noted. Given the cost, potential risks to the patient, and lack of evidence demonstrating its effectiveness, it would appear that radiation therapy for calcifying tendinitis is primarily of historical importance.

Extracorporeal Shock Wave Treatment

Dahmen initially reported on the efficacy of extracorporeal shock wave therapy using low-pulse energy.[24] There was no investigation into the changes of the calcific deposit after the shock wave application, but clinically there was a significant improvement in shoulder pain.

Loew studied 20 patients who were treated with a lithotripter in two sessions of 2,000 pulses each.[69] Twelve weeks following the treatment, 15 of the 20 patients had a marked reduction of symptoms, with a 30% improvement overall. Fourteen patients had a transient subcutaneous hematoma. MRI failed to demonstrate any damage to the tendon or the bone. These patients demonstrated chronic calcifying tendinitis, with a history of symptoms for longer than 12 months and radiologically proven calcification of the rotator cuff measuring greater than 10 mm in the anteroposterior roentgenogram, consistent with the formative stage. The calcific deposits were of homogeneous consistency and would correspond to the type A classification by the French Society of Arthroscopy. No patients had rotator cuff tears. Radiographic studies 6 weeks following the extracorporeal shock wave therapy demonstrated that 11 of the 20 patients had a change in their radiographic architecture. At 12 weeks, 12 patients demonstrated radiographic changes, with seven showing a complete resolution of the calcium deposit.

Rompe et al. evaluated the use of extracorporeal shock wave therapy in the treatment of 46 patients with calcific deposits of the supraspinatus tendon.[118] Inclusion criteria included persistent shoulder pain, in combination with the calcific deposit of the supraspinatus that had been present for more than 12 months and had failed conservative therapy for at least 6 months. The deposits were sharply outlined and densely structured, with a minimum diameter of 10 mm. This technique uses an electromagnetic shock wave generator in a mobile fluoroscopy unit. A regional anesthetic agent was necessary to complete the procedure. At 6 weeks, partial resorption of the calcium deposit was noticed in 43% of the patients, with complete resorption in 10%. By 24 weeks there was a 48% partial resorption and a 15% complete disintegration. Again, based on the results, Rompe noted that extracorporeal

shock wave therapy was more effective than injections or needle irrigation for the treatment of calcifying tendinitis in the formative stage.

Loew reported results of shock wave therapy in 195 patients with chronic calcifying tendonitis, including subjective, functional, and radiologic findings at 6 months after treatment. The treatment groups were split into two groups, the first of which was divided into low-energy or high-energy shock waves. The second group was treated with either one or two high-energy sessions. Pain relief correlated with the energy level applied to the calcific deposit, with 5% in the control group and 58% in the two high-energy session group. Constant scores increased only 3 points on average in the control group at 3 months, but increased 15 points on average in the two high-energy group. In addition, there was radiologic disappearance of disintegration of the calcific deposits in only two patients in the control group, and 12 patients in the two high-energy session group. The authors concluded that improvements seen with the use of shock wave therapy is dose-dependent. It should be noted that only 79% of the patients in the high-energy group were available for follow-up, with 11 patients electing other treatment (injection or surgery) and 13 refusing further examination.[71]

Haake et al. compared the results of extracorporeal shock wave therapy directed at the origin of the supraspinatus tendon versus the calcified area in 50 patients, and found that at 12 months, the group that had exact focusing at the calcific deposit had zero failures, while the group without exact focusing of the shock wave therapy had 14 failures. When the radiographic appearances of the calcific deposits were compared, there was no statistical difference between the two groups. There were no significant side effects in either group. The authors concluded that exact fluoroscopic focusing of extracorporeal shock wave therapy at the calcific deposit is recommended.[46]

Wang reported results of shock wave therapy in 31 shoulders treated with 1,000 impulses of shock waves at 14 kV. At 12 weeks, 21 shoulders were available for follow-up, with 62% showing significant improvement or having no complaints. Radiographic evaluation showed complete elimination of the calcific deposit in only six patients, and partial dissolution in another five patients. They were able to show a correlation between functional improvement and elimination of the calcific deposits.[144]

Rompe et al. compared the results of conventional surgery to shock wave therapy in 79 patients. Twenty-nine patients had surgical excision of the calcific deposit, and 50 patients were treated with high-energy shock wave therapy (3m000 impulses at 0.6 mJ/mm^2). The authors concluded that for patients with homogenous deposits, surgery was superior to shock wave therapy. For patients with inhomogenous deposits, high-energy extracorporeal shock wave therapy was equivalent to surgery, and should be given priority because of its noninvasiveness.[119]

Daecke et al. studied the long-term effects of extracorporeal shock wave therapy in 115 patients, 56 of whom received one session of shock wave therapy (group A), and 59 of whom received two sessions (group B). The authors noted that improvements in pain relief, Constant score, and radiographic improvement were energy-dependent. Additionally, there were significant differences between the two groups. At 4 years, 20% of the patients had undergone surgery on the affected shoulder. The authors concluded that while the failure rate was high, extracorporeal shock wave therapy was successful for 70% of the patients in this study, and no long-term complications were seen.[23]

Wang reported a 2-year follow-up study on 39 shoulders treated with shock wave therapy. The results showed that 91% of the patients obtained complete or nearly complete resolution of their symptoms. In addition, 57% of the shoulders showed complete dissolution of calcium deposits, with no recurrence at 2 years follow-up. It should be noted that 2 years postoperatively, six shoulders were eliminated from the study because of poor compliance or inadequate data. Additionally, there was no mention of how they were doing at their latest follow-up.[145]

Durst et al. reported one case of osteonecrosis of the humeral head 3 years and 4 months after undergoing extracorporeal shock wave therapy for chronic calcific tendonitis in a female patient. She had received three sessions of shock wave therapy, with 1,600 to 1,700 impulses at 12 to 13 kV over a period of 1 month. There were noted improvements in pain, as well as a reduction in the size of the calcific deposit, following this treatment. Unfortunately, the patient presented with stage IV osteonecrosis of the humeral head. The patient had no other predisposing factors for developing osteonecrosis. The authors have postulated that this may have been caused by injury to the anterior humeral circumflex artery. The arcuate artery was only 10 mm from the site of the calcific deposit, and the patient's MRI showed osteonecrosis in the portion of the humeral head that was supplied by the anterior humeral circumflex artery.[28]

In the past decade, there has been a growing enthusiasm for using extracorporeal shock wave therapy for the treatment of chronic calcific tendonitis. The majority of studies seem to indicate that while there seems to be an improvement in patients' symptoms short term, the best long-term results correlate with radiographic disappearance of the calcific deposit. Additionally, dissolution of the calcific deposit occurs more reliably when higher amounts of energy are directed at the deposit. While the complication rate of shock wave therapy seems low, and is most commonly an intramuscular hematoma, there have been reports of transient bone marrow edema and one case of osteonecrosis of the humeral head.[28] At this time, the results of shock wave therapy remain inferior to surgical débridement.

Surgical Treatment

Codman wrote: "My personal opinion is that surgical removal of the deposit is practically free from danger, sure to relieve the severe symptoms at once, and, in fact, that it generally will relieve all really troublesome symptoms within a few weeks."[21] He further opined that "it would be rational to thrust a large aspirating needle into the deposit under guidance of the fluoroscope, but I would prefer to be operated upon were I the patient." He suggested that the operation could be performed with a local anesthetic despite an open approach to the supraspinatus tendon. Bosworth concurred, stating that the most dependable way of eliminating the symptoms and the disease of calcifying tendinitis is by open surgery.[14]

Lippmann reviewed his results of 100 consecutive cases treated with surgical decompression of the calcific deposit.[67] His conclusion was that patients with calcifying tendinitis treated surgically can expect return of normal function to the shoulder. McLaughlin discussed the operative decompression and removal in over 200 cases.[82] Surgical treatment was believed to be necessary in less than 10% of all cases of calcifying tendinitis. In most of the surgical cases, he believed that the severity of the patients' symptoms and their request for treatment of their pain led to surgical management. He concluded that surgical treatment produced the most certain and permanent results.

Gschwend et al. recommended surgical treatment when there was a progression of symptoms, interference with activities of daily living, and a failure of conservative management.[45] Such treatment was correlated with a good or an excellent result in more than 90% of patients. Neer stated that surgical indications should include the failure of conservative treatment, as well as multiple hard, gritty deposits with long-standing symptoms.[96] Despite a practice dedicated entirely to the treatment of shoulder problems, he was performing the procedure only once or twice a year. He also was keenly aware that the recovery period for long-standing lesions is longer than one might expect from relatively minimal open surgery and removal of the calcifying deposit, suggesting residual tendinopathy despite removal of the calcific lesion.

McKendry et al. reported on the surgical treatment of 57 patients with calcifying tendinitis.[80] Surgery was performed after an average follow-up of 2.8 years after the onset of symptoms. Sixty percent of patients were pain-free postoperatively at 6 weeks, although 30% had continuing pain beyond 12 weeks. Preoperative factors predicting a longer convalescence could not be identified. They emphasized that a fluffy appearance to the calcium deposit is associated with the resorptive phase; therefore, a trial of conservative treatment was recommended.

In summary, many investigators have shown that surgical management is effective for the treatment of calcifying tendinitis. Surgery is primarily indicated for the treatment of symptomatic patients with calcifying tendinitis in the formative stage, which is confirmed on radiographs demonstrating a relatively homogeneous calcific deposit. Patients who have acute severe symptoms or patients with evidence of heterogeneous calcification are likely to be in the resorptive phase and, therefore, continued conservative management would be recommended. Patients treated surgically during the resorptive phase are likely to have favorable results because the natural history is that most of these patients will go on to resolve their calcifying tendinitis, no matter what treatment is performed.

Surgical Technique

Open Approach

Traditionally, an open surgical technique through a split in the deltoid muscle has been demonstrated to be effective in visualizing and removing the calcific deposit. Codman recommended a local anesthetic, exposure through a split in the deltoid muscle, and removal of the calcific deposit.[21] McLaughlin felt that local anesthetic and treatment in the office was an "invitation to catastrophe." Others have suggested a general anesthetic, with the patient in a sitting position and support for the head.[63] The incision begins over the margin of the acromion and extends downward for approximately 4 cm. The deltoid fibers are split and the calcium deposit is readily apparent if it is in the supraspinatus, the most common location (Fig. 6-12). The site of the deltoid split may need to be modified, depending on the exact location of the deposit. The deposit is incised in line with the fibers of the rotator cuff tendon, and the contents are allowed to escape or are removed with a curette. Postoperative immobilization is unnecessary.

Howorth reported on the surgical treatment of 23 shoulders and 22 patients over a 6-year period.[52] Relief of pain and improved motion was noted in all cases. Eighteen patients were reevaluated at an average of 19 months after their surgery. Only 5 of 18 patients demonstrated excellent results, with no pain, weakness, disability, or limitation of motion; 10 patients demonstrated good results, and three patients demonstrated fair results. Analysis of his study group suggests that four out of the five patients with excellent results were in the resorptive phase, whereas the 10 patients with good results were in the formative phase. Two of the three patients with fair results were also in the formative stage. The other patient had been initially treated for severe shoulder stiffness. Howorth concluded that operative removal of the calcific deposit was the surest and most rapid method of relief.

Friedman treated 20 shoulders in 15 patients with surgical removal.[33] Most of his patients had acute pain a few days to 2 weeks before the surgery. Twelve of the shoulders had deposits measuring over 2 cm, with five of the shoulders having deposits measuring more than 3 cm. Eleven of

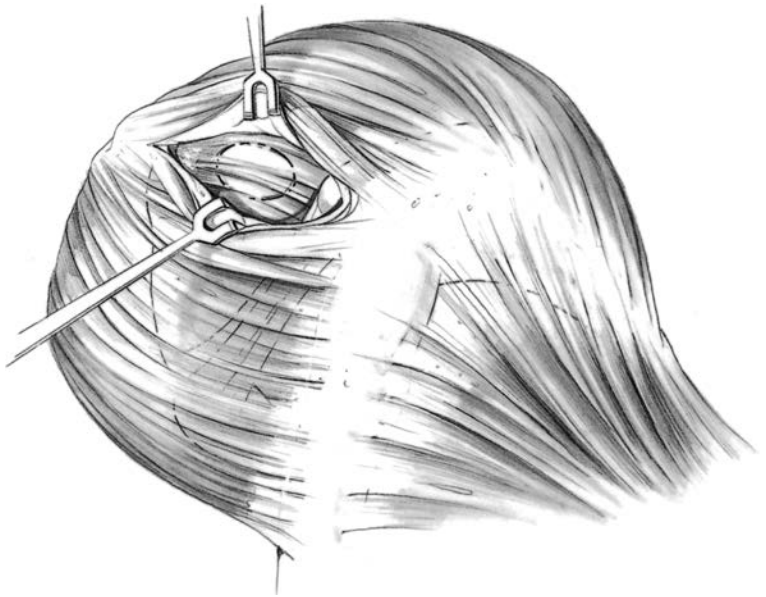

Figure 6-12 The approach to the calcific deposit is dependent on its location. For deposits in the supraspinatus tendon, the most common location, a small skin incision in Langer's lines is followed by a split of the deltoid at the anterolateral deltoid raphe. After incising the underlying bursa, the deposit is seen within the substance of the tendon. Incision of the tendon is performed in line with the fibers of the tendon, and then the calcific material is completely removed. At the completion of the procedure, all layers are closed "side to side," permitting an accelerated rehabilitation program.

the 20 shoulders had been treated initially with infiltration and needling that had failed to relieve the acute symptoms. A deltoid split was used to approach the deposit. The deposit was either decompressed by incising the center and allowing the material to escape under pressure, or curetted if the deposit was dry and gritty. In most patients, acute pain was relieved within 1 or 2 days after surgery. Friedman noted that there was a select group of patients who seemed to take an extended period of time to recover from a limited surgical approach. In one patient, severe stiffness developed, with range of motion returning after 4 months.

Harmon performed a direct surgical excision of the calcific deposit in 104 shoulders, which represented 17% of his patient population with calcifying tendinitis.[49] His indications for surgery included two different classes of patients: (a) those who had failed repeated needlings and injections and (b) those with fulminating hyperacute symptoms. He considered the latter group a surgical emergency and, after surgical decompression, relief was instantaneous. He recommended nonsurgical treatment in any case of calcific deposits in the subscapularis tendon, for none of his patients presented with acute symptoms, and all were recovering following a simple needling procedure. The outpatient procedure was performed using a local anesthetic and a split through the upper deltoid. Full active motion was attained in 80% of his patients within 3 to 5 days. It was unclear how many patients represented the second class or those with "fulminating hyperacute symptoms." Because these patients are in the resorptive phase of the calcifying tendinitis, it is likely that nonsurgical treatment would also have demonstrated good results.

Moseley recommended operative treatment for patients with mechanical symptoms in addition to pain, or when conservative treatment fails and the patient continues to demonstrate a "stiff and painful" shoulder.[92] He reported 304 cases treated with an open operative approach and direct exploration and removal of the deposit. In his opinion, the "few recurrences" are due to remaining calcific deposit after the procedure. Ghormley also stated that it was essential that all of the calcified material be removed and the tendon left intact. He reported three case reports, all with successful results.[38]

Litchman et al. analyzed 100 consecutive cases of calcific tendinitis treated with an open surgical approach over a 10-year period.[68] They stated that these 100 cases represented less than 1% of the patients seen for calcifying tendinitis, which suggests that 1,000 patients a year presented to their practice with evidence of calcifying tendinitis. The patients were divided into four clinical categories: acute (12%), acute–recurrent (13%), chronic (45%), and chronic with acute exacerbation (30%). These authors concluded that the patients presenting with chronic or chronic with acute exacerbation symptoms benefited the most from the surgical approach. The surgical procedure is performed under a general anesthesia with the arm draped free for rotation during the procedure. The deltoid muscle is split and the deposit identified. Serial vertical incisions in the rotator cuff tendon may be necessary to identify the deposit in chronic cases. The calcareous material is removed and an elliptical portion of the tendon is excised, followed by curettage. The tendon defect is then closed with an absorbable suture. In the review of the 100 cases, patients generally regained normal function of the shoulder. The duration of convalescence following the surgery to full recovery was directly related to the degree of chronic disability before the surgery. The average patient returned to full activities after 4 weeks, but in patients who demonstrated severe restrictions of glenohumeral motion, the time to full recovery was "often doubled or tripled."

Vebostad reported on the surgical treatment of 43 shoulders with calcifying tendinitis treated over a 13-year period.[143] He divided the groups into three different types of operations: Group A was simple excision of the calcific deposit; group B was excision of the deposit combined with partial resection of the acromion; and group C was a partial resection of the acromion alone. There were no specific indications for deciding whether the partial acromion resection should be performed when an identifiable calcific deposit was present; when the deposit could not be easily identified, patients were treated with a partial resection of the acromion alone (group C). Of 43 operations, 34 were considered to be "successful." On average, at 2.4 months following the surgery the pain had been relieved. Patients in the group that had undergone resection of the calcium alone had a much shorter period of recovery. There was no difference in the final results in all three groups. Vebostad recommended a simple removal of the deposit as the preferred procedure. However, in patients who have substantial increase in pain in the middle range of abduction or when the deposit could not be localized, an acromioplasty was beneficial.

Uhthoff et al. should be credited with much of our current understanding of the cell-mediated, nondegenerative characteristics of calcifying tendinitis.[135,138] Armed with an understanding of the basic pathophysiology underlying this disorder, they sought a better understanding of the surgical indications and pathologic findings for this disorder. In a report authored by McKendry et al., 57 patients with calcifying tendinitis were treated with an open procedure by 11 different orthopedic surgeons.[80] All patients were treated with a simple curettage of the calcified material, with removal of a small segment of the adjacent tendon. Surgery was performed an average of 2.8 years after the onset of symptoms. By 6 weeks, 61% of patients were pain-free, but 30% continued to have pain beyond 12 weeks. They concluded that patients with a radiographic fluffy appearance of the deposit associated with acute pain are in a self-healing stage of the disease, and nonoperative treatment is recommended. Patients with long-standing symptoms unresponsive to conservative measures with a radiographic homogeneous appearance of the deposit are appropriately treated with curettage of the calcified material.[141]

Despite the relative success of open decompression of the calcific deposit, some patients failed surgical treatment, with continued symptoms of pain and stiffness. Clinical findings suggested pathology localized to the relation between the affected tendon and the coracoacromial arch; therefore, some authors have investigated the efficacy of an open anterior acromioplasty in the treatment of calcifying tendinitis. Postel reviewed a group of 31 shoulders, with the diagnosis of calcifying tendinitis, that were treated by an acromioplasty alone, without excision of the calcification.[110] The mean duration of symptoms before the operation was 4.6 years. In 14 cases, lavage and needling was attempted, followed by an injection of cortisone, but relief of pain was incomplete. Normal mobility was noted in 15 patients, but the remainder of the patients had significant limitations in arm elevation. Preoperatively, the calcification in 13 cases was heterogeneous, corresponding to the resorptive phase. Eight cases demonstrated a dense homogeneous calcification, and six cases had multiple, small, and dense calcifications. Four cases had a history of calcifying tendinitis, but the calcification had resorbed despite their persistent symptoms. Sixteen cases demonstrated a type II acromion.[12] Acromioplasty was performed using an open technique in 24 cases, with an arthroscopic technique used in seven cases. Adding to the complexity of the evaluation, the acromioclavicular joint was also resected in 13 cases. The results were better in the group for whom the acromioclavicular joint was resected, with no failures and 70% excellent and very good results. Only 40% excellent and good results were achieved in the group with a simple acromioplasty. Improvements in range of motion and decrease in pain were noted in most patients. The authors proposed that when a superficial homogeneous deposit is noted, incision and curettage is effective. However, when there is intratendinous heterogeneous calcification, an acromioplasty should be strongly considered. The authors suggested that the acromioplasty permits reduction in the inflammation of the rotator cuff tendon. It is possible that there are other effects from the acromioplasty in addition to alleviating the mechanical aspects, such as decreasing the pressure within the tendon, thereby facilitating the resorptive process, and the natural cycle of calcifying tendinitis by improving blood flow to the rotator cuff tendon.

Gazielly et al. evaluated the results of open acromioplasty combined with excision of the calcium deposit in 39 patients who had at least a 1-year history of shoulder calcification.[36] All patients underwent an anterior acromioplasty, as well as an excision of the calcification and suturing of the curetted tendon. Follow-up averaged over 2 years. Seventy-four percent of the patients had calcification in the supraspinatus, 20% in the infraspinatus, and 6% in the subscapularis. Intraoperative findings of the calcification demonstrated 74% of patients with a solid or chalk-like consistency, 18% with a fluid consistency, and the remaining 8% with mixed consistency. The functional rating for the operative shoulder corresponded to 98% of the contralateral shoulder function compared with 63% preoperatively. Radiographic follow-up demonstrated that the main calcium deposit had been fully eliminated in 98% of the shoulders. Eighty-two percent of patients felt that they had recovered from their condition, whereas the remaining 18% judged that their condition was much improved or improved. It was the opinion of the authors that the clinical results were dependent on the total excision of the calcification, as well as the suturing of the edges of the tendon, which could only be done through an open

approach. The authors then went on to look at their own personal series of having treated more than 100 calcifications by arthroscopic surgery over a 6-year period. From a comparison of their personal series, it was their opinion that arthroscopic excision is difficult, the learning curve for the surgical skills is steep, and the postoperative morbidity from an open procedure is not significantly different from the arthroscopic technique.

Arthroscopic Approach

Arthroscopic treatment of calcifying tendinitis has several potential advantages. The deltoid split to approach the calcific deposit can now be performed through a small arthroscopic portal. Furthermore, as some authors have suggested, an acromioplasty can also be performed arthroscopically, minimizing the iatrogenic risk of deltoid detachment following open acromioplasty. Ark et al. reported on the results of the arthroscopic treatment of chronic calcific tendinitis in 23 patients at an average of 26 months after the procedure.[4] Indications for surgery were persistent shoulder pain in the presence of calcific tendinitis despite at least 1 year of conservative treatment. Conservative treatment included physical therapy (eight patients), nonsteroidal antiinflammatory medications (16 patients), and steroid injections (14 patients). All patients continued to have pain at night. The calcium deposit was localized to the supraspinatus tendon in 20 patients, the infraspinatus tendon in two patients, and the subscapularis in one patient. Nineteen patients demonstrated a dense calcific deposit consistent with formative phase, whereas four patients demonstrated a fluffy deposit. The arthroscopic procedure was performed in the beach-chair or the sitting position. The authors noted that hypertrophic bursitis was often noted on arthroscopic examination of the subacromial space, and a partial bursectomy was necessary. Other authors have demonstrated that the bursal reaction is primarily a localized reaction to the specific area of pathology.[55] Ark et al. reported the release of the coracoacromial ligament in nine of their patients for hypertrophy or localized inflammation. In three patients that demonstrated a prominence to the anterior acromion, an arthroscopic acromioplasty was also performed. A needle was used to identify and, if possible, release the calcific deposit (Fig. 6-13). Needling was followed by a small longitudinal incision within the cuff in line with its fibers (Fig. 6-14). If necessary, up to three incisions were made to completely expose the deposit. Finally, a small curette was used to further liberate the calcific deposit (Fig. 6-15). Any contents from the deposit and "inflamed tissue" were débrided. Bupivacaine without cortisone was injected at the completion of the procedure.

At follow-up at an average of 26 months after the procedure, 11 patients (50%) had full relief of pain, and an additional nine patients (41%) were satisfied with the results, although they had occasional episodes of discomfort. Two patients had persistent pain and after a second arthroscopic procedure were relieved following 5 months of recuperation. The authors felt that these patients had undergone an inadequate removal of the calcium deposit during the primary procedure.[4]

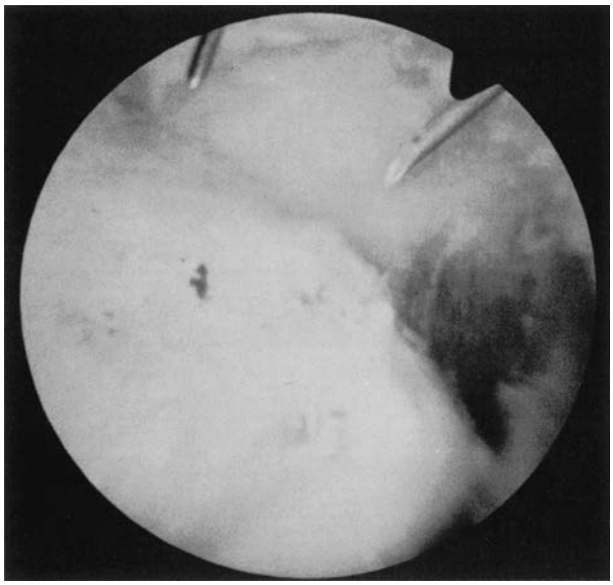

Figure 6-13 Arthroscopic treatment of calcifying tendinitis offers the ability to localize and decompress the deposit with minimal injury to the surrounding healthy tissues. Once the deposit is localized, puncturing the deposit will release the calcific contents. (Courtesy of Dr. Gilles Walch.)

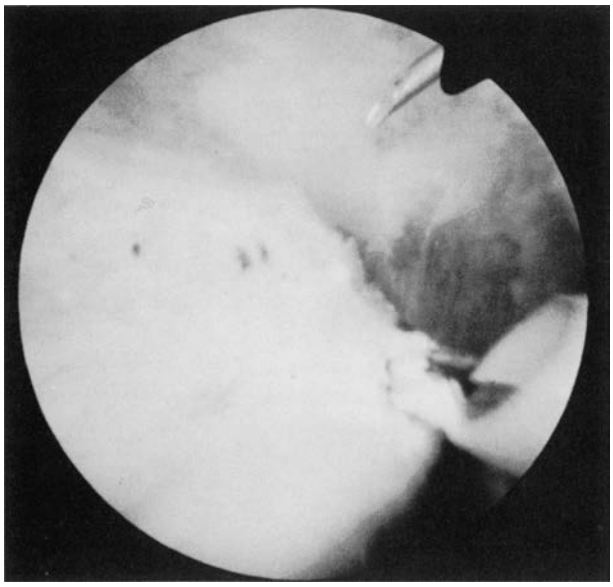

Figure 6-14 A small longitudinal incision in line with the fibers of the tendon can be performed with an 18-gauge needle or a knife. The release of the calcific material is dramatic when the contents are under pressure. (Courtesy of Dr. Gilles Walch.)

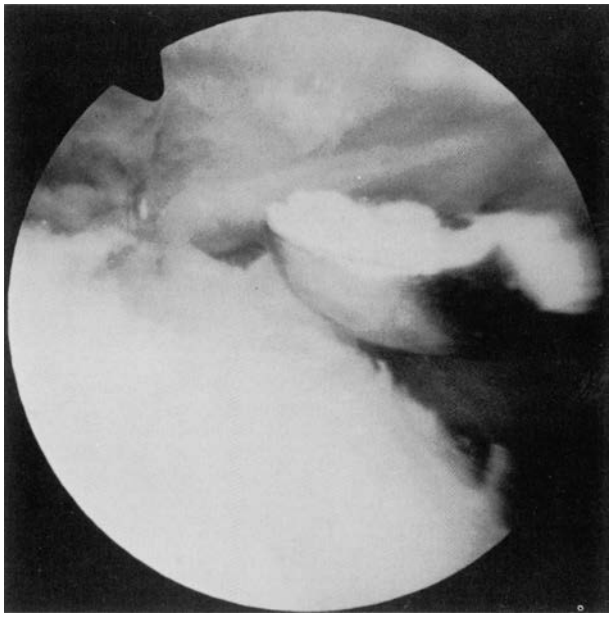

Figure 6-15 A curette can be used to remove any remaining calcific material from the deposit site. (Courtesy of Dr. Gilles Walch.)

Follow-up radiographic studies performed in this patient group demonstrated one patient with an intact large calcium deposit, 12 patients with partial removal of the deposit, and nine patients with complete removal of the calcium. Twelve of 14 patients in whom there was persistent calcium still had significant relief of their pain. The authors, therefore, concluded that complete excision of the calcific deposit during the arthroscopic procedure was not essential for a good outcome.

In fact, a report by Barchilon and Gazielly specifically looked at the amount of calcium deposit removed at the time of shoulder arthroscopy and its relation to overall results.[7] Over a 4-year period, 78 patients with chronic calcifying tendinitis were treated with arthroscopic evaluation and removal of the calcific deposit. From preoperative plain radiographs, the average area of the deposit was 2.1 cm^2. Overall, an average of 74% of the calcific deposit was removed. Removal of deposits from the infraspinatus was less effective than removing deposits from the more common location in the supraspinatus (86%). They also found no correlation between the amount of calcium remaining after surgery and the final result. Kempf et al. also favored isolated excision of the calcific deposit, emphasizing that calcifying tendinitis occurs in an otherwise globally healthy tendon.[60]

However, as noted before, not all patients respond to decompression of the deposit alone, whether it is performed with needling, an open procedure, or an arthroscopic procedure. The poor results have led some surgeons to consider the role of an acromioplasty in the treatment of calcific tendinitis. Ellman reported satisfactory results in 15 of 16 patients who were treated with a débridement or removal of the calcific deposit followed by an arthroscopic subacromial decompression.[30]

Synder and Eppley also described satisfactory results using arthroscopic techniques for decompression of the deposit in 13 of 13 patients, but also suggested that arthroscopic evidence of impingement or hypertrophy of the coracoacromial ligament indicates the need to include an arthroscopic acromioplasty.[132] Re and Karzel supported this recommendation, suggesting that arthroscopic treatment include decompression of the deposit, with an arthroscopic acromioplasty indicated only in those patients with clinical or arthroscopic evidence of impingement.[113]

Mole et al., in the French Society of Arthroscopy, organized a multicenter study to evaluate the results of arthroscopic treatment of chronic calcifying tendinitis.[88] This retrospective review did not randomize patient treatment, but instead looked at the results of treatment by the individual members of the society. One hundred twelve patients were included in the analysis. The surgeons used a variety of treatment options, including excision of the calcific deposit, excision of the deposit with acromioplasty, and acromioplasty without treatment of the calcific deposit. There was no statistically significant difference in the final results using these different treatments. Functional results were evaluated using the Constant score.[37] Excellent results were achieved in 61% of patients, very good results in 24%, good results in 7%, and fair results in 5%. Eight patients had poor results. Acromioplasty did not provide any additional improvement in the final results. However, the authors recommended that an acromioplasty be performed when the calcification could not be found, which occurred in 12% of their patients. The most important factor for a successful result appeared to be the ability to remove the deposit. Poor prognostic factors included the preoperative limitation of passive mobility, the existence of calcific deposits of the lesser tuberosity, and the existence of a rare complete or significant intertendinous tear of the rotator cuff tendon that was found in 4% of the cases.

Gleyze and colleagues also concluded that isolated excision of the calcification is the appropriate treatment, with little evidence for the routine performance of an acromioplasty.[39] However, using the French Society of Arthroscopy classification of radiographic findings in calcifying tendinitis, an acromioplasty is recommended with or without excision of the remaining calcific deposit in patients with type C calcification (heterogeneous) and a lack of clinical evidence of acute pain. This is true for supraspinatus calcific deposits alone. This pattern, radiographically, may be part of the resorptive process; however, the lack of hyperalgesic pain and the presence of chronic symptoms suggest that the resorptive process has paused or has failed. In this study, symptoms were present for more than 1 year. It is suggested by Kempf et al. that these tendons have been unable to complete the typical calcifying tendinitis cycle

and, therefore, the patient is left with a pathologic supraspinatus tendon.[60] Consequently, an acromioplasty may remove the mechanical irritation from the overlying acromion or decrease the intratendinous pressure, allowing increased blood flow and possibly stimulating the completion of the resorption cycle with improved tendon healing. The physiologic effects of an acromioplasty for chronic calcifying tendinitis are unknown.

AUTHORS' RECOMMENDED TREATMENT

The treatment of calcifying tendinitis is based on a thorough understanding of its cycle, the clinical presentation, and the radiographic findings. All three aspects are crucial to avoid treatment that is not only less successful but possibly harmful to the rotator cuff. Because calcifying tendinitis is generally a transient phenomenon, any treatment that is potentially harmful or may disrupt normal tissues around the shoulder must be clearly indicated before it can be recommended.

With these principles in mind, patients presenting with acute pain representing the resorptive phase of calcifying tendinitis are most appropriately treated with nonsurgical measures. Patients with calcifying tendinitis in the formative phase are best treated initially with nonoperative measures. If the condition fails to resolve, surgical treatment is effective in alleviating the patient's symptoms and allowing a return of shoulder function. The most difficult decision is with those patients for whom there appears to have been the initiation of the resorptive process, and yet symptoms and radiographic findings persist. Despite the same epidemiologic attributes, the various manifestations of calcifying tendinitis must be managed with unique strategies (Fig. 6-16).

Conservative Treatment

Virtually all patients with calcifying tendinitis are best treated nonoperatively. When patients present with the acute symptoms of the resorptive phase of this disorder, intervention is dictated by the patient's severity of symptoms. In this phase, patients often present with severe pain and an inability to move their shoulder. Many patients are desperate for relief from the pain that interferes with every aspect of their life, including sleep. Explaining to the patient the transient nature of their severe pain is not reassuring at this time. Although nonsteroidal antiinflammatory medications and even narcotics are helpful, their benefit is minimal, and usually it does not allow patients to sleep comfortably. Physical therapy and gentle motion exercises are likely to aggravate the symptoms; therefore, they are not initially indicated.

The primary goal of treatment is pain relief, and the most effective method to accomplish this task is needling of the deposit. The deposit is carefully evaluated using plain radiography. Bilobular or multilobular involvement should be noted. The anteroposterior views of the shoulder, including rotation views, will allow the deposit to be localized. Fortunately, most deposits are in the supraspinatus, which is easily approached without concern for injuring neurovascular structures. Deposits in the infraspinatus will often demonstrate an area of localized soft tissue prominence and tenderness on the lateral side of the shoulder. With the arm at the patient's side, lesions in the supraspinatus are referenced from the anterolateral corner of the acromion, which is usually in close proximity to the deposit. Furthermore, palpation of the bicipital groove provides an additional reference point on physical examination. Palpation directly over the deposit is accompanied by a severe worsening of the pain. If necessary, the arm can

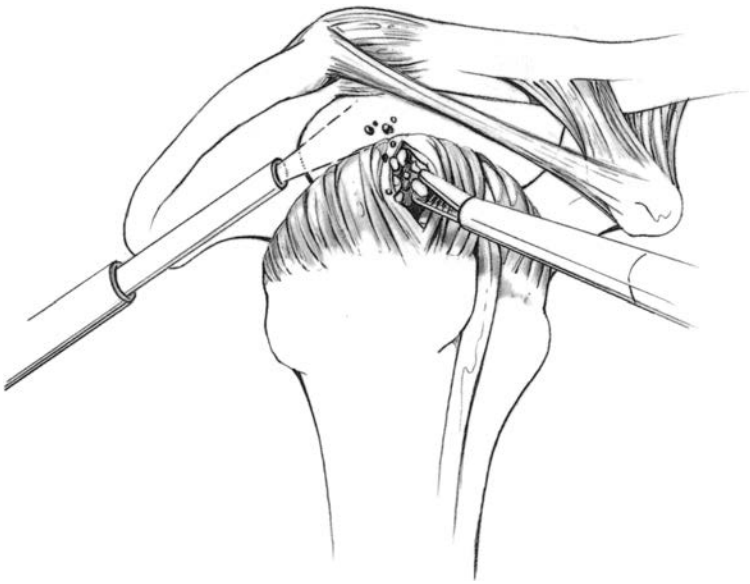

Figure 6-16 Arthroscopic approach to a calcific deposit within the tendon of the supraspinatus. The arthroscope is in the posterior portal, with the working instruments in the lateral portal. An anterior portal is created for outflow. A basket forceps or small curette placed in the lateral portal can be used to remove the calcific material.

be placed into a slight amount of extension to move the site of the deposit from under the acromion. Once this site is localized, then 20 to 30 mL of lidocaine is used to anesthetize the skin at a site that will allow directed needle penetration. Most commonly, this is at the anterolateral edge of the acromion. A local anesthetic is used to anesthetize the skin. The needle is then directed toward the deposit in the rotator cuff tendon. A small amount of local anesthetic is injected as the needle progresses toward the deposit, anesthetizing the entire path. Slowly progressing the tip of the needle may allow the physician to sense the resistance or roughness of the calcific material. Aspiration is attempted at this time, although this is difficult and often unsuccessful. A repeated needling or puncturing of the area containing the deposit is performed approximately five to 10 times. At the completion of the procedure, a corticosteroid injection accompanied with a long-acting anesthetic is placed into the subacromial space, not the tendon. The use of cortisone has not been associated with any adverse effects specific to the treatment of calcifying tendinitis. Patients are instructed to rest their shoulder for 1 to 2 days and then to gradually work on regaining their range of motion. Furthermore, they are provided with a prescription for either a nonsteroidal antiinflammatory medication or mild narcotic. Application of ice to the site of pain may also help alleviate their symptoms. Frequently, pain relief is dramatic, and the symptoms quickly dissipate. Although physical therapy may be necessary for patients who demonstrate shoulder stiffness, this is frequently not prescribed, for patients will return with close to a full range of motion and decreased pain within a few weeks, sometimes as quickly as a few days.

If the first attempt has been unsuccessful in alleviating symptoms, a second needling is performed. If a partial response was achieved, a second "blind" needling using the technique described is attempted in the office. However, if there was no response to the first needling, the second needling procedure is performed in the radiology suite with the assistance of fluoroscopy, or with the use of ultrasound if available, to accurately locate the deposit. After anesthetizing the skin and soft tissue along the path to the deposit, the deposit is directly needled, followed by an injection of a solution of anesthetic and cortisone into the subacromial space. In our experience, this treatment plan has been successful in resolving pain rapidly with generally a full return of shoulder function. Surgical intervention has been unnecessary for the treatment of acute symptoms associated with the normal resorptive phase of calcifying tendinitis.

Treatment during the formative stage, or resting stage, is based on the duration and severity of the symptoms, as well as the examination findings. Initial conservative measures include nonsteroidal antiinflammatory medications for pain relief. There is no evidence that these medications accelerate the disappearance of the calcium or positively affect the completion of the calcifying tendinitis cycle. When pain is under control, a daily program of stretching exercises will help maintain the mobility of the shoulder. Physical modalities, such as ice or heat, may be beneficial. Other physical modalities provided under the supervision of a therapist, such as ultrasound or diathermy, may have some short-term benefit by relieving pain, but again, these have not been proved effective in the resolution of this condition. The cost of these physical modalities is substantial and, therefore, the authors cannot recommend their use until some benefit is proved other than short-term pain relief.

Corticosteroid injections are recommended if the symptoms persist despite oral medications and therapy. Corticosteroids may be used initially in those patients with an intolerance or allergy to nonsteroidal antiinflammatory medications. There is no evidence that a corticosteroid injection will facilitate the resolution of the calcifying tendinitis cycle. Uhthoff and Sarkar have recommended against their routine use owing to the theoretical concern that the effect of corticosteroids may actually interrupt or delay the resorptive phase.[141] However, this concern has not been validated in a well-controlled study, and we have noted marked improvement in symptoms with one or two injections in those patients who have had symptomatic calcifying tendinitis for less than 6 months.

"Blind" needling of the calcific deposit during the formative stage is not recommended. These dense homogeneous deposits do not permit an easy release of the calcific material. Dual needling and lavage may be beneficial. To be successful, this technique requires fluoroscopic isolation and may also involve a regional or general anesthetic agent to relax the patient and permit the dual needling of the calcific deposit, followed by lavage. The goal of needling and lavage should be removal of as much of the deposit as possible. Following the procedure, a brief period of rest is recommended, along with nonsteroidal antiinflammatory medications or a mild narcotic for pain relief. Physical therapy is directed toward reestablishing normal shoulder motion, then progressing to recovery of shoulder function. Patients should be forewarned that even successful recovery from this procedure is extended, often lasting 3 to 6 months.

Patients who have had chronic symptoms for more than 6 months with radiographic evidence of calcifying tendinitis meet the appropriate criteria for surgical intervention. Imaging of the rotator cuff tendon is also recommended if surgical intervention is contemplated. Although we have rarely seen evidence of true tendinopathy, such as a significant partial-thickness or full-thickness tearing of the rotator cuff, others have reported an incidence of approximately 4% in this patient population.[88] Furthermore, two studies from the same institution in Taiwan suggested a significantly higher incidence of rotator cuff tearing in older patients and in patients with Asian heritage presenting with long-standing calcifying tendinitis in the formative

phase.[53,56] Knowledge of a significant tendinopathy will enable better preoperative planning for the patient and the surgeon.

We prefer an arthroscopic approach to the surgical treatment of calcifying tendinitis. Arthroscopy permits localization of the deposit and removal of the contents of the deposit, while minimizing injury to the unaffected tissues. We have also incorporated a side-to-side repair of the rotator cuff defect when the removed calcific deposit left a substantial defect in the tendon. In our opinion, an acromioplasty is rarely necessary. However, an acromioplasty may be indicated when significant clinical or arthroscopic findings of impingement are present. Furthermore, an acromioplasty appears to be beneficial when the calcific deposit cannot be localized owing to a poorly circumscribed lesion, usually seen as a type C calcification pattern on preoperative radiographs. Although arthroscopic techniques are preferred, open procedures performed through a split in the deltoid tendon without detaching the anterior acromion attachment of the deltoid origin are equally effective for localization of the deposit and removal of the contents. Both surgical procedures are performed on an outpatient basis, and patients are started on an early range-of-motion program. Postoperative corticosteroid injections have not been indicated.

Open Surgical Technique

Exposure of the involved rotator cuff tendon depends on its location. Most rotator cuff calcifications will be within the substance of the supraspinatus tendon. This tendon is readily approachable through a split in the deltoid muscle centered at the anterolateral edge of the acromion. Regional anesthesia, general anesthesia, or a combination of the two techniques can be used for the surgical procedure. A long-acting local anesthetic is injected at the surgical site. The use of local anesthesia alone has been described, but is not recommended. An incision is made in Langer's lines from the lateral corner of the acromion toward the coracoid process. The deltoid raphe is identified perpendicular to this skin incision. Dissection is carried through the anterolateral deltoid raphe, beginning at the acromion and progressing inferiorly. The fibers are split and separated by self-retaining retractors. Three centimeters of exposure provides a generous approach to the supraspinatus tendon without risk of injuring the innervation of the anterior deltoid. The patient is positioned in the beach-chair position for the surgical procedure.

Once the split in the deltoid tendon is made, the overlying bursa is incised to expose the rotator cuff tendon. A partial bursectomy is performed to have adequate visualization of the rotator cuff tendon. When locating the deposit, the most significant intraoperative landmark is the biceps tendon. In general, a supraspinatus calcific deposit will be approximately 1 cm posterior to the biceps tendon and approximately 1.5 cm from the attachment site of the supraspinatus tendon on the greater tuberosity. Once the site of the calcific deposit is identified, either by direct visualization, palpation, or estimation from the preoperative radiographs and intraarticular landmarks, an incision is made at the site of the calcific deposit in line with the fibers of the rotator cuff tendon. The calcium is exposed, irrigated, and then débrided with a curette to remove as much of the calcific deposit as possible. Although it is not necessary to completely remove all of the calcium, it does appear to be beneficial to remove as much of the contents as possible to decrease the intratendinous pressure, the thickness of the tendon, and the risk for an acute inflammatory reaction to remaining calcific debris. If a significant amount of the tendon appears to be involved, side-to-side repair of the tendon edges with absorbable sutures can be performed, but the benefit is unclear. At the completion of the removal of the calcific deposit, the subacromial space is irrigated thoroughly. The deltoid is closed with a side-to-side repair using absorbable sutures. The skin is closed with a running subcuticular closure supported with small adhesive strips. Patients are allowed range of motion as tolerated. Sutures are removed within 5 to 7 days. If the patient has difficulty regaining range of motion, a supervised therapy program may be initiated. Recurrence of the calcific deposit does not occur, although some of the deposit may persist after surgery. Patients may exhibit a prolonged course of recovery, taking 3 to 6 months to regain their motion, strength, and function.

Arthroscopic Technique

Preoperative assessment with radiographs including an anteroposterior view of the humerus in neutral rotation, external rotation, and internal rotation is essential to predict the site of the calcific deposit. Anesthesia can be delivered through a regional interscalene block, a general anesthetic agent, or a combination of the two. We prefer a beach-chair position, but a lateral decubitus position with a gentle amount of traction on the arm is also effective. In the lateral position, the arm is placed at approximately 20 degrees of abduction with slight forward flexion. Approximately 10 lb (4.5 kg) of traction are used for smaller patients, 15 lb (6.8 kg) for larger patients.

The glenohumeral joint inspection is carried out in a systematic fashion. Partial-thickness and full-thickness rotator cuff tears have been seen with calcifying tendinitis and can be evaluated with standard arthroscopic techniques. Marking the deposit is possible if the area of involvement can be identified from the glenohumeral joint. An 18-gauge spinal needle is passed through the skin, into the area of the deposit, then into the glenohumeral joint while the arthroscope is maintained in the glenohumeral joint. A stiff synthetic suture is then passed through the needle into the glenohumeral joint and a grasper is used to pull the suture

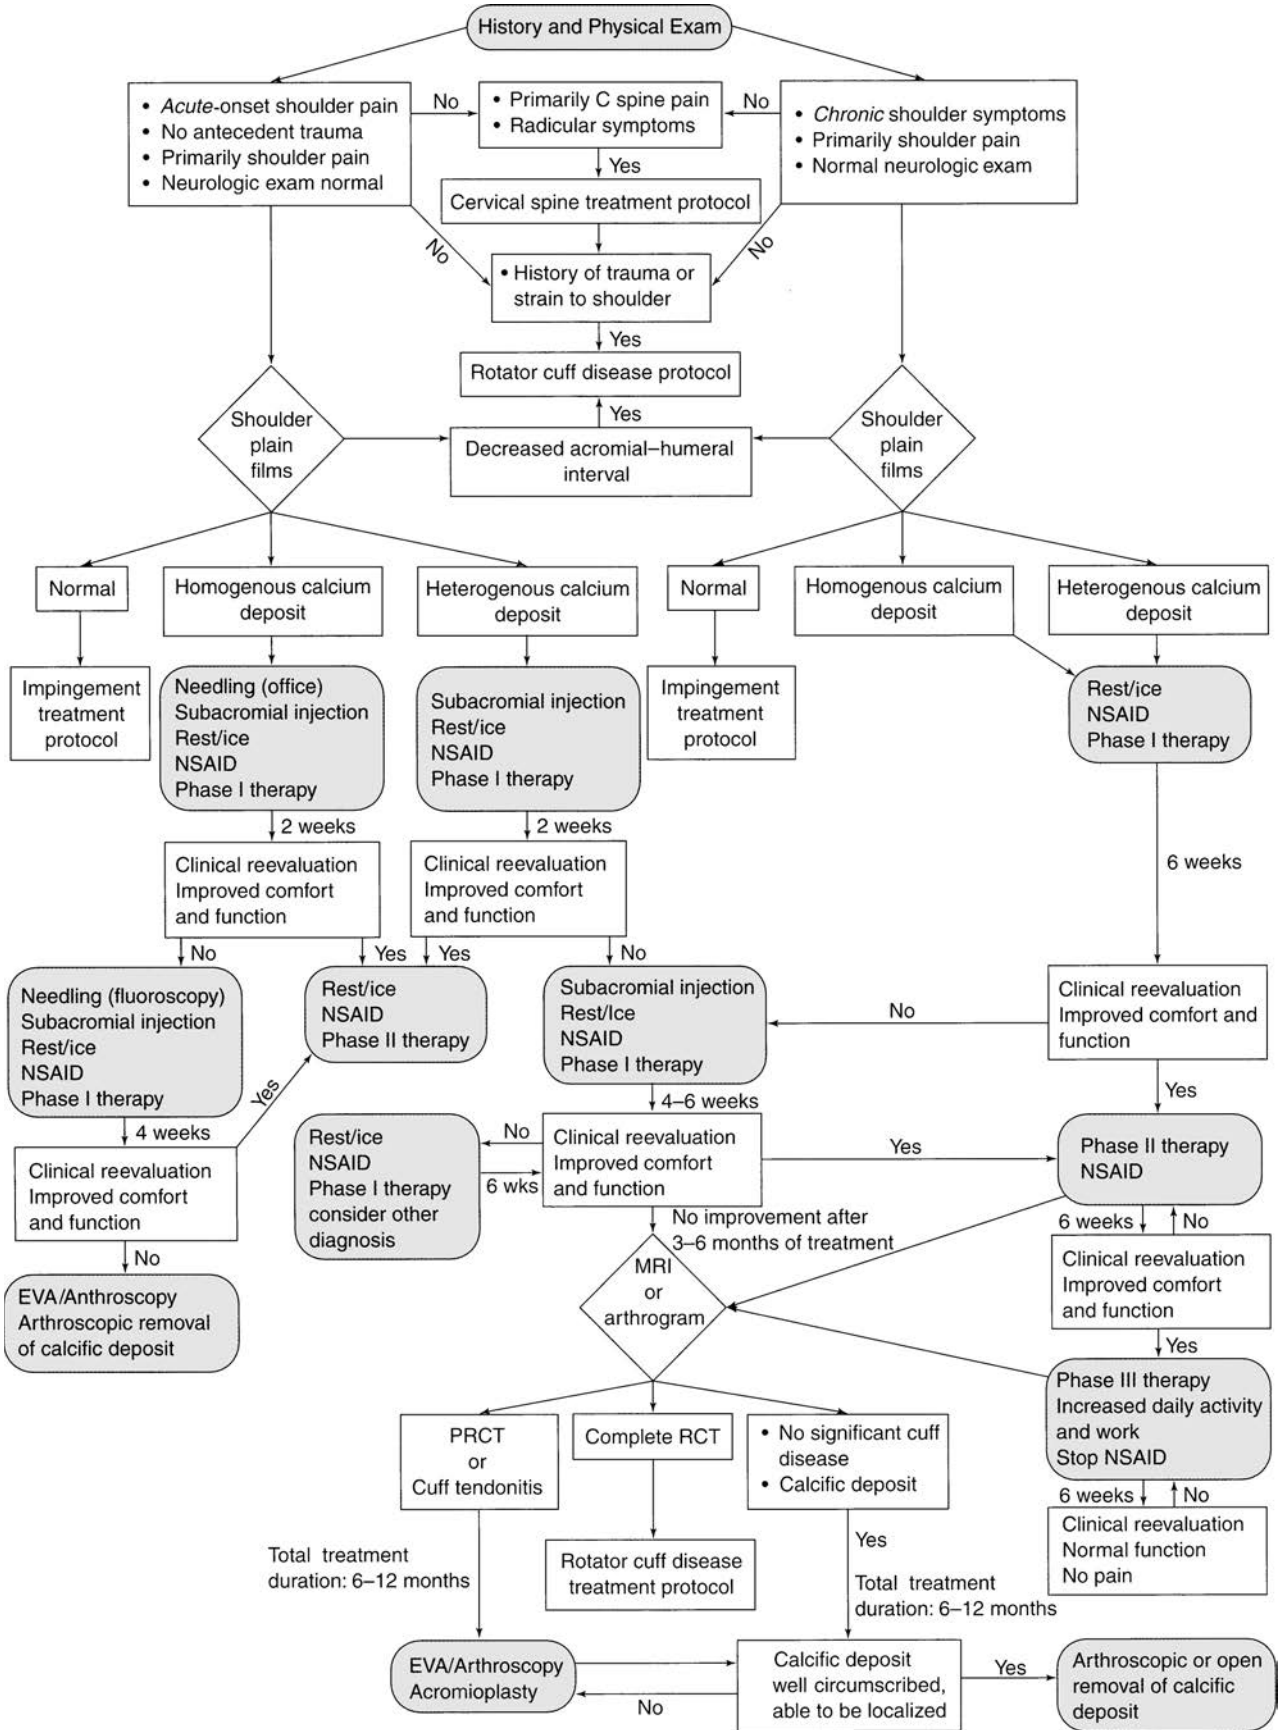

Figure 6-17 Algorithm for evaluation and treatment of calcifying tendinitis. EVA, ; MRI, magnetic resonance imaging; NSAID, nonsteroidal antiinflammatory drug; PRCT, partial rotator cuff tear; RCT, rotator cuff tear.

out of the anterior portal. This technique is also used to mark partial-thickness rotator cuff tears for later inspection from the subacromial space.

Once the subacromial space has been established and is acceptable, which often includes removing some of the bursa, the examination of the subacromial space also proceeds in a systematic fashion. In addition to evaluating the coracoacromial ligament and undersurface of the acromion, careful inspection of the rotator cuff tendon is necessary. Once the site of the calcific deposit is located, it is generally necessary to establish a third lateral portal for a direct approach to the calcific deposit. Once the calcific deposit has been clearly visualized, a no. 11 blade on a long-handled knife, an arthroscopic blade, or an 18-gauge needle can be advanced through the lateral portal. The supraspinatus tendon is incised in line with its fibers to expose the calcific material. Visualization is maintained using an arthroscopic pump. Once the calcific deposit has been incised and some of the material removed, a curette can be advanced through the lateral portal to débride the remaining contents of the deposit (Fig. 6-17). An arthroscopic power shaver is not recommended because inadvertent removal of some of the normal tendon is likely. A hooded shaver may be beneficial without risking injury to the remaining intact tendon. The shoulder should be irrigated thoroughly and exchange of fluid should be rapid to maximize removal of the calcific material. We have also incorporated a side-to-side repair of the rotator cuff defect when the removed calcific deposit left a substantial defect in the tendon. The skin is closed with an interrupted suture closure of the portals. Patients are allowed range of motion as tolerated. Sutures are removed within 5 to 7 days. If the patient has difficulty regaining range of motion, a supervised therapy program may be initiated. Recurrence of the calcific deposit does not occur, although some of the deposit may persist after surgery.

If the calcific deposit is indistinct or cannot be localized, an arthroscopic acromioplasty is advised. The benefit of the acromioplasty appears to be related to the decompression or widening of the subacromial space, decreasing the mechanical irritation of the rotator cuff tendon. There may also be underlying physiologic changes, such as decreased tendon pressure and improved blood flow, that may allow tendon healing or simply the resolution of pain. The need for an acromioplasty may be predicted from the preoperative radiographs. An inhomogeneous, poorly circumscribed lesion associated with chronic symptoms suggests a stop in the normal cycle of calcifying tendinitis. The calcific material is within the tendon fibers, but not readily accessible; therefore, it cannot be directly addressed with surgical removal. In our opinion, a well-performed arthroscopic acromioplasty in this setting has distinct clinical advantages over a traditional open acromioplasty.

SUMMARY

The key to successful treatment of calcifying tendinitis is a complete understanding of the pathophysiology of this disease. Calcifying tendinitis tends to follow a characteristic disease cycle in most patients. The cycle includes the formation of the calcific deposit, the resorption of the deposit, and then tendon restoration. Some patients demonstrate findings that suggest an aborted cycle, with chronic symptoms and radiographic evidence of persistent calcific material or incomplete resorption. However, clinical characteristics and cadaveric studies suggest that resorption of the deposit always occurs, even though the resorption may occur over many years.

Calcifying tendinitis is a condition of unknown cause, although it is understood that the calcium deposition is a cell-mediated process that occurs in nondegenerative rotator cuff tendons. The epidemiology of this disease is the same despite various physiologic, clinical, and radiographic stages. Understanding the pathology and then combining this understanding with the presenting clinical and radiographic features enable one to formulate successful treatment strategies.

Treatment options are numerous, but the most successful strategies have included decompression of the calcific deposit. During the acute hyperalgesic stage, consistent with the resorptive phase, pain relief is the primary goal. This can be rapidly accomplished by needling the calcific deposit without interrupting the natural resolution of the resorptive phase. Chronic symptoms are more difficult to treat, and they may require direct surgical intervention. The primary goal of surgery is the decompression and removal of the calcific material without causing undue harm to tissues not involved in the disease process. Arthroscopic decompression and removal of the deposit offers an accurate and effective approach for this condition. When symptoms persist despite the absence of a homogeneous, well-circumscribed lesion, an acromioplasty is beneficial in the treatment of the persistent tendinopathy, although the postoperative recovery is longer than expected. In the future, a better understanding of the cause and the cellular signals that trigger the resorptive process may permit better medical management of this condition.

SUMMARY 257

INTRODUCTION

The clinical significance of the long head of the biceps tendon to shoulder function has been a subject of controversy for some time. Opinions on the contribution of the intraarticular biceps tendon have varied the entire spectrum, with proponents suggesting a vestigial function analogous to an "appendix of the shoulder" to those who believe it can play a critical role in shoulder stability. Historically, there have been wide shifts in surgical treatment of the long head of the biceps tendon. In the 1940s, the biceps tendon was seen as a major source of shoulder pain and tenodesis favored as a primary procedure.[33,50,90] As the focus shifted to the rotator cuff, tenodesis of the long head of the biceps became less popular. Later, concerns regarding a possible secondary role of the long head of the biceps tendon led to recommendations for preservation whenever possible.[81,95,115] More recently, previously accepted theories on the functional role of the biceps in head depression have undergone reexamination in the context of an increased awareness about the symptomatic significance of a retained, chronically inflamed tendon.[12,97,110,137]

With the accumulation of research and clinical experience specific to the long head of the biceps tendon, it is becoming increasingly accepted that pathology in this structure can have significant symptomatic consequences that will require directed treatment plans. As with most controversial treatment issues, the proper strategy will ultimately reflect a balance of previously recognized concerns about functional deficits and persistent symptoms. The purpose of this chapter is to review the anatomic, functional, and clinical information about the long head of the biceps tendon required to formulate logical treatment plans.

ANATOMY

The long head of the biceps tendon arises from the posterosuperior labrum and the supraglenoid tubercle. The site of origin of the long head has been shown to be variable. Habermeyer et al. described the long head origin in the majority of cases (50%) as being completely labral. Attachment to the supraglenoid tubercle alone was less common (20%); the tendon more commonly (30%) arose from both origins, sometimes appearing bifurcated.[54] Another study of the origin of the tendon of the long head of the biceps in 105 cadaveric shoulders showed that 40% to 60% arose from the supraglenoid tubercle and surrounding labrum.[130] The rest of the origins were from labrum alone. The labral attachment has been further described as being in four types: type I, the labral attachment being entirely posterior (22%); type II, most of the labral contribution being posterior with some anterior component (33%); type III, equal contributions from both the anterior and posterior labra (37%); and type IV, with most of the contribution being anterior (8%)[130] (Fig. 7-1). Additionally, the orientation of the tendon attachment to the superior glenoid tubercle was dependent on the type of labral attachment. In those biceps tendons with a mostly posterior labral attachment, the superior glenoid tubercle origin was more likely to be posterior at a 1 o'clock position for a left glenoid. In those situations with an anterior labral attachment, the glenoid tubercle origin was more likely to be slightly anterior at an 11 o'clock orientation for a left glenoid.

The relative biomechanical contributions of the supraglenoid and labral attachments of the biceps origin have been investigated by Healey et al.[63] This cadaveric study focused on the effect of selective release of the long head of biceps origins on the linear stiffness and displacement of the biceps tendon. In all specimens, release of the bony anchor resulted in significantly greater displacement of the biceps tendon in comparison to release of the labral attachments. Isolated release of the bony anchor resulted in a 52% reduction of the stiffness of the biceps tendon in comparison to a 15% decline in stiffness observed with isolated release of the superior labrum.

The tendon is encased within the synovial sheath of the glenohumeral joint (Fig. 7-2). It traverses obliquely within the shoulder joint arching anteriorly over the head of the humerus and exits the shoulder joint beneath the transverse humeral ligament along the intertubercular sulcus, also referred to as the bicipital groove (Fig. 7-3). Open only at the glenohumeral cavity medially, the synovial sheath ends as a blind pouch at the end of the bicipital groove (see Fig. 7-2). In 50 cadaveric dissections, Habermeyer and coauthors found the mean length of the tendon to be 9.2 cm.[54,56] The tendon was widest at its origin (mean 8.5×2.8 mm) and progressively narrowed down to form the muscle belly (mean 4.5×2.8 mm). At the level of the insertion of the deltoid, the tendon evolves into an elongated muscle belly joined medially by the short head. The two bellies lie closely approximated but are separable until about 7 cm from the elbow joint.

The ascending branch of the anterior humeral circumflex artery runs adjacent to the tendon and is the main arterial supply to the long head in the bicipital groove. Labral branches of the suprascapular artery may also contribute to the blood supply of the long head of the biceps tendon at its origin.[30,113] The musculocutaneous nerve (C5–7) constitutes the motor innervation to the muscle.

RESTRAINTS OF THE LONG HEAD OF THE BICEPS TENDON

While the greater and lesser tuberosities help to contain the tendon within the bicipital groove, retention of the long head of the biceps is mainly provided for by the surrounding soft tissues.

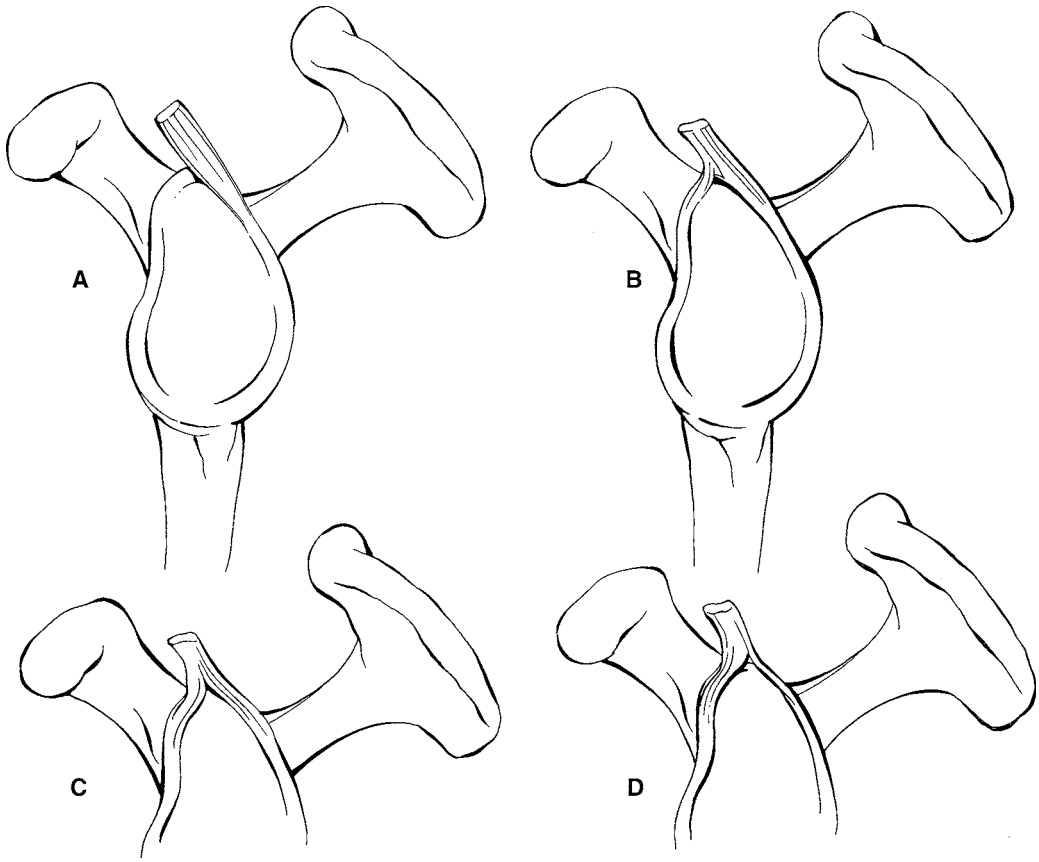

Figure 7-1 Schematic drawings of the variations in the biceps origin. **A.** Type I. The labral attachment is almost entirely posterior. This is seen 22% of the time. **B.** Type II. Most of the labral contribution is posterior with a small amount of anterior contribution. This is seen 33% of the time. **C.** Type III. There are equal contributions from both the anterior and posterior labra, and this is seen 37% of the time. **D.** Type IV. Most of the labral contribution is anterior with only a small posterior contribution, and this is seen 8% of the time.

The bicipital groove is hourglass shaped, being narrowest and deepest in its midportion. With a mean width of 9.6 mm and depth of 2.2 mm, it is wide and shallow at its entrance. The mean measurements at the midportion are 6.2 mm wide and 5.0 mm deep. The tunnel flattens out at its exit, 7.3 mm wide and 2.4 mm deep.[54,56] The medial wall angle varies widely among individuals, with reported mean values from 56 degrees to 64 degrees.[65] Although the humeral head size is larger in men, there is no significant difference between the two sexes in the relative size of the groove.[5] In some cases, a "supratubercular ridge" extends forward and downward from the region of the articular cartilage to the upper and dorsal portion of the lesser tuberosity. First described by Meyer, it is estimated to occur in 17.5% of humeri.[88,89] The significance of the supratubercular ridge is unclear; but according to Meyer, it diminishes the efficacy of the tuberosity as a trochlea, and when present can predispose to dislocation of the long head of the biceps tendon out of the groove.

Pfahler and coauthors investigated the bony anatomy of the biceps tendon radiographically, comparing differences in anatomy between patients diagnosed with anterior shoulder pain versus normal controls.[109] Radiographs of the bicipital groove were obtained to define the dimensions of the groove and to assess for local degenerative changes. A significant variation in the medial opening angle of the biceps groove was noted in all subjects, average 44 degrees, with a range of 9 to 74 degrees. The presence of degenerative radiographic changes in the biceps groove was noted in 44% of patients with ultrasound-proven biceps pathology. The authors were able to correlate specific anatomic variations in the bony anatomy of the biceps groove that correlated with pathologic changes of the biceps tendon on ultrasound. Compared with the control group, a flat biceps groove and a small medial opening angle were associated with ultrasonic abnormalities of the biceps tendon.

Laterally, the long head of the biceps tendon runs in the rotator interval. This triangular space between the supraspinatus and the subscapularis tendons is devoid of rotator cuff and bridged by fibrous tissue. The transverse humeral ligament bridging the bicipital groove forms the

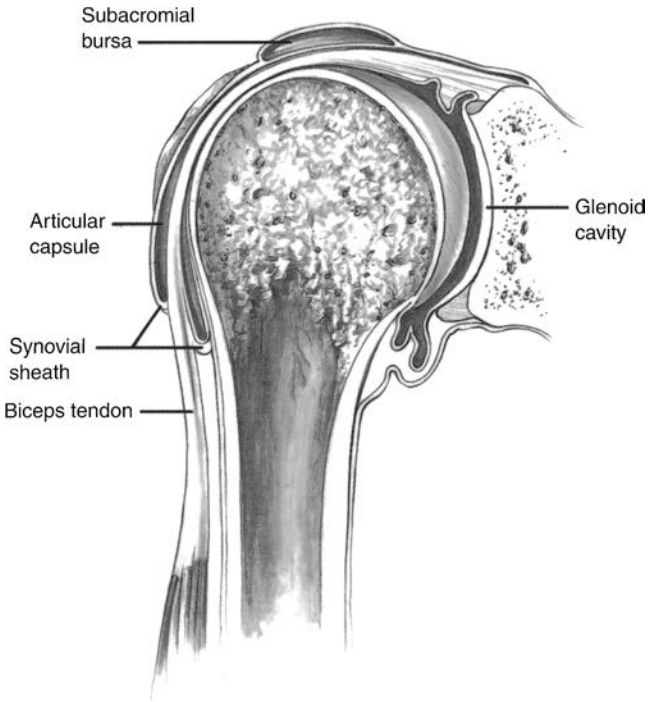

Figure 7-2 A schematic of a sagittal section taken through the glenohumeral joint. The biceps tendon is covered by reflection of the synovial sheath, which maintains a tendon as an extra synovial structure despite its intraarticular location. The synovial sheath ends as a blind path distally outside of the bicipital groove.

Figure 7-3 A schematic of an axial view of the glenohumeral joint showing the relative position of the biceps tendon from internal to external rotation. In internal or neutral rotation, the biceps maintains an oblique course across the joint starting from an anterior location. It is only in external rotation that the biceps tendon courses over the apex of the humeral head.

apex of the triangle laterally. The coracoid process with the origin of the coracohumeral ligament medially constitutes the base. The coracohumeral ligament has a broad origin extending from the base of the coracoid process along the lateral border of the coracoid for about 18 mm[61] and forms the roof of the space. Located in the floor are the long head of the biceps and the superior glenohumeral ligaments (Fig. 7-4).[26,27,49,56]

Most authors agree that the transverse humeral ligament bridging the bicipital groove does not play an important role in retaining the biceps tendon.[1,56,88,89,107] The ligament is often weak or absent and is present lower down in the bicipital groove. Rather, the coracohumeral ligament is believed to be more important. It consists of two bands, the superior band blending into the adjacent tendinous edge of the supraspinatus and inserting into the greater tuberosity.[26,27,38,56] The inferior band blends with the superior border of the subscapularis and inserts into the lesser tuberosity and the transverse humeral ligament. The superior glenohumeral ligament is also important for biceps tendon retention within the groove. It has two narrow osseous attachments medially. One attachment is from the apex of the labrum, shared with the biceps tendon, and the other is from the base of the coracoid process.[129] While distinct from the coracohumeral ligament at its medial attachment to the superior labrum and the neck of the scapula, the superior glenohumeral ligament blends imperceptibly with the coracohumeral ligament laterally at its insertion into the superior surface of the lesser tuberosity.[27] Thus, in the lateral part of the rotator interval, at the proximal portion of the bicipital groove, the roof and the floor blend to form a sling for the biceps tendon as it enters the bicipital groove.

Werner et al. studied the macroscopic and microscopic anatomy of the rotator interval in reference to the constituents of the biceps sling.[135] Cadaveric sections of the lateral portion of the rotator interval showed the superior glenohumeral ligament to form a U-shaped fold crossing under the biceps tendon before inserting into the proximal aspect of the intertubercular groove. The superior glenohumeral ligament appeared to form a semicircular anterior support for the lateral part of the biceps tendon. Microscopic analysis demonstrated that fibers of the superior glenohumeral ligament covered the inferior, anterior, and superior aspects of the biceps tendon with a collagen fiber orientation perpendicular toward the tendon. These authors emphasized the importance of the superior glenohumeral ligament in stability of the long head of the biceps within the rotator interval.

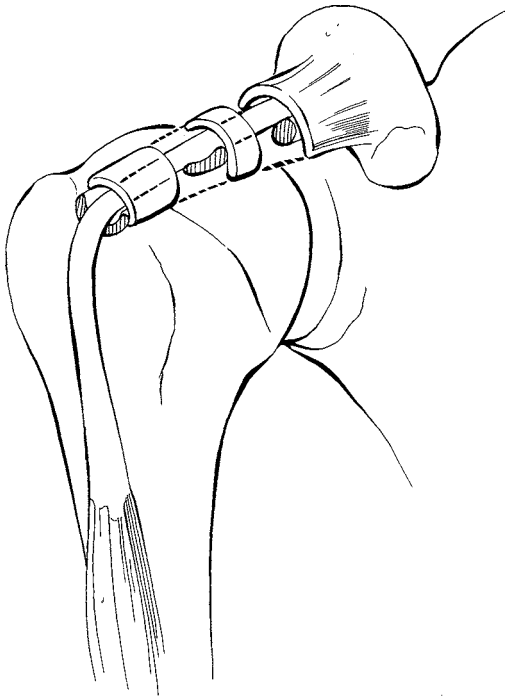

Figure 7-4 A schematic representation of the relationship of the coracohumeral ligament and superior glenohumeral ligament to the long head of the biceps tendon. The long head of the biceps tendon is stabilized in the bicipital groove by the coracohumeral ligament (*black*), which forms the roof, and the superior glenohumeral ligament (*hatched*), which forms the floor.

Distal to the summits of the greater and lesser tuberosities, it is the insertion of the pectoralis major tendon that appears to be important in retention of the long head of the biceps.[1] The sternocostal portion of the pectoralis major tendon, constituting the deeper lamina, inserts more proximally in the humerus than the clavicular portion. A fibrous expansion arises from this head, forming a falciform margin at the deep edge of the tendon, is attached to both sides of the groove, and blends proximally with the capsule of the shoulder joint.

In the absence of pathologic changes in the restraining structures, there are certain anatomic features that may predispose dislocation of the tendon of the long head of the biceps. These include (a) that the intraarticular portion of the tendon may lie more eccentrically over the anterior half of the sloping, smooth, rounded surface of the humeral head, favoring its medial dislocation; (b) a more widened and flattened tendon origin at the superior glenoid; (c) a shallow medial wall of the groove, which would not provide as significant a restraint to medial subluxation of the tendon as the tendon of the long head of the biceps makes an abrupt turn from a horizontal direction to a vertical course at the intertubercular sulcus (the lesser tuberosity acts as the "trochlea" for the tendon at this point); and (d) that the supracondylar ridge, when present, diminishes the prominence of the lesser tuberosity, decreasing its efficacy as a trochlea.[50,88]

FUNCTIONAL ANATOMY OF THE LONG HEAD

Perhaps no aspect of the long head of the biceps tendon has raised as much controversy as its function at the shoulder. The biceps extends from the scapula to the bones of the forearm and thus has potential function at both the shoulder and elbow. Elbow function has been well established to include both flexion and supination. The actions of the proximal tendon around the shoulder have been incompletely defined. Although the long head of the biceps has been postulated to have several roles or functions about the shoulder, definitive experimental proof has been sparse and contradictory, leaving its exact role as controversial.

More complete characterization of the functional role of the long head of the biceps can be clinically important in determining indications for tenodesis. Some reports have suggested a weak humeral head depressor role that increases in relative importance in the presence of rotator cuff tears. Other studies have suggested the long head of the biceps to work solely in relation to the elbow with no significant shoulder-related activity. Neer warned against thoughtless tenodesis of the long head of the biceps because it "destroys its function as a head depressor and may precipitate or escalate an impingement problem."[95] Leffert and Rowe offered the observation that increased size of the tendon with chronic rotator cuff rupture represented increased function compensating for the loss of the rotator cuff and strongly discouraged tenodesis.[81] However, this phenomenon has been seen only with large rotator cuff tears where the tendon was exposed to constant impingement and more plausibly reflected a chronic inflammatory response. Additionally, the more physiologic response of increased muscle mass as opposed to increased tendon size has not been noted. Aside from clinical observations, there have been several approaches employed to study the potential function of the biceps tendon. These include comparative anatomy observations, cadaveric biomechanical studies, and dynamic electromyographic analysis.

Comparative Anatomy

The asymmetrical size of the greater and lesser tuberosities and the angular orientation of the bicipital groove are exclusive to the human shoulder and represent an evolutionary adaptation to the vertical posture. The presence of two heads is unique to primates. In certain quadrupeds such as the horse, which does not have a deltoid muscle, this head is large and functions to elevate the extremity in conjunction with a comparatively large supraspinatus.[67] In quadrupeds the biceps passes over the center of the spherical humeral head in the bicipital groove, which is located between two symmetrical tuberosities and oriented perpendicular to the glenoid. As the scapula and

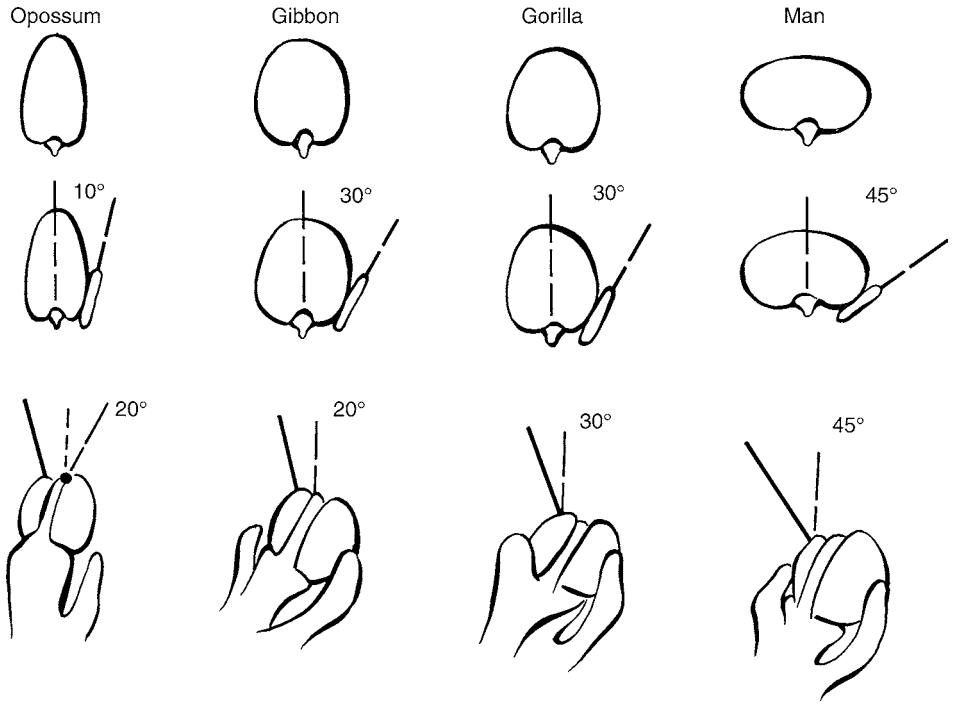

Figure 7-5 A schematic showing progressive change in positioning of the scapula and bicipital groove from the quadruped to the biped. As an adaptation upright posture, the anterior–posterior dimension of the chest wall has decreased progressively. This has resulted in secondary humeral torsion and a displacement of the bicipital groove medially and ventrally in relation to the scapula. Whereas the bicipital groove follows a straight course over the top of the humeral head in the quadruped (opossum), in man it now resides against the lesser tuberosity over the anterior portion of the head. This has resulted in a significant decrease in effectiveness of the biceps to act as an arm elevator.

glenoid face is oriented toward the forward plane, the biceps tendon in quadruped animals contributes to flexion of the shoulder.

In adaptation to an upright posture, the anteroposterior diameter of the chest wall has decreased progressively, and the scapula has rotated dorsally over the flattened chest wall.[65] To allow the articular surface of the humerus, which previously faced dorsally, to continue facing the scapula, the humeral shaft has undergone torsion. This has resulted in a displacement of the bicipital groove medially and ventrally to form an angle of 30 to 40 degrees with the plane of the scapula (Fig. 7-5). This developmental change in the tendon orientation to the glenoid has resulted in a significant decrease in effectiveness of the biceps as an arm elevator, which can only be partially restored with full external rotation of the arm. There has been a compensatory developmental adaptation by the deltoid muscle, which becomes a much more effective elevator in primates secondary to its more distal insertion, increased muscle mass, and adaptations of the acromion to increase the leverage of the muscle.[66]

Hitchcock and Bechtol studied the anatomy of the bicipital tuberosity in 100 dry human specimens and compared them to primate humeri from the Chicago Natural History Museum.[65] The human specimens demonstrated a wide variation in the depth of the bicipital groove. This was expressed as the angle of the medial wall, a smaller angle representing a shallow wide groove. While the majority of human specimens demonstrated a medial wall angle of 60 to 75 degrees, values of 45 degrees or less were observed in 20% of specimens. Except the orangutan (a primate with greater predisposition to tree climbing), who presented values similar to humans, other apes demonstrated deep bicipital grooves with consistent medial wall angles of 90 degrees in all specimens. The shallow bicipital groove in humans was postulated to be important for the development of instability and subsequent inflammation of the long head of the biceps.[65] The considerable variability of the biceps groove was considered to reflect a developmental loss of function in elevation for the biceps muscle. These authors also noted the relative ventral orientation of the long head of the biceps in relation to other mammals. Additionally, they emphasized that human beings will habitually hold their humerus in the forward plane and internal rotation, increasing the poor anatomic arrangement for the biceps to act in abduction. They concluded that an operation to fix the tendon in the bicipital groove, while removing a portion of the tendon above the groove, can relieve the symptoms caused by biceps tendon pathology and does not materially weaken the shoulder.[65]

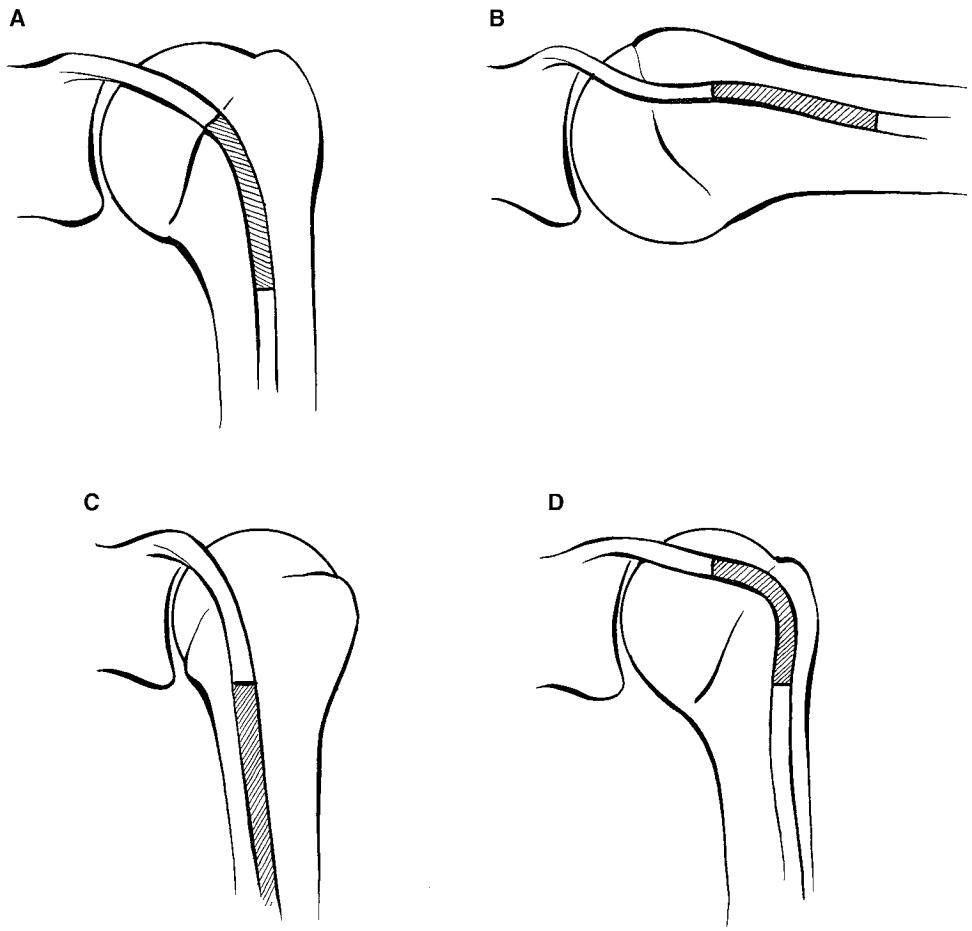

Figure 7-6 Schematic of the relationship of the biceps tendon to the humerus with glenohumeral motion. As described by Lippmann, with direct surgical observation, the biceps tendon played a passive role during humeral motion. The biceps tendon was found to slide freely between the sheath and the joint proper as the shoulder was moved. Varying amounts of the tendon were found to be intraarticular, dependent on shoulder position. A maximum of intraarticular tendon was seen with external rotation and adduction. A minimal amount of intraarticular tendon was present during elevation. **A.** Neutral rotation. **B.** Elevation. **C.** Internal rotation. **D.** External rotation.

Anatomic and Biomechanical Studies

Lippmann surgically observed in patients under local anesthesia that the long head of the biceps is a passive structure, sliding in its groove with movements of the shoulder[84] (Fig. 7-6). No motion was seen to be transmitted to the humeral head with long head of the biceps contractions during active elbow flexion. He believed the biceps played a minimal active role in producing motion at the shoulder joint. Rather, the humeral head was believed to passively move on the biceps tendon. This passive motion of the biceps tendon within the intertubercular groove has been found to be necessary for normal motion.[59] Biceps tendon adhesion within the bicipital groove either after injury, immobilization, inflammation, or incorporation of the tendon during tuberosity repairs was found to potentially limit the maximal recovery of motion. The shorter the intraarticular tendon length during adhesion is, the greater the motion restriction is. This was particularly evident if the adhesion occurred in internal rotation and adduction.

In contrast, by electrically stimulating the biceps muscle during shoulder arthroscopy in five cases, Andrews et al. observed that the tendon became taut and raised its origin at the superior labrum off the glenoid.[6] They also observed compression of the humeral head into the glenoid. The authors suggested that these compressive forces afford "stress protection" to the humerus during the act of throwing. They also suggested that sudden forceful transmission of contraction of the biceps on the superior labrum may be one mechanism for the development of superior labral anterior and posterior (SLAP) lesions.

Studies using simulated muscle contractions in freely hanging cadaveric specimens have been difficult to interpret because of difficulties in reproducing physiologic tension of the muscles around the shoulder. Extrapolation of the findings of these studies to the clinical situation has

been difficult. Kumar et al., in a cadaveric study of 15 dependent shoulder specimens, radiographically measured changes to the acromiohumeral interval when applying tension to the short and long heads of the biceps before and after division of the long head of the biceps.[79] There was no attempt to recreate contributions from the rotator cuff. An average decrease in the acromiohumeral interval by 15.5 mm was observed when the short head was tensed in the absence of an intact long head of the biceps. The authors suggested that a function of the long head of the biceps was to stabilize the humeral head on the glenoid during powerful elbow flexion and forearm supination by the biceps brachii. In this study, all recordings were performed with the arm by the side and the contribution of the biceps tendon in motion at the shoulder was not examined.

Flatow et al. studied possible restraints against superior humeral translation in a cadaveric model in which the long head of the biceps and rotator cuff muscle activity was simulated with a cable system.[42] Superior migration of the humeral head with abduction of the shoulder was then studied in the cuff-intact situation and with simulated tears of various sizes. Force along the biceps tendon restrained superior migration of the humeral head most significantly in the presence of a large rotator cuff defect.

Itoi et al., in two separate cadaveric studies, looked at the stabilizing function of the long head of the biceps.[67,68] In the first study, nine cadaveric specimens were tested in a hanging arm position in which the biceps was spring-loaded to simulate contractions.[68] In this model, with the biceps in the hanging arm position, anterior and posterior displacement was significantly decreased by long head of the biceps loading. Additionally, inferior displacement and external rotation was significantly decreased by long head loading. Interestingly, long head loading in this model produced small amounts of superior displacement of the shoulder. Similar to the study by Kumar et al., no attempt was made to recreate the actions of the rotator cuff. In the second study, biceps function was studied in simulated stable and unstable shoulders.[67] Again, anterior displacement of the head was significantly decreased by both the long head and short head loading when the arm was in 60 to 90 degrees of external rotation. It was concluded that the long head of the biceps and short head of the biceps have similar functions as anterior stabilizers of the glenohumeral joint when the arm is in abduction and external rotation, and that the stabilizing increases as shoulder stability decreases. Kuhn and coauthors, in studying the dynamic and ligamentous restraints to external rotation of the glenohumeral joint, also demonstrated that tension within the long head of the biceps contributed significant torsional resistance to external rotation at lower and midranges of glenohumeral abduction.[76]

Whereas previous authors have reported the long head of the biceps tendon to resist superior displacement of the humeral head, Soslowsky and coauthors found the biceps tendon to be an important stabilizer against inferior translation.[123] A cadaveric model was created looking at both the dynamic and static restraints to inferior translation of the humeral head in neutral abduction and the neutral or externally rotated positions. The influence of the magnitude of inferior translation on the stabilizing effects of the rotator cuff and biceps muscle and the glenohumeral ligaments was also studied. The long head of the biceps was found to be an important restraint against inferior translation of the humeral head independent of humeral rotation. The biceps tendon afforded more superior stability than the anterior and posterior rotator cuff and nearly equal resistance to inferior translation as the supraspinatus muscle.

A functional role for the long head of the biceps in anterior stability was also shown in a study by Rodosky et al.[116] In this study, performed in seven fresh frozen cadaveric shoulders, the biceps was tested in the context of simulated rotator cuff contractions by use of pneumonic cylinders. In this dynamic model, simulated contractions of the biceps muscle were shown to contribute to anterior stability of the glenohumeral joint by increasing the shoulder's resistance to torsional forces. This was particularly apparent in the vulnerable abducted and externally rotated position.

Pagnani, in a study of 10 cadaveric shoulders, also tested the effect of simulated contraction of the long head of the biceps on glenohumeral translation.[104] In the presence of a joint-reactive force of 22 N, a 50 N anterior, posterior, superior, and inferior force was resisted in part by contraction of the long head of the biceps. This was more pronounced at middle and lower elevation angles. The reduction in anterior translation was by 10.4 mm. There was only a 1.2-mm reduction in superior translation.

Interpretation of these cadaveric studies has been difficult because of an inability to reproduce the dynamic interplay and bulk effect of surrounding musculature. The dynamic forces implemented in most study designs have not been validated against actual in vivo muscles forces, which remain difficult to quantify. However, one in vivo analysis of the role of the long head of the biceps has been performed by Warner and McMahon.[133] In this study, performed in seven patients with isolated loss of the proximal tendon of the long head of the biceps, superior migration of the instant center of rotation of the humeral head was measured at 0, 45, 90 and 120 degrees of humeral abduction in the scapular plane. A significant increase in the superior translation was measured in comparison to the contralateral uninvolved side. The amount of the superior translation, however, was small, and the authors concluded that they may be more important in conditions where the acromial arch was more narrow, such as in patients with a type II or type III acromion.

Electromyographic Analysis Studies

Interpretation of cadaveric studies of the long head of the biceps muscle requires relevant electromyographic analysis

to predict the quality of applied loads. A consistent but potentially inaccurate assumption with all of these studies has been the inclusion of significant biceps muscle activity associated with shoulder motion. Multiple studies have attempted to evaluate biceps muscle function during shoulder motion through the use of electromyographic analysis. Electromyographic analysis has a significant advantage over cadaveric studies by allowing for an in vivo observation of potential long head of the biceps function.

With the use of electromyographic data gathering, some studies have suggested a biceps role in shoulder stabilization. Ting et al., in a study of five patients with unilateral rotator cuff tears, showed increased biceps activity on the ipsilateral side in comparison to contralateral controls.[128] Additionally, Jobe et al., in a study of baseball pitchers with symptoms consistent with instability, showed increased biceps activity in comparison to stable controls.[69] In a similar study, Basmajian and Latif noted activity in the long head of the biceps upon shoulder abduction only with an externally rotated and supinated forearm.[7] They concluded that the primary action of the biceps was at the elbow for flexion of the supinated forearm, the activity in the tendon diminishing with forearm pronation. The biceps tendon was also active with forearm supination with the elbow flexed or supination against resistance. The actions of the long and short heads of the biceps were similar, but the long head was generally more active.

Some electromyographic (EMG) studies of healthy subjects have shown significant activity of the biceps muscle with various shoulder tasks. Habermeyer et al. observed EMG activity in the biceps with shoulder abduction from 90 to 166 degrees, peaking at 132 degrees.[54] Upon flexion of the shoulder, EMG activity was recorded in the biceps from 0 to 164 degrees, peaking at 84 degrees. Lesser activity was recorded with other shoulder movements, with no activity observed in internal rotation. Goro and coauthors studied the EMG activity of the long and short heads of the biceps during various ranges of shoulder flexion and abduction combined with humeral rotation.[52] The forearm was braced in neutral rotation but the elbow was left free. Twenty-four different arm positions were analyzed while the healthy subjects generated 30% maximal voluntary contractions. Both heads of the biceps were found to be active during flexion and abduction tasks, with relatively greater activity at higher ranges of elevation (45 vs. 135 degrees reached statistical significance). In addition, increased biceps activity was seen when external rotation was combined with elevation in either plane.

In contrast, several EMG studies have shown the biceps to be active only during elbow motion. Furlani, in 30 healthy shoulders, showed the biceps to be completely inactive with abduction and elbow extension.[44] Only one subject showed slight activity in abduction with elbow flexion. When the shoulder was abducted against a significant load, only 3 of the 30 subjects showed some activity, and two of these subjects were considered "tense." Pauly et al., in a study of 18 volunteers, showed no significant biceps activity with shoulder abduction or rotation in any subject.[105] Gowan et al., in an EMG study of the shoulder during pitching, showed the biceps acting primarily in late cocking.[53] Moderate activity in the biceps was noted with elbow flexion in the cocking phase, reaching an intensity of about 34% of a maximal manual muscle test. With the elbow position relatively stable during the acceleration phase, the intensity of biceps action diminished to less than 25%. Peak activity in the biceps tendon was recorded during the follow-through phase, the muscle contracting to decelerate the rapidly extending elbow. Based on their findings, they concluded that the biceps acts in concert with the brachialis and triceps to control the elbow with no significant effect at the shoulder during the throwing action.

As the biceps muscle traverses two joints, interpretation of previous EMG studies has been difficult because no attempt was made to control for elbow-related actions. Yamaguchi et al., in a study of 44 shoulders, including 14 with rotator cuff tears, showed no significant shoulder-related activity of the biceps muscle when elbow function was controlled for with the use of a brace[137] (Fig. 7-7). Biceps levels remained relatively flat throughout various shoulder motions and were insignificant compared to supraspinatus levels, which increased in a motion-specific fashion. Brachioradialis controls were similarly minimal and mirrored biceps activity patterns, suggesting that any biceps activity was either background or elbow-related. No significant increase was seen in patients with rotator cuff tears. In contrast, supraspinatus activity levels showed significant increase in the presence of rotator cuff tears. The results of this study were further substantiated by Levy et al. in a study of 10 shoulders controlled for elbow motion.[82] In this study, fast and slow motions as well as loaded and unloaded shoulder motions were tested for the presence or absence of biceps activity. As previously reported by Yamaguchi et al., no significant electro-activity was identified in the long head of the biceps in response to isolated shoulder motion when elbow and forearm position were controlled. The authors of both of these studies concluded that any function attributed to the long head of the biceps was not likely to be active. Rather, the long head of the biceps had either a passive role or an active role dependent on an association with elbow and forearm activity.[68]

Summary of Functional Anatomy

To date, the exact function of the long head of the biceps tendon in shoulder function remains incompletely characterized. Whereas the comparative anatomy analysis and electromyographic observations would suggest a minimal role for the biceps tendon, the biomechanical data to date would suggest otherwise. However, electromyographic data with controlled elbow motion would suggest that very little

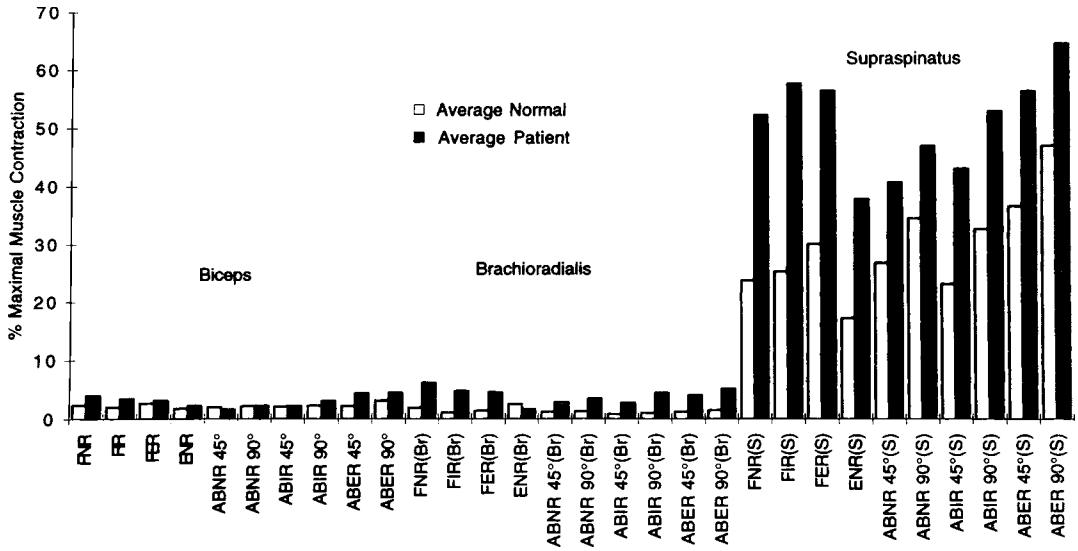

Figure 7-7 Column graph showing the combined electromyographic activity from the biceps, brachioradialis, and supraspinatus in normal control subjects and patients with rotator cuff tears. When elbow activity was controlled, minimal biceps and brachioradialis activity was achieved, which was shown for both normal and rotator cuff tear patients. In contrast, significant amounts of supraspinatus activity were seen and the amounts increased when a rotator cuff tear was present. The results suggest a lack of biceps activity coordinated with shoulder motion. y axis = electromyographic activity as a percent of maximal muscle contraction. x axis = various types of active shoulder motion. FNR, flexion, neutralrotation; FIR, flexion, internal rotation; FER, flexion, external rotation; ENR, extension, neutral rotation, ABNR, abduction, neutral rotation; ABER, abduction, external rotation; ABIR, abduction, internal rotation.

coordinated biceps activity occurs specific to the shoulder joint.[82,137] Previous studies using biceps tendon loads in cadaveric biomechanical analysis represent estimations at best. Even in complex activities such as pitching, the axial muscle contractions noted in the biceps muscle have been about 30% to 40% of those attainable.[53] Given vector analysis of the pull of the biceps, a head depression role would be unlikely to occur in most ranges of motion short of full external rotation. This does not preclude a role in anterior instability, which appears to be better supported by both the electromyographic and biomechanical analysis. In the context of anterior instability, the biceps has been shown to play a significant role in dynamic cadaveric models and in vivo where an increased EMG response was seen in unstable pitchers versus those without stability symptoms.

The absence of supportive evidence on a coordinated active role of the biceps does not preclude a significant passive role or active role secondary to elbow activity. It is possible that resting tension on the biceps may be helpful in both anterior and superior instability. Additionally, proprioceptive roles for the biceps tendon remain to be studied.

PATHOPHYSIOLOGY

Shoulder pain arising solely from the long head of the biceps can be quite severe, causing marked loss of shoulder motion. Disorders of the biceps tendon may arise from inflammatory changes in and around the tendon or may develop as a consequence of a significant injury or repeated microtrauma. These two major groups of pathologic processes (i.e., inflammatory and traumatic) are a result of the location of the tendon and its unique anatomic structure.[22,95–97,101,114] While the eventual clinical presentation of these afflictions of the long head of the biceps tendon is shoulder pain, they affect different patient populations with dissimilar pathogeneses. In this section, we will discuss the various disorders of the long head of the biceps tendon by classifying them as "inflammatory," "instability," or "traumatic" on the basis of the original initiating event. It must be stressed that the distinction is not always clear; the degenerate inflamed tendon is more prone to trauma and, conversely, repeated trauma may result in changes in the tendon indistinguishable from those of inflammation. Nevertheless, this classification can help with the organization of the pathogenesis of these disorders and formulation of protocols for appropriate management.

Biceps Tendinitis Concurrent with Rotator Cuff Disease

Tendinitis of the long head of the biceps was described by Neer to be secondary to impingement syndrome for the majority of cases encountered in clinical practice.[95] As the sheath of the biceps tendon is an extension of the synovial

lining of the glenohumeral joint and intimately related to the rotator cuff, any inflammatory process affecting one of the structures can eventually affect the others as well.[21,56,94,96–98,100,101] The terms *subacromial bursitis, rotator cuff tendinitis,* and *impingement syndrome* have been used to describe the inflammatory changes occurring in the subacromial space as a result of the impingement syndrome. This and other forms of bursitis such as rheumatoid arthritis, gout, and other crystal arthropathies and infections usually involve intraarticular synovitis.

In addition to a secondary involvement of the surrounding synovium, the long head of the biceps tendon is susceptible to the same mechanical abutment seen with impingement of the rotator cuff tendons.[22,95,101] Whether primary or secondary causes of impingement exist, the long head of the biceps occupies an anterior location within the impingement zone, which predisposes its involvement with rotator cuff disease. Besides these compressive forces, the biceps tendon is further subjected to a medial displacing force across the lesser tuberosity as it moves in the groove.[107,119]

The mechanical effects on the rotator cuff and long head of the biceps tendon appear to be age-related and tend to occur together.

Petersson performed 151 shoulder dissections in 76 cadavers.[106] No degenerative changes were observed before the age of 60. The long head of the biceps demonstrated fraying and flattening in 12 shoulders and was found ruptured in six. Four shoulders demonstrated dislocation of the tendon out of its groove. The number of shoulders with degenerative changes in the biceps tendon seemed to increase with increasing age, involving five of six cases over the age of 90.

Murthi et al. performed a prospective arthroscopic evaluation of the biceps tendon in 200 patients requiring surgery for chronic rotator cuff disease.[94] Soft tissue tenodesis was performed in 40% of the surgeries secondary to macroscopic abnormalities of the biceps tendon. The remaining 120 patients underwent open tenosynovectomy of the biceps sheath and rotator cuff repair when indicated. Synovial biopsies were collected and direct examination of the intertubercular groove portion of the biceps tendon was performed in all cases. Sixty-three percent of the specimens revealed histologic evidence of chronic inflammation, while only 18% were free of disease. Normal biceps tendons were found in only 25% of cases with no rotator cuff tear, 16% of cases with partial tear, and 11% of those with full-thickness rotator cuff tears. Thirteen percent had fibrosis of the biceps tendon. Thus, there appeared to be a strong association of coexistent biceps tendon disease with rotator cuff disease. This association increased with increasing severity of the rotator cuff disease. In the tenodesis group, only 49% of cases with gross evidence of degeneration were seen arthroscopically, even when the tendon was pulled into the joint with a probe. The remaining cases demonstrated abnormalities in the biceps tendon distal to the transverse humeral ligament.

Synovitis of the biceps tendon, likened to deQuervain's stenosing tenosynovitis, is generally found in the segment within the bicipital groove, under the transverse humeral ligament[97] (Fig. 7-8). Surgical exploration can reveal the synovial sheath of the tendon as hemorrhagic and bulging slightly above and below the transverse humeral ligament. Upon incision of the outer layer of the synovial sheath, an effusion can escape into the wound. Not present normally between the two layers of the synovial sheath around the tendon, this fluid represents the inflammatory exudate. The contained segment of the tendon will appear dull, swollen, and discolored but is still mobile in the groove. These findings correspond to the acute painful stage of the disease.[84] In later cases, the sheath appears thickened, fibrotic, and less vascular. The tendon is roughened and lies in a bed of hemorrhagic adhesions. The inflamed tendon can appear reddened but initially normal in size. In later stages, the tendon may appear atrophic or hypertrophic. The atrophic tendon is thin and frayed and represents a prerupture stage. In the "hypertrophic" type, inflammatory changes within the tendon result in an enlarged appearance. Boileau et al. described intraarticular entrapment of a hypertrophic long head of biceps tendon coined "the hourglass biceps."[17] A series of 21 cases were reported, all but one associated with a rotator cuff tear. Each patient reported anterior shoulder pain and loss of active and passive terminal elevation motion. Each subject was noted at the time of surgery to have a hypertrophic tendon that became mechanically blocked from entrance into the biceps groove with flexion of the shoulder.

Microscopically, the inflammatory changes in the tendon have been well documented. There is a pronounced round-cell infiltration of the tendon, degeneration of the tendon fibers, and edema.[84,94] The hypertrophied tendon seen in relation to large cuff tears most plausibly represents a chronic inflammatory response from continuing impingement of the tendon.[137] Eventually, the tendon can become firmly bound down in the groove with adhesions or spontaneously rupture. This can be associated with resolution of the symptoms of tendinitis. Rupture of the intraarticular portion of the tendon has been reported in 3% of anatomic dissections.[84] These changes appear age-related, with more pronounced changes occurring in patients past middle life.[33] When spontaneous rupture is seen, it is often accompanied with an instant and gratifying relief of the long-standing shoulder pain. Perhaps no other clinical observation is more supportive of the significant role biceps tendinitis can play in shoulder pain.

Primary Bicipital Tendinitis

The term *primary bicipital tendinitis* has been reserved for isolated inflammation of the long head of the biceps tendon in the intertubercular groove without any evidence of associated shoulder pathology. Most authors believe that

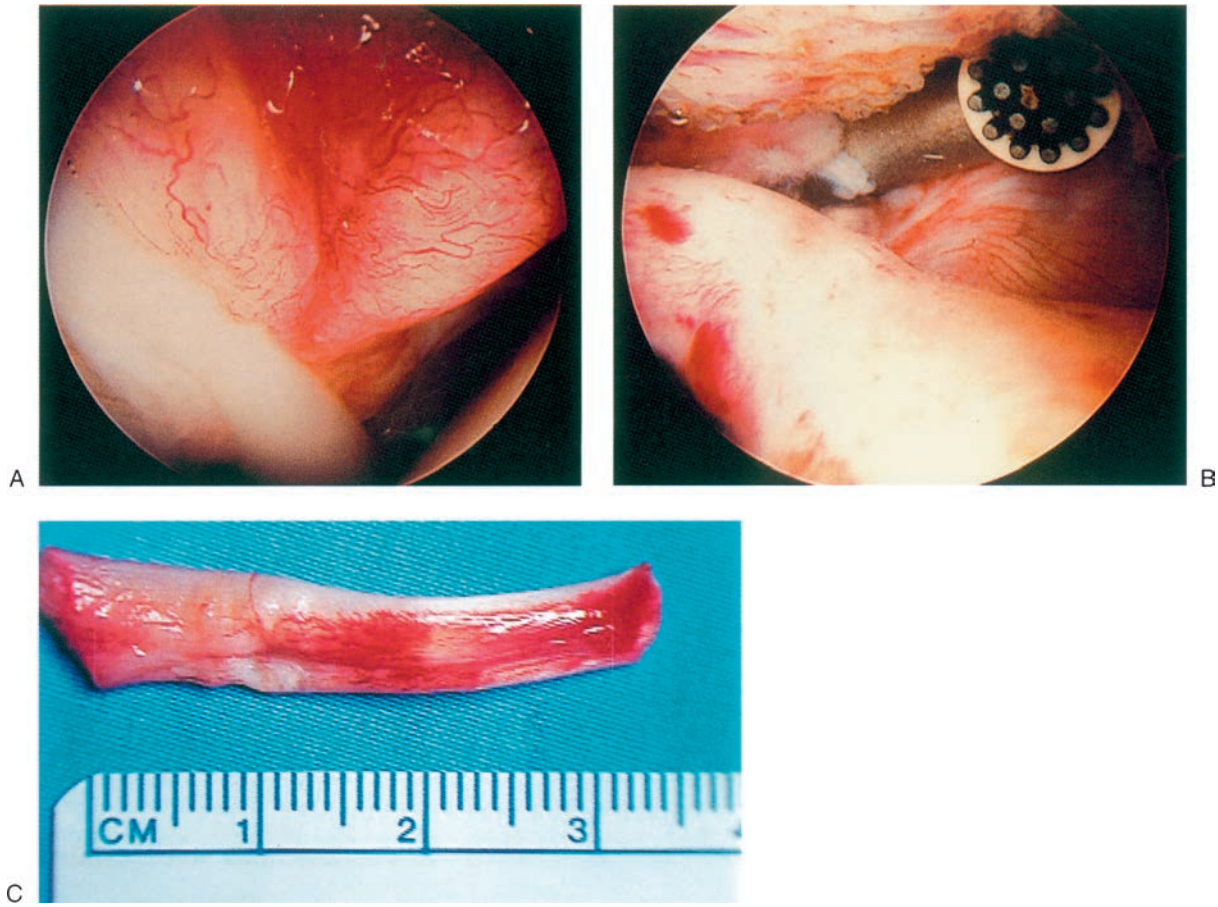

Figure 7-8 Intraoperative photos showing the marked synovitis that could be seen on the undersurface of the rotator cuff with chronic rotator cuff tendinitis. **A.** Synovitis on the undersurface of the rotator cuff is encircling the biceps tendon during its intraarticular path. **B.** Involvement of synovitis at the biceps origin. **C.** Removed tendon obtained from a patient who had failed a previous decompression for chronic rotator cuff tendinitis. Following this revision procedure, in which this tendon was removed, the patient had a resolution of symptoms.

primary tendinitis of the biceps tendon is uncommon and must be diagnosed only after exclusion of rotator cuff pathology or subacromial impingement.[34,95]

Tendinitis may be a result of direct or indirect trauma after increased activity or an underlying inflammatory disease, as a result of trauma, or secondary to instability of the tendon.[110] Often no specific factor is identifiable, constituting the idiopathic group, which in some series accounts for 43% of cases.[31] Whatever the inciting factor, the pathologic changes are restricted to the intertubercular groove and are indistinguishable from secondary tendinitis as mentioned above. However, primary tendinitis almost surely exists as a separate entity also. This bicipital tenosynovitis has been likened to that seen in deQuervain's tenosynovitis.[31,33,84,90,110] The thickening of synovitis of the tendon occurs under the transverse humeral ligament in the bicipital groove. The intraarticular portion of the tendon has been reported to always be normal.

The causes for biceps tendonitis can be multifactorial. DePalma described anomalies of the bicipital groove, together with repeated trauma, as a major factor in younger people.[33] Degenerative changes were described to be the more common factors in older people. Rathbun and Macnab, in a microvascular injection study of the shoulder, showed a critical zone in the long head of the biceps tendon similar to that seen in the supraspinatus.[113] However, this critical zone of avascularity was primarily in the intracapsular portion of the tendon.

Long Head of the Biceps Tendon Instability

The spectrum of instability of the biceps tendon varies from subluxation, which is excessive mobility of the tendon within the groove, to dislocation or complete displacement of the tendon out of its groove in the humerus.

We have used the term *primary instability* to include the spectrum of biceps instabilities from subluxation to frank

dislocation. The biceps tendon passes at an angle of 30 to 40 degrees from its origin to the groove in the humerus where it descends vertically. The tendon is relatively fixed from the point of its entrance into the bicipital groove and swings from one angle to another as the arm is rotated. When the arm is cocked to abduction and external rotation, the forces tend to displace the tendon medially, compressing it against the medial edge of the bicipital groove. In internal rotation, the tendon is thrust against the lateral margin of the groove, moving through an arc of more than 90 degrees in the process.[102] If the groove is shallow, the tendon may force its way over the greater or lesser tuberosity. If the groove is narrow and tight, the constant pressure on the tendon may lead to tendinitis.

Luxation of the long head of the biceps tendon is most commonly secondary to loss of the soft tissue restraints with degenerative rotator cuff tears.[21,56,107,131,132] It is generally agreed that the main restraint to medial dislocation of the tendon of the long head of the biceps is the integrity of the rotator interval, which can be disrupted with rotator cuff tears that involve either the superior aspect of the subscapularis or the anterior portion of the supraspinatus tendon.[21,26,27,56,61,131,132] Displacement of the biceps tendon out of its groove, in association with tears of the rotator cuff, has been reported with incidences as high as 20% of all cuff tears.[119] The tendon is found to lie medial to the lesser tuberosity, over the subscapularis, covered by a sling of the subscapularis tendon. In a cadaveric study of 153 shoulders, Petersson found two patterns of medial dislocation of the long head of the biceps tendon: the dislocated tendon sliding over the subscapularis and a dislocated tendon sliding beneath a deep tear of the subscapularis.[107] The latter pattern occurred in four of the five cases in Petersson's series. In cases with full-thickness tears of the supraspinatus tendon with rupture of the coracohumeral ligament, the tendon can displace medially over the subscapularis tendon. In the presence of a partial tear of the subscapularis tendon involving its deep surface, however, the tendon can sublux medially deep to the subscapularis muscle. Upon external inspection, the subscapularis tendon can appear intact and a dislocated tendon may be missed if the region is not carefully examined at surgery. Walch et al. described the presence of "hidden" lesions of the rotator interval in 19 of 116 cases with rotator cuff tears.[132] In these cases, exploration of the rotator interval showed associated tearing of the superior glenohumeral ligament, coracohumeral ligament, and superior portion of subscapularis. The biceps tendon was ruptured in two cases, subluxated in 14, and normal in five.

Habermeyer and Walch showed that 50% of all biceps subluxations were associated with degenerative changes in the anterosuperior aspect of the labrum, suggesting a correlation between these structural changes.[56] Gerber and Sebesta introduced a pathologic process termed anterosuperior impingement (ASI) as a distinct entity producing lesions of the biceps reflection pulley.[48] Impingement of the reflection pulley, biceps tendon, and uppermost portion of the subscapularis tendon against the anterosuperior labrum and glenoid was observed in a series of 16 patients with chronic anterior shoulder pain (the majority of which were engaged in manual labor) when the shoulder was flexed to 120 degrees in combination with horizontal adduction and internal rotation. Three cases were noted to have isolated lesions of the common insertion of the superior glenohumeral and coracohumeral ligaments (pulley lesion), 10 cases had pulley lesions and articular-side partial disruption of the subscapularis, and three cases had an intact pulley system. Pulley lesions alone or in combination with subscapularis rupture were usually associated with biceps tendon pathology manifested as degeneration, instability, or the presence of SLAP tears. Habermeyer and coauthors further supported the concept of anterosuperior impingement as a cause of biceps tendon degeneration and instability.[55] Eighty-nine patients with arthroscopically proven pulley lesions were studied, excluding all cases with full-thickness tears of the rotator cuff. Four patterns of injury to the superior glenohumeral ligament (pulley system) and subscapularis and supraspinatus tendons were identified and correlated with the intraoperative presence of ASI. Overall, abnormalities within the biceps tendon were seen in 90% of patients ranging from synovitis to frank dislocation. The presence of a pulley lesion combined with an articular-side subscapularis injury was correlated with the presence of ASI (seen in 59% of cases). The presence of a partial articular-side supraspinatus lesion and a partial subscapularis tear increased the risk of ASI to 75% compared to 26% of patients with a pulley lesion alone.

Contrary to common perceptions about subluxation, the biceps tendon does not intermittently reduce with arm motion. Rather, these luxations appear to be fixed. Subluxation has been classified by Habermeyer and Walch into three types[56] (Fig. 7-9).

Type I, a superior subluxation, comes as a consequence of a loss of the coracohumeral ligament and rotator interval sling. The subscapularis tendon is intact, preventing an otherwise true dislocation. There is often a partial lesion of the supraspinatus lesion. In type II subluxation, the biceps tendon is unstable at the entrance to the bony groove. In this situation, the tendon slips over the medial rim of the lesser tuberosity short of complete dislocation. The pathologic lesion here is a detachment of the superiormost fibers of the subscapularis tendon. Type III subluxations follow a malunion or nonunion lesser tuberosity. In this situation, a fracture of the lesser tuberosity without healing or any malunited fashion compromises the medial bony restraint to the long head of the biceps tendon allowing subluxation. Symptoms are more prominent in internal rotation. Each of these types of subluxation is associated with tendinitis and capsular synovitis in the area of the rotator interval. Chronic cases of this tendonitis can lead to attrition and later rupture of the long head of the biceps tendon.

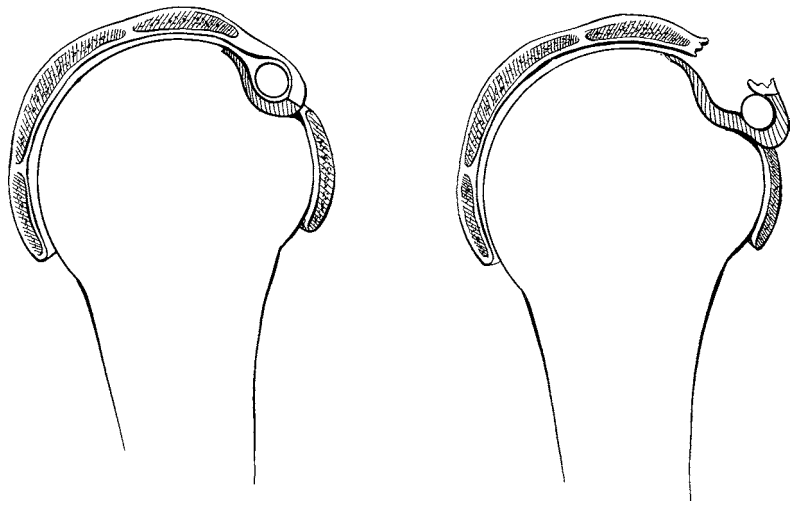

Figure 7-9 Schematic showing the anatomic basis of biceps subluxations. Subluxation can occur as a consequence of the loss of the coracohumeral ligament (*hatched*) and superior glenohumeral ligament sling (*black*). An intact subscapularis acts to prevent an otherwise complete dislocation. In type I lesions there is only a superior luxation from a loss of the interval sling. In type II subluxations, the biceps tendon is more unstable distally secondary to a tear of the superiormost fibers of the subscapularis tendon.

Frank dislocation of the long head of the biceps is nearly always associated with a tear of the subscapularis tendon. Thus, observation of a completely dislocated biceps tendon either by preoperative imaging such as magnetic resonance imaging or ultrasonography or during direct observation arthroscopically should alert the treating physician to the possibility of a concurrent full-thickness rupture of the subscapularis tendon. Habermeyer and Walch have classified these types of dislocations into type I and type II lesions.[56] Type I lesions are extraarticular dislocations combined with a partial tear of the subscapularis tendon. In this situation, the long head of the biceps tendon is completely dislocated over the lesser tuberosity. There is a rupture of the common attachment of the superior glenohumeral ligament and coracohumeral ligament. Superficial and lateral fibers of the subscapularis tendon are also torn, releasing the soft tissue restraints to the tendon. However, deep fibers of the subscapularis tendon remain intact, preventing intraarticular displacement. The lesion essentially corresponds to a more advanced evolution of a type II subluxation. In type II dislocations of the biceps tendon, there is an intraarticular dislocation of the long head of the biceps tendon. This occurs in conjunction with a complete full-thickness tear of the subscapularis. This type of dislocation is associated with an extensive tearing of the tendinous portion of the subscapularis tendon and approximately half of these have a traumatic cause.

The majority of cases of biceps tendon instability are associated with tears of both the subscapularis and supraspinatus tendons with the pattern of instability dictated by the severity of the subscapularis and biceps pulley injuries. Walch et al. reported a series of 71 cases of subluxation or dislocation of the biceps tendon describing the detailed anatomy of associated rotator cuff tears.[131] Of 445 rotator cuff tears treated over a 7-year period, biceps instability was seen in 16% of patients. All cases of biceps subluxation were associated with partial injury of the upper portion of the subscapularis tendon with concomitant abnormalities of the ligamentous pulley. An associated lesion of the supraspinatus tendon was noted in 70% of these cases. Frank dislocation of the biceps tendon was demonstrated in 46 patients (65% of cases) and was seen in two patterns: extraarticular and intraarticular. With extraarticular dislocations, deep fibers of the subscapularis and middle glenohumeral ligament remained partially intact, separating the tendon from the glenohumeral joint. Intraarticular dislocations of the biceps tendon were seen with complete detachment of the subscapularis tendon and incompetence of the biceps pulley. Seventy percent of cases of a dislocated biceps tendon were seen in the context of full-thickness tears of the supraspinatus and infraspinatus tendons.

Traumatic Rupture of the Long Head of the Biceps Tendon

Traumatic rupture of a normal long head of the biceps tendon is extremely uncommon. When long head of the biceps tendon ruptures are seen in the context of trauma, they are generally in the context of a previously degenerated tendon. Often the trauma can be relatively minor in these circumstances and is usually preceded by history consistent with rotator cuff tendinitis. However, isolated ruptures of the long head of the biceps can occur in the absence of previous history of subacromial impingement.[33,88,90,110,118] These can be seen in the context of significant trauma involving either a powerful supination force, powerful deceleration of the forearm during pitching, or fall on an outstretched arm as in SLAP lesions.[6,120–122] Type IV SLAP lesions, which include an extension of the labral tear into the intratendinous substance of the biceps, are an example of primary partial ruptures of the biceps tendon from trauma.

When partial tearing of the biceps tendon occurs, often significant pain and dysfunction are associated with the lesion. A higher suspicion of a partial-thickness traumatic tear of the biceps tendon again should be considered in the context of previous tendonitis or bicipital-like pain. In contrast, full-thickness traumatic ruptures of the biceps tendon are generally less consequential from a symptomatic point of view.[23,56,134] In these cases, the patient may have experienced significant pain in the upper and anterior brachium. This is often associated with bruising down the biceps muscle. After a period of discomfort, the pain generally subsides and the patients are generally without significant consequence to the shoulder function.

Tears of the Superior Labrum at the Origin of the Biceps Tendon

While tendinitis of the biceps tendon has been long recognized as a cause of shoulder pain, symptomatic tears of the superior labrum at the origin of the biceps tendon has only recently been established as a pathologic entity. First described in athletes by Andrews et al., the lesion has been further characterized and classified by Snyder et al., who are also responsible for attaching the acronym SLAP to these findings.[6,120–122]

While both reports included patients with tears of the superior labrum at the origin of the biceps tendon diagnosed arthroscopically, the patient populations seem to differ. Andrews et al. retrospectively identified 73 throwing athletes (51 baseball players) with no history of a single episode of significant trauma and a mean age of 23 years.[6] In Snyder et al.'s series, the 27 patients with superior labral lesions represented about 4% of the total arthroscopic procedures performed over a 4-year period.[120] With a mean age of 37.5 years, the commonest mechanism of injury (48%) was compression injury resulting from a fall on the outstretched hand. The remainder seemed to arise from traction injuries either as a sudden pull on the arm (22%) or repetitive traction with overhead throwing activities (8%). The mechanism was unclear in the remaining 22% with no history of the above.

Both of these populations, although different in presentation, most likely represent a spectrum of the same pathology, one arising from the repetitive trauma of overhead activities, the latter from a single traumatic episode.

It is postulated that a fall on the outstretched hand with the shoulder abducted and in slight forward flexion provides a proximal subluxating force resulting in direct compression at the superior labrum and biceps origin. An additional traction force may be provided by the reflex contraction of the biceps during the fall. Clavert and coauthors simulated forward and backward falls in a cadaver model to examine the likelihood of creating a SLAP lesion.[28] The humeral head was impacted against the glenoid with 1500 N in two of the test positions after preloading the rotator cuff and biceps tendons. A type II SLAP tear was reproduced in all five specimens simulating a forward fall and in two of the five specimens simulating a backward fall. The authors concluded that the compressive and shearing forces recreated during a fall on the outstretched hand is a plausible cause for type II SLAP tears.

Repeated forces transmitted through the origin of the long head of the biceps may account for the detachment of the labrum in throwing athletes. Several cadaveric studies have shown both the late cocking and deceleration phases of throwing to place high strains on superior labrum and biceps tendon. Kuhn et al. compared the late cocking and early deceleration phases of throwing in 20 cadaveric shoulders while the long head of biceps tendon was loaded to failure.[77] The early cocking test position was 60 degrees of scapular plane abduction combined with more than 125 degrees of external rotation, whereas the early deceleration position was set at 80 degrees of external rotation, 60 degrees of abduction, and 16 degrees of horizontal adduction. Baseline forces of 22 N were recreated within the rotator cuff tendons prior to biceps loading. Failure of the biceps anchor occurred at the biceps superior labral complex in 9 of 10 specimens in the late cocking position compared to 2 of 10 specimens in the early deceleration position. Five type II SLAP tears were created, four of which occurred in the late cocking position. In addition, the load to failure of the late cocking position (289 $\pm$ 39 N) was significantly less than the early deceleration position (346 $\pm$ 40 N). Pradham and coauthors investigated the strains on the anterior and posterior aspects of the superior labrum during various stages of throwing.[111] Predetermined loads based on the percent of maximum voluntary contraction of the biceps tendon during each phase of throwing from a prior EMG study were recreated. A 22-N force was simulated in the subscapularis and infraspinatus tendons during testing. The strain on the posterior and anterior portions of the superior labrum increased significantly in the late cocking position compared to the early cocking, acceleration, deceleration, and follow-through positions.

Yeh and coauthors used a finite element model to analyze the forces on the superior labrum–glenoid interface in four phases of throwing: early cocking, late cocking, acceleration, and deceleration.[138] Three types of biceps origin geometries were investigated to determine their influence in the stress distribution on the glenoid. Force transmission through the biceps tendon was determined based on the estimated biceps activity in the various stages of throwing. Rotator cuff forces were not simulated in this model. The stress magnitudes at the labrum–glenoid interface were highest in the deceleration phase of throwing for all types of biceps origins. In addition, an anterior biceps origin produced 50% higher strains on the labrum–glenoid

interface compared to a posterior biceps origin in the early deceleration phase of throwing.

Traumatic disruption of the superior labrum can occur to varying extents and has been classified into four types based on the labral injury and the stability of the labrum–biceps complex found at arthroscopy[122] (Fig. 7-10):

Type I: This lesion represents the mildest of the spectrum. The superior labrum appears degenerate and frayed (Fig. 7-10E). The attachment of the labrum and long head of the biceps tendon are preserved and stable upon probing. The long head of the biceps has a normal appearance. In an older-aged population this finding may be asymptomatic and associated with the normal age-related degenerative process.

Type II: The frayed superior labrum and the attached tendon of the long head of the biceps are stripped off the underlying glenoid in association with avulsion of the superior glenohumeral ligament complex. The superior labrum arches away from the glenoid and can be lifted off with a probe (Fig. 7-10F). The peripheral detachment of the labrum and the degenerative tissues seen at the attachment of the labrum to the superior glenoid seen in type II lesions differentiate these from the normal loose attachment of the superior labrum in its central portion.

Type III: In type III lesions, the superior labrum develops a tear with a stable labrum–biceps complex, similar to the "bucket-handle" tear of the knee meniscus (Fig. 7-10G). The origin of the long head of the biceps and the superior glenohumeral ligament complex retain their attachment to the glenoid, differentiating a type III from a type II lesion. The torn labrum devoid of any peripheral attachment can be displaced into the glenohumeral joint.

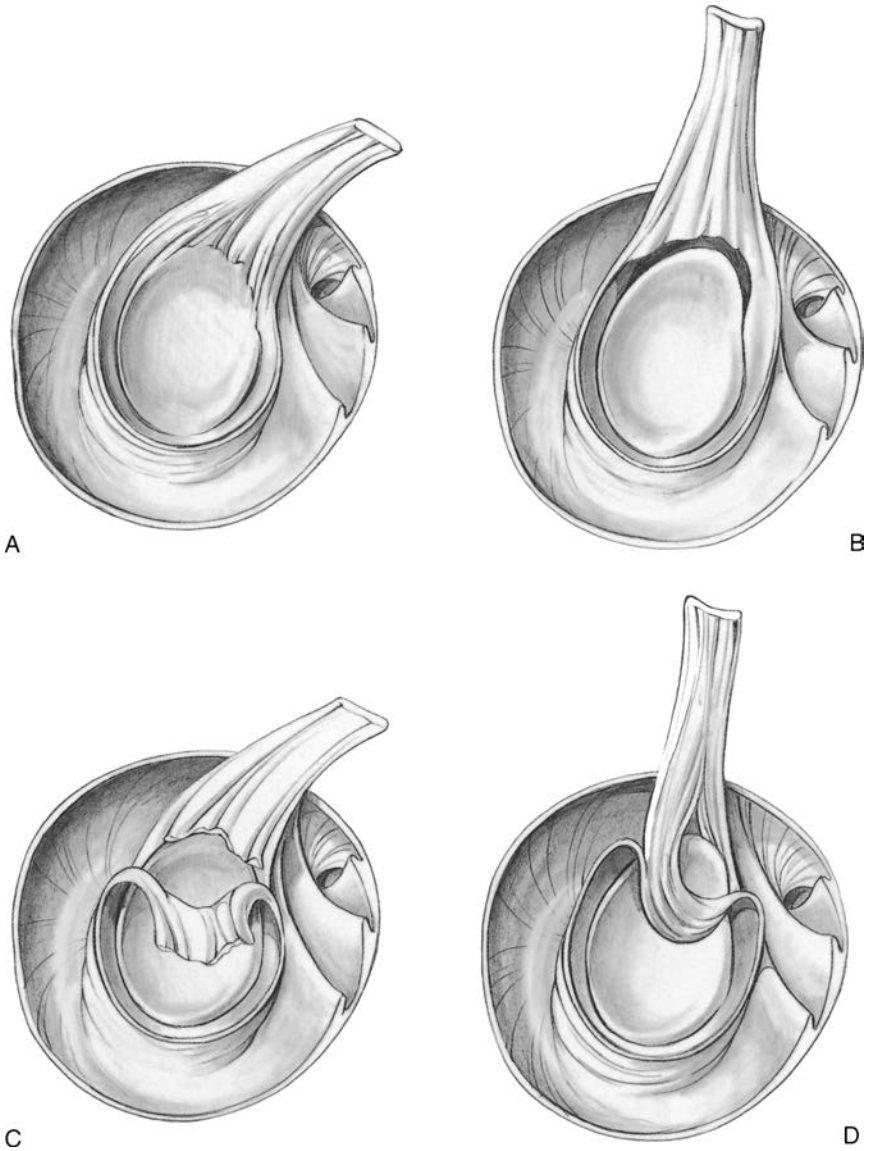

Figure 7-10 Schematic of the four types of superior labral anterior and posterior (SLAP) lesions. **A.** Type I SLAP lesions are characterized by a significant fraying or degeneration of the superior labrum. **B.** Type II SLAP lesions are characterized by detachment of the superior labrum and biceps tendon from the glenoid rim. **C.** Type III SLAP lesions are seen as a bucket-handle tearing of the superior labrum. The remaining labral tissue maintains the biceps as anchored to the glenoid rim. **D.** Type IV SLAP lesions consist of an extension of the bucket-handle labral tear into the substance of the biceps tendon. Arthroscopic views: **E.** SLAP I lesion; **F.** SLAP II lesion; **G.** SLAP III lesion; **H.** SLAP IV lesion.

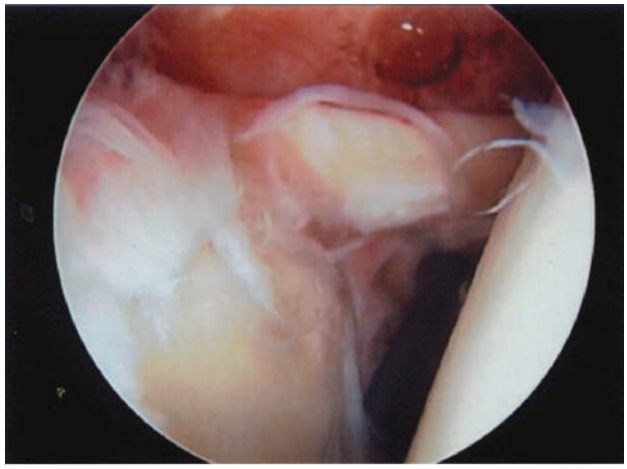
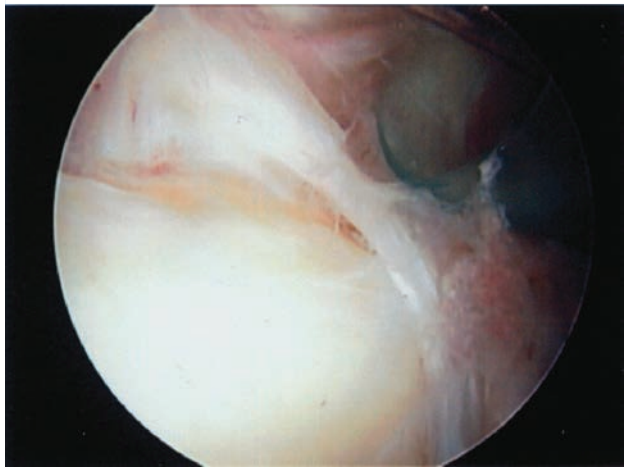
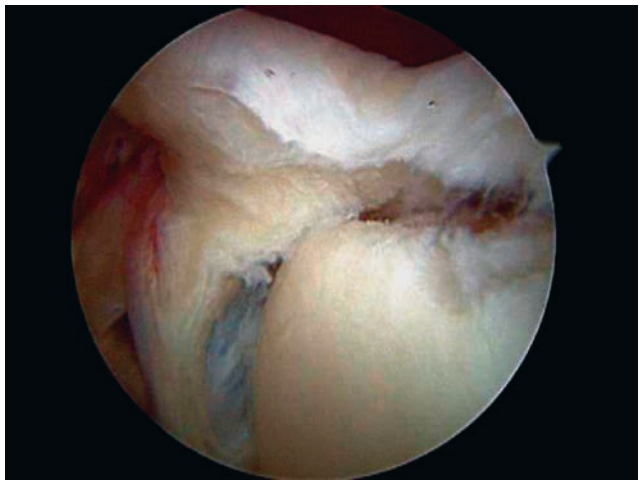
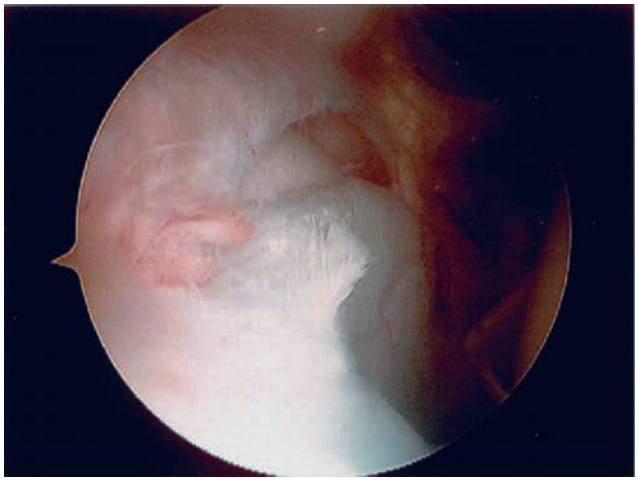




E



F



G

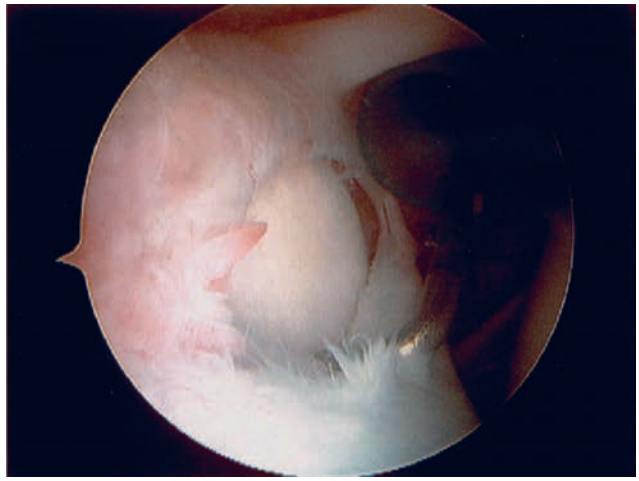


Figure 7-10 (*continued*)

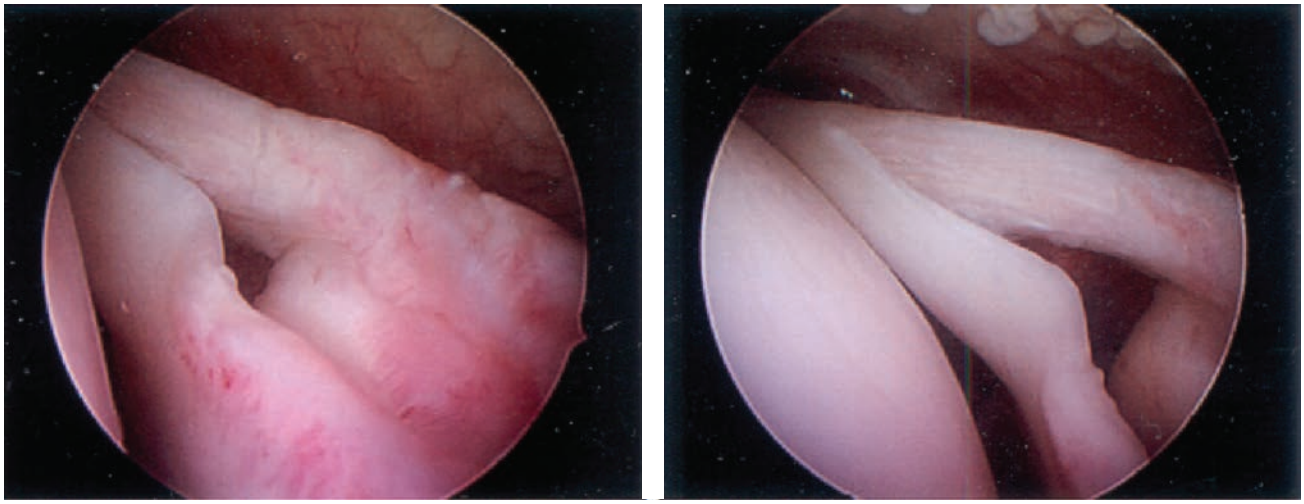
Type IV: The central tear includes a portion of the biceps tendon (Fig. 7-10H). The biceps tendon is thus split longitudinally into an intact peripheral portion and a central portion displaced into the joint with the attached bucket-handle tear of the labrum.

Type II and type III lesions were the commonest in Snyder et al.'s series accounting for 41% and 33% of the cases, respectively. While type IV lesions were observed in 15%, type I lesions were the least common, accounting for 11% of the series.



H

Figure 7-10 (*continued*)

The original classification of SLAP tears by Snyder et al. has been expanded to include superior labral tears associated with glenohumeral instability. Maffet et al. reported a series of 84 patients with arthroscopically proven SLAP tears.[85] Thirty-two of the 84 patients (36%) were noted to have associated labral and/or capsular pathology that precluded standard classification. The majority of these tears were seen in patients with associated glenohumeral instability. The authors further classified these SLAP lesions into three additional categories. Type V SLAP tears involved detachment of the superior labrum and biceps anchor with propagation of the tear into the anteroinferior labral tear (Bankart lesion). Type VI SLAP tears were seen as displaced flap tears of the superior labrum with an intact biceps root. Type VII SLAP tear included a detached superior labrum associated with a distinct capsular tear.

CLINICAL EVALUATION

History

As with all other orthopedic conditions, an accurate and directed history and physical examination are basic and essential parts of the clinical evaluation. This is particularly true in the case of biceps tendon disorders as imaging studies are often nondiagnostic.

Patients with biceps tendinitis or pain from subluxation always have pain at the bicipital groove.[21,56,96,98] This pain, however, can be difficult to distinguish from anterior subdeltoid pain from impingement syndrome or rotator cuff tendinitis. In most people, the bicipital groove can be felt as a distinct entity between the greater and lesser tuberosities when the arm is placed in neutral rotation. The pain felt in this location should migrate laterally with external rotation of the arm. Often, this pain radiates down anteriorly to the biceps muscle belly. This is different than rotator cuff tendinitis pain, which generally radiates to the deltoid insertion. Generally, the patient experiences the pain with activities, particularly repetitive overhead types seen in sports. Resting pain is seen later in the disease progression and can be a significant component of night pain. When involved with calcific tendinitis, the pain can be of such intensity that it may mimic a septic shoulder.

In the case of bicipital tendinitis, it is almost always accompanied by rotator cuff inflammatory symptoms.[95] The patient will complain of pain in the anterior aspect of the arm, particularly with extension and internal rotation. Impingement signs such as those described by Neer and Hawkins are generally positive.[48,55,96,99] We have found the lift-off sign, as described by Gerber and Krushell, to be helpful not only for detecting subscapularis tears but also as a sensitive test for eliciting impingement-type pain in patients with bicipital tendinitis.[47] Additionally, those patients with rotator cuff tendinitis with more severe symptoms and signs, including restriction of shoulder motion, are those more likely to have a component of bicipital tendinitis. Whether they are in association with tendinitis or full-thickness tears of the cuff, inflammation of the biceps tendon can be a significant source of additional discomfort. A significant pain that can sometimes accompany inflammation of the long head of the biceps has led some authors to believe it to be a possible cause in the development of frozen shoulder. DePalma and Callery reported a 40% incidence of frozen shoulder in bicipital tendinitis, particularly in the 45- to 55-year-old age group.[33] Modern interpretation of those findings is that the intraarticular synovitis associated with frozen shoulder preceded the bicipital involvement. When long-standing, the pain from the long head of the biceps tendon can spontaneously resolve following a full-thickness rupture (Fig. 7-11A). This dramatic relief of symptoms has been

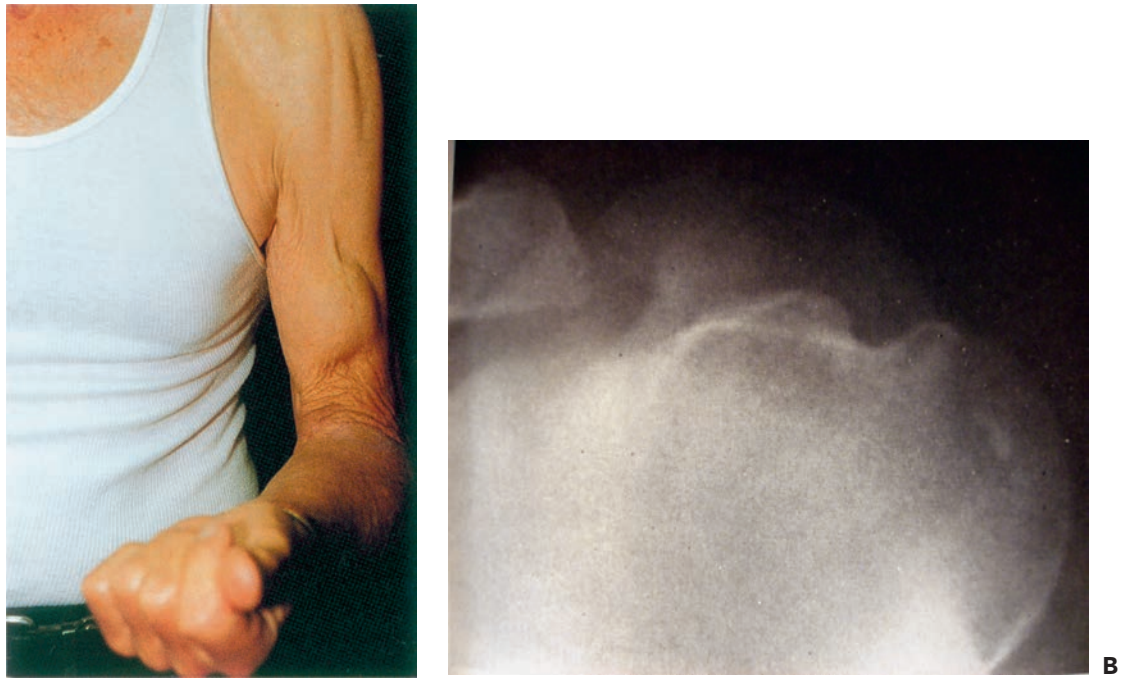


Figure 7-11 **A.** This is a 68-year-old patient with a long history of pain in the shoulder. The patient experienced a spontaneous resolution of the pain following a full-thickness rupture of the long head of the biceps tendon. The rupture of the long head of the biceps tendon is seen by a shortening of the lateral biceps muscle seen as a lump on the anterior lateral aspect of the arm. **B.** Biceps tendon view as described by Fisk. (Reprinted with permission, Fisk C. Adaptation of the technique for radiography of the bicipital groove. *Radiol Technol* 1965;37:47–50.)

termed rupture salvatrice, or "saving rupture." The rupture of the degenerated long head of the biceps is sometimes accompanied by bruising down the front of the arm along the biceps muscle belly in the presence of a lump on the anterior lateral aspect of the arm. When impingement-like pain is persistent following a rupture, further evaluation of the rotator cuff is warranted.

Stability of the biceps tendon in the form of subluxation is extremely difficult to assess nonoperatively. Patients that develop this condition are more likely to be young, overhead athletes.[102] They can often notice a painful snapping or clicking sensation in the shoulder, especially with overhead positions going from internal to external rotation. It is unclear why these symptoms occur as the tendon is generally fixed in a luxated location. As subluxation generally occurs in the presence of partial- or full-thickness surrounding rotator cuff defects, the symptoms are concurrent with those usually found with rotator cuff disease.

Frank dislocations of the long head of the biceps tendon are seen in the dominant shoulder of middle-age males.[106,107] The cause of this location is traumatic in the majority of cases. As with subluxation of the biceps, motion of the shoulder will aggravate the pain, especially in those of forced internal/external rotation as seen with throwing. Recurrent dislocation of the tendon of the groove can often be accompanied by a snapping sensation sometimes causing a sudden reflex dropping of the arm. The symptoms are similar to those seen in recurrent subluxation or dislocation of the glenohumeral joint. The series reported by Walch et al. highlights the fact that a large percent of patients with a dislocated biceps tendon will be seen in the context of a massive rotator cuff tear.[131] Approximately 40% of these patients were noted to have pseudoparalysis of the shoulder with attempted elevation.

Lesions of the superior labrum (SLAP) are similarly difficult to assess from history alone. These lesions are generally seen in younger patients that are extremely active in overhead activities. The cause is controversial but may involve posterior–inferior capsular contracture leading to a posterior–superior humeral head luxation. This luxation is proposed by Burkhart and Morgan to produce a sheer, peel-back mechanism for producing SLAP tears.[20] Alternatively, internal abutment of the articular surface of the supraspinatus against the labrum during maximal abduction, external rotation, and extension of the arm during throwing may be an alternative mechanism. A common cause is a fall on the outstretched arm in which the proposed mechanism is a compressive shearing of the humeral head against the superior labrum. A history of snapping or popping can also accompany these types of disorders.

Physical Examination

The most common physical examination finding for disorders of the long head of the biceps tendon is point tenderness over the intertubercular sulcus. This is most easily distinguished with the arm in 10 degrees of internal rotation where the biceps groove generally faces anteriorly and can be palpated approximately 7.5 cm distal to the acromion. In this position, the lesser and greater tuberosities can generally be palpated to locate the bicipital groove. The pain at the bicipital groove may be distinguished from anterior shoulder pain commonly associated with rotator cuff disorders by externally rotating the arm. Pain specific to the biceps tendon may move laterally with external rotation in the arm in contrast to subcoracoid pain.[48] Unless there is complete disruption of the transverse humeral ligament and luxation of the biceps tendon out of the groove, the long head of the biceps tendon can generally not be directly palpated. When dislocated, the biceps tendon can be rolled under the fingers of the examiner and this can exacerbate the tenderness.[33] Actual palpation of the tendon, however, is generally rare, and symptoms emanating from the bicipital groove are difficult to distinguish between tendinitis and instability.

Several specific physical examination tests have been described to isolate the biceps tendon as a source of pathology. These tests help to localize the tenderness to the biceps tendon but are not specific for any particular pathology. These tests include:

1. Speed's test or bicipital resistance test. The patient attempts to flex the arm with the forearm supinated and the elbow at approximately 30 degrees of flexion. A positive test is indicated by pain in the region of the bicipital groove.[50,96]
2. Yergason's test. Resisted supination of the forearm with the elbow flexed 90 degrees and the arm at the side can cause pain, specifically at the bicipital groove.[139]
3. Biceps instability test. In this case, dislocation of the tendon is elicited as a palpable and sometimes audible clicking as the biceps tendon is forcibly subluxated or dislocated. This is performed by placing the arm in full abduction and external rotation. The arm is then slowly brought down to the side in the plane of the scapula in progressive internal rotation.[1]
4. Shoulder compression test. This is performed with the patient supine and the shoulder is abducted to 90 degrees and the elbow flexed to 90 degrees. The axial compression force is applied to the humerus, which when rotated can sometimes elicit either pain or snapping of labrum. The test is analogous to the McMurray's compression test for meniscal tears in the knees.[120]
5. Modified biceps tension test. This test, designed to test superior labral lesions, is performed by holding the shoulder in 90 degrees of abduction and the forearm supinated. Pain is seen on application of a downward directed force applied to the distal forearm.[112]
6. Lift-off examination. Because instability of the biceps is so often associated with a loss of integrity of the subscapularis tendon, the lift-off test is an essential portion of the biceps evaluation. The lift-off test, as described by Gerber, is performed by placing the arm just short of maximal internal rotation and extension. The patient is then asked to actively lift the back of the hand off of the belt line or buttock depending on the amount of internal rotation achievable. The modified lift-off test (internal rotation lift-off sign) is performed by placing the arm in maximal internal rotation with the back of the hand posterior to the belt line or the buttock. A positive examination is seen when the patient cannot keep the hand in this position and it falls to the buttock or belt line. The hallmark of a positive test is a significant difference between active and passive maximal internal rotation and extension.[47] Positive examinations are highly suggestive of subscapularis tears. Additionally, as noted by Gerber, pain during this test serves as a sensitive indicator of impingement. Placement of the humeral head in internal rotation and extension positions the posterior rotator cuff under stretch and up against the acromial arch.
7. O'Brien sign. The shoulder is placed in sagittal plane forward flexion or slight adduction to the sagittal plane with the shoulder in full internal rotation. The examiner then pushes down against resistance when the patient is maintaining this position. The patient quantifies the level of pain caused. The examiner then positions the shoulder in full external rotation while otherwise maintaining the other positions of the shoulder and then forcibly pushes downward, and the patient quantifies the pain. A significantly greater amount of pain in the first position over the pain in the second position suggests biceps tendon, upper subscapularis tendon, and superior labrum pathology. Position one results in anterior internal glenoid impingement of these structures, and pathology of these tissues will elicit a position pain response.

Once these tests are performed, an essential part of the clinical evaluation for disorders of the long head of the biceps is the use of differential injections. Initially, a subacromial injection should be performed with lidocaine. The injection of a local anesthetic into a subacromial space is generally very effective for temporarily alleviating symptoms associated with rotator cuff tendinitis.[12,25,72] In the absence of a full-thickness tear, pain from the biceps tendon should remain persistent. Because the long head of the biceps occupies an intraarticular location, the use of a subacromial injection should not have a direct and immediate effect on pain associated with the tendon. In those cases with persistent pain, despite a subacromial injection, an

intraarticular injection of lidocaine is then administered.[12,21] Resolution of symptoms, particularly at the biceps groove or with any of the specific biceps examinations following an intraarticular injection, is relatively accurate for biceps tendon pathology.[12,98] When symptoms are not improved with an intraarticular injection, two clinical scenarios should be considered: (a) Marked inflammation within the intertubercular portion of the biceps tendon is preventing the infiltration of a local anesthetic in this location or (b) an alternate cause for anterior shoulder pain exists.

When a significant concern for biceps tendon pathology exists despite a negative intraarticular test, a direct injection of the biceps tendon sheath within the bicipital groove can be attempted. When done in a blind fashion, this injection can be difficult as direct injection of the tendon should be avoided.[72] Accuracy of this injection can be improved significantly by performing it under ultrasound guidance. If performed under high confidence, an injection of a local anesthetic should reliably relieve pain specific to the long head of the biceps tendon.

The clinical presentation of SLAP tears can vary significantly based on the age of the patient and the type of SLAP lesion. Kim et al. described the clinical presentation and arthroscopic findings of a series of patients with arthroscopic-proven SLAP tears.[73] One hundred and thirty-nine SLAP tears were diagnosed from a series of 544 (26%) consecutive primary shoulder arthroscopies. Most of the SLAP lesions were associated with other intraarticular pathology. Multivariate analysis showed that the majority of type I tears were seen in older patients and were associated with a positive Speed's test and the presence of a supraspinatus tear. The findings of those patients with type II SLAP tears differed according to the age of the patient. In older patients, type II SLAP tears correlated with a supraspinatus tear and osteoarthritis of the humeral head. In those under the age of 40 years, type II SLAP tears were associated with shoulder instability and Bankart tears. Type III and IV SLAP tears were seen in younger patients and were associated with high-demand occupations and a Bankart lesion.

The accuracy of physical examination tests commonly used for the diagnosis of SLAP tears is limited. McFarland et al. studied the accuracy of the active compression test (O'Brien's test), the anterior slide test, and the compression rotation test for the detection of SLAP tears.[87] The ability of these tests to correctly diagnose SLAP tears was examined in a group of patients with arthroscopically proven type II, III, and IV SLAP tears compared to a control group with a normal superior labrum or type I SLAP lesions. The incidence of positive results was not significant between groups. In those patients with SLAP lesions, the most sensitive test was the active compression test (47%) and the most specific test was the anterior slide test (84%). The test with the highest overall accuracy was the anterior slide test (77%) and with the lowest accuracy was the active compression test (54%).

DIAGNOSTIC IMAGING

Despite significant progress in shoulder diagnostic techniques such as magnetic resonance imaging (MRI) or high-resolution ultrasound, imaging for disorders of the biceps tendon and superior labrum has remained difficult and nonspecific. The value of plain films, MRI, ultrasonography, or arthrography has come more from the characterization of associated pathology such as rotator cuff disease. Although the long head of the biceps tendon and superior labrum can at times be well visualized by some of these methods, any finding must be strictly placed in the context of a history and physical examination. Conversely, the lack of positive findings does not rule out or even deem less likely the presence of significant long head of the biceps tendon pathology.

Plain Films

Imaging of a painful shoulder begins with plain films. In our institution a standard shoulder series of plain radiographs includes the anteroposterior (AP) view with the humerus in internal rotation, posterior oblique "true AP" view of the shoulder in external rotation, supraspinatus outlet view, and axillary lateral view. Plain radiography of the shoulder may demonstrate radiographic changes of an associated long-standing rotator cuff disease, with sclerosis of the greater tuberosity, anterior acromial spurs, and decrease in the subacromial space.[58] When a disorder of the long head of the biceps is suspected, specific additional views can be a useful adjunct.

While the tuberosities are visible on anteroposterior and axillary views, special views to visualize the bicipital groove have been described. The "groove view" described by Cone permits measurement of the depth and width of the groove as well as the slope of the medial wall and may demonstrate degenerative changes in half the patients with tendinitis[3–5,29a] (Fig. 7-11B). This study is obtained with the patient supine and the arm in external rotation. The x-ray beam is directed cephalad and 15 degrees medial to the long axis of the humerus toward the film cassette, which rests on the superior aspect of the shoulder. An alternative method of imaging the biceps groove was described by Fisk.[40] This view is obtained by positioning the patient in a semiprone position resting on the posterior aspect of the elbow. The shoulder is semiflexed and slightly externally rotated, the elbow is bent, and the cassette is positioned on the supinated forearm of the patient. The x-ray beam is directed from superior to inferior over the shoulder of the patient. This view also affords a direct longitudinal view of the biceps groove.

Arthrography

Arthrography can be a valuable adjunctive tool in the evaluation of biceps-related shoulder pain. The accuracy in the

diagnosis of rotator cuff disease has been well established when leakage of dye injected into the shoulder joint is seen in the subacromial space.[4] The ability to visualize the tendon sheath by arthrography has extended its indications to evaluation of the long head of the biceps tendon. There are two openings normally present in the shoulder capsule, the first being the subscapularis bursa and the second, the biceps tendon synovial sheath. Preliminary scout films are obtained, as are anteroposterior views in internal and external rotation and abduction of the shoulder, an axillary view, and a bicipital groove view. In obtaining anteroposterior views, the tube is tilted approximately 15 to 20 degrees caudad to allow visualization of the subacromial space without posterior overlap by the acromion.[115] Normally the entire shoulder should fill from the glenoid to the anatomic neck without any irregularities. When the biceps tendon sheath and tendon outline is easily visualized without any narrowing or vacuolization, significant inflammation is unlikely[99] (Fig. 7-12). Loss of the sharp delineation of the long head tendon may suggest the presence of associated synovitis. The main drawback of arthrography is that filling of the sheath of the biceps tendon is unreliable and may be absent in up to 31% of arthrograms, especially in the presence of full-thickness cuff tears.[91,92] The absence of filling of a normal tendon may therefore be difficult to differentiate from rupture. Although vacuolization of the sheath with narrowing of the contrast may be noted in some cases, often there may be no difference in the pattern of filling of the tendon sheath in cases of tendinitis compared to normal tendons.[3,5] Because of this, arthrography of the shoulder can be of limited value in the diagnosis of bicipital tendinitis without atrophy, fraying, or subluxation of the tendon.[3] Arthrography can be useful for demonstration of the bony configuration of the bicipital groove and sensitive for the detection of subluxation of the biceps tendon medially out of the groove.[96] The sensitivity for detection of subluxation or dislocation of the tendon can be enhanced with commuted tomographic (CT) arthrography.[56] Although useful at times, arthrography has become less popular in the age of MRI and ultrasonography because it is an invasive procedure with potential side effects, such as exacerbation of shoulder pain; complications, such as allergic reaction to the contrast medium; and infection.[57]

Ultrasonography

In the late 1980s, with improving technology and expertise, ultrasonography became increasingly applied for the diagnosis of shoulder pathologies. Ultrasonography has the advantage of correlating, in a dynamic fashion, abnormal findings with clinical sites of tenderness.[2,83,91,92] The test is noninvasive and relatively inexpensive, and offers the opportunity for bilateral examinations at the same sitting. The tendon can be best imaged by transverse scanning at the bicipital groove.[91,92] The normal tendon appears as an echogenic ellipse within the groove (Fig. 7-13). Proximal to the groove, the tendon is visible lying against the humeral head, covered by the supraspinatus posterosuperiorly and the subscapularis anteroinferiorly. On longitudinal imaging, the tendon appears as a narrow band of tissue between the humerus and the deltoid, differentiated from the latter due to its greater echogenicity. Absence of the biceps tendon in its sheath indicates rupture or dislocation out of the groove. Ultrasound can detect effusions within the sheath

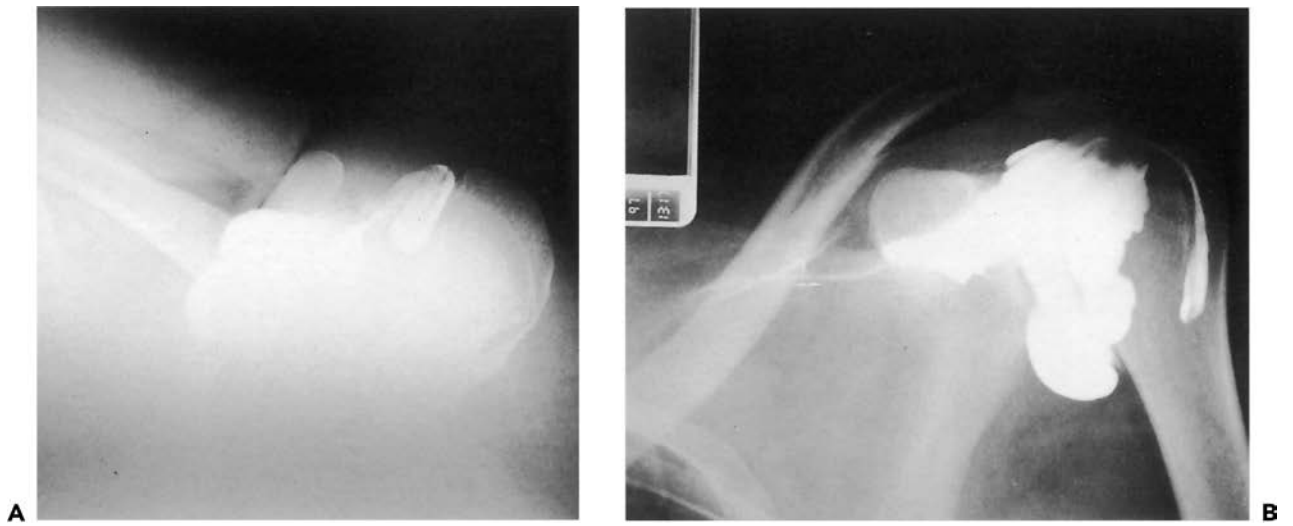

Figure 7-12 Arthrogram of the glenohumeral joint showing the relationship of the biceps tendon. **A.** Contrast dye is normally seen down the biceps tendon sheath and a tendon outline can generally be visualized. In absence of any significant narrowing or vascularization, this generally indicates that inflammation is unlikely. **B.** Dye in the bicipital groove can also be seen on the biceps view.

Figure 7-13 **A.** Ultrasound view shows a subluxated biceps tendon. The arrow is pointing to the hyperechoic (white) biceps tendon as it is perched on the lesser tuberosity. The transverse humeral ligament, which is also hyperechoic, is seen overlying the tendon. **B.** Ultrasound view showing a dislocated biceps tendon. The arrow is pointing to the hyperechoic biceps tendon, which is medially dislocated on top of the lesser tuberosity. **C.** Magnetic resonance image (MRI) of subluxated biceps tendon with partial subscapularis tear. **D.** MRI of dislocated biceps tendon and full-thickness subscapularis tendon tear.

of the biceps, and can detect other abnormalities in the groove such as osteocartilaginous loose bodies. In a prospective study of 80 patients, Middleton et al. compared the value of sonography and arthrography in the detection of lesions at the bicipital groove and distally in the biceps tendon.[92] In 20% of cases, with negative arthrograms for biceps lesions, effusions of the sheath of the biceps tendon were demonstrated by ultrasonography. Most of these patients had other associated pathology in the shoulder.

In our experience, ultrasonography has been extraordinarily accurate not only in defining the presence of associated rotator cuff defects, but also in precise characterization of the morphology.[125] Subtle partial-thickness or full-thickness defects in the anterior edge of the supraspinatus or superior edge of the subscapularis, seen with tendon instability, can be visualized with surprising accuracy. These improvements have followed recent technologic gains in the resolution of the scanners and refinements in technique gained with increasing clinical experience.

There are some limitations to ultrasonography. The test is highly dependent on the technical expertise of the radiologist and at this time is not widely available. Additionally, the viewing area is constrained by the bony anatomy. Because the acromial process cannot be penetrated, medial pathology at the joint line such as labral defects are not well visualized. Given these disadvantages, it is anticipated that ultrasonography will become increasingly popular secondary to significant advantages in cost effectiveness, patient tolerance, bilateral information, and associated accuracy.

Magnetic Resonance Imaging

Magnetic resonance imaging provides high-resolution soft tissue imaging in a noninvasive fashion and has the advantage of multiplanar study of the shoulder.[64] In addition, the morphology of the bicipital groove can be studied and bony osteophytes or other abnormalities detected.[24] Images in the axial plane and in the coronal oblique and sagittal oblique planes (with reference to the plane of the subscapularis) are used for a routine shoulder study. In axial images, the biceps tendon can be identified on T1-weighted images as a round, low-signal intensity structure contained in the bicipital groove. The tendon of the subscapularis muscle can be visualized sweeping anterior to the tendon to its insertion on the lesser tuberosity. In the coronal oblique sections, the tendon is seen as a linear structure between the greater and lesser tuberosities. Sagittal oblique sections can demonstrate segments of the tendon within the groove. In cases of bicipital tendinitis, an effusion may be noted in the tendon sheath with or without a corresponding effusion in the shoulder joint. Thickening of the tendon may be observed in some cases with hypertrophic tendinitis. An empty groove in the axial section suggests rupture or dislocation of the tendon. A medially dislocated tendon should be considered in these cases (Fig. 7-13B,C). It is important to follow the tendon on serial axial sections to avoid mistaking osteophytes in the groove for the tendon. As a high incidence of abnormalities or disruption of the subscapularis tendon is reported in association with luxation of the biceps tendon, special attention should be given to it. Because the long head of the biceps tendon is not visualized in continuity, it is easy to miss subluxations or even dislocations of the tendon between slices. Spritzer et al. examined the effectiveness of conventional MRI to detect the presence of biceps tendon instability. In this small series, MRI had a sensitivity of 67% and a specificity of 90% in detecting biceps tendon instability.[124] Another series reported the accuracy of MRI in detecting surgically confirmed lesions of the biceps tendon and their association with rotator cuff tears. The MR examinations were performed with IV contrast only. The sensitivity, specificity, and accuracy of unenhanced MRI for detecting biceps tendon tears were 52%, 86%, and 79%, respectively. When a tear was present in the biceps tendon, the prevalence of supraspinatus, infraspinatus, and subscapularis tendon tears was 96%, 35%, and 47%, respectively. Patients with biceps tendon tears were significantly more likely to also have subscapularis and supraspinatus tendon tears than patients with a normal biceps tendon.[8]

MRI has not proven useful in the diagnosis of superior labral lesions, with reports of a positive scan in only about a third of cases.[39] Magnetic resonance arthrography employing the intraarticular injection of gadolinium has been reported to provide better definition of labral lesions than conventional MRI.[41] Bencardino et al. evaluated the accuracy of MR arthrography for the detection of SLAP tears in a series of patients with confirmative surgical findings. MR arthrography showed a sensitivity of 89%, a specificity of 91%, and an accuracy of 90% for detecting SLAP injuries.[10]

The value of MRI appears to be more for defining associated shoulder pathology such as partial- or full-thickness rotator cuff tears.[64] However, it is an expensive and at times poorly tolerated test and is generally not recommended as the procedure of choice for imaging the long head of the biceps tendon or superior labrum.

NONOPERATIVE TREATMENT

Long Head of the Biceps Tendinitis

Nonoperative treatment of long head of the biceps tendinitis has generally been directed toward treatment of the rotator cuff. A failure to improve or an increase in symptoms is more often seen in those cases with a component of

biceps tendinitis. Biceps tendinitis is typically more resistant to treatment and does not respond to subacromial steroid injections.[21,96–98] For this reason direct tendon sheath injections have been suggested when subacromial ones have failed. DePalma and Callery, in a series of 18 cases treated for isolated bicipital tenosynovitis, reported improvement in 10 when given a series of hydrocortisone injections into the tendon directly under the transverse ligament.[33] More modern concerns for atrophic tendon changes from the steroid have led to recommendations for sheath injections in preference to intratendinous ones.[72] A 74% good and excellent result has been reported with this approach.[72] Technical difficulties associated with "blind" injection of biceps tendon sheath have led to recommendations for intraarticular injections as an alternative method.

Very little information is available about the nonoperative treatment of SLAP lesions or long head of the biceps instability. As tendon instability almost invariably follows the development of significant rotator cuff pathology, treatment is again directed primarily along those guidelines. With instability of the biceps, nonoperative measures are less likely to be successful and earlier operative intervention or prolonged activity restrictions are required.

Spontaneous or traumatic ruptures of the long head of the biceps tendon do not require operative intervention.[21,23,56] Although associated with a cosmetic defect, the long-term functional and symptomatic sequelae are minimal. Mariani et al. compared 26 patients who underwent early tenodesis of a rupture of the long head of the biceps with 30 patients who had nonsurgical treatment.[86] Residual pain was found to be infrequent for both groups. On biomechanical testing the nonsurgical group lost 21% of supination strength versus 8% for the surgical group. There was no significant difference in elbow flexion. The nonsurgical patients returned to work earlier. Similar results were reported by Warren, who showed no loss of elbow flexion strength and only 10% supination loss.[134] Although the vast majority of tears of the long head of the biceps are the result of attritional tendon changes in the elderly, there is a much lower incidence of traumatic tears in the younger and active patient. In these patients some (up to 30%) will have symptoms of cramping pain in the biceps muscle with strenuous activities. Some of these symptoms improve over time, but a percentage of these patients' symptoms persist. It may be advisable to tenodeseis the biceps in these younger and active patients.

Authors' Preferred Treatment—Long Head of the Biceps Tendinitis

Nonoperative treatment is primarily directed at the accompanying rotator cuff tendinitis. This includes rest, local modalities such as ice, nonsteroidal antiinflammatory medication, physical therapy, and local steroid injections.[93,108] When patients present with acute or significantly painful shoulders, initial treatment is directed toward inflammation control instead of strengthening. Starting physical therapy at this time may cause exacerbation of symptoms. Rather, a short period of rest or reduction of activities is started.

Nonsteroidal oral medication given at antiinflammatory doses is used in conjunction with local measures like ice. It should be noted here that many patients who present for orthopaedic consultation have some history of nonsteroidal use. However, dosages and compliance is often insufficient for anything more than an analgesic effect. To achieve maximal antiinflammatory benefit, nonsteroidal medication should be taken in a sustained fashion and at antiinflammatory doses.

Subacromial injections are given only in the context of severe night pain or a failure to improve with 6 weeks of treatment. Physical therapy is instituted only after some initial improvement in symptoms. It is directed toward range-of-motion stretching and rotator cuff strengthening. There is no attempt made to specifically strengthen the biceps muscle. If there are strong signs or suspicions of biceps-related pain, then an intraarticular injection of steroids is considered. Theoretically, to achieve maximum benefit, the steroid should be injected into the tendon sheath only and intratendinous injection avoided. Because this is technically difficult to achieve on a consistent basis, we prefer to inject the solution into the shoulder joint cavity, thereby addressing the intraarticular and extraarticular portions of the tendon.

We generally prefer to perform intraarticular injections from a superior approach analogous to the superior arthroscopic portal as described by Neviaser.[100] A spinal needle is required. The entry site is in the supraclavicular region. The needle is inserted 1 cm medial to the medial border of the acromion just posterior to the clavicle and anterior to the scapular spine. A "soft spot" can reliably be palpated there. The needle is advanced, aiming 30 degrees anteriorly and 30 degrees laterally. To assist in orientation, the arm is placed in 30 degrees of coronal plane abduction and the needle directed down the long axis of the arm. Upon contact with the humeral head, the needle is withdrawn by a few millimeters and a solution of local anaesthetic and water-soluble steroid suspension is injected. Immediate and temporary relief of symptoms is diagnostic and hopefully therapeutic.

The patient is monitored at 6-week intervals throughout the nonoperative treatment period (Fig. 7-14). At each of these follow-up consultations a reevaluation of progress is coordinated with indications for further workup or treatment changes. When significant improvements are made, a gradual tapering of nonsteroidal medication and progression of activities and physical therapy is attempted. When there are no significant changes, depending on the severity and nature of the symptoms, further observation without

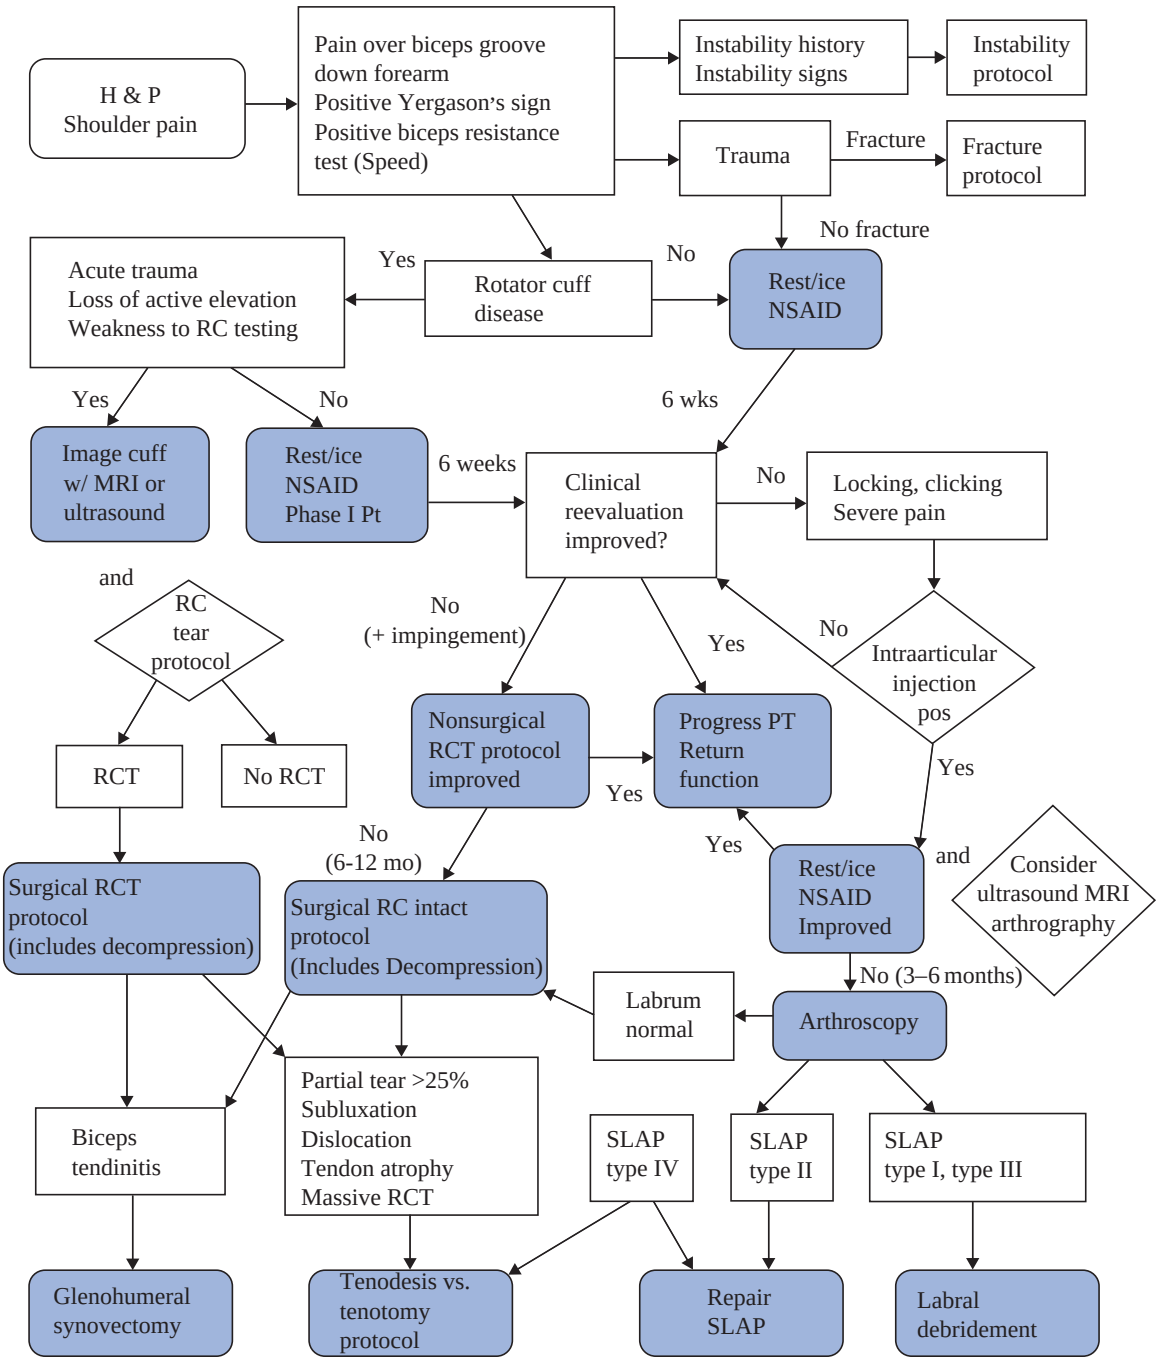

Figure 7-14 Algorithm for treatment of long head of biceps disorders. H&P, history and physical; MRI, magnetic resonance imaging; RC, rotator cuff; NSAID, nonsteroidal anti-inflammatory drug; RCT, rotator cuff tear; PT, physical therapy; SLAP, superior labral anterior posterior.

treatment changes is reasonable. The deterioration of symptoms or a continuation of severe symptoms should alert the treating physician that further workup or treatment modification may be indicated. Treatment modification should include differential injections, including intraarticular as described above. Further workup may include imaging for rotator cuff tears and biceps tendon subluxation. Ultrasound, MRI, and CT arthrography are examples of modalities that may provide information about both the rotator cuff and long head of the biceps tendon. If a strong suspicion remains for biceps-related pain despite a negative intraarticular injection, a bicipital groove injection is considered. In our institution, this injection can be performed with high accuracy with the use of ultrasound guidance. In the absence of significant findings with these studies, nonoperative treatment including repeat injections (maxi-

mum of three) is continued for a minimum of 6 months if the injections are positive (patient experiences some relief of symptoms). In the absence of copathology such as rotator cuff tears or tendon instability, a high percentage of patients (greater than 80%) are expected to experience satisfactory improvement. A negative finding for both imaging studies and injections should alert the treating physician for alternate causes of anterior shoulder pain including instability, adhesive capsulitis, glenohumeral arthritis, acromioclavicular arthrosis, coracoid impingement syndrome, neurogenic causes, and medical conditions.

Long head of the biceps instability and SLAP lesions are generally considered operative indications in those rare circumstances where a strong preoperative diagnosis is available and there is greater than 3 months of pain. Nonoperative treatment for these disorders is limited to rest and intraarticular injections.

SURGICAL TREATMENT

Reflecting remaining controversies about the functional and symptomatic significance of the long head of the biceps tendon, multiple and often contradictory treatment strategies and indications have been recommended. Options for surgical treatment include benign neglect with treatment of associated pathology only (i.e., rotator cuff, labral defects), inspection and synovectomy, repair of partial tears, tenodesis in the intertubercular groove, or simple intraarticular tenotomy. Historically, concerns about functional deficits created by loss of the long head of the biceps tendon have led to a prevailing operative strategy for avoidance of tenodesis whenever possible. If sacrifice of the biceps tendon is indicated, the decision to perform tenotomy versus tenodesis is based upon the age, functional demands, and cosmetic concerns of the patient.

Treatment for Biceps Pathology Associated with Rotator Cuff Disease

Pathophysiology

Surgery for rotator cuff disorders accounts for the majority of cases in which biceps pathology is encountered. The biceps tendon is susceptible to the same mechanical abutment seen with impingement of the rotator cuff tendons. Whether primary or secondary causes of impingement exist, the long head of the biceps occupies an anterior location within the impingement zone, which predisposes its involvement with rotator cuff disease. Besides these compressive forces, the biceps tendon is susceptible to inflammation and degenerative changes secondary to the synovitis initiated from primary rotator cuff disease.

Neer recommended routine inspection of the long head of the biceps and intertubercular groove as part of the surgical procedure for impingement syndrome.[95] Later reports by Neviaser have noted a high prevalence of pathologic changes in the biceps tendon macroscopically, as well as microscopically (in normally appearing intraarticular portions of the biceps tendon) in patients with rotator cuff disease.[94] Based on their experience, they recommended inclusion of biceps tenodesis with excision of the intraarticular segment as part of the surgical procedure for the treatment of impingement syndrome.[97] The work of Petersson and Murthi et al. has highlighted the strong association prevalence of biceps tendon pathology with rotator cuff disease.[94,107] In addition, the incidence of biceps pathology increases with advancing age the severity of the underlying cuff disease.

Treatment of Biceps Tendonitis Associated with Rotator Cuff Disease

While the high association of long head of the biceps tendon pathology has not been disputed, indications for surgical treatment have been varied and inconsistent. According to Crenshaw and Kilgore, the indications for tenodesis were pain present for an average of about 5 months, bicipital tenderness, and restriction of motion.[31] The authors reviewed 89 patients who had undergone surgery for bicipital tenosynovitis, with a minimum follow-up of 1 year. Average age at the time of surgery was 52 years. All patients were treated with bicipital tenodesis using various techniques. Maximum improvement was reached at about 12 months after surgery, with excellent and good results obtained in 87%. Pain relief was dramatic with relief from disabling pain in 80% by the end of the month, and in 95% by 3 months.

Neer highlighted the importance of mechanical impingement from the anterior acromial arch as the primary cause of anterior shoulder pain.[95] In a series of 50 shoulders with the preoperative diagnosis of biceps tenosynovitis, only 30% had significant biceps abnormalities and favorable results were obtained with acromioplasty alone. In this series, tenodesis was rarely performed, and biceps-related symptoms were reliably improved from decompression alone. Neer recommended avoidance of biceps tenodesis, whenever possible, to prevent a loss of head depressor effect.

Other early reports recommended tenodesis for shoulder pain unresponsive to conservative measures and regardless of the extent of operative findings. Lippmann observed a relief of symptoms in patients who developed spontaneous adhesion of the tendon in its groove and attempted to reproduce the same surgically in acute cases.[84] In this technique, the long head of the biceps tendon was anchored in its groove with several nonabsorbable sutures passed through drill holes in the lesser tuberosity. Hitchcock and Bechtol also described fixation of the tendon in the bicipital groove.[65] Their technique, however, created an osteoperiosteal flap raised from the floor of the groove. The tendon was placed deep to this flap and secured with nonabsorbable sutures. The transverse

humeral ligament was sutured over, reinforcing the repair. An alternative and popular technique for the long head of the biceps tenodesis after release of the intraarticular origin, as described by Froimson and termed the "keyhole" technique, involved placement of a rolled or knotted biceps tendon into a keyhole-shaped trough that had been drilled in the bicipital groove[43] (Fig. 7-15).

The importance of treating associated rotator cuff pathology was highlighted in several other series. In a retrospective review of 20 shoulders in 18 of patients who underwent biceps tenodesis without subacromial decompression, Dines et al. reported good results in 14 shoulders at a mean follow-up of 3 years.[34] The patients were categorized into two groups based on findings at surgery: those with inflammatory lesions in the bicipital groove and those with instability of the tendon. The majority of the patients were young with an average age of 33 and 35 years in the two groups, respectively. In addition to the biceps procedure, incision of the coracoacromial ligament was performed in 14 of 20 cases. Poor results were associated with younger age and failure to release the coracoacromial ligament. Of the six failures, four were attributed to impingement against the acromion and glenohumeral instability was observed in two. The authors recommended careful preoperative examination for the exclusion of glenohumeral instability in younger patients and suggested that acromioplasty be a major component of the surgical procedure in older patients. The authors did not report any complications, such as superior head migration, arising from tenodesis of the long head.

Becker and Cofield reported the long-term follow-up of 54 shoulders at an average of 13 years after surgical tenodesis of the long head of the biceps for the treatment of chronic tendinitis.[9] As part of the exposure, the coracoacromial ligament was routinely transected, the intraarticular portion of the long head was removed, and the remainder was tenodesed at the bicipital groove or to the short head. Acromioplasty was not performed. At latest follow-up, 22 shoulders had mild or no pain, whereas the other 22 continued to be moderately[113] or severely[137] painful. Twenty-nine patients needed additional treatment in the form of steroid injections or surgical procedures (8%) including rotator cuff tear repairs, anterior acromioplasty, and excision of the distal clavicle. They advised against bicipital tenodesis without decompression as the primary surgical procedure due to deteriorating long-term results. In their opinion tenodesis was indicated if, during a surgical procedure directed primarily at the rotator cuff, degenerative changes were encountered in the biceps tendon or if the tendon was unstable or displaced from its groove.

In contrast to the Becker and Cofield study, tenodesis of the long head of the biceps has been reported to have good results even when not performed in conjunction with a decompression of the coracoacromial arch. Post and Benca showed 94% excellent results in a series of 13 patients with primary bicipital tendinitis.[110] Berlemann and Bayley reported improved results of biceps tenodesis with long-term follow-up.[12] Of interest, 8 of the 15 cases in this series had persistent pain following decompression. Six of the eight then had complete resolution of the symptoms following biceps tenodesis.

While the long-term results as reported by Becker and Cofield would suggest a relatively poor outcome for an isolated biceps tenodesis, no studies have shown adverse results when performed in conjunction with a decompression of the coracoacromial arch. Neviaser and coauthors reported their experience with 89 patients who underwent routine biceps tenodesis as part of the procedure for subacromial decompression.[97] They operated on 89 patients, the average age being 42 years, and evaluated the results at 2 to 8 years. Patient results were based on pain relief and range of motion. All but one patient reported no pain (86%) or pain with unaccustomed exertion (13%). One patient was diagnosed to have adhesive capsulitis postoperatively and continued to have pain at night and intermittently during the day. The authors did not report any functional loss secondary to tenodesis of the biceps tendon.

Despite the excellent results reported for biceps tenodesis performed in conjunction with acromioplasty, the routine employment of a tenodesis is unsupported.[95,115] Multiple studies in which biceps tenodesis was generally avoided during treatment of the rotator cuff have shown good results with decompression and cuff repair alone.[13–16,29,36,37,46,60,62,78,127] It is, however, unclear how many of the failures may have been secondary to persistent biceps-related pain.

Recent advances in equipment and surgical techniques now allow biceps tenodesis to be performed arthroscopically. A variety of tendon fixation techniques have been described using suture anchors, tenodesis screws, or soft tissue tenodesis alone. Many of these techniques are technically demanding but offer the advantage of secure tendon fixation via small, cosmetic incisions.

Gartsman and Hammerman described a technique of arthroscopic biceps tenodesis using suture anchors.[45] The intraarticular portion of the biceps tendon is pierced with a spinal needle at the proximal aspect of the bicipital groove. The arthroscope is directed into the subacromial space and the needle is used to identify the biceps tendon. The biceps sheath is open and débrided with a shaver through the lateral cannula. The biceps groove can be deepened with a burr. One or two suture anchors are placed into the biceps groove. A Caspari punch is used to place a shuttle suture through the biceps tendon via the lateral cannula. One limb of the anchor suture is then shuttled through the tendon using the shuttle suture. These steps are repeated with the remaining limb of the anchor suture creating a mattress stitch, which is then secured arthroscopically. The biceps tendon is then divided and the intraarticular portion of the tendon is removed arthroscopically.

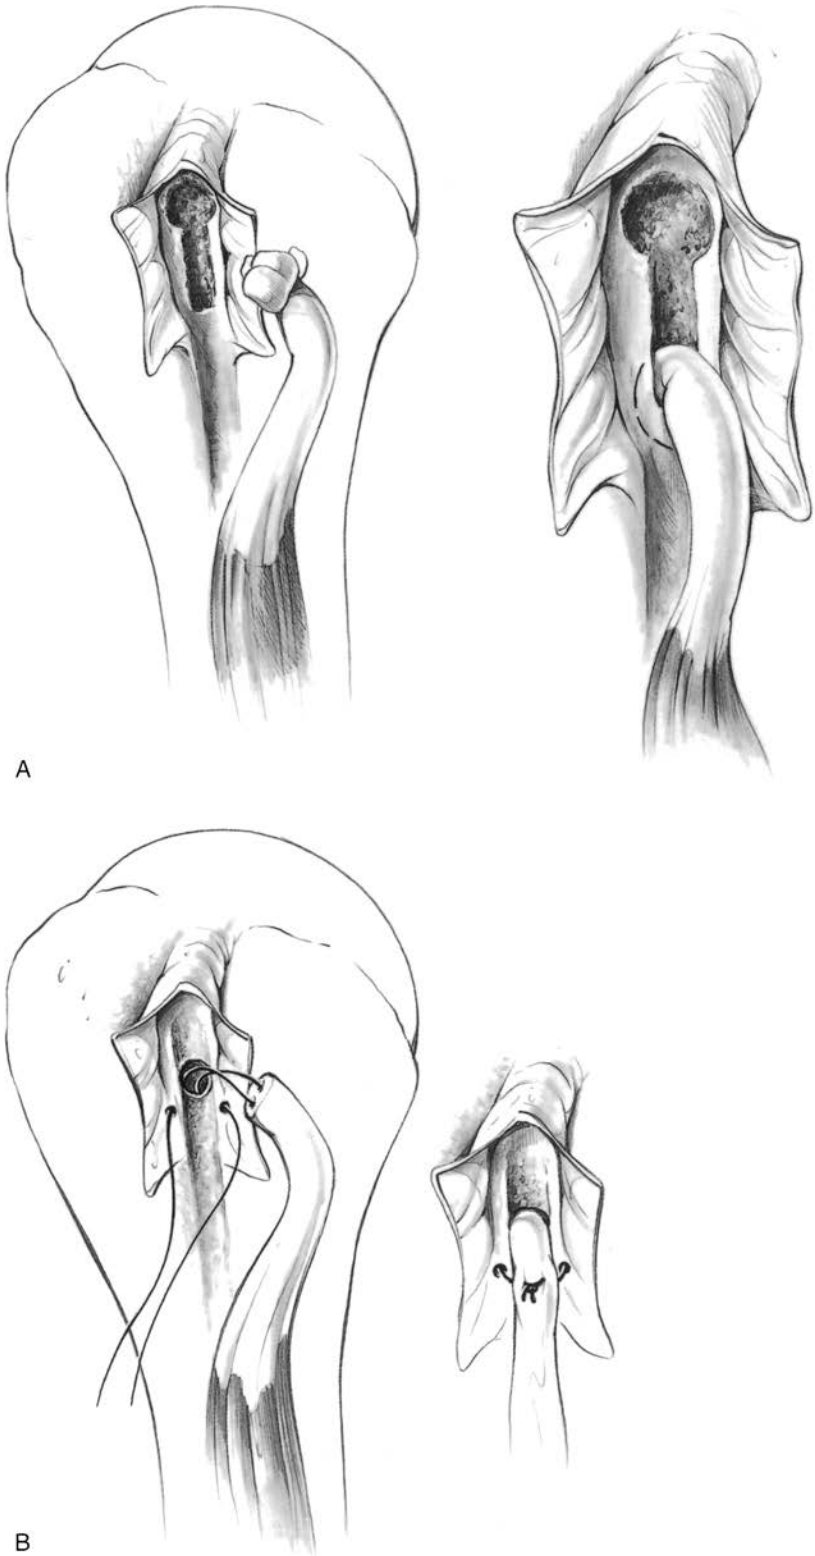

Figure 7-15 A schematic representation of two popular techniques for open biceps tenodesis. **A.** In the keyhole technique, as described by Froimson, the knotted proximal end of the biceps tendon is placed into a keyhole slot, which had been drilled into the bicipital groove. **B.** In the Post technique, the proximal portion of the biceps tendon is inserted into a round hole drilled into the bicipital groove. Tendon grasping stitch, which had been placed through the proximal end of the tendon, is brought into the hole and out through two drill holes. The tendon is then sutured into itself.

Boileau et al. and Klepps et al. have described techniques of arthroscopic biceps tenodesis using bioabsorbable interference screws for tendon fixation. Boileau et al. reported a technique of interference screw fixation after pulling the tendon into a tunnel in the proximal aspect of the bicipital groove with sutures that have been delivered out the back of the shoulder by drilling through the proximal humerus with Beath pins.[18] Results of this technique in 43 patients were recently reported.[19] The majority of cases were performed in conjunction with débridement of an irreparable massive cuff tear. The absolute Constant score improved from 43 to 79. Two failures of the tenodesis were noted. Elbow motion was full and biceps strength was 90% of the opposite side.

Klepps et al. described a technique of interference screw fixation utilizing a suture anchor at the base of the tunnel to feed the biceps tendon into the bone.[74] The intraarticular portion of the biceps tendon is tagged with a suture at the proximal aspect of the bicipital groove using a spinal needle. The origin of the tendon is released from the superior labrum. The arthroscope is then directed into the subacromial space. A lateral portal is established, through which a bursectomy and subacromial decompression are performed. An anterolateral portal is created directly over the biceps groove. After the biceps groove is opened and débrided, the biceps tendon is exteriorized through the anterolateral portal, shortened, and tagged with a heavy, nonabsorbable suture in a running fashion. The appropriate tunnel location within the bicipital groove is marked with a pin through the anterolateral cannula. The tunnel is enlarged with a cannulated reamer. The reamer size should be the same size or slightly larger than the width of the biceps tendon. The size of the interference screw should be the same width of the biceps tendon or 1 mm larger. If a "biotenodesis tray" is not available, a suture anchor can be used to shuttle the tendon into the tunnel and held while the interference screw is placed (Fig. 7-16). The anchor is placed into the base of the tunnel. One limb of the anchor suture is placed through the biceps tendon. The other limb of the anchor suture is pulled, thereby feeding the tendon into the tunnel. The Arthrex biotenodesis tray (Arthrex, Naples, FL) contains a cannulated screwdriver that will feed the tendon into the tunnel as the interference screw is placed. A flexible guidewire is used to feed one limb of the tendon suture through the driver. This suture is tensioned while the tip of the screwdriver guides the tendon into the tunnel (Fig. 7-17). The interference screw is advanced into the tunnel through the anterolateral cannula. The two limbs of the biceps tendon suture, one limb now inside and one outside the interference screw, are then tied, providing further fixation of the tendon to the screw.

An alternative method of arthroscopic biceps tenodesis can be performed using soft tissue fixation only. Soft tissue tenodesis can be accomplished quicker than those techniques requiring bone fixation. In addition, soft tissue tenodesis is less demanding technically and is associated with

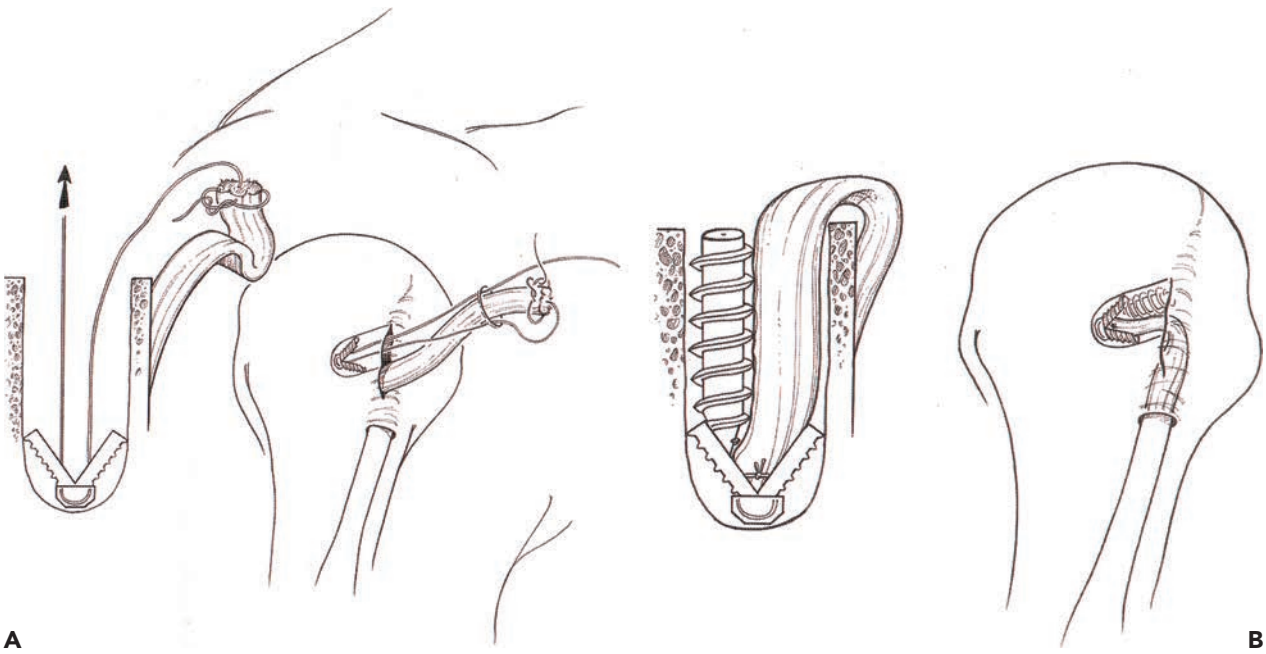

Figure 7-16 Illustration of suture anchor being used as a pulley system for interference screw tenodesis. **A.** Suture anchor at the base of the tunnel serves as a pulley to draw the tendon into the tunnel. **B.** The tendon is delivered to the base of the tunnel and secured with an interference screw. less soft tissue dissection than bone fixation techniques, thereby taking advantage of local tendon adhesions within the groove. Tendon scarring within the groove and proximal tendon hypertrophy may explain why some spontaneous ruptures or biceps tenotomies are not associated with significant distal retraction of the tendon stump. The primary concern with soft tissue tenodesis is limited strength of the repair. Wolf and coauthors compared the strength of simple tenotomy versus tenodesis with interference screw fixation in a cadaver model.[136] The biceps tendon was loaded in a cyclic manner with 50 N and observed for migration of the tendon distally. Load to failure was then performed in those shoulders without evidence of biceps migration. Interestingly, only 4 of the 10 tenotomized specimens failed after cyclic loading compared to none of the tenodesed specimens. The ultimate load to failure for the tenotomy group (110 N) was significantly lower than the tenodesis group (310 N).

Biceps Tenodesis Versus Tenotomy

Considerable controversy persists in the decision to perform tenodesis or tenotomy for the treatment of biceps tendon pathology. Factors that play a role in the decision making include the age and activity level of the patient and cosmetic concerns. The potential benefits of simple tenotomy must be tempered against the potential for residual biceps pain and spasm as well as a cosmetically unacceptable result. Ultimately, the decision to perform a tenodesis or tenotomy is based on the surgeon's personal preference and philosophy.

Historically, biceps tenodesis has been the preferred method of treatment for long of head biceps tendon disease. Numerous authors have reported good results following biceps tenodesis in various patient populations.[12,19,31,97,102,110] The advantages of biceps tenodesis in favor of tenotomy include improved cosmesis and potentially decreased incidence of biceps-related pain, spasm, and fatigue. These concerns are significant in younger patients and those participating in occupational and recreational activities that are demanding. Recovery following biceps tenodesis requires protection of the surgical repair. Active elbow flexion and forearm supination must be minimized while the repair is healing. In addition, biceps tenodesis increases the complexity of surgery, especially when performed arthroscopically. Residual tenderness in the biceps groove following tenodesis has been a concern as well.[75]

The presence of significant biceps muscle spasm and fatigue discomfort following tenotomy is a matter of debate. The literature regarding biceps-related pain following tenotomy is conflicting. Koening et al. reported the results of biceps tenotomy compared to tenodesis in a retrospective review of 61 patients.[75] Thirty-seven (mean age 48 years) had undergone a tenodesis and 24 (mean age 60 years) had either a tenotomy or spontaneous rupture. Follow-up ranged from 12 to 48 months. No significant differences were noted in the mean American Shoulder and Elbow Surgeons (ASES) score (74 vs. 72), pain (2.5 vs. 2.0), or activities of daily living scores (21 vs. 20) between the tenodesis and tenotomy groups. Fifty-three percent of the tenodesis group had local tenderness over the tenodesis site, but none had biceps muscle symptoms otherwise. In contrast, 68% of the biceps tenotomy and rupture patients did not like the cosmetic appearance and 72% had pain and cramping in the biceps muscle during activities requiring resisted supination and flexion of the elbow. Osbahr and coauthors reported the results of a retrospective review of 160 patients following either biceps tenotomy (mean age 58 years) or tenodesis (mean age 54 years).[103] The indications to perform tenodesis or tenotomy

were based on the age and physical demands of the patients and associated rotator cuff pathology. The average duration of follow-up was 20 months in the tenodesis group and 23 months in the tenotomy group. Patients were asked to subjectively report the degree of anterior shoulder pain, muscle spasms in the biceps, and cosmetic deformity. The authors found no significant difference between the groups with any of the measured outcomes. In addition, there were no differences in biceps-related symptoms between males and females.

In recent years, biceps tenotomy has become more popular for the treatment of patients with biceps tendon pathology, particularly older or low-demand individuals.[103,131] Potential benefits of tenotomy over tenodesis include ease of surgery and rapid postoperative recovery. The primary concern with tenotomy is the risk of residual biceps pain and spasm as well as cosmetic deformity. Numerous authors have reported successful results after biceps tenotomy combined with rotator cuff débridement in older patients with massive rotator cuff tears.[71,117,126] Walch et al. advocated release of the biceps tendon in cases of subluxation and dislocation associated with rotator cuff tear.[131]

Gill and coauthors reported good results in a group of relatively young patients following isolated biceps tenotomy.[51] Thirty patients with a mean age of 50 years were followed for an average of 19 months after surgery. All patients underwent arthroscopic biceps tenotomy for the treatment of biceps tendon tenosynovitis, partial rupture, and dislocation. Two patients underwent a concomitant arthroscopic subacromial decompression. The mean postoperative ASES was 81.8. Ninety-seven percent of patients returned to their previous occupation and 87% of patients were satisfied with the procedure. Four (13.3%) of the patients had poor results: one patient with an unacceptable cosmetic deformity, two cases of residual subacromial impingement, and one patient with residual shoulder pain.

Isolated biceps tenotomy is also effective when combined with other shoulder procedures in young patients. Kelly and coauthors reported the results of 40 of 54 patients with anterior shoulder pain treated with biceps tenotomy.[70] Only 9 of the 40 tenotomies were performed as isolated procedures. The mean patient age was 48 years. Seventy percent of patients were noted to have a Popeye sign on examination. The mean postoperative ASES score was 78. Sixty-eight percent of patients rated themselves as good or excellent. There were 7 of 40 self-rated poor results, all of which had concomitant procedures: five high-grade osteoarthrosis débridements, two rotator cuff repairs, and two acromioplasties. Overall, 95% of patients reported relief of tenderness on palpation of the biceps groove. However, 37.5% (13 patients) reported fatigue discomfort (soreness) isolated to the biceps muscle. The presence of residual biceps symptoms correlated with younger age. Seven of 11 patients under the age of 40 years were noted to have residual biceps symptoms following tenotomy compared to 8 of 19 between the ages of 40 to 60 years. No patients older than age 60 were noted to have residual biceps-related symptoms.

Treatment of Biceps Instability

Similar to biceps tendinitis, rotator cuff pathology is usually coexistent with tendon instability. Contrary to surgical treatment of tendinitis alone, sacrifice of the biceps tendon is the procedure of choice with biceps tendon subluxation or dislocation.[35,131] The rationale of tenotomy or tenodesis depends on the factors previously discussed. Biceps instability, both subluxation and dislocation, is known to occur in a variety of patient populations. However, a commonality to these patients is the presence of a rotator cuff tear, usually involving the subscapularis.[35,56,107,131] Those with frank biceps tendon dislocation have a high likelihood of both a full-thickness tear of the subscapularis tendon as well as the posterior cuff.[131] Walch et al. advocated biceps tenotomy for biceps instability associated with rotator cuff tear.[131]

O'Donoghue performed tenodesis of the biceps tendon in the groove by the technique of Hitchcock as a treatment for unstable biceps tendon in a young population involved in athletic pursuits.[102] Fifty-six operations were carried out in 53 patients with an age range of 15 to 35. Seventy-seven percent could throw satisfactorily and resumed sports. Edwards et al. reported the results of 84 patients following repair of a subscapularis tendon tear.[35] The mean age of the patients was 53 years. Fifty-four shoulders were noted to have medial subluxation or dislocation of the biceps tendon and 10 had complete rupture of the tendon. Forty-eight shoulders underwent concomitant tenodesis of the biceps tendon, while another 13 shoulders underwent concomitant tenotomy. The mean Constant score improved from 55 preoperatively to 79.5 postoperatively. Tenodesis or tenotomy of the biceps tendon at the time of subscapularis repair was associated with improved subjective and objective results, independent of the preoperative condition of the biceps tendon.

More recently, biceps instability concerns seen in the context of rotator interval lesions have been treated with attempted reconstruction of the coracohumeral ligament and rotator cuff tear.[132] In a series of 14 shoulders with subluxated biceps tendons an attempt at reinsertion of the tendon and repair of torn structures resulted in secondary rupture of the biceps tendon in 25%. When rupture is not seen there can still be concerns with autotenodesis with this operative strategy. Bennett attempted arthroscopic repair of the biceps sling in a series of 18 patients with interval lesions and partial-thickness rotator cuff tears, and otherwise healthy appearing biceps tendons. Improvement in shoulder pain and function was noted in the majority of patients.[11] One patient suffered rupture of the biceps tendon and two others had recurrence of biceps-related pain.

Treatment of Long Head of the Biceps Ruptures

Spontaneous or traumatic ruptures of the long head of the biceps do not generally require operative intervention.[23] While little information is available about operative treatment of long head ruptures, one study showed a 21% supination and 8% elbow flexion strength deficit.[89] Pronation, grip, and elbow extension strength were normal. When comparing operative versus nonoperative patient groups in 27 patients, residual pain was uncommon for both and nonoperative patients returned to work faster.

Treatment of Superior Labral Disorders (SLAP Lesions without Glenohumeral Instability)

Since the initial description of superior labral lesions, associated with the biceps origin by Snyder, treatment has generally been dependent on the type of pathology encountered.[32,121] Seen at most around 5% to 6% of the time, SLAP lesions without glenohumeral instability have been divided into four types as previously described.[122] Treatment options for these various types of SLAP lesions include simple débridement, suture repair, or tenodesis. In general, the type of treatment has been dependent on the type of pathology encountered.

Snyder, in his original description of SLAP lesions, described treatment for type I lesions as being simple débridement.[122] In type II lesions, the superior labrum and biceps tendon anchor was débrided at the bone–labral junction to obtain a bleeding base. Initially, further stabilization with a screw or suture was not performed secondary to an absence of available techniques. Type III lesions were treated with an excision of the bucket-handle portion of the tear. In type IV lesions, the torn portion of the biceps tendon and labrum were débrided. If more than 50% of the tendon was torn, then a tenodesis was performed. The short-term results were considered promising with 88% considered good or excellent. In a follow-up report by these same authors of 140 SLAP lesions treated arthroscopically, 21% were type I, 55% were type II, 10% were type III, and 5% were type IV.[120] Treatment included débridement alone for type I; débridement with glenoid abrasion alone for half of the type IIs and débridement with repair for the other half; débridement for type III; and débridement for type IV in half and repair in half. Repeat arthroscopy in 18 of the shoulders showed that three of five type II lesions treated with débridement alone had healed in comparison to four of five treated with repair. Type IV lesions that had been repaired all appeared healed on repeat arthroscopy. Additional data and outcome were unavailable.

Yoneda et al. described the use of an arthroscopically placed staple for type II lesions.[140] They performed the procedure in 10 young athletes and had a good or excellent result in eight. The two failures were thought to be secondary to persistent subacromial bursitis and multidirectional instability.

Field and Savoie prospectively treated 20 consecutive patients with type II and IV SLAP lesions of the shoulder with arthroscopic suture repair.[39] Sixteen patients had a history of a significant injury, the commonest mechanism being fall on the outstretched abducted arm. Arthroscopy revealed detachment of the superior labrum–biceps tendon anchor. The superior glenohumeral ligament was connected to the unstable fragment. A large number of patients had additional pathology including partial rotator cuff tears (eight cases), impingement syndrome (five cases), and acromioclavicular arthritis (three patients), which were addressed at the same time. All patients underwent arthroscopic débridement and reattachment of the lesion using transglenoid sutures. At an average follow-up of 21 months, the authors reported excellent results in 80% and good results in 20%. While the scores for motion, strength, and stability were improved after surgery, the increase in the pain and function scores was statistically significant.

Authors' Preferred Treatment—Surgical Management

Arthroscopic Evaluation

In the treatment of biceps tendon pathology, the initial treatment is generally arthroscopic. Arthroscopy provides a valuable tool to accurately visualize both intraarticular and intertubercular biceps pathology as well as any associated disorders such as rotator cuff tears. As we perform arthroscopy in the beach-chair position, open approaches can be easily conducted during the same sitting. Beach-chair arthroscopy is performed on a standard operating table. The patient is positioned as far lateral on the table as possible using a universal joint head holder and lateral pad to secure the patient safely. Arthroscopy is then initially performed in the glenohumeral joint through the standard posterior portal. The rotator interval is easily identified within a triangle demarcated by the biceps tendon superiorly, the subscapularis inferiorly, and the glenoid medially (Fig. 7-18). An anterior portal is established in an outside-in fashion by first placing a spinal needle just lateral to the coracoid tip. Needle placement is verified intraarticularly with arthroscopic visualization. A cannula is then placed with a sharp plastic trocar from outside to in. A standard diagnostic arthroscopy is performed with the arm under slight in-line traction. The articular surfaces of both the humerus and glenoid are thoroughly evaluated. The anterior glenoid labrum is visualized from the midportion of the glenoid to inferior observing for labral fraying or detachment that may suggest instability. Glenohumeral ligaments, particularly the inferior glenohumeral ligament, are then inspected. The scope is then brought to the rotator interval, the superior subscapularis muscle, and the tendon.

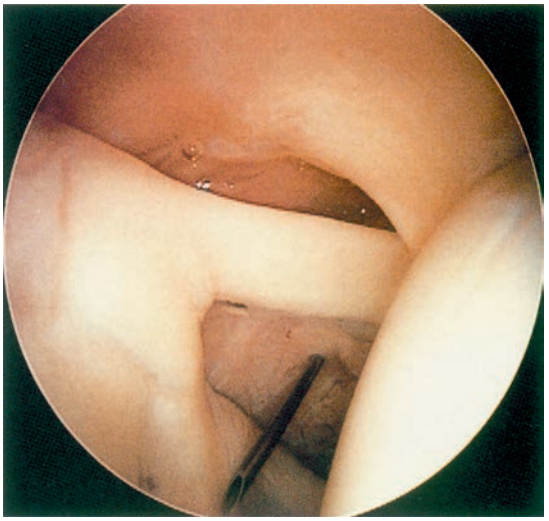

Figure 7-18 An arthroscopic view showing the rotator interval. A needle is placed just lateral to the coracoid under arthroscopic visualization to verify the location of the anterior portal.

From this position, the 30-degree scope is pointed laterally out toward the intersection of the biceps tendon and subscapularis (Fig. 7-19). In this fashion, the entire portion of the superior subscapularis is inspected. Internal rotation of the shoulder improves visualization of the subscapularis insertion. The scope is then brought posterior to the biceps tendon over the top of the humeral head to visualize the supra, infra, and teres minor insertions and the bare area of the humeral head. Following this, the scope is then brought up through the posterior aspect glenoid, inspecting for any posterior labral defects or any posterior–superior inflammation suggestive of internal

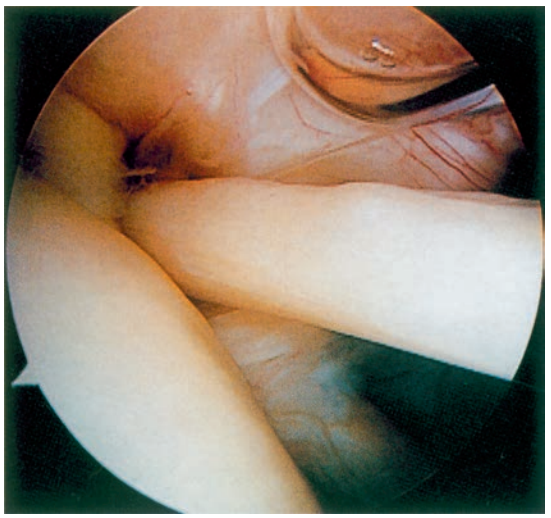

Figure 7-19 Arthroscopic view of the entrance to the bicipital groove. The intersection of the subscapularis and supraspinatus with the biceps tendon can be seen at the proximal portion of the bicipital groove. Pathology in this location may indicate a disruption of the rotator interval sling.

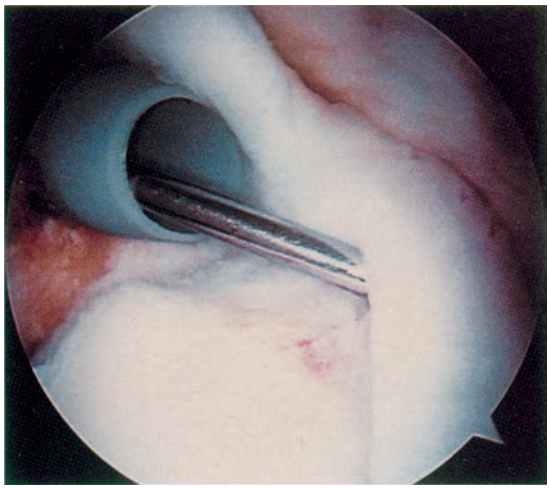

Figure 7-20 An arthroscopic view of a type II superior labral anterior and posterior (SLAP) lesion. A probe is placed under the anterior superior labrum to detect any detachment of the biceps origin. The probe is placed in from the anterior portal. Notice that easy access for abrasion of the glenoid rim can be achieved from this same portal.

impingement. The biceps tendon is then inspected at length from its superior labral attachment laterally to the bicipital groove. Under normal conditions, the entrance of the biceps tendon into the groove distally can easily be visualized. The probe is then placed anteriorly under the anterior–superior labrum and the origin of the biceps examined for any detachment suggestive of a superior labral lesion (Fig. 7-20). The probe is then placed over the top of the biceps tendon to pull the tendon farther into the joint to inspect the portion normally within the intraarticular groove (Fig. 7-21). The humeral head is brought from a position of external rotation into internal rotation to observe whether the biceps tendon is subluxated from the bicipital groove.

Treatment of Bicipital Tendinitis

We determine appropriate surgical treatment for the long head of the biceps tendon according to observations made during surgery and the preoperative physical examination findings. We feel that the biceps tendon can be a significant source of shoulder pain if not specifically addressed during a surgical procedure. This is based in part on multiple observations of patients who had spontaneous resolution of shoulder pain upon rupture of the long head. Additionally, as previously described in other studies, we have seen patients who have failed subacromial decompressions for chronic rotator cuff tendinitis or rotator cuff tears who later can achieve satisfactory pain relief from a revision surgery in which a biceps tenodesis is performed. However, we do not believe that routine biceps tenodesis is indicated. Given the symptomatic concerns of a significant biceps tendon disorder, we also do not believe that a policy

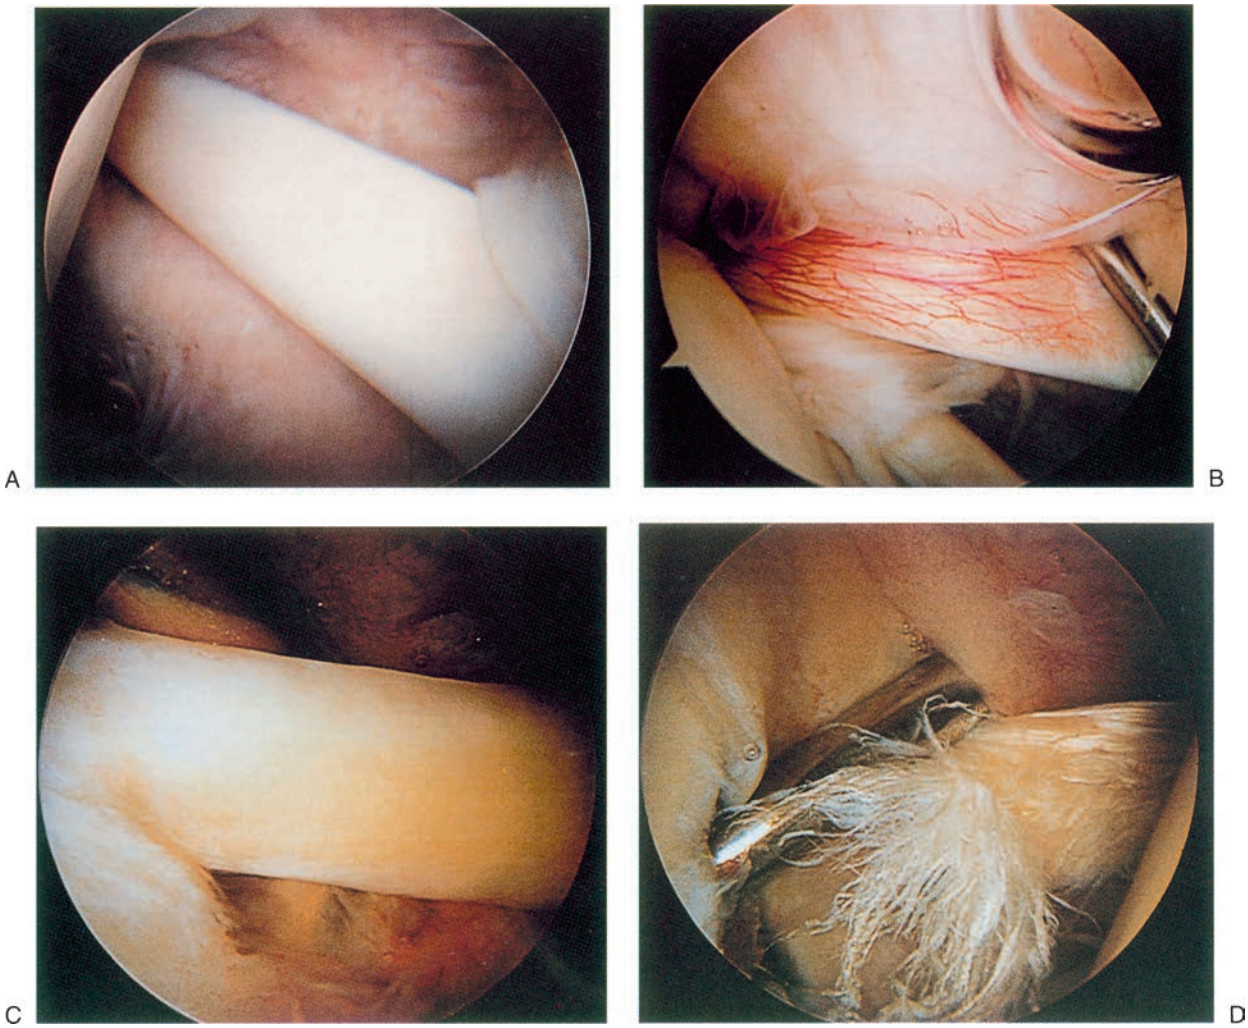

Figure 7-21 Inspection of the biceps tendon must include the intertubercular groove portion. This is inspected by placing a probe over the top of the biceps tendon and drawing the intertubercular groove portion into the joint. **A.** Shows a normal-appearing biceps tendon. **B.** When the intertubercular groove portion is drawn into the joint with a probe, a marked amount of synovitis is recognized. **C.** Again, the biceps tendon appears to be normal in the intraarticular portion. **D.** When a probe is used to draw in the intertubercular groove portion, a significant partial tear is detected.

of avoidance of tenodesis whenever possible is appropriate. Rather, avoidance of tenodesis is employed whenever it is felt that the inflammatory changes to the biceps tendon are reversible. In general, the criteria for a biceps tendon with reversible changes include less than 25% partial tearing from a normal-width tendon, a normally located tendon within the bicipital groove, and normal tendon size regardless of associated synovitis. Those surgical observations consistent with a biceps tendon with irreversible changes include partial-thickness tearing or fraying of the tendon greater than 25% of the normal width of the tendon, any luxation of the biceps tendon from the bicipital groove, any disruption of the associated bony or ligamentous anatomy of the bicipital groove that would make autotenodesis likely, and any significant reduction or atrophy in the size of the tendon greater than 25% of the normal width of the tendon (Fig. 7-22). Relative indications for sacrificing the biceps also include any biceps pathology in the context of a failed acromioplasty or any significant biceps pathology in the context of a SLAP lesion.

Inflammation of the biceps tendon or involvement of the biceps tendon within the marked inflammation seen with rotator cuff disease is treated in the standard fashion for rotator cuff disease alone. It is generally anticipated that adequate treatment of a rotator cuff tendinitis will resolve concurrent bicipital tendonitis. Generally, a florid subscapular synovitis is present, descending from the rotator interval to encompass the anterior–superior and posterior–superior labrum and bicipital groove portion of the biceps tendon (see Fig. 7-8). We have found a wide dispersion cautery device, such as the multifilament bipolar device (Arthrocare), quite useful in ablating the synovitis. The cautery

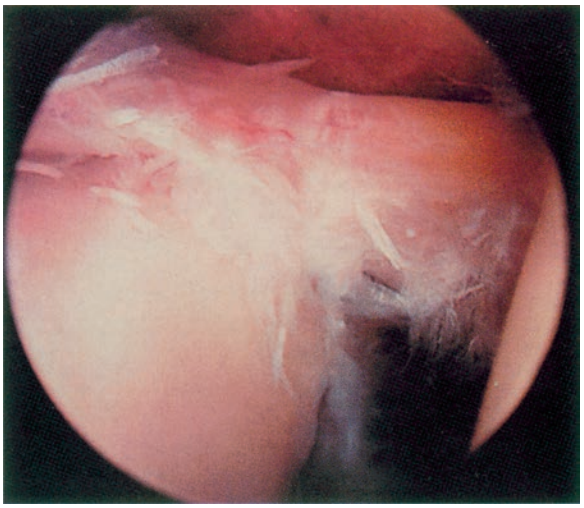

Figure 7-22 Arthroscopic view of a biceps tendon with greater than 25% fraying in the width of the tendon. In this situation, significant, chronic, or posttraumatic changes have occurred, which makes healing of the tendon less likely and concerns about persistent pain more significant. This is considered an indication for tenodesis.

device is used to vaporize the red, inflamed tissues on the undersurface of the rotator cuff without any penetration through the capsule to the cuff itself. No attempt is made to débride the inflamed synovium overlying the bicipital groove portion of the long head of the biceps.

If sufficient biceps pathology exists to warrant sacrifice of the tendon, the next decision in the treatment algorithm is biceps tenodesis versus tenotomy (Fig. 7-23). Preoperatively, we discuss the potential need to perform a biceps-related procedure in all patients undergoing surgery for the treatment of rotator cuff tendonitis or cuff tear. Specifically, the risks of cosmetic deformity and residual biceps spasm following tenotomy alone and the necessary biceps precautions observed with tenodesis are discussed. Review of patient preferences and concerns by the clinician as well as improved patient education play important roles in achieving a good outcome following surgery.

We prefer to perform a biceps tenodesis in younger patients (under 60 years); in those who remain physically active, at work or with recreation; and when cosmesis is a significant concern. When a biceps tenodesis is indicated, based on the above criteria, an arthroscopic-assisted approach is generally employed. In this technique, the biceps tendon is first tagged with a #1 polydioxanone (PDS) suture. This is accomplished by placing a spinal needle anterolaterally through the rotator interval. Under arthroscopic guidance, the needle is placed through the substance of the tendon near the bicipital groove entrance (Fig. 7-24). A #1 PDS suture is then threaded through the 18-gauge spinal needle into the joint. A suture grasper is inserted and the suture brought out through the anterior portal. In this fashion, the suture prevents any excursion of the long head of the biceps tendon down the arm. Once the biceps tendon is secured with the suture, the origin is released with either electrocautery or an arthroscopic scissor. Generally, after release of the origin, the excursion of the tendon is only 1 to 2 cm. The stay suture is only a preventive measure as the biceps tendon is wider at the base and generally will not travel down the bicipital groove unless atrophic changes are present.

Our preferred method of tenodesis employs bony fixation of the tendon under the pectoralis major tendon. We reserve this technique for young patients that are physically active. A subpectoral tenodesis is advantageous because the tenodesis site is well covered by soft tissue in this location. A 4-cm incision is placed in the axilla, centered on the inferior border of the pectoralis major tendon. The majority of the incision should be in the axilla, when the arm is at the side. This incision made along this line is quite cosmetic and for the most part not visible. Subcutaneous dissection is then taken to the deltoid pectoral interval, and this is then followed to the bicipital groove. The inferior portion of the transverse humeral ligament is then divided in line with the bicipital groove. The tendon is then visualized and drawn out of the groove using a curved clamp. The tendon is shortened 2 to 3 cm inferior to the PDS suture to maintain appropriate tension within the biceps. A tendon-grasping stitch is woven through the biceps with a heavy nonabsorbable suture. Soft tissues are dissected from the bicipital groove under the upper margin of the pectoralis tendon insertion. Fixation is accomplished using a bioabsorbable interference screw (Arthrex, Naples, FL). A tunnel is drilled with a cannulated reamer over a pin that has been placed in the desired location within the bicipital groove. The tendon and interference screw are then advanced into the tunnel using a cannulated tenodesis screwdriver. The two limbs of the tendon suture are then tied over the screw, further securing the biceps tendon.

If a mini-open rotator cuff repair is being performed, then tenodesis is accomplished through the mini-open deltoid splitting approach. The arm is externally rotated at the side to bring the bicipital groove out laterally underneath the deltoid split. The transverse humeral ligament is then divided in line with the groove. The biceps tendon is then delivered out through the deltoid split with the PDS suture in place (Fig. 7-25). The floor of the groove is then roughened with a curette. The length of the tendon in the tenodesis is determined by the stay suture, which was placed close to the insertion of the biceps tendon in the groove. The tenodesis is accomplished with an interference screw as previously described. The transverse humeral ligament is then sutured on top of the secured tendon. The excess intraarticular portion of the tendon is then excised.

An alternative technique of biceps tenodesis can be performed using soft tissue fixation alone. This technique is performed arthroscopically and is technically easier and faster than interference screw fixation. Because the biceps tendon is not dissected, adhesions within the bicipital

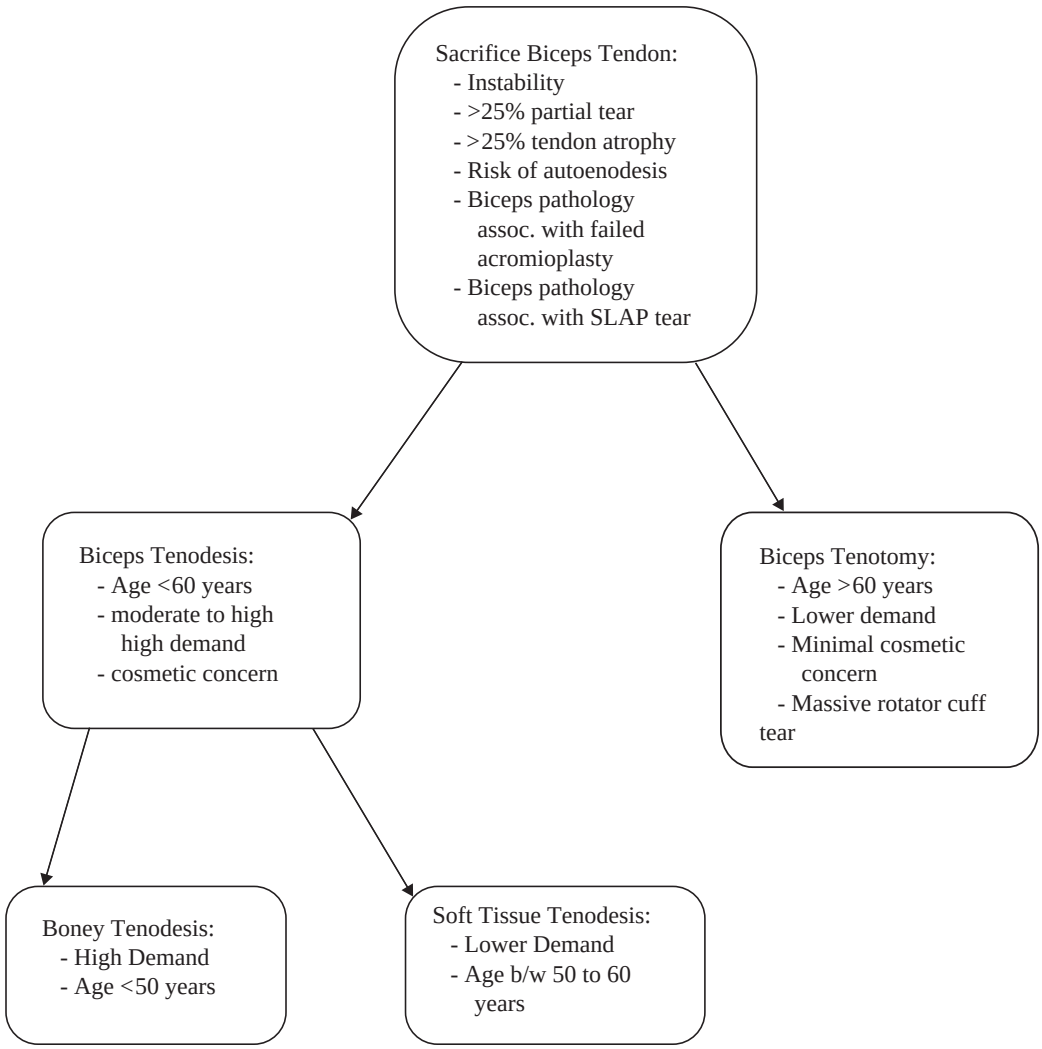

Figure 7-23 Algorithm for the treatment of biceps tendon pathology: tenodesis versus tenotomy.

groove may contribute to the strength of the tenodesis. We reserve this method of fixation in cases where tenodesis is preferred but the patient is less physically active. The tendon is tagged with multiple #1 PDS sutures through a percutaneous spinal needle at the apex of the bicipital groove. The biceps tendon is released from the labrum and transected just proximal to the tagging suture. The PDS sutures are then brought out through the anterior cannula and used to shuttle nonabsorbable sutures through the tendon in a closed-loop fashion. The arthroscope is directed into the subacromial space. After subacromial débridement, the nonabsorbable sutures are then identified and retrieved through the anterior–lateral cannula. The tendon is then secured to the transverse humeral ligament with an arthroscopic knot.

Tenotomy is the preferred method of treatment of biceps tendon pathology in older (older than 60 years) patients who are low demand. Tenotomy is often performed in the context of massive rotator cuff repair or débridement. Patients are counseled preoperatively regarding cosmetic deformity, which is often minimal in this group, as well as the possibility of residual biceps muscle spasm or pain. Tenotomy is accomplished arthroscopically by releasing the attachments to the superior labrum and glenoid. The tendon retracts 1 to 2 cm after release but usually remains visible within the joint. Excessive residual biceps tendon can be débrided if necessary.

Treatment of SLAP Lesions

We prefer the lateral decubitus arthroscopy position for all procedures that are primarily intraarticular. The patient is positioned with the affected side up and supported by a deflated bean bag. The patient is generally placed slightly diagonal on the table such that the affected shoulder is closest to the side of the table where the surgeon will be standing. Additionally, the head of the patient is generally as close to the top of the table as possible to allow the surgeon to access the shoulder from above. The patient is then

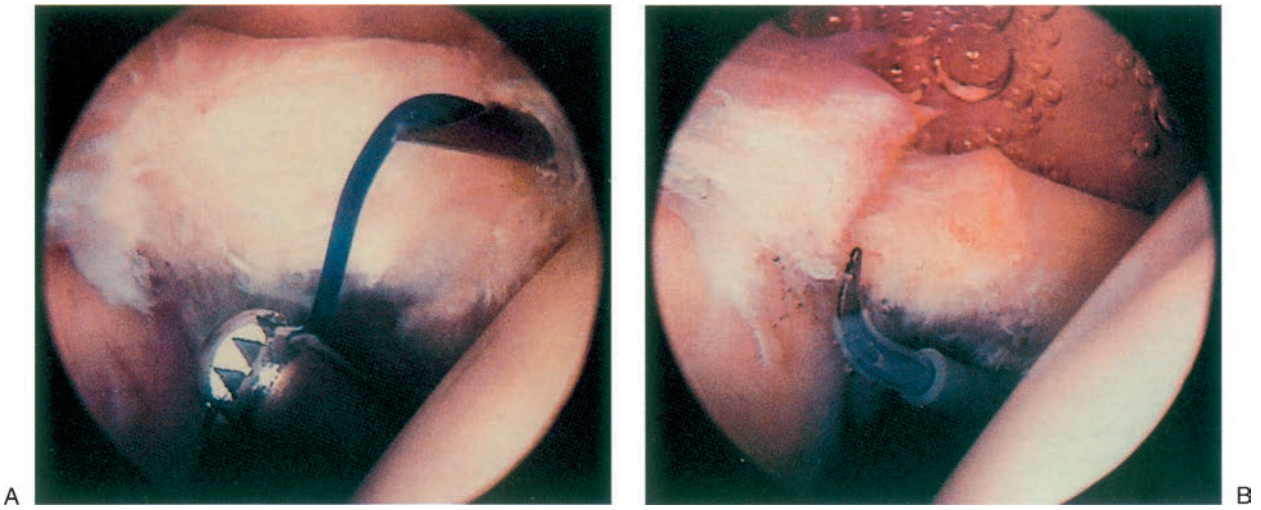

Figure 7-24 Arthroscopic views from a biceps tenodesis. **A.** A spinal needle is used to insert a #2 polydioxanone (PDS) suture into the biceps tendon near its entrance to the bicipital groove. This suture is then grasped and then brought out through the anterior portal. **B.** The origin is then released with an electrocautery device.

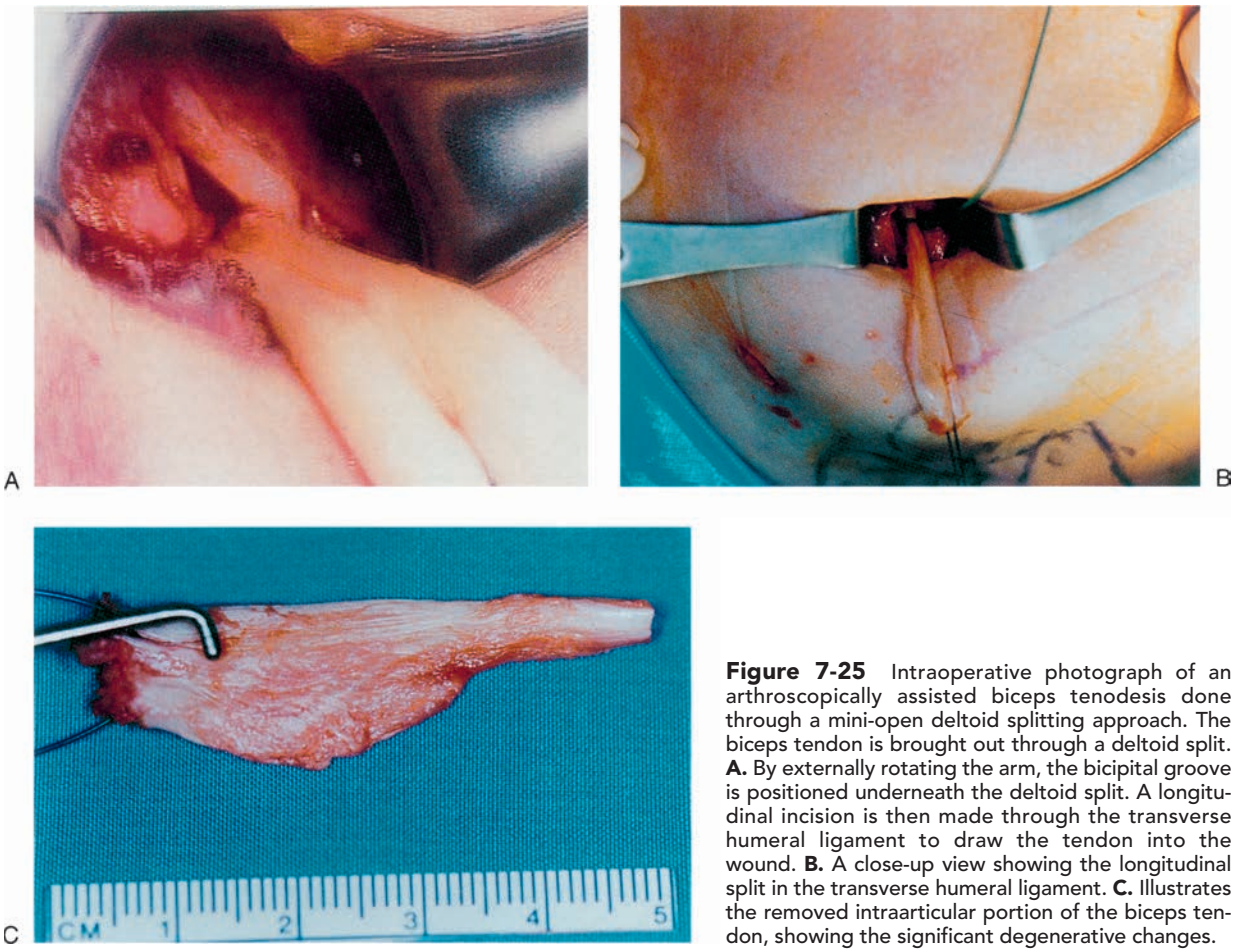

Figure 7-25 Intraoperative photograph of an arthroscopically assisted biceps tenodesis done through a mini-open deltoid splitting approach. The biceps tendon is brought out through a deltoid split. **A.** By externally rotating the arm, the bicipital groove is positioned underneath the deltoid split. A longitudinal incision is then made through the transverse humeral ligament to draw the tendon into the wound. **B.** A close-up view showing the longitudinal split in the transverse humeral ligament. **C.** Illustrates the removed intraarticular portion of the biceps tendon, showing the significant degenerative changes.

generally rotated approximately 30 degrees toward posterior to level the glenohumeral joint parallel to the floor.

Prior to prepping and draping, an examination under anesthesia is performed. Load-and-shift maneuvers are performed in both the anterior and posterior directions. The most consistent finding seen with labral abnormalities is a popping or clicking sensation as a humeral head luxates to the glenoid rim. Any associated laxity should be noted and considered as a potential source of symptomatology.

After routine prep and drape, the arm is then positioned in a lateral traction boom. We prefer a traction boom that allows both inline traction of the arm and lateral distracting traction to open up the glenohumeral joint (Arthrex, Naples, FL). This boom places the arm in foam padding for skin traction inline along the long axis of the upper extremity. It also has a second attachment that goes underneath the arm to provide a lateral distracting force. Generally, 15 lb of traction is employed and a lateral distracting force is applied equivalent to distracting force obtained when an assistant lifts the arm at the level of the axilla.

The glenohumeral joint is then located with a spinal needle and infiltrated with 10 mL of 0.25% Marcaine containing epinephrine. All bony landmarks are carefully outlined and portal sites drawn. Generally, four portal sites are used for SLAP repair. A standard posterior portal is employed approximately 2 to 3 cm inferior to the posterior border of the acromion. It is generally best to err this portal slightly laterally. The next two anterior portals are drawn, one lateral to the coracoid process and one just anterior to the acromion approximately 5 mm lateral to the acromioclavicular joint. More experienced surgeons may be comfortable doing SLAP repairs through a single anterior portal placed lateral to the coracoid process. Finally, a lateral portal just distal to the anterior lateral corner of the acromion is employed for anchor insertion. We generally do not prefer placement of a formal portal in this location. Alternatively, this location is used as a starting point for percutaneous entrance of a drill guide for anchor insertion. A cannula is not placed to avoid damage to the rotator cuff tendon or muscle.

Glenohumeral arthroscopy is initiated from posterior. After visualization is established from the posterior portal, the anterior portals are then established under direct visualization from outside to in. We prefer the use of guidewire and a cannulated portal expanding system (Arthrex, Naples, FL). The use of guidewire allows precise placement of portals, which are important for verifying utility of each of the portal sites for both suture passing and glenoid access. After establishment of the two anterior portals and posterior portal, a glenohumeral inspection is performed (Fig. 7-26). Treatment of superior–labral lesions of the biceps is generally done according to the recommendations of Snyder et al. Type I lesions are seen as significant fraying about the superior labrum and are débrided with a shaver through the anterior portal. No further treatment is necessary. Type II lesions in which the biceps origin and superior labrum are detached from the bony base of the glenoid are treated by arthroscopic repair. Care should be taken to properly identify a type II lesion as opposed to an extensive fraying seen with a type I lesion. The anatomy of the biceps and labral origin should be well recognized. It should be noted that articular cartilage generally overhangs the articular face of the glenoid, and because of this there will be a 2- to 3-mm area of detachment of the labrum laterally, which is normal. Medial detachment of the labrum more than 4 mm and fraying of the tissues on the undersurface of the labrum and biceps tendon anchor are abnormal. Type III lesions can be treated by débridement of the bucket handle tear alone if the remaining labrum is still firmly attached. Type IV lesions, which include extension into the substance of a biceps tendon, generally require both a repair of the labrum and a tenodesis/tenotomy of the long head of the biceps tendon. Type V lesions require superior labral repair, which then also encompasses normal anterior–inferior instability repair techniques.

In performing a repair of the labrum, a shaver is inserted from the anterior portal and the area of tear débrided fully to expose some bleeding bone and remove degenerated tissues. Once débridement is performed in the area of the tear, the percutaneous portal distal to the anterior lateral corner of the acromion is established for suture anchor placement (Fig. 7-26). The portal is generally performed approximately 1 to 2 cm distal to the anterior–lateral corner of the acromion for superior and anterior superior tears. A suture anchor placed in this location through a percutaneous drill guide will penetrate through the muscle belly of the supraspinatus, but not the tendon. The angle will give you good access to suture anchor placement around the biceps origin from 2 cm posterior to 1 cm anterior to this location. If further posterior anchors are required, a second portal may be required, which is 1 to 2 cm posterior to the previous portal and is near the posterior–lateral corner of the acromion. We generally like to establish this portal by first placing the percutaneous guide pin to verify accurate location. At this point, the guide pin can be removed and a drill guide inserted through a percutaneous technique using a trocar (Arthrex, Naples, FL). Alternatively, the guide pin can be left in place and a "mini-portal" formed by expanding over the guidewire as if forming the anterior portals. The drill guide can then be passed over the guidewire to expand tissues. In any case, at this point, all required suture anchors are generally placed into the superior–posterior glenoid. The average SLAP repair requires a minimum of two suture anchors. We prefer a bioabsorbable implant containing nonabsorbable high-strength sutures (Arthrex, Naples, FL). Once suture anchors are inserted into superior glenoid shuttle, sutures are then placed into the superior labrum to deliver one of the two suture strands from each anchor around the labrum. Generally, we employ the use of a suture-passing angled hook (Spectrum Instrument, Linvotec, FL). A zero

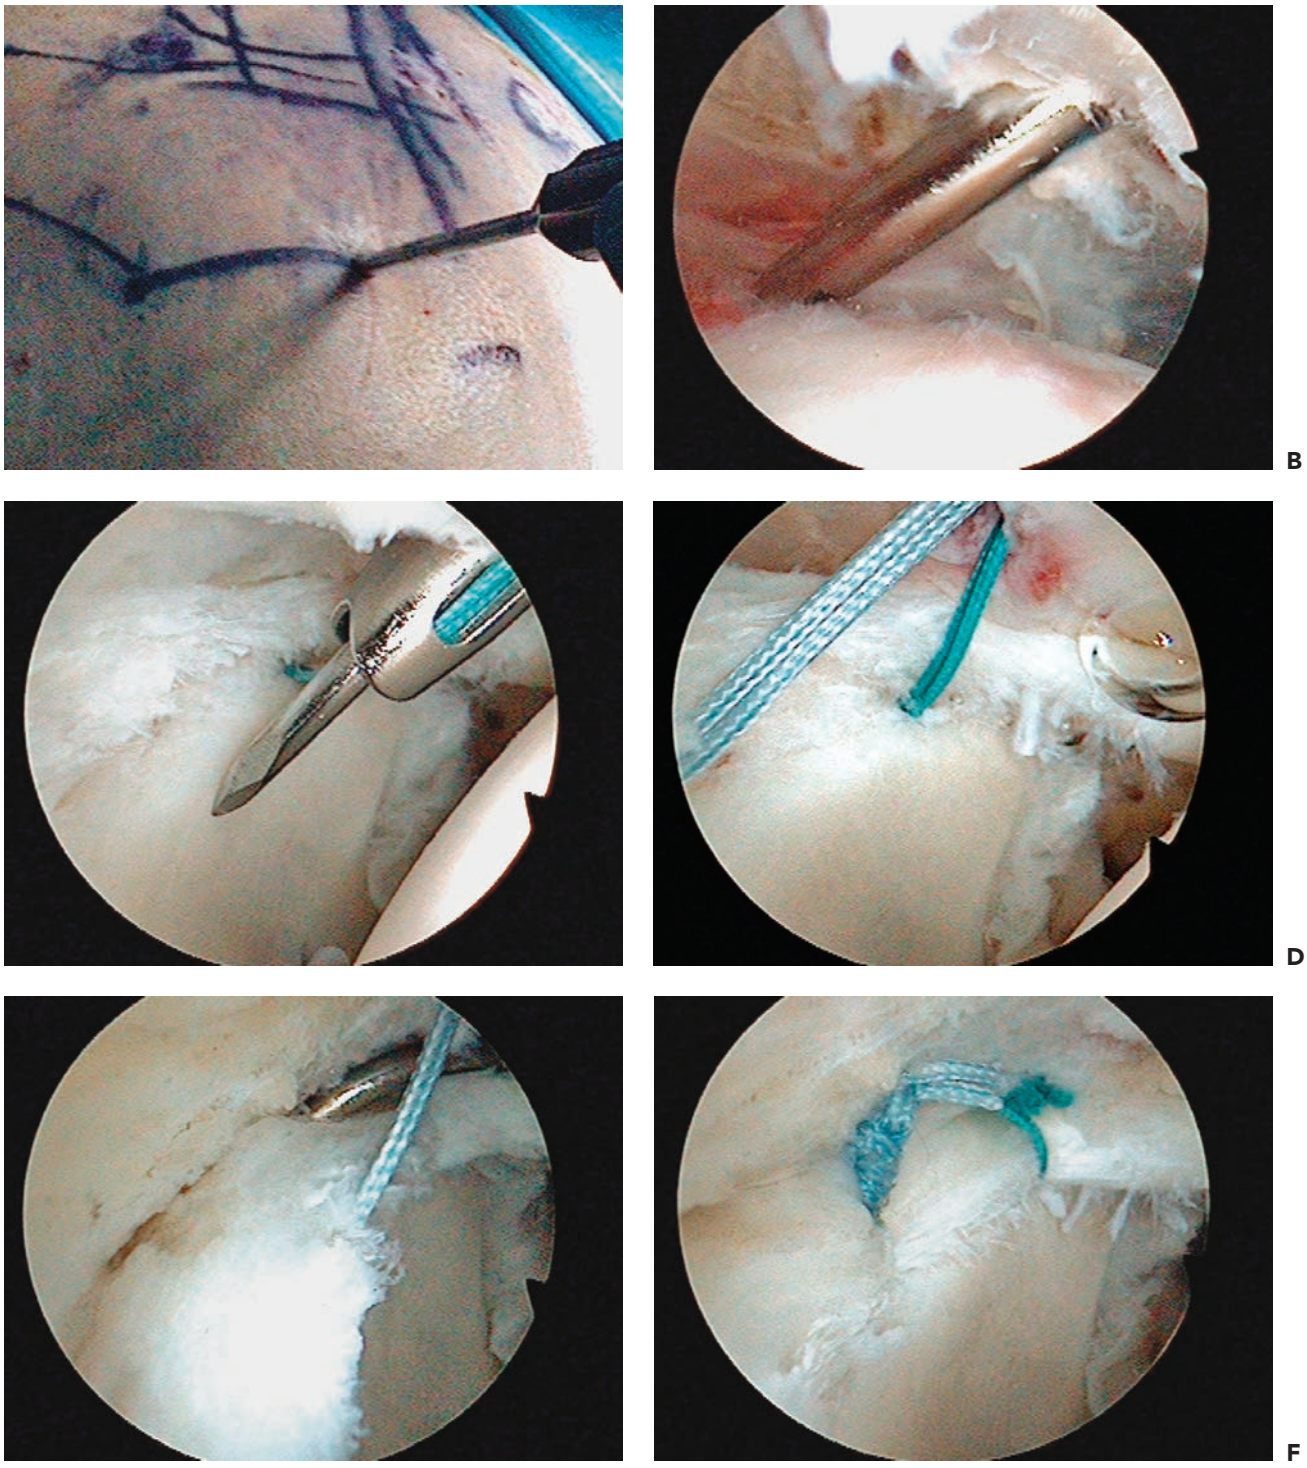

Figure 7-26 Intraoperative photographs from an arthroscopic repair of a superior labral anterior and posterior (SLAP) lesion. **A.** The superior–lateral portal is made just lateral to the anterior–lateral acromion and directed diagonally toward the glenoid. **B.** Penetration of the rotator cuff to enter the joint from this portal is through the muscle belly of the supraspinatus and not in the rotator cuff tendon that is more lateral. **C.** A drill guide is then inserted over the guidewire to maintain proper orientation for suture anchor insertion. **D.** Usually, a minimum of two suture anchors are required to fix most superior labrum tears. Both anchors are inserted prior to any suture passing. **E.** An angled, curved suture passing device is then inserted into the labrum from medial to lateral for shuttling of a single limb of suture from each of the anchors into the labrum. **F.** Standard knot tying is performed superior to the labrum. An effort should be made to keep the knot away from the articular surface.

Prolene stitch is delivered through the labrum and then used to shuttle a suture limb around the labrum. Knot tying is then performed from the anterior–superior portal.

Postoperative Rehabilitation

Postoperative rehabilitation for surgical treatment of the biceps tendon follows guidelines established for surgical treatment of the rotator cuff. Early range of motion is instituted in a passive to active assisted fashion. When a biceps tenodesis is performed, any resisted active motion of the elbow, either in flexion or supination, is avoided. This restriction remains for 6 weeks.

For patients with SLAP repairs, the arm is usually immobilized for 6 weeks in a sling. Passive rotation at the side is allowed as well as forward elevation to 90 degrees during the first 6 weeks. After 6 weeks, progressive active assisted elevation is performed with pulleys, and therapy until full elevation is achieved. Rotator cuff strengthening is started at 12 weeks.

Complications

Few complications have been recognized specific to surgical treatment of the long head of the biceps tendon. The primary complication noted has been spontaneous rupture and shortening of the lateral biceps. Although this may result in a significant cosmetic defect in the brachium, the functional effects of this are minimal. Thus, an intolerable cosmetic defect is the primary indication for revision surgical intervention. A rare case of heterotopic ossification has also been reported.

There are theoretical complications associated with arthroscopic repair or SLAP lesions. These include injury to the suprascapular nerve, which resides 1.6 cm medial to the superior glenoid labrum. Additionally, hardware such as suture anchors placed in this location may fail or loosen, resulting in intraarticular hardware. To date, these complications have not been reported in the literature but are a concern and have been recognized in clinical practice.

SUMMARY

Without a clear understanding of the functional role for the long head of the biceps tendon, treatment recommendations have been subject to controversy. An objective review of the available information would suggest that some humeral head stability may be imparted through the tendon. However, the magnitude of this function is likely to be small and possibly insignificant. In contrast, the symptomatic significance of the long head of the biceps is less controversial. It clearly can be an important source of shoulder pain that may remain persistent when not specifically addressed with either nonoperative or operative treatment. When present, persistent pain from the long head of the biceps is likely to have more negative functional consequences than loss of the tendon itself. Given these concerns, evaluation and treatment of patients with long head of the biceps disorders should be individualized based on the likelihood that biceps-related pain will resolve. Tenodesis is recommended in the context of irreversible structural changes such as atrophy, partial tearing of the tendon width, any luxation out of the bicipital groove, or surrounding bony abnormalities that make autotenodesis likely. When structural changes are not present, the tendon inflammation is likely to resolve and routine tenodesis is not supported.

SUMMARY 276

INTRODUCTION

Traumatic muscle ruptures involving the shoulder girdle are relatively uncommon. Excluding the rotator cuff and biceps, which are discussed in other sections of this text, the pectoralis major and triceps tendons are the most prone to avulsion. Traumatic injuries to the deltoid, trapezius, latissimus dorsi, teres major, coracobrachialis, and short head of the biceps are unusual but are also discussed.

Muscle injuries may vary in severity from minor strains to complete disruption of muscle fibers. These injuries involve different locations within the musculotendinous unit, including the site of origin, within the muscle belly itself, at the musculotendinous junction, and complete tendinous avulsion from bone. Clinical factors, such as mechanism of injury, rate of loading, and the specific anatomic features of a given muscle, determine the site of injury.[76,121] It has been shown experimentally that normal tendons are the strongest link of the muscle–tendon–bone construct.[76] Direct trauma to a contracted muscle generally causes disruption of fibers within the muscle belly.[45,75,113] Indirect trauma from which the affected extremity is subjected to an overwhelming force against a maximally

contracted muscle usually results in distal tendon avulsion from the bony insertion.[31]

Although traumatic ruptures of the shoulder musculature are uncommon, the physician's heightened awareness and understanding of the pathomechanics, combined with a careful clinical evaluation and judicious use of imaging studies, will lead to prompt diagnosis and optimal management.

PECTORALIS MAJOR RUPTURES

Surgical Anatomy and Biomechanics

The pectoralis major is a thick triangular muscle, with a broad origin including the medial clavicle, anterior surface of the sternum, costal cartilages down to the sixth rib, and aponeurosis of the external oblique muscle of the abdomen.[48] The muscle converges laterally to form two distinct heads: the smaller clavicular head and the larger sternocostal head (Fig. 8-1). The architecture of the tendinous insertion consists of two laminae that cross over the long head of the biceps and insert on the lateral edge of the bicipital groove. The upper clavicular head constitutes the anterior lamina, whereas the lower and deeper fibers of the sternocostal head form the posterior lamina. The sternocostal head spirals on itself approximately 180 degrees, inserting proximally underneath the clavicular portion. This rolled edge creates the anterior axillary fold. Kretzler and Richardson found that the actual pectoralis tendon was about 1 cm long on its anterior surface and 2.5 cm long on its posterior surface.[57]

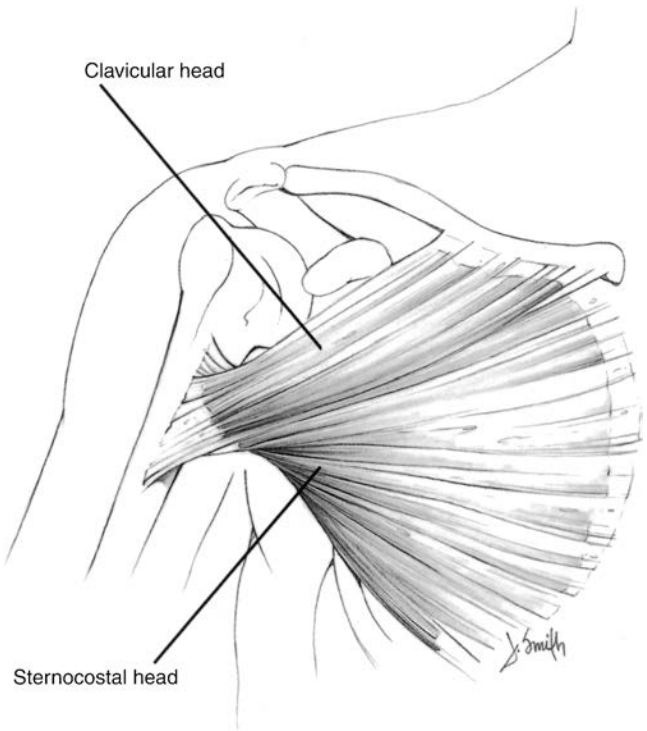

Figure 8-1 Anatomy of the pectoralis major. The triangular muscle converges to form two distinct segments: the smaller clavicular head and the larger sternocostal head. The sternocostal portion spirals on itself to insert proximally and underneath the clavicular portion of the muscle.

The function of the pectoralis major depends on the arm's relative position to the chest at the time of contraction. For example, the muscle functions to flex the humerus if it is extended behind the plane of the body; whereas the pectoralis major's lower fibers will extend the shoulder when the contraction is initiated with the arm in a flexed position. The pectoralis is also a powerful adductor and internal rotator of the humerus.[73] Weight lifting, and particularly the bench press, is a commonly reported mechanism of injury for pectoralis major rupture. Wolfe et al.[123] examined muscle fiber lengths at various points along the muscle, both at rest and during a simulated bench press maneuver in a cadaveric model. They demonstrated that the short inferior fibers of the muscle lengthened disproportionately during the final 30 degrees of humeral extension when compared with the superior fibers of the sternal head. Therefore, these inferior fibers are theoretically placed at a mechanical disadvantage in the eccentric phase of the lift, predisposing them to injury.[123]

The pectoralis major is innervated by the lateral and medial pectoral nerves, which principally serve the clavicular and sternocostal heads, respectively. These nerves course from a superior to inferior direction and enter the muscle along its posterior surface. The muscle's innervation is not in jeopardy during mobilization of the tendon for surgical repair.

Incidence and Pathophysiology

Rupture of the pectoralis major muscle is relatively uncommon, first reported in 1822 by Patissier.[86] Since that time approximately 200 cases have been reported, but many were not confirmed by exploration for surgical repair.[24] McEntire and associates published a literature review of pectoralis major ruptures in 1972 and added 11 new cases to the 45 already in the literature at that time.[75] However, only 22 of these 56 cases were confirmed surgically. Larger series of new cases have more recently been reported. Kretzler and Richardson, in 1989, reported 19 new cases, of which 16 were repaired.[57] Wolfe et al., in 1992, published 14 new cases, with seven being managed surgically.[123] Bak et al.[9] performed a meta-analysis of 112 cases of pectoralis major rupture. Hanna et al. reported on 22 cases, with 10 surgical repairs, in 2001.[43] Aarimaa et al. retrospectively reviewed 33 operatively treated cases of total or near-total pectoralis major ruptures at their own institution, along with a meta-analysis from the literature on the treatment and outcome of pectoralis major ruptures.[1] Most of these injuries occur in men during the third or fourth decade.[53]

The mechanism of injury usually described involves an overwhelming extension force applied to a maximally contracted pectoralis muscle, resulting in a complete tendinous avulsion from bone. The single most common mechanism causing pectoralis rupture has been the bench press exercise.[10,50,53,57,64,94,116,123,125] Other sports activities, such as boxing, football, ice hockey, sail boarding, skiing, water skiing, and wrestling, have been associated with cases of pectoralis rupture. Recently, rappelling in an active-duty soldier was responsible for acute rupture of the pectoralis major tendon.[119] There is also one report of pectoralis major rupture in a paratrooper when entanglement of the aircraft risers led to excessive traction in a malpositioned shoulder.[55] The mechanism of injury involves either an indirect sudden force applied to the upper extremity or, in a small number of cases, a direct blow to the contracted muscle. Reaching out to break a fall or grabbing a railing to prevent a fall are typical mechanisms.

Pectoralis major ruptures may be complete or partial. Partial injuries, though more common, are treated nonsurgically and, consequently, the pathoanatomy of these lesions has not been well documented.[44] Partial injuries of the musculotendinous unit may occur in the muscle belly, at the musculotendinous junction, or at the tendinous insertion site. Partial tendinous disruption at the bony insertion site most often involves a complete rupture of the sternal portion of the muscle, while the smaller clavicular part remains intact. Palpation of the intact clavicular head may be interpreted as an incomplete injury not requiring surgical intervention. However, the sternal portion constitutes approximately two-thirds of the muscle mass and its repair is warranted in active individuals. This pattern of disruption is consistent with the common mechanism of injury involving the terminal eccentric part of the bench press where the lower muscle fibers of the pectoralis are stretched disproportionately. Complete rupture of both the sternal and clavicular head is less common, but has been reported.[64,68,75,85,116,123] Additionally, Potter et al. reported one case of simultaneous bilateral rupture of the pectoralis major tendon, suffered while the patient was performing dips on a wide-grip parallel bar.[90]

A survey of the literature shows that most reported cases involving the pectoralis major are distal disruptions at the insertion site and musculotendinous junction, rather than proximal ruptures of the muscle belly. Proximal muscle belly ruptures occur occasionally and tend to result from a direct blow to the contracted muscle.[52,75] Interestingly, there are few cases in the literature where a bone fragment from the humerus was avulsed at the time of injury.[83,117] In one case the bone fragment was small and inconsequential. In the other, a large fragment of humeral cortex was reinserted with screws and spiked washers.[117]

Recently, there have been several reports in the literature regarding pectoralis major rupture in the elderly, all from Beloosesky et al.[11–14] In one paper, they reported on pectoralis major rupture in a 97-year-old woman.[11] These authors noted that these injuries are probably more common in the elderly population than generally believed, as indirect trauma to the muscle may occur with common nursing procedures such as transferring, positioning, and dressing when the upper extremity is placed in particular positions. Further, soft tissue in elderly individuals is frequently stiffer, more atrophic, and further at risk from a general decrease in muscular activity and changes in diet and nutrient intake. Lastly, an unfortunate but real consideration is that of elder abuse, suspected by Beloosesky et al. in some patients in their series.[12]

Evaluation

The principal clue to the diagnosis of a pectoralis major rupture is the patient's history of an acute traumatic event associated with burning pain and a tearing sensation of the upper arm and chest. Most often the mechanism of injury described by the patient involves an overpowering extension force on the extremity. An audible pop is not usually appreciated.

The specific physical findings depend on the exact site and extent of muscle rupture. The more common distal ruptures will have swelling and ecchymosis of the lateral chest and upper arm region. The muscle retracts medially and superiorly, although the absence of the anterior axillary fold may not be immediately obvious in the acute setting. With complete avulsion of the sternal head, one may still be able to palpate the thin, tendinous clavicular insertion. Zeman et al. described one patient who, at surgery, had a complete avulsion at the musculotendinous junction, but a persistent overlying fascia layer had clinically masqueraded as a segment of intact tendon.[125] Weakness of adduction and internal rotation with a medial muscle bulge that is accentuated with resistance can usually be appreciated.

Conversely, proximal or medial muscle injury causes ecchymosis and swelling on the anterior part of the chest wall. The muscle belly retracts toward the axillary fold and a visible and palpable medial defect is seen. Again, these injuries are often a result of a direct blow or crush injury. A useful clinical test involves having the patient firmly press his or her hands together in front of the chest to allow for simultaneous inspection and palpation of the involved and uninvolved pectoralis muscles.

In the chronic setting, the diagnosis is very straightforward. The patient will complain of fatigue, ache, and weakness to strenuous internal rotation and adduction activities. Weight lifters and body builders, in particular, will complain of the gross asymmetry compared with the uninvolved side. Weakness on manual muscle testing of adduction and internal rotation can usually be appreciated. Isokinetic testing has been used to quantify and document this weakness.[57,65,98,102,123]

Occasionally, associated injuries will present with pectoralis major ruptures. Injuries to the anterior deltoid, rotator cuff, latissimus dorsi, and brachial plexus have all been seen.[52,75] Interestingly, pectoralis major disruption has only been reported in combination with an anterior traumatic dislocation of the shoulder in one case.[6] The mechanism for these two anterior shoulder injuries is similar, albeit with traumatic instability usually occurring at greater degrees of abduction and external rotation. It is important to consider this differential diagnosis when assessing football players who have been injured while tackling with their arm in an abducted and extended position.

Radiographic evaluation of the shoulder and chest is usually negative, except in the rare case of an avulsion of a small bone fragment.[83,117] The subtle finding of a loss of the normal pectoralis major shadow has been described.[73,85,125] Magnetic resonance imaging (MRI) is potentially helpful in the early evaluation of this injury.[78] In the acute setting, an MRI can identify the extent and site of muscle injury when the clinical diagnosis is unclear because of swelling and pain (Fig. 8-2). In most cases, an MRI is unnecessary, as subsequent examination within 7 to 10 days after the acute event will usually clarify the diagnosis. This brief delay in diagnosis has no influence on decision making or the ultimate result. Some authors do advocate the utility of MRI in the early postinjury period to potentially delineate the extent of the injury and assist with surgical planning. Carrino et al. reported on 10 patients referred for MRI after injury to the pectoral muscle, and found that MRI is accurate and useful in detecting and grading tears.[23] In an unusual report, Povoski and Spigos presented an MRI of the breast, ordered to evaluate a suspected breast mass in an 87-year-old woman, which revealed a partial tear of the pectoralis major.[91] Ultrasound is another modality that has become increasingly popular for the diagnosis of pectoralis major tears.[13,96,120] These studies generally support the use of sonographic evaluation as a complement or alternative to MRI for high-resolution imaging with low cost and superior practicality.

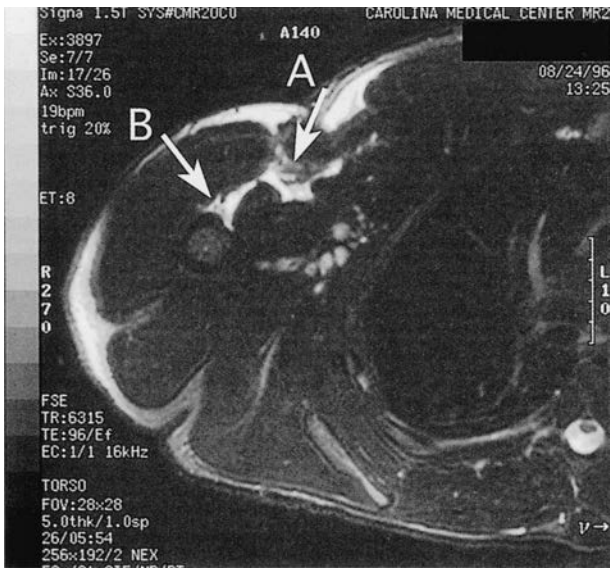

Figure 8-2 Magnetic resonance imaging depicting the retracted pectoralis major with adjacent hematoma *(A)* and the tract leading from the humeral insertion underneath the deltoid *(B)*.

Treatment

The treatment of pectoralis major muscle ruptures is determined by the specific location and degree of injury. Tears from the origin or within the muscle belly, whether a mild strain, partial tear, or complete disruption, are not amenable to surgical intervention and respond satisfactorily to conservative treatment.[24,45] There are several case reports in the literature of wrestlers who sustained medial pectoral injuries and successfully returned to competition. Injuries at the musculotendinous junction are usually of partial severity, and conservative management will yield acceptable function despite the residual cosmetic defect.[75,98,112] MRI may help the surgeon decide on operative versus nonoperative management by providing information on the exact location of a distal injury and the degree of muscle involvement.[29,78] Distal tendinous avulsion may be complete involving both heads of the pectoralis major, or partial where just the larger inferior sternal portion is detached. Most authors would recommend surgical repair of these injuries, particularly in athletes and laborers, who require optimal function and prefer upper body muscular symmetry (Fig. 8-3).[10,16,33,50,57,64,65,71,73,75,85,125] This recommendation is based on subjective complaints of weakness interfering with recreational or occupational function and cosmetic deformity. Isokinetic testing has demonstrated 25% to 50% muscle deficits in adduction and internal rotation in both preoperative patients and in those treated nonoperatively.[57,65,98,102,123]

The literature is divided in the recommendations for treatment of chronic ruptures. A few authors have suggested nonoperative treatment for the chronic tear, based on satisfactory functional recovery in a few cases while avoiding the potential difficulties of late repair.[73,98] The more recent literature tends to favor late repair of complete disruptions, with satisfactory results achieved with surgery done up to 5 years after rupture.[10,57,64,65,102,123,124] Anbari et al. reported on one patient who underwent successful repair of pectoralis major rupture 13 years after the initial injury, restoring strength and function as well as improving contour and cosmesis of the muscle complex.[3]

Nonoperative Treatment

Nonoperative treatment is recommended for medial ruptures of the pectoralis origin, muscle belly, and partial injuries at the musculotendinous junction. Conservative

Figure 8-3 **(A)** Preoperative photograph of a professional football player who had sustained a complete pectoralis major avulsion while reaching out to make a tackle. Note the web appearance of the anterior axilla. **(B)** Postoperative photograph showing restoration of the anterior axillary fold after a pectoralis major repair.

management is also appropriate for complete distal ruptures in lower-demand individuals, particularly if the nondominant extremity is involved. Initial treatment includes immobilization in a sling and icing to control pain and to allow stabilization of the hematoma. Gentle active and passive range-of-motion exercises are begun at 7 to 10 days postinjury. In the partial distal injury, care is taken to avoid humeral extension and abduction to protect the vulnerable inferior fibers of the sternal portion of the muscle. Resisted exercises are begun at 6 weeks. Isokinetic exercises for horizontal adduction can assist in the rehabilitation to develop strength and endurance. Depending on the severity of the initial injury and the specific occupational or athletic demands, patients may return to unrestricted activity at between 8 and 12 weeks.

Surgical Management

The goal of surgical intervention is to achieve optimal functional recovery in high-demand individuals requiring full strength. Surgery is best suited for complete tendinous avulsion of both the clavicular and sternal heads or complete disruption at the musculotendinous junction. Serious consideration for surgical repair should be given for partial tendinous avulsions in active athletes or heavy laborers in whom the sternal head has been completely avulsed but the smaller clavicular head remains. Surgery is not indicated for proximal tears of the muscle origin or muscle belly.

Anatomic repair is accomplished using heavy nonabsorbable suture placed in Bunnell fashion in the distal tendon passed through drill holes lateral to the biceps tendon at the humeral insertion site.[57,123] Other technical options reported include using pullout wires,[75] a barbed staple,[35] and, most recently, suture anchors.[78] Disruptions within the distal tendon itself occur rarely, but should also be secured directly to bone.

Repair of musculotendinous junction tears is more difficult because of the inability to obtain secure suture fixation in the torn muscle. For this reason, most partial tears are probably best managed nonoperatively. Very large defects or complete musculotendinous junction disruptions are accomplished with standard suturing techniques. Less vigorous postoperative rehabilitation is recommended in this setting.

Late primary repair for chronic ruptures—generally defined as greater than 2 weeks since injury—can be accomplished, even up to 5 years after the initial injury, although surgical dissection through scar and mobilization of the chronically retracted muscle is more difficult.[10,57,64,65,95,102,123] Schepsis et al. report on 17 patients with distal pectoralis major rupture, with 13 patients (six acute injuries and seven chronic injuries) undergoing surgical fixation while four patients were treated nonoperatively.[100] These authors concluded that there were no significant subjective or objective differences between patients treated operatively for acute or chronic injuries, though both groups of patients fared better than the group treated nonoperatively.

Postoperative management is relatively aggressive. The arm is immobilized for 1 to 2 weeks and then gradually weaned out of the sling by 4 weeks after surgery. Progressive active exercises and gentle use out of the sling are begun at 2 weeks postoperatively. Passive stretching is avoided. Resisted exercise begins at 6 weeks. Isokinetic machines can offer an objective assessment of strength and endurance and are used at 8 to 10 weeks in anticipation of return to full activities by 3 to 4 months after surgery. The postoperative rehabilitation program must be less aggressive in those cases of musculotendinous junction repair.

Results

Although nearly 200 cases are presented in the literature, the results of treatment, whether nonoperative or surgical, are frequently described anecdotally. There are very few

large series in the literature that offer objective criteria with which we can critically analyze results. In 1970 Park and Espiniella reviewed 30 cases of pectoralis major ruptures. The results in those patients treated with surgical repair were 80% excellent and 10% good. These results were superior to the 17% excellent and 58% good outcomes in patients treated nonoperatively.[85] McEntire et al., in 1972, presented 11 new cases and combined the results with the 45 cases that were already in the literature. They identified a similar trend favoring surgical management. In those patients for whom outcomes could be determined by the data available, surgical treatment yielded 77% excellent and 11% good results. By comparison, results in those patients who received conservative treatment or no formal treatment at all were 29% excellent and 54% good.[75]

Zeman et al., in 1979, reported on nine athletes with ruptures of the pectoralis major. Four cases were treated surgically and all had excellent results. The five patients managed nonoperatively had residual weakness, with two weight lifters and one professional boxer dissatisfied with their ability to perform at return to athletic competition.[125]

Kretzler and Richardson, in 1989, repaired 16 distal avulsions, and 81% achieved full return of range of motion, strength, and normal contour. Two patients were repaired 5 years after injury and, although they had a satisfactory clinical result, both patients have persistent weakness in horizontal adduction of 16% and 20%, respectively, by Cybex evaluation.[57]

Wolfe et al., in 1992, evaluated 14 sports-related ruptures, seven treated surgically and seven conservatively. Cybex testing demonstrated marked strength and work deficits in those patients treated conservatively, compared with normal strength in the repaired group.[123] Bak et al.,[9] in their meta-analysis of 112 cases, determined that prognosis was unrelated to patient age or location of the rupture, and that surgical treatment—preferably within the first 8 weeks after injury—had a significantly better outcome than repair after protracted delay or nonoperative management.

Surgical repair of chronic pectoralis ruptures is technically feasible, even up to 5 years after injury. Acceptable results can be obtained, albeit somewhat inferior in recovery of strength compared with those repaired immediately.[10,50,57,64,65,102,123] Jones and Matthews, in 1988, reviewed the literature and concluded that ruptures repaired within 7 days had 57% excellent and 30% good results, but those patients with delayed repair had no excellent and 60% good results.[50] Although delayed primary repair of chronic ruptures is possible, patients should be told that a satisfactory outcome is probable but that there is a likelihood of mild persistent weakness and cosmetic asymmetry.

Complications

Complications from surgical intervention are infrequent. One patient was slightly limited in abduction postoperatively,[57] and another had postoperative fourth and fifth digit paresthesias of unknown cause.[123] Interestingly, there have been several early reports of complications from pectoralis major rupture related to the associated hematoma in patients treated nonoperatively. Sepsis from an infected hematoma caused the death of one patient and precipitated the death of a second with pneumonia.[81,86] Additionally, a pseudocyst had formed from a hematoma,[99] and another reported case involved a partial rupture with subsequent hematoma that became infected, leading to persistent, low-grade morbidity prior to drainage.[25] Finally, myositis ossificans was reported to develop in a patient 4 months after rupture.[94] Interestingly, rerupture after surgical repair has not been documented.

Authors' Preferred Treatment

Conservative treatment is indicated for all proximal injuries involving the pectoralis major origin and muscle belly. Partial injuries at the musculotendinous junction can be similarly managed nonoperatively. One may wish to consider operative intervention if a large defect at the musculotendinous junction occurs in a high-demand individual or body builder who requires symmetry and optimal strength. An MRI can be helpful in this setting to determine the exact location and extent of the defect when the clinical evaluation is obscured by swelling and hematoma.

Acute surgical repair is recommended not only for complete avulsion, but also for partial distal injuries that involve the entire sternal head of the pectoralis major and leave the clavicular head intact. We prefer approximating the tendon to a bony trough with heavy, nonabsorbable, braided sutures passed through cortical bone tunnels. The humeral cortex in young, active individuals is fairly thick and the bone holes should be drilled in a convergent orientation. Suture passage can be facilitated using commercially available suture passing devices or alternatively a contoured loop of a 24-gauge wire. Sutures passed in mattress fashion through these tunnels maximize the tendon-to-bone contact (Fig. 8-4). Suture anchor fixation is another option, but cinching the tendon firmly down to the bone may be difficult, and to date there is only one case in the literature advocating this technique.[78]

Postoperative rehabilitation is fairly aggressive, with early mobilization and return to unrestricted activity by 3 to 4 months after repair.

DELTOID RUPTURES

Surgical Anatomy and Biomechanics

The deltoid is the largest muscle of the shoulder girdle and its integrity is critical to shoulder function. It consists of three major parts, with the anterior deltoid taking origin

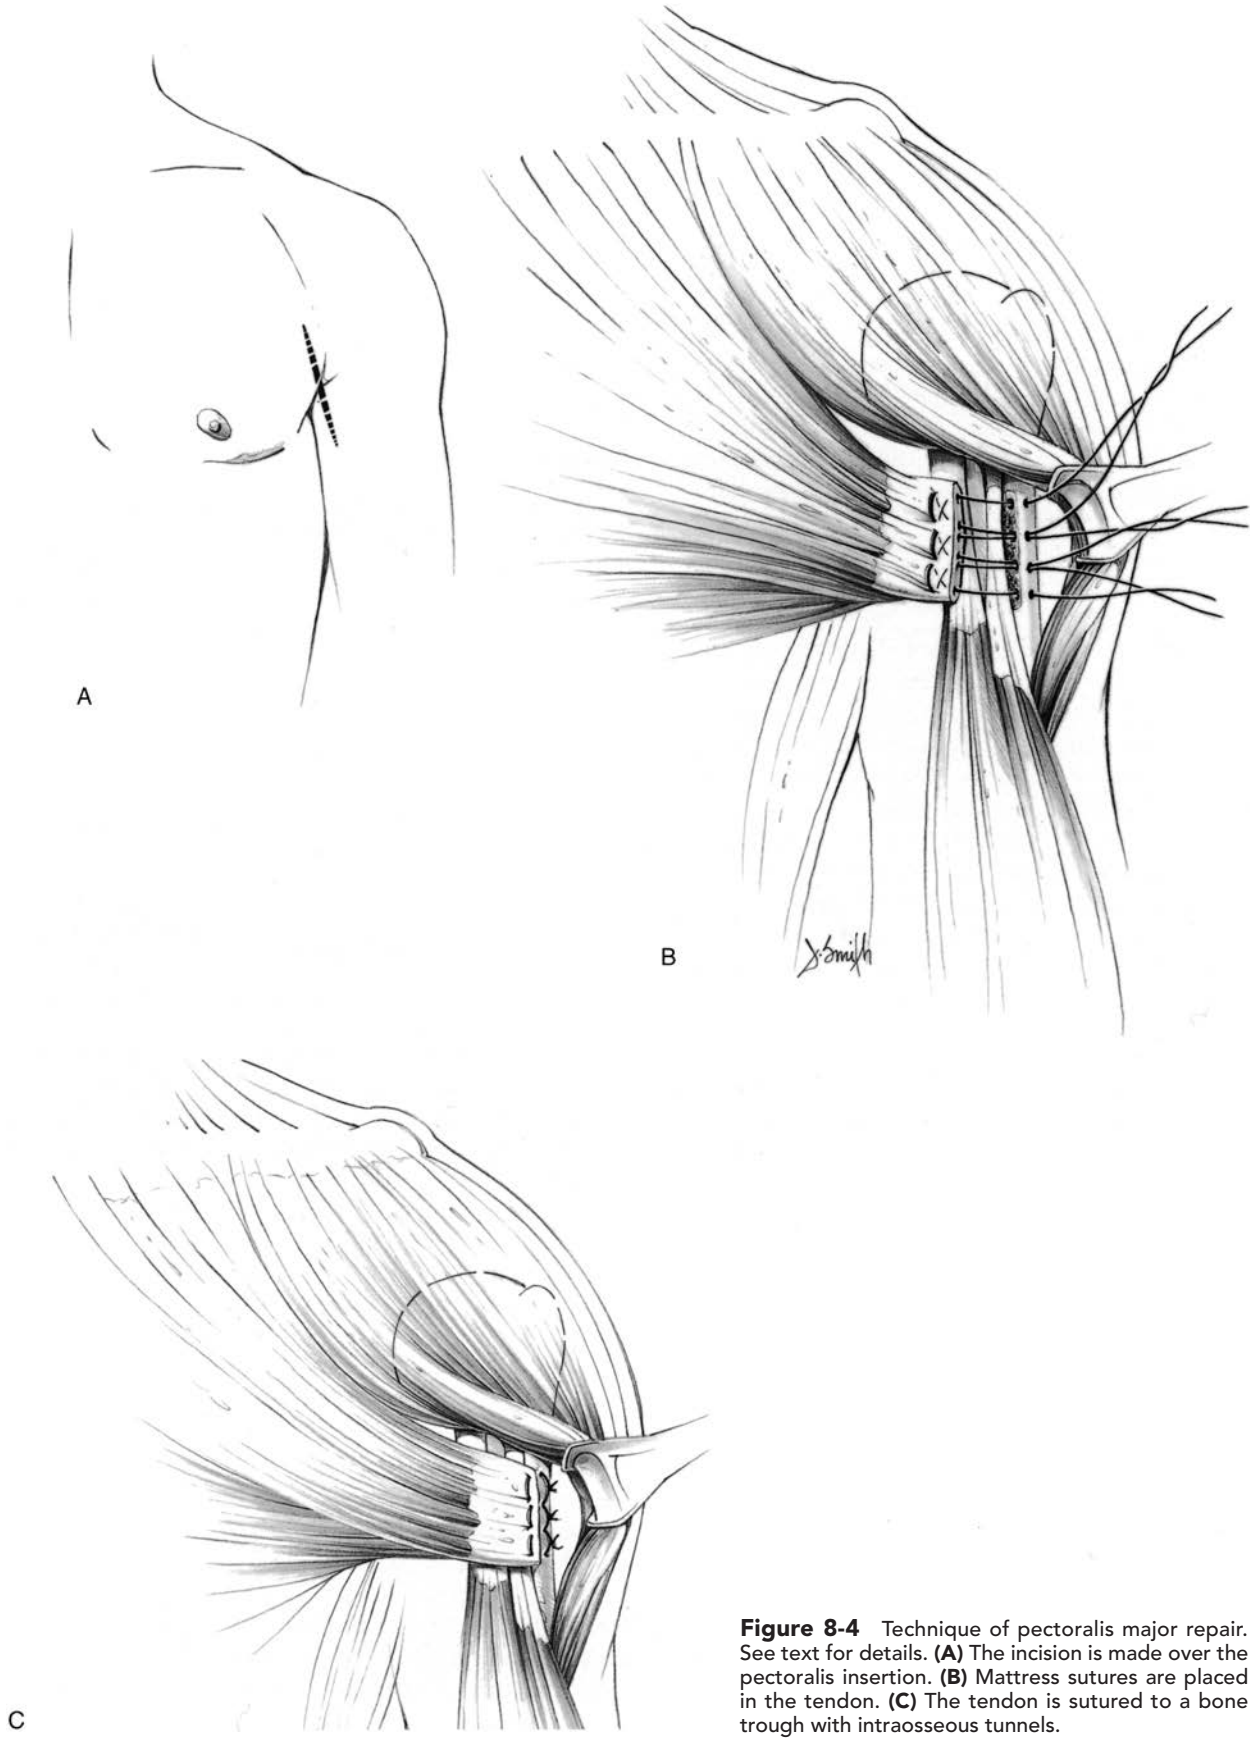

Figure 8-4 Technique of pectoralis major repair. See text for details. **(A)** The incision is made over the pectoralis insertion. **(B)** Mattress sutures are placed in the tendon. **(C)** The tendon is sutured to a bone trough with intraosseous tunnels.

from the anterior and superior surfaces of the outer third of the clavicle and anterior acromion, the middle deltoid from the lateral margin of the acromion, and the posterior deltoid from almost the entire scapular spine (Fig. 8-5).[48] The fibers converge from this wide origin to insert into the deltoid tuberosity on the lateral humeral shaft. Anterior and posterior fibers are essentially unipennate, meaning they run parallel to each other. The more powerful middle part is multipennate, with an internal structure consisting of tendinous septae serving as both origin and insertion sites for its relatively short and multiply oriented muscle fibers.[48] The axillary nerve innervates the muscle after exiting the quadrangular space posteriorly and courses along its undersurface from posterior to anterior.

The most important function of the deltoid is forward elevation in the scapular plane. The anterior and middle deltoids contribute to this motion. All three components of the muscle, but particularly the middle third, abduct the humerus, whereas the posterior deltoid extends the humerus.

Incidence and Pathophysiology

Traumatic rupture of the deltoid is rare. There are few reported cases in the literature from which we can draw information concerning the cause and management of this injury. Deltoid disruption appears to be a result of a sudden force applied to the muscle, sometimes associated with a concomitant direct blow. The first case was described by Clemens in 1913 and occurred while the patient was carrying a heavy rail.[28] Gilcreest and Albi reported two cases in 1939; one was sustained in an automobile accident and the other occurred with an overhead lifting accident.[39] McEntire et al. published a case of a deltoid rupture associated with a pectoralis major tear.[75] Caughey and Welsh, in review on this subject, described a chronic deltoid detachment in a 62-year-old guide who sustained the injury when a snowmobile rolled over him.[24] Davis, in 1919, reported a case not of traumatic cause, but of a deltoid origin detachment caused by osteomyelitis of the distal clavicle.[32] Allen and Drakos, in 2002, described

partial detachment of the posterior deltoid in a professional cricket player in the absence of a rotator cuff injury; the mechanism was thought to be due to fast-bowling movements associated with the sport of cricket.[2] Hydrocortisone injections may play a role in the cause, though in this case the patient denied such history. Finally, Lin and Nagler described partial tear of the posterior deltoid muscle in an elderly woman.[63] It was thought that the mechanism of injury in this case was due to repetitive motions associated with the patient's preferred hobby, golfing, on the backswing with the club. Combined with an older patient with more friable, weaker tissue, repetitive microtrauma may best explain a partial, acute-on-chronic partial tear of the right posterior deltoid in this left-handed patient. Blazar et al., in 1998, described four shoulders in three patients who suffered spontaneous detachment of the deltoid origin; all patients had chronic massive rotator cuff tears who then presented with the acute onset of shoulder weakness.[18] This type of tear is most likely due to the attritional changes of the fibers of the deltoid origin secondary to the superior migration of the humeral head associated with massive rotator cuff deficiency. Deltoid detachment as a complication of chronic cuff tear arthropathy or previous shoulder surgery is addressed in Chapter 5.

In a general orthopedic practice, minor strains of the deltoid are not uncommon and are often related to participation in athletic activity, particularly throwing sports. Contusions from direct blows may be associated with a subcutaneous hematoma, but usually do not involve significant muscle fiber disruption. Complete traumatic disruption as evidenced by the foregoing literature accounts is extremely rare and is caused by an abrupt external force applied either directly or indirectly to the contracted deltoid muscle.

Evaluation

Physical examination findings are dependent on the site of rupture and extent of muscle involvement. The clinical presentation is also determined by whether the injury is acute or chronic.

A mild strain or direct contusion will be manifest by local tenderness, mild swelling, and decreased active range of motion secondary to pain. The degree of weakness in either forward flexion or abduction will reflect the exact location and magnitude of the injury.

Acute complete deltoid rupture may occur in the context of a severe traumatic event to the upper extremity or in conjunction with a multiple trauma case. Rupture from the acromial origin can involve an isolated anterior, middle, or posterior head of the deltoid. Acute swelling may mask the proximal muscle defect. Resisted deltoid contraction will accentuate the distal muscle retraction and reveal the asymmetrical deltoid contour and muscle defect (Fig. 8-6).

Figure 8-6 Spontaneous detachment of the middle deltoid origin in a patient with a massive chronic rotator cuff tear.

Passive range of motion may be only slightly limited because of pain. Weakness in forward elevation, abduction, or extension reflects injury to the anterior, middle, and posterior heads, respectively. If significant weakness is present but no defect is appreciated, the possibility of axillary nerve injury must be entertained, particularly if there is a history of concomitant shoulder dislocation. Serial examinations, MRI, or electromyography may be helpful if the diagnosis is uncertain (Fig. 8-7).

Treatment

Deltoid strains and contusions are treated nonoperatively with early icing and passive range-of-motion exercises to avoid stiffness. After resolution of the acute injury phase, heat, electrical stimulation, and graduated stretching and strengthening exercises are instituted. Full recovery is anticipated within 4 to 6 weeks of injury.

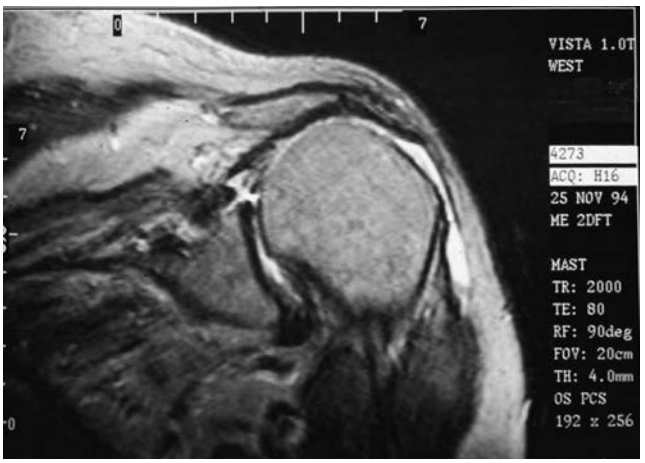

Figure 8-7 Magnetic resonance imaging of the same patient in Fig. 8-6 with a spontaneous attritional detachment of the middle deltoid origin.

There is limited published information with which to base recommendations for treatment of acute traumatic ruptures. Disruptions involving an entire segment of the deltoid, particularly the anterior or middle portions, will significantly alter shoulder function and should be surgically repaired back to the acromion. An MRI may help quantify the extent of deltoid origin involved. Prompt surgical repair is necessary to achieve an optimal result. A midsubstance muscle tear is certainly more difficult to repair securely, raising the question of whether repair should be attempted for these injuries. If severe soft tissue and muscle injury of the shoulder girdle presents in association with a closed head injury, one may wish to consider prophylactic use of indomethacin (Indocin) to avoid heterotopic ossification.

Postoperatively, the deltoid repair should be protected in an abduction pillow or splint for 4 to 6 weeks. Passive range of motion in forward elevation and internal and external rotation from the abduction pillow or brace should begin immediately. Humeral extension or internal rotation with the arm behind the back must be avoided for 6 weeks. Progressive active exercises are started at 6 weeks postoperatively.

Complications

A miss or a delay in diagnosis of an acute deltoid rupture will significantly compromise the surgeon's ability to restore normal shoulder function. Complications of deltoid detachment more commonly pertain to dehiscence of the deltoid repair following shoulder surgery and are discussed in Chapter 5 of this text.

TRAPEZIUS, LATISSIMUS DORSI, AND TERES MAJOR STRAINS AND RUPTURES

Surgical Anatomy and Biomechanics

Trapezius

The upper anterior border of the trapezius forms the posterior border of the posterior triangle of the neck, with the muscle completely overlying the supraspinatus and the majority of the rhomboids. The lower fibers of the trapezius typically overlie the upper fibers of the latissimus dorsi as well. The triangle of auscultation is an area between the trapezius, latissimus, and rhomboids whereby a triangle of variable size exists, particularly during scapular protraction.[48]

The trapezius has an extremely broad origin, extending medially from the superior nuchal line on the occipital bone, from the external occipital protuberance, from the ligamentum nuchae, and from the seventh cervical and all thoracic vertebral spinous processes. The insertion of the trapezius is less broad than its origin yet is still substantial. The upper fibers insert posterosuperiorly on the distal third of the clavicle, while the lower fibers insert into the base of the scapular spine as they form a triangular, flat tendon.[48]

The primary functions of the trapezius are elevation of the lateral scapular angle and scapular retraction; for the former, this is the only muscle capable of performing this function as no other muscle has a downward insertion onto the lateral scapular angle. The upper muscle fibers exert upward pull on the tip of the shoulder while the lower fibers have a downward pull on the root of the scapular spine; these fibers work synergistically to assist in upward rotation of the scapula.

Innervation of the trapezius is provided by the spinal accessory nerve (cranial nerve XI) and several cervical nerves that send fibers into the muscle. The spinal accessory nerve, after passing deep or through the sternocleidomastoid, passes through the posterior triangle of the neck to supply the trapezius. The nerve is joined by cervical nerve fibers arising from supraclavicular branches of the third and fourth cervical nerves. The ascending branch of the transverse cervical artery accompanies the spinal accessory nerve as it runs downward on the deep surface of the muscle.[48]

Latissimus Dorsi

The latissimus dorsi, like the trapezius, also has a broad origin. The muscle originates from the spinous processes of lower six thoracic vertebrae and from the spinous processes of the lumbar and sacral vertebrae; from an aponeurosis stemming from the iliac crest; and by muscular slips arising from the lower four ribs. The fibers converge as they run laterally and begin to spiral around the lower border of the teres major. The muscle fibers themselves end in a tendon in the axilla, along with the tendon to the teres major, that passes around to the medial surface of the humerus to insert into the medial wall and bicipital groove of the humerus; the insertions of the teres major and latissimus are quite close together with the teres major insertion located just medially to the insertion of the latissimus dorsi tendon on the anterior aspect of the humerus.[48]

Primary functions of the muscle are adduction, internal rotation, and arm extension. Secondarily, through its pull of the humerus on the scapula, it can participate in depression or downward scapular rotation, as is used when a crutch is placed in the armpit. The thoracodorsal nerve innervates this muscle, along with contributions from the seventh cervical nerve and frequently from the sixth and eighth cervical nerves as well.[48]

Teres Major

The origin of the teres major comes from the dorsal scapula from the medial third of the lateral border. As it

passes laterally it is in close contact with the latissimus as the two spiral together around to the anteromedial side of the humerus, where it inserts on the medial lip of the intertubercular groove in close proximity to the latissimus.[48] The muscle similarly functions as an internal rotator, adductor, and arm extensor. The teres major forms the inferior border of both the triangular space and the quadrangular space. Innervation comes from the lower subscapular nerve, which arises from the posterior cord or the axillary nerve.

Incidence, Evaluation, Treatment, and Case Reports

To our knowledge, isolated complete ruptures of the trapezius have never been reported. While the overwhelming majority of these injuries are intramuscular strains, work-related upper-extremity disorders, fatigue syndromes, psychosocial stressors, and many other pathologies can contribute to trapezius strain and fatigue, which may then mimic or present with unusual findings. Unusual symptoms, protracted pain, or other clinical concerns should warrant evaluation with MRI. Acute trapezius injuries are often typically associated with acromioclavicular (AC) joint separations and/or distal clavicle fractures. If the clavicle has perforated through the trapezius creating a button-hole perforation, surgical recommendation includes appropriate reduction and repair of the AC or distal clavicle injury along with reapproximation of the trapezius perforation with resorbable sutures. Lastly, lesions of the spinal accessory nerve lead to clinical scapular winging and show denervation edema on MRI and electrophysiological changes on electromyography (EMG). The recommended surgical management for symptomatic trapezius palsy secondary to spinal accessory nerve injury is the Eden-Lange procedure.[17,34,58,59] In this procedure, the levator scapula is transferred laterally to substitute for the upper trapezius and the rhomboids are advanced to compensate for the loss of the middle and lower trapezius function (Chapter 34).

Similar to the trapezius, complete ruptures of the latissimus dorsi are quite rare and reportable. The majority of injuries also represent intramuscular strains. Spinner et al. reported on a 38-year-old golfer who sustained an avulsion injury to the conjoined tendons of the latissimus dorsi and the teres major from the humerus. With conservative management, the patient was doing well 3 years postinjury.[108] Henry and Scerpella, in 2000, reported on a 42-year-old athletic patient who sustained an acute traumatic tear of the latissimus tendon from its insertion; the patient underwent successful surgical repair, with the only clinical deficit noted to be a 14% reduction in adduction strength compared to the uninjured side 6 months later.[46] Other isolated case reports of latissimus rupture[21,66] also exist in the literature. One of the editors (JPI) has had one case of traumatic latissimus dorsi rupture in an athletic young man injured in a surfing accident. The physical examination demonstrated asymmetry (Fig. 8-8A) and rupture at the tendon bone attachment site was confirmed on MRI (Fig. 8-8B). Surgical treatment was performed within a week of the injury through two incisions (Fig. 8-8C,D) with sutures passed through bone tunnels. The clinical result was excellent (Fig. 8-8E).

As seen with trapezius and latissimus dorsi injuries, partial tears or strains of the teres major far outweigh complete ruptures in their prevalence. MRI is the imaging modality of choice. Maldjian et al. reported on one case of isolated teres major rupture in a waterskiing accident, due to the acceleration of the tow rope,[70] leading to avulsion of the tendon.

CORACOBRACHIALIS AND SHORT HEAD OF BICEPS RUPTURES

Surgical Anatomy and Biomechanics

The coracobrachialis muscle originates underneath and medial to the short head of the biceps on the coracoid process with a fleshy, tendinous attachment. It inserts on the anterior medial surface of the middle of the humerus.[48] The short head of the biceps takes origin from the lateral tip of the coracoid. The muscle belly of the short head fuses distally with the larger long head, ultimately inserting by a singular stout tendon across the elbow into the radial tuberosity.

The musculocutaneous nerve penetrates the coracobrachialis muscle and runs between the biceps and brachialis muscles before emerging distally as the lateral antebrachial cutaneous nerve.[48] The innervation of the coracobrachialis is supplied by both a small direct branch from the lateral cord and the musculocutaneous nerve. The main nerve enters the coracobrachialis between 3.1 and 8.2 cm from the tip of the coracoid. Small nerve twigs may enter the muscle as close as 1.7 cm from the coracoid.[38] The coracobrachialis is a flexor and adductor of the arm. The short head of the biceps contributes to arm adduction, but is principally an elbow flexor.

Incidence and Pathophysiology

Rupture of the coracobrachialis muscle and short head of the biceps is extremely rare. Few case reports of coracobrachialis rupture exist in the literature. Gilcreest and Albi, in 1939, described a case of coracobrachialis muscle belly rupture caused by direct trauma, which was confirmed at surgery.[39] The second case, recorded by Tobin et al. in 1941, occurred in a parachutist who sustained a complete tear of the coracobrachialis and short head of the biceps as a result of direct trauma to the arm by his static line.[113] Gilcreest, in 1934, listed two cases of short head of biceps tendon rupture, but no additional clinical information was

provided.[41] Postacchini and Ricciardoi-Pollini, in 1977, reported on short head of the biceps rupture in a 67-year-old farmer in the absence of any direct trauma; the cause was felt to be severe degenerative changes in the quality and tensile strength of the tendon.[89] Finally, Shah and Pruzansky, in 2004, reported another case of a ruptured short head of the biceps that occurred in a 21-year-old man during a motor vehicle accident with the patient's arm out of the window where it struck the open door of a parked car. The isolated short head of the biceps rupture was identified by MRI and confirmed at exploration.[104]

The mechanism of this unusual injury most commonly appears to be direct trauma to a contracted muscle. Avulsion of these muscles' origin from the coracoid as a result of indirect forces is even more unusual.

Evaluation

The clinical presentation of a coracobrachialis or short head of biceps rupture is presumed to be a history of direct trauma to the arm associated with tenderness, swelling, and possibly a palpable defect in the muscle belly. Radiographs should be obtained to rule out a coracoid fracture. MRI may be very useful in identifying this unusual injury.

Treatment

The paucity of information available on this injury makes it difficult to give any firm recommendations for treatment. Gilcreest and Albi performed early surgical repair of the muscle belly and a complete recovery ensued.[39] It is not unreasonable to suggest exploration and appropriate surgical repair in those cases of direct trauma to the anterior arm when a significant muscle defect is appreciated by examination or MRI evaluation. Clinical factors, such as arm dominance and the patient's physical demands, should also play a role in the choice of treatment.

TRICEPS TENDON AVULSION

Surgical Anatomy and Biomechanics

The triceps muscle occupies the entire posterior aspect of the arm and comprises three distinct heads. The long head takes origin from the infraglenoid tubercle of the scapula and courses downward anterior to the teres minor and posterior to the teres major muscles. It serves as the medial border of the quadrangular space through which the axillary nerve and posterior humeral circumflex vessels emerge. The lateral head arises from the posterior surface of the humerus above the radial groove. The long and lateral heads converge distally to create the V-shaped triceps contour that can be appreciated superficially on the back of the arm. The medial head has a broad origin along the entire posterior surface of the humerus below the radial groove, and it fuses with the deep surface of the combined long and lateral heads. Ultimately, the entire muscle then transitions to form the substantial triceps tendon that inserts into the olecranon. Some of the superficial fibers of the tendon proceed over the surface of the olecranon and extend into the fascia of the forearm.[48]

The radial nerve innervates the triceps brachia, giving off multiple small branches to all three heads as it spirals downward along the posterior aspect of the arm. Although the nerve is at risk with posterior approaches to the humerus, it is not in jeopardy during the distal exposure associated with repair of a triceps avulsion.

The triceps muscle is essentially the sole extensor of the elbow, assisted only by the small anconeus muscle. The integrity of the triceps function is necessary to perform many activities of daily living, such as getting out of a chair and pushing objects away from the body.

Incidence and Pathophysiology

Anzel et al. reviewed a Mayo Clinic series of 1,014 tendon injuries and found only eight cases of triceps tendon injury, four of which were from a direct laceration.[5,80] The literature contains a few relatively small series, including Levy et al. (16 cases),[62] Pantazopoulos et al. (seven cases),[84] and Tarsney (seven cases).[110] Many of the remaining cases in the literature are presented as individual case reports.

Bach et al.[8] cumulated the cases of triceps tendon avulsion in the English literature up to 1987, and their study produced interesting epidemiologic data. The mean age at the time of injury was 26 years, ranging from 7 to 72. Males constituted 71% (29 of 41) of the patients. There was no correlation with the patient's dominant side.[8] Mair et al.[69] reported on a series of 10 partial and 11 complete ruptures of the triceps tendon in professional football players. Of the 19 players injured, 15 were offensive or defensive linemen. All complete tears were acutely repaired, while partial tears were managed either conservatively or operatively; it was not possible to draw firm conclusions about which partial tears would require surgery from their data.

The mechanism of injury for triceps tendon avulsion is a fall on an outstretched arm in most cases. The pathomechanics have been described as "a deceleration stress, superimposed upon a contracting triceps muscle with or without a concomitant blow to the posterior aspect of the elbow."[36] An abrupt, forceful, eccentric contraction of the triceps causes most triceps avulsions. Less frequently, a concomitant direct blow to the posterior aspect of the triceps at its insertion has been described in the mechanism of injury.[4,15,30,36,87,105,110] Additionally, there is one reported case of triceps avulsion during acceleration stress in a pilot in a high G-force training environment.[19] Recently, four

cases of triceps tendon avulsion injury have been reported in body builders and power lifters during the act of weight lifting, specifically the bench press or military press exercises.[8,22,47,51] The occurrence of this injury in body builders raises a question of the potential role of anabolic steroids in this injury.[8,47] Although steroid use was denied in these cases, this issue has been considered for predisposition to pectoralis major and distal biceps ruptures. Another study by Sollender et al. reported triceps rupture in four weight lifters, all of whom had taken oral anabolic steroids prior to injury.[107] The deleterious effects of either local steroid injections on tendons[54,115] or systemic anabolic steroid use on the strength of tendons and ligaments[49,56,77] have been well documented. A recent case report illustrates this point. A body builder who had received a series of six steroid injections for olecranon bursitis sustained an intrasubstance rupture of the triceps tendon while bench pressing.[109] In addition, he had a 5-year history of systemic anabolic steroid use. Individuals who use anabolic steroids are at risk for tendon ruptures because their abnormal muscular strength is applied to tendons that are stiffer and absorb less energy.[77]

The literature contains a number of systemically compromised patients in whom triceps tendon rupture has occurred spontaneously or as a result of trivial trauma. Medical conditions reported in association with tendon ruptures include renal osteodystrophy and secondary hyperparathyroidism,[26,37,67,72,74,82,92,93,103,114] chronic acidosis,[82] Marfan's syndrome,[101] and steroid treatment for lupus erythematosus.[114,122] The pathophysiology is not well understood, but calcification within the tendon from the chronic hypercalcemia of secondary hyperparathyroidism has been implicated.[93]

The site of triceps muscle injury may be at the muscle belly, musculotendinous junction, or osseous tendon insertion. The vast majority of authors have described tendo-osseous avulsions usually associated with a small fleck of bone.[36,80,110] Ruptures of the musculotendinous junction[40,47,79] and muscle belly tears[7,79,87] are unusual, having been noted in only a few cases. Although complete disruption is the rule, incomplete or partial tears do occur occasionally.[22,36,110] It is important to differentiate a partial tear from a complete rupture because surgical repair is necessary for the complete injury, whereas partial lesions are treated nonoperatively.[30,80]

Triceps tendon avulsions are sometimes associated with other upper-extremity injuries, resulting from the fall on the outstretched arm. Levy et al.[61,62] documented 16 patients with radial head fractures associated with triceps rupture. Lee[60] described a case of triceps rupture occurring in conjunction with a wrist fracture.

In the adolescent population, triceps avulsions involve complete separation of the olecranon epiphysis.[88,97] The secondary ossification center of the olecranon appears in the area of the triceps insertion at about 9 years of age. The physis fuses in an anterior to posterior direction at about 14 years of age.[20,106] The triceps expansion extends beyond the epiphysis, attaching to the surface of the metaphysis.[97] The injury sustained when the physis is incompletely fused produces a Salter-Harris type II fracture.[42]

Evaluation

The diagnosis of a complete triceps tendon avulsion is not difficult. The patient will relate a history of falling on the outstretched arm causing acute pain, a tearing sensation, and subsequent swelling and ecchymosis of the arm. The patient's complaint and physical findings will depend on whether the triceps is partially or completely torn. With a complete disruption, an indentation of the posterior contour of the arm can be seen, particularly as swelling subsides. A defect in the triceps mechanism is usually palpable. If a partial injury has occurred, tenderness is usually localized to the musculotendinous junction, and a discrete defect may not be appreciated. A complete tear results in the loss of extension against gravity, whereas an incomplete lesion is manifested by weakness, but the ability to actively extend the elbow is maintained.

In the acute setting, extension strength can be difficult to assess because of pain. In 1990, Viegas described a modification of the Thompson test[111] (traditionally used to identify complete ruptures of the Achilles tendon) for the assessment of a triceps injury.[118] The modified test can be performed either with the patient seated and the arm draped over the back of the chair or with the patient in the prone position, letting the forearm hang over the table. In the normal extremity, squeezing the triceps muscle belly produces slight elbow extension, but no motion will occur if a complete rupture is present.[118] This test is helpful for distinguishing between partial and complete triceps injuries.

The presence of associated injuries must be considered, particularly when falling on an outstretched hand is the mechanism of injury. Radial head fractures have been most frequently associated with triceps avulsions,[61,62,110] and distal wrist injuries[60] have also been reported. The differential diagnosis of triceps weakness includes nontraumatic causes. A C-7 nerve root lesion will cause isolated triceps weakness. As noted previously, spontaneous ruptures or injuries resulting from trivial forces may be the result of chronic medical conditions, including renal osteodystrophy with secondary hyperparathyroidism and long-term steroid use associated with systemic lupus erythematosus.

A plane lateral radiograph of the elbow will often confirm the diagnosis. A small avulsion fracture of the olecranon, called a "flake sign"[36,110] is estimated to be present in two-thirds of cases[47] and implies a complete rupture (Fig. 8-9). Additional studies, such as an MRI or ultrasound,[22] may be useful for defining the extent of partial lesions, but

Figure 8-9 "Flake sign": A small avulsion fracture of the olecranon, best seen on a lateral radiograph of the elbow, is pathognomonic of a complete triceps avulsion. (Adapted with permission from Morrey B. Tendon injuries about the elbow. In: Morrey B. ed. *The elbow and its disorders.* Philadelphia: WB Saunders,1993: 492–504.)

are usually not necessary in cases of complete rupture. Zionts and Vachon[126] reported one case where MRI was necessary to secure the diagnosis in an adolescent boy with severe soft tissue swelling and no "flake sign."

Treatment

Surgical repair is the recommended treatment for complete avulsions. As opposed to cases of pectoralis major or distal biceps tendon ruptures for which other muscles adequately compensate for the loss of these specific muscle functions, no compensatory muscle exists to substitute for triceps function. Even in those chronically ill patients who are suboptimal surgical candidates, triceps function is essential for transfers and the use of ambulatory aids. Operative repair is, therefore, necessary in this group as well.

The surgical technique universally proposed in the literature involves anatomic reattachment of the triceps tendon through drill holes in the olecranon, most commonly using a nonabsorbable suture. Primary repair can be accomplished, even with delays in diagnosis and treatment of up to 6 months. Several case reports involving 3-, 4.5-, and 6-month delays in surgical treatment have achieved excellent results.[8,105,110] Other authors have suggested augmentation of the repair when faced with poor-quality tissue or in the setting of a late repair.[27,36,80] Bennett described reinforcing the repair by reflecting a proximally based flap of the posterior forearm fascia and suturing it to the triceps.[15] Clayton and Thirupathi supplemented a triceps repair using an inverted tongue of triceps fascia in an elderly patient with chronic bursitis.[27] Carpentier et al. described Z-plasty lengthening of the triceps to avoid undue tension when repairing a chronic rupture.[22]

The results of operative repair are uniformly excellent in the literature. Authors usually have based their results on the patients' or physicians' subjective assessment. Range of motion is almost always reported as normal. Occasionally a loss of approximately 5 degrees of terminal extension has been seen, but this trivial loss of motion has not affected the functional outcome.[20,74,106] Cybex evaluation has provided objective confirmation of strength recovery in two case reports.[8,105]

Ulnar neuritis has been seen in conjunction with triceps injury in two cases. In both instances, a delay in surgical intervention resulted in the formation of scar tissue encompassing the ulnar nerve.[4,47] Anterior transposition of the nerve at the time of triceps repair has produced satisfactory results.

Nonoperative treatment is appropriate for a partial triceps injury. The rate of progression with range of motion and strengthening exercises following 2 to 3 weeks of immobilization is dependent on the degree of muscle involvement. With adequate rehabilitation, essentially full restoration of strength and function can be anticipated after a partial tear.[7,22,36]

Authors' Preferred Treatment

Early anatomic repair through bone holes in the proximal ulna is strongly recommended for all patients with acute complete avulsions.

A posterior approach to the arm and elbow can be accomplished with the patient in the supine, lateral, or prone position. A tourniquet may be used to facilitate the dissection, particularly around the ulnar nerve. However, it must be deflated to permit maximal advancement of the triceps mechanism in the latter stages of the procedure. A posterior linear incision is used, passing lateral to the olecranon and parallel to the lateral border of the ulna (Fig. 8-10A). The ulnar nerve must be identified and protected, but formal mobilization or transposition is not necessary. The small bone fleck often associated with triceps avulsion is excised. If a large fragment has been avulsed, which usually occurs in the adolescent population, repair is amenable to tension band technique or screw-and-washer fixation.

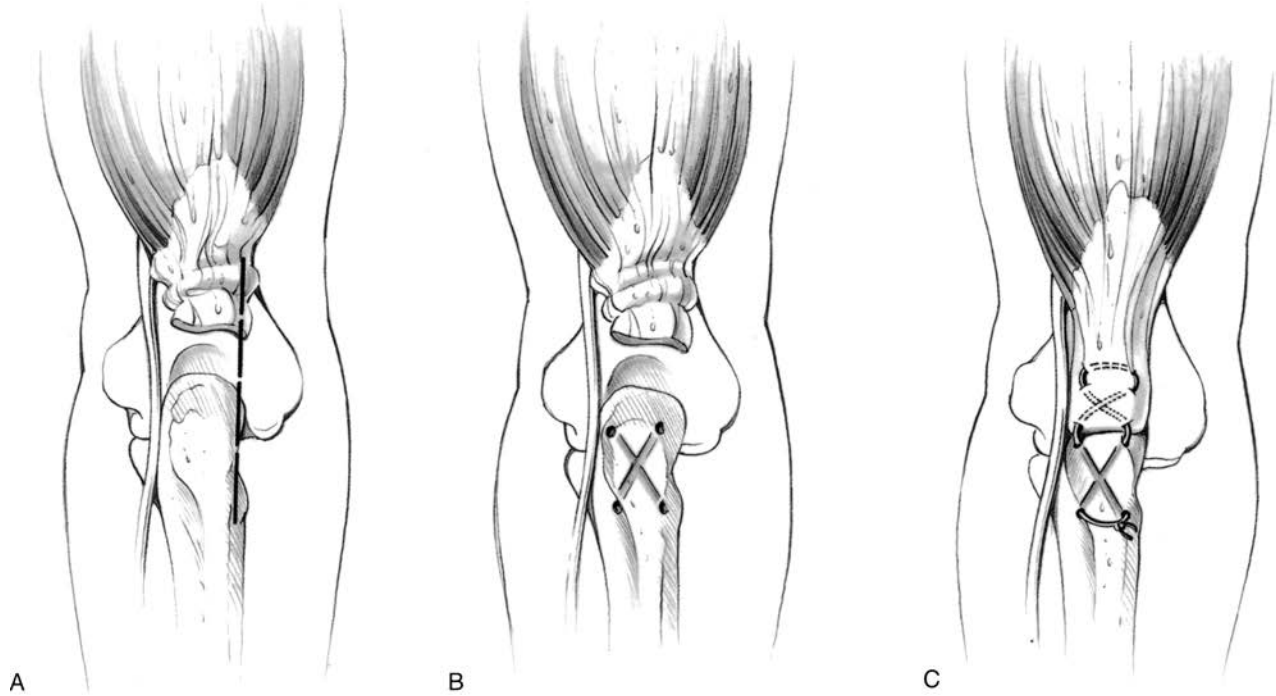

Figure 8-10 **(A–C)** Surgical technique for repair of triceps tendon avulsion. See text for details [79]. (Adapted with permission from Morrey B. Tendon injuries about the elbow. In: Morrey B. ed. *The elbow and its disorders.* Philadelphia: WB Saunders, 1993:492–504.)

A nonabsorbable no. 5 suture is woven through the freshened tendon in Bunnell fashion. Criss-crossed bone tunnels in the olecranon, as described by Morrey, is an excellent method to secure the suture (see Fig. 8-10B).[80] Again, care must be taken not to tether or entrap the ulnar nerve, which lies immediately adjacent to the repair. The suture is tied with the tourniquet deflated and the arm extended. Placing the knot on the lateral side of the ulna will help avoid ulnar nerve irritation and local tenderness when the arm is resting on a hard surface (see Fig. 8-10C). After routine closure, the arm is splinted at 30 to 45 degrees of elbow flexion, depending on the quality of tissue and tension on the repair.

We would recommend immobilizing the arm in a posterior splint for approximately 2 to 3 weeks postoperatively. The duration of postoperative immobilization in the literature ranges from 10 days to 6 weeks, averaging 3 weeks.[8] Gentle active elbow flexion and passive extension are begun 2 to 3 weeks after surgery. Resisted exercises are initiated at 6 weeks. Return to full unrestricted activity occurs between 4 and 6 months after surgery and is determined by the quality of the tissue repaired and the patient's specific functional demands.

Complications

No significant complications, such as rerupture or ulnar nerve injury, have been reported with operative repair of triceps avulsions. Wire sutures did cause a bursa over the olecranon in one case and, therefore, should probably be avoided.[84] Not a single case of failed repair was found in the literature.

SUMMARY

Complete muscle ruptures about the shoulder girdle are relatively uncommon. Unrecognized or untreated rupture of the deltoid origin will severely affect shoulder function. Complete pectoralis major rupture from its tendinous insertion will significantly impair strength in high-demand athletes and laborers. The triceps is the sole extender of the elbow, and therefore its integrity is essential for normal upper-extremity function. In general, anatomic repair of acute tendon ruptures is recommended to preserve normal shoulder function. It is difficult to predict the consequences of an isolated coracobrachialis or short head of biceps disruption. Traumatic injuries to the trapezius, latissimus dorsi, and teres major are usually intramuscular strain, although rare cases of tendon avulsion have been reported. The management of muscle belly ruptures is determined by the specific muscle involved and the extent of injury. Awareness of these injuries is the first step toward proper diagnosis and treatment.

CONCLUSIONS 306

INTRODUCTION

The complexity of the shoulder joint is best appreciated from our understanding of how shoulder anatomy and biomechanics are intrinsically related to the pathophysiology of shoulder instability. A multidisciplinary collaboration between surgeons, biomechanical engineers, anatomists, biochemists, and several other basic scientists is responsible for recent progress in these areas. Advances in experimental and clinical testing protocols have improved the current understanding of shoulder anatomy and biomechanics tremendously. No longer is our understanding of shoulder instability based on anecdotal and qualitative clinical experiences documenting shoulder pathology. A plethora of gross and histologic cadaveric studies, radiographic studies, and biomechanical studies now provides a sound foundation to understand how a minimally constrained articulation can balance mobility and stability. Alterations in any of the anatomic or biomechanical factors requisite for shoulder stability provide the pathogenesis for clinical instability.

The purpose of this chapter is to review the current anatomic and biomechanic factors that control glenohumeral joint motion and stability. Because anatomy and biomechanics are two interdependent disciplines, they will be discussed together as each of the relevant structures is reviewed. A deeper understanding of this relation will provide substantive data critical to classify and appreciate the pathophysiology of glenohumeral instability. More importantly, the application of anatomic and biomechanic principles provides a rational approach to the

treatment of glenohumeral instability for optimal functional restoration.

DEFINING THE PROBLEM

Laxity is asymptomatic, passive translation of the humeral head on the glenoid as determined by clinical examination and is unassociated with pain. Laxity is required for normal glenohumeral motion and may be affected by age,[62] gender, and congenital factors. In general, laxity changes with the position of the arm. At the extremes of rotation, the static restraints tighten and decrease laxity. Whether laxity is a risk factor for the development of clinical instability is a matter of debate.[184]

Instability is a pathologic condition that manifests as pain or discomfort in association with excessive translation of the humeral head on the glenoid fossa during active shoulder motion. Both clinical[48,62,73] and experimental studies[84,85,89,149,224,258,259,267] demonstrate a wide range of normal "play" in the glenohumeral joint; thus, it is the association with symptoms that clearly separates instability from excessive laxity. A spectrum of instability exists, representing increasing degrees of injury and dysfunction of the dynamic and static factors that function normally to contain the humeral head within the glenoid. Patients with multidirectional instability subluxate or dislocate in multiple directions, with concurrent reproduction of symptoms in at least two directions. Symptoms typically occur at midrange positions of glenohumeral motion, and often are associated with activities of daily living.[16,222] Recently, stability has been quantified as the force required to sublux the joint by a specified amount of translation. This has facilitated the study of the combined effects of muscle and capsular loads to joint stability and, therefore, represents an important advance in modeling the in vivo mechanical environment of the glenohumeral joint.[28,143,231]

ANATOMIC AND BIOMECHANIC CONSIDERATIONS

Anatomic control of glenohumeral joint stability can be divided into static (e.g., ligaments and tendons) and dynamic (e.g., muscular contraction) factors (Table 9-1). The cooperative role that these factors play is complex, and no single factor is responsible for glenohumeral joint stability. Similarly, no single lesion is responsible for clinical instability (Table 9-2). Contemporary approaches to the treatment of glenohumeral joint instability are directed at restoring normal anatomy and biomechanics, as opposed to simply constraining motion, as has been historically described.[46,64]

Establishing criteria for "normal" and "pathologic" conditions of the glenohumeral joint is often difficult owing

TABLE 9-2
NORMAL AND ABNORMAL ANATOMY AND BIOMECHANICS

Stability Factor	Pathoanatomy
Glenoid version	Congenital: abnormal version; dysplasia Fracture causing abnormal version
Humeral version	Congenital: abnormal version; dysplasia Fracture/surgery causing abnormal version
Articular congruity	Congenital: dysplasia Acquired: fracture, Bankart lesion, osteoarthritis
Labrum	Bankart lesion "Fraying" secondary to laxity
Capsuloligamentous	Traumatic tear, cumulative microtrauma with plastic deformation Congenital laxity Loss of proprioceptive feedback
Negative intraarticular pressure	Capsular tear "Rotator interval" defect Lax capsule
Rotator cuff deficiency	Traumatic tear, cumulative microtrauma
Biceps	SLAP lesion Tendon rupture
Scapulothoracic motion	Dyskinesis: fatigue and weakness of serratus Long thoracic nerve palsy

SLAP, superior labrum from anterior to posterior.

to the considerable individual variation in capsuloligamentous anatomy[58,64,180,182,258,259] and in inherent shoulder laxity.[62,84,85,139] Dynamic factors (i.e., rotator cuff and biceps) are affected by their level of conditioning and strength. Scapulothoracic motion[263] is a more subtle, but equally important, dynamic factor helping to maintain shoulder stability. To add to this complex equation, an interaction between static capsuloligamentous factors and dynamic muscular factors, mediated through proprioception, has been postulated.[25,42,135,136,139,243,252]

Anatomic and biomechanic dysfunction leading to glenohumeral instability results from varying levels of applied stress (i.e., a single traumatic event vs. cumulative microtrauma), the relative risk of injury associated with an activity, the quality and integrity of the static stabilizers, and the strength and conditioning of the dynamic stabilizers. An individual's "susceptibility" for glenohumeral instability is dependent on these factors, each of which will be discussed in the following sections. The consequences of deficiency of any one component will be presented.

Static Factors

Articular Version

Both arthrographic and roentgenographic studies have characterized the relation between the humeral head and the glenoid surface of the scapula. With the arm hanging at the side in an adducted position, the scapula faces 30 degrees anteriorly on the chest wall and tilts 3 degrees upward relative to the transverse plane and 20 degrees forward relative to the sagittal plane (Fig. 9-1).[180] As described by Saha,[218] in 75% of persons the average glenoid orientation is in 7 degrees of retroversion, with 25% of persons having anteversion ranging from 2 to 10 degrees. Churchill[43] et al. evaluated 334 cadaveric scapulae and found that Caucasians have more retroversion than African Americans. Further, there is no difference in retroversion seen between males and females. Saha[218] and others[14] have observed that the glenoid has an average superior tilt of 5 degrees (Fig. 9-2). Scapular inclination may have a contributory role in controlling inferior stability.[259] However, the difficulty in interpreting these studies arises from a wide range of interindividual variability, the reproducibility of techniques used to measure these factors, and an unknown relative contribution to clinical instability.

Recently, the anatomy of the proximal humerus has been significantly clarified. Saha[218] was one of the first to radiographically show that the neck-shaft angle averages 130 to 140 degrees and retroversion averages 30 degrees relative to the transepicondylar axis of the distal humerus (see Fig. 9-2).

Walch et al.,[254] using a micron precision probe and a computer to render a three-dimensional image of 65 humeri, determined that the inclination of the articular surface varies between 114 and 147 degrees with an average value of 130 degrees. In this same study, the average humeral retroversion measured 17.9 degrees (range, –6.5 to 47.5 degrees).

Articular Conformity

The glenohumeral joint in the adult consists of the humeral head and glenoid surface of the scapula. Understanding the glenoid and humerus as separate, but interdependent, congruent structures is integral to appreciate how

these two joint surfaces can maintain stability yet provide for a relatively large range of motion. Congruence can be defined as the difference in the radii of the humeral head and the glenoid articulating surfaces. The closer the difference is to 0, the more congruent is the joint.[23,229] This congruent articulation provides the foundation for the rotator cuff to establish a concavity–compression effect as it dynamically compresses the convex humeral head into the matched concavity of the glenoid.[140] Furthermore, as an extension of the glenoid, the labrum functions to increase the depth and surface area of the glenohumeral articulation, enhancing this effect.[95]

The glenoid surface is "pear-shaped," similar to an inverted comma, being approximately 20% narrower superiorly than inferiorly (Fig. 9-3). The average vertical and transverse dimensions are 35 and 25 mm, respectively.[43] In contrast, the larger humeral head has vertical and transverse dimensions averaging 48 and 45 mm, respectively.[180] Approximating a sphere, the humeral head has a surface area that is three times that of the glenoid.[229] In any position of rotation there is a surface area mismatch such that only 25% to 30% of the humeral head is in contact with the glenoid surface.[220] In other words, the glenoid's relatively smaller surface area is insufficient to cover the humeral head. This emphasizes the importance of the soft tissues and muscles surrounding the joint in providing stability during shoulder function.

Walch and Boileau[256] determined that the humeral head is comparable to a sphere in 90% of the 160 humeri they examined, with the articular surface constituting about one-third of the sphere. The diameter of the head was variable with an average of 43.2 mm (range, 36.5 to 51.7 mm) with an articular cartilage thickness on average of 15.2 mm (range, 12 to 18 mm). They demonstrated that the spherical humeral head sits with a frontal plane medial offset of 6.9 mm on average (range, 2.9 to 10.6 mm) and a

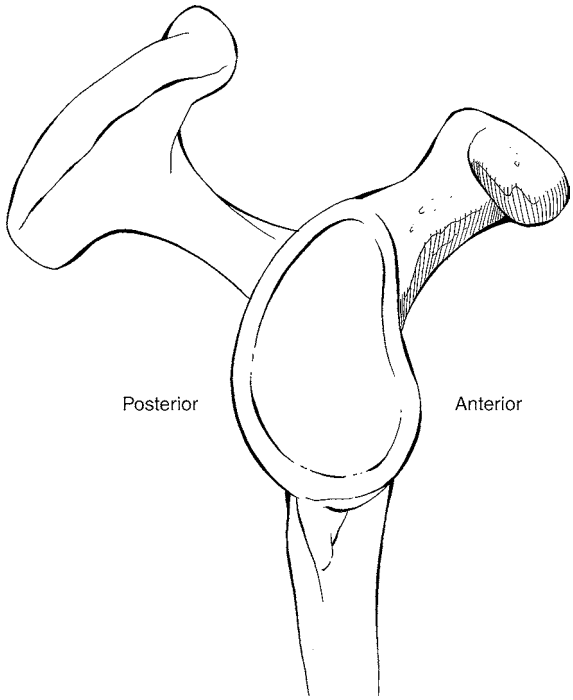

Figure 9-3 The "pear-shaped" face of the glenoid that articulates with the humeral head. (From Boardman ND III, Fu FH. Shoulder biomechanics. In: McGinty JB, Caspari RB, Jackson RW, Poehling GG, eds. *Operative arthroscopy.* Philadelphia: Lippincott-Raven, 1996:627, with permission.)

sagittal plane posterior offset of 2.6 mm (range, 0.8 to 6.1 mm). These parameters, however, may have more implications for shoulder arthroplasty design than for shoulder stability. Similarly, Iannotti et al.[100] reported that the humeral head approximates a sphere in the central articular areas and becomes slightly elliptical peripherally. Variations in these findings and their effect on the pathophysiology of shoulder instability are not clearly understood.

Conceptually, the glenohumeral joint has been compared to a "golfball sitting on a tee"[180] (Fig. 9-4). This analogy is based on historical beliefs sighting the relatively small area of the glenoid and its relative shallowness compared with the humeral head, allowing only a limited portion of the humeral head to contact the glenoid in any single shoulder position.[32,218,219] In fact, the articular surfaces of the humeral head and glenoid are almost perfectly matched with a congruence within 3 mm, with deviations from sphericity of less than 1%.[166,229] Additionally, the cartilage of the glenoid is thicker peripherally, and thus, plain radiographs tend to underestimate the relative concavity of the glenoid. This would imply that the glenohumeral joint would function similar to a ball-and-socket articulation as described by Kelkar et al.[118,119]

Although some coupled translation occurs at the extremes of glenohumeral rotation,[84,85,139] tracking of the geometric center of the cartilaginous articular surface with simulated muscle forces actually approximates ball-in-socket motion.[119] In the stable shoulder, external and internal rotation is associated with posterior and anterior humeral head translation, respectively. These relations may be altered in the unstable shoulder. McMahon et al.,[154] in an elegant model using a dynamic shoulder testing apparatus, measured muscle force values and tendon excursions across the glenohumeral joint during abduction in the scapular plane. They determined that humeral head translations on the glenoid were less than 2 mm under all testing conditions used and that the joint does behave kinematically as a "ball-and-socket" articulation during glenohumeral abduction. The importance of these findings is that articular incongruency is probably less of a predisposing factor for instability

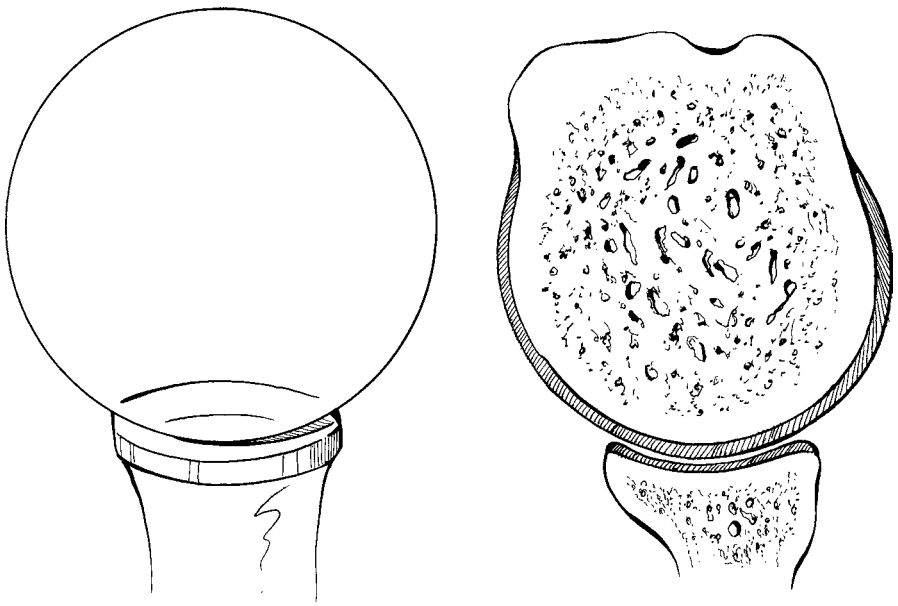

Figure 9-4 Analogy of the glenohumeral joint to a golf ball and tee. (From Boardman ND III, Fu FH. Shoulder biomechanics. In: McGinty JB, Caspari RB, Jackson RW, Poehling GG, eds. *Operative arthroscopy.* Philadelphia: Lippincott-Raven, 1996:627, with permission.)

than is surface area mismatch, as seen in glenoid dysplasia or glenoid fracture.[9,61,124,138,213,215] Additionally, the integrity of the soft tissues influences coupled translation, and this may also be a greater predisposing factor to instability than is articular incongruency.[35,84,94,95]

Glenoid Labrum

The relative lack of depth and surface area of the bony glenoid is compensated by the fibrous labrum acting to maintain normal glenohumeral biomechanics. As determined by Cooper et al.,[51] the labrum is a fibrous ring attaching to the glenoid articular cartilage through a narrow fibrocartilaginous transition zone. Above the glenoid equator, the labrum is relatively more mobile. In contrast, below the equator, the labrum is more consistently tightly attached to the glenoid articular cartilage. The tendon fibers of the long head of the biceps brachii blend with the superior labrum, and the inferior glenohumeral ligament (IGHL) blends into the inferior labrum. Cooper et al.[51] examined the vascular supply of the labrum and found that the superior and anterosuperior parts of the labrum were less vascular than the posterosuperior and inferior portions. Blood supply was limited to the periphery.

The labrum contributes to stability of the glenohumeral joint through several mechanisms. It acts as an anchor point for the capsuloligamentous structures.[51,164,204] Howell and Galinat[95] have shown how the labrum enhances stability by deepening the concavity of the glenoid socket to an average of 9 and 5 mm in the superoinferior and anteroposterior planes, respectively (Fig. 9-5). Loss of the labrum decreases the depth of the socket by 50% in either direction. Functionally, this acts as a "chock-block" preventing the head from slipping over the edge of the glenoid. Resection of the labrum reduces resistance to translation by 20%, and it is especially effective in doing so in combination with joint compression in the midrange of glenohumeral motion.[102,140] The labrum also acts to increase the surface area of contact, acting as a load-bearing structure similar to the function of the meniscus in the knee.[34,230] Unlike the meniscus, however, the labrum lacks the microscopic architecture to disperse hoop stress and, therefore, is unlikely to effectively bear load.

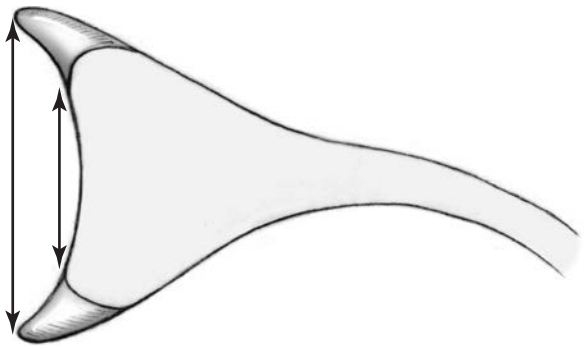

Figure 9-5 Glenoid labrum increases the surface area and depth of the glenoid socket. (Adapted from Warner JJP, Caborn DNM. Overview of shoulder instability. *Crit Rev Phys Rehabil Med* 1992;4:145–198.)

Vanderhooft et al.[250] and Bowen et al.[35] have shown that the labrum plays a significant stabilizing role during rotator cuff contraction, facilitating the concavity–compression mechanism as the humeral head is compressed into the glenoid. Lazarus et al.[130] have defined a *stability ratio,* a measure of the effectiveness of concavity–compression in the stabilization of the glenohumeral joint, as the ratio between the maximum dislocating force that can be stabilized in a given direction and the load compressing the head into the glenoid. They determined that by creating a chondral–labral defect, an 80% reduction in the height of the glenoid occurred, with a concomitant reduction in the stability ratio of 65% for translation in the direction of the defect.

A Bankart lesion represents a lesion of the labrum corresponding to the detachment of the anchoring point of the IGHL and middle glenohumeral ligament (MGHL) from the glenoid rim.[12,213] A Bankart lesion disrupts the concavity–compression effect during rotator cuff contraction, eliminates the "chock-block" effect, and decreases the depth of the socket by 50% with detachment of the capsuloligamentous structures. This lesion should not be confused with the normal anatomic variants of a sublabral sulcus underneath a cord-like MGHL, the Buford complex,[275] or a loosely attached labrum superiorly. Whether the Bankart lesion is the "essential lesion" leading to recurrent anterior instability, as suggested by several authors, is currently a topic of interest.[12,32,164] Isolated detachment of the labrum as a singular entity leading to recurrent instability was challenged early in the literature by Townley[245] and then by Speer et al.[232] Normal variations of the capsulolabral complex occur commonly.

The difference between acute and chronic shoulder instability is important clinically. In acute shoulder instability, the authors feel that the labrum is the "essential" lesion. In a classic article by Arciero et al.,[8] repair of the Bankart significantly reduced the recurrence rate of anterior shoulder dislocation. In patients with chronic anterior instability, it is the capsule and labrum combined, or capsulolabral tissue, that is the essential lesion.[148]

Pagnani et al.[190] have demonstrated the importance of the superior portion of the glenoid labrum. In a cadaver study, isolated lesions of the anterosuperior portion of the labrum did not have a significant effect on glenohumeral translation. However, complete lesions of the superior portion of the labrum associated with destabilization of the biceps insertion resulted in significant increases in anteroposterior and superoinferior glenohumeral translations in the lower and middle ranges of elevation. The implications of these findings are that destabilization of the glenoid insertions of the superior glenohumeral ligament (SGHL), MGHL, and biceps insertion may be associated with subtle increases in translation and may be

related to the symptoms present in patients who have isolated lesions of the superior labrum.[190,228]

Negative Intraarticular Pressure

In normal shoulders, a relative vacuum exists as a result of high osmotic pressure in the interstitial tissues, causing water to be drawn out of the glenohumeral joint.[147] As the articular surfaces are pulled apart, a suction effect develops to resist further displacement. The magnitude of this negative pressure has been shown to be about –42 cm of water in the adducted and relaxed shoulder. This increases to –82 cm of water during the application of a 25-N inferior force applied to the cadaver shoulder.[37] Negative intraarticular pressure becomes especially important when the rotator cuff is not contracting or when tension has not developed in the superior and coracohumeral ligaments during glenohumeral motion.

Pathologic conditions may include those that cause venting of the glenohumeral joint, leading to inferior subluxation, as has been shown experimentally by Warner et al.[257] and others.[127] Wuelker et al.[274] observed that venting of the joint increased displacement significantly in the anterior, posterior, and inferior planes. Anterior translation also increased by 55%[77] after capsular venting. This restraint becomes negligible, however, when the muscles contract with shoulder abduction or when the IGHL or superior capsular structures are under tension.[37,260] In a study by Helmig et al.,[91] venting of the capsule led to significant increases in anteroposterior translation and external rotation. The implications of their findings were that evaluation of shoulder stability in biomechanical investigations should be performed before violation of the negative intraarticular pressure mechanism occurs, or at the very least, measures should be corrected for this factor.

Thus, as a static restraint, negative intraarticular pressure appears to be important in limiting translation of the humeral head. Habermeyer et al.[82] noted that the presence of a Bankart lesion somehow eliminated the intraarticular seal to atmospheric pressure. A traumatic capsular rupture or an enlarged rotator interval capsular defect, possibly present at birth, presumably could lead to excessive glenohumeral translation, predisposing to instability.[49] Recently, Hashimoto et al.[87] have indicated that dynamic changes in intraarticular pressure can help differentiate patients with adhesive capsulitis, partial- and full-thickness rotator cuff tears, and instability. Practically, from a clinical perspective, reestablishing negative intraarticular pressure remains a theoretical concern and plays no role in the treatment of shoulder instability.

Adhesion–Cohesion

The glenohumeral joint contains less than 1 mm of synovial fluid that provides articular nourishment through diffusion and lubrication through several mechanisms (e.g., hydrodynamic, boundary, weeping, or boosted). Viscous and intermolecular forces help to create this adhesion–cohesion effect. Functionally, this is a stabilizing mechanism that permits sliding motion between the two joint surfaces while simultaneously limiting them from being pulled apart.[147] This is analogous to two glass plates separated by a thin film of water that slide easily over one another, but are difficult to separate. Negative intraarticular pressure and adhesive forces resulting from the presence of synovial fluid between the articular surfaces contribute static restraint, particularly when the capsule is lax and the muscles are relatively inactive.[101,127,145] Clinically, these factors probably play a minor role in maintaining glenohumeral stability and only at very low load levels.

Capsuloligamentous Structures

Few structures in the shoulder have received as much attention by investigators as the capsule and ligaments surrounding the glenohumeral joint. Traditionally, the ligaments of the capsule were described as discreet thickenings constituting the "glenohumeral ligaments."[58,180,183,221] Clinical observations at the time of surgery[4,32,70,164,169,192,213,215,217] or by cadaver shoulder dissections[12,45,58,64,95,126,133,174,182,213,217,246] Burkart and Debski[37a] have enhanced our understanding of these structures from an anatomic perspective. To obtain a concise appreciation of these structures, anatomic investigations must minimally distort the ligamentous relationships (Fig. 9-6). With increasing sophistication, the biomechanical function,[56,57,77,126,134,144,155,156,158,181,183,186,210,212,234,257,259] material properties,[21,29,56,83,117,134,144,155,156,158,207,210,234,244,257] and the interrelation of the rotator cuff and capsule have been described.[40,96,132,151,174,212,258] Synthesizing the available data into a cohesive algorithm applicable to the clinical setting of glenohumeral instability is a formidable task for most.

In a classic anatomic study, DePalma et al.[58] described the variability of the shoulder capsule, categorizing it into six basic types based on the pattern of the synovial recesses. Other anatomic studies have since confirmed and clarified the variable architecture of the glenohumeral ligaments.[64,164] Contemporary investigators suggest, as did DePalma et al.,[58] that some anatomic findings correlate with the risk of developing shoulder instability.[161,259] The basis for the functional roles of the capsular structures lies in their anatomic arrangement throughout the capsule. A significant advance in our knowledge came from Turkel et al.,[246] who confirmed by anatomic radiographic studies that different portions of the capsuloligamentous complex provided static stability that depends on arm position and the direction of the load applied to the proximal humerus.

The glenohumeral capsule is thin, less than 5 mm in thickness.[44] The glenohumeral ligaments function principally during rotation of the arm to reciprocally tighten and loosen, thus limiting translation and rotation in a

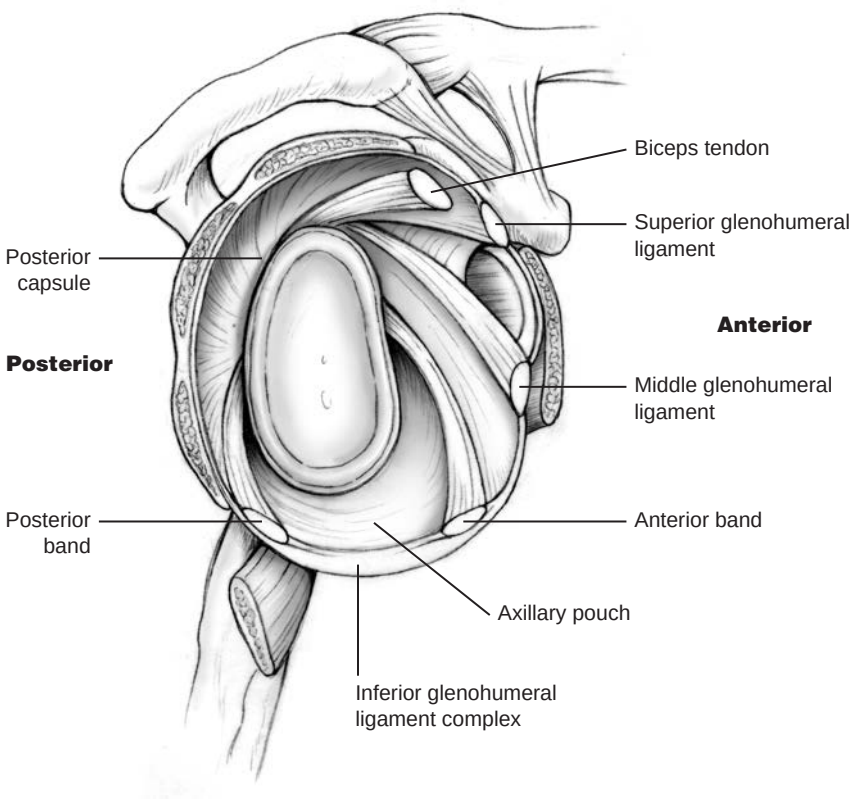

Figure 9-6 Capsuloligamentous anatomy viewed from the side with the anterior aspect to the right and the posterior aspect to the left. The humeral head has been removed, leaving the glenoid. The superior glenohumeral ligament and middle glenohumeral ligament are labeled. The inferior glenohumeral ligament complex consists of an anterior band, posterior band and interposed axillary pouch. The posterior capsule is the area above the posterior band. The biceps is also labeled. (Adapted from O'Brien SJ, Neves MC, Arnoczky SP, et al. The anatomy and histology of the inferior glenohumeral ligament complex of the shoulder. *Am J Sports Med* 1990;18: 449–456.)

load-sharing fashion.[261] In the midrange of rotation when these structures are relatively lax, stability is maintained primarily by the action of the rotator cuff and biceps through the concavity–compression effect across the glenohumeral joint.[85,140] The ligaments principally protect against instability when the joint is placed at the extremes of motion and become especially important when all other stabilizing mechanisms have been overwhelmed. [57,84,85,147,258]

Clinically, this becomes important during capsular reconstruction. Tensioning these structures in the midrange can potentially overtighten and constrain the joint, limiting rotation.[76,141,263] In the extreme case, this may lead to posterior humeral subluxation or arthritis.[18,22] The static role of each component of the capsuloligamentous structure is summarized in Table 9-3. In the sections that follow, each structure will be reviewed in terms of contemporary research describing the anatomy and biomechanics as well as a limited discussion on the relevant material properties.

Superior and Coracohumeral Ligaments

These structures are considered together because their anatomic courses are parallel and they constitute the reinforcing structures of the "rotator interval" region.[29,49,86,169,174,180,213] The rotator interval subtends a medially based triangular space, bordered superiorly by the anterior margin of the supraspinatus tendon, inferiorly by the superior border of the subscapularis tendon, medially by the base of the coracoid, and laterally by the long head of the biceps tendon and sulcus. The floor of the rotator interval is normally bridged by capsule. Occasionally, a complete opening within the tissue spanning the rotator interval is present and is described as a "rotator interval capsular defect" (Fig. 9-7).

The coracohumeral ligament (CHL) is a dense fibrous extraarticular structure originating on the lateral surface of the coracoid process as a broad (1 to 2 cm) and thin structure. It inserts into the greater and lesser tuberosities adjacent to the bicipital groove and becomes intermingled with the tendinous edges of the supraspinatus and subscapularis, respectively.[58,86] Cooper et al.[52] questioned the significance of the CHL, describing it as a capsular fold creating a "pup tent" of capsule within the rotator interval. Others argue that the CHL is a well-defined structure that prevents excessive inferior translation of the adducted humerus in either position of humeral rotation.[171,186] While the specific function of the CHL remains disputed, it is known to be geometrically more robust and mechanically stiffer than the SGHL.[30] It also provides stability to the biceps tendon.

The SGHL lies deep to the CHL, is variable in size, and is present in over 90% of cases.[58,180,183,217,224,259] Usually quite diminutive, it originates from the superior glenoid tubercle just inferior to the biceps tendon and runs parallel to the CHL as it inserts into the superior aspect of the lesser tuberosity just medial to the bicipital groove.

TABLE 9-3
FUNCTIONS OF THE LIGAMENTS

Author	SGHL	CHL	MGHL	IGHLC	Other

ABD, abduction; ADD, adduction; CHL, coracohumeral ligament; ER, external rotation; IGHLC, inferior glenohumeral ligament complex; IR, internal rotation; MGHL, middle glenohumeral ligament; SGHL, superior glenohumeral ligament.

Opinions vary on the specific functions of these two ligaments. Harryman et al.[86] characterized the relative biomechanical contribution of the rotator interval capsule to shoulder stability in cadaver specimens. A transverse incision in the rotator interval region including the capsule, CHL, and SGHL allowed statistically significant increases in humeral head translations in all planes tested. Imbrication of the rotator interval decreased inferior translation in adduction and posterior translation in flexion to less than the intact state. No attempt was made to isolate the role of specific capsular ligaments. Burkart and Debski[37a] performed a selective sectioning study of these ligaments and concluded that the SGHL is an important stabilizer in the anterior direction. The SGHL also limits external rotation of the adducted arm.[37a] Basmajian and Bazant,[14] using electromyographic and anatomic dissections, showed that the

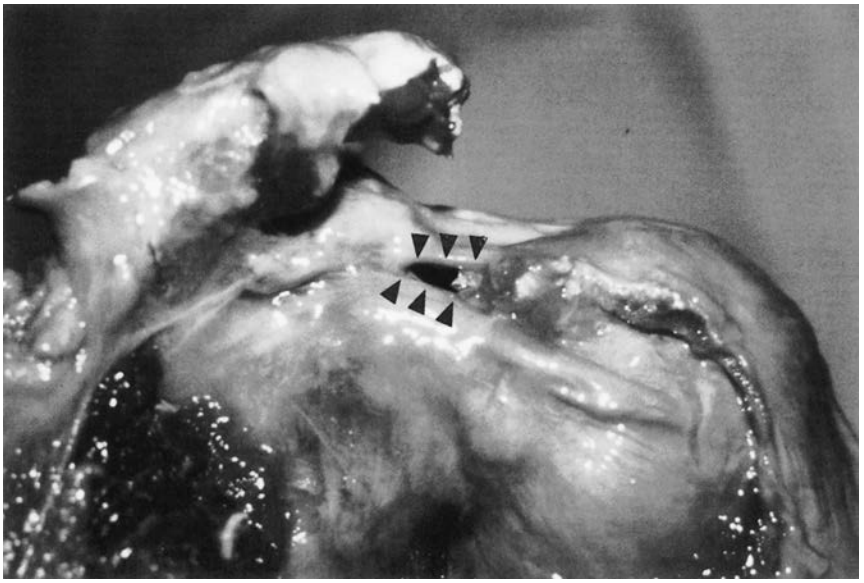

Figure 9-7 Gross anatomic specimen of a left shoulder demonstrating the opening within the rotator interval situated between the supraspinatus and subscapularis muscle tendons.

superior capsule and the CHL resisted downward displacement with the arm adducted, independent of load.

Patel et al.[193] described the CHL to consist of an anterior and posterior band originating at the coracoid and inserting into the lesser and greater tuberosities, respectively. During adduction and external rotation, the SGHL and anterior band of the CHL shortened from a maximally lengthened position. These changes were opposite those of the posterior band of the CHL that was maximally lengthened with adduction and internal rotation. Warner et al.[259] suggested that the SGHL resists inferior translation of the adducted shoulder and that the CHL is not important here. However, subsequent work by Boardman et al.[29] suggested that the CHL is the principal functional component of the capsule within the rotator interval. Observations by Lee et al.[133] suggest that the coracoacromial ligament has a role in static restraint of the glenohumeral joint as well. These authors propose that the coracoacromial ligament interacts with the CHL to prevent anterior and inferior translation, particularly between 0 and 30 degrees of abduction.

Despite varying opinions in the literature (see Table 9-3), the current consensus is that these two structures constrain the humeral head on the glenoid, limit inferior translation and external rotation when the arm is adducted, and limit posterior translation when the shoulder is in a position of forward flexion, adduction, and internal rotation. There has been renewed interest in this portion of the shoulder capsule because openings within the rotator interval have been associated with recurrent anteroinferior and multidirectional instability.[65,86,175,213] As suggested by several of these studies, addressing this pathology may be important in preventing recurrence. Conversely, contracture or scarring of this portion of the shoulder capsule has been associated with adhesive capsulitis.[86,171]

Middle Glenohumeral Ligament

As described by DePalma[58] and others,[180,182,224,258,259] the MGHL has the greatest variation in size and presence of all the ligaments of the shoulder. It is absent or poorly defined in 40% of individuals.[64,182] It originates from the supraglenoid tubercle and anterosuperior labrum, often along with the SGHL, and inserts just anterior to the lesser tuberosity, blending with the posterior aspect of the subscapularis tendon. Its variable morphology usually takes one of two forms: (a) sheet-like and confluent with the anterior band of the IGHL or (b) cord-like, with a foraminal separation between it and the anterior band of the IGHL. Moseley and Overgaard[164] reported that the MGHL originated from the scapular neck and formed an anterior pouch accommodating the humeral head in some patients with recurrent anterior instability.

It is generally believed that the MGHL functions as a passive restraint to both anterior and posterior translation of the humeral head when the arm is abducted in the range from 60 to 90 degrees in external rotation and limits inferior translation when the arm is adducted at the side. Those who are "MGHL dominant" individuals with a cord-like MGHL may be more dependent on this structure to provide a protective role against anterior instability.[161,259] Clinically, the MGHL may be detached from the anterior glenoid and constitutes the leading edge of a Bankart lesion, which typically includes the anterior band of the IGHL. However, the sublabral hole should not be confused with a detached labrum, for generally the labrum is more mobile above the equator of the glenoid.

Inferior Glenohumeral Ligament Complex

Originally described by DePalma,[58] several descriptions of the IGHL exist in the literature ranging from a triangular-shaped structure coursing from the labrum to the humeral neck, to one with well-defined thickenings at its leading edge.[182,244,246] Typically, it originates from the anteroinferior labrum or inferior half of the neck of the glenoid adjacent to the labrum and inserts just inferior to the MGHL at the humeral neck. Our current understanding has advanced to the point at which we now consider this structure to be quite developed, with very specific functions attributed to its individual components. O'Brien et al.[182] have defined this structure, through arthroscopic, gross, and histologic evaluation, as the inferior glenohumeral ligament complex (IGHLC) consisting of three components. They described discrete anterior and posterior bands (ligament) with an interposed thinner axillary pouch (see Fig. 9-6). The complex consists of three well-defined layers of collagen fibers extending from the glenoid to the humerus (inner and outer) and running circumferentially around the joint (middle). Ticker et al.[244] and Bigliani et al.[21] have recently challenged the presence of a discrete posterior band and found all regions of the IGHLC to be thicker near the glenoid than the humerus.

The IGHLC contributes to glenohumeral stability in several ways. Recently, Kuhn et al. found that the IGHLC is a restraint to external rotation of the arm in neutral and abducted positions.[126] O'Brien et al.[182] suggested that the IGHLC functions as a hammock to support the humeral head as it undergoes reciprocal tightening–loosening with abduction or rotation as the orientation of the complex changes. In adduction, it forms a dependent fold, acting as a secondary restraint limiting large inferior translations.[182,259] In abduction, however, this complex moves underneath the humeral head, becoming taut, in the fashion of a hammock, effectively limiting inferior translation. As the arm is internally rotated, the complex moves posteriorly, and as the arm is externally rotated, the complex moves anteriorly, forming a barrier to posterior and anterior dislocation, respectively (Fig. 9-8). Horizontal flexion and extension in abduction will also tighten the posterior or anterior components, respectively, thereby limiting anteroposterior translation.[224] Another biomechanical study by O'Brien et al.[181] verified that the primary anteroposterior

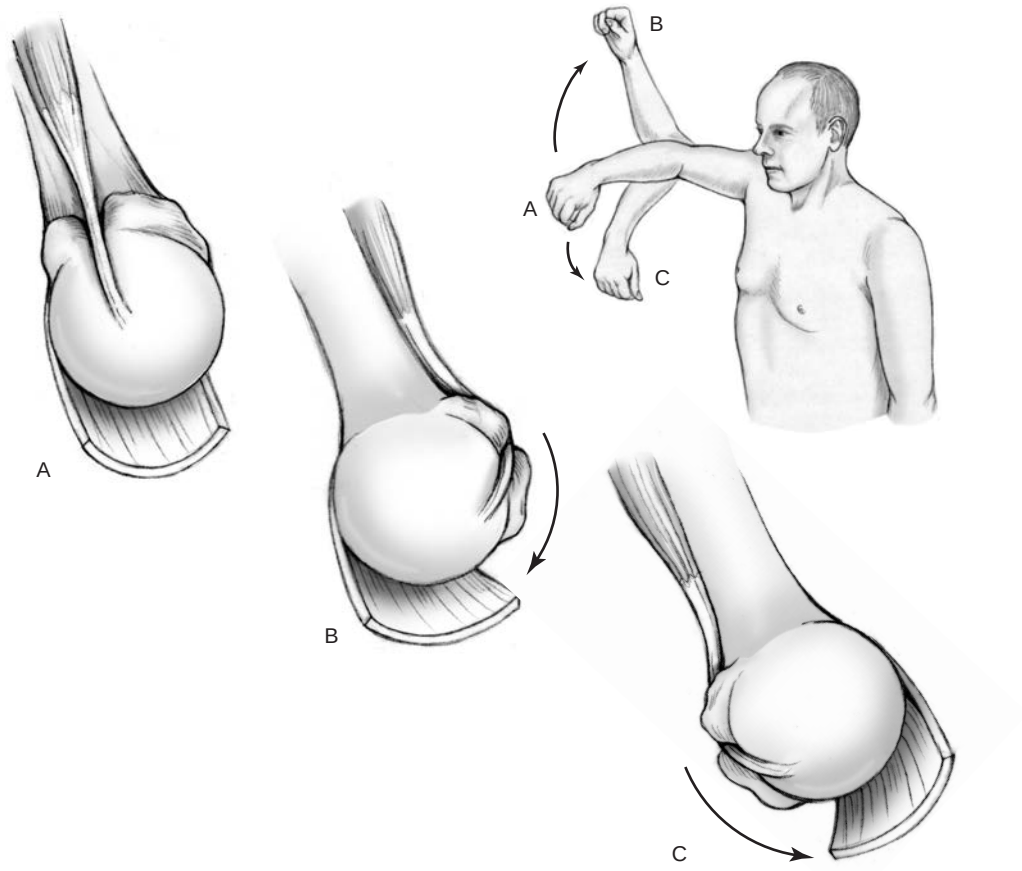

Figure 9-8 The "hammock"-like anatomy of the inferior glenohumeral ligament complex allows for reciprocal tightening of its anterior and posterior portions when the arm moves from neutral rotation in **(A)** abduction to external **(B)** and internal **(C)** rotation. (Adapted from Warner JJP, Caborn DNM. Overview of shoulder instability. *Grit Rev Phys Rehabil Med* 1992;4:145–198.)

stabilizer of the 90-degree abducted shoulder is the IGHL. The anterior band was the primary stabilizer in 30 degrees of horizontal extension and the posterior band at 30 degrees of horizontal flexion.

Injury to the IGHLC plays an integral role in the development of anterior instability. Surgical reconstruction directed at anatomic restoration of this part of the capsule has been advocated even in the earliest reports on the surgical management of shoulder instability.[12] Although all of the structures that define the shoulder capsule have at least a limited role, alterations of the IGHLC are believed by most to be a significant factor in the pathophysiology of anterior shoulder instability.

Posterior Capsule

This is the capsule extending from superior to the posterior band of the IGHLC to the intraarticular portion of the biceps tendon.[182] Other than the capsule found within the rotator interval, this is the thinnest region of the joint capsule.[49,182] There are no direct posterior ligamentous reinforcements. Its role is to limit posterior translation when the shoulder is forward-flexed, adducted, and internally rotated.[269] Clinically, this becomes relevant in patients who present with posterior instability. Unlike the other ligament structures about the glenohumeral capsule, the posterior capsule does not have a role in restraining external rotation.[5]

Material Properties

Because instability is often associated with failure of the static constraints (e.g., the capsuloligamentous structures), recent investigations have focused on the individual material properties and the modes of failure. The shoulder capsule is quite redundant, having a surface area two times that of the humeral head.[180] Material properties of the capsule refer to the intrinsic mechanical characteristics of its composition, molecular structure, and ultrastructure. Presumably anatomic variability (e.g., the SGHL and MGHL) may have clinical implications. In other words, a more robust ligament (e.g., IGHL) is presumably more tolerant of strain or force and would be expected to play a more significant role in helping to maintain glenohumeral stability.

Similar to other joint capsules in the body, the shoulder capsule is fibrous and rich in extracellular matrix. It is composed primarily of type I collagen, with lesser amounts of types II and III.[210] Debski et al.[56] quantified collagen fiber orientation in cadaveric capsule specimens and found that the collagen fibers of both the axillary pouch and the anterior band of the IGHL exhibited a random organization. Furthermore, there was no significant difference in fiber orientation seen in the bursal, middle, and articular portions of the axillary pouch. Malicky et al.[144] measured planar strains in the anteroinferior joint capsule and found considerable variability in maximum principal strains across specimens. The principal strain vectors were generally not aligned with the anterior band of the IGHL.[144] The results of these two recent studies strongly suggest that the IGHLC sustains loading in multiple directions rather than only along its length, as is the case with noncapsular ligaments.[259]

Reeves[207] determined that the average maximum tensile strength of the anteroinferior capsule measured in cadaver shoulders is 70 N (at least 20 kg), decreasing after age 50. Between the ages of 10 and 40, the anteroinferior labral insertion was the weakest portion of the whole complex, with more than two-thirds of the failures occurring there. Specimens in the fifth to seventh decades experienced capsular rupture and subscapularis tendon failure more frequently than failure at the labrum.[207] That the anteroinferior portion of the capsule fails first and capsular strength varies inversely with age has also been demonstrated by Kaltsas.[117] Hara et al.[83] evaluated the glenoid labrum and capsule and determined that the anteroinferior labrum close to the glenoid cartilage was weakest, rupturing with a mean force of 3.84 kg/5 mm.

The properties of the IGHL have been well described by Bigliani et al.,[21] who used tensile testing to analyze strength and failure modes in humerus–IGHLC–glenoid specimens. The region of the anterior band had the greatest thickness (average 2.8 mm), progressively decreasing in the axillary pouch (average 2.3 mm) and posterior capsular regions (average 1.7 mm). In contrast to O'Brien et al.,[182] no discrete posterior band was identified, and the axillary pouch was not the thickest region. Additionally, there were no significant differences in the resting length or width of these areas.[21]

Stress at failure of the anterior axillary pouch (average 5.5 MPa) was substantially lower than that described for the knee ligaments (estimated at 35 to 80 MPa198), emphasizing the importance of other stabilizing mechanisms in protecting the IGHLC from structural failure. Similar inferior strength characteristics have been described for the SGHL and CHL.[29] The superior band and anterior axillary pouch exhibit significant strain rate-dependent viscoelastic behavior. These effects were explained by compositional data determining that a proteoglycan content gradient exists, being greatest anterosuperiorly and least posteroinferiorly. Mechanically, this property leads to viscoelastic stiffening as the collagen fibers are "uncrimped" during tension.[21] This may also explain why the inferior glenohumeral ligament has the capacity to stretch considerably before ligament or insertion failure.[21] These investigators also determined that the predominant modes of failure were at the glenoid insertion, with slower strain rates as seen in the Bankart lesion, and in the midsubstance, with faster strain rates as seen with capsular laxity or stretching. This is explained by a nearly elastic behavior in the central region of the IGHL and principally viscoelastic behavior at the bony insertion.[21,244] These authors suggested

that viscoelastic behavior during tension and strain rate-dependent properties of the IGHL support its role as a humeral head stabilizer in the position of abduction and external rotation as force is rapidly applied. Subsequent tensile testing of the anterior band of the IGHLC in the apprehension position at substantially higher strain rates confirmed the viscoelastic property of increased failure stress that was previously noted.[133,155,156,158,234] Thus, functional adaptation may occur to stabilize the head during high-energy activities when other static or dynamic restraints are overwhelmed.

Morrey and Chao[163] have calculated that the anterior shear force in the position of apprehension is as high as 60 kg. To counteract these forces, contraction of the rotator cuff significantly reduces stress in the anterior capsule when the arm is in the maximally abducted and externally rotated position.[40] Thus, the dynamic restraints to stability function as a protective mechanism against structural failure of the static restraints. Although investigated to a lesser degree, the material properties of the restraints to posterior instability have been described. Weber and Caspari displaced the humeral head posteriorly in 90 degrees of flexion and full internal rotation, resulting in a horizontal split in the posterior capsule and posterior labral avulsion from the glenoid.[271] Because the results of these studies depend on a simulated mechanism of injury in the presence of an inactive rotator cuff, rigid interpretation and extrapolation to the pathoanatomy of instability is somewhat speculative.

Obligate Translations

A relatively new area of research interest is focused on understanding the relation between glenohumeral rotation and obligate translation caused by asymmetrical tightening–loosening of the capsuloligamentous structures. Tensile loading in either the anterior or superior structures is simultaneously accompanied by laxity in the posterior or inferior portion, respectively.[55,84,85,258] This is the so-called reciprocal load-sharing relationship of the capsule. Howell and Galinat[94] used axillary radiographs of patients to measure anteroposterior excursion during glenohumeral rotation. Except for maximal extension with external rotation, the humeral head remained centered on the glenoid. In normal subjects, the extended and externally rotated position caused the humeral head to translate posteriorly. In patients with anterior instability, posterior excursion did not occur. Taken a step further, Harryman et al.[85] monitored loads and translations with a magnetic-tracking device in cadaver specimens. Anterior translation occurred with flexion beyond 55 degrees, and posterior translation occurred with extension beyond 35 degrees. Interestingly, these authors found that surgical tightening of the posterior capsule resulted in increased anterior translation with flexion that occurred earlier in the arc of motion compared with normal specimens. Tightening of the rotator interval also increased obligate anterior translation with flexion. The effects of Bankart repair and overtightened inferior capsular shifts were also investigated by Janevic et al.[110] These procedures shifted the humeral head and joint contact posteriorly during loading with abduction, extension, and external rotation. The importance of these findings is that static restraints may function in positions other than the extremes of rotation. It is conceivable that unidirectional tightness, primary (e.g., overhead athlete) or iatrogenic (e.g., anterior capsulorrhaphy), could lead to instability in the opposite direction. Moreover, excessive translation in one direction may require damage to restraints on the same and opposite sides of the joint.[68] These concepts, while requiring further investigation, add an additional layer of complexity to the diagnosis and treatment of shoulder instability.

Rotator Cuff as a Static Stabilizer

Passive tension within the rotator cuff musculotendinous structures appears to have some static role in preventing glenohumeral translation. The "posterior mechanism of dislocation" occurs in older patients who sustain supraspinatus and infraspinatus tendon tears, with or without capsular injury, in association with anterior dislocation.[64,207] Rupture of the subscapularis has also been noted in patients with recurrent dislocations who are older than 35 years of age.[172] The subscapularis statically limits anterior translation in lower ranges of abduction with similar limitations to posterior translation found from the infraspinatus and teres minor.[186,187] Recently, the contribution of passive bulk tissues and the deltoid to static inferior glenohumeral stability was investigated by Motzkin et al.[165] This study determined that in both humeral adduction and abduction, passive bulk tissues (i.e., all tissues superficial to the deltoid) and the deltoid did not provide significant stability to the shoulder joint. Thus, the rotator cuff appears to be one of the few dynamic restraints that have a concomitant passive role in preventing glenohumeral instability.

Dynamic Factors

Clinical experience suggests that static stabilizers by themselves may not be as important in enhancing glenohumeral stability as that provided by the dynamic stabilizers or the relation between them. Experimentally, specimens dissected free of the rotator cuff and long head of the biceps tend to demonstrate at least some degree of inferior subluxation.[127,186] Active contraction of these structures contributes to the dynamic stabilization of the glenohumeral joint through two mechanisms: (a) joint compression (e.g., concavity–compression) resulting from synergistic and coordinated rotator cuff activity and (b) ligament dynamization through direct attachments to the rotator

cuff muscles. Augmenting these mechanisms are the long head of the biceps brachii, coordinated scapulothoracic rhythm, and proprioception providing feedback about extremity position and movement.

Joint Compression

Contraction of the rotator cuff and long head of the biceps brachii augments joint stability by enhancing the conforming fit and increasing the load needed to translate the humeral head through compression of the humeral head into the glenoid.[40,140,147] The rotator cuff muscle forces are ideally aligned for effective compression of the glenohumeral joint at all shoulder positions.[132] Lippitt et al.[140] quantified the magnitude of the tangential forces required to produce glenohumeral dislocation in the setting of applied joint-compressive loads of 50 and 100 N. Tangential forces were as high as 60% of the applied joint-compressive load. The stability of the joint was markedly reduced if a portion of the labrum was removed. Vahey et al.[249] introduced the concept of "scapulohumeral balance" to illustrate that glenoid geometry coupled with joint compression is a major stabilizing force. Bowen et al.[35] determined that a joint compression load of 111 N was sufficient to stabilize the glenohumeral joint in the face of a 50-N force, despite sectioning of three-fourths of the joint capsule. It has been suggested from the results of ligament-cutting studies and direct quantification of the efficiencies of the dynamic stabilizers that joint compression is a more important stabilizer to translation than are static capsular constraints.[27,35]

Poppen and Walker[200] showed that the joint reaction force was a maximum of 0.89 times body weight directed into the face of the glenoid at 90 degrees of abduction using a simplified two-dimensional cadaveric model with digitized radiographs. Also, the subscapularis had a greater mechanical advantage at lower abduction angles (i.e., 60 degrees), whereas the deltoid had a greater advantage at higher abduction positions. McKernan et al.[151] have validated these findings and attributed them to the anterior location of the subscapularis tendon in lower ranges of elevation, making it a more effective stabilizer against a given translation. This effect is reduced as the shoulder is elevated and the line action of the subscapularis moves superior to the joint.

All portions of the rotator cuff are probably important in enhancing stability, as was shown by Blasier et al.[26] In their biomechanical study, omission of tension in any one of the rotator cuff muscles led to a substantial reduction in anterior joint stability. Labriola et al. reported that all rotator cuff muscles contribute equally to anterior stability when the glenohumeral joint is in the anatomic position; at end range, the subscapularis is less important.[107,128] This is supported by an investigation by Wuelker et al., which found that a 50% decrease in the rotator cuff muscle forces resulted in nearly a 50% increase in anterior displacement of the humeral head in response to external loading at all glenohumeral joint positions.[278]

Rotator cuff tears result from either single traumatic or cumulative microtraumatic (i.e., overuse injuries) events. Because of age-related attrition, a dislocation in individuals older than the age of 40 is not uncommonly associated with a rotator cuff tear.[117,172,207] Rotator cuff tears result in superior translation of the humeral head during scapular plane abduction, and larger rotator cuff tears lead to increased displacement of the humeral head.[98] This demonstrates the importance of synchronous contraction of the entire cuff in maintaining containment of the humeral head in the glenoid.[200,267]

Increasing the joint compressive load appears to "center" the humeral head, reducing subsequent translation. This centering of the humeral head in the glenoid socket provides a stable fulcrum for elevation of the humerus.[67,97,240] Interestingly, the ability of isometric muscle contraction to "center" the humeral head is different in patients with traumatic instability compared to those with atraumatic instability. A recent evaluation of glenohumeral kinematics using magnetic resonance imaging revealed that such contraction led to recentering of the humeral head only in the patients with traumatic instability.[253]

In overhead athletes, for example, in whom the rotator cuff functions as an important decelerator to anterior translation, imbalanced muscle recruitment may play a role in those with more subtle forms of instability.[78,113] This has been validated by Warner et al.,[266] who demonstrated that patients with shoulder instability had altered rotator cuff strength patterns compared with normal controls. Asynchronous contraction of the rotator cuff, leading to voluntary instability, is an example in the extreme of the relative importance of the rotator cuff in enhancing dynamic stability of the glenohumeral joint.[214] Conversely, capsuloligamentous insufficiency could subject the rotator cuff to overuse, fatigue, and injury.

The importance of these findings is that rotator cuff–strengthening programs can improve the function of a weak or ineffective cuff by limiting translation of the humeral head on the glenoid during active shoulder motion.[39] Initial therapeutic approaches to shoulder instability, therefore, should emphasize strengthening, conditioning, and coordination of the rotator cuff as an integral part of the treatment program.

Ligament Dynamization

There appear to be direct connections between the rotator cuff tendons and the capsuloligamentous system.[45,64] Clark et al.[45] reported a complex anatomic relation between the tendons of the rotator cuff and the capsule adjacent to the humeral tuberosities. The joint capsule is adherent to the rotator cuff, except anterosuperiorly in the

rotator interval, found between the free margins of the supraspinatus tendon superiorly and subscapularis tendon inferiorly. Conceptually, active shoulder motion may "dynamize" the capsule and ligaments, thereby becoming a significant stabilizing factor in the midranges of rotation at which the ligaments and capsule are relatively lax. Warner et al.,[258] in a dynamic shoulder model, were able to define and document the orientation and interrelation between the glenohumeral ligaments during simulated rotator cuff contraction. Although this study clearly elucidated the effect of shoulder rotation on the orientation of the undisturbed and intact capsuloligamentous system, the dynamic effects of rotator cuff contraction upon the ligaments remains unclear.

Pagnani et al.[189] suggested that because the biceps inserts into the relatively mobile superior labrum, it is conceivable that tension would be transmitted by the labrum to the SGHL and MGHL to dynamize these static structures and indirectly enhance stability. A similar relation may exist owing to the proximity of the triceps to the medial aspect of the axillary pouch of the IGHLC.[45,51] Anterosuperiorly, the subscapularis and supraspinatus interconnect with the CHL, providing an additional site for dynamic interaction between static and dynamic restraints.

Active rotation may also have the effect of altering capsular tension, potentially providing a protective mechanism against failure. For example, coupled posterior humeral head translation with active external rotation may actually reduce anterior ligamentous strain.[85,94] McKernan et al.[152] and others[40,211] have shown in cadaveric experiments that contraction of the posterior rotator cuff muscles (i.e., infraspinatus and teres minor) and biceps tendon reduced IGHL strain in the late cocking phase of throwing. These dynamic factors may provide relative protection of the IGHLC or other anterior structures as they contribute to anterior stability by dynamically increasing the resistance to torsional forces in the position of apprehension. Recently, however, the role of the infraspinatus, as determined by electromyographic (EMG) analysis in patients with recurrent anterior instability, was not believed to be a critical component in providing anterior stability.[96] Clinically, that a stabilizing relation may exist between the capsule and musculature about the shoulder signifies the importance in reestablishing length–tension relations by either operative or nonoperative means in patients with shoulder instability.

Long Head of the Biceps Brachii

As the tendon of the long head of the biceps passes to its insertion in the supraglenoid tubercle, it occupies an intraarticular position. The relative importance as a dynamic stabilizer probably becomes significant when the rotator cuff or capsuloligamentous structures are overwhelmed. Several experimental studies have demonstrated the dynamic-stabilizing role of the long head of the biceps brachii for the glenohumeral joint.[3,78,103,106-108,121,162,189,203,211] Rodosky et al.[211] showed that, in the late cocking phase of throwing, contraction of the biceps tendon can significantly reduce anterior translation and increase torsional rigidity of the joint helping to resist external rotation. Additionally, strain in the IGHL was noted to increase after sectioning of the tendon.

Pagnani et al.[189] determined that the effect of the long head of the biceps is dependent on the shoulder position being greatest in middle and lower elevation angles. The biceps tended to stabilize the joint anteriorly when the arm was internally rotated and served as a posterior stabilizer when the humerus was externally rotated (Fig. 9-9). Itoi et al.[107] found that anteroposterior translation was significantly decreased with biceps loading, particularly with external rotation. Superoinferior translation was also reduced with simulated contraction of the biceps, which was believed to help center the humeral head on the glenoid, thereby stabilizing the fulcrum and allowing more efficient arm elevation. Levy et al.[137] emphasized through dynamic EMG analysis that elimination of elbow flexion or supination resulted in complete inactivity of the biceps brachii. Thus, the role of biceps function at the shoulder is either due to a passive mechanism or depends on tension developing in association with elbow and forearm activity.

Kim et al.[121] conducted a thorough EMG analysis of the biceps brachii muscle in patients with anterior instability. The voltage of the biceps muscle was significantly greater in the unstable shoulder compared to the opposite arm in all positions of the arm. Moreover, activity increased in abduction and external rotation of the unstable shoulder; there was no change in activity in the stable shoulder placed in this position. These findings imply a secondary stabilizing function of the biceps muscle, which compensates for failed primary static restraints.[121]

These concepts may help explain why the biceps tendon or superior labrum may demonstrate lesions in throwers[3,228] and why it is occasionally found to be hypertrophied in the rotator cuff–deficient patient.[146,238] Extreme external rotation loads the long head of the biceps tendon, which predisposes the throwing athlete to biceps or biceps–labrum complex injuries.[126,162,203] Clinically, this suggests that nonoperative treatment of instability or rotator cuff deficiency should be directed at rehabilitation of the biceps brachii in addition to the rotator cuff muscles.

Scapular Rotators

Until recently, scapulothoracic motion has been relatively ignored as an important dynamic factor maintaining stability of the glenohumeral joint. The scapular rotators include the following muscles: trapezius, rhomboids, latissimus dorsi, serratus anterior, and levator scapulae. Codman[47] first introduced the concept of "scapulohumeral

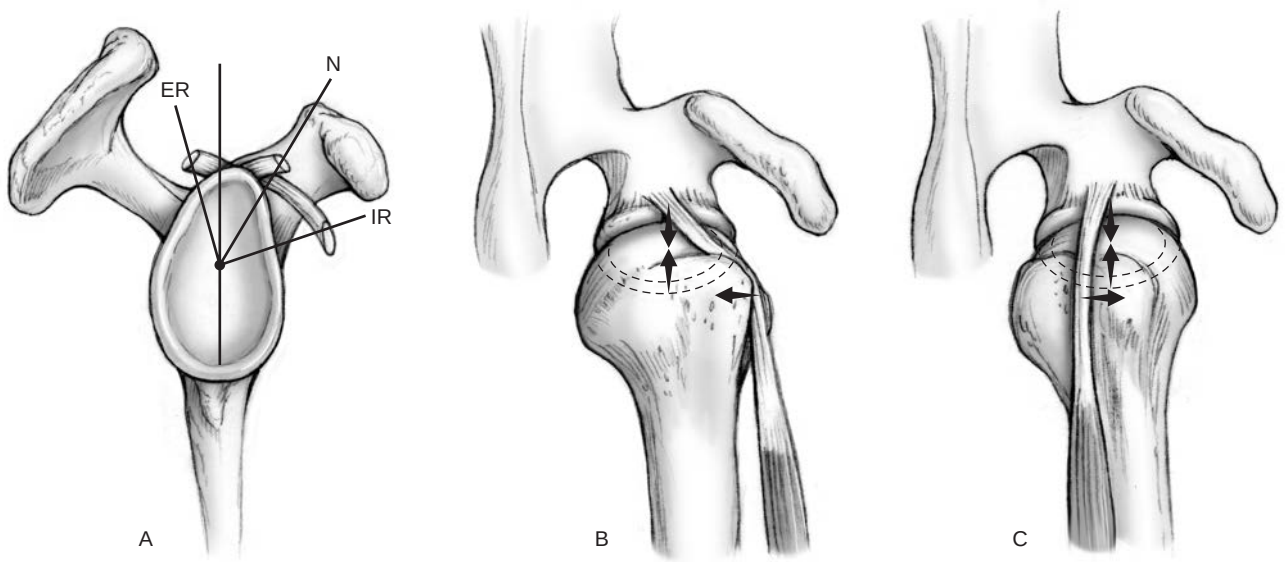

Figure 9-9 Diagrammatic representation of forces created with simulated contraction of long head biceps brachii. **(A)** Rotation of humerus changes orientation of biceps tendon relative to the joint. In neutral rotation (*N*) tendon generally occupies a slightly anterior position. With internal rotation (*IR*) the tendon lies anterior to joint. In contrast, the tendon occupies a slightly posterior position with external rotation (*ER*). **(B)** With internal rotation of humerus, the biceps appears to generate joint compressive forces (*paired arrows*) and posteriorly directed force (*single arrow*), which restrain glenohumeral translation. **(C)** With external rotation of the humerus, anteriorly directed force (*single arrow*) appears to accompany joint compressive forces (*paired arrows*). (Adapted from Pagnani M, Deng X-H, Warren R, Torzilli P, O'Brien S. Role of the long head of the biceps brachii in glenohumeral stability: a biomechanical study in cadavera. *J Shoulder Elbow Surg* 1996;5:255–262.)

rhythm," which has now been recognized by others to be an important contributor to joint stability.[14,105,218,265] Even though somewhat variable, the normal scapulohumeral rhythm motion relation is two of glenohumeral rotation for every one of scapulothoracic rotation during scapular plane abduction.[200,201] Clinical and radiographic studies have documented abnormal scapulothoracic motion in patients with shoulder instability.[188,265] EMG analysis of the scapulothoracic musculature has demonstrated fatigue of the serratus anterior and trapezius with repetitive overhead activities, leading to poor scapulothoracic control.[78,178] McMahon et al. demonstrated that patients with glenohumeral instability have decreased serratus anterior activity during abduction, scaption, and forward flexion.[157]

The scapular rotators function to provide a stable platform beneath the humeral head during shoulder motion (Fig. 9-10). These muscles allow the glenoid to adjust to changes in arm position. The scapular inclination angle is a significant factor preventing inferior translation of the adducted shoulder.[105] For example, the scapula normally rotates upward (i.e., protraction) in synchrony with arm elevation as the serratus anterior contracts. Thus, clinically, scapulothoracic weakness or dysfunction is associated with varying degrees of scapular winging, which is often found in patients with shoulder instability.[265] Warner et al.[265] have hypothesized that scapulothoracic dysfunction may be a cause of "nonoutlet" impingement, as the advancing greater tuberosity is unable to avoid impingement on the coracoacromial arch during forward flexion. Presently, however, it is unclear if scapulothoracic dysfunction is a cause or product of shoulder instability. Despite these unanswered questions, nonsurgical management of shoulder instability must include rehabilitation of the scapular rotators.

The roles of the deltoid and pectoralis major muscles about the glenohumeral joint have been evaluated in the last several years. Kido et al.[120] evaluated the stabilizing function of the anterior, middle, and posterior deltoid muscle in normal shoulders and in shoulders with instability. In normal shoulders, tension on the middle deltoid reduced the amount of anterior translation substantially. When the joint capsule was vented, or when there was a simulated Bankart lesion, loading each of the three segments of the deltoid muscle decreased anterior displacement. The authors concluded that the deltoid muscle is an anterior stabilizer of the glenohumeral joint with the arm in the position of apprehension, and that this function may become more important in the unstable shoulder.[120]

Lee and An[131] similarly found that deltoid muscle activity increases glenohumeral joint stability. However, this

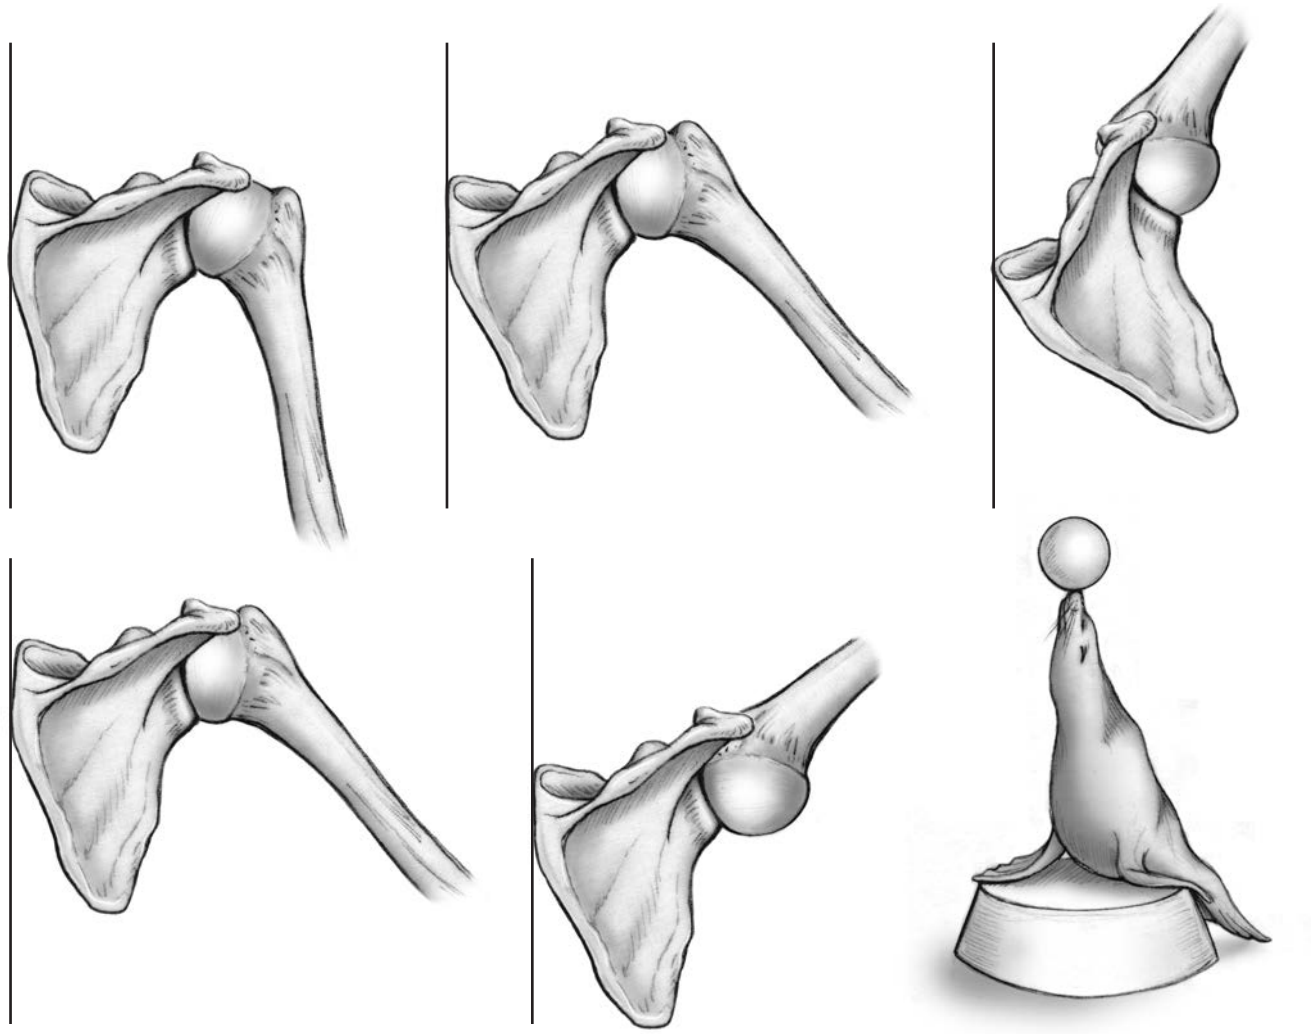

Figure 9-10 **(Top row)** Normal scapulothoracic rotation positions the glenoid underneath the humeral head so that it acts as a stable platform. **(Bottom row)** Failure of proper scapulothoracic motion results in loss of the stable glenoid platform underneath the humeral head. This is analogous to a seal balancing a ball on its nose. (Adapted from Warner JJP, Caborn DNM. Overview of shoulder instability. *Crit Rev Phys Rehabil Med* 1992;4:145–198.)

effect was most pronounced at 60 degrees of glenohumeral abduction in the scapular plane. Conversely, deltoid activity decreased glenohumeral stability when the glenohumeral joint was abducted to 60 degrees in the coronal plane. The role of the pectoralis muscle on glenohumeral joint stability is less clear, though Arciero and Cruser[7] reported a case of traumatic glenohumeral dislocation and pectoralis tendon rupture while bench pressing. They theorized that eccentric loading of the pectoralis led to both injuries. Sinha et al.[227] reported an irreducible glenohumeral dislocation that was successfully reduced only after paralysis of the pectoralis major with botulinum A toxin. Management of glenohumeral joint stability may be altered to consider these muscles as their role about the glenohumeral joint becomes clearer.

Proprioception

The perception of joint position and joint motion is termed *proprioception*. Proprioceptive interaction between ligaments and muscles may mediate a protective mechanism against capsular failure and instability.[25,42,123,135] Murakami et al.[167] described what were thought to be mechanoreceptors in the transition zone between the labrum and capsule in primates. Since then, others[112,251,252] have described similar findings in the capsule and ligaments of the glenohumeral joint.

Mechanoreceptors are specialized nerve endings (e.g., pacinian corpuscles, Ruffini endings, and Golgi tendon-like endings) that transduce mechanical deformation into electric signals that transmit information about joint

position and motion.[79,80] Vangsness et al.[252] evaluated the capsuloligamentous structures for the presence of these mechanoreceptors: Low-threshold, slow-adapting Ruffini afferents were most abundant overall, except in the glenohumeral ligaments where low-threshold, rapid-adapting pacinian-type afferents were more numerous. No mechanoreceptors were observed in the subacromial bursa or glenoid labrum.

Lephart et al.[135] and Warner et al.[264] have hypothesized that the capsuloligamentous structures may contribute to stability by providing an afferent feedback for reflex muscular contraction of the rotator cuff and biceps. It is plausible, as these authors discuss, that as these receptors respond to tension changes in the capsule during rotation, active stabilization may occur through reflex arcs from the capsule to the surrounding rotator cuff, allowing selective contraction of the rotator cuff and biceps muscles in response to changes in acceleration.

Several studies have found decreased proprioception in shoulders with instability.[13,25,135,136,168,243] Capsuloligamentous disruption combined with proprioceptive deficits contribute to functional instability.[136,243] Barden et al.[13] measured hand position error in patients with multidirectional instability (MDI) and compared this to patients without instability. The subjects with MDI had significantly greater hand position error than the control group. Interestingly, there was no difference between hand position error in the symptomatic arm and the contralateral arm in patients with MDI. The authors inferred that patients' capacity to use proprioception to refine upper-extremity movement is reduced in MDI.[13] Blasier et al.[25] reported similar findings.

With use of a specialized proprioception testing device, Lephart et al.[135] evaluated subjects with and without traumatic anterior instability preoperatively and postoperatively after arthroscopic or open Bankart repairs. In normal shoulders, the threshold to detect passive motion (TTDPM) averaged 1.5 to 2.2. In those with instability, TTDPM was 2.8. These differences were statistically significant. Postoperatively, patients' TTDPM was no different from normal. One criticism of this study was that the speeds at which patients were tested were much slower than the speeds that occur with overhead sports. Ito et al.[109] has stated that traumatic dislocation may, in fact, occur sooner than the response time of the rotator cuff stretch reflex. Thus, the relative importance of this proposed mechanism may be more significant in lower-energy situations when the rotator cuff or biceps has time to react to relative changes in capsular tension. Furthermore, it is postulated that proprioception may be a way to protect the capsuloligamentous structures from failure owing to repetitive microtrauma, leading to excessive translation or instability.[135,264]

Whether inherent deficits in proprioception predispose a patient to glenohumeral instability or instability reduces proprioceptive capacity remains unclear. It is interesting to find that surgical procedures that retension the capsuloligamentous structures improve glenohumeral joint proprioception.[135,202,243] One long-term follow-up study reported improvements in joint position sense for at least 5 years postoperatively; position sense may be comparable to normal, healthy shoulders.[202]

PATHOANATOMY OF SHOULDER INSTABILITY

In addition to the "essential lesion" (i.e., labral detachment), recurrent instability has been attributed to several pathologic entities. As indicated in Table 9-2, each of the factors already discussed plays a role in the pathogenesis of shoulder instability. Several authors have cited attenuation of the capsule and capsular ligaments[21,159,164,199,245,246] with associated histopathologic changes.[135,150,198,210,252] Impression fracture of the humeral head (Hill-Sachs or reverse Hill-Sachs lesion),[50,93,153] attenuation of the subscapularis tendon,[59,71,236] capsular rupture,[115,206,208] and humeral avulsion of the glenohumeral ligaments are other documented causes of anterior instability.[10,31,223,235,237,268,276] A thorough history is important to ascertain the mechanism of injury. A single violent trauma will focus the injury on a specific anatomic region (e.g., Bankart lesion or capsular damage). On the other hand, repetitive microtrauma may cause more subtle capsular stretch, emphasizing the pathoanatomic continuum of capsular injury. Clinically, appreciation of the pathoanatomy of shoulder instability is important because surgical intervention is ultimately directed at anatomic and biomechanic restoration.

Bankart Lesion

The most common form of shoulder instability is recurrent anterior subluxation or dislocation resulting from trauma. Perthes[195] and Bankart[12] (e.g., Perthes-Bankart lesion) originally described the detachment of the capsulolabral complex from the glenoid rim and scapular neck as the "essential lesion" leading to recurrent anterior dislocation. This has been challenged by Speer et al.,[232] who found that simulation of the Bankart lesion in cadaveric cutting studies resulted in only minimal increases in anterior translation. Baker et al.[11] established a classification system based on arthroscopic findings of initial anterior shoulder dislocations. Sixty-two percent had evidence of a Bankart or equivalent lesion, with all of these patients demonstrating gross instability with examination under anesthesia. Thirteen percent were stable on examination and demonstrated no evidence of labral detachment. Taylor and Arciero[237] studied first-time patients with traumatic anterior shoulder dislocations and determined arthroscopically that 97% had evidence of isolated detachment of the capsuloligamentous complex from the glenoid rim and neck, without evidence

of intracapsular injury. Others have noted a similarly high incidence of Bankart lesions at the time of surgery.[239]

Despite experimental and clinical evidence of increased anterior translation of the humeral head on the glenoid caused by a Bankart lesion, most patients present with recurrent anterior instability with additional pathology that may have developed or advanced over time. Additionally, plastic deformation or capsular injury in patients with first-time dislocations may not be appreciated by macroscopic evaluation because it may represent microscopic ultrastructural failure not visible to the naked eye. It is now believed that recurrent complete dislocation requires an additional pathoanatomic component (e.g., capsular plastic deformation or stretch).[12,21,213,232]

Recognition of this concept is clinically relevant. Isolated arthroscopic Bankart repair is technically challenging and with earlier reports associated with higher failure rates, possibly because of associated pathology, poor patient selection, and minimal scar formation.[6,53,129,160,233,254] Moreover, reduction in anterior translation, which is the goal of the procedure, is only significant with larger imbrication (5 mm) of the capsule. Larger imbrication leads to a more severe limitation of external rotation.[177] Conversely, open Bankart procedures that address "only" the labral detachment may create enough capsular scarring to prevent recurrence. Thus, the choice of operative procedure will depend on the patient's history, examination under anesthesia, arthroscopic anatomy, and appreciation for capsular injury. These tenants become more complex in the patient with multidirectional instability in whom capsular laxity is the dominant pathology, and Bankart lesions are less frequently found.

Capsular Injury

Traumatic Intrasubstance Injury

Clinical observations indicate that capsular injury is commonly associated with traumatic anterior shoulder dislocation. Capsular injury resulting from traumatic anterior shoulder dislocation was recognized as early as the 13th century. Reeves demonstrated capsular rupture by arthrography in 55% of the anterior dislocations he treated.[206,208] Symeonides[236] observed that 15% of his patients treated for anterior dislocation had both labral detachment and anterior capsular ruptures. Johnson[115] observed that 54% of his patients at the time of arthroscopy for anterior dislocation had torn glenohumeral ligaments. Conversely, others have shown that only minimal irrecoverable elongation of the inferior glenohumeral ligament occurs after traumatic unidirectional dislocations.[155,156,158,234]

Experimentally, Bigliani et al.[21] measured the stress–strain data at failure of the IGHLC in bone–IGHL–bone preparations and concluded that before failure, significant plastic deformation (e.g., strain) occurred. The implications of these findings are that laxity of the IGHLC leading to instability is not only a congenital finding, but that it may be acquired through submaximal trauma (single or repetitive) without causing rupture or detachment. When the anterior shear force overcomes the capsular tensile strength or when the rotator cuff fatigues or cannot effectively contract (e.g., rotator cuff tears), the ligaments may fail on an ultrastructural level.[135,198,252] Rodeo et al.[210] provided evidence of ultrastructural changes in the joint capsules of unstable shoulders. In joint capsules from patients with instability, there are increases in the amount of stable and reducible cross-links (the latter of which is abundant in remodeling tissue) as well as the mean collagen fibril diameter (which correlates positively with tissue strength) compared to patients with stable shoulders.[210] Others have shown histologic changes in shoulder capsules of patients with traumatic instability, such as a denuded synovial layer, subsynovial edema, increased cellularity, and increased vascularity.[150]

Similarly, age-related attrition of the rotator cuff tissues is greater than in capsular tissues such that anterior dislocation commonly results in a rotator cuff tear, potentially leading to capsular injury in older patients.[207] Gamulin et al.[71] evaluated the histomorphometry of the subscapularis muscle in 52 patients operated on for recurrent traumatic anterior shoulder dislocation. They observed interstitial fibrosis within the subscapularis muscle and modifications in the ratio of fiber types that are characteristic of disuse atrophy. Clinically, capsular injury leading to laxity and labral detachment can be found to coexist, supporting concomitant capsulorrhaphy and Bankart repair in the surgical management of instability. Bigliani et al.[19] and Altchek and Dines[2] have advocated addressing capsular pathology as part of the surgical treatment of recurrent anterior shoulder instability.

Humeral Avulsion

First described in 1942 by Nicola,[173] avulsion of the capsule from the humerus can occur with forceful hyperabduction. Disruption of the lateral capsule from the humeral neck is probably rare, but has been reported in two cases by Bach et al.[10] and in one case by Taylor and Arciero[237] in association with anterior dislocation. Wolf et al.[276] has termed this a "HAGL lesion" representing humeral avulsion of the glenohumeral ligament. Appreciation for this variant of capsular injury at the time of arthroscopy can be difficult, though these authors advocate searching for it in patients with traumatic anterior instability who show no signs of a Bankart lesion.[276]

The HAGL lesion appears as a thickened, rolled edge of capsular defect, typically found in the inferior pouch of the shoulder below the level of the subscapularis muscle.[31] Associated glenohumeral abnormalities are common, most often in the form of rotator cuff tears; greater than 90% of these tears involve the subscapularis muscle.[10,31,223,268,276] Only 20% of HAGL lesions may be viewed radiographically.[10]

If it is visualized it likely represents a bony HAGL (BHAGL) lesion, which may mimic a bony Bankart lesion.[179] The BHAGL lesion, first described by Bach et al.,[10] is a HAGL lesion associated with bony avulsion of the humeral neck. Oberlander et al.[179] recommended evaluating such lesions with axillary or West Point views of the glenohumeral joint. In either of these views the BHAGL is seen superimposed on the proximal humerus, whereas the bony Bankart lesion is seen along the inferior half of the glenoid cavity. Stoller[235] described the J sign of the HAGL lesion on magnetic resonance arthrography, whereby the axillary pouch changes from a fluid-distended U-shaped structure to a J-shaped structure. This is attributed to inferior displacement of the anterior band of the inferior glenohumeral ligament.[235] Humeral avulsion of the glenohumeral ligament should be repaired anatomically at the time of surgical reconstruction.

Repetitive Injury

The overhead athlete (e.g., pitchers, throwers, swimmers, volleyball players, tennis players, water polo players, and javelin throwers) represents a special category of patients with complaints relating to instability. These patients subject their shoulder to repetitive stresses that potentially lead to microtrauma not readily appreciated at the time of arthroscopy. In a novel study, Pollock et al.[199] evaluated the response of the IGHL to a range of cyclic deformations and different levels of strain in an attempt to identify mechanical microdamage caused by repetitive loading. They found a significant decrease in the residual strain magnitude of the IGHL after cyclic loading compared to baseline. It was concluded that the cumulative effect of repetitive subfailure strain causes irreversible stretching of the IGHL. This may contribute to the development of shoulder instability.[199] Malicky et al.[142] also identified irreversible changes in strain magnitude of the anteroinferior capsule after 16 mm of humeral translation.

Repetitive rotational motion of the glenohumeral joint may also contribute to instability. Remia et al.[209] reported on an experimental model of multidirectional instability of the glenohumeral joint and found that application of internal and external rotational stretches to the capsule causes increased translation in all directions, without capsular disruption. Likewise, Mihata et al.[159] found increased shoulder laxity after nondestructive stretching of 30% beyond maximal humeral external rotation. This was attributed to a significant lengthening of the anterior band of the IGHL. Repetitive injury may be the cause of acquired laxity, as seen in gymnasts, and may present as multidirectional instability rather than pure unidirectional instability. These patients are often confused as having isolated subacromial impingement and inappropriately treated as such.[69,241] It is now believed that "subtle glenohumeral instability" may be associated with secondary subacromial impingement, and capsular laxity is the primary pathology that should be addressed.[242]

Capsular Laxity

Intrinsic Capsular Laxity

Capsular laxity is a prerequisite to allow a large range of glenohumeral motion. The degree of laxity varies among individuals, and attempts at correlating the extent and direction of laxity under anesthesia can be confusing, for the overlap between normal laxity and clinical instability is difficult to ascertain.[48,62,73,85,86,184,248,266] Interestingly, shoulders of asymptomatic patients can exhibit a range of rotational or translational motion comparable to that seen in patients diagnosed with symptomatic instability.[85,89,89] In the preadolescent shoulder joint, more than two-thirds may be asymptomatically subluxated on examination.[62] That asymptomatic subluxation or even dislocation may occur in the "normal" shoulder at the time of anesthesia was also appreciated by O'Driscoll and Evans[184] and Warner et al.[262] Thus, it is unclear if constitutional laxity is a risk factor for clinical instability of the shoulder joint. With a proper history of the mechanism and symptoms, correlation with drawer testing under anesthesia can be useful if one considers the effect of arm position on different portions of the capsule.

Inherited Disorders of Collagen

Inherited disorders of collagen are relatively rare, but present an unusual challenge in the management of glenohumeral instability. The collagen disorder most associated with shoulder instability is Ehlers-Danlos syndrome (EDS), which is characterized by increased laxity, problems with wound healing, and vascular anomalies. Several subtypes of EDS have been identified based on which type and which synthetic step of collagen is aberrant. EDS I is inherited in an autosomal dominant pattern and is most commonly associated with hyperlaxity. EDS II is a milder form of EDS I. The other subtypes of EDS predominantly affect the blood vessels. A survey of 42 patients with EDS revealed that they had experienced a combined 214 shoulder procedures. The indications were pain, instability, poor range of motion, or a combination of these.[89] Another case report describes a 19-year-old female with EDS and bilateral multidirectional shoulder instability who underwent multiple operations to achieve stability, all of which were ineffective.[149] Thus, shoulder instability with EDS remains a difficult area to manage even with contemporary techniques.

Humeral and Glenoid Bone Loss

Humeral Bone Loss

Articular abnormalities of the humeral head can disrupt the anatomic relation of the glenohumeral joint, predisposing to recurrent instability. In an evaluation of radiographs from 160 patients with chronic anterior shoulder instability, Edwards et al.[61] identified humeral impaction

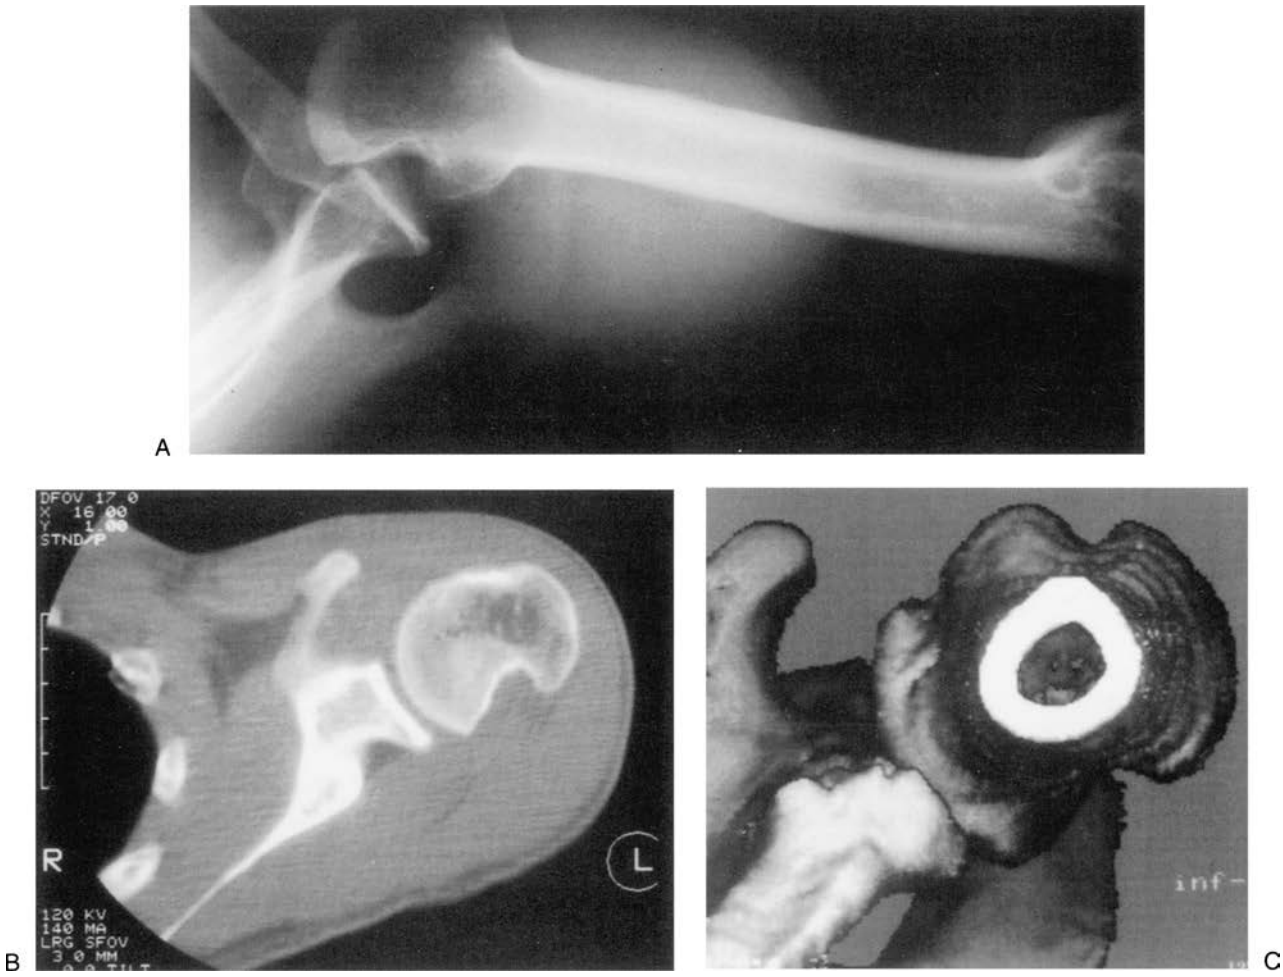

Figure 9-11 **(A)** Anterior dislocation in a patient with a large Hill-Sachs lesion (more than 30% of the humeral head). **(B)** Computed tomographic (CT) scan in the same patient. **(C)** A three-dimensional CT reconstruction also shows a large Bankart lesion in addition to the large Hill-Sachs lesion.

fracture in 117 shoulders (73%). A large Hill-Sachs or reverse Hill-Sachs impression fracture (Fig. 9-11) on the posterolateral or anterolateral margin of the humeral head, respectively, is created when the humeral head dislocates over the anterior or posterior glenoid rim.[41,194,213,216] This lesion is present in more than 80% of anterior dislocations and 25% of anterior subluxations.[41,194] Hill-Sachs lesions have been noted at the time of arthroscopy in patients with recurrent anterior instability up to 100% of the time.[41,176,237] Werner et al.[273] reported a prevalence of Hill-Sachs lesions approaching 60% in patients with atraumatic instability that did not respond to conservative therapy. The small Hill-Sachs lesions are not usually thought to be a major contributor to recurrent anterior instability.[41] The incidence with posterior instability is unknown.

The Hill-Sachs lesion is larger with dislocations of longer duration, recurrent dislocations, and inferior displacement of the humeral head.[66,92] In most instances this lesion is relatively small and plays little role in ongoing shoulder instability or its surgical management. Relatively small lesions may be prevented from coming into contact with the anterior glenoid rim simply by performing a more generous anterior capsulorrhaphy (Fig. 9-12). Caution is warranted with this practice because excessively tight anterior repairs may be associated with the development of late arthrosis.[18,22] However, when the Hill-Sachs lesion involves more than 30% of the humeral articular surface, it may contribute to recurrent anterior instability, even with capsular repair.[215,216]

The mechanism for this persistent instability is that with increasing external rotation, the lesion slips over the anterior glenoid (i.e., as in the original injury) and sits in an anteromedial position outside of the glenoid cavity. Surgical treatment of these defects involves filling the defect with allograft bone (Fig. 9-13),[74,114] muscle tendon transfer,[50,66,153] (e.g., infraspinatus or subscapularis), or humeral head replacement in older individuals. Alternatively, the lesion can be rotated out of contact with the glenoid with proximal humeral osteotomy.[270] Decision making is predicated on the ability to perform an anatomic

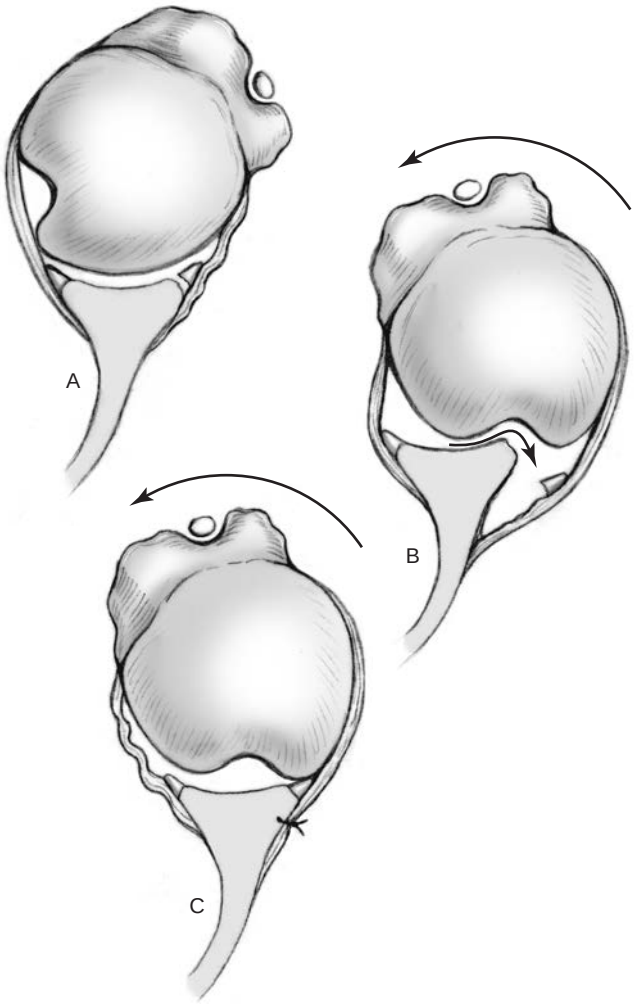

Figure 9-12 Role of the Hill-Sachs lesion in anterior shoulder instability. **(A)** With the arm in internal rotation, the Hill-Sachs lesion is not in contact with the glenoid. **(B)** With external rotation, the humeral head translates anteriorly because of the incompetent anterior capsular mechanism. This allows the humeral head to dislocate through the Hill-Sachs lesion. **(C)** An adequate Bankart repair keeps the Hill-Sachs lesion contained on the glenoid, unless it is greater than 30% of the humeral articular surface. (Adapted from Warner JJP, Schulte KR, Imhoff AB. Current concepts in shoulder instability. In: Stauffer RN, Erlich MG, Kostuik JP, Fu FF. *Advances in operative orthopaedics*, vol. 3. Philadelphia: Mosby-Year Book, 1995;217–247.)

reconstruction of the anteroinferior structures with an appropriate capsular plication followed by reassessment for the ability to engage the Hill-Sachs lesion in various positions of rotation with a simultaneously applied anterior force to the proximal humerus.

Glenoid Bone Loss

Glenoid bone loss has been implicated as a predisposing factor for recurrent instability after surgical repair.[24,104,247] Burkhart et al.[38] observed that glenoids with enough bone loss to convert the normally pear-shaped glenoid to an inverted pear configuration are at particular risk for redislocation after surgical repair. Recent work by Gupta and Lee[81] offers a cause for posterior erosion of the glenoid. They evaluated glenoid–humerus contact forces in 12 overhead activity positions and found that there is a significant increase in contact pressure between the humeral head and posterior glenoid when the humerus is horizontally abducted to 70 degrees. They concluded that repetitive overhead activities may load the glenohumeral joint asymmetrically and lead to posterior glenoid erosion.[81]

Bony lesions of the anterior or posterior glenoid rim have also been described and are believed by some to be important enough to be formally reconstructed during open capsulorrhaphy. Edwards et al. found osseous lesions of the glenoid in 126 of 160 (78%) patients with chronic anterior glenohumeral instability.[61] These were seen on the glenoid profile view. These lesions are either due to an osseous Bankart or wear related to repeated instability. Pavlov et al.[194] described an osseous Bankart lesion of the anterior glenoid in 15% of patients with recurrent anterior dislocation and in approximately 50% of patients with recurrent anterior subluxation. Gerber[75] has advocated intraarticular iliac bone graft to formally reconstruct the glenoid cavity before capsular repair to restore normal anatomy of the glenoid. Bigliani et al.[24] believes that compromise of 25% or more of the glenoid surface warrants bony reconstruction. Burkhart et al.[38] recommend a coracoid process transfer (i.e., Latarjet procedure) when a bony Bankart lesion narrows the inferior half of the glenoid to a width that is less than that of the superior half of the glenoid (i.e., the inverted-pear configuration).

Defects smaller than 20% can be rendered extraarticular by repairing the capsule and labrum back to the edge of the intact glenoid. Larger fragments can be mobilized and fixed through traditional means.[33] Unlike the Hill-Sachs lesion, there are few data available to suggest which glenoid defects require repair, débridement, or neglect. Itoi et al.[104] investigated the effect of glenoid defect size on anteroinferior stability after Bankart repair. These authors found that with the arm in the position of apprehension, the size of the osseous defect does not affect stability of the arm. However, increasing the size of the osseous defect reduces stability when the arm is placed in abduction and internal rotation.[104] The overall aim of any reconstructive procedure directed at larger defects is to deepen the socket and support the capsule.

Articular Version Abnormalities

Clinically, excessive glenoid retroversion is thought to be a contributing factor to posterior instability and may infrequently be due to a variant of glenoid dysplasia. In most cases, however, excessive version is acquired from eccentric articular surface wear. Magnetic resonance imaging reveals that shoulders with posteroinferior instability have greater

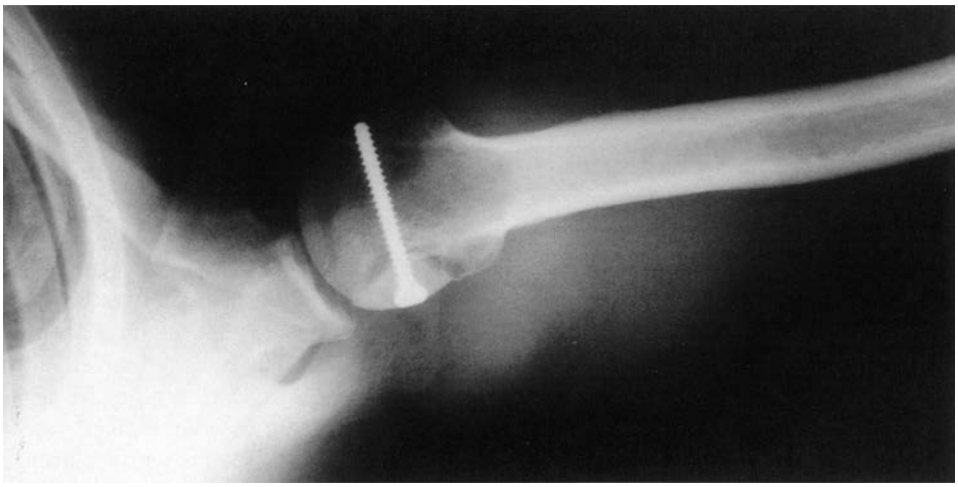

Figure 9-13 This large Hill-Sachs defect was treated with a Bankart repair and osteochondral allograft reconstruction of the humeral head.

retroversion of both the osseous and chondrolabral portion of the glenoid, and there is loss of height of the posterior portion of the labrum.[122] These features lead to loss in chondrolabral containment of the glenohumeral joint in patients with posteroinferior instability of the shoulder.[122]

Some surgeons recommend glenoid osteotomy in addition to soft tissue procedures.[36,125,225] Several other authors[125,205] have reported varying degrees of normal glenoid and humeral articular version, indicating that further study is needed to support a relation between the development of instability and bony alignment. Glenoid osteotomy and rotational humeral osteotomies, seemingly reasonable treatment options in the presence of articular version abnormalities, have been associated with the development of glenohumeral arthritis.[99,116] Currently, in North America, humeral rotational osteotomy or glenoid osteotomy is not commonly practiced, perhaps reflecting the unclear relation between these factors and clinical instability.

PUTTING IT ALL TOGETHER

Successful management of shoulder instability requires a thorough knowledge of all factors responsible for stability in addition to those pathologic factors contributing to instability. Shoulder instability may be viewed as any condition in which the balance of the various stabilizing structures is disrupted, leading to increased joint translation and the development of clinical symptoms.[89,191] Because the large spherical head of the humerus articulates with a relatively small and shallow glenoid, the glenohumeral joint requires several mechanisms to maintain stability while providing for a large range of motion. Static and dynamic stability is provided by the combined effects of the capsuloligamentous structures and rotator cuff and biceps. In the midranges of rotation, where the capsuloligamentous structures are lax, most joint stability is through the dynamic action of the rotator cuff and biceps tendons through concavity–compression of the humeral head within the glenoid socket. The ligamentous structures, which are primarily capsular thickenings, function only at the extreme positions of rotation, preventing excessive rotation of the humeral head on the glenoid. Contraction of the muscles around the shoulder may act secondarily by protecting the relatively weak ligamentous structures from being overwhelmed from excessive tension. Because interpretations of the literature are often confusing, this section is an effort to synthesize the findings already discussed.

The labrum provides an attachment site for the glenohumeral ligaments and the tendon of the long head of the biceps. Its principal function is to increase the depth of the glenoid socket and to act as a chock block in preventing the head from rolling over the anterior edge of the glenoid. Recently, however, the role of the labrum in preventing translation or instability has been challenged. The Bankart lesion, by its anatomic definition, implies dysfunction of the IGHLC, and possibly the SGHL and MGHL. Thus, virtually all labral lesions, especially those below the glenoid equator, are thought to be associated with glenohumeral instability. However, plastic deformation, capsular rupture, abnormal laxity, periosteal stripping, or any combination of these lesions may also be associated with complete dislocation, with or without the Bankart lesion. Thus, one of the goals of reconstructive surgery for glenohumeral instability is to anatomically reconstruct both the labral and capsular deficiency independent of cause (e.g., genetic predisposition or extrinsic forces).

The role of the capsule and ligaments in preventing instability is quite complex and depends on shoulder position and the direction of the applied force. Generally, the anterior capsule becomes more important during extension and the posterior capsule during flexion. Extremes of internal and external rotation have the effect of winding up the capsular structures, leading to joint compression and increased stability owing to tension developing in the relevant structures. In general, the inferior capsular structures

are most functional near full elevation and the superior capsular structures near full adduction.

The IGHLC is the primary static check against anterior, posterior, and inferior translation between 45 and 90 degrees of glenohumeral elevation. The SGHL and MGHL limit anteroposterior and inferior translation in the middle and lower ranges of elevation as the arm approaches the adducted position. Experimentally, posterior translation in the flexed, adducted, and internally rotated position may require disruption of the anterosuperior capsule (including the SGHL) in addition to the posterior structures. Although controversial, the SGHL, CHL, and IGHL probably function together to limit inferior translation of the adducted shoulder and act as secondary restraints against posterior translation. Clinically, these structures are addressed during either arthroscopic or open Bankart repair or capsulorrhaphy. However, simply overtightening the capsule to limit the end ranges of motion to achieve stability may lead to pathologic limitation of shoulder motion and late arthrosis.

The rotator interval region between the subscapularis and supraspinatus may be associated with abnormal translation, especially inferior translation of the adducted arm and, possibly, anteroposterior translation. Contraction of the rotator cuff and long head of the biceps brachii affects both static and dynamic factors that enhance stability. Primarily, they act in concert to increase compression across the glenohumeral joint, increasing the loads required to translate the humeral head. These factors are especially important in the midranges of motion where the capsuloligamentous structures are more lax. The long head of the biceps brachii is a significant secondary stabilizer when the capsuloligamentous structures begin to fail. The scapulothoracic stabilizers help accurately time and position the glenoid beneath the humeral head. Dysfunction in any of these stabilizers can lead to subsequent instability as residual stabilizing mechanisms become overwhelmed. Furthermore, proprioceptive mechanisms help to coordinate and time this system and can be restored after instability surgery.

Finally, the effects of abnormal articular surfaces, articular version, negative intraarticular pressure, and adhesion–cohesion, either in part or in combination, can lead to or worsen shoulder instability. By themselves, however, they may play only a small role in the pathogenesis of shoulder instability. Rarely is bone loss significant enough to warrant surgical correction. Unfortunately, clinical data are lacking for most of these factors, and an algorithmic approach to their treatment is currently evolving as experimental models improve.

CLASSIFICATION

The importance of a classification system for shoulder instability is best appreciated from observations of treatment failures resulting from improper matching of a surgical procedure with the appropriate pathology. Careful classification improves our ability to tailor individualized treatment programs for patients with glenohumeral instability. Although other classification systems exist for shoulder instability,[197] a system based on four factors is commonly employed: the degree of instability, the frequency of occurrence, direction, and cause of the instability (Table 9-4).

TABLE 9-4
SHOULDER INSTABILITY CLASSIFICATION

I. Degree
- A. Dislocation
- B. Subluxation
- C. Subtle

II. Frequency
- A. Acute (primary)
- B. Chronic
  - 1. Recurrent
  - 2. Fixed

III. Etiology
- A. Traumatic (macrotrauma)
- B. Atraumatic
  - 1. Voluntary (muscular)
  - 2. Involuntary (positional)
- C. Acquired (microtrauma)
- D. Congenital
- E. Neuromuscular (Erb's palsy, cerebral palsy, seizures)

IV. Direction
- A. Unidirectional
  - 1. Anterior
  - 2. Posterior
  - 3. Inferior
- B. Bidirectional
  - 1. Anteroinferior
  - 2. Posteroinferior
- C. Multidirectional

The degree of instability is proportional to the level of injury to the capsulolabral structures. *Dislocation* is defined as complete separation of the articular surfaces, often requiring a reduction maneuver to restore joint alignment. *Subluxation* is symptomatic instability without complete dislocation of the articular surfaces. These patients may complain of only pain without an appreciation for actual instability.

Subtle degrees of instability may be due to microtrauma, which may occur from overuse, as seen with repetitive overhead throwing. As in those with subluxation, some of these patients present with pain, with no knowledge of underlying instability. Additionally, patients with multidirectional or posterior instability may have associated tendinitis and pain without a sense of actual shoulder instability.[72,217,226] The avid overhead athlete may also present with pain in the posterior aspect (e.g., internal impingement of the posterior rotator cuff on the posterosuperior glenoid) of the shoulder

during the late cocking or early acceleration phase of throwing. Impingement, when present, is due to altered biomechanics and is a secondary phenomenon, rather than true mechanical impingement from the coracoacromial arch.[1,94,255] These can be difficult diagnostic and therapeutic problems.

The frequency of instability is described as acute or chronic. The temporal delineation between acute and chronic is not well defined in the literature, and those definitions that do exist may not have direct clinical relevance. However, for descriptive purposes, an *acute episode* of glenohumeral instability generally refers to the primary dislocation and is defined as one in which the patient is seen in the acute period (within several hours or even a few days) of the injury. These injuries may or may not need to be manually reduced, for occasionally they will reduce spontaneously. *Chronic instability* is in reference to either recurrent episodes of acute instability (a.k.a. recurrent instability) or dislocations that remain displaced for greater periods of time. The latter type may be more appropriately termed fixed or locked dislocations. Most commonly, this is seen in a missed or neglected posterior dislocation.[88]

The cause of instability may be categorized as traumatic, atraumatic, microtraumatic, congenital, or neuromuscular. As our understanding of the pathophysiology of shoulder instability has evolved, we now recognize that simplifying cause into atraumatic or traumatic is somewhat limiting. Thomas and Matsen[239] originally introduced the acronyms TUBS and AMBRI to help us think about the cause and treatment of most patients who have shoulder instability. The TUBS variety of instability describes a patient with macro*t*raumatic *u*nidirectional instability associated with a *B*ankart lesion that typically responds well to *s*urgery. The AMBRI variety of instability describes a patient with *a*traumatic *m*ultidirectional instability that is *b*ilateral and often responds to *r*ehabilitation; rarely, this type of instability requires an *i*nferior capsular shift.

Patients with this atraumatic instability may demonstrate the ability to voluntarily dislocate their shoulders. By selective muscle contraction and relaxation, these patients can position their shoulder to result in subluxation or dislocation. Most commonly, this is seen in cases of posterior and multidirectional instability, but pure anterior instability can also be produced. Rowe et al.[214] have observed that voluntary subluxation can be associated with emotional and psychiatric disorders of secondary gain. In general, this category of voluntary instability has a high rate of recurrence after surgical stabilization if the underlying psychopathology is not addressed.[169,214] A subtype of voluntary instability includes those who have an unconscious behavioral tic leading to selective muscular contraction. This form of voluntary instability may respond best to biofeedback techniques.[15]

Alternatively, dislocation may occur voluntarily with underlying involuntary instability, as with activities or even during sleep owing to instability that is positional. Although patients can voluntarily reproduce disabling instability just by positioning their arm, they prefer not to do so. Most commonly, these patients may have involuntary posterior instability that can be demonstrated by positioning the arm into flexion, adduction, and internal rotation. These patients often adapt by avoiding positions of risk where the shoulder might dislocate.[226] This positional type of involuntary instability, unlike voluntary instability caused by psychiatric factors or a behavior muscular tic, may respond well to surgical stabilization.[20,70]

Neer[170] recognized acquired instability that results from repetitive microtrauma (overuse) to the glenohumeral joint. These patients often provide a history of being an avid overhead athlete (e.g., baseball, swimming, tennis, and such) as they subject their anterior and inferior capsuloligamentous structures to repetitive injury and stretch causing symptomatic instability. These patients are not uncommonly found to have a preexistent constitutional congenital hyperlaxity.[60,62,184] Conceivably, these patients excel at their sport because of this excessive laxity and may develop symptomatic instability through subsequent trauma. Finally, neurologic disorders can lead to instability including stroke, Erb's palsy, and seizures, which can cause both anterior and posterior instability. Thus, rather than a discrete cause, there remains a spectrum of instability, with traumatic and atraumatic mechanisms occupying the extremes. This is reflected by the variety of findings observed at the time of surgery that may include any combination of a Bankart lesion, capsular laxity, or capsular rupture.

The direction of instability can be anterior, posterior, inferior, or any combination of these. Unidirectional instability occurs in only one of these directions. Multidirectional instability as in the AMBRI variety may demonstrate all three directions of instability in addition to generalized ligamentous laxity. The principal direction of instability in both the TUBS and AMBRI varieties of instability is usually anterior. However, the presence of inferior instability is the hallmark of the diagnosis of multidirectional instability. To add to already confusing nomenclature, Pollock and Bigliani[196] and Bigliani et al.[19] have described patients with an intermediate degree of instability, who demonstrate an inferior component in addition to an anterior or posterior component as bidirectional (e.g., anteroinferior or posteroinferior). This type of instability is more common in overhead athletes who expose their anterior and inferior capsular restraints to repetitive microtrauma, leading to plastic deformation and stretch. An additional subtlety is that patients with posterior instability often exhibit smaller degrees of inferior and even anterior instability.

Recognition of global capsular laxity and instability in more than one direction that is due to either of the extremes of causation (e.g., traumatic or atraumatic) is critical for determining appropriate surgical management so as not to exacerbate the instability in the direction left

unaddressed.[169] Often, it is the primary direction of instability that causes most of the patients' symptoms and is, therefore, most commonly addressed surgically. However, procedures that treat anterior capsular laxity by Bankart repair or capsular plication may not adequately manage the associated components of inferior and/or posterior instability. In the extreme, asymmetrical tightening during capsulorrhaphy can lead to a fixed subluxation in the opposite direction.[17,141] Thus, establishing the principal direction of the instability and acknowledging the lesser components by the time of surgical intervention is critical to obtain a successful outcome.

CONCLUSIONS

The aims of this chapter were to review the anatomy, biomechanics, and pathophysiology of shoulder instability. An understanding of what is "normal" provides a foundation for diagnosing and treating what is considered to be pathologic. Because current research endeavors have focused on the basic science of shoulder instability, we no longer have to rely on an anecdotal and qualitative account of the associated pathology noted at the time of treatment. We now have an organized and quantitative approach to the treatment of shoulder instability. Anatomic studies have provided abundant information on the macro- and ultrastructure of the static and dynamic restraints to stability. Experiments examining the biomechanics of shoulder instability have helped clarify the effects of articular version, the labrum, negative intraarticular pressure, the material properties and limits of function of the capsuloligamentous complex, and the dynamic interaction between static and dynamic restraints. There are still several unanswered questions. As technology is advancing, we must continue to evaluate how older and newer techniques correct anatomic and biomechanic abnormalities leading to glenohumeral instability. Newer forms of "heat therapy" and arthroscopic techniques are exciting means to perform less invasive surgery. However, meticulous analysis will be required to determine their value. Our current understanding of anatomy and biomechanics should greatly facilitate this goal.

REHABILITATION OF THE ATHLETE AND RETURN TO SPORTS 332

SUMMARY 335

INTRODUCTION

The goal in treating overhead athletes is not simply to eliminate their pain, but also to return them to play. Today, knowledge of shoulder anatomy, pathoanatomy, and biomechanics has dramatically improved treatment of injuries in the overhead athlete. Return to play is probable after treatment of numerous, common shoulder maladies.

To accommodate a large range of motion, there is less bony stability at the shoulder than other diarthrodial joints. Simple shoulder motion necessitates the coordinated actions at four separate articulations. The demands placed on the shoulder during rigorous overhead athletics are appreciable. Injury to the soft tissues that guide and limit motion can cause significant loss of function. Less common in the general population, this is a frequent finding in overhead athletes participating in activities that stress soft tissues near their physiologic limits.

In this chapter, the biomechanics and pathologic lesions of the shoulder in the overhead athlete are described. The stages of the throwing motion, including electromyographic (EMG) data, are described for both the normal and the injured shoulder. Baseball pitching is used as an example, but swimming, football, and tennis are also described. Then, patterns of shoulder injury and management principles in the overhead athlete are reviewed. Lastly we will detail postoperative care including rehabilitation of the overhead athlete and indications for return to play.

BIOMECHANICS OF THE OVERHEAD MOTION

Role of Arm Position

Clinical evaluation of the overhead athlete requires knowledge of normal mechanics of the sport and is best assessed during the athletic endeavor. The most important aspect of proper mechanics is that the motion is natural. This applies to all players, whether in baseball (when the ball is thrown from the outfield or the pitching mound), swimming, football, tennis, or any of the other activities that require an overhead motion.

Baseball is a good example of our needing to know the biomechanics and pathologic lesions common in the overhead athlete. Injuries to the shoulder account for most injuries to adult baseball players,[2] and most of these injuries occur during the throwing motion. A professional baseball pitcher may play 30 to 40 games in a season, throwing as many as 150 pitches in a game, many of these at high velocity.[72] Biomechanics change and improve with level of play from youth to professional. While amateur pitchers may not play as many games in a season, they still try to throw the ball as fast as possible while maintaining accuracy. It is not surprising that shoulder pain is a frequent complaint among baseball pitchers of all skill levels.

When an overhead athlete complains of shoulder pain, one should obtain the relationship of the shoulder pain to sports activity and arm position. A baseball pitcher who complains of shoulder pain during the cocking stage of the throwing motion may have anterior shoulder instability. The pitcher who has pain during the follow-through stage may have posterior shoulder instability. For best chances in correct diagnosis and treatment of shoulder injury in the overhead athlete, one should know the specific biomechanics of the athlete's sport and the specific activities that result in arm positions that make the shoulder vulnerable to injury.

Overhead throwing is a component of many sports. Caring for athletes participating in all of these different sports can be a challenge. Fortunately, the biomechanics of different overhead athletes are more similar than they are different. Of all overhead athletes, the complex biomechanics of throwing a baseball has been most studied.[14,29,32,33,47,48,50,72] Therefore, in the following section we will describe the biomechanics of baseball first. Because of differences that warrant special descriptions of other overhead athletic endeavors, we will also describe the biomechanics of football, swimming, and tennis.

Sport-Specific Biomechanics

Baseball

Stages of the Pitching and Throwing Motion, Including Electromyographic Data

Baseball throwing is a total body activity. It is an elaborate, synchronous progression of body movements that starts in the legs and trunk, proceeds to the upper extremities, and concludes in the rapid propulsion of the ball. The effectiveness of a baseball throw is determined by various factors, including velocity, accuracy, spin production, and endurance. Synchrony of muscular contractions and neurologic control throughout the body are essential to produce an effective throwing motion. Effectiveness also necessitates repetitive performance at a level that maximally stresses the physiologic limits of the shoulder. There is a delicate balance between mobility and stability of the joints of the upper extremities while throwing, and maintenance of this fragile balance is paramount. Small aberrations in the mechanisms that control stability have a significant and cumulative effect on upper extremity function and increase the risk of crossing the fine line between maximal throwing effectiveness and injury.

The mechanics of baseball throwing seem to differ slightly between player positions, but, in essence, the motions are quite similar. When an outfielder throws the ball, he or she first takes a step backward and then lands on the opposite forefoot with the knee slightly flexed. A pitcher should do the same. When the pitcher overthrows to get more speed on the ball, he tends to hyperextend the knee and land on the heel.[82] This places sudden, large forces on the shoulder during the cocking stage of throwing. Additionally, when the pitcher starts to fatigue, the elbow begins to drop and he or she increases the lordosis in the spine. This is how a pitcher with poor mechanics from back pain may later develop shoulder problems. For a specific athlete, any deviation from the normal, natural motion may be indicative of injury.

Most throwing studies have concentrated on the pitcher, because the motion is more constant, the collection of EMG data is easier, and pitchers frequently injure their arms. From a virtual standstill, a professional pitcher will accelerate a 142-g baseball to a release velocity of more than 90 miles per hour in just 50 msec. Tremendous tensile, compressive, and rotational forces must be created and dissipated in the shoulder. A detailed description of the throwing motion will help clarify how this is done.

The Normal Shoulder. The baseball pitch is divided into five stages (Fig. 10-1): windup, early cocking stage, late cocking stage, short propulsive stage of acceleration, and follow-through or deceleration stage, which can also be divided into early and late.

At stance, the pitcher stands facing the batter with the shoulders parallel to the rubber. The pivot foot (right for right-handers) is positioned on the rubber.

In the windup stage, the body mechanics are quite individual. In general, windup begins with the stride foot (left for right-handers) coiling backward, away from home plate, and the arms swinging overhead. At this time, the position of the fingers on the ball is finalized while screened by the glove. The pivot foot rotates on the rubber as weight is transferred to it. This stage ends with the ball

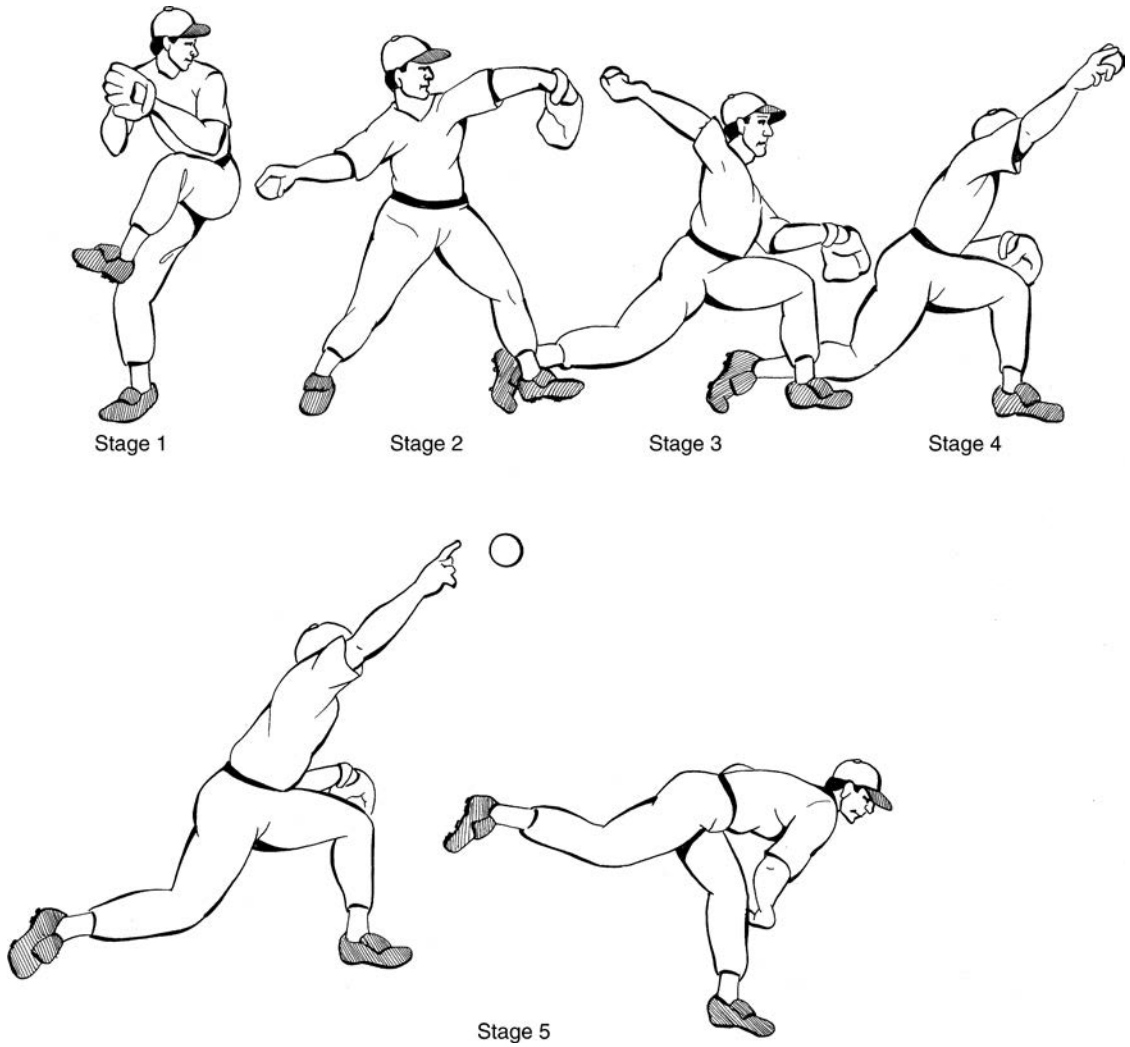

Figure 10-1 The five phases of the baseball pitch.

leaving the glove hand and the body balanced on the pivot foot. The EMG activity of the shoulder girdle and upper extremities is low during the windup, which reflects a lack of critical events in these anatomic locations related to performance or to injury potential. Instead, there is critical activity in the trunk and lower extremities during the windup. Common to all pitchers during the windup is a stable base to initiate the pitch. Good stance limb stability results from an upright and balanced trunk to minimize anterior-to-posterior sway of the body.

Cocking is divided into early and late stages. It begins when the ball leaves the glove. Early cocking starts with hip extension of the pivot leg that propels forward the stride leg, nondominant upper extremity, and trunk. The gluteus maximus of the pivot leg is important in providing this propulsion. This critical step in pitching is known as "leading with the pelvis." It is important that the pitcher strides to prevent early external rotation of hip. This "opening" of the pelvis and trunk pivot the body when it should be propelled forward. Temporarily, the dominant upper extremity lags behind the rest of the body. The trapezius and the serratus anterior muscles form a force couple to upwardly rotate and protract the scapula. This scapula motion is essential to place the glenoid in a stable position for the abducting and rotating humeral head. If the scapula is not positioned correctly, impingement can occur.[22] The deltoid and supraspinatus muscles act in synergy to abduct the humerus. Saha[81] described the glenohumeral muscles as drivers and steerers. In this case, the deltoid is the driver of the motion, and the supraspinatus is the steerer that fine-tunes the position of the humeral head in the glenoid. The remainder of the rotator cuff muscles have less activity during this phase,[22] indicating the importance of the supraspinatus in functioning with the deltoid in humeral abduction during this stage. The hand should be on top of the ball to prevent early external rotation of the shoulder and supination of the forearm.

Late cocking begins with rapid forward motion of the trunk.[29] The dominant shoulder rotates forward. Excessive horizontal abduction of this shoulder (e.g., "hyperangulation") is minimized by keeping the lead arm closed, in front

of the body. Abduction of the humerus is maintained and external rotation increases from 46 to 170 degrees.[25] Muscle forces are needed to overcome the inertia and gravity that act on the shoulder in horizontal abduction, external rotation, and adduction. Static and dynamic restraints combine to stabilize against these forces. In this position, the primary static anterior stabilizer of the glenohumeral joint is the anterior band of the inferior glenohumeral ligaments.[88] Although the supraspinatus and the deltoid activity diminish as the humerus ceases to abduct, the other rotator cuff muscles increase in activity to stabilize the humeral head.[22] The subscapularis acts as a barrier to anterior translation, together with the pectoralis major and the latissimus dorsi. These muscles act as a dynamic sling to augment the inferior glenohumeral ligament.[22] The posterior rotator cuff muscles are also quite active during late cocking as the infraspinatus and teres minor actively externally rotate the humerus. Their posterior placement also enables them to act as checkreins to anterior subluxation. Activity of the trunk and lower extremities is critical throughout pitching. Keeping the stride foot directed toward home plate minimizes over- or under-rotation of the body during the late cocking phase.

Although there is no further abduction of the shoulder during late cocking, the scapulothoracic muscles continue to be active to produce a stable platform for the humeral head and to enhance maximal humeral external rotation.[22] The middle portion of the trapezius, the rhomboids, and the levator scapulae are all key in providing scapular stabilization. The serratus anterior is also important in opposing retraction to stabilize the scapula. Sometimes symptoms of anterior instability of the glenohumeral joint are demonstrated during this stage because of an imbalance of the scapula-stabilizing mechanisms.[47] The cocking phase of pitching ends when the stride foot contacts the ground. It is important that the dominant arm is in a good throwing position at the end of cocking. Also, the lead shoulder should remain closed until the stride foot lands.

The acceleration stage begins with maximal shoulder external rotation and terminates with ball release. The humerus internally rotates approximately 100 degrees in one-half second.[25] The humeral internal rotation torque is 14,000 in.-lb, with an angular velocity of 6,100 degrees per second.[29,33] The acceleration of the arm is coincident with the deceleration of the rest of the body, producing efficient transfer of energy to the upper extremity and ball.[29] A large glenohumeral joint compressive force (860 N), which has a stabilizing effect, also occurs. Synchronous muscular contraction about the glenohumeral joint balances the requirements of stabilization and rapid motion. A stable scapula is needed, and all of the scapular muscles have high activity in providing this function.

Shoulder angular velocity during acceleration is transferred from the trunk, with augmentation by the latissimus dorsi and the pectoralis major. The latissimus dorsi has even higher activity than the pectoralis major,[22] and it is anatomically positioned to generate large torques.[6] These two muscles are important in actively contributing to ball velocity, evidenced by a clinical study that reported they are the only two muscles to have a positive correlation between peak torque in isokinetic testing and pitching velocity.[3] The subscapularis, especially the upper portion, also has very high activity during the acceleration stage and functions with the pectoralis major and latissimus dorsi.[22] Whereas the pectoralis major and the latissimus dorsi are the primary propellers of the arm, the subscapularis functions as a steering muscle to position the humeral head precisely in the glenoid. This coordinated function of the subscapularis with the latissimus dorsi has been observed in other overhead athletics as well.[74,75] The teres minor activity is also high, with the muscle acting as a checkrein to anterior instability. Athletes may note symptoms during this stage of throwing, the most typical problem being anterior instability.

Follow-through is after ball release and can also be divided into early and late stages. Initially, the trunk and dominant lower extremity rotate forward. The shoulder continues to adduct and internally rotate to 30 degrees. Kinetic energy not transferred to the ball must be absorbed by the decelerating arm and body. Deceleration is estimated to be 500,000 degrees per second^3 at the shoulder, with an external rotation torque of approximately 15,000 in.-lb at the humerus.[29,72] In general, deceleration of the upper extremity is accomplished by simultaneous contraction of opposing muscles around the shoulder.[22] The trapezius, serratus anterior, and rhomboids all demonstrate high or very high activity. The deltoid is active, especially the posterior and middle portions, which are positioned to oppose the motion of the upper extremity. The teres minor has the highest activity of all the glenohumeral muscles, continuing to provide a posterior stabilizing checkrein. Injury to the posterior glenohumeral joint stabilizers will commonly become apparent during this stage. Late follow-through is a noncritical stage, with all of the shoulder muscles exhibiting decreasing activity.[22] All of the kinetic energy has been dissipated, and the trunk is beginning to extend, allowing the pitcher to field the position.

In summary, the throwing motion requires the rapid transmission of immense forces throughout the shoulder. This has been estimated to be 27,000 in.-lb, which is four times that in the leg during a soccer kick[29]; this puts the shoulder at great risk for injury.

The Injured Shoulder. Alterations from these normal muscle activities occur in the injured shoulder. In athletes with anterior glenohumeral joint instability, Glousman and coworkers[32] found that elite pitchers with anterior joint instability had decreased serratus anterior EMG activity in all stages of the pitch when compared with normal. There were, in fact, significant differences between these two

groups in the EMG activity of all the muscles tested, except the middle deltoid. The biceps and supraspinatus muscles had more activity in the unstable shoulders. This was thought to be a compensatory mechanism to help stabilize the humeral head against the glenoid fossa. In addition, the infraspinatus showed increased activity during the late cocking phase of the pitching motion in those with instability.

Alterations from normal serratus anterior muscle activities are meaningful. Because of the rapidity of upper extremity motions, observation of scapula motion is nearly impossible during these overhead activities. However, during simple shoulder motions such as abduction, EMG activity in the serratus anterior muscle in the shoulder with anterior joint instability is diminished when compared to normal.[62] These findings indicate an abnormality in the coordinated rotation of the scapula on the thorax, termed *scapulothoracic rhythm*. Known primarily as a protractor that prevents winging of the scapula, the serratus anterior muscle is also important in the scapulothoracic rhythm during shoulder elevation.[5] Normal scapulothoracic rhythm has been extensively studied,[23,28,42,76] and these studies indicate that the normal scapulothoracic rhythm has been altered, possibly resulting in a scapular lag.

Football

The football throwing motion is similar to the baseball throw except that there is no windup.[52] Thus, there are four sequential phases (Fig. 10-2): early cocking, late cocking, acceleration, and follow-through. Early cocking is initiated at rear foot plant and continues to maximal shoulder abduction and internal rotation. Late cocking starts at maximal shoulder abduction and internal rotation and ends with maximal shoulder external rotation. The acceleration phase began with maximal shoulder external rotation and ends with ball release. Finally, the follow-through starts at ball release and ends with maximal horizontal adduction of the shoulder.

The rotator cuff muscles have the high levels of EMG activity throughout the football throw. Activity in the supraspinatus and infraspinatus muscles is similar. Both have moderate activity in early cocking, late cocking, and acceleration and high activity during follow-through. Activity in the subscapularis differs from the supraspinatus and infraspinatus muscles during the football throw. It is minimally active during early cocking and moderately active during late cocking but has high activity in both the acceleration and follow-through phases.

All three heads of the deltoid muscle are minimally to moderately active throughout all four phases. The anterior deltoid muscle is minimally active during early cocking and moderately active during late cocking, acceleration, and follow-through. The middle deltoid is minimally active during the first three phases and moderately active during follow-through. The posterior deltoid is minimally active during early cocking, late cocking, and acceleration, and moderately active during follow-through.

The pectoralis major muscle is minimally active during early cocking, moderately active during late cocking, and highly active during acceleration and follow-through. The latissimus dorsi muscle is minimally active during early and late cocking, moderately active during acceleration, and

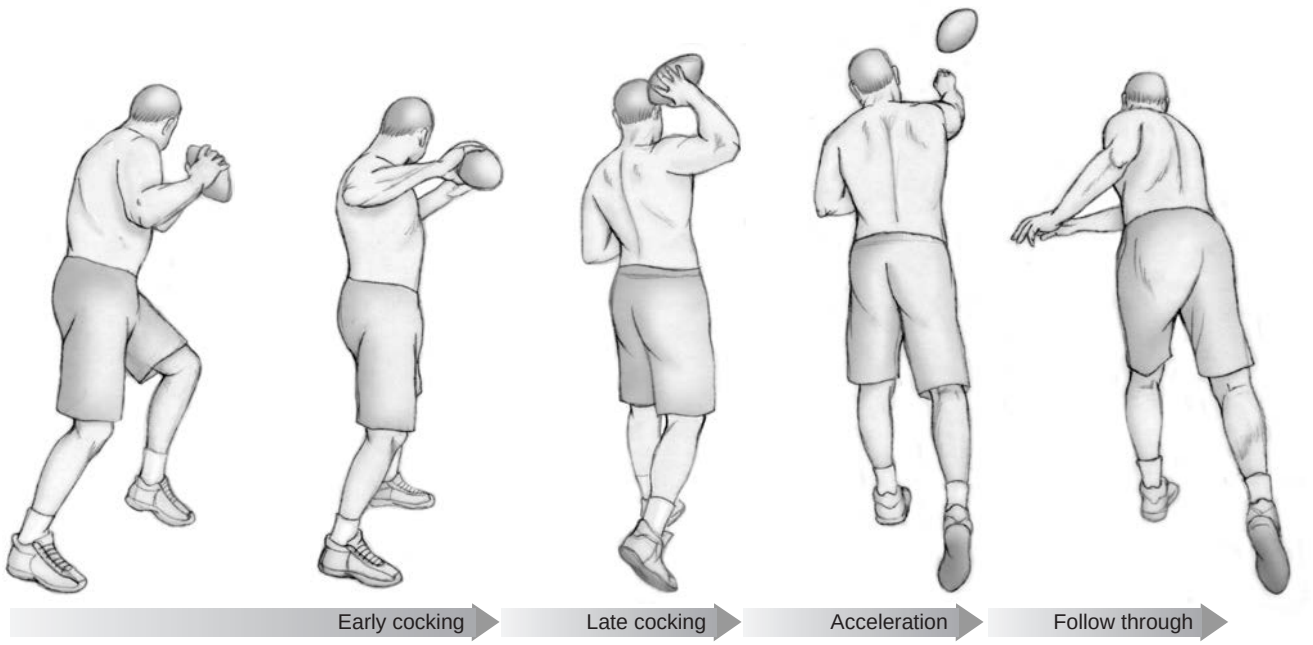

Figure 10-2 The five phases of the football throw.

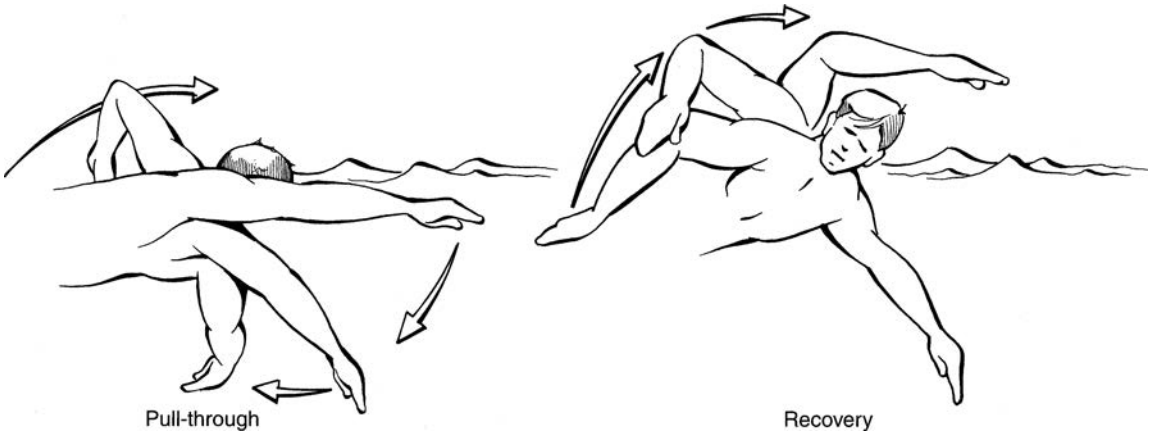

Figure 10-3 The pull-through phase of the freestyle stroke can be subdivided into hand entry, mid–pull-through, and end of pull-through. The recovery phase can be subdivided into elbow lift, midrecovery, and hand entry.

highly active during follow-through. Lastly, the biceps brachii muscle is minimally active throughout all four phases.

Swimming

The swimming strokes can be divided into the pull-through and recovery phases.[78] In the freestyle stroke the pull-through phase is subdivided into hand entry, mid–pull-through, and end of pull-through (Fig. 10-3). During hand entry, the shoulder is internally rotated and abducted, and the body roll begins. In mid–pull-through the shoulder is at 90 degrees abduction and neutral rotation. Body roll reaches a maximum of 40 to 60 degrees from horizontal. With the end of pull-through, the shoulder is internally rotated and fully adducted as the body returns to horizontal. The recovery phase is subdivided into elbow lift, midrecovery, and hand entry. In elbow lift, the shoulder begins to abduct and rotate externally. The body roll begins in the opposite direction from pull-through. In midrecovery, the shoulder is abducted to 90 degrees and externally rotated beyond neutral. Body roll reaches a maximum of 40 to 60 degrees in the opposite direction. Breathing occurs by turning the head to the side. In hand entry, the shoulder is externally rotated and maximally abducted, and the body is returned to neutral roll.

In the backstroke at hand entry, the shoulder is externally rotated and abducted as body roll begins from the neutral position. In mid–pull-through, the shoulder is abducted 90 degrees in neutral rotation with maximum body roll. At the end of pull-through, the shoulder is internally rotated and adducted, and body roll is horizontal. In the recovery phase of the backstroke, there is hand lift, rather than elbow lift. In hand lift, the shoulder begins with abduction and external rotation, and the body roll allows the arm to clear the water. In midrecovery, the shoulder is 90 degrees abducted and body roll is maximum.

In the butterfly stroke, the pull-through phase is the same as in the freestyle, but there is absence of body roll in all stages. To avoid shoulder flexion or extension, the hands are spread apart at the mid–pull-through stage. The recovery phase is again similar to that in the freestyle, with an absence of body roll. Body lift allows both arms to clear the water. Shoulder flexion and extension do not occur.

EMG activity indicates that the rotator cuff is important during swimming.[75,78] The supraspinatus, infraspinatus, and middle deltoid activities are predominant in the recovery phase. They abduct and externally rotate the extremity in preparation for a new pull-through. This position, similar to the cocking phase of throwing, places the shoulder at risk for subacromial impingement.[38] The serratus anterior also has an important function during recovery. It allows the acromion to rotate clear of the abducting humerus and provides a stable glenoid base on which the humeral head can rotate. The serratus anterior works at nearly maximal levels to accomplish this. Significantly decreased EMG activity of the serratus anterior muscle was found in swimmers with shoulder pain. During the pulling stage of the freestyle stroke there was significantly less activity in the serratus anterior in subjects with a painful shoulder when compared with normal.[83] The serratus anterior demonstrates similar findings during the pull-through stage of the butterfly stroke in subjects with a painful shoulder.[73] If this muscle becomes fatigued during the course of a number of cycles, scapular rotation may not coincide with humeral abduction. As a result, impingement syndrome may occur.

The biceps brachii muscle exhibited erratic activity during all of the strokes and functioned primarily at the elbow, which is similar to its role in pitching. The latissimus dorsi and pectoralis major were propulsive muscles, with a resulting action similar to that of the acceleration phase of throwing.

In summary, particular attention must be paid to conditioning the rotator cuff and serratus anterior muscles in an

effort to decrease the common problem of swimmer's shoulder impingement syndrome. Exercises must concentrate specifically on increasing the endurance of the serratus anterior muscle.

Tennis

The tennis serve can be divided into the same stages of complex muscle activity as a baseball pitch. The deltoid muscle function is low during cocking compared with pitching because trunk rotation contributes to shoulder abduction. The acceleration and follow-through stages in the tennis serve demonstrate muscle patterns and activity that are similar to those observed in throwing a baseball. Because the motions for serving the tennis ball are similar to those for pitching, tennis players may benefit from the same conditioning program as that outlined for pitchers. Likewise, emphasis should be placed on rehabilitating the rotator cuff and serratus anterior muscles.

The ground strokes, both forehand and backhand, can be divided into three stages (Fig. 10-4). In stage I, racquet preparation begins with shoulder turn and ends with the initiation of weight transfer to the front foot. Stage II is acceleration and begins with weight transfer to the front foot accompanied by forward racquet movement and culminates at ball impact. Stage III is follow-through and begins at ball impact and ends with completion of the stroke. The forehand ground stroke reveals a relatively passive windup sequence. Trunk rotation provides some of the force for shoulder motion. In follow-through, there is a marked decrease in activity among the accelerating muscles and a concomitant increase in the external rotators responsible for deceleration. The backhand ground stroke is similar in concept, but opposite in muscle activity, to the forehand. Follow-through demonstrates deceleration with increased activity of the internal rotators.

SPORT-SPECIFIC PATTERNS OF SHOULDER INJURY

Biomechanics of Pathology in the Overhead Athlete

Study of shoulder biomechanics has been invaluable in our understanding of pathogenesis,[61,86] pathoanatomy,[11,54,56,63,88] diagnosis,[37,64] and treatment [12,30] of common pathologic lesions. Recently, cadaveric models that simulate injury in the overhead athlete's shoulder were developed to improve our understanding of the athlete's shoulder.

Cadaveric Models of the Overhead Athlete without Muscle Forces (Fig. 10-5)[34]

First, nondestructive stretching of the anterior capsule was simulated while the humeral head was constrained in the glenoid. This resulted in a significant increase in external rotation of the shoulder. Next, posterior capsular contracture was simulated and resulted in decreased internal rotation. There was also a significant increase in anterior translation after nondestructive capsular stretching. The humeral head also was noted to have changed position during testing. Rotation of the humerus from neutral to maximum external rotation caused a posterior–inferior shift of the humeral head. This did not change significantly after anterior capsular stretching. Following a simulated posterior

Figure 10-4 The ground strokes of the tennis stroke, both forehand and backhand, can be divided into three stages: racquet preparation, acceleration, and follow-through.

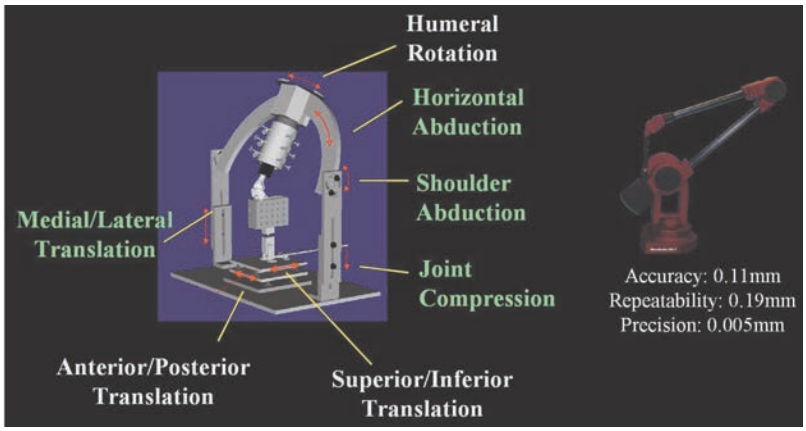

Figure 10-5 Cadaveric models of the overhead athlete without muscle forces.

capsular contracture, there was a significant superior shift of the humeral head at maximum external humeral rotation when compared to the stretched condition (2.0 ± 0.6 mm, $p = 0.013$). A posterior capsular contracture with decreased internal rotation would not allow the humerus to externally rotate into its normal posterior–inferior position in the cocking phase of throwing. Instead, the humeral head is forced posterior–superior (Fig. 10-6), which may result in a superior labrum from anterior to posterior (SLAP) lesion by a peel-back mechanism of humeral head impingement on the posterosuperior glenoid. (See the section on "SLAP lesions" in "Common Injuries in the Overhead Athlete" in this chapter for explanation of the proposed effect of posteroinferior capsular contracture as a cause of shoulder injury in the overhead athlete.)

Cadaveric Models of the Overhead Athlete with Muscle Forces

In a second cadaveric shoulder model for overhead athletes,[55] the shoulder muscles were simulated. Changes in glenohumeral kinematics and joint reactive forces were then studied through a range of motion. Cadaveric shoulders were tested in 90 degrees of shoulder abduction in the scapular plane using a custom shoulder jig with a six degree–of–freedom load cell and a microscribe digitizing system. The muscles were loaded with a pulley system used to approximate the muscle force vector toward the center of the muscle belly. The deltoid, infraspinatus, and teres minor were each loaded as were the supraspinatus, subscapularis, pectoralis major, and latissimus dorsi. Glenohumeral joint forces and the path of humeral head center were measured under three conditions; the final condition simulated the shoulder of an overhead athlete. These included an intact condition, a condition of nondestructive stretching of the anterior capsule, and a condition where posterior capsular contracture was simulated. The humeral rotational range of motion was measured from maximum external rotation to maximum internal rotation for each condition and the glenohumeral joint forces and the path of the humeral head center were quantified.

Nondestructive stretching of the anterior capsule in this cadaveric model resulted in external rotation increasing an average increase of 13 degrees, while internal rotation increased 1 degree. Internal rotation was decreased an average of 9 degrees in the condition where posterior capsular contracture was simulated and external rotation decreased 5 degrees. There was also a shift in the path of the humeral

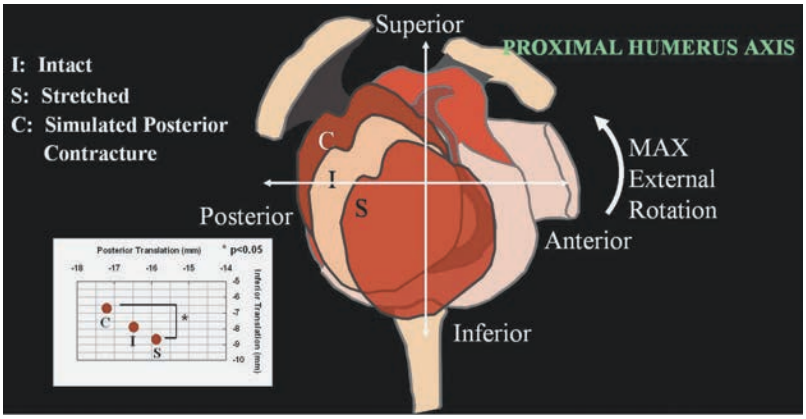

Figure 10-6 A posterior capsular contracture with decreased internal rotation does not allow the humerus to externally rotate into its normal posterior–inferior position in the cocking phase of throwing. Instead, the humeral head is forced posterosuperior, which may explain the cause of SLAP lesions in overhead athletes.

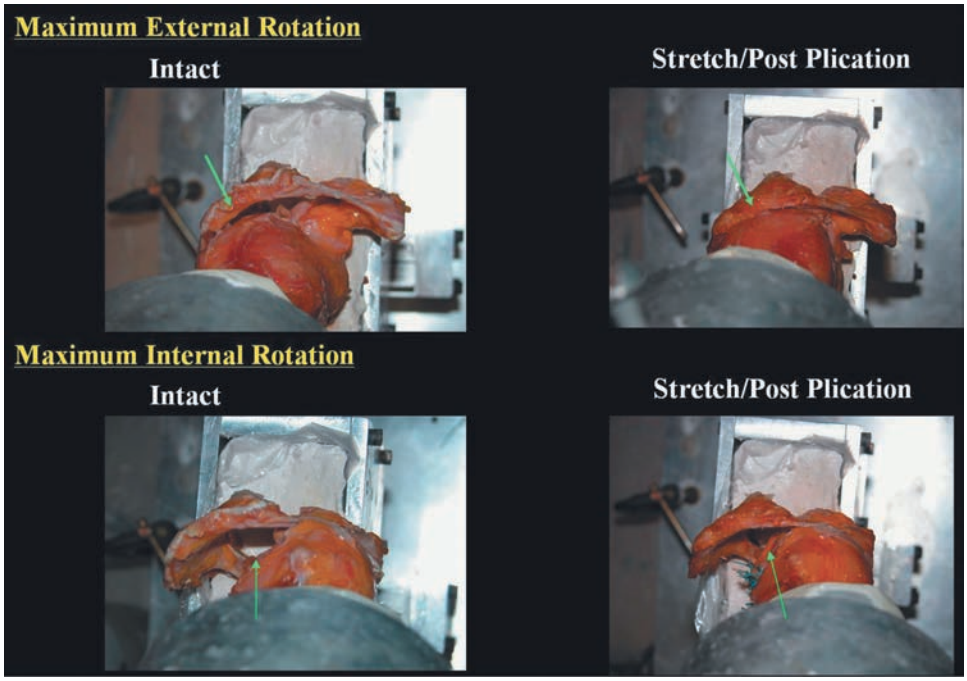

Figure 10-7 Glenohumeral joint forces and the path of the humeral head center were measured under three conditions with the final condition simulating an overhead athlete's shoulder. The path of the humeral head center with respect to the glenoid only exhibited statistically significant differences at extreme ranges of motion.

head center with respect to the glenoid near the limit of external rotation (Fig. 10-7). Compared to the intact condition, at maximum external rotation the humeral head was more inferior in the condition of nondestructive stretching of the anterior capsule and was more superior in the condition where posterior capsular contracture was simulated. With internal rotation of the abducted shoulder and in the condition where posterior capsular contracture was simulated, the humeral head was displaced inferiorly compared to the intact and stretched state.

In the anterior-to-posterior directions there were significant differences in the condition where posterior capsular contracture was simulated, but only at 15 degrees of external rotation. Then, the humeral head center was more anterior compared to the intact condition. It was also more anterior than that in the condition of nondestructive stretching of the anterior capsule. There were no statistically significant differences of the joint forces in comparison of the three conditions.

When comparing the path of the humeral head center from external rotation to internal rotation, capsuloligamentous effects were found throughout the range of motion but reached statistical significance only at the extremes where the static stabilizers make their greatest contribution. The concavity compression stability effect[56] afforded by the muscular forces was well demonstrated with this cadaveric model. In this study, the path of the humeral head center did not vary greatly and the forces about the glenohumeral joint did not vary significantly after differing conditions that simulated the shoulder of the overhead athlete. While this model does not simulate the varying muscles forces, both eccentric and concentric, through the throwing motion, it demonstrates that the muscles have a strong influence on glenohumeral joint stability. Also, impingement of the humeral head on the superior glenoid may occur secondary to the shoulder muscles functioning to maintain glenohumeral joint balance and congruency.

SLAP Lesion

In overhead athletes, lesions involving the superior labrum and the biceps anchor cause shoulder pain and instability.[84] The long head of the biceps tendon has long been thought to have a role in preventing superior translation of the humeral head.[24,31] Experimental work has subsequently demonstrated that it stabilizes the humeral head on the glenoid in both the anterior-to-posterior direction[44,69,79] and the superior-to-inferior direction.[45,69] Superior translation of the humeral head has also been demonstrated in vivo in individuals after isolated rupture of the long head of the biceps.[91] Both the long head and the short head of the biceps contribute to anterior stability, and this stabilizing effect is more significant when there is joint instability from a Bankart lesion.[45] Thus, the origin of the biceps is one of the structures that act in synchrony to stabilize the humeral head on the glenoid.

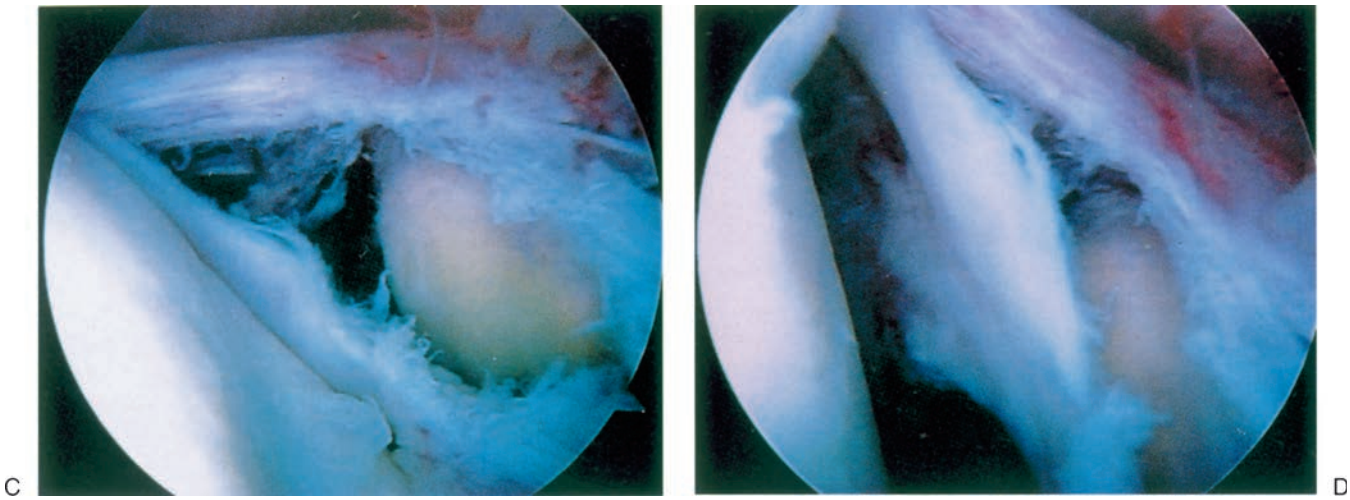

Figure 10-8 (*continued*)

Snyder and coworkers[85] described lesions of the biceps origin and the superior glenoid labrum, which they termed SLAP lesions as an acronym for superior labrum anterior and posterior. They postulated that these lesions were the result of superior subluxation of the joint. There may be a history of minimal trauma in older individuals, for there appears to be a propensity for degenerative lesions of the labrum and biceps tendon in this location.[77] These types of lesions were later ascribed to injury of the superior glenoid rim by the traction of the biceps tendon[10] as the elbow was decelerated during the follow-through phase of throwing.[1] SLAP lesions may also result from external rotation of the humeral head in the late cocking phase of throwing. Pannosian and coworkers[71] reported on the effects of type II SLAP lesions on glenohumeral rotation and translation in six cadaveric shoulders before and after repair. Glenohumeral translations with the application of 15N and 20N in the anterior, posterior, superior, and inferior directions were measured with the glenohumeral joint in 60 degrees abduction and 90 degrees external rotation. Data were recorded for intact shoulders, shoulders with arthroscopy portals, shoulders with arthroscopically created anterior type II SLAP lesions, shoulders with arthroscopically created anterior and posterior type II SLAP lesions, and shoulders having undergone arthroscopic repair. With the introduction of a SLAP lesion, significant increases in total range of motion, external rotation, internal rotation, anterior–posterior translation, and inferior translation were observed. Following arthroscopic repair, total range of motion, internal rotation, external rotation, and glenohumeral translations significantly decreased. These findings suggest that type II SLAP lesions cause significant glenohumeral instability and are similar to results found in other studies.[16,68] This study also found that type II SLAP lesions can be effectively treated with current arthroscopic techniques, which is a finding different from a prior study that found abnormal translations to be only partially restored after repair.[16] These differences in results may have been due to differences in repair techniques and warrant further investigation into the efficacy of repair of type II SLAP lesions.

Originally, five types of SLAP lesions were reported (Fig. 10-8). A simple degenerative fraying of the superior labrum is a type I lesion. The peripheral edge of the labrum remains firmly attached to the glenoid, and the biceps tendon attachment on the supraglenoid tubercle of the glenoid is intact. A type II lesion is a tear of the superior labrum and the biceps tendon attachment from the glenoid (Fig. 10-9). This lesion may be confused with an

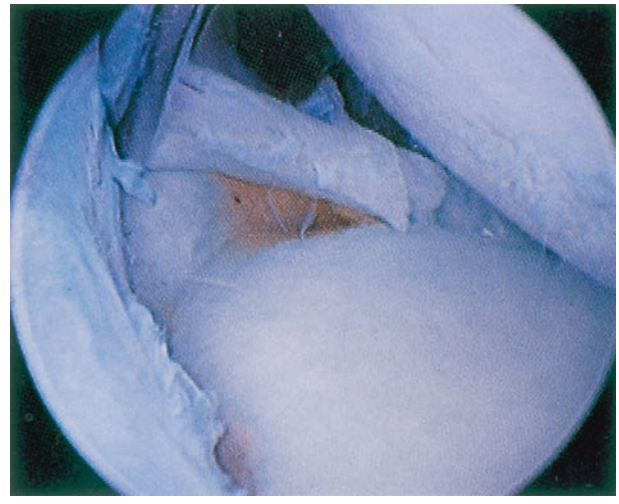

Figure 10-9 Arthroscopic view from the posterior portal of a joint that demonstrates a type II SLAP lesion.

anatomic variant where the labrum superiorly is meniscoid with a free edge.[20] Complete detachment of the labrum with exposure of bare bone from the superior glenoid neck is abnormal. Types I and II are most common, together accounting for over three-quarters of all SLAP lesions.[7,53] A bucket-handle tear of the labrum with preservation of the biceps anchor is a type III lesion (Fig. 10-10). In these cases the edge of the labrum is torn and can be displaced into the joint, whereas the peripheral portion of the labrum remains firmly attached to the glenoid. Additionally, the biceps tendon attachment is intact. When the biceps tendon is split with a portion remaining attached to the supraglenoid tubercle, the lesion is a type IV. This lesion is similar to the type III lesion except that a portion of the biceps tendon attachment is also involved. A type V lesion is any combination of these.

The effects of simulated type II SLAP lesions were studied by McMahon and coworkers[60] to determine if severity of the lesion affected glenohumeral joint translations. A robotic/universal force sensor (USF) testing system was used to simulate "load and shift tests" by applying an anterior or posterior load of 50N to each shoulder. The "apprehension test" for anterior instability was simulated by applying an anterior load of 50N with an external rotation torque of 3 Nm at 30 and 60 degrees of abduction. This loading protocol was repeated after creating two type II SLAP lesions of different severity. In the first, the superior labrum and the biceps anchor were subperiosteally elevated from the glenoid bone (SLAP-II-1), and in the second the biceps anchor was completely detached (SLAP-II-2). At 30 degrees of abduction, anterior translation of the vented joint from anterior loading significantly increased with the SLAP-II-2 lesion and compared to the SLAP-II-1 lesion. Increases in anterior translations at 60 degrees of abduction were not significantly different. Inferior translation also resulted from anterior loading. At 30 degrees of abduction, the inferior translation was greater for the type II SLAP lesions, regardless of severity, compared to the vented joint. No significant increases in anterior translation occurred in response to the combined loading condition. Glenohumeral translation was increased, regardless of severity, after simulation of type II SLAP lesions. During stabilizing surgical interventions, passive stabilizers that are injured in the type II SLAP lesion should be considered as well as dynamic activity in the tendon of the long head of the biceps brachii.

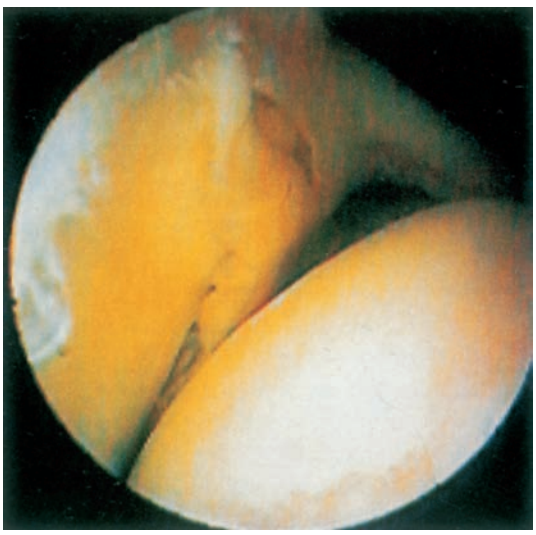

Figure 10-10 Arthroscopic view from the posterior portal of a joint that demonstrates a type III SLAP lesion.

Common Injuries in the Overhead Athlete

SLAP Lesion

Diagnosis of SLAP lesions is often difficult from the athlete's physical examination alone. The active compression test or O'Brien test[67] requires the standing patient to forward flex the affected arm to 90 degrees, with the elbow in full extension. The patient then adducts the arm 10 to 15 degrees medial to the sagittal plane of the body and internally rotates so the thumb points downward. The examiner, standing behind the patient, applies a downward force to the arm and the patient resists the downward motion. With the arm in the same position, the forearm is then fully supinated and the maneuver is repeated. The test is considered positive if pain is elicited during the first step and is then reduced or eliminated with the second step. Sometimes there is a painful click inside the shoulder. This test will also be positive if the patient has acromioclavicular joint pathology, but the pain will be localized on top of the shoulder. Jobe's relocation test[36] is also often positive in patients with a labral lesion. With the patient supine and the muscles relaxed, the shoulder is placed into the position of anterior apprehension by abducting to 90 degrees and then gently externally rotating the shoulder to the limit of motion (Fig. 10-11A). A gentle anterior-directed force may also be applied to the humeral head, resulting in posterosuperior shoulder pain. The relocation test is performed by reproducing this position and applying a posteriorly directed force to the humeral head (Fig. 10-11B) and the pain resolves.

Both the active compression and the relocation tests correlate with tears of the labrum.[35] However, problems remain in distinguishing a SLAP tear from other shoulder lesions. This results partly from SLAP lesions occurring concurrently with other shoulder pathology; isolated SLAP lesions are uncommon.[53] Also, the clinical findings associated with the different types of SLAP lesions overlap with the findings of other shoulder pathology. Overhead athletes are often able to compensate and compete successfully despite their shoulder injuries. This may result in a dilemma of treatment; is the shoulder pain coming from the SLAP lesion or from some other shoulder injury? Also, the underlying cause of SLAP lesions in overhead athletes

Figure 10-11 **(A)** With the patient supine and the muscles relaxed, the shoulder is placed into the position of apprehension by abducting to 90 degrees and then gently externally rotating the shoulder to the limit of motion. The overhead athlete with subtle instability feels pain as the tuberosity or the rotator cuff impinges against the posterior–superior glenoid rim. A gentle anterior directed force may be applied to the humeral head and the signs become more obvious. **(B)** The relocation test is performed by reproducing this position and applying a posteriorly directed force to the humeral head.

has been postulated to be a separate shoulder injury, namely posteroinferior capsular contracture.[17] Because the capsule changes in position with movement of the shoulder, the capsule is posteroinferior only with the arm at the side. In the shoulder of the overhead athlete and specifically the baseball pitcher, this capsular region ends up being anteroinferior in the cocking position of abduction and external rotation. When the contracture is severe, it forces the humeral head posterosuperior. The result is a SLAP lesion by a peel-back mechanism of humeral head impingement on the posterosuperior glenoid.

We recommend treatment of SLAP lesions based on mechanical symptoms and symptoms of instability. Fraying or tearing of the superior labrum, the biceps tendon, or both may result in mechanical symptoms of catching or clicking in the shoulder. Typical of types I and III SLAP lesions, these lesions may be débrided. Many individuals with a SLAP lesion, however, also have glenohumeral joint instability. In this case, the avulsed superior labrum and biceps tendon anchor should be fixed to glenoid bone. Types II and IV SLAP lesions are examples. Sometimes there is loose soft tissue that should be débrided as well. And, if there is minimal increase in joint translations, repair of the SLAP lesion alone is sufficient. With meaningful symptoms of instability, however, an anterior glenohumeral stabilization procedure should also be performed.

Instability Associated with Overuse Capsular Laxity

Anterior Instability

Repetitive shoulder motion in the overhead athlete may lead to tears of the anteroinferior labrum and anterior subluxation of the shoulder, leading to progressive instability. The glenoid labrum is a fibrocartilaginous rim around the glenoid fossa that deepens the socket and provides stability for the humeral head. It also is a connection for the surrounding capsuloligamentous structures. Glenoid labrum tears may also occur from acute trauma.

The load-and-shift test can also be used to confirm the diagnosis of anterior instability. For this test, the examiner applies a compressive load to the relaxed glenohumeral joint and an attempt is made to translate the humeral head. This test should be done in a number of different abduction positions simulating the cocking position of throwing and graded into one of three types. In a grade 1 load and shift the humeral head translates to the rim of the glenoid but not over it, which is a normal finding for testing in the anterior direction. For the test to be grade 2 the humeral head should translate over the rim of the glenoid and reduce spontaneously, whereas for the grade 3 test, the humeral head does not reduce and instead locks on the anterior glenoid rim. Only grade 2 and 3 load-and-shift tests are abnormal for testing in the anterior direction and in our experience are uncommonly found in overhead athletes with anterior instability associated with overuse capsular laxity.

Simple translational testing can also be helpful. The patient should be in a supine position and the shoulder muscles relaxed. Then the humeral head is grasped and an attempt made to translate it anteriorly. As with the load-and-shift test it is best to compare with the contralateral shoulder and examine the translation in several shoulder positions of abduction.

We always perform an examination under anesthesia on the shoulder of overhead athletes who we plan to treat surgically for glenohumeral joint instability, but we rarely are able to detect abnormalities; the instability

may be so subtle that it goes undetected. In our experience, valuable information can be gleaned from a variation of the simple translation testing of the shoulder when done with the athlete under anesthesia. With the shoulder abducted and in neutral rotation, the amount of anterior translation is assessed. With increasing external rotation of the shoulder, the amount of translation decreases and then becomes zero. At this point the position of the shoulder is noted. The test is then repeated with the contralateral shoulder. In the shoulder with instability, there is considerably more external rotation of the shoulder before anterior translation halts.

Arthroscopic findings, such as a classic Bankart lesion or a Hill-Sachs lesion, are unusual. Findings may include stretching of the anterior band of the inferior glenohumeral ligament, labral fraying, and mild labral separation. Chondral damage, seen as a defect in the posterior humeral head articular cartilage, may also be present. Rotator cuff damage is usually on the articular surface of the supraspinatus tendon. Conservative care emphasizes strengthening and conditioning of the rotator cuff and scapular muscles. Return to sport should be gradual, with careful attention to symptoms. Initially after return to overhead throwing, if pain occurs it should be mild in intensity and resolve within a few hours of cessation of the activity. Within a short time, pain should be absent during the overhead throwing activity. If the pain persists, the duration or vigor of the activity must be diminished. Most individuals will improve with such a program. If after 6 months of rehabilitation the symptoms continue, operative repair of the anterior capsuloligamentous structures is indicated. Isolated acromioplasty is not warranted and can lead to increased anterior instability.

Posterior Instability

Individuals with posterior instability of the glenohumeral joint can be divided into two distinct groups: those with traumatic posterior dislocation or subluxation and those with posterior subluxation from repetitive microtrauma. The traumatic posterior instability is usually the result of a fall on the outstretched upper extremity with a normal shoulder. Athletes very rarely suffer a posterior shoulder dislocation. Recurrent posterior subluxation is more typical in overhead athletes and results from chronic, insidious microtrauma to the posterior capsule, which subsequently becomes attenuated. For example, if a pitcher overthrows, does not warm up properly, or has poor mechanics that lead to a limited follow-through, then the posterior capsule can be injured. Repeated, daily injuries during participation in practice and games lead to chronic subluxation. However, chronic subluxation can also result from a single traumatic episode that results in subluxation with repeated use in overhead athletics. A football quarterback who is tackled and falls on his outstretched hand may feel a pulling sensation in the posterior shoulder. There may or may not be appreciation of joint instability. When the acute pain has subsided, there may be posterior shoulder pain with throwing, and velocity may be diminished.

It is common for overhead athletes with recurrent, posterior subluxation to complain of pain during the offending sporting activity. Pain may be absent at other times, and specific complaints of joint instability are unusual. On physical examination there is no asymmetry of the shoulders and range of motion is normal, as is strength. The pain of subluxation is sometimes felt when the shoulder is placed in the position of 90 degrees of forward flexion, horizontally adducted across the body, and internally rotated. Suspected posterior joint instability can be further evaluated by having the patient lie supine with the shoulder over the edge of the examination table, in the same position as described earlier, while a posterior force is applied to the shoulder. Although meaningful when positive, apprehension of posterior instability is rare. Accompanying symptoms of pain or apprehension are very important, for asymptomatic posterior subluxation may represent normal laxity and may not indicate pathologic instability. The athlete may be able to reproduce his or her symptoms by voluntarily subluxating the shoulder posteriorly with the shoulder in the forward-flexed and internally rotated position. These athletes are usually not psychologically disturbed and do not use their shoulders for secondary gain. They can be treated the same as the athlete who is unable to voluntarily subluxate the joint.

The load-and-shift test described previously in the assessment of anterior shoulder instability may also be helpful in assessing posterior instability. It is important to compare the contralateral shoulder because over half of shoulders in asymptomatic athletes have a grade 2 load and shift when tested in the posterior direction.[59]

Rehabilitation of the shoulder muscles, including the rotator cuff and the scapular muscles, is generally helpful in reducing symptoms of posterior instability. Strengthening of the infraspinatus, the teres minor, and the posterior deltoid muscles should be specifically addressed and biofeedback to rehabilitate the posterior shoulder muscles may have a place. When rehabilitation is maintained for at least 6 months, about 70% of individuals with posterior instability will improve symptomatically, and many athletes will be able to return to their sport.[40] When instability is recalcitrant to this rehabilitation program, we recommend a posterior capsulorrhaphy because the capsule is usually redundant. An osteochondral lesion (the reverse Hill-Sachs lesion) or a capsulolabral avulsion (the reverse Bankart lesion) is usually not seen. Generalized ligamentous laxity associated with posterior joint instability is a particular therapeutic problem best treated with an aggressive rehabilitation program; surgery is not recommended.

Internal Glenoid Impingement

The pitcher with internal impingement commonly complains of pain and decreased effectiveness. Pitch control is usually maintained, but velocity is diminished. Pain is located in the posterosuperior shoulder and is associated with throwing. After throwing is completed, the pain diminishes and then resolves after sufficient rest until throwing resumes.

The rotator cuff can be pinched against the posterosuperior glenoid rim with the shoulder abducted to 90 degrees and then maximally externally rotated.[70] With the glenohumeral joints fixed in this position, the greater tuberosity forces the rotator cuff against the glenoid rim (Fig. 10-12).[46,90] A subtle increase in anterior glenohumeral translation can also cause internal impingement.[21] Normally, both static and dynamic stabilizers act to prevent anterior instability, but in the apprehension position the normal distance from the rotator cuff to the posterosuperior rim of the glenoid is small so that little tolerance exists.

During the normal baseball pitch, the humerus stays in the plane of the scapula during the cocking and acceleration phases. Fatigue of the shoulder musculature from repetitive throwing may result in a lag of the humerus, posterior to the plane of the scapula during these phases; internal impingement results. There may also be damage to the static stabilizers, such as stretching of the anterior band of the inferior glenohumeral ligament. As the humeral head translates anteriorly with the shoulder in the apprehension position, more of the rotator cuff would contact the glenoid rim. This increased anterior translation then aggravates the internal impingement.

The shoulder relocation test is the best test for internal impingement. Reproducing the anterior apprehension position produces posterosuperior shoulder pain as the tuberosity or the rotator cuff impinges against the posterosuperior glenoid rim. Then, during the relocation test the distance between the rotator cuff and the posterosuperior rim of the glenoid increases from the posteriorly directed force being applied. In the athlete with anterior instability, this keeps the joint located, so the pain resolves. If continuous maximal external rotation is applied throughout the test, the shoulder can usually be externally rotated further.

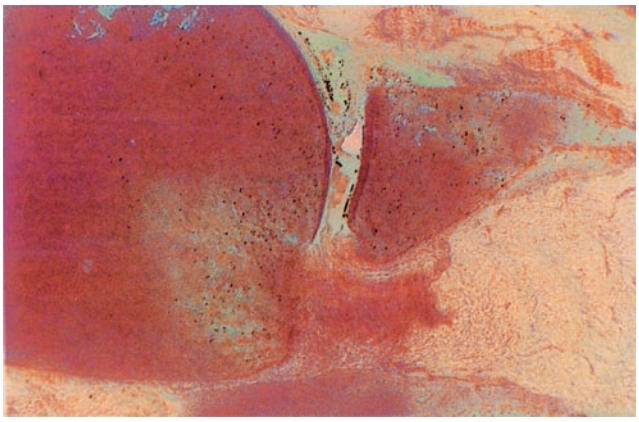

Figure 10-12 Cadaveric section of the glenohumeral joint with the shoulder put into the apprehension position of abduction and maximal external rotation; the rotator cuff pinches against the posterior superior glenoid rim.

When necessary, arthroscopic evaluation of the glenohumeral joint reveals characteristic lesions. There is fraying of the supraspinatus tendon in a location slightly more posterior to that seen with classic impingement. Fraying of the posterosuperior glenoid rim is also seen. At arthroscopy the intraarticular effects of the relocation test can be directly visualized. With the arthroscope in the posterior portal, the shoulder is put into the apprehension position of abduction and maximal external rotation, and the internal impingement can be seen as the rotator cuff abuts against the posterior superior glenoid rim (Fig. 10-13A). Then, with a posteriorly directed force applied to the humeral head, this is relieved (Fig. 10-13B). This can also be visualized with magnetic resonance imaging (MRI) (Fig. 10-14).

In the normal glenohumeral joint, the humeral head translates slightly posteriorly when the shoulder is abducted and externally rotated.[39] This normal posterior translation helps to minimize abnormal contact of the rotator cuff on the posterosuperior glenoid. Individuals with anterior joint instability, by contrast, did not demonstrate movement in the posterior direction, and in some cases the humeral head translated anteriorly. This abnormal translation increases internal glenoid impingement. During the first part of the relocation test in the joint with instability, the anterior translation of the humeral head results in rotator cuff tendon compression between the greater tuberosity and the posterosuperior glenoid rim. The application of the posteriorly directed humeral force then relocates the humeral head to its normal posterior position and the rotator cuff tendon does not contact the glenoid rim.[21]

Because internal impingement is usually a secondary problem, treatment must be directed toward the underlying causes, which are excessive humeral angulation, subtle anterior glenohumeral joint instability, and fatigue. Muscular development of the dynamic restraints and correction of problems with the throwing mechanics are indicated. Physical therapy aimed at strengthening and conditioning the shoulder muscles, including the rotator cuff, deltoid, and scapular muscles, is instituted. It is important to include the scapular muscles in the rehabilitation efforts to restore the normal scapulothoracic rhythm. Both concentric and eccentric strengthening and conditioning exercises are included. Although posterior capsular stretching may also be beneficial, care is taken not to stretch the static restraints to anterior translation. Additionally, cardiovascular and general muscular conditioning is incorporated in the rehabilitation program to minimize fatigue. Generally there will be meaningful improvement

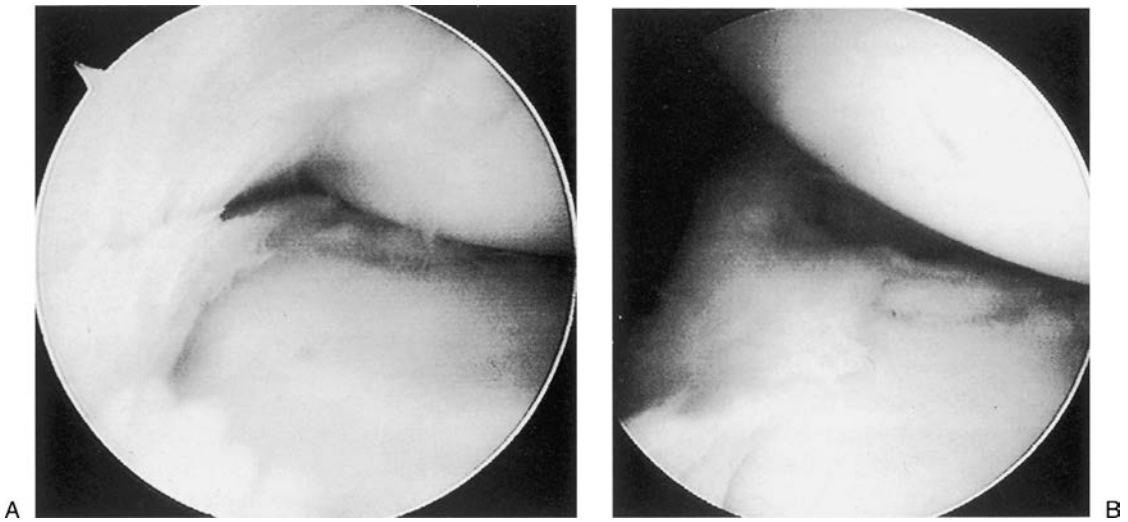

Figure 10-13 **(A)** View of the relocation test from inside the joint demonstrating internal impingement. With the arthroscope in the posterior portal, the shoulder is put into the position of abduction and maximal external rotation. The rotator cuff pinches against the posterior superior glenoid rim. **(B)** With a posteriorly directed force applied to it, the humeral head returns to a normal position, and the greater tuberosity is posterior to the glenoid rim.

in symptoms within 3 months, and throwing can resume with return to the prior level of competition after 6 months of treatment. Most overhead athletes (greater than 80%) can be successfully treated without surgery.

When anterior translation is markedly increased, these efforts may prove to be insufficient to allow the overhead athlete to return to pain-free activities. If the individual is intent on returning to overhead athletics, surgery is then indicated. In our experience, arthroscopic débridement of the rotator cuff and posterior superior glenoid fraying is unsuccessful if there is meaningful anterior joint instability. Only those individuals who would have responded successfully to the rehabilitation program have successful results with débridement alone. If there is meaningful anterior instability, operative repair of the anterior capsuloligamentous structures is required. Rehabilitation is then instituted, with expectation to return to the prior level of competition after 12 months.

Bennett Lesion

The Bennett lesion is an ossification or calcification of the posterior inferior glenoid found in overhead athletes, most commonly baseball players. Generally, the overhead athlete complains of pain while throwing and physical examination reveals tenderness in the posterior inferior glenoid region.

In 1941, Bennett[9] described a posteroinferior glenoid lesion, similar to an arthritic osteophyte, that he thought

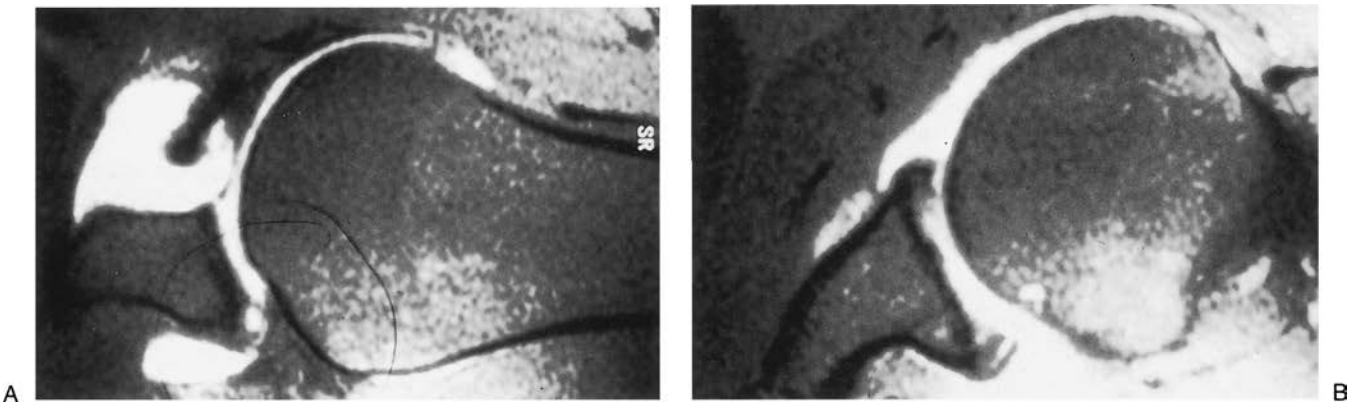

Figure 10-14 **(A)** Magnetic resonance imaging (MRI) of a shoulder positioned in the apprehension position demonstrating internal glenoid impingement. **(B)** MRI of a normal shoulder positioned in the apprehension position. The rotator cuff does not impinge on the posterior superior glenoid rim.

was the result of a traction injury of the long head of the triceps brachii. Pain accompanied the lesion. This was thought to be because of proximity to the axillary nerve and subsequent irritation. Radiographic analysis of the lesion necessitated direction of the x-ray beam 5 degrees cephalad, with the shoulder abducted and externally rotated. Initially, treatment of the Bennett lesion was resection from a posterior approach, but later Bennett stated that this was not necessary.[8] Ferrari and coworkers[26] used computed tomography–arthrography in seven elite pitchers to demonstrate that the Bennett lesion was extraarticular. Six had posterior labral tears. The Bennett lesion was described as a posteroinferior ossification associated with posterior labral injury.[26] Treatment included a period of rest followed by a rehabilitation program and treatment with nonsteroidal antiinflammatory drugs for 3 to 4 months. If this failed, arthroscopic débridement of associated labral lesions may be indicated.

Suprascapular Nerve Injury

Chronic neurologic injuries about the shoulder can present in overhead athletes of all ages. The neurologic examination should include complete sensory evaluation, testing of reflex arcs, observation for atrophy, and strength testing.

Cervical spine pain can be confused with shoulder pathology. These athletes may initially complain of shoulder pain, but neck pain is usually present on careful questioning. Physical examination and cervical spine radiographs enable correct localization of the pathology. A herniated nucleus pulposus can cause nerve root compression in the neck, with pain radiating down the arm in the distribution of the affected nerve.

The suprascapular nerve originates from the upper trunk of the brachial plexus to innervate the supraspinatus and infraspinatus muscles. Along its path, there are two areas of the scapula where it can be tethered and compressed: the suprascapular notch and the neck of the spine (spinoglenoid notch). Compression results in pain or weakness. Symptoms may preclude pitching more than one or two innings. In the chronic situation, the correct diagnosis can be elusive, because the disease has an insidious onset and vague symptoms. Muscle pain and diminished endurance are the important presenting symptoms. There is weakness of external rotation and sometimes of abduction, depending on the location of the compression. Either the infraspinatus is involved alone or both shoulder muscles are, depending on the location of the compression. Physical examination demonstrates muscle atrophy. The trapezius overlies the supraspinatus muscle, but atrophy of this muscle can be appreciated as a depression over the supraspinatus fossa of the shoulder. Atrophy of the infraspinatus is easy to appreciate as a depression over the lower half of the scapula. EMG can be used to confirm the diagnosis. Suprascapular nerve palsy can be confused with rotator cuff tears, which present with pain in a similar area and weakness of the same musculature. Surgical exploration and decompression of the nerve generally give good results when the nerve is compressed at the suprascapular notch. In this case, the supraspinatus and infraspinatus muscles are both involved. However, if atrophy and EMG changes are confined to the infraspinatus muscle, the nerve is injured at the spinoglenoid notch. A ganglion cyst can be responsible, and MRI is helpful in determining its location.[41] When present, resection of the ganglion cyst is effective treatment. However, when the injury is a result of traction, nonsurgical treatment is recommended, because surgical decompression has not always been successful. The effects of chronic compression may not be reversible in either event. If the infraspinatus is not completely deinnervated, the authors have had good results with maximizing the residual muscle function with a daily exercise program. Because this muscle seldom contracts more than 30% to 40% of its maximum effort, the return to the prior level of pitching is sometimes possible. A meticulous history and physical examination for proper diagnosis early in the disease course yields the best chance for success.

Quadrilateral Space Syndrome

Bounded by the humerus, teres major, long head of the triceps brachii, and the inferior rotator cuff (the subscapularis anteriorly and the teres minor posteriorly), the quadrilateral space is crossed by the axillary nerve and the posterior humeral circumflex artery. Cahill and Palmer[19] described the cause of pain in this location as compression of the axillary nerve by fibrous bands in the quadrilateral space. Symptoms occur when the athlete abducts and externally rotates the shoulder as in the cocking stage in throwing. There is tenderness over the teres minor muscle, and symptoms can be reproduced by placing the shoulder into this position. The neurologic examination is usually normal, as are EMG studies. Arteriography of the subclavian artery, which enables visualization of the posterior humeral circumflex artery as it passes through the quadrilateral space, is helpful in making the correct diagnosis. With the arm at the side, the artery is patent, but with abduction and external rotation of the shoulder, the artery occludes. It is necessary to perform comparative studies of the contralateral shoulder. A test is positive only if the symptomatic side occludes and the normal side does not. In the athlete with this condition, a short period of rest and cortisone injections into the space are often helpful. If symptoms persist, operative decompression of the quadrilateral space is indicated. This can be performed through a posterior approach, inferior to the deltoid. The tendon of the teres minor can be incised to decompress the axillary nerve, but in our experience, the long head of the triceps is often the offending structure. Results have been favorable.

Rotator Cuff Injuries

Neer,[65] among others, described impingement syndrome as compromise of the space between the humeral head and the coracoacromial arch. In the classic case, the coracoacromial ligament and the anterior inferior aspect of the acromion are compressed against the bursal side of the rotator cuff during forward flexion of the shoulder. Anterior acromial spurs may be present. Unlike acute tears, chronic rotator cuff tears often present insidiously, with slow progression from subacromial bursitis to rotator cuff tendonitis and eventual tendon tear. Over time, small tears may progress to larger, more severe tears. Active range of shoulder motion is limited, and if the tear is severe, there will be atrophy of the shoulder muscles. Manual muscle testing demonstrates weakness. The Neer impingement sign is positive and the pain resolves with subacromial injection of lidocaine. Differentiating severe rotator cuff tendonitis from partial or small full-thickness chronic rotator cuff tears may be a difficult task.

Overhead-throwing athletes with rotator cuff injuries from classic impingement syndrome are generally an older population, more than 45 years of age. Tears are most common at the humeral insertion site of the supraspinatus tendon, where stress is greatest with the joint in abduction. Tears may involve either the partial or full thickness of the tendon. Tears are most common in the anteriormost portion of the supraspinatus tendon. Small tears are located here and more severe tears, even when the entire supraspinatus and portions of the infraspinatus tendons are involved, have a margin of the tear at the anteriormost supraspinatus tendon. The size may be small (less than 1 cm), medium (1 to 3 cm), large (3 to 5 cm), or massive (greater than 5 cm). Chronic rotator cuff tears may result partly from degeneration within the rotator cuff tendon. Poor vascularity and repetitive activity, especially in the athlete with a restricted subacromial space, may be contributing factors. A minor traumatic event may also cause a full-thickness tear in an athlete with mild or moderate tendon degeneration.

If the tear is small, a prolonged period of rest, lasting 4 to 9 months, may relieve symptoms. Range-of-motion exercises are also recommended, unless they cause significant discomfort. If this fails to control the symptoms, surgical repair of the tear is recommended. The thin degenerated tissue of a chronic rotator cuff tear makes surgical repair more difficult than repair of an acute tear. Surgical decompression of the subacromial space to remove spurs should also be performed.

Rehabilitation lasts from 6 months to a year, with gradual exercise progression needed to restore normal, or near-normal, function and strength. This varies with the tear size repaired and type of surgery performed. Typically, immediately after the procedure, passive motion and isometric strengthening exercises start, along with elbow-, hand-, and grip-strengthening exercises. At 6 weeks, the athlete may be able to begin low-intensity active strengthening exercises against gravity. The goals are to bring the athlete to normal strength with a functional, pain-free range of motion.

While the lesion location and size are helpful in describing the rotator cuff tear, symptoms do not correlate with these factors alone. Both epidemiologic and imaging studies indicate a high incidence of partial-thickness rotator cuff tears at younger ages and a high incidence of full-thickness rotator cuff tears at older ages. Small full-thickness rotator cuff tears may be asymptomatic as long as the force couple of the anterior and posterior rotator cuff is preserved. Instead, a number of other factors influence the severity of symptoms, including acute/chronic nature of the injury, patient age, activity level, humeral head superior migration, shoulder muscle strength, arthritis, pain tolerance, and workman's compensation.

A partial articular-sided tendon avulsion is much more common than a bursal side tear of the rotator cuff. As with other rotator cuff injuries, symptoms may resolve with appropriate physical therapy and analgesics. Yet, some individuals with a partial-thickness tear have persistent or recurrent symptoms. If a conservative program of exercises and gradual return to activity does not lead to steady improvement, then further diagnostic evaluation with ultrasonography, MRI, or arthroscopy may be helpful. Arthroscopic débridement of the abnormal cuff may promote healing in athletes with partial-thickness posttraumatic tears. Following débridement, immediate resumption of range-of-motion and muscle-strengthening exercises begins. Typically, it requires 6 to 12 months for a throwing athlete to return to athletics following arthroscopic débridement of a partial-thickness rotator cuff tear.

In those younger than 35 years of age, when symptoms of impingement syndrome are present, it is almost exclusively associated with anterior glenohumeral instability. Classic impingement syndrome is unusual in these young overhead-throwing athletes. They have positive impingement signs and a positive relocation test. Tears are found in the posteriormost portion of the supraspinatus tendon and most commonly are partial-thickness, articular-sided tears. The cause of these rotator cuff injuries may be internal impingement or the loads of prolonged, repetitive overhead throwing. In these young athletes, treatment of the instability results in resolution of the rotator cuff injury.

Vascular Problems

Shoulder and arm pain in the overhead athlete does not often elicit a diagnosis of vascular injury, but misdiagnosis can result in disastrous outcomes, such as arterial thrombosis and embolization. Identifying vascular compression injuries is difficult in the overhead athlete, and these injuries are relatively uncommon. Unless vascular compromise is recognized as a possible source of pain, misdiagnosis is likely.

Early fatigue of the upper extremity in a well-conditioned athlete is a frequent initial complaint. In baseball pitchers, decreased endurance and measurable loss of pitch velocity after three innings are common findings. Forearm pain, throwing arm heaviness, and hand coldness are sometimes present. Loss of pitching control is not a symptom. Physical examination may reveal a diminished pulse or a loud bruit. Doppler ultrasonography and duplex scanning indicate that subclavian artery compression by the scalene muscles is the most likely cause in symptomatic athletes.[58,66] When the shoulder is positioned in abduction and external rotation, this finding is common in asymptomatic individuals as well as overhead athletes[80] and, therefore, is not specific. Physical examination findings must correlate. Sometimes symptoms are the result of subclavian artery aneurysm with thrombosis, and in these cases, embolization to the hand and severe ischemia may occur.[66] Compression of the axillary artery,[66] the posterior humeral circumflex artery,[43] the suprascapular artery, or the subscapular artery[58] can also result in localized symptoms. Treatment includes avoidance of all exacerbating activities until symptoms subside and a carefully supervised program of muscle strengthening for the entire shoulder girdle. Postural training may also be helpful, but this requires strengthening and conditioning of the trunk muscles. If conservative measures fail, the involved areas can be surgically decompressed with excellent results.[66]

MANAGEMENT PRINCIPLES IN THE COMPETITIVE ATHLETE

Management of the overhead athlete begins with a meticulous history and physical examination. Loss of velocity, accuracy, and distance usually alert the overhead athlete to injury more serious than usual aches and pains. The effect of the injury on the patient's activities of daily living may provide as many clues to the diagnosis as does the effect of the injury on sports performance. Pain is a subjective symptom, but careful assessment can provide insight into disease pathology. The duration, anatomic location, and character of the pain should be specifically assessed. In addition, the presence of night pain and analgesic requirements should be considered. The temporal relation to sports activity and the postural relation to arm motion should be obtained from the patient with shoulder pain. For example, a pitcher who complains of shoulder pain during the cocking stage of the throwing motion usually has anterior shoulder instability. The pitcher who has pain during the follow-through stage may have posterior shoulder instability. The onset of night pain, especially when lying on the affected side, indicates rotator cuff injury, as does pain with overhead activities.

The physical examination of the shoulder consists of several phases, including visual inspection, palpation, range-of-motion testing, strength testing, neurovascular assessment, and general physical evaluation. Visual inspection includes examining the skin and the contour of the entire shoulder girdle. Special attention should be given to areas of swelling or muscle atrophy. Side-to-side differences should be recorded, with knowledge that there are some normal changes that occur in the throwing arm. For example, the musculature is usually hypertrophied and the scapula is often displaced slightly inferiorly in the throwing arm. Palpation should be performed from the neck to the fingers on all sides of the upper extremities. Motion of all four joints (sternoclavicular, acromioclavicular, scapulothoracic, and glenohumeral) is essential to normal shoulder kinematics. This can be assessed both actively and passively. Differences between active and passive motion can be the result of a deficiency, such as a rotator cuff tear. Motion should always be compared with the contralateral shoulder. Brown and coworkers[15] found that Major League pitchers have different ranges of motion between the shoulders. In the pitching arm, with the shoulder in abduction, there is 11 degrees less extension, 15 degrees less internal rotation, and 9 degrees more external rotation. Therefore, comparison with the contralateral arm should be done with this variance in mind.

MRI, computed tomography (CT), and other imaging studies can be used to reinforce the physical findings in the difficult case. They can also be helpful in a few special circumstances. If there is suspicion of rotator cuff abnormality, the MRI is useful in delineating the extent of injury. An MRI can also be used when the radiographs are not sufficient in identifying humeral and glenoid abnormalities. It is also helpful in the athlete with a strong suspicion of instability, but without a strong indication for surgery unless a specific labral lesion can be identified. The use of an intraarticular contrast agent is generally recommended. Iodine injection into the glenohumeral joint before CT or gadolinium or saline injection into the glenohumeral joint before MRI is helpful to outline the labrum.

Nonoperative and Operative Decision Making

Treatment of the overhead athlete may differ depending on timing of the injury to the athlete's sporting season. Factors to take into consideration include the athlete's ability to effectively participate, propensity for further injury, number of years for play remaining, and the effectiveness of operative and nonoperative treatments. In general, operative treatments require a longer period of rehabilitation than nonoperative treatments. For athletes who play professionally, consideration of the value for continued participation may also be important.

If the athlete believes that effective participation is possible and the caregiver has determined that propensity for

further injury is small, then overhead throwing in a controlled setting is indicated. In the case of a baseball pitcher, throwing pitches under the supervision of the coach and the athletic trainer or physical therapist may be best before the athlete returns to participation. The athlete's condition is carefully monitored during play. Recurrence of the injury necessitates further evaluation, and worsening of the injury precludes further participation. The optimal time for treating injuries in the overhead athlete is at the conclusion of the season. This leaves the athlete with the longest length of time for recovery.

In Season

As is true throughout the year, shoulder injuries suffered during the season necessitate a thorough evaluation that yields the correct diagnosis. Then, initial treatment for most injuries is a period of rest and nonsteroidal antiinflammatory drugs, followed by supervised rehabilitation. If 6 weeks of this treatment is ineffective, a magnetic resonance arthrogram may be helpful in determining the severity of the injury. If the athlete returns to play, careful supervision of performance is needed to minimize the risk of the injury worsening. In a recent study of return to play, most athletes were able to return to their sport and complete their seasons after an episode of anterior shoulder instability.[18] However, many of these were not overhead athletes and over one-third had at least one recurrence of shoulder instability before the end of the season. If a surgical procedure is able to improve the athlete's condition, it may be performed at the end of the season to minimize the time lost from participation.

Off Season

Treatment of shoulder injuries in the overhead athlete that occur during the off season require consideration of the additional factor of the length of rehabilitation. If treatment of the injury requires many months of rehabilitation and injury occurs near the beginning of the season, return to play at the start of the season may not be possible. Also, operative treatment may not be best if it requires a longer period of rehabilitation than nonoperative treatments and the previous considerations have been discussed with the athlete.

REHABILITATION OF THE ATHLETE AND RETURN TO SPORTS

Treatment of the overhead athlete requires knowledge of what is normal and what is abnormal in these athletes. For example, external rotation of the abducted shoulder is greater than normal in baseball players, while internal rotation is diminished. It is erroneous to consider the "excessive" external rotation as pathologic as the athlete has no symptoms and competes successfully. Likewise, it is important to understand which shoulder structures are at risk during the overhead activity. The underlying cause of most baseball players' shoulder problems is instability of the glenohumeral joint. Treating associated symptoms of rotator cuff injury does not prevent further problems. Wise practitioners always ask themselves, "Is this the core of the problem or simply a secondary effect?"[51] The earlier the core of the problem is diagnosed, the better the chances are for a quick recovery. An astute practitioner who has knowledge of the athlete's sport-specific mechanics has the best opportunity for success. Early in the course of the problem, complaints may be vague; the athlete may recognize that it takes longer to warm up or "get in the groove." If the injury progresses, performance diminishes. Unfortunately, many athletes continue to participate and injury occurs to shoulder structures. Recovery of the secondary injury may be necessary before the underlying core of the problem can be diagnosed.

The goals in rehabilitation of the overhead athlete's shoulder are to restore flexibility, reestablish joint stability, strengthen shoulder muscles, and restore proprioception. This must be done without exacerbating injury. Ice is valuable in diminishing pain and inflammation and other modalities such as ultrasound and electrical stimulation may also be helpful. It is usually best for the overhead athlete to rest for a period of time to allow for healing. The length of rest is dictated by the severity of the injury. For mild injuries, a week of rest is usually sufficient, but for moderate to severe injuries, 4 to 12 weeks of rest may be best. When the athlete returns to overhead throwing, its length and intensity is modified to a pain-free level.

Also important is restoration of shoulder motion, particularly internal rotation and horizontal adduction. There may be meaningful loss of internal rotation of the abducted shoulder in overhead athletes, particularly in baseball pitchers. This often results from posterior capsular contracture, and specific stretches and flexibility exercises that passively stretch the abducted shoulder in internal rotation are best. These stretches are best done with the scapula stabilized. The humerus of the abducted shoulder is stretched in internal rotation with the athlete positioned on the scapula of the affected side. Athletes may also be instructed to do posterior capsular stretching, known as a "sleeper stretch," by themselves. The athlete lies on a table on the effected side with the arm in front. Rolling toward the arm places the shoulder into horizontal adduction. Then, with the elbow bent to 90 degrees, the athlete pushes the forearm toward the table, stretching the shoulder in internal rotation (Fig. 10-15).

The shoulder muscles must be strengthened to overcome weakness, which may have preceded and, in part, resulted in the shoulder injury, which may have been from shoulder pain, and which may have resulted from the

Figure 10-15 An athlete doing a sleeper stretch.

enforced rest that allowed for healing. Because there are numerous muscles essential to the normal shoulder, rehabilitation can be complex. An easy way to remember the strengthening concepts for the overhead athlete's shoulder is to think of "E^{14} and the 4 Ps":[51] Effective, efficient exercises focus on the glenohumeral "protectors" (i.e., the rotator cuff muscles), the scapulothoracic "pivotors" (i.e., the scapular rotator muscles), the humeral "positioners" (i.e., the three heads of the deltoid muscle), and the shoulder "power drivers" (i.e., the pectoralis major and the latissimus dorsi). The glenohumeral protectors and the scapulothoracic pivotors are strengthened first to allow for restoration of glenohumeral stability. The humeral positioners are strengthened next because they are important for normal synchronous motions of the shoulder. The power drivers are strengthened last to prevent overpowering the other three groups when the others are weakened.[51]

If the injured athlete is extremely sore or painful, it is best to start with submaximal isometric exercises; conversely, if there is only mild soreness, then lightweight isotonic exercises can be started.[94] Exercises to restore joint stability are aimed at the force couples of the shoulder. Reciprocal isometric muscle contractions are begun for the internal and external rotator muscles of the shoulders, as are agonist and antagonist co-contraction exercises for these and other muscles. Exercise of the rotator cuff muscles is initiated with the athlete lying on the side. To exercise the external rotators, the athlete lies on the opposite side with a small pillow between the thorax and the arm to be exercised. The arm is rotated away from the body and then back to the starting position and repeated. Progressively larger weight is added to make these exercises more challenging. Prone rowing into external rotation can also be used as it has been shown to elicit high EMG activity of the posterior rotator cuff muscles.[27] To exercise the internal rotators, the athlete lies on the affected side with the arm slightly in front of the thorax and is rotated toward the body. Exercises of prone horizontal abduction with external rotation and supine horizontal adduction with internal rotation are also added as strengthening continues. It is especially important to strengthen the teres minor muscle by externally rotating the shoulder in positions of abduction. This is done with the shoulder in about 70 degrees of abduction. Excessive external rotation and excessive horizontal abduction are blocked to minimize symptoms of anterior shoulder instability.

The supraspinatus muscle is isolated when the shoulder is elevated in the plane of the scapula. This motion, termed "scaption," was reported by Jobe and Moynes[49] to result in high levels of EMG activity in the supraspinatus muscle with the "empty can" exercise of internal rotation; this places the hand in the thumb-down position. Highest EMG activity in the supraspinatus muscle results when the shoulder is elevated from 90 to 120 degrees, but this may exacerbate rotator cuff tendonitis if it is present.[87] The "full can" exercise may be helpful to exercise the supraspinatus muscle in athletes who have rotator cuff tendonitis. With the patient lying prone and with the arm abducted to 100 degrees and fully externally rotated, high EMG activity is produced in the supraspinatus muscle,[13] but this position may exacerbate anterior shoulder instability if it is present. It is best that the therapist personalize exercise of the supraspinatus muscle to minimize the athlete's symptoms.

Eccentric exercises are then begun under the supervision of a therapist. The athlete also progresses to isokinetic exercise of the rotator cuff muscles. This begins at slow speed and submaximal effort and progresses to high speed and large effort.

Full, active scapular motion is very important to the overhead athlete, as is strengthening of the scapular pivotors. The muscles responsible for this motion are the trapezius, levator scapulae, rhomboids, serratus anterior, and pectoralis minor. These muscles act to position the scapula for maximum glenohumeral joint stability while minimizing impingement syndrome. For example, scapular upward rotation entails three complementary actions: upward rotation, retraction, and an anterolateral force from the inferior angle of the scapula.[42] The upward rotation results from the upper and lower portions of the trapezius and the serratus anterior.[51] The retraction results from the middle portion of the trapezius and the rhomboids and the anterolateral force by the serratus anterior. Muscles from all three boarders of the scapula function.[51] Rowing and horizontal abduction exercises exercise all portions of the trapezius, levator scapulae, and rhomboid muscles. Flexion and scaption exercises are also valuable scapular muscle strengthening. Wall pushups and the shoulder shrug are good for initiating scapular muscle strengthening and the pushup plus can be used later in the rehabilitation program. The "plus" exercise during the pushup is performed by emphasizing scapular protraction at the "top"

Figure 10-16 The pushup-plus exercise emphasizes scapular protraction at the top of the pushup.

of the pushup and has been demonstrated with EMG to be the very beneficial (Fig. 10-16).[51] The athlete must be careful to lower the chest only as far as the shoulder during the pushup-plus exercise to avoid putting the shoulder in the position of apprehension for anterior instability. It is best for the therapist to start the athlete on the knees and forearms when the athlete begins to do these exercises on the floor to prevent excessive scapular muscle effort early in the rehabilitation program.

Because serratus anterior muscle activity is often high during overhead activity,[73,74,83] it is important to introduce endurance exercises for this muscle. An upper-extremity ergometer can be used with the height of the hand pedals varied to ensure optimal training of all portions of this broad-based muscle.[51] Specific exercise drills may be used to enhance neuromuscular control of the scapulothoracic articulation (Fig. 10-17).[93]

Strengthening of the humeral positioners and the power drivers ensues only after the protectors and pivotors are strong. Scaption, forward flexion, and prone horizontal abduction are good exercises for the humeral positioners. When adding weights to these exercises, the therapist must note if the athlete substitutes muscle weakness by shrugging the shoulder. Additional exercises include rowing and the military press. Strengthening of the pectoralis major and the latissimus dorsi muscles, the power drivers, are the last shoulder muscles to be incorporated into the rehabilitation program. Actually, most power during the overhead throw comes up the body from the legs to the trunk to the

Figure 10-17 Neuromuscular control exercise drill for the scapular muscles: The athlete lies on her side with the hand placed on the table **(A)** and the clinician applies manual resistance to resist scapular movements (such as protraction and retraction) **(B).** The athlete is instructed to perform slow and controlled movements.

arm and out to the projectile object.[92] The pectoralis major and the latissimus dorsi muscles are the only muscles of the upper extremity to demonstrate a positive correlation between peak torque, measured in isokinetic testing, and pitching velocity.[4] The seated press-up, the bench press, and the pull-down are all good exercises to strengthen these muscles.

The overhead athlete should also perform core strengthening exercises for the abdomen and lower back musculature. Lower-extremity strengthening is also initiated with a running program, including jogging and sprinting. Fatigue can diminish performance. Once the overhead athlete is fatigued, shoulder external rotation decreases and ball velocity diminishes, as does lead knee flexion and shoulder adduction torque. Voight and coworkers[89] documented a relationship between muscle fatigue and diminished proprioception. Lyman and coworkers[57] reported that the predisposing factor that correlated to the highest percentage of shoulder injuries in Little League pitchers was complaints of muscle fatigue while pitching. Thus, endurance exercises are critical for the overhead athlete. Specific endurance exercise drills include wall dribbling with a ball, wall arm circles, and isotonic exercises using small weights with high repetition. Other techniques that may be beneficial to enhance endurance include throwing a ball weighted more or less than that of normal play. Also, during this phase the athlete may perform shadow throwing or mirror throwing; this mimics throwing mechanics without actively doing so. This allows the athlete to work on proper throwing mechanics.[93] Drills to enhance proprioception and neuromuscular control, such as pushups onto a ball, can also be done.

The last phase of the rehabilitation program is the return-to-throwing phase. A throwing program is initiated once the athlete can fulfill the criteria of (1) satisfactory clinical examination, (2) painless range of motion, (3) satisfactory isokinetic tests, and (4) appropriate rehabilitation progress. The throwing program is designed to gradually increase the quantity, distance, intensity, and type of activity needed for the gradual restoration of normal biomechanics.

We use baseball as an example, but the principles we describe apply to all overhead athletics. Overhead throwing is initiated from 30 to 45 ft and progresses to throwing from 60 ft. The athlete is instructed to use a crow-hop type of throwing mechanism and lob the ball with an arc for the prescribed distance. Flat ground, long-toss throwing is used before throwing off the mound to allow the athlete to gradually increase loads to the shoulder while using proper throwing mechanics. In addition, during this phase of rehabilitation, we routinely allow the position player to initiate a progressive batting program. We routinely use a program that progresses the athlete from swinging a light bat, to hitting a ball off a tee, to soft-toss hitting, to batting practice.

For baseball pitchers, we progress the long-toss program to 120 or 145 ft, whereas position players would progress to throwing from 180 ft. Once the pitcher has successfully completed throwing from 120 or 145 ft, he or she is instructed to throw 60 ft from the windup on level ground. Once this is accomplished, throwing from the mound is allowed. Position players continue to progress the long-toss program to 180 ft and then perform fielding drills from their specific position. While the athlete is performing the throwing program, the clinician should carefully monitor the overhead athlete's mechanics and throwing intensity. In addition, during this last phase of rehabilitation, the overhead athlete is instructed to continue all of the earlier exercises to maintain upper-extremity strength, power, and endurance. The athlete is also instructed to continue the stretching program, core exercise training, and lower-extremity strengthening activities. Lastly, the athlete is counseled on a year-round conditioning program. To prevent the effects of overtraining or throwing when poorly conditioned, it is critical to instruct the athlete on specific exercises to perform throughout the year.

SUMMARY

To successfully treat the overhead athlete, knowledge of the biomechanics of the sport and common shoulder pathology is necessary. There may be several pathologic lesions in the shoulder of an overhead athlete, so attention to symptoms and signs are essential to appropriate treatment. Appropriate imaging studies, examination while the patient is anesthetized, and arthroscopy may also aid the clinician in making the proper diagnosis. Rehabilitation of the shoulder muscles and appropriate surgical intervention optimize return to overhead athletics. Lastly, one should consider when the injury has occurred relative to the season of play to optimize the athlete's participation and performance.

Fluoroscopic Evaluation 360
Computed Tomography Arthrography 361
Magnetic Resonance Imaging 362
MR Arthrography 363

INTRODUCTION

Our knowledge of glenohumeral instability has evolved over the years. The original description of a single "essential lesion" by Perthes[95] and Bankart[2] has expanded with the identification of several causes and mechanisms of instability. A clear understanding of the various types of instability and associated pathology is essential to the formulation of a proper diagnosis and treatment plan. Clinical evaluation through a detailed history, physical examination, radiographic imaging, and the appropriate use of other modalities (such as magnetic resonance imaging, examination under anesthesia, and diagnostic arthroscopy) will facilitate an optimal treatment strategy for most patients. This chapter presents an algorithmic approach to the evaluation of glenohumeral instability.

DEFINITION OF INSTABILITY

Consideration of the different types of glenohumeral instability requires the distinction between laxity and instability. *Laxity* is the normal, asymptomatic, and necessary passive translation of the humeral head on the glenoid that allows normal shoulder motion. Laxity may be affected by age[17] gender,[29,70] and congenital factors. It is also a trait that varies among individuals. Harryman et al. found considerable

variability in glenohumeral translation in normal subjects, with substantial humeral excursion in some asymptomatic normal shoulders.[37] Similarly, Hawkins et al. noted overlap in the amount of translation found during examination under anesthesia between symptomatic unstable and normal shoulders, affirming the normal variability in capsular laxity among individuals.[43] *Instability,* on the other hand, is a pathologic condition of excessive translation of the humeral head on the glenoid during shoulder motion that manifests in pain and clinical symptoms of subluxation or dislocation. Both conditions may exist independently, as patients with hyperlaxity may be asymptomatic or can exhibit pathologic instability. Moreover, hyperlaxity may be a risk factor for the development of shoulder disorders.[28,85]

CLASSIFICATION

The importance of a designated classification system for glenohumeral instability lies in the ability to develop optimal treatment strategies for a given set of pathologic findings. Some factors common to most currently accepted schemes include direction, etiology, frequency, degree, and volitional control.[27,28,31,35,44,55,59,102,114]

Prior to the description of more sophisticated shoulder classification systems, glenohumeral instability had been simply characterized by direction: anterior or posterior. Neer and Foster[76] expanded on that theme and described multidirectional instability as either anterior or posterior, in addition to an inferior instability component. The "sulcus sign" represented passive inferior subluxation of the humeral head on physical examination and was also the hallmark of multidirectional instability. However, as previously noted, the ability to passively subluxate the shoulder inferiorly only determines the degree of laxity in an individual, whereas the diagnosis of instability rests in whether the inferior subluxation is symptomatic, manifesting in pain or apprehension.[28]

Etiologic categorization of instability was addressed by Thomas and Matsen,[123] who described the acronyms TUBS and AMBRI to classify most patients with glenohumeral instability. TUBS (Traumatic Unidirectional Bankart treated with Surgery) refers to patients with a traumatic lesion who have a unidirectional component to their disease that frequently has a Bankart lesion and responds well to surgery. AMBRI (Atraumatic Multidirectional Bilateral treated with Rehabilitation or Inferior capsular shift) refers to patients who have an atraumatic cause of their multidirectional disease that often has bilateral shoulder findings and responds to rehabilitation. With the further understanding of multidirectional instability and the high incidence of rotator cuff interval lesions, the latter acronym was modified to AMBRII and included an inferior capsular shift with rotator interval repair.

Rockwood[100] added the concept of volition in describing four types of instability: type I—traumatic subluxation without previous dislocation; type II—traumatic subluxation after a previous dislocation; type IIIA—voluntary subluxation in patients with psychiatric problems; type IIIB—voluntary subluxation in patients without psychiatric problems; and type IV—atraumatic involuntary subluxation.

Gerber and Nyffeler[28] developed a classification scheme that divides instability into three classes: static, dynamic, and voluntary. Static instabilities (class A) are diagnosed radiographically and lack the classic signs and symptoms of instability. The humeral head is fixed in either an anterior, a posterior, or a superior position. Dynamic instabilities (class B) are posttraumatic (either through microtrauma or a single traumatic event), resulting in capsulolabral lesions or bone deficits that render the shoulder symptomatically unstable. Voluntary dislocations (class C) are classified separately from instabilities as the patient has complete control over the event.

The frequency of instability can be defined as either a primary or recurrent episode. While most acute primary dislocations are recognized, recurrent events, if overlooked or missed, can become chronic, locked dislocations that are associated with significant morbidity or dysfunction.[41,73]

Classification based on degree of instability differentiates subluxation from dislocation. *Dislocation* is defined as a complete separation of the articular surfaces often requiring a reduction maneuver to restore joint alignment. *Subluxation* is the symptomatic excessive translation of the humeral head against the glenoid without complete dissociation of the articular surfaces.

In general, as our understanding of the natural history, pathology, and treatment of shoulder instability has evolved, so has the classification scheme. The authors prefer to use an algorithmic approach to the classification of instability based on cause, direction, frequency, and volition (Fig. 11-1).

Traumatic Anterior Dislocation

The most common mechanism of a traumatic initial dislocation is an anteriorly directed force applied to the posterior aspect of the externally rotated and abducted arm. The humeral head becomes levered anterior in relation to the glenoid typically when the arm is in the overhead position. The patient's age and the force required to cause an initial dislocation are important factors in determining prognosis and associated injuries. Younger individuals typically sustain anterior shoulder dislocations during contact sports, whereas a low-energy fall may be the cause in the elderly. Patients who are younger than 30 years of age at the time of initial dislocation are more likely to experience recurrent dislocations, whereas patients older than 40 years of age are more likely to incur rotator cuff tears with the initial dislocation. Neviaser et al.[80] noted an 85.7% and 10.8% incidence of rotator cuff tears and axillary nerve palsy, respectively, in patients with an initial traumatic

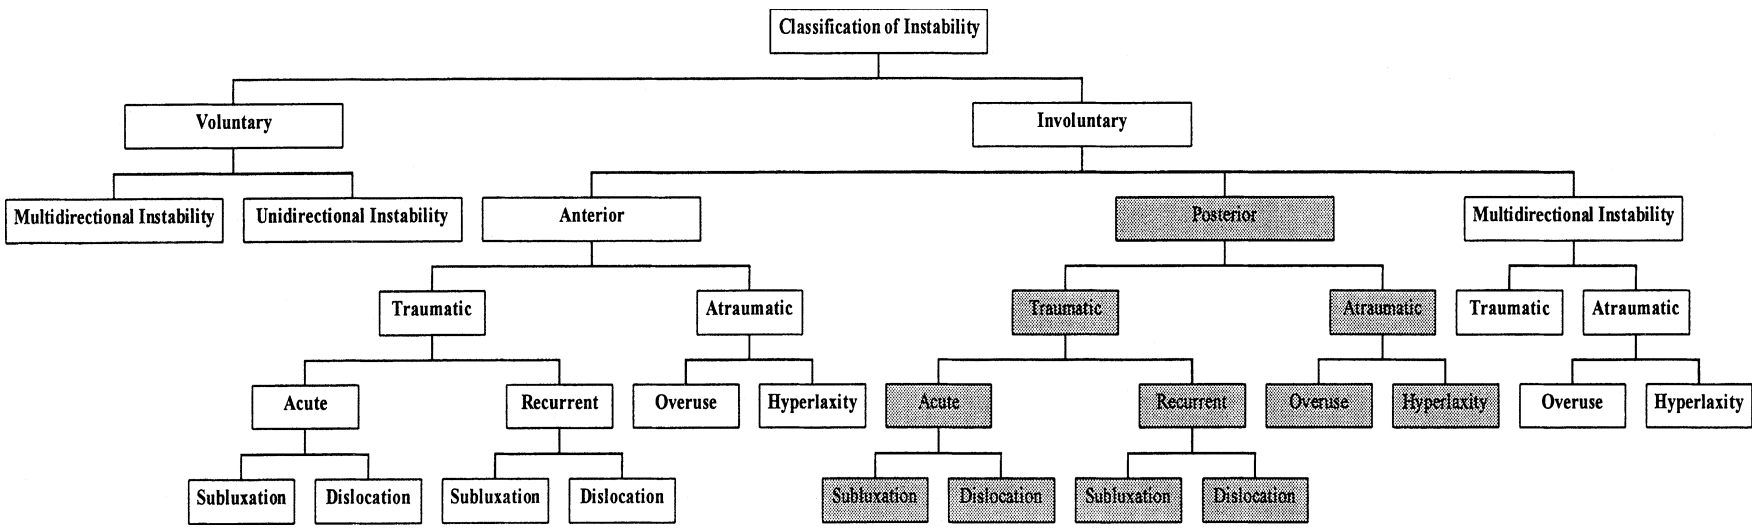

Figure 11-1 Classification of instability. (Modified from ref. 81 with permission.)

shoulder dislocation occurring after age 40. In patients older than 60, Gumina and Postacchini reported a 61% incidence of rotator cuff tears and a 9.3% incidence of axillary nerve palsy.[34] The inability to lift the arm overhead in older patients after an initial traumatic anterior dislocation is more likely to be related to a rotator cuff tear than to an axillary nerve palsy.

Traumatic instability may involve injuries to the capsulolabral complex or the osseous structures of the shoulder. These injuries typically take place with the arm in the "at risk" position of shoulder abduction and external rotation. Injuries to the inferior glenohumeral ligament complex may be at the humeral insertion site (HAGL—humeral avulsion of glenohumeral ligament),[132] midsubstance, glenoid (Bankart lesion), and rarely at both the humeral and glenoid.[21] The lesion may also be associated with a stripping of the periosteum off the glenoid (ALPSA—anterior labroligamentous periosteal sleeve avulsion).[81] Anterior inferior glenoid rim fractures (bony Bankart) and Hill-Sachs lesions can occur as the humeral head passes anterior to the glenoid. Large osseous lesions of either type may result in significant instability.

An anterior shoulder dislocation is diagnosed on the basis of the physical and radiographic examinations. Patients may present with an adducted and internally rotated arm and may be unable to externally rotate or fully abduct the extremity. The humeral head can often be palpated along the anterior aspect of the shoulder, whereas the posterior aspect may appear hollow. The posterior acromion may also seem more prominent. Manual reduction maneuvers are required to relocate the shoulder.

Recurrent anterior dislocations after an initial traumatic event can occur secondary to both traumatic and atraumatic causes. The rate of recurrent instability varies widely and is age dependant. Patients younger than 30 years have a higher redislocation rate when compared to older populations. Estimated rates of dislocation in patients younger than 30 years have been reported to be as high as 92% in some studies.[129] In a study of patients with primary traumatic anterior dislocations, Kralinger et al. found the only factor associated with recurrent dislocation was age between 21 and 30 years.[60] Other factors have also been noted to influence the rate of dislocation, including activity level, compliance with rehabilitation, contralateral shoulder instability,[86] glenoid rim avulsion fractures,[5] and large Hill-Sachs lesions.

Recurrent atraumatic instability (e.g., positional related dislocations) suggests a structural hyperlaxity with significant associated dysfunction. The time interval between the initial traumatic episode and subsequent nontraumatic dislocations will depend on the treatment after the original event and the degree of injury to the soft tissue or osseous stabilizers of the shoulder.[51] Early recurrent dislocations are seen in patients with concomitant large rotator cuff tears, severe disruption of the capsulolabral complex, and large fractures of the glenoid rim and/or greater tuberosity. Prompt operative fixation is recommended when these conditions are present.[99]

Anterior Subluxation

In an anterior subluxation, it is often difficult to identify an initial traumatic event. Rowe and Zarins[104] described recurrent transient subluxation of the shoulder causing a "dead arm syndrome." It is characterized by a sudden, sharp or paralyzing pain in the affected arm when the shoulder is forcibly moved into a position of maximum external rotation in elevation or is subjected to a direct blow. This condition is most common in overhead-throwing athletes.

The shoulders of baseball pitchers are exposed to high-energy repetitive stresses that can exceed the rate of tissue repair.[62] This process can damage or stretch the static stabilizing structures and, in turn, place an increased amount of demand for stability on the dynamic stabilizers. As the static stabilizers become attenuated, increased stress is placed on the dynamic stabilizers or rotator cuff muscles, which can fatigue. Anterior subluxation may occur as the compensatory mechanism becomes overloaded. This, in turn, can lead to subacromial impingement as the humeral head subluxates anteriorly and contacts the coracoacromial arch. Moreover, with anterior subluxation, the tendinous portion of the supraspinatus and infraspinatus may impinge on the posterosuperior border of the glenoid rim, resulting in glenoid impingement. Swimmers, volleyball players, and other overhead-throwing athletes may experience similar symptoms. These overhead athletes generally present with pain or discomfort that affects performance, rather than presenting with frank episodes of dislocation.

Occult instability may also be present in nonthrowing athletes. For weight lifters,[32] anterior subluxation may be the primary etiologic factor of shoulder dysfunction and pain. Weight-lifting maneuvers that produce forced abduction, extension, and external rotation (such as military presses, flies, bench presses, and latissimus pull-downs) may cause subluxation.

Multidirectional Instability

Patients with multidirectional instability have symptomatic instability in more than one plane of motion. Signs and symptoms can be subtle, and the condition in athletes is often mistaken for unidirectional instability. Most commonly, multidirectional instability is atraumatic, resulting from repetitive stress on a loose or hyperlax shoulder. The pathology is related to a large, lax capsule. This laxity may extend anteriorly, inferiorly, and even posteriorly. However, multidirectional instability may also present in patients without excess laxity of the shoulder. An acquired form can develop in individuals who sustain multiple traumatic events or repetitive microtrauma to the shoulder.

The traumatic forms may also exhibit a labral detachment in association with capsular laxity.[97]

Although diagnosis is frequently difficult, certain physical examination findings differentiate this condition from unidirectional instability. The patient with multidirectional instability exhibits inferior instability on examination of the affected shoulder.[77] Application of downward longitudinal traction on the humerus may exhibit a sulcus sign. A 2-cm distance between the humeral head and inferior acromion or an asymmetrical difference in sulcus signs between the shoulders is considered positive when symptomatic. When the sulcus sign is asymptomatic, it is considered a sign of inferior laxity.[28,71] These patients may also have generalized ligamentous laxity. Swimmers and gymnasts with multidirectional instability will often demonstrate capsular laxity without other pathologic lesions, in contrast to athletes in contact sports who will frequently exhibit an associated Bankart or Hill-Sachs lesions.[1,78]

The accurate diagnosis of multidirectional instability is essential as treatment options differ significantly from unidirectional instability. Neer and Foster highlighted three types of errors in diagnosis in their description of the inferior capsular shift[77]:

1. Treatment of subacromial impingement or biceps pathology rather than instability
2. Failure to address the redundant inferior capsule with resultant residual inferior instability
3. Overtightening of a hypermobile joint with secondary fixed subluxation or dislocation resulting in severe arthritis

Significant pitfalls exist in both the over- and underdiagnosis of multidirectional instability. Patients with unidirectional instability may undergo unnecessary procedures in an attempt to prevent laxity in other directions. Or, those with multidirectional instability, if unrecognized, may undergo stabilization procedures that do not address the inferior instability. McFarland et al. recognized the importance of establishing clearly defined parameters for diagnosing multidirectional instability. They demonstrated significant variability in the number of patients diagnosed with multidirectional instability when comparing four existing classification systems. The use of capsular laxity testing without uniform and well-defined criteria resulted in an overestimation of patients with multidirectional instability.[71]

Acute Posterior Dislocation

Acute posterior dislocations are rare and account for approximately 5% of all dislocations. They are considered acute when recognized within the first 6 weeks of injury.[42] Direct trauma to the front of the shoulder, a posteriorly directed force on an adducted arm (e.g., fall on an outstretched hand), and indirect muscle forces (e.g., seizure or electric shock) can all cause posterior dislocations. Acute posterior dislocations are unrecognized in 50% to 80% of patients at initial presentation[42,73,104] and are often misdiagnosed as a frozen shoulder. Emphasis on clinical examination and complete radiographic evaluation are essential in establishing the diagnosis. Posterior dislocations are also associated with impaction fractures of the humeral head (reverse Hill-Sachs lesion) and sometimes fractures of the surgical neck or tuberosities.

Chronic Posterior Dislocation

Chronic posterior dislocations are missed acute episodes that have remained unrecognized for at least 6 weeks. Chronic dislocations usually present with large impression fractures or reverse Hill-Sachs lesions that lock the humerus in a posterior position and demonstrate limited motion, shoulder dysfunction, and deformity.

Volitional Recurrent Posterior Subluxation

Voluntary recurrent posterior subluxation describes a group of patients with an underlying conscious or unconscious ability to subluxate their shoulder by using abnormal patterns of muscular activity. In this group, there is no initial anatomic pathology of the glenohumeral joint. Over time, stretching of the glenohumeral ligaments can occur such that an involuntary component to the instability develops. Some of these patients have underlying psychiatric disorders as a cause for willful and voluntary posterior subluxation. Rowe et al. labeled these patients habitual dislocators.[103] Habitual dislocators are distinguished from other patients with posterior subluxation who may have learned how to reproduce their instability by their willful desire to subluxate their shoulders (Fig. 11-2). Despite the best intentions of the treating physician, habitual dislocators will frustrate all treatment efforts (operative and nonoperative) because of their abnormal psychological need to subluxate their shoulder.[103] The predominant pathologic process in this group of patients is psychologic and treatment should be directed toward their psychological needs. Surgical intervention in this group is contraindicated.

A second group of patients can voluntarily reproduce their instability, but they have no underlying psychological need to do so. This is a learned behavior that over time may develop an involuntary component. It is this involuntary component that is bothersome to the patient and often initiates evaluation by a physician. This type of instability is not based on secondary gain, but can be demonstrated repetitively by the patient.

Electromyographic evaluation of these patients demonstrates selective inhibition of certain muscle groups that results in an unbalanced force couple leading to posterior subluxation. Activation of the deltoid and pectoralis major, without opposition from the posterior short rotators,

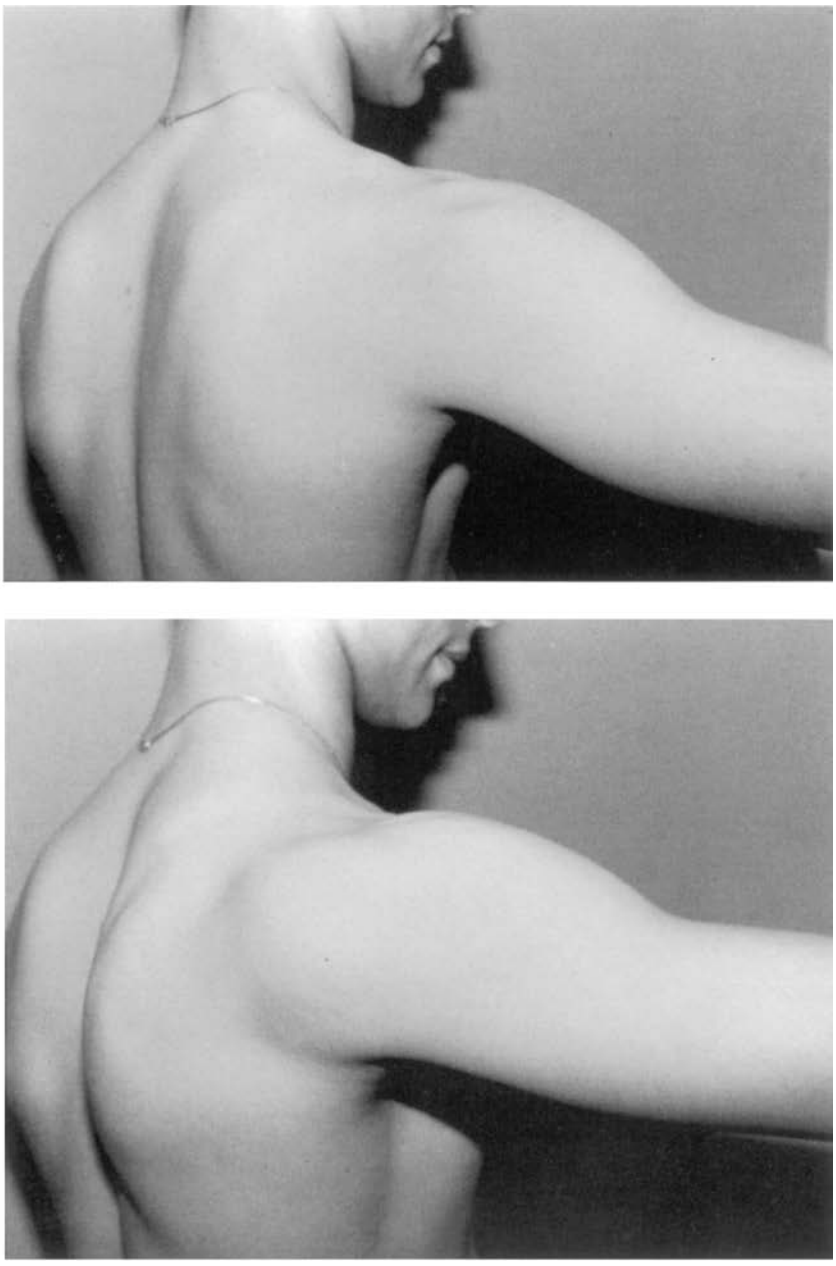

Figure 11-2 Photograph of a patient **(A)** before and **(B)** after dislocating his shoulder posteriorly with asymmetrical muscular contraction.

resulted in pushing of the humeral head posteriorly in several patients.[103] Alternately, Pande et al. demonstrated that unopposed activation of the posterior short rotators and posterior deltoid could pull the humeral head posteriorly.[92]

Dysplastic Recurrent Posterior Subluxation

Dysplasia of the glenohumeral joint is another uncommon cause of recurrent posterior subluxation.[15] Localized posterior glenoid hypoplasia, increased glenoid retroversion, and increased humeral head retroversion are potential causes of recurrent posterior subluxation. Recent investigations have documented a relatively low incidence of abnormal bony architecture in patients with instability and have postulated that developmental bony deformities can be a cause of recurrent posterior subluxation.[26,98,130] In a cadaveric study of 11,000 shoulders, up to 35% of the specimens had deficiencies in the posteroinferior aspect of the glenoid.[15] While the anatomic findings are of interest, correlation with instability could not be ascertained.

Recent computed tomography (CT) scan studies assessing glenoid version vary widely on the incidence of abnormal glenoid geometry and its contribution to instability. Gerber et al. and Randelli and Gambrioli found no correlation between altered glenoid version and instability.[26,98] Conversely, Hurley et al. and Wirth et al., in their respective

series, demonstrated increased glenoid retroversion and isolated posterior glenoid hypoplasia, respectively, in all patients with recurrent posterior subluxation.[49,131] While the true incidence of increased glenoid retroversion or hypoplasia in patients with recurrent posterior subluxation is unknown, it is likely that these factors can contribute to recurrent instability in some cases.[130]

Several findings on routine shoulder radiographs have also been associated with this condition. Radiographic findings include a shallow or irregular glenoid fossa, prominent coracoid process, enlarged acromion, hooking of the distal clavicle, associated hypoplasia of the upper ribs, and flattening of the humeral head.[9,18,119] The appearance and degree of these abnormalities vary in patients with this condition. CT scans can also be useful in delineating the severity of glenoid hypoplasia. Smith and Bunker reviewed 12 patients with primary glenoid dysplasia and noted that while younger patients may respond well to physical therapy, results will become less predictable with increasing age.[116]

Abnormalities of humeral torsion can lead to glenohumeral instability. While accurate measurement of humeral retrotorsion can be difficult, Schutte et al. described a reliable measuring technique using CT imaging.[108] This allows direct measurements of humeral retrotorsion, thereby eliminating the inaccuracy of plain radiographs. Kronberg and Brostrom have documented a correlation between decreased humeral retrotorsion and anterior glenohumeral instability in some patients. However, a relation between increased humeral retrotorsion and recurrent posterior subluxation has not been established.[61]

Reports of proximal humerus rotation osteotomy for the treatment of recurrent posterior subluxation are not supported by radiographic data demonstrating increased humeral retrotorsion.[9,121] The rationale for osteotomy in these series is that patients with recurrent posterior subluxation can provoke symptoms of instability by internal rotation of the arm. Limiting internal rotation through osteotomy was believed to correct the problem by preventing the patient from placing the arm in a position that would incite dislocation.

Acquired Recurrent Posterior Subluxation

Recurrent posterior subluxation is predominantly acquired either as a result of repetitive microtrauma or a single traumatic event. Traumatic events can cause both osseous and soft tissue abnormalities resulting in recurrent posterior instability. More importantly, in this group, the underlying pathologic lesion is critical to treatment and is used to categorize or define the instability. Lesions of the capsule, labrum, rotator cuff musculature, and glenoid can all contribute to recurrent posterior subluxation. The most common deficiency is a redundancy of the posterior capsule.[110] Additionally, dysfunction of normal scapulothoracic mechanics can place the glenohumeral joint at risk for recurrent instability.

Unlike the anterior capsule, the posterior capsule is thin. Together with the buttress provided by the glenoid labrum, they function as the primary static stabilizers to unidirectional posterior translation. Dynamic posterior stability is conferred by the rotator cuff musculature. The posterior capsule either stretches over time due to repetitive microtrauma or tears as a result of a single event. It can heal in an elongated position and thereby increase capsular volume. Posterior labral tears have been described with recurrent posterior subluxation; however, they are generally degenerative lesions rather than the rare capsular and labrum avulsion (i.e., reverse Bankart lesion) (Fig. 11-3).

The circle concept of capsuloligamentous stability addresses the relation between the anterior soft tissues and posterior stability.[109,110,117,122,127] Several biomechanical studies have investigated the contribution of anterior soft tissue structures to posterior stability. In addition to posterior capsular avulsion and partial or complete tearing of the tendinous portion of the posterior rotator cuff, various lesions of the anterior soft tissue structures have been identified. These include complete anterior capsular avulsions from the humeral neck and tears of the muscular portion of the subscapularis.[76,88]

Selective cutting of soft tissue structures thought to contribute to posterior stability has further defined the role of the anterior and posterior restraints to static posterior stability. Increased posterior translation consistently required a lesion of the posterior capsule, particularly the posterior band of the inferior glenohumeral ligament.[88] Isolated sectioning of the posterior rotator cuff musculature in the absence of a capsular lesion did not increase posterior translation.[87] Only when the posterior capsule was sectioned

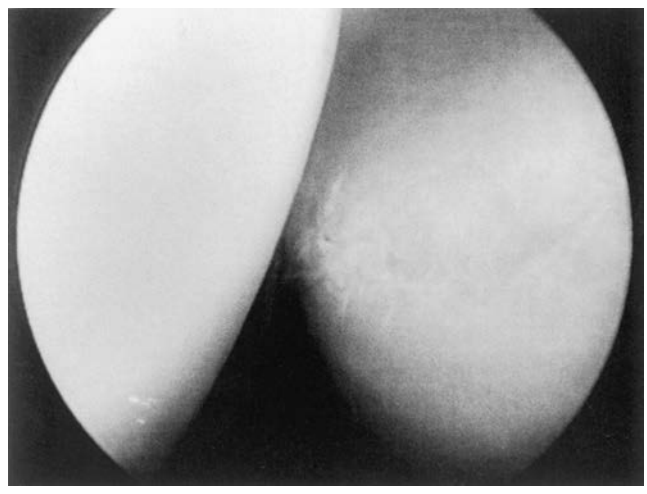

Figure 11-3 Arthroscopic photograph of a degenerative posterior labrum in a patient with recurrent posterior instability. Degenerative lesions of the labrum are typical for recurrent posterior instability. True reverse Bankart lesions are rare.

inferiorly was an increase in posterior translation noted. To effect subluxation or dislocation, sectioning of the anterior capsule and subscapularis tendon were required.

Several studies have found that the superior capsule (rotator interval) also plays an important role in posterior stability.[38,110,111] Sectioning the soft tissues of the rotator interval capsule often increased posterior and inferior translation to the point of dislocation, whereas imbrication of the rotator interval increased resistance to posterior and inferior translation.[38]

Acquired posterior subluxation is less commonly caused by posterior glenoid rim deficiency. Although it is uncommon, it can exist and should be investigated with imaging studies if suspected.[23,84,110] The relation between the degree of posterior glenoid erosion and recurrent posterior subluxation has not been established. It seems reasonable to assume that a large posterior glenoid defect will compromise the buttress effect of the glenoid to posterior translation.

In the resting state, the scapula lies on the posterolateral thorax at an angle of 45 degrees.[63] This position on the thorax places the posterior glenoid behind the humeral head, buttressing it against posteriorly directed forces. With shoulder elevation, the scapula rotates under the humeral head and provides a platform for glenohumeral motion.[101] A requisite for shoulder stability is that scapulothoracic and glenohumeral rhythm remains synchronous.[11,126]

Dysfunction of the scapulothoracic rhythm may compromise the stability of the glenohumeral joint.[126] The serratus anterior muscle plays a key role in this relationship. Its paralysis will result in scapular winging and loss of power in elevation that can potentially influence glenohumeral stability.[20] Warner et al. used Moire topographic analysis to study patients with glenohumeral instability and demonstrated abnormal scapulothoracic mechanics compared with those of asymptomatic patients.[126] Although no patient demonstrated severe scapular winging, the degree of scapulothoracic dysfunction was variable. In patients with glenohumeral instability and lesser degrees of scapulothoracic dysfunction, it is unclear whether instability is the result of altered scapulothoracic mechanics or the cause of it.

CLINICAL EVALUATION

A thorough history and physical examination are paramount to the diagnosis of glenohumeral instability. Plain radiographs will often augment or confirm the diagnosis; however, they are frequently normal. Further evaluation with more sophisticated imaging techniques such as fluoroscopy, CT, and magnetic resonance imaging (MRI) provides useful information but is not essential for the diagnosis. Examination under anesthesia and diagnostic arthroscopy are helpful tools in establishing the diagnosis in difficult cases and may serve as further confirmation of established clinical diagnoses.

History

Knowledge of the details surrounding the onset of symptoms is critical to establishing a diagnosis of glenohumeral instability. The age when symptoms began has significant prognostic value on determining the likelihood of recurrent instability. Detailing the mechanism of initial injury will help delineate between high-energy traumatic events (i.e., motor vehicle accidents), minimal traumatic events (i.e., throwing or swimming), or atraumatic events (i.e., combing hair). Similarly, the position of the arm during dislocation and the direction of the trauma help in understanding the potential direction of instability. The ease of relocation (i.e., need for manual reduction) and documentation of the direction of instability with radiographs aid in the diagnosis. Important information is gained by delineating further episodes of instability, the frequency at which they occur, the position at which they occur, and the ease of relocation after each event.

Prior treatment of any instability should be ascertained. If the patient was immobilized, then the position and duration of immobilization as well as any subsequent rehabilitation should be detailed. Past attempts at surgical management and the details of the operations should be obtained. Changes in the pattern of dislocation after surgery also provide essential information.

In nonlocked dislocations, patients will often complain of positional shoulder pain or discomfort; this pain may be present only after a frank subluxation or dislocation. Some patients may report shoulder pain that is dependant solely on the position of the shoulder, while others may only complain of a dull ache that is independent of arm position. Careful delineation between apprehension and pain is essential as pain may be indicative of other intraarticular pathology in the shoulder (e.g., rotator cuff tears). Apprehension with shoulder abduction and external rotation suggests anterior instability, while symptoms with the arm in flexion, adduction, and internal rotation suggest posterior instability. Patients may note pain while carrying heavy objects in an adducted position consistent with inferior instability. Overhead athletes may note a decrease in velocity, accuracy, or distance without episodes of dislocation that may be suggestive of more subtle forms of instability. In these athletes, the position of the arm where symptoms occur may help further elucidate the pathology. Pain during the cocking phase may indicate anterior instability, whereas pain in the follow-through phase may indicate posterior instability.

Further questioning is necessary to exclude other causes of shoulder pain. Pain radiating from the neck may be secondary to cervical spine disease. Pain referred from the hand may be secondary to compressive neuropathies.

Finally, the issue of volitional control over the instability should be addressed. A history of voluntary dislocation should alert the physician. Identification of the habitual dislocator, who dislocates for secondary gain, can have an important impact on prognosis.[102] The physician should be watchful of nonverbal clues that may signify underlying psychiatric illness. Patients who develop painful instability and subsequently learn to voluntarily dislocate, however, should be grouped separately.

Physical Examination

General Principles

It is important to obtain an overall evaluation of the musculoskeletal system through a systematic approach of inspection, palpation, range-of-motion analysis, strength testing, neurologic evaluation, shoulder stability assessment, and specialized testing. Range-of-motion and provocative testing of the cervical spine are required to exclude spinal disorders that may present as shoulder pain. Neurologic manifestations of cervical disease may be assessed by range-of-motion testing. It is unlikely that a patient with a full, painless range of motion will have clinically significant cervical spine pathology.

Visual inspection before examination may provide valuable information. The skin should be inspected for evidence of collagen disorders, which can present as thinning or widening of surgical or traumatic scars. Shoulder dislocation may injure the axillary nerve, so it is important to evaluate for deltoid atrophy and weakness. The sulcus sign, a visible depression inferior to the lateral edge of the acromion, may occur in patients with multidirectional instability caused by inferior luxation of the humeral head. Winging of the scapula may be evident in patients with anterior or posterior subluxation or secondary impingement and pain.

Both active and passive range of motion should be recorded. Forward flexion, abduction, internal rotation, and external rotation should be tested. The clinician should note dyskinesia and whether accessory muscles are activated with range-of-motion testing.

The shoulder girdle should be palpated for local tenderness and muscle tone. Patients with anterior subluxation often have tenderness over the posterior capsule, whereas those who are compensating for multidirectional instability may be tender along the medial angle of the scapula. Patients with anterior instability caused by subluxation and secondary impingement may have tenderness over the greater tuberosity or biceps tendon. Crepitation occurring on range-of-motion testing should be noted. While the motion of the upper extremity is being assessed, it is important to examine strength in the pain-free range of motion, paying particular attention to external rotation, internal rotation, and abduction strength to rule out rotator cuff pathology. These results should be compared with the uninjured side.

Generalized ligamentous laxity may be associated with shoulder instability. This should be assessed by evaluating range of motion in several joints. The degree of thumb hyperabduction with volar flexion of the wrist as well as index finger, elbow, and knee hyperextension should be noted. The tip of the thumb should not touch the volar aspect of the wrist and the index metacarpophalangeal angle should not exceed 90 degrees in the absence hyperlaxity (Fig. 11-4).

Specific Tests

After the preliminary examination, specific tests for instability should be performed. Asymptomatic shoulders often have considerable capsular laxity[37]; thus, the examination should first be initiated on the unaffected shoulder to obtain baseline data for each subsequent test. This approach also provides the

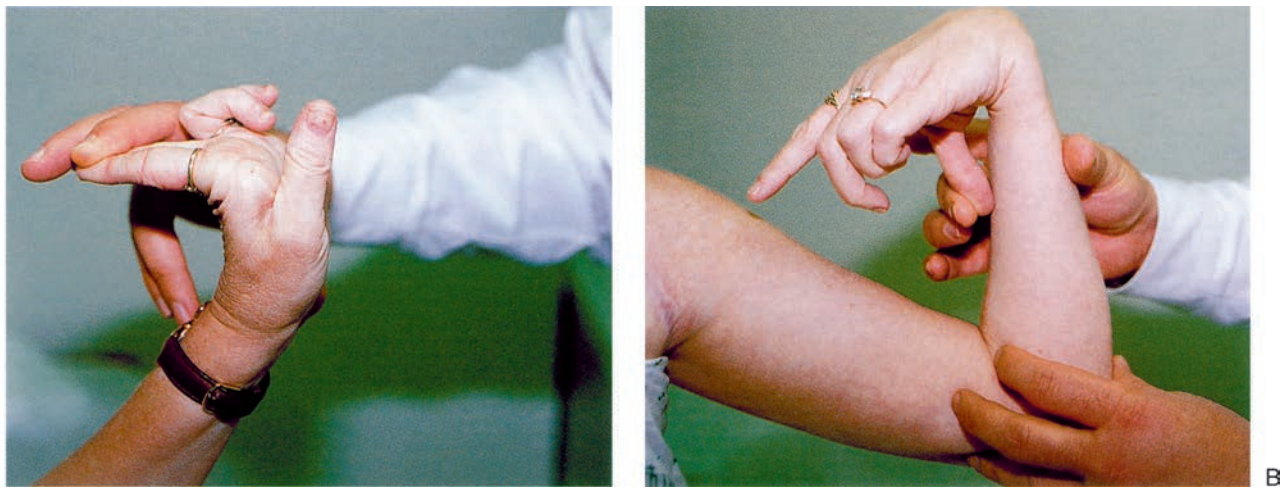

Figure 11-4 Patient with ligamentous laxity and index metacarpophalangeal angle of 90 degrees.

patient with the opportunity to become comfortable with each maneuver. Two components are considered when assessing the stability of the glenohumeral joint: (1) the amount of passive translation of the humeral head and glenoid fossa on stress testing, and (2) attempts to reproduce the symptoms of subluxation and apprehension by provocative testing of the shoulder in positions of compromise.

Sulcus Sign Test

The sulcus sign test[76] establishes the presence of inferior laxity, which if symptomatic is necessary to establish the diagnosis of multidirectional instability. In a patient with gross instability, a depression may be seen inferior to the anterior aspect of the acromion when the arms of a sitting patient are positioned along the side of the body. However, it is usually necessary to apply a traction force along the longitudinal axis of the humerus by pulling the humerus in an inferior direction. The distance between the acromion and the humeral head is then observed and recorded in centimeters. A measurement of 2 cm or more or an asymmetrical symptomatic sulcus sign is considered positive for inferior instability (Fig. 11-5).

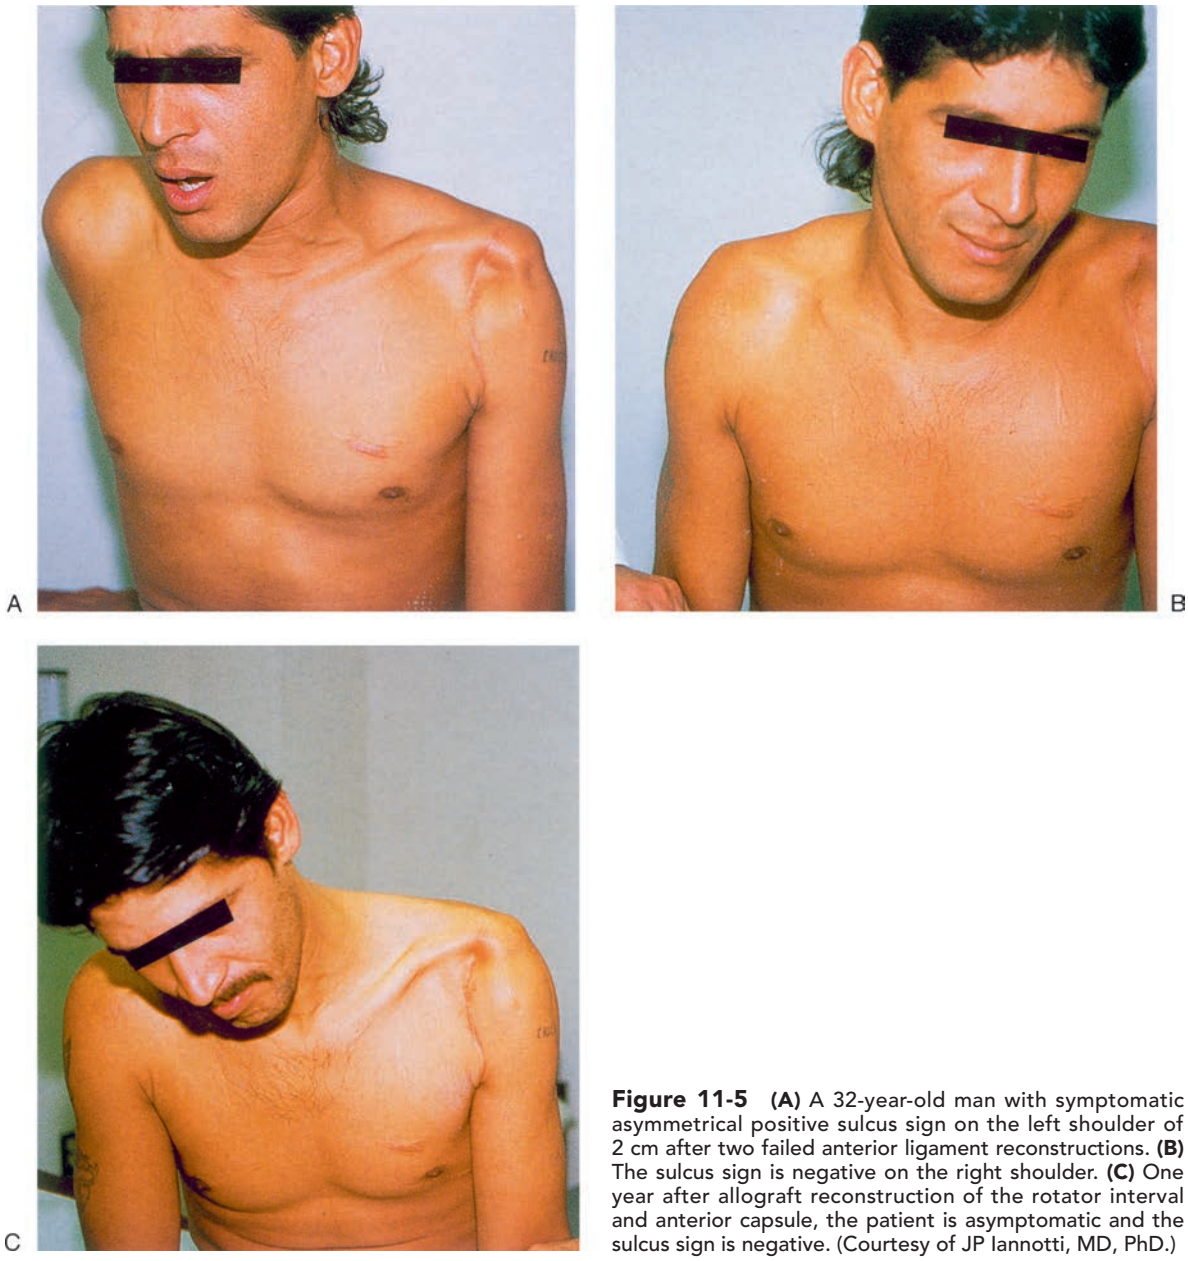

Figure 11-5 **(A)** A 32-year-old man with symptomatic asymmetrical positive sulcus sign on the left shoulder of 2 cm after two failed anterior ligament reconstructions. **(B)** The sulcus sign is negative on the right shoulder. **(C)** One year after allograft reconstruction of the rotator interval and anterior capsule, the patient is asymptomatic and the sulcus sign is negative. (Courtesy of JP Iannotti, MD, PhD.)

Translation Tests (Load and Shift)

Glenohumeral translation should be evaluated in both the upright and supine positions. The load-and-shift test establishes whether clinically significant translation of the humeral head is possible and if this translation reproduces the patient's symptoms. The examiner stands behind the seated patient with one hand on the affected shoulder. The other hand holds the proximal humerus with the thumb on the posterior aspect of the humeral head and the index finger on the anterior aspect. The initial movement is to load the humeral head into the glenoid fossa, reducing the inherent subluxation. Then the examiner attempts to shift the humeral head in anterior, posterior, and inferior directions while observing the area adjacent to the acromion for a sulcus sign.

Translation should also be evaluated in the supine position. The patient is positioned such that the center of the scapula rests on the edge of the examination table to eliminate a portion of scapulothoracic motion. The examiner grasps the humerus in a position of 20 degrees of abduction and forward flexion (the plane of the scapula) with neutral rotation. The humeral head is loaded and then stressed anteriorly, posteriorly, and inferiorly while the examiner notes the amount of excursion. The amount of excursion can be graded based on the degree of humeral head translation relative to the glenoid: grade 0, minimal movement; grade 1+, humeral head rides up onto the labrum (greater than contralateral side); grade 2+, humeral head subluxed but spontaneously reduces; and grade 3+, humeral head dislocates and remains dislocated.[1,125] The reproduction of the patient's symptoms during the translation tests confirms instability in the corresponding direction.

There have been several attempts to obtain an objective assessment of glenohumeral instability.[37,56,124] However, there has been no mechanism to assess quantitative translation of glenohumeral instability to date. The clinical methods described previously are subjective and rely heavily on clinical experience. Several studies have looked at the reproducibility of these tests. The reproducibility of the load-and-shift translation test was found to be 46% overall; however, when grades 0 and 1 were equalized, the reproducibility improved to 74%.[64] McFarland et al. and Ellenbecker et al. have found similar rates of reproducibility.[16,71]

Authors' Preferred Technique

Anterior Instability

Examination of the shoulder for instability using the load-and-shift technique is performed with the patient in the supine position. To test for anterior translation on the patient's right shoulder, the examiner positions the patient's arm in the plane of the scapula, at 45 to 60 degrees of abduction and neutral external rotation (Fig. 11-6). The examiner then places the left hand around the patient's arm

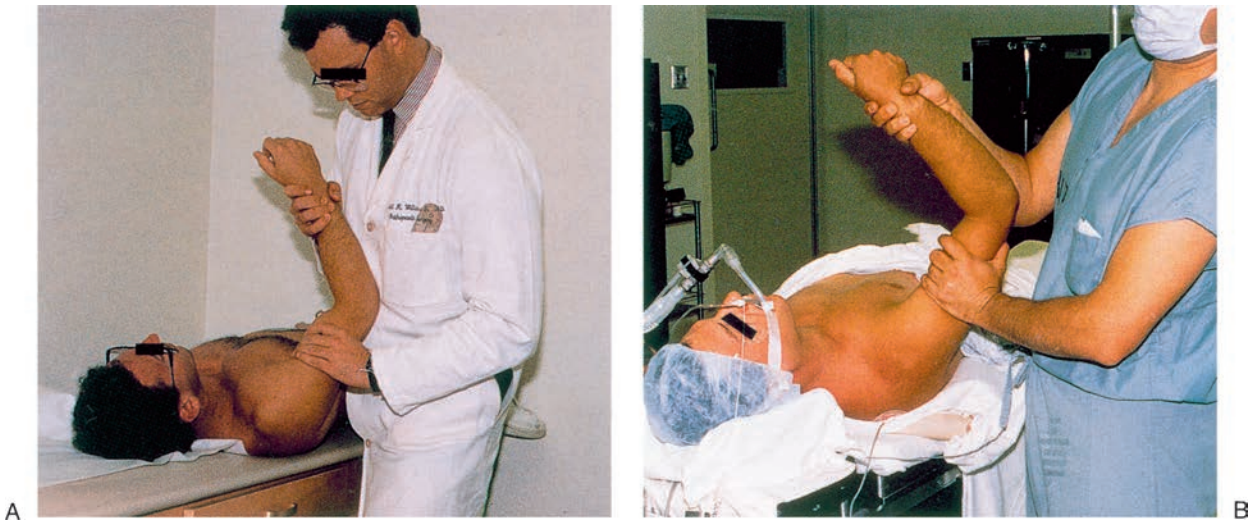

Figure 11-6 Initial position for load-and-shift test for anterior instability testing of the shoulder. For a right shoulder examination, the examiner's left hand grasps the patient's upper arm with the fingers anterior. The examiner's right arm positions the patient's arm and controls its rotation. The arm is placed in the plane of the scapula, abducted 40 to 60 degrees, and maintained in 0 degrees of rotation. The examiner's right arm places an axial load to the patient's arm through the humerus. The examiner's left hand then shifts the humeral head anteriorly, or anteroinferiorly over the glenoid rim. Grade 1 translation occurs when the humeral head rides over the anterior glenoid rim. Grade 2 translation occurs when the entire humeral head rides over the glenoid rim, but reduces when the dislocation force is released. Grade 3 translation occurs when the entire humeral head translates over the glenoid rim and does not reduce when the dislocation force is released. This test can be performed in **(A)** the relaxed awake patient or **(B)** the anesthetized patient.

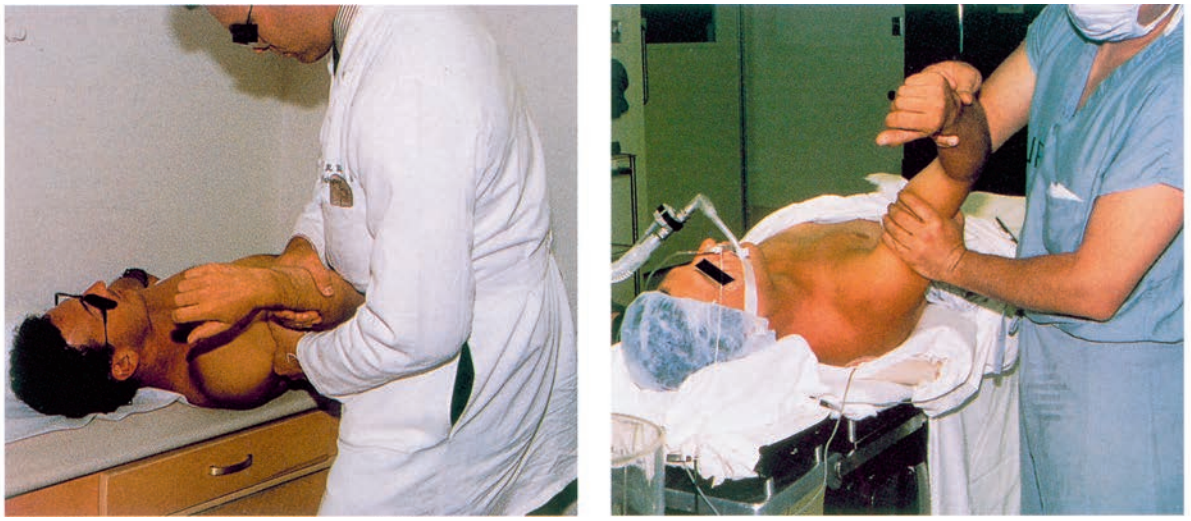

Figure 11-7 The second position for the load-and-shift test for the anterior stability is as described in Fig. 11-6 for the initial position, except that the arm is progressively externally rotated in 10- to 20-degree increments while the anterior dislocation force is alternatively applied and released. The examiner quantifies the degree of external rotation required to reduce the translation from grade 3 or 2 to grade 1. The examiner compares the normal and abnormal shoulders for this difference in translation with humeral rotation. The degree of rotation required to reduce the translation is an indicator of the functional laxity of the anterior inferior capsular ligaments. The examination is performed in **(A)** the relaxed awake patient or **(B)** the anesthetized patient.

at approximately the level of the deltoid insertion site with the thumb posterior and the remaining fingers anterior. The examiner's right arm controls arm position and provides an axial load to the humeral head to center it into the glenoid fossa. The examiner uses the left hand to provide an anterior or anteroinferior translation force to the humerus. When performed correctly, the scapula remains still and the amount of humeral head translation can be determined by both visual inspection and palpation. In almost all patients, there is some anterior or anteroinferior translation of the humeral head. As the examiner maintains an axial load to the humerus with the right arm, the patient's arm can be incrementally rotated into external rotation. With progressive external rotation of the humerus, the inferior glenohumeral ligament (IGHL) complex becomes taut (Fig. 11-7). With increased tension on the IGHL, there is decreasing anterior translation of the humeral head in the glenoid fossa.

Posterior Instability

To examine the patient's right shoulder, the arm is held in the plane of the scapula at 45 to 60 degrees of abduction and 45 to 60 degrees of external rotation. The examiner's hands are positioned in the same way as described for anterior translation testing, and an axial load is placed onto the humerus. The examiner's left hand is used to shift the head posteriorly. The examiner's right arm is used to incrementally internally rotate the patient's arm. During internal rotation, the posteroinferior capsule becomes increasingly tight, which should result in decreased posterior translation of the humeral head. It is important to note that in a normal shoulder, the humeral head can subluxate posteriorly up to 50%.[39,82]

Inferior Instability

The patient is examined in the seated position. The examiner first places a downward distraction force on the dependent humerus by applying traction at the distal humerus. The arm is in neutral rotation and the degree of humeral inferior translation (sulcus sign) is assessed in centimeters. The distraction force is then released, and the patient's arm is placed in maximum external rotation. The traction force is then reapplied and the sulcus sign is again measured. With external rotation, the anterior and rotator interval capsule is tightened (Fig. 11-8). Tightening these tissues should decrease the amount of inferior translation of the humeral head.

The examiner evaluates differences between shoulders, assuming the opposite shoulder is normal. In the awake patient, this examination may be limited by muscular guarding, which is not an issue with the examination under anesthesia. The examination in the awake patient may elicit painful grating or apprehension that can reproduce the patient's symptoms. The symptoms in the awake patient can help in defining the diagnosis; these symptoms are, of course, absent in the anesthetized patient. Therefore, it is our practice to perform this examination in both the awake and anesthetized patient as both examinations provide useful and complementary pieces of information.

Silliman and Hawkins[115] have provided a clinical grading system for this test. Grade I translation indicates that the humeral head can be felt to ride up on the face of the glenoid but cannot be moved over the glenoid rim. In grade II translation, the humeral head can be felt to glide over the glenoid rim, but it reduces spontaneously with release of pressure. This corresponds to clinical subluxation. Grade III

Figure 11-8 The sulcus sign tests the functional integrity of the superior glenohumeral ligament and rotator interval capsule. These tissues are lax in neutral rotation and tighten with external rotation. **(A)** A mildly positive sulcus sign (1 cm) on the *right*, which **(B)** does not reduce with external rotation, whereas the minor translation on the *left* does reduce with external rotation.

exists when the head remains dislocated after release of pressure, corresponding to clinical dislocation.

Apprehension Test

The apprehension test[104] places the shoulder in a provocative position of abduction and external rotation in an attempt to reproduce the patient's sensation of impending subluxation or dislocation (Fig. 11-9). This test should be performed in both the seated and supine positions. The examiner stands behind the seated patient, raises the patient's arm to 90 degrees of abduction, and begins to externally rotate the humerus. The hand of the examiner is placed over the humeral head with the thumb pushing the posterior aspect of the humeral head for extra leverage. Fingers are placed anteriorly to control any sudden instability

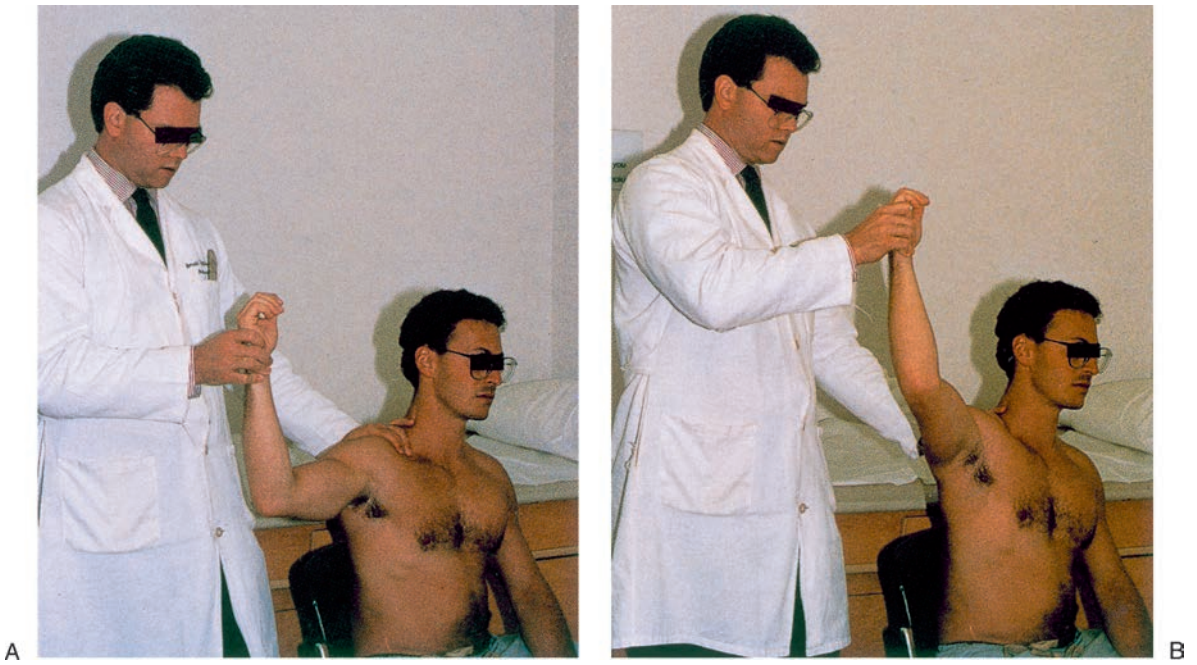

Figure 11-9 The apprehension test is performed by placing the arm in a position of abduction and external rotation in an attempt to produce a patient's feeling of subluxation or dislocation. The patient is tested in the seated position with the arm **(A)** at 90 degrees of abduction and **(B)** at 120 degrees of abduction. The higher degree of abduction places greater stress on the inferior capsular pouch.

that might occur. With increasing external rotation and controlled gentle forward pressure exerted against the humeral head, the patient may have an apprehensive feeling of impending instability. The patient communicates this apprehension verbally, by facial expression, or by protectively contracting the shoulder muscles.

This test is more easily performed in the supine position because the scapula is stabilized against the edge of the examining table, giving the examiner more control over the maneuver. The edge of the table acts as a fulcrum and the arm acts as a lever. As the humeral head is levered anteriorly, the amount of external rotation required to produce apprehension is noted.

In evaluating throwing athletes, Jobe et al.[54,55] described pain as the only positive finding in apprehension testing. Pain is suggestive of anterior subluxation, even in the absence of apprehension. Shoulder pain in this position must be differentiated from that of impingement by performing a relocation test (discussion follows). However, Speer et al.[118] showed that pain was poorly correlated with instability and that apprehension was more specific to the diagnosis. When apprehension rather than pain was used to determine a positive test, the accuracy of the relocation test improved from less than 50% to greater than 80%.[118] Pain with abduction and external rotation that is relieved by the relocation test may reflect internal glenoid impingement.

Relocation Test

The relocation test[55] should be performed in conjunction with the apprehension test (Fig. 11-10). With the arm in the position that produces apprehension, a posteriorly directed stress is exerted on the proximal humerus. Both the apprehension and the pain should disappear with this maneuver. This test presumably reduces the subluxation by pushing the humeral head posteriorly and thus relieving symptoms.

However, patients with rotator cuff involvement but no instability may have pain in the apprehension position and experience relief of pain with the relocation test. Such a patient may have a deep surface tear of the supraspinatus tendon, which is painful in the apprehension position because the tendon is trapped between the greater tuberosity and superior glenoid rim. The augmentation test, performed by pulling the humeral head forward while in the apprehension position, will increase the pain felt by rotator cuff patients, but will not augment pain in those with pure instability.

Release Test

The release test[115] is performed immediately after the relocation test. The examiner releases the posteriorly directed force on the humerus. A positive test occurs when the patient's symptoms return.

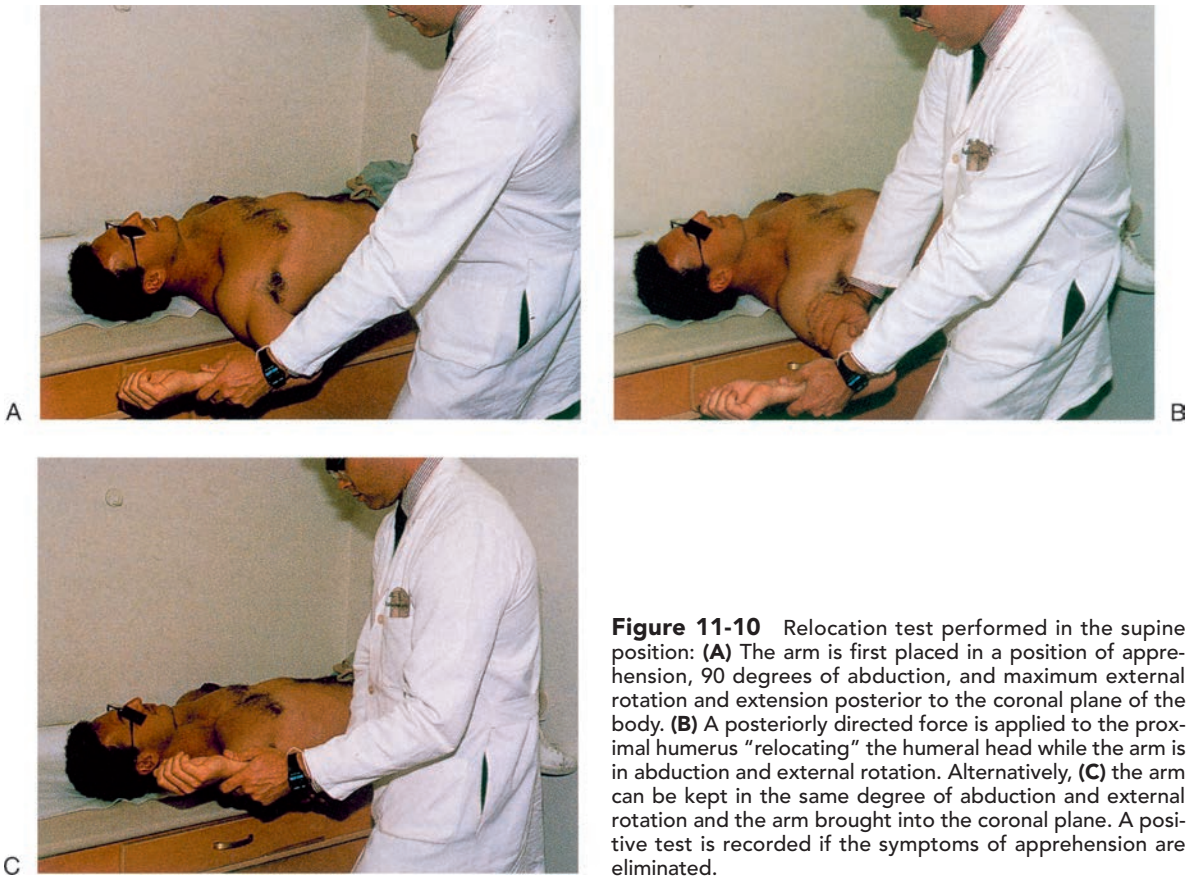

Figure 11-10 Relocation test performed in the supine position: **(A)** The arm is first placed in a position of apprehension, 90 degrees of abduction, and maximum external rotation and extension posterior to the coronal plane of the body. **(B)** A posteriorly directed force is applied to the proximal humerus "relocating" the humeral head while the arm is in abduction and external rotation. Alternatively, **(C)** the arm can be kept in the same degree of abduction and external rotation and the arm brought into the coronal plane. A positive test is recorded if the symptoms of apprehension are eliminated.

Tzannes et al. assessed the interexaminer reliability of provocative tests of the shoulder. Similar to the findings by Speer et al.,[118] they found the greatest consistency among examiners when apprehension rather than pain was used to determine a positive test. Additionally, they demonstrated a greater reliability for relocation and release tests than for the apprehension test.[125]

Lo et al. evaluated the validity of the apprehension, relocation, and release tests in detecting anterior instability. When the patient exhibited apprehension in all three tests, the positive and negative predictive values were 93.6% and 71.9%, respectively. The release maneuver was the single most accurate test of the three. Interobserver reliability was 83%.[66]

Posterior Apprehension Test (Posterior Stress Test)

The posterior apprehension test is performed with the shoulder adducted, internally rotated and flexed to 90 degrees. A posteriorly directed force is applied. A positive test occurs with subluxation causing pain. Apprehension typical of anterior instability is unusual.[40,96]

Hyperabduction Test (Range of Passive Abduction Test)

The hyperabduction test[24] was described to specifically address laxity of the inferior glenohumeral ligament. The physician stands behind the patient and places an inferiorly directed force on the scapula, while the neutral upper arm is abducted with the elbow flexed to 90 degrees. A positive test occurs with abduction of greater than 105 degrees. A positive hyperabduction test indicates laxity of the IGHL.

After a thorough physical examination, further diagnostic testing should be performed to clarify the nature and pattern of the instability.

Examination under Anesthesia

The numerous methods available for diagnosing shoulder instability may not provide sufficient information to proceed confidently toward operative treatment. Anesthesia is sometimes necessary to produce sufficient muscle relaxation and freedom from pain for an adequate examination. Under anesthesia, only a small amount of force is necessary to stress the ligaments of the joint capsule. Additionally, patients with subtle instability in the office may exhibit significant laxity under anesthesia. While examination under anesthesia (EUA) provides important information, it may not change the treatment algorithm.

Cofield and Irving[12] noted that EUA is the "most definitive, accurate, noninvasive test of shoulder instability." They described a systematic method for shoulder examination in the anesthetized patient that should be applied to both shoulders:

The examiner stands by the side being examined and supports the limb in one hand by holding the midforearm. The other hand rests across the top of the shoulder with the proximal aspects of the fingers resting on the acromion as a point of reference. The thumb can then be used to force the humeral head forward and the index and long fingers can be used to force the humeral head posteriorly. When assessing inferior translocatability, the hand supporting the limb moves proximally to the elbow to pull the arm downward. The sequence of examination is listed in Table 11-1.

TABLE 11-1
SEQUENCE OF INSTABILITY EXAMINATION

Direction	Force of Examining Hand	Force of Positioning Hand	Position of Arm
Anterior	Anterior	None	Abd 30° Ext 10° ER 0°, 45°, 80°
Anteroinferior	Anteroinferior	Toward joint in axis of arm	Abd 100° Ext 10° ER 0°, 45°, 80°
Posterior	Posterior	None	Abd 45° Flexion 30° IR 0°, 45°, 80°
Posteroinferior	Posterior	Toward joint in axis of arm	Abd 80° Flexion 45° IR 0°, 45°, 80°
Inferior	None	Away from joint (distraction)	Abd 0° Flexion 0° Rotation 0°

Abd, abduction; ER, external rotation; EXT, extension; IR, internal rotation.

The sensitivity and specificity of EUA is improved by examining the shoulder in various positions of shoulder elevation and rotation.[13] For the optimal determination of translation in the anterior direction, the arm is positioned in 80 degrees of external rotation and a load-and-shift test is performed. If the affected side demonstrates a higher grade of translation than does the unaffected side, then the test for instability is positive.[114] In one study,[114] negative examinations correlated with negative surgical findings in 28 of 28 cases, and 25 of the 27 patients with positive findings on examination under anesthesia had pathologic findings at surgery.

Faber et al. studied examination findings in patients with anterior instability while awake and under anesthesia. They found that anterior translation was higher during EUA than during awake examination in both symptomatic and asymptomatic shoulders. A subtle increase in instability during the awake examination was amplified during the EUA. They concluded that EUA is useful in confirming the direction and degree of glenohumeral instability.[19]

For the optimal determination of translation in the posterior direction, the arm is placed in 45 to 60 degrees of abduction and the humerus is placed in variable amounts of humeral rotation. With the arm in external rotation, the posterior capsular structures are lax, allowing posterior translation of the humeral head against a posteriorly directed force. Progressive internal rotation tightens these structures, resulting in capture of the humeral head and elimination of posterior translation against a posteriorly directed force. It is important to note the degree of internal rotation at which posterior translation is minimized. Differences in posterior translation in different arm positions when compared with the opposite shoulder are indicative of posterior capsular insufficiency.

Yoldas et al. evaluated patients with multidirectional instability. These patients demonstrated increased translation in all three directions when compared to the asymptomatic side during both the awake examination and EUA. The same study evaluated patients with posterior instability using awake examination and EUA. They found increased anterior translation in both symptomatic and asymptomatic shoulders during EUA; however, the posterior translation noted during awake examination did not change.[133]

EUA, when combined with diagnostic shoulder arthroscopy, can provide an accurate assessment of instability in most cases.

Diagnostic Arthroscopy

We routinely perform diagnostic arthroscopy on all patients before surgical repair of shoulder instability. It provides a precise diagnosis of the type of instability and associated injuries. A systematic approach should be developed in examining a shoulder with suspected instability.[68]

Shoulder arthroscopy may be performed in the lateral decubitus or beach-chair position. The beach-chair position requires additional assistance for control of the arm. It does, however, provide more versatility in arthroscopic examination and allows easier positioning for conversion to an open procedure if desired. After systematic examination of the joint for other pathology, we examine the inferior recess for loose bodies and the humeral head for the presence and size of a Hill-Sachs deformity. We evaluate for ease of movement of the arthroscope anteriorly through the glenohumeral joint and into the axillary pouch. A positive "drive-through" sign (described by Pagnani and Warren[90]) results from substantial laxity in the IGHL. A positive drive-through sign is considered present when, under distraction loading, the humeral head separates widely from the glenoid, facilitating easy passage (or "drive through") of the arthroscope from posterior to anterior. McFarland et al. recently reported a high sensitivity (92%) and low specificity (37.6%) for the drive-through sign in patients with instability. They concluded that the sign should not be used as the definitive or sole criterion for diagnosing instability. However, it is useful in identifying laxity.[72] Finally, we direct our attention to the anterior labrum and capsule to confirm the diagnosis and direct the appropriate treatment.

If present, a Bankart lesion is usually obvious, and it confirms the diagnosis of anterior instability (Fig. 11-11). It is not uncommon, however, to find a detached labrum with scar filling the defect. These lesions are not always apparent with initial inspection of the labrum, but can be

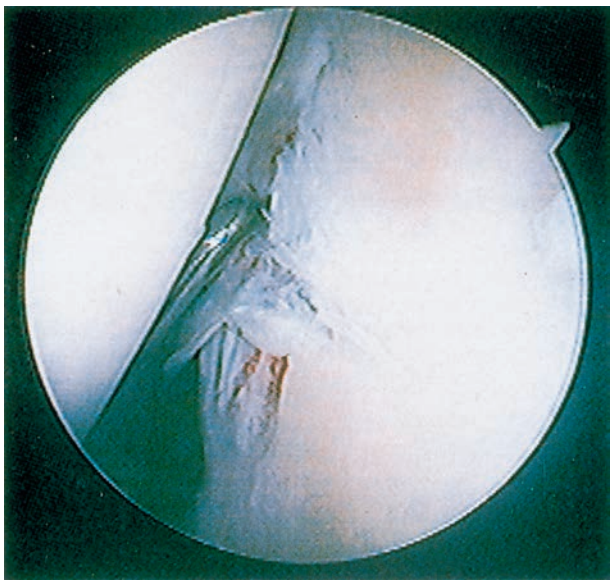

Figure 11-11 Arthroscopic photograph of an acute Bankart lesion.

defined with careful probing. A similar lesion of the posterior–inferior labrum seen in posterior or multidirectional posteroinferior instability was described by Kim et al.[58] This lesion is identified as a superficial tearing between the posteroinferior labrum and the glenoid articular cartilage. The labrum is not completely detached, but it appears flat with loss of its normal height.

Hintermann et al.[46] performed a prospective arthroscopic study of 178 patients, each of whom had at least one episode of shoulder dislocation. Reporting the arthroscopically determined pathologic findings, they concluded that associated injuries were more common than expected and that there were significant differences between preoperative and postoperative diagnoses. The most frequent arthroscopic findings were anterior glenoid labral tears (85%), ventral capsule insufficiency (80%), Hill-Sachs lesions (67%), glenohumeral ligament insufficiency (55%), rotator cuff tears (20%), posterior glenoid labral tears (8%), and superior labral anterior-to-posterior (SLAP) lesions (5%). They also noted that the labrum and anteroinferior glenoid rim showed abnormalities corresponding to different types of anterior instability. They concluded that prestabilization shoulder arthroscopy increases the accuracy of diagnosis and has the potential to identify the optimal surgical procedure. Caspari and Geissler[7] described other arthroscopic manifestations of anterior shoulder subluxations and dislocations that directed their surgical treatment. They included labral and anterior capsular injuries of varying severity.

Mok et al. reviewed 166 shoulder arthroscopies in patients with symptoms of subluxation without dislocation. Arthroscopy confirmed the working diagnosis in 80% and changed the diagnosis in 20%. They concluded that arthroscopy is instrumental in establishing a diagnosis in this difficult group of patients.[74]

Werner et al. reported the arthroscopic findings in patients with atraumatic shoulder instability that failed conservative treatment.[128] They found intraarticular lesions of the capsulolabral complex similar to those in posttraumatic instability.

Radiographic Evaluation

Initial plain film evaluation of the shoulder should include an anteroposterior (AP) view (Fig. 11-12), a true AP view of the glenoid (also called the Grashey projection; Figs. 11-13 and 11-14), a scapulolateral "Y" view (Fig. 11-15), and an axillary view (Fig. 11-16) Additionally, the West Point, Stryker notch, Didiee, and Velpeau views are useful.

West Point View

To obtain a West Point axillary view the patient is positioned prone with the shoulder abducted 90 degrees and the elbow bent and hanging off the edge of the table. The film cassette is positioned at the superior aspect of the shoulder (Fig. 11-17). The x-ray beam passes through the axilla at a 25-degree angle to the table top and is centered inferomedial to the acromioclavicular joint. This view

Figure 11-12 **(A,B)** Initial radiographic series should include an anteroposterior view of the shoulder. This example shows the glenohumeral articulation to be overlapping (i.e., the x-ray beam is taken in the coronal plane of the body). This x-ray film was taken in both internal and external rotation, as shown by the position of the tuberosities and the metal staple used for a Magnussen-Stack procedure.

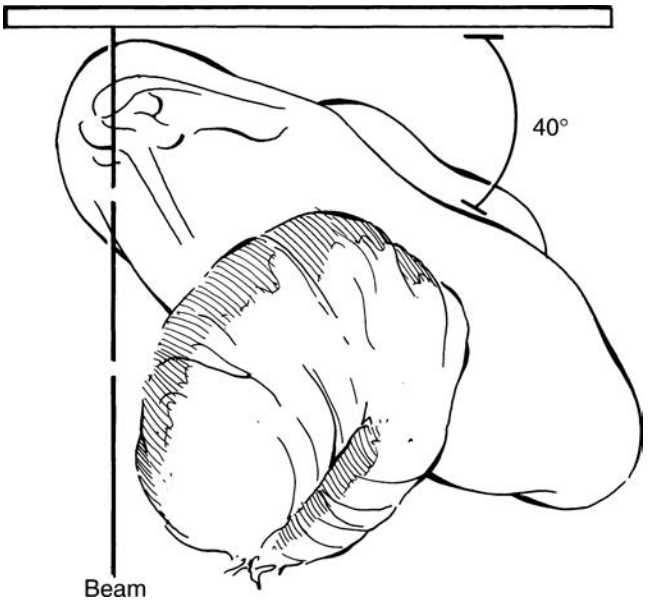

Figure 11-13 Positioning for the Grashey view.

provides the best evaluation of the anteroinferior glenoid rim, which is seen in tangent (Fig. 11-18).

Velpeau View

The Velpeau view is a modified axillary view that does not require arm abduction. With the arm in internal rotation at the side of the body (while wearing a sling), the standing patient leans backward 30 degrees over the cassette, which is on the table (Fig. 11-19). The beam is directed superoinferiorly through the shoulder.

Stryker Notch View

For the Stryker notch view, the patient is positioned supine, with the elbow elevated over the head and facing forward. The film cassette is placed under the shoulder, and the beam is directed cephalad at a 45-degree angle centered on the axillary fold (Fig. 11-20). This view demonstrates the posterolateral humeral head to advantage and is useful for evaluating Hill-Sachs deformity (Fig. 11-21).

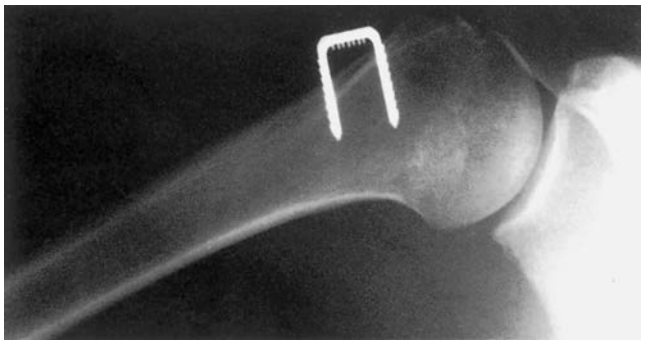

Figure 11-14 A Grashey/anteroposterior view of the glenoid: The same patient is shown as in Fig. 11-12. The glenohumeral articulation is not overlapping and the glenoid is better visualized. With the arm in external rotation, the metal staple is seen in profile. This radiographic view is taken in the plane of the scapula.

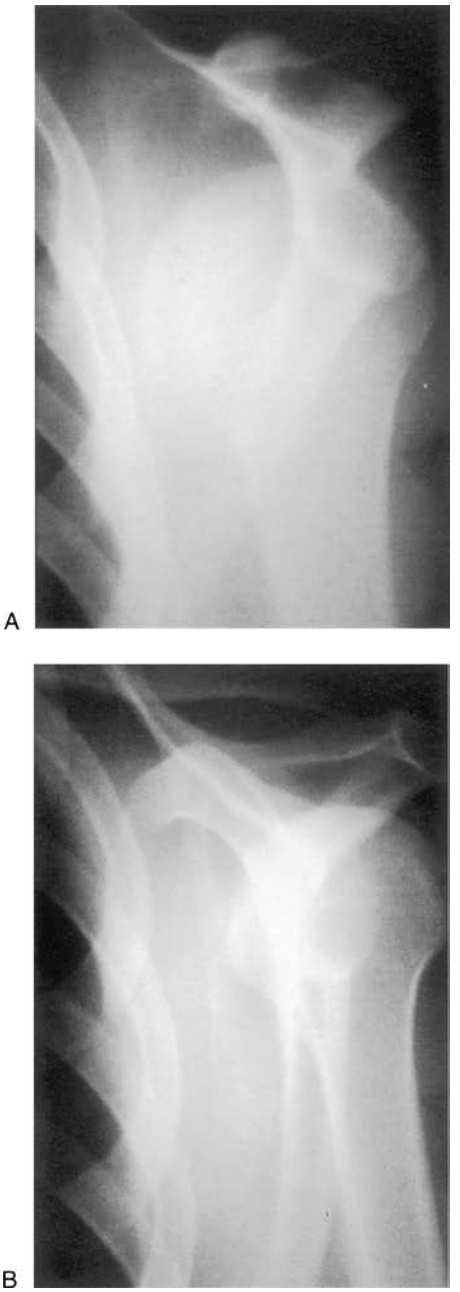

Figure 11-15 Scapulolateral "Y" view showing **(A)** anterior dislocation and **(B)** reduction of the glenohumeral joint.

Didiee View

The Didiee view is obtained with the patient in the prone position and the arm abducted and slightly flexed at the

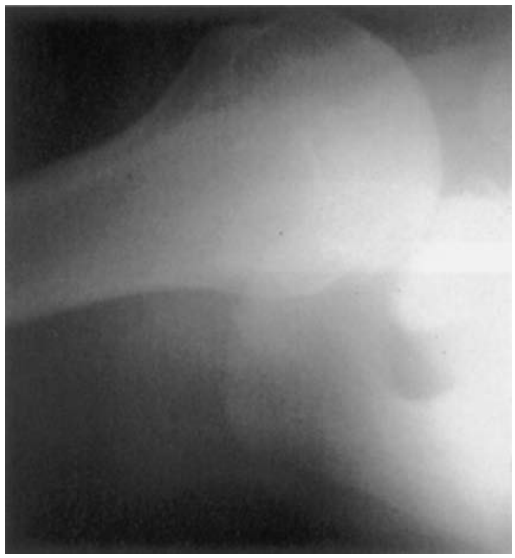

Figure 11-16 Axillary view of the shoulder showing a bony Bankart lesion.

elbow; the dorsum of the hand is on the iliac crest. The film cassette is placed under the shoulder and the beam is directed from the lateral aspect toward the humeral head at a 45-degree angle (Fig. 11-22) These radiographic views allow assessment of glenohumeral alignment as well as detection of fractures, degenerative changes, loose bodies, and calcification around the joint capsule.

Apical Oblique (Garth) View

The apical oblique view was described by Garth et al.[25] to best visualize the anterior inferior glenoid rim for fractures or calcification. The patient is seated, and the arm is on the patient's lap. The x-ray beam is angled 45 degrees to the thorax (plane of the scapula) and 45 degrees caudad. The beam is centered over the glenohumeral joint, and the cassette is placed posterior to the shoulder (Figs. 11-23 and 11-24).

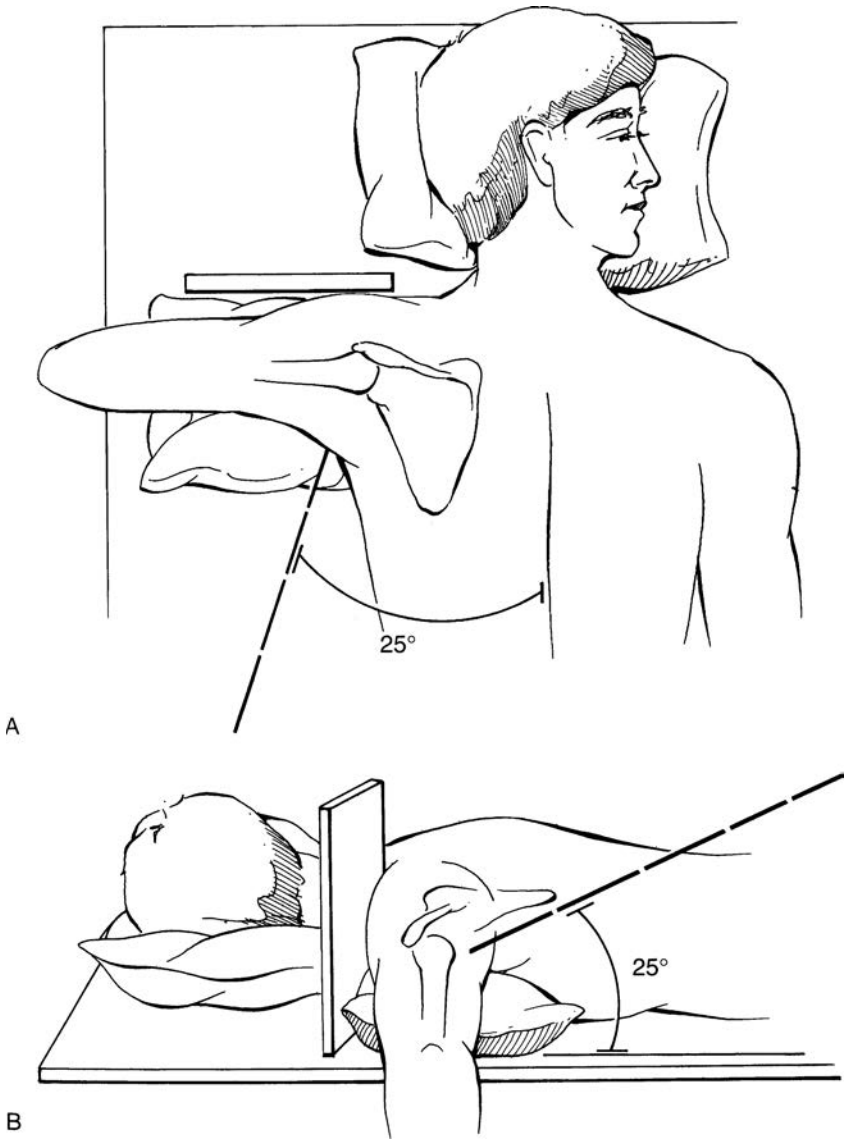

Figure 11-17 Positioning for the West Point view.

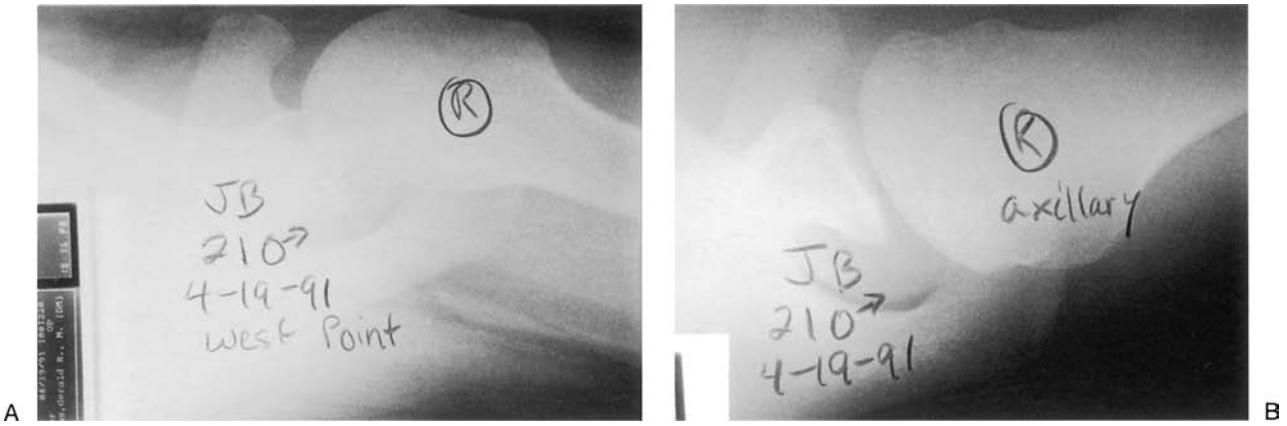

Figure 11-18 **(A)** West Point axillary view showing the anterior and posterior glenoid rim. There is no abnormal glenoid bone identified, although it appears as if there is some anterior glenoid wear. **(B)** In this patient, the standard axillary view demonstrates a small glenoid rim fracture.

General Considerations

Anterior Instability

Anterior dislocations are usually accompanied by a degree of inferior displacement that makes the injury apparent on the AP projection. Because of pain in the acute setting, the patient may be unable to abduct or rotate the shoulder, making the axillary, West Point, Stryker notch, and Didiee views difficult to obtain. The Velpeau and scapulolateral Y views are usually more comfortable for the patient because they do not require abduction. External rotation views are not recommended after reduction, as this position predisposes the patient to redislocation.

The anterior, inferior, and medial displacement that occurs during anterior dislocation of the shoulder causes the posterolateral aspect of the superior humerus to impinge on the anteroinferior rim of the glenoid. This may result in an osteochondral compression fracture of the posterolateral humeral head, also known as the Hill-Sachs lesion.[45] Fracture can occur as a sequela of the first or any subsequent dislocation episode. It is best seen on the AP view of the shoulder with internal rotation of the humeral head or on the Stryker notch view.[94,105]

Osteochondral glenoid lesions may also occur and are difficult to detect on prereduction films. A fracture of the glenoid rim, also called a bony Bankart lesion,[2,3] is best

Figure 11-19 Positioning for a Velpeau view.

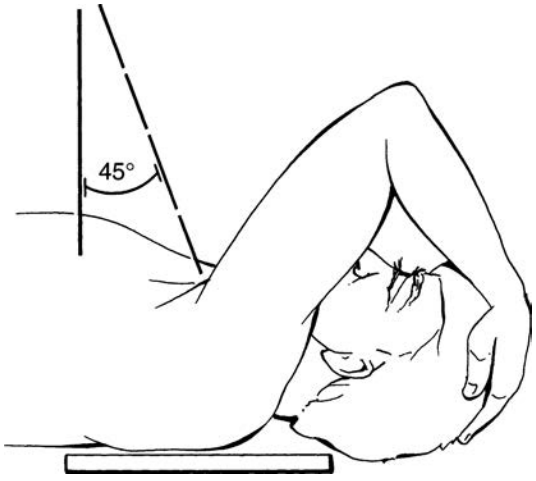

Figure 11-20 Positioning for a Stryker notch view.

Figure 11-21 Stryker Notch view of the same patient in Fig. 11-18 shows a small wedge-shaped defect on the posterolateral humerus, which represents the Hill-Sachs lesion.

visualized on West Point or Didiee views[94] or on a Grashey view.[30]

The nonosseous Bankart lesion involves only the cartilaginous glenoid labrum; therefore, it cannot be evaluated by plain films. This lesion is best demonstrated by MRI (Fig. 11-25), but may also be visualized by CT arthrography (Fig. 11-26) or arthroscopy (Fig. 11-27).

Posterior Instability

In posterior dislocations, particular attention should be directed toward the axillary view. If positioning is not possible because of painful abduction, then a Velpeau axillary can be obtained. This will diagnose the position of the humeral head and any associated bony lesions. The classic radiographic features of posterior dislocation include humeral head overlap on the glenoid rim on an AP radiograph, an empty glenoid on axillary or lateral radiograph, fracture of the lesser tuberosity, and a reverse Hill-Sachs lesion.

In posterior subluxation without dislocation, routine radiographs may not demonstrate any abnormalities. The axillary view may show evidence of calcification of the posterior capsule, fracture or erosion of the posterior glenoid (Fig. 11-28), or reverse Hill-Sachs defects (Fig. 11-29).[23,83,84]

Stress axillary radiographs or fluoroscopy are generally not necessary, as the history and physical examination

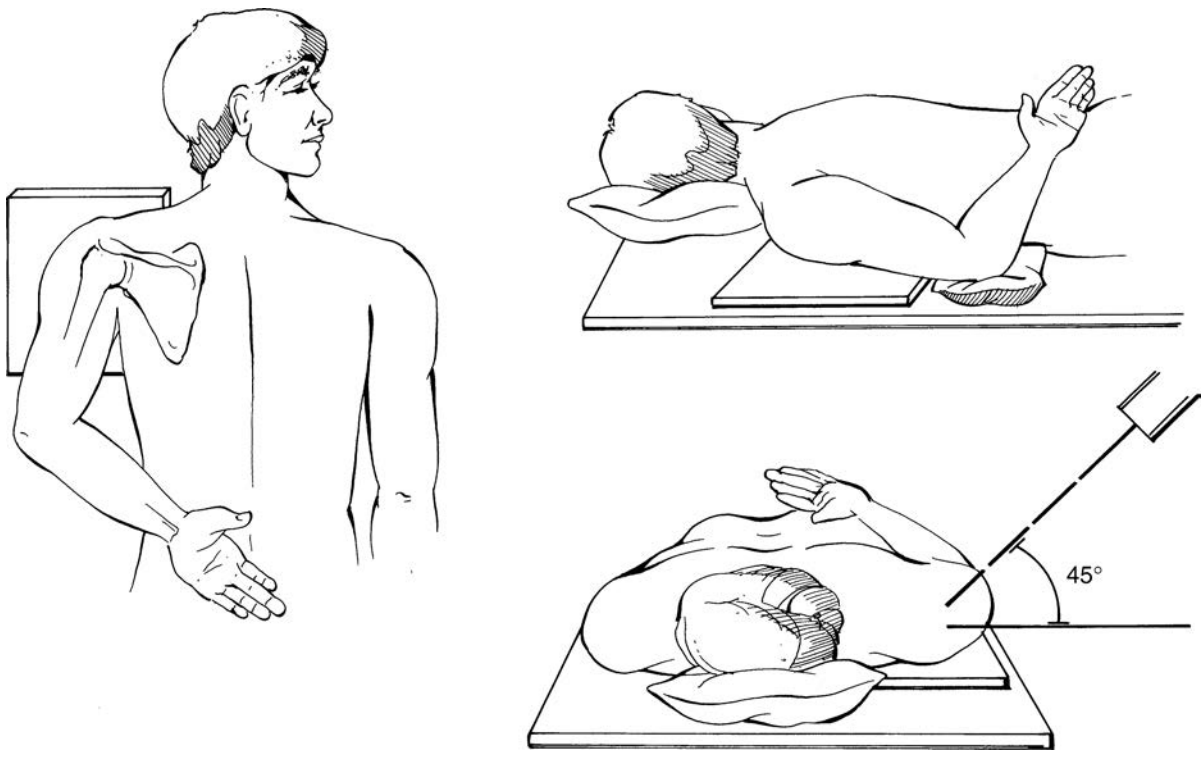

Figure 11-22 Positioning and technique for a Didiee view.

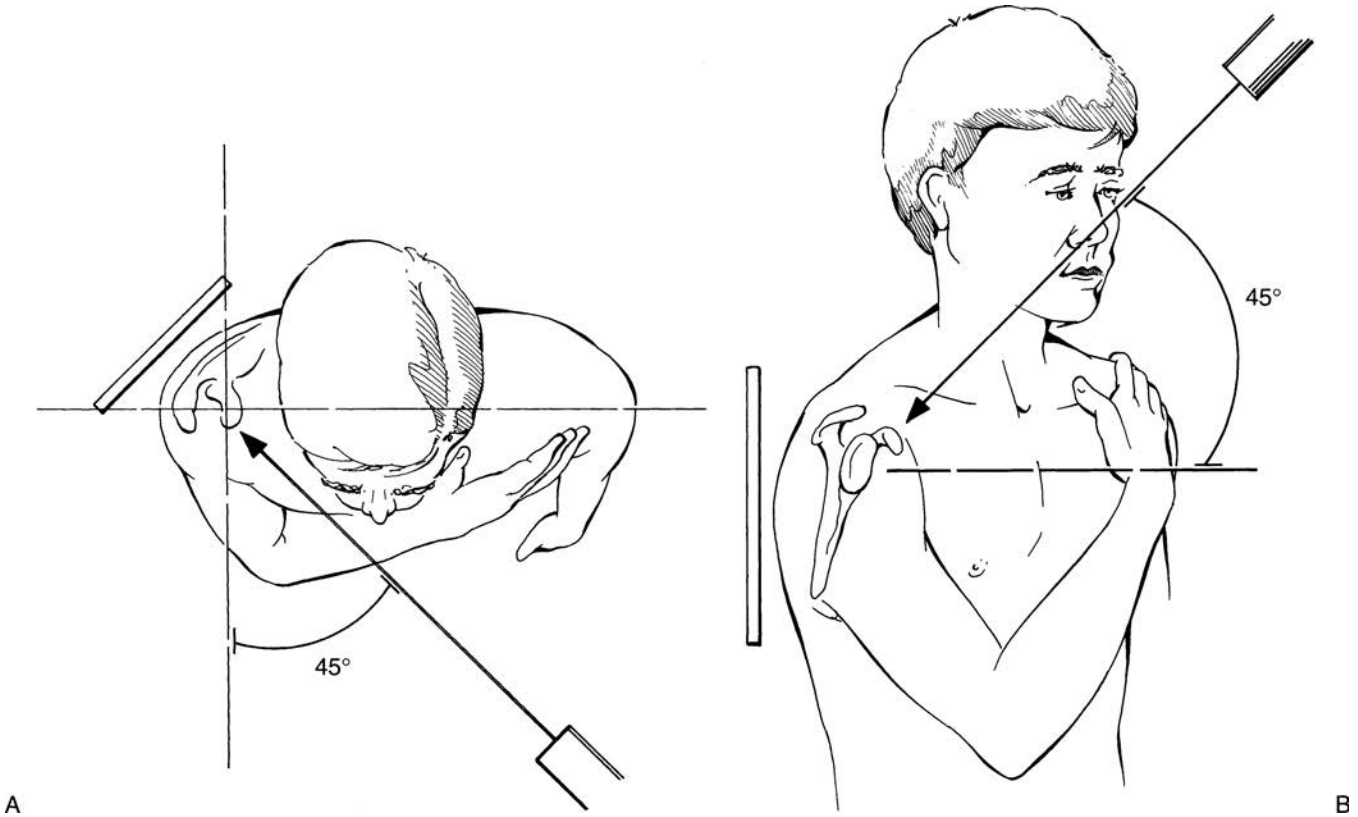

Figure 11-23 **(A,B)** Positioning and technique for the apical oblique (Garth) view.

usually clarify the diagnosis. However, some authors have found these imaging modalities quite helpful in the small group of patients with a dubious diagnosis.[18,53,82] Comparison with the unaffected side is recommended, as posterior glenohumeral translation of 50% has been demonstrated in normal subjects.[39,83]

Figure 11-24 An apical oblique view of the same patient in Figs.11-18 and 11-21 demonstrates calcification of the anterior inferior glenoid rim associated with anterior glenohumeral instability.

Multidirectional Instability

In multidirectional instability, plain radiographs are generally normal. Nonetheless, they should be evaluated for the presence of humeral head defects and glenoid lesions. Stress radiographs can be used to demonstrate inferior subluxation; however, this technique is generally not needed.[53]

Fluoroscopic Evaluation

Although imaging studies can provide useful anatomic information, they do not reflect a dynamic situation. Additional information can be obtained by fluoroscopic stress evaluation of the glenohumeral joint. In a study of 50 patients, Papilion and Shall[93] evaluated fluoroscopic examination of shoulder instability under general anesthesia. Translation was expressed as the percentage of displacement of the humeral head relative to the glenoid. They found that up to 14% anterior translation and 37% posterior translation are "normal." A greater percentage of translation indicated instability. These criteria had an overall sensitivity of 93% and specificity of 100% for the diagnosis of the presence and direction of instability. It must be emphasized that an absolute degree of translation cannot be correlated with

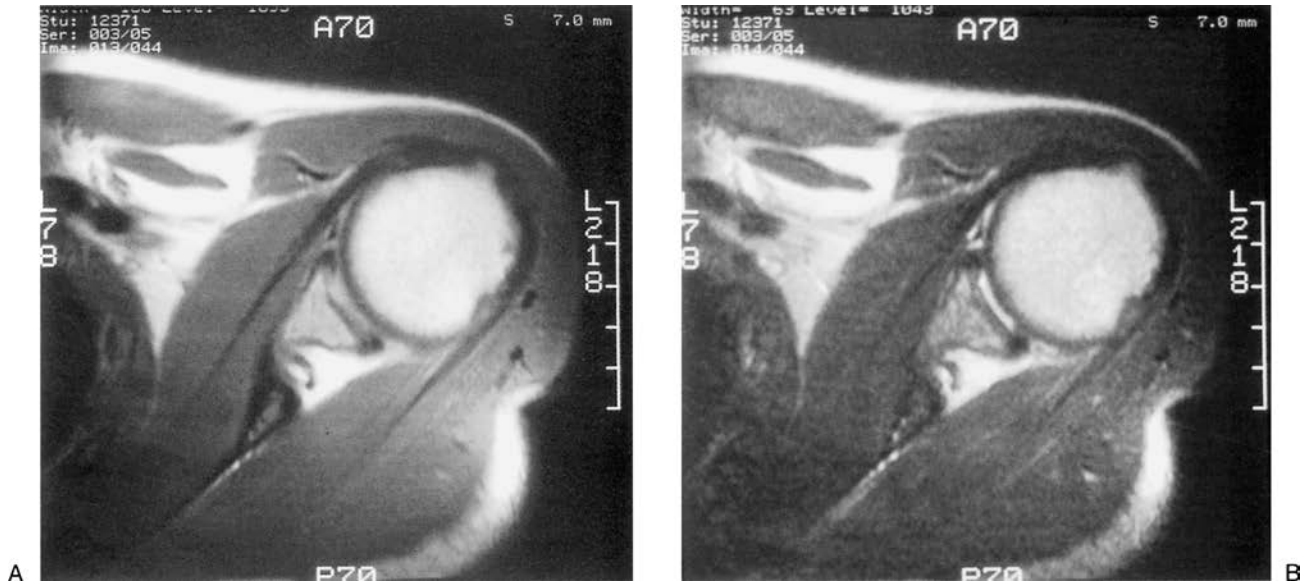

Figure 11-25 **(A)** T-1-weighted and **(B)** T-2 weighted axial cuts demonstrating a small Hill-Sachs lesion on the posterosuperior humeral head and an anterior labrum tear that is best indicated by the high signal fluid between the labrum and the anterior glenoid rim.

instability. The amount of translation can vary greatly among individuals, and comparative examination of the contralateral normal shoulder should be routinely carried out.

Computed Tomography Arthrography

Prior to the use of MRI, CT arthrography was widely used, as it was considered the standard for imaging the glenoid labrum. CT arthrography can reliably define the osseous structures of the shoulder and assess both labral and capsular integrity. CT also excels in its ability to define bony detail. If plain radiographs suggest abnormalities of glenoid version, glenoid hypoplasia, or glenoid erosion, CT is often the study of choice. The value of CT arthrography in defining intraarticular pathology has been studied. While Bigliani et al. found one-third of CT arthrograms to be

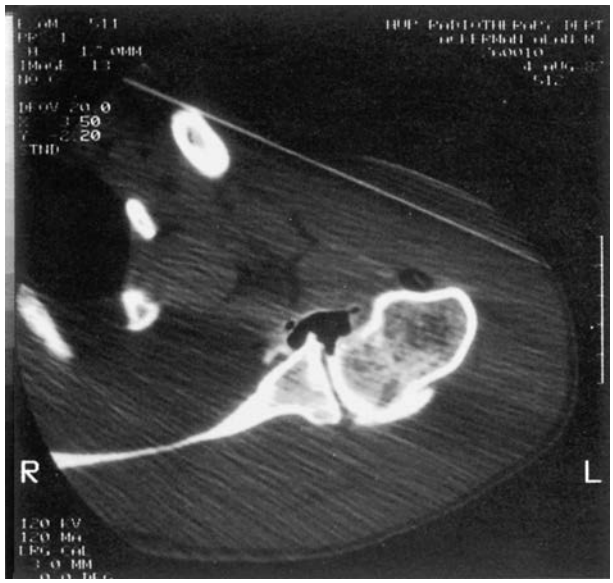

Figure 11-26 Computed tomography arthrogram demonstrating avulsion of the anteroinferior capsule from the glenoid rim.

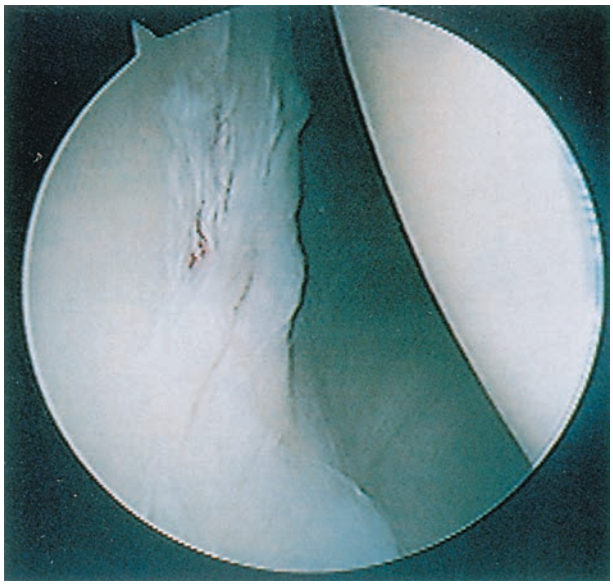

Figure 11-27 Arthroscopic photograph of an anteroinferior capsular avulsion (Bankart lesion).

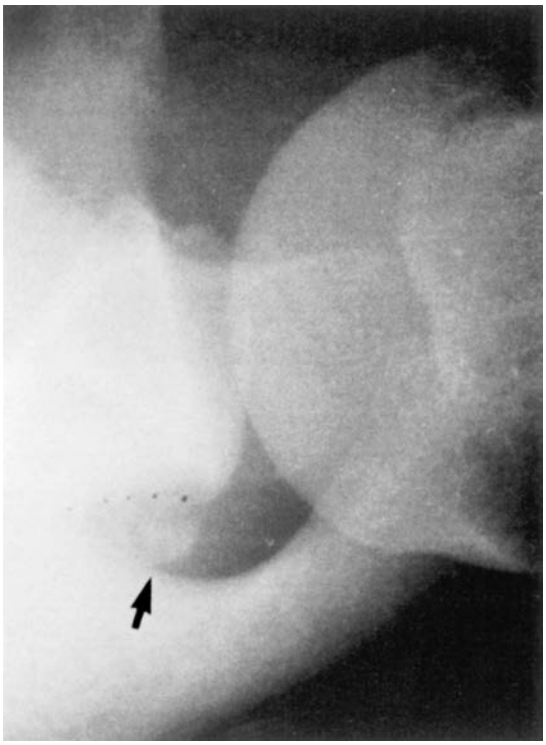

Figure 11-28 Axillary radiograph showing fracture of the posterior glenoid rim (*arrow*). The fracture fragment has healed to the posterior glenoid neck.

over- or under-read for labral pathology when correlated with findings at surgery, Callaghan et al. found CT arthrography to be 100% accurate, sensitive, and specific for posterior labral defects[4,6] (Fig. 11-30). While MRI and MR arthrography have been shown to be more sensitive in the detection of many labral abnormalities,[106] CT arthrography may be used in cases where MRI is contraindicated. The disadvantages of this technique include exposure to ionizing radiation, invasiveness of the procedure, and inability to assess partial-thickness tears of the rotator cuff, biceps tendon, or labrum.

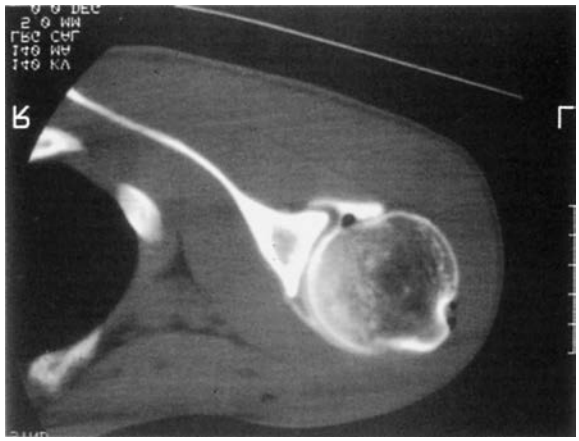

Figure 11-30 A computed tomography arthrogram of the shoulder. Intraarticular contrast improves visualization of the glenoid labrum.

Magnetic Resonance Imaging

MRI has improved our ability to assess soft tissue pathology about the shoulder. The advantages of MRI over plain radiographs and CT include no exposure to ionizing radiation, excellent soft tissue resolution, noninvasiveness, and ability to image in multiple planes. Numerous studies have shown that MRI is superior to other imaging studies at defining labral and capsuloligamentous pathology.[33,48,50,52,57,112] An MRI of the shoulder can demonstrate additional shoulder pathology, such as rotator cuff pathology, labral morphology, and osseous integrity.

Several investigators have studied labral morphology in normal patients. Although the posterior labrum maintains either a triangular or rounded shape, the appearance of the anterior labrum is variable. Neumann et al.[79] studied 30 asymptomatic volunteers and found cleaved, notched, or flat anterior labra in 30% and described absent portions of the anterior superior labrum in 6%. McCauley et al.[69] disagreed and found labral clefts in only 4% of healthy subjects.

Figure 11-29 A computed tomography scan of a large reverse Hill-Sachs lesion.

Figure 11-31 Magnetic resonance imaging demonstrating the posterior capsule insertion on the labrum and not the glenoid.

Congenital and age-related variations in the anterior labrum have also been noted. Because of the variability in the appearance of normal glenoid labra, an MRI scan may overestimate the frequency of labral tears.

Complex labral tears are easier to detect. One can often see fragments that have migrated into the axillary pouch or cysts associated with labral tears. Gusmer et al.[36] found noncontrast MRI to be 95% accurate in detecting labral tears. An MRI scan can also show capsular stripping from the glenoid, rotator cuff tears, muscle atrophy caused by suprascapular and axillary nerve injury, and osseous injuries such as Hill-Sachs lesions. Focal thinning of the articular cartilage of the glenoid may indicate areas of recurrent instability.

The posterior capsule inserts directly onto the posterior glenoid labrum, not the bony glenoid (Fig. 11-31). This anatomic relation of the capsulolabral complex often confuses accurate interpretation of MR images. The capsulolabral complex is best demonstrated with the arm in neutral position. Imaging in external rotation can simulate a labral tear by creating posterior capsular redundancy at the capsulolabral junction.[120] Additionally, in the nondistended joint, the close proximity of the glenohumeral ligaments to the posterior glenoid labrum can be mistaken for a labral tear.[65,79]

MR Arthrography

While MRI is considered superior to CT arthrography, several studies have shown MR arthrography to more consistently diagnose instability lesions. Chandnani et al. found MR arthrography to be superior to conventional MR and CT arthrography at detecting labral tears, detached labral fragments, and labral degeneration.[8] Flannigan et al.[22] believed that the presence of intraarticular contrast affords improved visualization of the labrum and rotator cuff and enhances the accuracy of MRI for the detection of labral and rotator cuff tears. Palmer and Caslowitz[91] evaluated MR arthrography and found this method to have 92% sensitivity and 92% specificity for the detection of labral tears. One pitfall of MR arthrography is that the presence of intraarticular contrast may lift the meniscoid superior labrum from the articular margin and simulate a labral detachment.[67] Normal anatomic structures adjacent to the labrum, such as the glenohumeral ligaments and glenoid articular cartilage, may be misinterpreted as labral tears.[67]

Recently, MR arthrograms have been performed by placing the arm in abduction and external rotation during imaging.[14] In this position, tension is placed on the inferior glenohumeral ligament, allowing for increased accuracy in the diagnosis of nondisplaced tears. This technique has been reported to demonstrate a sensitivity and specificity of greater than 95% for anterior labral tears.[14]

MR arthrography is able to detect variations of the capsulolabral pathology, which include the anterior labroligamentous periosteal sleeve avulsion lesion (ALPSA), glenolabral articular disruption (GLAD) lesions,[107] humeral avulsion of the glenohumeral ligament, humeral avulsion of the posterior band of the inferior glenohumeral ligament,[10] and floating anterior inferior glenohumeral ligament.[47]

The use of MR arthrography for multidirectional instability provides the joint distention necessary to evaluate the capsular volume and the uncommon labral or capsular detachments.

As noted by Oxner,[89] the clinical use of MRI in managing shoulder instability is seen best in four examples: making the difficult diagnosis, timing of treatment in the professional athlete, choosing the most appropriate surgical mode, and identifying unsuspected extraarticular pathology. As noted by Mok et al.,[74] patients with subtle instability and pain without dislocation often present with a diagnostic dilemma. MRI may help define the underlying pathology. In the treatment of professional athletes, choosing the timing of operative intervention after dislocation may be influenced by the identification of additional pathology on MRI (i.e., tears of the subscapularis tendon). MRI may help to better define the pathology and potentially influence the choice between arthroscopic and open management. Sher et al. noted that MRI examination impacted clinical decision making in 29% of patients with glenohumeral instability.[113]

Authors Preferred Technique

We prefer to obtain a series of plain films that include AP, Grashey, scapulolateral Y, and axillary or Velpeau views. We use CT of the shoulder to evaluate the glenoid rim and extent of a Hill-Sachs deformity and use MRI only if there is a question of rotator cuff pathology (Fig. 11-32).

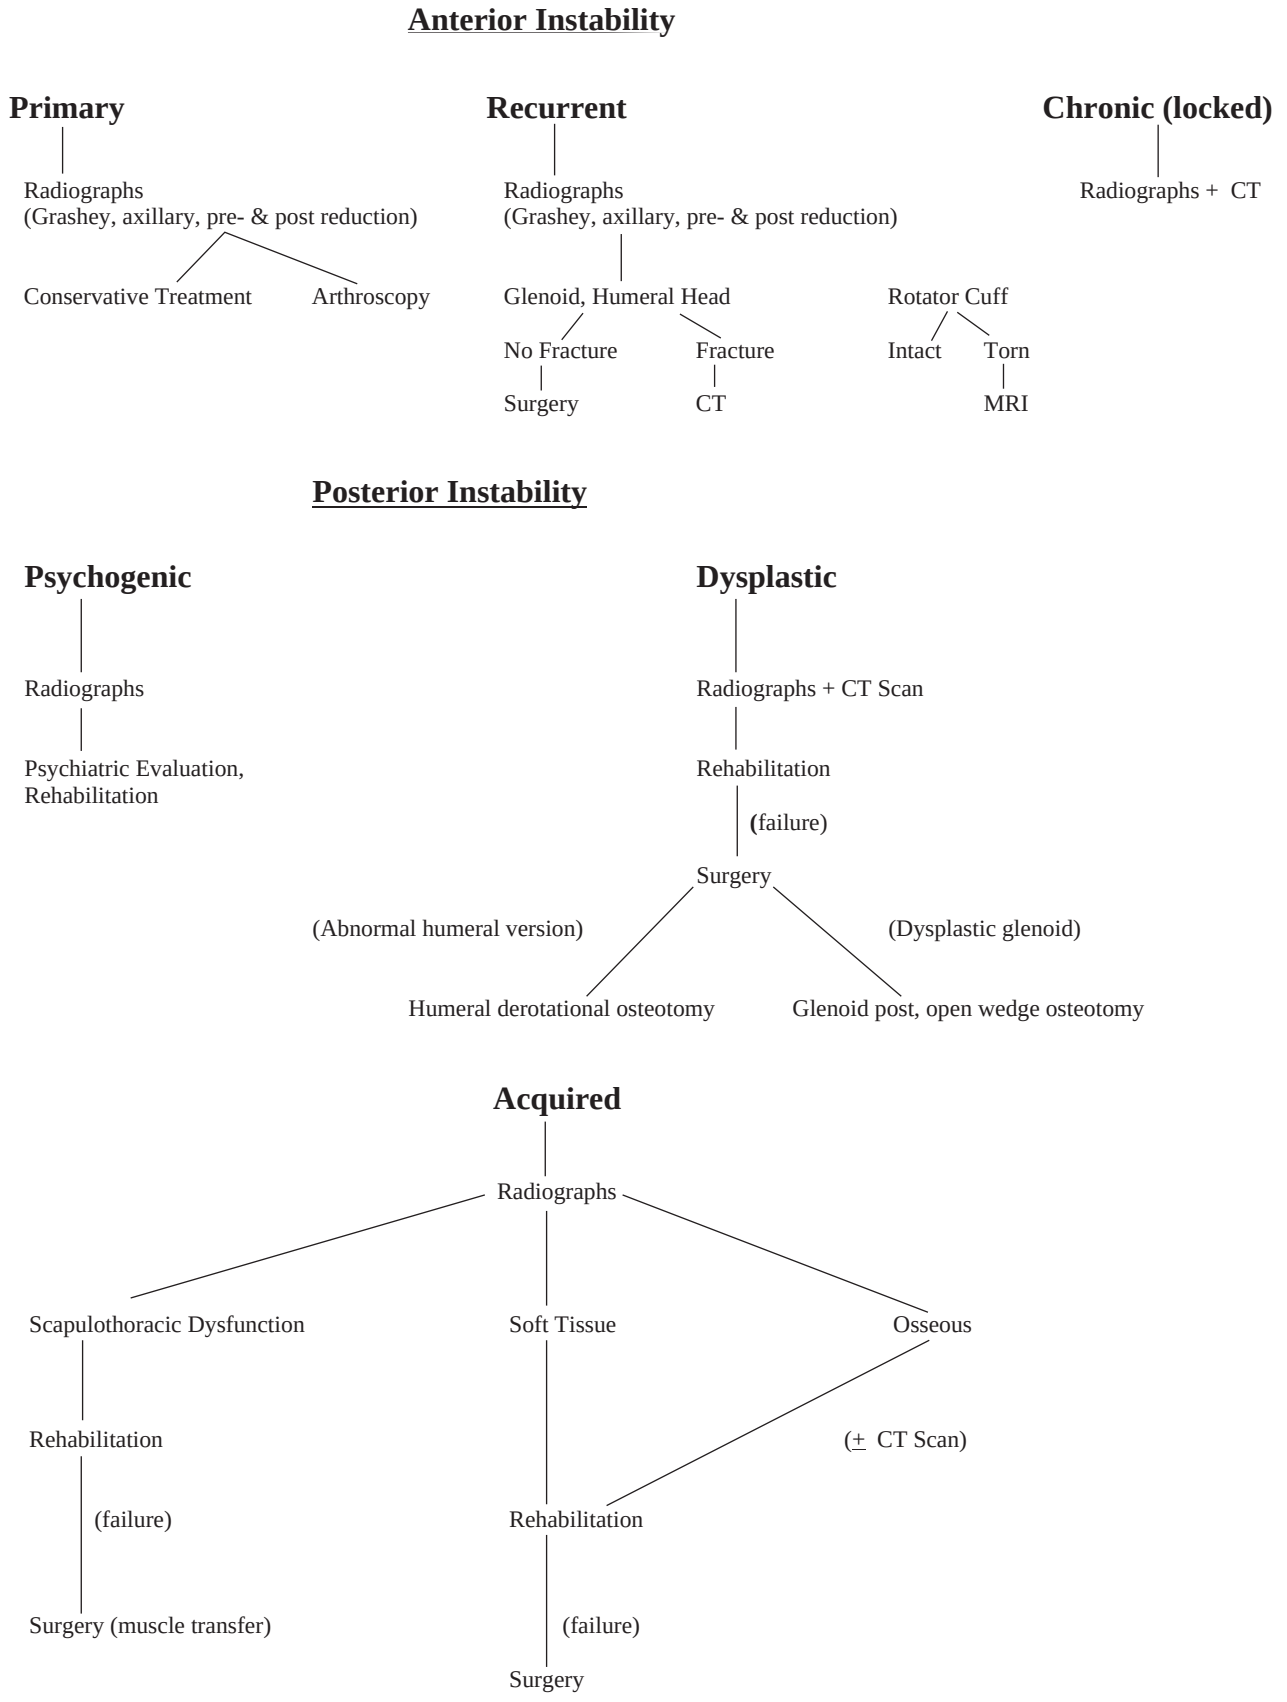

Figure 11-32 Diagnostic algorithms. CT, computed tomography; MRI, magnetic resonance imaging.

CONCLUSION 396

INTRODUCTION

An understanding of the pathomechanics and treatment of the unstable shoulder has evolved over the past 100 years. The current belief that multiple mechanisms and anatomic variations combine to create an unstable shoulder has evolved from the original theory of Perthes[108] and Bankart[11] that a single "essential lesion" creates instability. Etiologic theories continue to develop based on the advances in understanding of the disease process. The manifestations of instability will vary based on host factors and the magnitude of force required to create the injury. A traumatic force creating an initial dislocation is the most frequent cause of anterior instability. More subtle events may create a spectrum of instability, such as subluxations in patients with increased capsular laxity and microtrauma secondary to repetitive large forces (e.g., in overhead-throwing athletes or in swimmers). The diagnosis and management of anterior shoulder instability should be individualized based on cause, various host factors, and associated pathology. This chapter presents an algorithmic approach to the treatment of anterior shoulder instability based on the natural history and pathology of the condition.

The clinician should distinguish between subluxation and dislocation events to help identify the severity of the event and determine prognosis. For the purposes of this chapter, subluxation is defined as a pathologic increase in glenohumeral translation without loss of articular contact

between the humerus and the glenoid; dislocation is the complete loss of contact between the articular surfaces.

CLASSIFICATION AND PATHOLOGY

Many classification systems have been proposed and exist. As the understanding of the natural history, pathology, and treatment of shoulder instability has evolved, so have the classification schemes. Thomas and Matsen[131] have described the acronyms TUBS and AMBRI to classify most patients with instability. TUBS refers to patients with a *t*raumatic lesion who have a *u*nidirectional component to their disease that frequently has a *B*ankart lesion and responds well to *s*urgery. AMBRI refers to patients who have an *a*traumatic cause of their *m*ultidirectional disease that often has *b*ilateral shoulder findings and responds to *r*ehabilitation. Rockwood[111] described four patterns of instability: type I, traumatic subluxation without previous dislocation; type II, traumatic subluxation after a previous dislocation; type IIIA, voluntary subluxation in patients with psychiatric problems; type IIIB, voluntary subluxation in patients without psychiatric problems; and type IV, atraumatic involuntary subluxation. O'Brien et al. have proposed classification based on some combination of degree, frequency, direction, and cause.[104] Gerber and Nyffler have proposed a classification system in which instability is static (class A), dynamic (class B), or voluntary (class C). Class A is further subdivided by direction of instability and class B by the presence or absence of hyperlaxity. The key point in this system is to differentiate hyperlaxity from instability, which will assist in treatment strategies. The general principle is that hyperlaxity is not pathologic, but may be a risk factor for shoulder problems and may be present in combination with pathologic instability.[38] The authors prefer to use an algorithmic approach (Fig. 12-1) to classify anterior instability based on cause, direction, frequency, and volition.

Although trauma is the most commonly identified cause of anterior instability, more subtle factors may exist in patients with anterior subluxation and multidirectional instability. Patients who are classified as having multidirectional instability by definition demonstrate a component of inferior instability. Multidirectional instability does not usually exist in all planes, but it commonly exists in two. For a diagnosis of instability, patients must have symptoms that accompany increased translation.

Acute Traumatic Anterior Dislocation

The most common mechanism of a traumatic initial anterior dislocation is an indirect force with the arm in the externally rotated abducted position. The force levers the humeral head anterior in relation to the glenoid, as when the patient's arm is in the throwing position. The inferior glenohumeral ligament is the main stabilizing force resisting anterior dislocation.[135] This structure is commonly injured in the acute traumatic anterior shoulder dislocation. The patient's age and the force required to create an initial dislocation are important factors in determining prognosis and associated injuries.

The pathology associated with an acute anterior shoulder dislocation in young patients has been well documented.[8,130] Taylor and Arciero[130] examined 63 shoulders with an average age of 19.6 years arthroscopically within 10 days of an acute traumatic dislocation and found complete detachment of the capsuloligamentous complex from the anterior–inferior glenoid rim and neck in 97%. This lesion (Bankart lesion) includes the inferior glenohumeral ligament and the anterior labrum with its periosteal insertion on the glenoid neck.[8,10,117] Ninety percent of patients had a Hill-Sachs lesion and 10% had a superior labrum anterior posterior (SLAP) lesion. No rotator cuff tears were observed in this patient population. Baker et al.[8] found similar pathology in a study of 45 shoulders. They found complete labral and capsular detachment in 62% and capsular tears with partial labral tears in an additional 24%. Hill-Sachs lesions were present in 18 shoulders and rotator cuff tears were found in five shoulders.

The pathology associated with an acute traumatic dislocation in young patients is manifested clinically as recurrent instability being either dislocations or subluxations. Multiple studies have looked at recurrence in this population, documenting recurrence rates between 33%[52] and 90%.[4,48,130,140]

Patients older than 50 years of age are more likely to suffer rotator cuff tears with the initial dislocation. In older patients, the inability to lift the arm over the head is more likely to be related to a rotator cuff tear than to an axillary nerve palsy, whereas the opposite is true in the younger population. Neviaser et al.[101] noted an 85.7% incidence of rotator cuff tears and a 10.8% incidence of axillary nerve palsy in patients with initial traumatic shoulder dislocation occurring after age 40.

Anterior shoulder dislocation is diagnosed on the basis of the physical and radiographic examinations. The patient may present with an adducted and internally rotated arm and may be unable to externally rotate or fully abduct the arm. The humeral head may be visible and palpated on the anterior aspect of the shoulder; whereas the posterior aspect may appear hollow and the acromion stepped off.

Anterior Subluxation

In patients with anterior subluxation, it may be difficult to identify an initial traumatic event. Rowe and Zarins[116] described recurrent transient subluxation of the shoulder, causing a "dead arm syndrome." Alternatively patients may feel their shoulder slide in and out of the joint, may

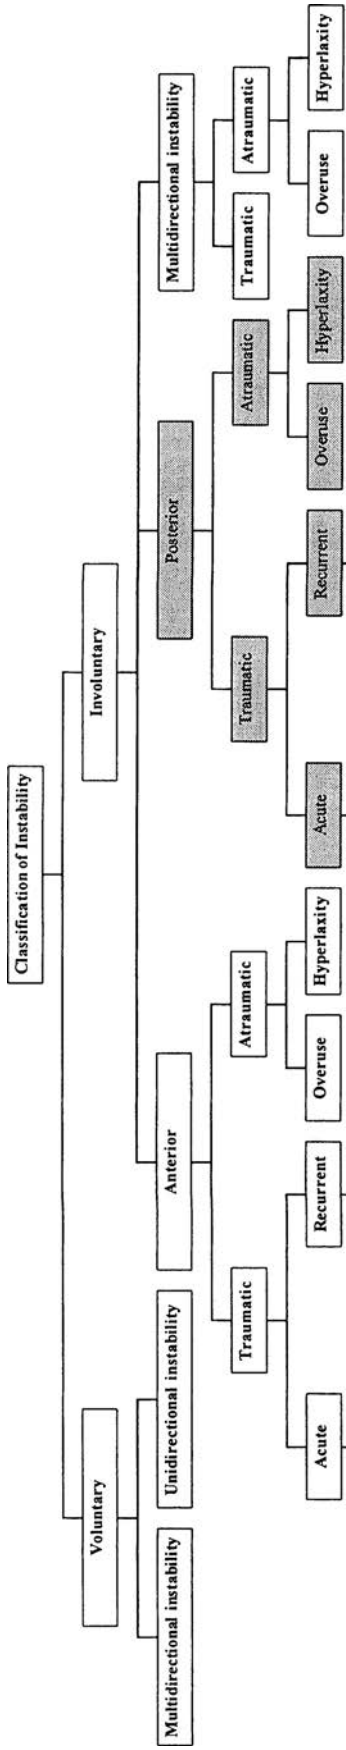

Figure 12-1 Classification of instability. (Modified from Silliman JF, Hawkins RJ. Classification and physical diagnosis of instability of the shoulder. *Clin Orthop* 1993;291:7–19.)

complain of clicking or catching in provocative positions, or may simply have pain.

The Overhead Athlete

The shoulders of baseball pitchers or other overhead athletes are exposed to high-energy repetitive stresses or overuse that can exceed the rate of tissue repair[74] or cause structural pathology. The static stabilizers, which include the bony geometry, labrum, capsule, and glenohumeral ligaments,[20] can be damaged and, in turn, place an increased amount of responsibility for glenohumeral stability on the dynamic stabilizers. These dynamic stabilizers include the deltoid, the biceps, and the rotator cuff muscles.[20] As the soft tissue static stabilizers become more attenuated and more stress is placed on the dynamic stabilizers, they may become fatigued. As the compensatory mechanism becomes overloaded, anterior subluxation may occur. As the humeral head subluxes anteriorly and contacts the coracoacromial arch, subacromial impingement occurs. Over time, anterior laxity with the arm in abduction and external rotation can occur. This anterior translation has been shown radiographically in patients with symptomatic anterior instability.[57] With anterior subluxation, the tendinous portion of the supraspinatus and infraspinatus may impinge on the posterosuperior border of the glenoid rim, resulting in glenoid impingement as well. This so-called "internal impingement" was suggested by Bennett and others[13,81] and is now well described.[27,64,93,94] Swimmers, volleyball players, and other overhead-throwing athletes are vulnerable to this pathophysiology.

Occult instability may also be present in nonthrowing athletes. For weight lifters,[43] anterior subluxation may be the primary etiologic factor of shoulder dysfunction and pain. Weight-lifting maneuvers that produce forced abduction, extension, and external rotation (such as military presses, flies, and latissimus pull-downs) may cause subluxation.

Glenoid Bone Loss

Glenoid bone deficiency related to shoulder instability has been described by various authors. The injury can occur as an associated anteroinferior glenoid fracture attached to the inferior glenohumeral ligament or can be related to continued episodes of dislocation or subluxation and eburnation or rounding off of the anterior glenoid. Bone defects of the glenoid have been documented and studied radiographically. Edwards and associates noted that with examination by fluoroscopically guided radiography, 79% of shoulders with recurrent dislocations had an osseous lesion of the glenoid.[33] Three-dimensional computed tomography (CT) has been used in the assessment of glenoid bone loss in recurrent instability. In a study of 100 shoulders with recurrent glenohumeral instability, 50% of patients had a bony fragment and an additional 40% had bone loss from erosion or compression.[128] A separate study using CT evaluation documented osseous lesions in 91% of recurrent dislocations and suggested quantification of moderate to severe bone loss using the contralateral, unaffected shoulder to determine a difference in the maximum glenoid width.[42] These high rates of glenoid bone defects have raised concerns about the associated bone loss as a negative prognostic factor resulting in higher failure rates and perhaps the necessity for alternative treatment plans to standard soft tissue procedures.

Burkhart et al.[22] proposed an arthroscopic quantification of this glenoid bone loss. The method involves locating the bare spot in the glenoid, which they showed to be reliably equidistant from the anterior and posterior rims of the inferior circular portion of the articulating glenoid. Significant bone loss is that amount which increases the risk of recurrence following a soft tissue–only repair. They propose that if the bare spot–anterior rim distance is less than half that of the bare spot to the posterior rim, then the shoulder is at high risk for failure of soft tissue repairs only as treatment for their anterior instability (Fig. 12-2). Arthroscopically, the appearance of the glenoid is that of an "inverted pear" (Fig. 12-3). Burkhart et al. have documented a 61% recurrence rate following arthroscopic Bankart repairs when the glenoid bone loss caused an "inverted pear" appearance. The authors noted that a loss of greater than 25% of the diameter of the inferior glenoid will create the "inverted pear" appearance.[21,22] They recommended treatment of this bone defect as well as the soft tissues when glenoid bone loss of this magnitude is seen.

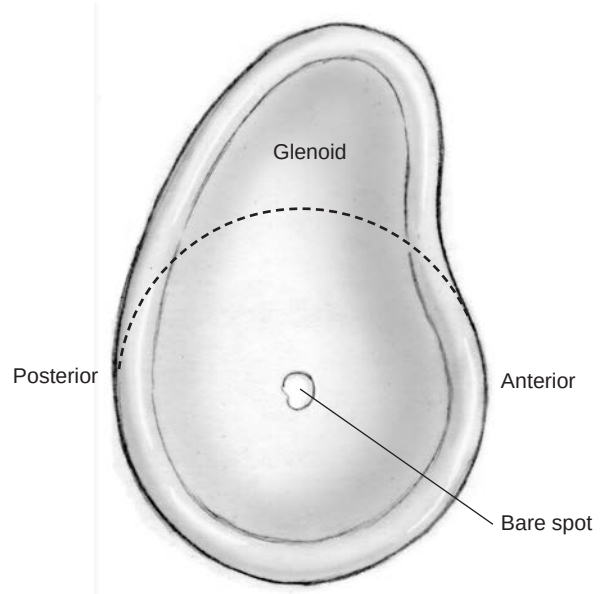

Figure 12-2 Glenoid morphology. (Modified from Burkhart SS, Debeer JF, Tehrany AM, Parten PM. Quantifying glenoid bone loss arthroscopically in shoulder instability. *Arthroscopy* 2002;18[5]: 488–491.)

Traumatic glenohumeral bone defects and their relationship to failure of arthroscopic Bankart repairs: significance of the inverted-pear glenoid and the humeral engaging Hill-Sachs lesion. *Arthroscopy* 2000;16[7]:677–694.21)

Bigliani et al. also recommended that bone loss of greater than 25% of the anterior–posterior diameter should be treated with coracoid transfer.[15] In a cadaver study, Itoi and associates[62] simulated Bankart lesions with varying degrees of glenoid bone loss. They examined anterior–inferior stability with and without soft tissue repair. After soft tissue Bankart repair, a decreased force was required to cause instability when the width of the defect was 21% of the superior–inferior glenoid length. In a separate radiographic study, Griffith et al.[42] propose 1.5 cm as a critical length of the lesion.

Humeral Bone Loss

A posterior–superior humeral head impaction fracture was originally described by Flower in 1861.[36] In 1940, Hill and Sachs described the mechanism by which these lesions occur, that is, compression of the humeral head against the anterior glenoid rim.[50] These so-called Hill-Sachs lesions are common in glenohumeral instability;[33,52] however, their quantification is not well described. Burkhart and De Beers described "engaging Hill-Sachs lesions" in which the long axis of the grooved humeral head defect is parallel to the anterior rim of the glenoid when the shoulder is in the position of abduction and external rotation.[21] They suggested that these lesions contributed to failure of arthroscopic Bankart repair, which is consistent with others who advocate that Hill-Sachs lesions contribute to recurrent instability.[52,117] Miniaci[97] has described a group of patients with Hill-Sachs lesions larger than 25% of the humeral articulating surface with or without associated glenoid bone loss that may require attention to the humeral head defect. These patients commonly demonstrate significant apprehension even at levels of abduction below 70 degrees. The usual history is one of multiple traumatic dislocations or failed repairs, often associated with contact sports, and can be present in patients with seizure disorders and anterior instability. These patients often have reduced external rotation and significant apprehension at low levels of abduction, and may have failed previous surgical attempts at repair. Because the large humeral defect alters joint stability, it may need surgical attention in certain cases. The surgical management of those soft tissue and bone lesions that contribute to recurrent instability is discussed later in this chapter.

MANAGEMENT

The goal of management of anterior shoulder instability is to return the patient as rapidly as possible to his or her preinjury level of activity. The first step toward this goal is adequate, prompt, and atraumatic reduction of an anteriorly dislocated shoulder. Decisions (often individualized) then need to be made for immobilization and rehabilitation (Fig. 12-4).

Once the diagnosis is made, the glenohumeral joint should be reduced as rapidly and gently as possible. If diagnosed in the field, a reduction maneuver may be attempted immediately before spasm of the shoulder muscles has occurred. A neurovascular examination should be performed before and after the reduction. When attempting such a reduction in the field without sedation, we prefer to place the patient's shoulder in a small amount of forward flexion and abduction and then slowly internally rotate the arm. If this does not achieve the desired results, the patient should be transported to an emergency room where reduction under sedation may be performed.

Many reduction maneuvers have been successfully performed with appropriate muscle relaxation. One technique is that of the traction and countertraction method described by Matsen et al.[86] (Fig. 12-5). In this method, the patient lies supine with a sheet passed around his or her thorax and around the assistant's waist. The assistant should be standing on the unaffected side of the patient to provide a countertraction force. The surgeon should be standing on the affected side of the patient with a second sheet looped around his or her waist and the patient's forearm. The surgeon leans back and applies steady, gradually increasing traction while grasping the forearm at the same time as the assistant provides countertraction around the patient's thorax. The surgeon may be required to gently rotate the arm internally and externally or to attempt to apply gentle outward pressure to the humeral head with his or her hand in the axilla.

In Stimson's technique, the patient is placed in the prone position on the edge of the examining table, with the affected arm hanging over the side. If the weight of the arm is not sufficient to reduce the shoulder, gentle downward traction is applied with an appropriate weight (usually 5 lb or less) attached to the wrist. With this technique, reduction may take 15 to 20 minutes[86] (Fig. 12-6).

The Milch technique involves placing the patient's affected extremity in an overhead position. This can be

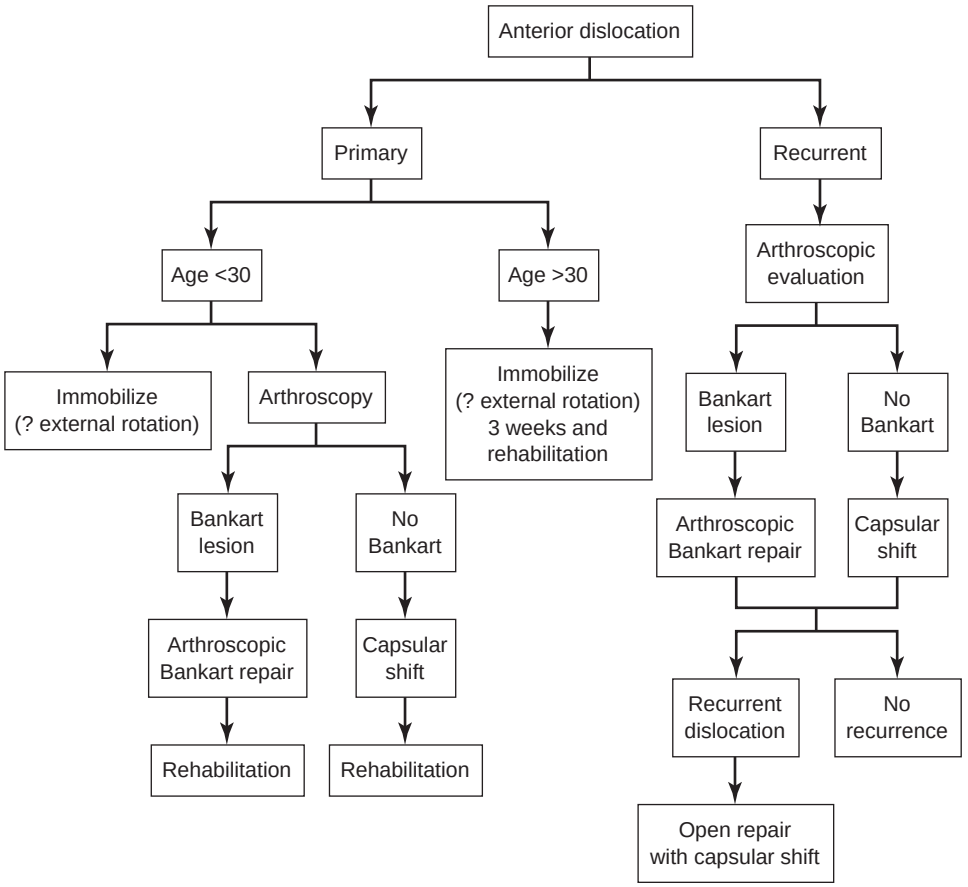

Figure 12-4 Algorithm for treatment.

achieved slowly with little discomfort. With the arm overhead and fully abducted at the shoulder, gentle traction and external rotation is applied. Gradual adduction and pressure applied to the humeral head are helpful maneuvers if reduction is not achieved initially.[136]

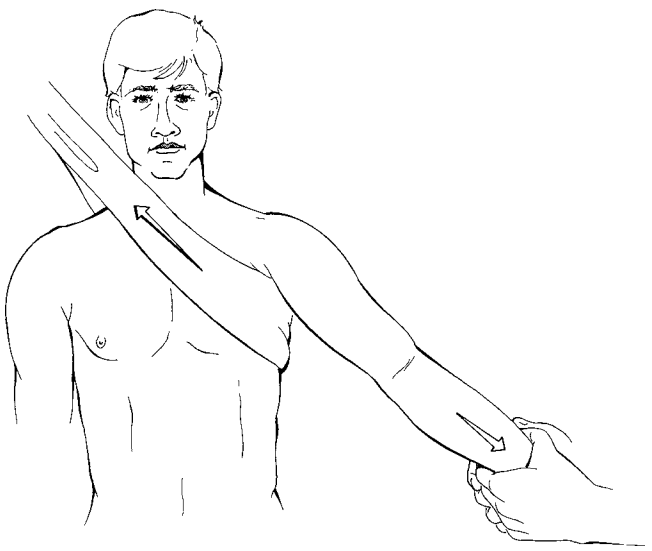

Figure 12-5 Reduction technique using the traction–countertraction method.

Reduction by scapular manipulation is based on the principle of repositioning of the glenoid fossa. The patient may be prone or seated with the scapula exposed. Longitudinal traction is placed on the extremity with the shoulder at 90 degrees of forward flexion. The superior aspect of the scapula is stabilized while adducting the tip of the scapula, effectively moving the glenoid toward the anterior and medial location of the dislocated humeral head.[136]

The Spaso technique is performed with the patient in the supine position. The affected extremity is held by the wrist and gentle traction is applied toward the ceiling. While applying traction, the extremity is externally rotated. This technique may take several minutes; however, it is generally well tolerated by the patient.[136]

Nonoperative Indications and Management

Nonoperative management, although controversial, begins with shoulder immobilization (the duration and position of which is controversial), followed by physical therapy and (occasionally) bracing. Indications for nonoperative treatment include atraumatic instability, voluntary instability, children with instability, and selected athletes whose sport requires supraphysiologic motion at the glenohumeral joint.[86]

Figure 12-6 Stimson's technique for closed reduction of dislocation

Immobilization

Shoulder instability in athletes has been managed by brace treatment, but with unclear results. The purpose of bracing is to prevent abduction and external rotation, thereby avoiding the position that places the patient at risk for dislocation. In sports such as basketball, baseball, and volleyball, this is nearly impossible because of the shoulder mobility required. Football players may have varying results based on the field position. Wide receivers, quarterbacks, and defensive backs require more shoulder motion than these braces usually will allow. However, braces have been used successfully for football linemen, hockey players, and wrestlers, where the motions of extreme abduction and external rotation are not necessary for participation in the sport. Restriction of motion is adjusted by a trainer to each individual athlete's needs to prevent subluxation and dislocation. Data available on the usefulness of these braces are largely anecdotal, and no biomechanical data exist, despite manufacturer's claims of success.

Controversy remains over the role of traditional sling immobilization (arm in internal rotation) after first-time anterior shoulder dislocations and this treatment's ability to affect the rate of recurrence. Available data on sling immobilization also fail to provide conclusive evidence of the appropriate length of treatment.

Hovelius et al.[53] prospectively followed 257 patients (all younger than 40 years) after first dislocation. Approximately half were treated with immobilization for 3 to 4 weeks; the others were treated with early range of motion. At the 2-year follow-up, recurrence rates were similar, with the highest recurrence rates seen in the younger patients, regardless of treatment. Yoneda et al.[145] reported the results of a more prolonged period of immobilization (5 weeks) and limited range of motion for an additional 6 weeks in a young, athletic population. At 13 years follow-up, 17.3% had had a recurrence; 13.5% of those required surgical repair. Kiviluoto et al.[72] showed a higher incidence of recurrence among patients younger than 30 years and, in this younger group, there was a higher incidence in those immobilized 1 week compared with those immobilized for 3 weeks. These authors recommended longer immobilization (3 weeks) for patients younger than 30 years old and shorter immobilization (1 week) for patients older than 30 years.

A young, athletic population when treated with sling immobilization can have recurrence rates as high as 90%.[4,48,130,140] However, in an older population, recurrence is much less of a problem, with recurrence rates documented as low as 10% in patients over 40 years of age.[92] Rowe reported a recurrence rate of 14% in his series of patients over 40 years old.[113]

Recent studies show decreased recurrence rates with arthroscopic stabilization after an initial, traumatic, anterior glenohumeral dislocation when compared to immobilization.[18,70] However, these studies compared arthroscopic stabilization to traditional immobilization in internal rotation followed by rehabilitation.

Recent work by Itoi et al. has provided data from a cadaveric study,[61] a magnetic resonance imaging (MRI) study,[63] and a preliminary clinical study[60] to support immobilization in external rotation. The rationale for this theory is that in external rotation, the Bankart lesion is reapproximated to its correct anatomic position on the glenoid, thereby allowing healing of this pathology in its anatomic position. The cadaveric study showed that a simulated Bankart lesion is approximated to the glenoid throughout an arc of motion from full internal rotation to 30 degrees of external rotation. The MRI study revealed that a Bankart lesion secondary to an acute traumatic dislocation was reduced better in external rotation than in internal rotation. The most recent data is a clinical study in which 40 patients were treated with immobilization. Twenty patients were treated with traditional immobilization in internal rotation and 20 were treated with immobilization in external rotation for 3 weeks following shoulder dislocation. At an average follow-up of 15.5 months, the

traditional immobilization group had a recurrence rate of 30% and 45%, whereas the external rotation group had a 0% recurrence rate. Many studies are now ongoing evaluating this concept. If these early results can be reproduced, the treatment of first time dislocators will be altered and directed toward immobilization in external rotation.

Rehabilitation

A physical therapy program is appropriate for patients with anterior instability, regardless of the underlying pathology. The patient's ultimate goals should always be taken into account when a rehabilitation program is designed. We are uncertain whether a rehabilitation program will affect the primary outcome measure (recurrence rate) or secondary outcome measures (pain, range of motion, function). The willingness to modify one's activity, however, can significantly affect outcome. Several studies support the usefulness of early rehabilitation programs in diminishing the rate of redislocation.[4,6] When using a strict rehabilitation protocol in a population of Naval midshipmen, Aronen and Regan[6] reported a 75% success rate in preventing dislocation over a 3.5-year period. Arciero et al.[4] reported an 80% reduction rate in consistently treated West Point cadets after primary dislocation. It is uncertain what other factors were involved in the development of further instability. Hovelius[51] reported that age at time of initial dislocation was more important than rehabilitation or length of immobilization. Simonet and Cofield found that activity restriction in a group of patients with 9-year follow-up had a significant role in reducing recurrence.[121]

Individualizing a rehabilitation program should take into account several factors, including knowledge of the patient's instability pattern and associated injury pathology. Patients with multidirectional instability should be encouraged to avoid activities that stress the shoulder in an inferior direction, and those who have had severe trauma causing dislocation should avoid prolonged time in positions at risk. Patients with subluxation may require less immobilization time than those patients sustaining a severe traumatic dislocation before initiating a therapy program. As a general rule, it should be stressed that throughout the rehabilitation period, the patient should not be exercising in pain. If pain develops during a particular exercise, the patient should limit or modify the existing exercise level and avoid progressing to the next level until the pain resolves.

Attempting to restore range of motion is the initial goal in any shoulder rehabilitation program. After an acute injury and appropriate initial immobilization, modalities should be performed to decrease the amount of pain. Ice, heat, ultrasound, and electrical stimulation treatments may improve pain and swelling. Oral nonsteroidal antiinflammatory medications may help decrease inflammation. Pendulum exercises are begun as soon as the immobilization is removed.

Isometric exercises are also initiated for resisted internal rotation and resisted adduction at this time. The position of abduction is to be avoided. When the patient can perform isometric exercises without pain, he or she may advance to isotonic exercises that strengthen the stabilizers. The scapular stabilizers are strengthened to provide a stable base for humerus rotation and maintain the glenoid in a position that has maximal congruency with the humeral head. Any change in position of the scapula will produce increased stress on the rotator cuff. In addition, many overhead athletes present with anterior tilt and lateral displacement of the scapula. This produces additional stress on the anterior structures of the shoulder. Moseley et al.[99] described a series of four scapular stabilizer exercises based on electromyographic findings to strengthen the scapula-stabilizing musculature. They recommended rowing, pushups with maximal protraction, scaption (which involves elevation of the humerus in the scapular plane with the humerus externally rotated), and press-ups (which utilize the pectoralis minor). Closed-chain exercises, such as pushups, enhance joint stability by providing a compressive force across the joint and diminish tensile forces across the capsule. However, care must be taken to avoid abducting the shoulder, which places increased pressure on the anterior joint.

Muscle strengthening of the rotator cuff may help stabilize the humeral head by providing compression across the glenohumeral joint and preventing impingement. Initially, exercises for shoulder strengthening should occur in the scapular plane. This provides several advantages.[118] This position offers an optimal length–tension relation between the deltoid and rotator cuff muscles and minimizes the stress on the anterior and posterior capsule and rotator cuff.[31] The supraspinatus may be selectively strengthened in the scapular plane or by prone horizontal lifts with the shoulder slightly externally rotated. The subscapularis may be strengthened by side-lying internal rotation lifts against resistance. The isotonic program should be followed by an isokinetic strengthening program as pain allows.

Internal and external rotation exercises can be performed using Theraband tubing. When strengthening the rotator cuff, it is important to include both concentric and eccentric strength exercises.[30] Before progressing to strengthening in an overhead position, apprehension must be eliminated. Muscular balance of the rotator cuff is important in restoring dynamic stability, and all muscular stabilizers must be taught to act synchronously.

Many overhead-throwing athletes present with excessive external rotation, reduced internal rotation, and a tightened posterior capsule.[19] Posterior tightness can lead to superior migration of the humeral head and anterior instability symptoms, with secondary impingement occurring as a result. When asymptomatic, such a patient should begin a stretching program to correct posterior capsular

tightness. Gentle internal rotation stretches in 90 degrees of shoulder abduction is a more specific stretch for posterior capsular tightness, which tend to stretch the scapular muscles,[41] than cross-body adduction stretches.

The biceps brachii should be strengthened to assist in anterior stabilization, and the deltoid should be able to provide abduction. The latissimus dorsi and pectoralis major should then be strengthened because they play an important role in deceleration of the shoulder in overhead activities.

Proprioception and neuromuscular control must also be emphasized in rehabilitation for shoulder instability. Lephart et al.[78] recommended four steps for the progression of activities. First, joint position and kinesthesia is accomplished through functional arcs of abduction and external rotation. Second, dynamic joint stabilization is accomplished with a wobble board to stimulate the activation of shoulder muscle force couples. Third, reactive neuromuscular exercises in the form of open-chain plyometric exercises can then be performed. Fourth, once joint sensibility and dynamic muscular control is obtained, training for functionally specific activities may be initiated. Continued muscle strengthening as well as endurance training specific for each sport should be performed. Posterior capsular stretches should be continued. An interval training program should be initiated and continued until the patient is able to return to full function in the chosen activity.

Athletes require strong legs and trunk to provide torque to their arms. The legs and trunk are responsible for more than 50% of the kinetic energy consumed during throwing.[12,142] Therefore, any rehabilitation program involving the arm must include conditioning exercises for the legs, hips, abdominal muscles, and back muscles before the patient resumes overhead activities to diminish the amount of work required of the arms in reestablishing preinjury overhead performance.

Surgical Indications and Management

Significant advances have occurred in the arthroscopic and open surgical treatment of glenohumeral instability. These advances include basic science principles of shoulder biomechanics as well as surgical techniques. A careful clinical evaluation with consideration of indications can yield appropriate patient selection for a given procedure.

In general, indications for surgical treatment include irreducible, open, or recurrent dislocation, failed nonoperative treatment, young patient age, or failed procedures with significant glenoid or humeral bone defects. Significant defects can be described as greater than 25% of the glenoid and large, engaging Hill-Sachs lesions.[21,22,97] First-time dislocation in a young patient is a controversial indication for operative treatment; however, multiple studies have shown a high recurrence rate in young patients treated nonoperatively as well as the ability of early operative intervention to decrease these recurrence rates.[4,18,52,53,70] Whether newer techniques of immobilization in external rotation will be successful may change recent trends to early operative intervention.

Role of Surgery for Patients with Initial Dislocations

Management of initial dislocations in young, active, athletic patients has become controversial. A high incidence of recurrence in young, active, athletic patients has been previously reported.[51,121] Physical therapy alone has provided mixed results. Aronen and Regan[6] reported a 75% success rate among 20 midshipmen at the Naval Academy using a strict physical therapy regimen. Because these results have not been replicated by others, many clinicians believe that patients with initial dislocations would benefit from a more aggressive surgical approach, given the natural history and associated pathology. The high rate of redislocation that exists in patients younger than 30 years old reinforces the concept that such patients may have a different clinical course than those older than 40, who have a much lower redislocation rate. In a cadaveric study of 182 shoulders, Hertz[49] demonstrated a difference in pathology in the two age groups. He showed that identical movements producing dislocation caused different lesions. In the younger age group, there was either disruption of the labrum from the osseous margin of the scapula or splitting of the fibers near their bases. In the older age group, there were no lesions of the labrum, but ruptures of the joint capsule occurred. Increased forces were required to produce dislocations in the younger group. Hertz[49] believed that these data supported the explanation that the primary disruption of the labrum in younger patients was responsible for redislocation and that these lesions could not heal by immobilization alone. This work supported a previous cadaveric study by Reeves,[109] who showed decreased capsular tensile strength as individuals aged. This occurred while the strength of the glenoid labral attachment remained constant.

Baker et al.[8] reported arthroscopic results on the pathology of first-time dislocators younger than age 30. They examined 45 shoulders within 11 days of the initial dislocation and developed a classification system based on the pathology observed: group I, capsular tear with no labral lesion; group II, capsular tear with partial labral detachment; and group III, capsular tears with complete labral detachment. Group III patients were grossly unstable on examination under anesthesia, whereas group I patients were stable. Of the 45 patients in the study, only six (13%) had no labral lesion; 39 (87%) had Bankart lesions.

Military personnel have provided a large population for studying the results of treatment in young, active patients with first-time dislocations. Wheeler et al.[140] reported a

92% recurrence rate after initial anterior dislocation of the shoulder in West Point cadets. This occurred despite traditional nonoperative treatment programs, which included 3 weeks of immobilization and a physical therapy program that was poorly followed. Given these retrospective results, Wheeler et al. performed an arthroscopic Bankart repair in nine subsequent patients and noted labral detachment in all nine, but no interstitial damage in the inferior glenohumeral ligament (IGHL). The recurrence rate for the nine was only 22%.

Arciero et al.[4] performed a prospective study using two treatment modalities for patients with first-time dislocations. One group of patients was treated nonoperatively with immobilization for 4 weeks and subsequent rehabilitation. The second group underwent diagnostic arthroscopy, arthroscopic Bankart repair, and the same rehabilitation program as the first group. Of the 15 patients in the nonoperative group, 80% developed recurrent instability. Of the 21 patients in the operative group (all with grade III Bankart lesions), only 14% developed recurrent instability. Arciero et al. noted that after initial dislocation, one would not expect to see a degenerated or absent labrum, marked capsular attenuation, or a large Hill-Sachs lesion, which are commonly encountered in a patient with chronic instability. This led them to believe that acute dislocation provides the optimal situation for success with arthroscopic repair. Neither West Point study, however, addressed the treatment of patients with other than grade III lesions of the labrum. This is inconsistent with Baker's study, which showed that 18 of 45 patients had such lesions.

Kirkley et al.[71] demonstrated decreased recurrence rates at an average follow-up of 75 months with immediate arthroscopic stabilization. This long-term follow-up also showed that those patients treated surgically had 11% higher quality-of-life scores. While not statistically significant, the authors concluded that this small difference is likely clinically meaningful. In a previous study, Kirkley et al.[70] showed that patients treated with traditional immobilization who did not experience a dislocation still had a significant deficit in disease-specific quality-of-life scores.

At present, the concept of immobilization is radically changing based on Itoi et al.[63] observations and recommendations that shoulders be immobilized in external rotation. Until we evaluate this concept, it will be very difficult to make definitive recommendations regarding a surgical versus a nonsurgical approach in a first-time dislocator.

Arthroscopic Surgical Treatment

The role of arthroscopy in the treatment of anterior shoulder instability has continued to evolve. Although there are no clearly defined indications for arthroscopic repair of anterior instability lesions, the ideal patient is a noncontact-sport athlete with anterior instability secondary to a traumatic injury, with a thick mobile Bankart lesion and little or no discernible capsular laxity.

Historically, the rate of recurrence reported with open surgical procedures has been less than 10% (Table 12-1).[41] However, one should also consider that many of these procedures resulted in significant reduction of shoulder motion helping prevent further instability. This reduced range of motion is not without consequences and therefore, some of the secondary outcome measures will need to be evaluated before we can truly determine the benefits of one technique over another. Nevertheless, arthroscopic repair has several theoretical advantages compared with open procedures, including minimizing surgical dissection, damage to surrounding tissues, and scarring. These factors may allow more rapid rehabilitation and improved range of motion. The arthroscope also allows improved visualization of the capsulolabral complex as well as other articular lesions[124] and may be associated with less morbidity than open techniques. Theoretically, increased scarring associated with open surgery may contribute to postoperative loss of motion. Limited external rotation after anterior shoulder surgery may be caused by loss of normal elasticity of the shoulder or by overtightening of the anterior capsule and subscapularis. Unlike some open procedures, all arthroscopic methods address the pathology of the anterior capsulolabral complex. However, the technical manner by which the anterior capsulolabral complex is reattached to the glenoid rim and how much the anterior capsule is advanced also differs between arthroscopic and open procedures. One potential disadvantage of the arthroscopic approach is that it may not afford as precise a repair of the attenuated anterior aspect of the capsule as the open approach.

Early reports of arthroscopic capsulorrhaphy involved the use of metal staples.[29,87] Significant complications of loose

TABLE 12-1

or painful hardware, articular cartilage injury, and recurrent instability led to the introduction of transglenoid sutures[90,98] (Fig. 12-7). This method was technically difficult for most surgeons. Fixation was dependant on tying of knots over the posterior fascia and was implicated as a possible cause for variable rates of recurrence. Some have shown success rates as high as 90%,[133] but other long-term follow-up showed unacceptable recurrence rates.[40] Risk of suprascapular nerve injury was also present with this technique. The most recent literature describes stabilization with bioabsorbable tacks, suture anchors, thermal capsulorrhaphy, and capsule-ligament suture plication.

Bankart Repair

Arthroscopic repair of Bankart lesions continues to evolve and reports of the effectiveness of this procedure continue to increase in the literature. A common theme in many of the reports is appropriate patient selection. Relative contraindications to arthroscopic repair include significant glenohumeral bone defects, humeral avulsions of the glenohumeral ligaments, and capsular insufficiency.[5,127] Some would add collision athletes to this list, although no study exists to show that the technique and not the pathology is the important factor in high recurrence rates. Each individual patient's mechanism of injury, expected postoperative activity level, and personal preferences should also be considered.

Repair of Bankart lesions using cannulated bioabsorbable tacks was reported by Speer and associates in 1996.[125] These barbed tacks are used as a transfixing anchor placed through the capsulolabral tissue (Fig. 12-8). Documentation on the effectiveness of bioabsorbable tacks has come mostly from studies comparing arthroscopic to open stabilization. Karlsson and associates[67] reported on 117 cases, 66 of which were arthroscopic. They showed a recurrence rate of 15% in the arthroscopic group and 10% in the open group. Rowe and Constant scores showed no significant differences between the two groups. Sperber et al.[126] reported on 56 patients, 30 treated arthroscopically and 26 treated with an open procedure. The recurrence rate in the arthroscopic group was 23% and in the open group was 12%.

An arthroscopic technique for anterior stabilization of the shoulder with a bioabsorbable tack. *J Bone Joint Surg Am* 1996;78(12): 1801–1807, with permission.)

Several studies illustrate the importance of patient selection in arthroscopic Bankart repair with bioabsorbable tack fixation. Aciero et al.[3] and DeBerardino et al.[28] described arthroscopic stabilization for initial anterior dislocation in a young, military patient population and showed recurrence rates to be comparable to documented recurrence rates of open procedures. Laurencin et al. also showed a low recurrence rate of 10% when indications were limited to traumatic, anterior instability with an isolated labral lesion and no significant bone defects.[76] Cole and associates[24] performed a study on 63 patients with recurrent instability. The patients were divided into arthroscopic or open groups based on findings during examination under anesthesia and diagnostic arthroscopy. Thirty-nine

patients with only a labral lesion and anterior instability were treated with bioabsorbable tack fixation. Twenty-four patients were found to have anterior–inferior instability and capsulolabral laxity and underwent open capsular shift. No significant differences were found between the two groups at mean follow-up of 54 months. These results demonstrate, again, the importance of patient selection when using bioabsorbable tacks. The advantages of this technique include decreased operative time and that it is technically easier than intraarticular knot tying. The disadvantages of this method of stabilization are no proven effective ability to address capsular laxity and the risk of synovial reaction, which has been reported in a few small reports[25,137] but never proven as a general problem.

Arthroscopic Bankart repair with suture anchors was reported in 1991[139] and has since been described by Wolf[144] using absorbable sutures and by Synder[123] using nonabsorbable sutures. Many studies have documented recurrence rates using suture anchors (Table 12-2). The differences in the definition of recurrence or failure make absolute comparisons among studies difficult. However, this has also been the case historically and therefore the trend in these studies toward a recurrence rate of less than 10% may indicate an improvement over previously documented recurrence rates of 15% to 33% for arthroscopic repair.[24,44,67,126]

Kim et al.[69] reported on 167 patients treated with arthroscopic stabilization with suture anchors. Mean follow-up was 44 months. They found 95% good to excellent results according to the Rowe scale and a recurrence rate of 4%. Ninety-one percent of patients returned to their preinjury level of activity. Fabbriciani et al.[35] recently described a comparative study on arthroscopic versus open treatment of Bankart lesions with 60 patients, 30 in each group. No recurrences were noted in either group at 2-year follow-up. The only significant difference was the mean value for range of motion (ROM) using the Constant score. The open group had a lower ROM score. The authors concluded that both procedures were effective and that the open procedure negatively affects postoperative ROM in the treatment of an isolated Bankart lesion. These recent studies continue to build a body of evidence that supports the theory that arthroscopic Bankart repair is an effective procedure and comparable to open stabilization.

The appropriate procedure (arthroscopic vs. open) for glenohumeral instability in the contact or collision athlete continues to be controversial. Unacceptable rates of recurrence have been seen with arthroscopic stabilization,[73] and Pagnani and Dome[107] reported on 58 professional American football players treated with open stabilization with suture anchors and had only two postoperative subluxations. They concluded that open stabilization was the procedure of choice in contact or collision athletes. Two recent studies have looked at arthroscopic treatment in athletes. Mazzocca et al.[89] reported on 18 collision or contact athletes that were treated with suture anchor, capsulorrhaphy, and adjunct thermal treatment of the capsule and rotator interval closure as needed. The recurrence rate was 11% (two recurrences). All patients returned to sport and only one of the two recurrences occurred during a collision sport. Ide et al.[59] reported on 55 athletes, 21 of whom were contact athletes, treated with arthroscopic stabilization with suture anchors. Overall recurrence rate was 7%, and there was no statistically significant difference between contact and noncontact athletes. The authors concluded that arthroscopic stabilization was a reliable procedure in this patient population. Further prospective randomized clinical trials comparing open and arthroscopic stabilization in this patient population are needed before any definite conclusions will be evident. However, the burden of proof lies with the arthroscopic procedures, as the open stabilization remains the gold standard.

Thermal Capsulorrhaphy

Thermal capsulorrhaphy is based on the response of the collagen molecule to thermal energy applied via a laser or radiofrequency probe (monopolar or bipolar). The thermal energy interrupts the collagen triple helix, thus shortening the molecule. The collagen fibers contract up to 60% of their length.[46] Cadaveric studies also showed decreased translation of the humeral head following treatment of the capsule with thermal energy[132] as well as reduction of capsular volume of up to 33%.[66]

Clinical studies followed and paralleled the information about the basic science rationale. These studies investigated thermal capsulorrhaphy for the treatment of many diagnoses including multidirectional instability (MDI), unidirectional instability, and rotator interval insufficiency. Miniaci and McBirnie[96] reported on 19 patients with MDI and showed nine recurrences at 9-month follow-up and significant complications of stiffness and neurologic symptoms. Others have also shown unacceptable failure rates in patients treated with thermal capsulorrhaphy only for MDI.[103]

In the setting of unidirectional instability with a Bankart lesion, several studies have investigated thermal capsulorrhaphy as an adjunct to capsulolabral repair. Gartsman et al.[37] followed 53 patients for an average of 33 months after arthroscopic treatment of anterior–inferior instability. The Bankart lesion was repaired with suture anchors and the capsule was treated with laser thermal capsulorrhaphy in 48 of 53 patients. Rotator interval repair was performed in 14 of 53 patients. According to Rowe score, 92% had good to excellent results. They found only four failures and concluded that the procedure provided results similar to open repair. Another similar study using suture anchors to repair a Bankart lesion and supplementing the repair with thermal capsulorrhaphy and rotator interval closure when indicated showed 11% recurrence in collision and contact athletes.[89] Thus, evidence exists that thermal capsulorrhaphy can be used as an adjunct to traumatic anterior and anterior–inferior instability and achieve low recurrence rates.

Controversy exists over the use of thermal energy in overhand athletes. Decreasing anterior capsular laxity and thus excessive external rotation with thermal capsulorrhaphy has been investigated. Evaluation of baseball players with internal impingement treated arthroscopically with and without adjunct thermal capsulorrhaphy showed that 97% of those treated with thermal energy returned to play. Significantly less, only 80%, of those treated without thermal energy returned to play.[80] It is important to note that the thermal treatment of the capsule was an adjunct to the treatment of other existing pathology and was not used in isolation. Enad et al.[34] reported on 19 overhand athletes treated with isolated thermal capsulorrhaphy with an average follow-up of 23 months. Six athletes were unable to return to play and the authors concluded that as an isolated treatment, thermal capsulorrhaphy was inadequate treatment.

In summary, thermal capsulorrhaphy may be effective as an adjunct treatment for anterior or anterior–inferior glenohumeral instability. Controversy remains over its role in the overhead athlete, but it may have a role as an adjunct in this patient population. Further studies are needed to define the clinical effectiveness and determine if any benefit outweighs the potential complications of nerve injury, stiffness, and attenuation of capsular tissue.

Capsule-Ligament Suture Plication

The open capsular shift has been described for the stabilization of instability without a labral lesion and for a patulous capsule after a labral lesion has been repaired. Few articles have documented the effects of arthroscopic suture plication of the capsule. It has been shown in a cadaveric model that a reduction of capsular volume of 19% can be achieved.[66]

Clinical studies have documented capsular suture plication. Caspari and Savoie[23] described an arthroscopic modification of the open anterior–inferior capsular shift. When a Bankart lesion is present, the capsulolabral complex is shifted superiorly on the glenoid and repaired to bone. In the absence of a Bankart lesion, the capsule is removed from the anterior inferior neck of the glenoid and shifted superiorly and secured to bone in the shifted position. Duncan and Savoie[32] showed satisfactory results in a small group of 10 patients with MDI. Others have also described capsular plication in patients with MDI.[91,141] Tauro[129] has described a modification of the capsular shift that involves a radial split at the 6 o'clock position. This procedure was used in combination with Bankart repair. A recurrence rate of 6.9% was demonstrated in a group of 34 patients with 2- to 5-year follow-up. Twenty-nine patients were treated with suture anchors and five patients were treated with transglenoid sutures. Two recurrences occurred in the suture anchor group and two in the transglenoid suture group. Given the recent studies showing high recurrence rates and significant potential complications associated with thermal capsulorrhaphy, capsular-ligament suture plication is the preferred arthroscopic treatment for capsular laxity.

Open Surgical Treatment

Indications for an open surgical procedure often depend on the experience of the surgeon. Advanced arthroscopic reconstruction requires technical expertise and special equipment. If appropriate technical experience or equipment is lacking, then an open procedure should be performed. Regardless of experience, relative indications for open surgical treatment exist. These indications include humeral avulsions of the glenohumeral ligaments, capsular rupture, previous failed open or arthroscopic repair,

prior failed thermal capsulorrhaphy, significant glenoid or humeral bone loss, and irreparable or chronic rotator cuff deficiencies, especially of the subscapularis.[95]

Although arthroscopic repair of anterior instability has seen good results in recent reports, open procedures are still the gold standard. A decision to perform surgery and the choice of procedure performed should be individualized based on the pathologic process creating the instability and on the training and experience of the surgeon. Patients with voluntary anterior instability are often poor surgical candidates; they require psychologic testing and may benefit from a rehabilitation program.[115] A trial of prolonged rehabilitation should also be used for patients with generalized ligamentous laxity or those with multidirectional instability. In addition, the presence of a Hill-Sachs lesion or glenoid deficiency may change the surgical approach.

Many open surgical procedures have been described as successful treatments for anterior glenohumeral instability. The major procedures can be divided into three different groups: capsular, subscapularis, and bony. Capsular reattachment procedures, such as the Bankart and Matsen repairs, are based on repairing the "essential lesion," as described by Perthes[108] and Bankart.[11] Subscapularis tightening procedures, such as the Magnuson-Stack and Putti-Platt procedures, are designed to realign and tighten the subscapularis and to limit external rotation. Bony procedures have been developed to augment the deficient anterior glenoid. The Bristow and Latarjet procedures provide a bony block and a musculotendinous sling across the anteroinferior glenohumeral joint by transferring the coracoid to the glenoid neck. Other conditions, such as a large Hill-Sachs lesion, may require an osteotomy or an infraspinatus transfer. In Sweden, osteotomies of the proximal humerus have been performed to realign the version of the glenohumeral joint.[138]

Glenoid deficiency may present a unique management problem. An acute glenoid fracture involving greater than one-fourth of the glenoid fossa and associated with shoulder instability is an indication for open reduction of the fragment with screw fixation.[16] A CT scan may be useful in determining fragment size and displacement.

Capsulolabral Repair

Bankart[11] and Perthes[108] described capsular repair by reattaching the detached anterior capsule to the anterior glenoid. Bankart[11] described the repair of the capsule to the bone of the anterior glenoid through the use of drill holes and sutures. The subscapularis muscle, which is carefully divided to expose the capsule, is reapproximated without any overlap or shortening. He reported no evidence of recurrence in 27 consecutive patients.

In describing long-term results with the Bankart procedure, Rowe et al.[114] developed a rating system for repair based on stability, motion, and function (Table 12-3). Over a 30-year period, they noted a 3.5% recurrence rate in 162 operatively managed shoulders, indicating that the results were excellent in 74% and good in 23%; 69% of the patients had full range of motion. They also noted that a fracture of the rim of the glenoid did not increase the risk of recurrence, but that a moderate to severe Hill-Sachs lesion increased the risk slightly. They performed primary repairs on patients with up to one-fourth of the glenoid fossa avulsed, achieving good to excellent results in all but 1 of 15 patients. They reported that 33% of the patients in throwing sports were able to return to their sports with the same level of proficiency, and that the other 67% could throw a baseball hard, but not with the same velocity as before surgery. There was no evidence of osteoarthritic changes in the 124 patients seen in follow-up.

Rosenberg et al.[112] reported that of 31 patients managed with the Bankart repair, only 13 were normal at follow-up; 14 had minimal degenerative changes, three had moderate changes, and one had severe degenerative changes (average follow-up, 15 years). Rowe et al.[117] also reported on recurrent anterior dislocation of the shoulder after surgical repair: Of 11 patients with lesions previously repaired by the Bankart procedure, three had intact repair at the time of reoperation. The underlying cause of the postoperative instability appeared to be severe laxity of the capsule. The other eight patients had disruption of the Bankart repair as well as capsular laxity.

Currently, suture anchors (which can simplify the procedure) are commonly used in open Bankart reconstructions. In a follow-up report by Levine et al.,[79] 32 patients underwent this procedure, with no complications from the suture anchor technique. However, there were two failures (recurrent anterior dislocations). Hovelius et al.[56] found a 2% redislocation rate after Bankart procedure compared with a 19% redislocation rate with the Putti-Platt procedure. More than one-third of the patients younger than age 25 were dissatisfied with the Putti-Platt procedure. The Bankart repair is frequently modified to adjust for capsular laxity, which makes this the procedure of choice for many orthopedic surgeons.

In 1989, Thomas and Matsen[131] described a procedure for repairing the anterior glenoid labrum without separating the subscapularis from the capsule (Fig. 12-9). They recommended detaching the capsule with the subscapularis tendon from the lesser tuberosity and reflecting it medially, exposing the anterior glenoid. A direct repair of the capsule can then be performed by placing the suture through the anterior glenoid. The subscapularis can then be reattached without advancement. For patients with capsular laxity, they recommended advancing the subscapularis. At 5.5 years average follow-up, good to excellent results were reported in 97% of patients. Range of motion was maintained with an average of 171 degrees of forward flexion and 84 degrees of external rotation in abduction.

TABLE 12-3
RATING SYSTEM FOR BANKART REPAIR

Scoring System	Units	Excellent (100–90)	Good (89–75)	Fair (74–51)	Poor (50 or less)
Stability					
No recurrence, subluxation, or apprehension	50	No recurrences	No recurrences	No recurrences	Recurrence of dislocation
Apprehension when placing arm in certain positions	30	No apprehension when placing arm in complete elevation and external rotation	Mild apprehension when placing arm in elevation and external rotation	Moderate apprehension during elevation and external rotation	Marked apprehension during elevation or extension
Subluxation (not requiring reduction)	10	No subluxations	No subluxations	No subluxations	
Recurrent dislocation	0				
Motion					
100% of normal external rotation, internal rotation, and elevation	20	100% of normal external rotation; complete elevation and internal rotation	75% of normal external rotation; complete elevation and internal rotation	50% of normal external rotation; 75% of elevation and internal rotation	No external rotation; 50% of elevation (can get hand only to face) and 50% of internal rotation
75% of normal external rotation, and normal elevation and internal rotation	15				
50% of normal external rotation and 75% of normal elevation and internal rotation	5				
50% of normal elevation and internal rotation; no external rotation	0				
Function					
No limitation in work or sports; little or no discomfort	30	Performs all work and sports; no limitation in overhead activities; shoulder strong in lifting, swimming, tennis, throwing; no discomfort	Mild limitation in work and sports; shoulder strong; minimum discomfort	Moderate limitation doing overhead work and heavy lifting; unable to throw, serve hard in tennis, or swim; moderate disabling pain	Marked limitation; unable to perform overhead work and lifting; cannot throw, play tennis, or swim; chronic discomfort
Mild limitation and minimum discomfort	25				
Moderate limitation and discomfort	10				
Marked limitation and pain	0				
Total units possible	100

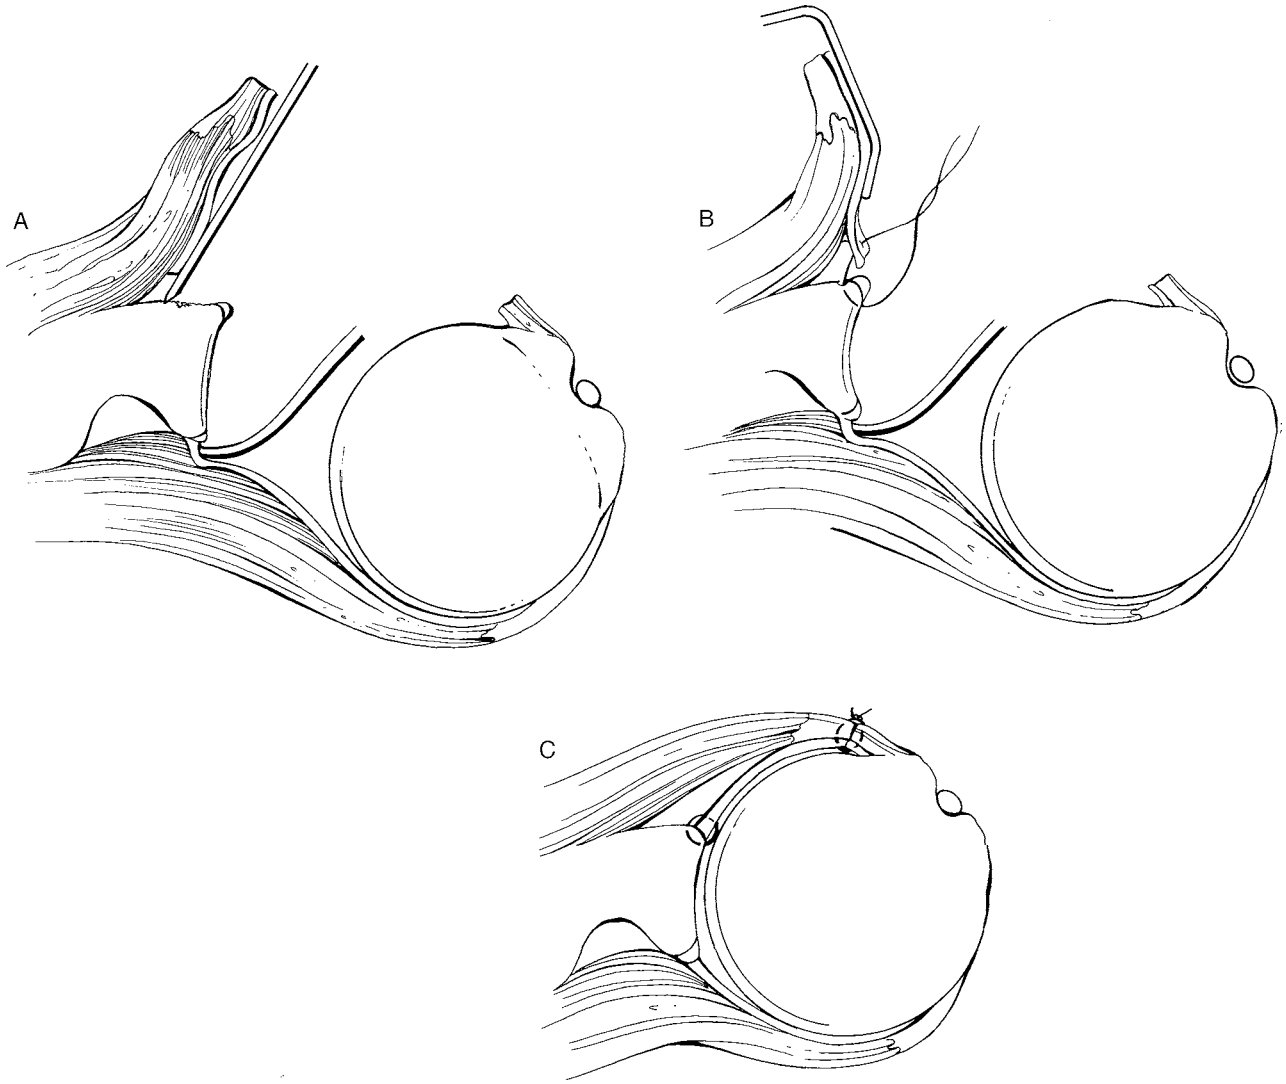

Figure 12-9 Matsen procedure. **(A)** The subscapularis is reflected with the capsule, exposing the Bankart lesion. **(B)** After the anterior glenoid neck is roughened with a curette, the Bankart lesion may be repaired. **(C)** The subscapularis is then reattached in its anatomic position to limit loss of external rotation. (From Thomas SC, Matsen FA 3rd. An approach to the repair of avulsion of the glenohumeral ligaments in the management of traumatic anterior glenohumeral instability. *J Bone Joint Surg Am* 1989;71(4):506–513, with permission.)

Capsular Shift Procedures

The effect of selective capsulorrhaphy has been documented. Gerber et al.[39] showed unique restrictions of passive motion with capsulorrhaphy of different areas of the capsule. Anterior plications restrict external rotation and posterior plications restrict internal rotation. Superior capsular plications restrict motion when the shoulder is in an adducted position and inferior plications restrict motion in abduction. A notable specific finding was that closure of the rotator interval decreased external rotation of the adducted arm 30.1 degrees, but caused no significant limitation of external rotation in abduction.

The Rockwood method of capsular imbrication (Fig. 12-10), as described by Wirth et al.[143] and Lusardi et al.,[84] addresses not only the repair of the capsule to the anterior labrum, but also the issue of capsular laxity. The subscapularis tendon is divided and reflected off the capsule. The lateral stump of the subscapularis tendon is also reflected from the capsule, exposing the entire capsule. The capsule is then divided vertically midway between its attachment on the glenoid rim and the humeral head. The joint is inspected for labral tear and stripping of the labrum, capsule, and periosteum off their normal attachments on the glenoid rim and the neck of the scapula. If stripping is noted, the capsule is reattached using sutures, followed by imbrication of the anterior capsule. The extent of the anteroinferior capsular laxity determines the degree of imbrication necessary to reduce the glenohumeral joint. In

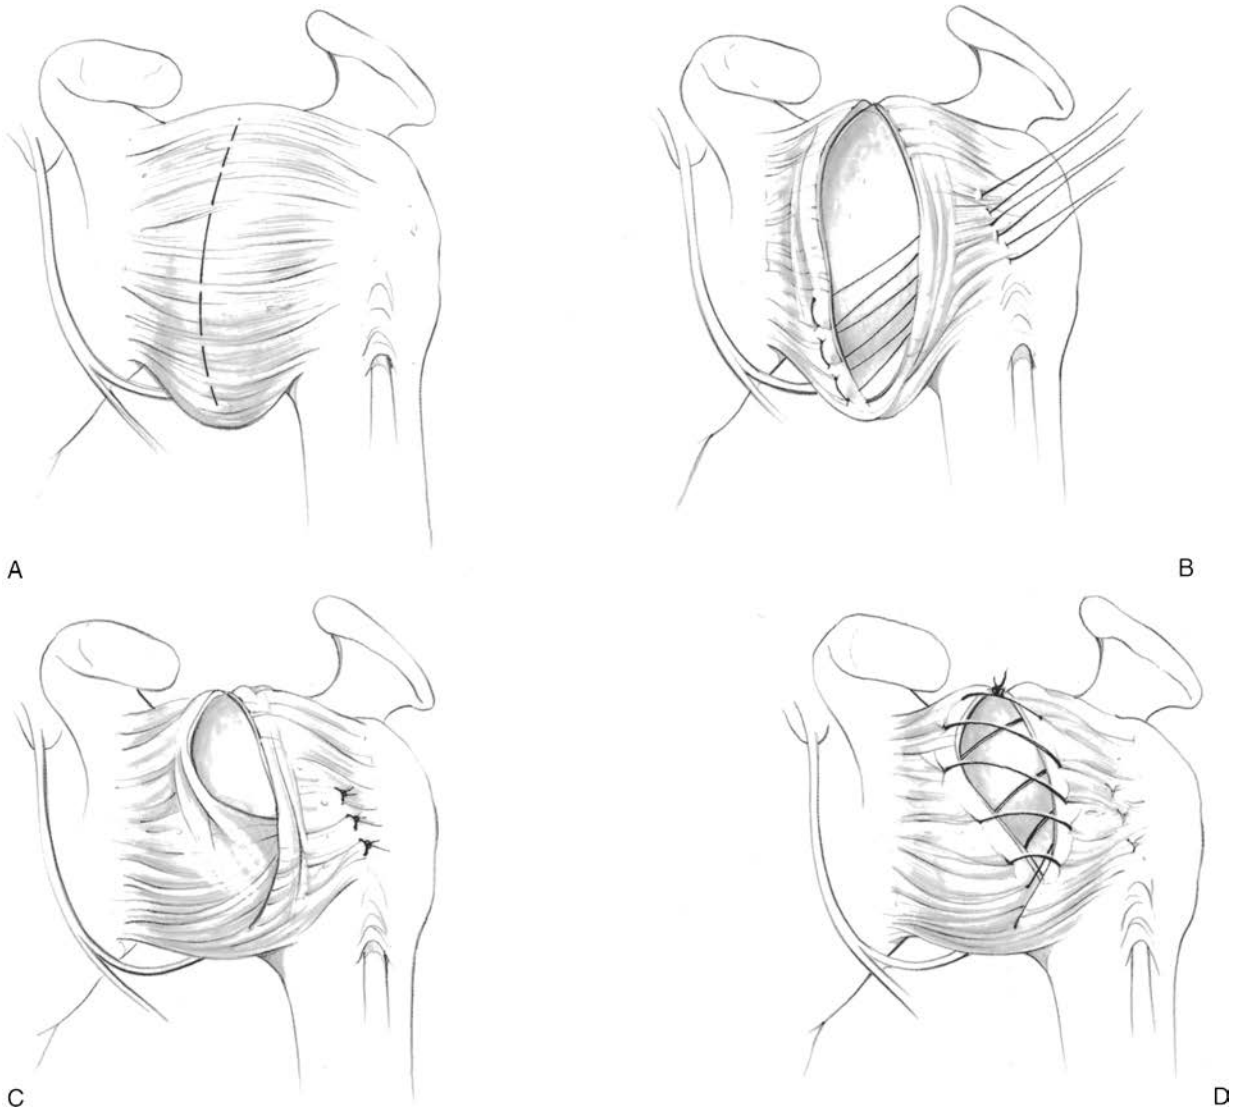

Figure 12-10 Rockwood method. **(A)** Division of the capsule vertically midway between the glenoid and humeral attachment. **(B)** The medial aspect of the capsule is overlapped laterally and superiorly under the lateral aspect of the capsule. **(C)** The medial aspect of the capsule is secured under the lateral aspect of the capsule with the arm held in 30 degrees of external rotation, and the lateral aspect of the capsule is advanced superiorly and medially over the medial aspect of the capsule, creating a double thickness of the weakened capsule. **(D)** If a capsular gap occurs, the defect may be repaired by lacing 1-mm–wide Dacron tape across the gap. (From Lusardi DA, Wirth MA, Wurtz D, Rockwood CA Jr. Loss of external rotation following anterior capsulorrhaphy of the shoulder. *J Bone Joint Surg Am* 1993;75(8):1185–1192, with permission.)

shoulders with a large degree of capsular laxity, the medial aspect of the capsule is often shifted 10 to 15 mm medially and superiorly and is imbricated for 15 to 20 mm by the lateral aspect of the capsule. After this procedure, the lateral aspect of the capsule is "double-breasted" by shifting the lax lateral capsule medially and superiorly and suturing it down to the anterior surface of the medial aspect of the capsule. Lusardi et al.[84] believed that this procedure eliminated laxity and provided added strength to the anterior capsule. Subsequently, the subscapularis tendon is anatomically repaired. In a study of 132 patients,[143] 93% had good or excellent results from this procedure at a minimum follow-up of 2 years. Patients sustained a loss of external rotation of 7 degrees compared with the contralateral side, and there was a 96% success rate on apprehension testing.

Neer and Foster[100] described a capsular shift procedure to address involuntary inferior and multidirectional instability related to capsular laxity (Fig. 12-11). The goal of this operation is to reduce joint volume. After thorough psychiatric evaluation, followed by initial rehabilitation, a capsular shift is performed, reducing the volume of the inferior portion of the capsule by detaching the capsule from the

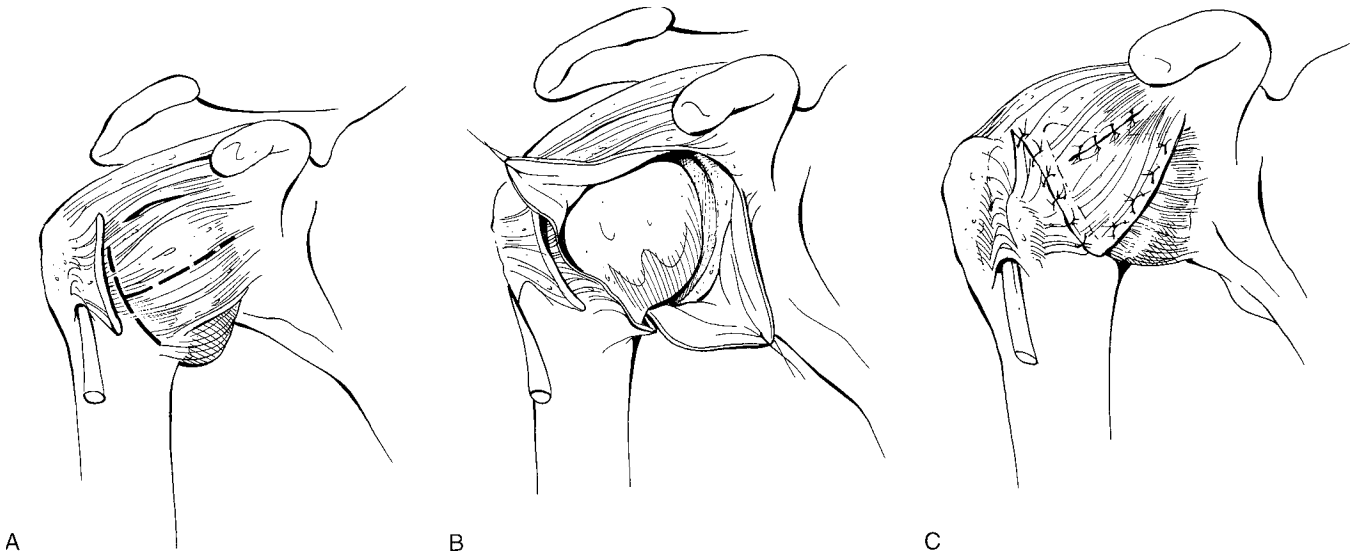

Figure 12-11 Neer inferior capsular shift. **(A)** Capsular incisions. The opening between the superior glenohumeral ligament and the middle glenohumeral ligament (which is almost constant) is closed with nonabsorbable sutures. A T-shaped opening is made by incising longitudinally between the middle glenohumeral ligament (MGHL) and the inferior glenohumeral ligament (IGHL) and detaching the capsule and ligaments from the neck of the humerus anteriorly, inferiorly, and to the posterior part of the neck. **(B)** Preparation of flaps and slot. The arm is externally rotated as the inferior flap is detached from the inferior part of the neck of the humerus, all the way back to the posterior aspect of the neck. During this step, a flat elevator is used to protect the axillary nerve. A shallow slot is made in the neck of the humerus anteriorly and inferiorly. **(C)** Relocating the flaps. The arm is held in slight flexion and 10 degrees of external rotation on the arm board. The inferior flap is relocated first. It is pulled forward to tighten the posterior part of the capsule until posterior subluxation no longer occurs, and it is pulled upward until the inferior capsular pouch is eliminated. The flap is then sutured to the stump of the subscapularis tendon and to the part of the capsule remaining on the humerus to hold it against the slot. The surplus portion of the flap is usually folded over to further reinforce the capsule. The superior flap, which contains the MGHL, is then brought down over the inferior flap so that it acts to suspend the humerus and also reinforces anteriorly. Note the sutures used to close the cleft between the MGHL and the IGHL before making the capsular incision. Finally, the subscapularis tendon is brought to its normal position and secured with nonabsorbable sutures so that it will remain a strong internal rotator. (Modified from Neer CS 2nd, Foster CR. Inferior capsular shift for involuntary inferior and multidirectional instability of the shoulder. A preliminary report. *J Bone Joint Surg Am* 1980;62(6):897–908.)

neck of the humerus and shifting it to the opposite side of the calcar. This maneuver not only obliterates the inferior pouch and capsular laxity on the side of the approach, but also reduces laxity on the opposite side. In a cadaveric study, Lubowitz et al.[83] showed that the inferior capsular shift reduced shoulder volume by 57%. Bigliani et al.[14] performed the Neer capsular shift procedure on 68 shoulders in 63 athletes. There was a 7-degree average loss of external rotation and a 2.9% incidence of recurrent postoperative dislocation. Of the 63 athletes, 92% returned to their sports and 75% of those returned to the same level of competitiveness. All 31 athletes involved in overhead sports returned to their sports (71% at the same level). Of the 10 overhead athletes who were involved primarily in throwing, five returned to the same level and five returned to throwing, but at a lower effectiveness rate than before surgery. Of the six professional or varsity athletes, only two returned to the same level of sports. In this series, 31% of the patients had a history of dislocation and had a Bankart lesion. The Bankart lesion is repaired at the time of the capsular shift. The series showed a 96% rate of good or excellent results and a redislocation rate of only 1.5%. No patient had recurrent subluxation.

The Jobe reconstruction[65,74,75] is a modified anterior capsulolabral shift, in which the subscapularis tendon is split transversely in line with its fibers at the junction of the upper two-thirds with the lower third (Fig. 12-12). A horizontal anterior capsulotomy is then made in line with the split of the subscapularis tendon. The labrum is left intact if still attached. If it is not, the anterior neck is decorticated and a superior flap is shifted inferiorly, overlapping and reinforcing the inferior flap that was previously shifted superiorly but not medially. Kvitne et al.[75] obtained 97% good or excellent results, with 81% of the patients returning to the same level of competition; 100% of the patients were subjectively satisfied with the operation. At the 2-year follow-up, no complications related to the use of fixation devices had occurred.

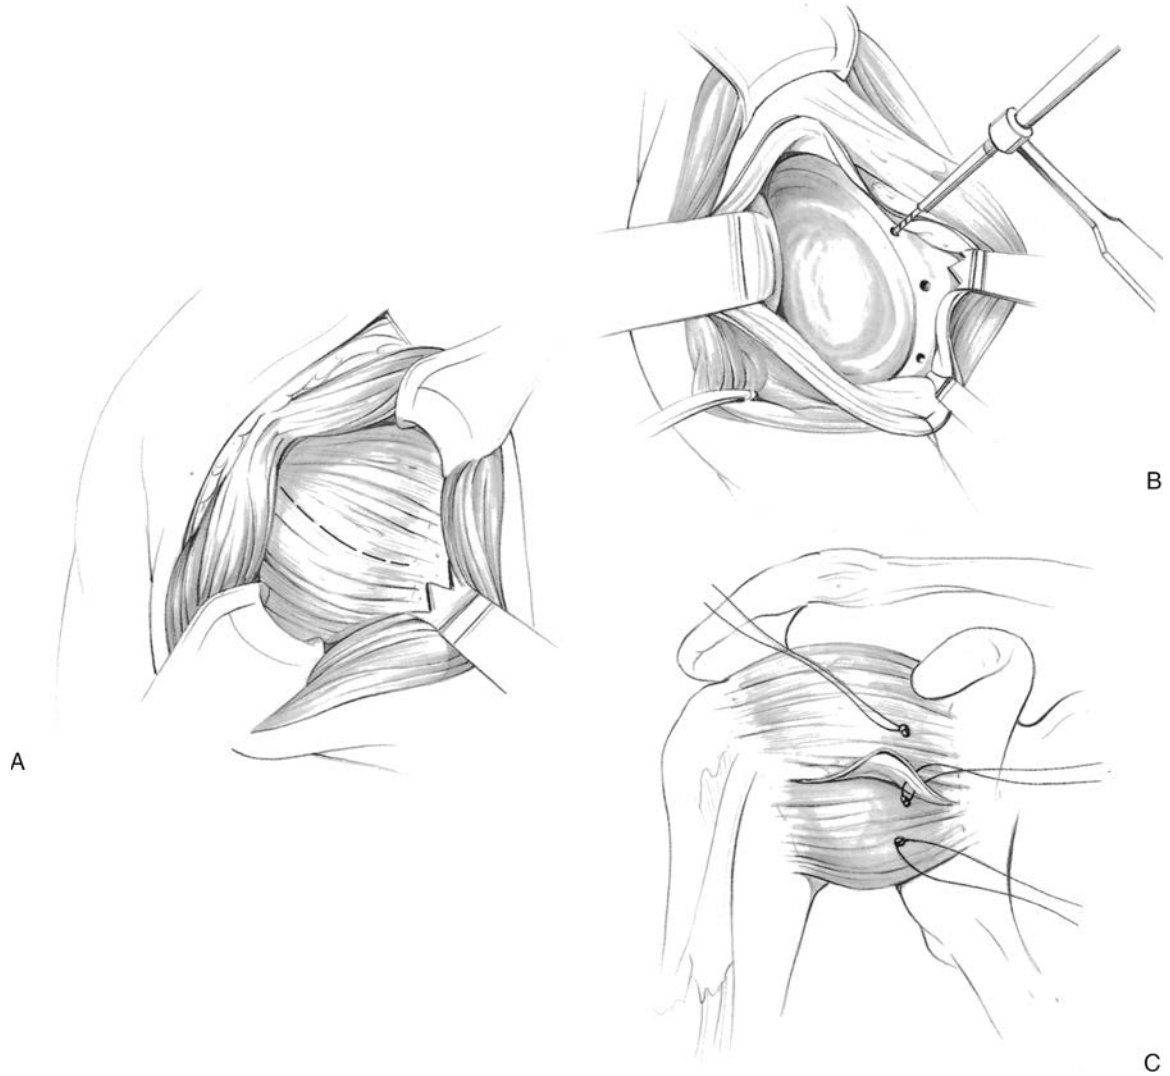

Figure 12-12 **(A)** Glenohumeral joint capsule exposure: *Dotted line* indicates site of capsulotomy. **(B)** Suture anchors are placed. **(C)** Superior capsular flap is shifted anteriorly, overlying the inferior flap. (From Kvitne RS, Jobe FW. The diagnosis and treatment of anterior instability in the throwing athlete. *Clin Orthop* 1993;291:107–123, with permission.)

Subscapularis Procedures

The current trend in orthopedics is away from subscapularis-based procedures. These procedures have a tendency to decrease external rotation and, although results are excellent in terms of redislocation rates, the patients have higher rates of dissatisfaction and osteoarthritis.

The Putti-Platt operation was described by Osmond-Clark in 1948.[105] This procedure shortens the subscapularis muscle unit by doubling it in a vest-over-pants fashion over the anterior glenohumeral joint. This limits external rotation and causes scarring in the anterior portion of the shoulder. Magnuson and Stack[85] described a procedure that involves transfer of the subscapularis tendon from the lesser to the greater tuberosity across the bicipital groove and 1 cm distally, which is believed to strengthen the anterior muscle barrier. As described by Magnuson and Stack, the operation results in 25% to 50% limitation of external rotation. Results of the Putti-Platt procedure show a long-term success rate of approximately 95%,[77,110] but it limits external rotation by 12 to 28.8 degrees. Regan et al.[110] reported that 22% of patients who had a Putti-Platt procedure had to modify throwing (compared with 38% in the Magnuson and Stack study[85]) and that 52% of patients with Magnuson-Stack procedures returned to their preinjury levels of competition.

Glenoid Bone Procedures

Significant glenoid bone loss, as described earlier in this chapter, is documented as approximately 25% of the anterior–posterior dimension.[15,21,22] Increased rates of recurrent instability with significant bone loss have revealed the need to address bony deficiencies.[21,22,38]

Glenoid Augmentation with Iliac Crest Bone Graft

Multiple authors have reported on reconstruction of the anterior glenoid with a free bone graft.[17,45,58,102] The goal of this technique is to restore the arc of the glenoid.[95] Techniques vary among different studies, but the most recent results have been good. Haaker et al.[45] and Hutchinson et al.[58] reported no recurrences in their series of 24 and 14 patients, respectively. In these two studies, patients were satisfied and had minimal loss of motion. Niskanen et al.[102] reported on a bone grafting procedure of the anterior glenoid that involved an iliac crest graft being press-fit into a trough created in the anterior glenoid. No other fixation was used. Fifty-two shoulders were included with a mean follow-up of 6 years. The recurrence rate was 21% and significant degenerative changes were present in 27 shoulders.

Coracoid Process Transfers

The Bristow procedure, originally described by Helfet[47] and later modified several times,[88] provides a bony block to dislocation by transferring the coracoid with the attached conjoined tendon to the neck of the scapula through an opening in the subscapularis tendon. This also reinforces the capsule with the conjoined tendon. Prevention of dislocation with this procedure has been very good (0% to 6%).[9,54,82,88,122] Nevertheless, Young and Rockwood[146] reported an overall good to excellent outcome in only 50% of 34 patients treated. A high rate of subluxation and hardware complications have been reported with the modified Bristow procedure; in addition, external rotation is frequently limited and overhead athletes usually cannot return to a highly competitive level.[9,82] Average loss of external rotation has been reported as high as 23 degrees.[134]

Burkhart and Debeer[21] contend that the Laterjet procedure with its larger coracoid bone block and soft tissue reinforcement with the attached conjoined tendon is more effective than the Bristow procedure, which has a smaller bone block. The Bristow procedure, they argue, relies more on the soft tissue restriction provided by the attached conjoined tendon when the shoulder is brought into abduction and external rotation. Allain et al.[2] demonstrated the Laterjet to be a stable reconstruction for recurrent instability. Of the 52 shoulders included in the study, none had redislocated at an average follow-up of 14.3 years. The same study showed osteoarthritis in 34 patients (58%) following the Laterjet procedure; however, the majority (25 patients) were only grade 1 changes. The factor most associated with osteoarthritis was placement of the coracoid too far laterally on the glenoid. Using the Rowe score as an outcome measure, 88% had a good or excellent result.

Hovelius et al.[55] recently showed results of the Laterjet procedure that are encouraging. In 118 shoulders with 15.2-year follow-up, only three experienced redislocation. Fourteen patients (12%) experienced dislocation or subluxation. Loss of external rotation was 12.4 degrees with the shoulder in abduction and 86% were able to return to their previous level of sports activity.

Humeral Bone Procedures

The interest in addressing large Hill-Sachs lesions is related to the increased recurrence rate in patients with these lesions noted by Rowe et al.[114] They noted that 100% of their patients with mild deficits had good to excellent results after Bankart repair, with no recurrences, but that those with moderate and severe defects had 5% poor results. Millett et al.[95] recommended addressing any glenoid bone deficiencies before surgical options for humeral defects are considered. These options include allograft reconstruction (Fig. 12-13) of the humeral defect (Hill-Sachs lesion) or rotational osteotomy of the proximal humerus.

Miniaci and Gish[97] recently reported on 18 patients with posterolateral defects that were greater than 25% of the humeral head. Average follow-up was 50 months. The average Constant-Murley score postoperatively was 78.5 and the Western Ontario Shoulder Instability Index showed significant improvement. There were no episodes of recurrent instability and 16 of 18 patients returned to work.

Derotation osteotomies of the humerus for instability have been described by Saha and Das.[119] They noted that the retrotorsion of the upper humerus is converted to relative antetorsion as the arm is raised overhead to 120 degrees. An osteotomy was performed that would align the articular surface of the humerus with the glenoid with the arm in 120 degrees of abduction. Although their early results showed no complications in the initial series, this technique has never become popular in the United States.

Postoperative Care

The timing of our postoperative rehabilitation protocol is described in Table 12-4. The patient returns for follow-up at 10 days, at which time the immobilizer is removed and rehabilitation is begun with pendulum exercises, isometric shoulder abduction, and internal rotation exercises. The patient should not proceed to regular activity before 3 months.

Authors' Preferred Surgical Technique: Anterior Capsulorrhaphy

Superficial Exposure

The anterior approach advocated by the authors is the same for both capsular repair and capsular plication and glenoid or humeral bone augmentation procedures. This unified anterior approach allows correction of any degree

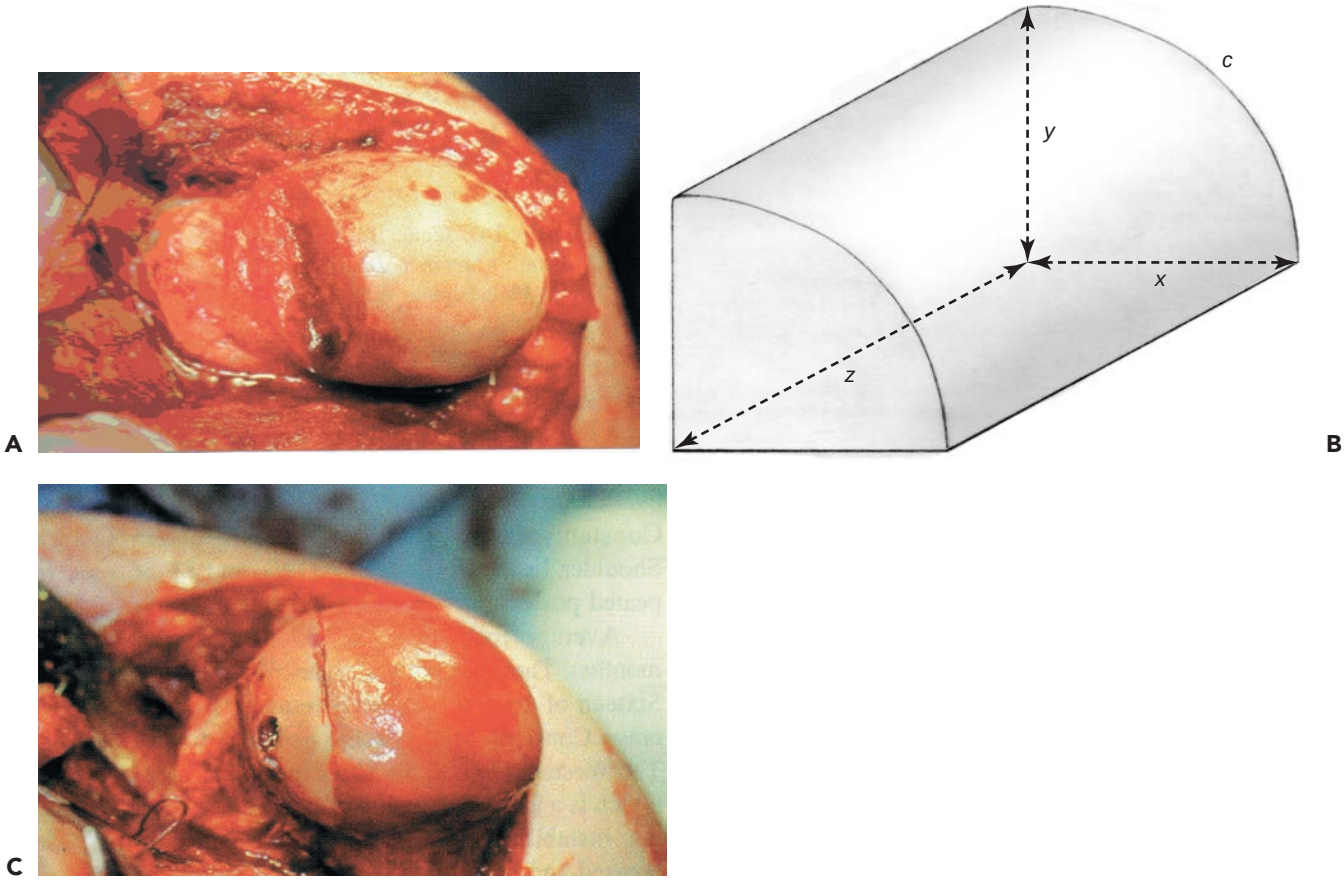

Figure 12-13 Humeral head allograft reconstruction. **(A)** Excised lesion. **(B)** Shaping the allograft. **(C)** Reconstructed humeral head.

of anterior capsular–labrum avulsion, capsular laxity, or bone loss that is defined intraoperatively.

The anterior axillary fold is identified by internal rotation of the arm. The incision begins in this anterior skin crease at the inferior border of the pectoralis major tendon and is extended superiorly approximately 5 cm. The subcutaneous plane is developed along the cephalic vein to the level of the clavicle and within 3 cm of the deltoid insertion site. The investing fascia on the medial side of the cephalic vein is incised over the extent of the subcutaneous dissection, the vein and deltoid muscle are retracted laterally, and the pectoralis major muscle is retracted medially. In heavily muscled patients, incising the upper 1 cm of pectoralis major tendon insertion can facilitate retraction. This is usually not necessary. In many patients, there is a leash of vessels superficial to the clavipectoral fascia that crosses over the deltopectoral interval at the level of the tip of the coracoid. These vessels, when necessary, can be ligated to improve exposure. The clavipectoral fascia is incised lateral to the coracobrachialis and the short head of the biceps (strap muscles), the musculocutaneous nerve is palpated on the undersurface of the muscle to define its location, and these muscles are then retracted medially.

Subscapularis Dissection

The structures to be identified are the subscapularis tendon from its bony insertion to its musculotendinous junction, the rotator interval, the long head of the biceps tendon within its groove, and the anterior humeral circumflex vessels. The axillary nerve can be palpated as it courses over the superficial inferior portion of the subscapularis muscle and enters the area under the inferior capsular pouch. The subscapularis tendon is incised with a coagulation Bovie cautery to the level of the capsule. The subscapularis incision begins 1 cm medial to the musculotendinous junction from the uppermost portion of the subscapularis, at the rotator interval, and extends inferiorly to the anterior circumflex vessels (Fig. 12-14A). These vessels are not generally ligated, but if more inferior exposure is required, then they can be. At the level of these vessels, the fibers of the subscapularis muscle are bluntly dissected toward the axillary nerve, taking care to protect the nerve from injury. Blunt dissection of the subscapularis at this level will identify the interval between the muscle and capsule. This is more easily accomplished at the inferior portion of the subscapularis than more superiorly where the tendon and capsule are more confluent.

TABLE 12-4
POSTOPERATIVE PHYSICAL THERAPY PROTOCOL

Time Frame	Procedures
0–2 days	Sling can be removed for bathing, dressing, and exercises Active exercises for elbow, wrist, and grip
7–21 days	Wean from sling Pendulum exercises Isometric shoulder abduction and internal rotation exercises
3 weeks	Wall climbing Active assisted ROM, abduction, and flexion Continue above
4 weeks	Progressive ROM Active assisted ROM, active ROM, and progressive ROM in flexion, abduction, and internal rotation Progressive resisted exercises Upper body ergometer
6 weeks	Progressive strengthening exercises Isokinetic strengthening when appropriate for patient Isolate external rotation and internal rotation
8–10 weeks	Progressive isokinetic strengthening of internal and external rotation in increasing ranges of abduction Add isotonic internal and external rotation strengthening
10–12 weeks	Plyoball
3 months	Patient returns to normal activity

ROM, range of motion.

After dissection of the interval between the muscle–capsule inferiorly, the plane of dissection is then bluntly carried superiorly with a narrow elevator. When it is ensured that the interval between the muscle and capsule is developed superiorly, sharp dissection can then be performed laterally between the tendon and capsule to meet the previously placed vertical incision in the tendon (Fig. 12-14B). The tendon is retracted medially with traction sutures and the subscapularis muscle is bluntly dissected medially from the capsule to a level 1 cm medial to the glenoid rim. The glenoid rim can then be easily palpated and the subscapularis tendon and muscle can be retracted medial to it with an anterior Bankart-type retractor or Hohmann retractor. The entire anterior capsule should now be exposed from the rotator interval to the anterior humeral circumflex vessels. The inferior capsular pouch is then exposed by blunt dissection deep to these vessels and deep to the most inferior portion of the subscapularis tendon. The axillary nerve can now be seen and palpated as it courses over the inferior capsule, and it can be retracted and protected by a blunt retractor if the surgeon prefers. We do not routinely expose it but are acutely aware of where it resides so as not to damage it. The entire anterior and inferior capsule is now exposed, and the interval between the capsule and lateral stump of the subscapularis tendon is sharply dissected a distance of 5 to 7 mm toward the lesser tuberosity (Fig. 12-14B).

Lateral Capsulotomy

The arm is placed in the plane of the scapula at 45 degrees abduction and 45 degrees of external rotation. In this position, the capsule is usually closely applied to the humeral head without any redundancy. If the capsule can be easily pulled away from the humeral head in this arm position, then there is redundancy of the anterior capsular pouch and a capsular shift will likely be necessary. In all anterior procedures, the capsule is incised 5 to 10 mm medial to its insertion on the humeral neck from the rotator interval to the anteroinferior capsular pouch (Fig. 12-14C). The humeral head is then retracted with a ring retractor and the capsule is retracted medially to inspect the glenoid rim and labrum–capsular attachments. With this exposure, the entire labrum can be examined along with the origin of the biceps tendon, the undersurface of the supraspinatus tendon, and the articular surfaces of the glenoid and humeral head. Hill-Sachs lesions can be palpated and, if large, can be seen with extension and external rotation of the arm.

Repair of the Bankart Lesion

If an avulsion of the capsule and labrum is noted (Bankart lesion), then the lesion is dissected from the glenoid rim medially to the glenoid neck, and the

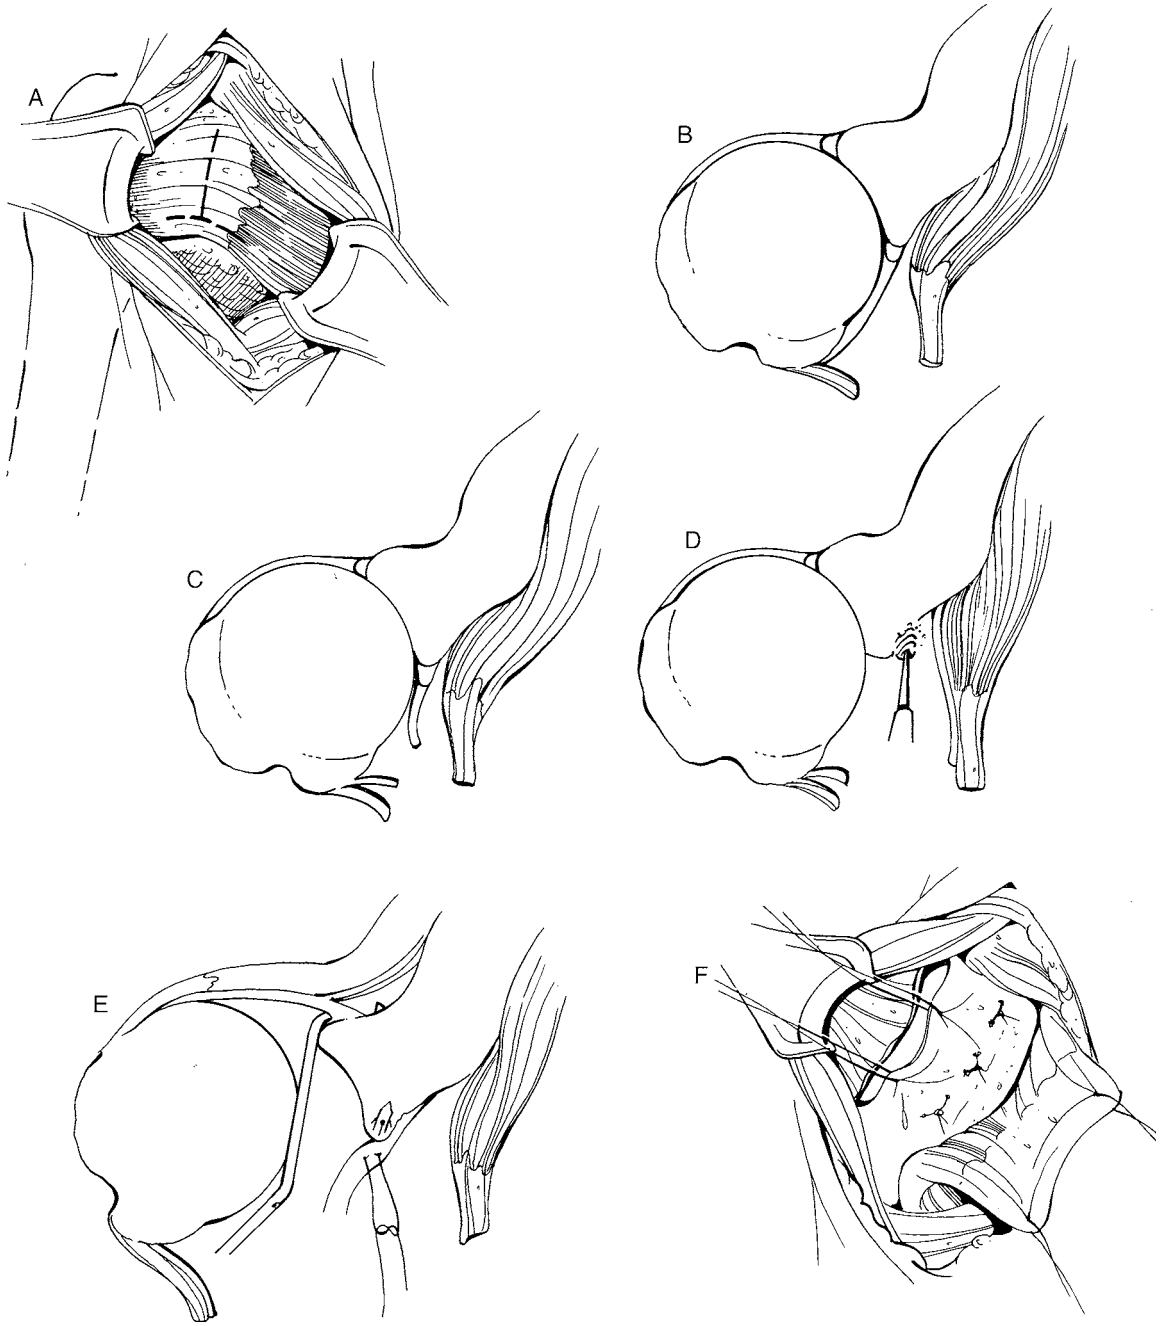

Figure 12-14 **(A)** The subscapularis incision begins 1 cm medial to the musculotendinous junction from the uppermost portion of the subscapularis at the rotator interval, and extends inferiorly to the anterior circumflex vessels. **(B)** The subscapularis is separated from the underlying capsule medially to the glenoid rim and laterally to the lesser tuberosity. The lateral stump of the subscapularis is defined to allow separated closure of the lateral capsule and subscapularis. **(C)** The capsule is then incised 7 to 10 mm from its humeral insertion site from the rotator interval to the inferior capsular pouch. **(D)** The capsule and subscapularis are reflected medially, the glenoid labrum is inspected, and, if a Bankart lesion is noted, it is reflected medially and the glenoid rim and neck are decorticated with a burr. **(E)** The suture anchors are placed exactly at the glenoid rim, and both limbs of the sutures are passed through the labrum and capsule. **(F)** The capsule is brought laterally and the limbs of the sutures are tied on the outside of the capsule.

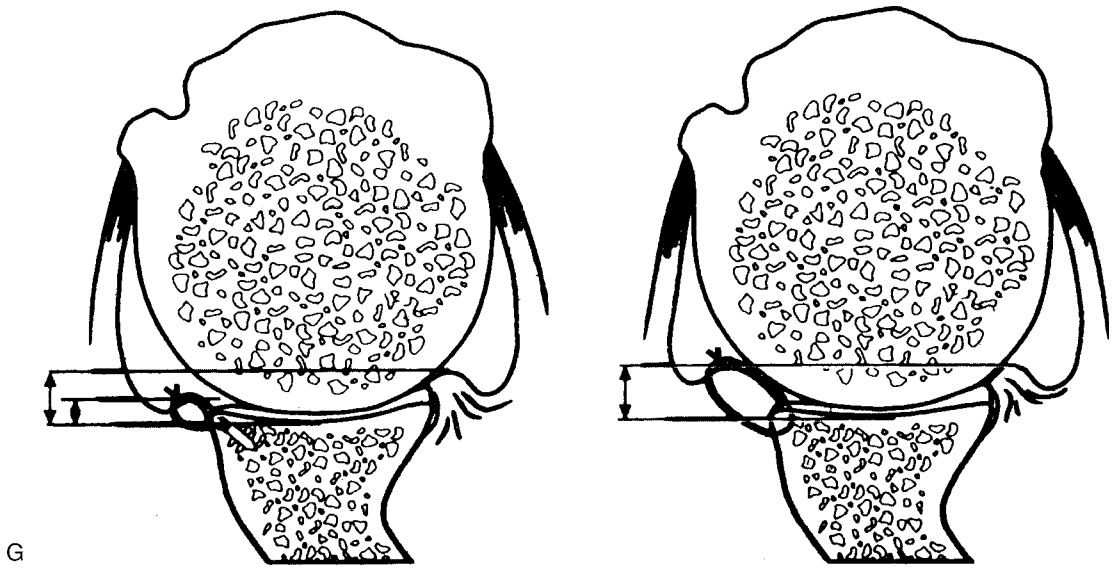

G

Figure 12-14 *(continued)* **(G)** The goal of the surgery is to repair the capsule and labrum so that a "bumper" effect of the labrum is reconstructed onto the glenoid rim. It therefore is necessary to put the anchors at the rim of the glenoid, to pass the suture through the labrum, and, if the labrum is attenuated, to use a barrel stitch to gather up the capsule to form a thickened mass of tissue to reform an anterior bumper.

anterior Bankart-type retractor or Hohmann retractor is placed deep to the lesion, thereby exposing the entire anterior glenoid rim. If this exposure is limited by the superior and inferior attachments of the labrum, then additional exposure can be obtained by incision through the rotator interval capsule and labrum at the superior apex of the avulsed labrum. When this is performed, the entire anteroinferior capsule can be retracted medially and inferiorly, because it is hinged on the most inferior extent of the Bankart lesion. The anterior glenoid rim and glenoid are gently decorticated to bleeding bone (Fig. 12-14D).

Suture anchors are placed at the osteochondral rim of the glenoid. Care is taken not to place these anchors medial to this point (Fig. 12-14E). If the glenoid rim has been eroded to a surface that is rounded or flat and even with the glenoid neck, then placement of osseous tunnels is more difficult. When this occurs, but the bone loss is less than 20% of the anterior to posterior glenoid dimension, then bone augmentation is not performed. In this circumstance, the anchors are placed at the margin of the glenoid rim. Two to five suture anchors are placed, with the number of sutures dependent on the size of the lesion. The capsule is then pulled laterally, and the Bankart retractor is placed superficial to the capsule and deep to the subscapularis. The capsule–labrum junction is identified, and both limbs of each suture are passed through this tissue so that when the sutures are tied, the labrum is firmly and anatomically approximated to the glenoid rim (Fig. 12-14F). When the labrum and capsule are attenuated, the suture is passed through the labrum and capsule tissue using a "barrel stitch" (Fig. 12-14G). With the barrel stitch, the tissue is rolled up, creating a thickened tissue to act as a "new labrum" and as such provide a new "bumper" and restore the concavity of the glenoid fossa.

Lateral Capsular Closure

After completion of the repair of the Bankart lesion, the lateral capsulotomy is closed. The arm is placed in the plane of the scapula at 45 to 60 degrees of abduction and 45 to 60 degrees of external rotation. The arm is held with a sterile intraoperative arm positioner (McConnell, Ft. Worth, Texas). The capsule is then pulled, with a forceps, laterally and superiorly to simulate closure of the capsule to the capsule on the humeral neck. If there is no capsular redundancy, then the rotator interval and lateral capsule are closed anatomically with nonabsorbable sutures, without any intended shortening of the tissue. The position of the arm is determined by the patient's degree of external rotation in this arm position under anesthesia before making the skin incision, by the degree of humeral head anterior translation measured under anesthesia and compared with the normal shoulder, and by the degree of generalized ligamentous laxity. In the overhead-throwing athlete, with a Bankart lesion but without generalized ligamentous laxity, the arm is externally rotated to equal the opposite shoulder, and the lateral capsule is closed. When performed in this manner, intraoperative loss of external rotation is approximately

10 to 20 degrees. This intraoperative loss of motion is regained in the postoperative rehabilitation.

If there is mild capsular redundancy noted in the foregoing arm position, then the entire anterior–inferior capsule can be shifted superiorly at the rotator interval and sutured. Under the less common circumstance of excessive capsular redundancy and a Bankart lesion, the rotator interval is closed and the capsule is incised between the middle glenohumeral ligament (MGHL) and the anterior–superior band of the IGHL, taking care not to incise the glenoid labrum. This capsular incision now creates a superior flap (superior glenohumeral ligament and MGHL) and an inferior flap (IGHL and inferior pouch). The arm is positioned in the plane of the scapula at 45 to 60 degrees of abduction and 45 degrees of external rotation. In this arm position, the inferior flap is shifted superiorly, thereby obliterating the inferior capsular pouch. The arm is then placed in 20 degrees of abduction and 35 degrees of external rotation, and the superior flap is shifted inferiorly. The capsular closure is performed with nonabsorbable suture. The extent of the shift and the capsular tightening by this method is determined by the arm position, thereby ensuring that the intraoperative external rotation will be at least 30 degrees measured in neutral abduction and 70 to 90 degrees of external rotation in the abducted position. This technique will avoid overtightening the capsule and ensure reproducible results.

Capsular Shift without a Bankart Repair

The exposure, subscapularis dissection, and lateral capsulotomy for an isolated anterior–inferior capsular shift is as described previously. The degree of capsular redundancy is assessed as described, and the labrum attachment and intraarticular structures are evaluated. In most cases of atraumatic or repetitive microtraumatic anterior, anteroinferior, or multidirectional instability, there is minimal labral or articular cartilage pathology. In these patients, the extent of the inferior capsulotomy is determined by the degree of posterior humeral head translation. The greater the degree of asymmetrical posterior translation is, the greater the degree of posterior capsular tightening is necessary; therefore, the capsulotomy is carried further posterior along the humeral neck. After completion to the lateral capsulotomy, the rotator interval is closed with nonabsorbable sutures. The capsule is incised in the midaxial plane between the MGHL and the anterior–superior band of the IGHL to the labrum, thereby creating superior and inferior capsular flaps. The arm is positioned and the capsular flaps sutured as described previously.

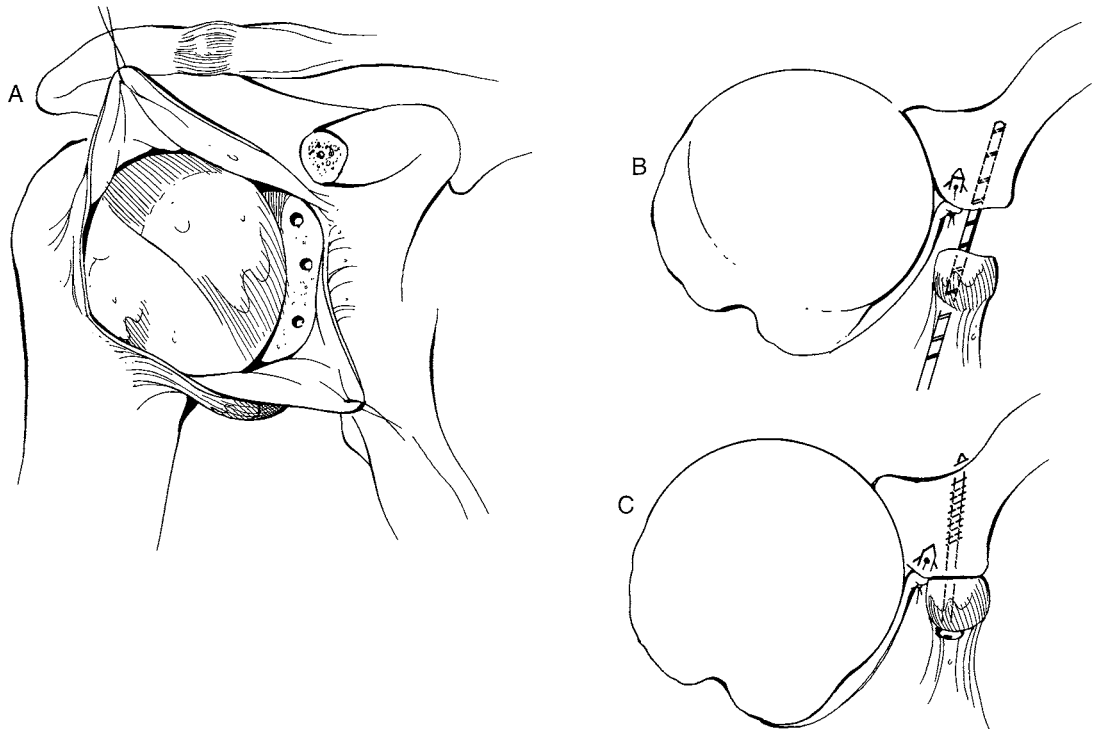

Figure 12-15 With moderate glenoid bone loss, an anterior capsulorrhaphy and coracoid transfer are performed. **(A)** The anchors are placed at the glenoid rim and the sutures are passed through the capsule and labrum, but not yet tied. **(B,C)** The glenoid defect is decorticated and the distal 1.5 cm of the coracoid are transferred to the defect and secured with a partially threaded screw.

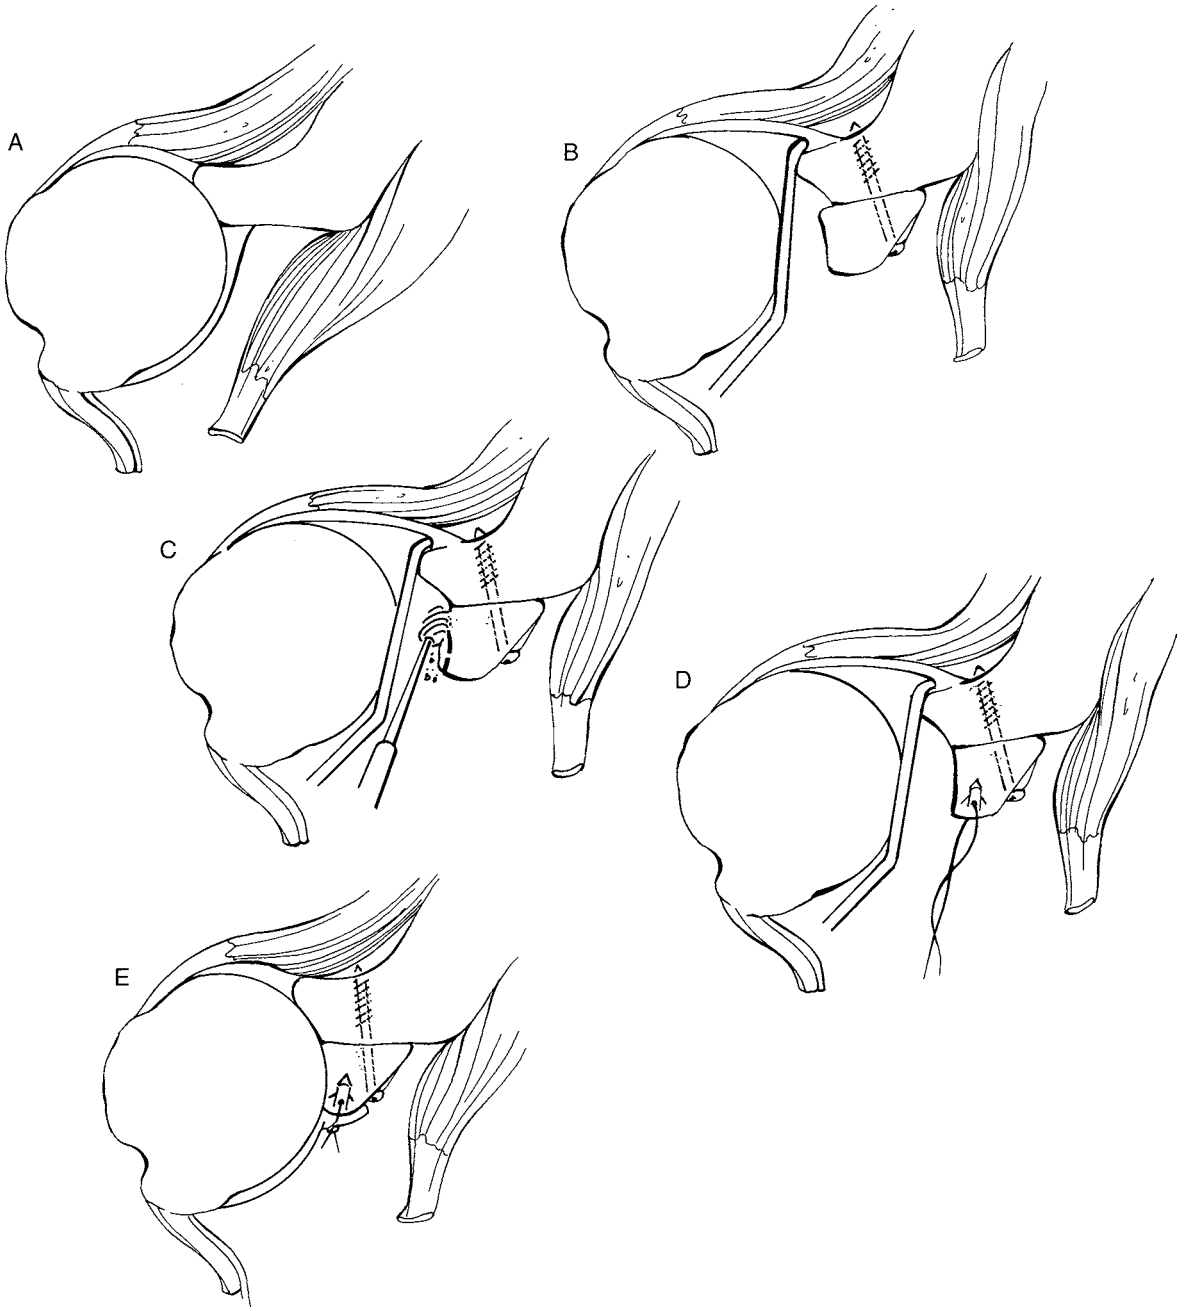

Figure 12-16 **(A)** For large anterior glenoid defects, an iliac crest graft is used to reconstruct the glenoid defect. **(B)** The defect is decorticated and made flat. A bicortical iliac crest graft is placed with its cancellous surface against the cancellous bone of the defect and secured with two partially threaded screws. **(C)** The position of the graft, which overhangs the face of the glenoid, is burred down to make a smooth contour with the native glenoid. **(D)** Suture anchors are placed into the rim of the graft. **(E)** The limbs of each suture are passed through the capsule and labrum, thereby repairing the ligaments to the new glenoid rim.

Subscapularis Closure

Closure of the subscapularis is with nonabsorbable suture without any shortening. In a similar way, the interval between the subscapularis and supraspinatus is closed. A drain is placed in the subdeltoid space. The subcutaneous tissues are closed with absorbable sutures, and the skin is closed with a nonabsorbable monofilament suture using a subcuticular technique. Steri-Strips, a sterile dressing, and a sling are applied, and the patient is reversed from the anesthetic.

Anterior Glenoid Deficiency

There is no consensus about the degree of glenoid bone loss that justifies bone reconstruction of the anterior glenoid. In our practice, we perform a bone reconstruction for cases with approximately 25% loss of the anterior-to-posterior glenoid dimension. In most people, this is approximately 6 mm of bone loss at the anterior–inferior aspect of the glenoid margin. Bone loss in the 20% to 30% range can be compensated by using a coracoid transfer; larger defects can be managed using an iliac crest graft.

The exposure, subscapularis dissection, and lateral capsulotomy for the bone augmentation procedures are as described previously, with the exception that the skin incision is extended superiorly to the tip of the coracoid. With significant glenoid bone loss, the glenoid defect is burred to a flat surface. Nonabsorbable sutures are placed with suture anchors at the osteochondral junction and passed through the labrum and capsule, but they are not tied (Fig. 12-15A). The periosteum over the osseous defect is then incised to expose the defect in an extraarticular fashion. The distal 1.5 cm of the coracoid with its attached strap muscles are osteotomized with a right-angle microsagittal saw. The tip of the coracoid is drilled with a 3.2-mm bit in a retrograde fashion and measured with a depth gauge. The drill bit is reversed, the tip of the coracoid is placed into the glenoid defect, the drill is advanced through the posterior glenoid cortex, and the depth of the glenoid hole is measured (Fig. 12-15B,C). A partially threaded 4.5-mm cancellous screw is then used to secure the coracoid tip into the glenoid defect. The previously passed capsular sutures are tied, thereby repairing the Bankart lesion to the rim; the coracoid transfer and screw remain extraarticular. The lateral capsular repair can be completed as just described; the technique is based on the degree of capsular redundancy. The subscapularis closure is as described.

For severe bone loss, an iliac crest graft is employed. The exposure, subscapularis dissection, and lateral capsulotomy are as described above. A bicortical iliac crest graft (appropriate size, 1.5 × 2.0 × 1.0 cm) is harvested. The anterior glenoid is decorticated and made flat to receive the flat cancellous surface of the iliac crest graft. The graft is placed so that the cortex of the iliac crest will constitute a new glenoid rim, and so that it slightly overhangs the articular surface of the glenoid. The graft is then secured with two 2.5-mm partially threaded cancellous screws (Fig. 12-16A,B). With a high-speed burr, the new articulating surface of the graft is contoured to match the level and radius of curvature of the remaining articular cartilage of the glenoid (Fig. 12-16C). Nonabsorbable sutures are placed at the rim of the iliac crest graft, as described for repair of a Bankart lesion. The lateral capsular and subscapularis closure is as described earlier (Fig. 12-16D,E).

Algorithm for Treatment

See Fig. 12-4.

CONCLUSION

The management of patients with anterior shoulder instability must be based on a thorough knowledge of the etiologic factors associated with the instability and the resulting pathology. The results of arthroscopic shoulder procedures continue to improve and in some cases have equaled the results of open procedures, with fewer complications. However, indications for open stabilization remain and the recurrence rates for open procedures are the gold standard.

Stability of the shoulder results from a marvelous harmony of static and dynamic factors. The challenge facing the physician treating anterior shoulder instability is to restore this often delicate balance. The choice of treatment necessary to accomplish this goal will vary according to host factors, the specific pathology, and the skill and experience of the surgeon.

CONCLUSIONS 430

INTRODUCTION

Posterior instability of the shoulder is defined as the symptoms expressed as a result of excessive posterior glenohumeral translation. The symptoms associated with posterior instability may be due to *recurrent subluxation* or acute *dislocation*. Diagnosis depends on the clinical history of instability reported by the patient, reproduction of symptoms during physical examination, and the results of diagnostic evaluation.

Acute posterior dislocation is rare in comparison with its anterior counterpart. Recurrent posterior subluxation is the most common form of posterior instability and represents the principal topic of this chapter. Although posterior instability is uncommon in comparison with its anterior counterpart, it is being recognized with increased frequency.[27,32,81] Historically, the literature has been unclear on the distinction between recurrent posterior subluxation and posterior dislocation. This, combined with a limited understanding of the pathophysiology of recurrent posterior subluxation, has resulted in a lack of consensus on its diagnosis and management.

McLaughlin recognized the distinction between (locked) posterior dislocation and recurrent posterior subluxation.[49] Attempts to further classify recurrent posterior subluxation have employed the same terminology as anterior instability. This classification defines instability based on its degree (subluxation, dislocation), origin (traumatic, atraumatic), direction (anterior, posterior, inferior, multidirectional), or patient volition (voluntary, involuntary). In anterior instability, for which the origin and direction of instability often correlate with an underlying pathologic lesion and direct appropriate treatment, these terms are invaluable. The same is not true of posterior instability.

TABLE 13-1
CLASSIFICATION OF POSTERIOR INSTABILITY

Posterior dislocation
Acute posterior dislocation
Chronic (locked) posterior dislocation
Recurrent posterior subluxation
Volitional
Psychogenic
"Learned"
Dysplastic
Glenoid retroversion
Humeral head retrotorsion
Acquired
Soft tissue deficiency
Bony deficiency
Scapulothoracic dysfunction

Describing posterior instability based on a traumatic or atraumatic basis or as voluntary or involuntary does not necessarily define the underlying pathology or assist in treatment decisions. Regardless of the cause of posterior instability, the nature of the underlying pathology is not predicted based on current classification schemes. The absence of a classification system that unifies posterior instability has made it difficult to evaluate various treatments and their results.

An anatomically based classification of recurrent posterior subluxation, as opposed to the more traditional cause-based methods of classification, facilitates treatment by defining the pathologic process that produces the instability. The salient features of this anatomic-based classification system are summarized in Table 13-1.

POSTERIOR DISLOCATION

Acute Posterior Dislocation

Acute posterior dislocations are rare, accounting for approximately 5% of all dislocations. Direct trauma to the front of the shoulder, a posteriorly directed force on an adducted arm (fall on an outstretched hand), and indirect muscle forces (seizure or electrical shock) all can cause posterior dislocation.

Diagnosis

The diagnosis of posterior dislocation should be readily made through a careful history, physical examination, and supporting radiographic studies. Before the advent of radiographs, the distinctive presenting features and physical findings of posterior dislocation were described.[17] The routine use of radiography for injuries of the shoulder should increase the diagnostic accuracy. Unfortunately, nearly half of all posterior dislocations are missed.[36]

Patients with posterior dislocation typically present with the arm splinted at the side in adduction and internal rotation. The classic physical findings in posterior dislocation include the following: (a) limited external rotation of the shoulder with the arm at the side; (b) limited forward elevation of the arm; (c) a void in the anterior aspect of the shoulder; (d) prominence of the coracoid process; and (e) fullness of the posterior aspect of the shoulder. Appreciation of these features is facilitated by examining the shoulder from above. A thorough neurovascular examination before and after shoulder reduction is essential.

Radiographic evaluation for a suspected posterior dislocation includes at least an anteroposterior (AP), scapular lateral, and axillary view of the shoulder. If positioning the patient for a standard axillary radiograph is not possible because of painful abduction, a Velpeau axillary or a trauma axillary radiograph can be obtained. The views are sufficient to diagnose the position of the humeral head and any associated bony lesions (Fig. 13-1). The classic radiographic features of posterior dislocation include humeral head overlap on the glenoid rim on an AP radiograph, an empty glenoid on an axillary or a lateral radiograph, fracture of the lesser tuberosity, and a reverse Hill-Sachs lesion.

A computed tomography (CT) scan is recommended when a satisfactory trauma series is difficult to obtain or interpret. If there is any concern about an associated fracture that is not appreciated on the radiographic evaluation, a CT scan is helpful in characterizing the fracture pattern.

Treatment

The management of an acute posterior dislocation requires care to avoid further damage to the humeral head. Forceful reduction attempts in the face of a locked dislocation or a nondisplaced fracture risks displacing the humeral head. A closed reduction can be attempted if the reverse Hill-Sachs lesion involves 40% or less of the humeral head. The reduction maneuver may require the involvement of an assistant. The arm is flexed to 90 degrees and adducted to disimpact the humeral head from the glenoid rim. The arm should not be externally rotated until the humeral head has cleared the glenoid rim. Lateral traction on the arm assists in disimpacting the humeral head from the glenoid rim. Gentle pressure on the humeral head guides it into the glenoid fossa and provides tactile input on its location relative to the glenoid. Once the humeral head clears the glenoid, the arm is externally rotated and brought down to the side.

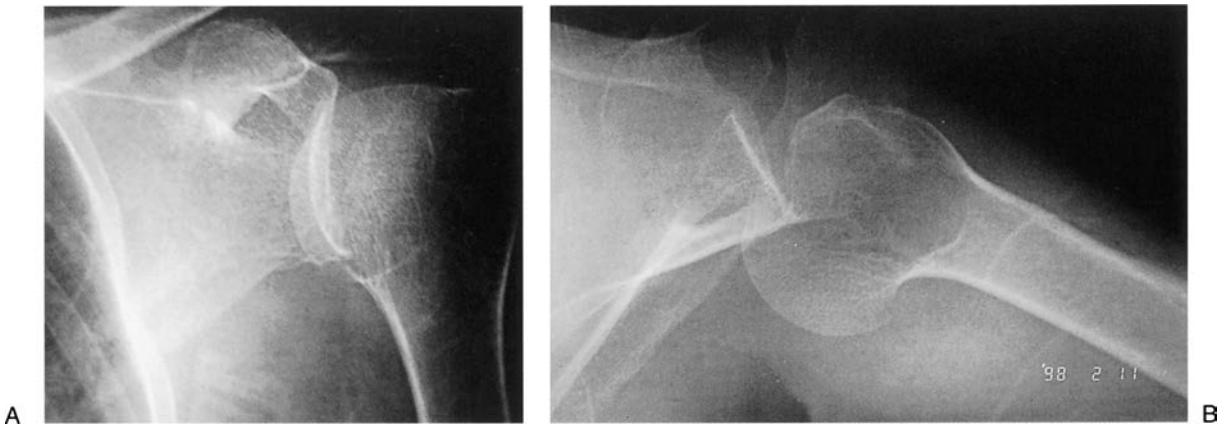

Figure 13-1 **(A)** Anteroposterior and **(B)** axillary radiograph of a locked posterior dislocation. Note the impression fracture of the humeral head and the nondisplaced anatomic neck fracture (*arrow*).

The arm is immobilized in a brace, with the arm in slight abduction and neutral to slight external rotation for 4 to 6 weeks. If there is a large (30% to 50%) humeral head defect and the humeral head dislocates with internal rotation when the arm is in neutral (0 degrees of abduction), then consideration should be given to transfer of the subscapularis, bone grafting, or humeral head replacement (see section on locked posterior dislocation in Chapter 15).

RECURRENT POSTERIOR SUBLUXATION

Volitional Recurrent Posterior Subluxation

Voluntary recurrent posterior subluxation describes a group of patients with an underlying conscious or unconscious ability to subluxate their shoulder by using abnormal patterns of muscular activity. In this group of patients there is no initial anatomic pathology in the glenohumeral joint. Over time, stretching of the glenohumeral ligaments can occur such that an involuntary component to the instability develops. Some of these patients have underlying psychiatric disorders as a cause for willful and voluntary posterior subluxation. Rowe et al. labeled these patients habitual dislocators.[65] Habitual dislocators are distinguished from other patients with posterior subluxation, who may have learned how to reproduce their instability, by their willful desire to subluxate their shoulders (Fig. 13-2). Despite the best intentions of the treating physician, habitual dislocators will frustrate all treatment efforts (operative and nonoperative) because of their abnormal psychologic need to subluxate their shoulder.[65] The overwhelming pathologic process in this group of patients is psychologic, and treatment should be directed according to their psychologic needs. Surgical intervention in this group is contraindicated.

A second group of patients can voluntarily reproduce their instability, but they have no underlying psychologic need to do so. This is a learned behavior that over time may develop an involuntary component. It is this involuntary component that is bothersome to the patient and often initiates evaluation by a physician.

Electromyographic evaluation of patients who can voluntarily subluxate their shoulders demonstrates selective inhibition of certain muscle groups that results in an unbalanced force couple, leading to posterior subluxation. Activation of the deltoid and pectoralis major without opposition from the posterior short rotators, resulting in the humeral head being pushed posteriorly, was identified in several patients.[65] Conversely, Pande et al. demonstrated unopposed activation of the posterior short rotators and posterior deltoid that in effect pulls the humeral head posteriorly.[60]

Dysplastic Recurrent Posterior Subluxation

Dysplastic bony architecture of the glenohumeral joint is another uncommon cause of recurrent posterior subluxation.[19] Localized posterior glenoid hypoplasia, increased glenoid retroversion, and increased humeral head retrotorsion are potential causes of recurrent posterior subluxation. Recent investigations have documented a low incidence of abnormal bony architecture in patients with instability and have postulated that developmental bony deformities are rare causes of recurrent posterior subluxation.[28,63,84] Edelson reported the incidence of posterior glenoid dysplasia in over 11,000 cadaveric specimens studied. In this group as many as 35% of the specimens had deficiencies in the posteroinferior aspect of the glenoid. Even though this condition may be more prevalent than previously thought, it is impossible to correlate these findings with clinical symptoms of instability.[19]

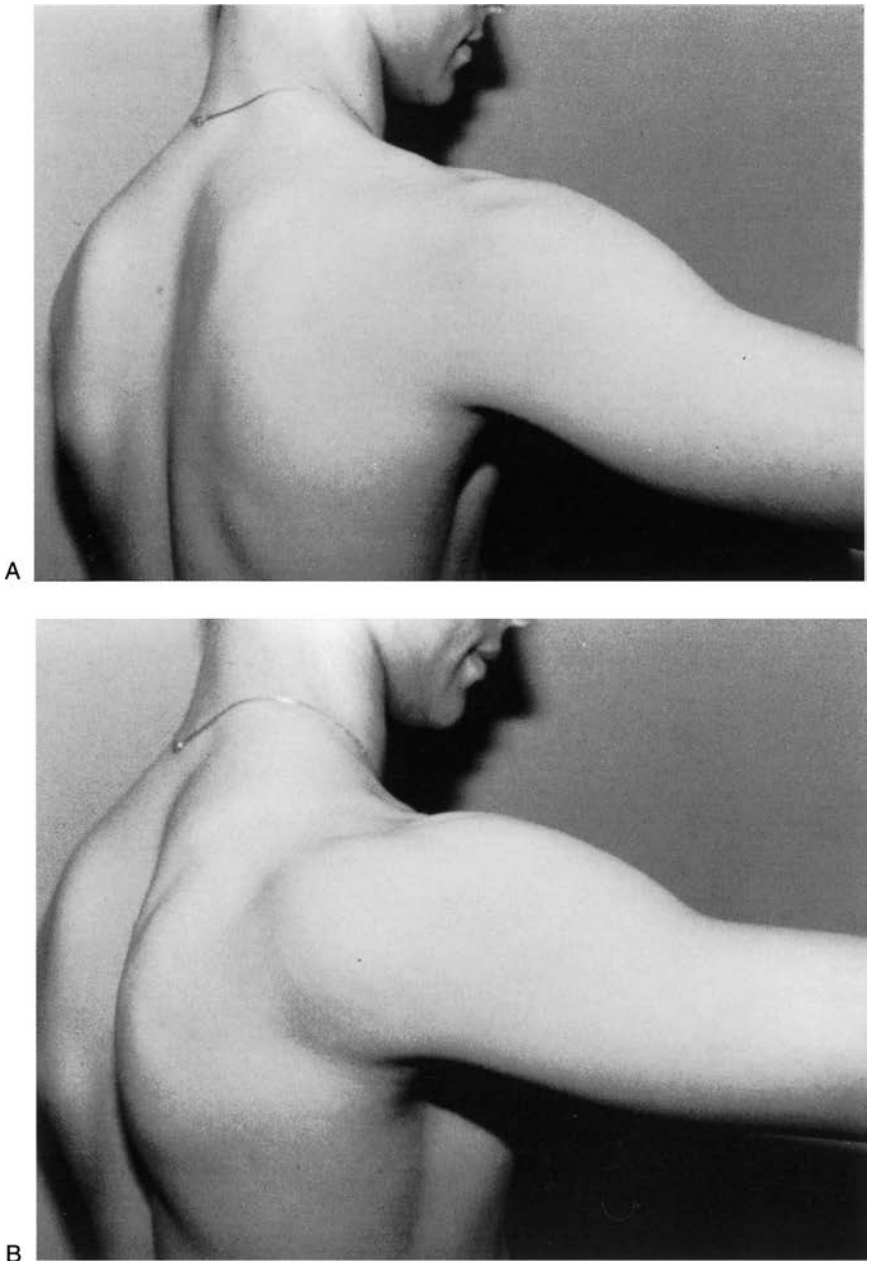

Figure 13-2 Photograph of a patient **(A)** before and **(B)** after dislocating his shoulder posteriorly with asymmetrical muscular contraction.

In the past, the theory that increased glenoid retroversion contributed to recurrent posterior subluxation was supported by radiographic techniques that indirectly measured glenoid retroversion, but are now felt to be inaccurate.[20] The advent of CT has allowed direct measurement of glenoid geometry and has renewed interest in this area. Recent studies based on CT scan assessment of glenoid version vary widely on the incidence of abnormal glenoid geometry and its contribution to instability. Gerber et al. and Randelli and Gambrioli found no correlation between altered glenoid version and instability.[28,63] Conversely, Hurley et al. and Wirth et al. have separately demonstrated increased glenoid retroversion and isolated posterior glenoid hypoplasia, respectively, in all patients with recurrent posterior subluxation reported in their respective series.[38,85] Although the incidence of increased glenoid retroversion or hypoplasia in patients with recurrent posterior subluxation is confused by these conflicting reports, it is clear that increased glenoid retroversion or hypoplasia can contribute in some cases to recurrent posterior instability.[84] The true incidence, however, is unclear.

Although the exact cause of glenoid hypoplasia is unknown, an abnormality in the formation or development of the proximal (subcoracoid) or inferior centers of ossification may be the cause. As these centers do not appear and ossify until well into the second decade of life,

these patients usually do not present with symptoms until their second or third decades.[64] Whereas a CT scan is useful in defining the severity of glenoid hypoplasia, several findings on routine shoulder radiographs have been associated with this condition. Among these are a shallow or irregular glenoid fossa, a prominent coracoid process, an enlarged acromion, hooking of the distal clavicle, an associated hypoplasia of the upper ribs, and flattening of the humeral head.[14,20,74] The appearance and the degree of these radiographic findings vary in patients with this condition.

Abnormalities of humeral torsion could lead to glenohumeral instability. Accurate measurement of humeral retrotorsion is difficult. Schutte et al. described a technique for measuring humeral retrotorsion by CT scan.[67] This allows direct measurements of humeral retrotorsion, thereby eliminating the inaccuracy of plain radiographs. Kronberg and Brostrom have documented a correlation between decreased humeral retrotorsion and anterior glenohumeral instability in some patients. However, a relation between increased humeral retrotorsion and recurrent posterior subluxation has not been established.[45]

Reports of proximal humerus rotation osteotomy for the treatment of recurrent posterior subluxation are not supported by radiographic data demonstrating increased humeral retrotorsion.[14,77] The rationale for osteotomy in these series is that patients with recurrent posterior subluxation can provoke symptoms of instability by internal rotation of the arm. Limiting internal rotation through osteotomy was believed to correct the problem by preventing the patient from placing the arm in a position that would incite dislocation.

Acquired Recurrent Posterior Subluxation

The largest group of patients with recurrent posterior subluxation acquires posterior instability as a result of repetitive microtrauma or as a result of a single traumatic event. Traumatic events leading to both osseous and soft tissue abnormalities can result in subsequent recurrent posterior instability. Because the cause of this instability is not as crucial to treatment as the underlying pathologic lesion that results in recurrent posterior subluxation, we define acquired recurrent posterior subluxation based upon the anatomic lesion. Lesions of the capsule, labrum, rotator cuff musculature, and glenoid can contribute to recurrent posterior subluxation. The most consistent deficiency relates to redundancy of the posterior capsule. Additionally, dysfunction of normal scapulothoracic mechanics can place the glenohumeral joint at risk for recurrent instability.

Unlike the anterior capsule, the posterior capsule is thin. The posterior capsule and the buttress provided by the posterior glenoid labrum are the primary static stabilizers to unidirectional posterior translation. Dynamic posterior stability is conferred by the rotator cuff musculature. The most consistent finding in patients with recurrent posterior subluxation is a patulous posterior capsule.[68] The posterior capsule either stretches over time or tears as a result of single-event trauma and heals in an elongated position, thereby increasing capsular volume. Posterior labral tears have been described with recurrent posterior subluxation; however, they are generally degenerative tears, rather than the rare capsular and labrum avulsion (i.e., reverse Bankart lesion; Fig. 13-3).[12,25,33,35]

The relation between the anterior soft tissues and posterior stability is referred to as the circle concept of capsuloligamentous stability.[68,69,73,76,82] Several biomechanical studies have investigated the contribution of anterior soft tissue structures to posterior stability. In a cadaver model, the soft tissue lesions caused by posterior dislocation have been identified.[52,59] In addition to posterior capsular avulsion and partial or complete tearing of the tendinous portion of the posterior rotator cuff, various lesions of the anterior soft tissue structures were identified. These included complete anterior capsular avulsion from the humeral neck and tears of the muscular portion of the subscapularis.

Selective cutting of soft tissue structures thought to contribute to posterior stability has further defined the role of these anterior and posterior soft tissues to static posterior stability. Increased posterior translation consistently requires a lesion of the posterior capsule, particularly the posterior band of the inferior glenohumeral ligament.[59] Isolated sectioning of the posterior rotator cuff musculature in the absence of a capsular lesion did not increase posterior translation.[58,68] However, when the posterior capsule was sectioned inferiorly, an increase in posterior translation was noted. Subluxation and dislocation occurred only after the anterior capsule and subscapularis tendon were cut.

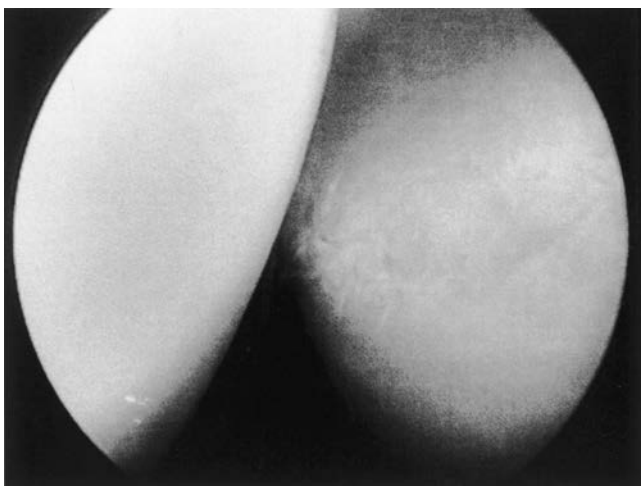

Figure 13-3 Arthroscopic photograph of a degenerative posterior labrum in a patient with recurrent posterior instability. Degenerative lesions of the labrum are typical for recurrent posterior instability. True reverse Bankart lesions are rare.

Several studies have found that the superior capsule (rotator interval capsule) plays an important role in posterior stability.[31,68,69] Sectioning the soft tissues of the rotator interval capsule increased posterior and inferior translation, often to the point of dislocation. Imbrication of the rotator interval increased resistance to posterior and inferior translation.[31]

Acquired posterior subluxation is less commonly caused by posterior glenoid rim deficiency. Although it is uncommon, it does exist and should be investigated with imaging studies if suspected.[25,57,68] The relation between the degree of posterior glenoid erosion and recurrent posterior subluxation has not been established. It seems reasonable to assume that a large posterior glenoid defect will compromise the buttress effect of the glenoid to posterior translation.

In the resting state, the scapula lies on the posterolateral thorax at an angle of 45 degrees.[46] This position on the thorax places the posterior glenoid behind the humeral head, buttressing it against posteriorly directed forces. With shoulder elevation the scapula rotates under the humeral head and provides a platform for glenohumeral motion.[64] A requisite for shoulder stability is that scapulothoracic and glenohumeral rhythm remain synchronous.[15,80]

Dysfunction of scapulothoracic rhythm may compromise the stability of the glenohumeral joint.[80] The serratus anterior muscle plays a key role in scapulothoracic rhythm. Paralysis of this muscle results in scapular winging and loss of power in elevation that potentially may influence glenohumeral stability.[22] Warner et al. used Moire topographic analysis to study patients with glenohumeral instability and demonstrated abnormal scapulothoracic mechanics compared with those of asymptomatic patients.[80] Although no patient demonstrated severe scapular winging, the degree of scapulothoracic dysfunction was variable. In patients with scapular winging from paralysis of the serratus anterior, glenohumeral instability may result from altered scapulothoracic mechanics. In patients with glenohumeral instability and lesser degrees of scapulothoracic dysfunction, it is unclear whether instability is the result of altered scapulothoracic mechanics or the cause of it.

Diagnosis

The most important components in diagnosing recurrent posterior subluxation are a meticulous history and physical examination. Patients typically present with complaints of pain or a sensation of the shoulder dislocating when the arm is placed in a provocative position. The provocative position is variable, but usually includes some degree of flexion, adduction, and internal rotation. An axial load may occasionally be required. In most patients pain is usually limited to episodes of subluxation. Persistent pain is unusual and may be associated with rotator cuff or biceps tendinitis and posterior capsule irritation.[35,78] Pain as a predominant complaint is more common in athletes and may indicate a predisposition to capsular or rotator cuff irritation with overuse during athletic activity.[25,77,78]

A traumatic event initiating recurrent posterior subluxation is not typical. Most often patients cannot recall an initiating event. Over time, with certain activities, they begin to notice shoulder subluxation that readily reduces when the shoulder is taken out of the provocative position. Many of these patients will ultimately learn the position where subluxation occurs and can reproduce the subluxation with specific arm positioning. However, unlike habitual dislocators, patients with nonpsychogenic instability do not voluntarily subluxate their shoulders, unless requested by an examiner, because of the discomfort associated with their instability. In these patients, the most prominent complaint is the involuntary component to the instability that is particularly bothersome and ultimately prompts the patient to seek medical attention.

The disability associated with posterior subluxation is variable and is dependent on the severity of the symptoms. As a general rule, activities of daily living and simple work activities are not limited by symptoms of recurrent posterior subluxation.[33–35] Participation in sports, however, is generally more troublesome, and often requires modification or complete elimination of activity. In more severe cases of posterior subluxation (i.e., patients ultimately requiring surgery), activities of daily living and work may be interrupted.[61]

Physical Examination

The physical examination is directed at reproducing the patient's symptoms and defining the character of instability. Range of motion is generally normal in patients who have not had prior surgery. Occasionally, internal and external rotation may be slightly limited. In athletes there is often activity-specific loss of motion. Overhead-throwing athletes often demonstrate increased external rotation, with an associated mild loss of internal rotation.[77,78] It is critical to evaluate scapulothoracic function during the physical examination for scapular winging or disruption of normal scapulothoracic rhythm.

Most patients can demonstrate their subluxation.[34] Once the position of subluxation is demonstrated by the patient, symptoms of instability can usually be recreated by the physician. In patients who cannot demonstrate their instability, the diagnosis of recurrent posterior instability is more difficult.

Testing for posterior subluxation should be performed with the patient in the sitting and supine position. Testing for increased posterior translation must be performed on the opposite side for comparison. It is important to realize that in a normal shoulder, the humeral head can subluxate posteriorly up to 50%.[30,55]

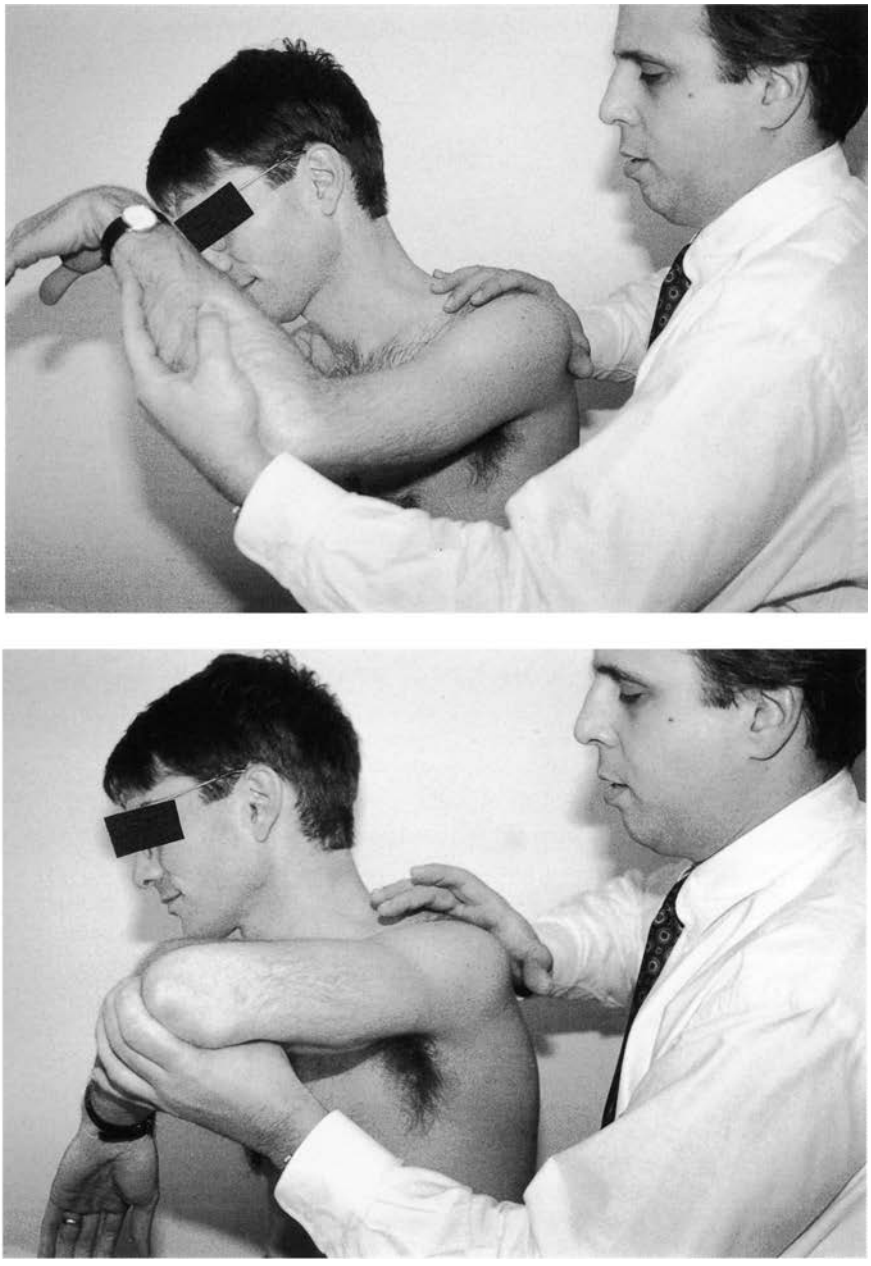

Figure 13-4 Seated posterior stress test: The examiner stands to the side of the patient and stabilizes the scapula. With the arm in 90 degrees of forward elevation in the plane of the scapula, a posteriorly directed force is applied with the arm in **(A)** external rotation and **(B)** internal rotation. The degree of posterior translation in each position is assessed.

The posterior stress test is performed with the patient seated and the examiner at the affected side (Fig. 13-4). The scapula is stabilized while the opposite hand positions the arm in flexion, adduction, and internal rotation and applies a posteriorly directed force. If the patient is able to demonstrate subluxation, replacing the arm in this provocative position should recreate the patient's symptoms with posterior stress testing. Otherwise, testing must be performed in varying degrees of flexion (between 90 and 120 degrees), adduction, and internal rotation to determine the arm position where subluxation occurs. With coronal plane extension, the humeral head will relocate into the glenoid fossa. The relocation is sudden and can be felt by the patient and examiner. Most patients with recurrent posterior subluxation have a positive posterior stress test.[25,61] However, apprehension typical of anterior instability is unusual.[33,34] The predominant symptoms are pain or reproduction of instability symptoms.

The load-and-shift test should be performed with the patient in the sitting and supine positions.[64] In the seated position, with the examiner behind the patient, the scapula is stabilized to minimize scapulothoracic motion (Fig. 13-5). With the opposite hand, the humeral head is grasped and a centering force is applied. Anterior and posterior translation is assessed and compared with that of the opposite side. We prefer the load-and-shift test to be

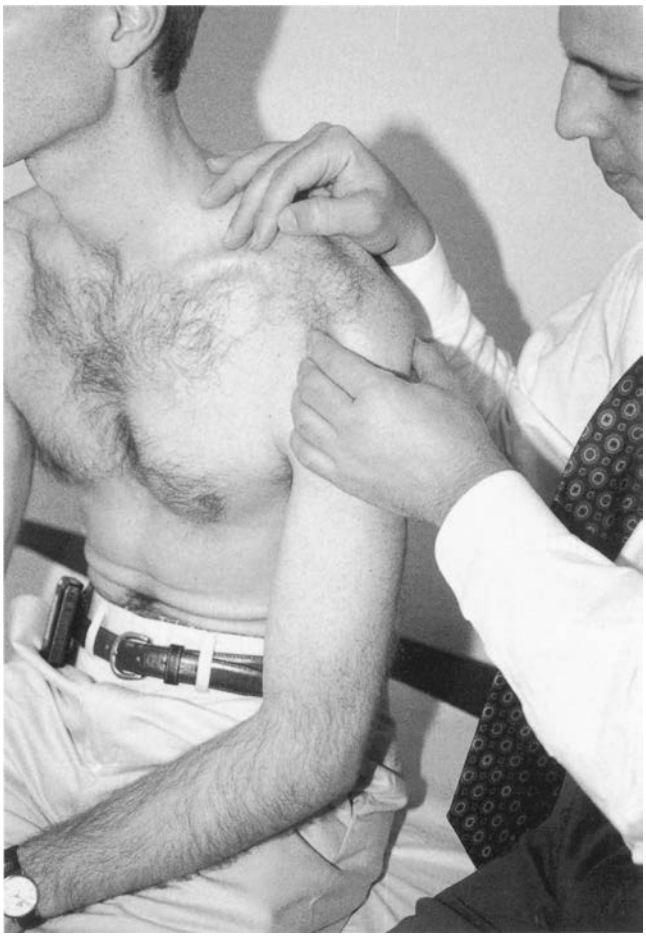

Figure 13-5 Seated load-and-shift test. The examiner is seated at the side of the patient. The scapula is stabilized with opposite hand. A centering force is applied to the glenohumeral joint, and the amount of anterior and posterior translation is assessed.

performed in the supine position with the arm in the plane of the scapula, in 45 to 60 degrees of abduction, with varying degrees of rotation from full external to full internal rotation (Fig. 13-6). Positive testing will result in a reproduction of the patient's symptoms of instability, pain, and crepitation. Side-to-side difference in the amount of internal rotation necessary to obliterate or minimize posterior translation is a clinical measure of residual pathologic capsular laxity.

Inferior translation is assessed next by grasping the elbow, with the arm at the side, and applying an inferiorly directed force. Attention to the region below the acromion will show an indentation, indicating a sulcus sign if inferior instability exists, and should be estimated and recorded in centimeter increments (Fig. 13-7).[64] In most normal patients, passive external rotation will cause a decrease in the sulcus sign, which indicates an intact and functioning rotator interval capsule. Asymmetrical loss of this finding supports the diagnosis of a rotator interval lesion and, therefore, would help explain the cause of the instability.

The zone of instability is most often posteroinferior, but can also be straight posterior or multidirectional. It is important to remember that increased laxity in one direction does not always correlate with, or mean, instability. In patients in whom an isolated posterior component of instability exists, the posterior stress test and load-and-shift test demonstrate subluxation at approximately 80 to 90 degrees of forward elevation. In the more common instance of a posteroinferior instability, subluxation occurs with more forward elevation (110 to 120 degrees). Additionally, a positive sulcus sign may exist. A sulcus sign that is asymmetrically positive identifies the inferior component of the instability and should raise the suspicion for insufficiency of the rotator interval capsule. In both instances, the degree of subluxation may be exaggerated by simultaneous adduction and external rotation. Rotator interval capsular insufficiency may be an isolated process or, more commonly, a component of multidirectional laxity. In cases of multidirectional laxity with instability primarily manifested in the posteroinferior zone, physical signs of generalized ligamentous laxity (i.e., hyperextension of the elbows, knees, metacarpophalangeal joints, or other) are often present. In addition, there is increased humeral head translation in all directions, but symptoms occur primarily with posterior translation. Distinguishing between these cases of isolated posterior, posteroinferior, and multidirectional laxity with a primarily posteroinferior component is important in determining treatment options. Depending on the cause and pattern of instability and the anatomic lesions, the most appropriate treatment may be isolated posterior capsulorrhaphy (reverse Bankart procedure; posteroinferior capsular shift), a bony procedure (bone block or posterior glenoid osteotomy), or an anteroinferior capsular shift combined with rotator interval plication.

Imaging Studies

Routine radiographs of the shoulder should be obtained and include a true AP view obtained in the plane of the scapula, a lateral scapular or Y view, and an axillary view. These radiographs may not demonstrate any abnormalities. However, particular attention should be directed toward the axillary radiograph for evidence of calcification of the posterior capsule, fracture or erosion of the posterior glenoid (Fig. 13-8), or reverse Hill-Sachs defects (Fig. 13-9).[25,56,57]

Stress axillary radiographs or fluoroscopy are generally not necessary, for the history and physical examination usually clarify the diagnosis. However, in the small group of patients for whom doubt of the diagnosis remains, some authors have found these imaging modalities quite helpful.[20,51,55] Comparison with the unaffected side is recommended, for posterior glenohumeral translation of 50% has been demonstrated in normal shoulders.[30,56]

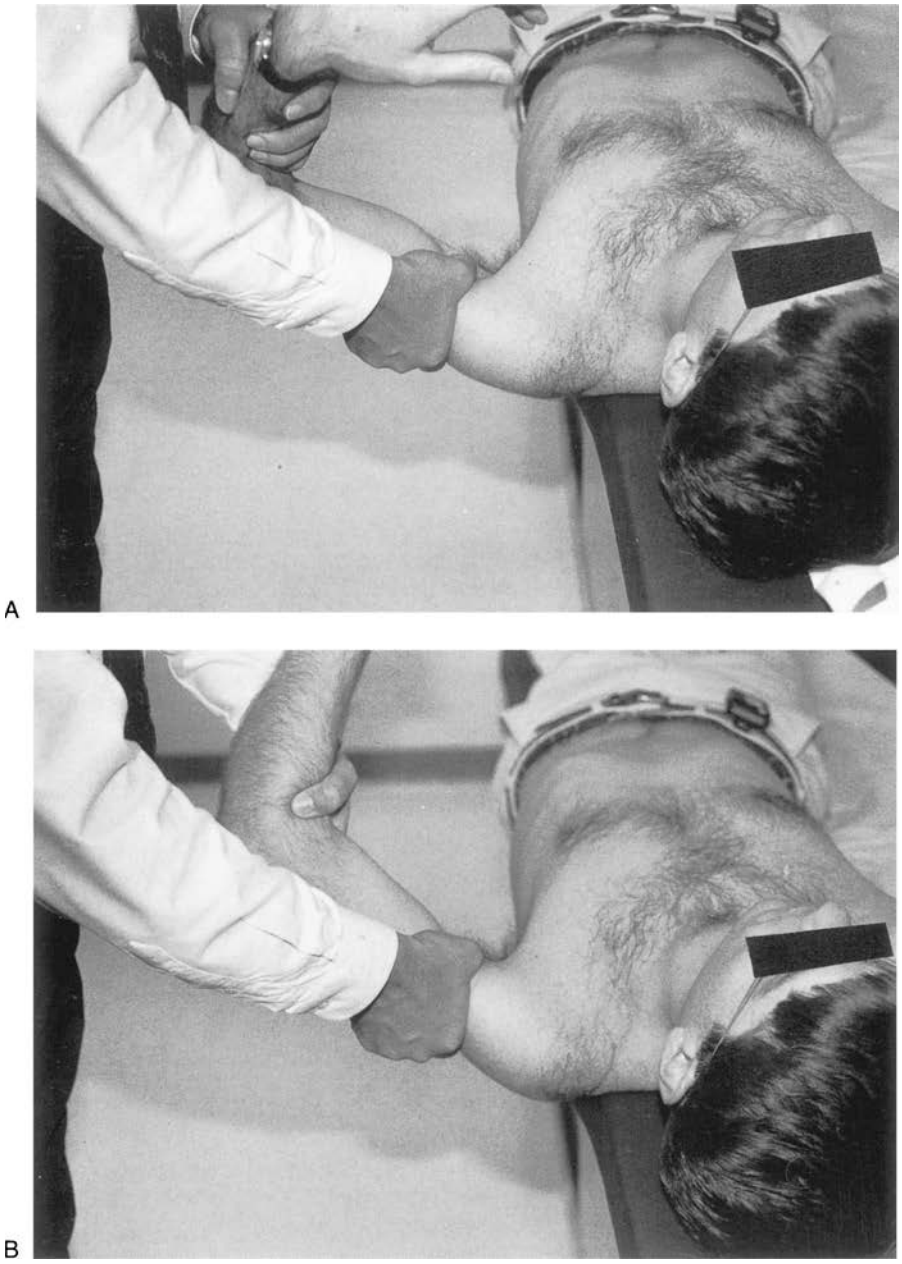

Figure 13-6 Supine load-and-shift test: The patient is supine on the examining table. The arm is brought into approximately 90 degrees of forward elevation in the plane of the scapula. A posteriorly directed force is applied to the humerus with the arm in varying degrees of rotation from **(A)** external rotation to **(B)** internal rotation.

Advanced-imaging studies are not routinely used, but are considered when the specific pathologic lesion underlying recurrent posterior subluxation is unclear. CT excels in its ability to define bony detail. If plain radiographs suggest abnormalities of glenoid version, glenoid hypoplasia, or posterior glenoid erosion, CT or magnetic resonance imaging (MRI) is useful (Fig. 13-10).[28,63]

Computed arthrotomography was developed to better define intraarticular soft tissue pathology and to allow assessment of capsular volume. Whereas Bigliani et al. found one-third of CT arthrotomograms to be over- or underread for labral pathology when correlated with findings at surgery, Callaghan found CT arthrotomography to be 100% accurate, sensitive, and specific for posterior labral defects (Fig. 13-11).[5,11]

MRI has improved our ability to assess soft tissue pathology about the shoulder. The advantages of MRI over plain radiographs and CT include no exposure to ionizing radiation, excellent soft tissue resolution, noninvasiveness, and ability to image in multiple planes. Numerous studies have shown that MRI is superior to other imaging studies at defining labral and capsuloligamentous pathology.[29,37,39,40,42,71] The posterior capsule inserts directly onto the posterior glenoid labrum, not the bony glenoid (Fig. 13-12). This anatomic relation of the capsulolabral complex often confuses accurate interpretation of MRIs. The capsulolabral complex is best

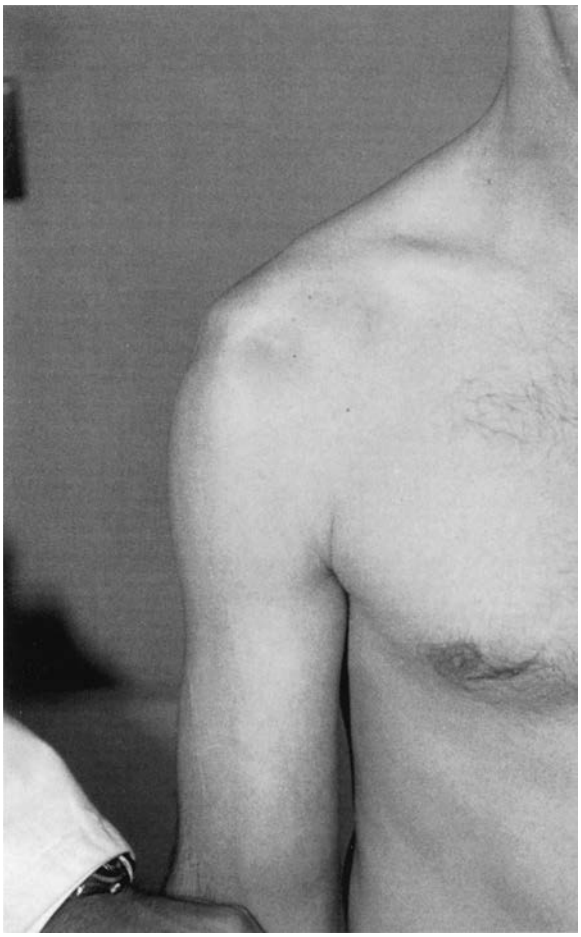

Figure 13-7 Sulcus sign: The examiner is seated next to the patient. The forearm is grasped and an inferiorly directed force is applied to the arm in neutral glenohumeral rotation. Attention is directed to the region immediately inferior to the acromion. A positive sulcus sign will reduce with external rotation of the shoulder in a patient with a competent rotator interval capsule.

demonstrated with the arm in the neutral position. Imaging in external rotation can simulate a labral tear by creating posterior capsular redundancy at the capsulolabral junction.[74] Additionally, in the nondistended joint, the close proximity of the glenohumeral ligaments to the posterior glenoid labrum can be mistaken for a labral tear.[47,53]

Magnetic resonance arthrography (MRA) has been more sensitive at detecting labral pathology than MRI.[13,23] Distention of the joint with contrast affords better visualization of the glenoid labrum and glenohumeral ligaments. Chandnani et al. found that MRA more consistently detects labral tears, detached labral fragments, and labral degeneration than conventional MRI and CT arthrography.[13]

Advanced-imaging techniques have evolved rapidly and afford better definition of intraarticular pathology than do standard radiographic techniques. However, the information obtained can be misleading if not considered in context with the history and physical examination. These studies should be used to confirm the presence of suspected, specific pathologic lesions, rather than as a screening tool.

Examination Under Anesthesia

Before beginning definitive surgical stabilization, examination under anesthesia (EUA) is useful to confirm one's clinical suspicions, even in the most clinically obvious cases of recurrent posterior instability. The sensitivity and specificity of EUA is improved by examining the shoulder in various positions of shoulder elevation and rotation.[16] By placing the arm in 45 to 60 degrees of abduction and varying the degree of humeral rotation, the posterior band of the inferior glenohumeral ligament and posterior capsule are placed under varying degrees of tension. With the

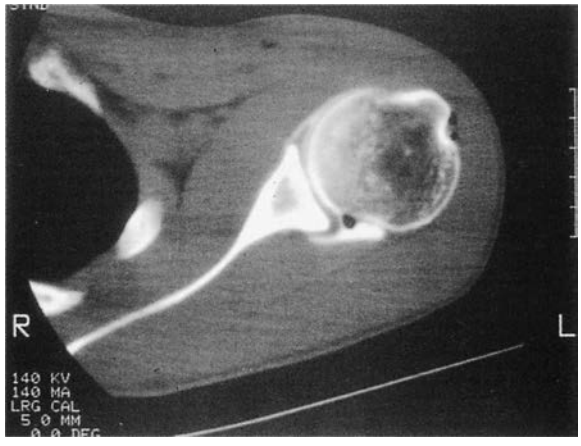

Figure 13-11 A computed tomographic arthrogram of the shoulder. Intraarticular contrast improves visualization of the glenoid labrum.

Figure 13-12 A magnetic resonance image demonstrating the posterior capsule inserting on the labrum, not the glenoid.

arm in external rotation, the posterior capsular structures are lax, allowing posterior translation of the humeral head against a posteriorly directed force. Progressive internal rotation tightens these structures, resulting in capture of the humeral head and elimination of posterior translation against a posteriorly directed force. It is important to note the degree of internal rotation at which posterior translation is minimized. Differences in posterior translation in different arm positions when compared with the opposite shoulder are indicative of posterior capsular insufficiency. With the patient in the supine position, the superior capsular structures are tested by applying inferior traction while loading the joint. A sulcus sign is demonstrated and quantitated using the acromion as a reference. Progressive external rotation tightens the superior capsular structures and should eliminate any sulcus sign present in internal rotation if the superior capsular structures are competent.

In those circumstances under which a high degree of suspicion exists for posterior subluxation, one may further consider diagnostic arthroscopy after an equivocal EUA. Although not as helpful in detecting specific pathologic lesions, such as anterior instability, observation of an incompetent posterior inferior glenohumeral ligament or an excessively redundant posterior capsule may assist one in defining the pathology present before attempting posterior stabilization in special situations.[16]

TREATMENT

The diagnostic workup along with the treatment algorithm employed by our Shoulder and Elbow Service for recurrent posterior subluxation is summarized in Fig. 13-13.

Nonoperative

The recommended initial treatment by most authors for symptomatic recurrent posterior subluxation is nonoperative.[10,25,34,48,57,61,78] Nonoperative treatment should include activity modification; psychologic counseling for patients with voluntary, psychogenic recurrent posterior subluxation; and a shoulder-strengthening program for the dynamic muscular stabilizers, including the rotator cuff (especially infraspinatus and teres minor), posterior deltoid, and scapular stabilizing muscles. Activity modification is aimed at preventing further injury or stress to the posterior capsule, labrum, or rotator cuff. Activities that place the shoulder in the provocative position of forward elevation, adduction, and internal rotation are best avoided during rehabilitation.

Strengthening is accomplished through resisted external rotation exercises with rubber bands of increasing resistance or free weights, and in time, may progress to isokinetic exercises. It is important to balance the strengthening program with internal rotation exercises. Additionally, periscapular strengthening is vital to reestablish synchronous scapulohumeral rhythm.[50]

Patients who fail a prolonged trial of nonoperative therapy and remain symptomatic should be considered for surgical stabilization. Some authors have found that patients with incapacitating symptoms do poorly with nonoperative management compared with patients with moderate symptoms and suggest early surgical intervention.[7,25] Surgery should be directed at correcting the underlying pathologic lesion causing recurrent subluxation. This underscores the value of an anatomically based classification system, rather than the cause-based system currently favored.

Surgical Options and Rationale for Surgical Treatment

Numerous posterior procedures have been described for recurrent posterior subluxation. These procedures include posterior capsulorrhaphy, with or without a bone block; posterior bone block alone; glenoid osteotomy; posterior infraspinatus capsular tenodesis; and posteroinferior capsular shift.[3,5,8,9,24,25,41,44,49,51,52,54,57,61,70] Historically, the results of surgery have been poor, with recurrence rates of up to 50% with significant complications.[34,77] The use of procedures when the pathology of recurrent posterior subluxation was not well understood preoperatively or not completely addressed at surgery no doubt contributed to these poor results. Recently, surgical techniques have been employed that anatomically correct the underlying pathology. This has resulted in more-encouraging results.[6,25] Consequently, the importance of accurately defining the pathologic lesion preoperatively cannot be overstated. The specific surgical techniques are determined by the underlying pathology in each particular case.

Arthroscopic evaluation of shoulders with recurrent posterior instability has the added benefit of identifying anterior joint pathology that would not be visible from an open posterior approach of the shoulder. Technologic advances have permitted all soft tissue pathology identified arthroscopically to be managed arthroscopically. Bone involvement contributing to recurrent posterior instability is not as successfully managed arthroscopically.

Acquired recurrent posterior subluxation is most often caused by soft tissue deficiency (capsule, labrum, or both), erosion or deficiency of the posterior glenoid, or scapulothoracic dysfunction. A patulous posterior capsule is usually the primary pathologic lesion. If a reverse Bankart lesion coexists with a redundant posterior capsule, a combined repair of the reverse Bankart lesion and posterior capsular plication or shift is necessary. When posterior capsular redundancy or detachment is combined with erosion of the posterior glenoid rim or increased glenoid retroversion (i.e., hypoplasia), the posterior capsular procedure is combined with posterior glenoid bone graft or posterior opening wedge osteotomy, respectively. Posterior bone block may

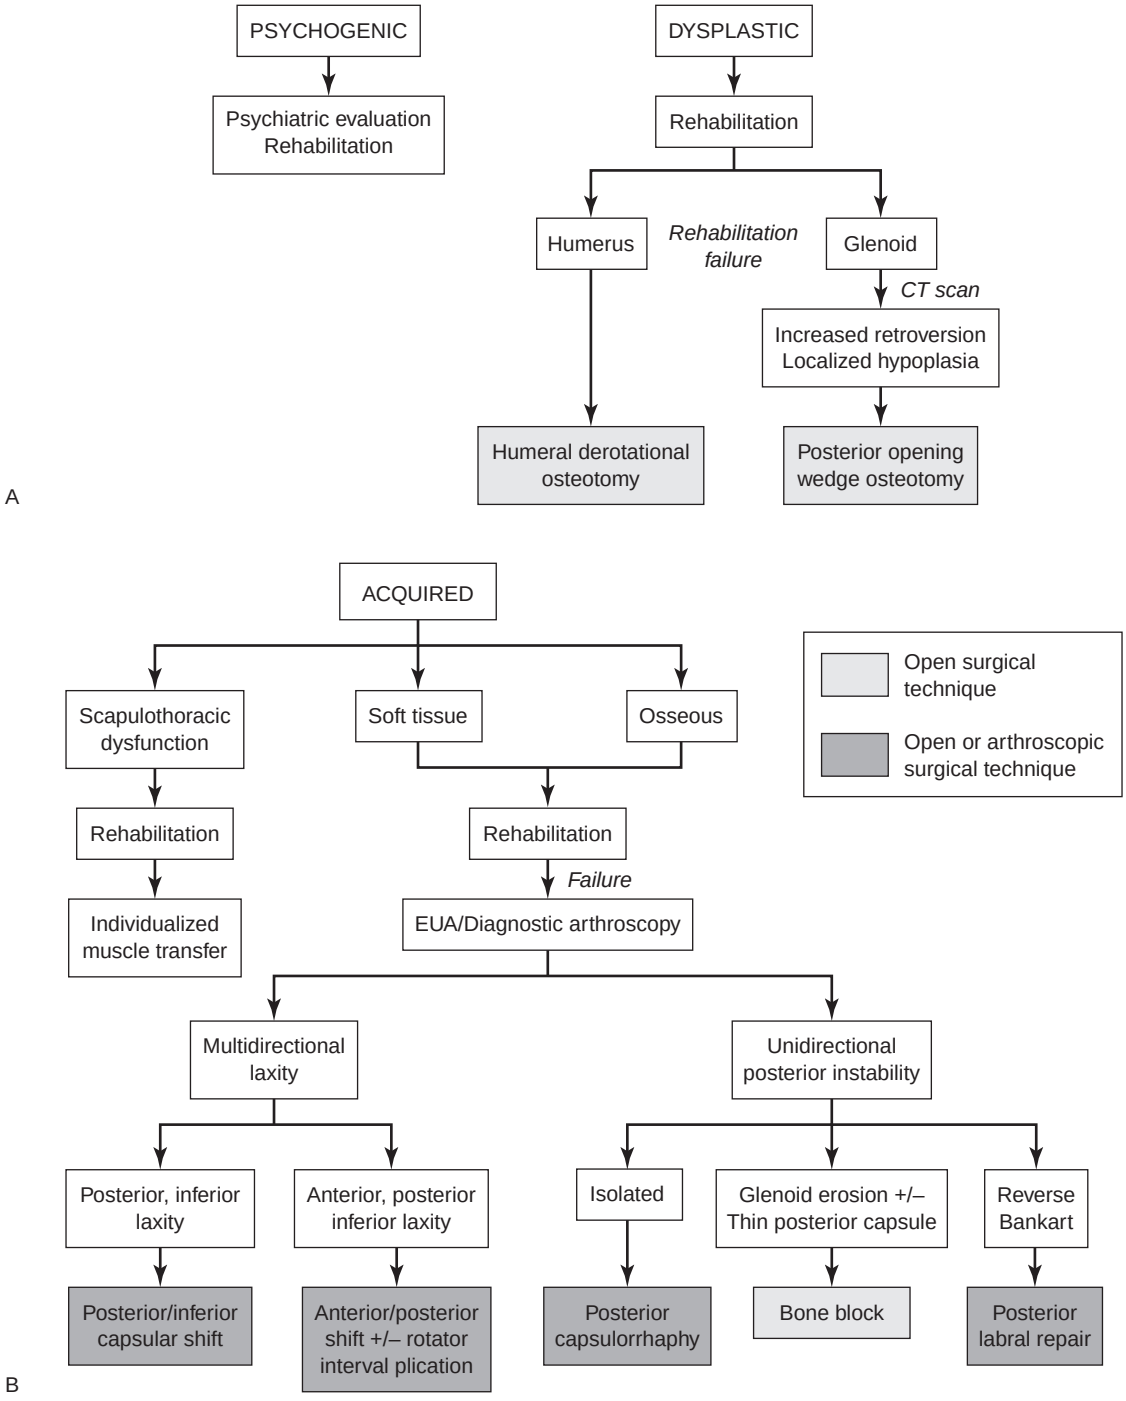

Figure 13-13 University of Pennsylvania treatment algorithm for recurrent posterior subluxation. **(A)** Psychogenic and dysplastic recurrent posterior subluxation and **(B)** acquired posterior subluxation.

also be indicated for properly performed but failed capsular procedures, even if the glenoid architecture is normal.

Patients with recurrent posterior subluxation due to loss of soft tissue restraint are considered for arthroscopic repair. Contraindications for arthroscopic posterior repair include bone abnormalities and volition. Patients with excessive glenoid retroversion may need bone alteration (i.e., osteotomy) to correct posterior subluxations. This includes patients with traumatic unidirectional posterior instability due to a tear or detached restraint.

Patients that have multidirectional instability have symptomatic inferior subluxation and either anterior or posterior symptoms, or both. Many patients with posterior and inferior symptomatic subluxation are termed "bidirectional" or posterior symptomatic multidirectionally unstable patients.

It is critical to determine the direction of instability before surgery. If instability is only posterior, a procedure addressing the redundant posterior capsule is warranted. However, posterior subluxation is often accompanied by varying degrees of inferior and multidirectional laxity. In cases of posteroinferior subluxation when there is no anterior component to the instability pattern and the rotator interval capsule is functionally intact, a posteroinferior capsular shift from a posterior approach should be performed. In patients with multidirectional laxity, the surgical approach depends on the primary location of their symptoms. If their symptoms are directed to the posterior aspect of the shoulder, we prefer to approach these posteriorly and perform a posteroinferior capsular shift. Conversely, anterior symptoms are addressed with an anteroinferior capsular shift. In the rare patient with true multidirectional instability with anterior and posterior symptoms, combined anterior and posterior capsular procedures may be necessary.

Surgical treatment of scapular winging is beyond the scope of this chapter. However, the importance of restoring scapulothoracic mechanics in controlling posterior instability cannot be overemphasized. Scapular winging can be an important contributor to recurrent posterior subluxation. When caused by long thoracic nerve injury, pectoralis major transfer, alone or in combination with posterior capsulorrhaphy, may be indicated.[62] In these cases, it is often difficult to determine the need for posterior capsulorrhaphy in addition to the pectoralis major transfer. In most instances, pectoralis major muscle transfer alone is sufficient to correct the posterior instability symptoms.

Glenoid or humeral dysplasia is an uncommon cause of posterior subluxation. However, in the presence of glenoid hypoplasia or increased glenoid retroversion, a glenoid osteotomy should be considered.[70] Humeral rotational osteotomy is considered only when there is documented abnormal humeral retrotorsion.[14,75]

Patients with a psychologic cause for recurrent posterior subluxation should be managed with an exercise program combined with psychologic counseling.[65] Surgery is contraindicated as long as the underlying psychologic needs leading the patient to voluntarily subluxate his or her shoulder exist. Surgery should be considered only after the underlying psychologic problems are resolved and the patient still demonstrates symptomatic involuntary recurrent posterior subluxation. Extreme caution is still warranted in performing surgery in this group of patients. If any element of psychogenic posterior subluxation remains, surgery is doomed to failure.

Open Surgical Technique

Patient Positioning

The patient is positioned in the lateral decubitus position and secured with anterior and posterior posts or a bean bag. The head and neck should be supported in neutral position and the knees and ankles padded. Impervious drapes are placed at the base of the neck and around the axilla, medial to the vertebral border of the scapula, and a minimum of 6 cm medial to the anterior axillary crease (Fig. 13-14). The arm is prepared and draped free. The arm may be supported anteriorly on a Mayo stand, or an intraoperative sterile shoulder positioner (McConnell Orthopedic Manufacturing Co., Greenville, TX) may be used.

Figure 13-14 Intraoperative photograph demonstrating patient positioning and draping in the lateral decubitus position. The shoulder should be draped widely to allow palpation and visualization of topographic structures that will aid in dissection.

Surgical Approach

The incision begins at the posterior axillary crease and extends superiorly to the spine of the scapula (Fig. 13-15). Medial subcutaneous dissection is carried out to the border of the posterior deltoid. The lateral subcutaneous dissection is to the lateral border of the acromion. The fibers of the posterior deltoid are split in that portion of the deltoid that overlies the posterior glenohumeral joint line, from the spine of the scapula distally for a distance of 4 to 5 cm. Blunt dissection of the posterior deltoid fibers is carried deep to the subdeltoid bursa, exposing the underlying infraspinatus and teres minor muscles (Fig. 13-16). An alternative approach for exposure of the infraspinatus and teres minor muscles is to elevate the posterior deltoid along its inferior margin. Identification of the inferior border of the posterior deltoid allows this margin to be defined. Dissection to the subdeltoid space and abduction of the shoulder facilitate superior retraction of the posterior deltoid. Deep retractors are placed to expose the infraspinatus and teres minor tendons (Fig. 13-17). Inferior to the teres minor is the quadrangular space that

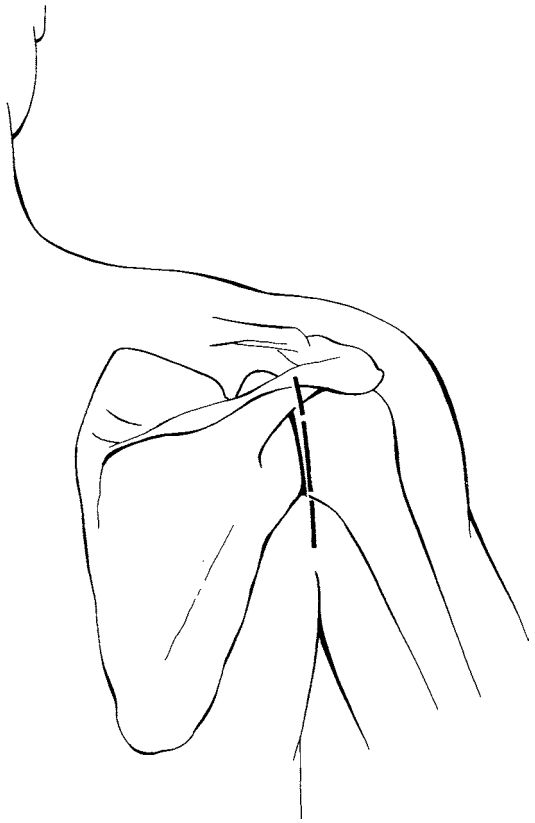

Figure 13-15 Drawing of incision for posterior shoulder surgery. A vertical incision is preferred for cosmetic reasons. The incision begins at the spine of the scapula and extends to the posterior axillary crease.

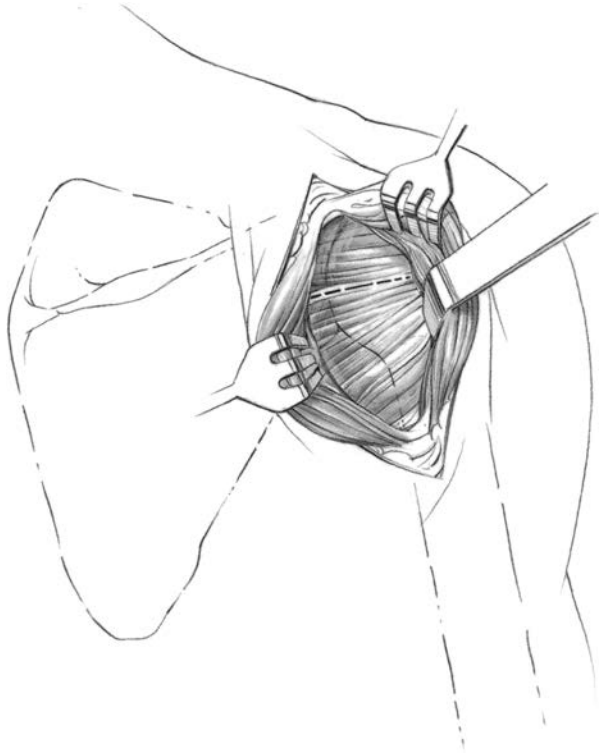

Figure 13-16 The longitudinal split in the deltoid should be performed so that the operative field is over the center of the glenohumeral joint, exposing the infraspinatus and teres minor muscles.

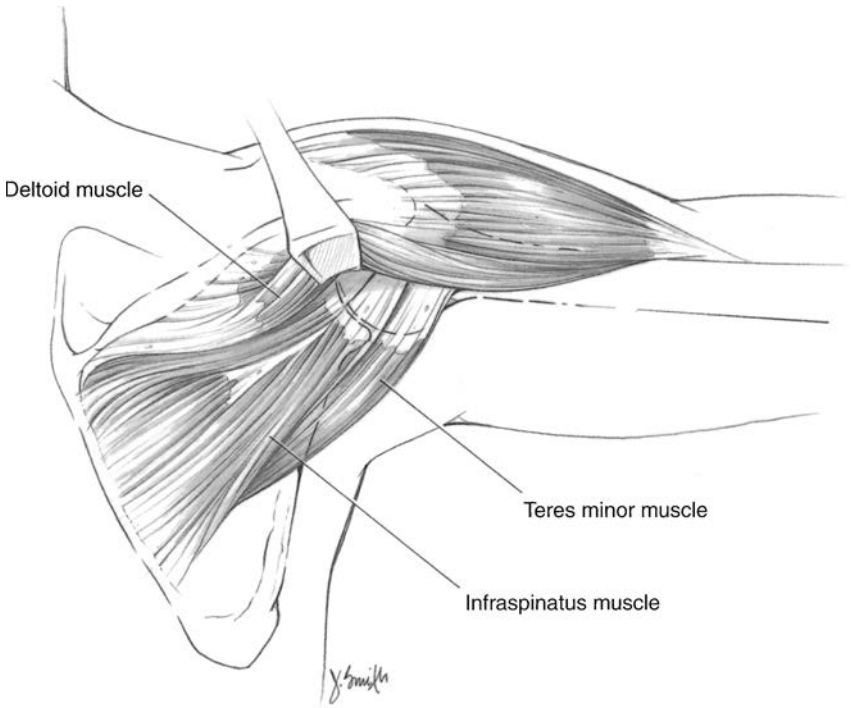

Figure 13-17 Superior elevation of the deltoid is an alternative to a deltoid split. The arm must be placed in 90 degrees or more of elevation to allow the deltoid to be retracted cephalad.

contains the axillary nerve and posterior humeral circumflex vessels.

Exposure of the posterior capsule can be accomplished either in the internervous plane between the infraspinatus (suprascapular nerve) and teres minor (axillary nerve) or within the posterior fat stripe that separates the upper and lower portions of the infraspinatus muscle.[72,83] The fat stripe commonly seen between the upper and lower halves of the infraspinatus muscle is located at the midequator of the glenohumeral joint. Dissection through the infraspinatus fat stripe will place the operative procedure more central within the glenohumeral joint and, thereby, facilitate better exposure of the upper portion of the joint. It is possible to perform posterior capsulorrhaphy through this interval without detaching the infraspinatus insertion, and it is our preferred technique. In this approach, this interval is developed to the posterior capsule (Fig. 13-18). Dissection superiorly to the supraspinatus tendon and inferiorly to the posteroinferior aspect of the joint is undertaken, and reverse Homans retractors are placed to expose the capsule. Medial dissection along the infraspinatus muscle is limited to 1.5 cm medial to the glenoid margin to avoid injury to the inferior branch of the suprascapular nerve that would denervate the inferior portion of the infraspinatus muscle. Medial exposure is the primary limitation of this approach.

The most extensile exposure of the posterior capsule is obtained by dissecting the interval between the infraspinatus and teres minor. This interval can be extended medially without fear of denervating the infraspinatus (Fig. 13-19). The infraspinatus muscle and tendon are then bluntly dissected from the underlying capsule. The thickness of the infraspinatus tendon can then be assessed. The midtendinous portion of the infraspinatus tendon is then incised to the level of the capsule, approximately 1 cm medial to its humeral attachment. Further blunt dissection is performed to separate the infraspinatus tendon from the capsule superiorly, medial to the glenoid rim and laterally toward the greater tuberosity. The infraspinatus is then reflected medially. Caution should be used in retracting the infraspinatus medial to the glenoid rim to avoid excessive traction on the suprascapular nerve at the spinoglenoid notch. Using a narrow blunt elevator, the posteroinferior capsule is dissected from the underlying teres minor. A narrow, deep blunt retractor is placed deep to the teres minor to expose the posteroinferior capsule.

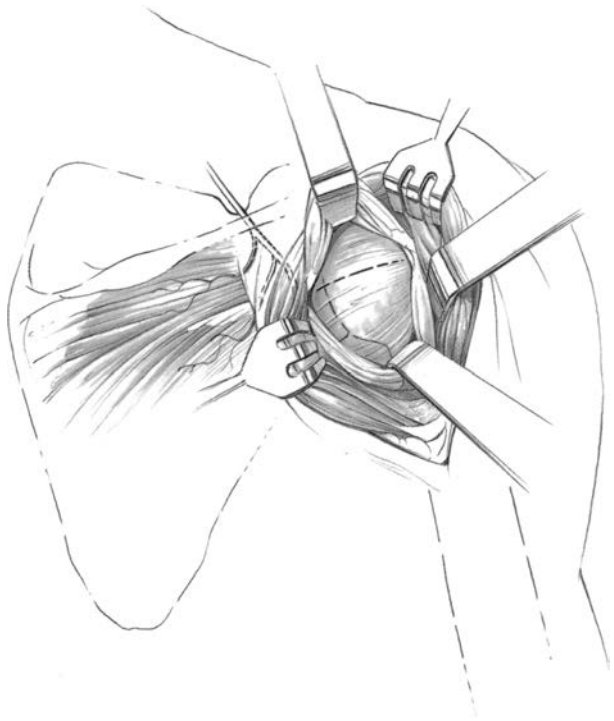

Figure 13-18 Posterior capsular exposure through a fat stripe split between the upper and lower portion of the infraspinatus. Medial dissection is limited to 1.5 cm medial to the glenoid so that injury to the inferior branch of the suprascapular nerve is avoided.

Posterior Capsulorrhaphy (Author's Preferred Technique)

The capsule is incised in a medial to lateral direction midway between the superior and inferior poles of the glenoid. Traction sutures may be placed in the superoinferior portions of the capsule. A humeral head retractor is inserted, and the glenoid rim is inspected. When a capsular avulsion is not identified, then the vertical capsular incision is performed approximately 5 mm medial to the humeral insertion site of the capsule (Fig. 13-20). The capsulotomy is performed superiorly to the posterior insertion site of the supraspinatus tendon. The inferior extent of the lateral capsulotomy is dependent on the degree of inferior capsular redundancy. In general, the lateral capsulotomy is carried out past the inferiormost portion of the inferior capsular pouch to the 6 o'clock position. The arm is then placed in the plane of the scapula in 45 degrees of abduction and neutral rotation to approximately 15 degrees of external rotation. The inferior leaflet is then shifted superiorly to obliterate the inferior capsular pouch and place the inferior leaflet under slight tension. Lateral capsular closure is accomplished with nonabsorbable sutures. The superior capsular flap is then shifted inferiorly to the point of slight tissue tension.[52] Lateral capsular closure is achieved with nonabsorbable sutures. The interval between the superior and inferior flaps is then closed and reinforced with nonabsorbable sutures (Fig. 13-21).

If the infraspinatus tendon was cut, it is then closed with slight overlap of the tissue using nonabsorbable sutures. If it was not incised, the infraspinatus is allowed to retract to its normal position and the fascia is closed with absorbable sutures. The deltoid is allowed to retract to its normal position. Absorbable suture is placed in the superficial fascia, and a drain is inserted in the depth of the wound. The subcutaneous tissues are closed with absorbable suture and the

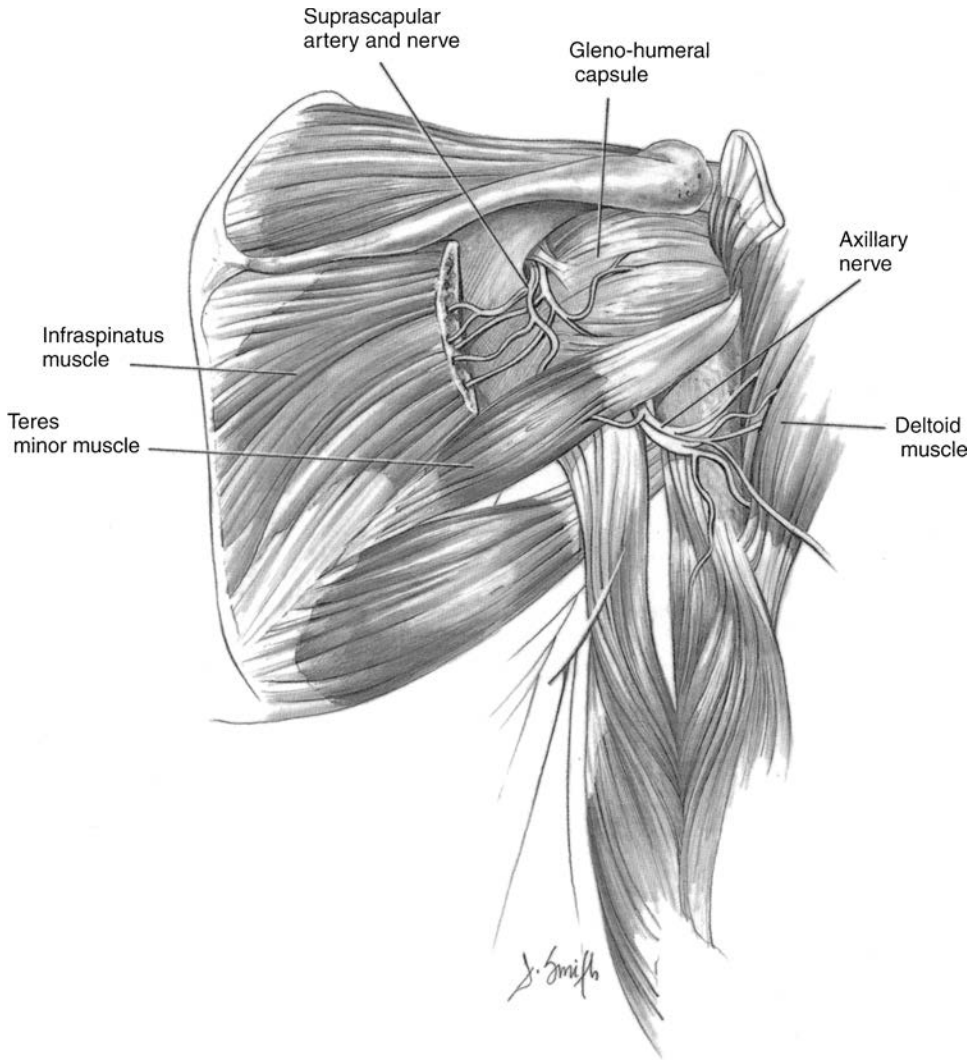

Figure 13-19 Posterior capsular exposure through the interval between the infraspinatus and teres minor muscles. This is an extensile exposure to the posterior aspect of the shoulder. Vigorous medial retraction of the infraspinatus should be avoided to prevent traction on the suprascapular nerve at the spinoglenoid notch.

skin with nonabsorbable suture using the subcuticular technique. Steri-Strips and a sterile dressing are placed and the arm is positioned in a prefabricated prefitted thoracobrachial orthosis. The arm is positioned slightly posterior to the coronal plane of the thorax in 20 degrees of abduction and 10 degrees of external rotation.

Posterior Labral Repair

The patient positioning and surgical exposure are described above. The horizontal capsulotomy is performed, a humeral head retractor is inserted, and the joint is inspected. If a reverse Bankart lesion is identified, the scapular neck must be prepared and the capsule reattached to the glenoid rim. The vertical capsular exposure is made by dissection of the Bankart lesion, thereby reflecting the capsulolabral tissue from the glenoid margin. The posterior glenoid and scapular neck are then decorticated with a curette or power burr. The labrum is reattached to the articular margin of the posterior glenoid using commercially available suture anchors or transosseous tunnels (Fig. 13-22).

A posteroinferior capsular shift is performed, with repair of the reverse Bankart lesion if excessive posteroinferior capsular redundancy exists. The capsular shift can be performed on the glenoid side when the labrum is repaired or on the humeral side after the labrum is repaired. The humerus is positioned in less external rotation (10 degrees) to avoid overtightening. If the shift is performed on the glenoid side, the capsule and labrum are cut at the midglenoid, creating both a superior and inferior flap. The inferior capsular leaflet is then shifted superiorly to obliterate the inferior

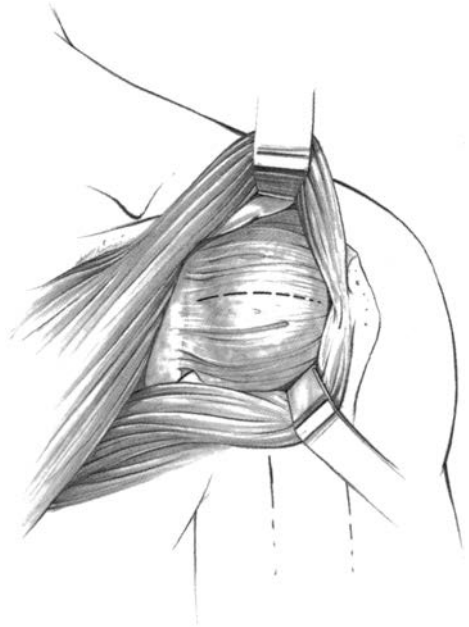

Figure 13-20 A horizontal capsulotomy is performed at the mid-equator of the joint, allowing intraarticular inspection. The lateral vertical limb of the capsulotomy is performed 5 mm medial to the humeral attachment when no posterior labral pathology is noted.

capsular pouch and place the inferior leaflet under slight tension. The inferior leaflet is repaired to the glenoid margin with suture anchors placed at the glenoid margin. The superior leaflet is subsequently shifted inferiorly to a point of slight tissue tension. The sutures used to secure the inferior leaflet to the glenoid margin are used to secure the superior leaflet (Fig. 13-23). Infraspinatus closure, skin closure, and bracing are performed as discussed in the foregoing section.

If the capsular shift is performed on the humeral side in the presence of a reverse Bankart lesion, the capsule is incised at the midglenoid level to, but not through, the labrum. The labrum is repaired anatomically (without shift) to the glenoid margin using suture anchors or transosseous tunnels (see Fig. 13-22). The capsule is then incised vertically 5 mm medial to its humeral insertion site. The arm is positioned in the position of 45 degrees of abduction, and neutral to 10 degrees of external rotation, and a posteroinferior capsular shift procedure is performed, as previously described (see Figs. 13-20 and 13-21). This is our preferred technique when a capsular shift is required in the presence of a reverse Bankart lesion.

Posterior Infraspinatus Capsular Tenodesis

Patient positioning and exposure are described previously in this chapter. Once the deltoid is split or elevated, the underlying infraspinatus is exposed. The arm is then placed in neutral position and a 2.5-cm vertical incision is made through the infraspinatus and underlying capsule, centered on the superior and inferior glenoid margins. This is medial

Figure 13-21 Posteroinferior capsular shift: The inferior leaflet is shifted superiorly to slight tissue tension with the arm positioned in approximately 45 degrees of abduction and neutral to slight external rotation. The superior leaflet is subsequently shifted inferiorly.

to the insertion of infraspinatus and leaves a lateral cuff of infraspinatus and underlying capsule for tenodesis (Fig. 13-24). The posterior labral tissue is then identified. If a posterior labral detachment (i.e., reverse Bankart) is found, it is repaired with sutures or a suture-anchoring system, as previously described. The lateral flap of infraspinatus and capsule are then mobilized and secured to the posterior glenoid

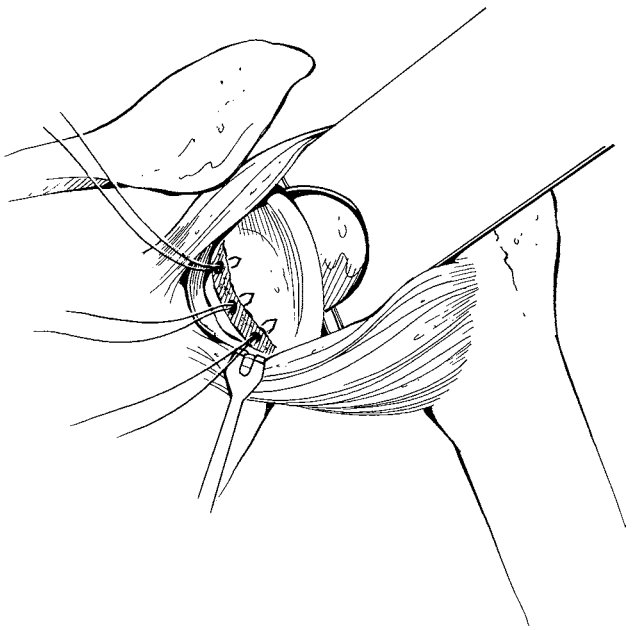

Figure 13-22 Posterior labral repair: The horizontal capsulotomy is performed. A humeral head retractor and forked retractor provide exposure to the posterior glenoid neck. The glenoid neck is decorticated and suture anchors or transosseous sutures are placed along the glenoid margin, passed through the detached labral tissue, and tied, thereby reestablishing the normal anatomy of the posterior labrum and glenoid.

Figure 13-23 Posterior labral repair with medial-based capsular shift: **(A)** The horizontal capsulotomy continues through the capsule and labrum. **(B)** The inferior capsular leaflet and labrum are shifted superiorly to slight tissue tension with the arm in 45 degrees of abduction and neutral to slight external rotation. The superior capsular leaflet and labrum are then shifted inferiorly.

labrum with nonabsorbable suture, with the arm in slight external rotation (Fig. 13-25). The remaining portion of infraspinatus and underlying capsule is overlapped over the primary repair with the arm in neutral to slight internal rotation. The deltoid is then allowed to retract back to its normal resting position and the subcutaneous tissue is approximated with absorbable suture. The skin is closed with a nonabsorbable suture in a running subcuticular fashion.[32]

Posterior Bone Block

Patient positioning and exposure are as described previously. The capsule is incised in the medial lateral direction at the midlevel of the capsule and the joint is inspected. A 2 × 2-cm, 7- to 10-mm–thick bone graft is obtained from the posterior iliac crest or posterior scapular spine (Fig. 13-26). The posterior glenoid neck is exposed and the inferior half is decorticated. The capsular–labral attachment

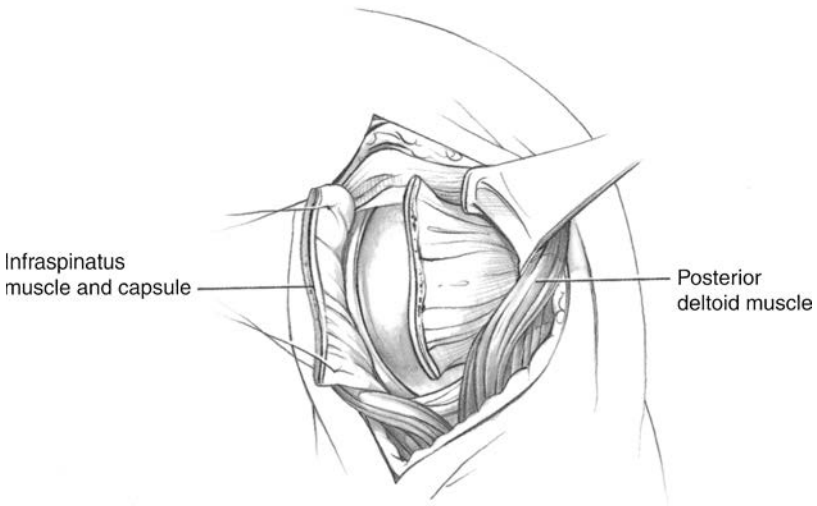

Figure 13-24 Posterior infraspinatus capsular tenodesis: The arm is positioned in neutral rotation and the infraspinatus muscle and underlying posterior capsule are incised at, and parallel to, the glenoid rim.

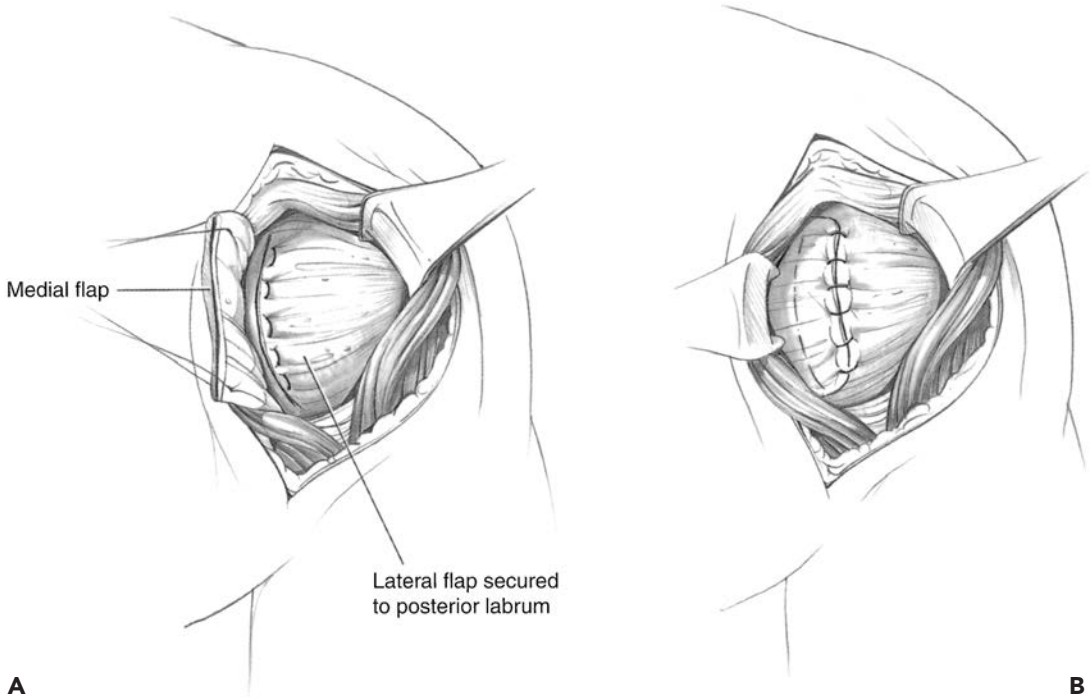

Figure 13-25 **(A)** The arm is placed in slight external rotation and the lateral flap of infraspinatus, and the capsule is secured to the posterior labrum. **(B)** The medial flap of infraspinatus and capsule overlaps the lateral flap.

Figure 13-26 Bone graft is harvested from the **(A)** scapular spine or **(B)** posterior iliac crest.

to the inferior glenoid is left intact. The cancellous side of the bone graft is placed against the posterior glenoid neck so that it extents to, but not beyond, the posterior glenoid rim (Fig. 13-27). The bone graft is secured with one or two partially threaded cancellous screws. A burr may be used to contour and trim the bone graft to the level of the posterior glenoid rim after it is secured. The capsule, infraspinatus, and wound are closed as described earlier. If a capsular plication or shift is performed at the time of the bone block procedure and a reverse Bankart lesion is not present, then a humeral-sided vertical capsulotomy is performed and a capsular shift is carried out as previously described.

Posterior Opening Wedge Glenoid Osteotomy

Patient positioning and exposure are as described previously. The capsule is incised in a superior-to-inferior direction at the midlevel of the capsule, and the joint is inspected. A straight, flat instrument, such as an osteotome, is placed along the surface of the glenoid fossa. The osteotomy is made parallel to the face of the glenoid surface 10 mm medial to the posterior glenoid rim. The glenoid osteotomy is taken to, but not completely through, the anterior glenoid cortex. Keeping the anterior cortex and periosteum intact is important in keeping the osteotomy stable. The osteotomy is then opened and a cortical bone graft harvested from the spine of the scapula is used to maintain the osteotomy in the open position (Fig. 13-28). Internal fixation is generally not required, but a small staple may be used if the osteotomy is unstable. If capsular redundancy is present, a horizontal capsular incision in the medial-to-lateral direction is performed and a medial-based capsular shift is performed. Infraspinatus and wound closure are performed in standard fashion.

Arthroscopic Surgical Techniques

Examination Under Anesthesia

Examination under anesthesia was discussed previously in this chapter. The goal of examination under anesthesia is the same whether the surgery is to be performed open or arthroscopically.

Patient Positioning and Portal Placement

Arthroscopic shoulder stabilization can be done either in the lateral decubitus or the beach-chair positions. For those choosing the lateral decubitus position, the patient is approximately 20 degrees rolled back from perpendicular to the operating room table. An axillary roll is placed

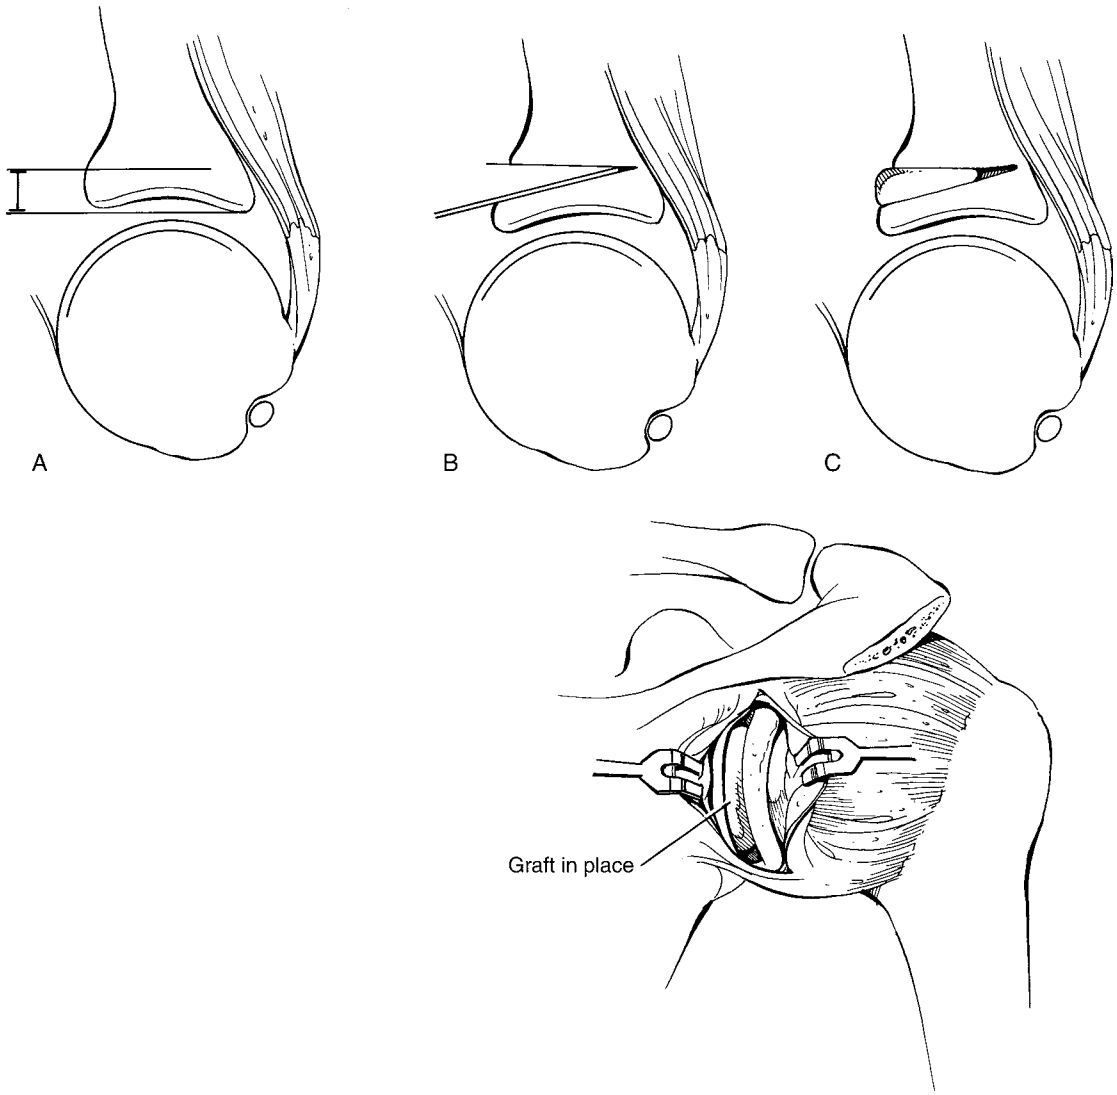

Figure 13-28 Posterior opening wedge osteotomy. **(A)** An osteotomy is performed 10 mm medial to the glenoid margin, parallel to the face of the articular surface. **(B)** The osteotomy extends to, but not through, the anterior cortex of the glenoid. **(C)** Bone graft is placed in the opened osteotomy to maintain the relocated position of the articular surface.

under the dependent axilla, and a supportive bean bag is used along with tape to support the torso and chest wall. The patient's arm is abducted approximately 20 degrees with 7 to 12 lb of longitudinal traction applied. The table should be rotated so that the anesthesiologist is in front of the patient, allowing for the surgeons to have access to the front, top, and posterior quadrants of the affected shoulder. If the beach-chair position is selected, the affected shoulder needs to be free from the edge of the table, allowing for posterior, anterior, and superior exposure to the affected shoulder. This may require additional support to the head and neck of the anesthetized patient.

The majority of shoulders undergoing arthroscopic stabilization will require a standard posterior viewing portal, anterosuperior portal, and occasionally an additional posteroinferior portal. The initial portal is developed 2 cm inferior to the spine of the scapula at the junction with the lateral margin of the acromion. This is slightly lateral to the usual posterior viewing portal. The joint is often inflated with fluid through a spinal needle, followed by introducing a blunt trochar and cannula, which allows the scope to be placed in the posterior viewing portal. An anterior portal is then developed from outside in, using a spinal needle placed anterior to the acromion and entering the joint midway between the biceps and subscapularis superior border. Transferring the scope to the anterior portal, the original posterior portal can be inspected from inside of the joint to see whether it is appropriate for anchor placement. Often these portals are parallel to the glenoid and do not always allow for favorable angulation

to the glenoid to allow for anchor penetration. A third portal inferior and lateral can be demonstrated by an outside-to-inside technique using a spinal needle (Fig. 13-29). The spinal needle is directed at the posteroinferior glenoid margin and can be further developed should anchor placement be indicated. This portal does not require an additional cannula and can be used as a percutaneous portal for suture anchor placement.

Diagnostic Arthroscopy

Pathologic findings associated with posterior and posteroinferior shoulder instability can be appreciated arthroscopically.[2,86] The most common finding is an enlarged posteroinferior capsule, into which the humeral head is allowed to sublux (Fig. 13-30). Posterior labral changes found in shoulders with recurrent subluxation vary from intact labrum to tears.[4,43] Labral pathology is different than what is normally associated with recurrent anterior instability. The author's review of arthroscopic posterior labral pathology identified 22% posterior labral detachments (reverse Bankart lesions), 18% capsule tears at the junction of labrum, 43% labral tears with intact capsules, and 17% absent glenoid labral or capsule tears (Fig. 13-31). Additional capsular problems include midsubstance capsule tears, as well as lateral capsule avulsions from the humeral head (Fig. 13-32).[1] Articular findings associated with recurrent glenohumeral instability may include glenoid chondral injuries, loose bodies, and articular-side rotator cuff tears (Fig. 13-33).

There may be additional labral pathology opposite the site of posterior glenohumeral subluxation.[2] Patients may have associated type II superior labral avulsions, anterior labral detachment, and enlarged rotator intervals (Fig. 13-34). The rotator interval viewed arthroscopically includes the space between the superior and middle anterior glenohumeral ligaments. Normally this space allows for visualization of the superior aspect of the subscapularis tendon. As this interval enlarges, a greater amount of the subscapularis tendon is easily seen from the posterior viewing portal (Fig. 13-35). Dilation of the rotator interval is determined by clinical testing as well as arthroscopic appearance. Excessive sulcus signs in neutral and external rotation, combined with the arthroscopic appearance of widening of this interval and exposure of the subscapularis tendon, would suggest that this is a pathologic finding associated with recurrent posterior subluxation. This compromise of the anterosuperior supporting structures is felt to be an important stabilizer in the adducted shoulder.[31]

Figure 13-29 Arthroscopic portals for posterior repair in the right shoulder. Scope is anterior; working portal is posterior. An optional portal is lateral and inferior for anchor placement.

Figure 13-30 Enlarged posterior pouch: Right shoulder visualized from posterior portal demonstrates enlarged capsular pouch and intact labrum.

Suture Anchor Repair

A suture anchor repair is indicated in cases where the labrum is detached from the glenoid, the labrum is insufficient to anchor capsular sutures, and the glenoid articular surface has been disrupted along the margin of the labrum attachment. In these situations, the glenoid can be roughened with a burr or rasp and the labrum mobilized onto the articular edge with or without a posteroinferior capsular shift.

After visualization from the posterior portal, a scope is placed in the anterior portal. The posterior portal is replaced with a large cannula that allows for introduction of suture hooks and instrumentation. Through this portal, the glenoid and labrum can be prepared by shaving the junction and removing devitalized tissue. Additional abrasion can be applied to the capsular ligaments to create a tissue response at the site of repair.

Through the optional accessory posteroinferior portal, a drill hole is made on the inferior glenoid articular margin, and a suture anchor is placed percutaneously (Fig. 13-36).

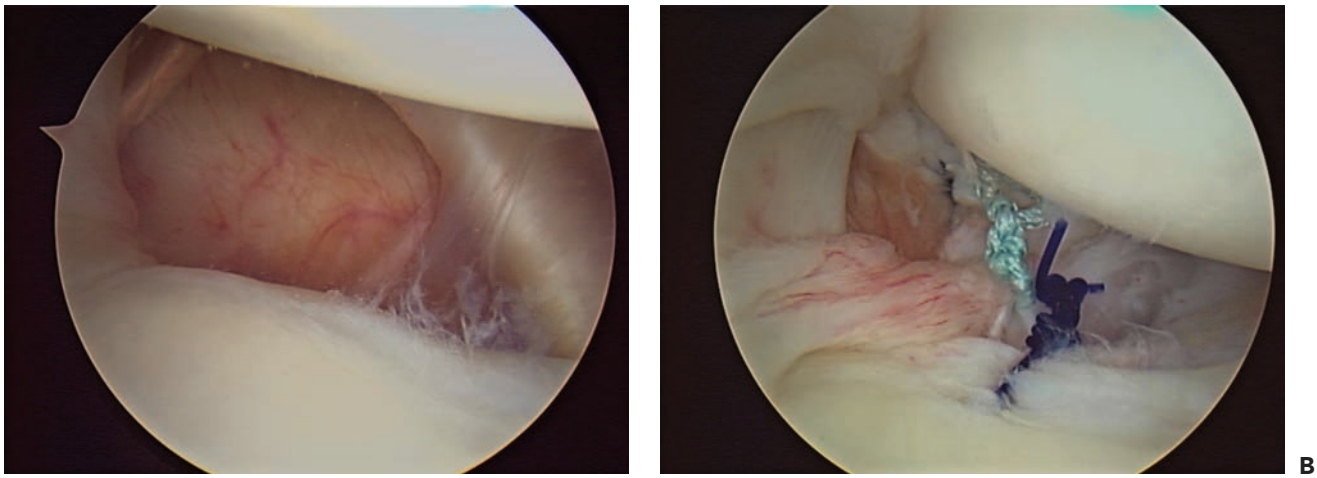

Figure 13-35 Rotator interval enlargement. **(A)** Stretched interval between superior and middle glenohumeral ligaments exposes a greater amount of subscapularis. **(B)** Reduction of the interval is performed by advancing the superior border of the middle glenohumeral ligament to the superior ligament.

A Spectrum suture hook (Linvatec, Largo, FL) is introduced through the posterior portal, grasping the labrum at the inferiormost aspect of the labral tear adjacent to the suture anchor. A suture shuttle (Linvatec, Largo, FL) is introduced and retrieves one arm of the braided suture through the labrum. As the suture is tied, the labrum is reapproximated to the posterior glenoid rim (Fig. 13-37). If there is concomitant capsular redundancy that needs to be addressed as the labrum is repaired, a suture hook is used to grasp the posteroinferior capsule, reposition it more superiorly, and pass the hook a second time underneath the labrum. This creates a capsular pleat that is incorporated into the labral repair, resulting in a superior shift of the posteroinferior capsular tissue (Fig. 13-38). Additional suture anchors are used as needed throughout the length of labral deficiency. Additional capsule plication sutures can be used to further reduce the posterior capsular pouch.

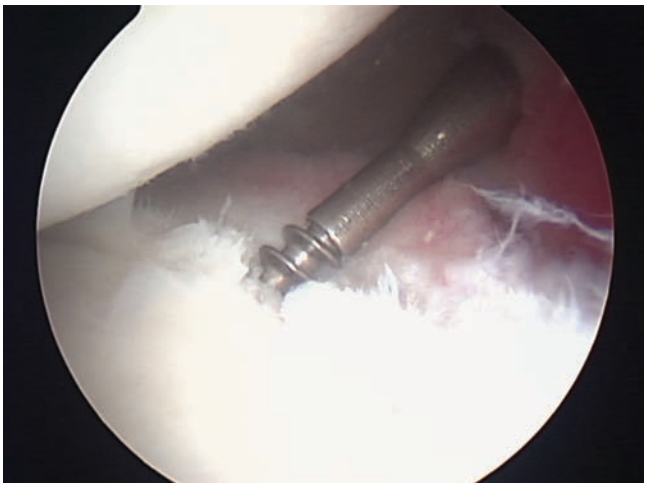

Figure 13-36 Suture anchor placement. An anchor is placed percutaneously using needle guidance into the posterior inferior quadrant.

Capsular Plication

In cases where the labrum is attached to the glenoid margin, plication sutures can be used to reduce the posteroinferior capsular pouch. A shaver is placed through the posterior portal, and the capsule is abraded with the suction off in the areas of anticipated repair. A curved suture hook is introduced into the inferior pouch and a full-thickness capsular bite is taken. A second pass through the intact inferior labrum completes the capsular plication (Fig. 13-39). Either a monofilament suture or suture shuttle can be introduced for later substitution with a braided suture. The definitive suture is tied beginning inferiorly. The capsule plication continues, grasping the inferior pouch with full thickness and again through the labrum, moving superiorly along the posterior glenoid. The sutures are tied sequentially below the cannula. The pouch is reduced and the capsule is secured in a superior direction. The reverse hooks can be used to further tension the capsule above the cannula. Once all the sutures are secured, the plastic cannula is removed, and the suture hook can be percutaneously passed through the skin portal, grasping the superior edge of the capsule and closing down the portal hole with an absorbable monofilament suture.

Anterior and Superior Repair Including Rotator Interval

There are a number of patients with type II superior labrum from anterior to posterior (SLAP) lesions as well as anterior labral avulsions, associated with recurrent posterior shoulder subluxation. In cases of significant labral pathology, additional suture anchor fixation is suggested. This may include a superior labral anchor repair or selective anterior labral suture anchor repair. It is important not to ignore these potential additional lesions, to minimize

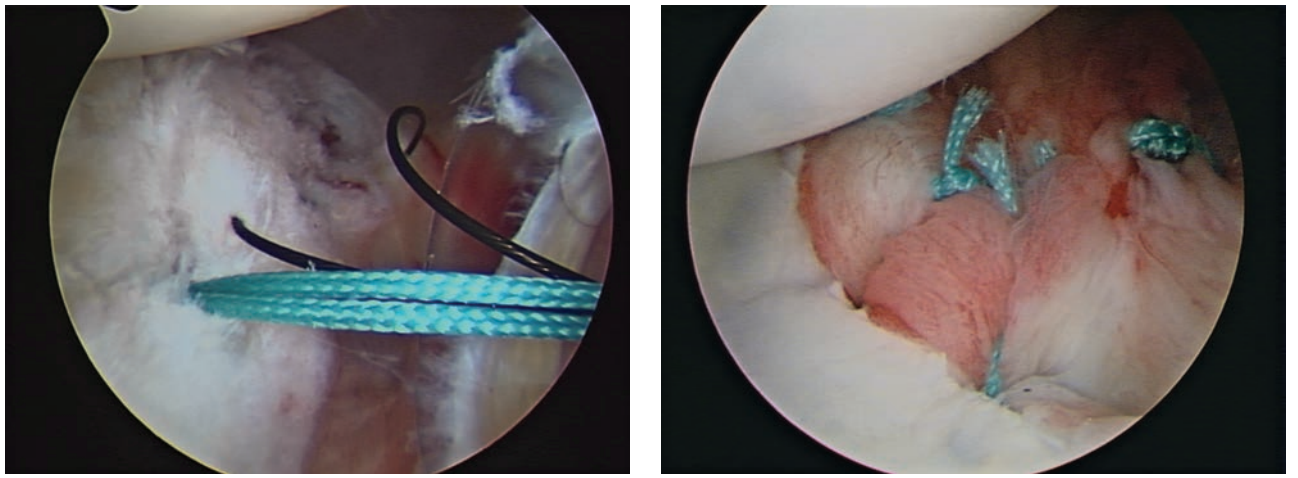

Figure 13-37 Suture anchor repair. **(A)** Anchor has been placed along glenoid rim. Shuttle is passed through inferior capsule and under labrum to retrieve braided sutures. **(B)** Completed capsule-to-glenoid repair with suture anchors.

risk of recurrence as well as avoid the potential for coracoid impingement syndrome.[2] With the posterior structures stabilized, the shoulder may be predisposed to increased anterior translation, reducing the space between the rotator cuff and the coracoid process. Anterior suture anchor repairs are designed to reattach the labrum and not create significant capsular shifts. A suture anchor is placed on the articular margin and sutures attach the labrum without significant capsular advancement.

The rotator interval has gained recognition as being important in shoulders that have increased posterior and posteroinferior translation. In selective shoulders, this interval may be closed by reapproximating the middle and superior glenohumeral ligaments (see Fig. 13-35). With the arthroscope in the posterior portal, curved suture hooks are used to grasp the superior edge of the middle glenohumeral ligament and introduce a suture that could be retrieved through the superior glenohumeral ligament. This may be further assisted by a second suture with the reverse curved suture hook, grasping the full thickness of the superior glenohumeral ligament and reapproximating to the advanced middle capsular ligament. No attempt to incorporate tendinous structures is made. By grasping the full thickness of the superior glenohumeral ligament, portions of the coracohumeral ligament are incorporated in this repair. The repair begins adjacent to the glenoid, and subsequent sutures are placed from medial to lateral. The most lateral sutures may be difficult to see and are tied in the subacromial space. Blind knot-cutters may be helpful in dividing the sutures after the interval has been securely closed.

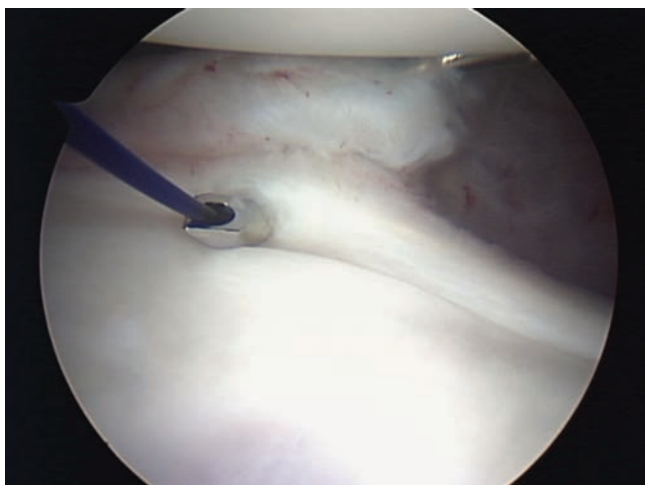

Figure 13-38 Inferior quadrant stabilizing stitch is made by using a suture hook, grasping capsular pouch, and plicating to inferior labrum.

POSTOPERATIVE CONSIDERATIONS

Postoperative management after open or arthroscopic posterior shoulder surgery requires the use of a thoracobrachial orthosis or external rotation brace. Prior to surgery, patients are fitted for the orthosis or brace with the arm positioned in slight abduction in or slightly posterior to the coronal plane of the body and in neutral to 10 degrees of external rotation (Fig. 13-40). The prefitted orthosis is applied in the operating room at the conclusion of the surgical procedure.

Patients are begun immediately on active assisted external rotation beyond the brace with the elbow at the side, elbow flexion and extension exercises, and shoulder shrugs. No inferior traction or lifting weights is allowed. Immobilization is maintained for a 4- to 6-week period. The time period is determined by the degree of passive motion measured 4 weeks postoperatively. If the shoulder demonstrates inability to internally rotate past the neutral position, the brace is discontinued at 4 weeks. The arm is

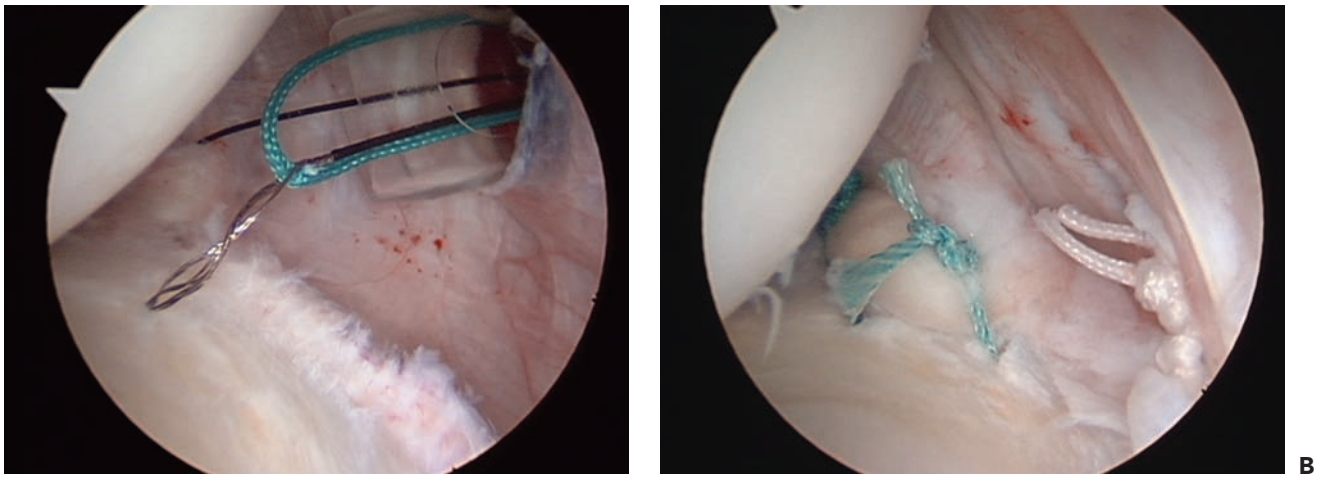

Figure 13-39 Capsular plication. **(A)** A suture shuttle is introduced with a suture hook and a braided suture is retrieved. **(B)** Capsular plication repair: Posterior capsular pleats created, eliminating the posterior pouch.

then kept in a sling for an additional 2 weeks, during which time the patient starts a gentle exercise program. Patients with generalized ligamentous laxity are generally treated with a brace for 6 weeks. During the time that the brace is used, the patient is allowed to remove the brace to dress and bathe, as long as the arm is not allowed to internally rotate beyond the neutral position.

After the brace is removed the patient starts active assisted supine forward flexion, external rotation, and internal rotation. With the scapula well supported by the table, the neuromuscular coordination of forward elevation without winging is more easily achieved. Once the arm approaches near full forward flexion, the patient is allowed to sit and stand and continue to perform active assisted

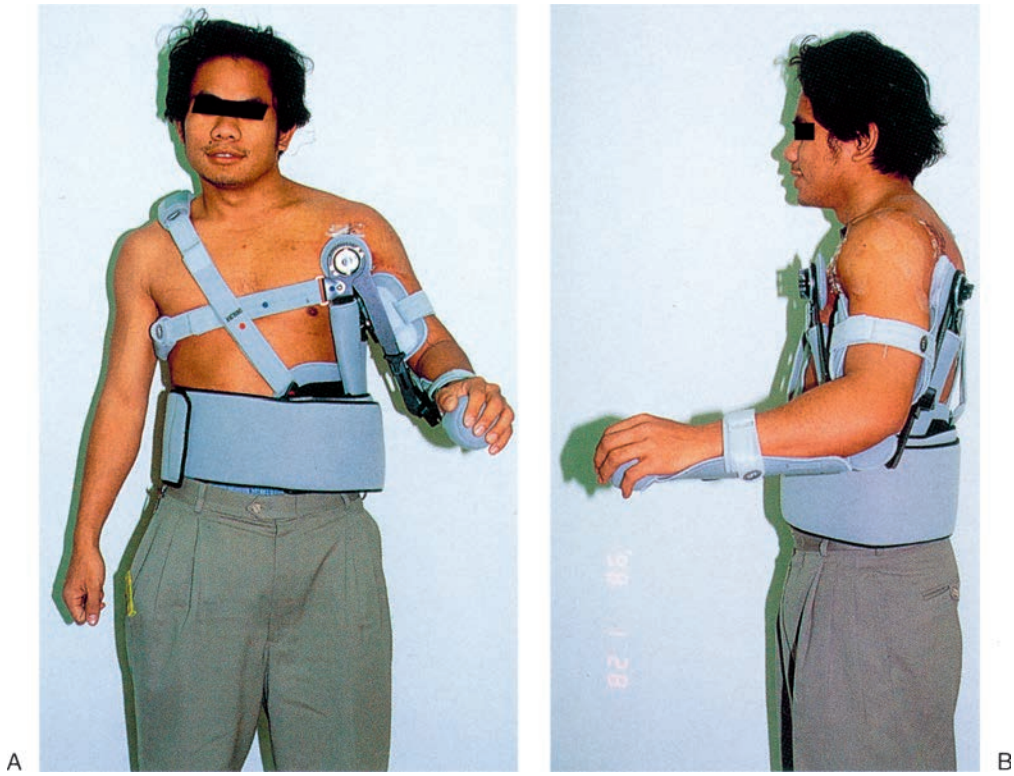

Figure 13-40 **(A)** Frontal and **(B)** side view of postoperative brace positioning after posterior capsulorrhaphy. The arm is placed in slight abduction and neutral to slight external rotation. The arm should be in the plane of the body or slightly posterior to this plane.

forward elevation. Visualizing the scapula from behind, one can determine when it is safe to begin independent forward arm elevation without the assistance of the other extremity. At 8 weeks postoperatively, the patient is begun on gentle resistive exercises. This will include external rotation resistive exercises and scapular stabilizing exercises. The scapular stabilizing exercises include strengthening of the latissimus, rhomboids, and trapezius. This can be achieved with bent-over rows, seated rows, and latissimus pull-downs to the chest in front. Wall pushups are not attempted until 3 months, and then a widened-grip pushup and/or bench press with light weights and high repetition is begun.

An anticipated return to athletics includes noncontact sports at 4 months and contact sports at 6 months. Sports that run the risk of a forward fall on an outstretched arm are considered contact sports. Patients may consider returning to work depending on the nature of their job. Sedentary work can often be achieved early on, depending on the ability for transportation to and from the job. More strenuous activities may require 8 to 16 weeks, depending on the nature of the job and the level of recovery that has been achieved. Total rehabilitation time is generally 16 to 24 weeks for primary capsulorrhaphy surgery. Revision surgery and complex situations, including scapulothoracic reconstruction, may require longer periods for rehabilitation.

RESULTS

The lack of a universally accepted and applied classification system for posterior instability makes interpretation of treatment results presented in the literature more difficult.

Success in treating recurrent posterior subluxation of the shoulder using a nonoperative exercise program is dependent on the amount of disability the patient is experiencing at the time of presentation, as well as on how one judges treatment success or failure. Fronek et al. reported a 63% success rate using nonoperative measures in patients with moderate disability when performing strenuous activities, but who had no interference with activities of daily living on initial presentation.[25] Hurley et al. demonstrated similar improvement in 68% of the patients treated under a similar treatment protocol.[38] Success in both of these clinical investigations was defined as clinical improvement that satisfied the patient to the extent that no further treatment other than maintenance muscular conditioning was required. These patients often demonstrate persistent posterior instability. However, the involuntary subluxations that in many cases prompted them to seek treatment are significantly improved. These studies combined with the mixed results of surgical intervention warrant the inclusion of nonoperative measures as an initial form of treatment in any algorithm.

At first glance, the results of the surgical treatment of recurrent posterior subluxation are discouraging. This has led some authors to conclude that recurrent posterior subluxation should not be treated surgically.[34] However, a more detailed examination of the literature shows cause for guarded optimism. Historically, confusion over the classification of posterior instability, a poor understanding of the underlying pathophysiology, and the routine use of surgical procedures that failed to address the pathology of the underlying instability resulted in high surgical failure rates.

The surgical management of recurrent posterior subluxation can be divided into soft tissue and osseous procedures. Because the cause of posterior instability usually resides in the posterior soft tissue structures, repairs aimed at reinforcing these deficient structures are more commonly employed. More recently, identification and correction of the specific pathologic lesion has gained favor over so-called nonanatomic repairs.

The most common finding in patients with recurrent posterior subluxation is a patulous posterior capsule. Although treatment of this pathologic lesion depends on the direction of the instability, all anatomic repairs stress a rebalancing of this patulous capsule to restore glenohumeral stability. Fronek and colleagues reported on 24 patients with isolated posterior subluxation treated with posterior capsulorrhaphy, with a 91% success rate.[25] The capsular repair is reinforced by the infraspinatus tendon and a posterior bone block if the posterior soft tissues are deficient. Hawkins et al. also favor utilization of the infraspinatus tendon to reinforce the capsular repair posteriorly and reported an 85% success rate.[32,35] In 1980, Neer and Foster introduced the inferior capsular shift in patients for whom there are inferior and posterior components to the instability.[52] Bigliani et al. reported the early results with this procedure in 25 patients with recurrent posterior subluxation, with 88% satisfactory results.[5] Pollock and Bigliani reported longer-term follow-up of this procedure, with an overall satisfactory rate of 80%.[61] Interestingly, several of these failures occurred in patients with revision surgery. Excluding revision cases, the success rate improved to 96%, highlighting the importance of meticulous soft tissue repair at the first surgery.

Although labral detachment from the posterior glenoid rim is rare in recurrent posterior subluxation, several authors have successfully treated recurrent posterior subluxation with an anatomic labral repair when a reverse Bankart lesion is present. Rowe and Yee performed reverse Bankart repairs on two patients with recurrent posterior subluxation with no recurrence of instability.[66]

Arthroscopic repairs for posterior instability typically group isolated labral repairs, capsular plication, and combined labral repairs and capsular plication together.[4,43] This makes it more difficult to determine the effectiveness of repairs for each specific pathology. However, these combined reports indicate satisfactory results when all identified contributing pathologies are addressed.

Several nonanatomic procedures have been previously described, with mixed results. Among these is the reverse

Putti-Platt operation. Dugas et al. treated 18 patients with recurrent posterior subluxation with a reverse Putti-Platt procedure.[18] Satisfactory results were obtained in 16 of 17 patients available for follow-up. Six patients experienced mild loss of motion. Similarly, Hawkins et al. reported good results in their patients undergoing this procedure, but in a separate group of patients, who were originally operated on by other surgeons, they reported a recurrence rate of 83% using this repair. This suggests that success with this procedure may depend on the surgeon's experience.[34] Boyd and Sisk reported nine nonanatomic soft tissue repairs that were augmented by posterior transfer of the long head of the biceps tendon.[8] All patients reportedly did well without recurrence of instability. The second group of procedures for recurrent posterior subluxation addressed bony pathology by either redirecting abnormal osseous anatomy (glenoid osteotomy or proximal humerus rotational osteotomy) or by augmenting deficient glenoid bone stock or incompetent posterior soft tissues (bone block procedures).

Glenoid osteotomy (glenoplasty), first reported by Scott, is a posterior opening wedge osteotomy of the glenoid neck with interposition of bone graft, thereby redirecting the glenoid more anteriorly.[70] In his original report of three cases, one patient dislocated anteriorly in the early postoperative period and another had recurrent posterior subluxation. Norwood and Terry reported 19 patients with recurrent posterior subluxation, from various causes, treated by glenoid osteotomy.[57] Three patients (16%) continued to experience isolated posterior instability, four patients (21%) developed isolated anterior instability, and two patients (12%) had multidirectional instability in the postoperative period.

English and McNab advocated an anatomic approach to recurrent posterior subluxation.[21] The surgical results of eight patients were reviewed. All demonstrated increased glenoid retroversion on preoperative radiographs. Four of eight patients were treated with posterior glenoid osteotomy without recurrence. Interestingly, they noted that in patients with ligamentous laxity, there was a tendency for the humerus to subluxate anteriorly. More recently, glenoid osteotomy has been successfully employed in patients with localized posterior glenoid hypoplasia and recurrent posterior subluxation.[85]

The role of posterior glenoid opening wedge osteotomy in the treatment of recurrent posterior subluxation is open to many criticisms. Gerber et al. have documented coracoid impingement following posterior glenoid osteotomy.[28] There has been a spectrum of anterior instabilities reported following glenoid osteotomy that range from coracoid impingement to anterior dislocation.[57,70] Posterior glenoid osteotomy is a technically demanding procedure, with the potential for significant complications. Hawkins et al. reported a 41% complication rate with this procedure, including subsequent glenohumeral arthritis in two patients, one caused by intraarticular extension of the osteotomy.[34] Finally, earlier studies that justify glenoid osteotomy based on radiographic evidence of increased glenoid retroversion may have overstated this problem.[20] In the past, the ability to document increased glenoid retroversion by plain radiographs has been questioned. Galinat et al. have recently reported a reproducible means of determining glenoid version from plain radiographs.[26] However, this method was not used in previous studies. Currently, CT scan is the most accurate method of determining glenoid version.

Increased proximal humeral retrotorsion has been implicated as a cause for recurrent posterior subluxation. Rotational osteotomy has been used to treat recurrent posterior subluxation, based on the assumption that increased humeral retrotorsion contributes to posterior instability. However, the relation between humeral retrotorsion and posterior instability has not been established. By limiting internal rotation through proximal humeral rotational osteotomy, it was theorized that posterior instability would subside. Surin et al. reported 12 cases of recurrent posterior instability treated with external rotation osteotomy of the proximal humerus.[75] One patient had pain after osteotomy that was attributed to anterior impingement. A second patient developed recurrent instability. Most patients had significant restriction of external rotation postoperatively. Chaudhuri et al. reported a series of patients who had rotational osteotomy for glenohumeral instability.[14] Only 1 of 16 cases underwent osteotomy for recurrent posterior subluxation. This patient developed postoperative anterior instability requiring muscle transfer.

Another group of bony procedures act to buttress the posterior glenoid with bone graft from the iliac crest or spine of the scapula. Several authors have reported the use of posterior bone block procedures for recurrent posterior instability.[3,41] Ahlgren and colleagues treated five patients with a posterior bone block procedure.[3] Two of the five patients had normal shoulders postoperatively, whereas three demonstrated varying degrees of recurrent posterior instability. More commonly, posterior bone block procedures are combined with a posterior capsulorrhaphy or performed for failed posterior soft tissue procedures.[41,51,79]

CONCLUSIONS

Recurrent posterior subluxation is less common than anterior subluxation, but it is being diagnosed more frequently than in the past. The treatment of recurrent posterior subluxation is dependent on the underlying pathology. An anatomically based classification system facilitates the diagnosis and appropriate treatment plan. The earlier literature on surgical treatment has yielded inconsistent results. More recently, improved recognition of the underlying pathology coupled with more anatomic surgical approaches have resulted in consistently improved results. An algorithm for

the evaluation and treatment of posterior instability based upon an anatomic classification is presented.

INTRODUCTION

Although Neer's original description of multidirectional instability was published more than 20 years ago, our collective understanding of the cause and optimal treatment protocols remain incomplete. Reviewing more historical publications, we learn that although the term "multidirectional" had yet to be applied, several authors recognized that there were patients who had instability patterns that did not fit into the known classification schemes of the time.[8,22,23,80] Multidirectional shoulder instability is a complex entity, and even 20 years after its first discussion in contemporary literature, relatively few series of patients with this condition have been reported. An accurate and encompassing definition of this clinical entity also remains elusive. The pathognomonic anatomic finding is redundancy of the inferior capsule allowing the shoulder to sublux, not only anteriorly but inferiorly and posteriorly as well.[21,63,65,71] Patients with multidirectional instability (MDI) possess two clinical features. First, most symptoms are experienced in the midrange positions of the glenohumeral motion, such as those that occur

during activities of daily living. These symptoms may be incapacitating enough that patients tend to avoid the extremes of glenohumeral motion. Second, the physical examination demonstrates the ability to dislocate or sublux-ate the glenohumeral joint in three directions (anteriorly, posteriorly, and inferiorly) with concurrent reproduction of symptoms in one of these directions. Importantly, both features are thought to be necessary for a diagnosis of multidirectional instability and are useful in distinguishing this instability pattern from other types of instability.

More recent investigations and analysis of this unique type of instability pattern suggest that pathology of the rotator interval may be implicated in the cause of this clinical syndrome.[24,29] Despite the increased awareness of MDI and the increased attention in research efforts to better understand its cause, understanding of this disorder remains woefully incomplete. Patient presentations are quite variable, the cause multifactorial, and treatment algorithms incomplete. In addition, MDI still lacks a uniform definition accepted by the body of orthopaedic surgeons.[61,78] Because of these ambiguities, the diagnosis of multidirectional instability is somewhat subjective, with the current tendency being to overdiagnose this once overlooked complex condition. Treatment of multidirectional instability employs nonoperative, open

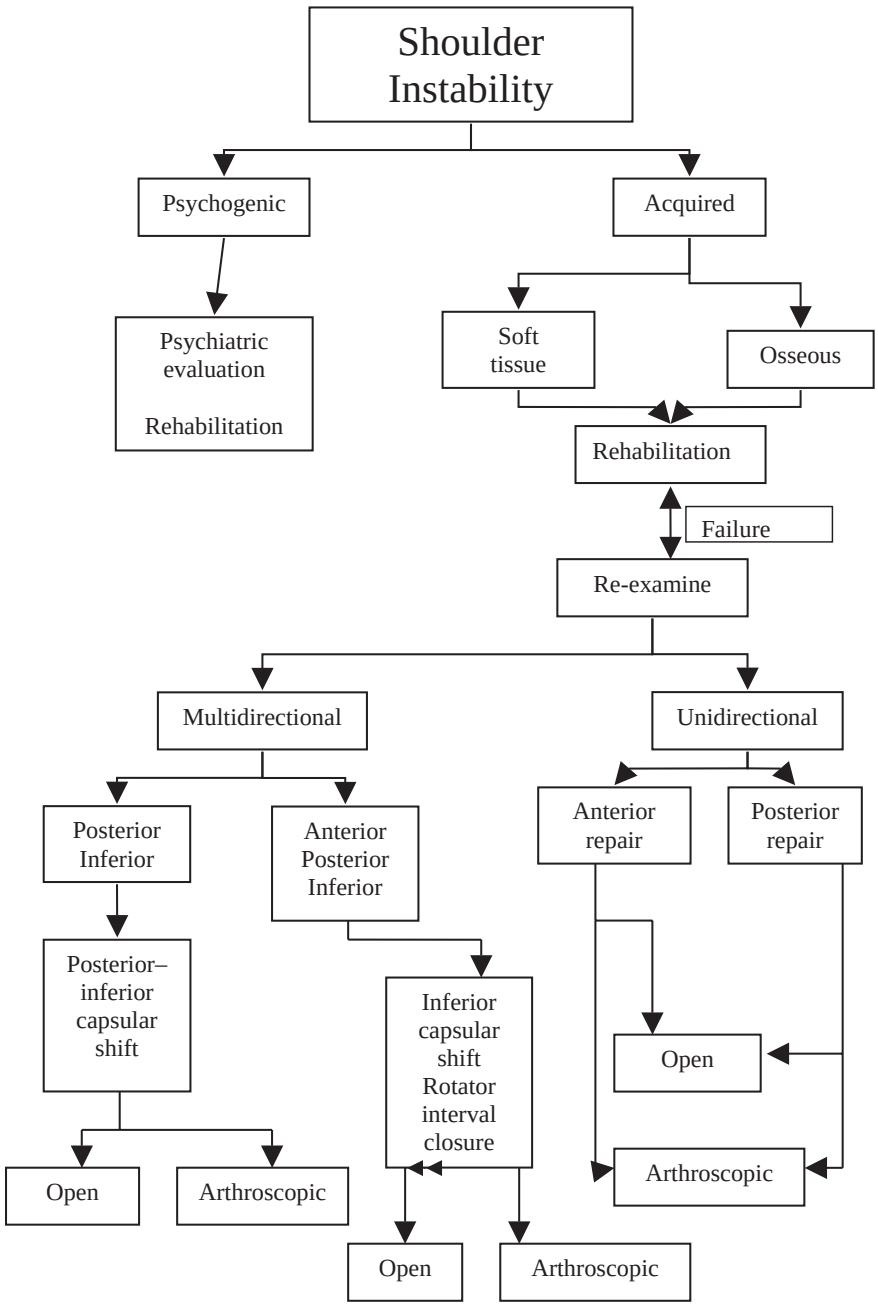

Figure 14-1 Treatment algorithm for multidirectional instability.

surgical, and arthroscopic surgical techniques. Figure 14-1 depicts a treatment algorithm for such management.

DEFINITION

Multidirectional instability has been defined simply as "global instability" or "instability in more than one direction," and in more complex terms, as part of a classification system with multiple subtypes.[57] A useful and comprehensive description of multidirectional instability defines it as *a global shoulder laxity (anterior, posterior, and inferior) that is associated with the concurrent reproduction of symptoms inferiorly and in at least one other direction. Additionally most symptoms are experienced in the midrange of glenohumeral motion, resulting in frequent limitation in activities of daily living.*[44]

It is important to discern the difference between instability and laxity. Laxity is the clinical condition associated with ligaments that have the ability to stretch beyond what is considered normal. Bear in mind that there is no absolute "norm" in measuring or assessing ligament compliance to tensile force. The more important concept to understand is that laxity, by definition, is not symptomatic in itself, nor does any "lax" joint lead to clinical awareness or complaint. By contrast, "instability" is a clinical syndrome manifest by patient complaint, pain, apprehension, or fear that application of a physiologic or nonphysiologic force may result in a mechanical dissociation of the joint.

CLASSIFICATION

Classification systems have been developed to assist the physician in organizing the variety of pathologic states of a given medical condition. They serve to assist in characterizing a condition by either its anatomic, histologic, or functional state. A classification system may also be utilized to direct a potential therapeutic algorithm. To be a functional classification system, it should be simple, applicable, predictable, and most of all, reproducible among physicians. In short, it should result in high levels of intraobserver and interobserver reliability when applied to the same pathologic condition.

Classification systems, when used to define and characterize shoulder instability, have been notoriously difficult to apply. Cofield and Irving noted that as proof of the complexity of classifying shoulder instability, there are between 24 and 54 subclassifications depending on the system used.[19] In an effort to ensure completeness, several systems have been employed based on different parameters. Some systems are based on the direction of the instability, others on cause (traumatic or atraumatic), and still others on volition.

Thomas and Matsen have provided perhaps the simplest classification of instabilities based on the mnemonics AMBRII and TUBS.[83] *A*traumatic *M*ultidirectional *B*ilateral *R*ehabilitation *I*nferior capsular shift with *I*nterval closure defines the typical clinical scenario and within, describes

Figure 14-2 This young woman with multidirectional instability displays hyperextensibility of the elbow joints. This finding would suggest a congenital collagenopathy.

predictable treatment regimens. So, too, the *T*raumatic *U*nidirectional *B*ankart—*S*urgery defines the other common clinical scenario and treatment. But within such a simple classification, other important parameters of clinical or therapeutic significance are lost.

It may be important to classify multidirectional instability by cause. The condition may be acquired, congenital, or traumatic in origin. In patients with the congenital type, there are usually multiple manifestations of lax ligaments involving many joints. The most classic manifestations that occur in the upper extremity include hyperextensibility of the elbow, hyperflexion at the wrists, and hyperextensibility of the metacarpophalangeal joints (Fig. 14-2). Laxity at these joints is rarely, if ever, of clinical significance. Patients with multidirectional shoulder instability may also have painful instability of one or both sternoclavicular joints, which can become disabling. In the lower extremity, the patient with congenital ligamentous laxity may complain of chondromalacia patella due patellar instability. Furthermore, ankle instability and recurrent ankle sprains may occur.

Some patients are thought to have acquired their pattern of multidirectional instability through activity or trauma.[20,32,63] The trauma is usually not overt, macrotrauma where there is a single episode of high energy absorption such as occurs in a motor vehicle accident, a fall while skiing, or a contact sport such as football. Rather, the laxity develops through the cumulative effect of repetitive use involving extremes of glenohumeral motion. Acquired laxity has been known to occur in competitive athletes (specifically gymnasts, weight lifters, and butterfly and backstroke swimmers) and in manual laborers. Athletes

who participate in racquet or throwing sports may also develop acquired laxity.[81] A number of factors may lead to the conversion of a functionally stable, ligamentously lax shoulder to one with clinically significant multidirectional instability. Precipitating events tend to be relatively atraumatic. The history obtained from the patient is one of trivial or mild injury, a moderate injury (defined as sufficient energy to disrupt ligament tissue), a period of overuse or fatigue, or even disuse. Occasionally, the precipitating event cannot even be identified. Consequently, a relatively atraumatic onset of instability suggests multidirectional instability as the cause of the clinical problem. The issue is made somewhat more complex because there are situations where an episode of significant trauma can be a factor in a shoulder with excessive laxity. The literature documents a significant number of cases where athletes with lax shoulders sustain traumatic events and then develop a clinical scenario consistent with multidirectional instability.[1,12] In this cohort of patients, Bankart lesions are occasionally found.

Classification schemes may be based on the direction of the instability. Inferior capsular redundancy and rotator interval lesions are considered the hallmark lesions of multidirectional instability, making inferior instability a universal finding in patients with multidirectional instability.[44] There are combinations of patterns of instability, which include the inferior component such as anteroinferior and posteroinferior, but it is the pure inferior component of the instability that defines the multidirectionally unstable patient. In their original study, Neer and Foster separated his patients into three groups based on the direction of the instability and the degree of instability: those with anterior and inferior dislocation with posterior subluxation; those with posterior and inferior dislocation with anterior subluxation; and those with dislocation in all three directions.[63] Gerber noted that while patients may have symptomatic instability in only one direction, they may exhibit asymptomatic laxity in other directions within the same shoulder.[25,26]

Another useful method of classifying instability is based on duration of symptoms. Instability may be either acute or chronic. These terms are more often applied to the patient with unidirectional instability as it is distinctly uncommon for a physician to see a patient with an acute episode of instability on a physiologic background of MDI. Most often patients will present *without* a known episode of subluxation or dislocation and remain oblivious to the fact that instability of the joint is responsible for their clinical presentation of shoulder pain. Therefore, a patient with multidirectional instability may present with a history of chronic shoulder pain, but *not* a history of chronic shoulder instability.[63,81]

One last method of classifying shoulder instability is based on volition. Volitional instability includes both voluntary dislocators (with or without documented psychiatric history or secondary gain issues) and habitual or positional dislocators. These are critically important distinctions to make. It has been said that a scalpel to the shoulder will never satisfactorily treat an intracranial disease! Patients with psychiatric illness, both overt and subtle, must be treated in the appropriate forum. Obsessive compulsive disorders, hysteria, and frank malingering for secondary gain must be considered—and ruled out—when treating any patient with shoulder instability. Voluntary instability is present in some form in a substantial number of patients with posterior instability and, less commonly, in the patient with multidirectional instability. Patients with voluntary instability do not necessarily have a psychiatric condition despite the connotation. Indeed, the history of voluntary instability complicates the evaluation and treatment of such patients, but in the absence of psychiatric illness or secondary gain, many patients with symptomatic multidirectional instability can be helped with surgery. Habitual instability refers to a dislocation or subluxation that occurs as a result of a neuromuscular imbalance: Abnormal muscle contraction and relaxation patterns result in the simultaneous activation and suppression of two halves of a force couple causing subluxation.[44] Habitual dislocators, regardless of their mental status, are very poor surgical candidates and remain refractory to surgical treatment. Biofeedback and muscular retraining must remain the mainstay of treatment in these patients. A positional dislocator is one who is able to demonstrate his or her instability by being able to place the arm in a position of risk. Unlike the person with psychiatric issues, these patients know their risk positions and carefully avoid them. A patient with multidirectional instability who is able to demonstrate the provocative positions that cause symptoms but otherwise tries to avoid them in life may benefit from treatment.

PATHOLOGY

There is no single pathologic lesion in multidirectional instability; there is no "essential" lesion, though a patulous inferior pouch is always present. Norris has stated that the most consistent physical finding is the "sulcus sign"[67] (Fig. 14-3). However, Harryman et al. demonstrated that a healthy control group of people will demonstrate significant degrees of inferior translation on physical examination.[30] It is the combination of inferior translation, which is symptomatic, that most appropriately defines multidirectional instability. Current understanding, though perhaps incomplete, focuses on structural or anatomic abnormalities, biochemical abnormalities, and neuromuscular abnormalities.[54] Another way to categorize etiologic factors considers global shoulder laxity and precipitating events, which may be either traumatic or atraumatic.[64]

In the normal shoulder, glenohumeral stability is conferred by an intricate balance of static and dynamic

Figure 14-3 The arrow documents a "dimple" sign or a "sulcus" sign, which is considered pathognomonic of multidirectional instability. A gentle inferiorly directed force on the shoulder is used to elicit this clinical finding.

mechanisms that include muscle, nerves, ligaments, bone, and geometry.[55] The capsuloligamentous restraints in the shoulder should be considered as checkreins that provide stability at the extremes of motion. The function of these individual ligaments has been defined by several authors through basic science and cadaveric studies.[35,69] However, outside the endpoints of motion, stability of the glenohumeral joint is conferred by other mechanisms. The precise centering of the humeral head on the glenoid by the rotator cuff muscles is achieved by a mechanism defined as concavity–compression.[56,91] The presence of synovial fluid within the finite volume of the glenohumeral joint contributes to the formation of passive stabilizing articular adhesion–cohesion forces.[60] Also of importance is that an intact glenohumeral joint possesses negative intraarticular pressure.[49] These factors combine to create a stabilizing vacuum effect when inferior translation is placed on the glenohumeral joint. Howell et al. found that the humeral head resisted tangential forces up to 60% of the compressive force applied.[37,38] Studies have shown that when a cadaver shoulder is stripped of all muscle, the humeral head remains centered on the glenoid, but when the joint is vented with a needle, the head then demonstrates increased inferior translation.[49] In multidirectional instability, a defect in the rotator interval capsule may "vent" the joint and reduce the effectiveness of the dependent passive restraints. With recurrent instability, there is deconditioning of the dynamic stabilizers and, ultimately, loss of effective concavity–compression. Furthermore, with loss of labral integrity, which functionally deepens the glenoid fossa by 50%, concavity–compression is further compromised. The importance of concavity–compression and glenoid positioning may be reflected by the fact that many patients respond to a rehabilitative exercise program directed at improving strength and neuromotor coordination of the rotator cuff and scapular musculature.[16,20,52]

Long before Neer's contemporary description of multidirectional instability, Basmajian and Bazant studied the problem of inferior glenohumeral translation.[7] They postulated that the glenoid inclination in the resting state faced superiorly. According to their hypothesis, the humeral head could only translate inferiorly if it moved laterally simultaneously (Fig. 14-4). Subsequent investigators found that the resting glenoid actually faces inferiorly, not superiorly.[48,58] Despite the glenoid inclination, lateral motion of the humeral head is *obligatory* if the head is to translate inferiorly. This is thought to be related to the increased thickness of the anterior inferior labrum.[31,82] Itoi et al. also studied biomechanical relationships of the

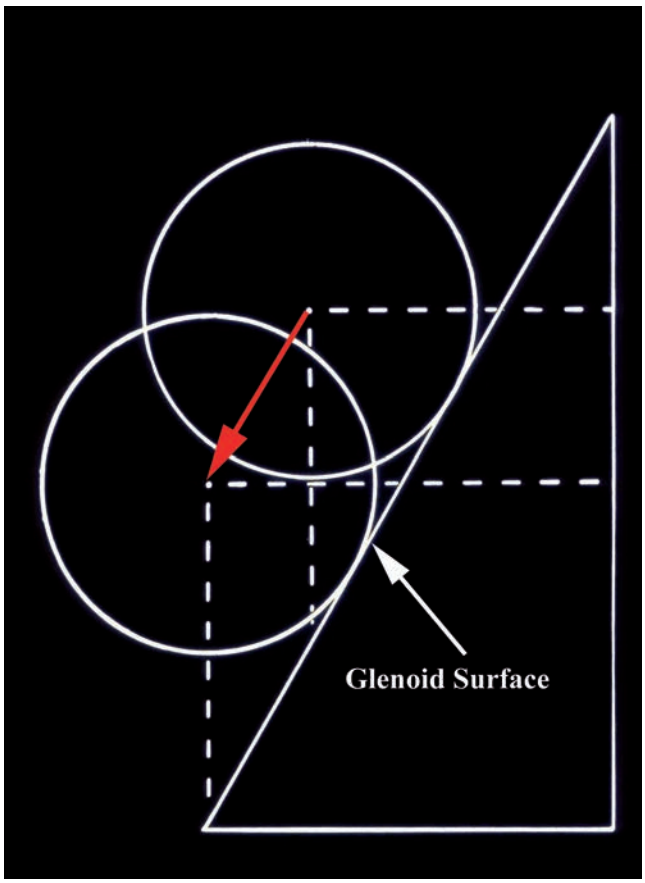

Figure 14-4 Biomechanical analysis of the glenohumeral joint suggests that regardless of glenoid inclination, the humerus is "obligated" to move laterally as it moves inferiorly. Although the natural glenoid may be inclined inferiorly, the thickened inferior labrum results in lateral motion of the head as it translates inferiorly.

glenohumeral joint and concluded, like Basmajian and Bazant, that there is a correlation between inferior scapular inclination and instability of the shoulder.[43] Several other authors have analyzed biomechanical effects that contribute to multidirectional instability.[42,72,77]

Two other anatomic lesions that result in multidirectional instability include a redundant inferior capsule and deficient rotator interval tissue. The triangular space separating the anterior edge of the supraspinatus from the superior edge of the subscapularis is defined as the rotator interval. It is normally bridged by a tissue considered capsule and is further defined as a "rotator interval capsule." Anatomically, the rotator interval includes the underlying superior glenohumeral ligament and is reinforced by the overlying coracohumeral ligament. Anatomic studies in cadaver specimens have led to the understanding that these structures together resist the inferior and posterior displacement of the humeral head. The superior glenohumeral ligament is thought to be the primary biomechanical restraint to inferior subluxation in the adducted arm. Patients with multidirectional instability consistently are found to have incompetence of this tissue. The rotator interval capsule is consistently characterized by the presence of either a discrete cleft or insubstantial and attenuated tissue. Defects in the rotator interval further disrupt the concavity–compression negative intraarticular pressure and may contribute to instability in this respect.[49,56] As the arm is progressively abducted, the inferior glenohumeral ligament complex functions as the primary restraint to inferior translation. In this abducted position, the anterior and posterior bands of this ligament reciprocally tighten with internal and external rotation. With a very large and redundant inferior capsule, it is easy to see how a patient may be clinically unstable in various positions of arm rotation while the arm is abducted.

Despite much investigation, a consistent biochemical explanation for capsular laxity remains elusive. Numerous studies have failed to identify a difference in the type or quantity of collagen between patients with multidirectional instability and controls.[79,84] Bell and Hawkins found that although there is no difference in the types of collagen between patients with multidirectional instability and controls, the patients with multidirectional instability had a significant increase in the rate of collagen formation.[10] Collagen fibril diameter and cross-linking are properties that are directly related to fiber tensile strength. Studies comparing capsular tissue from the shoulders of patients with multidirectional instability with those from patients with unidirectional anterior instability and from normal controls revealed some interesting findings. The capsular tissue from both instability groups demonstrated more stable and reducible collagen cross-links, greater mean collagen fibril diameter, higher cysteine concentration, and a higher density of elastin than did the normal samples.[79] However, one cannot conclude that these differences predispose clinical laxity. Skin samples from these same patients revealed significantly smaller mean collagen fibril diameter in patients with multidirectional instability than in those with unidirectional instability. This may suggest a possible underlying connective tissue abnormality.

More recent investigations of the cause of clinically significant multidirectional instability have sought a neurologic explanation.[6,51,86,88,96] Several observations support the idea of an underlying neuromuscular cause. Many patients with multidirectional instability in one shoulder have an equal or greater amount of laxity in their other, asymptomatic shoulder. In this condition, most symptoms occur in the midrange of motion where contribution of the ligaments to stability is minimal. High-speed photography of patients with symptomatic multidirectional instability reveals altered glenohumeral and scapulothoracic rhythms.[72] Most importantly, mechanoreceptors have been identified in shoulder joint capsule and proprioceptive deficits have been demonstrated both in patients with anterior instability and more recently in patients with multidirectional instability. It is possible that known proprioceptive receptors in the glenohumeral joint capsule, in addition to providing joint position sense, reflexly modulate rotator cuff forces during arm use to promote shoulder stability.[14,53] Patients with recurrent traumatic anterior instability appear to have deficits in joint-position sense compared with normal controls.[53] Although yet to be proven scientifically, a defect in proprioception may be a component of the cause of multidirectional instability. Interestingly, these deficits were shown to be reversible by surgical stabilization.[75,95]

One further plausible hypothesis is that the provocation of multidirectional instability occurs when the system of dynamic restraint is overwhelmed such as occurs when the arm is suddenly and unexpectedly moved or is fatigued due to repetitive use. This event, whether or not it results in identifiable trauma, results in pain and initiates a self-perpetuating cycle of increasing symptoms. When the now painful shoulder is protected, muscular weakness and subtle losses of refined neuromotor coordination are thought to ensue. Continued disuse further deconditions the dynamic constraints against glenohumeral instability, which are critical to maintaining stability in lax shoulders. With the further use of a deconditioned shoulder, the patient is more prone to experience painful episodes of instability, which promotes further disuse—and so on.[81]

Putting these various thoughts to practical use results in the concepts of the "shoulder at risk." These patients have multidirectionally lax shoulders that function well for years until a minor injury produces a loss of "balance" of the shoulder musculature. The resultant symptoms stem from an inability to control the entire shoulder girdle. The instigating incident may be small, repetitive, or large, but the result is an asynchronous firing pattern that eventually extends to the larger muscles of the shoulder

girdle, producing scapular winging, malpositioning of the shoulder girdle, secondary impingement, loss of proprioception, weakness, and pain. The scapula begins to protract, the humeral head begins to subluxate, and irritation develops in the rotator cuff and trapezius as these muscles try to compensate for the lack of normal dynamic serratus and rotator cuff function. It is the irritation of the tendons of the rotator cuff that produces pain in these lax shoulders.

The role of dynamic muscle contraction and coordination likely also play a role in shoulder stability. Dynamic, in vivo, electromyographic studies document rotator cuff and deltoid muscle activity throughout all shoulder motions.[39,73] Calculations reveal that the combined activity of the subscapularis, infraspinatus, and teres minor is balanced by the superiorly directed deltoid force vector.[73] The supraspinatus, which is more horizontally oriented, contributes more joint compression and, hence, stability. The net result of these muscle forces is that the force couple ensures that the humeral head remains precisely centered on the glenoid regardless of arm position.[27,39]

A relatively atraumatic onset of instability strongly suggests multidirectional instability. However, an episode of significant trauma can be a factor in a shoulder with excessive laxity. Reports in the literature suggest that athletes with symptomatic instability have such a history.[1,12] In this scenario, the athlete has a multidirectionally unstable shoulder in the presence of a Bankart lesion. Therefore, the presence of a Bankart lesion either on a radiograph or on a magnetic resonance arthrogram does not rule out multidirectional instability as the correct diagnosis. As Neer noted, this is a critical distinction to make.[64] He noted that when there is a history of significant traumatic event, multidirectional instability can be mistaken for a traumatic unidirectional instability. If a surgical repair designed for a unidirectional instability is performed, it is likely to result in a fixed subluxation in the opposite direction. Not only will the surgery fail in the short term, but the likelihood of developing arthritis of dislocation becomes a very concerning consequence.[33,81]

MANAGEMENT: NONOPERATIVE

Nonoperative management includes a physical therapy program *and* patient education. Perhaps in this group of patients education is the more important initial program because if patients do not understand or comprehend the nature of their problem, they are less likely to participate in the rigorous therapy program. Patients have ready access to many sources of information: magazine stories, the Internet, sportscasters, television, etc. Typically the media outlets are deemed to have more "authority" than the treating physician. Professional and collegiate athletes are often deified in the press and, in the eyes of the public, athletes with media visibility always seem to recover faster, have less pain, and return to sport sooner! Therefore, it is our obligation to educate our patients about the nature and natural history of their conition.

As physicians, we must take the time to compare and contrast, in understandable words and terms, the nature of multidirectional instability. We must take the time to explain anticipated time frames of improvement and realistic goals in return to sport. The patient must be made to understand that the nonoperative program has a good record of improving symptoms and returning their arm to their premorbid level of comfort and function.[2,4,20,60,63,64]

One helpful tactic to use in patients with multidirectional instability who also have laxity of their uninvolved shoulder is to emphasize that compensated laxity (such as their asymptomatic shoulder) can result in a normally functioning arm. Patients must learn that their unstable shoulder has become deconditioned from its usual state and that they need to regain both strength and neuromotor coordination of the stabilizing muscles of the rotator cuff, deltoid, and scapula. Burkhead and Rockwood reported satisfactory results in 88% of patients who had symptomatic multidirectional instability treated with a specific program of physical therapy.[16,57]

If patients present with pain, suggesting an inflammatory synovitis, a program of oral nonsteroidal antiinflammatories should be initiated before commencing the rehabilitation program. Only rarely are mild narcotic analgesics required. The need for such medications should suggest some other cause of the patient's symptoms. When using antiinflammatories, one should respect the fact that effort is being made to treat the *condition,* not just the *symptoms.* Accordingly, the antiinflammatory choice should be one that allows the patient to obtain, and then maintain, a therapeutic level of the medication 24 hours a day for about 6 weeks. Long-acting antiinflammatories that have a half-life of at least 12 hours (twice-a-day dosing) result in the best therapeutic response and ensure the greatest probability of patient compliance.

From a basic science standpoint, the goals of shoulder rehabilitation are to restore effective concavity–compression through strengthening, to identify and correct abnormal muscle firing patterns, and to improve deficient proprioceptive function.[17,52,62,87] The exercise program consists of two phases. Phase I concentrates on progressive resistance exercises utilizing elastic bands for strengthening of the rotator cuff and deltoid musculature. Initial emphasis is directed toward the infraspinatus and subscapularis muscles. They are performed with the elbow at the side and with the arm below 90 degrees of abduction to avoid the possibility of shoulder impingement. Within several weeks, as progress is made, strengthening routines for the scapular muscles, including the rhomboids, levator scapulae, and serratus anterior, are incorporated.[46] Phase II exercises are added at about 3 months, which are designed to develop and retrain humeroscapular coordination.

The specific technique of the strengthening is a critical component for successful rehabilitation.[3,92] Several important concepts are conveyed to the patient to ensure the most successful outcome of this nonoperative program. The elastic tubing is pulled only through a short arc in an isotonic contraction, not more than 45 degrees. The resistance is held for at least 5 seconds in an isometric contraction, and then released *very slowly* to maximize the eccentric component of the muscle function. It has been demonstrated that the eccentric phase of muscle physiology is the most efficient type of contraction that restores or improves its strength.[36] The exercises are repeated in sets of 10 and are performed twice daily.

Because the patients who develop symptomatic instability of any type are usually teenagers and young adults who are not known to be especially compliant with exercise routines, special emphasis must be given to review the anticipated time frames of anticipated benefit. Frequently, if the patients do not perceive benefit from the exercise routines within the first week, they become less compliant and the exercise program is doomed to failure. The patients must be made aware that it may take at least 3 months before any benefit from the muscle exercises is perceived. Thus, it is nearly always appropriate to initiate treatment with an exercise program if only to evaluate patient compliance. It has been well understood that a surgical procedure does not make an otherwise noncompliant patient suddenly compliant in the necessary postoperative rehabilitation program. The exercises are continued for a minimum of 6 months. If successful, a program of maintenance exercises is given to be performed indefinitely.

Rehabilitation Concerns

Nonoperative treatment centers initially on dynamic stabilization of the scapulothoracic articulation and pain-free strengthening of the rotator cuff. Active abduction and "empty can" exercises that increase impingement in these unbalanced shoulders should be avoided until symmetrical scapulothoracic and glenohumeral motion develops. Attentive physical therapy is essential for biofeedback during the early phases of rehabilitation. All exercises must be performed with the scapula retracted to avoid rotator cuff irritation. As the patient is usually unaware of the malpositioned scapulothoracic articulation, hands-on therapy, taping, or bracing is required to ensure correct shoulder position during rehab. Recently, biofeedback braces emphasizing correct scapula position have been utilized with excellent improvement in correct positioning of the scapula (Fig. 14-5A,B). Correct scapular positioning is essential, as any rotator cuff exercises done with a protracted shoulder will increase irritation of the rotator cuff rather than strengthen it. As these patients do not have an awareness of the position of the shoulder, these braces hold great potential in increasing the success and compliance of nonoperative treatment.

Patients must be informed that they need to regain both strength and neuromuscular coordination of the rotator cuff, deltoid, and scapula. It is essential that the treating physician emphasize the need for correct scapula positioning during all exercises.[56]

Wirth, Burkhead, and Rockwood have reported on conservative therapy in patients with multidirectional instability, and reported satisfactory results in 88% of

Figure 14-5 **(A,B)** The biofeedback scapular brace used to restore normal scapular kinematics.

patients who underwent a specific program of physical therapy.[16]

In the acute painful phase, antiinflammatory treatment is beneficial. Although many physicians recommend nonsteroidal antiinflammatory drugs, we have not found them to be particularly helpful. In addition to a course of physical therapy, an intraarticular shot of corticosteroids and a short course of low-dose oral prednisone may be initiated before beginning therapy in an attempt to calm the inflammation. We generally recommend this aggressive treatment plan if the patient is experiencing night pain and has palpable swelling. It is emphasized to our patients that although this will help with the pain, it is merely palliative to allow proper rehabilitation and not curative. These patients will begin utilizing the scapular brace immediately as tolerated, progressing to utilization of the dynamic supports during all waking hours.

A minimum of 6 months of adequate therapy is recommended before consideration of surgical intervention.

Results of Nonoperative Treatment

Burkhead and Rockwood reviewed 140 shoulders in 115 patients who had a diagnosis of traumatic, atraumatic, or multidirectional instability who were treated with a specific set of muscle strengthening exercises. They noted that in the subgroup of traumatic instability, only 16% of the shoulders had a successful outcome from exercises alone compared to 80% of the shoulders with a diagnosis of multidirectional instability.[16] They concluded that it is critically important to define the exact nature of the instability through history, physical examination, and radiographic studies so that appropriate treatment programs can be initiated.

Kiss and coinvestigators reviewed a series of 84 shoulders in 59 patients who had a diagnosis of multidirectional instability.[47] All patients were treated nonoperatively with a specific exercise routine. At an average 3.7-year follow-up, 38 shoulders were either "cured" or improved with an exercise program alone and only four required surgery. They also concluded that those patients who had a failed surgery for instability prior to the exercise program had a much poorer outcome with physical therapy alone.[47]

Brostrom and coworkers reviewed a series of 33 shoulders in 29 patients with recurrent instabilities of several types.[15] Twenty-eight shoulders improved and only four required surgery at 1 year. As has been stated with respect to surgical stabilization, failures may occur many years later. Nonoperative treatment should also be evaluated over similar lengths of time before ascribing success to the treatment plan.

There is little guidance in the literature regarding either long-term or short-term bracing in the treatment of multidirectional instability. Ide and investigators have recently reviewed their experience combining a custom-made brace with a shoulder strengthening program.[41] They studied a cohort of 46 patients (73 shoulders) with multidirectional instability and quantified changes in muscle strength over the time of the study. All patients performed a structured exercise routine for 8 weeks. At a mean follow-up of 7 years, only three patients required surgical stabilization of the persistent shoulder instability. Uhl and Kibler have recently reported on the use of a biofeedback scapular brace in the preoperative treatment of MDI with increased success.

MANAGEMENT: OPEN INFERIOR CAPSULAR SHIFT

Patients who fail to respond to 3 to 6 months of nonsurgical treatment are considered candidates for surgical intervention. The patient must have been compliant in the execution of the nonoperative rehabilitation program. Surgery is not offered to voluntary dislocators with emotional problems or to behaviorally immature teenagers. Neer and Foster described the open inferior capsular shift in 1980, and it remains the standard procedure for surgical repair.[63] Over the years, numerous variations of capsular dissection, plication, and repair have been added, but the original inferior capsular shift remains the standard to which other modifications are compared.[1]

In recent decades, advances in the field of surgical anesthesia have found direct benefit in this procedure. In the 1980s, regional interscalene block anesthesia had not been in widespread use for shoulder surgery. The use of general anesthesia made it difficult to apply a modified shoulder spica in the operating room at the conclusion of the surgical procedure. Neer and Foster felt it especially important to place the patient in a cast immediately upon completion of the procedure to minimize forces on the newly repaired capsule.[63] Recognizing the need to free the repaired capsule from multidirectional forces, the arm could not be placed in a sling in the internally rotated position because it would stress the posterior portion of the repair. The inferior forces created by the weight of the arm had to be eliminated by supporting the arm in the spica with the downward forces absorbed by the pelvic brim. Lastly, the spica cast had to be placed to keep the arm in neutral rotation, superiorly and anteriorly directed. Today this may be accomplished by a removable brace, but there will be further discussion of this issue later in the chapter. It is easy to understand that applying a cast to a patient who is under the effects of general anesthesia is a sizeable challenge.

With the more widespread use of interscalene block anesthesia, patients can be awake, alert, and, most importantly, cooperative during cast or brace application. Additionally, there have been numerous reports in the literature on the benefits of ultra–long-acting anesthetic agents in the management of postoperative pain. The authors' present choice is the use of Chirocaine supplemented with

Diprivan (propofol). This combination provides for excellent hypotensive surgical anesthesia and effective muscle relaxation while providing up to 18 hours of postoperative analgesia. A disadvantage of using interscalene block alone is that it prevents the ability to examine the uninvolved shoulder. Perhaps its most valuable asset is that this combination of agents allows the patient to be awake and cooperative at the completion of the procedure to allow placement of the cast or brace in the operative suite.

After the patient is fully anesthetized, a careful examination of *both* shoulders is performed. Assessment of instability patterns, including direction and degree, is documented for each shoulder. This examination should be used to reinforce the office clinical examination and to make a more detailed assessment of the instability and laxity patterns. It is particularly dangerous to use the examination under anesthesia as a substitute for an office clinical examination. Great harm can be done to a patient if asymptomatic laxity is misinterpreted during an examination under anesthesia and an inappropriate capsular tightening procedure is performed.[94] It should be restated for emphasis: The examination under anesthesia should be used to *reinforce* a clinical diagnosis made during repeated office examinations.

The direction of the surgical approach is dictated by the associated pathology. The presence of a labral defect will usually direct the surgical approach. Some authors feel that the surgical approach should be made from the direction of the maximal instability, while others feel that the anterior approach should be the default approach, unless there is a posterior labral tear.[13] An approach from the most unstable side allows for direct imbrication and reinforcement while simultaneously shifting the capsule to reduce global capsular laxity. If there is an anterior labral tear documented by magnetic resonance arthrography, an anterior approach is made even in the presence of a significant component of posterior instability. Similarly, if there is a documented posterior labral tear, a posterior approach is made for the capsular shift procedure even in the presence of significant anterior translation. When an open repair is appropriate for isolated posterior instability, this author performs an anterior approach in an effort to protect the critical function of the infraspinatus muscle and its role in dynamic stabilization. A potential drawback to the posterior approach is the thin and pliable nature of the posterior capsule. The more robust anterior capsular tissues provide for a more secure repair, and appropriate posterior capsular tensioning can be achieved through the capsular shift. An anterior approach also facilitates closure of the rotator interval, a necessary step in the surgical management of most multidirectionally unstable shoulders.[29] A posterior labral lesion, in the presence of a multidirectionally unstable shoulder, demands a posterior approach, either arthroscopic or open.

The patient is placed in a semi-recumbent, beach-chair position (Fig. 14-6). A special headpiece is used to permit access to the superior aspect of the shoulder. It is useful to have the longitudinal axis of the body at the far edge of the bed so the arm and shoulder extend beyond the operating table itself (Fig. 14-7). This allows the operative shoulder to be unencumbered by the bed and facilitates shoulder extension.

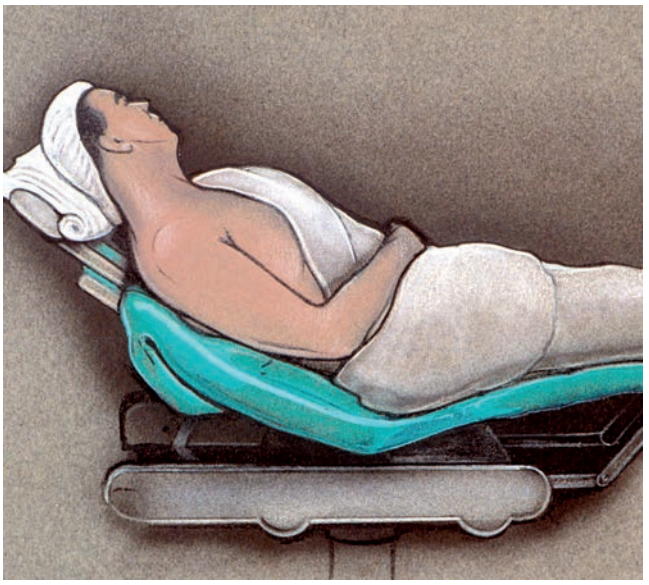

Figure 14-6 The patient is placed in a beach-chair position with the back at 45 degrees from the horizontal. This position allows excellent access to the medial and inferior aspects of the joint capsule.

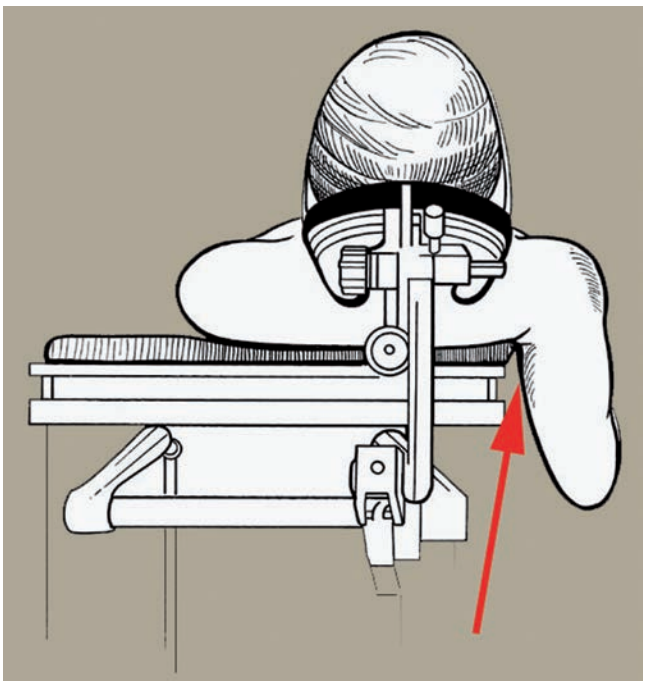

Figure 14-7 The head is placed on a head support, which allows the patient's body to be translated off the edge of the bed. As the arrow shows, this facilitates extension of the arm during the procedure.

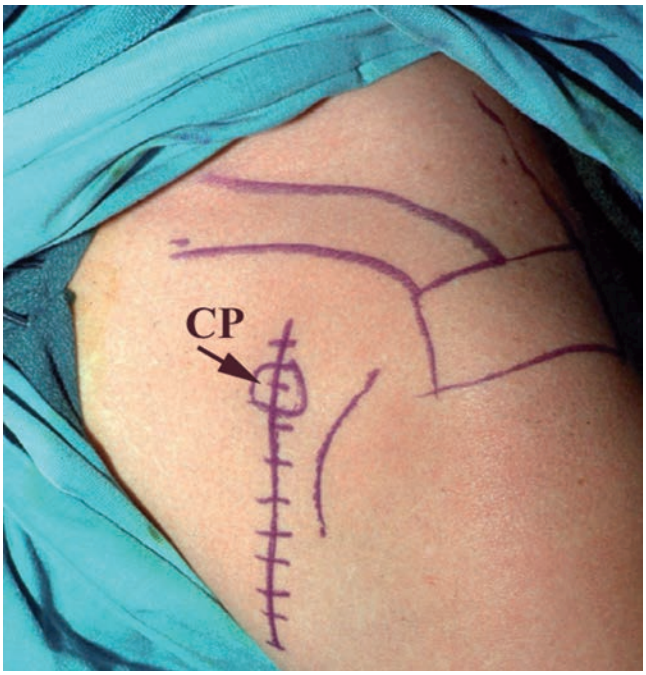

Figure 14-8 The incision is vertical in orientation and begins in a skin crease at the apex of the axilla. It extends superiorly to the coracoid process (*CP*).

The location and placement of the surgical skin incision is made according to the surgeon's choice but must permit access to both the deltopectoral interval while also allowing access medial to the glenohumeral joint. Therefore, the incision of choice is one that originates at the tip of the coracoid process and extends inferiorly to the superior aspect of the axilla (Fig. 14-8). Prior to making the incision, the arm is adducted across the chest and a skin fold at the superior margin of the axilla is marked. In making an incision along this skin fold, which joins the coracoid tip, a very cosmetically acceptable scar predictably results. Some surgeons choose to confine the incision to the axilla itself, thereby avoiding a scar on any part of the anterior aspect of the shoulder. While this is commendable from a cosmesis standpoint, deep surgical exposure becomes much more challenging.

Once the incision is carried down to the investing fascia of the pectoralis major and deltoid muscles, extensive skin flaps are developed. Care must be exercised during the initial incision down to the fascia because the incision will cross the cephalic vein in the midportion of the wound. Although the vein often lies deeper, embedded in fat, on occasion it has been found more superficial within the deltopectoral interval and can be lacerated inadvertently. The skin flaps must be extended laterally to the anterolateral margin of the deltoid, superiorly to the level of the clavicle, medially to the base of the coracoid process, and inferiorly to the apex of the axilla. This degree of tissue mobilization is necessary to ensure medial and inferior access to the capsule. This degree of exposure also provides the ability to visualize and protect the axillary nerve, which is at considerable risk during the capsular shift procedure. The vascular supply to the shoulder is abundant, and this author has never seen or read of a circumstance where skin necrosis resulted either from the location of the incision or from the extensive dissection of skin flaps.

Once the flaps have been created, the deltopectoral interval is developed from the clavicle at the superior extent of the wound, and distally to the deltoid insertion. It is predictably easier to take the vein laterally with the deltoid muscle because the majority of the feeding veins drain from the deltoid. On the other hand, it is not altogether uncommon to find some smaller veins from the pectoralis major also draining into the cephalic vein, but they are easily coagulated and divided. There is some risk in taking the vein laterally in that it must take a relatively longer course during retraction of the deltoid muscle. This is especially problematic if the superior aspect of the cephalic vein penetrates the clavipectoral fascia medial and inferior to the coracoid. In this circumstance, either the vein should be kept in continuity and dissected in such a way that it is retracted medially with the pectoralis major, or it is ligated proximally and the distal portion retracted laterally with the deltoid. Ligation of the cephalic vein in a young patient, free from other vascular or lymphatic problems, is not known to have any adverse effects.

As the deltopectoral interval is developed and opened, the deltoid branches of the thoracoacromial trunk are encountered in the upper third of the wound. They course from the medial to the coracoid to the medial aspect of the deltoid on its deep surface and consist of an artery and several veins. Once these vessels are ligated or coagulated, the deltopectoral interval can be widely opened from the clavicle at the proximal extent to the deltoid insertion at the distal extent.

The clavipectoral fascia is incised parallel to the deltopectoral interval. This incision should be made lateral to the muscle fibers of the short head of the biceps. In more muscular individuals, a moderate amount of muscle tissue extends lateral to the tendon of the short biceps, even up to the coracoid process where it originates. In keeping the clavipectoral fascial incision lateral to the muscle fibers, bleeding is minimized. At its superior extent, the clavipectoral fascia is initially incised up to the anterior border of the coracoacromial ligament. Inferiorly, the clavipectoral incision extends to the superior border of the tendons of the pectoralis major insertion.

Returning to the superior aspect of the wound, the acromial branch of the thoracoacromial trunk is coagulated as it courses on the superior aspect of the coracoacromial ligament. The anterior third of the coracoacromial ligament is incised over the rotator interval. This interval is easily palpated just inferior to the coracoacromial ligament and approximately 1 cm lateral to the coracoid process. The

posterior two-thirds of the coracoacromial ligament is kept intact to provide whatever component of superior stability it may contribute. There is no indication to "decompress" the shoulder in a patient with a clinical instability problem.

Inferiorly, the superior 2 cm of pectoral major insertion are divided from their insertion on the shaft of the humerus. Both the superficial and deep heads are divided simultaneously, which provides significantly better exposure to the inferior aspect of the glenohumeral joint. Furthermore, by mobilizing the now released portions of the pectoral major, the areolar tissue joining the long and short heads of the biceps can be divided. Doing this with the cautery minimizes bleeding of the numerous small vessels that inhabit this area. At the completion of this inferior dissection, the inferior aspect of the glenohumeral joint should easily be seen; the axillary nerve can be safely palpated and protected. For those surgeons who are more comfortable only after visualizing the nerve, this inferior exposure also facilitates that effort.

To permit the medial exposure, a plane is developed under the lateral border of the short head of the biceps and conjoined tendons. A retractor is placed to reflect the conjoined tendons medially, thus protecting the musculocutaneous nerve specifically and the entire brachial plexus. This maneuver brings the anterior humeral circumflex vessels into view at the inferior aspect of the subscapularis muscle. These vessels tend to run an extremely variable course with respect to the muscle and tendon of the subscapularis. While some surgeons have advocated their preservation, routine ligation or coagulation has not resulted in any documented cases of avascular necrosis in this patient group. Furthermore, when dissecting the capsule inferiorly and posteriorly for a complete inferior capsular shift, these vessels must be transected for capsular exposure and repair.

At this point, the subscapularis insertion should be exposed in its entirety. One will notice that the superior portion of the muscles has thick tendon that attaches to the lesser tuberosity. The tendinous portion of the tendon extends medially, usually for several centimeters. Conversely, the inferior portion of the muscle has no tendon and the muscle fibers themselves insert directly onto the humeral shaft inferior to lesser tuberosity. The rotator interval defines the superior aspect of the subscapularis. An incision is made in the *superficial* portion of the subscapularis only, beginning at the rotator interval superiorly and extending to the inferior aspect of the glenohumeral joint. This incision is made 1 cm medial to the tip of the lesser tuberosity (Fig. 14-9). By making the incision at this location with respect to the lesser tuberosity, there should be an adequate sleeve of tendon tissue remaining on the tuberosity to allow a tendon-to-tendon repair at the completion of the procedure.

Once through the anterior one-half of the tendon, the scalpel is placed in the coronal plane and the dissection proceeds medially. An important concept is to split the subscapularis tendon coronally with the desire to keep the posterior fibers of the tendon in their normal intimate contact with the underlying capsule (Fig. 14-10). This will serve to reinforce the often tenuous capsule. The anterior half of the tendon is dissected medially until the muscle fibers are encountered. At this point, the muscle fibers are teased from the capsule and the construct composed of the muscle belly of the subscapularis in continuity with the anterior half of its tendon is retracted medially. This then results in the anterior capsule with overlying posterior subscapularis tendon attached (Fig. 14-11). During the dissection of the subscapularis tendon, it is important to note the horizontal orientation of the tendon fibers. Dissection performed within this layer of horizontally oriented fibers ensures the proper dissection plane. Lastly, it is critical to understand the three-dimensional aspect of the dissection. Because the humeral head (and overlying soft tissue) is essentially spherical, as the subscapularis dissection proceeds inferiorly, the scalpel begins relatively posterior, advances relatively anterior at the midaxis, and finally becomes relatively posterior again at the inferior portion of the dissection. At the same time, as the dissection is developed medially, the scalpel begins relatively posteriorly, becomes more anterior as the dissection progresses medially, and finally becomes more posterior at the medial extent of the tendon release. The concept of peeling an apple with a scalpel *and keeping the skin intact* becomes a convenient visual aid.

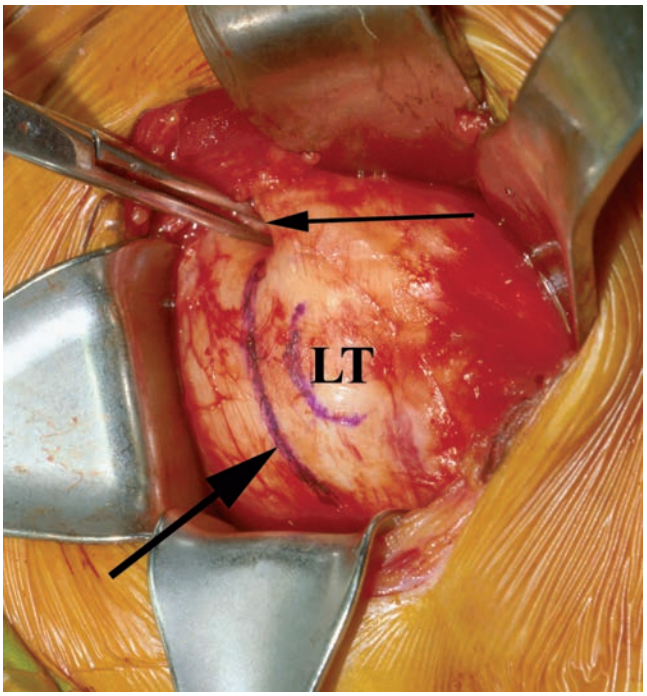

Figure 14-9 The thick arrow marks the line of subscapularis incision. It begins 1 cm medial to the lesser tuberosity (*LT*) and starts at the rotator interval (*narrow arrow*).

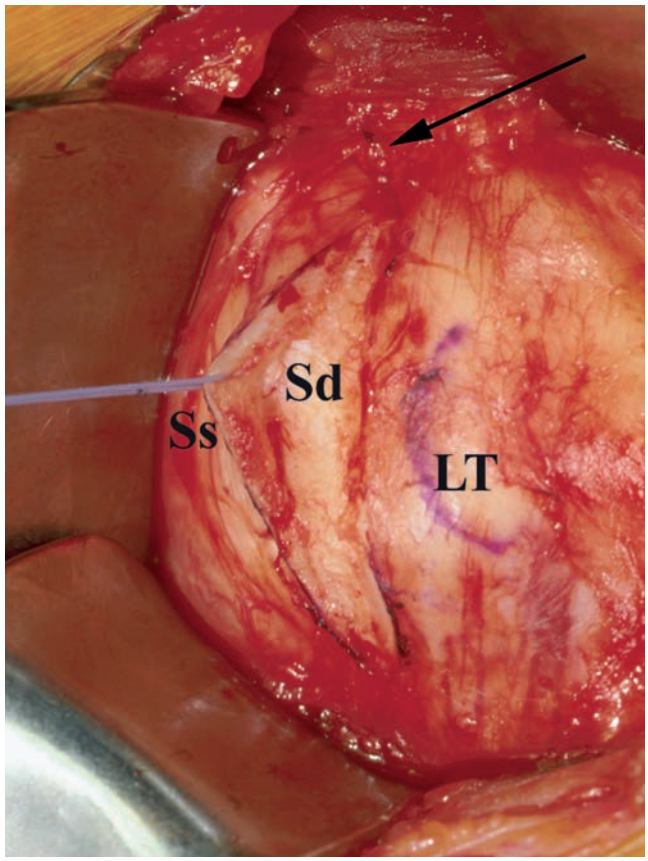

Figure 14-10 Once the subscapularis incision (*Ss*) is made to the appropriate depth, horizontal fibers will be seen in the deep portion of the tendon (*Sd*). The dissection continues medially separating the superficial portion of the tendon from the deeper portion. The arrow delineates the superior extent of the tendon at the rotator interval. LT = lesser tuberosity.

With the subscapularis retracted medially, the rotator interval is easily seen and, in the patient with multidirectional instability, is typically widely opened (Fig. 14-12A,B). This interval is reapproximated at this time with nonabsorbable suture. It is easiest to begin the closure medially and progress laterally. At the upper portion of the interval, just beneath the anterior border of the superior glenohumeral ligament, lays the long head of biceps tendon (Fig. 14-13). During the rotator interval closure, care must be taken to ensure that this tendon is not inadvertently tenodesed. During the interval closure, the anterior border of the superior glenohumeral ligament complex is approximated to the superior border of the middle glenohumeral complex. As will be seen, this maneuver will result in a superior capsular flap based off of this closed interval.

At this point, before the capsular incision is made, a surgical skin marker is used to mark a line along the margin of the resected subscapularis tendon at the lesser tuberosity. This will ensure the ability to repair the subscapularis at its anatomic length. Furthermore, as traction sutures are placed in the subscapularis during its dissection, notation is made on the lateral flap with the marking pen to ensure the anatomic superior and inferior relationship at the time of reconstruction.

The capsulotomy is made, again beginning at the rotator interval and extending down to the 6 o'clock position on the humeral neck (Fig. 14-14). This incision is made at the anatomic neck of the humerus, which can be palpated before the incision is made. The capsular incision should be made in a way that leaves approximately 1 cm of capsular tissue remaining in the humeral neck. It is this remaining tissue on the humerus to which the capsule will be repaired after the shift is completed. At the midportion of the capsular incision, a separate capsular incision is made toward the center of the joint. Traction sutures placed in the corners of the superior and inferior capsular flaps facilitate the exposure. As the capsular incision proceeds medially, it should be aimed toward the Bankart lesion if one is present. Variations on capsulotomies have been described by several authors.[1,40] Some recommend midcapsular incisions while others prefer a glenoid-based capsular release and repair.[40] While each author advocates a specific technique for specific reasons, the classic description that has yielded exceptional results is reviewed here. Releasing the capsule laterally provides the greatest options in capsular management with the least risk to vital neural structures while providing excellent surgical outcomes.

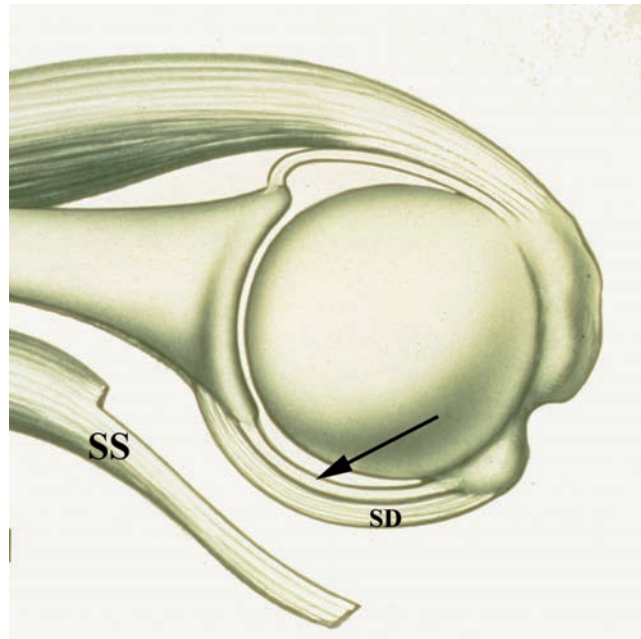

Figure 14-11 This cross-sectional view demonstrates how the anterior portion of the subscapularis tendon (*SS*) is continuous with the entire muscle belly. The deeper portion of the tendon (*SD*) is kept in continuity with the anterior shoulder capsule (*arrow*) to reinforce it.

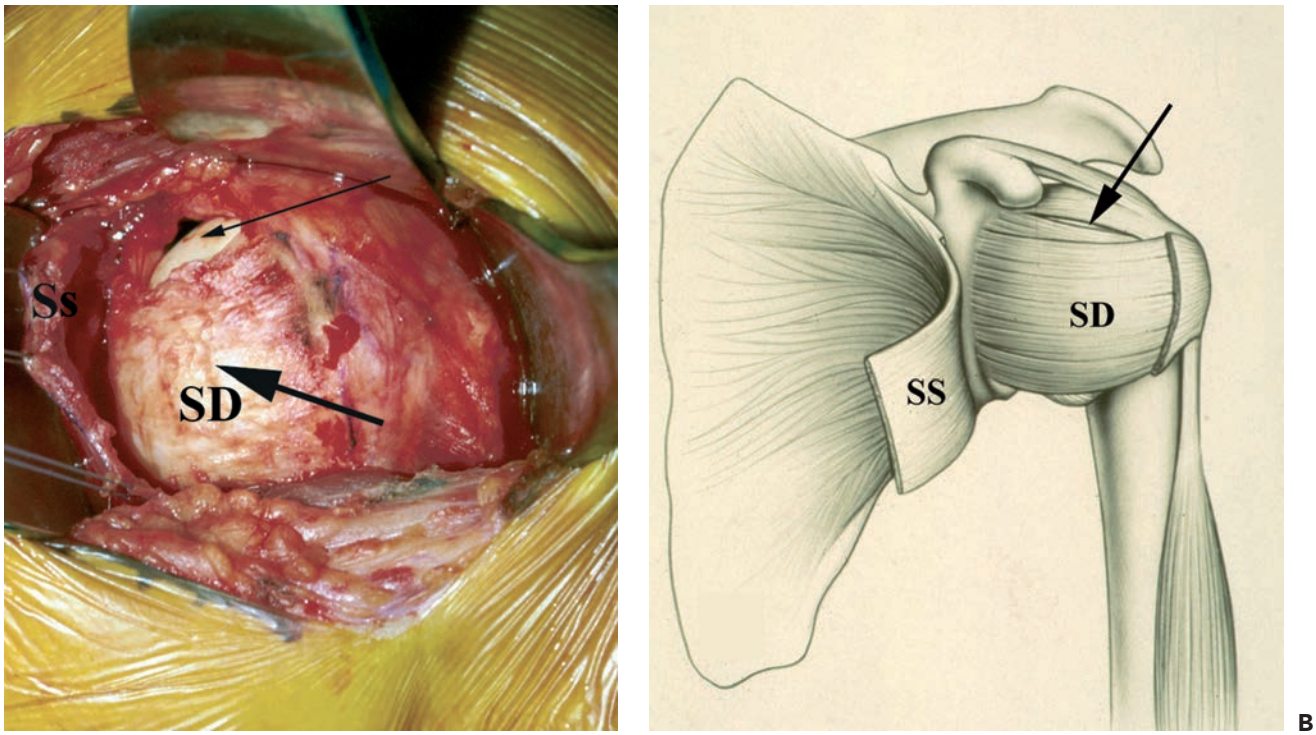

Figure 14-12 **(A)** The anterior half of the subscapularis tendon (*SS*) is retracted medially. The deeper portion of the tendon remains fixed to the deeper shoulder capsule (*SD* and *thick arrow*). The thinner arrow demonstrates the widely patent rotator interval. **(B)** Schematic drawing of the intraoperative photograph (A). Note that the entirety of the muscle belly of the subscapularis is contiguous with the anterior half of its tendon. The arrow points to the open rotator interval, which is a cleft between the superior border of the middle glenohumeral ligament and the anterior border of the superior glenohumeral ligament. The long head of the biceps tendon lies immediately beneath the upper edge of the superior ligament.

A ring retractor is placed in the joint to carefully displace the humeral head posteriorly. This permits a thorough examination of the joint and the labrum in particular. Often there is evidence of synovitis and hemosiderin deposition in the periarticular tissue as evidence of instability and hemorrhage. The articular surface of the glenoid may appear "scuffed" and discolored. In the classic case of multidirectional instability, the humeral head will fall so far posteriorly that the entire glenoid fossa is visible with little retractor force.

At the completion of the joint inspection, any labral pathology is addressed and repaired. With the ring retractor removed, an assessment is made of the inferior capsular volume. Although there is no truly objective means to measure the inferior capsular volume, it is generally understood that during intraoperative assessment, it should not be able to accept more than the distal phalanx of an average index finger! Perhaps a slightly more scientific way of judging the presence of symptomatic inferior capsular laxity is at the time of the clinical examinations with manifestation of a symptomatic sulcus (dimple) sign.

With global multidirectional instability, the capsular dissection proceeds from inferior to posterior (Fig. 14-15). It is this segment of the dissection that places the axillary at most risk. Knowledge of the location of the nerve in three dimensions becomes absolutely critical. Even in Neer and Foster's hands, in their original description, they documented temporary axillary nerve dysfunction in several patients.[63] The key to a safer dissection is to continually and progressively forward flex the arm with simultaneous increasing external rotation. These maneuvers alone enhance the ability to release the capsule from the humerus inferiorly and posteriorly while maximizing nerve safety. The axillary nerve is at most risk with the arm in the adducted or abducted position. The inferior and posterior capsule is released as one contiguous structure to include the posterior band of the inferior glenohumeral complex. This is generally at the midequatorial level of the posterior humeral neck (Fig. 14-16). As the capsular dissection progresses, traction sutures are placed in the tissue at 1-cm intervals. They serve to pull the capsule anteriorly and further buffer the axillary nerve from injury.

When the capsule is completely released, the shoulder is reduced, allowing the head to become centered and balanced on the glenoid. By placing gentle traction on the capsular sutures, the posterior capsule is advanced inferiorly and the inferior capsule is simultaneously advanced anteriorly, thus reducing the overall capsular volume (Fig. 14-17). Predictably, the anterior corner of the capsule where the initial capsulotomy was made will be pulled superior to the

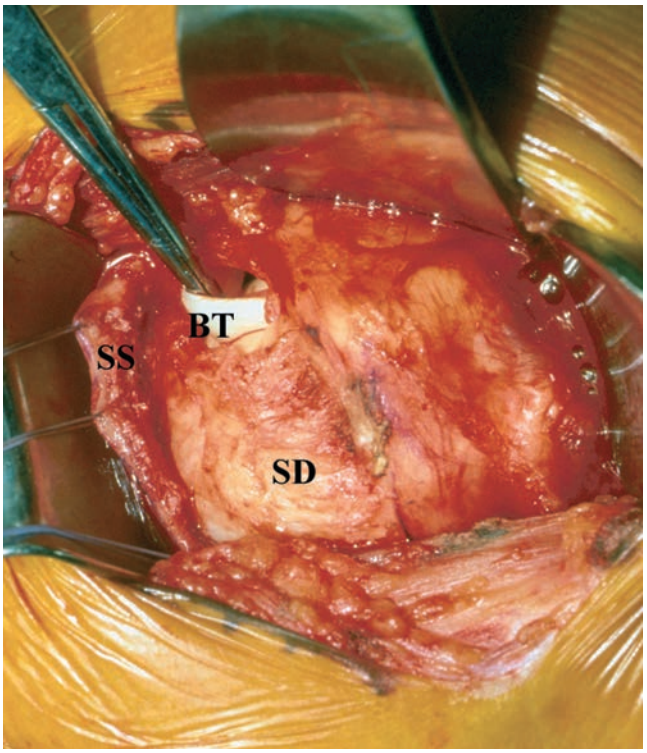

Figure 14-13 The long head of biceps tendon (*BT*) is immediately under the upper edge of the interval tissue. Care must be taken not to tenodese it inadvertently at the time of interval closure. The superficial (*SS*) and deep (*SD*) portions of the subscapularis are shown.

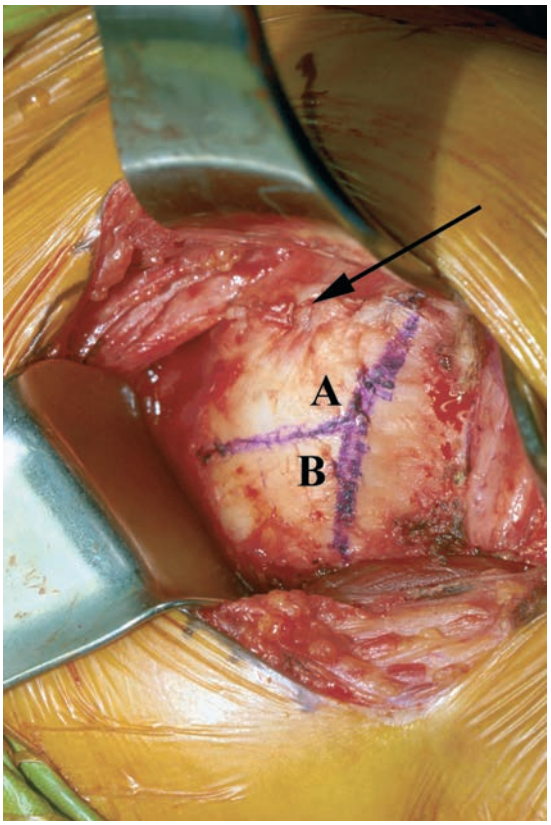

Figure 14-14 The blue marks show the line of the reinforced capsular incision. The incision begins at the rotator interval superiorly and extends to the inferior portion of the humeral neck. The horizontal incision extends to the glenoid and is aimed at the Bankart lesion if one is present. This results in capsular flaps based at the glenoid. The superior flap is tagged with a suture at (*A*); the inferior flap is similarly tagged at (*B*).

rotator interval and well above the superior capsular flap. This represents the amount of excess capsular tissue. While holding these traction sutures, the surgeon can now place his or her finger in the inferior pouch and verify that the capsular volume has been eliminated. Once satisfied that the capsular release is complete, the repair is initiated.

A high-speed burr is used to decorticate the anatomic neck of the humerus where the capsule is to be repaired. Again, holding the arm in forward flexion and external rotation while decorticating the inferior and posterior humeral neck will facilitate axillary nerve protection. At the time of capsular reconstruction, the arm is positioned in 10 degrees of forward flexion and in 45 degrees of external rotation. It is critical not to overtighten the capsule while at the same time making every effort to balance the capsular forces posteriorly, inferiorly, and anteriorly. The development of arthritis of dislocation has been well established when capsular forces are excessive in any direction or when an imbalance of capsular tension is iatrogenically produced.[33]

The capsular repair incorporates a "pants-over-vest" suture technique, which lays the mobilized capsule along the decorticated humeral neck and positions the lateral capsule that remained on the humerus over it. As the repair is performed, the capsule is pulled cephalad to hold the capsular volume reduced and balanced. Frequently, at the

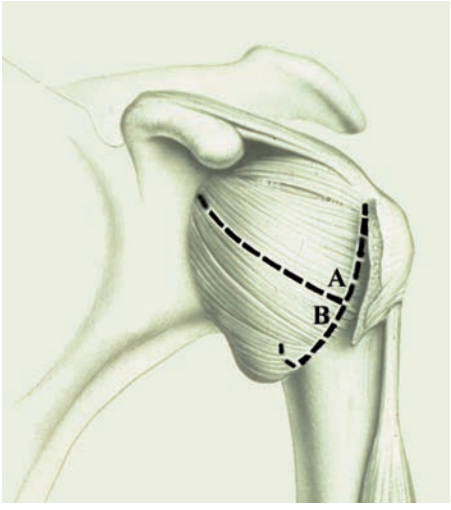

Figure 14-15 Schematic representation of Fig. 14-14. Note that the capsular incision is carried well around posteriorly while simultaneously forward flexing and externally rotating the arm. This position minimizes risk of injury to the axillary nerve.

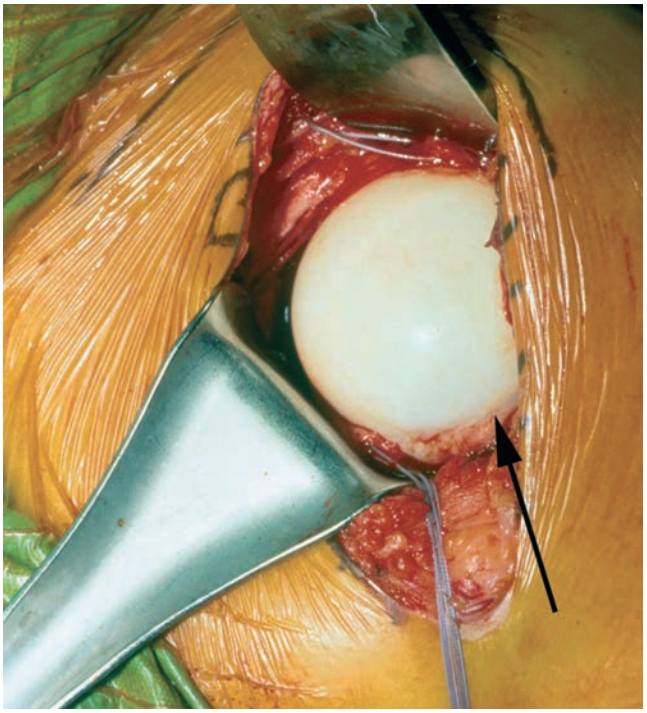

Figure 14-16 When a complete capsular release is accomplished, the entire humeral head can be seen. The arrow points to the inferior aspect of the humeral neck when the shoulder is reduced and the arm is in the anatomic position. That region between the arrow and the blue traction sutures represents the posterior aspect of the humeral neck where the capsule has been released.

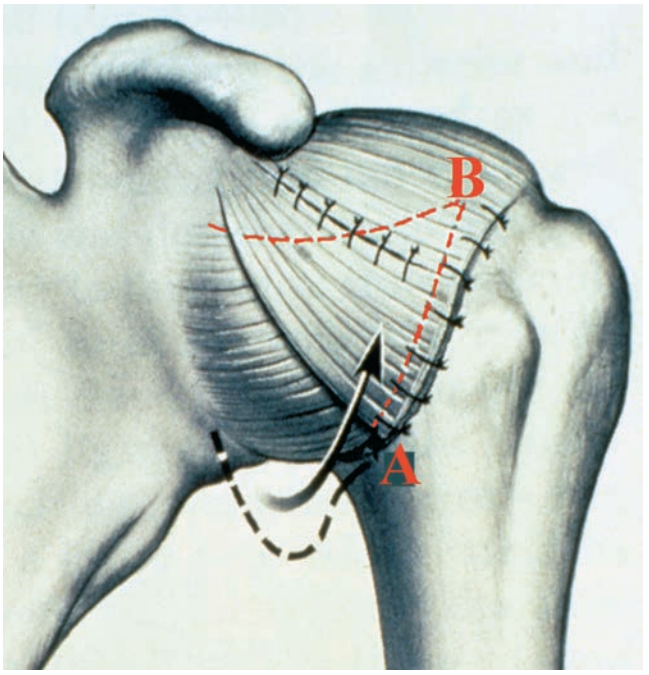

Figure 14-17 This schematic drawing demonstrates how the capsule is advanced during the capsular shift. Point (*B*) is the apex of the inferior flap, which has been advanced from posterior to inferior to anterior, reducing the capsular volume. The apex of the superior flap (*A*) is pulled inferiorly. This results in a "double breasting" of the anterior capsule.

completion of the inferior flap repair, there is excess capsular tissue, which is resected at the level of the rotator interval. Once the inferior flap is secured to the humeral neck, the superior flap is pulled inferiorly and laterally and similarly repaired to the humerus. This has the effect of doubly reinforcing the anterior capsule in a "cruciate" fashion. When both portions of the capsule have been secured, joint motion and stability are assessed. Perhaps the most critical assessment is that of external rotation with the arm at the side. With rare exception the arm should fall to a point of 45 degrees of external rotation with *no force applied*. Forward flexion should be to 160 degrees effortlessly. Any motion short of these goals should result in revision of the capsular repair.

At the completion of the capsular repair, the subscapularis is sutured back at its anatomic length as determined by the previously placed marked tissue. Not only is restoration of anatomic length important, but also appropriate position with reference to the superior and inferior placement is necessary for normal physiologic function.

Following irrigation of the wound, a drain is placed in the subacromial space and the deltopectoral interval is repaired. The skin is closed with a running absorbable subcuticular suture, which provides a nearly invisible incision line when healing is complete.

ARTHROSCOPIC TECHNIQUES

The indications for surgery via arthroscopy are the same as those previously written for open surgery. A further consideration involves the experience and skill of the operative surgeon with both arthroscopic and open surgery. The need for preoperative rehabilitation and counseling is similarly the same. Functional impairment and pain along with a failure of adequate nonoperative treatment, including integrated rehabilitation, is the only indication for surgical intervention of any kind.

Arthroscopy offers several advantages over open surgery in the management of MDI. Diagnostically one can get an overview of the joint under direct inspection, ascertaining the presence of labral tears, capsular tears, and capsular and rotator interval laxity. Although the surgeon will already know the primary directions of instability by the history and physical examination both awake and under anesthesia, repeating the examination while visualizing the movement with the arthroscope in the joint is quite useful (Fig. 14-18). The usual advantages of arthroscopy—preserving muscle attachment, better visualization of pathology, anatomic specific repairs based on this visualization, small incisions, and less pain—also apply.

Once the decision to operate is confirmed by the patient and the operating physician, surgery can be initiated. The surgery can be performed in either the beach-chair or lateral

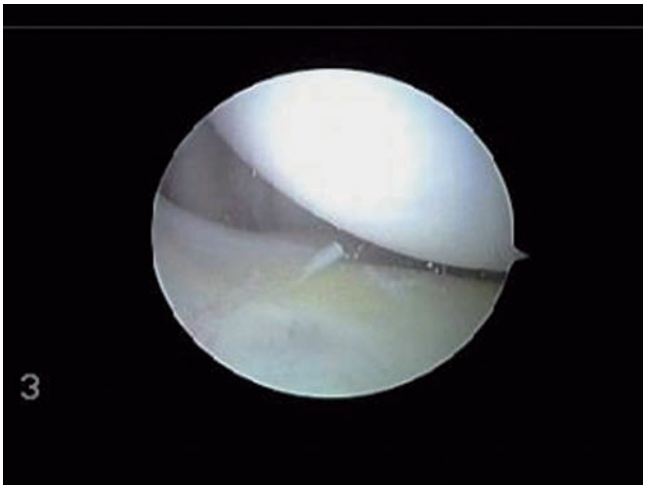

Figure 14-18 Arthroscopic view of a shoulder showing shifting of the humeral head on the glenoid during diagnostic arthroscopy.

Figure 14-20 A lax anterior capsule.

decubitus position. We feel the lateral decubitus position is easier in the management of MDI, but both have been shown to be successful.

We routinely use an interscalene block for postoperative analgesia placed by an experienced regional anesthesiologist prior to general anesthesia. This helps significantly with postoperative pain and allows the use of less anesthetic agents and narcotics during the surgery. In the beach-chair position the head and neck must be carefully controlled to prevent traction injury to the brachial plexus. In the lateral decubitus position a minimal amount of weight (5 to 10 lb, just enough to suspend the arm) is used for the same reason.

Once adequate positioning, prepping, and draping have occurred, the diagnostic arthroscopy can begin. Specific areas of evaluation include the rotator interval (Fig. 14-19), anterior capsule (Fig. 14-20), inferior capsule (Fig. 14-21), and posterior capsule (Fig. 14-22A). In many patients with MDI the posterior capsule may be so thin that the muscle of the infraspinatus can be readily visualized through the capsule (Fig. 14-22B).

One should also visualize the attachment of the anterior and posterior capsule to the humerus, looking for capsular splits, perforations, or humeral avulsion of the glenohumeral ligament lesions (Fig. 14-23A,B).

TREATMENT OF THE LAX CAPSULE

The lax capsule of reasonable quality is best managed by plication sutures. It is up to the individual surgeon as to the use of absorbable or nonabsorbable suture. The initial step involves abrasion or cutting of the capsule from the preserved labrum. This may be performed with a

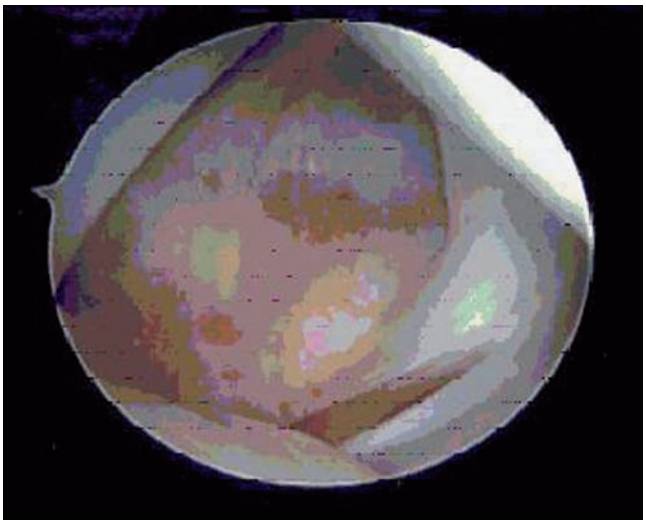

Figure 14-19 A lax rotator interval.

shaver or with a rasp (Fig. 14-24) to create a healing bed of tissue. A suture hook is then used to perforate the capsule approximately 1 cm from the labrum. The exact site is determined by drawing an imaginary line parallel to the glenoid and to the capsule; the first suture is placed through the capsule at the 6 o'clock inferior position and rotated until the hook emerges from the capsule. The entire capsule is then advanced superiorly and anteriorly (Fig. 14-25A) until the capsule appears taught (Fig. 14-25B). This is the point of advancement of the first suture. The hook is then placed beneath the labrum and delivered into the joint between the labrum and the articular surface (Fig. 14-25C). The suture is delivered and then retrieved and tied by arthroscopic knot tying. We favor a self-locking knot, but half-hitches or knot-tying devices may certainly be used.

These steps are repeated along the anterior aspect of the capsule. The second stitch is usually placed through the capsule at the 5 o'clock position and advanced to the

4 o'clock position on the glenoid. Additional sutures are placed until the entire anterior capsule is reconstructed (Fig. 14-26).

The posterior capsule is then addressed in a similar way, beginning with the 7 o'clock position and continuing superiorly until all capsular redundancy is eliminated (Fig. 14-27A,B). In many cases of MDI the posterior capsule is insufficient for plication sutures. In these cases one may use a suture plication technique that includes the infraspinatus tendon. In these cases the lateral capsule is pierced percutaneously with a large lumened spinal needle (Fig. 14-28A) and a suture placed though the needle into the joint. The initial stitch should enter the capsule around the 7 o'clock position. The suture is grasped and the needle removed. A suture retrieval device is then placed through the capsule adjacent to or under the labrum and the suture retrieved out of the posterior canula (Fig. 14-28B). The canula is then retracted until it is just outside the infraspinatus and, using a switching stick, it is placed into the subacromial bursa. A crochet hook is utilized to blindly grab the suture while watching from inside the joint. One should see the canula indenting the infraspinatus during this retrieval. This suture is then tied and the capsule tightening assessed (Fig. 14-28C). These steps are repeated until the posterior capsule is sufficiently tightened. In most cases two to four sutures are needed.

The arthroscope is then placed posterior above the reconstruction and the rotator interval assessed. In many cases the superior–anterior plication may have already closed a majority of the interval and the procedure may be finished by using the same suture hook to close the middle and superior glenohumeral ligaments as described by Wolf (ref here of Eugene Wolf treatment of mdi). In most cases, however, additional suturing of the interval is necessary. To tighten both the inner and outer layers of the interval, a spinal needle is inserted approximately 1 cm from the articular margin just at the anterior edge of the supraspinatus (Fig. 14-29A). A nonabsorbable suture is placed through the needle into the joint and placed for retrieval. The anterior canula is then pulled out of the joint until it is just anterior to the anterior layer of the rotator interval (which is anterior to the subscapularis). A suture retriever device is placed through the anterior layer of the rotator interval tissue, around the subscapularis, and through the capsule (Fig. 14-29B). The suture is then grasped and pulled out the anterior canula. A switching stick is then used to rotate the canula over the subscapularis tendon into the bursa. The suture is then grasped blindly with a crochet hook as described for the posterior technique and tied using a self-locking knot, tightening the rotator interval (Fig. 14-29C). Additional sutures may be placed using the same technique as needed.

TREATMENT OF THE TORN CAPSULE AND SPECIAL TECHNIQUES

In many cases MDI may be associated with labral or capsule tears. In these patients it is important to remember that additional treatment of the capsule is necessary. The labral tear and/or capsule split are repaired using techniques described elsewhere in this text (see Chapter 12). Once the repair has been accomplished, the inferior capsule and opposite side are plicated as described above. If this restores adequate stability, the rotator interval may be addressed. In all patents with MDI it is important to close both layers of the interval in addition to any other procedures that are performed.

Several modifications can be made in the previously described techniques. The capsule may be incised rather than abraded to allow a more complete shift. The initial suture may be used as a shuttle, pulling a larger, nonabsorbable suture through the same area (Fig. 14-30). A retrieval device may be used through the capsule in the same area to create a mattress suture while still using the labrum as an anchor.

In cases in which there is a labral tear or the labrum is deficient, an anchor may be placed into the glenoid and the sutures retrieved through the capsule. The recent availability of dual-sutured anchors makes this an attractive option in some cases with capsular splits or tears.

The use of thermal devices in the management of MDI has fallen into disfavor in recent years. Although still utilized by many surgeons with excellent results, the variability of the effect of such devices on the tissue and the long-term effects of intraarticular temperature extremes on articular cartilage may present a caution as to its ongoing use. If utilized for capsular laxity, we recommend suturing around the treated area and additional sutures in the rotator interval to supplement the thermal procedure.

COMPLICATIONS

Arthroscopic management of MDI has the same risk of complications as the open procedures. Stiffness and recurrence of instability both can occur, although the incidence of each has been quite low in published reports.

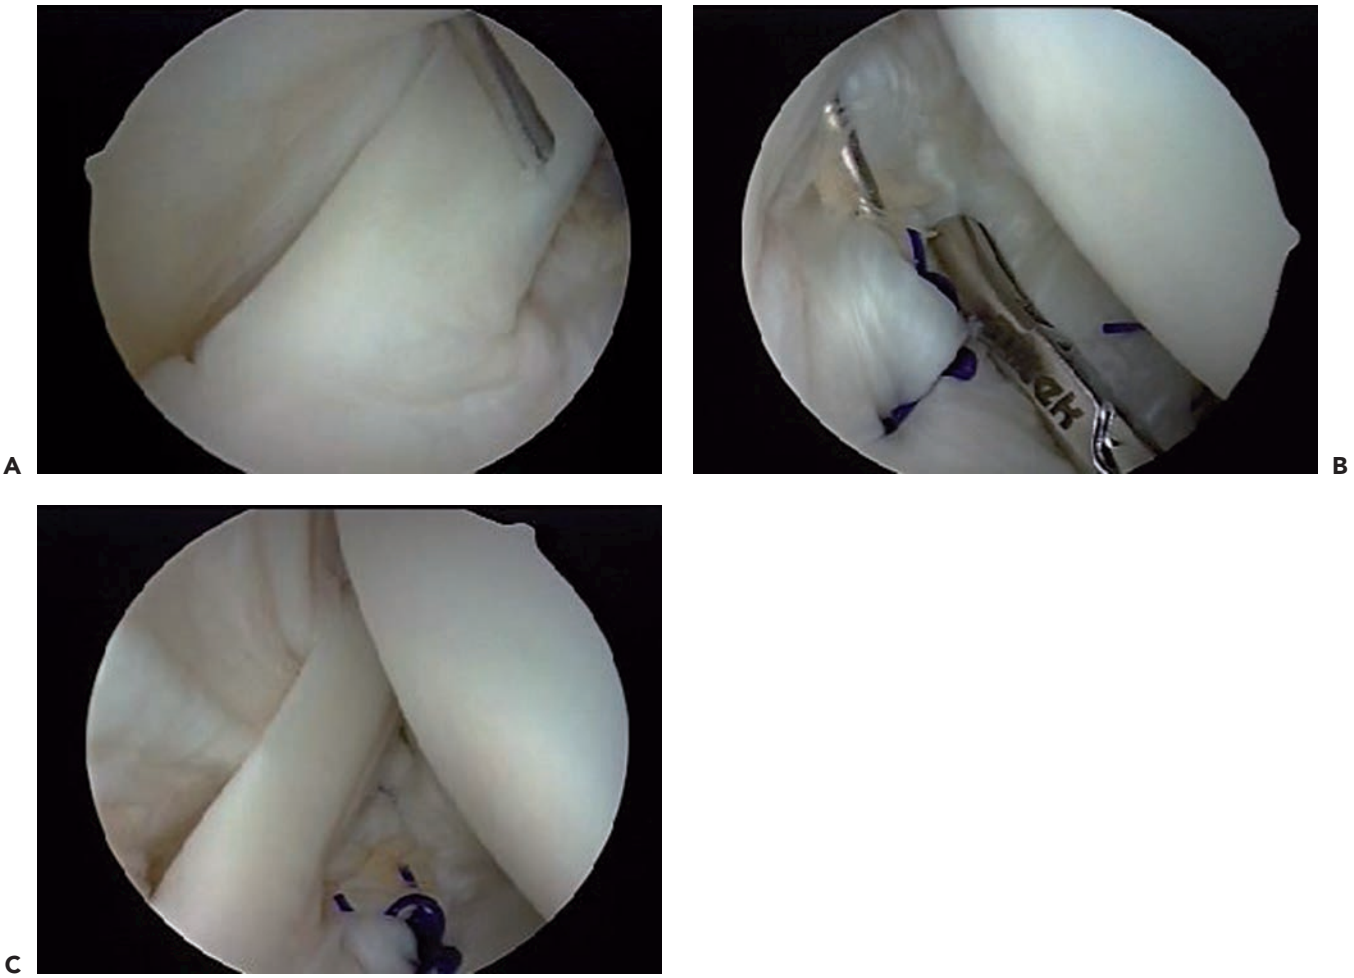

Figure 14-29 **(A)** View from posterior showing the spinal needle coming in from superiorly at the posterior edge of the rotator interval (anterior edge of the supraspinatus). **(B)** The retriever is used to pierce the anterior layer of the rotator interval, around the subscapularis, and through the posterior layer of the interval and perhaps the middle glenohumeral ligament. **(C)** View from the posterior of the closed rotator interval.

Figure 14-30 View from the posterior of the plicated anterior capsule using a nonabsorbable suture.

The most devastating complication reported as a result of thermal management has been chondrolysis. The exact mechanism by which this destructive disease occurs has yet to be elucidated, and chondrolysis has also been reported in association with other procedures. Management of the shoulder with chondrolysis includes intraarticular injections of steroids or hyaluronic acid, arthroscopic débridement, interposition grafting, and humeral head replacement.

POSTOPERATIVE MANAGEMENT

The patient is placed in either a gunslinger brace or an abduction sling before transport to the recovery room. The brace is maintained with the exception of personal hygiene for 6 weeks. Initial rehabilitation centers on trying to maintain correct shoulder posture while in the brace.

Each of these shoulders has a unique response to surgery. In those in whom the capsule repair is maturing rapidly, passive motion and scapular stabilization exercises may begin at 4 weeks, but in most cases these are delayed until 6 weeks postoperatively. Occasionally the abduction sling is maintained and exercise delayed until 8 weeks postreconstruction. Active exercise begins at 6 to 8 weeks with careful attention to maintain correct scapular position during all exercises. In patients in whom the scapula remains protracted, early dynamic bracing is initiated to retrain the scapula to remain in its correct retracted position. This may include static bracing or taping for short periods of time. It is vital that the patient and therapist recognize the need to reestablish proper shoulder positioning in space at all times, but especially during all exercises. The more quickly normal shoulder posture is reestablished, the more likely there will be a good recovery.

Once the capsule reconstruction has matured, based on clinical endpoint examination and lack of palpable capsular edema (usually 4 to 6 months) and the patient is able to maintain correct scapular position, the therapy is progressed to include rotator cuff strengthening exercises, proprioceptive neuromuscular facilitation exercises, and plyometrics. No passive stretching by the therapist is allowed during the first 6 months. Sometime in the 4 to 8 months postoperatively, integrated rehabilitation as described by Kibler is initiated along with sport-specific conditioning in the athletic population. Sports are allowed between 6 and 12 months postoperatively, depending primarily on shoulder position and tracking patterns.

POSTOPERATIVE CONSIDERATIONS

The immediate aftercare following an inferior capsular shift has become "debatable" with the introduction of a variety of orthotic brace devices. Nevertheless, the *principles* of postoperative management should not change. If the patient had a true inferior capsular shift procedure as detailed above, then it follows that the capsular repair must be protected in *all of its components and directions.* Surgeons generally understand that following an anterior repair such as a Bankart procedure, the arm is kept in internal rotation by means of a sling device. Similarly, following a posterior repair, the patient's arm is held in external rotation with some type of brace device or cast to protect the posterior capsular repair. Since the inferior capsular shift also addresses the inferior capsule, it too must be protected during the healing phase for a minimum of 6 weeks. Conventional braces that can be removed by the patient are a poor choice of immobilization in the initial postoperative management following an inferior capsular shift. My considerable experience suggests that if a brace can be removed, *it will be removed,* especially in the age group that undergoes this type of procedure. Gravity is ever present and removing a brace for dressing, showering, etc., subjects the repair to inferiorly directed forces that place the capsular repair in a precarious situation. Several authors have reported on the importance of cast immobilization following inferior capsular shift.[4,20,59]

This concept of immobilization is neither new nor revolutionary. We have learned this lesson in the initial early return of patients following arthroscopic repairs and thermal procedures. The capsular ligaments and tissues can certainly stretch out in the early weeks following surgical intervention, either open of arthroscopic. Therefore, the capsular repair that involved the management of at least three directions of instability must be immobilized in those same three directions. Removable braces and other forms of removable immobilizers cannot possibly provide the degree and certainty of joint immobility that a well-placed spica cast is capable of providing. Altcheck et al. reported on their series of 40 patients, and although they were not placed in a conventional cast, they were placed in a specially fabricated orthosis for 6 weeks.[1]

The cast is placed in the operating suite immediately following the procedure. By using regional anesthesia, the patient is fully awake and cognitive in the moments following the procedure. Cooperative patients are critical because they must stand erect as the cast is being applied. At all times during the cast application, an assistant is holding the arm in neutral rotation to balance the anterior and posterior capsule while simultaneously holding the arm in a cephalad position. The waist belt portion of the cast is applied and molded around the iliac crests bilaterally. The iliac crests will ultimately bear the downward force of the arm and prevent any forces on the inferior capsular repair (Fig. 14-31). The arm cylinder, which extends from just above the wrist to the upper arm, is then applied. Lastly, the waist piece is fixed to the arm piece with a strut of casting material. While the cast epoxy is curing, the arm is continually held in the position of neutral rotation with superior force. Despite the apparent weight of the cast, which appears enormous to the patient, measurement of the weight following cast removal has determined that it rarely exceeds 2 lb.

Following surgery, regardless of the surgeon's choice of immobilization, significant alterations in activities of daily living become readily apparent. Patients cannot (should not) drive, shower, or dress in pullover shirts, sweaters, and other similar garments. If braces are provided because of "convenience," the patients must be instructed to wear the brace at all times to protect every element of their repair. Again, if the immobilization device is removable, it will be removed! Over the years, I have had more than one occasion when less than discriminating patients took a saw to their cast to remove it.

The cast is worn for 6 weeks and adjusted or trimmed as necessary throughout the 6-week course. Most patients have their cast trimmed or padded the morning following surgery just prior to discharge. Only rarely are other adjustments ever necessary during the subsequent 6 weeks (Fig. 14-32).

Figure 14-31 Immobilization of the arm is a necessary component of the procedure to allow capsular healing without tension in any direction, especially inferiorly (see text).

When the cast is removed 6 weeks following the surgery, a formal period of rehabilitation begins. The initial several weeks are devoted to recovery of motion through passive and active assisted techniques. Specific limits are given so elevation does not exceed 160 degrees and external rotation does not exceed 60 degrees. These limits are usually attained within 6 weeks of initiation of the program. Once the passive motion has recovered, a structured strengthening program follows. Particular attention is devoted to eccentric strengthening of the internal and external rotator cuff muscles. Shortly after the cuff program is started, further emphasis is given to strengthening of the scapular stabilizing muscles. Patients should be encouraged to remain compliant with their exercise routines for a minimum of 1 year following their surgery.

Return to activities and sport are dependent on recovery of motion, strength, and endurance of shoulder-related muscles. Generally, caution is recommended for those activities that have a higher incidence of injury to the shoulder such as downhill (alpine) skiing, water skiing, gymnastics, and certain types of swimming. Also, weight lifting routines that place excessive mechanical forces on the glenohumeral joint such as bench press and pushups should be avoided.

Figure 14-32 A well-motivated patient can learn to adapt to the "challenges" of a cast for 6 weeks. The outcomes are likely worth the misery.

RESULTS OF OPEN SURGICAL MANAGEMENT

The first series of results reported for surgical management of multidirectional instability were those of Neer and Foster following the inferior capsular shift procedure.[63] The original series included 32 patients, and there was only one patient who was considered to have an unsatisfactory result related to an episode of subluxation 7 months following the procedure. However, only 17 patients were followed for longer than 2 years, and eight patients in the series were evaluated less than 12 months following their reconstruction. In his book published a decade later, Neer reported that more than 100 additional patients underwent the inferior capsular shift with similar results.[65]

In a much longer follow-up series, Pollock et al. reviewed 52 shoulders in 49 patients at an average of 5 years following inferior capsular shift, but some patients were seen 11 years following surgery.[74] In their series, there were 94% excellent or good results and only two patients had a poor result over this relatively longer follow-up time frame. In terms of stability, 94% of patients were stable at an average of 5 years following their surgical reconstruction.[74]

In another relatively longer follow-up analysis, van Tankeren and coworkers studied 17 patients following an inferior capsular shift for multidirectional instability at an average of 3 years following their surgery. Using the Constant and Rowe scores, 14 of the 17 patients had an excellent outcome, and there was only one poor result.[85]

Other authors confined their postoperative evaluation to the athletic age group. Bak et al. reviewed 26 shoulders in 25 athletes who underwent an inferior capsular shift for multidirectional instability.[5] At an average of just short of

5 years, 84% of the athletes returned to their preinjury level of activity within 5 months of surgery. More importantly, with respect to athletes who required the use of their involved arm for overhead throwing activities, 76% returned to their preoperative level of sport.[5] Choi and Ogilvie-Harris noted similar results in their series of athletes who underwent an inferior capsular shift.[18]

Altcheck et al. reviewed a series of 40 patients who had both an inferior capsular shift and a Bankart repair for a labral injury.[1] At average of 3 years follow-up, 95% rated their result as excellent, although 10% had a recurrent episode of instability within the follow-up period. The authors emphasized that a patient with a Bankart lesion and multidirectional instability may have a better prognosis than one without a Bankart lesion. They suggested that in the presence of a Bankart lesion, the multidirectional component of the instability had a traumatic origin and therefore may have a better prognosis.

Cooper and Brems[20] reported on the results of 38 patients with an average follow-up of 39 months with a minimum of 24 months following an open inferior capsular shift procedure. Eighty-six percent of patients were improved; however, 10% continued to have clinical instability. In their series, despite early satisfactory results, six patients (15%) felt their shoulders had deteriorated over time.

Lebar and Alexander reviewed a series of 10 patients at an average of 28 months following an inferior capsular shift.[50] In this small series from the Oakland Naval hospital, all 10 patients felt they were improved, yet one had recurrent symptoms enough to require a revision procedure.

Care must be taken when trying to interpret results of these few series because follow-up intervals are short. Several authors have noted that meaningful results demand much longer follow-up time frames.[45,60,68,76] Shoulder instability may recur many years following the repair. Furthermore, patients in the age group who typically undergo this type of surgery are very active and subject to recurrent trauma through their activity. Hawkins et al. reported a failure rate of 39% (12 of 31 patients) at a longer follow-up of 2 to 5 years.[34] Because of the concern of failure at longer follow-up, some surgeons advocated additional or secondary procedures.[9,29,66,70,89-91]

Bigliani and coworkers reviewed a series of 52 patients following an inferior capsular shift with a minimum follow-up of 5 years. They reported a satisfaction rate of 94% in nonathletic patients.[11] In a more recent study, Bigliani et al. reviewed the outcome of 75 athletically active patients who underwent an inferior capsular shift.[12] Eighty-nine percent were able to return to their major sport, while 73% remained at their anticipated level of competitiveness.

In the series with the longest follow-up, Hamada and colleagues reviewed the outcome of 26 patients (34 shoulders) who underwent an inferior capsular shift for multidirectional instability with a mean follow-up of 8.3 years.[28] They reported that 85% had satisfactory outcomes and 59% were rated as good and excellent on the Rowe rating scale. In this study, the authors were able to re-review 19 of their patients 3.5 years and 8.3 years following their surgery. Remarkably, they reported no change in the Rowe rating scale in any of these patients over the 8-year period.

Several reports have documented high success rates for arthroscopic capsular shift in the treatment of MDI. Duncan and Savoie reported preliminary results of arthroscopic capsular shift in 10 patients for patients with MDI with follow-up from 1 to 3 years.[58] No patients in the study developed recurrent instability. Four athletes returned to sports participation, although no information regarding their preoperative level of activity was reported. Two patients developed pain postoperatively over the posterior suture knot that required removal. All 10 patients had a satisfactory rating score according to the Neer criteria. Treacy and Savoie reported on 25 patients who underwent arthroscopic capsular shift for MDI with an average follow-up of 5 years.[31] Three patients had episodes of instability after the procedure but none had repeat episodes of dislocation. Eighty-eight percent of patients had satisfactory results according to the Neer system.

Tauro and Carter reported preliminary results of a modified arthroscopic capsular shift for anterior and anteroinferior instability in four patients with a minimum follow-up of 6 months.[82] No patients developed recurrent instability, although follow-up is short term.

Gartsman reported on 47 patients who underwent arthroscopic capsular plication for MDI.[43] The average follow-up was 35 months and 94% had good to excellent results. Eighty-five percent of athletes retuned to their desired level of sports participation.

McIntyre reported results of arthroscopic capsular in patients with MDI using a multiple suture technique in the anterior and posterior capsule with follow-up of 32 months.[42] Recurrent instability occurred in one patient (5%) who was treated successfully with a repeat arthroscopic stabilization. Thirteen athletes (93%) returned to their previous level of performance.

Wichman and Snyder reported results of arthroscopic capsular shift for MDI in 24 patients with an average age of 26 and a minimum follow-up of 2 years.[72] Five patients (21%) had an unsatisfactory rating using the Neer criteria. Three of these patients were involved in worker's compensation cases that were not yet resolved, and an additional patient was involved in litigation over a motor vehicle accident.

Lyons et al. reported on laser-assisted capsulorrhaphy for MDI in 26 patients (27 shoulders) with a minimum follow-up of 2 years.[77] Twenty-six of the 27 shoulders remained stable and 86% returned to their previous level of sports participation.

McIntyre et al. reviewed the results of 20 consecutive shoulders in 19 patients treated with arthroscopic capsular shift for posterior instability at an average of 31 months postoperatively.[79] They had 15 excellent, two good, one

fair, and three poor results. They reported two recurrent dislocations and three subluxations for an overall recurrence rate of 25%.

Williams et al. reported on a series of 26 patients (27 shoulders) treated with arthroscopic repair for traumatic posterior instability (posterior Bankart lesion) with an average follow-up of 5 years.[84] Symptoms of pain and instability were eliminated in 92% of patients. Two patients required additional surgery.

Wolf reported on a series of 14 patients with recurrent posterior instability treated with arthroscopic capsular plication.[10] Follow-up averaged 33 months and 12 patients reported excellent results. There was one recurrence of instability that was remedied by a second operation. All 14 patients were satisfied with their procedure. Hovis et al. reported on a series of six elite golfers with posterior instability who underwent posterior thermal capsulorrhaphy.[88] At an average of 4.5 years follow-up all six had returned to their previous level of play. Antoniou presented results on 41 patients undergoing arthroscopic capsulolabral augmentation for posteroinferior instability.[86] Patients were followed for an average of 28 months and 35 (85%) of patients had improved stability of the shoulder.

Jorgensen et al. followed 41 patients with posterior instability that were treated with either open or arthroscopic technique.[6] Patients were evaluated for an average of 36 months and no significant difference was seen in outcome between the two groups. The group treated with the open procedure had a longer hospitalization, slight decrease in external rotation, and more frequent cosmetic complaints.

These multiple reports document the efficacy of arthroscopic management of MDI. The ability to see within the joint allows an extremely accurate assessment of the pathology and thereby improves the results of operative treatment. Current techniques utilizing multiple capsular plication techniques with various sutures hold great promise in increasing the success in the management of symptomatic MDI. Progress in rehabilitation holds much promise to help both operative and nonoperative patients.

SUMMARY

Although it has been more than two decades since multidirectional instability became recognized as a distinct clinical entity, our understanding of the condition remains incomplete. Despite research efforts on multiple fronts, the instability remains incompletely defined and characterized. Perhaps there is not one unified pathologic process or concept that fully explains the multiple characteristics of the condition. Research efforts continue to explore the many seemingly disparate causes including biologic, biomechanical, biochemical, neurologic, and genetic in an effort to define this unique instability pattern. Because it is likely that each of these issues contributes in some way to the clinical manifestations of multidirectional instability, continued efforts to expand our knowledge and understanding remains an obligation to both our profession and to our patients.

Treatment options likewise remain confusing and long-term outcomes disappointing in this population of patients who are predictably young, active, and challenging. What does seem clear is that a prolonged trial of nonoperative management is appropriate. Relatively high success rates have been achieved when a well-executed rehabilitation program has been dutifully executed by a well-motivated patient. What remains less clear is the management of the patient who has been refractory to a well-performed trial of nonoperative management. Both open and arthroscopic procedures have been reviewed and outcome studies have been published by talented surgeons in both camps. Nevertheless, the orthopaedic community still lacks the necessary long-term outcomes of a procedure performed on a cohort of patients who predictably live 50 years following their treatment.

SUMMARY 485

INTRODUCTION

Dislocations of the shoulder account for approximately 45% of the dislocations seen in the major joints.[20] In 1974, Cave et al.[5] presented the demographics of a large series of shoulder girdle dislocations. In their series, anterior glenohumeral dislocations accounted for 84% of shoulder girdle dislocations, acromioclavicular dislocations for 12%, sternoclavicular dislocations for 2.5%, and posterior glenohumeral dislocations for 1.5%. Although these injuries are common and are usually diagnosed by careful physical examination and appropriate radiographic examinations, they are occasionally missed.

In 1968, Schulz and colleagues reported on 61 chronic shoulder dislocations.[36] In their review of both anterior and posterior shoulder dislocations, they found the following: (a) 50% had associated fractures about the joint, (b) 33% had neurologic injury (5 of the 17 posterior dislocations and 18 of the 44 anterior dislocations), and (c) 28% of the dislocations were posterior. They also found that seizures were the cause of 29% of these dislocations and that 11 of the 18 dislocations caused by seizures had associated fractures. In addition, 50% of seizure-related injuries were posterior dislocations.

In 1982, Rowe and Zarins performed a survey of 208 New England orthopedists to determine how often chronic dislocations were seen by the average orthopedist.[35] Their survey found that 50% of orthopedic surgeons in practice for 5 to 10 years had seen a chronic dislocation, 70% of those in practice for 10 to 20 years had seen this injury, and 90% of orthopedic surgeons in practice for over 20 years had seen at least one chronic dislocation. Based on their survey, 65% of chronic dislocations were anterior and 35% were posterior. Rowe and Zarins also presented 23 patients with 24 dislocations: 14 were posterior, eight were anterior, one was inferior, and one was superior. Remarkably, 79% of the posterior dislocations that they evaluated were missed by the original treating physician.

A more recent study presented by Checchia et al.[6] reviewed 66 patients with a total of 73 posterior fracture dislocations of the shoulder treated at Santa Casa Hospital in Sao Paulo, Brazil. The causative facture was a convulsive episode in 37 patients. Sixteen shoulders had an associated fracture of the proximal humerus. Thirty-six patients with 42 locked dislocations were considered to have chronic

injuries. Over 50% of the chronic cases had been misdiagnosed as contusions at the time of the original injury.

The true incidence of chronic dislocations of the shoulder is unknown. One reason for this is the lack of consistent criteria for defining what time frame should be used to declare a dislocation to be chronic. In the literature, the definition of a chronic dislocation has ranged from as early as 24 hours to as late as 6 months.[6,8,14,15,35,36] Schulz and colleagues[36] used 24 hours as their definition of chronic. Since the treatment of these dislocations is likely to be the same both before and after 24 hours, a longer time point seems more logical. Checchia et al.[6] used 4 weeks and Rowe and Zarins[35] used 3 weeks as the cutoff between acute and chronic dislocations. In this chapter, 3 weeks will be used as the definition of chronic dislocation. The term "locked dislocation" has also been used to describe these injuries, presumably because of the difficulty in reducing them.[15] The term "locked dislocation" may apply to both acute and chronic injuries. The time from injury is an important factor in determining treatment of locked dislocations.

The purpose of this chapter is to review the diagnosis, treatment, and the results of treatment of locked dislocations of the glenohumeral joint. An algorithmic approach is presented based on the time from injury as well as the pathologic findings. This treatment algorithm can be used effectively to treat acute as well as chronic injuries. As mentioned above, for the purposes of this chapter, the term *chronic* is used to describe any dislocation that has been present for at least 3 weeks. This time frame is chosen not only because there is historical precedent for it, but also because of its implication in treatment. If the injury is less than 3 weeks old, a closed reduction with or without open treatment of associated fractures may be effective, and if the injury is more than 3 weeks old, this option is unlikely to be successful. The time from injury also affects the structural quality of the articular cartilage and its underlying bone. If the injury is greater than 6 months old, it is unlikely that the articular cartilage surfaces of the glenohumeral joint will be viable and the bone quality of the humeral head will be of sufficient quality to allow for salvage of the native joint. Therefore, the treatment of chronic locked dislocations will be variable, depending on, among other things, the time from dislocation.

The outcomes of specific types of locked dislocations are discussed later in this chapter. However, in general, the number of series reported in the literature is small and the number of patients in each report ranges from a single case report to 61 patients.[6,8,11–15,19,26,32,35–42] Because of the small numbers in each series or groups of patients within a single series, evaluation of outcomes in specific groups is difficult. In addition, there is a lack of consistency with regard to outcome measurement tools among series, making comparison of results among series difficult. Despite these limitations, the treatment algorithm outlined in this chapter is based on analysis of the literature as well as personal experience of the senior authors.

POSTERIOR LOCKED DISLOCATION

Although posterior dislocations account for only 1.5% of shoulder dislocations, they account for a much higher relative percentage of locked dislocations of the glenohumeral joint. This is due to the fact that these injuries are more easily missed than anterior dislocations. In fact, Rowe and Zarins[35] reported that 11 of the 14 locked posterior dislocations that they evaluated, in a referral practice, were unrecognized by the initial treating physician. In Checchia et al.[6] series of locked posterior dislocations, 22 of 36 chronic lesions were missed at initial presentation. It is estimated that more than 60% of posterior dislocations of the glenohumeral humeral joint are missed at the time of initial evaluation.[6,14,15,35]

There are several potential reasons that these injuries may be missed on initial evaluation. Most posterior dislocations of the shoulder occur from either seizures or violent trauma. These patients may present to the emergency department with more urgent medical problems. Additionally, the outward appearance of a posteriorly dislocated shoulder may be subtle. In posterior dislocations the contour of the shoulder may appear normal, particularly if the shoulder is large, and the injured arm is locked in a position of internal rotation with the elbow at the side. To suspect a posterior dislocation, one must attempt to passively rotate the humerus to identify the characteristic loss of external rotation. Finally, the radiographic findings of a posterior dislocation on standard anteroposterior radiographs are extremely subtle and often misinterpreted as being normal (Fig. 15-1).

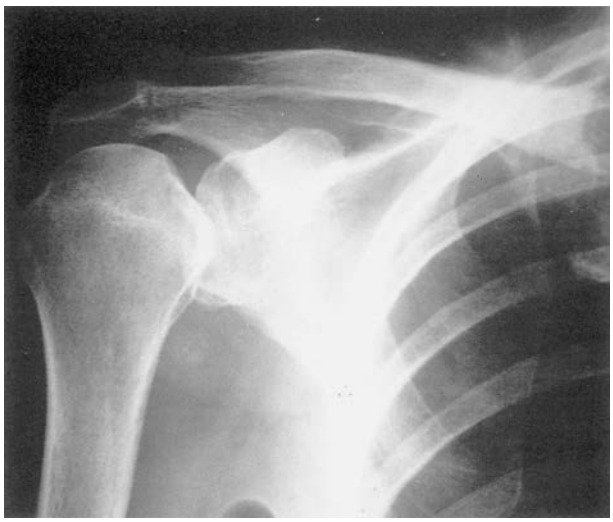

Figure 15-1 An almost normal-appearing anteroposterior radiograph of the shoulder in a patient with a chronic posterior dislocation.

History

Patients presenting with chronic posterior dislocations of the shoulder usually give a history of major trauma or a history of a convulsive episode from either an intrinsic seizure disorder or an electrical shock. They initially had substantial pain in the shoulder with a loss of use of the arm. The initial shoulder discomfort often resolves to a tolerable level within a few weeks of the injury and the patient may begin to use the shoulder for waist-level activities. Many times, this slow resolution of pain and the return of limited function are mistaken for the process of recovery by the patient or the treating physician. In fact, there are multiple reports of patients with locked posterior dislocations being sent to therapy with the diagnosis of a frozen shoulder, only to later be given the correct diagnosis once treatment fails.[6,15,35,36]

One group of patients to be especially wary of are those with alcohol or drug dependence. Often these patients present days to weeks after a traumatic episode with pain and inability to use their arm. They will be unable to give a clear history of the event and may not have sought initial treatment. The examining physician should have an extremely high index of suspicion for posterior dislocation, especially if external rotation is lacking. The presence of alcohol and drug dependence confounds not only the diagnosis, but also the treatment of the locked posterior dislocation, as patient compliance may not be adequate for some treatment options.

It is important to obtain a thorough past medical history to determine if there are any important medical problems that would influence the choice of treatment. These patients may surprisingly adapt sufficiently to the limitations of motion and to the discomfort produced by this injury. This allows the surgeon to forgo surgical management in elderly, medically infirm patients or in patients that are at risk due to compliance issues. It is important to obtain a thorough past medical history to determine if there are any important medical problems that would influence the choice of treatment.

Physical Examination

The patient should be examined with the entire shoulder exposed to allow adequate visual inspection. The contour of the shoulders is best visualized by standing behind and slightly superior to the patient. The dislocated shoulder will appear to have less fullness anteriorly. While standing behind the patient, the examiner should palpate both shoulders, noting any asymmetry between the anterior deltoid and the coracoid processes. If the shoulder is dislocated posteriorly, the coracoid of the involved shoulder may be more prominent, and there will be a loss of the normal anterior contour of the shoulder. These findings can be subtle in patients with bulky shoulders.

Loss of external rotation beyond neutral is almost pathognomonic of a locked posterior dislocation of the shoulder. In fact, in any patient with less than 0 degrees of passive external rotation following a shoulder injury, a posterior dislocation is assumed present until proven otherwise. Limitation of glenohumeral abduction to less than 60 degrees is also usually present (Fig. 15-2). With long-standing dislocations (6 months to a year) in which the humeral head is locked onto the glenoid, the windshield wiper effect of the glenoid against the humeral head during motion can create a large enough defect to permit surprisingly functional motion. The physician should also note the level of discomfort experienced by the patient while moving the extremity in his or her adapted range of motion. This information will be important when determining the treatment plan.

Figure 15-2 Clinical photographs of a patient with a locked posterior dislocation of the shoulder: **(A)** loss of forward elevation; **(B)** loss of external rotation.

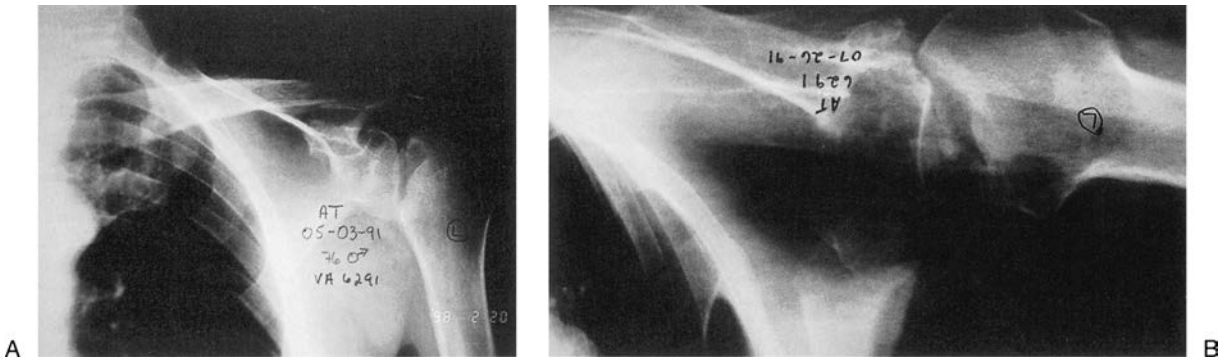

Figure 15-3 **(A)** An anteroposterior radiograph showing a posterior dislocation of the humeral head. **(B)** The axillary lateral radiograph of the same patient confirming the direction of the dislocation.

In cadaver studies, posterior dislocations of the shoulder have been associated with disruptions of the rotator cuff.[30] Gerber stated that he has seen three such lesions in the patients on whom he has operated.[12] Functional testing of the rotator cuff muscles with the shoulder posteriorly dislocated is not reliable. Therefore, the muscles of the rotator cuff should be examined for any evidence of increased atrophy compared to the deltoid. If there is any suspicion of a rotator cuff tear, it should be confirmed with appropriate imaging studies such as a magnetic resonance imaging (MRI) scan. A thorough examination of the remainder of the extremity must be done to rule out associated neurovascular injuries.[10,29] Schulz et al. reported that 5 of the 17 posterior dislocations that they evaluated had an associated nerve injury.[36]

Radiographic Evaluation

Plain radiographs will confirm the clinical diagnosis of a posterior dislocation of the shoulder only if the appropriate views are obtained.[31] Hawkins and colleagues showed that in 50% of the cases that they evaluated, the diagnosis could not be made with certainty based solely on an anteroposterior radiograph taken with the beam directed at 90 degrees to the plane of the scapula.[15] However, the diagnoses could be made in all patients when an axillary lateral radiograph was obtained. It is therefore imperative that any injury of the shoulder have, at a minimum, an anteroposterior and axillary lateral radiograph taken of the shoulder (Fig. 15-3A, B). If for any reason a patient with suspected posterior dislocation cannot obtain an axillary radiograph, a computed tomographic (CT) scan or MRI scan is necessary.

These views will permit evaluation of the glenohumeral joint and are essential for preoperative planning. The axillary view will often show the extent of glenoid wear and the amount of humeral head impaction that invariably is present with the locked posterior dislocation (see Fig. 15-3B). These radiographs should also be evaluated for evidence of associated fractures of the humerus and glenoid. In the series reported by Schulz et al.,[36] Hawkins et al.,[15] and Wilson and McKeever,[40] 50% of posterior dislocations had an associated fracture of the humeral neck or tuberosities. The presence of these injuries will influence the surgeon's choice of treatment. In the patient with a more chronic dislocation, these fractures may have developed into a malunion or a nonunion, and this will add further challenges to successful treatment (Fig. 15-4).

The axillary lateral radiograph is important for preoperative evaluation of the impaction fracture of the humeral head. By dividing the arc of the impacted surface of the humeral head and comparing it with the length of the arc created by the articular surface of the humeral head in its preinjury state, the surgeon can estimate the percentage of the humeral head involved in the impacted segment (Fig. 15-5). If there is difficulty in estimating the size of the humeral head defect, glenoid deficiency or fracture is suspected, or if the area of impaction is measured to be greater

Figure 15-4 An anteroposterior radiograph of a shoulder that is posteriorly dislocated. A malunion of the tuberosity can be seen.

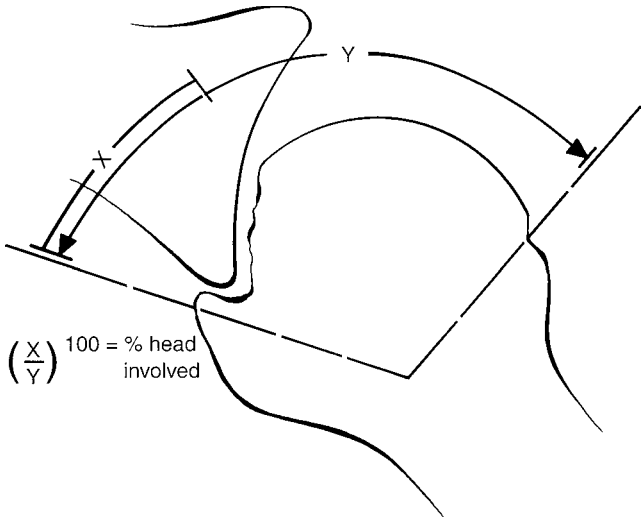

Figure 15-5 The percentage of the head involved can be determined by measuring the arc of the area of impaction and dividing by the arc of the intact humeral head. This number is then multiplied by 100 to give the percentage of the head involved.

than 20% of the humeral head surface, then a CT scan should be obtained. The CT scan is used to evaluate the amount of humeral head and glenoid erosion[22,27] (Fig. 15-6), the status of any fractures, and the quality of the remaining bone stock of the humeral head.[12] Changes in the appearance of the humeral head, such as thinning of the subchondral bone and loss of the normal trabecular architecture, indicate the presence of osteopenia. This information will prepare the surgeon for the possibility of the shoulder requiring replacement.

Many patients are referred to our office having already undergone an MRI study. If the study is adequate to determine the size of the humeral head defect, the presence of a glenoid fracture, and the amount of any glenoid deficiency, a CT scan is not ordered (Fig. 15-7). An electromyogram (EMG) should be obtained if there is any evidence of nerve injury. An arteriogram is needed if there is any evidence of vascular compromise.

Treatment Choice and Preoperative Planning

The first step to choosing the proper treatment of these patients is to have an understanding of the patients' perceived disability, their general health, their ability to undergo a surgical procedure, and their ability to understand and comply with the postoperative rehabilitation. In general, if the patient has low demands on the shoulder, has adapted his or her activities to cope with the limitations of the shoulder, or has pain that is easily controlled, then he or she should be considered for conservative treatment. Patients with the inability to follow the directions of rehabilitation and patients who are considered a high risk for surgery should also be considered for nonoperative treatment. Under these circumstances, it is imperative that the patient understand the rationale and expected limited outcome goals of nonoperative management.

Once surgical treatment has been established, the specific method of operative management must be chosen. This is determined by the patient's age, the time from the

Figure 15-6 Computed tomography can provide valuable information. Here, it shows a posterior fracture–dislocation, with evidence of glenoid wear and osteopenia.

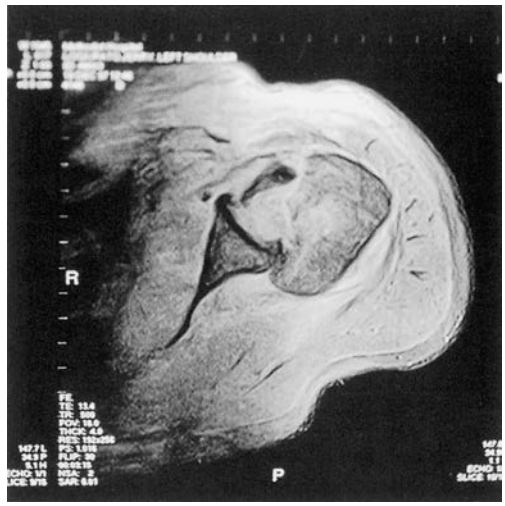

Figure 15-7 A magnetic resonance imaging scan obtained before referral can also be used to evaluate the humeral head defect and glenoid. An axial cut is shown. We prefer computed tomography scan, owing to the better visualization of the bony architecture.

initial injury, the demands on the shoulder, and the available bone stock present in the shoulder. Here, bone stock refers not only to the amount of bone loss because of the injury, but also to the intrinsic quality of the bone. The duration of the dislocation greatly influences the choice of treatment. Generally, the more chronic the injury is, the more likely there will be disuse osteopenia, loss of the articular surface's structural integrity, or both. Hawkins et al.,[15] Rowe and Zarins,[35] and Checchia et al.[6] suggest that any injury of longer than 6 months' duration may have irreversible damage to the articular surfaces. If significant osteopenia or loss of articular surface viability are suspected, the surgeon must be prepared to perform an arthroplasty. Patients with long-standing dislocations are also more likely to have erosion of the glenoid rim, requiring reconstruction and prosthetic arthroplasty. A preoperative CT scan will help determine whether this will be needed.

If the injury is relatively fresh (defined as less than 3 weeks), there is a possibility that the defect in the humeral head can be disimpacted and bone grafted. In this circumstance, the patient must give consent for the possibility of a bone graft and should be positioned and draped appropriately at the time of the procedure.

With the foregoing preoperative evaluation, the patient can be placed into a "likely" treatment group. The surgeon, however, must be prepared to move along the treatment algorithm (Fig. 15-8). The goals are to have a general treatment plan before surgery, an understanding of which choices are available, and the knowledge required to make the correct intraoperative surgical decision.

For the purposes of preoperative evaluation, we will use 3 weeks or greater to define a chronic injury. Three weeks is chosen because after this time it becomes difficult to perform a successful closed reduction.

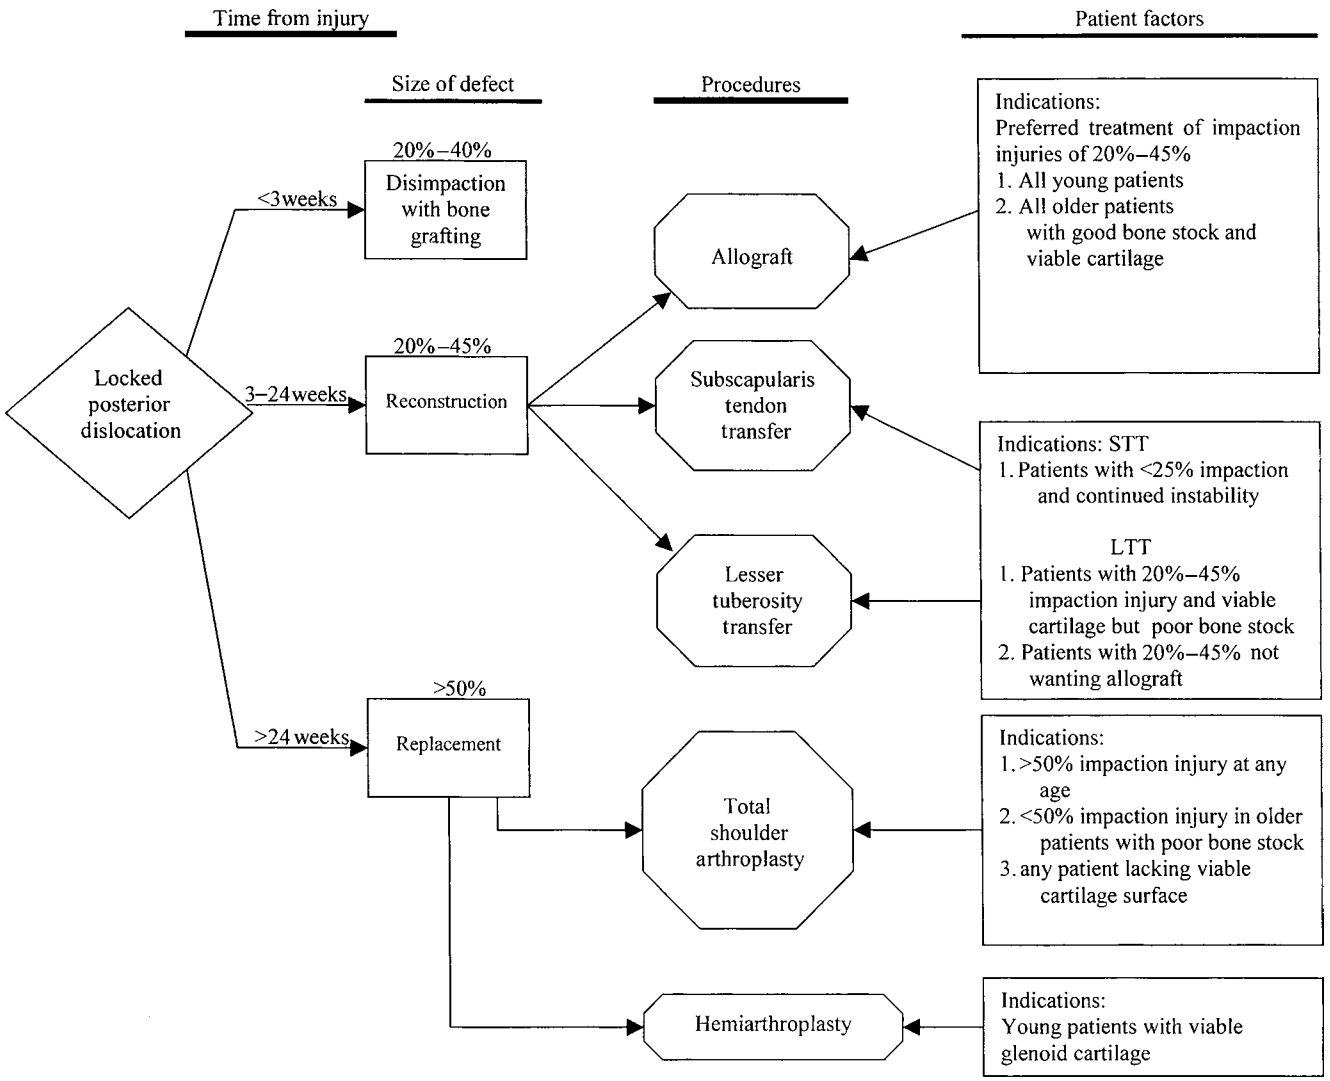

Figure 15-8 The treatment algorithm giving our approach to the surgical treatment of locked posterior dislocations. LTT = lesser tuberosity transfer; STT = subscapularis tendon transfer.

Treatment Options

Nonoperative Treatment

Nonoperative treatment includes the skillful neglect of chronic injuries of longer than 3 weeks' duration. Patients with acute injuries, with rare exceptions, are treated operatively. For patients with chronic dislocations who have minimal pain and do not perceive their limited motion as disabling, or for patients who are at high risk for surgery or have mental illnesses, skillful neglect is an acceptable treatment option. These patients are best treated with supportive measures to control pain and are encouraged to use their arm for daily activities as the pain subsides.

Closed Reduction

The criteria for choosing a patient who will be suitable for an attempt at closed reduction are the following: The patient can be of any age, the injury should be less than 3 weeks old, the impaction injury to the humeral head should be less than 25%, and the humerus must have no other fractures present. If these criteria are met, the patient may undergo an attempt at closed reduction.

The closed reduction is best performed under scalene block or general anesthesia.[7] The patient is placed supine and gentle traction is applied to the humerus in line with the long axis of the body. Gentle adduction and flexion are then applied. The humerus is gently externally rotated, and pressure is applied to the humeral head in a posterior to anterior direction. With this technique, the shoulder should reduce.

Once the joint is reduced, the humerus should be internally rotated and the point of instability noted. This position is the "danger zone" for dislocation. Patients who have no instability with the humerus internally rotated enough to place the hand on the abdomen are considered to have a stable injury. This is unlikely to occur with a chronic posterior dislocation, but may occur for acute injuries. If the shoulder is stable with the arm in internal rotation, the patient is immobilized in an orthosis. The humerus is held at the side in neutral rotation with the shoulder extended a few degrees.

Rehabilitation of the shoulder is begun on day 2 after the reduction. The patient is allowed unlimited external rotation and is allowed to perform isometric strengthening of the shoulder girdle. The brace is removed after 4 weeks, and the patient is encouraged to use the shoulder as tolerated. The patient is not allowed to bring the arm behind the trunk (maximum internal rotation) for 6 weeks. Lifting more than 5 lb above the plane of the chest is discouraged for 6 weeks. Heavy labor is discouraged for 3 months.

If after closed reduction the shoulder remains unstable and dislocates with internal rotation at a point before the hand reaches the abdomen, the patient should be placed in a prefabricated splint. The shoulder should be slightly extended and the humerus should be externally rotated 20 degrees from neutral. The patient is then further evaluated to determine why the shoulder continues to be unstable. A CT scan should be obtained to evaluate the glenoid for fracture and to reassess the size of the humeral head defect.[23] If a CT scan was obtained before closed reduction and the cause for instability after reduction can be determined, open surgical intervention is performed at that time.

If a fracture of the glenoid is present but well reduced with the arm in the splint, the patient continues to be treated conservatively. Weekly follow-up radiographic evaluation is required until early fracture union occurs. This usually takes 6 weeks. During this period of immobilization, the patient is allowed to externally rotate the humerus passively, and after 3 weeks is allowed to internally rotate to within 20 degrees of the danger zone, as determined at the time of reduction. At 6 weeks, the patient is allowed full passive range of motion and is allowed to progress with active motion as pain permits. Strengthening is not started until 10 to 12 weeks.

If the glenoid fracture is displaced or unstable, the patient will require an open reduction with internal fixation of the glenoid as described in Chapter 26. If the humeral head impaction fracture is the cause of continued instability and involves less than 45% of the articular surface, then the patient will need to undergo open repair of the humeral head defect.

If there are fractures present of the tuberosities or humeral neck, the reduction should be performed under general anesthesia. Because there is a risk of displacing these fractures during closed reduction, the humeral neck or tuberosity fractures should undergo percutaneous pin fixation before any attempt at reduction[16] or an open reduction and internal fixation should be performed (Chapter 28).

If closed reduction is successful, a good outcome is to be expected. Hawkins et al.[15] reported excellent results in the three patients whose shoulders could be reduced and were stable after reduction. Schulz et al.[36] reported satisfactory results in the three posterior dislocations that they were able to reduce. All six of these shoulders were reduced within 4 weeks of injury. Checchia et al.[6] reported that the nine patients (out of 10) available for follow-up that were treated with closed reduction and splinting had excellent results with a mean University of California, Los Angeles (UCLA) score of 34.9.

Open Reduction

Open reduction of locked posterior dislocations will be required if the injury is more than 3 weeks old, if the shoulder is unstable after closed reduction, if the impacted area of the humeral head involves greater than 25% of the

articular surface, or if there is a displaced fracture of the surgical neck or tuberosities. The best treatment of these injuries will be determined by the following factors: (a) the size of the humeral head defect, (b) the amount of time from injury, (c) the patient's age, (d) the amount of posttraumatic arthritis present, and (e) the quality of the humeral head bone stock. Most articles addressing the treatment of locked posterior dislocations have used the size of the humeral head impaction injury to determine the approach to treatment.[6,8,12–15,26,28,35,36] The other factors listed above are also important in determining the final choice of treatment.

Note that these injuries are uncommon, and the number of reported patients treated with each method is small; therefore, it is impossible to draw any statistical conclusions from the data presented in the literature regarding the treatment of these injuries. The surgeon should choose the method with which he or she is most comfortable.

Disimpaction and Bone Grafting

This method of treatment is best reserved for an acute injury (less than 3 weeks old) with a humeral head defect that involves less than 45% of the articular surface. The patient must have adequate bone stock to provide for secure fixation and must have structurally intact articular cartilage to be considered for this procedure. It is ideal for use in the younger patient, but may also be effectively used in older patients with good bone stock. The patient is positioned and the ipsilateral iliac crest is prepared and draped, so that bone graft can be obtained if needed.

The standard deltopectoral approach is used. The axillary nerve is always identified and protected. The ascending branch of the anterior humeral circumflex artery is identified and protected in procedures where the humeral head will be preserved. The subscapularis tendon is incised 1 cm from its insertion and dissected from the underlying capsule. This may be difficult, owing to the scarring caused by the injury. A vertical capsulotomy is then performed. It is important to maintain and repair the coracohumeral and superior glenohumeral ligament at their attachment sites as these structures provide posterior stability. The joint is débrided of any scar tissue. Once the articular surfaces are identified, an evaluation of the injury is performed. The glenoid is inspected for fracture or articular injury. The humeral head is reduced by placing a Cobb elevator into the site of impaction and using it to lever the head over the glenoid rim. In cases of long-standing dislocation (6 months), reduction of the head may not be possible. Alternatively, a laminar spreader (with a padded edge) placed on the glenoid rim and the other side placed on the proximal humerus can disengage the locked posterior dislocation and allow easy and gentle reduction. The posterior labrum and capsule are inspected. In the majority of shoulders with posterior dislocations, there is an avulsion of the capsule as a sleeve of tissue. Unlike the Bankart lesion seen with anterior dislocations, the injury to the posterior labrum and capsule does not always need to be reattached to the glenoid.[12,13,15] Usually, it is only necessary to roughen the posterior aspect of the glenoid with a curved curette, with the expectation that the capsule will heal to its origin. The impacted region of the humeral head and the remaining intact humeral head are inspected. A determination is made as to whether the cartilage surface at the site of impaction can be salvaged. If the articular surface can be salvaged, then disimpaction with bone grafting is performed as follows (Fig. 15-9).

Disimpaction of the articular cartilage with its underlying subchondral bone is performed by creating a bone window in the greater tuberosity directly opposite the impacted area (Fig. 15-9A). This will require internal rotation of the humerus to create the window and to disimpact the fracture through it. The surgeon will have to externally rotate the humerus to visualize the progression of the disimpaction of the articular defect. Once the window is created, a bone tamp or the blunt end of a 10-mm drill is placed into the window and impacted toward the defect opposite it (Fig. 15-9B). This will disimpact the humeral head defect in its central portion. Once the articular surface's contour is properly restored centrally, a small curved osteotome placed into the bone tunnel can be used to lever the edges of the defect. After the area is disimpacted, a void will have been created below the area of the fracture. This void is filled by packing the area with cancellous bone. The bone tamp is used to pack the defect (Fig. 15-9C). Once the void is filled, the cortical window is closed. Collapse of the disimpacted area is prevented by placing parallel screws along the articular margin and aiming them just inferior to and across the area of disimpaction (Fig.15-9D,E). Placed in this fashion, these screws act as a lattice to support the area of the grafting. The bone graft must be of good quality and adequate quantity. Cancellous bone can be obtained from the iliac crest. However, cancellous allograft or synthetic bone graft substitutes may also be used if the patient and surgeon so choose.

After the fragments are secured, the shoulder is taken through a range of motion in internal rotation. The position in which the grafted area comes into contact with the glenoid is noted. This position should be avoided postoperatively until the graft has consolidated, which usually requires at least 6 weeks. The anterior capsule is closed side to side and overtightening of the capsule is avoided. The subscapularis is reattached anatomically, and the wound is closed. Humeral internal rotation is avoided during closure. The patient is placed into a postoperative brace in neutral to 20 degrees of external rotation. If the defect is not repairable by this method, the patient is treated by either transfer of the subscapularis tendon into the defect, by insertion of the lesser tuberosity into the defect, or by allograft reconstruction. Hemiarthroplasty is generally not

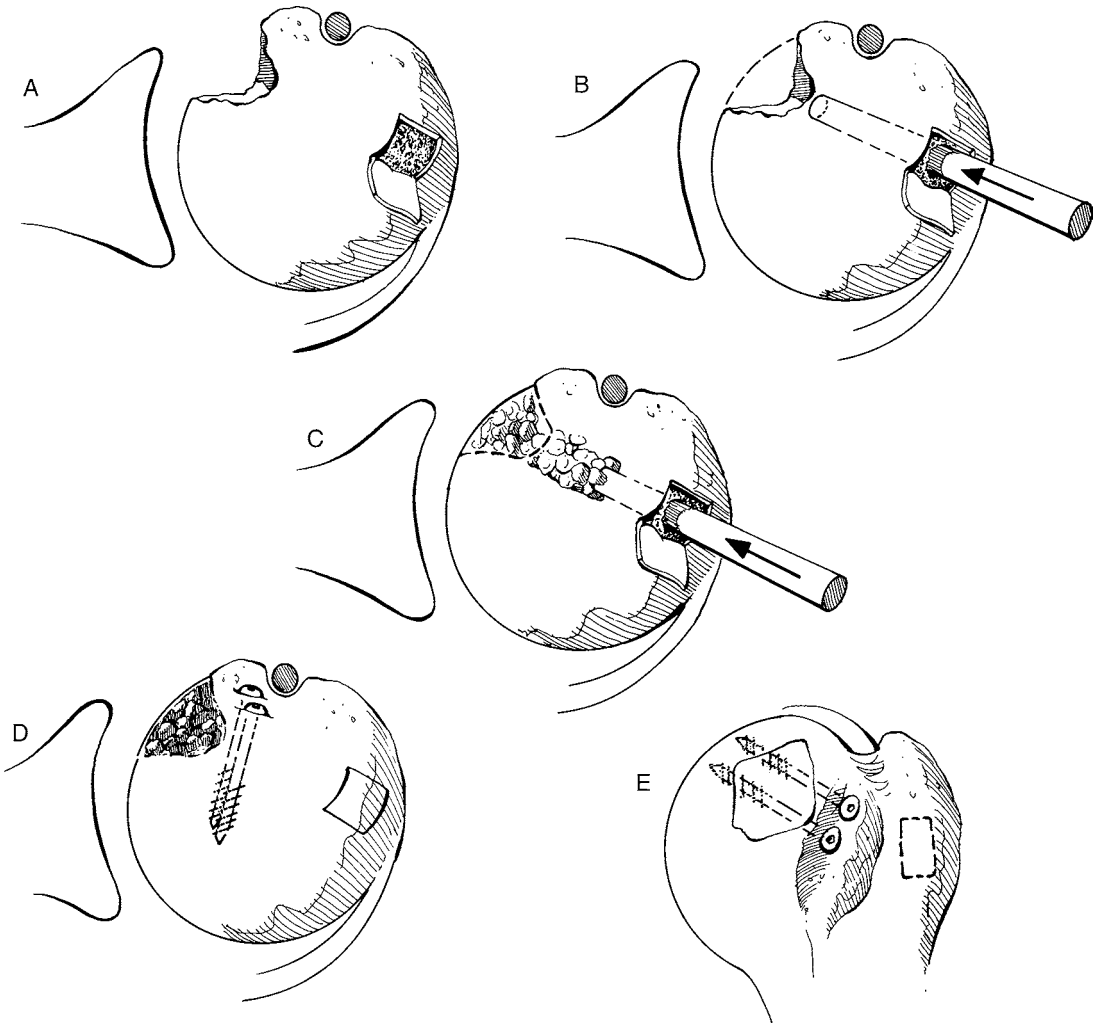

Figure 15-9 This schematic represents the technique of disimpaction and bone grafting of injuries less than 3 weeks old: **(A)** A bone window is made in the greater tuberosity opposite the fracture; **(B)** a bone tamp is used to disimpact the area; **(C)** cancellous autograft is packed into the defect to support the area; and **(D,E)** fixation is provided to shore up the area of grafting.

required for defects of this size, unless the remaining bone and cartilage viability is inadequate.

Rehabilitation is the same as that for closed reduction, with a few exceptions. The patient is not allowed internal rotation into the danger zone as determined intraoperatively for 6 weeks and, therefore, must wear the brace for 6 weeks. Gentle passive external rotation and isometric exercises are started on postoperative day 2.

Gerber has reported success with this technique.[12,13] No clinical series has been reported in the English literature.

Open Reduction with Transfer of the Subscapularis Tendon or Transfer of the Lesser Tuberosity

To successfully perform either subscapularis transfer or transfer of the lesser tuberosity, the patient must have adequate bone stock to securely hold either sutures or screws. The articular surface of the remaining intact humeral head must be structurally viable and the defect of the head should be less than 25%.

If the shoulder has been dislocated for more than 6 months, the possibility of the shoulder requiring a shoulder arthroplasty must be discussed with the patient, and the prosthesis must be available at the time of surgery.

Transfer of the Subscapularis

This procedure should be considered for patients with small humeral head defects (less than 25%) and continued symptoms of instability following reduction. The approach used to perform the subscapularis transfer is the same as that used for performing an arthroplasty, with the exception that the tendon of the subscapularis is released from

its insertion. The joint is exposed and débrided of scar tissue. The humeral head is reduced, as described earlier. The articular cartilage is evaluated and the size of the defect is confirmed visually. If the articular cartilage of the intact humeral head is viable and the defect is less than 25%, then transfer of the subscapularis is undertaken. If the remaining articular cartilage is not significantly damaged and the defect size is between 25% and 45%, a transfer of the lesser tuberosity or osteochondral allograft is considered. If the articular surface of the remaining humeral head is not viable or the defect is larger than the anticipated 45%, the patient is moved into the arthroplasty group. Arthroplasty is also performed if the bone in the intact portion of the humeral head is markedly osteoporotic.

The deltopectoral approach is used. The entire subscapularis tendon is raised from its insertion. Any adhesions to the subscapularis are released from its anterior and posterior surfaces. The humeral head is reduced and the posterior rim of the glenoid is inspected for the presence of any significant erosion that would preclude stability without reconstruction. If needed, the glenoid is reconstructed with bone graft. If minimal erosion is present the posterior rim of the glenoid is roughened to create a healing surface for the capsular structures. The defect in the humeral head is then cleared of all scar tissue until a bed of cancellous bone is prepared. Transosseous sutures are used to secure the subscapularis into the defect. The shoulder is taken through a full range of motion and should be stable. If the shoulder dislocates despite the repair, then the defect should be considered too large for this technique, and either an allograft or arthroplasty should be performed. If the shoulder is stable, then the sutures are tied and the wound is closed. The patient is then placed in a prefabricated splint with the arm held at the side in 20 degrees of external rotation.

Transfer of the Lesser Tuberosity

The standard deltopectoral approach is used, and the biceps tendon is identified. The rotator cuff interval is identified and released sharply. This allows access to the superior aspect of the lesser tuberosity and helps to visualize the articular side of the osteotomy. Once the lesser tuberosity is identified, it is osteotomized. The biceps is released from the supraglenoid tubercle and is routinely tenodesed. Once the lesser tuberosity osteotomy is complete, the freed tuberosity is secured with a traction stitch. With traction applied, the subscapularis and the underlying capsule are dissected as one layer away from the anterior surface of the glenoid. The subscapularis must be freed of adhesions. The joint is débrided of scar tissue. The articular surfaces are evaluated for viability. The glenoid is addressed as before and the area of the humeral defect prepared. The lesser tuberosity is secured into the defect with one to two cancellous lag screws at 90 degrees to the plane of the defect. The humerus is internally rotated to assess the stability of the shoulder. The shoulder should be stable after this procedure. If dislocation continues, then the defect was too large for this procedure, and the patient should be considered for allograft reconstruction or prosthetic arthroplasty.

Rehabilitation

Patients with subscapularis or lesser tuberosity transfer are immobilized in the brace in neutral to 20 degrees of external rotation for 4 weeks. The patient is allowed to begin passive external rotation and abduction of the shoulder on postoperative day 2. At this time, the patient also begins isometric strengthening of the external rotators of the shoulder.

At 4 weeks, the brace is removed and the patient is allowed full motion of the shoulder, except for active internal rotation. Active internal rotation is discouraged until week 6. At this point, gentle active internal rotation and light strengthening of the shoulder girdle muscles are commenced. More strenuous activity is not allowed for an additional 6 weeks.

McLaughlin[26] was the first to report the use of the subscapularis tendon transfer technique in the treatment of locked posterior dislocations of the humeral head. He reported using this technique in four patients and found the results to be satisfactory in the two patients with sufficient follow-up. Rowe and Zarins[35] reported satisfactory results in their two patients treated by subscapularis transfer.

In 1982, Hawkins et al.[15] reported on nine patients who had been treated with subscapularis transfer and reported excellent results in four of the patients they had treated with this procedure. The average range of motion obtained in these patients was 165 degrees of active forward elevation, 40 degrees of external rotation, and internal rotation to the level of the 12th thoracic vertebra. The remaining five patients were referred to them after already having undergone subscapularis transfer by the referring physician. These patients were therefore considered failures and were treated with a different procedure.

Hawkins et al.[15] and Neer[28] advocated transfer of the lesser tuberosity for patients with humeral head defects involving 20% to 45% of the articular surface. Neer developed the lesser tuberosity transfer procedure and treated four patients using this technique.[28] All four patients were reported to have excellent results. The average range of motion in these four patients was 160 degrees of active forward elevation, 45 degrees of external rotation, and internal rotation to the 12th thoracic vertebra.

Walch et al. reported the results of subscapularis transfer in 10 patients: three patients had excellent results, one good, five fair, and one poor.[39] Checchia et al.[6] used either a subscapularis transfer or lesser tuberosity transfer in 13 of their patients. Nine out of 13 patients were available for follow-up. Three of the outcomes were considered excellent,

four good, one fair, and one poor. The average UCLA score for this group was 28.8 points. They grouped both the tendon and tuberosity transfers together so that it is impossible to determine more than the general results or to determine if there was any difference in the outcomes between the two techniques.

Gerber[12,13] has argued against this method because it distorts the anatomy of the proximal humerus and limits the arc of humeral articular surface available for internal rotation. He also argued that this would cause revision to an arthroplasty to be difficult if the tuberosity transfer were to fail. Therefore, he advocates the use of an allograft to reconstruct defects of this size. Of note, no patient treated by Neer required a revision operation after transfer of the lesser tuberosity. However, his follow-up of these patients was limited at a range of 2 to 9 years.[28]

Allograft Reconstruction

In 1996, Gerber[13] reported on the use of allografts to treat the humeral head defects associated with chronic locked posterior dislocations of the shoulder. He recommended using this technique in patients whose shoulder had been dislocated at least 4 weeks and had defects involving up to 50% of the humeral head.[12,13] He advised against the use of this technique if there was significant osteoporosis present in the remaining portion of the humeral head. A suitable fresh frozen allograft must be available for this type of reconstruction. A size-matched, fresh frozen humeral head allograft is best suited for obtaining the graft. If this is not available, a fresh frozen femoral head will suffice. This procedure should be reserved for the younger patient and for the older patient with good bone stock. A CT scan is helpful in evaluating for significant osteopenia.

The exposure is the same as previously described for elevation and bone grafting. Again, a vertical capsulotomy should be used, so that the insertion of the coracohumeral ligament and the superior glenohumeral ligament are preserved or repaired. If the cartilage and bone quality are sufficient, then the reconstruction is performed. If the quality of either tissue is poor, then an arthroplasty is performed. The glenoid is addressed as previously described.

Instead of curetting the base of the humeral head defect, an osteotome or oscillating saw is used to cut a wedge out of the humeral head, which includes the edges of the defect (Fig. 15-10A). Once this is done, the breadth of the excised wedge, as well as its depth, should be ascertained (Fig. 15-10B). The allograft head should then be inspected for a surface that will match the contour of the humeral head at its defect. An oscillating saw is then used to cut a wedge from the allograft that is approximately 2 mm wider than the width of the true defect (Fig. 15-10C). This will

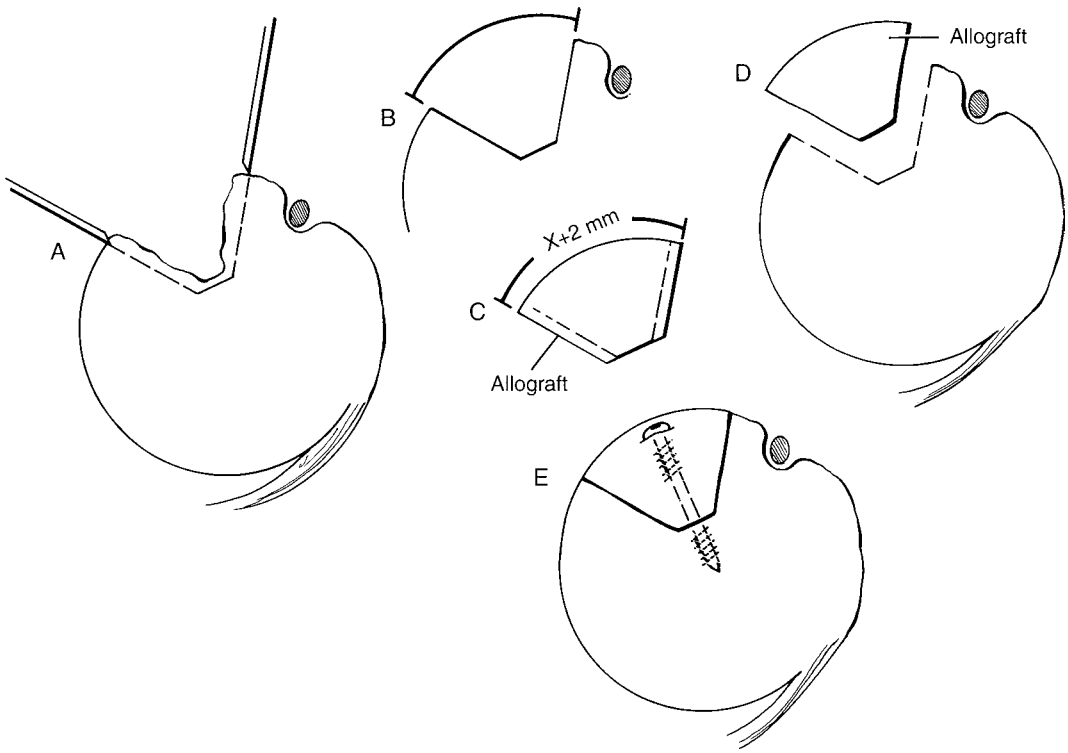

Figure 15-10 This schematic represents the technique of allograft reconstruction: **(A)** The edges of the defect are prepared sharply; **(B)** the defect is measured; **(C)** a suitable surface of the allograft is used to cut a wedge 2 mm larger than the defect; **(D)** the allograft is impacted into place; **(E)** the allograft is fixed into position with a cancellous screw.

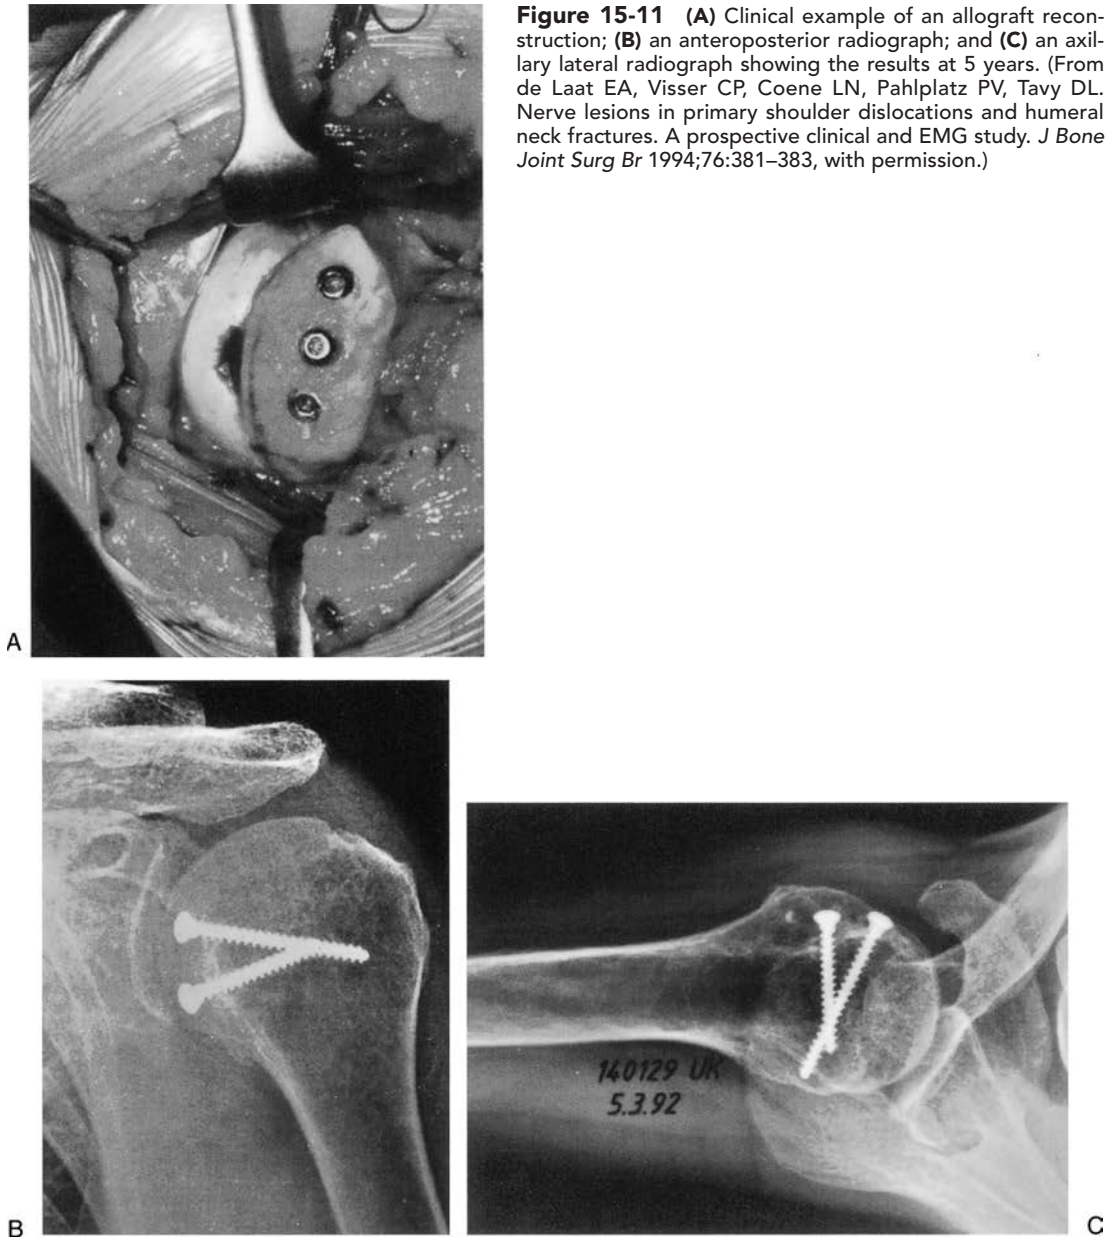

Figure 15-11 **(A)** Clinical example of an allograft reconstruction; **(B)** an anteroposterior radiograph; and **(C)** an axillary lateral radiograph showing the results at 5 years. (From de Laat EA, Visser CP, Coene LN, Pahlplatz PV, Tavy DL. Nerve lesions in primary shoulder dislocations and humeral neck fractures. A prospective clinical and EMG study. *J Bone Joint Surg Br* 1994;76:381–383, with permission.)

permit impaction of the allograft into the defect, creating a press fit (Fig. 15-10D). The graft is then fixed with one or two countersunk cancellous lag screws or Herbert screws (Figs. 15-10E and 15-11). The shoulder is then taken through a full range of motion and should be stable, with no further tendency for dislocation. If the shoulder is unstable, this can be remedied by either imbrication of the posterior capsule or by postoperative immobilization of the shoulder in a stable position. The posterior capsule avulsion or redundancy rarely, if ever, needs to be addressed by formal posterior capsulorrhaphy because experience has shown that the muscular and capsular tension about the shoulder will return with proper rehabilitation.[12] The subscapularis is repaired anatomically and the wound is closed. The patient is immobilized in a prefabricated brace in neutral rotation for 6 weeks. Rehabilitation is similar to that following subscapularis tendon transfer, with the exception of the additional 2 weeks of immobilization.

Allograft reconstruction of articular surface defects has been an efficacious and safe treatment for articular surface defects in lower-extremity, weight-bearing joints.[24,25] These data support the use of allografts in the reconstruction of defects in the humeral head. Moreover, the shoulder is typically less of a weight-bearing joint than lower-extremity joints. Therefore, fewer demands are placed on the allograft. In 1996, Gerber[12] presented the preliminary results in four patients treated for locked posterior dislocations of the humeral head using allograft reconstruction. Three of

the patients had satisfactory results, with an average score of 95% of that of an age- and sex-matched normal population. This scoring was based on the system of Constant and Murley.[9] The follow-up period for these three patients was more than 5 years from the time of the procedure. The one poor result was in a patient who developed avascular necrosis and collapse of the head after 6 years from the time of surgery. It was felt that this development was related to the patient's history of alcohol abuse and not to the reconstruction. Gerber later stated that he has had similar results in an additional six patients. He did, however, stress that this procedure should not be used if the patient's bone was osteoporotic by CT scan or by examination at the time of surgery.

The results of allograft reconstruction given by Gerber's series are similar to those shown with the other humeral head–preserving techniques. This technique potentially allows preservation of normal kinematics in the shoulder joint and preserves the normal anatomy of the proximal humerus. We agree with Gerber and believe that, if at all possible, allograft reconstruction should be performed as the treatment of choice in young patients and in older patients with adequate bone stock and intact articular cartilage on the remaining portion of the humeral head.

Hemiarthroplasty and Total Shoulder Arthroplasty

Indications for either a hemiarthroplasty or a total shoulder arthroplasty are a defect measuring more than 50% of the articular surface of the humeral head, severe articular cartilage damage, marked osteopenia, or erosion of the glenoid rim, leading to instability (see Figs. 15-3 and 15-6).

The choice of whether to use a hemiarthroplasty versus a total shoulder arthroplasty depends on the condition of the glenoid surface. If the glenoid has significant wear and erosion, then the glenoid may require resurfacing. If the dislocation has not been present long enough to irreversibly damage the cartilage of the glenoid, then a hemiarthroplasty is preferred (Fig. 15-12). In patients too young for glenoid resurfacing, consideration is given to arthrodesis or hemiarthroplasty with soft tissue interposition.

The standard deltopectoral approach is used. The tuberosities should not be osteotomized if at all possible. If a malunion of the neck is present, an osteotomy of the neck may be required. An osteotomy of the neck is preferred because it allows placement of the humeral component into correct rotational alignment, which restores more normal anatomy. In some cases, the humeral prosthetic may be placed in significantly less retroversion (0 degrees) to compensate for the change in the soft tissue balance caused by the dislocation. In general, the more chronic the injury is, the less retroversion is used. Hawkins et al.[15] reported that, with experience, they felt that they could dial in the precise amount of version required to restore immediate joint stability. Oversizing of the humeral head to make up for a redundant capsule, in general, should be avoided. The size of the prosthetic head should be chosen to match the anatomic size of the patient's native head. Once the trials are in place, the

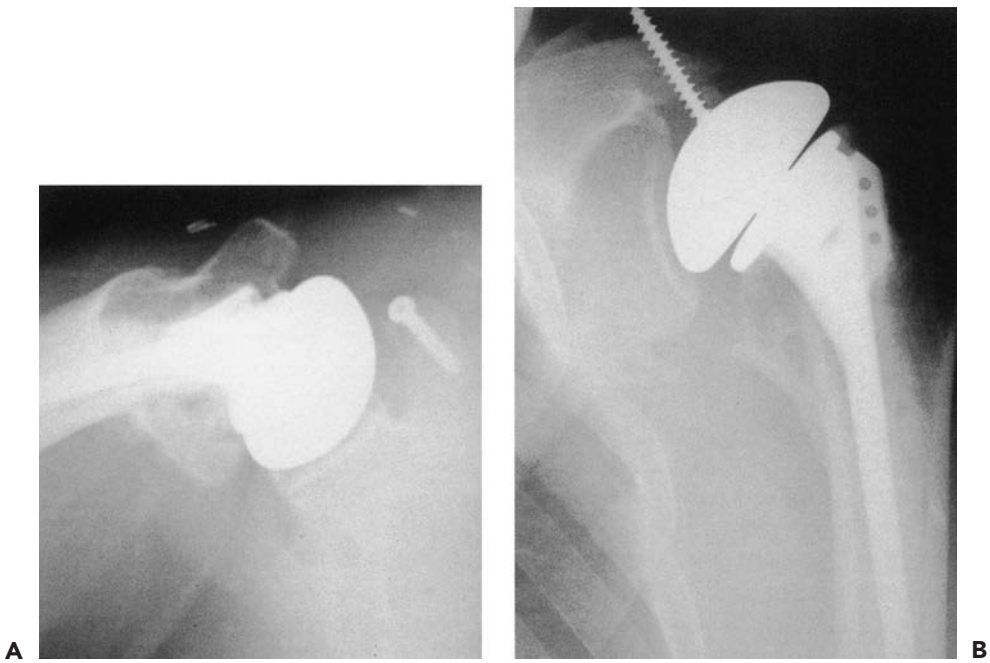

Figure 15-12 Radiographs taken 2 years after a hemiarthroplasty was performed on the patient whose computed tomography scan is shown in Fig. 15-6.

shoulder is taken through a full range of motion to determine joint stability. Because the posterior capsule may be patulous as a result of chronic distension, a posterior capsular plication may be necessary. In our experience, this is rarely needed. Stability of the joint must be evaluated intraoperatively. Active contraction of the rotator cuff in the awake patient will improve shoulder stability. This may correct subtle intraoperative instability, but will not correct for gross instability. This must be corrected intraoperatively through a combination of soft tissue balancing, bone grafting, glenoid reaming, and component version.

Rehabilitation

If the shoulder is stable after shoulder arthroplasty, the patient does not require bracing. The patient is allowed to perform range-of-motion exercises by postoperative day 3, and by 2 weeks active and light resistive exercises are added. No heavy use of the extremity is allowed for 3 months. If at the time of surgery the shoulder was found to be unstable despite plication of the posterior capsule, then the arm is immobilized in neutral rotation for 6 weeks. On postoperative day 1, the patient is allowed gentle active external rotation and is allowed isometric strengthening of the external rotators and deltoid. These exercises are performed in the brace. The brace is removed at 6 weeks, and the patient is allowed full motion of the joint. He or she is also started on muscle conditioning exercises at that time.

Hawkins and colleagues[15] remedied the tendency for posterior dislocation in patients undergoing prosthetic arthroplasty by changing the version of the humeral component. During the early period of their study, they suggested that the humeral component be placed in neutral rotation if the dislocation had been present for longer than 6 months, and in 20 degrees of retroversion if the dislocation had been present for less than 6 months. With more experience, the authors stated that they felt that they could adjust the precise degree of version to restore immediate stability. By using this technique, they were able to obtain satisfactory results in 11 of 16 patients. Their best results were seen in patients who had been treated with primary total shoulder arthroplasty (TSA), which was available only during the later part of their patient series. Of the six patients who underwent primary TSA, five showed excellent results and had an average active forward elevation of 152 degrees, external rotation of 40 degrees, and internal rotation to the level of the 12th thoracic vertebra. The one failure had a postoperative dislocation and refused further treatment. These results led them to recommend TSA as the procedure of choice in the treatment of chronic locked posterior dislocations in patients not felt to be candidates for humeral head preservation. Others have also advocated changing the version of the humeral component to control the tendency toward redislocation.[8,28,32]

Cheng et al.[8] reported on seven cases treated with TSA. Utilizing the American Shoulder and Elbow Society shoulder score, they noted an improvement from a preoperative mean of 20.1 to a mean of 55.6 postoperatively. Checchia et al.[6] reported their results of hemiarthroplasty in eight patients. The mean UCLA score was 25.6 points; three cases were classified as excellent, two as good, one as fair, and two as poor. Of the two poor results, one required revision to a total shoulder arthroplasty. They performed a TSA in five patients but did not distinguish the chronicity of the dislocation prior to treatment. Four of these patients were considered to have unsatisfactory results. Their poor results with TSA are in contrast to most other reported series of chronic dislocations treated with this method.[8,12,14]

It is Gerber's recommendation that the normal axis of rotation be recreated whenever treating a chronic posterior dislocation with an arthroplasty.[12] He felt that this would lead to more normal joint kinematics than would be seen if the humeral component was placed in excessive anteversion. To prevent postoperative instability, he recommended balancing of the soft tissues of the posterior capsule, the subscapularis, and the anteroinferior capsule. It was his belief that with postoperative immobilization and properly modified rehabilitation, the soft tissues would rebalance toward their normal tensions. He stated that the balancing of these tissues may require the use of a brace for 6 weeks after the surgery. The authors of this chapter agree with these recommendations and place the prosthetic in natural version and balance the soft tissues to achieve stability. It is the editors' experience that change in humeral version does not afford a significant improvement in joint stability. No clinical outcome data are available for the patients that he has treated with this technique. Gerber does concur with Hawkins and Neer that TSA is the treatment of choice in patients with long-standing dislocations.

CHRONIC LOCKED ANTERIOR DISLOCATION

Although many of the same principles used in the diagnosis and treatment of posterior dislocations are employed in the diagnosis and treatment of anterior dislocations, anterior dislocations have unique characteristics that require a distinct approach to diagnosis, treatment, and rehabilitation. For instance, an anterior dislocation leaves the arm in relative abduction and external rotation. If the arm remains locked in this position, the patient will be unable to reach the mouth and will be unable to perform daily care activities. This nonfunctional position of the arm is the likely reason that the functional outcome in patients with neglected anterior dislocations yields a poorer result than the results seen in locked posterior dislocations. In 1982, Rowe and Zarins reported on a series of seven patients with chronic, untreated shoulder dislocations.[35] In this study, they found that the three patients with

untreated posterior dislocations scored better in objective and subjective testing of shoulder function than the four untreated anterior dislocations. A recent case report by Jerosch et al.[18] reported a single patient with a locked anterior dislocation of 4 years' duration. The surprising function seen in this patient may represent expansion of the Hill-Sachs defect over the long period of follow-up. This case does point to the importance of an objective functional assessment of each patient prior to making a recommendation for surgery.

Classic teaching would lead one to believe that locked posterior dislocations are more common than locked anterior dislocations; however, this is not the case. The larger number of missed anterior dislocations likely occurs as a result of the proportionally larger rate of occurrence of acute anterior dislocations, compared with that of posterior dislocations. However, as a percentage of the type of injury, posterior dislocations are more frequently missed.

History

As with posterior dislocations of the shoulder, anterior dislocations of the shoulder may result from trauma or a convulsive episode. Classically, seizures have been related to the occurrence of posterior dislocations of the shoulder; however, anterior dislocations have been reported to occur in one-half of all dislocations caused by a seizure.[3,36] Clinical suspicion should, therefore, be raised in any seizure disorder patient who has shoulder pain or a diagnosis of a frozen shoulder that is not responding to therapy. Patients suffering from a multiple trauma can often have a shoulder injury that is overlooked because of the severity of other injuries (Fig. 15-13). Thorough repeat examinations of the trauma patient are necessary to avoid these unrecognized injuries.

Physical Examination

The physical examination of a patient with a chronic locked anterior dislocation of the shoulder typically reveals severe limitation of rotation. The patient usually is seen to hold the arm away from the body in external rotation. Pain with chronic dislocations is variable and may be relatively mild after a long-standing dislocation. Fig. 15-14 shows the clinical photographs of a patient who was misdiagnosed as having a shoulder contusion and was later treated as a frozen shoulder. After 3 months of failed therapy, the diagnosis of a locked anterior shoulder dislocation was made. The diagnosis was rendered by simply obtaining the appropriate radiographs (Fig. 15-15).

A thorough neurovascular examination should also be performed. Schulz et al. showed in their series that 40% of anterior dislocations had an associated neurologic injury.[36] In a prospective evaluation using EMG, de Laat and colleagues found evidence of a nerve injury in 45% of patients after an acute dislocation of the shoulder or fracture of the humeral neck.[10] Therefore, electromyography should be performed to document any suspected brachial plexus or axillary nerve injury before surgical correction of any chronic deformity. Damage or rupture of the axillary artery with anterior dislocations of the shoulder have also been reported.[1,21,29]

(Courtesy of Jeffrey S. Noble, MD, Akron, Ohio.)

Radiographic Evaluation

Radiographic evaluation of the locked anterior dislocation should include an anteroposterior and lateral view of the shoulder in the plane of the scapula, as well as an axillary lateral view (see Fig. 15-15). As with locked posterior dislocations, the axillary lateral is essential for diagnosis as well as to determine the extent of humeral head impaction. It will also provide information regarding the integrity of the glenoid. Associated fractures of the proximal humerus or glenoid can be seen in up to 50% of these injuries and should be ruled out.[36] Preoperative determination of bone quality is important for surgical planning where an allograft may be needed for reconstruction of a large Hill-Sachs lesion. A CT scan will give valuable information relative to bone loss in the humeral head and glenoid (Fig. 15-16).

Intraoperative Findings

Locked anterior dislocations of the shoulder are characterized by intraoperative findings different from those seen in posterior dislocations. In anterior locked dislocations, the humeral head compression fracture is found in the posterolateral aspect of the head (the classic Hill-Sachs lesion[17]). In contrast to posterior dislocations, anterior dislocations commonly have glenoid loss as well as humeral head deficiency. The anteroinferior aspect of the glenoid cavity may become deficient from chronic wear against the posterolateral aspect of the humeral head (Fig. 15-17). In locked posterior dislocations, the posterior capsule and labrum are usually avulsed from the glenoid as a contiguous sleeve and are not felt to require reattachment to the glenoid during repair. In contrast, reattachment of the anteroinferior capsular structures and glenoid labrum to the glenoid is very important in the recreation of a stable shoulder after reduction of a locked anterior dislocation.

The neurovascular structures are also at a much greater risk during surgical reconstruction of locked anterior dislocations than with posterior dislocations. Scarring of the brachial plexus and axillary vessels may occur to the anterior aspect of the subscapularis muscle, making soft tissue dissection difficult. The axillary nerve is frequently stretched and scarred to the inferior aspect of the subscapularis muscle, placing the nerve at risk during open reduction. The axillary nerve must be identified and protected throughout the procedure. Neurapraxias are not uncommon after open reduction of a chronic anterior dislocation. Recovery is common, as long as the nerve is gently protected and not transected.

Treatment Choice and Preoperative Planning

As with the treatment of locked posterior dislocations, the treatment options for locked anterior dislocations range from benign neglect to total shoulder arthroplasty. The treatment of choice will depend on the size of the defect, the time from injury, the condition of the humeral head and glenoid, and the patient's medical status. The surgeon must develop an algorithmic approach to the treatment of these injuries, so that the proper preoperative plan can be made and the surgeon can move along the algorithm if intraoperative findings require a change of treatment (Fig. 15-18).

Nonoperative

Nonoperative treatment is an option in the treatment of locked anterior dislocations of the shoulder. Benign neglect may be the treatment of choice in patients with little discomfort and minimal functional limitation.[18] It is also indicated in patients not felt to be medically fit for surgical intervention.[11,12,35,36] Although the functional

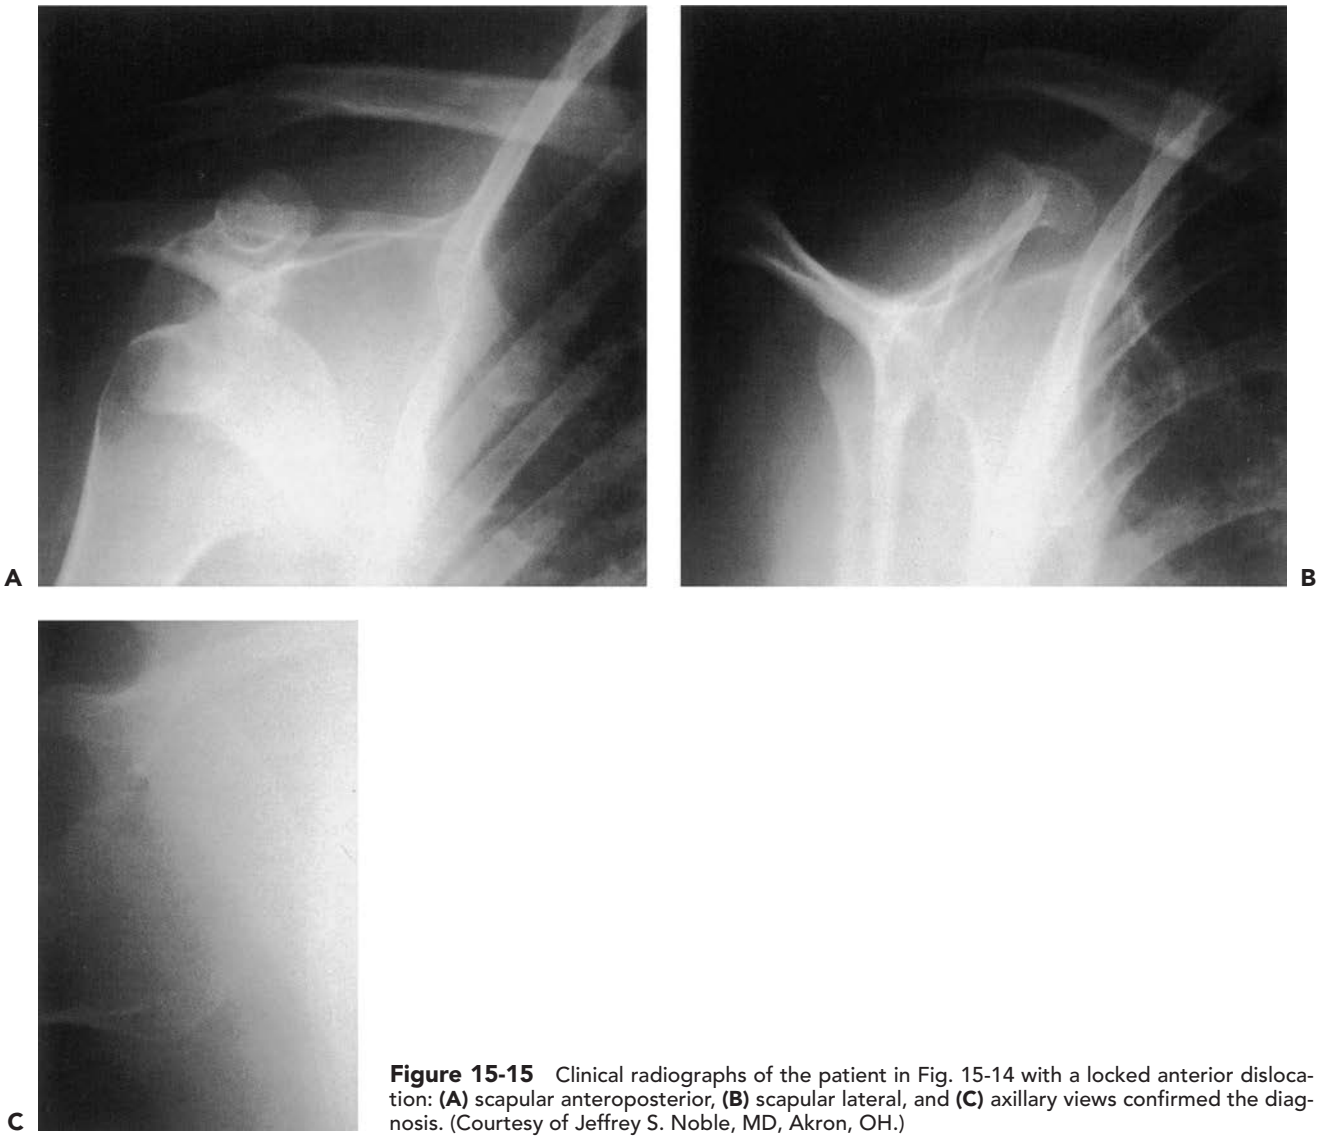

Figure 15-15 Clinical radiographs of the patient in Fig. 15-14 with a locked anterior dislocation: **(A)** scapular anteroposterior, **(B)** scapular lateral, and **(C)** axillary views confirmed the diagnosis. (Courtesy of Jeffrey S. Noble, MD, Akron, OH.)

results of untreated anterior shoulder dislocations are inferior to the results obtained after reduction, some patients have a surprisingly functional range of motion (Fig. 15-19). Patients treated with benign neglect must usually have a functioning contralateral shoulder to be able to function independently in their activities of daily living.

Closed Reduction

The success of closed reduction is very unlikely in a locked anterior dislocation more than 3 weeks old.[12,36] Because the incidence of vascular injuries reported with closed reductions performed in the setting of a chronic injury is high, we do not recommend an attempt at closed reduction if the injury is older than 3 weeks.[4] This holds especially true for older patients. If a closed reduction is to be attempted, careful evaluation of preoperative radiographs must be done to ensure that there is not an associated fracture of the tuberosities, humeral neck, or glenoid. If an associated fracture is present, it should be addressed, as described in the treatment of locked posterior dislocations. To perform a closed reduction, slow gentle traction under general anesthesia or scalene block is required. Torque on the arm must be kept to a minimum to prevent humeral fracture.

Open Reduction

If the impaction fracture of the humeral head involves more than 25% of the articular surface or the dislocation is more than 3 weeks old, the patient will require an open reduction. As previously stated, surgical exposure in chronic anterior dislocations requires careful handling of soft tissues to prevent damage to the neurovascular

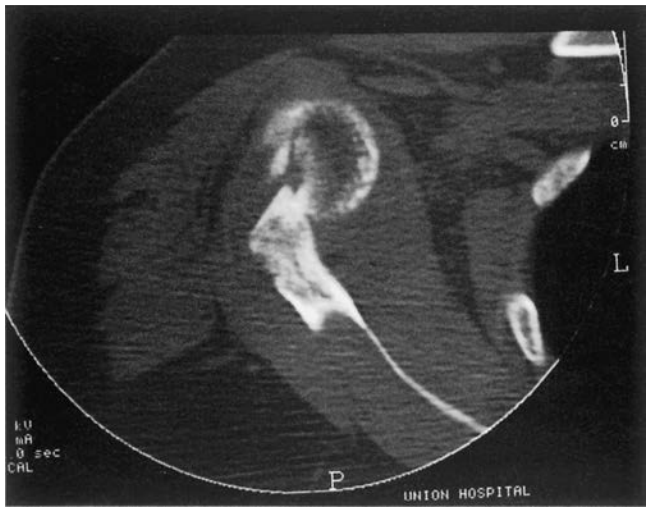

Figure 15-16 Computed tomography scan of the patient in Figs. 15-14 and 15-15 with a locked anterior dislocation. The glenoid was relatively preserved, with a Hill-Sachs lesion of approximately 25%. (Courtesy of Jeffrey S. Noble, MD, Akron, OH.)

structures. The anterior labrum and glenoid will also require special attention to regain stability after reduction.

We will first describe the surgical approach to the shoulder and then we will discuss the surgical management of the capsulolabral complex and the deficient glenoid. This will then be followed by a discussion of the surgical options for treatment of the humeral head defect.

Surgical Approach

A long deltopectoral approach is employed for anterior dislocations. The incision extends from just proximal to the coracoid to just medial to the deltoid insertion. An osteotomy of the coracoid process with its attached conjoined tendon is often necessary to aid in exposure of the medially displaced humeral head in chronic cases. If an osteotomy is necessary, the coracoid may be predrilled and the hole tapped prior to performing the osteotomy. This will ensure anatomic alignment of the coracoid at the time of reduction. At the time of closure, the coracoid is fixed with a partially threaded cancellous screw. Alternatively, the coracoid can be reattached with interfragmentary sutures; this does not provide rigid fixation nor anatomic reduction but is often sufficient for stable healing. After the osteotomy is complete, the conjoined tendon is reflected medially to allow identification of the neurovascular structures. These structures must be gently retracted to avoid injury. Release of the superior portion of the pectoralis major tendon is helpful to gain access to the

inferior portion of the subscapularis tendon and axillary nerve.

The subscapularis is then carefully dissected. Its anterior surface is freed of any adhesions to ensure that the brachial plexus is not adherent to it. The axillary nerve must be identified and freed from the inferior border of the subscapularis. For chronic dislocations requiring extensive dissection in this area, the axillary artery is at risk of injury and may require repair. Identifying an available vascular surgeon to be immediately available to scrub into the case is suggested in case severe bleeding occurs. This added precaution is particularly important in older persons in whom the vascular tissue tends to be more friable and at greater risk for tearing during dissection. Once free of adhesions, the entire subscapularis tendon is released just medial to its insertion into the lesser tuberosity.

The next step is the capsulotomy. The capsulotomy is performed by releasing the capsule from its humeral insertion. This is in contrast to the vertical capsulotomy performed during the approach to the posteriorly dislocated shoulder. The anterior capsule is attenuated by the dislocated humeral head. The inferior capsule, on the other hand, is contracted and tethers the humeral neck to the anteroinferior glenoid.[11] Before releasing the inferior capsule, the axillary nerve must be clearly identified and retracted to prevent injury. Once take-down of the capsule is performed, a Cobb elevator can be used to reduce the humeral head. Scar and granulation tissue must be débrided from the glenoid to allow reduction.

Once reduction is obtained, a posterior capsulotomy is performed along the glenoid margin. This maneuver allows internal rotation of the arm and helps to prevent the tendency toward redislocation caused by the tight posterior capsule. A humeral head retractor is often required to allow access to the posterior capsule. After the capsulotomy is completed, a Cobb elevator is used to ensure that the capsule is free from the posterior aspect of its glenoid insertion.

Locked anterior dislocations of the shoulder require reconstruction of the anteroinferior capsulolabral complex

Figure 15-19 Nonoperatively treated patient with a chronic, locked anterior dislocation who refused surgery: **(A)** Plain radiograph demonstrates the osteopenia associated with a chronic dislocation. The patient has decreased functional capacity **(B–D)** of the right arm, but is able to perform her daily activities with only mild discomfort.

(the Bankart lesion), as described by Rowe and Zarins in 1981.[34] A soft tissue Bankart lesion can be repaired with suture anchors placed onto the glenoid margin (Fig. 15-20). A bony Bankart lesion requires fixation of the bony fragment and its attached labrum back onto the glenoid. If there is marked loss of the glenoid surface by erosion, then a reconstruction of the glenoid may be required.

Glenoid Reconstruction

In cases of glenoid bone loss, a bone graft may be required to reconstruct the anterior glenoid rim. Smaller defects involving less than 20% of the glenoid surface may be reconstructed with a capsulolabral repair, reinforced with a Bristow procedure. A standard Bankart repair is performed, using suture anchors to reattach the capsulolabral complex to the margin of the remaining glenoid. The tip of the coracoid with its attached conjoined tendon is then fixed in an extraarticular fashion to the anteroinferior portion of the glenoid with a bicortical screw (Fig. 15-21). This bone block acts as a secondary restraint to anterior translation. The capsule and subscapularis tendon are then repaired in typical fashion.

If the lesion involves greater than 20% of the glenoid, then reconstruction with a tricortical iliac crest bone graft is required. The reconstruction must create a stable surface for the humeral head to articulate. Reconstruction of the glenoid is performed by first exposing its anterior surface

Figure 15-20 The patient in Figs. 15-14, 15-15, and 15-16 was reduced with an open reduction and take-down of the coracoid process for exposure: **(A)** Postreduction radiograph reveals a concentric reduction of the glenohumeral joint with repair of the capsulolabral complex. Follow-up clinical radiographs show excellent return of **(B)** forward elevation and **(C)** rotation after return of the axillary nerve. (Courtesy of Jeffrey S. Noble, MD, Akron, OH.)

by subperiosteal dissection. A burr is used to roughen the anterior glenoid to create an adequately flat surface for grafting. The size of the defect is then estimated, and a size-matched corticocancellous piece of iliac crest is harvested. The cortical surface of the graft is placed flush with the articular surface of the glenoid. The graft is then fixed to the anterior glenoid by partially threaded cancellous screws. The screws are placed parallel to the joint surface in a lagged fashion and in an anteroposterior direction. The donor graft is fashioned with a burr to allow a smooth transition from the glenoid cartilage to the graft reconstruction. The anteroinferior capsulolabral complex is then attached to the graft, using suture anchors (Fig. 15-22).

In the presence of degenerative arthritis or defects involving more than 50% of the glenoid surface, a total shoulder replacement is the treatment of choice. In this instance, the resected humeral head is used to reconstruct the glenoid. This reconstructed surface is used to support the glenoid component in a total shoulder replacement.

Postoperative rehabilitation for glenoid reconstruction must protect the anterior glenoid. A sling is worn for approximately 6 weeks and external rotation and motions posterior to the plane of the scapula are avoided.

Goga reported on 10 cases that he treated with an open reduction followed by a Bankart repair reinforced with a Bristow procedure.[14] He also utilized an acromiohumeral pin for 4 weeks. Outcomes evaluated using the method proposed by Rowe and Zarins: there were three excellent, five good, and two fair results.

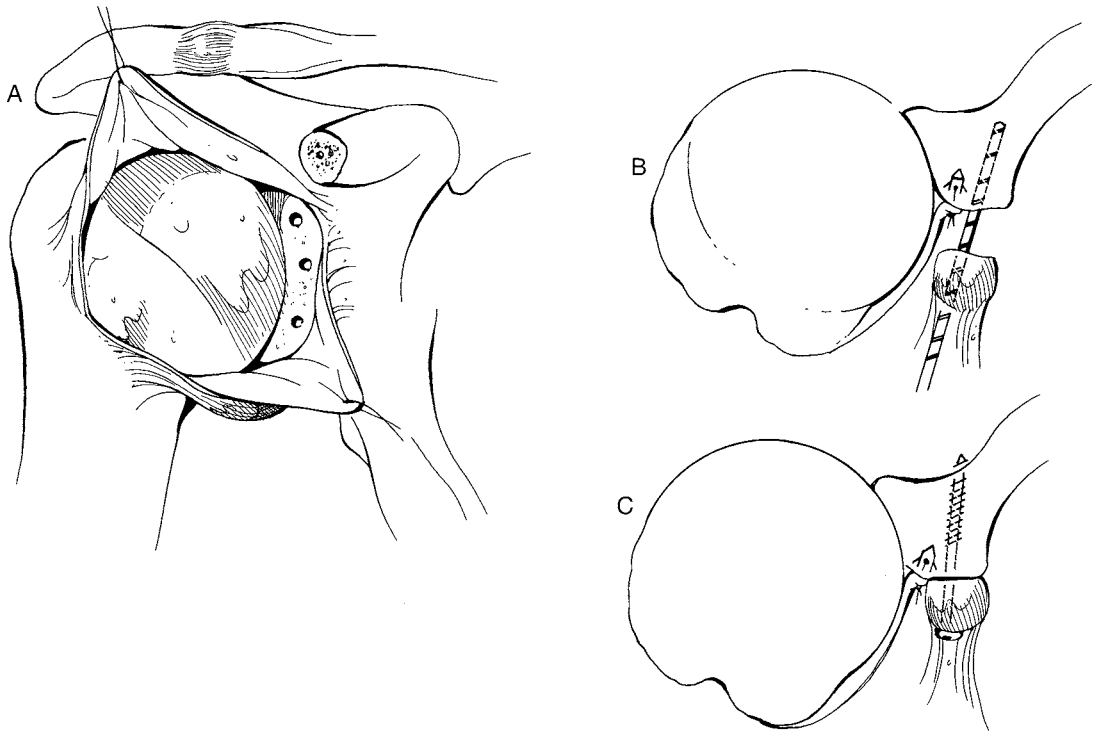

Figure 15-21 With moderate glenoid bone loss, an anterior capsulorrhaphy and coracoid transfer are performed. **(A)** The anchors are placed at the glenoid rim and the sutures are passed through the capsule and labrum, but not yet tied. **(B,C)** The glenoid defect is decorticated and the distal 1.5 cm of the coracoid are transferred to the defect and secured with a partially threaded screw.

Reconstruction of the Humeral Head Defect

As seen in the treatment of locked posterior dislocations of the shoulder, the choice of treatment will greatly depend on the size of the humeral head impaction fracture and the time from injury. Small Hill-Sachs lesions involving less than 25% of the humeral head often do not require attention. However, if the shoulder remains unstable after reduction, then transfer of the infraspinatus tendon may be required to obtain stability.

Defects larger than 25% of the humeral head should be addressed if the reduction of the glenohumeral joint is to be maintained. If the defect involves between 25% and 45% of the articular surface, the choices for treatment are the following: disimpaction with bone grafting, if the injury is less than 3 weeks old and there is adequate bone stock; allograft reconstruction, if the injury is more than 3 weeks old and the bone stock is adequate; or shoulder arthroplasty, if there is marked osteopenia or articular cartilage wear. Any defect involving more than 50% of the humeral head should be treated with an arthroplasty.

Disimpaction and Bone Grafting

If the humeral head defect involves between 20% and 40% of the humeral head and the injury is less than 3 weeks old, then disimpaction and bone grafting can be attempted. The indications and intraoperative evaluation of the humeral head are similar to those described for the posterior locked dislocation. In treating the Hill-Sachs lesion, the cortical window is created in the lesser tuberosity. Disimpaction and bone grafting are then carried out as described in Fig. 15-9.

The patient is placed in a sling for 3 weeks. Rehabilitation is begun on postoperative day 1. Gentle range of motion is begun, with care taken to avoid placing the arm in a position that would place stress on the disimpacted area. The positions to avoid should be determined at the time of surgery. In general, these will be abduction and external rotation. These motions should be avoided for approximately 6 weeks, until the graft has had time to consolidate.

Transfer of the Infraspinatus Tendon (Defects Less Than 25%)

The glenohumeral joint is exposed, as described previously. The shoulder is reduced and the size of the defect confirmed. The shoulder is then taken through a range of motion, and the position of instability is noted. If the shoulder is unstable at less than 90 degrees of abduction and 90 degrees of external rotation, an infraspinatus

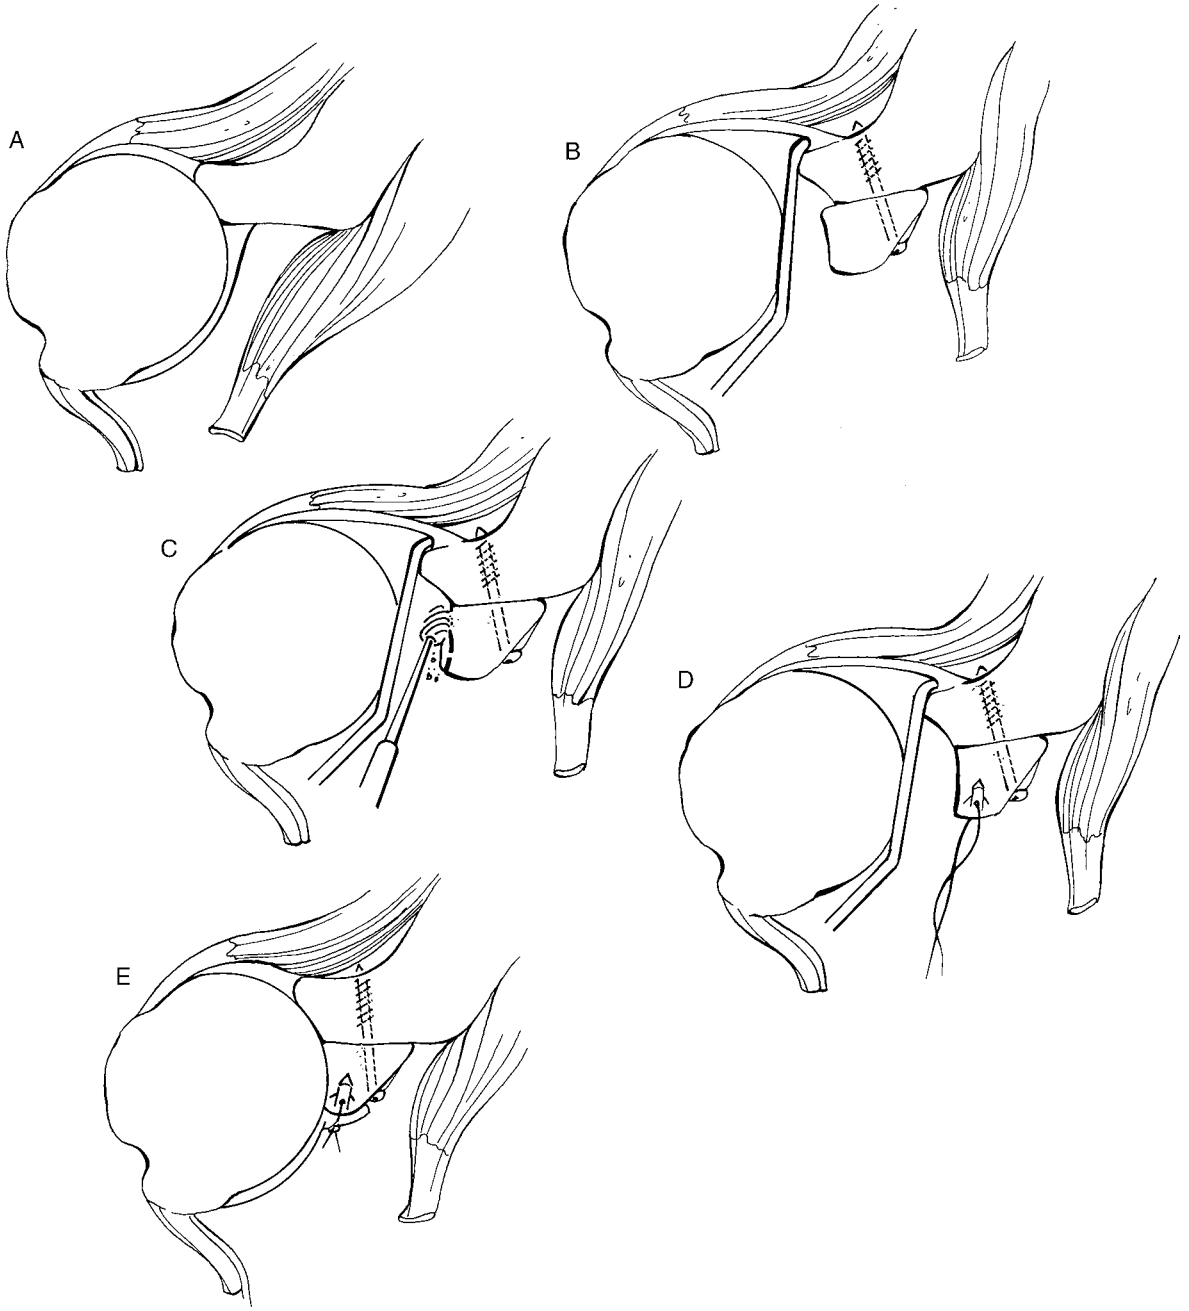

Figure 15-22 **(A)** For large anterior glenoid defects an iliac crest graft is used to reconstruct the glenoid defect. **(B)** The defect is decorticated and made flat. A bicortical iliac crest graft is placed with its cancellous surface against the cancellous bone of the defect and secured with two partially threaded screws. **(C)** The position of the graft, which overhangs the face of the glenoid, is burred down to make a smooth contour with the native glenoid. **(D)** Suture anchors are placed into the rim of the graft. **(E)** The limbs of each suture are passed through the capsule and labrum, thereby repairing the ligaments to the new glenoid rim.

transfer is performed through a posterior approach. The Hill-Sachs defect is débrided and the infraspinatus is released from its insertion and reattached into the base of the defect by transosseous sutures.

Postoperative rehabilitation is centered around early passive motion that avoids the position of recurrent dislocation. In anterior dislocations, the position to avoid is motion posterior to the plane of the scapula, such as abduction and external rotation. On postoperative day 1, pendulums and supine forward elevation with the arm in internal rotation are begun. After 6 weeks, the patient is allowed to begin stretching in external rotation and abduction.

Strengthening is reserved for approximately 10 to 12 weeks after surgery, and after a full stable range of motion is obtained.

Arthroscopic Repair

In 2003, Yanmis et al. presented their technique and preliminary results using arthroscopy to assist in the treatment of locked anterior dislocations of the shoulder.[42] They felt that the addition of an arthroscopic evaluation of the shoulder could aid in reduction of the shoulder, be used to clear the joint of fibrotic tissue, and assess the status of the articular surfaces. Any associated labral detachment could then be repaired arthroscopically. The success of this method of treatment is substantially dependent on the pliability of the soft tissues. Therefore, it is less likely to be successful if the dislocation has been present for more than 6 weeks. If preoperative evaluation indicates that the impaction of the humeral head involves less than 25% and that the only reconstruction that will be required is that of the detached labrum, arthroscopic management may be possible. However, advanced arthroscopic skills are required. Therefore, the applicability of this method to more than a small number of highly skilled arthroscopists is questionable.

Allograft Reconstruction

If the Hill-Sachs lesion involves between 25% and 45% of the humeral head, then allograft reconstruction can be performed.[12,41] For this technique to be successful, the patient must have good bone stock and a suitable articular cartilage. Historically, defects of this size have been addressed with infraspinatus transfer into the defect, structural bone grafting of the defect, or humeral head replacement. More recently, Gerber has reported success treating this type of defect with allograft reconstruction[12] (Fig. 15-23). He stressed that allograft reconstruction requires good bone

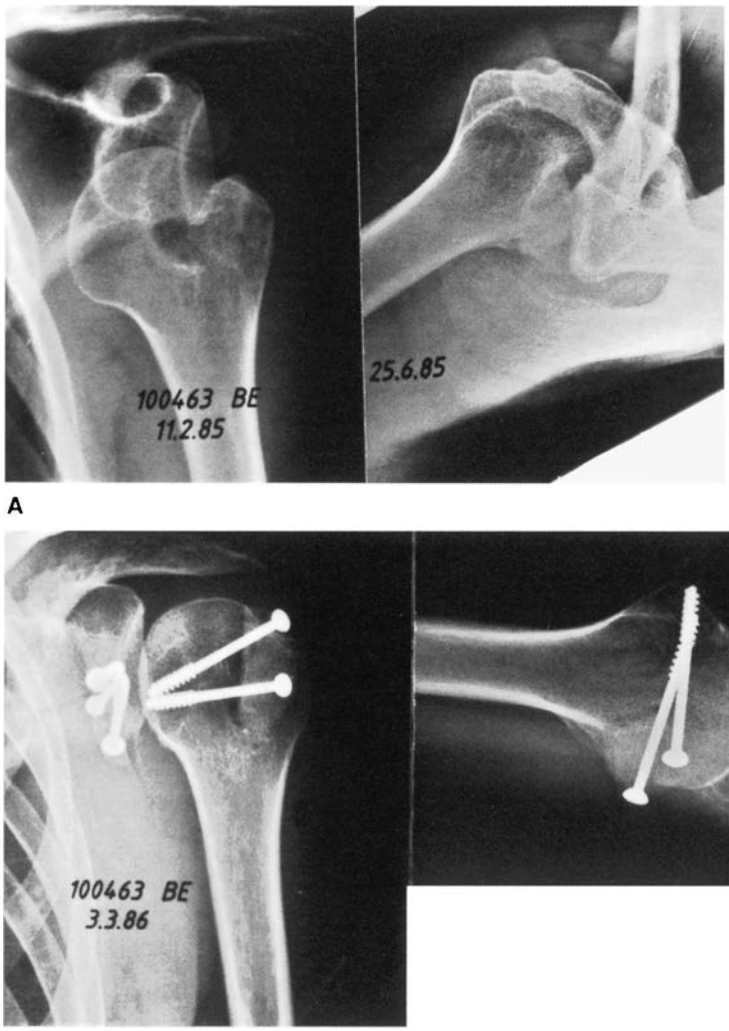

Figure 15-23 Radiographs of a patient with **(A)** a severe humeral head defect that was reconstructed with **(B)** an allograft and the glenoid augmented with a modified Bristow bone block. (From de Laat EA, Visser CP, Coene LN, Pahlplatz PV, Tavy DL. Nerve lesions in primary shoulder dislocations and humeral neck fractures. A prospective clinical and EMG study. *J Bone Joint Surg Br* 1994;76:381–383, with permission.)

stock in the remaining humeral head to prevent collapse. Dislocations of more than 6 months often have poor bone stock, and collapse of the humeral head following reduction is common.[11,33] If osteopenia is present, then humeral head replacement would be the better option in these patients.

Allograft reconstruction of a posterolateral Hill-Sachs lesion from an anterior approach requires extensive exposure. To allow access to the posterior aspect of the humeral head, the entire subscapularis insertion needs to be detached. The ascending branch of the anterior circumflex humeral artery must be protected to prevent vascular compromise to the humeral head. The capsule must then be released around its circumference. The arm can then be brought into adduction, external rotation, and extension to gain access to the posterior head. The allograft is fashioned to fit the defect and is fixed into place with either a headless compression screw such as the Herbert screw or a counter sunk 3.5-mm screw.

Postoperatively, the patient is placed in a sling. Rehabilitation consists of gentle pendulums and passive supine elevation, with avoidance of external rotation beyond 0 degrees for 6 weeks. At 6 weeks, the patient is allowed full motion of the shoulder and light strengthening is begun. No heavy lifting is allowed for 3 months.

Gerber has reported good results in a small series of patients treated with this procedure. Postoperative elevation averaged 145 degrees with a Constant score averaging 70%.[12]

Prosthetic Reconstruction

In patients with greater than 50% involvement of the articular surface of the humeral head, shoulder arthroplasty is the treatment of choice. Arthroplasty is also the treatment of choice in patients with marked osteopenia or loss of articular surface integrity. Some authors have actually reported collapse of the articular surface of the humeral head after reduction of a long-standing dislocation.[11,33] Therefore, a humeral head replacement will often be needed for dislocations that are older than 6 months.

When performing a humeral head replacement to treat a locked anterior dislocation, the surgeon should attempt to place the prosthesis in approximately 30 degrees of retroversion. If the glenoid is deficient, it must be reconstructed using autograft bone from the resected head. If the defect in the glenoid is larger than 50% of the glenoid surface or the remaining glenoid is arthritic, then placement of a glenoid component is required.

Any rotator cuff tears encountered during prosthetic replacement should be repaired.[11,33] The rotator cuff aids in stability of the shoulder and prevents superior migration of the humeral head. The repair is performed after the head is excised and before prosthetic fixation.

Flatow and colleagues reported on nine chronic anterior dislocations of the shoulder treated with total shoulder replacement, with four excellent, four satisfactory, and one unsatisfactory result.[11] The surgically treated group far outscored the nonsurgically treated group, with average active forward elevation to 147 degrees and average active external rotation to 69 degrees. All were able to function well with activities of daily living.

Some authors suggest that the version of the prosthesis can be adjusted to compensate for the chronic dislocation and aid in preventing a recurrent dislocation.[11,32] Pritchett and Clark reported a series of seven patients for whom the retroversion was increased 30 to 50 degrees, with no episodes of recurrent dislocation. All patients improved, with five good and two poor results.[32]

Postoperative rehabilitation is instituted on day 1. Gentle range of motion anterior to the plane of the scapula, with avoidance of provocative positions, is performed for 4 to 6 weeks. If the shoulder remains unstable at the end of the procedure, then the shoulder can be immobilized in a sling for 3 weeks to allow the soft tissues to scar. After 3 weeks, the sling is removed and gentle range of motion is begun. In this scenario, the position of instability is avoided for 6 weeks. No heavy activity is allowed for 3 months.

Resection of the Humeral Head

Resection is undertaken only for intractable pain in a shoulder that can not be reconstructed. In Rowe and Zarins' series, three out of four resections resulted in only fair results.[35] Although reported series are small, resection is inferior to nonoperative treatment, as far as functional outcome is concerned.

SUMMARY

Locked dislocations of the shoulder are rare injuries. Because of this, there are only a small number of series addressing the management of these difficult injuries. In this chapter, we have attempted to summarize the treatment recommendations given in the literature and the results obtained using each method. We have added to this information our own approach to the treatment of locked dislocations of the shoulder. For injuries involving less than 20% or more than 50% of the humeral head, the choice of treatment is rather straightforward. However, injuries involving 20% to 50% of the humeral head require that the surgeon understand the benefits and limitations of each of the treatments discussed. The percentages of humeral head involvement given for determining which treatment to use, as well as the time from injury listed, are only meant to serve as a guide during decision making. The surgeon must make his or her surgical choice based on the individual patient factors discussed and on the findings at the time of surgery.

SUMMARY 531

INTRODUCTION

Rarely do we as surgeons proceed as confidently as when we operate for recurrent instability. For traumatic instability, a surgeon can confidently inform his or her patient that the patient's chances of returning to near-normal function are greater than 90%. When instability surgery fails, however, that surgical confidence can deflate as fast as a punctured balloon. Faced with the patient who has suffered multiple failures of instability surgery, we as surgeons can become thoroughly humbled. This chapter will explore the common causes of failure after instability surgery, how to avoid these failures, and techniques for recovery.

OPEN REPAIRS FOR ANTERIOR INSTABILITY

Recurrent anterior glenohumeral instability occurs most often following a significant traumatic incident and is often referred to as recurrent traumatic instability. This traumatic event usually takes place with the arm in an abducted, extended, and externally rotated position. Glenohumeral dislocation reproduced in the laboratory demonstrates a severe and explosive event, supporting the destructive pathology noted in the shoulders of these patients. As many as 84% to 97% of these patients will have avulsions of the anteroinferior capsulolabral complex from the glenoid rim (the so-called Bankart or Perthes lesion).[16,166,168,225,259] A wide array of factors can be responsible for failure of this repair (Table 16-1).

Recurrence of Instability

Incidence

The most common complication reported after repair for anterior instability is recurrence of instability.[35,98,200,221,228,294] The exact rate of instability recurrence depends on the specific surgical correction employed at the time of the index procedure, but ranges from 3% to almost 50%.[18,75,168,169]

Etiology

Numerous causes may be responsible for recurrence of instability after previous surgical repair (Table 16-2).

TABLE 16-1
CAUSES OF FAILURE OF OPEN ANTERIOR INSTABILITY REPAIRS

Recurrence of instability	Subscapularis failure
Loss of motion	Hardware complications
Capsulorrhaphy arthropathy	Neurovascular injury

TABLE 16-2
ETIOLOGY OF RECURRENT INSTABILITY AFTER ANTERIOR REPAIR

Decision-making errors	Anatomic factors
Incorrect diagnosis	Glenoid concavity defect
Incorrect surgical procedure	Residual capsular laxity
Voluntary instability	Anterior capsular deficiency
Surgical errors	Hill-Sachs lesion
Technical errors	
Other	
Severe recurrent trauma	

Although discussed individually, several of these situations may coexist in the same patient. In the patient with instability recurrence, the revision surgeon must consciously rule out each of these causes before choosing a course of action.

Incorrect Diagnosis

In an ideal world, every patient with recurrent traumatic anterior instability would present to the surgeon with a radiograph demonstrating the dislocation. In the absence of a radiograph, the patient would give a clear history of instability events directly related to positioning the arm in abduction, extension, and external rotation. Unfortunately, as is usually true in medicine, patients rarely read the textbook before giving their history. Deciding on the direction of instability, or differentiating unidirectional traumatic from multidirectional instability, can sometimes be a confusing task, and the diagnosis should be made by thorough history, examination, and radiographic analysis.

Accurate determination of the direction of instability is crucial for obtaining satisfactory results after instability surgery. Even Hippocrates recognized the importance of performing the corrective procedure at the precise location of instability and the worsening that might result from misdiagnosis:[4]

> For many physicians have burned the shoulders subject to dislocation, at the top of the shoulder, at the anterior part where the head of the humerus protrudes, and a little behind the top of the shoulder; these burnings, if the dislocation of the arm were upward, or forward, or backward, would have been properly performed; but now, when the dislocation is downward, they rather promote than prevent dislocations.

If a patient with recurrent anterior instability is incorrectly diagnosed as having posterior instability, a posterior repair would result in continued or worsened anterior instability.[18,35,101,143,168,294] Subsequent appropriate anterior repair would result in an excessively tight shoulder. Similarly, if an anterior repair is performed, but the true diagnosis

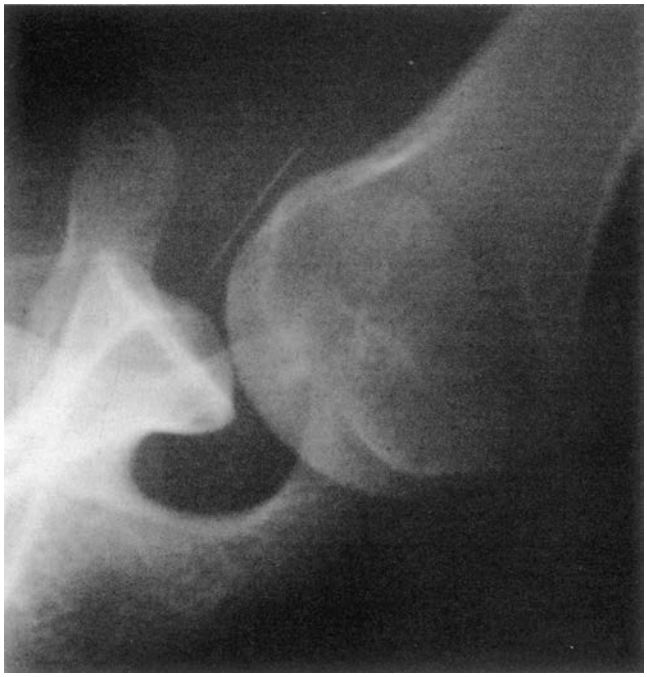

Figure 16-1 Axillary radiograph of a 24-year-old man who underwent a Putti-Platt procedure for presumed recurrent anterior instability when the true diagnosis was recurrent posterior instability. Symptomatic posterior instability was worsened by the anterior repair. (Courtesy of Douglas T. Harryman II, University of Washington Medical Center, Seattle, WA.)

is multidirectional or posterior instability, posterior displacement may be worsened (Fig. 16-1).

Hawkins and Hawkins reviewed cases of recurrent instability after surgical repair and attempted to retrospectively assign a cause to the repair failure.[98] In 12 of 31 patients, the authors believed that the primary cause of surgical failure was in the diagnosis, usually a confusion of direction of instability or type of instability. McAuliffe et al., in an analysis of 36 patients with failed instability repairs, found that 15 of those patients had recurrence secondary to misdiagnosis.[175] Norris and Bigliani determined that 9 of 42 patients with recurrent instability were incorrectly diagnosed, including four who underwent surgery on the incorrect side of the shoulder.[198] Rockwood and Gerber thought that the cause of recurrent, postoperative instability in 68% of 57 reported patients was failure to recognize multidirectional instability.[221] Finally, Burkhead and Richie analyzed 23 patients with postoperative instability and determined that, for 5 of 23, the diagnosis of multidirectional instability had been missed.[35]

Surgery for glenohumeral instability will also result in failure if the underlying diagnosis is not instability.[198] Through recent teachings, we have correctly become more alert to the potential of instability as a cause of shoulder pain in the young population. However, not all shoulder pain in the young patient indicates occult instability. Unless the diagnosis of glenohumeral instability is truly indicated by history and physical examination and is demonstrated by an examination under anesthesia, instability surgery should not be performed.

Incorrect Surgical Procedure

In most patients with recurrent anterior instability, the pathologic defect is a tear of the anteroinferior glenoid labrum and origin of the inferior glenohumeral ligament, necessitating a repair of this defect to provide stability.[16,166,168,225,259] In the literature, however, more than 150 different operative procedures have been described in the treatment of recurrent traumatic anterior instability. The "anatomic" surgical correction restores the labrum to its preinjury anatomic position. Other surgical techniques to correct instability are "nonanatomic." As a general rule, these alternative procedures do not address the inherent pathology and are associated with a greater likelihood of instability recurrence.[110,168,169] These procedures attempt to compensate for labral or capsular pathology by osseous blocks or soft tissue tightening or advancements. No attempts are made to correct labral pathology. Examples include the Putti-Platt, which shortens the subscapularis; the Bristow or Laterjet, which osteotomizes and transfers the coracoid to the glenoid rim and blocks translation; or the Magnuson-Stack, which advances the subscapularis. Despite advances in arthroscopic treatment of instability, open treatment remains a reliable method with low recurrence. It may, indeed, be the preferred treatment for pathology not adequately treated by arthroscopic means including soft tissue or bony deficiency. Although surgeries that involve bone blocks, subscapularis reefing, and musculotendinous slings may be technically easier than a Bankart repair, these procedures do not address the pathologic anatomy; therefore, they have higher rates of postoperative instability.

Rowe et al. reviewed the results of surgical correction after a prior failure of instability surgery.[228] In 84% of their patients, they found residual, unrepaired Bankart lesions at the time of revision surgery. With revision surgery, usually a Bankart repair, they were able to restore stability in 92% of patients. Hawkins and Hawkins found residual anteroinferior labral detachments in most of their patients who underwent surgery for recurrence of instability.[98]

Revising non-Bankart instability operations can often be a formidable challenge. These procedures are all usually accomplished through an anterior deltopectoral approach. If a surgeon is contemplating revision surgery when he or she did not perform the index procedure, review of the operative note from that index procedure is crucial to determine the nature of the index operation and possible difficulties revision might entail. Radiographs should also be evaluated for hardware and other hints as to the index operation.

Particular note is made of revision of procedures that involve transfer of the coracoid process (Bristow and Laterjet

operations). Coracoid transfer procedures carry historic recurrence rates ranging from 2% to 33.5%. In addition, arthritis may occur in up to 60% of patients. Subscapularis shortening secondary to dense scar formation has also been reported with subsequent loss of external rotation. Several new studies, however, have shown improved results. Hovelius et al.[109] reviewed 118 cases over 15 years and found a 3.4% recurrent rate with high patient satisfaction. Allain et al.[5] reviewed 95 Laterjet procedures over 14 years. There were no redislocations and an 88% satisfaction rate. Although nonanatomic repairs such as the Laterjet or Bristow technique have enjoyed some recent success, these techniques are not commonly performed unless severe bone loss or irreparable capsulolabral deficiency exists.

Young and Rockwood described in detail the surgical difficulties encountered in revising a failed Bristow procedure.[292] Specifically, loss of normal anatomic landmarks, extensive scar formation, and subscapularis deficiency all made surgery difficult. Matsen et al. have coined the phrase "lighthouse of the shoulder" to describe the coracoid process, meaning that the coracoid can guide a surgeon between the "safe" lateral side of the conjoined tendon and the "suicide" medial side.[166] Revision surgery without this lighthouse, as in after coracoid transfer procedures, is technically demanding and dangerous.

Surgical results after a previous Bristow operation may also be less gratifying than after other surgical procedures. For those patients with recurrent instability, Young and Rockwood obtained good or excellent results in 8 of 13.[292] Because of the associated problems of scar formation, hardware problems, and articular degeneration, the overall success rate at revision surgery was only 50%.

Technical Error

As much as we all wish to perform the perfect surgery in each and every case, there are times when the procedure does not proceed exactly as anticipated. The goal of the Bankart procedure is repair of the anterior glenoid labrum and inferior glenohumeral ligament (IGHL) to the glenoid rim. Although the surgeon may set out to perform a Bankart repair, difficulty with the exposure or unfamiliarity with the anatomy may result in the surgical goals being left unaccomplished.
