History and physical examination are usually sufficient to exclude systemic causes of edema. ED visits for this minor heat-related syndrome are usually by elderly patients with concerns focused on the early development of congestive heart failure or deep venous thrombosis. Heat edema usually resolves spontaneously in a few days but may take up to 6 weeks. No special treatment is necessary. If a patient is insistent on treatment, elevation of the legs and the use of support hose will facilitate the removal of the interstitial fluid. Diuretics are not effective and can predispose to volume depletion, electrolyte abnormalities, or a more serious heat illness.¹⁰

Prickly Heat

This is a pruritic, maculopapular, erythematous rash over clothed areas of the body. Also known as *lichen tropicus*, *miliaria rubra*, or *heat rash*, it is an acute inflammation of the sweat ducts caused by blockage of the sweat pores by macerated stratum corneum. The ducts become dilated under pressure and ultimately rupture, producing superficial vesicles in the malpighian layer of the skin on a red base. Itching is the predominant clinical feature during this phase and is treated successfully with antihistamines. Wearing clean, light, and loose-fitting clothing and avoiding sweat-generating situations can prevent prickly heat. The use of talc or baby powder is of no benefit. Chlorhexidine in a light cream or lotion is the treatment of choice in the acute phase.

With prolonged or repeated heat exposure, a keratin plug fills the sweat duct, causing obstruction in the stratum malpighian layer. When the duct ruptures a second time, the resultant vesicle will be driven deeper into the dermis. This vesicle simulates the white papules of piloerection and is not pruritic. This is known as the *profunda stage* of prickly heat (*miliaria profunda*) and can readily advance into a chronic dermatitis. Infection with *Staphylococcus aureus* is a common complication and requires the use of dicloxacillin or erythromycin. The skin can be desquamated by applying 1% salicylic acid to the affected area three times a day. Caution should be used to avoid salicylate toxicity.

Heat Cramps

Heat cramps are painful, involuntary, spasmodic contractions of skeletal muscles, usually those of the calves, although they may involve the thighs and shoulders. These cramps usually occur in individuals who are sweating profusely and replace fluid losses with water or other hypotonic solutions. Heat cramps may occasionally occur during exercise or, more commonly, during a rest period after several hours of vigorous physical activity. Nonacclimatized or unconditioned individuals who are just starting manual labor in a hot environment are at high risk for developing heat cramps. Although heat cramps are self-limited and do not cause significant morbidity, the pain associated with them can readily precipitate an ED visit. In fact, the pain associated with heat cramps usually does not respond to opiates alone. In general, heat cramps are short in duration, limited to a definitive group of muscles, and do not involve enough muscle mass to cause rhabdomyolysis.

The pathogenesis of heat cramps is attributed to a relative deficiency of sodium, potassium, and fluid at the cellular level of the muscle. The production of large amounts of sweat, which has high sodium content, coupled with inadequate sodium replacement result in cellular hyponatremia. This in turn produces muscle cramps with calcium-dependent muscle relaxation. Hypokalemia from hyperventilation and volume depletion may be contributing factors.

Treatment consists of fluid and salt replacement (PO or IV) and rest in a cool environment. **For mild cases, or if an overwhelming number of patients require treatment, a 0.1 to 0.2% saline solution can be given PO. Two 10-grain (650 mg) salt tablets dissolved in a quart of water provide a 0.1% saline solution.** Many such electrolyte solution drinks (sports drinks) are commercially available and are much more palatable than 0.1% saline solution. More severe cases of heat cramps will respond to intravenous rehydration with NS. Patients with severe heat cramps may actually have hyponatremia and hypochloremia. Rarely, rhabdomyolysis occurs secondary to diffuse and protracted muscle spasm.

Heat cramps can be prevented by maintaining adequate dietary salt intake or by drinking commercial electrolyte beverages. Salt tablets by themselves should not be used because the tablets are a gastric irritant and often result in nausea and vomiting, and alone, they do not replace volume.

Heat Tetany

Heat tetany is produced by hyperventilation associated with exposure to short periods of intense heat stress. This syndrome presents as typical hyperventilation resulting in respiratory alkalosis, paresthesia of the extremities, circumoral paresthesia, and carpopedal spasm. Heat tetany can be differentiated from heat cramps by the fact there is very little pain or cramps in the muscle compartments, and paresthesias of the extremities and perioral region are more prominent. In general, concomitant heat cramps are not present. Treatment consists of removal from the heat and decreasing the respiratory rate.

Heat Syncope

Heat syncope is a variant of postural hypotension resulting from the cumulative effect of relative volume depletion, peripheral vasodilatation, and decreased vasomotor tone. It occurs most commonly in nonacclimatized individuals during the early stages of heat exposure. Accordingly, geriatric patients tend to demonstrate the highest incidence of this "minor" heat illness. It does not necessarily represent a state of significant volume depletion.

Evaluation of patients with heat syncope requires exclusion of metabolic, cardiovascular, and neurologic disorders that may produce syncope. In geriatric patients, this will commonly require a significant evaluation. Treatment consists of removal from the heat source, oral or intravenous rehydration, and rest. Many patients with heat syncope re-

cover promptly with fluids, and hospitalization usually is not necessary. Patient education about measures to diminish the effects of venous pooling when standing are very important to prevent future syncope episodes or injury.

Heat Exhaustion

Heat exhaustion is an acute heat-related illness that reflects significant volume depletion and may or may not have an elevated temperature. This is a syndrome characterized by nonspecific symptoms, such as weakness, malaise, lightheadedness, fatigue, dizziness, nausea, vomiting, frontal headache, and myalgias. Clinical manifestations include orthostatic hypotension, sinus tachycardia, tachypnea, diaphoresis, and syncope. The core temperature is variable and can range from normal to 40°C (104°F). In heat exhaustion, the mental status remains normal. Because of the ill-defined and nonspecific symptoms, heat exhaustion is a diagnosis of exclusion. Heat cramps and/or rhabdomyolysis may also be present on rare occasions. Physiologically, heat exhaustion is characterized by a combination of salt depletion and water depletion.

Laboratory studies almost universally will demonstrate hemoconcentration, although specific electrolyte abnormalities depend on the ratio of fluid and electrolyte losses to intake. Patients who have no fluid intake of any kind usually will have hypernatremia, whereas those who partly rehydrate with salt-containing fluids may develop isotonic hypovolemia with normal sodium and chloride levels. Serum potassium and magnesium levels are variable.

Heat exhaustion is treated with volume and electrolyte replacement and rest. Mild cases may be treated with oral electrolyte solutions. Rapid infusion of moderate amounts of intravenous fluids (1 to 2 L of saline solution) may be necessary in some patients who demonstrate significant tissue hypoperfusion. Ideally, the choice of intravenous solutions should be guided by laboratory determinations, but isotonic salt solutions may be used until specific electrolyte abnormalities are identified. In general, these patients do not require hospitalization. Patients with congestive heart failure or severe electrolyte disturbances may require admission, because of the time element needed to correct their fluid and/or electrolyte deficits.

Heat exhaustion has the potential of progressing to heatstroke. Historically, the differentiation between heat exhaustion and heatstroke consisted of anhidrosis, CNS dysfunction, and a core temperature higher than 40°C.¹³ However, this distinction is suspect for the following reasons. First, the definition of "CNS dysfunction" is not standardized. Is CNS dysfunction delineated by confusion or agitation? Or does it require more severe neurologic impairment, such as delirium, seizure, or coma? Second, the presence of anhidrosis is not always clinically apparent, and patients with exertional heatstroke may still be perspiring upon arrival to the ED. Third, there is no arbitrary core temperature threshold for heatstroke. Thus, the diagnosis of heatstroke is not standardized. However, elevated hepatic enzymes is one objective tool that is really helpful in differentiating between heat exhaustion and heatstroke, especially if the patient presents with "soft" signs of CNS dysfunction, such as confusion or agitation. The only drawback is that elevated hepatic enzymes are a delayed complication of heatstroke.

Heatstroke

The classic definition of heatstroke includes the presence of a core temperature higher than 40°C, CNS dysfunction, and anhidrosis.^{11,13} However, anhidrosis, or a lack of sweating, may not be present for a variety of reasons and is not considered an absolute diagnostic criterion. Subsequently, anyone with hyperpyrexia and CNS dysfunction should be considered to have a heatstroke, which is a medical emergency with multiple organ system involvement and a high mortality rate and requires immediate intervention.^{11,13}

The CNS is particularly vulnerable in heatstroke, with symptoms such as irritability, confusion, bizarre behavior, combativeness, hallucinations, seizures, or coma. The cerebellum is highly sensitive to heat, and ataxia can be an early neurologic finding. Virtually any neurologic abnormality may be present in heatstroke, including plantar responses, decorticate and decerebrate posturing, hemiplegia, status epilepticus, and coma. Seizures are quite common in heatstroke and may be a complication of its treatment when cold-water immersion is used. Cerebral edema is common. Central nervous system dysfunction is universal at core temperatures higher than 42°C (107.6°F), but there is no arbitrary core temperature threshold for neurologic dysfunction in heatstroke. Neurologic injury is a function of the maximum temperature reached and the duration of exposure.¹² Patients with lower temperatures for longer periods do worse than patients with higher temperatures for shorter periods. Further, prehospital treatment may result in the patient having a normal temperature or resolution of the CNS dysfunction when evaluated in the ED.

The presence or absence of sweating has traditionally been one of the important distinctions between true heatstroke and other heat emergencies. Patients with classic heatstroke typically demonstrate marked sweating early on but eventually develop anhidrosis by the time of medical evaluation due to profound volume depletion or sweat gland dysfunction. Conversely, sweating is observed in 50 percent of patients with exertional heatstroke on initial medical assessment. Heatstroke is a total breakdown of thermoregulation. The primary cause is increased endogenous heat production.

The distinction between exertional and nonexertional heatstrokes is not clinically important, because signs, symptoms, and management are the same. The primary factor that contributes to the morbidity and mortality of heat illness is the severity of underlying or comorbid disease¹⁰ and not the absolute height of the core temperature.^{10,13}

The definitive diagnosis of heatstroke is a diagnosis of exclusion (Table 193-1). Once heatstroke is suspected, efforts to lower the body temperature should be initiated immediately by whatever means available, whether in the prehospital or ED setting. A delay in cooling contributes to the mortality rate associated with heatstroke.

TREATMENT OF HEATSTROKE

Initial Resuscitation Standard initial resuscitative measures (adequacy of airway, breathing, and circulation; initiation of high-flow oxygen; use of continuous cardiac monitoring and pulse oximetry; and intravenous access) are appropriate. An initial infusion of NS or LR solution at a rate of 250 mL/h is recommended for most patients. Glucose level should be promptly assessed with a test strip due to the high incidence of hypoglycemia in exertional heatstroke. If a patient has cardiovascular disease or is elderly, it is wise to monitor cardiac filling pressures to guide fluid therapy. This may require a central venous pressure line or a pulmonary artery catheter. A urinary drainage catheter should be inserted. Serial monitoring of the patient's core temperature is best accomplished by inserting an electronic rectal thermistor probe or a temperature probe-equipped urinary drainage catheter. Another option, especially in intubated patients, is the use of an esophageal thermometer.

TABLE 193-1 Differential Diagnosis of Heatstroke

Drug toxicity: anticholinergic toxicity, stimulant toxicity (phencyclidine, cocaine, amphetamines, ephedrine), salicylate toxicity
Drug withdrawal syndrome: ethanol withdrawal Serotonin syndrome Neuroleptic malignant syndrome
Generalized infections: bacterial sepsis, malaria, typhoid fever, tetanus
Central nervous system infections: meningitis, encephalitis, brain abscess
Endocrine derangements: diabetic ketoacidosis, thyroid storm
Neurologic: status epilepticus, cerebral hemorrhage

Diagnostic studies necessary to detect the end-organ sequelae of heatstroke include a complete blood cell count, comprehensive metabolic panel, coagulation profile, creatine phosphokinase, myoglobin, urinalysis, toxicology screen, electrocardiogram, and chest radiograph. A lumbar puncture and computed tomography of the head may also be indicated as part of the evaluation of altered mental status.

Cooling Techniques Rapid reduction of the core temperature to below 40°C (104°F) is the primary goal of treatment and is accomplished by physical cooling techniques.¹³ At present, there are no pharmaceutical agents that facilitate or induce the cooling process in heat stroke. Antipyretics (aspirin and acetaminophen) are not effective in reducing the temperature and can be deleterious to the patient. In clinical practice, the primary physical cooling technique that should be used allows easy patient access, is readily available, is tolerated well by the patient, and is relatively effective (Table 193-2). The two primary methods for physical cooling in the clinical setting are evaporative cooling and cold-water immersion. We feel that the primary cooling modality that best meets these criteria is evaporative cooling. Further, evaporative cooling can be used in the prehospital setting and the ED.

Evaporative cooling is performed by positioning fan(s) close to the completely undressed patient and then spraying tepid water on the patient. Inexpensive plastic spray bottles work best. We avoid covering the patient with sheets and then wetting the sheets, because this impairs evaporation of heat from the skin. Also, one person is needed to monitor and continue cooling the patient. Another effective means of providing evaporative cooling is the Makkah body-cooling unit, which is used widely in the Middle East. It is a common method of treatment for pilgrims traveling to Mecca who succumb to heatstroke. Patients are placed undressed on a modified hammock or litter and sprayed with lukewarm water (15°C; 59°F), and warm air (45°C; 113°F) is blown over them with powerful fans. The unique feature of the Makkah body-cooling unit is that it works best in patients who are vasodilated and live in a dry environment. This modality of therapy would not be ideal for patients in shock or in a humid environment.¹³ Evaporative cooling by means of alcohol sponge baths is not effective

and should not be used due to the possibility of isopropyl alcohol toxicity.

Two problems associated with complications of evaporative cooling are shivering and inability of the cardiac electrodes to adhere to the skin. Shivering is treated primarily with short-acting benzodiazepines and secondarily with phenothiazines. Phenothiazines should be used with caution, because they lower the seizure threshold, can cause hypotension, and their anticholinergic properties may impair sweating. Electrodes can be applied to a patient's back.

Immersion cooling is performed by placing an undressed patient into a tub of ice water deep enough to cover the trunk and extremities. The head must be kept out of the ice water. Cardiac monitoring electrodes and temperature probes must be secured to the patient. Problems associated with immersion cooling include shivering, displacement of monitoring leads, and inability to perform defibrillation or resuscitative procedures. Also, the tub or receptacle in which the patient is placed may not be readily available. The efficiency of immersion has been documented primarily in young, healthy patients without comorbid diseases. Observations suggest that the peripheral vasoconstriction induced by the ice-water immersion may be beneficial in some patients with peripheral vascular disease or hypotension. However, this observation should not be extrapolated to all such patients, and the low peripheral resistance seen in heatstroke cannot be explained by vasodilation alone, implying that a toxin or chemical may be released by the heat-damaged tissues. Needless to say, the efficacy and safety of immersion in classic heatstroke victims or patients with significant comorbid diseases (i.e., coronary artery disease) have not been established, and there have been no controlled studies comparing the effects of these various cooling techniques on cooling times and outcome in patients with heatstroke.

Other adjuncts to evaporative cooling include ice packs to the neck, axillae, and groin. The ice packs are positioned in areas of the body where large blood vessels are relatively superficial and can facilitate the cooling process. Further, ice packs are readily available and non-invasive. Cooling blankets preclude the use of evaporative cooling and work too slowly to be considered an effective primary means of physical cooling.

Special consideration should be given for invasive cooling techniques to be used as adjuncts when the two primary means of physical cooling are not sufficient. The most rapid method of cooling a heatstroke victim is cardiopulmonary bypass. In addition, cardiopulmonary bypass has been established as an effective tool in the treatment of malignant hyperthermia. Although the availability and logistics are major drawbacks, it may be required if a patient is recalcitrant to all other measures. Cold-water gastric lavage, cold-water urinary bladder lavage, and cold-water rectal lavage are other adjunctive measures that can be performed in the ED but require some element of patient cooperation, are labor intensive, have the potential for inducing water intoxication, and are not that effective. Cold-water peritoneal lavage is yet another option but has not been validated in humans. Intravenous infusion of cold intravenous fluids should not be performed due to many complications.

Regardless of the cooling technique chosen, cooling efforts should be discontinued when the rectal temperature reaches 40°C (104°F); continued cooling below this temperature will lead to *overshoot hypothermia*.

TREATMENT OF COMPLICATIONS Complications associated with heatstroke characteristically occur early or late (Table 193-3). In patients with a relatively intact cardiovascular system, heat stress causes a marked increase in heart rate and cardiac contractility; most patients have a high cardiac index, elevated central venous pressure, and low peripheral resistance. The low peripheral resistance is due to the vasodilatation of the vasculature in the skin. Accordingly, hypotension is a common initial finding. The tendency is to treat the hypotension with an aggressive fluid challenge ("fluids wide open");

TABLE 193-2 Comparison of Cooling Techniques

Technique	Advantages	Disadvantages
Evaporative	Simple Readily available Noninvasive Easy patient access Relatively effective	Shivering Difficult to maintain monitoring electrodes in position
Immersion	Noninvasive Relatively effective	Shivering Cumbersome Poorly tolerated Logistically difficult to access Difficult to maintain monitoring electrode and temperature probes
Ice packing	Noninvasive Readily available	Shivering Poorly tolerated
Strategic ice packs	Noninvasive Readily available Can be combined with other techniques	Shivering Poorly tolerated Medium efficiency
Cold gastric lavage	Generally available	Invasive Labor intensive Potential for water intoxication May require airway protection Limited human experience
Cold peritoneal lavage	Theoretically beneficial	Invasive Limited human experience

TABLE 193-3 Complications of Heatstroke

	Initial	Delayed
Vital signs	Hypotension Hypothermia overshoot Hyperthermic rebound	
Muscular	Shivering Rhabdomyolysis

however, pulmonary edema can occur from excessive fluid administration even in young healthy individuals. A pulmonary artery catheter may be necessary in the assessment of appropriate volume replacement. Usually the blood pressure will rise in response to a cautious fluid challenge (250 mL/h), in addition to body cooling. In any age group, the presence of hypotension, decreased cardiac output, and a falling cardiac index indicates a particularly poor prognosis; the combination of a low cardiac output and an elevated central venous pressure or pulmonary artery occlusion pressure warrants the use of vasoactive catecholamines such as dopamine or dobutamine.

The fluid and electrolyte abnormalities vary with the onset and duration of the disorder, underlying disease (especially cardiovascular disease), and prior use of medications, such as diuretics.^{7,10} The most important consideration with respect to fluid and electrolyte abnormalities in heatstroke is that dehydration and volume depletion may not occur in classic heatstroke but are common findings in heat exhaustion. Patients with classic heatstroke usually have a respiratory alkalosis, and those with exertional heatstroke also have a metabolic (lactic) acidosis. Accordingly, if a patient with classic heatstroke has lactic acidosis, the condition is associated with high morbidity and mortality.

Hematologic disorders may be apparent clinically and on laboratory evaluation. Findings of abnormal hemostasis include purpura, petechiae, and conjunctival, gastrointestinal, renal, or pulmonary hemorrhage. Coagulation studies may show thrombocytopenia, hypoprothrombinemia, and hypofibrinogenemia. Thermal injury to the vascular endothelium causes increased platelet aggregation, changes in capillary permeability, thermal deactivation of plasma proteins resulting in a decreased level of clotting factors, and, rarely, disseminated intravascular coagulation or fibrinolysis. All these coagulopathies tend to be a delayed complication of heatstroke, taking several days to develop.

Thermal injury to the liver is such a common finding in heatstroke that it can be used as a marker to help establish the diagnosis of heatstroke as opposed to heat exhaustion, especially if there are "soft" signs of CNS dysfunction, such as confusion or agitation. Although jaundice does not always develop, hepatic enzymes will become sig-

nificantly elevated in a delayed fashion with heatstroke. Enzyme values usually peak 24 to 72 h after the thermal insult and can be attributed to centrilobular necrosis. This in turn can have an impact on the regulation of glucose and clotting factors.¹⁰ The liver damage is almost always reversible, with a full recovery.

Renal damage is also common in heatstroke and can be the result of direct thermal injury to the kidney, rhabdomyolysis, or volume depletion. Clinically, this will be manifested by oliguria, microscopic hematuria, proteinuria, myoglobinuria, and many granular or red cell casts.

DISPOSITION

All the minor heat illnesses except heat exhaustion can be managed totally in the ED, and then patients can be safely discharged to home care and for outpatient follow-up. Patients with heat exhaustion who are at the extremes of age and have substantial volume depletion, significant electrolyte disturbances, comorbid diseases, or heat-induced end-organ damage should be admitted to the hospital.

Heatstroke is a true medical emergency, and all patients with this diagnosis should be admitted to an area appropriate for the level of care required. Patients who are intubated, hemodynamically labile, require invasive hemodynamic monitoring, or who need continued cooling should be admitted to the intensive care unit. If the original health care facility is unable to provide the services needed for quality care, then the patient should be referred to a higher-level facility.

PREVENTION

Serious heat-related illnesses are preventable. General recommendations directed at the individual include (1) decreasing or rescheduling strenuous activity for cooler parts of the day, (2) wearing clothing that is light colored and loose fitting, (3) increasing carbohydrate intake and decreasing protein intake to decrease endogenous heat production, (4) drinking plenty of fluids even when not thirsty, (5) avoiding alcoholic beverages because they promote dehydration, (6) not using salt tablets, (7) avoiding direct exposure to the sun, and (8) taking advantage of the shade.^{10,13}

The incidence of heat-related illnesses also can be significantly reduced by the institution of several public health or public education measures that (1) pay attention to environmental conditions, especially the heat index; (2) provide access to air conditioning for individuals at risk, i.e., promoting visits to malls, distributing air conditioners; (3) emphasize adequate hydration; (4) extend social service care for the chronically ill and the elderly; (5) allow for acclimatization for workers, athletes, and the military; (6) implement paced work schedules for those who need to work under adverse conditions; (7) train coaches, teachers, and youth group leaders about heat-related illnesses; (8) educate the elderly at senior citizen centers; and (9) remind parents that they should never leave their children unattended in an automobile during hot weather.^{13,16} Community health officials and governmental leaders should recognize the need to coordinate and plan the implementation of these measures in advance and not resort to crisis management.

ARTHROPOD BITES AND STINGS

Richard F. Clark Aaron B. Schneir

The phylum Arthropoda is the largest division of the animal kingdom. Venomous bites and stings are a significant worldwide problem.¹ In the United States, the American Association of Poison Control Centers reported 85,713 cases of exposures to arthropods in 2000.² Just over 100 of these were listed as resulting in major or severe reactions, including severe pain, neurotoxicity, or other signs and symptoms. Fatalities among these exposures are rarely reported to poison centers, and usually result from allergic reactions to Hymenoptera stings. Clearly, these numbers are the tip of the iceberg. Toxic reactions to multiple stings by members of the order of Hymenoptera and severe systemic allergic reactions to one or more stings or bites of other insects such as deerflies, blackflies, horseflies, and kissing bugs can all present as emergency, life-threatening situations (Table 194-1).³ Other arthropod envenomations merit review either for causing specific organ system toxicity or as infectious disease vectors. This chapter discusses the more common and serious arthropod envenomations encountered by emergency physicians.

HYMENOPTERA (WASPS, BEES, AND ANTS)

The Hymenoptera are the most important venomous insects known to humans, and more fatalities result from stings by these insects than by stings or bites from any other arthropod. There are three major subgroups or superfamilies of medical importance: (1) *Apidae*, which includes the honeybee and bumblebee; (2) *Vespidae*, which includes yellow jackets, hornets, and wasps; and (3) *Formicidae*, or ants (Figure 194-1).

Bees and Wasps (*Apidae* and *Vespidae*)

Apids, such as honeybees and bumblebees, are usually docile, stinging only when provoked. A female bee is capable of stinging only once (male bees have no stinger) because its stinger has multiple barbs that cause the sting apparatus to detach from its body, leading to evisceration and eventual death.

Africanized honeybees, or so-called killer bees, are now found in Texas, Arizona, California, and most of the temperate southeastern

and southwestern states. These bees are hybrids of African bees that escaped from laboratories in Brazil during the 1950s, which have successfully spread northward along the coasts and temperate regions of the continent. Their venom is no more toxic than that of the American counterpart, but African honeybees are very aggressive and a hive can respond to a perceived threat with more than 10 times the number of bees as a typical North American bee response. An attack from Africanized bees can lead to massive stinging resulting in multisystem damage and death from severe venom toxicity.⁴ With no natural predators, it is predicted that hybrids of Africanized bees eventually will inhabit much of the southern United States.

Most of the allergic reactions reported each year from Hymenoptera occur from vespids (wasp, hornet, and yellow jacket) stings. These arthropods nest in the ground or in walls, have volatile tempers, and may be disturbed by work taking place around the nest. As with bees, only the females have adapted a stinger from the ovipositor on the posterior aspect of the abdomen. Although vespids also possess barbed stingers, they have the ability to withdraw their stingers from the victim, enabling multiple stings.

VENOM Hymenoptera venom contains several components.⁵ Although histamine is one of those components and was once thought to be responsible for most of the reactions observed following envenomation, other substances have now been recognized as more important. Melittin, a known membrane-active polypeptide that can cause degranulation of basophils and mast cells, constitutes more than 50 percent of the dry weight of bee venom. Because all Hymenoptera share many of these components, cross-sensitization may occur in individuals allergic to one species. Yellow jacket venom is perhaps the most potent sensitizer.

Fire ant (*Solenopsis invicta*). (Reproduced with permission from Merck, Sharp & Dohme, Division of Merck & Co., Inc.)

CLINICAL FEATURES The most common response to Hymenoptera venom consists of pain, slight erythema, edema, and pruritus at the sting site. In addition to this response, more significant reactions may occur.⁶

Local Reaction A local reaction consists of an urticarial lesion contiguous with the sting site. Although there are no systemic signs or symptoms, a severe local reaction may involve one or more neighboring joints. A local reaction occurring in the mouth or throat can produce airway obstruction. Stings around the eye or on the lid may result in the development of an anterior capsule cataract, atrophy of the iris, lens abscess, perforation of the globe, glaucoma, or refractive changes. When local reactions become increasingly severe, the likelihood of future systemic reactions appears to increase and, if skin tests are positive, may warrant immunotherapy.

Toxic Reaction When there is a history of multiple stings, such as in an Africanized bee attack, a systemic toxic reaction from venom may occur. Symptoms of a toxic reaction may resemble anaphylaxis, but there is generally a greater frequency of nausea, vomiting, and diarrhea. Light-headedness and syncope are common. There also may be headache, fever, drowsiness, involuntary muscle spasms, edema without urticaria, and occasionally convulsions. Urticaria and bronchospasm do not need to be present, although respiratory insufficiency and arrest may occur. Renal and hepatic failure also has been reported, as well as disseminated intravascular coagulation (DIC). Symptoms usually subside within 48 h, but may last for several days in severe cases. Toxic reactions are believed to occur from a direct multisystem effect of the venom.

Anaphylactic Reaction A generalized systemic allergic or anaphylactic reaction, whether in response to a single sting or multiple stings, may range from mild to fatal, and death can occur within minutes. The majority of such reactions occur within the first 15 min, and nearly all occur within 6 h. There is no correlation between systemic reactions and the number of stings. In general, the shorter the interval between the sting and the onset of symptoms, the more severe is the reaction. Fatalities that occur within the first hour of the sting usually result from airway obstruction or hypotension. Initial symptoms usually consist of itching eyes, facial flushing, generalized urticaria, and dry cough. Symptoms may intensify rapidly with chest or throat constriction; wheezing; dyspnea; cyanosis; abdominal cramps; diarrhea; nausea; vomiting; vertigo; chills and fever; laryngeal stridor; shock; syncope; involuntary bowel or bladder action; and bloody, frothy sputum. Initial mild symptoms may progress swiftly to shock.

Generalized systemic allergic reactions to Hymenoptera venom are thought to be IgE-mediated. When an individual predisposed to allergy to bees is stung, there is usually an increase in the production of IgE antibodies, which become attached to the mast cells and basophils. This sensitizes the individual so that a subsequent sting may result in an antigen-antibody interaction releasing pharmacologically active mediators such as histamine, the slow-reacting substance of anaphylaxis (SRS-A) and eosinophil chemotactic factors of anaphylaxis (ECF-A). It is these mediators that actually cause tissue damage and systemic symptoms.

Delayed Reaction A delayed reaction, appearing 5 to 14 days after a sting, consists of serum sickness-like signs and symptoms of fever, malaise, headache, urticaria, lymphadenopathy, and polyarthritis.⁷ Frequently, the patient has forgotten about the encounter and is puzzled by the sudden appearance of symptoms. This reaction is believed to be immune complex-mediated.

Unusual Reactions Infrequently, a reaction to Hymenoptera venom produces neurologic, cardiovascular, and urologic symptoms, with signs of encephalopathy, neuritis, vasculitis, and nephrosis. A case of Guillain-Barre syndrome has been reported as a possible consequence of a Hymenoptera sting.

Identification of the offending insect can be difficult, except for the honeybee, which predictably leaves its stinger with venom sac attached in the lesion. In general, definitive identification is unnecessary because signs and symptoms of envenomation are similar among all species of Hymenoptera. If edema persists at the sting site, secondary infection, such as cellulitis, should be considered. Severe local reactions on the foot or ankle can be misdiagnosed as gout if the insect sting is not visible.

TREATMENT If the bee stinger is present in the wound, it should be removed. Although conventional teaching suggested scraping the stinger out to avoid squeezing remaining venom from the retained venom gland into the victim, involuntary muscle contraction of the gland continues after evisceration and the venom contents are quickly exhausted. Immediate removal is the important principle and the method of removal is irrelevant. The sting site should be washed thoroughly with soap and water to minimize the possibility of infection. For local reactions, intermittently applied ice packs at the site will diminish swelling and delay the absorption of venom while limiting edema. Oral antihistamines and analgesics may limit discomfort and pruritus. Nonsteroidal anti-inflammatory drugs (NSAIDs) can be effective in relieving pain. Standard doses of opioid analgesics also can be administered. If edema is significant, elevation and rest of the affected limb should limit swelling unless secondary infection develops, in which case antibiotics will be necessary. In local tissue reactions, there is often significant inflammatory erythema and swelling, making it difficult to distinguish from infection; as a general rule, infection is only present in a minority of cases.

TABLE 194-2 Long-Term Management for Patients with Reactions to Hymenoptera Stings

Type of Reaction	Risk of Systemic Reaction on Subsequent Stings	Should Skin Testing Be Performed	Results of Skin Testing	Recommended Treatment
Never stung	Minimal	No		None
Local reaction				
Minor local reaction: immediate pain, swelling and itching at sting site, resolves in 1 day	Minimal	No		None
Extensive local reaction: swelling develops 24–48 h after sting and resolves in 3–7 d	Less than 10 percent	No		Epinephrine syringe
Systemic reaction				
Adult (urticaria, angioedema, anaphylaxis)	High	Yes	+	Venom immunotherapy
			–	Epinephrine syringe
Child (urticaria and mild angioedema)	Low	Yes	+	Venom immunotherapy or epinephrine syringe
			–	Epinephrine syringe
Child (anaphylaxis)	Moderate	Yes	+	Venom immunotherapy
			–	Epinephrine syringe

While the initial signs and symptoms of a systemic reaction may be mild, victims can deteriorate rapidly in a matter of minutes. Treatment begins similar to that for anaphylaxis (see Chap. 34), and the most important agent to administer is epinephrine 0.3 to 0.5 mg (0.3 to 0.5 mL of 1:1000 concentration) in adults and 0.01 mg/kg in children (never more than 0.3 mg). It should be injected IM and the injection site massaged to hasten absorption. The patient should then be observed for several hours to ensure that symptoms do not intensify or relapse. Parenteral administration of standard antihistamines (diphenhydramine 25 to 50 mg IV, IM, or PO) and H₂-receptor antagonists (ranitidine 50 mg IV) is recommended. While steroids (methylprednisolone 125 mg) are of little help in combating the immediate effects, their administration tends to limit ongoing urticaria and edema and may potentiate the effects of other measures. Bronchospasm is treated with β -agonist nebulization. Hypotension may require massive crystalloid infusion, and central venous pressure monitoring may be helpful in these patients. Persistent hypotension after massive volume replacement may require dopamine. If dopamine is ineffective, an intravenous infusion of epinephrine can be used. The patient who suffers a severe systemic reaction should be admitted and monitored for potential cardiac, bleeding, renal, or neurologic complications. Antivenoms have been studied for the treatment of mass bee attacks, but are not yet commercially available.⁸

LONG-TERM MANAGEMENT AND PREVENTIVE CARE Skin tests and radioallergosorbent tests (RASTs) are not fully reliable for determining which patients are at risk for systemic reaction during future encounters with Hymenoptera (Table 194-2).⁹ Patients with negative results may have been sensitized by the skin tests themselves. **Every patient who has had a systemic reaction should be provided with an insect sting kit containing premeasured epinephrine and be carefully instructed in its use. The physician should stress that the patient must inject the epinephrine at the first sign of a systemic reaction.** Physicians should also advise their patients who are allergic to insects to wear identification (e.g., Medic Alert tags) concerning their severe allergy.

Ants (*Formicidae*)

There are five known species of fire ants (*Solenopsis*) in the United States: the native species *S. aurea*, *S. geminata*, *S. xyloni*, and at least two imported species, *S. invicta* and *S. richteri*. These two imported species entered the United States through Mobile, Alabama, in the

1930s, have now become well established throughout the Gulf Coast states, and are spreading throughout the southwest.¹⁰ The fire ant inhabits a loose amount of dirt and breeds 9 to 10 months of the year. One mature nest can produce 200,000 ants during a 3-year period, which accounts for the rapid spread of this arthropod. The venom of the fire ant is almost entirely an insoluble alkaloid. There is potential cross-reactivity between the venoms of fire ants and other Hymenoptera, and individual stings may produce systemic toxicity in sensitized individuals.

Fire ants are characterized by their tendency to swarm when provoked and they may attack in great numbers. Most often fire ants in a swarm position themselves on their victim and sting simultaneously in response to an alarm pheromone released by one or several individuals. Immobilized or elderly patients can become rapidly covered by swarms of these ants, resulting in severe stings or death.¹¹ Each sting usually results in a papule that becomes a sterile pustule in 6 to 24 h (Figure 194-2). Localized necrosis, scarring, and secondary infection can result. Rarely, a systemic reaction manifested by urticaria and angioedema can occur. Fatalities within 20 min have been reported in Australia following a single sting from the jumper or red bull ant (*Myrmecia* spp.), but most fatalities had a history of prior venom al-

FIG. 194-2. Multiple stings from fire ants on ankle of child. Lesions are 2 days old.

lergy, all had prior cardiopulmonary disease, and none carried in-jectable epinephrine.¹²

Studies estimate a hypersensitivity rate to the fire ant of 16 percent in the general population, with significant crossover in those sensitized to other Hymenoptera. Treatment of fire ant stings consists of local wound care.¹¹ If there is evidence of systemic reaction, the usual treatment for anaphylaxis is indicated. Desensitization may be necessary in victims exhibiting potentially life-threatening reactions to these arthropods.

SPIDERS (ARANEAE)

There are more than 34,000 species of spiders worldwide, of which only a few dozen produce medically significant envenomations in humans (Tables 194-3 and 194-4). All spiders are carnivores, using venom to paralyze their prey prior to ingestion.¹³ The vast majority of spiders pose little harm to humans because either their venom-injecting fangs are too small to penetrate human skin, the amount of venom injected is too little to produce toxicity, or the toxins in the venom do

not affect mammalian cells. Even if a reaction is elicited, it is often local and systemic toxicity is confined to a few specific species.

Necrotic Arachnidism (Loxosceles)

Loxosceles spiders have a worldwide distribution; their bite has the ability to produce local necrotic skin lesions and systemic toxicity.¹⁴ Three species, *L. reclusa* (true brown recluse), *L. laeta* (corner spider), and *L. arizonica* (Arizona brown spider) produce the majority of *Loxosceles* bites in the United States. The brown recluse spider is one of the most common species found in the United States, with an endemic range in the south-central United States, from Texas to Georgia and Iowa to Louisiana. The spider has an approximately 1-cm body, a tan to brown coloration, and a violin-shaped mark on its dorsal cephalothorax. *L. reclusa* prefers warm, dry areas such as abandoned buildings, woodpiles, and cellars (Figure 194-3). The venom of the brown recluse has multiple enzymes including hyaluronidase, alkaline phosphatase, 5'-ribonu-cleotide phosphohydrolase and the major one responsible for necrosis, sphingomyelinase D.¹³ Significant necrotic wounds are possible through neutrophil activation, platelet aggregation, and intravascular thrombosis.

TABLE 194-3 Medically Important Spiders by Geographic Location

Genus	Species	Common Name	Distribution
<i>Loxosceles</i>	<i>L. reclusa</i>	True brown recluse spider	North America (central and southeast U.S.)
	<i>L. arizonica</i>	Arizona brown spider	North America (southwest)
	<i>L. rufescens</i>		Worldwide
	<i>L. laeta</i>	Corner spider	South America, North America
	<i>L. spinulosa</i>		South Africa
	<i>L. intermedia</i>		Brazil
	<i>L. gaucho</i>		Brazil
	<i>L. parrami</i>	Violin spider	South Africa
<i>Tegenaria</i>	<i>T. agrestis</i>	Hobo or Northwestern brown spider	Europe, North America Europe, Asia (west central): native North America (Pacific Northwest): introduced
<i>Latrodectus</i>	<i>L. mactans</i>	Black widow spider	Worldwide
	<i>L. bishopi</i>	Red-legged spider	North America
	<i>L. variolus</i>		North America
	<i>L. hasselti</i>	Red-backed spider	North America
	<i>L. katipo</i>	Katipo spider	Australia, New Zealand, Asia (southern)
	<i>L. hesperus</i>	Western black widow spider	New Zealand
	<i>L. tredecimguttatus</i>		North America
	<i>L. pallidus</i>		Mediterranean countries
	<i>L. indistinctus</i>	Black button spider	Mediterranean countries, Middle East, Russia (south)
	<i>L. geometricus</i>	Brown button spider	Africa
<i>Phoneutria</i>	<i>L. rhodesiensis</i>	Brown button spider	Worldwide
			South Africa
<i>Phoneutria</i>	<i>P. nigriventer</i>	Brazilian armed spider	South America Brazil, Paraguay, Argentina, Uruguay
<i>Atrax/Hadronyche</i>	<i>A. robustus</i>	Sydney funnel-web spider	Australia
	<i>H. formidabilis</i>	Northern funnel-web spider	Australia (east)
	<i>H. versutus</i>	Australian Blue Mountains funnel-web spider	Australia (east)
	<i>H. infensus</i>		Australia (east)
	<i>H. cereberus</i>		Australia (southeast)
<i>Cheiracanthium</i>	<i>C. inclusum</i>		Worldwide
	<i>C. mildei</i>		North America
	<i>C. diversum</i>		Europe, eastern and central U.S.
	<i>C. punctatorium</i>		Australia, Pacific Islands, Hawaii
	<i>C. longimanus</i>		Europe
	<i>C. mordax</i>		Australia
	<i>C. japonicum</i>		Australia
	<i>C. lawrencei</i>	Sac spider	Japan, China
	<i>(furculatum)</i>		Africa

TABLE 194-4 Medically Important Spider Bites by Local Reaction and Systemic Signs

Genus	Local Reaction	Systemic Signs
<i>Loxosceles</i>	Initially painless Most common manifestation a mild firm erythematous lesion heals with little or no scar over several days to weeks Occasionally mild to severe pain several hours after the bite followed by erythema and blister formation within 24 h Necrotic lesion develops over the next 3 to 4 days, with eschar formation by the end of the first week	Systemic effects are rare, appear more often in children, and typically occur 24 to 72 h after the bite Nausea, vomiting, fever, chills, arthralgias, hemolysis, thrombocytopenia, hemoglobinuria, and renal failure Disseminated intravascular coagulation and death are rare
	Initial bite is often painless Induration may initially occur with surrounding erythema Followed by blistering, rupture, and necrosis Healing may take as long as 45 days and permanent scarring may result	Headache is the most common systemic symptom Nausea, vomiting, and fatigue can also occur Aplastic anemia and death are rare complications
<i>Latrodectus</i>	Local pinprick almost always felt Immediate mild to moderate pain Pain may spread quickly to include the entire extremity Erythema appears approximately 20 to 60 min after the bite. Erythema evolves into a target lesion 1 to 2 cm in diameter	Muscle cramp-like spasms in large muscle groups Physical examination of the "cramping" extremity rarely exhibits rigidity Pain increases and becomes generalized, involving the trunk, back, and abdomen Pain lasts for 24 h or more than can be intermittent Severe hypertension may occur
<i>Phoneutria</i>	Severe local pain	Sympathetic stimulation: tachycardia, hypertension Parasympathetic hyperactivity: nausea, vomiting, diaphoresis, salivation Spinal cord impairment: priapism Central nervous effects: vertigo, visual changes Death from respiratory failure can be seen in 2 to 6 h
<i>Atrax/Hadronyche</i>	Local pain Wheal with surrounding erythema Localized sweating and piloerection	Perioral paresthesias Parasympathetic hyperactivity: nausea, vomiting, diaphoresis, salivation, lacrimation, bronchorrhea Neuromuscular stimulation: muscle fasciculation, tremors, spasms, weakness Central nervous system toxicity: altered level of consciousness Death as a result of cardiac arrest, hypotension, or pulmonary failure

FIG. 194-3. Mature *Loxosceles reclusa*. Notice the violin or fiddle-shaped marking on the cephalothorax. [Reproduced with permission from Elston DM: What's eating you? *Loxosceles reclusa* (brown recluse spider). *Cutis* 69:94, 2002.]

CLINICAL FEATURES Bites by *Loxosceles* spiders are initially painless, often prohibiting definitive identification of the spider. The most common manifestation of a *Loxosceles* bite consists of a mild erythematous lesion that may become firm and heal with little or no scar over several days to weeks.¹⁴ However, occasionally a more severe local reaction occurs, beginning with mild to severe pain several hours after the bite, followed by erythema and blister formation, and a bluish discoloration within the first 24 h (Figure 194-4). This lesion may become necrotic over the next 3 to 4 days, with eschar formation by the end of the first week. The necrotic, slowly healing ulcers may not reach maximum size for many weeks after envenomation, and can result in a significant cosmetic defect.

Systemic effects are rare, appear more often in children, and typically occur 24 to 72 h after the bite. Effects include nausea, vomiting, fever, chills, arthralgias, hemolysis, thrombocytopenia, hemoglobinuria, and renal failure. Disseminated intravascular coagulation and death are extraordinarily rare. Definitively diagnosing a brown recluse envenomation is difficult. The presence of a consistent clinical presentation combined with the actual spider (unusual because the bite is typically painless) or residence in an endemic area can be helpful. However, a wide variety of unrelated arthropod species and medical causes can appear similar to a *Loxosceles* envenomation. It is likely that a large number of wounds are incorrectly attributed to the bite of the brown recluse.

In patients suspected of having a bite from the brown recluse and exhibiting signs and symptoms of envenomation, a complete blood

FIG. 194-4. Brown recluse spider bite approximately 12 h old.

count (CBC), basic chemistry tests, blood urea nitrogen (BUN), creatinine, and coagulation profile should be performed. Research is being done on an assay to confirm envenomation.¹⁵ Currently, a commercial test does not exist and it remains unclear if one would be beneficial.

TREATMENT Treatment of any possible necrotic spider bite should include the usual supportive measures. Antibiotics should be given if signs of infection are present. Analgesia may be required in some cases. Close follow-up for the patient should be arranged so that serial evaluations of the wound are performed. If ulceration does develop, surgical debridement should be delayed until clear margins are established, often 2 to 3 weeks after the bite. Patients with systemic symptoms following a brown recluse bite warrant hospitalization and close observation.

Various treatments have been advocated for brown spider bites, including hyperbaric oxygen, cyproheptadine, dapsone, steroids, and topical nitroglycerin. None of these therapies has shown clear benefit. The leukocyte inhibitor dapsone continues to be advocated by some. However, a controlled animal study failed to show benefit of dapsone, and this drug is associated with hemolysis and methemoglobinemia.¹⁶ Antivenom could possibly be beneficial for brown recluse bites if a reliable test for envenomation can be demonstrated. However, recent research suggests diminished efficacy if antivenom administration is delayed after inoculation.¹⁷ *Loxosceles* antivenom is not commercially available at this time.

Hobo Spider (*Tegenaria agrestis*)

A native of Europe and central Asia, the hobo or Northwestern brown spider is now found in the Pacific Northwest of the United States and Canada after its introduction through the port of Seattle in the 1930s. Because of similarity in presentation, envenomations in this area are often incorrectly attributed to the brown recluse spider, which lives elsewhere.¹⁸ As suggested by its scientific name, the species is considered to be aggressive because of reports of biting with minor provocation. Hobo spiders are brown with gray markings, have a 7- to 14-mm body length, and a 27- to 45-mm leg span. They live in moist dark areas such as woodpiles or basements.

CLINICAL FEATURES The clinical presentation of victims of hobo spider envenomations is similar to that of the brown recluse spider. Like brown spiders, the initial bite is often painless, delaying patient

presentation until symptoms begin. Induration may initially occur with surrounding erythema, followed by blistering, rupture, and necrosis. Healing may take as long as 45 days and permanent scarring may result. Headache is the most common systemic symptom, but nausea, vomiting, and fatigue can also occur. Aplastic anemia and death are rare complications.

TREATMENT There is no diagnostic test for hobo spider envenomation, nor is there proven treatment for local or systemic complications.¹⁸ Surgical resection with skin grafting may be necessary but should probably not be initiated until the necrotizing process is completed.

Widow Spiders (*Latrodectus*)

Latrodectus or "widow spiders" have a worldwide distribution. In the United States, the black widow is the most well known, although of the five *Latrodectus* species found commonly in the United States, only three (*L. mactans*, *L. varians*, and *L. hesperus*) are actually black (Figure 194-5). Other varieties may be predominantly brown (*L. geometricus*) or red (*L. bishopi*). The classic orange-red hourglass-shaped marking is noted only in *L. mactans*. Female spiders are relatively large, with a body size ranging up to 1.5 cm in length, with leg spans of 4 to 5 cm. The male spider is approximately one-third the size of the female, lighter in color, and his bite cannot penetrate human skin. Black widow spiders are found most often in woodpiles, basements, garages, and sheds. *Latrodectus* will aggressively defend her web, particularly when guarding her eggs. Most black widow bites occur between April and October and are usually seen on the hands and forearms.

The black widow spider injures its victim and its prey with a highly potent venom.¹³ The most active component of the venom is α-latrotoxin, acting through a calcium-mediated mechanism leading to the release of predominantly acetylcholine and norepinephrine from nerve terminals.

CLINICAL FEATURES Most *Latrodectus* bites are immediately felt as a pinprick sensation at the bite site, followed by increasing local pain that may spread quickly to include the entire bitten extremity. Erythema appears approximately 20 to 60 min after the bite. In the about

FIG. 194-5. Large female *Latrodectus mactans*. (Reproduced with permission from Stack LB: *Latrodectus mactans*. *New Engl J Med* 336:1649, 1997. Copyright © 1997 Massachusetts Medical Society. All rights reserved.)

two-thirds of bites, a small, <5-mm erythematous macule develops and in about one-third of cases, initial erythema evolves into a larger "target lesion" with blanched center and surrounding erythema (Figure 194-6).¹⁹ Victims frequently complain of muscle cramp-like spasms in large muscle groups, although physical examination of the "cramping" extremity rarely exhibits rigidity. The pain often increases progressively, becomes generalized, and can involve the trunk, back, and abdomen.¹⁹ Severe abdominal wall musculature pain and cramping may be mistaken for a surgical abdomen. Approximately 60 percent of victims develop hypertension and other symptoms include headache, nausea, diarrhea, diaphoresis, photophobia, and dyspnea.¹⁹ *Latrodectus* envenomation victims may experience severe pain for 24 h or more that can be intermittent. Rarely, pain may persist for several days.

Because an immediate pinprick sensation is almost always reported with *Latrodectus* bites, it is rare for victims not to see the offending spider. Although confirmatory testing is not available, the presence of the characteristic lesion in association with severe pain and muscle spasms is virtually pathognomonic.

TREATMENT The initial therapy is supportive care of the airway, breathing, and circulation. Cleansing of the bite site is reasonable. Pain and muscle spasms can be effectively controlled with liberal doses of opioids and benzodiazepines in approximately 70 percent of victims.¹⁹ Although intravenous calcium gluconate has been advocated to relieve symptoms, a retrospective review of 163 patients with *Latrodectus* envenomation found this treatment to be ineffective.¹⁹ For severe envenomations, admission is often required for continued analgesia. The most effective therapies for severe envenomation are parenteral opioids and *Latrodectus* antivenom.¹⁹

Administration of *Latrodectus* antivenom often causes rapid resolution of symptoms, and unlike opioids can significantly shorten the course of illness. Even in severely symptomatic cases of *Latrodectus* envenomation, patients can often be discharged from the ED after a short observation period when antivenom is administered. *Latrodectus* antivenom is produced in at least three countries with specificity for indigenous species: Red-Back Spider Antivenom (Commonwealth Serum Laboratories CSL Ltd., Australia), Button Spider Antivenom (South African Vaccine Producers Institute, South Africa), and Antivenin *Latrodectus mactans* (Merck & Co., Inc., United States). Indications, amount, and route of administration vary according to product. Antivenin *Latrodectus mactans* and Button Spider Antivenom are administered IV and Red-Back Spider Antivenom is administered by intramuscular injection. *Latrodectus* antivenom is derived from horse serum and hypersensitivity reactions are possible. One death from ana-

phylaxis has been reported after administration of Antivenin *Latrodectus mactans* in the United States; in that case, however, the antivenom was given undiluted and was IV "pushed" in a patient with asthma who had known allergies to multiple medications. Slow administration of diluted Antivenin *Latrodectus mactans* is considered safe.²⁰

Armed Spiders (*Phoneutria*)

The armed spiders of South America are aggressive hunters and possess potent neurotoxic venom. Being nocturnal hunters, these spiders may enter houses during the night and hide in clothes during the day. These spiders have also been reported to hide in banana bunches during shipping and can bite workers handling these bananas at their destination. The best-known armed spider, *Phoneutria nigriventer* is large, with body size up to 3.5 cm and leg length up to 6 cm. *P. nigriventer* venom contains a mixture of potent neurotoxins that produce central nervous system, spinal cord, and autonomic effects.

CLINICAL FEATURES The majority of *P. nigriventer* bites are reported to produce no significant symptoms. Significant envenomation produces local symptoms (severe pain) followed by sympathetic stimulation (tachycardia, hypertension), parasympathetic hyperactivity (nausea, vomiting, diaphoresis, salivation), and spinal cord impairment (priapism) and central nervous effects (vertigo, visual changes). Death from respiratory failure can be seen in 2 to 6 h, usually in children or debilitated adults. Most healthy adults will recover in 1 to 2 days.

TREATMENT In most cases, supportive care is adequate. Local anesthetic infiltration at the bite site is useful for local pain control. A polyvalent antivenom (Instituto Butantan, Brazil) is available for cases of severe envenomation from *P. nigriventer*. Opioids are contraindicated for pain control in severe envenomation, as they appear to enhance the adverse effect of venom on respiration.

Funnel-Web Spiders (*Atrax/Hadronyche*)

Funnel-web spiders are so named because they contract a cylindrical web that extends into a recess, such as a burrow in the ground or a hole in a tree. Medically significant funnel-web spiders are found in southern and southeastern Australia, and the adjacent islands of Tasmania, Papua New Guinea, and the Solomon Islands. Funnel-web spiders of this region were originally classified into the genera *Atrax* and *Hadronyche*, but are now considered one genus. To prevent confusion, species are identified using their original genus name.

Funnel-web spiders have a shiny black body, long fangs, and females can grow up to 4 cm in body length. Females stay close to their web, but the smaller and more aggressive males tend to wander, especially during the summer following a rain. *Atrax* venom contains a potent mixture of neurotoxins with neuromotor and autonomic effects.

CLINICAL EFFECTS *Atrax* bites may result in local reaction with immediate pain, followed by wheal formation and surrounding erythema. Later, localized sweating and piloerection have been observed. The vast majority of *Atrax* bites do not appear to result in significant envenomation or systemic toxicity. Symptoms and signs of systemic toxicity include perioral paresthesias, parasympathetic hyperactivity (nausea, vomiting, diaphoresis, salivation, lacrimation, bronchorrhea), neuromuscular stimulation (muscle fasciculation, tremors, spasms, weakness), and central nervous system toxicity (altered level of consciousness). Death following *A. robustus* envenomation has been reported as a result of cardiac arrest, hypotension, or pulmonary failure between 15 min and 3 days following a bite.

TREATMENT To reduce venom absorption and systemic toxicity for a bite on an extremity, a compressive elastic bandage should be ap-

FIG. 194-6. Classic target lesion from patient bitten by a black widow spider.

plied the entire length of the limb and the extremity splinted to prevent movement. The victim should be immobilized and transported promptly to the hospital.

The specific treatment for systemic toxicity is Funnel-web Spider Antivenom (Commonwealth Serum Laboratories CSL Ltd, Australia). If the patient has signs of systemic toxicity upon arrival or develops them after the compressive elastic bandage is carefully removed, two ampules of antivenom should be administered IV every 15 min until symptoms improve; most reported cases require four vials. Supportive therapy for hypotension (intravenous fluid), bronchorrhea (atropine), tremors and agitation (benzodiazepines), and hypertension and tachycardia (β -blockers) may be necessary, but antivenom is the only therapy known to consistently improve survival.

Sac and Running Spiders (*Cheiracanthium*)

Cheiracanthium are medium-sized (7- to 15-mm body size and 30-mm leg span) house-dwelling spiders. The venom is cytotoxic and neurotoxic, but only the South African *C. lawrencei* appears capable of producing skin necrosis.

CLINICAL FEATURES The most common symptoms are local pain, swelling, and erythema at the bite site. Mild systemic symptoms of headache, malaise, dizziness, and nausea have occasionally been reported. Skin necrosis following a *C. lawrencei* bite typically becomes apparent by the third day and heals in 7 to 10 days.

TREATMENT Treatment is symptomatic with local wound care. Even if skin necrosis develops, healing is expected provided no secondary infection develops.

Tarantulas (*Degesiella*, *Aphonopelma*, and Others)

Tarantulas are large, hairy spiders belonging to the family *Theraphosidae* that have become increasingly popular as pets. The hairs found on the abdomen of most species of tarantulas in North and South America appear grossly as a velvety covering and are used defensively. When threatened, tarantulas may "flick" these hairs a short distance with their two back legs. Although North American tarantula hairs rarely penetrate human skin, the hairs have been found in some cases to imbed deeply into the conjunctiva and cornea, and can cause inflammation in all levels of the eye, from conjunctiva to retina. Patients who manifest a red eye and pain after handling a tarantula should be examined to determine if offending barbed hairs are present in the cornea or conjunctiva. Although hairs are sometimes easily seen on slit-lamp examination, they may at times be very difficult to detect. Therapy includes surgical removal of the hairs and topical steroids to control inflammation. Ophthalmia nodosa is a granulomatous, nodular reaction that can occur in cases of ocular exposure to tarantula hairs.²¹ Patients may also develop a diffuse contact dermatitis from indirect hair exposure while cleaning a tarantula cage. Bites from tarantulas are typically painful, with local erythema and edema, and some patients describe local joint stiffness following nearby bites. Systemic symptoms other than fever are unusual.

Other Spiders

Wolf spiders (*Lycosa*) are small- to medium-size (3- to 5-mm body length) ground-dwelling spiders with a worldwide distribution. The venom is cytotoxic and produces local pain and occasionally induration and erythema, but no systemic symptoms. The venom is not felt to produce skin necrosis and those purported cases of *Lycosa* skin necrosis are probably either misidentification of the biting spider or a concomitant infection.

Jumping spiders (family *Salticidae*) are typically small (<15 mm), brightly colored, and very active spiders with a worldwide distribution.

A bite may produce pain, swelling, pruritus, and erythema that resolves in 2 days. There are case reports of minor skin ulceration (United States) and headache and vomiting (Australia) following a jumping spider bite.

Daddy long-legged spiders (family *Pholcidae*) are common cellar and outbuilding dwellers along the Pacific coast and southwestern deserts. A repeated myth is that these spiders possess highly toxic venom, but their fangs are too short to penetrate human skin. This is false, there are no research studies on *Pholcidae* venom in mammals and no case reports of human envenomation.

SCORPIONS (SCORPIONIDAE)

Scorpions have a world-wide distribution. Highly toxic species are found in the Middle East, India, North Africa, South America, Mexico, and the Caribbean island of Trinidad. Several species of scorpions are found in the warmer parts of the southern United States. All are generally nocturnal and capable of stinging humans, but most species cause little more than localized pain similar to that following Hymenoptera stings. Cytotoxicity or inflammation does not occur from North American scorpion venom, and the exact site of the sting may not be readily apparent. In the United States, only *Centruroides exilicauda*, or the bark scorpion, found throughout Arizona, New Mexico, and parts of Texas and California, possesses venom potent enough to cause systemic toxicity.

Clinical Features

C. exilicauda venom can open neuronal sodium channels and cause prolonged and excessive depolarization. Both somatic and autonomic nerves may be affected. Systemic symptoms from the sting of this scorpion are not common but can be severe, particularly in children. Immediate onset of pain and paresthesias in the stung extremity is usually noted and may become generalized. In severe cases, cranial nerve and somatic motor dysfunction can develop, resulting in abnormal roving eye movements, blurred vision, pharyngeal muscle incoordination and drooling, occasionally leading to respiratory compromise. Excessive motor activity may present as restlessness or uncontrollable jerking of the extremities, appearing to be seizure-like activity. Nausea, vomiting, tachycardia, and severe agitation can also be present. Without antivenom treatment, symptoms can last 24 to 48 h. Cardiac dysfunction, pulmonary edema, pancreatitis, bleeding disorders, skin necrosis, and occasionally death can be seen with stings from Asian and African scorpions.

Diagnosis of a scorpion sting is clinical. Stings can be confused initially with anything that causes local pain, particularly in children. As the syndrome progresses in moderate to severe cases to include autonomic and motor findings, the diagnosis should become more apparent.

Treatment

Initial treatment is supportive with analgesics. In the United States a *Centruroides-specific* antivenom (Antivenom Production Laboratory, Arizona State University, United States) has been available only in the state of Arizona and is produced from goat-serum. Production of this antivenom has been stopped, and supplies will likely be exhausted in several years. Scorpion antivenom directed against different species have been produced for research or clinical use in more than 10 other countries. Recommendations for use and dosing of these products vary widely. Like all animal-derived antivenoms, both immediate and delayed allergic reactions including serum sickness are possible. For this reason, *Centruroides-specific* antivenom administration should be reserved for cases of severe systemic toxicity. One study outside of the United States found no benefit in routine administration of antivenom for scorpion stings.²² Consultation with a toxicologist experienced in

scorpion envenomation is recommended before using antivenom. Treatment with antivenom in cases of severe toxicity can lead to rapid resolution of symptoms; one to two vials of antivenom are usually sufficient.

TICKS (*IXODES*, *DERMACENTOR*, AND OTHERS)

Ticks are found throughout the world, mostly in rural areas. They are obligate, bloodsucking arthropods that are second only to mosquitoes in numbers of pathogens vectored to humans. Their bodies consist of a fused abdomen and thorax in an oval shape and vary from 1 mm or less in length to more than 1 cm when engorged with blood. Ticks attach to humans painlessly with strong jaws and cement-like adhesive.

The main concern with ticks is that they are disease vectors. Viruses, bacteria (including spirochetes and rickettsiae), and protozoa may all be transmitted by ticks. Lyme disease, Rocky Mountain spotted fever, ehrlichiosis, babesiosis, Colorado tick fever, tularemia, tick-borne relapsing fever, and tick-borne encephalitis are all tick-transmitted diseases. Lyme disease is caused by the *Borrelia burgdorferi* spirochete transmitted by the bite of *Ixodes scapularis*. Certain species of ticks have a neurotoxin and are capable of inducing tick paralysis, a symmetric ascending flaccid paralysis associated with loss of deep tendon reflexes. Most cases have been reported in children and the presentation can be nearly identical to Guillain-Barre syndrome (GBS), including progression to respiratory paralysis. A diagnosis of GBS in a child should not be considered until after a thorough search for an engorged tick. Removal of the tick leads to rapid reversal of symptoms.

Insect repellants and tight-fitting clothing can be helpful in preventing tick bites and a daily tick check is reasonable in tick-infested areas.²³ Although organic solvents, heat, and other methods have been advocated to aid in dislodging a tick so as not to leave its mouth parts beneath the skin surface and to prevent disease transmission, no technique has definitively proven superior. The generally recommended method is mechanical, and involves grasping the tick with forceps or fine-point tweezers near the point of attachment and pulling straight outward with steady, gentle traction. Transmission of pathogens is time-dependent, so prompt removal of ticks is important. Concern over the acquisition of tick-borne disease, particularly Lyme disease, has led to studies regarding the use of prophylactic antibiotics following bites. A reasonable approach is to administer a single 200-mg doxycycline oral dose to persons in Lyme disease-endemic regions who remove a partially engorged tick from their bodies.²⁴

CHIGGERS (*TROMBICULIDAE*)

Chigger infestations result from mite larvae feeding on host skin cells. Mites are found in almost every habitat, are 0.3 to 1 mm in length, and attach themselves to host skin with mandibular structures. They tend to attach in areas where an obstacle such as tight fitting in clothing is met, such as the tops of socks, the leg bands of underwear, the waistband, or the edges of a bra. Once attached, the larvae release digestive enzymes to liquefy epidermal cells. The combination of digestive enzymes secreted by the mite and subsequent host immune response produces the "chigger bite."

Clinical Features

Although diseases such as rickettsialpox have been spread by mite vectors, the major clinical manifestation of chiggers is most often intense pruritus. The attached chigger may be seen initially as a bright red fleck on the skin, and it along with the larvae may be easily scratched off. However, the localized allergic response may last for weeks, and significant excoriation may occur at the site from intense scratching. Severe reactions may be accompanied by fever, edema, erythema multiforme-like lesions, and cellulitis (Figure 194-7).

The diagnosis of chigger infestation may be difficult as many other arthropods cause similar clinical manifestations. The history of out-

FIG. 194-7. Intense local edema from chigger bites.

door exposure combined with the presence of signs and symptoms localized to areas of snug-fitting clothing may be helpful.

Treatment

Treatment is primarily symptomatic to control the itching and consists of oral antihistamines and topical steroids. Oral steroids may be helpful in severe cases. Chiggers themselves may be killed with lindane, crotamiton, and other topical scabicides. Crotamiton may also help to relieve the pruritus. If secondary infection occurs, antibiotics are indicated.

MOSQUITOS, FLIES, FLEAS, AND LICE (*DIPTERA*)

Mosquitoes

Mosquitoes are aquatic-breeding arthropods found in all parts of the world. Like other members of this group, they possess one pair of wings, the second pair having evolved into smaller structures used as stabilizers.

Mosquitoes penetrate skin with a piercing motion of a bayonet-like proboscis. The actual puncturing of the skin surface causes minimal trauma and is frequently not felt by the host. A local anesthetic is injected into the wound that causes local tissue damage and local hypersensitivity. Bites can lead to both immediate and delayed reactions. An immediate skin reaction includes redness, a wheal, and itching. A delayed reaction can occur and usually consists of edema and pruritus. The immediate reaction tends to be of short duration, whereas a delayed reaction may persist for hours, days, and even weeks. Severe local reactions with skin necrosis are possible. Patients can acquire allergy to mosquito saliva constituents and develop symptoms consisting of an increasing reaction to seasonal exposures with increasingly pronounced edematous and pruritic lesions, sometimes accompanied by fever, malaise, generalized edema, severe nausea and vomiting, and necrosis with resulting scarring. Treatment is symptomatic with antihistamines (e.g., cetirizine) and NSAIDs.²⁵

The greatest danger from mosquitoes in other countries is as disease vectors. Even with extensive pest control programs, arboviruses and malaria are epidemic in many parts of the world. Japanese B encephalitis, yellow fever, dengue hemorrhagic fever, and various types of equine encephalitis are among the many viruses transmitted by mosquitoes. West Nile virus-induced encephalitis is now becoming more common in the temperate regions of the United States.²⁶ Malaria is also encountered frequently in patients in the United States after travel, and in immigrant populations from areas where malaria is endemic. Insect repellents offer some protection from mosquito bites.²⁷

Flies

Bloodsucking flies range in size from the tiny sand fly, approximately 1 to 3 mm in length, to horse flies that can be larger than 2 cm. All members stab and pierce the skin, causing some degree of pain and pruritus. Several species, such as deerflies, blackflies, horseflies, and sand flies, can produce allergic reactions, although rarely as severe as those produced by Hymenoptera venom. There is also the possibility of myiasis with fly bites, but this is rare in the United States.

The diagnosis of fly bites depends chiefly on the patient's history and a knowledge of the arthropods that frequent the area of encounter. Treatment for most local reactions to *Diptera* bites is symptomatic, whereas treatment of systemic reactions is the same as it is for Hymenoptera venom. Cold compresses may alleviate localized edema. Secondary infection from *Diptera* bites can occur, and antibiotics may be necessary in some cases. Oral antihistamines such as diphenhydramine and hydroxyzine may be helpful in relieving pruritus in these cases, but topical steroids can be used when local reactions are severe, and oral steroids are indicated when systemic hypersensitivity symptoms are present.

Fleas (Siphonaptera)

Bites of fleas, lice, and scabies produce lesions so similar that diagnosis is often difficult. Flea bites are frequently found in zigzag lines, especially on the legs and in the waist area. The lesions most often have a hemorrhagic appearing center surrounded by erythematous and urticarial patches. Flea bites are usually quite pruritic, and red spots can persist at bite sites for some time.

The main concern in the treatment of these bites is the possibility of secondary infection. Children may develop impetigo as a complication. The lesions should be washed thoroughly with soap and water. Children with flea bites should have their fingernails cut short to prevent scratching. To relieve discomfort and itching, starch baths at bedtime (about 1 kg starch to a tub full of water), local application of calamine, cool soaks, and oral or topical antihistamines might be helpful. For severe discomfort, application of a topical steroid cream or spray may be necessary. If secondary infection develops, topical or oral antibiotics may be needed.

KISSING BUGS AND BED BUGS (HEMIPTERA)

The order Hemiptera includes two blood-sucking families of arthropods with medical importance. These are *Reduviidae* (reduviid, or "kissing" bugs) and *Cimicidae* ("bedbugs" and their relatives).^{28,29} Various species of kissing bugs exist predominantly in the southern United States and Central and South America. The common name "kissing bugs" derives from their habit of feeding at night on any exposed surface of a sleeping victim, commonly the face. Bedbugs are also nocturnal feeders and their distribution is worldwide. Both bugs are attracted to warm bodies and hide near beds. Bedbugs are found in nearby cracks and crevices. Both bugs are potential vectors for disease. Kissing bugs of Central and South America are vectors of Chagas' disease (trypanosomiasis), and bedbugs have been implicated as a vector for hepatitis B.

Clinical Features

Bites from both bugs are typically painless. Erythematous papules, bullae, and wheals may develop. Diagnostically, kissing bug bites can be differentiated from bedbug bites in that kissing bug bites are not in a linear formation and usually are not accompanied by telltale brown or black patterns of excrement on the bed linen, which is characteristic of bed bugs.²⁸ A thorough search of bedding and nearby cracks and crevices will often reveal the bugs.

Treatment

Treatment of both bites is symptomatic. Cool compresses, topical steroids, and antihistamines can be used to relieve associated pruritus. Some individuals become highly sensitive to kissing bugs and react with systemic allergic symptoms following a bite. They should be treated as previously outlined for Hymenoptera envenomation.

CATERPILLARS AND MOTHS (LEPIDOPTERA)

Lepidopterism refers to the adverse effects resulting from contact with butterflies, moths, or their caterpillars. With the exception of dermatitis from female moths of the *Hylesia* genus found in Central and South America, most symptoms are a result of contact with caterpillars.

Clinical Features

Caterpillars are the larval stage of moths and have either spines or hairs for protection. The spines can be hollow, branched, and connected to a venom gland. The spines and hairs may cause mechanical irritation, whereas the venom can produce additional symptoms. The vast majority of caterpillars are harmless to humans. Pruritus from localized "caterpillar dermatitis" and occasional diffuse urticaria are the predominant symptoms with exposures to the hairs and venom. The puss caterpillar (*Megalopyge opercularis*) is found in the southeastern United States and accounts for most of the serious envenomations in this country. After initial contact, intense local burning pain rather than pruritus is typical. A gridlike pattern of hemorrhagic papules may be seen within 2 to 3 h of these exposures and may last for several days. Regional lymphadenopathy is common, and the affected limb can swell considerably. Other symptoms include headaches, fever, hypotension, and convulsions. No deaths have been reported. Ingestion of the hickory tussock caterpillar (*Lophocampa caryae*), found in the eastern United States, has been reported with symptoms ranging from drooling to diffuse urticaria. Spines have been visualized in the oropharynx and even the esophagus in some of these patients requiring general anesthesia to help removal.³⁰

Treatment

No antivenom exists for lepidopterism and treatment is symptomatic and supportive. Spines can be removed by adhesive tape. Antihistamines and steroids may be administered for pruritus. For the rare patient with hypotension, intravenous fluids and subcutaneous epinephrine should be administered.

BLISTER BEETLES (COLEOPTERA)

Although the order Coleoptera includes a large number and variety of beetles, clinically significant envenomation occurs only from blister beetles. There are approximately 1500 species of blister beetles worldwide, including 200 species in the United States. Although not naturally found in the United States, the most well known blister beetle is the "Spanish fly" (*Cantharis vesicatoria*).

Clinical Features

Blister beetles contain the highly potent vesicant cantharidin that is exuded from their joints when disturbed, or from their body when crushed. For this reason a blister beetle should be removed from the skin by blowing or flicking. Cantharidin-containing preparations are used medicinally in wart removal. Application of these substances in low concentration is without adverse effect.³¹ However, higher concentrations, or contact with the beetle's venom may cause local inflammation leading to bullae formation. Severe conjunctivitis may also occur if cantharidin contacts the eyes from contaminated hands.

Owing to its lipophilicity, high concentrations of cantharidin may result in dermal absorption and systemic toxicity. Systemic toxicity also occurs following ingestion, either of the whole beetle or of cantharidin-containing preparations. Severe vomiting, hematemesis, abdominal pain, and diarrhea may occur, followed by dysuria, hematuria, oliguria, and renal failure as the toxin is concentrated in the kidneys. Death has occurred after large ingestions. Although the exact mechanism by which cantharidin produces systemic toxicity is unknown, the vesicant action may explain much of the symptoms observed. Fortunately, most preparations sold as "Spanish fly" for purported aphrodisiac properties have very low concentrations of cantharidin. It is thought that the local vascular congestion and urethral inflammation that occurs following ingestion may be interpreted by some as enhanced sexuality.

Treatment

Treatment of blister beetle toxicity is largely supportive. The skin should be irrigated thoroughly after topical exposure to remove any persistent cantharidin followed by local wound care. Symptomatic ingestions should be admitted and treated supportively.

REPTILE BITES

Richard C. Dart
Frank F. S. Daly

An estimated 3 million bites and 150,000 deaths occur each year from venomous snakes in the world.¹ The American Association of Poison Control Centers reports an average of 6000 bites each year, approximately 2000 of them from venomous snakes. Because of underreporting, the true number of snake bites is possibly as high as 45,000 per year in the United States, with 7000 to 8000 from venomous snakes.² The major venomous snakes of the world can be divided into three groups: Viperidae (vipers), Elapidae, and Hydrophiinae (sea snakes, see Chap. 196).

Approximately 20 of the 120 snake species indigenous to North America are venomous. Most bites occur in the warm summer months, when snakes and victims are most active. In the past, it was estimated that mortality from venomous snakebite approached 25 percent. Because of the availability of antivenom and advances in emergency and critical care, mortality rates today are less than 0.5 percent; approximately 5 to 10 deaths occur per year.³

Except for bites by imported species, North American venomous snakebite involves the pit vipers (*Crotalinae* subfamily of Viperidae) or coral snakes (Elapidae family). The crotaline snakes are represented by the rattlesnakes (*Crotalus* species), pygmy rattlesnakes, and masasauga (*Sistrurus* species), and the copperheads and water moccasins (*Agkistrodon* species). Poisonous snakebites from imported exotic species are infrequent but may occur in zoo personnel as well as in amateur herpetologists. A regional poison center can provide information on snake identification, expected toxicity, and location of antivenom.

CROTALINAE (PIT VIPER) BITES

The crotaline snakes are called pit vipers because of bilateral depressions or pits located midway between and below the level of the eye and the nostril (Figure 195-1). The pit is a heat receptor that guides strikes at warm-blooded prey or predators. Crotaline snakes are also distinguished by two fangs that fold against the roof of the mouth, in contrast to the coral snakes, which have shorter, fixed, and erect fangs. Within the pit vipers, the rattle distinguishes the rattlesnake from other crotaline snakes. The mistaken belief that rattlesnakes always rattle be-

FIG. 195-1. Rattlesnake surface anatomy.

fore striking has persisted for centuries. In truth, many strikes occur without a warning rattle.

Pathophysiology

Crotaline venom is a complex enzyme mixture that causes local tissue injury, systemic vascular damage, hemolysis, fibrinolysis, and neuromuscular dysfunction, resulting in a combination of local and systemic effects. Crotaline venom quickly alters blood vessel permeability, leading to loss of plasma and blood into the surrounding tissue, causing hypovolemia. Crotaline venom activates and consumes fibrinogen and platelets, causing a coagulopathy. In some species, specific venom fractions block neuromuscular transmission, leading to cranial nerve weakness (e.g., ptosis), respiratory failure, and altered sensorium.

Clinical Features

Up to 25 percent of crotaline snakebites are termed dry: venom effects do not develop. The manifestations of crotaline venom poisoning involve a complex interaction of the venom and the victim. The species and size of the snake, the age and size of the victim, the time elapsed since the bite, and characteristics of the bite (location, depth, and number, the amount of venom injected) all affect the clinical appearance. The severity of poisoning following a crotaline bite is therefore variable. An initially minimal bite may evolve into a more serious bite and require large amounts of antivenom.

The cardinal manifestations of crotaline venom poisoning are the presence of one or more fang marks, localized pain, and progressive edema extending from the bite site.² Other early symptoms and signs of envenomation are nausea and vomiting, weakness, oral numbness or tingling of tongue and mouth, tachycardia, dizziness, and muscle fasciculation. Envenomation may produce systemic effects with tachypnea, tachycardia, hypotension, and altered level of consciousness. In general, local swelling at the bite site becomes apparent within 15 to 30 min, but in some cases, it may not start for several hours. In severe cases, edema may progress to involve an entire limb within an hour. In less-severe cases, edema may progress over a 1- to 2-day period. Edema near an airway or in a muscle compartment may threaten life or limb without the presence of systemic effects.

Progressive ecchymosis may also occur because of leakage of blood into subcutaneous tissue. Ecchymoses may appear within minutes or hours and hemorrhagic blebs may occur within several hours. Hemoconcentration often develops as a result of fluid extravasation into subcutaneous tissue, followed by a decrease in hemoglobin over several days from blood loss secondary to coagulopathy.

Diagnosis

The diagnosis of snakebite is based on the presence of fang marks and a history consistent with exposure to a snake (e.g., walking through a field). Snake envenomation involves the presence of a snakebite plus evidence of tissue injury. Clinically, the injury may be manifest in three ways: local injury (swelling, pain, ecchymosis), coagulopathy (thrombocytopenia, elevated prothrombin time, hypofibrinogenemia), or systemic effects (e.g., oral swelling or paresthesias, metallic or rubbery taste in the mouth, hypotension, tachycardia). Abnormalities in any one of these areas indicate that venom effect is developing. The absence of any of these manifestations for a period of 8 to 12 h following the bite indicates a dry bite.

Treatment

FIRST AID First aid measures should never substitute for definitive medical care or delay the administration of antivenom (Table 195-1). All patients bitten by a pit viper should be taken to a health care facility. **First aid treatments such as suction and incision are dangerous and should not be used.** The Coghlan's Snake Bite Kit (Coghlan's Ltd.) and similar products should not be used because they contain cups that produce little suction and seal poorly on digits. The blade in the kit, or any method of incision, can injure digital nerves, arteries, and tendons; incision is not recommended. The Sawyer Extractor (Sawyer Products) suction pump purportedly removes venom without incision; however, serious questions regarding its safety and efficacy have been raised.⁴ Other useless or dangerous techniques are electric shock and ice. Electric shock treatment of the bite site is mentioned only to be condemned. This dangerous procedure is not effective and has resulted in electrical injuries. Ice-water immersion worsens the venom injury.

Tourniquets are contraindicated because they obstruct arterial flow and cause ischemia. Constriction bands may be of some use, especially when immediate medical care is not available. A constriction band is an elastic bandage or Penrose drain, rope, or piece of clothing wrapped circumferentially above the bite, applied with enough tension to restrict superficial venous and lymphatic flow while maintaining distal pulses and capillary filling. The band should be snug but loose enough to comfortably slide a finger underneath. In theory, a constriction band retards venom absorption. This should increase local tissue injury but reduce the severity of systemic effects. Anecdotal human reports and animal studies suggest that constriction band use delays venom absorption without causing increased swelling.⁵ Human controlled studies are needed to better define the clinical indications for constriction band use.

EMERGENCY MANAGEMENT In the prehospital phase, personnel should be directed to immobilize the limb, establish intravenous access in another limb, administer oxygen, and transport the victim to a medical facility. Previously placed tourniquets and constriction bands should not be removed until intravenous access is established.

As in any emergency, initial snakebite management should include advanced life support. If the patient is hypotensive, initial treatment should include rapid intravenous isotonic fluid infusion. Supplemental

TABLE 195-1 Recommended First Aid Measures

Retreat well-beyond striking range. Many victims are bitten again while trying to capture the snake.
Remain calm. Movement will increase venom absorption. Immobilize the extremity in a neutral position below the level of the heart. Keep physical activity minimal. Promptly transport the victim to a medical facility regardless of whether overt signs of envenomation are quickly apparent. Signs and symptoms of snakebite may be delayed.

oxygen should be started and limb immobilization continued during transport to reduce further venom absorption. Consultation with a physician or poison center familiar with the management of snake envenomation is recommended for most cases.

Antivenom is the mainstay of therapy for poisonous snakebite.²

Antivenom is composed of heterologous antibodies derived from the serum of animals immunized with the appropriate snake venoms. The antibodies bind and neutralize the venom molecules.

Antivenin (Crotalidae) Polyvalent is an equine-derived product, once widely used, which has been discontinued. A newer product, Polyvalent Crotalidae Immune Fab (ovine) (CroFab; FabAV) is now available in the United States. The new antivenom is produced by immunizing flocks of sheep with one of four crotaline snake venoms: Eastern diamondback (*Crotalus adamanteus*), Western diamondback (*C. atrox*), Mojave (*C. scutulatus*), or Cottonmouth (*Agkistrodon piscivorus*). The immune serum is harvested from each group and then digested with papain to produce antibody fragments (Fab and Fc). The more immunogenic Fc portion of the antibody is eliminated during purification. The four individual monospecific Fab preparations are combined to form the final antivenom product.

All crotaline bites that show evidence of progressive signs and symptoms should immediately receive antivenom. Progression is defined as worsening of local injury (e.g., pain, ecchymosis, or swelling), laboratory abnormalities (e.g., worsening platelet count, prolonged coagulation times, decreased fibrinogen), or systemic manifestations (e.g., unstable vital signs or abnormal mental status).

In clinical trials and initial clinical reports, FabAV has been effective and appears to have a better safety profile than Antivenin (Crotalidae) polyvalent.^{6,7} FabAV also dissolves into solution quickly and skin testing is not required.

FabAV is administered as a larger "initial control" dose followed by three smaller maintenance doses (Figure 195-2). Initial control is defined as cessation of progression of three clinical evaluation parameters: local effects, systemic effects, and coagulopathy. The initial dose is four to six vials, which may be repeated to establish initial control of the envenomation. After initial control has been established, two-vial maintenance doses are recommended (see Figure 195-2).

Under no circumstances should antivenom be injected directly into a digit. Intramuscular injection is also not recommended because

venom-induced hypovolemia may retard absorption of antivenom. Hospital pharmacies in those regions of the United States where poisonous snakes are prevalent should maintain adequate stocks of antivenom. Unfortunately, many hospitals stock insufficient amounts of antivenom, even in endemic areas.⁸

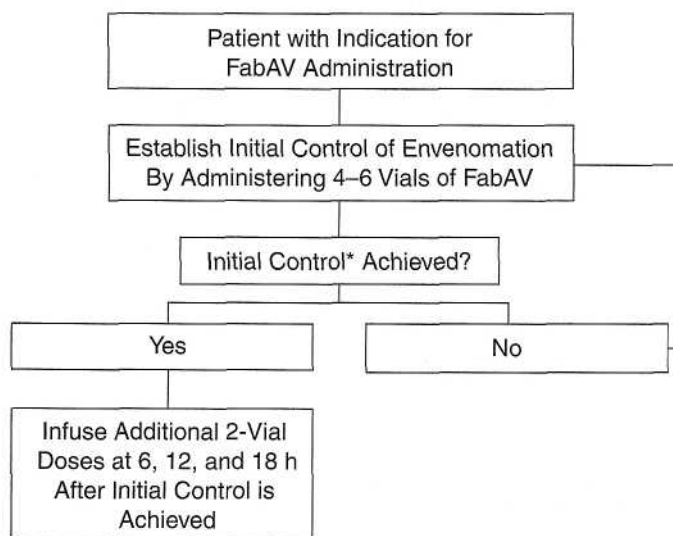

The package insert is useful as a guide for antivenom preparation. Antivenom should be administered only in a critical care facility such as an ED or intensive care unit, under direct physician supervision, and with resuscitative drugs and equipment immediately available. After reconstitution, each dose of FabAV is diluted in 250 mL of crystalloid and infused slowly for the initial 10 min, until it is evident that anaphylaxis will not occur, then the rate should be increased in a stepwise manner until the infusion is complete, usually in 1 h. The total volume, but not the number of vials, may be reduced in small children.⁹

The incidence of acute reactions to FabAV is about 14 percent.^{2,7} If an acute allergic reaction occurs, the infusion should be stopped immediately and antihistamines administered (both H₁ and H₂-receptor blockers). Epinephrine infusion should be readily available and used, depending on the severity of the reaction.

It is extremely important that observation for progression of edema and systemic signs of envenomation be continued during and after antivenom infusion. Limb circumference should be measured at several sites above and below the bite, and the advancing border of edema should be outlined with a pen every 30 min. This serves as an index of the progression as well as a guide for antivenom administration. Laboratory determinations are repeated every 4 h, or after each course of antivenom therapy, whichever is more frequent. Additional doses of FabAV may be warranted if the patient's condition worsens. FabAV has been formally tested only in rattlesnake bites. Initial case reports support its efficacy in copperhead snakebite, but controlled data are needed.¹⁰

The value of aggressive supportive care cannot be overemphasized. Isotonic fluid resuscitation followed by vasopressor agents is appropriate for hypotension. Antivenom is the best treatment for coagulopathy, but if active bleeding occurs, blood component replacement may be necessary. Another complication of snakebite is compartment syndrome. Increased compartment pressure may occur when venom is injected or spreads into a compartment. This is often manifested by severe pain, localized to a compartment and usually resistant to opiate analgesia. Treatment of compartment syndrome is difficult (Table 195-2). The use of fasciotomy is controversial and there is no firm evidence supporting its use.

The wound area should be cleaned and the need for tetanus immunization determined. Cultures and antibiotic therapy should be initiated only if signs of infection are present. Although recommended by some authors, the data available do not support the prophylactic use of antibiotics.¹¹ The use of steroids is also controversial. Several studies suggest lack of efficacy or even deleterious effects. Without evidence of efficacy, steroids should be reserved for the treatment of allergic reactions or serum sickness.

* Initial control of the envenomation syndrome is defined as cessation of progression of all components of envenomation: local effects, systemic effects, and coagulopathy. FabAV; Polyvalent Crotalidae Immune Fab (ovine). FIG. 195-2. Use of Polyvalent Crotalidae Immune Fab (ovine).

TABLE 195-2 Management of Compartment Syndrome*f

Determine intracompartmental pressure.
If not elevated, continue standard management.
If signs of compartment syndrome are present and compartment pressure is >30 mmHg:
Elevate limb
Administer mannitol 1-2 g/kg IV over 30 min
Simultaneously administer <i>additional</i> antivenom, 4 to 6 vials IV over 60 min
If elevated compartment pressure persists another 60 min, consider fasciotomy

*Elevated compartment pressure is caused by the action of the venom on the tissues; thus, the most effective treatment is to neutralize the venom, which may reduce the compartment pressure.

f This protocol delivers a high osmotic load and should not be used when contraindicated. The protocol must be completed promptly so that, if ever needed, fasciotomy may be performed as early as possible.

Delayed serum sickness develops in about 5 percent of patients after FabAV treatment. The symptoms are fever, rash, and arthralgias. Oral prednisone 60 mg/d should be started and tapered over 1 to 2 weeks.

Disposition

Patients are ready for discharge when swelling begins to resolve, the coagulopathy has been reversed, and the patient is ambulatory. During recovery, physical therapy of the bitten part (particularly the hand) is recommended after swelling has lessened and coagulopathy has resolved. Outpatient follow-up is necessary to monitor for infection and serum sickness.

It cannot be overemphasized that one can easily be deceived by a bite that initially appears innocuous. An unremarkable physical and laboratory examination at presentation does not reliably indicate an insignificant envenomation. **We recommended that physicians observe patients for at least 8 h.** Patients with severe or life-threatening bites and patients receiving antivenom should be admitted to an intensive care unit. The general ward is appropriate for patients with mild or moderate envenomations who have completed or do not require further antivenom therapy.

Patients with dry bites who have been observed for at least 8 h may be discharged. They should return if pain, swelling, or bleeding develops.

CORAL SNAKE (ELAPID) BITE

North American coral snakes include the eastern coral snake (*Micrurus fulvius fulvius*), the Texas coral snake (*M.f. tenere*), and the Arizona (Sonoran) coral snake (*Micruroides euryxanthus*). The eastern coral snake is found primarily in the southeast United States. The Texas and Arizona coral snakes are found primarily in the states that bear their names. Coral snakes account for 20 to 25 bites a year.

Elapids are found throughout the world in tropical and warm climates. Medically significant groups include most venomous snakes of Australia [tiger snakes (*Notechis*), brown snakes (*Pseudonaja*), costal taipan (*Oxyuranus*), dead adder (*Acanthophis*), red-bellied black snake (*Pseudechis*)], and cobras (*Naja*), mambas (*Dendroaspis*), and kraits (*Bungarus*) found in Africa and southern Asia.

All coral snakes are brightly colored with black, red, and yellow rings. The red and yellow rings touch in coral snakes, but they are separated by black rings in nonpoisonous snakes, creating the well known rhyme: "Red on yellow, kill a fellow; red on black, venom lack." This rule is not always true outside of the United States.

Coral snake venom is primarily composed of neurotoxic components that do not cause marked local injury. Elapid bites produce primarily neurologic effects: tremors, salivation, dysarthria, diplopia, bulbar paralysis with ptosis, fixed and contracted pupils, dysphagia, dyspnea, and seizures. The immediate cause of death is paralysis of respiratory muscles. Signs and symptoms may be delayed up to 12 h.

The potential coral snake victim should be admitted to the hospital for observation. Coral snake venom effects may develop hours after a bite and are not easily reversed. It is suggested that three to five vials of the Antivenin (*Micrurus fulvius*) be administered to patients who have definitely been bitten because it may not be possible to prevent further effects or reverse effects that have already developed.¹² Additional coral snake antivenom is reserved for the appearance of symptoms or signs of coral snake envenomation. Because respiratory failure may result from clinical effects of the neurotoxin, baseline and serial pulmonary function parameters (such as inspiratory pressure and vital capacity), in addition to intensive care observation, may be useful. Prolonged ventilatory support may be required in severe cases. The patient must be observed closely for signs of respiratory muscle weakness and hypoventilation. Bites by the Sonoran coral snake are mild and antivenom is not usually needed.

AUSTRALIAN ELAPIDS

Approximately 3000 people are bitten by snakes each year in Australia, of whom at least 200 receive antivenom.¹³ In the decade up to 1992, there was an average fatality rate of 1.8 per year, but in the years 1992 to 1994, the rate was 3.7 deaths per year (the Australian population is approximately 19 million).

Pathophysiology

The venomous snakes of Australia are members of the family Elapidae, of which the cobras are also members. The Elapidae possess a relatively unsophisticated venom delivery apparatus with nonretractile small- to medium-sized paired fangs that have grooved venom channels rather than hollow venom ducts. It is thought that the Elapidae exert voluntary control over the injection of venom, hence the occurrence of the "dry bite," without envenomation.

The venom of the Australian elapids contains several important components.¹⁴ Neurotoxins (tiger snake, taipan, and death adder) act at the neuromuscular junction and cause paralysis. Signs usually become apparent within 2 to 4 h after the bite and may include ptosis, partial ophthalmoplegia (diplopia), dysarthria, loss of facial expression, and loss of airway control, as well as respiratory paralysis in severe cases. The procoagulant toxins (brown snake, tiger snake, taipan) act as prothrombin converters, leading to fibrinogen depletion and a consumptive coagulopathy. Intracranial hemorrhage is a recognized complication.

The brown snake can cause rapid collapse and death.¹⁵ Brown snake venom produces severe cardiovascular depression in anesthetized dogs, and these effects may account for the sudden deaths described. Renal impairment or failure may also result from snakebite. The mechanisms are poorly understood and may include hypotension, myoglobinuria, coagulopathy, and direct renal toxicity (the brown snake). Myolysins (tiger snake, taipan, mulga snake) are structurally related to the neurotoxins but instead produce rhabdomyolysis, which may result in muscle pain, weakness, myoglobinuria, renal failure, and hyperkalemia. Local tissue destruction is uncommon with any Australian species, although mild to moderate ecchymosis and swelling may occur.

Clinical Presentation

The severity of envenomation cannot be estimated by the appearance of the bite site or initial symptoms.¹⁶ Despite significant envenomation, patients may initially feel well and manifest no untoward clinical features. Conversely, depending on the snake involved, patients may present with myriad symptoms, including nausea, vomiting, headache, diplopia, dysphonia, progressive muscle weakness, neck stiffness, discolored urine, and seizures. Young children may not provide a history of snakebite; therefore a high index of suspicion is required in this group.

Diagnosis

Local signs after brown snake envenomation may be minimal, and unless the patient gives a history, diagnosis may be difficult. To aid in diagnosis and direct therapy, the Commonwealth Serum Laboratory Ltd. (CSL) in Australia has developed a Snake Venom Detection Kit (S VDK) to detect snake venom at the bite site or in the urine. Positive SVDK identification of venom at the bite site or in the urine is not an indication for antivenom therapy without other evidence of systemic venom effect. False-positive and false-negative results have been described for blood testing by the SVDK and so only the bite site or urine should be tested.¹³

Treatment

FIRST AID The aim of first aid is to delay absorption of venom from the bite site until the patient is in a facility that can administer antivenom if required. The pressure-immobilization method is used for

elapid bites as local soft tissue swelling is usually minimal, but this technique is not recommended for crotaline bites because the immobilization dressing causes severe pain when swelling develops.¹⁷ All patients with elapid bites should immediately have the bitten extremity wrapped in a snug elastic bandage, applied initially over the bite site "and then extending to cover the entire limb. The bandage should be applied as if to a sprained joint; if it is too loose or too tight, it will be ineffective. The limb is then splinted to prevent motion. The patient should rest until help arrives. The principle is to contain the venom within lymphatic vessels and prevent systemic absorption. Examination of lymphatic flow rates with simulated venom has demonstrated that even if the upper or lower limb is appropriately bandaged and immobilized, walking will hasten systemic envenomation.¹⁷ Tourniquets are contraindicated because they obstruct arterial flow and add ischemic injury to venom effect. In the rare circumstance that a bite is inflicted on the trunk, firm pressure should be applied without restricting breathing.

EMERGENCY MANAGEMENT Any history suggestive of snakebite should prompt the initiation of first aid, investigation, and observation. Snakebite cases often present a number of complex clinical problems; therefore early consultation with an expert is recommended. The pressure bandage should remain in place until the patient can receive antivenom. Once in a suitable facility, objective evidence of envenomation should be sought. If signs are absent, bandages and splints should not be left on for prolonged periods. Similarly, if antivenom is indicated, the bandage should be removed once administration has commenced so that venom is available for interaction with circulating antivenom. There is no evidence that venom is inactivated by being trapped at the bite site.¹³ If the patient's condition deteriorates immediately after bandage removal, the bandages may be reapplied while antivenom is given.

Antivenom should be given only in cases when there is clear clinical or laboratory evidence of systemic venom effect. Clinical indications for immediate antivenom therapy include vomiting and severe headache; neurotoxic effects such as ptosis, cranial nerve involvement, progressive muscle weakness, or diaphragmatic involvement; or evidence of coagulopathy. Pertinent investigations include complete blood count, coagulation studies, serum electrolytes, renal function, creatine kinase levels, and urine testing for hematuria or myoglobinuria.¹⁴ Abnormal renal or coagulation studies may provide laboratory evidence of systemic venom effect before neurotoxic effects are apparent. If prothrombin or activated partial thromboplastin times are prolonged, then levels of fibrinogen and fibrin degradation products should be obtained.

In the absence of clinical or laboratory evidence of venom effect, the elastic bandage should be removed and the patient observed for 12 h. Delayed envenomation after benign presentation has been documented, but most envenomated patients will develop clinical or laboratory evidence of envenomation within 2 h of removing a bandage.¹³ Therefore, coagulation studies should be repeated 2 h after bandage removal and at intervals thereafter, depending on the patient's condition.

Five antivenom products, derived from equine IgG, are produced by CSL to treat envenomation by certain groups of terrestrial Australian snakes; these are termed monovalent antivenoms.¹⁴ A polyvalent antivenom, also equine IgG, neutralizes the venom of all five major groups of dangerous Australian snakes.

If indicated, antivenom should be given immediately in sufficient doses to improve coagulation studies. A child should receive the same dose of antivenom as an adult.¹⁴ Pregnancy is not a contraindication to antivenom therapy. Skin testing before antivenom administration is not recommended as it may sensitize the patient to future antivenom use and delays definitive therapy.¹⁴ If the type of snake cannot be identified, usually two appropriate monovalent antivenoms may be selected by correlating the clinical presentation with knowledge of snakes found in the geographic area. Polyvalent antivenom is used in the fol-

lowing circumstances: (1) monovalent antivenom is not available; (2) the SVDK is not available or has failed to identify the type of snake and the range of possible snakes would require the mixing of three or more monovalent antivenoms; (3) the patient is severely envenomated, there is insufficient time to wait for SVDK results, and the range of possible snakes would require the mixing of three or more monovalent antivenoms; or (4) stocks of appropriate monovalent antivenom have been exhausted and the patient requires further antivenom treatment.¹⁴ Anaphylaxis is a rare complication of antivenom therapy in Australia perhaps because of the common practice of premedication with epinephrine, antihistamines and/or corticosteroids.^{18,20} Nevertheless, patients should be treated in a setting where anaphylaxis can be managed. Premedication with a subcutaneous dose of 0.3 mL of 1:1000 epinephrine (adrenaline) in an adult or 0.1 mL in a child along with a parenteral antihistamine is not used universally but recommended by some authors.¹⁹ Although prospective data are lacking, corticosteroids may have a role in premedication and prevention of serum sickness. Most treatment protocols dictate that patients with a history of allergy to equine proteins should receive corticosteroids. In addition, a 5-day course of prednisolone may be prescribed in an attempt to reduce the incidence of serum sickness in those patients who receive large doses of antivenom.¹³

COBRA BITE

Cobras are large snakes, typically 1 to 1.5 m in length, and indigenous to most of Africa and southern Asia.²¹ Cobras adapt readily to different habits and can be found around villages and inhabited areas. The bold defensive posture cobras adopt, by elevating the head and spreading the neck, is not unique to this group of snakes. Not all cobra bites result in envenomation; perhaps as much as 45 percent are dry bites. Some species of cobras have the ability to spit jets of venom toward a victim, often hitting the eyes. The incidence of cobra bite and subsequent mortality is difficult to determine because of the lack of accurate reporting systems in most of Africa and southern Asia. In rural Congo, an annual incidence of 430 cobra bites per 100,000 population has been described. In Burma and India, an annual mortality incidence between 3 and 10 per 100,000 has been reported.

Pathophysiology

Cobra venom contains a mixture of toxins. In most cobras, neurotoxins in the venom pose the greatest threat to the victim. These neurotoxins bind to postsynaptic acetylcholine receptors and produce depolarizing neuromuscular blockade. A second group of toxins are cell membrane poisons that act in a general fashion, but their chief effect is on the heart, producing arrhythmias and impaired contractility. The third group of toxins contains enzymes that break down protein and connective tissue. These necrosis-producing toxins are typical of the venom from the spitting cobras (*Naja* spp.) of Africa, China, and Sumatra.

Clinical Features

Immediate pain at the bite site is almost always present. Other symptoms and signs are variable and can include local and progressive soft tissue swelling, cranial nerve dysfunction (ptosis, diplopia, dysphagia), generalized muscle weakness followed by flaccid paralysis, and parasympathetic stimulation (salivation, bronchorrhea, nausea, vomiting). Victims who were sprayed in the eye by a spitting cobra will describe pain, tearing, and blurred vision.

Signs include impaired sensorium (drowsiness), respiratory distress, hypotension, ptosis, ophthalmoplegia, and generalized weakness or paralysis. Reaction around the bite site may develop over 48 h with local hemorrhage, bullae, and necrosis. Venom spit into the eye will produce inflammation, edema, and discharge, but no systemic symptoms.

toms or signs. Coagulopathy is rare following a cobra bite, with the exception of a bite from a spitting cobra.

Diagnosis

Because of venom potency and size of the snake, a bite resulting in envenomation will usually produce obvious symptoms. The difficulty is distinguishing cobra envenomation from bites from other snakes that possess neurotoxic venom. When possible, the snake should be killed and brought in for identification. A variety of snake venom detection assays have been developed that can identify the offending snake with reasonable accuracy from wound aspirate or urine. The availability of these kits is, unfortunately, poor in most of Africa and Asia. Standard laboratory should be obtained with local or systemic signs of envenomation: complete blood count, serum electrolytes, creatinine, and coagulation tests.

Treatment

FIRST AID Most common first aid measures have either no proven efficacy or increase toxicity. The pressure-immobilization technique used for Australian elapids has not proven beneficial with cobra bites. The proximal lymphatic- and venous-constricting elastic-band approach used in North American crotalines is probably more reasonable, although unproven. Incisions, vacuum extractors, cooling, or ice are not beneficial. The one first aid measure beneficial is prompt and copious irrigation of the eyes having sustained a venom exposure.

EMERGENCY TREATMENT There is no correlation between local tissue damage and systemic toxicity, so grading systems based on bite site appearance should not be used. The only proven and specific therapy for cobra envenomation is antivenom.²² Laboratories in Africa, Asia, and Europe have developed cobra antivenom; some products are monovalent, specific for a single species, but most are polyvalent, containing antibodies against several important or common cobra species in that country or region. The animal of origin varies, as does potency and purity. All cobra antivenoms should be considered experimental agents and a high incidence of allergic reactions should be anticipated.

If the patient has evidence of systemic toxicity on arrival to the hospital, antivenom should be started before the constricting band is loosened. For patients without signs of systemic toxicity, the constricting band should be loosened only after antivenom is available. Antivenom is effective at reducing systemic toxicity but does not reduce local tissue damage and necrosis.

For patients with significant muscle weakness or paralysis, a cholinesterase-inhibiting drug, such as edrophonium or neostigmine, may produce temporary benefit until antivenom is available.²³ Respiratory failure should be treated with endotracheal intubation and ventilation.²⁴ Hypotension is treated with intravenous fluids initially and followed by vasopressors if there is an inadequate response. Tetanus immunization should be provided as appropriate.

DISPOSITION Patients without signs of envenomation should still be admitted for observation for 24 h. Death from cobra envenomation typically occurs 2 to 6 h after the bite. Survival is possible without antivenom treatment provided there is good respiratory and cardiovascular supportive care.^{22,24} With prompt and appropriate antivenom and supportive pulmonary care, recovery from neurotoxicity is expected, but may take up to 6 days.

GILA MONSTER BITE

Gila monsters are slow-moving lizards that inhabit the desert in the southwestern United States. They possess venom as potent as rattlesnake venom but lack the apparatus to effectively inject it. Instead

of fangs, they have short, grooved teeth down which their venom flows. Therefore, envenomation requires a prolonged bite. Gila monsters bite tenaciously and may be difficult to remove from the bitten extremity.

Most bites result in local pain and swelling only, which worsens over several hours and then subsides over several more hours. Dislodged teeth often contaminate the wound. Occasionally, a more severe syndrome of systemic toxicity develops, including weakness, light-headedness, paresthesia, and diaphoresis. Severe hypertension may occur, which also resolves over several hours. There are few if any documented deaths from Gila monster bite.

First aid involves removal of the reptile from the bite site without sustaining another bite. This may require force. It helps to place the animal on a solid surface; it often loosens its grip when it is no longer suspended in midair. Otherwise, standard local wound care is sufficient, taking care to remove any teeth in the wound. The usefulness of prophylactic antibiotics is unknown and tetanus status should be updated as appropriate.

TRAUMA AND ENVENOMATIONS FROM MARINE FAUNA Geoffrey K. Isbister David G. Caldicott

Despite the fact that 71 percent of the surface of the earth is covered with water and half the population of the planet lives within 125 miles of the coast, the marine environment remained largely uncharted territory until the twentieth century, when technological innovation permitted closer exploration. Today, the underwater world is increasingly important for recreation, industry, and communications, with the inevitable consequence of increased exposure to marine fauna.

The marine environment is dangerous to humans for several reasons: we can't breathe, we can't see, and swimming must be learned. The marine environment is remote to points of definitive care. Marine fauna can inflict injury through trauma (often with infection) or envenomation. Many marine animals have developed venomous systems of defense and predation. Marine toxins can be extremely potent and knowledge of these toxins lags far behind that of their land-based equivalents. Consequently, the development of marine antivenoms is still in its infancy.

EPIDEMIOLOGY

There is little information on the epidemiology of marine injuries and envenomations.¹ A notable exception is the data collected by the International Shark Attack File, maintained by the Florida Museum of Natural History, Gainesville, Florida, U.S. It contains details of more than 3000 shark attacks, and this information is available to selected marine biologists and health care professionals.²

One U.S. study reviewed more than 6 years of aquatic animal exposures reported to poison information centers. The commonest exposures were jellyfish stings in 31 percent, stingrays in 16 percent, venomous fish stings in 28 percent (including lionfish, catfish, and others), and gastropods in 6 percent of cases.³ However, these percentages are likely to be biased to more severe injuries, and do not include common minor injuries such as envenomation by *Physalia* spp., sea bathers eruption, and sea urchin stings. In the United States, thousands of cases of minor jellyfish stings occur yearly from *Physalia physalis* (Portuguese Man-of-War) and *Chrysaora* species.⁴

MARINE TRAUMA

Shark Attacks

Of the many animals that live in the sea, the shark is the species best equipped to inflict severe injuries. Sharks, along with skates and rays, make up the subclass Elasmobranchii of the class Chondrichthyes ("cartilaginous fishes"), so called because their skeletons are made completely of cartilage. They are an ancient class of fish, with many living species belonging to the same genera as species that swam in the cretaceous seas 100 million years ago. They have maintained this position as top-level predators. There are 373 species of shark, up to 80 of which are currently endangered, and 32 species have been described in attacks on humans.

Any shark that can grow larger than 1.8 m (6 ft) is potentially lethal to a man, but smaller sharks, if provoked, can inflict nasty injuries.⁵ Certain species appear to be disposed to attacking humans. These include the white shark (*Carcharodon carcharias*), the tiger shark (*Galeocerdo cuvier*), and several members of the *Carcharhinus* spp. There are probably between 70 and 100 shark attacks in the world each year, with between 5 and 15 deaths.^{2,6,7} The mortality of shark attacks has fallen from 40 percent in the 30 years following World War II to its current rates of approximately 10 to 20 percent.⁶ Death is usually a result of lack of on-scene resuscitation, hemorrhagic shock, or drowning. Despite the public perception, the risk of shark attack is extremely small when compared with almost any other injury, and one is more likely to be killed driving to a beach than by a shark attack.

Three general types of unprovoked shark attack are described: (1) The hit-and-run attack, where the victim is seized and released, or slashed on an extremity, before the victim has any time to react, and often occurs in shallow water, accounts for approximately 80 percent of shark attacks; (2) sneak attacks, or the "out-of-the-blue" attack, usually involving divers or swimmers in deeper water; and (3) bump-and-bite attacks, where the shark circles and bumps the victim prior to attacking.^{5,6} These last two types tend to occur in deeper water, are multiple and sustained, involve bigger sharks, and cause the majority of deaths by shark attack.

The direct traumatic effects of a shark attack are dependent upon the severity and nature of the attack, as well as the size and species of the shark. Sharks attack the appendages of their victims (be they seals or humans), which tend to dangle lower than heads and torsos while swimming on the surface. In 70 percent of surface swimmers, the lower limb only is involved. The upper limb can be subsequently injured when patients try to fend off their attacker. Sharks are unable to chew their prey, and so sequentially strip it.⁶ In more serious, concerted attacks, substantial tissue loss and extremity amputation is common.

The two major concerns regarding shark attack injuries are (1) massive tissue injury with hemorrhagic shock, and (2) an extremely high incidence of atypical microorganisms that produce wound infections. The increased survival associated with shark attack is the result of improved training of first-responders and insight into early appropriate antibiotic usage. These same principles can be applied to any major marine trauma.

Patients may be exhausted, hypothermic, and near drowned. The patient should be removed from the surf, but only as far out of the water as is necessary to commence immediate resuscitation. Injuries should be treated with the same priorities and approach like any major trauma. Plain radiographs of all injured areas should be obtained, to identify fractures or periosteal stripping, and retained foreign bodies (e.g., particles of teeth) which can remain imbedded in bone and act as a future source of sepsis. Wounds should be swabbed and sent for culture. Abrasions and small punctures can be treated with thorough irrigation and topical antibiotics, but most injuries require debridement and treatment in an operating room. Devitalized tissue should be debrided, and copious irrigation should be used in cleaning the wounds. Plastic surgical procedures and repeat surgery is often required for many months after the initial attack.

Prophylactic antibiotics are currently recommended for all shark bites.⁶ The choice of antibiotics should provide coverage for *Vibrio* spp., *Staphylococcus* spp., and *Streptococcus* spp. Abdominal injuries should receive coverage effective against enteric and anaerobic organisms.

Other Major Marine Trauma

Other marine creatures have been reported in attacks on humans, but more usually in defense of territory than for feeding purposes. The great barracuda (*Sphyraena barracuda*) is the only barracuda species implicated in human attacks.⁷ Attacks are generally by solitary fish and occur only in tropical climates. Moray eels, found in tropical to tem-

perate waters, can inflict severe puncture wounds or lacerations, commonly to the hands of inquisitive divers. Other marine vertebrates known to cause traumatic injuries to humans include giant groupers, sea lions, seals, crocodiles, alligators and piranhas. Some fish (needlefish, wahoos, and triggerfish) with sharp spines and fins can inadvertently injure humans. Wounds resulting from interactions with such creatures are a combination of crush injury, abrasion, puncture, and laceration. Treatment of such injuries is analogous to that of shark bites, with an emphasis on irrigation, removal of foreign bodies (e.g., teeth), and allowing adequate wound drainage (e.g., leaving puncture wounds open).

Minor Trauma

Coral cuts are probably the most common injuries sustained underwater, usually involving the hands, forearms, elbows, and knees. The initial reactions to a coral cut are stinging pain, erythema, and pruritus. Within minutes, the break in the skin may be surrounded by an erythematous wheal, which fades over 1 to 2 h. With or without treatment, the local reaction of red, raised welts and local pruritus may progress to cellulitis with ulceration and tissue sloughing. The wounds heal slowly over 3 to 6 weeks. In extreme cases, the victim develops cellulitis with lymphangitis, reactive bursitis, local ulceration, and wound necrosis. *Coral poisoning* usually refers to systemic malaise, fever, diarrhea, and general exhaustion associated with a wound from coral.

Coral cuts should be promptly and vigorously irrigated to remove all foreign matter. Any fragments that remain can become embedded and increase the risk of infection or foreign-body granuloma. If stinging is a major symptom, there may be envenomation by nematocysts. A brief rinse with dilute acetic acid (vinegar) or papain solution may diminish the discomfort. If a coral-induced laceration is severe, it should be closed with adhesive strips, rather than sutures, if possible. Sharp debridement each day for 3 to 4 days is recommended if the wound is deep. For superficial (no fat showing) wounds, use daily saline solution or dilute povidone-iodine wet-to-dry dressing changes, or apply a topical antiseptic under a nonadherent dressing.

Bacteriology of the Marine Environment and Antibiotic Therapy

The majority of infections from marine-associated wounds are from the normal skin commensals: *Staphylococcus aureus*, *S. epidermidis*, α - and (3-hemolytic streptococci, and certain bacilli. However, microorganisms unique to seawater or freshwater can contaminate and infect wounds. The severity of these infections can be exacerbated by toxins associated with stings or bites, mechanical trauma from larger vertebrate injuries, and potential compartment syndromes from extremity injuries that penetrate deeply into tight anatomic compartments. Organisms which cause infection are referred to as marine bacteria, and halophilic, gram-negative rods cause the majority of these marine-associated infections. The most common organisms involved are *Vibrio* spp. (especially *V. vulnificus*, nontoxigenic *V. cholerae*, *V. alginolyticus*, *V. parahaemolyticus*, and *V. hollisae*) *Aeromonas* spp. [*A. hydrophila*], *Erysipelothrix rhusiopathiae*, *Photobacterium damsela*, *Edwardsiella tarda*, *Shewanella putrefaciens*, and *Mycobacterium marinum*? The natural habitat of marine organisms is warmer seawater that, along with the degree of human exposure, explains the geographic distributions of wound infections.

Marine-associated infections are often diagnosed late, the history of marine exposure or injury is poorly recalled, and patients are often initially managed with inappropriate antibiotics, potentially increasing morbidity of an already virulent infection. Certain patients with underlying conditions (hepatic impairment, immunosuppression, diabetes) are susceptible to halophilic vibrio infections.^{9,10} Halophilic vibrio skin infections can develop extremely rapidly, from initial con-

tact and local painful inflammation, through subepidermal bullae containing hemorrhagic fluid and vasculitis, to necrosis and small vessel thrombosis, bacteremia, and septicemia.^{9,10}

The management of infected marine injuries begins with meticulous wound care, including irrigation and debridement of devitalized tissue, with particular attention to retained foreign bodies, such as teeth, vegetable matter, and spines. In all but the most superficial of injuries, debridement should take place at the soonest opportunity, in an aseptic environment, preferably an operating room. Where the patient is stable, radiographs should be obtained to identify the nature and position of foreign bodies. Quantitative wound culture prior to the appearance of clinically evident wound infection has not been shown to be useful. Similarly, the issue of prophylactic antibiotics in the treatment of most marine wounds has not been well studied.

The priority for the management of infections from marine microorganisms is recognition that they are often more serious than other common soft tissue infections. Appropriate culture techniques should be employed. Many marine microorganisms require special selective media for culture and sensitivity testing, so the clinician should alert the microbiology laboratory that a marine-acquired organism might be present. Empirical antibiotic therapy should be initiated based on the clinical condition. The need for early treatment with antibiotics is well established in definite marine infections and at risk wounds or patients.^{8,10}

The choice of antibiotic is less clear. Antibiotic sensitivities vary and there is considerable discrepancy between the in vitro antibiotic susceptibility data and the clinical outcomes. Many marine wound infections are polymicrobial, and the choice of antibiotics should reflect this. Because there are no evidence-based guidelines, recommendations are tentative (Table 196-1). For all marine-acquired infections, antibiotic coverage against staphylococcal and streptococcal species is necessary, because these organisms remain the most common causes of infection. In addition, for seawater-associated infections, coverage against *Vibrio* species with a third-generation cephalosporin or fluoroquinolone should be provided (Table 196-2). For freshwater-associated infections, a fluoroquinolone, third-generation cephalosporin, trimethoprim-sulfamethoxazole, or imipenem to cover *Aeromonas* spp. is appropriate (see Table 196-2).

There are several special clinical situations of note. A patient with rapidly progressive cellulitis, myositis, or necrotizing fasciitis warrants consideration of *V. parahaemolyticus* or *V. vulnificus* infection. *V. vulnificus* can also cause primary septicemia in chronically ill individuals, particularly those with hepatic disease.^{8,9} *Aeromonas hydrophila* also causes wound infections that can rapidly progress to necrotizing

TABLE 196-1 Recommendations for Antibiotic Treatment of Marine-Associated Wounds

No Antibiotics Indicated	Prophylactic/Outpatient Antibiotics	Hospital Admission for IV Antibiotics
Healthy patient	Late wound care	Predisposing medical conditions
Prompt wound care	Large lacerations/injuries	Long delays before definitive wound care
No foreign body	Early or local inflammation	Deep wounds; significant trauma
No bone/joint involvement		Wounds with retained foreign bodies
Small or superficial injuries		Progressive inflammatory change
		Penetration of periosteum, joint space, or body cavity
		Major injuries associated with envenomation
		Systemic illness

TABLE 196-2 Antibiotics for Marine-Associated Wound Infections

For All: Staphylococci and Streptococci Coverage	Seawater- Associated: <i>Vibrio</i> spp. Coverage	Freshwater- Associated: <i>Aeromonas</i> spp. Coverage
First-generation cephalosporin (e.g., cefazolin), or Penicillinase-resistant penicillin (e.g., nafcillin)	Third-generation cephalosporin (e.g., ceftazidime), or Fluoroquinolone (e.g., ciprofloxacin)	Fluoroquinolone (e.g., ciprofloxacin), or Third-generation cephalosporin (e.g., ceftazidime), or Trimethoprim/ Sulfamethoxazole, or Imipenem

myositis. *Erysipelothrix rhusiopathiae* is the infectious agent in "fish-handler's disease," and causes sharply marginated, painful, expanding plaques on the fingers or hands following cutaneous inoculation. It is sensitive to penicillin, fluoroquinolones, and the cephalosporins.⁸ *Mycobacterium marinum* is an acid-fast bacillus that causes "swimming-pool granuloma" or "aquarium granuloma." Some 3 to 4 weeks following an abrasion or puncture wound, the patient develops a red papule, which progresses to a cutaneous granuloma. Because of the delay between the infecting event and presentation, patients often don't make the link, further clouding the diagnosis. It is resistant to most penicillins and is uniformly resistant to isoniazid. Clarithromycin has been recommended initially, in combination with ethambutol or rifabutin for deep-seated infections.⁸ It has also been suggested that treatment with heat lamps or hot water baths may be beneficial. In common with other mycobacterial infections, therapy can be protracted. Excision is sometimes preferred.

MARINE ENVENOMATIONS

Venomous marine animals produce venom in a specialized gland, which can then be applied or injected parenterally into other organisms using a specialized venom apparatus. This is in contrast to poisonous marine animals that may have special glands that produce toxic substances, but the animal lacks a particular apparatus to deliver these substances and the poisons have to be ingested to be effective.¹⁴ Venom is not a pure substance but a mixture of mainly protein and peptide toxins. The effect of a specific toxin depends on its site of action; it may be neurotoxic, hemotoxic, cytotoxic, or myotoxic. The toxins in marine venoms are usually heat labile, high-molecular-weight proteins, whereas marine poisons are usually heat and gastric-acid stable metabolic byproducts of lower molecular weight.⁴

INVERTEBRATE ENVENOMATIONS

Envenoming invertebrates are found in five phyla: Cnidaria (jellyfish), Porifera (sponges), Echinodermata, Mollusca (including octopus and cone snails), and Annelida.¹⁴

Cnidaria (Coelenterate)

The phylum Cnidaria (formerly named Coelenterate) is an enormous group of about 10,000 named species, at least 100 of which are dangerous to humans.¹⁴ The phylum contains four classes: Hydrozoa, Scyphozoa, Cubozoa, and Anthozoa. Cnidariae are characterized by their unique stinging apparatus, referred to as the nematocyst.¹¹ These structures occur in the thousands, mainly on the tentacles of the jellyfish, but also in lesser numbers on the body or bell. The nematocysts contain a minute dose of venom, in some cases highly potent venom, and a harpoon like mechanism. A physical or chemical stimulus trig-

gers the release of the hollow, sharply pointed threadlike tube from the contained nematocyst. This process is extremely rapid (thousandths of a second), and results in the threadlike tube penetrating the skin and delivering venom SC.

HYDROZOA The class Hydrozoa includes the hydroids, millepora (fire corals), *Physalia* species (Portuguese man-of-war and bluebottle jellyfish), limnomedusae, and Gonionemus.¹⁴ The Hydrozoa class has worldwide distribution.

The feather *hydroids* are the most numerous of the hydrozoans and are plumelike animals that sting the victim when they brush against or handle it. They have nematocysts on their arms and surfaces. They occur in tropical and temperate waters, and are often attached to wrecks and wharfs. Coastal storms can break off feather hydroid branches and infest a local swimming area. Contact with hydroids generally causes only minor problems. There is an immediate sting following even a superficial brush contact, followed by itching pain, associated with the development of painful wheals and urticaria after 30 min. The welts may last for up to a week, but leave no permanent mark. With more extensive exposure, blistering and a "hemorrhagic and zosteriform" reaction can occur. These crust over after a period of days. First aid is to blot the area carefully with a dry tissue. Vinegar has been shown to inhibit nematocyst discharge in *Lytocarpus philippinus*, but studies on other species are required.¹ Pain relief can be provided with ice packs or analgesia. Itching can be treated with topical steroids.

The *Millepora* species, or fire corals, are not true corals. They resemble hard corals except they are relatively smooth. Fire corals are widely distributed in shallow tropical waters and are often mistaken for seaweed because of their innocuous appearance.¹ Tiny nematocyst-bearing tentacles protrude from numerous minute surface gastropores. The clinical effects are similar to hydroids with immediate burning or stinging pain, with rare proximal radiation. Over the course of an hour or longer, initially small mosquito-bite-size marks progress to urticarial wheals. The pain generally resolves without treatment over 1 to 2 h and in most cases, there is no further reaction. Blistering is uncommon, although occasionally lesions may become infected. First aid and treatment is similar to hydroids and minor jellyfish stings, with drying the area, ice packs and topical steroids if required.

There are at least three important *Physalia* spp., although the taxonomy remains unclear. *P. physalis* are multitentacled hydrozoan colonies, rather than single jellyfish, and include the larger, more lethal Atlantic Portuguese man-of-war, and the smaller Pacific man-of-war, although these may be separate species. The third, *P. utriculus*, a single-tentacled variety, found commonly in Australia, is often referred to as the blue bottle.¹ *Physalia* spp. have a large gas-filled float, which suspends multiple tentacles that are as long as 30 m (100 ft) in Atlantic specimens. The nematocysts occur on the tentacles, but not on the float. *Physalia* spp. are the most widely distributed jellyfish and are responsible for thousands of human envenomations in Florida, parts of Asia and Africa, Australia, and Portugal.³⁴ All species occur in swarms in shallow water and usually cause stings in the surf or are washed up on the shore. Nematocysts from fractured tentacles may remain active for months.

Stings from *Physalia* species cause immediate, intense pain that often fades over an hour, but may persist for many hours, particularly with *P. physalis*. The sting causes a characteristic linear erythematous eruption.¹² Respiratory distress and death have been reported following *P. physalis* envenomation, but not from *P. utriculus*.¹³ More serious delayed effects have been reported following *P. utriculus* stings.¹

A number of other hydrozoans are of medical importance, including the genera *Gonionemus* and *Olindias*.¹ There are at least two *Gonionemus* spp. that cause envenomation, *G. oshoro* from Japan and *G. vertens* from the eastern Russian coast. Both cause a similar clinical syndrome. There is an initial sting and erythema at the sting site. After 15 to 20 min, victims develop severe pain in muscles, joints, abdomen, chest, and back, associated with nonspecific features such as

weakness, fatigue and fever. In some cases, there are respiratory symptoms. The effects resolve over 2 days. The syndrome appears to be similar to the Irukandji syndrome seen in Australia (see below). A number of *Olindias* spp. have been reported to cause stings. The most important is *O. sambaquiensis*, which occurs in coastal waters off eastern South America, including Brazil, Uruguay, and Argentina. The clinical effects are similar to other hydrozoans, with immediate pain and white welts with surrounding erythema. The pain usually lasts hours, but the marks may take weeks to resolve.

SCYPHOZOA (TRUE JELLYFISH) The class Scyphozoa, or true jellyfish, include a number of well-known and important groups: *Cyanea* spp. (hair jellyfish), *Catostylus* spp. (blubber jellyfish), *Chrysaora quinquecirrha* (sea nettle), the *Rhizostoma*, *Pelagia noctiluca* (mauve stinger), and *Linuche unguiculata* (thimble jellyfish).^{1,4}

Sea nettles or *Chrysaora* species are found in tropical and temperate waters. Members of the best-known species *C. quinquecirrha* are abundant in the Chesapeake Bay of North America, but also South America, the Philippines, and Japan. Envenomation from *C. quinquecirrha* are similar to those from *Physalia* species.¹² Despite possibly millions of local stings annually, there are few reports of severe signs of reactions.¹

Cyanea species, or hair jellyfish, may grow to enormous size and occur in open and colder oceans. They have numerous hairlike tentacles with nematocysts extending for meters under the bell. The sting causes only moderate pain with a localized red reaction that may persist and appears worse than the symptoms.¹

Catostylus mosaicus, or the common blubber jellyfish, occurs mainly in the Indo-Pacific region. However, the blubber jellyfish is unlikely to cause more than a faint prickle so is not medically significant.¹

Pelagia noctiluca, the mauve stinger or purple jellyfish, occurs in abundance in the Mediterranean where it is a common cause of sting, and is also well known in Australia. The sting usually causes immediate intense pain and blanching, followed by urticaria and edema. The pain usually subsides but localized vesicles, blistering, edema and itchiness may last longer. Recurrence of local lesions is reported and there has been one report of a near fatal anaphylactic reaction to a sting.^{1,4}

Seabather's eruption, commonly referred to by the misnomer "sea lice," is a vesicular or morbilliform pruritic dermatitis resulting from contact with the planula larvae of *Linuche unguiculata*, of the class Scyphozoa.⁴ It typically occurs within 24 h after saltwater exposure. The eruption primarily involves skin surfaces covered by bathing suits, swim caps, or fins. Divers may be afflicted on the neck when floating in water churned by boat propellers that have ground floating jellyfish into fragments. Dermatitis persists for 2 to 14 days and resolves spontaneously. Other symptoms, including headache, chills, pronounced nocturnal pruritus, malaise, conjunctivitis, and urethritis, are rare.

CUBOZOA (BOX JELLYFISH) The class Cubozoa, or box jellyfish, is divided into two important orders: Chirodropidae, including the Indo-Pacific box jellyfish (*Chironex fleckeri*), and Carybidae, typified by *Carukia barnesi*, an Australian jellyfish that causes Irukandji syndrome.^{14,15} The Indo-Pacific chirodropids have some of the most potent venoms in existence. *C. fleckeri* is sometimes described as the world's most venomous animal.¹⁴ It is found along the northern coast of Australia and has caused at least 65 fatalities in the past century. The exact mechanism of toxicity and toxins involved in this rapid death, often within 20 min, remains unclear, but a primary cardiotoxic role is postulated. Severe reactions or death can occur following skin contact with tentacles in excess of 6 to 7 m, especially in children.¹⁴ However, the vast majority of cases are mild to moderate and cause skin welts and immediate, sometimes severe pain.¹⁴ The toxic skin reaction may be quite intense, with rapid formation of wheals, vesicles, and a darkened reddish-brown or purple whiplike flare pattern with

stripes of 8 to 10 mm in width. In more severe stings blistering occurs and superficial necrosis develops after 12 to 18 h. On occasion, a pathognomonic crosshatched pattern may be present. Following the acute toxic reaction, a delayed hypersensitivity reaction occurs in approximately 60 percent of cases with papular urticaria at the sting sites.¹⁴ Other important chirodropids include *Chiropsalmus quadrigatus*, which has caused deaths in the Philippines and Japan.¹ Deaths have also been reported from *Chiropsalmus quadrumanus*, which is found along the U.S. Atlantic coast.¹ The Hawaiian box jellyfish (*Carybdea alata*) produces numerous stings to beachgoers in Hawaii, although no deaths have been confirmed from this organism.¹⁶

Although there are numerous Carybidae, *Carukia barnesi* has been best characterized and is responsible for the systemic envenomation referred to as the Irukandji syndrome.^{1,15} The sting initially causes mild local effects with localized pain and erythema. Approximately 20 to 30 min later, severe generalized pain in the abdomen, back, chest, head, and limbs develops. The pain is usually associated with other systemic features including tachycardia, hypertension, tachyarrhythmias, sweating, piloerection, and agitation. In severe cases, pulmonary edema occurs with myocardial depression.^{1,15} Other carybids include *Carybdea* spp. and morbakka types (*Tamoya virulenta*).¹

ANTHOZOA The class Anthozoa is the largest class of jellyfish and includes the sea anemones, stony (true) corals, and the soft corals. Anemones are common attractive seashore creatures often found in tidal pools, where the unwary may brush up against them or inquisitively touch them. They possess tentacles loaded with nematocysts.¹ There is considerable variation in the sting of anemones, but immediate localized pain of varying severity is usual. The skin may initially blanch and then wheal formation occurs with surrounding erythema. Pain may last hours and soreness for a number of days. Severe stings may lead to vesicle formation. Systemic effects are uncommon. Treatment is symptomatic, and there is currently no evidence to support the use of any type of decontamination.

Clinical Features of Jellyfish Stings

The clinical features of Cnidaria envenomation are similar across a wide spectrum of severity. The severity depends on the venom dose, the marine species, and the victim (age and size). Mild envenomation results in bothersome acute skin reactions, with immediate stinging pain and erythema or wheal formation at the site. This usually resolves spontaneously over days to a couple of weeks, with occasional postinflammatory hyperpigmentation. Anemones, *Physalia* species, and scyphozoans may cause moderate to severe envenomations compounded by systemic symptoms. These symptoms may appear immediately or within several hours. Severe envenomation occurs most commonly with cubozoan jellyfish. Chirodropids cause severe pain from local effects and rapidly life-threatening systemic envenomation. Cubozoan jellyfish have been associated with severe systemic envenomation seen with the Irukandji syndrome, and often with only minor local effects. Severe allergic reactions have been seen with a number of jellyfish, and fatalities have been seen after *Physalia* spp. envenomation.¹³

Management of Jellyfish Stings

Therapy consists of deactivation of attached nematocysts, reversal of venom effects if possible, and symptomatic and pain relief. All victims with systemic signs or symptoms should be observed for at least 8 h, because of ongoing envenomation or delayed reactions.

FIRST AID Deactivation of attached nematocysts is important but controversial, because of locale-dependent variations in therapy. A generally accepted method is to immediately apply a topical decontaminant, if available, to putatively inactivate undischarged nematocysts.

Freshwater rinsing is not recommended because the hypotonic solution is thought to stimulate nematocyst discharge. After decontamination, visible tentacles can be removed with forceps or a double-gloved hand.

As a decontaminant, 5% acetic acid (vinegar) is the treatment of choice to inactivate most nematocysts and is absolutely indicated in the event of a sting from *Chironex* and *Lytocarpus*. An alternative therapy for most nematocysts is isopropyl alcohol (40 to 70 percent), although it is not recommended for *Chironex*. For *Chrysaora* or *Cyanea*, a slurry of baking soda (sodium bicarbonate) is effective. Pressure immobilization bandages are not recommended for any jellyfish envenomations, including box jellyfish, despite previous suggestions.¹⁷

The venoms are heat labile, and despite previous advice to apply cold packs, research studies suggest heat may reduce toxicity and lethality.¹⁶ In addition, a controlled trial of the sting from *Carybdea alata* found hot water immersion of the affected site more efficacious.¹⁷ Some lifeguards report that a victim of a *Physalia* sting may find relief from being showered with a forceful stream of water, which implies that the mechanical removal of nematocysts may help.

TREATMENT Symptomatic treatment is often all the treatment that is required with minor stings. Either topical anesthetics or systemic analgesia should be used. Prophylactic antibiotics are not required, but standard tetanus prophylaxis and diligent wound care should be carried out. The vast majority of jellyfish stings are not seen in EDs.

In general, only severe *Physalia* and box jellyfish stings will result in rapid decompensation. Treatment for severe *Chironex* envenomation consists of standard resuscitative measures and sheep-derived antivenom specific for *C. fleckeri* [Commonwealth Serum Laboratories (CSL) Ltd, Melbourne, Australia].¹⁸ Pain may be severe and require opioid analgesia. Corneal envenomations can be irrigated with an isotonic solution and treated judiciously with topical steroids.

Porifera (The Sponges)

The phylum *Porifera* contains thousands of species of sponges that are composed of horny but elastic skeletons. Embedded in the connective tissue matrices are spicules of silicon dioxide or calcium carbonate. A number of sponges produce crinotoxins (slimes or surface liquids) that cause skin irritation and dermatitis referred to as stinging sponge dermatitis.¹⁴ The condition is possibly worsened by embedded spicules from the sponges. There is little evidence to suggest that hypersensitivity or allergy plays a role in this dermatitis, although patch testing has produced anaphylactoid reactions.

The clinical features of sponge injuries are variable and usually referred to as stinging sponge dermatitis. Often there is no initial sensation following contact with the sponge, but after a few minutes to hours an itching or burning sensation develops. The stinging or itching sensation usually increases in intensity over 2 to 3 days, and may become almost unbearable. The effects are usually confined to the area of contact or just adjacent. There may be associated local joint stiffness, and an acute inflammatory reaction with erythema and edema develops when symptoms are severe. Untreated mild reactions subside over 3 to 7 days. Papules, vesicles and bullae may develop in some cases, followed by desquamation of the area days to weeks later. A case of erythema multiforme has been reported 10 days after initial contact. Direct eye contact or contamination of the eyes with the fingers, can cause corneal injury or iritis. Plaques and postinflammatory pigmentation may last for months and recurrent eczema and persistent arthralgias are rare complications.

The literature suggests that most sponge injuries will run their natural course, despite various first aid and medical interventions.⁴ Spicules should be removed, if possible, using fine forceps, although some suggest adhesive tape. The area should be washed as soon as possible. Cold water compresses can be applied, which may reduce the

local symptoms. Although topical steroids may help to relieve secondary inflammation, they have not been found to be useful early in the treatment. Similarly topical antihistamines have also not been helpful. Pain relief with either oral or parenteral analgesia is indicated. Delayed primary therapy or inadequate decontamination may result in the persistence of bullae. Severe inflammatory reactions may be treated with systemic glucocorticoids. Severe itching may be controlled with an antihistamine.

The condition referred to as Mediterranean sponge diver disease is caused by contact with coinhabiting sea anemone on the sponge, resulting in an irritating skin rash, not as a direct result of sponge crinotoxins.

Echinodermata

The phylum Echinodermata is characterized by organisms that have penta-numerous (five parts) radial symmetry. There are two classes that contain venomous species, Asteroidea (sea stars or starfish) and Echinoidea (sea urchins). Organisms in other classes, such as Holothuroidea (sea cucumbers) contain poisons, but no venom apparatus.¹

Sea urchins are found in all oceans. They have a globular, sometimes flattened body shape, with numerous short and long spines attached to the body shell.⁴ The majority of sea urchins have solid (non-toxic) spines, and injury from these causes localized pain from cutaneous puncture or as the spines break off into the wound. The venom apparatuses of venomous sea urchins range from short sharp spines with venom glands on their tips (*Asthenosoma* spp.), to longer and hollow spines that can inject venom (*Diadema* spp.), to the triple-jawed pedicellariae (mobile grasping organs) of some other species. Contact with the venomous spines causes immediate, intense burning pain, with erythema, swelling, and often bleeding of the skin surrounding the puncture sites. The pain usually exceeds that produced by the mechanical injury, supporting the involvement of venom. The pain usually subsides over hours, but the area remains tender for a longer period of time.¹ Frequently, venomous spines break off and lodge in the victim. If a spine enters a joint, it may rapidly induce severe synovitis. Wounds from black sea urchin spines may leave a black discoloration of the skin. Secondary infection and granuloma formation from remaining spine fragments are well-described delayed effects. Systemic features have been reported, often if multiple spines are involved and may include nausea, vomiting, paresthesias, muscular paralysis, hypotension, and respiratory distress.¹ Pedicellariae can cause more severe pain and other clinical effects, predominantly neurologic.

The majority of sea stars are unlikely to cause medically significant injuries, except the crown-of-thorns sea star, *Acanthaster planci*. Crown-of-thorns sea stars are found on most reefs in the Indo-Pacific region, and have caused outbreaks in Japan and in Australia.¹ These creatures are covered with sharp, rigid spines that can passively deliver a variety of substances when they penetrate skin. This includes venom produced in special glandular tissue, mucous, bacteria and dermal tissue. Injury by the spines causes severe burning pain, often greater than expected for the mechanical injury, and lasts 1 to 2 h. Other local effects include bleeding, erythema and mild edema. In more severe cases, particularly with multiple puncture wounds the wound may become dusky or discolored. Pruritus and persisting edema can occur; perhaps as a result of allergy. Systemic effects are uncommon but may include paresthesias, nausea, vomiting, lymphadenopathy, and muscular paralysis.^{1,4}

Sea cucumbers (Holothuroidea) produce a toxin that is concentrated in the tentacular organs. Direct contact may induce a contact dermatitis, which is usually mild, because the venom is diluted in seawater. The greater risk is to the corneas and conjunctivae, which may become intensely inflamed.

First aid for echinoderm wounds consists of immediate immersion in hot water to tolerance [45°C (113°F)] for 30 to 90 min or until there

is significant pain relief. Prompt removal of pedicellariae and spines, especially those in intraarticular areas, is necessary but not always possible without proper imaging. Soft-tissue radiographs or magnetic resonance imaging are helpful in locating retained spines. Bolus injection of local anesthetics has also been used to remove spines to avoid surgical debridement.¹⁹ Treatment of systemic symptoms is supportive, and analgesia may be needed. Delayed granuloma formation may require excision.

Annelida

The phylum Annelida contains the fireworms, or bristleworms, which are segmented worms covered with cactus-like bristles that can penetrate the skin.^{1,4} These bristles easily detach in the skin and can be difficult to remove. Envenomation causes intense inflammation with a burning sensation and erythema. Untreated, the pain generally resolves within a few hours, but erythema may last for 2 to 3 days. Bristles should be removed with forceps or adhesive tape, and topical vinegar or isopropyl alcohol may be applied. The inflammatory response may require a course of corticosteroids.

Mollusca

The phylum Mollusca contains two envenomating classes: the gastropods (cone snails and nudibranchs) and the cephalopods (octopuses).^{1,4} Cone snail shells are beautiful, univalve creatures found in shallow Indo-Pacific waters. They are predators that feed by injecting a potent mixture of neurotoxins using detachable, dart-like, radicular teeth. Stings by cone snails are rare, with few published cases in the literature. Most cases are caused by *Conus geographus* although other *Conus* spp. are implicated.⁴ Most cases occur following prolonged contact with the shell, or if there is significant interference with the creature such as breaking the shell. The sting causes pain, usually similar to a bee or wasp sting. With significant envenomation, local pain is followed immediately by local numbness, which quickly spreads from the extremity to the trunk then face and throat. Partial paralysis develops within 30 min, progressing to complete voluntary muscle paralysis, respiratory failure and unconsciousness. Less-severe cases cause muscle pain, partial paralysis or ataxia, or in mild cases only local effects. Treatment is supportive and there is no specific antidote or antivenom.

The bite of the Australian blue-ringed octopus (*Hapalochlaena* spp.) causes small puncture marks. The octopus can inject tetrodotoxin, which it stores in modified venom glands. Octopus bites typically occur on the upper extremity almost always when the animal is picked up. Pain is often absent, and generalized paresthesia may be the first indication of envenomation. Further neurologic effects may develop, with flaccid paralysis progressing to ventilatory failure typical of tetrodotoxin poisoning.⁴ Treatment is supportive, with mechanical ventilation as required, and full recovery is usual. No antivenom is available.

For both cone snail shell and paralytic octopus envenomations, the most commonly recommended first aid technique is pressure-immobilization, done by wrapping the limb with a lymphatic occlusive bandage and then applying a splint. The wrap is maintained until the victim is brought to a medical facility where advanced life support can be provided.

VERTEBRATE ENVENOMATIONS

The most common and important marine vertebrates to cause envenomation are stingrays, venomous fish, and sea snakes. The first two have venomous spines that cause both mechanical trauma and introduce venom into the wound as the spine sheath is ruptured upon penetration. Sea snakes have fangs and inject venom in a manner similar to terrestrial snakes.

Stingrays (Order Rajiformes)

All stingrays have a characteristic dorsoventrally flattened appearance with pectoral flaps (fins) they use for propulsion. They have a whip like tail, which houses the venomous spines.¹ When not swimming, these creatures rest on the bottom and may become buried in the sand. When an unwary human treads on a stingray, the tail reflexively whips upward and accurately thrusts the spines into the victim. This produces a puncture wound or jagged laceration and simultaneously allows the injection of venom. Most injuries occur to the lower limb from stepping on the stingray in shallow water, although injuries occur to the hands when they are caught, or divers may sustain injuries to the torso. Rarely, the spine tip breaks off and remains in the wound. Envenomation causes immediate local intense pain and variable bleeding depending on the site of injury. The pain may radiate proximally, and may last for many hours. There is often significant bleeding and the wound may be erythematous or dusky. Systemic effects have been uncommonly reported and related more to the systemic response to severe pain.

The length and size of stingray spines result in an increased risk of significant trauma and secondary infection. Morbidity and mortality can result from penetrating trauma to the trunk and internal organs, and both penetrating cardiac injuries and abdominal injuries have been reported.^{1,20} The other important problem is secondary infection, mainly a concern for patients susceptible to infections, or wounds penetrating joint or tendon spaces, or wounds that are not cleaned and managed appropriately.

A number of different families of rays have been implicated in human injuries. In temperate regions, Urolophidae (stingarees) are commonly implicated, including Australia and the West coast of the United States. The family dasyatidae (stingrays, whipsnakes) are another important family in tropical regions, including northern Australia and the southeast coast of the United States.

Venomous Fish Stings

Venomous fish are found in tropical and, less commonly, temperate oceans, although increasing numbers are being kept in private aquariums. The important venomous fish include catfish (Siluriformes), stonefish (Synaceiidae), weeverfish (Trachinidae), and scorpion and lion fish (Scorpaenidae). The effects of the stings range in severity from severe with stonefish, to minimal from some types of catfish and other fish with nonvenomous spines.^{1,20}

STONEFISH [SYNACEIA SPP.] Stonefish belong to the family Synaceiidae, in which there are a number of stinging fish in the genus *Synanceia*, the Australian estuarine stonefish *Synanceia trachynis*, *S. horrida* (Indian stonefish), and *S. verrucosa* (reef stonefish). Stonefish occur throughout tropical and warmer temperate oceans from the central Pacific, west through the Indo-Pacific to the east African coastline. Stonefish are stationary bottom-dwellers usually frequenting shallow water. They can camouflage themselves effectively, and most encounters with humans occur when they are stepped upon.

Despite the presence of myotoxic, neurotoxic and cardiotoxic components in *S. trachynis* venom, these are not important parts of the clinical effects of stonefish envenomation. Human envenomation following penetration of stonefish spine is characterized by immediate severe and increasing local pain, which may radiate proximally. The wound site usually has significant local edema and erythema.^{1,20} Non-specific systemic effects, such as sweating, nausea, hypotension, and even syncope, may occur but are more likely a result of severe pain. Despite the severe local pain and swelling, extensive tissue necrosis is not seen unless a secondary infection develops.¹

SCORPIONFISH AND ROCKFISH (SCORPAENIDAE) Scorpion fish (Scorpaenidae) occur in all oceans of the world, but more commonly in tropical and temperate regions. At least 80 members of the

family have been implicated in envenomation. Some important genera include *Pterois* spp. and *Dendrochirus* spp., the best-known species being *Pterois volitans*, the lionfish or butterfly cod. Other important ones include *Scorpaena* spp. (scorpionfish) and the bullrout (*Notesthes robusta*). They are a diverse group of fish, with differing habitats, swimming patterns, and ability to camouflage.¹ Their venom apparatus varies between species, but most have 10 to 15 dorsal spines, as well as 2 pelvic and 3 anal spines associated with venom glands. Although they are frequently large, plumelike, and ornate, the pectoral spines are not associated with venom glands.

The clinical effects are similar to stingray and stonefish envenomation, but there is usually less trauma. There is immediate and intense pain, which often radiates proximally. Untreated, the pain peaks at 60 to 90 min and persists for 4 to 6 h, but this varies considerably for different fish. There is often associated erythema and edema, and in more severe cases, there may be local discoloration and necrosis. Systemic effects are variable, but again probably relate more to the severity of pain, rather than toxin effects.

CATFISH (SILURIFORMES) Approximately 1000 species of catfish inhabit both fresh and saltwater. Catfish have a single dorsal spine and two pectoral spines that can inflict painful wounds. The spines have venom glands within the integumentary sheath covering, which rupture and the contents are forced into the wound. Catfish also produce a crinotoxin that can be introduced into the wound during envenomation and can occasionally cause severe pain in fish handlers by merely coming in contact with the fish.¹

Eel-tailed catfish (Plotosidae) occur in the Indo-Pacific region and live in marine, estuarine and freshwater environments. The striped catfish, *Plotosus lineatus*, is an important member of this family and can cause severe pain requiring hospitalization.^{1,20} Other commonly reported catfish are the forktailed catfish (Ariidae), that occur worldwide and are reported to cause minor effects only. Other families have a more restricted distribution such as the family Ictaluridae, which includes the common freshwater catfish in the United States, also responsible for serious envenomations. Siluridae occur throughout Europe and Asia and cause injuries in these regions.²⁰

WEEVERFISH (TRACHINIDAE) Weeverfish (or Weaver fish) are all seawater fish and are the most venomous fish in the temperate zone. They are found in the Mediterranean and European coastal areas, and include the greater weeverfish (*Trachinus draco*) and the lesser weeverfish (*I. vipera* or *Echilchthys*). Weeverfish are bottom dwellers that sting when stepped on. The five to seven envenoming dorsal spines can penetrate a leather boot and create a substantial puncture wound. The pain from a weeverfish wound is described as being as severe as a stone fish injury, and is reported to be prone to necrosis.¹

OTHER VENOMOUS FISH There are a number of other groups of venomous fish. Scats (family Scatophagidae) are a less-well-known cause of envenomation. They occur in the Indo-Pacific Ocean, and there are a few reports of stings from northern Australia.²⁰ The most common species, the silver scat, striped butterflyfish or spadefish (*Selenotoca multifasciata*) causes immediate severe pain that lasts about 30 to 60 min, and has minimal local effects. Scats have become popular aquarium fish, particularly in the United States.²⁰ Another group of venomous fish are the family Siganidae (rabbitfish or happy moments). These fish occur in the tropical regions of the Indo-Pacific ocean. *Siganus* spp. are reported to cause severe pain that may last hours.¹

Management of Venomous Fish and Stingray Injuries

Successful therapy for venomous fish stings requires managing both the traumatic injury and the envenomation. Treatment is directed at reversing the effects of venom, alleviating pain, and preventing infec-

tion. The wound should be irrigated immediately, and any visible pieces of the spine or integumentary sheath should be removed. Other first aid measures include control of any bleeding and hot water immersion therapy. Hot-water immersion should be done as soon as possible, using hot water to tolerance [45°C (113°F)] for 30 to 90 min or until there is pain relief. During the hot-water soak, the wound can be explored and foreign material removed.

Medical management should include first aid measures. If the pain does not respond to hot-water immersion, then oral, or more often parenteral, analgesia is required. However, local infiltration of the wound with local anesthetic without epinephrine, or a regional nerve block may be more effective.

There remains no consensus on the treatment of wounds following venomous fish stings. Once the pain is controlled the wound can be cleaned using an aseptic technique, reexplored, any foreign material removed, and debrided if there is necrotic tissue. Soft tissue radiography should be employed to visualize calcified matter. Lacerations, more often caused by stingrays, should generally be left open for delayed primary closure or sutured loosely, ensuring adequate drainage. Some authors suggest exploration and even excision of the wound to remove all foreign material.¹ Puncture wounds, usually from other venomous fish, uncommonly require exploration, but there is little evidence to support this approach.

There continues to be controversy regarding prophylactic antibiotics. The few series of venomous fish stings, and the experience of aquarium workers, is that most injuries are minor and do not require antibiotics.²⁰ Although some authors routinely recommend prophylactic antibiotics, the majority do not unless the wound is large or there is considerable foreign material. This is more likely in stingray wounds that have the greatest potential to cause necrosis and infection. Prevention of infection by careful cleaning of the wound and debridement, if required, are more important. A stonefish antivenom (CSL Ltd, Melbourne, Australia) is available for severe systemic reactions to stonefish and possibly other venomous fish.¹

Sea Snakes

There are numerous species of sea snakes that are closely related to Asian and Australian elapids, all of which are venomous. They occur in the tropical and warm temperate Pacific and Indian Oceans. None are found in the Atlantic Ocean, the Caribbean, or North American coastal waters, except Hawaii. Probably the most important species is the beaked sea snake (*Enhydrina schistosa*), which has caused fatalities in southeast Asia.⁴

Most sea snakes are about 1 m (3 to 4 ft) long, although some attain lengths of up to 3 m (9 ft). They can be distinguished from land snakes by their flat tails and valvelike nostril flaps, and from eels by the presence of scales and the absence of gills and fins. Sea snakes swim in an undulating fashion and can move backward or forward in the water with equal speed. The venom apparatus consists of two to four short, hollow maxillary fangs, and a pair of associated venom glands.¹ About 20 percent of bites cause significant envenomation and up to 40 percent of these can be fatal.⁴ The venom of sea snakes contains neurotoxins and myotoxins; one tends to dominate the clinical features. However, there are no toxins that affect coagulation.¹

There is usually no pain from the bite, and it may initially go unnoticed. Symptoms typically become apparent 30 min to 4 h after the bite. The first complaint is usually because of myotoxicity, which causes muscle aches and pains, and nonspecific muscle weakness. Other symptoms include nausea, vomiting, malaise, and tachycardia. Myalgias usually occur in the neck, face, trunk, arm, and thigh. The muscle pain may become so severe that movement is limited, which is typified by trismus that develops in the jaw. Immobility secondary to pain should be distinguished from weakness or paralysis caused by neurotoxicity.¹ In some sea snakes, neurotoxicity has been reported, with ascending flaccid or spastic paralysis accompanied by ophthalmoplegia,

ptosis, facial paralysis, and pupillary changes. Death is most commonly a result of ventilatory failure.

Diagnosis of a sea snake bite is based on the combination of snake identification and the presence of a puncture bite wound that was initially painless and occurred in the water. Envenomation should be suspected if the characteristic symptoms, primarily myalgias, develop. The presence of myoglobinuria and an elevated creatine kinase is also typical, indicating rhabdomyolysis. Neurotoxic symptoms are rapid in onset and usually appear within 2 to 3 h. If no symptoms develop by 6 to 8 h, envenomation is unlikely to have occurred.

First aid treatment of a sea snake bite involves pressure-immobilization of the affected limb. Supportive measures are essential, but the most effective treatment is sea snake antivenom if available. Polyvalent sea snake antivenom (CSL Ltd, Melbourne, Australia) is indicated if there is any evidence of systemic envenomation. Although tiger snake (*Notechis* spp.) antivenom and crotalid antivenom have been recommended, there is no evidence of cross-reactivity. The responses in the past to tiger snake antivenom were more likely a result of antivenom being made from animals immunized to both tiger and sea snake venom. The administration of antivenom should commence as soon as possible. Intensive supportive care and monitoring of renal, metabolic, and respiratory functions are critical.

DYSBARISM AND COMPLICATIONS OF DIVING

Brian Snyder

Tom Neuman

Millions of recreational, commercial, and scientific dives are logged annually, and the vast majority of dives are completed without incident. However, there are physiologic effects and injuries relatively unique to the underwater environment. Generally, these effects and injuries are secondary to pressure changes on the submerged human body and the breathing of compressed gas.¹ This chapter will outline the most common diving injuries: barotrauma (otic, sinus, and pulmonary), decompression sickness ("the bends"), immersion pulmonary edema, oxygen toxicity, and nitrogen narcosis.

THE GAS LAWS

Understanding of diving injuries requires familiarity with the three relevant gas laws most pertinent to diving: Boyle's law, Dalton's law, and Henry's law.

Boyle's law states that given a constant temperature, the pressure and volume of an ideal gas are inversely related. That is, if pressure is doubled, the volume of gas is halved. This law is stated as: $P_1V_1 = P_2V_2$.

Pressure can be measured in a variety of units. The International System of Units defines pressure using the pascal (Pa). Other commonly used units of pressure include millimeters mercury (mm Hg), torr, pounds per square inch (psi), bar, or atmosphere (atm). 1 atm = 760 mm Hg = 760 torr = 14.7 psi = 1.013 bar = 101,325 Pa = 101.325 kPa. Additionally, pressure in diving settings is often described using feet of seawater (fsw) or meters of seawater (msw) (see below). In this chapter we will use atmospheres, mm Hg, and fsw for pressure units.

Because of the high density of water, a relatively small change in depth causes a great change in the pressure exerted on a body. The weight of seawater produces a change of 1 atm for each 33 ft of depth. For freshwater, pressure increases 1 atm for each 34 ft of depth. Therefore the pressure exerted on a diver at a depth of 33 ft in seawater = 1 atm for the seawater + 1 atm for the atmosphere above the water = 2 atmospheres absolute (ATA). A diver at 165 ft of seawater would experience 6 ATA of pressure (1 atm for each 33 ft of seawater = 5 atm + 1 atm for atmospheric pressure at sea level).

Thus Boyle's law dictates that as a diver descends in the water column, the volume of air-containing structures will decrease. For example, if the lungs contain volume V at the surface, a diver who descends to 33 ft of seawater holding his or her breath would have a lung volume of $1/2 V$. If he or she breathes compressed air at this depth (from scuba equipment or from a surface-supplied source of gas), lung volume would return to V . If the diver then ascends to the surface without exhaling, lung volume would be $2V$ at the surface. This pressure-volume relationship governed by Boyle's law is important in the etiology of injuries due to barotrauma and produces the volume changes of bubbles in the tissues and circulation that are associated with recompression therapy.

Dalton's law states that the total pressure exerted by a mixture of gases is the sum of the partial pressures of each gas. Therefore, the partial pressure of a given component of a gas mixture will increase as the ambient pressure increases, although the proportion of gas in the mixture remains constant. The partial pressure of nitrogen in air at sea level is approximately 600 mm Hg or 0.79 ATA (the fraction of nitrogen in air, 0.79, times 760 mm Hg or 1 ATA). At a depth of 99 fsw, the partial pressure of nitrogen in air would be $4 \times 600 = 2400$ mm Hg (or 3.16 ATA).

Henry's law, which states that at equilibrium, the quantity of a gas in solution in a liquid is proportional to the partial pressure of the gas,

along with Dalton's law explains the uptake of inert gas into tissues when breathing compressed air at depth. It is the uptake of inert gas that is intrinsic to the development of decompression sickness.

BAROTRAUMA

Barotrauma of Descent

During descent, the volume of gas in all air-containing body cavities decreases. The air space in the middle ear makes the tympanic membrane the tissue most commonly affected by this phenomenon, if active measures such as "clearing the ears" with a Valsalva or other maneuvers are not successful. As the volume of gas decreases, the tympanic membrane is bent inward, causing a feeling of fullness or pain in the ear. Forcing air through the eustachian tube with a Valsalva maneuver will equalize the pressure between the middle ear and external ear canal by filling the middle ear with additional gas. Generally, divers who experience pain in an ear during descent will attempt to clear the ear and, if unsuccessful, will ascend to decrease the pressure difference and attempt equalizing again. If the diver is unsuccessful in equalizing and continues the descent, prolonged pain and injury to the tympanic membrane may result, known as barotitis or "ear squeeze."

Barotitis can range from symptoms of pain or fullness without otoscopic changes, to hemorrhage within the tympanic membrane or hemorrhage into the middle ear with hemotympanum. Ultimately, the tympanic membrane may rupture, resulting in relief of the pain, but which might also cause an influx of water into the middle ear. This in turn might cause calorically-induced vertigo and potential panic, near-drowning, or other injury. Barotitis is treated conservatively with analgesics and decongestants. If tympanic membrane rupture occurs, antibiotics can be prescribed, especially if the diving occurred in contaminated water. Divers with perforated tympanic membranes should refrain from diving until the perforation heals. Most such perforations heal without difficulty, but referral to an otolaryngologist is appropriate for individuals with larger perforations or when healing does not occur spontaneously. Divers with barotitis without perforation should refrain from diving until symptoms have resolved and the diver is again able to insufflate the middle ear.

If the external canal is occluded by cerumen or an ear plug, the inability to equalize pressure between the external canal and the tympanic membrane causes the bending of the tympanic membrane outward, producing an injury called "external ear squeeze" that produces pain and tympanic membrane hemorrhage.

If the ostia to the sinuses are occluded, air cannot enter the sinuses during descent to equalize the increasing pressure. This causes pain and mucosal edema and can lead to submucosal hemorrhage and stripping of the sinus mucosa from bone, hemorrhage (often causing bleeding from the nose into the mask), and rarely paresthesias in the infraorbital nerve distribution. Sinus barotrauma is treated with conservative measures, including decongestants and possibly antibiotics.

The inner ear is also susceptible to barotrauma, occasionally causing significant, long-term damage. If a diver attempts a forceful Valsalva maneuver to equalize the middle ear against an occluded eustachian tube, the pressure differential between the cerebrospinal fluid (CSF), transmitted through the vestibular and cochlear structures, and the middle ear air space can cause rupture of the oval or round window, fistulization of the window, tearing of Reissner membrane, or a combination of such injuries. Additionally, if the diver is able to open the eustachian tube in this situation, a rapid increase in middle ear pressure may occur. This pressure wave is transmitted to the inner ear and can also cause a similar injury. Divers with inner ear barotrauma will generally present with unilateral roaring tinnitus, sensorineural hearing loss, and profound vertigo. A "fistula test" may be positive; that is, insufflation of the tympanic membrane on the affected side

causes the eyes to deviate to the contralateral side. As this injury usually occurs on descent and divers will provide a history of difficulty clearing the ears, this condition can usually be easily differentiated from other causes of vertigo, such as inner ear decompression sickness, cerebral arterial gas embolism, or alternobaric vertigo (discussed below).

Immediate complications of inner ear barotrauma are potential panic or disorientation, leading to possible drowning or a rapid ascent that predisposes the diver to pulmonary barotrauma. Divers with barotraumatic injuries to the inner ear require immediate otolaryngologic evaluation. Treatment is controversial, with some authors advocating immediate exploration, and others suggesting a trial of bed rest (head upright), medications to control vertigo, and measures to reduce CSF pressure spikes (e.g., stool softeners, no nose blowing, etc.). These authors reserve exploration for those patients whose symptoms do not respond to conservative therapy or those with severe hearing defects or significant abnormalities on an oculonystagmogram. Divers with potential inner ear barotrauma who will be treated with hyperbaric oxygen for decompression sickness or cerebral arterial gas embolism require emergent tympanostomy, as hyperbaric treatment will recreate the same pressure differentials that caused the injury, potentially causing more perilymph leakage and possibly worsening the injury.²

Other air-containing structures can be compressed during descent producing "squeeze" symptoms. A face squeeze occurs when air is not added to the facemask during descent, causing the face and eyes to be forced into the collapsing mask. This produces facial bruising, conjunctival injection or hemorrhage, and, rarely, changes in vision. A tooth squeeze occurs when air spaces inside a tooth—due to either decay, a filling, or abscess—become compressed during descent. A dry-suit squeeze occurs when suit folds are compressed into the underlying skin, producing local trauma manifested by painful red streaks.

Barotrauma of Ascent

During ascent the physics of gas in air-containing organs is, of course, opposite than that of descent; that is, air will expand as the pressure decreases. Air will flow through the ostia of the sinuses, and the expanding air in the middle ear will open the eustachian tube (much like during takeoff in an airplane). Should air be trapped temporarily in one middle ear cavity, the pressure differential may cause unequal vestibular impulses to the brain, resulting in vertigo (alternobaric vertigo). This is usually transient and generally requires no specific treatment.

Air also expands within the lungs. If a diver breathing compressed air ascends with a closed glottis (holds breath, coughs, vomits), most frequently seen in a rapid, panicked out-of-air ascent, the expanding air may rupture the lung. This can occur even in shallow water (e.g., a swimming pool). Pulmonary barotrauma, also called pulmonary overinflation or burst lung syndrome, can lead to pneumomediastinum. This generally only requires symptomatic treatment and may be subtle on the chest radiograph.³ Mediastinal air can track superiorly into the neck, resulting in subcutaneous air on physical examination or air on a cervical spine radiograph. Rarely, a pulmonary overinflation injury causes pneumothorax, requiring aspiration or tube thoracostomy. If air enters the pulmonary venous circulation, embolization of the gas through the arterial system occurs. The most sensitive end organ to such embolization is the brain, and *cerebral arterial gas embolism* (CAGE) is the term applied to this condition, although the air emboli distribute to other tissues and organs.⁴ Any neurologic symptom or sign in the setting of barotrauma associated with ascent should be considered to be secondary to CAGE. The symptoms, signs, and treatment of CAGE will be discussed below.

Pulmonary barotrauma (Figure 197-1) can occur without a rapid ascent or closed glottis in divers with congenital cysts, obstructive pulmonary disease, or other processes that cause air trapping. There is some debate over the safety of divers with asthma, and though the relative risk of pulmonary barotrauma may be higher (possibly as much

FIG. 197-1. Pulmonary barotrauma. Note the air in the mediastinum in this radiograph (arrow). There is also air in the soft tissues of the neck.

as twice that of the general diving population), the absolute risk is still low because of the rarity of pulmonary barotrauma in diving (approximately 1 in 125,000 dives).⁵ A physician who specializes in diving medicine should examine all divers or potential divers with asthma, and an exercise pulmonary function test (PFT) should be performed. Asthmatics can be cleared for diving if, using their usual medications, they have a normal exercise PFT, and if they understand the potential increased risk of pulmonary barotrauma.⁵ Additionally, a diver who experiences a lung injury that cannot be explained by the circumstances of the dive (i.e., the diver did not have a rapid, breath-holding ascent), should be evaluated for congenital or acquired structural lung disease. These divers should probably be counseled not to dive.

An air pocket underneath a tooth may equilibrate with ambient pressure while diving, only to expand during ascent. This produces severe pain and may dislodge a filling or fracture a tooth. Swallowed air during diving may expand during ascent, producing gastric distention and abdominal cramps.

DECOMPRESSION SICKNESS AND ARTERIAL GAS EMBOLISM

Decompression Sickness

The pathophysiology of decompression sickness (DCS) is related to the obstructive and inflammatory effects of inert gas bubbles in tissues and the vascular system.⁶ Besides divers breathing compressed air, DCS may also occur in caisson workers or high-altitude pilots. Bubbles may form when a body saturated with inert gas experiences a decrease in ambient pressure that causes liberation of the gas. Uptake of

inert gas occurs at different rates in different tissues and is mainly a function of blood flow.

The U.S. Navy has published dive tables to provide the limits to a dive (measured by bottom depth and time) that can be undertaken without a decompression stop ("no decompression" or "no stop" dives). Other Navy tables provide in-water decompression schedules for longer dives. A multitude of dive computers using a variety of mathematical models provide divers with relatively safe diving limits. DCS is unlikely to occur if the limits of the dive tables or dive computer are adhered to; however, adherence to such limits does not guarantee safety.

Bubbles are necessary but not sufficient to cause DCS, as bubbling occurs following many dive profiles that do not lead to DCS. Obviously, there must be a threshold at which the bubble load causes symptoms. The exact mechanism of bubble formation in DCS has yet to be determined, although preexisting gas micronuclei in circulation likely form a nidus for gas accumulation. This is inferred, as the energy required to form bubbles *de novo* is much higher than the energy state caused by the saturation of inert gas in tissue.⁷ Bubbles may form directly in tissues or the circulation (usually the low-pressure venous circulation). Bubbles may directly obstruct blood flow, leading to direct ischemia. Additionally, the air-blood and air-endothelial interfaces initiate a variety of inflammatory and thrombotic processes, activate the endothelium leading to neutrophil adhesion and activation, and change the permeability of the endothelium, resulting in third spacing of fluid.

There is no agreed upon classification system for DCS (or "the bends" in the diving vernacular). However, the most common classification divides DCS into two main groups. Type I DCS is also called "pain-only" DCS and involves the joints, extremities, and skin ("cutis marmorata"). Lymphatic obstruction can occur in type I DCS, causing lymphedema, which usually takes days to resolve despite recompression therapy. Type II DCS (or "serious" DCS) includes neurologic DCS involving the CNS (mainly the spinal cord in compressed air divers and the brain in high-altitude decompressions), vestibular DCS ("staggers"), and cardiopulmonary DCS ("chokes"). To further complicate the nomenclature and classification of DCS, there is evidence suggesting that DCS can also occur when an arterial gas embolus causes inert gas to come out of solution after a dive profile that would otherwise not be expected to cause DCS (called type III decompression sickness).⁸ As the presentation may make it difficult to discern DCS from air embolism (and in fact both can occur simultaneously), some advocate the use of the term *decompression illness* (DCI) to encompass all pathologic syndromes following a reduction in ambient pressure.

DCS in commercial and military divers, caisson workers, and aviators tends to manifest most often as joint pain. Sport divers, who usually perform multiple dives, often over a period of days, are more prone to DCS affecting the spinal cord.

Generally, the symptoms of DCS occur minutes to several hours after surfacing, but cases of DCS symptoms occurring days after diving have been reported. Symptoms from DCS occurring between dives may improve during a subsequent dive (as recompression has occurred), but get worse upon resurfacing (as the inert gas load has increased and ambient pressure has decreased). Additionally, flying with the resultant decrease in ambient pressure may precipitate or worsen DCS symptoms, and divers are generally advised to refrain from flying for at least 12 h after the last dive.⁹

Divers with type I DCS typically describe a deep pain, unrelieved but not worsened with movement. This pain can be attributed to or confused with pain caused by injury, making diagnosis problematic. The pain from type I DCS is thought to be due to distention from bubbles in ligaments or fascia, intramedullary bubbles at the ends of long bones, or the activation of stretch receptors caused by bubbles in tendons. The mechanism of simple distention of tissues is supported by the rapid improvement of symptoms with recompression. Common locations for type I DCS are knees and shoulders, and most often only a

single joint is involved. Poorly localized and difficult-to-describe back pain may herald the more serious signs of spinal cord DCS.

Pulmonary DCS, generally seen only after prolonged exposures, is caused by large numbers of pulmonary artery bubbles and manifests symptoms of cough, hemoptysis, dyspnea, and substernal chest pain. Cardiovascular collapse can occur. Although now uncommon, this was the most lethal form of DCS, and was seen predominantly in aviators before the importance of oxygen prebreathing prior to high-altitude flights was recognized.

The classic description of divers with neurologic DCS (type II) begins with a sensation of truncal constriction or girdle-like pain. Often a wooly feeling begins in the feet, developing into an ascending paralysis, producing a presentation similar to a transverse myelitis. This form of DCS is usually rapid in onset and has a tendency to affect the lower cervical and thoracic regions. However, in type II DCS, neurologic deficits do not necessarily cause distinct spinal cord syndromes (i.e., an anterior or posterior spinal artery syndrome), nor will a definitive level necessarily be found, as lesions may be scattered throughout the spinal cord.¹⁰ Autonomic involvement, with resulting incontinence and sexual dysfunction, is not uncommon. The pathophysiology of spinal cord DCS seems to be initial bubbling in the low-pressure venous plexus system that first impedes, then causes cessation of venous outflow from the cord. Decreasing venous blood flow prevents dissolved nitrogen in spinal cord tissues to egress, and in-situ bubbles within the spinal cord develop (called *autochthonous bubbles*).

An unusual initial symptom of DCS is profound fatigue. This can be difficult for the diver and clinician to differentiate from the expected fatigue resulting from the exertion of diving. Other, nonspecific symptoms such as headache, nausea, and dizziness are also frequently reported.

Vestibular decompression sickness usually occurs after deep, long dives, although it has been reported in sport divers. It manifests with vertigo, hearing loss, tinnitus, and dysequilibrium. Vestibular DCS can be differentiated from inner ear barotrauma mainly by the history, as those with barotrauma develop symptoms in the water, and generally immediately after a forced Valsalva maneuver to equalize the middle ear pressure.⁴

Arterial Gas Embolism

Arterial gas embolism (AGE) occurs when air enters the left side of the vascular system. In the setting of diving this most often occurs from pulmonary barotrauma; however, it can also occur due to a variety of complications of medical procedures, including central vascular catheterization and operations requiring cardiac bypass. Air inadvertently introduced into the venous circulation can cross from the right side of the circulation from intracardiac shunts or, presumably, pulmonary arteriovenous shunts. Air bubbles formed secondary to decompression sickness may also arterialize through these same shunts, sometimes obscuring the source of arterial bubbles. Whatever the source, when air embolizes systemically, its distribution is dependent mainly on blood flow and not gravity.

Despite its systemic nature, its most dramatic effect is on the brain. CAGE causes a variety of stroke syndromes, symptoms, and signs, depending on the part of the brain affected. In approximately 4 percent of cases, diving-related AGE from pulmonary barotrauma causes immediate apnea and cardiac arrest. The mechanism of this cardiovascular collapse is uncertain, although persons who die from AGE generally have air in the entirety of the large arteries and veins of the central vascular bed. Older hypotheses of brainstem reflexes or coronary artery air embolization to account for the cardiovascular collapse are not supported by the time course of experimental models or the clinical course of individuals who suffer from other forms of cerebrovascular accidents.

The effects of AGE secondary to pulmonary barotrauma usually occur on ascent or immediately upon surfacing. If the victim does not

die immediately, the symptoms of CAGE often include loss of consciousness, seizure, disorientation, or hemiplegia. The symptoms of CAGE may spontaneously improve as the gas enters the venous cerebral circulation after a spike in blood pressure. Sometimes, by the time the patient reaches the clinician, the only signs that remain are subtle defects. In particular, parietal lobe signs and symptoms are easily overlooked. Similar to that seen in DCS, a cascade of inflammatory processes also occurs in air embolism.⁴

Treatment of Decompression Sickness and Arterial Gas Embolism

The treatment for DCS and air embolism includes administering 100% oxygen, increasing tissue perfusion with intravenous fluids, and rapid recompression. Some advocate placing patients with air embolism in the Trendelenburg position or in the left lateral decubitus position to "trap" air in the left ventricle. By the time the victim is brought onto the dive boat or the ambulance arrives, the air has usually been distributed, and the Trendelenburg position merely increases intracranial pressure, decreases cerebral perfusion, and interferes with other first aid measures. Nonetheless, some divers with AGE have collapsed when placed in a sitting or standing position. As a result, a supine position is recommended for patients with AGE. Vomiting patients should be placed in the left lateral decubitus position to prevent aspiration.

Recompression therapy with hyperbaric oxygen (HBO) treats DCS and air embolism by several mechanisms. HBO is delivered in a hyperbaric or recompression chamber. Chambers can either be *monoplace*, which are designed to treat a single patient with no inside attendant, or *multiplace*, with room for multiple patients and an inside attendant. Multiplace chambers compress the inside environment with air and provide oxygen through a mask or hood system. Some monoplace chambers are also compressed with air and provide oxygen through a mask, but most are compressed with oxygen.

The administered pressure decreases the size of bubbles, and the high partial pressure of oxygen in solution increases inert gas washout from bubbles and tissue. Mass action dictates that a gas will travel down pressure gradients; therefore nitrogen will move from bubbles with a high partial pressure of nitrogen into plasma, where it will travel to the lungs and be exhaled. Conversely, oxygen from plasma with a high partial pressure of oxygen will enter bubbles, but ultimately will diffuse into cells and be metabolized, further reducing bubble size. Additionally, HBO decreases tissue edema, increases oxygen delivery to ischemic tissues, and reduces neutrophil adhesion to the endothelium and neutrophil activation.¹¹

Recompression using the United States Navy Treatment Table 6 is a commonly used method of management for DCS, employing a maximal treatment pressure of 2.8 ATA (60 fsw). Table 6 is also used for air embolism, although some advocate an initial pressurization to 6 ATA (165 fsw) to maximize bubble compression, then continuation at 2.8 ATA (the United States Navy Table 6A). Different treatment tables are utilized in other parts of the world, and there is some experience using lower treatment pressures for DCS in monoplace chambers with comparable results.¹² Some patients may benefit from repeated treatments if symptoms do not fully resolve. Recompression should occur as soon as possible, and it should not be withheld in cases with delayed presentation.⁴

Many adjuncts to standard recompression therapy have been used and studied in the treatment of DCS and CAGE.¹³ For example, corticosteroids, aspirin, heparin, and lidocaine all have been advocated at some time. None have been shown to be clearly effective in humans, and heparin has been shown to be harmful in animal models. The most promising current adjunct is lidocaine in CAGE. Animal data using a model of severe air embolism show lidocaine improved somatosensory evoked potentials and cerebral blood flow.¹⁴ Additionally, lidocaine has been shown to decrease neuropsychiatric deficits when

given during anesthesia for cardiac procedures requiring bypass.¹⁵ These operations commonly cause the entry of air into the arterial system. Dosing of lidocaine in this setting is not standardized, although typical cardiac dosing is commonly used.¹⁶

Divers Alert Network (Tel: 1-919-684-8111, website: www.divers-alertnetwork.org) has staff available 24 h a day to provide assistance to divers and to help clinicians treat patients with DCS or arterial gas embolism, and they can provide information and the location of the nearest recompression facility.

IMMERSION PULMONARY EDEMA

Pulmonary edema can occur while diving, and the first reported cases occurred in cold water; therefore, it was first described as "cold water" or "cold-induced" pulmonary edema. However, cases have subsequently been reported in warm water, up to 27°C (80.6°F).¹⁷ Typical symptoms of pulmonary edema (dyspnea, chest discomfort, coughing up pink frothy secretions) occur at depth and usually improve over time or with standard treatments for pulmonary edema. This syndrome generally occurs in divers with no structural or ischemic heart disease, but evaluation for these conditions should be done. The mechanism of this condition is unknown and may be multifactorial, involving hydrostatic forces, thermal stress, and possibly increased capillary permeability. Immersion pulmonary edema is not caused by decompression and is not treated with recompression therapy. Interestingly, some divers will experience repeated episodes, while others may never experience another episode. This makes counseling of divers experiencing immersion pulmonary edema very difficult.

NITROGEN NARCOSIS

Inert gas narcosis occurs when air is breathed at a depth of 100 fsw or greater. Symptoms include loss of fine motor skills and high-order mental processes as well as behavior similar to that seen in alcohol intoxication. Symptoms increase as depth is increased beyond 100 fsw. Divers have codified this increase in symptoms as the "martini rule" (with many variations). A common description is that each 33 ft of depth (1 ATA) in excess of 100 fsw is the equivalent to drinking one martini. At depths greater than 300 fsw, unconsciousness may occur secondary to the anesthetic effect of nitrogen. At depths below 200 fsw, helium is often used in lieu of nitrogen in diving mixtures to prevent nitrogen narcosis. Symptoms of nitrogen narcosis improve upon ascent and can be worsened by fatigue, cold, and work. The effects of nitrogen narcosis are important in that divers may engage in dangerous or foolish activities during deep dives when breathing air, and the history from divers following such dives should be evaluated in this context.

OXYGEN TOXICITY

Oxygen toxicity generally affects one of two organs, the brain or lungs, depending on the partial pressure of oxygen delivered and duration of exposure. Cerebral oxygen toxicity occurs at high partial pressures with generally short exposures, whereas the clinical manifestations of pulmonary oxygen toxicity occur at lower partial pressures of oxygen but with longer exposures. Of course, pulmonary oxygen toxicity can also occur at higher partial pressures; however, the symptoms are generally not manifested, as the cerebral effects require removal from the exposure. Pulmonary oxygen toxicity can occur at partial pressures of oxygen at or below 1 ATA, as is seen in patients requiring prolonged mechanical ventilation with high fractions of inspired oxygen. Pulmonary oxygen toxicity is unusual in diving. In commercial, military, and deep diving, careful consideration is given to breathing mixtures and environmental conditions to avoid this and other complications of gas toxicity.

Cerebral oxygen toxicity most often occurs with partial pressures of oxygen greater than 1.6 ATA in the water (218 fsw while breath-

ing compressed air). Some divers may breathe "nitrox" or *oxygen-enriched air* with fractions of oxygen of 32 to 36%. Therefore cerebral oxygen toxicity can occur at lesser depths and actually is the factor that limits diving depth with nitrox. Additionally, there are oxygen rebreather systems (so-called closed circuit systems), with the diver breathing within a continuous circuit of gas that has a very high fraction of oxygen (>95%), with carbon dioxide being scrubbed out. With these systems, cerebral oxygen toxicity can occur at depths as little as 25 ft.

Cerebral oxygen toxicity manifests with twitching, nausea, paresthesias, dizziness, and seizures. A seizure may be the initial manifestation of cerebral oxygen toxicity and in the water may cause drowning. Of note, higher partial pressures of oxygen are used clinically in hyperbaric chambers (2.4 ATA, 2.8 ATA, and sometimes 3.0 ATA); however, cerebral oxygen toxicity in this setting is rare, reported in less than 1 per 1000 patients. This is because patients in hyperbaric chambers are dry, warm, and at rest, while divers are wet, often cold, and exerting themselves. Cerebral oxygen toxicity is affected by P_{aCO_2} and cerebral blood flow and may be caused by an increase in nitric oxide production, although this is still an area of active investigation.¹⁸

Besides nitrogen narcosis and oxygen toxicity, other gas-related conditions important in diving medicine are toxicity from carbon monoxide and the adverse effects of elevated partial pressures of carbon dioxide. Additional issues, especially with very deep dives, include heat loss from breathing helium and the high-pressure nervous syndrome, characterized by tremor and loss of fine motor function caused by the direct effects of pressure.

NEAR-DROWNING

Alan L. Causey
Mark A. Nichter

Submersion injuries that result in death in less than 24 h are termed *drowning*. *Near-drowning* is defined as survival longer than 24 h after a submersion event. As with other causes of accidental death, submersion injuries typically involve otherwise healthy, young individuals.

EPIDEMIOLOGY

Over the last decade more than 50,000 people have died from drowning in the U.S., and over 100,000 die each year worldwide. In the U.S., drowning is the fourth leading cause of accidental death overall, and is the second leading cause of death in those under 15 years of age. In addition, there are an estimated over 500,000 submersion events per year in the U.S. The vast majority of victims survive submersion events with outcomes ranging from minimal or transient injury to profound neurologic insult.

There are three peaks in near-drowning incidence: the first in toddlers and young children, a second in adolescents and young adults, and a third in the elderly. In addition to pools and bodies of water, infants and toddlers can drown in toilets, buckets, and bathtubs. The elderly also have an increased risk of bathtub drowning. Even in coastal areas most submersion events take place in warm, freshwater bodies of water (especially swimming pools).

Additional injuries or disorders that either precipitate or are associated with submersion events include: 1) spinal cord injuries that occur after diving into shallow water or boating mishaps, 2) hypothermia, 3) panicking, 4) syncope (e.g., due to hyperventilation prior to underwater diving), 5) seizures, and 6) other premorbid conditions (e.g., heart disease).¹²

PREVENTION

Submersion episodes among children less than 1 year of age are best prevented by parental vigilance during bathing. Child abuse should be considered when the victim is less than 6 months of age, or in toddlers with atypical presentations.³ In preschool children, adult supervision in conjunction with properly installed and maintained four-sided pool fences that completely isolate the pool could prevent 50 to 90 percent of preschool-aged drownings.^{4,3}

Teen and young adult drowning may be reduced by the control of alcohol and illicit drug consumption that have been implicated in 40 percent of all adult drownings and 75 percent of boating-related adult drownings.⁶ The use of personal flotation devices decreases boating-related drowning. Practical experience suggests that the ability to swim is protective against teen and adult drowning, but there is little evidence to support the efficacy of swimming instructions for preventing drowning in infants and young toddlers.⁷

Drowning locations in the elderly closely parallel locations of infant and toddler drowning. Adequate pool fencing and bathtub handrails are important preventive means for the elderly population and in those patients with premorbid conditions.

PATHOPHYSIOLOGY

After submersion, the degree of pulmonary, and in particular central nervous system (CNS) insult determines the ultimate outcome. It is thought that there could be transient protection from parasympathetic activation of the diving reflex (i.e., bradycardia, apnea, peripheral vasoconstriction, and central shunting of blood flow) during submersion. However, the diving reflex may not provide significant protection in humans as was once thought. The diving reflex is strongest in young

infants <6 months old, but the effects decrease with age.⁸ In adults, vertical immersion (head out) and vertical submersion (head under) activates both the sympathetic and parasympathetic systems, blunting any effect of the diving reflex.⁹ Physiologic stress associated with submersion undoubtedly also activates the sympathetic nervous system. Cerebral protection in cold-water submersions most likely results from rapid CNS cooling before significant cardiac dysrhythmia.

"Dry-drowning," which accounts for 10 to 20 percent of submersion injuries, occurs when there is laryngospasm, followed by hypoxia leading to loss of consciousness. More commonly, "wet drowning" occurs in which there is aspiration of water into the lungs. The effect is dilution and washout of the pulmonary surfactant with resultant diminished gas transfer across the alveoli, atelectasis, and ventilation-perfusion mismatch. In fresh-water aspiration, there is transient hemodilution, and if large enough volumes are aspirated, significant hemolysis is possible. Factors such as aspiration of contaminated foreign material, particulate matter, bacteria, vomitus, or chemical irritants can affect eventual pulmonary recovery.

Prediction of eventual outcome in near-drowning is possible using factors such as submersion time and physiologic scoring systems.^{10,11} However, the utility of this prediction is debatable; the vast majority of patients who arrive at the hospital with fair cardiovascular and neurologic function survive with minimal disability, and those that arrive with unstable cardiovascular function and coma do poorly because of the hypoxic, ischemic CNS insult. Predictors are not accurate or useful for the 15 to 20 percent of near-drowning victims whose arrival condition is between these two extremes.¹²

Other end organs can also be affected from resultant hypoxemia and metabolic acidosis. Electrolyte abnormalities are seldom significant and usually transient unless there is significant renal injury from hypoxic injury, hemoglobinuria, or myoglobinuria.^{12,13} Hematologic values are usually normal unless there has been massive hemolysis. Rarely, disseminated intravascular coagulation can be a complicating factor in near-drowning.

TREATMENT

Prehospital Care

Resuscitation of a submersion victim as quickly as possible optimizes outcome. This emphasizes the need to train laypersons in cardiopulmonary resuscitation (CPR), particularly swimming pool owners. After careful removal of the victim from the water (with cervical spine control/protection if there is an unknown mechanism of injury or suspicion of spinal injury), CPR should be initiated as quickly as possible.

High-flow oxygen therapy by facemask should be administered if the patient is breathing, or by positive-pressure bag-valve-mask if the patient is not breathing. For those patients who do not recover spontaneous respiratory effort, endotracheal (ET) intubation with positive-pressure ventilation should be considered, particularly if the patient remains unconscious, because of the risk of aspirating emesis.

All patients with submersion associated with amnesia for the event, loss or depressed consciousness, an observed period of apnea, or those who require a period of artificial ventilation should be transported for evaluation to an ED, even if they are asymptomatic at the scene. The patients should be warmed and monitored, and intravenous access considered (Table 198-1).

TABLE 198-1 Prehospital Care of Submersion Victims

Rapid, cautious rescue	Spinal precautions
Cardiopulmonary resuscitation	Supplemental oxygen (all patients)
Transport	(all patients)

Emergency Department

Upon arrival at the ED, the treating physician should assess and secure the airway, provide oxygen, and assist ventilation as necessary. Warmed isotonic intravenous fluids should be administered and warming adjuncts (e.g., blankets, overhead warmers, warming devices) should be used. Any associated injuries should be addressed.

Patients who present to the ED with a Glasgow Coma Scale (GCS) score of ≥ 13 should be administered oxygen as necessary to keep their oxygen saturation (Sao_2) >95 percent (Table 198-2). They should be observed for 4 to 6 h, and if the pulmonary examination and room-air Sao_2 remain normal, they can be safely discharged home. Laboratory examination and radiographs are unnecessary, and are not predictive of discharge.¹⁴ If, after 4 to 6 h, the patient still requires oxygen, has an abnormal pulmonary examination (rales, rhonchi, wheeze, retractions, etc.), or deteriorates in the ED, reassessment and admission or transfer to a monitored bed is needed.

Patients who present to the ED with $\text{GCS} < 13$ should be maintained on supplemental oxygen and ventilatory support as needed. If high-flow oxygen (Fio_2 40 to 60 percent) cannot maintain an adequate Pao_2 (>60 mm Hg in adults, >80 mm Hg in children), then the patient should be intubated and receive positive-pressure ventilation. Chest radiography and laboratory studies should be done to evaluate for pulmonary aspiration and other complications (see Table 198-2). Infrequently, childhood victims of freshwater near-drowning develop dilutional hyponatremia and seizures. In these cases, seizures are generally easily controlled with correction of the electrolyte abnormality, and residual seizure disorder is uncommon. Continuous cardiac monitoring, pulse oximetry, and frequent reassessments should be performed on all patients.

If the patient presents to the ED in cardiopulmonary arrest or asystole after a warm-water submersion event, serious thought should be given to discontinuing resuscitation efforts, as recovery without profound neurologic handicaps is rare.¹⁵

TABLE 198-2 Hospital Care of Submersion Victims*

	Presentation GCS ≥ 13	Presentation GCS < 13 *†
Cervical spine	Clear	Clear
Ancillary tests	Only as indicated (routine studies such as CXR are not predictive of outcome)	ABG CBC, electrolytes, glucose, PT/PTT, UA, CK, urine myoglobin, urine drug screen CXR ECG
Respiratory support	Oxygen to keep Sao_2 $>95\%$	Oxygen to keep Sao_2 $>95\%$ Intubation and positive- pressure ventilation as needed (PEEP, CPAP)
Monitor	Oxygen saturation	Oxygen saturation Acid-base status Temperature Volume status (urine output, central venous pressure, etc.)

*Evaluate and treat any associated injuries or other conditions (e.g., hypovolemia, hypothermia, hypoglycemia, myocardial ischemia, seizures, etc.). Including those patients presenting with GCS ≥ 13 who have abnormal examinations and/or abnormal oxygen saturations after observation for 4-6 h. Abbreviations: CBC = complete blood count; CK = creatine kinase; CPAP = continuous positive airway pressure; CXR = chest radiograph; ECG = electrocardiogram; GCS = Glasgow Coma Score; PEEP = positive end-expiratory pressure; PT = prothrombin time; PTT = partial thromboplastin time; Sao_2 = oxygen saturations (via pulse oximetry); UA = urinalysis.

Hospital

Hospital management of near-drowning victims is largely supportive.¹⁶ All near-drowning victims who require emergency department resuscitation should be admitted to an intensive care unit (ICU) for continuous cardiopulmonary and frequent neurological monitoring. Most victims of significant submersion injury benefit from mechanical ventilation. Supranormal levels of positive end-expiratory pressure (PEEP) may be used to recruit fluid-filled lung units and aid oxygenation. Most victims demonstrate rapid improvement in oxygenation in the first 24 h. Victims presenting with significant aspiration pattern or severe cardiovascular collapse are predisposed to develop acute respiratory distress syndrome (ARDS). Care should be taken to avoid lung overdistension and ventilator-associated lung trauma. Bacterial pneumonia is rare and prophylactic antibiotics are not indicated.

For victims who have been resuscitated from cardiac arrest, the hemodynamic response to exogenously administered epinephrine is frequently short lived, and most will require a continuous infusion of dopamine or epinephrine in the ED or ICU. Invasive (pulmonary artery catheter) or noninvasive (echocardiogram) measures of ventricular function are often instructive. Hemodynamic recovery, when it occurs, can be expected within 48 h. Victims demonstrating no hemodynamic recovery after 48 h may slowly improve over the first week, but are more likely to have long-term neurologic damage.¹²

Results of "brain resuscitation" following significant warm-water near-drowning have been disappointing.^{12,16} The degree of cerebral edema is largely determined by the duration of the anoxic or ischemic insult at the time of submersion. Efforts to control cerebral edema including the administration of mannitol, loop diuretics, hypertonic saline, fluid restriction, and mechanical hyperventilation have not shown benefit.¹⁶ Controlled hypothermia, barbiturate "coma," and intracranial pressure monitoring have not been shown to improve outcome in pediatric near-drowning victims.¹²

Family members should be counseled about likely outcome. Using initial presentation, resuscitation, laboratory data, and serial examinations, experienced practitioners should be able to provide accurate predictions of outcomes in most cases.¹⁷

PROGNOSIS AND DISPOSITION

Uncomplicated

As noted above, submersion victims who are asymptomatic or mildly symptomatic can be observed for 4 to 6 h. If they continue to have a normal pulmonary examination and normal room air oxygen saturation, they can be safely discharged home. The concern for "secondary drowning" (respiratory deterioration after initial stable presentation) is unwarranted, because if deterioration is going to occur, it will do so within the 4- to 6-h observation period. No data is available for long-term outcomes for these patients, but it is unlikely that there are any measurable adverse effects. Parents and patients should be advised to have close follow-up and to be evaluated for any respiratory complaints or fever.

Complicated

Since submersion time is frequently unknown or only estimated, the extent of required resuscitation is often the most objective measure of the degree of anoxic or ischemic insult. Details of initial presentation and resuscitation are frequently strong prognostic indicators.

If the submersion victim does not require cardiopulmonary resuscitation at the scene or in the ED, complete recovery within 48 h is expected. A small fraction of these patients with significant aspiration may develop severe, even life-threatening ARDS.

Victims requiring bystander CPR at the scene have a guarded prognosis. For scene-resuscitated pediatric victims, about 20 percent later

die in hospital and about 5 percent are left with severe hypoxic-ischemic encephalopathy.²⁰ Those victims who demonstrate continuous neurologic and cardiovascular improvement after hospital admission will generally make a complete recovery. Frequently, neurologic and cardiovascular examinations are normal within 24 h of the submersion event. Victims who later die in hospital usually demonstrate deteriorating cardiovascular status. Victims who are left with severe hypoxic-ischemic encephalopathy typically have persistent abnormal cranial nerve dysfunction and coma.

Victims undergoing ED CPR have a poor prognosis. These victims have usually sustained a significant anoxic or ischemic insult to the brain and other vital organs. Complete neurologic recovery is rare, although there are anecdotal reports of neurologic recovery following ED CPR of pediatric warm-water near-drowning, possibly due to the poor descriptions of the term "CPR." In our experience of over 500 pediatric warm-water submersion victims, 75 patients required ED CPR (defined as intravenous or endotracheal epinephrine or atropine with chest compressions and artificial ventilation). Of these cases, 84 percent died in the hospital, and 16 percent survived with severe hypoxic-ischemic encephalopathy. Asystole, whether noted at the scene or in the emergency department, is a near-universal sign of poor prognosis in warm-water pediatric submersion injuries.

For the emergency physician, the question of whom and how vigorously to resuscitate remains unclear.²⁰ Though rare, complete or near-complete neurologic recovery after asystole has been reported following icy-water submersion episodes in children and adults. Consequently, victims of icy-water submersion, if removed from the water quickly, might reasonably undergo prolonged resuscitation maneuvers until CNS and cardiopulmonary viability are clear. Asystolic victims of warm-water submersion injuries with short submersion and transport times and CPR en route might reasonably undergo a vigorous resuscitation attempt.²¹ CPR should be abandoned if no response is noted. Conversely, because of the poor prognosis for intact neurologic survival, emergency department resuscitation attempts might reasonably be withheld from asystolic victims of warm-water submersion with longer submersion and transport times.

ACKNOWLEDGMENT

THERMAL BURNS Lawrence
R. Schwartz Chenicheri
Balakrishnan

INCIDENCE

The American Burn Association estimates there are more than 1 million burn injuries each year in the United States, generating about 700,000 ED visits and 45,000 hospitalizations.¹ Thus, the majority of burn patients are treated and discharged from the ED to be followed as outpatients. Approximately half of those hospitalized are admitted to the 125 specialized burn treatment centers, and the others are cared for in community hospitals. Fire and burn deaths account for about 4500 deaths each year.¹

The risk of burns is highest in the 18- to 35-year-old age group. There is a male to female ratio of 2:1 for both injury and death. There is a higher incidence of scalds from hot liquids in children 1 to 5 years of age and in the elderly. The death rate in patients over 65 years of age is much higher than that in the overall burn population.^{2,3}

Significant strides have been made in the overall care of the burn patient during the last two decades.^{4,5} These advances are reflected in a decreased mortality rate among patients with major thermal injury; only about 4 percent of those treated in specialized burn treatment centers die from their injuries or associated complications.⁶ The incidence of inpatient admissions has decreased over time owing to improvements in outpatient care both in the ED and in the burn unit. Currently, the risk of death from a major burn is associated with increased burn size, increased age, the presence of inhalation injury, and female sex.³

PATHOPHYSIOLOGY

Skin consists of two layers: the epidermis and the dermis. In the very young and the elderly, the skin thickness is less than that of a person in the prime of life. Skin thickness also varies significantly throughout the body. The skin is very thick in the palm of the hand and the sole of the foot. The skin on the upper part of the back is thicker than that of other parts of the body. Thus exposure to the same temperature for the same duration will lead to different depths of injury in different parts of the body.

Skin functions as a semipermeable barrier to evaporative water loss. Other functions of the skin include protection from the adversi-

ties of the environment, control of body temperature, sensation, and excretion. Partial-thickness thermal injury can result in disruption of the barrier function and contribute to free water deficits. The effect may be significant in moderate to large burns.

Thermal injury results in a spectrum of local and systemic homeostatic derangements that contribute to burn shock. These include disruption of normal cell membrane function, hormonal alterations, changes in tissue acid-base balance, hemodynamic changes, and hematologic derangement.

Fluid and electrolyte abnormalities seen in burn shock are largely the result of alterations of cell membrane potentials with intracellular influx of water and sodium and extracellular migration of potassium secondary to dysfunction of the sodium pump. In burns of greater than 60 percent of body surface area, depression of cardiac output is frequently observed with lack of response to aggressive volume resuscitation. Although disputed by others, Baxter and Shires⁷ have explained this phenomenon on the basis of circulating myocardial depressants. Also, there is increased systemic vascular resistance. A significant metabolic acidosis may be present in early stages of a large burn injury.

Hematologic derangements associated with massive thermal injury consist of an increase in hematocrit with increased blood viscosity during the early phase, followed by anemia from erythrocyte extravasation and destruction. However, transfusion is not often required for patients with isolated burn injury.

Thermal injury is a progressive injury. Local effects of thermal injury include liberation of vasoactive substances, disruption of cellular function, and edema formation. The systemic response consists of responses by the neurohormonal axis and profound alterations of all organ systems. Substances implicated in these events are histamine, kinin, serotonin, arachidonic acid metabolites, and free oxygen radicals. These substances exert their primary effects at the local level and cause progression of the burn wound. Preservation of the blood supply by decreasing the inflammatory response has been attempted with pharmacologic manipulations using drugs such as nonsteroidal anti-inflammatories.^{4,5}

Although many factors may influence prognosis, the severity of the burn, presence of inhalation injury, associated injuries, the patient's age, preexisting disease, and acute organ system failure are most important.^{2,3} The burn's size and depth are functions of the burning agent, its temperature, and the duration of exposure. Cell damage occurs at a temperature greater than 45°C (113°F) owing to denaturation of cellular protein. The burn wound is described as having three zones: the zone of coagulation, where tissue is irreversibly destroyed with thrombosis of blood vessels; the zone of stasis, where there is stagnation of the microcirculation; and the zone of hyperemia, where there is increased blood flow. The zone of stasis can become progressively more hypoxic and ischemic if resuscitation is not adequate. In the zone of hyperemia, there is minimal damage to the cells and spontaneous recovery is likely.

CLINICAL FEATURES

Burn Size

The size of a burn injury is quantified as the percentage of body surface area (BSA) involved.⁵ One method of calculating the percentage of BSA burned is to use the Rule of Nines (Figure 199-1). This method divides the body into segments that are approximately 9 percent or multiples of 9 percent, with the perineum forming the remaining 1 percent. In infants and children, this method must be modified because of their larger heads and smaller legs.

Another method is based on the fact that the area of the back of a patient's hand is approximately 1 percent BSA. The number of "hands" that equal the area of the burn can approximate the percentage of BSA burned.

FIG. 199-1. Rule of Nines to estimate percentage of burn.

A more precise estimation of the percentage of BSA burned is obtained by using a Lund and Browder burn diagram (Figure 199-2). This allows for accurate determination of the size and depth. These charts are age-adjusted, which allows for changes in children at different ages as they grow.

Experienced burn-care nurses and physicians are reliable in estimating burn size regardless of the method used. However, it is common for inexperienced individuals to estimate burn size incorrectly when patients are first assessed in the ED.

Burn Depth

The depth of a burn has historically been described in degrees: first, second, and third. However, a classification of burn depth according to the need for surgical intervention has become the accepted approach in burn treatment centers: superficial partial-thickness, deep partial-thickness, and full-thickness burns.⁴ Determination of burn depth requires judgment, using commonly seen clinical features. There is no objective method of measuring burn depth, and burn wound biopsy has not become routine practice.

A first-degree burn involves only the epidermal layer of skin. Sunburn is usually given as a common example of a first-degree burn, although sunburn is caused by ultraviolet light instead of thermal injury.⁸ The burned skin is red, painful, and tender without blister formation. First-degree burns usually heal in about 7 days without scarring and require only symptomatic treatment.

Second-degree burns extend into the dermis and are divided into superficial partial-thickness and deep partial-thickness burns.

In superficial partial-thickness burns, the epidermis and the superficial (papillary layer) dermis are injured. The deeper layers of the dermis, hair follicles, and sweat and sebaceous glands are spared. Superficial partial-thickness burns are often caused by hot water. There is blistering of the skin and the exposed dermis is red and moist at the blister's base. These burns are very painful to touch. There is good perfusion of the dermis with intact capillary refill. Superficial partial-thickness burns heal in 14 to 21 days, scarring is usually minimal, and there is full return of function.

Deep partial-thickness burns extend into the deep (reticular layer) of the dermis. There is damage to hair follicles as well as sweat and sebaceous glands, but their deeper portions usually survive. Hot liquids,

steam, grease, or flame usually cause deep partial-thickness burns. The skin may be blistered and the exposed dermis is pale white to yellow in color. The burned area does not blanch; it has absent capillary refill and absent pain sensation. Deep partial-thickness burns may be difficult to distinguish from full-thickness burns. Healing takes 3 weeks to 2 months. Scarring is common; it is related to the depth of the dermal injury. Surgical debridement and skin grafting may be necessary to obtain maximum function.

Third-degree or full-thickness burns involve the entire thickness of the skin. All epidermal and dermal structures are destroyed. Full-thickness burns are usually caused by flame, hot oil, steam, or contact with hot objects. The skin is charred, pale, painless, and leathery. These injuries will not heal spontaneously, as all dermal elements are destroyed. Surgical repair and skin grafting are necessary, and there will be significant scarring.

Fourth-degree burns are those that extend through the skin to the subcutaneous fat, muscle, and even bone. These are devastating, life-threatening injuries. Amputation or extensive reconstruction is sometimes required.

SPECIFIC ISSUES

The American Burn Association has devised a classification of burns, dividing them into major, moderate, and minor, along with indications for referral to a burn unit (Table 199-1).^{5,9} Children younger than 10 years of age and adults above age 50 are considered high-risk patients. Patients with underlying medical illnesses such as heart disease, diabetes, or chronic pulmonary problems are considered poor-risk.

TABLE 199-1 American Burn Association Burn Unit Referral Criteria

Partial-thickness burns greater than 10% total body surface area (BSA)
Burns that involve the face, hand, feet, genitalia, perineum, or major joints
Third-degree burns in any age group
Electrical burns, including lightning injury
Chemical burns
Inhalation injury
Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality
Any patients with burns and concomitant trauma (such as fractures) in which the burn injury poses the greatest risk of morbidity or mortality
Burned children in hospitals without qualified personnel or equipment for the care of children
Burn injury in patients who will require special social, emotional, or long-term rehabilitative intervention.

Major Burns

Major burns are defined as 1) partial-thickness burns greater than 25 percent BSA in the 10- to 50-year-old age group; 2) partial-thickness burns greater than 20 percent BSA in children under 10 or adults over 50; 3) full-thickness burns of greater than 10 percent BSA in anyone; 4) burns involving the hands, face, feet, or perineum; 5) burns crossing major joints; 6) circumferential burns of an extremity; 7) burns complicated by inhalation injury; 8) electrical burns; 9) burns complicated by fractures or other trauma; 10) burns in infants and the elderly; and 11) burns in poor-risk patients. These burns typically require referral to a specialized burn treatment center.

Moderate Burns

Moderate burns are 1) partial-thickness burns of 15 to 25 percent BSA in the 10- to 50-year-old age group; 2) partial-thickness burns of 10 to 20 percent BSA in children under 10 or adults over 50; and 3) full-thickness burns of less than 10 percent BSA in anyone. Partial-thickness burns of the hands, face, feet, or perineum or circumferential burns of an extremity are excluded. These patients typically require hospitalization for burn care.

Minor Burns

Minor burns include 1) partial-thickness burns of less than 15 percent BSA in the 10- to 50-year-old age group; 2) partial-thickness burns of less than 10 percent BSA in children under 10 or adults over 50; and 3) full-thickness burns of less than 2 percent BSA in anyone, without associated injuries. These burns generally require only outpatient treatment.

Inhalation Injury

With improvements in the treatment of burn shock and sepsis, inhalation injury has emerged as the main cause of mortality in the burn patient.^{2,3,6} Despite advances in respiratory support, smoke inhalation injury significantly increases mortality; half of all fire-related deaths are due to smoke inhalation. Inhalation injuries are associated with closed-space fires and conditions that decrease mentation—such as overdose, alcohol intoxication, drug abuse, and head injury. Exposure to smoke includes exposure to heat, particulate matter, and toxic gases.¹⁰

There is general consensus that direct thermal injury is limited to the upper airway. Thermal injuries below the vocal cords occur only in cases of steam inhalation.

Smoke contains particulate matter, usually less than 0.5 μ m in size, which is formed from incomplete combustion of organic material.

Small particles may reach the terminal bronchioles, where they can initiate an inflammatory reaction, leading to bronchospasm and edema.

Toxic inhalants are divided into three large groups: tissue asphyxiants, pulmonary irritants, and systemic toxins.¹⁰ The two major tissue asphyxiants are carbon monoxide and hydrogen cyanide.

Carbon monoxide poisoning is a well-known consequence of smoke inhalation injury. Severe carbon monoxide poisoning will produce brain hypoxia and coma. Comatose patients lose airway protective mechanisms, which may result in aspiration, thus further exacerbating the pulmonary injury from smoke inhalation. All patients with suspected carbon monoxide exposure should be started on 100% oxygen by non-rebreather mask and be evaluated for hyperbaric oxygen therapy (see Chap. 203).

Hydrogen cyanide is formed when nitrogen-containing polymers—such as wool, silk, polyurethane, or vinyl—are burned. Cyanide binds to and disrupts mitochondrial oxidative phosphorylation, leading to profound tissue hypoxia. Specific treatment for cyanide toxicity may be required (see Chap. 188).

Inhalation injury damages endothelial cells, produces mucosal edema of the small airways, and decreases alveolar surfactant activity, leading to bronchospasm, airflow obstruction, and atelectasis. With time, tracheal and bronchial epithelial sloughing occurs. As these patients are resuscitated with large quantities of fluid for their burn injury, pulmonary edema develops. Approximately half of intubated burn patients admitted to burn centers develop acute respiratory distress syndrome (ARDS).¹¹ Therefore, when inhalation injury is present, fluid resuscitation should be done carefully to avoid exacerbating pulmonary edema, and early institution of hemodynamic monitoring is recommended.

Bronchospasm may occur early, but lower airway edema is usually not clinically evident for up to 24 h. Upper airway edema, however, can occur rapidly. Although the injury is mainly to the airways, pulmonary vascular changes do occur. There is no single method capable of demonstrating the extent of inhalation injury. Diagnosis of smoke inhalation is made from the history of a fire in an enclosed space and physical signs that include facial burns, singed nasal hair, soot in the mouth or nose, hoarseness, carbonaceous sputum, and expiratory wheezing. Carboxyhemoglobin levels are useful to document prolonged exposure within an enclosed space with incomplete combustion. The chest radiograph may be normal initially; bronchoscopy and radionuclide scanning are useful in determining the full extent of injury.

Treatment of suspected inhalation injury should be instituted prior to definitive diagnosis. Humidified oxygen (100 percent) should be administered by mask. Arterial blood gases including carboxyhemoglobin levels should be obtained. In suspected cases, control of the upper airway is achieved by prompt endotracheal intubation. Indications for intubation include 1) full-thickness burns of the face or peri oral region, 2) circumferential neck burns, 3) acute respiratory distress, 4) progressive hoarseness or air hunger, 5) respiratory depression or altered mental status, and 6) supraglottic edema and inflammation on bronchoscopy.

TREATMENT

The management of patients with *moderate to major* burns can be divided into three phases: 1) prehospital care, 2) ED resuscitation and stabilization, and 3) admission or transfer to a specialized burn center.

Prehospital Care

The following principles are the basis of prehospital care for burn patients: 1) stop the burning process, 2) establish the airway, 3) initiate fluid resuscitation, 4) relieve pain, 5) protect the burn wound, and 6) transport the patient to an appropriate facility.

On-site assessment of a burned patient is divided into primary and secondary surveys. In the primary survey, immediate life-threatening conditions are quickly identified and treated. Initial management of the burned patient should be the same as for any other trauma patient, with emphasis on airway, breathing, circulation, and cervical spine immobilization. During the secondary survey, a thorough head-to-toe evaluation is carried out.

The patient must be removed from the burning process and burning clothing must be immediately removed and the remainder of the clothing removed after the airway, breathing, and circulation (ABCs) are secured. All rings, watches, jewelry, and belts should be removed, as they can retain heat and produce a tourniquet-like effect on the extremity, causing ischemia. A 100 percent oxygen mask should be applied. Thought should be given to an airway that has the potential to swell rapidly, even though initial assessment may be acceptable. Prophylactic intubation should be considered in burns about the face sustained in a closed-space fire. Intravenous fluids are started with isotonic crystalloid, usually LR solution. The patient should be covered with clean sheets to protect the wound. Early cooling can reduce the depth of burn and reduce pain, but uncontrolled cooling will result in hypothermia. Analgesia can be given upon direction of the on-line medical control physician. The patient should be transported to the nearest hospital capable of caring for a burn patient or, if none is available, the nearest hospital for stabilization.

Emergency Department Management

Upon arrival at the ED, a directed history should be obtained from the patient and emergency medical services (EMS) personnel. What was the burning agent? Were chemicals involved? What was the duration of exposure? Was the fire in an open or enclosed space? If the fire was in an enclosed area, what substances were burned? Was there an explosion causing the patient to suffer a blast injury? Was there any contact with electricity? Was there any other trauma or loss of consciousness? A general history including past medical and surgical illnesses, chronic disease, allergies, medications, and tetanus immunization status should be obtained from the patient or family.

The patient's respiratory and circulatory status should be reassessed and stabilized. The adequacy of or need for cervical immobilization should also be reassessed. The patient should be examined for signs of inhalation injury, evidenced by facial burn, carbonaceous sputum, singed nasal hair, and soot in the mouth. If there is any evidence of airway compromise with swelling of the neck, burns inside the mouth, or wheezing, endotracheal intubation should be performed.

The adequacy of circulation is initially assessed by the blood pressure, pulse rate, capillary refill time, mental status, and urinary output. When possible, intravenous lines should be inserted in nonburned areas, but when this is not possible, a burned area can be used and resuscitation started according to the burn fluid-resuscitation formula.

During the secondary examination, a head-to-toe assessment, including an eye examination for corneal burns, should be done. The size of the burn and its depth should be estimated and recorded. Patients with a greater than 20 percent partial-thickness burn routinely require a nasogastric tube, as ileus frequently occurs. A urinary drainage catheter should be inserted to measure urinary output and prevent urinary retention in patients with perineal burns.

Routine laboratory tests including a complete blood count (CBC), electrolytes, blood urea nitrogen (BUN), creatinine, and glucose should be obtained. In patients with suspected inhalation injury, arterial blood gases, carboxyhemoglobin level, chest radiograph, and electrocardiogram (ECG) should be obtained. Fiberoptic bronchoscopy is indicated when there is a suspicion of inhalation injury and in intubated patients, as this is both diagnostic and therapeutic in clearing the airways. A urinalysis for myoglobin and creatine kinase (CK) levels should be done, along with an ECG in patients with electrical injury.

SECTION 15 . ENVIRONMENTAL INJURIES

to assess muscle or cardiac injury. Additional radiographs should be taken as indicated for other suspected trauma.

The burn shock resuscitation formulas in use today are derived from laboratory studies of burn shock and resuscitation. The value of these formulas has been questioned.¹² In general, it appears that the traditional approach using crystalloid may underestimate fluid requirements when compared to resuscitation guided by cardiorespiratory monitoring. The value of early fluid resuscitation is supported by clinical experience.^{12,13} However, no consensus exists on the appropriate assessment of resuscitation and its effect on outcome.¹² At this time, the formulas only provide a *guide* for fluid resuscitation that must be monitored and adjusted according to patient response.

The Baxter or Parkland formula is probably the most widely used thermal injury resuscitation regimen in North America.^{4,5} This formula calls for 4 mL of LR solution multiplied by the percentage of BSA burned (second- and third-degree burns only) multiplied by the body weight in kilograms. Half of this total is given in the first 8 h after injury and the rest during the next 16 h (Table 199-2). The amounts may be large, and hemodynamic monitoring techniques are now commonly used to protect against inadvertent volume overload.

Electrical injuries, incineration burns, and associated crash injuries may produce rhabdomyolysis and myoglobinuria, leading to renal failure. Acute renal failure occurs in approximately 15 percent of patients admitted to burn centers and is associated with severe burns (mean BSA involvement 48 percent).¹⁴ Therapy may be required to limit renal damage from myoglobinuria (see Chap. 279).

Thermal injury in the presence of concomitant multisystem trauma generally requires fluids in excess of calculated needs. Inhalation injuries have been shown to increase total fluid needs. Burn patients with preexisting cardiac or pulmonary disease require much greater attention to fluid management. Fluid resuscitation should be monitored closely by frequent assessment of the patient's vital signs, signs of cerebral and skin perfusion, and urinary output as well as hemodynamic monitoring. The urinary output should be 0.5 to 1.0 mL/kg per h.

There are several methods of calculating fluid resuscitation for infants and children. One method is to use the Parkland formula and modify it to maintain urinary output of 1 mL/kg per h. Alternatively, a pediatric maintenance rate for 24 h can be calculated plus an additional 2 to 4 mL/kg multiplied by percentage of BSA burned, with the entire amount infused over the first 24 h. In children weighing less than 25 kg, a urine output of 1.0 mL/kg per h is necessary.

It is possible for patients with major burns to receive excessive intravenous fluids during the prehospital and ED phases, particularly if two large-bore peripheral catheters are in place with fluid infusing wide open. Total fluids infused should be documented and titrated to the patient's response.

Two additions or modifications to isotonic crystalloid resuscitation have been studied: adjuvant colloid and hypertonic saline. However, neither improves patient outcome. Adjuvant colloid given along with isotonic crystalloid resuscitation has not proven beneficial and is associated with increased accumulation of water in the lungs and de-

creased glomerular filtration rate.¹⁵ Hypertonic saline has produced an increased rate of renal failure and death.¹⁶

Routine tetanus toxoid prophylaxis should be administered based on the patient's immunization history. Tetanus immune globulin should be administered in patients without a history of full primary immunization. The use of systemic prophylactic antibiotics is inappropriate.

Treatment of inhalation injury includes humidified oxygen, intubation and ventilation, bronchodilators, pulmonary toilet, and hyperbaric oxygen for severe carbon monoxide poisoning.

Burns to a pregnant patient are associated with significant morbidity to mother and child. The outcome of the pregnancy is determined by the extent of the mother's injury; spontaneous termination of pregnancy is the common outcome in large-BSA burns. Fluid requirements may exceed those estimated using the formula. Fetal monitoring and early consultation with the obstetrician is recommended.

Wound Care

After evaluation and resuscitation, the burn wounds are addressed.¹⁷ Initially in the ED, the wound is best covered with a clean, dry sheet. Later, small burns can be covered with a moist saline-soaked dressing while the patient is awaiting admission or transfer. The soothing effect of cooling on burns is most likely due to local vasoconstriction. Studies have shown that cooling stabilizes mast cells and reduces histamine release, kinin formation, and thromboxane B₂ production. In large burns, sterile drapes are better, as saline-soaked dressings applied to a large area can cause hypothermia. The admitting service should be consulted early. The use of antiseptic dressing should be avoided in the ED as the admitting service will need to assess the wound. If the patient is going to be transferred, the accepting burn unit should be contacted for specific instructions regarding burn care. Do not delay transfer for debridement of the wound. The transferring facility should utilize the regional burn center's treatment protocol.

Patients with circumferential deep burns of the limbs may develop compromise of the distal circulation. Distal pulses need to be monitored closely; a Doppler flow probe may be very helpful. If there is compromise to the circulation, escharotomy will be needed. The eschar needs to be incised on the midlateral side of the limb, allowing the fat to bulge through. This may be extended to the hand and fingers (Figure 199-3). Escharotomy may provoke substantial soft tissue bleeding.

If there are circumferential burns of the chest and neck, the eschar may cause mechanical restriction to ventilation. An escharotomy of the chest wall needs to be done to allow adequate ventilation. Incisions need to be made at the anterior axillary line from the level of the sec-

FIG. 199-3. Escharotomy of the hand.

ond rib to the level of the twelfth rib. These two incisions should be joined transversely so the chest wall can expand (Figure 199-4).

Pain Control

All burns are painful, and superficial partial-thickness burns are the most painful. Burn injury not only makes an injured area and surrounding tissue more painful, but also causes hyperalgesia, chiefly due to the A fibers. Local cooling may be soothing, but does not provide pain control.¹⁸ Therefore pain management should be provided.

During the emergency phase, the preferred route for most medication is intravenous, because of the potential problems with absorption from the muscle and gastrointestinal tract related to decreased perfusion. Morphine is the most widely used drug for relief of pain, and relatively large doses may be required. Anxiolytic agents should be used as adjuvants in pain management.

During the acute phase and for ambulatory patients treated in the ED, opioid analgesics are required for procedural pain. Oral analgesics such as codeine, hydrocodone, oxycodone, or nonsteroidal anti-inflammatory drugs may be used for the background pain.

CARE OF MINOR BURNS IN THE EMERGENCY DEPARTMENT

The American Burn Association has defined minor burns that can be treated on an outpatient basis. To qualify as a minor burn, the injury should be isolated and not involve hands, face, feet, or perineum. The burn should not cross major joints or be circumferential. In treating a minor burn, the patient's social and medical situation should be considered. For example, an elderly patient or one with medical problems is best treated as an inpatient, even though the burn involves less than 10 percent of the BSA. The patient's reliability should be considered as an important factor for outpatient treatment. Care of minor burns requires coordination between the ED and the referral specialist who will see the patient in follow-up.¹⁷

As burns are painful, appropriate analgesia is required. After appropriate analgesia, the burn wound is cleaned with mild soap and water or dilute antiseptic solution. Blisters may be left intact or drained, or the overlying epithelium may be debrided; the decision depends on size and location. Large blisters or those over very mobile joints should be debrided. Small blisters on nonmobile areas should be left intact. Where compliance is questionable, patients should have the blisters debrided, because an intact or spontaneously collapsed blister may serve as a focus for wound infection. The patient's tetanus immunization status should be assessed and tetanus toxoid and/or immunoglobulin should be administered as needed.

FIG. 199-4. Escharotomy of the chest wall.

Topical antimicrobials have an important role in reducing bacterial colonization and enhancing the rate of healing in burns.^{4,5} A wide variety of topical agents are commonly used for minor burns. The most common is 1% silver sulfadiazine because it is easy to apply and has relatively little toxicity. The usual practice is to apply a thin layer of silver sulfadiazine cream to the burn and then cover it with gauze dressing. Silver sulfadiazine should not be used in patients with sulfa allergy, or on the face because of potential staining. Alternative opinions about the routine use of silver sulfadiazine have been expressed.¹⁹

Alternative topical agents to use in these circumstances are bacitracin or triple-antibiotic (neomycin, polymyxin B, and bacitracin zinc) ointments. Although 8.5% mafenide acetate cream and 0.2% furacin ointment are available for topical use, these should be used with caution if applied to large burns in an outpatient setting. Mafenide is a carbonic anhydrase inhibitor and can cause metabolic acidosis. Furacin is in a polyethylene glycol vehicle that can be toxic if absorbed in patients with compromised renal function. Mafenide penetrates the eschar well and has utility in treating patients with invasive infections.

Dressings are ideally changed twice daily as long as the wounds continue to weep; then they are changed daily until the burn is healed. Synthetic occlusive dressing is an alternative method of managing partial-thickness burns in outpatients. The wounds are cleansed and debrided prior to application of these dressings (e.g., Biobrane, Dow Hickam Pharmaceuticals; Tegaderm, 3M Health Care; DuoDERM, Bristol-Myers Squibb). This method is most successful for clean burns on flat surfaces. The goal is to have the dressing adhere to the wound so that it acts as artificial skin. Adherence is important, as most of the bacteria causing infection produce fibrinolytic agents. Wounds are checked at 24 to 48 h for adherence, and the dressing is left in place until spontaneous separation occurs. There is evidence that wounds treated with these synthetic occlusive dressings are better tolerated by patients, require fewer dressing changes, and heal with better appearance.²⁰

Patients must be given discharge instructions that explain home burn care and symptoms and signs of infection. The patient should be advised to return to the ED immediately if there are any signs or symptoms of infection. Extremity burns should be elevated for 24 to 48 h to prevent edema. All burn wounds should be reassessed at 24 h for depth and extent of burn. The follow-up visit schedule should be clearly explained and analgesics prescribed. Deep partial-thickness, full-thickness, and mixed-thickness burns should be referred to a plastic surgeon or burn-care specialist in 2 to 4 days for reevaluation and consideration of skin grafting.

CHEMICAL BURNS

Fred P. Harchelroad, Jr
David M. Rottinghaus

More than 25,000 products are capable of producing chemical burns. Exposures occur both occupationally and during use of chemicals for activities in daily life. It is estimated that chemical burns account for 5 to 10 percent of all U.S. burn center admissions. Nonoccupational exposures number about 100,000 per year, the vast majority being minor. Deaths are rare and usually from caustic ingestion. In 2001, there were 9481 reported nonfatal chemical exposures in private industry causing days missed from work, representing about 0.5 percent of all injuries. Also, there were 96 deaths from chemical exposure in the workplace reported in 2001.¹

Common household chemical burns are caused by lye (drain cleaners), paint removers (halogenated hydrocarbons), phenols (deodorizers, sanitizers, disinfectants), sodium hypochlorite (disinfectants, bleaches), methacrylic acid (artificial nail products), and sulfuric acid (toilet bowl cleaners). In industries, chemicals are used for cleaning, tanning, curing, extracting, preserving, soldering, and other functions. The most commonly used industrial acids are tungstic, picric, sulfosalicylic, tannic, formic, sulfuric, acetic, cresylic, trichloroacetic, chromic, hydrochloric, and hydrofluoric. Widely used alkalis are the hydroxide salts of sodium, potassium, ammonium, lithium, barium, and calcium. White phosphorus used in munitions was the most common cause of chemical burns to military personnel during times of armed conflict in the 1960s. White phosphorus also may be found in rodenticides, pesticides, and fireworks.

The body sites most often burned by chemicals are the face, eyes, and extremities. In general, chemical burns are smaller than thermal burns and the mortality rate is lower. However, wound healing and duration of hospital stay are longer. Disability and time away from work tend to be greater than that of other occupational injuries.

PATHOPHYSIOLOGY

The skin constitutes a barrier and transition zone between the internal and external environments. The outer stratum corneum layer of the skin functions as an excellent barrier against many chemicals, although some may penetrate it readily.

Chemicals can produce burns, dermatitis, allergic reaction, thermal injury, or systemic toxicity. Pathophysiologically, burns produced by all chemicals are similar because the skin has a limited variety of toxic responses.² Toxic reactions are described mainly on the basis of morpho-

logic rather than functional responses.³ Skin has protective mechanisms and elements, including the epidermal barrier, eccrine sweating, phagocytic cells, metabolic detoxification, immunologic processes, and melanin pigmentation. However, these protective mechanisms vary according to phenotype and may be affected by systemic or local disease.

Skin damage by chemicals may demonstrate the classic manifestations of thermal injury (erythema, blistering, or full-thickness loss). However, an acute injury may be deceptively mild, only to be followed by extensive skin damage and systemic toxicity. A superficial (first-degree) burn causes capillary and arterial dilatation. Initially, this involves only the superficial vessels, but then extends to the deeper subcutaneous vessels by both direct and reflex action. Tissue hyperemia and congestion result in symptoms of itching, burning, or pain. More extensive inflammatory reactions result in an outpouring of fluid into the extracellular space, causing edema and vesicle or bulla formation characteristic of partial-thickness (second-degree) burns. Continued chemical damage through the dermis or into the hypodermis results in a full-thickness (third-degree) burn.

Tissue damage is determined by: 1) strength/concentration of the agent, 2) manner of contact, 3) quantity of agent, 4) phase of agent (i.e., liquid vs. solid), 5) duration of contact, 6) mechanism of action, and 7) extent of penetration. Factors enhancing percutaneous absorption of chemical are body site (areas of thin skin, i.e., genitalia, face; chemical contact between skinfolds; amount of surface area exposed); integrity of skin (traumatized skin, elderly skin, dehydration, inflammation); nature of the chemical (lipid solubility, pH, concentration); and occlusion (garments, occlusive dressings).

The majority of chemical burns are caused by acids or alkalis. At similar volumes and manner of contact, alkalis usually produce far more tissue damage than acids. Acids in general cause coagulation necrosis with protein precipitation, tending to form a tough leathery eschar. The eschar typically limits deeper penetration of the agent. Alkalis produce liquefaction necrosis and saponification of lipids. The result is a poor barrier to chemical penetration and deeper, ongoing burns. Not all chemicals causing burns can be considered acid or alkali. A useful classification by Jelenko groups chemicals by the manner in which they damage protein:⁴

1. Oxidizing agents: Damage is produced when a chemical becomes oxidized in contact with tissue. Often a toxic moiety is released during this reaction.
2. Corrosives: Extensive protein denaturation is produced, resulting in soft eschar and shallow, indolent ulcers.
3. Reducing agents: Protein denaturation is produced by binding of free electrons in tissue protein.
4. Desiccants: Severe cellular dehydration is produced, and thermal injury occurs due to exothermic reaction.
5. Vesicant: Blisters are produced, tissue cytokines are liberated, local ischemia and anoxic tissue damage and pandermic inflammation occur.
6. Protoplasmic poisons: Protein is denatured by salt formation or by metabolic competition/inhibition (i.e., binding calcium or other inorganic ions is necessary for tissue viability and function).

GENERAL APPROACH

The goal of treatment is to minimize any area of irreversible injury and maximize salvage in the zone of reversible damage. With few exceptions, aggressive hydrotherapy is the cornerstone of initial treatment for chemical burns. Chemical agents may continue to damage tissue until they are removed or inactivated. Immediate removal from the offending chemical, removal of garments, and counteraction of the chemical remaining on the body by dilution, debridement, or neutralization are important measures. Dry chemical particles such as lime should be brushed away before irrigation. Sodium metal and related compounds should be initially covered with mineral oil or excised,

since water can cause a severe exothermic reaction. Dilution of phenol (carbolic acid) with water may enhance penetration. For the most part, however, use of water or saline to irrigate a chemical burn should not be delayed while searching for other treatment agents and should begin at the scene of the accident. Almost universally, earlier irrigation means a better prognosis.

The amount of elapsed time to initiate dilution or removal of chemical agents relates to the depth and degree of injury. Wounds irrigated 3 min after contact with some chemicals have a twofold greater chance of becoming full-thickness burns than wounds irrigated within 1 min of chemical contact. When using agents to neutralize a chemical burn, additional tissue injury may occur through heat production. In some cases, heat may be produced by using water irrigation, but copious amounts will decrease the rate and amount of chemical reaction and dissipate the heat. Irrigation should be maintained at a gentle flow to avoid driving the chemical deeper into tissue or splashing chemical into the victim or rescuer's eyes. The time required for irrigation varies; irrigation may need to be continued for hours in the case of severe alkali burns. Use of pH indicator paper may help determine continued presence of alkali or acid in burn wounds and possible need for further irrigation. A more accurate pH result will be obtained if the test is performed 10 to 15 min after completion of irrigation. This will allow residual chemical in the deeper areas to diffuse to the surface.

After irrigation and debridement of remaining particles and devitalized tissue, topical antimicrobial agents should be used and tetanus immunization should be updated. Other than measures specific for a particular chemical burn, treatment following initial therapy is basically the same as for thermal burns. Patients sustaining extensive chemical burns require the same aggressive fluid replacement as those with thermal burns. Analgesics may be needed, and in the case of allergic responses to chemicals, antihistamines, steroids, and epinephrine may be required. Early tangential excision and surgical management of severe burns, especially from alkalis or those with ongoing tissue destruction, have been shown to reduce burn size. This method, in conjunction with persistent hydrotherapy, also reduces operative blood loss.⁵ Autografts, heterografts, homografts, or synthetic material may be necessary for full-thickness burns. Hyperbaric oxygen may be utilized to assist healing of resistant burn wounds.

SPECIFIC CHEMICALS

Acids

With the exception of hydrofluoric acid, strong acids produce coagulation necrosis from the desiccating action of the acid on proteins in the superficial tissue. Injury severity is related to the physical characteristics of the acid. Most substances with a pH less than 2 are strong corrosives. Other important tissue-damaging properties of acids include concentration, molarity, and complexing affinity for hydroxyl ions. The higher each of these factors is, the greater is the tissue damage. Contact time with the skin is the most important chemical burn feature that health care professionals may alter. Instantaneous skin decontamination of 18 M sulfuric acid will cause no burn; however, a 1-min exposure can cause full-thickness skin damage. Examination of a patient with a significant chemical burn from these acids should not be limited to observation of the skin, because several of these acids are respiratory and mucous membrane irritants as well. Furthermore, skin absorption of some compounds may occur and result in systemic signs and symptoms.

ACETIC ACID The dilute (<40%) acetic acid solution found in hair-wave neutralizer solutions is perhaps the most common cause of chemical burns to the scalp in women. Prolonged contact, especially with an already damaged scalp, may cause a partial-thickness burn that heals slowly because of the constant bacterial flora on the scalp.

Initial treatment is copious water irrigation. As trimming the hair is not a viable option in these patients, oral antibiotics are often given if the entire scalp is involved.

CARBOLIC ACID (PHENOL) Phenol (carbolic acid), a corrosive organic acid used widely in industry and medicine, denatures proteins and causes chemical burns characterized by a white or brown coagulum that is relatively painless. Systemic absorption may result in life-threatening complications. Its unpleasant, acrid odor, detectable in air at 0.047 parts per million, and its low volatility, help prevent airborne exposure. Though commercially available in concentrations up to 90% even dilute solutions of 1 to 2% phenol may cause a burn if contact is prolonged. Hexylresorcinol is a bactericidal phenol derivative. Chemically related phenolic compounds that induce skin damage include cresol, creosote, and cresylic acid.

Coagulation necrosis of the involved area is common. Necrotic tissue may delay absorption temporarily, but phenol may become entrapped under the eschar. Contaminated clothing should be removed and water lavage begun immediately. Water lavage alone may be ineffective, presumably because the necrotic coagulum inhibits water penetration to the deeper layers. Paradoxically, dilute phenol penetrates tissue more readily than when concentrated.

More effective decontamination has been demonstrated with a 5- to 10-min swab with a combination of polyethylene glycol 300 (PEG 300) and industrial methylated spirits (IMS) in a 2:1 mixture. This should not only reduce the extent of cutaneous corrosion but also decrease systemic toxicity. The PEG 300 is mixed with the IMS for a more liquid (and therefore easier to use) formulation. However, the viscous PEG 300 or PEG 400 may be used alone, and, indeed, glycerol is an acceptable substitute if the PEG-IMS mixture is not available. The use of an isopropyl alcohol rinse appears to be equal to PEG-IMS in removing phenol.⁶ The advantage of isopropyl alcohol is its ready availability.

CHROMIC ACID The toxicity of chromium compounds is related to the powerful oxidizing action of the hexavalent compounds (Cr^{6+}). The chromate ion in chromic acid will produce a chronic penetrating ulcerating lesion of the skin. Associated signs and symptoms are conjunctivitis, lacrimation, ulceration of the nasal septum, and systemic chromium toxicity with liver or renal failure, GI bleeding, coagulopathy, and CNS disturbances. A 10 percent total body surface area (BSA) cutaneous burn caused by chromic acid can be fatal due to systemic toxicity. Significant symptoms may occur after only 1 to 2 percent BSA burns. Any acute skin exposure to chromic acid should be treated with copious water irrigation and observation for systemic effects. Aggressive excision has been shown to be the best method for prevention of systemic effects because depth of the burn is difficult to determine and absorption of chromium may continue.⁷ Topical agents such as 5% thiosulfate and ascorbic acid are useful in preventing toxicity while preparing for surgical excision.

FORMIC ACID Formic acid in 60% solution is used by acrylate-glue makers, cellulose formate workers, and tanning workers. Formic acid produces coagulation necrosis of the skin. Systemic effects including decreased respiration and an anion-gap metabolic acidosis have been reported.⁸ Treatment includes immediate decontamination and irrigation with water. Open lesions should be treated like any damaged skin: with debridement of devitalized tissue, prevention of further damage and infection, and skin grafting if the defect is full-thickness and of a size requiring coverage.

HYDROCHLORIC AND SULFURIC ACIDS The dermal toxicity of hydrochloric acid and sulfuric acid is so well recognized that early decontamination and water irrigation usually prevent severe burns to the skin. These acids can burn the skin dark brown or black. Toilet bowl cleaners may contain 80% solutions of sulfuric acid, and some drain

cleaners may be 95 to 99% sulfuric acid solutions. Munitions, chemical, and fertilizer manufacturers commonly use 95 to 98% sulfuric acid solutions in their industrial processes. Automobile battery fluid is 25% sulfuric acid. Most household bleaches are only 3 to 6% hypochlorite solutions, which, though acidic, cause little damage unless they are in contact with skin for a prolonged time. Treatment is the same as for formic acid burns.

HYDROFLUORIC ACID Hydrofluoric acid (HF) is unique among the corrosives in its mechanism of action and degree of toxicity. HF applications include use in production of high-octane fuel, etching and frosting glass, semiconductors, microelectronics/microinstruments, germicides, dyes, plastics, tanning, and fireproofing material, and use in cleaning stone and brick buildings. It is also a very effective rust remover.

HF acts like alkalis and will cause progressive tissue loss, including bony destruction. HF produces burns in two ways. First, hydrogen ions cause direct cellular damage, often producing deep burns. Second, free fluoride ions are released, causing deeper burns and toxicity by immobilization of intracellular calcium and magnesium and poisoning of cellular enzymatic reactions. Potassium permeability is increased and results in spontaneous depolarization of nerve tissue and pain. Pain will persist until all free fluoride ions have been neutralized.

HF rapidly penetrates the skin and causes both local and potentially lethal systemic toxicity. Its systemic effects include hypocalcemia, hypomagnesemia, and hyperkalemia. The dermal effects may not be immediately noted and appear to be more related to the concentration of HF than to the duration of exposure. Solutions greater than 50% produce immediate pain and tissue destruction; solutions less than 20% may not produce signs and symptoms until 12 to 24 h after exposure. The skin may develop a blue-gray appearance with a surrounding region of erythema.

Unlike the treatment of dermal injury caused by other acids, the treatment of HF burns consists of two phases. The first, which should be immediate, is copious water irrigation of the affected skin for 15 to 30 min. This may be the only treatment that is needed if the HF solution is less than 20% concentration, the duration of exposure was very brief, and decontamination is begun immediately. Unfortunately, this is rarely the case. Severe, persistent pain denotes a more serious injury requiring the second phase of treatment.

The second phase of treatment is aimed at detoxifying the enzyme-poisoning fluoride ion. Two ions—calcium (Ca^{2+}) and magnesium (Mg^{2+})—have been shown to be beneficial in binding the fluoride and curtailing its toxic effects. However, the overwhelming clinical experience to date has been with the use of calcium gluconate, and it should be considered the agent of choice. Several therapeutic modalities are available for using calcium gluconate: topical, subcutaneous/intradermal injection, or intraarterial infusion. An intravenous regional perfusion technique based on Bier's method has been described and reported effective.⁹ High-dose intravenous magnesium sulfate appears to be effective in animal models, but human data are lacking.¹⁰

A calcium gluconate gel made with either Surgilube (E. Fougera & Co.) or dimethyl sulfoxide (DMSO) in a 2.5 to 10% concentration may be applied directly to the affected area.¹¹ The main limitation of topical therapy is the impermeability of the skin to calcium. Penetration into the dermis and subcutaneous tissues may be enhanced if the formulation with DMSO is used, but DMSO can cause toxicity. The topical therapy can be used in the outpatient setting, and industries utilizing HF should keep this topical formulation on hand for emergency use.

Subcutaneous and intradermal injection of a 5% calcium gluconate solution through a 30-gauge needle into the HF-burned skin is the most widely used treatment. A maximum dose of 1.0 mL of 5% calcium gluconate per square centimeter of burned skin is recommended. Pain relief is nearly immediate, and indeed, the elimination of pain may be used as a guide for further therapy. Recurrence of pain indicates the need for further therapy. Unfortunately, injection therapy has several disadvantages: 1) only limited amounts of calcium are deliv-

ered to the tissue; 2) hyperosmolarity and inherent toxicity of free calcium ions cause more pain initially, and more tissue damage is possible if calcium is not bound to fluoride; 3) vascular compromise can result if too much fluid is injected, especially into digits; and 4) rapid penetration of HF beneath the nail requires nail removal to administer the calcium gluconate into the nailbed adequately.

Intraarterial infusion of calcium gluconate may be used to prevent tissue necrosis and stop the pain associated with HF burns. This should be performed as soon as possible after the initial burn, preferably within 6 h of insult. An intraarterial catheter should be placed in the appropriate vascular supply (the brachial artery if the entire hand is affected) and connected to a three-way stopcock to which is attached an arterial pressure-monitoring device and the infusion syringe of calcium gluconate. A 50-mL syringe may be filled with 10 mL of a 10% calcium gluconate solution and 40 mL of D5. This should be infused over 2 to 4 h. The arterial pressure-monitoring device ensures that the catheter has not dislodged from the lumen of the cannulated artery. Infusion of the calcium solution into the deep tissues may cause further tissue damage. Repeat infusion may be needed if pain recurs within 4 h. This intraarterial infusion avoids the disadvantages of local infiltration therapy; however, it has its own disadvantages: an invasive vascular procedure that 1) may result in arterial spasm or thrombosis and 2) requires more time and resources, including hospital admission.

Nebulized calcium gluconate is a recognized treatment for inhalational exposures to HF. Ocular exposure to HF requires water irrigation for at least 30 min. Treatment with calcium chloride or magnesium chloride by subconjunctival injection or irrigation may increase corneal damage. Complete and quick recovery by utilizing 1% calcium carbonate eyedrops in a patient who had sustained a large corneal erosion due to a 49% HF burn has been reported.

Iontophoresis has recently been explored as a means to enhance penetration of calcium through the dermis and tissues more effectively by using an electric field across the skin. Patches are placed on the skin and an electrical field is established, creating a gradient by which ions are transported across the skin, enhancing delivery. This technique shows promise, but limitations include time to set up the apparatus and ability to treat only small burns.¹²

Systemic toxicity related to dermal HF exposure has resulted in death. This appears to be related to myocardial irritability and subsequent ventricular fibrillation as a result of systemic acidosis, hyperkalemia, hypomagnesemia, and hypocalcemia. Cardiac monitoring, intravenous access, and electrolyte monitoring should be performed in cases of all significant HF dermal burns.

METHACRYLIC ACID Methacrylic acid found in many artificial nail cosmetic products can produce severe dermal burns, usually in preschoolers.¹³

NITRIC ACID Nitric acid is used in industry for casting iron and steel, electroplating, engraving, and fertilizer manufacturing. Upon contact with skin, nitric acid can produce tissue damage by oxidation and may turn the skin yellowish as it is burned.

OXALIC ACID Oxalic acid is used for leather tanning and blueprint paper. Like hydrofluoric acid, it poisons enzymatic processes. Oxalic acid binds calcium and prevents muscle contraction. The wounds should be irrigated with water, and intravenous calcium may be required. Serum electrolytes and renal function should be evaluated, and cardiac monitoring should be instituted after serious dermal exposure.

Alkalis

Alkalis penetrate skin much more deeply and longer than acids, with a greater danger of toxicity from systemic absorption. Wounds may initially look superficial and in 2 to 3 days become full-thickness

burns. Alkalis combine with protein and lipids in tissue to form soluble protein complexes and soaps that permit passage of hydroxyl ions deep into tissue. Soft, gelatinous, friable, brownish eschars are often produced. Strong alkalis have a pH ≤ 12 .

LYES Strong, corrosive alkalis ("lyes") include ammonium, barium, calcium, lithium, potassium (caustic potash), and sodium (caustic soda) hydroxides. Lyes are widely used in industry and are found in home products (drain and toilet cleaners, detergents, and paint removers). The urine sugar reagent tablet Clinitest (Bayer) contains anhydrous sodium hydroxide. As a mode of assault, lyes have a lower mortality rate than gunshot wounds or stabbings, but victims often suffer long-term pain, scarring, and blindness.¹⁴ Lyes are extremely corrosive and penetrating, and burns require copious irrigation for long periods. Suicidal ingestion of lye may result in rapid death from upper airway occlusion. Late morbidity related to esophageal and gastric necrosis may be minimized by early surgical intervention with esophagogastrectomy.

Ammonium hydroxide is used in the production of synthetic fibers and extensively in agriculture. Toxicity can be severe and include mucous membrane, ocular, dermal, gastrointestinal, and inhalational/pulmonary injury. Treatment is as with other lyes, with immediate, voluminous, and persistent irrigation.¹⁵

LIME Lime (calcium oxide) is found in agricultural products and cements. There is considerable variability of lime content in different grades of cement, with fine to textured masonry cement having more lime than concrete. Lime is converted by water to the alkali calcium hydroxide. Upon skin contact, lime draws water out of the skin. All dry lime particles should be brushed away prior to irrigation. Paradoxically, a small amount of water may generate an exothermic reaction with tissue injury secondary to calcium hydroxide formation, so a large amount and strong stream of water (taking care to avoid splashing in eyes) should be used and will permit dissipation of heat.

PORTLAND CEMENT Portland cement, which accounts for a major proportion of the cement used in the United States, is a mixture of sand, lime, and other metal oxides. In the presence of water, calcium hydroxide, sodium hydroxide, and potassium hydroxide may all be formed. Workers who kneel in wet cement or get cement in their boots may discover burns hours after initial contact. In addition, skin may become irritated from gritty material, and a contact dermatitis may develop in individuals sensitive to the chromate contained in the material.

Metals

Foundry workers are sometimes burned by molten metal, which may spill or splash on body parts and run down into the boots. Elemental metals, sodium, lithium, potassium, magnesium, aluminum, and calcium may all cause burns. When exposed to air, some elemental metals spontaneously ignite. Water is generally contraindicated in extinguishing burning metal fragments embedded in the skin, because the explosive exothermic reaction that may result can lead to significant tissue injury. Burning metal may be extinguished with a class D fire extinguisher or smothered with sand. Covering metal fragments with mineral oil, however, appears to be the favored treatment method. Wound debridement should include excision of metal fragments that cannot be wiped away. Metal fragments should be placed in mineral oil to prevent further ignition.

Others

HYDROCARBONS Hydrocarbons will cause a fat-dissolving corrosive injury to the skin. In our present petroleum-dependent society, gasoline is a common agent of chemical burns. Patients sustaining

gasoline immersion burns usually have undergone some other traumatic insult (e.g., a motor vehicle accident). Gasoline is a complex mixture of alkanes, cycloalkanes, and aromatic hydrocarbons. A hydrocarbon chemical burn resembles either a thermal scald or a partial-thickness burn.¹⁶ Full-thickness burns secondary to prolonged contact with gasoline have been reported. Topical gasoline exposure in cold weather can result in frostbite of the digits due to rapid evaporation of gasoline resulting in heat loss from the skin. Systemic effects of the involved hydrocarbon (or what it was a solvent for) may expose the patient to greater morbidity than the skin damage. Dehydration of the skin associated with solvent contact contributes to injury. Patients should be advised not to use harsh soaps over the areas of defatting dermatitis caused by hydrocarbons, as these will cause further skin damage. Treatment involves decontamination; otherwise, management is as for a thermal burn.

Hot tar is derived from long-chain petroleum and coal hydrocarbons. Roofing tars and asphalt are heated to temperatures in excess of 500°F (260°C), and the burns sustained are usually thought of more as thermal than chemical. Cold tar can produce a liquefaction injury to tissue. Though the surface area size of the burn is usually small, solidified material stuck to skin and hair is hard to remove. If hot, the tar should be cooled to prevent continued thermal injury. Manual mechanical debridement can be painful and destructive to skin structures. Polyoxylene sorbitan (polysorbate) contained in many antibiotic ointments is an emulsifying agent that can be used to remove tar. Industrial removal agents such as De-solv-it, a citrus and petroleum distillate, are also effective in tar removal. Mayonnaise has been reported as a home remedy used topically in a similar fashion.

VESICANTS (DMSO, CANTHARIDES, AND MUSTARD GAS)

DMSO, cantharides, and mustard gas are considered to be vesicant agents. Skin burns with edema and blister formation can occur due to production of ischemia and anoxic necrosis at the site of contact. DMSO is a water-soluble organic solvent that has been used industrially since the 1940s. General therapeutic interest in DMSO began in the 1960s, when it was used topically by thousands of patients for sprains, bruises, minor burns, and arthritis. Its use has declined substantially because of eye toxicity, although it is still used for research and some clinical problems. Cantharides ("Spanish Fly") is used as a veterinary aphrodisiac and occasionally by human beings as well for its supposed aphrodisiac effects. Mustard gas is a vesicant in which public interest has resurfaced because of the threat of biochemical warfare and terrorist attack. Sulfur mustard is the most widely used of these agents. The development of British anti-lewisite was initiated by the threat of the arsenical war-gas, lewisite. It was found to effectively chelate arsenic as well as donate sulfur to minimize skin damage.

Skin damage following vesicant exposure can be severe and result in deep skin penetration, edema, blisters, ulcers, and serious morbidity. Burns resulting from vesicants should be irrigated copiously with water or saline. Skin can be decontaminated by using adsorbent powders (flour, talcum powder, Fuller's earth) if the supply of water is limited. The powder adsorbs the mustard from the skin and should be wiped away with a moist towel. The military uses M258A1 kits for skin decontamination. These kits contain three sets of towelettes, one of each containing phenol, sodium hydroxide, and sodium benzene-sulphonochloramine (chloramine). Chloramine produces "free" chlorine, which inactivates sulfur mustard. Povidone iodine shows great promise in the prevention and early treatment of skin damage caused by sulfur mustard. Human data are currently lacking, but in animal models both prevention of burns and immediate (<10 min) treatment of exposure yielded impressive skin protection.¹⁷

POTASSIUM PERMANGANATE Potassium permanganate is an oxidizing agent that is mildly irritating in dilute solution, but in concentrated solution can produce dermal burns with a thick, brownish purple eschar of coagulated protein. Burns should be copiously irrigated.

ALKYL MERCURY COMPOUNDS Alkyl mercury compounds, which are reducing agents used in disinfectants, fungicides, and wood preservatives, can produce dermatitis or burn lesions. Lesions typically are erythematous with blister formation. The blister fluid is high in metallic mercury content. The burning process continues as long as the agent remains in contact with skin. Partial-thickness burns deepen if the blister fluid is allowed to remain, so the blisters should be debrided, drained, and copiously irrigated.

DIQUAT DIBROMIDE Full-thickness skin burns have been reported to occur after prolonged exposure to the herbicide diquat dibromide. These burns were treated with skin grafting. It is unknown whether earlier therapy would have prevented the chain of events.

LACRIMATORS (CHLOROACETOPHENONE, CHLOROBENZYLIDENEMALONITRILE, AND DIBENZOXAZEPINE) Lacrimators (tear gas) such as chloroacetophenone (CN), chlorobenzylidenemalonitrile (CS), and dibenzoxazepine (CR) cause skin and mucosal irritation and contact dermatitis. The epidermal injury is limited, in contrast to the possible pulmonary parenchymal damage. Burns to the skin are treated with standard water irrigation. Ocular irritation is treated with copious water irrigation, followed by slit-lamp exam for corneal damage. Structural damage to the cornea occurs at high concentrations of these lacrimators. Pepper gas (trichloronitromethane), so named because of its pepper-like odor and propensity to induce sneezing, is used in some areas by law enforcement agencies. As with the other lacrimators, it will cause mucous membrane, ocular, and upper airway irritation (as well as bronchospasm in susceptible patients). Treatment is copious irrigation with saline and removal of the patient from the offending agent.

WHITE PHOSPHORUS White phosphorus is a chemical used as an incendiary and in insecticides, rodenticides, and fertilizers. It can ignite spontaneously when exposed to air and is rapidly oxidized to phosphorus pentoxide. White phosphorus is commonly found in hand grenades and other warfare munitions and thus is implicated in wartime and accidental burns to military personnel. In munitions, white phosphorus is solid, but some of it may liquefy with detonation. Burns may be caused by liquid or solid forms. White phosphorus burns may be complicated by multiple traumatic injuries as a result of shell fragments and the force of weapon explosions. Because of its many uses, white phosphorus burns also occur in civilians.

Flaming droplets of inorganic phosphorus may embed beneath the skin. The heat of reaction can be directly destructive to tissue. Particles continue to oxidize slowly until either debrided, neutralized, or completely oxidized. Contaminated clothing should be removed, visible particles debrided, and burns copiously irrigated with normal saline or water. A brief rinse with 1% copper sulfate solution may be helpful. Copper sulfate combines with phosphorus to form a dark-copper phosphide coating on the particles that makes them easier to see and debride, and also impedes further oxidation. However, copper sulfate can cause hemolysis and hemoglobinuria, and should be used with caution. Inorganic phosphorus particles may reignite if allowed to dry out, so wounds should be submerged or packed with soaked dressings.

White phosphorus burns are characterized by slow healing and ongoing burning, necessitating early and aggressive treatment. Systemic toxicity is a major risk, with hypocalcemia, hyperkalemia, and hepatic and renal injury all reported. Even patients with small burns should be considered for admission or transfer to a burn center for hydration, monitoring, and further treatment.¹⁸

Airbag Burns

Approximately 8 percent of individuals suffering injuries related to airbag deployment are burned. Airbags deploy by ignition of a solid

propellant—sodium azide—that creates an exothermic reaction leading to quick inflation of the airbag. Many other gases are created during activation, including corrosives such as sodium hydroxide, nitric oxide, ammonia, and multiple hydrocarbons. An airbag is deflated within 2 s of inflation through exhaust side ports on the bag. Burns associated with airbags include friction, thermal, and chemical burns.¹⁹ Sodium hydroxide has been implicated in the chemical keratitis reported after airbag deployment. Sodium azide may cause cutaneous burns in addition to severe systemic effects, but its contribution to airbag chemical burns is limited. Treatment of airbag chemical burns is similar to any alkali burn: immediate and copious water irrigation.

OCULAR BURNS

Chemical burns to the eyes are common and considered true ocular emergencies requiring immediate treatment.²⁰ Typically, chemical burns to the eye occur in the industrial setting, in laboratories, or as a result of accidents such as battery explosion and intentional assaults. Rupture of automobile airbags with spillage of chemicals onto the face represents a new potential source of ocular as well as skin burns. Early signs and symptoms of eye burns include tearing, rubbing, redness, pain, and blepharospasm. The conjunctiva, if severely injured, may appear pale due to ischemia and destruction of vascular supply. Swelling of the corneal epithelium, clouding of the anterior chamber, pupillary dilatation, and corneal ulceration may all occur.

If the nature of the chemical is not known, pH paper should be used to determine the presence of acid or alkali. Acid quickly precipitates the superficial tissue proteins of the eye, producing the typical "ground glass" appearance of the cornea. Penetration is limited by local buffering and barrier effects of the precipitated proteins. Damage sustained secondary to acid burns in most cases is immediate and limited to the area of contact. The posterior segment of the eye rarely suffers injury, and there are usually no late effects such as cell disruption or tissue softening.

Alkali burns are more severe, and results are frequently unsightly and disastrous. In general, the higher the pH of the alkali, the more damage. In a short period, strong alkali can penetrate the cornea, anterior chamber, and the retina, with destruction of all sensory elements, thus causing complete blindness. Severe chemosis, blanched conjunctiva, and an opacified cornea obscuring view of the iris or lens may occur. The penetration of alkali can continue for hours to days, resulting in globe perforation. The conjunctiva, and scleral blood vessels and collecting veins of the anterior chamber may be destroyed, leading to secondary glaucoma. Second- and third-degree burns of surrounding tissue can complicate the burn.

Chronic inflammation of the iris and ciliary body (iridocyclitis) and adhesions between lens and iris (posterior synechiae) are possible complications of ocular burns. Other complications of eye burns include ectropion (lid deformity), cataract formation, scarring and marked revascularization of the cornea, and scarring of both palpebral and bulbar conjunctiva with resulting adhesions between the lids and globe (symblepharon).

Treatment of eye burns should begin immediately, utilizing non-sterile or tap water if needed. Immediate treatment is copious and continuous irrigation at the scene, in transport, and at the hospital. Special eye-irrigating kits may be used. In general, 1 to 2 L of NS for each eye for 30-min continuous irrigation is the minimum treatment. Neutralizing substances should not be used.

Acid burns may not require as much volume or treatment time as alkali burns. For treatment of severe alkali burns, 24 h or more of continuous irrigation has been recommended by some. Checking the pH in the conjunctival sac to see whether it has returned to normal may be helpful in determining need for further irrigation (the goal is a neutral pH of 7.4). The eyelid may have to be held open manually or with retractors, due to severe orbicularis spasm. The eyelids should be everted if they are not too edematous. It is useful to routinely sweep the for-

nices with a wet cotton applicator to remove any particulate matter, especially if the pH is not responding well to irrigation.

Pain control with topical anesthetics and systemic analgesics may be necessary. Cycloplegics, mydriatics, and antibiotics should be used, though the efficacy of an eye patch to encourage corneal reepithelialization is uncertain. Phenylephrine should be avoided because of its vasoconstrictive properties. The patient should be hospitalized and ophthalmology consultation obtained for severe corneal burns.

For severe corneal damage, a collagenase inhibitor such as cysteine or acetylcysteine is used to prevent loss of corneal stroma, which occurs with liberation of collagenase from injured corneal and conjunctival epithelium. Topical steroids may reduce iridocyclitis, but may also exacerbate collagenase-induced corneal ulceration. A scleral contact lens may reduce adhesions and scarring. Intraocular pressure should be checked, and agents to reduce intraocular pressure should be used if glaucoma develops. Paracentesis may be required in severe alkali burns to introduce sterile phosphate buffer solution into the anterior chamber in an attempt to reduce the pH of the inner eye. Surgery to the eye is usually not indicated during the early phase of burn management unless for corneal grafting following corneal perforation. Blepharoplasty, keratoplasty, or keratoprosthesis may be eventually required.

IATROGENIC CHEMICAL BURNS

Iatrogenic chemical burns have been caused by the use of potassium permanganate at an inappropriately high concentration to treat dermatologic problems. DMSO used as a transcutaneous vehicle for minor sprains has caused burns. Patients in the operating room may develop burns from skin-prep solutions; thimerosal, which has high mercury content, is the most common agent implicated. Mechanical abrasion of the skin from scrubbing and from pooling of the skin-prep agent under the torso or tourniquet predisposes patients to burns. Blister formation, skin sloughing, and eschar development have been reported in neonates when isopropyl alcohol pledgets were substituted for conducting paste beneath limb electrocardiograph electrodes. Silver nitrate utilized to cauterize umbilical granulomas in infants reportedly has caused periumbilical burns.

SYSTEMIC TOXICITY

Death early after severe chemical burns is usually related to hypotension, acute renal failure, and shock as a result of fluid loss. However, systemic toxicity and subsequent morbidity and mortality may also occur with some chemicals that are absorbed through denuded dermis. Acidosis, hypotension, and shock can occur with significant absorption of acids. Hypocalcemia has been reported with both oxalic acid and hydrofluoric acid burns. Profound hypocalcemia and hypomagnesemia may be accompanied by hyperkalemia, cardiac arrhythmias, and sudden death. Tannic acid, chromic acid, formic acid, picric acid, and phosphorus may cause hepatic necrosis and nephrotoxicity.

Cresol can cause methemoglobinemia, massive hemolysis, and multiple organ failure. Gasoline immersion with large surface area exposure and absorption of hydrocarbon aromatic components may result in severe pulmonary, cardiovascular, neurologic, renal, and hepatic complications. Gasoline lead additives such as tetraethyl and tetramethyl can cause lead encephalopathy. Carburetor-cleaning solvent containing phenol and methylene chloride may cause renal and hepatic failure. When absorbed, phenol (carbolic acid) can lead to intravascular hemolysis and cardiovascular, pulmonary, and central nervous system toxicity.

Sodium nitrate and potassium nitrate can cause a severe toxic methemoglobinemia from absorption with refractory cyanosis. Significant absorption of dichromate solution can result in liver failure and acute renal failure and death despite hemodialysis.

ELECTRICAL INJURIES

Raymond M. Fish

Electric shock may be defined as a sudden violent response caused by electric current flow through any part of the body or head. Electrocutation is death caused by electricity. Electrical injury is tissue damage produced by the flow of electrical current through tissue. Electrical burns are cutaneous injury and necrosis resulting from electrical current flow through the skin.

EPIDEMIOLOGY

The true incidence of electrical accidents is unknown. Many persons receiving an electric shock fall from a height, have a fatal dysrhythmia, or otherwise are found dead, and in many of these cases, the

occurrence or significance of the electric shock is not recognized. A fall may be attributed to the victim tripping or a sudden death may be attributed to myocardial infarction from natural causes. Medical personnel should obtain careful histories from witnesses and survivors that may help in diagnosing and treating the victim. This information may also help to prevent others from being injured from contact with the same voltage source.

The total number of electrocutions in the United States was reported to be 550 in 1998.¹ A study in Dade County, Florida, where the Dade County Medical Examiner's Office aggressively investigated possible electrical deaths, found the incidence of electrocution in that county to be 50 percent higher than that reported in the rest of the United States.² This apparent difference was attributed to underreporting in most of the country. Investigation of possible electrocutions included an "autopsy" of the circumstances and equipment. This study also found and explained that in nearly half of low-voltage deaths (<1000 volts AC), there will be no visible burns or electrical marks on the victims.²

Severe nonlethal electrical injuries account for 3 to 5 percent of admissions to burn centers, usually a result of contact with high-voltage power lines. These injuries are frequently disabling, sometimes involving amputations of one or more extremities. The incidence of minor and nonsevere electrical injuries is unknown, but up to 17,000 victims of electrical injury are estimated to be treated each year in U.S. emergency departments.

Three distinct populations are at risk for electrical injury, each accounting for approximately 20 to 25 percent of electrical injuries. The first trimodal peak occurs in toddlers who sustain electrical injuries from household electrical sockets and cords. The second peak occurs in adolescents who engage in risky behavior around electrical power lines. The third population at risk is those that work with electricity for a living. Electrical utility workers in the United States have an annual death from electrical incidence of approximately 1 per 10,000.³

PATHOPHYSIOLOGY

Electrical current is the movement of electrical charges; this flow is measured as amperes. Current flow is driven by an electrical potential difference; this difference is measured as volts. The intervening material resists electrical current flow; this resistance is measured as ohms. Ohm's law describes the relation between current (I), voltage (V), and resistance (R): $I = V/R$. For example, in a person who grasps a grounded pipe in one hand and a wire connected to a 120-volt source in the other hand, with the total resistance from power source through person to ground of 1000 ohms, the peak current would be: $I = (120 \text{ volts})/(1000 \text{ ohms}) = 0.120 \text{ amperes} = 120 \text{ milliamperes}$.

Materials that allow electrical current to flow easily are called conductors. Materials that do not allow electrical current flow are called insulators. Most biologic materials conduct electricity to some extent. Tissues with high fluid and electrolyte content conduct electricity better than tissues with less fluid and electrolyte content. Bone is the biologic tissue with the greatest resistance to electrical current. Dry skin has high resistance, but sweaty or wet skin has much less resistance by a factor of 100 or more.

Electrical current can be either continuous in one direction (direct current or DC) or with periodic reversal in the direction of current flow (alternating current or AC). Alternating current is found in the electricity supplied to homes and businesses. The frequency of AC electricity is the number of complete cycles (from positive through negative back to positive) made in one second. In the United States, most AC, including household electricity, is 60 Hz (cycles per second), while in Europe and Australia, 50 Hz AC is used. Most electronic and many medical devices use DC that is supplied by batteries or power supplies that convert AC supplied from an electric socket to DC for use in the device.

Many of the physiologic effects of electric shock are related to the amount, duration, type (AC or DC), and path of current flow (Table

201-1). For current to flow through an individual, a complete circuit must be created from one terminal of a voltage source to a contact area on the body, through the subject, and then from another contact area back to the other terminal of the voltage source. Current flows through the body (and head, if the circuit includes it) from one contact area to another, along multiple, somewhat parallel paths. Unless there is just one type of tissue present, the current does not flow through a single "path of least resistance," as is sometimes claimed in medical articles. Electrical contacts on the left hand and left leg would give current flow through those limbs and the trunk, but not through the other limbs or head.

Electric current flows through multiple paths in various proportions depending on tissue type, cross-sectional area, anatomic location, and resistance. In a typical limb, nerves and blood vessels have the lowest tissue resistance per unit of cross-sectional area, followed by that of muscle (about twice the resistance of blood vessels and nerves) and then bone, with resistance roughly 3 to 12 times as high, depending on the type of bone. In a typical limb, the cross-sectional area of muscle is approximately 100 times that of blood vessels or nerves, so that the total current flow through muscle is approximately 50 times that in blood vessels or nerves. However, while only a few percent of the total current flows through nervous tissue, nerves have a higher current density (current flow per unit cross-sectional area).⁴ This is one reason that nerves can be significantly injured, even though most of the current flow was through other nearby tissues with little effect.

As current flows through a resistor, energy is deposited in the form of heat. If resistance and other factors remain constant, heating from current flow through tissue is proportional to duration of current flow and the square of the current intensity according to Joule's law: $\text{energy} = I^2 \times R \times \text{time} = (V^2 \times \text{time})/R$. Therefore, as long as the resistance remains constant (i.e., until the tissue burns and changes resistivity), heating of tissues increases according to the square of applied voltage. Direct tissue heating predictions by applying Joule's law are generally implicated as the etiology of most tissue damage from electricity.

High voltage is usually defined as greater than 1000 V, although there is evidence that the risk for serious and fatal electrical injury increases significantly with voltages above 600 V Power lines in U.S.

TABLE 201-1 Effects of Current

Effect	Current Path	Minimum Current 60 Hz AC Milliamperes*
Tingling sensation, minimal perception	Through intact skin	0.5 to 2
Pain threshold	Through intact skin	1 to 4
Inability to let go: tetanic contractions of hand and forearm tighten grasp, decreasing skin resistance	From hand, through forearm muscles, into trunk	6 to 22
Respiratory arrest: can be fatal if prolonged	Through chest	18 to 30
Ventricular fibrillation	Through chest	70 to 4000
Ventricular standstill (asystole): in effect, cardioversion; if current stops, sinus rhythm may resume	Through chest	>2000

*Ranges are approximate and depend on various factors. *Source:* Reprinted (with slight modification) with permission from Fish RM, Geddes LA: *Medical and Bioengineering Aspects of Electrical Injuries*, Lawyers and Judges Publishing Company, Inc, Tucson, AZ, p 404, 2003.

residential areas are typically 7620 V, which is stepped down by transformers to 220 V before entering the house. Urban subway electrical third rails are typically 600 V. Although high voltage is more dangerous, the general population has much greater access to low-voltage sources and these low-voltage sources account for about half of all electrical injuries and deaths.

Electrical skin burns tend to be severe with high voltages, where only a fraction of a second of contact time is necessary for severe damage.⁵ Conversely, cutaneous burns tend to be minimal with household voltages (110 V) unless there is several seconds of contact time; even then the burns tend to be minor. Moreover, in low-voltage electrocution deaths, electrical burns are absent in more than 40 percent of cases because 110 V AC is capable of producing ventricular fibrillation, but deposits relatively little heat energy into the skin.²

Electrical current can induce sustained muscular contraction or tetany, the overall effect varies according to type (AC or DC), frequency, voltage, and extent of contact.^{5,6} For example, when AC current flows through the arm, flexor tetany of the fingers and forearm overpowers that of the extensors, and if the hand and fingers are properly positioned, the hand will grasp the conductor tighter, leading to extended contact to the power source. Alternatively, if the person has not grasped the contact tightly, tetanic flexor contraction of the hand and forearm may not occur, but current flow through the trunk and legs may cause opisthotonic (arching) postures and leg movements. Such involuntary muscle contractions may be very strong, leading to the person appearing to "be thrown" from a voltage source, and produce mechanical trauma. High-voltage AC and DC contacts are also more likely to produce a single violent skeletal muscle contraction that tends to throw the victim away from the source. Forceful muscle contractions can cause fractures and joint dislocations, especially around the shoulders.⁷

Electrical current can induce immediate cardiac (arrhythmias) and neurologic (respiratory arrest and seizures) effects. Current that traverses the body vertically ("hand to foot" or "head to toe") can produce arrhythmias and respiratory arrest as can current that traverses horizontally ("hand to hand").

An electrical arc is a spark of current through the air between objects of differing electrical potential. A typical arc burn is from the electrical source to the patient. The voltages required to create an electrical arc are extreme and the temperatures created can be as high as 2500°C (4532°F), so thermal tissue destruction from an electrical arc can be excessive.

Electric control devices, such as the stun gun or Taser, produce a series of damped sinusoidal electrical impulses, typically 10 to 15 Hz, designed to induce involuntary muscle contraction and incapacitation in the victim. These electromuscular disruptive devices deliver electricity at high voltage (50,000 V for a Taser) but low amperage and low average energy.

PATIENT CARE AND RESCUER SAFETY AT THE ACCIDENT SCENE

The scene of a high-voltage electrical incident contains many hazards for rescue personnel. Power lines are almost never insulated, although a line may appear to be insulated because of atmospheric contaminants deposited on the line over time. Electrocution is possible when walking on ground near a downed power line. It is recommended that persons stay at least 9 m (30 ft) from downed power lines, though 3 m (10 ft) is sometimes suggested as a safe distance. Additionally, reapplication of voltage to downed lines sometimes occurs as circuit breakers reset, making the lines physically jump many feet with great force. It is possible to place a heavy object over downed lines to prevent "jumping," though this can be difficult and very dangerous. Metal cables that support telephone and power poles are normally grounded, but may be energized if broken or disconnected from an attachment and make contact with a nearby power line.

Victims still in contact with a source of voltage may transmit an electric current to would-be rescuers. If it can be done quickly, it is best to first turn off the source of electricity. If this cannot be done quickly, precautions must be taken to prevent electric injury to the rescuer. With voltages above about 600 volts, dry wood and other materials may conduct significant amounts of electric current and therefore cannot be used to remove the person from a voltage source. A rescuer standing on the ground touching any part of a vehicle that is in contact with a power line is likely to be killed or seriously injured. Electrical shock is not prevented in this situation by the rescuer wearing rubber gloves and boots (unless these are designed for the voltage present and have been recently tested for insulation integrity). Persons inside a vehicle in contact with a power line are likely to be killed as they step out of the vehicle, and may also receive a shock if they touch objects at different potentials inside the vehicle.

It is recommended that mouth-to-mouth breathing for lineworkers in respiratory arrest on utility power poles be initiated by rescuers while still on the pole. As soon as the patient is lowered to the ground, chest compressions can be added if there is cardiac as well as respiratory arrest.

Spinal fractures can be caused by tetanic muscle contractions, as well as by falls and other secondary trauma. Therefore, spinal immobilization during resuscitation, to the extent possible under the circumstances, should be done.

EMERGENCY DEPARTMENT EVALUATION AND TREATMENT

The usual evaluation (airway, breathing, circulation) and resuscitation for major trauma victims should be provided as appropriate. Cardiac arrhythmias can be treated according to accepted advanced life support guidelines. Cardiac monitoring should be instituted for all high-voltage patients, patients with neuromuscular or cardiac symptoms (loss of consciousness, amnesia, altered mental status, episode of tetany, chest pain, palpitations), and those with transthoracic current paths. Spinal fractures can be caused by tetanic muscle contractions, as well as by falls and other secondary trauma. Therefore, spinal immobilization should be maintained during resuscitation until adequate radiographs and examination are possible.

The physical examination should assess tissue damage and identify associated complications. A careful vascular and neurologic examination of involved extremities is important. Occult and delayed injuries occur and a normal initial assessment does not exclude serious injury.

Patients with high-voltage injury, extensive cutaneous burns, or evidence of systemic injury should have laboratory tests done: serum electrolytes, creatinine, blood urea nitrogen, creatine kinase, serum and urine myoglobin, and complete blood cell count. An electrocardiogram is recommended for the same indications as cardiac monitoring. Imaging studies (plain radiography, computed tomography, angiography) are indicated for suggested injuries.

Fluid resuscitation is commenced using isotonic crystalloid (normal saline or Ringer's lactate solution). Fluid requirements for serious electrical injuries are higher than estimates provided by thermal burn injury formula (e.g., Parklands formula) because the visible cutaneous damage underestimates the internal damage. An initial fluid volume of 20 to 40 mL/kg over the first hour is appropriate for most patients and further fluid administration is guided by clinical and hemodynamic assessment.

If there is rhabdomyolysis, fluid loading is desirable to prevent myoglobinuric renal failure. Myoglobinuria should be considered present if a urine dipstick test registers positive for hemoglobin, but the freshly spun urine sediment shows no red blood cells. In rhabdomyolysis, a serum sample has normal color, whereas in hemolysis, the serum sample has a red or brown color indicating free hemoglobin. In ambiguous cases, myoglobin can be tested for in the serum or urine.

Specific Injuries

CARDIAC ARREST Cardiac arrest is the primary cause of death from electrocution. The specific fatal arrhythmia varies; low-voltage AC is likely to produce ventricular fibrillation, whereas high-voltage AC and DC are more likely to produce transient ventricular asystole. Cardiac arrhythmias can be seen in up to 30 percent of high-voltage victims and include sinus tachycardia, premature atrial contractions, premature ventricular contractions, supraventricular tachycardia, atrial fibrillation, and first- or second-degree atrioventricular block. Arrhythmias other than ventricular fibrillation are rare if voltage is less than 220 V and water contact was not involved.

Vigorous resuscitation efforts should be initiated for cardiac arrest from electric shock because 1) many victims are young and without prior cardiovascular disease, so the chance of recovery and survival is good, and 2) it is often not possible to predict the outcome of attempted resuscitation based on age and initial rhythm in electric shock-induced cardiac arrest.⁸ Usual basic or advanced resuscitation protocols should be used, with modifications for rescuer safety, patient access, and injuries that interfere with airway access.

CENTRAL NERVOUS SYSTEM INJURIES Neurologic impairment occurs in approximately 50 percent of patients with high-voltage injuries.^{5,7} Transient loss of consciousness is common, followed by other changes such as agitation, confusion, coma, seizures, quadriplegia, hemiplegia, aphasia, and visual disturbances.

SPINAL CORD INJURIES Spinal cord injuries can be the result of vertebral fractures, usually present on initial evaluation, and sometimes occurring at multiple levels in the same patient.⁷ Delayed spinal cord injury can occur from the electrical current itself and presents as ascending paralysis, complete or incomplete spinal cord syndromes, or transverse myelitis.

With purely electrical trauma, spinal cord magnetic resonance imaging (MRI) results are not closely correlated with prognosis. With high-voltage electrical trauma, diagnosis of spinal cord injury can be hindered by altered mental status or associated severe injuries. Even in patients who are alert, a delayed onset of spinal cord dysfunction is sometimes noted. In rare cases, the initial MRI may be normal in electrical trauma patients with permanent spinal cord injury.⁹ Conversely, the great majority of patients with spinal cord impairment following mechanical trauma who have a normal initial spinal MRI will have complete resolution of neurologic dysfunction.¹⁰

PERIPHERAL NERVE INJURIES Peripheral nerve injuries often involve the hands after touching a power source. Paresthesias may be immediate and transient or delayed in onset, appearing up to 2 years after injury.⁷ Most delayed neurologic deficits after high-voltage trauma involve the spinal cord. Electrical contact with the palm produces median or ulnar neuropathy more than radial nerve injury. Brachial plexus lesions have been reported.

CUTANEOUS WOUNDS Cutaneous burns are often seen at the electrical contact areas ("entry and exit" points). The majority of serious cases have burns on either the arm or skull, paired with burns on the feet. These burns are typically painless, gray to yellow depressed areas.

After cleansing, burns of the skin can be dressed with silver sulfadiazine or mafenide acetate. Mafenide is preferred by some for full-thickness burns because of its better eschar penetration. However, if used on more than 15 to 20 percent of the body, inhibition of carbonic anhydrase by mafenide acetate can cause electrolyte and pH abnormalities. Another disadvantage of mafenide is that it is painful. Extremities with burns need careful examination for neurovascular compromise, compartment syndromes, and the need for escharotomy or fasciotomy. Extremities with burns should be splinted. The hand should be splinted in 35 to 45 degrees of extension at the wrist, 80 to

90 degrees of flexion at the metacarpophalangeal joints, and almost full extension of the proximal interphalangeal and distal interphalangeal joints. Surgical debridement of necrotic tissue should be done early, with vascular and other reconstruction as needed. Early excision and skin grafting is recommended, and a variety of commercial skin substitutes are available for use.¹¹

ORTHOPEDIC INJURIES Fractures may be caused by tetanic muscle contractions or associated falls. Fractures may be missed on initial assessment because there is often pain associated with burns and other injuries, and patients are not always alert because of their injury or pain medications. All joints should be put through a full, active range of motion if possible; otherwise, passive range of motion should be tested. If such movements are not possible, radiographic study is indicated. Limited motion, fixed internal rotation, and deformities are suggestive of shoulder dislocation and fracture. Fractures and dislocations of the shoulders have been reported from sources of 110 to 440 volts AC.⁷

BLAST INJURIES Electric arcs in the industrial environment or near a power line can produce a strong blast pressure, similar to those of other explosions.¹² Cognitive complaints following blast injury sometimes resemble those that result from mild to moderate mechanical head trauma. Mechanisms of brain injury include mechanical trauma related to the blast, as well as arterial air emboli associated with blast-related alveolar disruption.

INHALATION INJURIES Chemical toxins such as ozone can be produced by coronas and arcs.¹³ Acute effects of ozone include mucous membrane irritation, temporarily reduced pulmonary function, and pulmonary hemorrhage and edema. Fires and explosions associated with electric incidents may lead to inhalation of carbon monoxide and other toxic substances.

EYE INJURIES Cataract formation has been described weeks to years after electrical injury to head, neck, or upper chest.⁷ Cataracts have also occurred after electric arc or flash burns. Therefore, it is important to document the absence of cataracts following such an injury. Retinal detachment, corneal burns, intraocular hemorrhage, and intraocular thrombosis may be seen after high-voltage injury.

AUDITORY SYSTEM INJURY The auditory system may be damaged by current or by hemorrhage in the tympanic membrane, middle ear, cochlea, cochlear duct, and vestibular apparatus. Delayed complications include mastoiditis, sinus thrombosis, meningitis, and brain abscess. Hearing loss may be immediate or develop later as a result of complications. Hearing should be checked in the emergency department as well as formal testing in any patient who appears to have a deficit.

ORAL BURNS An oral injury can occur in children who chew through the insulation of a power cord. The electrical arc created between the two wires can produce high temperatures and significant tissue damage. Most injuries are unilateral and involve the lateral commissure, tongue, or alveolar ridge.^{5,7} Systemic complications of oral burns are uncommon. Vascular injury to the labial artery is not immediately apparent because of vascular spasm, thrombosis, and the overlying eschar. Severe bleeding from the labial artery occurs in up to 10 percent of cases when the eschar separates, usually after 5 days. For this reason, children with this injury are often admitted to the hospital. However, some authors believe that outpatient management is adequate.¹⁴ If parents are reliable, can monitor the child, and can be shown how to control bleeding, outpatient management may be considered. The parents need to be told that bleeding may occur up to 2 weeks later. Home care may include saline or hydrogen peroxide rinses and swabs that will debride necrotic tissue and promote formation of healthy granulation tissue. Topical petrolatum-based antibiotics may have a soothing effect. Specialty consultation should be obtained,

as splinting and other measures are often needed to prevent residual deformity and dysfunction.

GASTROINTESTINAL INJURIES There are reports in the literature of lethal intraabdominal injuries from electric current being found only at autopsy. Intraabdominal injury should be suspected in patients having burns of the abdominal wall or a report of trauma, such as in a fall or explosion. Similar to other critically ill patients, major electrical trauma patients can develop stress injury and bleeding from the gastrointestinal tract.

VASCULAR AND MUSCLE INJURY Vascular and muscle injury occur most commonly in the setting of high-voltage injury, such as from power lines. Electrical current passing along peripheral arteries may cause early spasm and delayed thrombosis or aneurysm formation. Extensive vascular injury may produce a muscle compartment syndrome.

DISSEMINATED INTRAVASCULAR COAGULATION Thermal injury or tissue necrosis from electrical current can cause disseminated intravascular coagulation (DIC). Low-grade DIC may be a result of hypoxia, vascular stasis, rhabdomyolysis, and release of procoagulants from damaged tissue. Treatment consists of elimination of the precipitating factor by early surgical debridement. If bleeding is present, coagulation factors should be replaced with fresh-frozen plasma or cryoprecipitate (see Chap. 219).

ELECTRONIC RESTRAINT DEVICES Stun guns, stun belts, shock batons, Taser, and electric cattle prods (goats) generate high voltages that can be used for self-defense, as weapons, and to control violent persons. The likelihood of electrical injury is minimal with the rare potential for application of electricity to the eye that might result in ocular injury. However, falls or other forceful movements made as a result of the electric current can lead to injury. Some devices shoot wires with fishhook-like barbs on the ends that may need removal from the skin. Although most victims do not sustain demonstrable injury from electromuscular disruptive devices, several case reports have documented death within minutes of their use, presumably from cardiac arrhythmias. Most reported deaths were associated with concomitant drug use (usually phencyclidine or cocaine), trauma as a result of struggling, or pre-existing cardiac disease. Usually the main concern of the physician treating a person who has been shocked with such a nonlethal restraint device will be the issue of why the person was in need of restraint.

TREATMENT OF ELECTRIC INJURY IN PREGNANCY

A number of pregnant women who have received apparently harmless contacts with electric current have later suffered fetal damage or loss.¹⁵ In most cases, the mechanism of fetal injury is uncertain. General recommendations for maternal and fetal monitoring after electrical shock in pregnancy include 1) fetal heart rate and uterine activity monitoring for 4 h in women beyond 20 to 24 weeks' gestation and 2) maternal cardiac and fetal heart rate and uterine monitoring for 24 h if there was loss of consciousness, if there are electrocardiogram (ECG) abnormalities, or if the woman has cardiovascular disease.¹⁵ Fetal ultrasonography is also recommended. That said, there is no proof that monitoring or treatment can influence the fetal outcome in pregnant women following electric injury without mechanical trauma. In addition to these indications for immediate monitoring, it is recommended that ultrasonography or fetal heart Doppler be done 2 weeks after the accident.

Disposition

All patients having contact with over 600 V should be admitted for observation, even if there is no apparent injury. Routine cardiac monitoring is not required unless the initial ECG is abnormal. Patients with

symptoms (chest pain, palpitations, loss of consciousness, confusion, weakness, dyspnea, abdominal pain), signs (weakness, burn with subcutaneous damage, vascular compromise), or ancillary changes (abnormal ECG, elevated creatine kinase or urine myoglobin) suggestive of systemic injury also require admission.

Adults with electrical injury caused by household voltage (110 to 220 V) have negligible risk for delayed arrhythmias.¹⁵ Asymptomatic patients who sustain a household electrical shock can be discharged home if they have a normal ECG on presentation and normal examination findings.

Children with only hand wounds from electrical outlet injuries and no evidence of cardiac or neurologic involvement can be discharged with local wound care. A child with a home situation of equivocal safety or reliability should be considered for admission, although cardiac monitoring is not required for these "social" admissions.

LIGHTNING INJURIES

Raymond M. Fish

EPIDEMIOLOGY

Lightning causes approximately 300 injuries each year in the United States and is the second leading cause of weather-related death, with approximately 100 reported deaths each year.¹ Reported mortality rates vary, from approximately 0.5 per million in the general U.S. population, to as high as 8.8 per million in the rural South African population.²

Lightning injury reporting is biased to the more severe and fatal events, and it is estimated that more unreported lightning injuries occur each year, perhaps up to several thousand cases per year. Approximately 70 to 90 percent of persons struck by lightning survive, but as many as three-quarters of these survivors will have permanent sequelae.^{3,4} Livestock and other animals also suffer deaths and injuries from lightning.

Lightning most often occurs during thunderstorms in association with large cumulonimbus clouds. However, approximately 10 percent of lightning occurs without rain and when the sky is blue.⁵ In addition, lightning can occur during dust storms, sandstorms, snowstorms, nuclear explosions, and in the clouds over volcanic eruptions. The U.S. locations with the highest lightning-strike mortality rates are Arizona, Arkansas, Florida, Mississippi, New Mexico, and Wyoming.¹

A number of lightning injuries are associated with transportation; most commonly when the victim is standing outside near a vehicle. Lightning injuries are also associated with airplanes (both private and commercial) and water sports. Lightning injury from indoor telephone use has been reported. A report from Australia indicated up to 80 such injuries yearly without any reported fatalities.⁶

Even though lightning is electrical energy, lightning injuries differ substantially from high-voltage electrical injuries seen from human-generated sources; different injury patterns, different injury severity, and different emergency treatment (Table 202-1).^{2,7,8}

PATHOPHYSIOLOGY

Lightning is an extremely high-voltage direct current (DC) electrical discharge. Unlike alternating current (AC) injury from human-generated sources, lightning often travels over the surface of the body in a phenomenon called *flashover*, and is less likely to cause internal cardiac injury or muscle necrosis. Wet skin may actually decrease the risk of internal injury, helping the current travel along the outside of the body. Flashover explains how victims may survive exposure to tremendous amounts of electrical current. Lightning occasionally does cause internal injury through blunt force mechanisms.

Lightning emits brief but intense thermal radiation that produces rapid heating and expansion of the surrounding air. This energy is transmitted as a blast or shock wave that can cause tympanic membrane perforation and internal organ contusion (see Chap. 9). The blast associated with lightning can tear clothing, giving the appearance of an assault.⁹ Lightning may inflict thermal injury as moisture on the victim's skin is transformed into steam or through resistance heating of

metal objects on the body or in clothing pockets. Lightning is attracted to metallic objects on the victim and these are sometimes melted. Intense photic injury may damage the retina or produce cataracts.

The nature and severity varies according to the type of lightning strike. A *direct strike* occurs when the victim is struck directly by the lightning discharge, producing the most serious injuries associated with lightning strike. A *side flash* occurs when a nearby object is struck and current then traverses through the air to strike the victim. A side flash may injure multiple victims at once, as when a group huddles close to a structure that is struck. A *contact strike* occurs when lightning strikes an object the victim is holding and current is transferred from the object through the person to the ground. Lightning injuries from indoor telephone use during a lightning storm is an example of contact strike. A *ground current* occurs when lightning hits the ground and current is transferred through the ground to a nearby victim. The electrical voltage and amount of current decreases as the distance between the victim and strike point increases. This ground current can create a stride potential or step voltage between the victim's separated feet. The foot closer to the strike point will experience a higher electrical potential than the foot further away. Therefore, electrical current can enter one foot, travel up that leg, through the torso, and down the other leg and exit the other foot. This can result in isolated neurovascular injury to the legs. Recently, a fifth mechanism, where a weak *upward streamer* does not become connected to the completed lightning channel, was implicated in a fatal lightning injury.¹⁰

Immediate cardiac arrest from lightning strike results from direct current depolarization of the myocardium and sustained asystole. Immediate respiratory arrest after lightning strike is a result of depolarization and paralysis of the medullary respiratory center. Both cardiac and respiratory arrest may be present without evidence of external injury. Although cardiac automaticity may spontaneously return, concomitant respiratory arrest may persist and lead to a secondary hypoxic cardiac stoppage. The duration of apnea, rather than the duration of cardiac arrest, appears to be the critical prognostic factor.

DIAGNOSIS AND MANAGEMENT

Care at the Injury Scene

TRIAGE CONSIDERATIONS Lightning can produce multiple victims because of multiple lightning strikes, stride potentials, and side

TABLE 202-1 Comparison of Lightning and Electrical Injuries

Factor	Lightning	High-Voltage AC	Low-Voltage AC
Current duration	1–3 ms	Generally brief (1–2 s), but may be prolonged	Prolonged
Typical voltage and current range	10 million to 2 billion V; 20,000–200,000 A	600–70,000 V; < 1000 A	<600 V; usually <20–30 A
Current characteristics	Unidirectional (DC)	Alternating (AC)	Alternating (AC)
Current pathway	Skin flashover	Horizontal (hand to hand), vertical (hand to foot)	Horizontal (hand to hand), vertical (hand to foot)
Tissue damage	Superficial, minor	Deep tissue destruction	Sometimes deep tissue destruction
Initial rhythm in cardiac arrest	Asystole	Asystole greater than ventricular fibrillation	Ventricular fibrillation
Renal involvement	Myoglobinuria is uncommon and renal failure is rare	Myoglobinuria and renal failure are common	Myoglobinuria and renal failure occasionally
Fasciotomy and amputation	Rarely necessary	Relatively common	Sometimes necessary
Blunt injury	Explosive effect with shock wave	Being thrown from current source or falls	Tetanic contraction or falls
Immediate cause of death	Prolonged apnea	Apnea	Ventricular fibrillation

Abbreviations: AC = alternating current; DC = direct current.

flashes.² In contrast to multiple-victim events caused by mechanical trauma, persons with lightning injury who appear to be dead (in respiratory arrest, with or without cardiac arrest) should be treated first. Such victims often have little physical damage, and they have a reasonable chance of resuscitation.

EXAMINATION OF THE SCENE AND RESCUER SAFETY Power lines may fall to the ground as a result of high winds or lightning-related damage to power poles or to the lines. Therefore, a person thought to have been hit by lightning may actually have been shocked by the stride potential related to a nearby power line lying on the ground. It is important that rescuers visually survey the area, especially if there is plant growth or darkness that may hide lines on the ground. While patient care should not be delayed unduly, everyone's safety may be improved by a brief survey looking for burns on the ground or nearby objects, melting of metal objects on or near the person, and unusual sounds, smells, or smoke. If a downed power line is found, safety precautions are important (see Chap. 201).

Patient physical findings suggestive of lightning injury may be subtle or nonexistent. Therefore, information about the scene of the accident may be more informative than examination of the patient, similar to other types of electrical injury. Important information about the accident scene includes: history of an electric storm in the area at the time, blast effects on nearby objects, areas of burned vegetation, melted or magnetized metal objects, and melted nylon underclothing.

Emergency Department Diagnosis and Treatment

The usual advanced cardiac and trauma treatment principles apply: assessment and stabilization of airway, breathing, and circulation. Intravenous access, supplemental oxygen, and continuous cardiac monitoring should be instituted. Lightning victims in cardiac arrest have a better prognosis than those in cardiac arrest from coronary artery disease, so aggressive resuscitative efforts are indicated.^{11,12} Hypotension is not an expected finding from lightning injury and warrants an investigation for hemorrhagic blood loss.

A careful secondary examination should be done to detect occult injuries.¹¹ Cutaneous burns may help determine the current path and suggest potential organ injury. Initial ancillary studies include complete blood count, serum electrolytes, creatinine, blood urea nitrogen, glucose, creatine kinase, urinalysis, and electrocardiogram. Imaging studies (plain radiography, ultrasound, or computed tomography) should be obtained for suspected injuries. Other ancillary studies may be indicated according to clinical circumstances.

CARDIAC In the victim with spontaneous circulation, hypertension and tachycardia are common findings, presumably because of sympathetic nervous system activation; specific treatment is not necessary as blood pressure and pulse rate will spontaneously decrease. Cardiac effects reported after lightning injury include global myocardial contractility depression, coronary artery spasm, pericardial effusion, and atrial and ventricular arrhythmias. The electrocardiogram (ECG) may show acute injury with ST-segment elevation and QT-interval prolongation. T-wave inversions may be seen, especially in the presence of neurologic injury. Myocardial infarction after lightning injury is unusual.

NEUROLOGIC Many lightning strike victims are rendered unconscious or have temporary lower extremity paralysis. Seizures may result from the passage of electric current through the brain with no permanent effects, as with electroconvulsive therapy. Or, seizures may be the result of mechanical brain injury or hypoxia. The most lethal neurologic injuries involve heat-induced coagulation of the cerebral cortex, development of epidural or subdural hematoma, or intracerebral hemorrhage. Autonomic dysfunction caused by lightning may produce pupillary dilation or anisocoria not related to brain injury but has no prognostic significance in comatose lightning-strike victims.

Neurologic injury after lightning strike is usually classified as immediate and transient or delayed and permanent. However, some effects may be immediate and permanent. Transient effects that typically resolve in 24 h include loss of consciousness, confusion, amnesia, and extremity paralysis. Delayed and usually progressive disorders include seizures, spinal muscular atrophy, amyotrophic lateral sclerosis, parkinsonian syndromes, progressive cerebellar ataxia, myelopathy with paraplegia or quadriplegia, and chronic pain syndromes.

Lightning can cause intracranial injury directly when passing through the head, as well as by secondary trauma. Therefore, computed tomography (CT) scan is indicated in cases of coma, altered mental status, or persistent headache or confusion.

VASCULAR Vasomotor spasm in an extremity is sometimes seen as a local response. Possible mechanisms include sympathetic nervous stimulation, local arterial spasm, and ischemia of peripheral nerves. Color changes, from white to blue to red, have been reported in extremities after lightning strike; presumably from cycles of vasoconstriction and vasodilatation, with pallor and cyanosis followed by hyperemia. Severe vasoconstriction is thought to be responsible for loss of pulses, mottling of skin, coolness of extremities, loss of sensation, and paralysis due to ischemia of peripheral nerves. As vasoconstriction resolves spontaneously, these signs and symptoms often resolve. Because skeletal muscle injury is rare in lightning strike, compartment syndromes are not usually a consideration and fasciotomy is not indicated. If in doubt, the presence of compartment syndrome and the need for fasciotomy may be confirmed by measuring intracompartmental pressures.

OCULAR Ophthalmic injuries are common in lightning-strike victims, and lightning-induced cataracts are the most frequently observed ocular sequela.¹³ Cataracts caused by thermal injury are generally unilateral, while cataracts induced by lightning are usually bilateral. Cataract formation has been described without evidence of current flow through the head or eyes, as after brief exposure to an electric arc. Perhaps this is a result of damage of the lens by radiant energy. Cataracts may form weeks to years after the lightning injury. Therefore, it is important to document lack of cataracts when a person has been exposed to lightning. Lightning can affect any part of the eye, producing hyphema, vitreous hemorrhage, corneal abrasion, uveitis, retinal detachment or hemorrhage, and optic nerve damage. Discomfort or visual changes suggest a careful examination with follow-up should be done.

AUDITORY Blast effect producing tympanic membrane rupture is relatively common. Victims sustaining lightning strike along a conventional corded telephone are at higher risk for otologic injury, including persistent tinnitus, sensorineural deafness, ataxia, vertigo, and nystagmus.⁶ In patients who are sleeping with an ear or eye on the ground near a lightning strike, temporary deafness or blindness can result.

MUSCULOSKELETAL A variety of skeletal fractures can be seen from the blunt force injury associated with lightning strike. Intense myotonic contractions can produce posterior shoulder dislocations and cervical spine fractures. Rhabdomyolysis after lightning strike is unusual.

SPINAL CORD Spinal fractures can be caused by tetanic muscle contractions, as well as by falls and other secondary trauma. Therefore, spinal immobilization should be maintained during resuscitation, to the extent possible under the circumstances, until spinal stability can be assessed. Plain-film radiography and clinical examination are usually adequate to evaluate these patients. Because spinal fractures often occur at multiple levels in the same patient, the entire vertebral column should be imaged when a fracture is found at one level. For patients with spinal cord motor or sensory findings, but without radiographic fracture, magnetic resonance imaging (MRI) may show spinal cord and ligamentous injuries not seen by plain film and CT studies.

CUTANEOUS There are six main dermatologic manifestations of lightning injury. *Lichtenberg figures* are considered pathognomonic for lightning strike and consist of a superficial feathering or ferning pattern (Figure 202-1). These figures are the result of electron showering over the skin and are not true thermal burns; they disappear in 24 h. *Flash burns* are similar to those found in arc welders, appearing as mild erythema, and may involve the cornea. *Punctate burns* look similar to cigarette burns in that they are usually smaller than 1 cm and are full-thickness burns. *Contact burns* occur when metal close to the skin is heated from the lightning current. *Superficial erythema* and *blistering burns* have been described. *Linear burns*, less than 5 cm wide, occur in areas of skin folds such as the axilla or groin. Contact, so-called entrance and exit, wounds characteristic of electrical injury from human sources are not commonly seen in lightning injuries. Cutaneous wounds are treated with standard wound or burn care; tetanus prophylaxis, cleaning, debridement, and dressing.

PREGNANCY Fetal injury and death have been noted to follow lightning strike with little or no maternal injury, presumably because amniotic fluid serves as a preferential path for current flow. In a review of 11 pregnant women who survived being struck by lightning, there were 5 cases of fetal death in utero, abortion, stillbirth, or neonatal death.¹⁴ Placental abruption has been reported, and uterine/fetal ultrasonography is recommended for pregnant lightning-strike victims.

DISPOSITION

The majority of lightning-strike victims will have moderate to severe injuries that require admission for specialized care. For patients with

minor injuries, admission for observation is recommended because of the potential delayed sequelae. For the rare patient with no neurologic injuries and normal cardiovascular evaluation, a period of monitoring in the emergency department is recommended, and discharge can be considered if no new abnormal symptoms or signs develop. Neurologic and ophthalmologic referral is recommended.

Maternal uterine activity and fetal heart rate monitoring is recommended for 4 h after a lightning strike to a pregnant woman.⁷ That said, there is no evidence that fetal monitoring after lightning strike prevents fetal demise, aside from the associated physical trauma leading to abruptio placentae.

PREVENTION

Prevention of lightning injury through the development of safety guidelines was the subject of a meeting of the Lightning Safety Group in 1998.⁵ The basic principles are to anticipate potential lightning storms (hot humid days), seek safer shelter when lightning is first seen or thunder heard, to use safer shelters (large structures with plumbing or electrical wiring, or fully enclosed metal vehicles), and to avoid dangerous locations (tall structures, open fields, open structures or vehicles, near or in water, contact with conductive materials).

ACKNOWLEDGMENT

The author would like to thank Neil Abarbanelle, MD, who reviewed this paper and gave many helpful suggestions.

CARBON MONOXIDE POISONING Keith W. Van Meter

Carbon monoxide (CO) exposure and toxicity is a potentially lethal disorder with immediate and delayed side effects. Carbon monoxide is produced by incomplete combustion of carbon-containing material. Treatment of CO poisoning remains controversial because of conflicting clinical studies.

EPIDEMIOLOGY

Estimates of CO toxicity and fatality in the United States vary according to the data source and methodology. Analysis of data from the National Center for Health Statistics for calendar years 1994 to 1998 identified an average of 516 deaths each year from unintentional non-fire CO poisoning.¹ These fatality figures do not include intentional poisoning and deaths from fire and smoke inhalation, some of whom undoubtedly died from carbon monoxide toxicity. During roughly the same period, an estimated 11,000 individuals were seen in U.S. emergency departments for nonfatal nonfire CO poisoning. Unintentional CO toxicity and deaths are more common in northern climates and during the winter months.²

Industrial sources of CO from combustion include fossil fuel engine exhaust, gas- or coal-heater emissions, smoke from accidental fires, and fumes from cupolas of steel foundries, pulp paper mills, or formaldehyde-producing plants. Indoor burning of charcoal—particularly in some countries such as Korea, with a tradition of charcoal subfloor home heating—produces a disproportionate level of accidental CO intoxication. Interestingly, industrial sources produce slightly less environmental CO per land area than does the burning of tropical forests.³ Little is known about the impact of low CO atmospheric levels on health. Regular cigarette smoking can produce carboxyhemoglobin (COHb) levels of 5 to 10 percent, and this chronic CO exposure is implicated in the acceleration of atherosclerosis seen in smokers. Truck drivers sitting in the cabs of their vehicles in heavy traffic can attain COHb levels similar to tobacco smokers.

CO toxicity has also been reported as a result of inhaling methyl chloride vapor, which is a component of paint stripping solutions, or from leaking "bubble" electric Christmas tree lights.⁴

PATHOPHYSIOLOGY

CO is an odorless, clear gas (in extremely high concentrations, it has a lavender odor), with a density of 0.97 that of air. In most instances, CO mixes evenly in turbulent air. A small amount of CO is endogenously produced from the metabolism of hemoglobin to bilirubin, and COHb levels rise slightly in hemolytic anemia. CO may function as an endogenous central nervous system (CNS) neurotransmitter.⁵

CO forms a ligand with respiratory pigments and enzymes such as hemoglobin, myoglobin, cytochrome P450, and cytochrome *aa*₃. In fact, cytochrome P450 was named after the *peak* (P) absorption of light at 450 nm when the enzyme is 50 percent saturated with CO. Respiratory enzymes have varying binding affinities for CO compared to oxygen. For example, hemoglobin binds CO 230 to 270 times as tenaciously as oxygen, myoglobin binds CO with 20 to 25 times the affinity for oxygen, and most respiratory enzymes have equal or less affinity for CO than for oxygen. In fact, cytochrome *aa*₃ has only one-ninth the affinity for CO as it does for oxygen.⁶ When CO competes with oxygen for binding sites, it prevents utilization of oxygen by that enzyme or pigment. Thus, COHb will carry less oxygen according to the number of binding sites occupied by CO.

In addition, the binding of CO to hemoglobin also transforms the oxyhemoglobin dissociation curve from a sigmoid shape to an asymptotic shape, increasing the ability of COHb to hold on to oxygen at the remaining available heme moiety sites and reducing the availability of oxygen to metabolically active tissues (Figure 203-1). In CO toxicity, both the reduced oxygen carriage and the transformation of oxyhemoglobin dissociation curve impair tissue oxygen delivery. In effect, high COHb imposes the equivalent of a sudden "chemical" anemia in the patient.

The tolerance of the patient to this sudden chemical anemia may be worse than its hemorrhagic equivalent because of the toxic effects of CO on other respiratory pigments and enzymes. While tissue oxygen delivery is decreased, CO delivery still occurs by the dissolved CO in the circulating plasma. Experimental exchange transfusion in dogs of autologous red blood cells (RBC) exposed extracorporeally to CO be-

FIG. 203-1. COHb "shift to the left" reshaping of the oxyhemoglobin (HbO₂) dissociation curve, (a) Carbon monoxide-affected HbO₂ dissociation curve (asymptotic) and (b) normal HbO₂ dissociation curve (sigmoid).

fore transfusion, resulting in 60 percent COHb, demonstrated no signs of CO toxicity. Thus, while impairment of O₂ delivery by reduction of O₂ carriage is a part of CO toxicity, it may be that delivery of CO contributes more to the toxic effects of CO. In fact, hemoglobin may provide a protective buffer, preferentially binding CO and preventing binding to other respiratory pigments and mitochondrial cytochromes.

CO binding to mitochondrial cytochromes stops electrons—derived from aerobic metabolism of lipids, protein, and carbohydrates—from flowing through the cytochrome chain and halting the generation of adenosine triphosphate (ATP) in oxidative phosphorylation. CO binding to cytochrome *aa*₃ prevents the attachment of O₂, preventing the reduction of O₂ to H₂O. The cessation of cytochrome oxidative phosphorylation causes CO to "wreck the machine," as Haldane so aptly described the role of CO toxicity in aerobic metabolism.

CO binds strongly to intracellular pigments, such as myoglobin. In muscle with high oxygen use, such as the heart, the binding of CO to myoglobin markedly reduces the availability of oxygen for aerobic metabolism. CO poisoning of myocardial myoglobin reduces myocardial contractility, diminishes cardiac output, and further decreases tissue oxygen delivery. CO may likewise bind to neuroglobin in the human central nervous system, impairing neuronal function.⁷

CO toxicity, by imposing ischemic damage, causes white blood cells to become adherent to endothelial surfaces of tissue microvasculature upon reperfusion of ischemic tissue.⁸ Immediately after reperfusion of ischemic CO-poisoned tissue, oxidative free radical products from these adherent white cells accelerate cell membrane lipid peroxidation, a process in part responsible for reperfusion injury.⁹

CLINICAL FEATURES

High-oxygen-extracting organs, such as the brain and the heart, easily become dysfunctional from CO intoxication. Neurologic symptoms and signs include fatigue, malaise, or flulike symptoms; nausea; difficulty in thinking, concentration, and memory; emotional lability; dizziness; paresthesias; weakness; vomiting; lethargy; somnolence; stroke; coma; seizure; and respiratory arrest. Cardiovascular symptoms and signs include chest pain from myocardial ischemia, palpitations from dysrhythmias, mildly to severely mottled skin from diminished circulation, poor capillary refill, hypotension, and cardiac arrest. In a pattern of secondary injury from ischemia imposed by severe CO poisoning, the following clinical injury syndromes may occur: 1) rhabdomyolysis; 2) noncardiogenic pulmonary edema (NCPE); 3) multiorgan failure (MOF); 4) disseminated intravascular coagulation (DIC); 5) dermal blistering or increased dermal susceptibility to dermal pressure wounding; 6) circulatory shock from direct

CO-induced vasodilatation of vasculature and direct CO-induced impairment of myocardial function; 7) acute renal failure; and 8) "interval CO syndrome" of leukoencephalopathy of the centrum ovale (cerebral subcortical white matter) along with ischemic damage to basal ganglia and hippocampus.¹⁰

The symptoms and signs of CO toxicity are exacerbated by circumstances that increase neurologic and myocardial oxygen demand. Patients describe the onset of symptoms while at rest, with a marked increase after physical exertion. One example would be a patient who develops toxicity from using an internal combustion engine in a closed space. Starting to feel ill, the patient may walk or run outside to fresh air, only to collapse as the heart and brain are not able to deliver or utilize oxygen to meet the increased metabolic demands. CO intoxication is more severe in patients who have increased oxygen demands from the comorbidities of trauma, concurrent drug ingestion, burns, myocardial ischemia, cerebrovascular disease, or smoke inhalation.¹¹

DIAGNOSIS

Signs and symptoms of CO injury correlate reasonably well with on-the-scene co-oximetry determination of COHb levels. However, by the time the patient gets to the ED after breathing air and with prehospital oxygen administration, the predictive value of COHb levels falls considerably. A very careful history, coupled with a screening neurologic examination that includes a CO neuropsychometric screening battery (CONSB), is a sensitive but not specific assay for CO intoxication. The CONSB has a good positive predictive value for discerning neurologic dysfunction or injury from CO intoxication.¹² The CONSB should be done with the patient breathing room air to be most sensitive.

Patients with CO exposure and only mild symptoms (no loss of consciousness, no cardiopulmonary symptoms, awake and cooperative) require minimal ancillary testing: a measure of COHb and possibly an electrocardiogram (ECG) to detect silent myocardial ischemia. Patients with moderate to severe exposures should have additional studies done to assess the extent of ischemic injury, including 1) COHb determination; 2) arterial blood gases (ABG), serum electrolytes, and serum lactate to detect metabolic acidosis; 3) complete blood count (CBC) and arterial oxygen content [CaO_2]; 4) an ECG if the patient has chest pain, palpitations, or dysrhythmia on the monitoring lead; 5) serum creatine phosphokinase MB isoenzyme (CK-MB) and troponin levels to detect potential myocardial ischemia; 6) serum CK, serum myoglobin, and urine myoglobin to detect skeletal muscle injury; 7) chest radiograph for patients with dyspnea, with abnormal auscultatory findings, or with multiple trauma; and 8) urine toxicologic screens when concurrent drug ingestion is suspected.

Imaging studies, such as computed tomography (CT) and magnetic resonance imaging (MRI) of the brain are modestly sensitive but non-specific in documenting CNS ischemic injury 6 h after CO exposure.¹³ Diffusion-weighted MRI brain scanning is being investigated for its utility in defining brain injury from CO intoxication. Single-photon emission computed tomography (SPECT) with radiolabeled hexamethylpropyleneamine oxime (HMPAO)-technetium 99m is immediately sensitive but not specific for acute ischemic CNS injury in CO poisoning.¹⁴ Brain HMPAO/SPECT scan has the advantage that the radionuclide may be initially injected as the patient arrives in the ED without interrupting the resuscitation effort. The patient can be scanned later after stabilization, with a lasting "snapshot" of preresuscitation brain metabolism and perfusion. The bulk of HMPAO is taken up by the brain on first pass as it crosses the blood-brain barrier. Accordingly, the HMPAO "locks" into CNS tissue without much redistribution during the successive half-lives of the HMPAO radionuclide. The positron emission tomography (PET) brain scan may be helpful in illustrating CNS ischemic injury, but the scanner is rarely available and hard to obtain for critically ill patients.

SPECIFIC ISSUES

CO intoxication is especially harsh on the very old and very young. Pregnant patients with CO intoxication have no greater risk, but the fetus is at greater risk than the mother for ischemic injury because fetal hemoglobin has greater affinity than adult hemoglobin for CO.¹⁵

CO intoxication is more severe in patients with the comorbidity of multiple trauma, thermal or chemical burns, smoke inhalation, cerebral ischemia, or myocardial ischemia. CO intoxication coupled with drug intoxicants increases the risk of failure at self-evacuation from a toxic atmosphere. Further, concurrent inhalation of inert gas (natural gas), carbon dioxide, or chemical asphyxiants [nitrous oxide (NO), hydrogen sulfide (H_2S), hydrogen cyanide (HCN)] can augment ischemic insult in a CO patient. Also performing the CONSB assessment of the patient while the patient is breathing supplemental O_2 has led to false-negative normal exam results. If the CONSB is normal, the patient should have repeat evaluation on room air.

TREATMENT

The ABCs (airway, breathing, and circulation) of resuscitation apply to the seriously ill or injured victim with presumed CO intoxication. Normobaric oxygen (NBO) therapy should be administered as soon as possible with 100 percent fraction of inspired oxygen (Fio_2) by mask (nonbreathing mask with reservoir). Patients who require ventilatory assistance should have bag-valve-mask ventilation with 100 percent oxygen until spontaneous ventilation recovery or endotracheal intubation can be performed in the field or the ED. **Pulse oximetry cannot be used to access adequacy of arterial oxygenation because the device confuses COHb for oxyhemoglobin and gives spuriously high values for percent of oxygen saturation.**¹⁶

Once the patient reaches the ED, decisions about further treatment are guided by the clinical evaluation (Table 203-1). Patients with only mild symptoms (nausea, headache, weakness, or flulike malaise) should receive 100 percent NBO for a period of about 4 h, with periodic reassessment. The ability of oxygen treatment to eliminate CO from the body has often been estimated using the half-life of COHb with different treatment regimens. The half-life of COHb is approximately 3 to 4 h while breathing room air, approximately 60 min by breathing 100 percent NBO, and 15 to 23 min with 100 percent hyperbaric oxygen (HBO) at 2.5 to 2.8 atmospheres of pressure [2.5 to 2.8 atmosphere absolute (ATA)]. Failure of mild symptoms to resolve after 4 h of NBO administration, if no other likely cause for the symptoms can be found, should lower the emergency clinician's threshold for the use of HBO therapy.

Major symptoms (any history of loss of consciousness, profound dip in blood pressure, amnesia, or myocardial ischemia) have tradi-

TABLE 203-1 Indications for Hyperbaric Oxygen Treatment in Acute Carbon Monoxide Poisoning

Definite Indication	Relative Indication
Altered mental status and/or abnormal neurologic examination (if patient has normal evaluation while on supplemental oxygen, temporarily take patient off oxygen and repeat evaluation)	Persisting neurologic symptoms including headache and dizziness after 4 h of 100% normobaric oxygen
History of loss of consciousness or near-syncope	Persisting acidosis
History of seizure	Concurrent thermal or chemical burns
Coma	Pregnancy with history of carbon monoxide exposure regardless of COHb level
History of hypotension during or shortly after exposure	
Myocardial ischemia	
History of prolonged exposure	
Pregnancy with COHb >15%	

tionally been an indication for initial HBO treatment. While dramatic improvement in symptoms and signs is generally seen, there is continued debate as to whether HBO is better than NBO with regard to short- and long-term outcomes.¹⁷ Prospective, randomized studies comparing HBO and NBO have yielded conflicting results, possibly because of different entry criteria, treatment regimen, the intensity of the outcome measure, and the duration of follow-up.¹⁷⁻¹⁸ There appears to be some benefit to HBO in reducing neurophysiologic sequelae, but that difference may be detectable only with specific testing and the benefit may be less apparent after 12 months of follow-up.¹⁸

Two recent controlled, prospective, randomized human trials yielded different results. Scheinkestel and colleagues found little difference between HBO and NBO in most neuropsychological tests at the completion of treatment, but noted that no patients in the NBO group developed **delayed neurologic sequelae, versus 4.8 percent in the HBO group. But the statistical significance of this result is questionable.** Scheinkestel used a hyperbaric regimen of 3 to 6 treatments at 2.8 ATA for 60 min (total chamber time of 100 min) over 3 to 6 days and the unconventional approach of placing all patients on continuous supplemental oxygen at 14 L/min by nonocclusive facemask for the duration of treatment (mean of 3 days).¹⁹ Weaver and colleagues demonstrated marked reduction in neurologic sequelae at 6 weeks with hyperbaric treatment (46 percent in the NBO group versus 25 percent in the HBO group; absolute reduction 21 percent, 95% CI 6.2 to 35.9%).²⁰ This difference was sustained to a lesser degree at a 12-month follow-up. Weaver and colleagues used a protocol of three hyperbaric treatments 6 to 12 h apart, initiated within 24 h after the end of CO exposure, and without supplemental oxygen after the first treatment. Hyperbaric treatment duration and pressures were 1) first treatment at 3.0 ATA for 60 min followed by 2.0 ATA for 60 min, with total chamber time of 150 min, and 2) second and third treatments at 2.0 ATA for 100 min, with total chamber time of 120 min.

While the patient is being prepared for referral to a hyperbaric chamber, the patient should be maintained on 100 percent NBO. Traditional recommendations for HBO treatment for CO poisoning have sometimes stressed the use of COHb levels. **This approach is no longer advocated because of the poor correlation between clinical symptoms, morbidity, mortality, and ED COHb levels.** In addition, there is no evidence that HBO treatment based on COHb level alone is beneficial. Patients with mild to moderate symptoms improve dramatically after one HBO treatment, often becoming asymptomatic, and a common practice is to provide only one treatment. The benefit of a single treatment is unproven, retrospective analysis suggests that more than two treatments provided better outcomes than a single treatment, and the only prospective study finding benefit to HBO used three treatments. Thus, a single HBO treatment cannot be recommended.

In addition to enhancing the elimination of CO from the body, HBO treatment has several theoretical advantages over NBO treatment. HBO improves oxygen delivery to ischemic tissue and CO elimination from hemoglobin. HBO, not NBO, lessens CO-induced reperfusion injury by truncating lipid peroxidation and lessening leukocyte endothelial adherence in microvasculature.^{8,9}

Complications of HBO treatment include a very low incidence of oxygen-induced seizures (approximately 1 per 1000 patients) and ear and sinus barotrauma. While possible, pulmonary barotrauma and vascular gas embolism are extraordinarily rare with clinical HBO treatment. Pregnancy is not a contraindication to HBO treatment; the only absolute contraindication to HBO treatment is an untreated pneumothorax.

The added mortality or morbidity incurred by transport to an HBO treatment facility has been established to occur in less than 5 percent of cases so handled. Both monoplace and multiplace hyperbaric chambers have critical care capability for ventilator support of endotracheally intubated patients, blood pressure monitoring, central venous manometry, and cardiac monitoring. U.S. emergency physicians can find the location of the nearest hyperbaric chamber by calling the

Divers Alert Network (DAN), Duke University, Durham, NC, at 1-919-684-8111.

DISPOSITION

CO-intoxicated patients with mild symptoms (headache, nausea, flu-like symptoms, weakness, and dizziness) that remit after 4 h of 100 percent NBO may be discharged with the proviso that they return for evaluation if symptoms return. Patients should be reevaluated in 24 to 48 h. If patients with minor symptoms do not improve after 4 h of NBO therapy, they should be referred for HBO treatment. CO-intoxicated patients with the history of loss of consciousness, amnesia, myocardial ischemia, or seizure should be admitted even if symptoms improve with initial HBO treatment. CO-intoxicated pregnant patients at greater than 20 weeks' gestation should be admitted for fetal monitoring.

A subset of CO patients has "interval CO injury" or delayed development of neurologic symptomatology from 2 days to 1 month after initial improvement. Discharge instructions should include this information. Amelioration of neurologic residual injury with delayed treatment has occurred up to at least 20 days postinjury with HBO treatment. A short series of daily "tailing" low-dose HBO treatments has been anecdotally used to resolve or ameliorate lingering residual neurologic injury.

MUSHROOM POISONING Anne F. Brayer Sandra M. Schneider

Mushrooms are a common toxic exposure, with more than 8400 mushroom exposures reported to poison centers in 2001.¹ More than 85 percent of these ingestions were unintentional, with nearly 70 percent occurring in children younger than age 6 years. Most reported ingestions result in little or no toxicity.^{2,3}

Depending on the type of mushroom, adverse effects from ingestion range from mild gastrointestinal (GI) symptoms to major cytotoxic effects resulting in organ failure and death. Toxicity may also vary based on the amount ingested, the age of the mushroom, the season, the geographic location, and the way in which the mushroom has been prepared prior to ingestion. Individuals also vary in their response to any given mushroom ingestion, so that one person may show significant effects while others may be asymptomatic ingesting the same mushroom (Table 204-1).

Mushroom toxicity is divided into early toxicity (within 2 h after ingestion) and delayed toxicity (6 h to 20 days). In general, if toxicity begins within 2 h of ingestion of a mushroom, the clinical course will most

likely be benign. If symptoms begin 6 h or later after ingestion, the clinical course will likely be more serious and potentially fatal. Nearly all fatalities in the United States occur from the ingestion of the *Amanita* species (*Amanita phalloides*, *Amanita virosa*, said *Amanita verna*).

Mushroom poisoning occurs among four main groups of individuals: young children who ingest mushrooms inadvertently, wild-mushroom foragers, individuals attempting suicide or homicide, and individuals looking for a hallucinatory "high." Identification of the mushroom ingested may be difficult and time-consuming. Very often, foragers will mix different species of mushrooms together, so it is not always clear that the species being identified is the same one that was ingested. In all cases, treatment should be directed by a patient's symptoms rather than by attempts at mushroom identification.

However, identification of the *Amanita* species may be helpful, but difficult, as there are many *Amanita* mushrooms that are nontoxic. *Amanita* species generally have warts on the cap (remnants of the membrane covering the emerging mushroom), which often give it a spotted appearance. The gills are "free," ending before the stem begins. The stem characteristically has a membrane ring around it and widens as it enters the soil. In most cases, the stem of the mushroom is contained in a cup or volva, which may be underground.

EARLY ONSET GASTROINTESTINAL SYMPTOMS

Pathophysiology

The most commonly ingested toxic mushrooms are those that cause GI irritation. These mushrooms can be of many types. In North America, *Chlorophyllum molybdites* is particularly common and is sometimes mistaken for an *Amanita*. Many of the so-called little brown mushrooms found commonly in lawns, and often accidentally ingested by children, are in this category. The actual toxin varies with the species of mushroom, but most toxins are poorly described.

TABLE 204-1 Mushrooms: Symptoms, Toxicity, and Treatment

Symptoms	Mushrooms	Toxicity	Treatment
Gastrointestinal symptoms			
Onset <2 h	<i>Chlorophyllum molybdites</i> <i>Omphalotus illudens</i> <i>Cantharellus cibarius</i> <i>Amanita caesarea</i> <i>Gyromitra esculenta</i> :	Nausea, vomiting, diarrhea (occasionally bloody)	IV hydration Antiemetics
Onset 6-24 h	fall season <i>Amanita phalloides</i> , <i>Amanita verna</i> , and <i>Amanita virosa</i> : spring season	Initial: nausea, vomiting, diarrhea Day 2: rise in AST, ALT Day 3: hepatic failure	IV hydration, glucose, monitor AST, ALT, PT, PTT, bilirubin, BUN, creatinine For <i>Amanita</i> : activated charcoal Penicillin G 300,000-1,000,000 units/kg per d Silymarin 20-40 mg/kg per d Consider cimetidine 4-10 g/d Hyperbaric oxygen
Muscarinic syndrome	<i>Inocybe</i> <i>Clitocybe</i>	SLUDGE	Supportive atropine 0.01 mg/kg repeated as needed for severe secretions
CNS excitement	<i>Amanita muscaria</i> <i>Amanita pantherina</i>	Intoxication, dizziness, ataxia, visual disturbances, seizures, tachycardia, hypertension, warm dry skin, dry mouth, mydriasis (anticholinergic effects)	Supportive sedation with phenobarbital 30 mg IV or diazepam 2-5 mg IV as needed for adults
Hallucinations	<i>Psilocybe</i> <i>Gymnopilus</i>	Visual hallucinations, ataxia	Supportive sedation with phenobarbital 0.5 mg/kg or, for adults 30-60 mg IV, or diazepam 0.1 mg/kg or 5 mg IV for adults
Disulfiram	<i>Coprinus</i>	Headache, flushing, tachycardia, hyperventilation, shortness of breath, palpitations	Supportive IV hydration (3-blockers for supraventricular tachycardia Norepinephrine for refractory hypotension)

Abbreviations: ALT = alanine aminotransferase; AST = aspartate aminotransferase; BUN = blood urea nitrogen; CNS = central nervous system; PT = prothrombin time; PTT = partial thromboplastin time; SLUDGE syndrome = salivation, lacrimation, urination, defecation, gastrointestinal hypermotility, and emesis

Clinical Features

Typically, patients will present with acute onset of vomiting and diarrhea less than 2 h after ingesting the mushroom. There may be intestinal cramping, chills, headaches, and myalgias. The diarrhea is usually watery, but occasionally may be bloody, with fecal leukocytes. Most commonly, symptoms are mild and self-limited. Infrequently, the vomiting and diarrhea may lead to significant dehydration and electrolyte imbalance. The patient frequently offers the history of ingestion, but in cases where it is not, the presentation may be confused with acute gastroenteritis or acute food poisoning.

Treatment

General treatment for toxic mushroom ingestion includes GI decontamination. Activated charcoal 0.5 to 1.0 g/kg PO or via nasogastric tube is indicated for all ingestions unless toxic species can be excluded. Syrup of ipecac use may confuse the clinical picture, and is of little benefit. Treatment for ingestion of GI irritants is largely supportive, including IV fluid and electrolyte replacement when necessary. Judicious use of antiemetics is probably justified, but antidiarrheal agents are best withheld, because they may prolong the exposure to the toxin.

In most cases, the illness is self-limited, with symptoms resolving within 12 to 24 h. Rarely, symptoms may persist and hospitalization may be indicated for fluid and electrolyte replacement.

EARLY ONSET NEUROLOGIC SYMPTOMS

Pathophysiology

There are several classes of mushrooms that can cause neurologic symptoms. These include the hallucinogenic mushrooms ("magic" mushrooms) that are intentionally ingested for their mind-altering qualities. These mushrooms contain psilocybin or psilocin toxins, which are neuroactive chemicals similar to lysergic acid diethylamide (LSD). They act on serotonin-dependent neurons in the central nervous system (CNS), causing effects similar to those of LSD. Mushrooms from the *Psilocybe* genus, which are the most commonly ingested in this class, are small brown or gold mushrooms that commonly grow on dung in warmer climates and often turn a greenish blue when bruised or cut. They may also be cultivated at home from purchased spores. Nontoxic mushrooms may also be laced with phencyclidine (PCP) or LSD and sold as hallucinogenic mushrooms. Mushrooms containing the isoxazole derivatives, ibotenic acid and muscimol, also possess neurologic effects, which are thought to be mediated by 7-aminobutyric acid (GABA) and anticholinergic activity. *Amanita muscaria* is an easily identified member of this group. It has an orange or red cap with white warts (remnants of the universal veil present in young specimens), as well as a ring (annulus) and cup (volva) on the stem. *Amanita pantherina*, another member of the group, is 5 to 14 cm in length and diameter, with a white to brown cap, and with the ring and cup on the stem. Both specimens grow under trees in woodlands throughout North America.

Clinical Features

Ingestion of hallucinogenic mushrooms usually leads to development of symptoms within 2 h. Euphoric sensation, a heightened imagination, a loss of time sensation, and visual distortions or hallucinations are common. There may be tachycardia and hypertension. Fever and seizures have rarely been reported. Symptoms typically last 4 to 6 h. There are infrequent reports of patients suffering from flashbacks for up to 4 months after ingestion.

Patients ingesting isoxazole mushrooms usually present with symptoms within 30 min of ingestion. Dizziness, mild intoxication,

ataxia, muscular jerking, and difficulty with size, time, and place perceptions are common. Uncommonly, there may be anticholinergic symptoms, including tachycardia, hypertension, warm, dry skin and mucous membranes, and mydriasis. Seizures have been reported in children. Symptoms are typically self-limited, resolving within 3 to 4 h after ingestion.

Treatment

Treatment for ingestion of hallucinogenic mushrooms is largely supportive. Placing the patient in a darkened quiet room, devoid of visual stimuli, and providing reassurance are often sufficient. If sedation is required, benzodiazepines such as diazepam 0.1 mg/kg for children and 5 mg for adults, administered intravenously are preferred to phenothiazine derivatives because the latter can lower seizure threshold. The use of anticholinergic agents should be avoided, as they may aggravate the delirium.

Treatment of symptomatic ingestion of isoxazole containing mushrooms begins with GI decontamination. Syrup of ipecac may be appropriate if it can be administered within 30 to 60 min of ingestion, but caution is advised because of the potential for CNS depression and seizures. Activated charcoal administration is advised in most cases. In patients with significant vomiting and diarrhea, fluid and electrolyte replacement may be necessary. Patients who are agitated should be appropriately restrained. Sedation may be provided as necessary with benzodiazepines (diazepam or lorazepam) or phenobarbital. Seizures have been successfully treated with benzodiazepines.

For patients with severe anticholinergic symptoms, treatment with physostigmine may be considered. Physostigmine has been known to produce bradycardia, hypotension, and seizures, so administration should be reserved for severely symptomatic patients. The dosage is 1 to 2 mg intravenous slowly in adults, and 0.5 mg in children. Patients should have continuous cardiorespiratory and blood pressure monitoring during administration.

EARLY ONSET MUSCARINIC SYMPTOMS

Pathophysiology

Mushrooms containing muscarine cause neurologic symptoms and muscarinic or cholinergic effects. The symptoms are characterized by the SLUDGE syndrome (salivation, lacrimation, urination, defecation, GI hypermotility, and emesis). Mushrooms of the *Inocybe* and *Clitocybe* genus are common causes of muscarinic poisoning. The *Inocybe* mushrooms are small brown mushrooms with conical caps, typically found under hardwoods and conifers. The *Clitocybe* mushrooms are usually found individually on lawns and in parks, and are white to gray, with a cup-shaped cap. *Amanita muscaria*, despite its name, contains far less muscarine than these other families, and only rarely causes cholinergic poisoning symptoms.

Clinical Features

In addition to the SLUDGE syndrome, patients with muscarine ingestions can present with diaphoresis, muscle fasciculations, miosis, bradycardia, and bronchorrhea. Symptoms typically present within 30 min of ingestion and spontaneously resolve in 4 to 12 h.

Treatment

In most cases, symptoms are mild and self-limited. Supportive care is often sufficient. Because emesis is a common presenting symptom, activated charcoal administration is often difficult. Patients with severe vomiting may require intravenous fluid and electrolyte replacement.

Atropine is an antidote for muscarinic symptoms and can be administered in severe cases. It can be effective in treating bradycardia

and hypotension unresponsive to intravenous fluids. Atropine is helpful in the treatment of diaphoresis, increased oral secretions, and bronchorrhea. It may also help reduce GI cramping, emesis, and diarrhea. The dose is 0.5 to 1.0 mg for adults and 0.01 mg/kg for children, administered intravenously. The dose can be repeated as necessary to control bronchorrhea, bradycardia, or hypotension. Large doses may be necessary to treat severe toxicity. Patients should be carefully monitored during administration. Oxygen and inhaled β -agonists (e.g., albuterol) are recommended for the treatment of patients with increased pulmonary secretions and bronchospasm.

DELAYED GASTROINTESTINAL SYMPTOMS

Pathophysiology

Two different mushrooms, *Gyromitra* and *Amanita*, cause significant toxicity, which characteristically present several hours after ingestion. *Gyromitra esculenta* (the false morel) grows primarily in the spring in North America and is also found in several European countries. It has a brown convoluted top resembling a brain and is often mistaken for the tasty morel mushroom. Gyromitrin (JV-methyl-iV-formylhydrazine) is a volatile heat-labile toxin and primarily responsible for symptoms. Parboiling the mushroom can partially eliminate the toxin. Gyromitrin is hydrolyzed in the stomach to form JV-methyl-iV-formylhydrazine (MFH) and iV-methylhydrazine (MH). MH is chemically identical to rocket fuel, and workers exposed to MH develop CNS toxicity. MH binds to pyridoxine and interferes with enzymes that require pyridoxine as a cofactor. GABA is lowered in the CNS, which may be a possible etiology for the seizures. MFH is converted into a free radical in the liver and causes local hepatic necrosis by blocking the activity of the P450 system, glutathione, and other hepatic enzyme systems.⁴ These two chemicals explain the CNS and hepatic dysfunction characteristic of gyromitrin toxicity. The etiology of the initial GI symptoms remains obscure.

Amanita phalloides, *Amanita virosa*, and *Amanita verna* commonly occur in the Northern Hemisphere and are particularly common in North Central Europe. Mushrooms of this species are found throughout the West Coast, Midwest, and in parts of the Northeast of the United States. Immigrants may mistake these mushrooms for edible varieties common in Eastern Asia. Mushrooms of the *Amanita* species are responsible for 95 percent of deaths associated with mushrooms. Toxic ingestions in North America occur most commonly in the autumn.

Amanita phalloides contains several amatoxins and phallotoxins. Phallotoxins are bicyclic peptides that inactivate F-actin. Although this action has been of interest to basic scientists, phallotoxins do not appear to be active in human toxicity. Amatoxins are bicyclic octapeptides that are rapidly absorbed through the intestinal mucosa. They are carried to the liver, and undergo enterohepatic circulation, which leads to prolonged toxin exposure after ingestion. Kinetic studies in humans show that a-amanitin is cleared from the plasma within 48 h.⁵ Concentrations in the plasma are quite small; amatoxins are not protein bound, but actively transported into hepatocytes, where they bind to RNA polymerase II and inhibit the formation of messenger RNA. Some literature regarding studies with animals suggests that free radical formation may also be involved in toxicity.⁶ Pathologic evidence of nuclear fragmentation and condensation of chromatin occur within 24 h after ingestion. Amanitin has the greatest effect on cells that undergo rapid protein synthesis and turnover, including cells of the GI mucosa, hepatocytes, and renal tubular epithelium.⁷

The diagnosis of gyromitrin toxicity is generally assumed from the clinical features and the identification of the mushroom, either by the patient or from samples. Identification of *Amanita* species generally requires a trained mycologist. The Meixner colorimetric test is used to look for the presence of amatoxin. Although it is sensitive, it is not

very specific, as other nontoxic mushrooms may test positive. Thin-layer chromatography, high-performance liquid chromatography, and radioimmunoassay have been developed to detect amatoxin. Amatoxin can be detected in plasma, urine, GI contents, and feces. However, its presence merely confirms amatoxin poisoning. Levels do not appear to correlate with clinical severity, and many patients do not have amatoxin detected, presumably because of rapid clearance.

Clinical Features

The distinct characteristic of these mushrooms is the onset of intense GI symptoms (nausea, vomiting, and diarrhea) 6 to 24 h after ingestion. In cases of *Amanita* species ingestion, the later the onset of the GI symptoms, the milder is the disease. After resolution of the initial GI symptoms, patients may develop hepatic injury.

Patients who ingest a gyromitrin-containing mushroom typically have a delayed onset of GI symptoms, which appear 6 to 8 h after ingestion. Initial GI symptoms are accompanied by neurologic symptoms, including dizziness and headache. In a mild ingestion, patients will have neurologic symptoms for several days and recover without difficulty. In severe cases, however, hepatic failure becomes symptomatic on day 3 and may result in death by as soon as day 7. Hypovolemia is common in the first phase of toxicity. Hypoglycemia occurs during the GI phase and again in the acute hepatic failure phase. Seizures, lack of coordination, and muscle cramps may occur.

Patients who ingest amatoxin-containing mushrooms also have delayed onset of GI symptoms (6 to 24 h). The gastroenteritis is intense, often requiring fluid and electrolyte replacement. Hypovolemia and hypoglycemia are quite common during the early GI phase. The gastroenteritis generally subsides after 12 h, and patients enter a second phase, where they often are asymptomatic despite ongoing liver damage. Hepatic failure becomes symptomatic on day 3 or 4, and death may follow as soon as day 7. Patients rapidly develop jaundice and right-upper-quadrant pain, and may develop a decreased level of consciousness, an elevated ammonia level, and cerebral edema. Liver enzymes, bilirubin, and prothrombin time rapidly become abnormal. Renal failure occurs either as a direct result of the toxin or as part of the hepatorenal syndrome.

In both toxicities, serum transaminases begin to increase 36 to 72 h after ingestion. Levels may be quite elevated. Prothrombin time may be elevated and unresponsive to vitamin K or fresh frozen plasma replacement. Amylase and lipase elevation suggests pancreatic damage, although symptomatic pancreatitis is rare. Abnormal laboratory findings in amatoxin poisoning include a decrease in neutrophils, lymphocytes, and platelets, and abnormal thyroid function. Hypophosphatemia (primarily noted in children), hypocalcemia, and elevated insulin levels occur. None of these laboratory abnormalities correlate with clinical disease, and their cause is unknown.

Pathologic changes are noted in both gyromitrin and amatoxin toxicity. Patients who ingest gyromitrin show diffuse hepatocellular damage and interstitial nephritis. Patients who ingest amatoxins show fatty degeneration of the liver, with intranuclear collection of lipids and extensive hepatic necrosis. Electron microscopy shows vacuolization of the mitochondria and clumping of the chromatin in the nucleoli. There are extensive lipid peroxidation changes in both the nucleus and the cytoplasm.

Toxic mushroom exposure during pregnancy has been reported.⁸ In one series, a slightly lower birth weight was noted, as compared with normal controls. Most infants appeared to be healthy and developmentally normal, in keeping with the findings that amatoxins do not cross the placental barrier.⁹

The mortality rate from *Gyromitra* ingestion is estimated at 15 to 35 percent. Although historically amatoxin hepatic failure had a mortality rate as high as 50 percent, more recently mortality has been reduced to 10 to 15 percent, based on improved care for hepatic failure.

Patients who survive severe hepatic failure from amatoxin may develop signs of chronic active hepatitis with persistent elevation in liver transaminases, development of antismooth muscle antibodies, and cryoglobulins; the long-term consequences are unclear. No prolonged effects from gyromitrin toxicity have been reported.

Treatment

Most patients present with initial GI symptoms—severe vomiting and diarrhea. If a patient presents within a few hours of ingestion, gastric decontamination is indicated. Repeated doses of charcoal may be effective, particularly in the presence of amatoxin (as it undergoes enterohepatic circulation), at least for the first 24 h, but no clinical studies show the efficacy of charcoal for gyromitrin or amatoxin. Fluid and electrolyte replacement is mandatory. Glucose should be monitored and replaced, if necessary. **Hypoglycemia is one of the most common causes of death in early mushroom toxicity.**

All patients who have ingested amatoxin- or gyromitrin-containing mushrooms should be closely monitored for 48 h for the development of hepatic failure. Liver enzymes and prothrombin time should be monitored several times a day. Patients should be treated with a low-protein diet and receive standard supportive therapy for hepatic failure. Fresh-frozen plasma and vitamin K can be used for the treatment of prolonged prothrombin time; in many cases, however, coagulopathy does not respond to treatment.

Patients who develop hepatic failure should be monitored closely and, in severe cases, preparations made for liver transplantation. Although no firm criteria exist, progressive coagulopathy and encephalopathy, in spite of maximal medical therapy, are frequently listed indications for emergency liver transplantation.¹⁰ Many patients have met this criteria and survived without transplantation, and many patients have died without achieving these "target" values. Liver transplantation, however, does provide the only option for patients in fulminant hepatic failure and has been quite successful. Auxiliary liver transplantation has also been used. In this case, a portion of the damaged liver is removed, and a temporary transplant provided, allowing time for the native liver to regenerate.¹¹

Gyromitrin-Specific Treatment

The neurologic symptoms associated with gyromitrin are successfully treated with high-dose pyridoxine. *Pyridoxine* provides the cofactor required for the regeneration of GABA. High doses of pyridoxine, 25 mg/kg up to a maximum of 25 g/d, are recommended, but doses of pyridoxine in excess of 40 g are associated with severe peripheral neuropathy.¹² Pyridoxine does not affect the development or course of hepatic failure, and there is no specific therapy for gyromitrin-induced hepatic failure.

Amatoxin-Specific Treatment

Historically, there have been many anecdotal and largely ineffective treatments used to counteract this deadly toxin. Because 80 percent of the toxin is eliminated in the urine, forced diuresis may have some theoretical basis, but no clinical trials have shown efficacy. Charcoal hemoperfusion or hemodialysis may remove amatoxin, but studies have questioned their benefit.¹³ Attempts to interrupt enterohepatic circulation have also been tried but are of limited usefulness. Plasmapheresis has been reported to be useful, in combination with other detoxification techniques.¹⁴

Thioctic acid, which has been used for many years in Europe, is a known free radical scavenger and may be effective in the treatment of acute hepatic failure of undifferentiated cause. Thioctic acid and glutathione appear to protect against microsomal lipid peroxidation and therefore may be of theoretical use in amatoxin poisoning. Animal and human studies, however, have not shown thioctic acid to be effective.

High doses of penicillin have been advocated for amatoxin poisoning because penicillin blocks the uptake of amatoxin into the liver by its shared active transport system. In addition, penicillin increases renal excretion of the toxin. Other antibiotics, such as rifampin and cephalosporins, have a similar effect in animal studies. Huge doses of penicillin G 300,000 to 1,000,000 units/kg per day, are required to decrease toxicity in animal studies. Such doses are associated with seizures, and if used, patients should be appropriately monitored. If amatoxin is suspected, penicillin should be started very soon after ingestion. Penicillin-allergic patients either should not be treated with penicillin or should undergo desensitization. Unfortunately, a retrospective review of amatoxin poisoning found little efficacy to penicillin therapy.¹⁵

Silymarin (silybinin), which has been used successfully in Europe to treat amatoxin ingestion, acts as a free radical scavenger and may interrupt the enterohepatic circulation of amatoxin when given orally. It is not available in the United States, but a recent study in Europe showed success in patients with amatoxin poisoning.¹⁶

There have been animal studies and isolated human case reports of other therapies for amatoxin poisoning. High-dose *cimetidine* 10 g/d, is effective in animals and recently was used successfully in humans.⁶ Vitamin C, zinc, and thiol compounds have also been useful in animal models.

DELAYED-ONSET RENAL FAILURE

Pathophysiology

Orellanine and ortinarin A and B are nephrotoxic compounds found in species of *Cortinarius* (*C. orellanus*, *C. speciosissimus*, and *C. gentilis*). These toxins are heat stable, and their mechanisms of action are unknown. Mushrooms of this species are found primarily in Europe and do not represent a significant problem in the United States. A similar delayed onset of renal toxicity has been reported following the ingestion of *Amanita smithiana*.¹⁷ This mushroom is commonly mistaken for pine mushrooms and grows commonly in the Pacific Northwest. Nephrotoxins in this mushroom are norleucine (amino-hexadrenoic acid) and chlorocrotylglycine.

Clinical Features

Patients who ingest mushrooms containing nephrotoxins often initially present with gastrointestinal symptoms including nausea, vomiting and nonbloody diarrhea. Symptoms begin several hours after ingestion, and may persist for 3 days. Occasionally, paresthesias, abnormal taste, and cognitive dysfunction are reported. Symptoms of renal failure, including lumbar and flank pain, oliguria, or more rarely polyuria begin between 3 and 20 days following ingestion. There is some evidence to suggest that patients who ingest *Amanita smithiana* may develop renal failure earlier. Many patients who ingest these mushrooms never go on to develop renal dysfunction, suggesting host variability. Supportive hemodialysis may be required in as many as 30 to 50 percent of patients, but 50 percent of patients will have spontaneous return of normal renal function.

Treatment

There is no specific treatment for patients who develop renal failure from *Cortinarius* or *Amanita smithiana*. Urine output and electrolyte, calcium, magnesium, blood urea nitrogen, and creatinine levels should be monitored. Hemodialysis support is indicated for refractory hyperkalemia, refractory acidosis, uremic symptoms, or severe renal dysfunction. As spontaneous improvement is reported, renal transplant should be withheld for several months to monitor patient response. Renal transplant has been used in several patients with good success.¹⁸

DELAYED-ONSET DISULFIRAM REACTION

Pathophysiology

Perhaps the most interesting, but clinically least important, is a mushroom toxin contained in the *Coprinus* genus. This mushroom, which is very common in North America, is known as the "inky-cap" or "shaggy mane." It is a tall, white, thin mushroom with a shaggy cap. As the mushroom ages, the cap liquefies and blackens, and black liquid drips from the necrosing cap. The mushroom contains coprine, which is chemically related to disulfiram. Coprine causes inhibition of alcohol dehydrogenase within 2 h of ingestion, and activity may last up to 72 h. If alcohol is consumed during this "sensitive" period, patients will develop a typical disulfiram reaction. Mushrooms ingested at the same time as alcohol produce no toxicity.

Clinical Features

Because of the delay between mushroom consumption and alcohol consumption, few patients will link their symptoms to the ingestion of a mushroom. Patients present with facial flushing, diaphoresis, headache, tachycardia, nausea, and vomiting. Most symptoms are mild.

Treatment

Because alcohol is readily absorbed from the GI tract, GI decontamination has no role. Likewise, charcoal would not be expected to have great benefit. Patients occasionally become hypotensive and respond to intravenous fluids or, in refractory cases, norepinephrine. Patients should be educated about the link between the alcohol and mushroom ingestion.

POISONOUS PLANTS

Mark A. Hostetler
Sandra M. Schneider

Poisonous and injurious plants number in the hundreds and have a wide variety of toxicities. Rather than attempting a comprehensive listing, this chapter focuses on the most important plant-related encounters clinically relevant to emergency medicine, with descriptions of the most severely poisonous and commonly encountered plants (Tables 205-1 and 205-2), and those most frequently encountered during the holiday season.^{1,2} Individual plants are discussed in terms of their pathophysiology, clinical features (toxidromes), and treatment.³

EPIDEMIOLOGY

According to statistics gathered by the American Association of Poison Control Centers (AAPCC), plants are the fourth most common reason for poison center notification and account for 5 to 10 percent of all calls received.^{1,3} This high rank is a reflection of their wide availability rather than any unusually high level of innate toxicity. Children younger than 6 years of age account for 70 to 80 percent of all plant-related exposures, the vast majority of which (96 percent) are unintentional.⁴ The most common plant-related call received by a poison control center is for completely nontoxic plants (21 percent) and, on average, fewer than 10 percent of patients require treatment in a health care facility. Dermatitis and gastrointestinal irritation are most common reported sequelae of plant toxicity and occur in approximately 20 percent of patients, but contrary to its emphasis in the literature, vomiting is not a common manifestation of plant ingestions.⁵ Moderate effects of a more systemic nature occur in 1 percent of patients. Severe effects associated with life-threatening or disabling injuries are extremely uncommon and occur in only 0.04 percent of patients. Death as a consequence of plant-related exposures is rare, and occurs at a rate of less than 0.001 percent of patients.

Toddlers experience the world by first putting it into their mouth. Because 80 percent of the exposures occur among toddlers younger than age 6 years, and most within the home, prevention is paramount. All poisonous and injurious plants should be kept out of the reach of toddlers and preschoolers. Homes should be purged of all potentially toxic plants, just as they are for medications and cleaning supplies, and children should be specifically instructed never to eat plants or wild berries.^{4,6}

TREATMENT

Most plant-related exposures require no treatment, and those that do often can be managed by simple decontamination procedures. Those

TABLE 205-1 Most Highly Poisonous Plants

Castor bean (<i>Ricinus communis</i>)
Foxglove (<i>Digitalis purpurea</i>)
Jequirity bean (<i>Abrus precatorius</i>)
Oleander (<i>Nerium oleander</i>)
Poison hemlock (<i>Conium maculatum</i>)
Water hemlock (<i>Cicuta maculata</i>)
Yew (<i>Taxus</i> spp)

TABLE 205-2 Most Commonly Encountered Poisonous and Nonpoisonous Plants

Poisonous/Injurious	Nonpoisonous
<i>Aloe</i> spp	African violet (<i>Episcia reptans</i>)
Azalea (<i>Rhododendron</i> spp)	<i>Coleus</i> spp
Cactus spp	<i>Dracaena</i> spp
<i>Caladium</i> spp	Ficus plant (<i>Ficus</i> spp)
Colchicine (autumn crocus, meadow saffron)	Honeysuckle (<i>Lonicera</i> spp)
Dumbcane (<i>Dieffenbachia amoena</i>)	Jade plant (<i>Crassula</i> spp)
Fava beans	<i>Pyracantha</i> spp
Holly (<i>Ilex</i> spp)	Rubber tree plant (<i>Ficus elasticus</i>)
Jimsonweed (<i>Datura</i> spp)	Spider plant (<i>Chlorophytum</i> spp)
Lily of the valley (<i>Convallaria majalis</i>)	Umbrella plant (<i>Schefflera</i> spp)
Mistletoe (<i>Phoradendron flavescens</i>)	Wandering jew (<i>Tradescantia albiflora</i>)
Nightshade (<i>Solanum</i> spp)	
Peppers (<i>Capsicum</i> spp)	
<i>Philodendron</i> spp	
Poinsettia (<i>Euphorbia</i> spp)	
Poison ivy (<i>Toxicodendron</i> spp)	
Pokeweed (<i>Phytolacca</i> spp)	
Pothos (<i>Epipremnum</i> spp)	

patients with a potentially serious exposure who are asymptomatic should be observed in the ED for at least 4 to 6 h. If they remain asymptomatic, they may be discharged with appropriate instructions and follow-up. Symptomatic patients require ongoing monitoring and care and should be admitted to the hospital, because toxicity may continue to evolve. Few plants have specific antidotes.

It is recommended that all exposures be reported to the regional poison control center, so that accurate data can be collected on poisonous and injurious plant exposures, for help with plant identification, and for valuable input regarding patient management.

SEVERELY POISONOUS PLANTS

Castor Bean (*Ricinus communis*)

Ricin is a potent toxalbumin that inhibits protein synthesis and causes severe cytotoxic effects on multiple organ systems. It may be one of the most poisonous naturally occurring substances known.⁷ Although present in all parts of the plant, ricin is concentrated most in the bean. Castor beans are covered by a hard, relatively impervious outer shell that must be chewed or in some way broken in order for the ricin to result in toxicity.

Symptoms include delayed gastroenteritis, which may be severe and hemorrhagic, followed by delirium, seizures, coma, and death. Beans are particularly antigenic and may cause severe hypersensitivity and cutaneous and systemic allergic reactions.

Whole-bowel irrigation (WBI) has been advocated to ensure rapid and complete decontamination of the gastrointestinal (GI) tract. Rapid elimination of the bean before erosion of the outer shell occurs may decrease or prevent the release of potent toxins. Beans should be counted to assure complete recovery. Patients should be observed for at least 8 to 12 h. Once symptomatic, supportive care involves attention to fluid, glucose, and electrolyte replacement.

Foxglove (*Digitalis purpurea*)

Foxglove contains cardiac glycosides similar in structure and action to digitalis. Its toxicity lies somewhere between lily of the valley and oleander (see "Oleander" below).

Jequirity Bean (*Abrus precatorius*)

Jequirity beans contain the toxalbumin abrin, one of the most lethal naturally occurring toxins known.⁸ Children have died as a result of chewing alone (without swallowing) the beans. Chewing and swallowing just one bean may also be lethal to an adult. Symptoms include a delayed gastroenteritis, which may be severe and hemorrhagic, followed by delirium, seizures, coma, and death. Like castor bean, recovery of the intact bean by WBI is recommended. Patients should be observed for at least 8 to 12 h. Treatment is otherwise supportive, with attention to fluid replacement and monitoring of electrolytes.

Oleander (*Nerium oleander*)

Similar in structure and effect to digitalis, all parts of the plant contain the cardiac glycosides oleandrin, oleandroside, nerioside, and digitoxigenin. Cardiac glycosides act by inhibiting the sodium- and potassium-activated adenosine triphosphatase ($\text{Na}^+\text{K}^+\text{ATPase}$) pump and lead to hyperkalemia and a variety of dysrhythmias (see Chap. 174). Of all plants containing cardiac glycosides (lily of the valley, foxglove, and oleander), oleander is the most toxic.⁹

These glycosides cross-react sufficiently so that a positive serum digoxin level will qualitatively confirm ingestion. However, quantitative levels are not and should not be used to quantify the amount of ingestion or potential toxicity. Effects include nausea, vomiting, diarrhea, abdominal pain, confusion, and cardiac dysrhythmias.

Potassium levels should be closely monitored. Hyperkalemia may be severe, refractory to the usual treatments (insulin, glucose, bicarbonate), and may require hemodialysis.¹⁰ Calcium is generally not recommended, as it may theoretically exacerbate the digitalis toxicity, although there is no published human experience. In addition to GI decontamination and routine antidysrhythmic therapy, digoxin-specific Fab antibody fragments are recommended for patients with ventricular dysrhythmias.¹¹

Poison Hemlock (*Conium maculatum*)

All parts contain coniine alkaloids similar in structure and effect to nicotine, and with the ability to induce neuromuscular blockade. Symptoms occur rapidly in 15 min to 1 h after ingestion and begin with complaints of burning and dryness of the mouth. Tachycardia, tremors, diaphoresis, mydriasis, profound muscle weakness, and seizures may develop. In severe cases, ascending paralysis, rhabdomyolysis, acute renal failure, bradycardia, coma, and death occur. Although most cases are unintentional, there are some case reports of toxicity resulting from the intentional use by patients for a presumed narcotic-like effect.¹² Treatment consists of GI decontamination, activated charcoal, and supportive care which may include intravenous fluids, antidysrhythmics, and anticonvulsants.

Water Hemlock (*Cicuta maculata*)

Cicutoxin, a Cn-polyacetylene, is found in highest concentrations in the root, but all parts contain the poison. Its mechanism of action appears to involve inhibition of noncompetitive γ -aminobutyric acid (GABA) antagonists to GABA receptors. One mouthful may be fatal in as soon as 15 min. Initial symptoms include nausea, vomiting, and abdominal pain, followed by delirium, seizures, and death. Seizures may be severe and refractory to conventional anticonvulsant therapy. The mortality rate may be as high as 30 percent.¹³ GI decontamination is important, otherwise, treatment is supportive with intravenous fluids and anticonvulsants.

Yew (*Taxus* spp)

Yew contains taxine alkaloids in the leaves and seeds, a potent toxin with effects on cardiac myocytes.¹⁴ Case reports of near-fatal human

ingestions and fatal livestock ingestions have created the reputation that yew berry ingestions are highly toxic. However, a retrospective review of *Taxus* species ingestions found that while symptoms, predominantly gastrointestinal, were common, moderate to life-threatening complications were rare (< 1 percent) and there were no human fatalities.¹⁵ Symptoms after ingestion include nausea, vomiting, and abdominal pain. Rarely, seizures, cardiac dysrhythmias, and coma occur. Treatment consists of GI decontamination, activated charcoal, fluids, anticonvulsants, and antidysrhythmics as necessary.

COMMON POISONOUS AND INJURIOUS PLANTS

Aloe (*Aloe barbadensis*)

Sap from this common succulent houseplant contains an anthraquinone that acts as a cathartic. Symptoms include abdominal pain and diarrhea within 6 to 12 h of ingestion. It may occasionally turn the urine red, and large doses may cause nephritis. There is no specific antidote. Intravenous fluids may be necessary to support GI fluid losses.

Azalea (*Rhododendron* spp)

Andromedotoxins are found in the leaves, flowers, and nectar. Potential symptoms after ingestion include salivation, lacrimation, bradycardia, hypotension, progressive paralysis, and potentially (but rarely) death. Most cases of ingestion result in minimal toxicity. In addition to GI decontamination, treatment consists of atropine for symptomatic bradycardia and fluids or vasopressors for hypotension.

Cactus

Needles or spines may embed in the skin and cause direct mechanical injury. Patients typically complain of pain and irritation at the site. Unlike other foreign bodies, such as glass, that are inert, spines contain proteinaceous material and should be removed if possible. Multiple small cactus spines may be removed by applying a thin layer of rubber cement or other similar type substance over area, allowing the material to dry, and then gently peeling it off, removing the spines that have become embedded in the adhesive. Complications such as infection and granuloma formation occur, but are uncommon.

Caladium spp

Toxicity is similar to dumbcane (calcium oxalate raphides), but less severe.

Colchicine (Autumn Crocus, Meadow Saffron, Glory Lily)

Colchicine is contained in all parts of the autumn crocus, meadow saffron, and glory lily. Colchicine causes a delayed and severe gastroenteritis, followed by severe multisystem organ failure.¹⁶ Common effects include coagulopathy, bone marrow suppression with granulocytopenia and thrombocytopenia, cardiac dysrhythmias, cardiogenic shock, adult respiratory distress syndrome, hepatic failure, delirium, seizures, coma, and death. In addition to GI decontamination, treatment usually requires aggressive fluid resuscitation. Colchicine-specific Fab fragments are commercially available for severe poisonings.

Dumbcane (*Dieffenbachia amoend*)

These plants contain calcium oxalate crystals packaged into bundles known as raphides. In addition, these plants also contain proteolytic enzymes with antitrypsin-like activity, which stimulates the release of histamine and bradykinin. It remains unclear why some plants such as schefflera, which also contain calcium oxalate crystals, are completely

nontoxic. Children who chew the leaves develop immediate burning and irritation of the oral mucosa. Cases of severe swelling, drooling, dysphagia, and respiratory compromise have been reported, but are not common.¹⁷ Most cases of human ingestion report minor symptoms that resolve with little or no treatment. Demulsifying agents, such as cold milk or ice cream, may help and analgesics may be necessary. Steroids are considered beneficial for severe cases, although there have been no controlled trials.

Fava Beans

A portion of persons affected by glucose-6-phosphate dehydrogenase (G6PD) deficiency provide one of the few examples where genetic predisposition is associated with increased potential for toxicity after plant exposure; an estimated 10 to 20 percent of G6PD deficiency patients will develop favism after consuming fava beans. Symptoms include GI upset, fever, and headache and patients may develop hemolytic anemia with hemoglobinuria and jaundice (see Chap. 221).

Jimsonweed (*Datura* spp)

Jimsonweed (also known as thorn apple, devil's trumpet, or locoweed) is a widely occurring weed infamous for its hallucinatory properties. Exposures most commonly are intentional and occur through experimentation.¹⁸ All parts of the plant are toxic and contain atropine-like alkaloids (hyoscyamine, atropine, and scopolamine) capable of precipitating acute anticholinergic crises by competitive inhibition of cholinergic muscarinic receptors.

Symptoms occur within 30 to 60 min and may last for up to 48 h because of delayed gastric motility. Symptoms include hyperthermia ("hot as a hare"), flushed skin ("red as a beet"), dry skin and mucous membranes ("dry as a bone"), mydriasis ("blind as a bat"), and hallucinations or delirium ("mad as a hatter"). Tachycardia and urinary retention are also common.

Treatment includes GI decontamination with emesis or lavage, activated charcoal, and supportive care (intravenous fluids, external cooling, and restraints for patient protection). GI decontamination may be useful for up to 48 h after ingestion if the patient remains symptomatic. Physostigmine, a cholinesterase inhibitor, antagonizes both the central and peripheral effects and may be required in 30 to 40 percent of cases.¹⁸ It should be considered for severe cases exhibiting hyperthermia, seizures, or frank psychosis. An initial dose of 0.5 mg for children or 1.0 to 2.0 mg for adults is given slowly IV over 5 min. Repeat doses may be required (see Chap. 183).

Lily of the Valley (*Convallaria majalis*)

In addition to ingestion of the plant itself, toxicity has been reported from drinking of water in which the freshly cut flowers were kept (see "Oleander" above).

Nettle (Stinging Nettle, Bull Nettle)

Nettles contain a specialized system for injecting their toxins. Stinging hairs are connected to a bladder filled with various irritants (histamine, acetylcholine, 5-hydroxytryptamine). Handling of the plant stimulates the injection of these substances via the hair tube. An immediate burning response may last for hours. Treatment is symptomatic.

Nightshade, Common or Woody (*Solanum* spp)

The glycoalkaloid solanine is present in all parts of the plant. Ingestion results in nausea, vomiting, diarrhea, and abdominal pain. Delirium, hallucinations and coma may also occur with larger doses. There is no specific treatment.

Nightshade, Deadly (*Atropa belladonna*)

This plant contains atropine-like substances with anticholinergic properties (see "Jimsonweed" above).

Peach, Apricot, Pear, Crab Apple, and Hydrangea

Amygdalin, a cyanogenic glycoside, is metabolized by the enzyme emulsin to hydrocyanic acid. In sufficient quantities, hydrocyanic acid may lead to acute cyanide toxicity. The requisite enzyme (emulsin) is present in the pits or seeds of these plants noted above and may be present to some degree in intestinal bacteria. Ingestion of large amounts of seeds or pits results in diaphoresis, nausea, vomiting, abdominal pain, and lethargy. Symptoms develop over hours. GI decontamination is needed. If symptomatic, antidotal therapy may be needed for cyanide toxicity (see Chap. 188).

Pepper (*Capsicum* spp)

Capsicum causes irritation, burning, and pain upon contact with mucous membranes as a result of depletion of substance P from terminal nerve endings. There is intense burning of the mucous membranes with contact. Patients typically self-inoculate their eye while preparing peppers. Police use pepper sprays to subdue combative individuals. In addition to cutaneous decontamination with copious amounts of water and gentle hand soap, demulsifying agents, such as cold milk or ice cream, may help. Analgesics may be necessary.

Philodendron spp

All parts contain oxalate raphides and may produce symptoms similar to dumbcane, although less severe.

Pokeweed (*Phytolacca americana*)

All parts of the plant are toxic, but especially the roots, unripe berries, and seeds. Phytotoxins (phytolaccotoxin and phytolaccine) cause direct mucosal irritation and GI symptoms. Patients complain of burning in the mouth and throat, with abdominal pain, nausea, vomiting, and profuse diarrhea that may be foamy.¹⁹ Severe intoxications may result in coma and death. Although their safety remains somewhat controversial, ripe berries are occasionally used in pies and the leaves boiled for greens. Treatment is GI decontamination with emesis or lavage, charcoal, and supportive care consisting of fluid-electrolyte replacement.

Potato, Eggplant (*Solanum* spp)

Solanine is contained in green potatoes and in the sprouts, and is destroyed by cooking. Delayed gastroenteritis may be seen (see common nightshade above).

Pothos (Devil's Ivy, *Epipremnum* spp)

This plant has toxicity similar to dumbcane, but less severe.

Yellow Sage (*Lantana camara*)

Leaves and unripe fruit contain the toxin lantadene, which may produce dilated pupils, vomiting, diarrhea, weakness, and coma. Symptoms may be delayed for 2 to 6 h. Treatment is GI contamination and fluids for dehydration.

Toxicodendron Species (Poison Ivy, Oak, and Sumac)

These plants contain the antigenic resin urushiol. Once exposed, most, but not all, individuals develop sensitization as the antigenic resin binds with skin proteins and forms a complete antigen. Reexposure then stimulates a

T-cell-mediated immune response. Reactions begin with itching, burning and redness developing over 12 to 48 h, and may progress to include varying degrees of vesicubullous formation. Resin may remain after the plant has dried and may be aerosolized during burning. Antipruritic and topical therapies (oatmeal baths and topical steroids) are commonly used. Facial, genital, or widespread involvement requires systemic steroids for 10 to 14 days. Patients should be advised to clean under their fingernails and wash all contaminated clothing. IvyBlock, a new product recently approved by the Food and Drug Administration, contains bentoquatam and binds urushiol to prevent absorption. Skin cleansers (such as Tecnu) may be used up to 8 h after exposure to decontaminate the skin.

COMMON HOLIDAY OR SEASONAL PLANTS (POISONOUS AND NONPOISONOUS)

Holly (*Ilex* spp)

The leaves are nontoxic, whereas the berries contain a variety of toxins known as saponins. Gastroenteritis is most common effect after ingestion and may occur with as few as 2 or 3 berries, whereas 20 to 30 berries may be fatal. Treatment is GI decontamination followed by intravenous fluids to prevent dehydration.

Poinsettia (*Euphorbia pulcherrima*)

Poinsettia is a much-maligned plant ubiquitous during the Christmas holidays. Originally implicated as being toxic, recent evidence suggests that, at most, it may occasionally cause some local irritation to skin, mouth, or conjunctiva.²⁰

American Mistletoe (*Phoradendron flavescens*)

All parts are poisonous and contain phoratoxin, a toxalbumin. Gastroenteritis may occur following ingestion of a large number of berries, but significant morbidity is rare.²¹ Treatment is GI decontamination with fluid and electrolyte monitoring.

Easter Lily (*Lilium longiflorum*)

Toxicity has not been reported in humans.

EMERGENCY MEDICINE IN UNIQUE ENVIRONMENTS

WORLD TRAVELERS

Michael J. VanRooyen
Chayan C. Dey Raghu
Venugopal

"The art of being wise is the art of knowing what to overlook."
William James

The evaluation of the world traveler is a growing concern as a consequence of the increase in the popularity of transcontinental travel that allows even exotic destinations to be reached within 36 h. Greater numbers of immunologically naive travelers venture abroad each year, and more than half of these travelers travel to tropical nations whose illness burden is largely due to poverty, civil unrest, poor environmental hygiene, malnutrition, and tropical illnesses.¹ One needs a logical and organized approach to patients who have been exposed to uncommon tropical infections, since most returning travelers have neither serious nor exotic illnesses. The likely causes of acute symptoms are common problems such as upper respiratory infections, diarrheal illnesses, or reactions to stress, fatigue or new medications. The ED physician often does not routinely confirm the final diagnosis, but rather begins diagnostics and provides appropriate referral. It is important to identify local or regional travel health facilities for referral of patients who need more advanced evaluation, serologic testing, and long-term follow-up.

POPULATIONS AT RISK

Each year, some 8 million Americans travel to lesser-developed nations and up to 1 in 10 seek posttravel medical care. Most such travelers are in their early forties, although there is a rise in the number of travelers at extremes of age. Among travelers, 64 percent report one or more illnesses during travel, 26 percent are ill upon return, and 56 percent of those ill upon return develop symptoms after arrival in the United States.² Many disease incubation times are longer than the transit times of most modern travelers.

Travelers are at risk for certain infectious diseases based on the duration of travel, the endemic exposure, and preexisting immunity. Most travelers on vacation or business are abroad for fewer than 20 days, and less than 5 percent spend extended time overseas. A variety of travelers originate from disease-endemic nations, including tourists or newly arrived immigrants seeking U.S. domicile. Such visitors and foreign nationals are at risk for typical infectious diseases and newly emerging infections. Others at risk include nonvoluntary travelers, such as refugees and displaced persons, as well as landed immigrants with permanent U.S. residence who are returning from visiting their homeland. A high degree of clinical suspicion is warranted for this latter group because many presume they still have acquired immunity for diseases such as malaria, but remain susceptible to endemic illnesses. Western travelers also have an increasing risk of tropical illness as a result of increasing exotic adventure-type travel to remote locales that were previously inaccessible (Table 206-1).

Many travelers are exposed to diseases such as *Plasmodium falciparum* (malaria) that are uncommon in the United States, but which are leading causes of mortality overseas. Other parasitic agents, such as helminths and rickettsia, also occur with increased frequency and severity in the tropics. Helminths are discussed in Chap. 149 and rickettsia in Chap. 151. It is important to suspect when patients may be infected by a tropical infection because diagnosis often requires a unique

set of tests and therapy is organism specific. Also, in all cases of suspected tropical illnesses, the potential for a bioterrorist agent should be suspected when plausible. Factors suggesting intentional releases include divergence of the disease presentation from the typical epidemiology of the community and an atypical number of patients presenting with similar clinical syndromes. Examples of diseases which could be weaponized include anthrax, plague, viral hemorrhagic fevers, and tularemia. These are discussed in detail in Chap. 7.

HISTORY

Imported disease should be suspected among recent world travelers. This is particularly important in those arriving from an endemic nation presenting with otherwise typical chief complaints. These include shortness of breath, fever, abdominal pain, diarrhea, hematuria, headache, and skin rash (Table 206-2). Noting previous medical conditions is paramount because those with risk factors such as immunosuppression, early childhood, advanced age, pregnancy, or diabetes are often less tolerant of tropical infections.

The risk of infection depends on historical aspects such as the duration of travel (suggesting specific disease incubation periods) and destination or origin (suggesting possible etiology). Knowing the region of travel can reduce the differential diagnosis of possible causative agents (Table 206-3). Other important considerations are the living conditions and locale of the traveler (rural areas have greater infectious risks), type of accommodation, and travel-related activities (suggesting possible exposure) (Table 206-4). A review of systems, pretravel immunizations and medications, high-risk behaviors, and prior medical conditions should be queried. This is relevant because proper vaccination against hepatitis A, hepatitis B, and yellow fever can effectively rule these out as causes of illness. In addition, adherence to appropriate chemoprophylaxis can significantly reduce the risk of acquiring malaria—which is the most important tropical emergency—yet the possibility of malaria should never be discounted, regardless of compliance with prophylaxis. Because of increasing malaria resistance, febrile returning travelers must be assumed to have malaria even if chemoprophylaxis was correctly used for 4 weeks after return. A history of medications, herbs, and traditional medicines consumed is also useful. The use of mefloquine prophylaxis and antipyretics can still result in late-appearing fever caused by malaria breakthrough. For tropical emergencies such as cerebral malaria, the clinician may need to depend on only what is uncovered during the patient interview, physical examination, and available diagnostic tests. When patients cannot give a full history because of altered mental status, suspect cerebral malaria or meningitis and consider early treatment for both until the diagnosis is confirmed.

PHYSICAL EXAMINATION

The physical examination should be as detailed as practically possible, even though positive physical findings may be nonspecific. Focus should be paid to evaluating the abdomen for hepatosplenomegaly or focal abdominal discomfort. Examine the patient for lymph node involvement and inspect the skin and mucosal surfaces. Ophthalmologic examination should note scleral icterus, conjunctival injection or petechiae. Imported diseases should be suspected in the presence of high fever, signs of hemorrhage, profuse diarrhea, shortness of breath, skin lesions, and neurologic disturbances. Table 206-5 lists other signs of tropical illness.³

TABLE 206-1 Overall Risk of Exposure to Infectious Agents

High risk (1 in 10 travelers): Diarrhea, URIs, and noninfectious illnesses such as injuries and cardiac problems Moderate risk (1 in 200): Dengue, enteroviral infection, gastroenteritis, giardiasis, hepatitis A, malaria, salmonella, STDs, shigella Low risk (1 in 1000): Amebiasis, ascariasis, measles, mumps, enterobiasis, scabies, TB, typhoid, hepatitis B Very low risk (1 in >1000): HIV, anthrax, Chagas, hemorrhagic fevers, pertussis, plague, typhus, hookworm

Abbreviations: HIV = human immunodeficiency virus; STD = sexually transmitted disease; TB = tuberculosis; URI = upper respiratory illness.

LABORATORY TESTING

Initial investigations may include standard tests like complete blood count (CBC) with differential and platelet count, absolute eosinophil count, liver enzymes and hepatic function tests, and urinalysis; thick and thin blood smears for malaria, blood cultures, urine cultures and stool analysis for white blood cells (WBCs), ova, and parasites. Specific serologic tests may be indicated, such as erythrocyte sedimentation rate (ESR), purified protein derivative (PPD), Venereal Disease Research Laboratory (VDRL), HIV, and serology for arboviruses. The absolute eosinophil count should be elevated to greater than 500/ μ L in parasitic diseases such as helminths (worms). It is helpful to consult an

TABLE 206-2 Travel-Specific Aspects of the Medical History

Pretravel information
Previous medical condition
Pediatric patient, diabetes, pregnancy, immunosuppression (especially HIV/AIDS) Pretravel consultation and preparation (self-treatment medications, vaccination history, prophylaxis, etc.)
Type and compliance with chemoprophylaxis—particularly malaria
History of routine childhood immunization
Nation of birth and citizenship
Exact itinerary of departure and arrival (within the last 3-5 years may be relevant)
Season of travel (monsoon, dry season) Destinations visited (including locations of transit or stopovers)
Urban or rural, altitude Purpose of travel and activities in-country
General purpose of visit or travel (e.g., "adventure travel" with high exposure to remote, natural elements) Contacts and their health
Habitat and location of lodging (bednets, window screens)
Crowded living or sleeping conditions High risk activities (e.g., medical care of refugees, spelunking in caves, cohabitation with indigenous, poor populations) Opiate use or intravenous drug use Sexual intercourse with any foreign national and very high-risk populations
such as commercial sex-trade workers (dates and nature of sexual contact) Exposure to environment (swimming, hiking, trekking, digging, or soil contact) Consumption of high-risk foods (wild game or bush meat, raw or undercooked meats or fish, unpasteurized milk products, food from street vendors, natural sources of water, salads)
Exposure to dogs, birds, or rodents Adverse incidents
Insect or animal bites Saliva from animals to open wounds Assault or trauma Status and health of fellow travelers
Possible ill contacts
In-country medical consultations sought, remedies used, and procedures (injections, acupuncture, transfusions, dental procedures, body piercing, or tattooing)

TABLE 206-3 Regional Tropical Illnesses

Africa: Hookworm, malaria, HIV dengue, brucellosis, yellow fever (and other hemorrhagic fevers), dracunculiasis, relapsing fever, tapeworm, roundworm, schistosomiasis
Central and South America: Malaria, relapsing fever, dengue, filariasis, TB, schistosomiasis, Chagas, typhus
Mexico and the Caribbean: Dengue, hookworm, malaria, cystercercosis
Australia, New Zealand: Dengue, Lyme disease, Q fever
Middle East: Hookworm, malaria, anthrax, brucellosis
Europe: Giardiasis, Lyme disease, tick-borne encephalitis, babesiosis
China and East Asia: Dengue, hookworm, malaria, strongyloidiasis, hemorrhagic fever, Japanese encephalitis

Abbreviations: HIV = human immunodeficiency virus; TB = tuberculosis.

infectious disease specialist early in evaluation to be certain that the proper laboratory tests have been ordered.

CLINICAL DIAGNOSIS BASED ON SYNDROMIC PRESENTATION

The presentation of tropical disease is often subtle and necessitates a high degree of clinical suspicion. However, there are usually one or more hallmark symptoms or signs that most infections elicit. Hereafter, tropical conditions are categorized by their classical symptoms. These include fever, central nervous system (CNS) complaints, abdominal pain, diarrhea, skin and eye complaints, and respiratory symptoms.

TABLE 206-4 Specific Exposures and Associated Tropical Infections

Contact/Exposure	Possible Infections
Untreated water, unpasteurized dairy products	Salmonellosis, shigellosis, hepatitis, amebiasis, brucellosis, tuberculosis
Raw or undercooked shellfish	Clonorchiasis, paragonimiasis, vibrios, hepatitis A
Raw or undercooked animal flesh	Trichinosis (e.g., pig, horse, bear), salmonella, enterohemorrhagic <i>E. coli</i>
Raw vegetables, water plants (e.g., watercress)	Fascioliasis
Animal contact (and animal products)	Rabies, Q fever, tularemia, brucellosis, echinococcosis, anthrax, plague, Nipah virus, toxoplasmosis
Rodent contact	Hantavirus, viral hemorrhagic fevers, murine (endemic) typhus, Lassa fever, plague
Arthropod vectors	
<i>Mosquitoes</i>	Malaria, dengue, filariasis, yellow fever, and other arboviral infections
<i>Ticks or mites</i>	Rickettsioses, tularemia, scrub typhus, Crimean-Congo hemorrhagic fever
<i>Reduviid (kissing) bugs</i>	American trypanosomiasis (Chagas disease)
<i>Tsetse flies</i>	African trypanosomiasis (African sleeping sickness)
<i>Fleas</i>	Typhus, plague
<i>Sandflies</i>	Leishmaniasis
Freshwater exposure	Schistosomiasis, leptospirosis
Barefoot exposure	Strongyloidiasis, cutaneous larva migrans
Sexual contacts	HIV, hepatitis B, syphilis, gonorrhea, herpes simplex
Infected persons contact	Viral hemorrhagic fever, enteric fever, meningococcal infection, tuberculosis

TABLE 206-5 Physical Findings in Selected Tropical Infections

Physical Finding	Likely Infection or Disease
Rash	Dengue fever, typhoid, typhus, syphilis, gonorrhea, Ebola, brucellosis
Jaundice	Hepatitis, malaria, yellow fever, leptospirosis, relapsing fever
Lymphadenopathy	Rickettsial infections, brucellosis, dengue, HIV, Lassa fever, leishmaniasis
Hepatomegaly	Amoebiasis, malaria, typhoid, hepatitis, leptospirosis
Splenomegaly	Malaria, relapsing fever, trypanosomiasis, typhoid, brucellosis, kala-azar, typhus, dengue fever
Eschar	Typhus, borrelia, Crimean-Congo hemorrhagic fever
Hemorrhage	Lassa, Marburg, or Ebola viruses; Crimean-Congo hemorrhagic fever; meningococcemia, epidemic louse-borne typhus

Diseases Commonly Associated with Fever

Although fever is often a nonspecific symptom, it should arouse suspicion of a potentially life-threatening infection (Table 206-6).⁴ It is important to differentiate diseases that may be rapidly fatal, easily treatable, and/or potentially contagious. In all cases, fever associated with confusion, hypotension, or hypoxemia necessitates emergent care. Although exotic diseases should be considered, it is more important to determine the existence of common and easily treatable infections. Even in the international tropical traveler, the most common life-threatening infectious diseases are caused by organisms causing pneumonia, meningitis, and acute gastrointestinal illness (Table 206-7).^{5,6}

The fever pattern is sometimes helpful because onset, pattern, and duration can suggest a particular illness. Determining an approximate incubation period (the time between exposure and signs and symptoms) can be helpful in ruling in or out certain etiologies. For example, if fever begins more than 21 days after return, dengue, yellow fever, and other arboviruses are unlikely, irrespective of the exposure history (Table 206-8). In comparison, those acutely infected by schistosomiasis may only exhibit symptoms 5 weeks postexposure. Incubation periods should be used cautiously because some diseases have variable incubation depending on factors such as host immunity and the use of chemoprophylaxis and other medications.

Malaria

Malaria is the most important tropical disease. The classic clinical triad for all species of malaria is fever, splenomegaly, and anemia.^{7,8} Fever is typically irregular for the first week and later demonstrates periodicity. Illnesses with similar presentation include viral influenza, dengue fever, meningococcal meningitis, typhoid fever, pneumococcal pneumonia, and viral hepatitis.

Patients usually have continuous symptoms initially, followed by episodic pyrexia every 2 to 3 days, depending on the infecting species. Serious infections occur primarily in young children, gravid women, individuals never previously infected (such as Western nationals), and debilitated patients with comorbid medical problems. Because associated symptoms such as headache, cough, and gastrointestinal (GI) problems mimic other conditions, malaria should be seriously considered in all febrile travelers.

Diagnosis is based on clinical presentation and confirmed with lab evidence of blood-borne protozoa. Patients with fever >38.5°C (101.4°F) of unclear origin and with recent or past travel to an endemic area should be screened by obtaining blood smears. Refer to Chap. 142 for a detailed discussion of malaria diagnosis and treatment.

Dengue Fever

Dengue is the most significant arbovirus affecting humans, and most serious febrile tropical disease after malaria. It should be suspected among febrile travelers within 2 weeks of tropical travel. Dengue may occur more than once because each of the four strains offers no cross-protective immunity. Worldwide, it annually causes an estimated 100 million cases, including 25,000 deaths. With increasing global population, transcontinental travel, and tropical urbanization, the frequency of imported dengue is predicted to rise. More than 500 laboratory-confirmed cases occurred in the last 20 years in the United States, although this is an underestimation, because many cases are self-limiting and the illness is nonreportable.⁹ Also, the long serology processing time also means it usually does not aid acute diagnosis or treatment, so many physicians do not order it.

Dengue fever occurs in most urban environments in most tropical nations and is borne by the peridomestic day-biting *Aedes aegypti* mosquito. Urban dengue in the Americas, Africa, and the Indian subcontinent is usually classical dengue fever, whereas in Southeast Asia it manifests as hemorrhagic fever and shock. Classic dengue fever presents after a typically short incubation period of 4 to 7 days with sudden high fever, headache, nausea, vomiting, myalgias, and rash usually lasting a week. Facial flushing, conjunctival injection, retro-orbital pain, and facial edema (termed dengue facies) also occur. Following defervescence a fine pale morbilliform rash develops on the trunk and spreads to extremities and face. Small children may only present with a mild upper respiratory infection and classic dengue may be confused with influenza, measles, or rubella. While other causes of fever can present with a similar clinical picture, such as West Nile fever (transmitted by the *Culex* mosquito), West Nile fever causes lymphadenopathy, which is usually absent in dengue. Dengue can also cause petechial hemorrhages indistinguishable from meningococcemia.

Dengue hemorrhagic fever (DHF) preferentially occurs among infants of immune mothers, children older than age 1 year and those with second and subsequent infections. It begins as classical dengue with fever and myalgias. After 2 to 7 days as pyrexia improves, lassitude, fatigue, and shock develop with an ensuing mortality that is greater than 10 percent. Patients demonstrate hemorrhagic pleural effusions, bleeding diathesis, epistaxis, purpura, petechia, and thrombocytopenia with elevated hematocrit because of vascular permeability. DHF, if untreated, rapidly evolves into dengue septic shock (DSS) which is often fatal. DSS is heralded by abdominal pain, severe encephalitis, mental status changes, and alternating severe pyrexia and hypothermia. Diagnosis of dengue and DHS-DSS is based on clinical findings, and while serology is confirmatory, cross-reactivity often occurs with other flaviviruses. Enzyme-linked immunosorbent assay (ELISA) for IgM can provide a more accurate and rapid confirmation of infection by day 6 of the illness. Laboratory abnormalities include leukopenia, thrombocytopenia, and hepatic dysfunction. In uncomplicated dengue fever, treatment is supportive and consists of oral fluids and analgesics. Only acetaminophen is recommended for managing pain and fever because aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) are contraindicated due to anticoagulant properties. Dengue often requires intravenous hydration with LR solution or NS. Supplemental oxygen and sedation may be required.

Typhoid Fever

Enteric fever or typhoid is a serious infection diagnosed in 2 percent of febrile travelers and caused by *Salmonella typhi* and *S. paratyphi*. Once malaria has been ruled out, this is typically the cause of a febrile illness lasting greater than 10 days. Imported cases are typically among children or adolescents; recently, travelers in Mexico, Indonesia, Peru, and India accounted for more than half of imported cases. Vaccination is recommended before travel (especially to India) yet is only 75 percent effective. The disease is transmitted in a dose-related

TABLE 206-6 Tropical Infectious Diseases Causing Fever Among International Travelers

Disease	Distribution	Mode of Transmission
<i>Incubation <14 days</i>		
Undifferentiated fever		
Malaria	Most tropical and subtropical areas	Infected mosquito bite
Dengue	Worldwide	Infected mosquito bite
Spotted fever	Worldwide	Infected tick or mite bite
Scrub typhus	Asia, Australia	Infected mite bite
Leptospirosis	Widespread, mostly tropics	Percutaneous contact with animal urine or contaminated soil; ingestion
Typhoid fever	Developing countries, especially Indian subcontinent	Contaminated food/water ingestion
Acute HIV infection	Worldwide	Per mucosal or percutaneous exposure to infective blood or fluids
East African trypanosomiasis	Sub-Saharan Africa	Infective tsetse fly bite
Shigella	Widespread, most common developing countries	Contaminated food/water ingestion
Salmonella	Widespread, most common developing countries	Contaminated food/water ingestion
Campylobacter		Contaminated food/water ingestion
Fever with hemorrhage		
Meningococcemia		
Leptospirosis	Worldwide	
Malaria		
Viral hemorrhagic fever		Infected mosquito or tick bite
Other bacterial infection		
Fever with CNS involvement	Common in Africa, Asia, and Latin America	
Meningococcemia		
Rabies		Infected animal saliva exposure
Malaria	World wide	
Many viral and bacteria forms	Widely scattered, most common in East Asia and Southeast Asia	
Arboviral encephalitis	Primarily Africa and parts of Asia	Infected mosquito or tick bite
Angiostrongyliasis		Ingestion of contaminated food/water with snail or slug slime
Polio		Ingestion of feces contaminated food/water
Fever with respiratory findings		
Influenza	Widespread; outbreaks on cruise ships	China, Hong Kong, other regions in East Asia
SARS	Widespread; outbreaks in hotels and cruise ships	
Legionellosis	Worldwide; inhalation of infective aerosol from animal source	Direct or airborne transmission
Q fever		Airborne droplet transmission
Acute HIV infection		Inhalation or aspiration
<i>Incubation 14 days to 6 weeks</i>		
Malaria		
Typhoid fever		
Hepatitis A and E		
Acute schistosomiasis	Widespread; most common in developing countries	Contaminated food/water ingestion
Amebic liver disease	Africa, Asia, and Latin America	Penetration of skin by cercariae
Leptospirosis	Widespread; developing countries	Ingestion of cysts usually in feces
East African trypanosomiasis		contaminated food/water
Q fever		
Acute HIV infection		
<i>Incubation > 6 weeks</i>		
Malaria		
Tuberculosis	Worldwide	Inhalation
Hepatitis B	Widespread	Per mucosal or percutaneous exposure to infective blood or fluids
Visceral leishmaniasis	Many parts of Africa, Asia, South America, and Mediterranean basin	Infective sand fly bite
Lymphatic filariasis	Widespread in tropical areas	Infected mosquito bite
Schistosomiasis		
Amebic liver abscess		
Rabies		
African trypanosomiasis	Sub-Saharan Africa	Infected tsetse fly bite

fashion after food contamination by feces or urine from actively infected cases or healthy disease carriers. Incubation times and disease severity depend on bacteria dose exposure and are thus variable from 1 to 3 weeks. After ingestion, bacteria adhere to the small-bowel mucosa, invade lymphoid tissues, and disseminate via lymphatics to the bone marrow, gall bladder, and spleen to reproduce in macrophages.

Most pathology occurs in the gut as a consequence of inflammation, necrosis, and ulceration.

Typhoid fever classically begins with vague symptoms, progressive high fever with chills, headache, abdominal distention, myalgias, constipation, and prostration. Fever and headache are the most common early symptoms. The differential diagnosis includes malaria, typhus,

viral hepatitis, amebic liver abscess, and other infective causes of enteritis. In epidemics, patients can present with acute diarrhea and vomiting, headache, and meningeal signs. Most patients, however, present with constipation rather than diarrhea. Bradycardia relative to fever is classic (but may be absent) and after several days of fever a pale red macular rash may appear on the trunk ("rose spots") among the fair-skinned. As disease progresses, splenomegaly is appreciable and complications may arise after even mild disease. Complications include small bowel ulceration, anemia, disseminated intravascular coagulopathy (DIC), pneumonia, meningitis, myocarditis, cholecystitis, and renal failure. Sequelae include epistaxis, deafness, and in 10 percent there is neurologic involvement including psychosis, ataxia, and seizures.

TABLE 206-8 Typical Incubation Periods for Selected Tropical infections

Incubation Period	Infections Likely
<10 Days (short incubation)	Traveler's diarrhea Dengue fever and arboviral infections Yellow fever Spotted fevers Anthrax Diphtheria Malaria Rabies Typhoid fever Meningococcal infections Plague Tularemia Typhus (louse and flea borne)
<21 Days (intermediate incubation)	Leptospirosis Viral hemorrhagic fevers Malaria Enteric fevers (typhoid, paratyphoid) Typhus Africa trypanosomiasis
>21 Days	Viral hepatitis (A, B, C, D, E) Malaria Acute HIV infection Amebic liver abscess Shistosomiasis (Katayama fever) Visceral leishmaniasis Filariasis
>Months	Tuberculosis Malaria caused by <i>Plasmodium vivax</i> Filariasis Viral hepatitis B, C HIV Visceral leishmaniasis Rabies Syphilis African and American (Chagas disease) trypanosomiasis

Diagnosis is clinical and confirmed by culturing blood, urine, or stool (during the second week), or by "rose spot" aspiration biopsy. Although most cultures have a low yield, bone marrow culture is most sensitive and is even possible following empirical treatment. Patients may develop leukopenia and elevated liver enzymes, though most cases have nonspecific lab values. Typhoid is treated with several antimicrobials, and chloramphenicol is the traditional drug of choice yielding a rapid and reliable cure. However, antibiotic resistance has caused ampicillin, trimethoprim-sulfamethoxazole (TMP-SMX), and chloramphenicol to be unreliable first line treatments. Current recommendations are either ceftriaxone 2 g IV every 24 h for 14 days, ciprofloxacin 400 mg IV every 12 h for 10 days, or ciprofloxacin 500 mg PO bid for 10 days. Alternatives include azithromycin 1 g PO on the first day followed by 500 mg PO per day for 6 days, azithromycin 1 g PO per day for 5 days, or cefixime 10 to 15 mg/kg IV every 12 h for 8 days. For patients with severe typhoid fever with delirium, coma, shock, or DIC, dexamethasone 3 mg/kg IV loading dose over 30 min followed by 1 mg/kg IV every 6 h for 8 doses should be administered. Supportive treatment includes intravenous rehydration, and in the event of serious GI bleeding, blood transfusion. If untreated, mortality is 10 to 15 percent, mostly occurring in young children.

Spotted Fever (Rickettsial Infections)

Spotted fevers are an underappreciated source of fever among returned travelers. They are transmitted by the bite, body fluid, or feces of ixodid arthropod ticks and are widely distributed around the world. Among the eight major rickettsial infections there is great variation in severity, and mortality without treatment approaches 25 percent and with treatment 5 percent. In particular, scrub typhus (*Rickettsia orientalis*) and African tick typhus (*R. conorii* var. *pijperi*) should be suspected after African safaris, adventure travels, and military activity. After 3 to 14 days incubation, when the tick bite may go unnoticed, patients demonstrate sudden fever, malaise, myalgias, severe headache, and nausea/vomiting. Whereas fever and centripetal rash are classic, the rash may be absent. Scrub typhus presents with a papule at the bite site later becoming necrotic and forming a crusted black "tache noire" eschar. As organisms metastasize, patients develop fever, malaise, headache, lymphadenopathy, and splenomegaly. African tick typhus presents like scrub typhus, but with less-severe symptoms. Diagnosis is clinical and serologic tests are confirmatory. Doxycycline 100 mg PO twice per d for 7 to 10 d is the empirical treatment of choice and chloramphenicol is an alternative. In severe cases, death occurs from a multiorgan toxemia within 1 to 2 weeks of illness onset if untreated. Therapy should be continued for at least 5 days and for 48 h after defervescence. Despite treatment, long-term complications are common.

Leptospirosis (Weil Disease)

This is the world's most widespread zoonotic infection and is commonly found in tropical climates. It follows mucous membrane or percutaneous exposure to fresh water contaminated by *Leptospira interrogans* from infected animals that excrete the spirochete in their urine. Infected patients typically have had contact with dogs; swam, rafted, or waded in contaminated surface water; or farmed or gardened. Outbreaks have been known to occur following flooding. While the risk to most routine travelers is low, recent ecotourists and adventure travelers have been infected following intense water exposure. During Eco-Challenge-Sabah 2000, in Malaysia, many participants were infected while swimming, kayaking, or swallowing water from the Segama River. The clinical course can be asymptomatic but often symptoms illustrate a biphasic pattern. After an incubation of 2 to 20 days, high fever, severe headache, chills, myalgias, jaundice, and nonspecific influenza-like symptoms develop along with conjunctival injection without purulent discharge. Symptoms resolve in 4 to 7 days, followed

several days later by the severe, icteric "Weil disease" or aseptic meningitis lasting up to 4 weeks duration, renal failure, uveitis, rash, and, rarely, circulatory collapse caused by circulating antibodies. Isolation of leptospires from blood or cerebrospinal fluid (CSF) is diagnostic, but requires a prolonged incubation period. The illness is self-limited, but treatment reduces the severity and duration of symptoms and may prevent the second disease phase. Mild disease can be treated within the first 3 days of illness with oral amoxicillin or doxycycline, whereas more severe cases require intravenous penicillin or ampicillin. Empiric therapy with oral doxycycline or intravenous penicillin (or ampicillin) should be considered if leptospirosis is suspected.

Relapsing Fever

Relapsing fever is a bacterial infection caused by the spiral-shaped *Borrelia* species transmitted by lice or ticks. It is rare among travelers, yet should be suspected among contacts with refugee and disrupted populations in whom epidemics are common. Tick-borne disease results from a bite or tick body fluid exposure. Subsequently, *Borrelia* reproduce in body fluids and produce endotoxins affecting the liver, spleen, and capillaries. After incubation of 3 to 10 days, patients present with sudden fever, chills, headache, myalgias, and prostration, along with abdominal pain and jaundice. In severe cases, mental status changes, meningoencephalitis, myocarditis, hepatic failure, and DIC occur. After 5 to 7 days, fever may spontaneously abate, accompanied by hypotension, and near day 14, fever may recur. Such relapses number 1 to 2 among louse-borne fever, 3 to 6 among tick-borne fever, and up to 11 among African varieties. Diagnosis is made by clinical suspicion and confirmed by performing a Romanowsky-stained thick smear (similar to malaria) taken during the febrile period to identify spirochetes. Both louse-borne and tick-borne relapsing fever can be treated with a single oral dose of 500 mg tetracycline, 200 mg doxycycline, or 1 g of erythromycin.

Typhus (Epidemic Louse-Borne)

This bacteria is transmitted by the arthropod body louse and is common in Ethiopia, Mexico, Guatemala, and the Himalayas. It is also common in cold mountainous regions affected by famine, war, or mass population movement, but where adequate clothing exists to harbor the louse or lice. Louse-borne disease occurs after louse body fluids and feces are rubbed into abrasions after it is crushed or after it bites humans. Infection by the etiologic agent, *Rickettsia prowazekii*, causes high fevers and other nonspecific symptoms after an 8 to 12 day incubation period. Severe headache is common and a maculopapular rash appears between days 4 and 7, generally sparing palms and soles, and if severe, may be hemorrhagic. Diagnosis depends on serologic testing and treatment is doxycycline (100 mg PO bid) or chloramphenicol (60 to 75 mg/kg per d PO in four divided doses) to be administered for 7 days and for 48 h after defervescence. Untreated, mortality is as high as 60 percent.

Diseases Commonly Associated with Fever and Hemorrhage

Among the most feared tropical diseases are viral hemorrhagic fevers (VHFs). However, they are rare when compared to other febrile hemorrhagic infections such as leptospirosis, plague, rickettsia, and vibrio. While travel-related VHFs are public health and medical emergencies, non-travel-associated causes of fever and hemorrhage should not be discounted because *Neisseria meningitidis* is the most common temperate infection causing acute hemorrhagic fever. Among travelers, several treatable infections, including Lassa fever, malaria, meningococcemia, leptospirosis, and rickettsial infection can cause fever associated with hemorrhage. Most people with VHFs, such as dengue, hantavirus, Lassa, Ebola, Marburg, and Rift Valley, develop fever within

3 weeks after exposure. It is therefore important to establish a precise travel itinerary to estimate the incubation time. VHF usually follows the bite of infected mosquitoes, ticks, or close contact with rodent excreta. In the event of a suspected VHF of tropical origin, control measures such as isolation in a negative-pressure room and the use of high-efficiency particulate-arresting (HEPA) respirators, gloves, and gowns is warranted. For contagious VHFs such as Marburg, Lassa, Ebola, or Crimean-Congo hemorrhagic fever, public health officials and the Centers for Disease Control and Prevention (CDC) should be immediately notified. If an intentional bioterrorism is suspected, local law-enforcement officials, the Federal Bureau of Investigation (FBI), and the CDC should be notified. The CDC Emergency Response Hotline is 1-770-488-7100.

Yellow Fever

This acute zoonotic flavivirus has a jungle monkey reservoir and its equatorial belt lies in South/Central America and Africa, yet it is notably absent in Asia throughout recorded history. Recent outbreaks in Bolivia, Kenya, and Nigeria indicate that it could reappear in the southern United States, where the mosquito vector *Aedes aegypti* (also transmitting dengue) is endemic. It is rare among travelers, because the yellow fever vaccination is mandatory in endemic areas. Outbreaks are common near tourist areas and may occur among nonimmunized adventure travelers who travel to endemic areas. Yellow fever ranges in severity from an undifferentiated self-limited flulike illness to a hemorrhagic fever fatal in 50 percent of cases. After an incubation of 3 to 6 days, patients develop fever, headache, myalgias, conjunctival injection, abdominal pain, prostration, facial flushing, and relative bradycardia. In most cases patients recover, but among others fever remission lasts a few hours to several days, followed by renewed high fever, vomiting, headache, back pain, shock, multiorgan failure, and bleeding diathesis. The classic presentation is a triad of jaundice, black emesis and albuminuria. In severe cases, hypotension, shock, and metabolic acidosis may develop, complicated by myocardial dysfunction and arrhythmias. Confusion, seizures, and coma are common in the late stages of the illness and death can occur within 7 to 10 days after onset. The diagnosis is primarily clinical, although confirmation is possible through virus identification or rising antibody titers in recovering patients. Leukopenia and albuminuria are typical, direct bilirubin levels rise, and liver enzymes are elevated for several days during when azotemia and oliguria ensue. Treatment is generally supportive, with fluid replacement and management of hematologic complications.

Lassa Fever

This arenavirus was first detected in Lassa, Nigeria, and is spread by contact with bush rat excreta. Epidemics have been associated with civil unrest and forced migration of populations. Although mostly found in rural West Africa, it has been exported to Europe and North America by infected patients and is a concern because it is highly contagious via close contact with blood and body fluids. The likelihood of travelers becoming infected is low because it is primarily a disease of rural communities where bush rats thrive.

After an incubation period of 3 to 16 days, the disease presents as a viral syndrome with insidious onset of fever, malaise, headache, sore throat, retrosternal chest pain, back pain, abdominal pain, and myalgias. Varied and nonspecific symptoms persist for 4 to 6 days, when the patient suddenly deteriorates and becomes gravely ill. Among those infected, 80 percent have few or no symptoms and 20 percent have severe multiorgan disease. The main features are high fever, severe prostration out of proportion to the fever, severe sore throat with dysphagia and yellow-white exudates, abdominal pain, diarrhea, and vomiting. Diagnosis is made by ELISA serology, culture, or immunohistochemistry, and should be carried out in a secure laboratory. Similar to Ebola, strict isolation and personal protection must be taken.

Treatment is largely supportive, but patients with severe disease may benefit from early treatment with ribavirin IV or PO, 30 mg/kg (max 2 g) initially, then 16 mg/kg (max 1 g) q6h for 4 days, followed by 8 mg/kg (max 500 mg) q6h for 6 days. Death, primarily from septic shock and multiorgan failure, can occur after 7 to 14 days. Survivors will defervesce within 10 days of disease onset and, except for sensorineural deafness, can make a complete recovery.

Diseases Commonly Associated with Fever and CNS Involvement

Febrile patients with acute mental status changes, headache (Table 206-9), nuchal rigidity and focal neurologic signs may have a number of serious infections. CNS involvement with fever in travelers returning from malaria-endemic regions requires emergent diagnosis and presumptive treatment for both malaria and meningitis. The differential diagnosis for fever with CNS involvement includes malaria, bacterial meningitis, TB, typhoid fever, rickettsial infections, and rabies. Other causes are viral encephalitides, including Japanese and West Nile encephalitis, which often present similarly.

Patients with altered mental status suspected of tropical illness may demonstrate coma, decreased level of consciousness, meningeal signs, or seizures. While seizures should arouse suspicion of cerebral malaria, cysticercosis should be suspected among those with long-term residence in Latin America with a first-time seizure. Meningococcal meningitis occurs with regularity in sub-Saharan Africa along the "meningitis belt." Aseptic meningitis may be caused by enteroviruses or, less commonly, by typhoid fever, leptospirosis, or rickettsiae. Encephalitis may be caused by an arboviral infection, such as Japanese B encephalitis.

JAPANESE ENCEPHALITIS This *Culex* mosquito-borne flavivirus occurs in an epidemic or sporadic pattern over large areas of Asia and the western Pacific. It is rarely transmitted to U.S.-bound travelers, because the vector breeds primarily in rural rice-paddy fields. Infected patients present with a sudden high fever, headache, nuchal rigidity, vomiting, and seizures (especially infants) after the incubation time of 5 to 15 days. A variety of pyramidal and extrapyramidal signs may develop soon after fever. If the outcome is fatal, it usually occurs in the first 10 days. Diagnosis is based on clinical suspicion, although virus can be isolated from CSF and antibody titers can rise. Treatment is supportive with intravenous fluid and electrolyte management, assisted respiration if necessary, anticonvulsants, and neuropsychiatric consultation during convalescence. Recovery may take months and varying degrees of residual neurologic damage may persist indefinitely. Immunization is recommended for travelers to rural, endemic regions in Asia.

CYSTICERCOSIS Cysticercosis is a systemic illness caused by dissemination of the larval form of the pork tapeworm, *Taenia solium*. The disease affects an estimated 50 million people worldwide. Endemic areas include Mexico, Latin America, sub-Saharan Africa, India, and East Asia. The incidence in the U.S. is increasing due to increased immigration from endemic areas and increased travel to endemic areas. Humans are definitive *T. solium* hosts and carry an in-

testinal adult tapeworm. Intermittent fecal shedding of egg-containing proglottids or *T. solium* eggs are ingested by the intermediate host (typically pigs). When undercooked pork is consumed, an intestinal tapeworm will again be formed, completing the life cycle of the worm.

Infestation can occur in almost any tissue. Involvement of the central nervous system, known as neurocysticercosis (NCC), is the most clinically important manifestation of the disease and may present with dramatic CNS findings. NCC is a leading cause of adult-onset seizures worldwide and an estimated 1000 new cases are diagnosed per year in the U.S. NCC is frequently asymptomatic. Symptoms are generally similar to those found with other intracranial mass lesions, and may include seizures, obstructive hydrocephalus, meningoencephalitis, and vascular accidents. Patients may also present with seizures, chronic headache, nausea and vomiting, and visual or mental status changes.

Brain CT scan is the first-line imaging study, followed by MRI as an adjunctive study. Noncontrast CT scan commonly shows calcifications of inactive disease, and can reveal mass effect or hydrocephalus. Anthelmintic agents are the mainstay of treatment, although steroids should be used in those with significant pretreatment encephalitis, hydrocephalus, or vasculitis to avoid inflammation as cysts involute, leading to worsening clinical status.

Diseases Commonly Associated with Chronic Fever

Chronic or relapsing fever lasting beyond 3 weeks following travel should first be evaluated for non-travel-related infections such as pneumonia, endocarditis, cholangitis, as well as noninfectious causes such as occult neoplasms, collagen vascular disorders (e.g., systemic lupus erythematosus and rheumatic fever), and inflammatory diseases (e.g., gout, sarcoidosis, inflammatory bowel disease). Tropical illnesses that cause chronic fever can include protozoal infections (such as trypanosomiasis, leishmaniasis, malaria), typhoid or paratyphoid and TB of the bone, CNS, gut, joints, lungs, peritoneum, and urinary tract (Table 206-10).

TABLE 206-10 Selected Causes of Chronic and Relapsing Fevers

Etiological Organism	Organism Species
Bacterial	Bartonellosis Brucellosis Leptospirosis Q fever Relapsing fever Syphilis Tuberculosis Tularemia Typhoid fever
Fungal	Blastomycosis Coccidioidomycosis Cryptococcosis Histoplasmosis

HUMAN AFRICAN TRYPANOSOMIASIS (AFRICAN SLEEPING SICKNESS) Two kinds of trypanosomiasis exist in sub-Saharan Africa and South/Central America with different vectors, clinical manifestations and therapies. Sleeping sickness is caused by the two identical endemic protozoan subspecies, *Trypanosoma brucei gambiense* and *T. brucei rhodesiense*, transmitted by the aggressive tsetse fly, which is indigenous only to vegetation near rivers, lakes, forests, and wooded savannah. Approximately 30 cases were imported to the United States in the last century, primarily from East Africa, and is a low risk to U.S. travelers, with 1 to 2 cases imported each year, usually following intensive fly exposure during game-park exposure. After a bite, a localized inflammatory reaction occurs followed in 2 to 3 days by a painless chancre that increases in size for 2 to 3 weeks, and then gradually regresses. Trypomastigotes mature and divide in the blood and lymph after the development of the chancre and cause intermittent fever unresponsive to antimalarials. Malaise, rash, wasting, and eventual CNS involvement occurs, causing behavioral and neurologic changes, encephalitis, coma, and death. Other complications include hemolysis, anemia, pancarditis, and meningoencephalitis.

Lab findings include anemia, hypergammaglobulinemia, elevated ESR, thrombocytopenia, and hypoalbuminemia. Diagnosis is made by rapid evaluation of blood smears for the mobile parasite. Organisms can also be identified by aspiration of lymph nodes, chancres, bone marrow or by CSF examination. Treatment for *T. brucei rhodesiense* when CSF is normal (stage 1) is suramin and for *T. gambiense* is eflornithine. Treatment with CNS involvement (stage 2) first involves treating underlying health concerns, eliminating parasites outside the CNS with suramin, and then eradicating parasites in the brain with melarsoprol, which is the only available agent to treat the advanced stage (however, for *T. gambiense* eflornithine can be used). Melarsoprol is given as 3.6 mg/kg IV qd for 3 days. The three dose treatment is repeated after 7 days and again after 10 to 21 days.

AMERICAN TRYPANOSOMIASIS (CHAGAS DISEASE) The protozoan *T. cruzi* is found in up to 5 percent of emigrants from endemic parts of Latin America and is reported as far north as Texas. It is spread by the reduviid, "kissing" or "assassin" bug, typically biting nocturnally after emerging from rural adobe walls or thatched roofs. Among travelers, it is rare. It causes an acute illness and, commonly, an asymptomatic infection with complications arising years later in the heart and GI tract. It is transmitted during a blood meal when the bug defecates trypanosome-infected feces around the meal site, causing a local inflammatory reaction and trypanosome inoculation after the host rubs the organism into the bite wound, or into adjacent mucus membranes or conjunctiva. Infection can also be acquired by blood transfusion, lab accidents, and congenitally.

Unilateral periorbital edema (Romana sign) or painful cutaneous edema at the site of skin penetration (chagoma) is followed by a toxemic phase with parasitemia causing lymphadenopathy and hepatosplenomegaly. Death can occur in this acute phase, which is generally 2 to 4 weeks but may last up to 3 months, and is often a result of cardiac damage or meningoencephalitis among infants and the immunosuppressed. Patients commonly progress into a long, asymptomatic, latent phase when ganglion cells are gradually destroyed leading to depressed cardiac and GI function. These result in asymptomatic infections or complications years later such as myocarditis, dysrhythmias, and sudden death. Chronic cardiomyopathy, megaesophagus, or megacolon occur. Chagas induced heart disease is the leading form of congestive heart failure (CHF) in much of Latin America. The acute diagnosis is from peripheral smears demonstrating motile parasites, blood culture, or muscle biopsy. In the chronic phase, serologic tests or tissue biopsy are useful. Several drugs eliminate the parasite in the acute phase, including nifurtimox (Lampit), 8 to 10 mg/kg per d PO divided qid X 120 days, other nitrofurazones, or primaquine.

LEISHMANIASIS (VISCERAL) *Leishmania* is an intracellular protozoan transmitted by *Lutzomyia* or *Phlebotomus* sandflies. It is scat-

tered throughout rural Africa, Asia, the Mediterranean basin, and Central/South America, and occasionally leads to outbreaks, such as in Brazil, India, and the Sudan, which place resident expatriates and travelers at risk. There have been several hundred cases among U.S. military personnel and their dependents in the last four decades. It is a low risk to most travelers, although European travelers to nonendemic Mediterranean nations occasionally export cases, as do 30 to 40 U.S. travelers each year, who mostly export the cutaneous form and rarely the visceral form. HIV-infected persons are at risk to both forms. Physicians should suspect leishmania among military and their families living proximal to jungles, adventure travelers, field biologists, and emigrants from endemic zones.

The infecting species determines the pathology ranging from a localized self-healing lesion to widespread, persistent and potentially destructive disease. Four major clinical syndromes are recognized (Table 206-11).

The most important diagnostic information is patient's origin and travel itinerary because endemic areas suggest the infection type. Definitive diagnosis requires isolating motile extracellular parasites aspirated from bone marrow, spleen or lymph nodes, or on smears or sections taken from the ulcer edge by punch biopsy. Stained smears can show nonmotile intracellular amastigotes (Leishman-Donovan bodies) from bone marrow, spleen, liver, lymph nodes, or blood.

Visceral disease should be treated with the effective pentavalent antimonials, either sodium stibogluconate, single daily dose of 20 mg/kg per d IM or IV for 20 to 30 days [available from the CDC (<http://www.cdc.gov/ncidod/srp/drugservice/immuodrugs.htm>, or 1-404-639-3670 or after hours, 1-404-639-2888)], or meglumine antimonate same dose and duration of treatment. Oral miltefosine (hexadecylphosphocholine) is also effective. Relapses with drug-resistant disease are treated with amphotericin B or pentamidine, which are not used routinely because of toxicity. Amphotericin is useful against pentavalent antimony-resistant mucocutaneous and visceral leishmania.

Diseases Commonly Associated with Abdominal and Urinary Complaints

Illnesses causing abdominal pain and diarrhea are common among world travelers, because of infecting bacteria, viruses, soil-transmitted helminths, and other parasites. Most of these infections are caused by the consumption of undercooked or fecal-contaminated foods, and are preventable by adequate hygiene, potable water, and careful food preparation.

SCHISTOSOMIASIS (BILHARZIASIS OR SNAIL FEVER) This blood fluke, found in Africa, the Middle East, South America, and Asia, infects more than 200 million people worldwide, with 20 million people suffering severe consequences. It should be suspected among travelers following long exposure to endemic zones. For most short-term trav-

TABLE 206-11 Clinical Syndromes of Leishmaniasis

<i>Visceral leishmaniasis</i> (Kala-azar or Black fever): the most devastating and fatal form caused by <i>L. donovani</i> . A progressive, chronic and systemic disease with high mortality if untreated but with a good prognosis if provided adequate care. Fatality is a result of secondary infections such as TB, pneumonia, and dysentery. It is typified by the pentad of fever, weight loss, hepatosplenomegaly, pancytopenia, and hypergammaglobulinemia.
<i>Cutaneous leishmaniasis</i> : old world disease is the most common form, and found in most of the world, whereas new world disease is only found in the Americas.
<i>Mucocutaneous leishmaniasis</i> (espundia): chronic and relentless disease complicated by secondary infections and pneumonia.
<i>Diffuse cutaneous leishmaniasis</i> : typically chronic, difficult to treat, and with few resulting deaths.

elers, the risk is generally low, although significant outbreaks now occur among adventure tourists, Peace Corps workers, and patients who swim in infested streams and lakes. The larvae are released into freshwater by snails which are intermediate hosts. Infection occurs by tiny, free-swimming cercariae that penetrate wet, unbroken skin or are ingested from slow-moving fresh water. Brief or even single exposures like washing or wading can cause infection in previously unexposed asymptomatic expatriates. Following inoculation an immediate cercarial allergic and pruritic dermatitis occurs which can last days. In the following 4 to 8 weeks, fever occurs, accompanied by headache, cough, urticaria, diarrhea, hepatosplenomegaly and hypereosinophilia (Katayama fever). Worms mature into adults in the venous blood and for the next 30 to 40 years deposit eggs into selective body tissues (*Schistosoma haematobium* in the bladder and *S. mansoni* and *S. japonicum* in the GI tract).

Symptoms follow granulomatous scarring from eggs deposited throughout the brain, skin, liver, and GI tract, and depend on the infecting species. CNS symptoms such as seizures, paralysis and acute transverse myelitis can occur if eggs ectopically migrate. *S. haematobium* leads to dysuria, frequency, and terminal hematuria, and can cause bladder scarring, calcification, and squamous cell carcinoma. *S. japonicum* and *S. mansoni* lead to hepatosplenomegaly, periportal fibrosis, hepatic granulomas, and jaundice. These two species also can cause diarrhea, abdominal cramps, acute abdominal pain, and late in the disease course, portal hypertension. *S. dermatidis*, a non-human-infecting schistosome, has cercariae that only penetrate the superficial skin, causing an irritation known as swimmer's itch.

Diagnosis is by detecting eosinophilia, and microscopic identification of eggs in the first-morning urine or stool, or in a biopsy specimen. Serologic methods such as ELISA plus Western blot may be also used. Treatment should be offered to symptomatic patients and seropositive travelers. Praziquantel 20 mg/kg PO bid for 1 day is effective for all *Schistosoma* parasites with a 70 to 85 percent cure rate. Oxamniquine 15 mg/kg in a single dose is effective against *S. mansoni* and for *S. haematobium* metrifonate 10 mg/kg PO on three occasions with intervals of 2 to 4 weeks is effective. For swimmer's itch, no treatment is required.

CLONORCHIASIS (CHINESE OR ORIENTAL LIVER FLUKE) This trematoid disease of the bile ducts is caused by *Clonorchis sinensis* and follows ingestion of poorly cooked freshwater fish containing encysted larvae. Travelers are at low risk despite the tremendous prevalence among those living in endemic zones such as Southeast Asia. Once ingested, larvae mature into adults, migrate to bile ducts, survive for 30 or more years, and cause fibrosis. The extent of pathology is related to parasite burden, and among the millions infected, only few are symptomatic. Acute symptoms include anorexia and diarrhea, and may progress to chronic bile duct obstruction, liver tenderness and/or jaundice, and in advanced cases, biliary cirrhosis and cholangiocarcinoma. Diagnosis is made by detecting the characteristic embryonated eggs in stool or duodenal aspirate and eosinophilia is common. Serologic tests using ELISA have 70 percent sensitivity and computed tomography (CT) or abdominal ultrasonography exams are useful. Treatment of choice is praziquantel in 25 mg/kg PO tid for three doses.

Diseases Commonly Associated with Abdominal Pain and Diarrhea

Diarrhea and gastroenteritis are the most common travel ailments, affecting up to one-half of travelers (Table 206-12). Gastroenteritis can be accompanied by fever, flatulence, nausea, emesis and abdominal pain which is usually spasmodic and colicky with the exception of *Campylobacter jejuni*, which causes severe and constant pain, and cholera causing somatic muscle cramps. Nonbloody gastroenteritis is usually caused by bacteria or bacterial toxins, whereas dysentery usu-

TABLE 206-12 Common Infectious Diseases Causing Diarrhea Among Travelers

Cause	Organism	Comments
Acute (duration <2 weeks)		
Viral	Norwalk-like virus Rotaviruses Enteroviruses	Often not diagnosed; may account for 5–10% of acute traveler's diarrhea
Bacterial	<i>Escherichia coli</i> (enterotoxigenic or enteroaggregative) <i>Campylobacter jejuni</i> <i>Salmonella</i> <i>Shigella</i> <i>Vibrio</i>	Most common identified cause of acute traveler's diarrhea; 50–70%
Parasitic	<i>Clostridium difficile</i> <i>Giardia lamblia</i> <i>Cryptosporidium parvum</i> <i>Entamoeba histolytica</i> <i>Cyclospora cayetanensis</i> <i>Isopora belli</i> <i>Balantidium coli</i> <i>Trichinella spiralis</i>	Accounts of <1–5% of acute traveler's diarrhea
Chronic or persistent (duration >2 to 4 weeks)		
Bacterial	See above	Rare cause of chronic diarrhea
Parasitic		
Microsporidial	<i>Enterocytozoon bienersi</i> <i>Encephalitozoon intestinalis</i>	Almost exclusively in immunocompromised
Protozoal	<i>Giardia lamblia</i> <i>Entamoeba histolytica</i>	Most commonly identified cause Bloody diarrhea with fever; fecal white blood cell count may be present
Helminthic	<i>Trichuris trichiura</i> <i>Strongyloides stercoralis</i> <i>Fasciolopsis buski</i> <i>Schistosoma</i>	Rarely associated with chronic diarrhea; usually in persons with heavy parasite burdens

ally results from toxigenic and invasive bacteria such as *Shigella*, *Salmonella*, *Campylobacter*, *Aeromonas*, *Escherichia coli*, or *E. histolytica* (Table 206-13). Acute abdominal pain among travelers should first be considered to be caused by nontravel causes with an expanded travel-based differential diagnosis. For example, intestinal obstruction that causes colicky pain as a consequence of heavy infestation by *Ascaris lumbricoides* can cause pain similar to acute appendicitis, and attempts should be made to distinguish between diagnoses. Chap. 83 more specifically addresses the etiology and workup of routine diarrheal illnesses.

AMEBIASIS Amebiasis is a fecal-oral parasite found worldwide. Pathogenic species such as *Entamoeba histolytica* are endemic to Asia, Africa, and Latin America. Amebiasis is typically spread by asymptomatic carriers whose excrement contains the encysted organism. Short-term travelers are at low risk, but longer-term travelers such as Peace Corps volunteers are at significant risk. The disease is most severe among young children, the elderly, and pregnant women.

TABLE 206-13 Causes of Diarrhea With and Without Fever or Blood

	With Fever	Without Fever
With blood	Bacillary dysentery <i>Campylobacter</i> enterocolitis <i>Salmonella</i> enterocolitis <i>Escherichia coli</i>	<i>Amebiasis</i> <i>Balantidium coli</i> <i>Schistosoma</i> <i>Trichuris</i>
Without blood	<i>Salmonella</i> enteritis Malaria (especially <i>Plasmodium falciparum</i>) Mild shigellosis <i>Campylobacter</i> infections Almost any infections in a child	<i>Staphylococcus aureus</i> <i>Escherichia coli</i> (enterotoxigenic) <i>Clostridium perfringens</i> Viral infections of the gut Food toxins

Incubation times are typically 1 to 3 weeks for colitis and 2 weeks to several months for liver abscesses. Once cysts are ingested, amebic trophozoites invade the colon wall, lyse tissues, and cause necrotic abscesses. Symptoms range from alternating constipation and diarrhea over 1 to 3 weeks, abdominal pain, fever, dehydration, and weight loss. Extraintestinal metastases can infect the liver, skin, pericardium, lung, and the brain. Complications such as liver abscesses may present acutely with fever, right upper quadrant pain, or chronic, vague abdominal pain accompanied by weight loss. Hepatic abscesses can be fatal if rupture occurs.

Stool ova and parasites examination (O + P) is diagnostic, and organisms are found either as motile trophozoites or cysts. Stool wet mount should be performed within 30 min of specimen collection to detect trophozoites, and fixative (polyvinyl alcohol) should be used to identify cysts. It can be difficult to differentiate pathogenic organisms (*E. histolytica*) from those benign (*E. coli*) without use of stool antigen-detection tests. Serology for elevated antibody titers is 90 percent sensitive for extraintestinal disease and 80 percent sensitive for invasive colon disease. Ultrasonography or CT scans may be useful to identify hepatic abscesses. Treatment of asymptomatic cyst passers includes either iodoquinol 650 mg PO tid for 20 days, paromomycin 500 mg PO tid for 7 days, or diloxanide furoate 500 mg PO tid for 10 days. For symptomatic disease, choices include metronidazole 500 to 750 mg PO tid for 10 days or tinidazole 1 g PO bid for 3 days, followed by either iodoquinol or paromomycin in the doses and duration noted before. For liver abscess, metronidazole 750 mg PO or IV tid for 10 days followed by paromomycin 500 mg PO tid for 7 days is given.

GIARDIASIS *Giardia lamblia* is a flagellated protozoan infecting the small intestine and biliary tree. It is distributed worldwide and is food- or waterborne by fecal contamination with encysted parasites. It is common to rural areas with poor sanitation and impure surface water, but has also occurred in day-care settings in the United States. In Eastern Europe, it is a common cause of traveler's diarrhea and is found at camping sites and rural swimming areas. Long-term residents of tropical nations are at high risk; short-term travelers are also at risk. Ingested parasites reside in the duodenum, and may lead to malabsorption because of duodenal microvilli obstruction. Symptoms include abdominal cramping, flatulence, and foul-smelling, watery diarrhea without blood or mucus. Chronic infections cause weight loss and anemia, and a common complication is lactose intolerance. Diagnosis is by stool ova and parasites showing either motile (trophozoites) or cysts. A "string test" (Entero-Test) can obtain duodenal samples but is cumbersome. Serology can demonstrate *Giardia* antigen in stool with good sensitivity and specificity. Treatment is with metronidazole (250 mg PO tid for 3 to 5 days), tinidazole (2 g PO for 1 dose), quinacrine (100 mg PO tid for 5 days), or furazolidone (100 mg PO

qid for 7 days) for children. It should be noted that treatment is not always successful regardless of drug used.

CHOLERA Cholera is an acute diarrheal disease caused by the bacterium *Vibrio cholerae*. It is endemic and epidemic to many tropical nations. Most recently, South America, which was relatively free of epidemic disease, has seen a marked increase among travelers and its nationals. Epidemics occur after flooding or acute population displacement with disruption of the water-sanitation system. Transmission is by fecal contamination of water or food (including raw or poorly cooked seafood and shellfish). Significant bacterial ingestion is required to cause symptoms. The incubation time is 2 to 3 days and symptoms follow sodium pump inhibition by the cholera toxin. Infection is usually mild, but can be life-threatening, particularly among vulnerable populations, such as malnourished children, refugees, and those with chronic illness. Another group at risk are patients with achlorhydria or those using medications decreasing gastric acidity. Approximately 80 clinical cases of cholera are imported into the United States each year, although there are many more suspected asymptomatic carriers.¹⁰

Severe disease is characterized by profuse, usually painless, watery diarrhea ("rice water stools"), severe dehydration causing "dishwater hands," vomiting, leg cramps, and occasionally fever. Rapid fluid loss (up to 15 L per d) leads to extreme dehydration and shock. Without aggressive rehydration, death can occur within hours. With proper fluid resuscitation, most patients can recover uneventfully. Diagnosis is clinical and, when suspected, a rectal swab or stool specimen should be sent to a reference lab for culture confirmation. Aggressive fluid resuscitation with oral rehydration solution or intravenous fluids is imperative, accompanied by correction of metabolic acidosis and hypokalemia. Tetracycline 500 mg PO qid (drug of choice, although resistance exists) or in children, TMP-SMX 5 mg/25 mg/kg PO bid for 3 days can shorten the illness course, diminish vomiting, lessen volume resuscitation needs, and ensure that bacteria are eradicated from stool. Other antimicrobial choices include erythromycin, ciprofloxacin, and norfloxacin. Though secondary transmission is rare, close contacts should be given a tetracycline as a prophylaxis.

ASCARIS (ROUNDWORM) *Ascaris himbricoides* is the most common geohelminthic infection. The risk to short-term travelers is low, yet it should be suspected following ingestion of street vendor foods or vegetables fertilized by "night soil" (human feces) or animal feces. Eggs survive for years in moist soil and transmission is typically fecal-oral or via poorly cooked food. Symptoms are usually minimal; however, a dry cough or pneumonia may occur as young worms are expectorated and migrate from the lungs to the esophagus and gut. A large worm burden can lead to malnutrition, weakness, and a mass of worms may lead to bowel obstruction. Wandering ascaris also traverse internal organs leading to biliary obstruction, hepatic abscess, acute pancreatitis, acute appendicitis, or hypersensitivity pneumonitis. For details of diagnosis and treatment, see Chap. 149.

ENTEROBIASIS (PINWORM, SEATWORM) *Enterobiasis vermicularis* is common tropical disease caused by a small intestinal parasite transmitted fecal-orally, and often acquired from contaminated objects such as toys, utensils, and bedding. It is a common disease among U.S. children, and is more likely to be peridomestic rather than following tropical travel. For more discussion of diagnosis and treatment, see Chap. 149.

TRICHURIS (WHIPWORM DISEASE) Whipworm (*Trichuris trichiura*) is a nematode parasite of the large intestine distributed globally but most heavily in the tropics. It is a low risk among short-term travelers, but long-term travelers, former tropical residents, and visitors from the tropics are at high risk. It is obtained by ingesting contaminated soil or vegetables and is not transmissible from person to person. See Chap. 149 for diagnosis and treatment.

HOOKWORM Hookworm is a common chronic nematoidal infection caused by *Ancylostoma duodenale* and *Necator americanus*, which are globally distributed but most heavily in the tropics and subtropics. Because symptoms require large worm burdens, it is a low risk among short-term travelers. Hookworm is a significant global health problem, causing chronic, severe anemia among children. Transmission is by direct skin contact with soil contaminated by human feces, often in children with poor footwear exposed to raw sewage, allowing filariform larvae to penetrate the skin. See Chap. 149 for further diagnosis and treatment.

CESTODES (TAPEWORMS) Among the cestodes, taeniasis and cysticercosis are the most pathologic. Infections occur worldwide, but especially in the tropics, and suspicion should be raised among children, the mentally disabled, and immigrants or visitors from endemic nations. Risk to travelers is low but is increased with consumption of undercooked pork, fish, or beef. For further discussion of diagnosis and treatment, see Chap. 149.

Pork tapeworm (*Taenia solium*) infection can also cause cysticercosis when cysts (small sacs with developing worms) form throughout the body, including the brain, causing pathology depending on their location. For further discussion of cysticercosis, see Chap. 149.

STRONGYLOIDES *Strongyloides stercoralis* is a helminthic infection of the small intestine with worldwide distribution, but is most commonly found in the humid tropics. It is common in overseas military personnel, refugees, or immigrants. Among short-term travelers, the risk is low. Almost all infections cause minimal or no symptoms, yet it can be serious among those immunosuppressed or malnourished. For further discussion, see Chap. 149.

Diseases Commonly Associated with Skin or Eye Complaints

These complaints among travelers are common, nonspecific, and have many etiologies. In the evaluation of skin complaints in the international traveler, applying a few basic principles may simplify the diagnosis and management. For example, travel-related skin disease is generally caused by one of three etiologies: 1) exacerbations of previous conditions (e.g., atopic dermatitis, psoriasis); 2) environmental conditions (e.g., photosensitivity, contact allergies); or 3) infective organisms causing infestations or infections.¹⁰ The distribution and timing of the dermatosis may aid diagnosis of rashes associated with system illness (Table 206-14).¹¹ Among rashes reported by travelers, most are minor problems such as sunburn, phototoxic/sensitivity reactions, insect bites, prickly heat, and are often self-limiting and necessitate symptomatic care. It has been suggested the top ten tropical travel dermatoses requiring specific therapy include: cutaneous larva migrans, pyoderma due to staphylococcal or streptococcal ecthyma, arthropod reactive dermatoses, myiasis, tungiasis, urticaria, febrile syndromes with rash, cutaneous leishmaniasis, scabies, and fungal infections.¹² The risk of serious conditions tends to increase with the amount of time spent overseas and thus, short-term travelers rarely contract dermatoses such as filariasis, Buruli ulcer, yaws, and Hansen disease. To further aid diagnosis, travelers with dermatoses can fit into 5 syndromic and morphological categories (Table 206-15).

Management includes arranging biopsy for patients with chronic ulcerative lesions. Beware of the rare patient presenting with anxiety or delusions of parasitosis regardless of travel history. Hereafter are presented dermatoses associated with tropical exposures that frequently prompt patients to seek ED attention.

ONCHOCERCIASIS (RIVER BLINDNESS) River blindness is a chronic, nonfatal filarial disease leading to subcutaneous skin changes and blindness. It is caused by a *Onchocerca volvulus*, a nematode

TABLE 206-14 Cutaneous Manifestations of Selected Infections

Appearance of Lesion	Possible Diagnosis
Maculopapular rash	Dengue fever Viral hemorrhagic fevers Leptospirosis Acute HIV infection
Erythema chronicum migrans	Lyme disease
Rose spots	Typhoid fever
Pustules	Disseminated gonococcal infection
Petechiae, ecchymoses, hemorrhage	Meningococcemia Dengue fever Viral hemorrhagic fevers Yellow fever Rocky Mountain spotted fever Epidemic louse-borne typhus Leptospirosis
Eschar	Tick or scrub typhus Anthrax
Ulcer	Tularemia Cutaneous diphtheria
Urticaria	Helminthic infections

Source: MacLean JD, Lalande RG, Ward B: Fever from the tropics, section 5, in *Travel Medicine Advisor*. Atlanta, GA: American Health Consultants, 1994, p. 271.

transmitted by the female black fly, *Simulium* sp., found near fast-moving rivers in parts of Central/South America and mostly equatorial Africa. Despite global eradication campaigns, the disease burden is increasing. It should be suspected among long-term travelers, immigrants from endemic zones, and, rarely, among short-term adventure travelers. Early treatment can prevent blindness and reduce systemic spread, because the incubation period from fly bite to microfilariae appearing in skin is often more than a year. Symptoms include intractable pruritus, altered skin pigmentation, skin nodules (typically found on the head and shoulders in South America, and pelvic girdle and lower extremities in Africa), lymphadenitis, and gradual visual impairment leading to blindness. Adult female worms reside in 2-3 cm painless nodules in skin and bones near joints, and release microfilariae that migrate through the skin, causing intense pruritus when they die, causing chronic dermatitis, edema, and skin atrophy. Skin pigment changes result in "leopard skin," while loose pelvic skin is called "hanging groin." Blindness is a result of microfilariae migrating to the eye, invading it and causing permanent damage when they die. Diagnosis is made by identification of microfilariae from a fresh skin

TABLE 206-15 Syndromic Categories of Travel-Related Dermatoses with Select Examples

Fever and rash (petechial or hemorrhagic): dengue, arboviruses, rickettsial infections (e.g., scrub typhus), meningococcemia, leptospirosis, malaria, and erythema multiforme cause by drug reaction or common infection
Papular eruptions: insect bites, persistent lesions (chiggers), scabies, allergic drug reactions, cercarial dermatitis (swimmers), <i>Pseudomonas</i> folliculitis (hot-tubbing), onchocerciasis (long-term travel)
Persistent nodules: furunculosis, myiasis (moving lesions), chancroid, syphilis, systemic parasites/fungi
Migratory swellings or skin lesions: cutaneous larva migrans, strongyloidiasis (fast-moving and often on the buttocks), urticaria from various causes, and <i>Loa loa</i> (rarely)
Ulcerative lesions: pyoderma, spider bites, chancroid and syphilis, cutaneous leishmaniasis

SECTION 16 ■ EMERGENCY MEDICINE IN UNIQUE ENVIRONMENTS

biopsy, nodule biopsies, or in the urine. Slit-lamp examination may reveal microfilariae in the cornea, anterior chamber, or the vitreous. Treatment is one dose of ivermectin 150 μ g/kg PO, which does not kill the adult worm, but when repeatedly dosed every 6 to 12 months, reduces morbidity by killing microfilariae, suppressing microfilariae release from adults, and preventing spread to eyes and skin. Diethylcarbamazine citrate and suramin (which can kill adult worms and microfilariae) have been used but because of their potentially serious side effects, they should be avoided. Surgical removal of nodules can reduce symptoms, the incidence of worms, and if removed from the frontal scalp can help prevent progression of visual impairment and blindness.

DRACUNCZULIASIS (GUINEA WORM) Guinea worm is the largest tissue parasite and is a painful, debilitating nematoid infection of the subcutaneous tissues. It is found in sub-Saharan Africa and Asia, and especially in dry climates. While risk among short-term travelers is low, it can occur among long-term residents in rural communities or among nonvoluntary migrants such as refugees. Guinea worm remains endemic in isolated regions in Africa such as southern Sudan, although international efforts are underway and are expected to successfully eradicate the parasite. The infection is acquired from ingestion of water contaminated by the larvae within its intermediate host, a minute crustacean copepod (*Cyclops* spp.). A year after infection, a painful swelling starts on a lower extremity (typically the foot). After 1 week, a blister appears and upon rupture, a 60-100 cm gravid female worm discharges larvae upon water contact. Fever, itching, nausea, vomiting, and diarrhea may accompany sore formation. Diagnosis is made by identifying the adult worm in the sore or finding microscopic larvae in which the sore is bathed. Although no drug exists to definitively kill the parasite, ivermectin and metronidazole with corticosteroids may be of value. Tetanus toxoid should be administered, antibiotics used for secondary wound infection, and a local antibacterial ointment and occlusive bandage should be used over the lesion. The worm can be removed slowly over a week or longer by attaching it to a thread, pulling gently a little more each day and rolling the worm around a small appliance or stick. Because the worm may measure more than a meter, care must be taken not to break it as it is removed. Aseptic surgical excision can be used to remove the adult worm if done before emergence. Prognosis is usually good unless the ulcer made by the worm becomes infected.

LOA LOA (EYE WORM) Loiasis is a filarial nematode confined to the rain forests of western and central Africa. It is a low risk to short-term travelers but should be suspected among immigrants, refugees, visiting nationals, and expatriates living several months or more in endemic zones. Among such travelers, worm burden is usually low and symptoms are related to hypersensitivity syndromes and not serious disease. The adult worms inhabit subcutaneous tissues, move about freely and can live for up to 18 years after the patient's last possible exposure. They are spread from the bite of the *Chrysops* fly and take 1 year to mature. Infections are usually asymptomatic; however, at times, infections cause painful or itchy subcutaneous swellings near the face and extremities known as Calabar swellings. The most dramatic presentation is when a worm passes across the eye under the conjunctiva, thus coining the disease "eye worm."

Patients will complain of "something in their eye," intense irritation, pain, and swelling of the periorbital tissues. The worm usually moves out of the conjunctiva in 30 min, but it takes usually several days for symptoms to subside.

Diagnosis is made by clinical presentation and by evaluating daytime-drawn blood drawn for distinctively sheathed microfilariae and high-grade eosinophilia. Treatment for microfilariae and adult worms is diethylcarbamazine citrate (DEC) 2 mg/kg PO tid for 3 weeks. In patients with very high microfilariae counts, DEC may induce sud-

den severe hypersensitivity and encephalitic syndrome, therefore treatment should start with a very small dose in this patient population. Surgical excision is not recommended because multiple worms may not be visible. Subconjunctival worms, however, can be removed from the eye with analgesia and fine tweezers.

CREeping ERUPTION (CUTANEOUS LARVA MIGRANS) This erythematous "creeping eruption" commonly occurs among tropical travelers and beach resort vacationers who walk barefoot or sit in beach sand contaminated by dog feces harboring the parasite *Ancylostoma braziliense*.¹³ The lesions are typically slow moving, tracking and serpiginous, and are a result of an inflammatory reaction from the worm, which is unable to complete its growth cycle in humans (it is only an effective parasite of dogs or cats). Pruritus causes sleeplessness and restlessness, and diagnosis is based on clinical presentation and eosinophilia. Treatment consists of thiabendazole 10 percent suspension topically qid for 2 to 7 days, and liquid nitrogen freezing or surgical excision is not recommended because of scarring. If a patient has multiple lesions, systemic treatment with albendazole 400 mg PO bid for 5 days is effective.

CUTANEOUS LEISHMANIASIS This is the most important cause of chronic skin ulceration in the world and is spread by sandflies in tropical and subtropical regions of Latin America, the Middle East, and Asia. This should be suspected among travelers such as military personnel, biologists, ecotourists, and adventure travelers, and should be part of the differential diagnosis of cutaneous ulcers among travelers, foreign visitors, and immigrants from endemic areas. Although there are a variety of subtypes causing varying infections, the common presentation is of a small papule slowly enlarging and forming a painless shallow skin ulcer with a noticeable rolled edge like a volcano, with a raised edge and central crater, often with a scab. Diagnosis is made by tissue biopsy of the indurated ulcer margin. Many forms are self-limiting, and treatment should be guided by clinical presentation and in concert with infectious disease consultants or CDC's Parasitic Diseases Branch.

BANCROFTIAN FILARIASIS (WUCHERERIA BANCROFTI) This filarial disease is caused by nematodes residing in the subcutaneous tissues and lymphatics for up to 10 years. It is common to the tropics and subtropics (especially Asia), and the risk to short-term travelers is low, although cases are imported by long-term travelers. It is transmitted by flies or mosquitoes permitting larvae to enter the puncture wound during their blood meal. Adult filariae then reside in lymphatics and produce microfilariae that migrate to the bloodstream at night. Because the incubation period is long, first symptoms usually develop after 6 months or later (up to 5 years). The most common symptom is recurrent bouts of "filarial fevers" lasting 2 to 3 weeks, associated with warmth and tenderness overlying a lymphatic vessel, followed by retrograde lymphangitis. The most frequently affected sites are extremities, breasts, and spermatic cord. As more attacks occur, lymphatics are chronically damaged and the most important consequence is the disfiguring and ostracizing condition, elephantiasis. Diagnosis depends on finding the sheathed microfilariae in a nocturnal peripheral blood smear and eosinophilia, as well as hematuria and proteinuria. Treatment is ivermectin 120 μ g/kg PO for one dose which is equivalent to DEC at full dose of 2 mg/kg tid for 3 weeks. This drug is well tolerated but can cause hypersensitivity reactions because of early antigen liberation with fever, headache, nausea, and urticaria. Symptoms can be reduced by starting with a small dose and checking for reactions. Established elephantiasis may be treated surgically.

Diseases Commonly Associated with Pulmonary Complaints

Returning travelers frequently present for persistent cough, sinus congestion, and fever, and such nonspecific symptoms may be caused by travel-related causes such as malaria, typhoid fever, typhus, and dengue. Yet a search should also occur for common respiratory pathogens such as viral causes, *Streptococcus pneumoniae*, and mycoplasma. Risk factors for pulmonary disease include prolonged air travel with recirculation of dry cabin air and exposure to fellow travelers with infectious agents. Long-term travelers are at increased risk for TB which may manifest many years posttravel. The approach to respiratory problems in the returned traveler is no different than nontravel patients with regards to examination, identifying risk factors (e.g., smoking, occupational exposures, and immunization history) and workup. Additionally, travel-related risk factors should be assessed for a variety of pathogens such as viruses (viral hemorrhagic fevers), helminths (*Strongyloides*, *Schistosoma*, *Paragonimus*, *Ascaris*), and protozoa (*Entamoeba histolytica*, *Trypanosoma*, *Leishmania*), which may produce pulmonary symptoms or radiographic infiltrates.

SEVERE ACUTE RESPIRATORY SYNDROME (SARS) SARS has emerged as a serious international health threat since March 2003. Although initial cases were seen in late November 2002 in Guangdong Province in China, they were not reported. The first confirmed cases were in Hong Kong. The disease has since spread to Vietnam, Singapore, Canada, and more recently Taiwan. As of May 28, 2003, a total of 8240 cases with 745 deaths in 28 countries have been reported by WHO.

SARS is caused by a coronavirus. Although the means of transmission has not been fully understood, it is likely to be spread by "droplet infection," that is, through exposure to respiratory droplets spread by a cough or sneeze from an infected person. Laboratory tests can be used to detect the SARS-associated coronavirus (SARS-CoV), including PCR testing, serologic testing, or viral cultures.

Preventative measures are aimed at reducing close contact with infected persons and nosocomial transmission. For those in high risk areas (countries where community spread has been identified), this includes proper travel precautions and enhanced personal hygiene measures, such as hand washing and droplet precautions. Persons who have traveled from high risk areas should monitor their health for at least 10 days following their departure. Should a fever and respiratory symptoms occur—such as cough, shortness of breath, or difficulty breathing—medical assistance should be sought as soon as possible.

TUBERCULOSIS *Mycobacterium tuberculosis* should be considered among patients with appropriate risk factors presenting with cough, fever, diaphoresis, weight loss, and malaise. Risk factors include populations like refugees and immigrants or expatriate workers (especially health care workers) with prolonged exposure to TB-prone populations (e.g., Eastern Europe, Africa, North Korea). Exposure to multidrug-resistant mycobacteria is increased in Russia, Asia, the Dominican Republic, and Argentina. The initial management of suspected TB includes a PPD tuberculin skin test, sputum culture, and chest radiograph. See Chap. 65 for more details.

PARAGONIMUS (LUNG FLUKE DISEASE) *P. westermani* is a trematoid infection primarily affecting the lungs. It is widely distributed, but is mostly found in Far East and Southeast Asia (China is the major endemic site). It is uncommon in short-term travelers, but should be considered among immigrants or long-term residents of Asia suspected for TB, and among travelers indulging in local exotic foods. Humans are infected by swallowing larvae contaminating raw or pickled crustaceans. Incubation lasts 6 to 12 weeks, as larvae mi-

grate from the duodenum to the lungs where they cause cough (sometimes with rusty sputum), pleuritic chest pain, and hemoptysis. Chest pain is often present, and fever with night sweats may occur during early infections causing TB to be incorrectly diagnosed. Chest radiographs will be similar to TB (diffuse segmental infiltrates, nodules, ring cysts, or pleural effusions). Paragonimiasis should be suspected when no sputum smear acid-fast bacilli are found. If parasites do not reach the lung, patients may present with symptoms, depending on fluke location, such as abdominal pain, diarrhea, migrating subcutaneous swelling, blindness, epididymis, testicular inflammation, and a variety of cerebral symptoms. Seizures can occur in response to encysted adults residing intracranially. Diagnosis is made by finding the characteristic eggs in sputum, urine, or stool, or by serological tests such as CF, ELISA, or antigen detection. The treatment of choice is praziquantel 25 mg/kg PO tid for 3 days.

PARASITE-INDUCED BRONCHOSPASM The most common helminths causing pulmonary symptoms are *Ascaris* and *Strongyloides*. A suggestive clinical history includes recent travel and ingestion of local food of uncertain quality. Suspicion should be raised by any new pulmonary symptoms such as cough or wheezing associated with patchy infiltrates on chest radiograph and hypereosinophilia, which indicates a hypersensitivity reaction to migrating parasites. For diagnosis and treatment for each helminth, see previous respective sections.

HIGH-ALTITUDE MEDICAL PROBLEMS Peter H. Hackett

Millions of people annually visit the mountainous areas of the western United States at altitudes over 2440 m (8000 ft). In addition, tens of thousands travel to high-altitude regions in other parts of the world.¹

Physicians working or traveling in or near these locations are likely to encounter high-altitude illness or preexisting conditions that are exacerbated by altitude. Although the focus of this chapter is hypoxia-related problems, patients in the mountain environment also may require care for associated illnesses such as hypothermia, frostbite, trauma, ultraviolet keratitis, dehydration, and lightning injury.

High altitude is a hypoxic environment. Because the concentration of oxygen in the troposphere remains constant at 21 percent, the partial pressure of oxygen decreases as a function of the barometric pressure. In Denver (1610 m), air pressure is 17 percent less than at sea level, and therefore the air contains 17 percent less oxygen. The air of Aspen, Colorado (2438 m), has 26 percent less oxygen, and the barometric pressure on top of Mt. Everest is merely one-third that of sea level. Supplemental oxygen prevents symptoms of altitude illness during hypobaric exposure, and hypoxia, not hypobaria, is responsible for illness.

For the purposes of discussion, altitude may be divided into stages according to physiologic effects. *Intermediate altitude*, 1500 to 2440 m (5000-8000 ft), produces decreased exercise performance and increased alveolar ventilation, without major impairment in arterial oxygen transport. Acute mountain sickness starts to occur at 7000 to 8000 ft and sometimes lower in particularly susceptible individuals. Patients with cardiovascular and pulmonary diseases may become more symptomatic in this range of altitude. *High altitude*, 2440 to 4270 m (8000-14,000 ft), is associated with a decrease in arterial oxygen saturation, and marked hypoxemia may occur during exercise and sleep. Most cases of medical problems associated with altitude occur in this range because of the availability of overnight tourist facilities located at these heights. *Very high altitude*, 4260 to 5490 m (14,000-18,000 ft), is uncommon in the United States but is encountered by visitors to the mountainous regions of South America and the Himalayas. Abrupt ascent can be dangerous, and a period of acclimatization is required to prevent illness. *Extreme altitude*, over 5490 m (18,000 ft) is available only to mountain climbers and is accompanied by severe hypoxemia and hypocapnia. At this height, progressive physiologic deterioration eventually outstrips acclimatization, and sustained human habitation is impossible. Since hypoxemia is maximal during sleep, the sleeping altitude is the critical altitude to consider.

ACCLIMATIZATION TO HIGH ALTITUDE

Persons rendered acutely hypoxic become dizzy, faint, and rapidly unconscious if hypoxic stress is sufficient ($SA_{O_2} < 65\%$). These same individuals, given days to weeks to develop the exact same degree of hypoxia, are able to function quite well. While the fundamental process of this acclimatization takes place in the metabolic machinery of cells and mitochondria, acute "struggle" responses are critical while allowing the cells time to adjust.

Ventilation

Defense of alveolar PO_2 through increased ventilation is the primary initial adaptation. The hypoxic ventilatory response (HVR) is effected by the carotid body, which senses a decrease in arterial oxygenation and inputs to the central respiratory center in the medulla to increase ventilation. The vigor of this inborn response is related to successful acclimatization and increased performance. Respiratory depressants or stimulants may affect HVR, as does chronic hypoxia, which eventually blunts the response. A low hypoxic drive may allow extreme hypoxemia to develop during sleep. The initial hyperventilation is attenuated quickly by respiratory alkalosis, which acts as a brake on the respiratory center. As renal excretion of bicarbonate compensates for the respiratory alkalosis, pH returns toward normal, and ventilation continues to increase. This process of maximizing ventilation, termed *ventilatory acclimatization*, culminates after 4 to 7 days at a given altitude. With continuing ascent to higher altitudes, the central chemoreceptors reset to progressively lower P_{CO_2} values, and the completeness

of acclimatization can be gauged by the arterial P_{CO_2} . Acetazolamide, which forces a bicarbonate diuresis, greatly facilitates this process. An appreciation of the normal values for blood gases and acid-base status with acclimatization at various altitudes is necessary to distinguish abnormalities (Table 207-1).

Blood

We know that within 2 h of ascent to altitude, erythropoietin is increased in plasma and, over days to weeks, results in increased red cell mass. This adaptation has no importance during initial acclimatization when altitude illness develops and, when excessive, results in chronic mountain polycythemia. Shifts in the oxyhemoglobin dissociation curve are thought to be minimal in vivo at altitude because the increase in 2,3-diphosphoglyceric acid, which is proportional to the severity of hypoxia and shifts the curve to the right, is offset by the respiratory alkalosis, which shifts the curve to the left. Naturally occurring left-shifted hemoglobin is an advantage at high altitude.

Fluid Balance

Peripheral venous constriction on ascent to altitude causes an increase in central blood volume that triggers baroreceptors to suppress antidiuretic hormone (ADH) and aldosterone and induce a diuresis. Combined with the bicarbonate diuresis from the respiratory alkalosis, this can result in decreased plasma volume and hyperosmolality (serum osmolality of 290-300 mosmol/kg) that the body appears to permit by a reset of the osmolar center of the brain. Clinically, diuresis and hemoconcentration are considered a healthy response. Antidiuresis is a hallmark of acute mountain sickness.

Cardiovascular

Stroke volume is decreased initially, and an increased heart rate maintains cardiac output. Maximum exercising heart rate declines at altitude proportional to the decrease in maximum oxygen consumption (VO_{2max}). Cardiac muscle in healthy persons is able to withstand extreme levels of hypoxemia ($P_{aO_2} < 30$ mm Hg) without evidence of ST-segment changes or ischemic events. Blood pressure is mildly elevated on ascent secondary to increased sympathetic tone.

The pulmonary circulation constricts with exposure to hypoxia. This is an advantage during regional alveolar hypoxia, such as pneumonia, but is a disadvantage during the global hypoxia of altitude exposure. As a result, pulmonary pressure increases. This degree of hypertension is quite variable, with those having a hyperreactive response much more susceptible to high-altitude pulmonary edema.

Cerebral blood flow transiently increases on ascent to altitude (despite the hypocapnic alkalosis), which increases oxygen delivery to the brain. This response, however, is limited by the increase in cerebral blood volume, which may increase intracranial pressure and aggravate symptoms of altitude illness.

TABLE 207-1 Blood Gases and Altitude

Altitude (meters)	P_{aO_2} (mm Hg)	$SA_{O_2}\%$	P_{aCO_2} (mm Hg)
Sea level	90-95	96	40
1524 (5000 ft)	75-81	95	35.6
2286 (7500 ft)	69-74	92-93	31-33
4572 (15,000 ft)	48-53	86	25
6096 (20,000 ft)	37-5	76	20
7620 (25,000 ft)	32-39	68	13
8848 (29,029 ft)	26-33	58	9.5-13.8

Effects on Exercise

Exercise capacity, as measured by $\text{Vo}_{2\text{max}}$, drops dramatically on ascent to altitude, approximately 10 percent for each 1000-m altitude gain above 1500 m. During acclimatization, submaximal endurance increases appreciably after 10 days, but $\text{Vo}_{2\text{max}}$ does not. The mechanism of this decrement might be lack of adequate oxygen supply to the muscle cells due to the low driving pressure for diffusion of oxygen from the capillary. Another theory suggests that the central nervous system (CNS) limits muscle activity to preserve its own oxygenation.

Limitations to Acclimatization

There are limits to acclimatization. Even those who are by nature good acclimatizers cannot tolerate the hypoxia of extreme altitude for long. Miners in South America report that they cannot live at altitudes above 5800 m because of weight loss, increasing lethargy, poor-quality sleep, weakness, and headache. High-altitude mountaineers cannot survive for more than a few days above 8000 m without supplemental oxygen because of acute deterioration in physiologic functioning. Considerable weight loss, due to loss of fat and lean body mass, is unavoidable. Other factors limiting ability to acclimatize to extreme altitude include right ventricular strain from excessive pulmonary hypertension, intestinal malabsorption, impaired renal function, polycythemia and microcirculatory sludging, and prolonged cerebral hypoxia. Even at more modest altitudes, some individuals are very slow or poor acclimatizers for reasons not entirely known but, at least in part, due to poor carotid body function and inadequate ventilation.

Sleep at High Altitude

Sleep stages III and IV are reduced at altitude, whereas sleep stage I is increased. More time is spent awake, with a significant increase in arousals, but with only slightly less rapid eye movement (REM) time. The frequent arousals are a common source of bitter complaints from skiers and others, but they are innocuous and improve with time at altitude. The typical periodic breathing (Cheyne-Stokes) in those sleeping above 2700 m (9000 ft) consists of 6- to 12-s apneic pauses interspersed with cycles of vigorous ventilation. Interestingly, the frequent awakenings are not necessarily related to the sleep periodic breathing, and neither are they related to acute mountain sickness. Presumably, the mechanism of the lighter sleep is related to cerebral hypoxia. Quality of sleep and arterial oxygenation during sleep improves with acclimatization and with acetazolamide.

HIGH-ALTITUDE SYNDROMES

High-altitude syndromes are those attributed directly to the hypoxia: acute hypoxia, acute mountain sickness, pulmonary edema, cerebral edema, retinopathy, peripheral edema, sleeping problems, and a group of neurologic syndromes. The other syndromes, not necessarily related to hypoxia, include thromboembolic events (which may be attributable to dehydration, prolonged incapacitation, polycythemia, and cold), high-altitude pharyngitis and bronchitis, and ultraviolet keratitis. Although the different hypoxic clinical syndromes overlap, all share a fundamental mechanism, all are seen in the same setting of rapid ascent in unacclimatized persons, and all respond to the same essential therapy: descent and oxygen.

Acute Hypoxia

The syndrome of acute hypoxia occurs in the setting of sudden and severe hypoxic insult, such as accidental decompression of a pressurized aircraft cabin or a failed oxygen system in a pilot or high-altitude mountaineer. Sudden overexertion precipitating arterial desaturation, acute onset of pulmonary edema, carbon monoxide poisoning, and

sleep apnea may result in relatively acute hypoxia as well. Unacclimatized persons become unconscious at an arterial oxygen saturation of 50 to 60 percent, a Pao_2 of less than about 30 mm Hg, or a jugular venous Po_2 of less than 15 mm Hg. Acute hypoxia is reversed by immediate administration of oxygen, rapid descent, and correction of the underlying cause, such as removal of the carbon monoxide source or repair of the oxygen delivery system. Symptoms of acute hypoxia reflect the sensitivity of the CNS to this insult: dizziness, light-headedness, and dimmed vision progressing to loss of consciousness. Hyperventilation has been shown to increase the time of useful consciousness during acute alveolar hypoxia.

Acute Mountain Sickness (AMS)

INCIDENCE AMS occurs in the setting of more gradual and less severe hypoxic insult than with acute hypoxic syndrome. Its incidence varies by location, depending on ease of access, rate of ascent, and sleeping altitude reached. One study found a 25 percent incidence of AMS in physicians attending a continuing-education meeting held at 2100 m (6900 ft) in Colorado. Other studies at resorts between 2220 and 2700 m (7200 and 9000 ft, respectively) claim an incidence between 17 and 40 percent, and a sleeping altitude of 2750 m (9000 ft) seems to be a threshold for increased attack rate.² Approximately 40 percent of trekkers in Nepal on the path to Mt. Everest suffer AMS, whereas climbers on Mt. Rainier have a very high incidence of 70 percent because of the rapidity of ascent.

In addition to rate of ascent and sleeping altitude, inherent factors determine individual susceptibility to AMS. Factors identified so far are low hypoxic ventilatory response and low vital capacity. Age has little influence on incidence, with children being as susceptible as adults. Women are just as likely, if not more so, to develop mountain sickness but appear to have less pulmonary edema. Susceptibility to AMS generally is reproducible in an individual on repeated exposures. Persons living at intermediate altitudes of 1000 to 2000 m already are acclimatized partially and do much better than lowlanders on ascent to higher altitudes. There is no relationship of susceptibility to AMS and physical fitness.

CLINICAL FEATURES The diagnosis of AMS is based on the setting, symptoms, and physical findings. The setting is rapid ascent of an unacclimatized person to 2000 m (6600 ft) or higher. Typically, the person on arrival feels light-headed and slightly breathless, especially with exercise. Between 1 and 6 h later, but sometimes delayed for 1 day or more (and especially after a night's sleep), the typical symptoms of mild AMS develop; they are similar to an alcohol hangover. The headache usually is described as bifrontal and worsened with bending over and the Valsalva maneuver. Gastrointestinal symptoms include anorexia, nausea, and sometimes vomiting, and the chief constitutional symptoms are lassitude and weakness. The person with AMS is often irritable and wants to be left alone. Sleepiness and a deep inner chill also are common. If the illness progresses, headache and dyspnea become more severe, and vomiting and oliguria develop. Lassitude may progress so that the victim requires assistance for eating and dressing. The most severe form of AMS, high-altitude cerebral edema (HACE), is heralded by onset of ataxia and altered level of consciousness. Coma may ensue within 12 h if treatment is delayed. The diagnosis of AMS can be difficult in preverbal children.³

Physical findings in mild AMS are nonspecific. Heart rate and blood pressure are variable and usually in the normal range, although postural hypotension may be present. Localized rales are detectable in up to 20 percent of persons with AMS. Funduscopy reveals venous tortuosity and dilatation, and retinal hemorrhages are common over 5000 m or in those with pulmonary and cerebral edema. Fluid retention is a hallmark of AMS, in contrast to the usual diuresis of acclimatization, and may result in peripheral and facial edema. Differential diagnosis

in this setting includes hypothermia, carbon monoxide poisoning, pulmonary or CNS infection, dehydration, and exhaustion.

The natural history of AMS at a Colorado resort (3000 m or 10,000 ft) was 15 h for mean duration of symptoms, with a range to 94 h, despite the fact that one-half of those with symptoms self-medicated. At higher sleeping altitudes, the illness may last much longer, even weeks if untreated, and is more likely to progress to pulmonary or cerebral edema. Eight percent of those with AMS at 4243 m (14,000 ft) in Nepal developed cerebral or pulmonary edema or both.

PATHOPHYSIOLOGY AMS is due to hypobaric hypoxia, but the exact sequence of events leading to illness is unclear. Figure 207-1 (left side) offers a schema for the pathophysiology. The brain enlarges in all persons ascending to high altitude because of increased cerebral blood flow and accompanying increased blood volume. Whether this is sufficient to cause the symptoms of mild AMS is unclear; in fact, the cause of mild AMS remains a mystery. However, in persons who go on to become ill with high-altitude cerebral edema, vasogenic edema is evident as increased T_2 signal on magnetic resonance imaging.⁴ The leaky blood-brain barrier is due either to loss of autoregulation and overperfusion or to hypoxia-induced increased permeability via mediators such as vascular endothelial growth factor (VEGF) or bradykinin, or to a combination of the two processes. The fact that dexamethasone so effectively treats AMS also supports the notion of vasogenic edema because this is the only type of cerebral edema responsive to steroids.

The cerebral edema, interstitial pulmonary edema, peripheral edema, and antidiuresis observed in AMS all point to an abnormality of water handling by the body. The mechanism is thought to be increased renin-angiotensin, aldosterone, and ADH in contrast to the normal ADH and aldosterone suppression at high altitude and usual diuresis. A decrease in glomerular filtration also has been observed. Increased sympathetic activation is thought to play a role in the pulmonary and renal circulations, contributing to the pathophysiology (see Figure 207-1).

TREATMENT

Descent and Oxygen The goals of treatment (Table 207-2) are to prevent progression, abort the illness, and improve acclimatization; early diagnosis is essential. Initial clinical presentation does not predict eventual severity, and all persons with AMS must be observed carefully for progression. The three principles of treatment are 1) to not proceed to a higher sleeping altitude in the presence of symptoms, 2) to descend if symptoms do not abate or become worse despite treatment, and 3) to descend and treat immediately in the presence of a change in consciousness, ataxia, or pulmonary edema. Mild AMS is self-limited and generally improves with an extra 12 to 36 h of acclimatization if ascent is halted. Descent is the definitive treatment for all forms of altitude illness, although it is not always an option, nor always necessary. Remarkably, a drop in altitude of only 500 to 1000 m usually is effective promptly. Evacuation to a hospital or to sea level is unnecessary except in the most severe cases. To simulate descent, portable hyperbaric bags are being used in various locations to treat AMS. The patient is inserted into the fabric chamber, and a pressure of 2 lb/in² is achieved by means of a manual or automated pump; the pressure is equivalent to a drop in altitude of 1500 m (5000 ft). A valve system creates sufficient ventilation to avoid CO₂ accumulation or O₂ depletion.

Oxygen effectively relieves symptoms, but it often is unavailable in the field and generally is reserved for moderate to severe AMS in order to conserve supplies. Oxygen promptly relieves headache, dizziness, and most other symptoms, although ataxia may resolve more slowly. Nocturnal low-flow oxygen (0.5-1 L per min) is particularly helpful and efficient. The combination of oxygen and descent provides optimal therapy, especially in more severe cases.

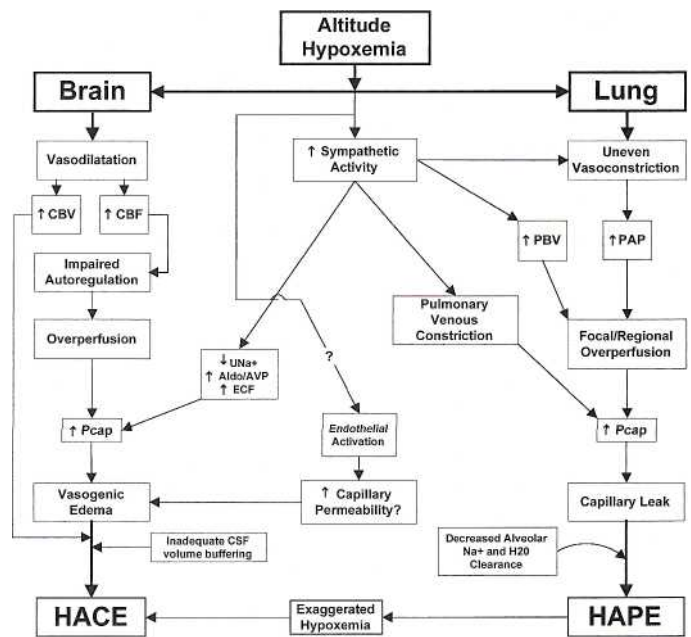

FIG. 207-1. Proposed pathophysiology of high-altitude illness. At high altitudes, hypoxemia can lead to overperfusion, elevated capillary pressure, and leakage from the cerebral and pulmonary microcirculation. Increased sympathetic activity has a central role in this process, and increased permeability of capillaries as a result of endothelial activation (inflammation) also may have a role, especially in the brain. Aldo/AVP = aldosterone/arginine vasopressin; CBF = cerebral blood flow; CBV = cerebral blood volume; CSF = cerebrospinal fluid; ECF = extracellular fluid compartment; PAP = pulmonary artery pressure; PBV = pulmonary blood volume; Pcap = capillary pressure; UNa = urinary sodium excretion. (From Hackett and Roach,⁵ with permission.)

Medical Therapy Pharmacologic treatment offers an alternative to descent or oxygen in mild to moderately severe AMS. Acetazolamide is very helpful in speeding acclimatization and aborting illness, especially when used early. The drug acts by inhibiting the enzyme carbonic anhydrase, slowing the hydration of carbon dioxide to hydrogen and bicarbonate ions. In the kidney, acetazolamide reduces reabsorption of bicarbonate, causing a bicarbonate diuresis and metabolic acidosis that stimulates ventilation. The drug essentially mimics the process of ventilatory acclimatization. As a result, Pao₂ is higher, and sleep oxygenation remains high and stable, without periods of apnea. The drug also maintains cerebral blood flow despite greater hypocapnia, and because of its diuretic action, it counteracts the fluid retention of AMS. Many trials have shown its value for prevention, whereas one documented its effectiveness for treatment. **Indications for acetazolamide are 1) a history of altitude illness, 2) abrupt ascent to over 3000 m (10,000 ft), 3) for treatment of AMS, and 4) bothersome sleep periodic breathing. The dosage regimen varies; 5 mg/kg PO per d in two or three divided doses is sufficient, whether for prevention or treatment, or 125 mg PO twice daily, which is empirically effective.**⁵ Treatment should be continued until symptoms of AMS resolve, and then the drug can be restarted if symptoms return. Because the drug acts by improving acclimatization, fear of masking serious illness is unwarranted. Common side effects of acetazolamide include peripheral paresthesias and sometimes nausea or drowsiness. It contains a sulfhydryl moiety, so it should not be given in patients with allergy to sulfa. Because the drug inhibits the instant hydration of CO₂ on the tongue, the carbon dioxide in carbonated beverages can be tasted, ruining the flavor of beer and other drinks.

TABLE 207-2 Suggested Treatment of High Altitude Illness

Mild AMS	Stop ascent Descend to lower altitude or acclimatize at same altitude Acetazolamide 125–250 mg PO bid to speed acclimatization Symptomatic treatment as necessary with analgesics and antiemetics
Moderate AMS	Immediate descent for worsening symptoms Low flow oxygen if available Acetazolamide 250 mg PO bid and/or dexamethasone 4 mg PO q6h Hyperbaric therapy
HACE	Immediate descent or evacuation Oxygen 2–4 L/min or titrated to $SpO_2 >90\%$ Dexamethasone 8 mg PO, IM, or IV, then 4 mg q6h Hyperbaric therapy if cannot descend
HAPE	Immediate descent or evacuation to medical facility Oxygen 4 L per min or titrated to $SpO_2 >90\%$ Nifedipine 10 mg PO q4–6h or 30 mg extended release q12h if no oxygen or descent Hyperbaric therapy if cannot descend Continuous positive airway pressure Minimize exertion and keep warm Dexamethasone if cerebral signs 4 mg PO q6h. Consider albuterol, 2–4 inhalations q4h
Periodic breathing	Acetazolamide 125 mg PO at bedtime as needed

Symptomatic treatment of AMS is sometimes sufficient. Aspirin 650 mg, acetaminophen 650 to 1000 mg (with or without codeine), or ibuprofen 600 to 800 mg can be effective for headache. Aspirin is also effective for prophylaxis of headache in persons not exercising.⁶ Prochlorperazine 5 to 10 mg IM is useful for nausea and vomiting. A short-acting benzodiazepine such as triazolam 0.25 mg or temazepam 15 mg or the non-benzodiazepine zolpidem 10 mg can be used to treat the complaint of frequent awakening, but these agents are potentially dangerous in ill persons because of possible respiratory depression. Combining acetazolamide with one of these agents works well for insomnia and is safe.

Dexamethasone 4 mg PO, IM, or IV every 6 h is quite effective therapy for mountain sickness, but it is best reserved for moderate to severe AMS because of potential side effects and because it does not aid acclimatization, sometimes resulting in rebound symptoms when discontinued. A short taper period may prevent this rebound phenomenon. The use of acetazolamide to speed acclimatization and a brief course of dexamethasone to treat illness can be a useful combination.

PREVENTION Graded ascent with adequate time for acclimatization is the best prevention. A recommendation for those visiting medium-altitude resorts in the western United States is to spend a night at an intermediate altitude of 1500 to 2000 m (Denver or Salt Lake City) before sleeping at altitudes above 2500 m (8200 ft). Mountaineers and trekkers should avoid abrupt ascent to sleeping altitudes over 3000 m and then allow two nights for each 1000-m gain in camp altitude starting at 3000 m. Other preventative measures include avoiding overexertion, alcohol, and respiratory depressants and eating a high-carbohydrate diet.

Acetazolamide is a useful prophylactic agent for those with a history of AMS or for forced abrupt ascent without acclimatization stages. The drug should be started 24 h before the ascent and continued for the first 2 days at altitude. The medication then can be discontinued and started again if illness develops. Acetazolamide reduces the symptoms of AMS by approximately 75 percent in persons ascending rapidly to sleeping altitudes of over 2500 m. An alternative for those allergic to sulfa is dexamethasone 4 mg PO every 12 h starting the day of ascent and continuing for the first 2 days at altitude.

Neurologic Syndromes of High Altitude

Until recently, most neurologic events at high altitude were attributed to HACE or AMS. Clearly, this has been a diagnostic oversimplification.

Other syndromes now recognized as related to high altitude include altitude syncope, cerebrovascular spasm (migraine equivalent), cerebral arterial or venous thrombosis (infarct), transient ischemic attack, and cerebral hemorrhage. These syndromes are characterized by more focal neurologic findings than in cerebral edema, although differentiation in the field may be impossible.

Other symptoms may be due to exacerbation or unmasking of underlying disease, such as previously asymptomatic brain tumors and epilepsy. Presumably, space-occupying lesions become symptomatic because of increased brain volume at altitude. Hyperventilation (hypocapnic alkalosis), which is commonly used to induce seizure activity on electroencephalography, may explain unmasking of a seizure disorder at altitude, whereas changes in cerebral blood flow may exacerbate vascular lesions.

High-Altitude Cerebral Edema (HACE)

HACE is defined clinically as the presence of progressive neurologic deterioration in someone with AMS or high-altitude pulmonary edema (HAPE). It is characterized by altered mental status, ataxia, stupor, and progression to coma if untreated. Headache, nausea, and vomiting are not always present. Because of raised intracranial pressure, focal neurologic signs such as third and sixth cranial nerve palsies may result from distortion of brain structures and compression.

HACE usually is associated with pulmonary edema. Pathologically, necropsies have described severe, diffuse cerebral edema with multiple small hemorrhages and sometimes thrombosis.

The treatment of HACE is the same as for severe AMS: oxygen, descent, and steroids (Tables 207-2 and 207-3). Descent is the highest priority. Acetazolamide may be an adjunct, but immediate reversal of the illness is the goal; improving acclimatization comes later. In acutely ill patients who cannot descend, the combination of steroids, supplemental oxygen, and a hyperbaric bag is optimal therapy but rarely available. Persons remaining ataxic or confused after descent should be admitted to the hospital. Comatose patients require additional airway management, bladder drainage, and other coma care. For coma, the use of hyperventilation to decrease intracranial pressure is a reasonable approach, keeping in mind that the $Paco_2$ is already low and the pH high in these individuals. Additional acute hyperventilation could produce cerebral ischemia; monitoring of arterial blood gases and, if available, cerebral blood velocities by transcranial Doppler ultrasonography may be advisable. Loop diuretics such as furosemide 40 to 80 mg or bumetanide 1 to 2 mg IV may help reduce brain overhydration, but hypoperfusion and ischemia must be avoided. Hypertonic solutions of saline, mannitol, or urea have been used too infrequently to establish clinical guidelines. In the hospital setting, mannitol is worth considering in a patient who does not respond immediately. Coma may persist for days, even for weeks, after evacuation to lower altitude, and the patient may still recover, only rarely with permanent sequelae. Persistent coma is unusual, however, and mandates exclusion of other possible etiologies.

Cerebrovascular Syndromes of Altitude

Strokes, due both to infarct and hemorrhage in the arterial circulation, as well as venous thrombosis, have been reported in young, healthy persons at altitude who otherwise would not be considered at risk for such conditions. Transient ischemic attack, cortical blindness, and various focal neurologic signs, such as hemiparesis or hemiplegia of a transient nature, also occur. Because these latter events are reversible, they suggest etiologies such as vasospasm, migraine, watershed hypoxia between arterial zones, and transient ischemic attack.

Differentiation of the various neurologic syndromes may be impossible in the field, and treating as if cerebral edema were present may be reasonable, with a rapid descent to lower altitude, oxygen, steroids, and evacuation to a hospital if symptoms persist despite treatment.

TABLE 207-3 Medications for High-Altitude Illnesses

Agent	Indication	Dose	Adverse Effects	Comments
Acetazolamide	Prevention of AMS	125–250 mg PO bid beginning 24 h before ascent and continuing during ascent and to at least 48 h after arrival at highest altitude	Common: Paresthesias, polyuria, alters taste of carbonated beverages Precautions: Sulfonamide reactions possible, avoided in breast-feeding, can decrease therapeutic levels of lithium	Can be taken episodically for symptoms, no rebound effect, pregnancy category C
	Treatment of AMS	250 mg PO q8–12h		
	Pediatric AMS	5 mg/kg per day PO in divided doses q8–12h		
	Periodic breathing	125 mg PO 1 h before bed		
Dexamethasone	Treatment of AMS	4 mg every 6 hr PO, IM, or IV	Mood changes, hyperglycemia, dyspepsia	Rapidly improves AMS symptoms, can be lifesaving in HACE, may improve HACE enough to facilitate descent, no value in HAPE, pregnancy category C but preferably avoided by women who are pregnant or breast-feeding
	HACE	8 mg initially, then 4 mg q6h PO, IM, or IV		
	Pediatric HACE	1–2 mg/kg initially, then 0.25–0.5 mg/kg q6h PO, IM, or IV, not to exceed 16 mg/d		
Ginkgo biloba	Prevention of AMS	80–120 mg PO bid starting 5 days before ascent and continuing to highest altitude	Occasional headache, rare reports of bleeding	Requires further study, preparations vary, may be used by women who are pregnant or breast-feeding
Nifedipine	Prevention of HAPE	20–30 mg of extended-release formulation PO q12h	Reflex tachycardia, hypotension (uncommon)	No value in AMS or HACE, not necessary if supplemental oxygen available, pregnancy category C
	Treatment of HAPE	10 mg PO initially, then 20–30 mg of extended-release formulation PO q12h		

Abbreviations: AMS = acute mountain sickness; HACE = high-altitude cerebral edema; HAPE = high-altitude pulmonary edema.

Source: From Hackett 2001,⁵ with permission.

Fortunately, focal neurologic signs usually resolve spontaneously and do not recur on reascent. However, a thorough cerebrovascular evaluation before advising reascent may be prudent.

High-Altitude Pulmonary Edema (HAPE)

HAPE is the most lethal of the altitude illnesses. Because the condition is easily reversible with descent and oxygen, the cause of death is usually lack of early recognition, misdiagnosis, or inability to descend to a lower altitude.

EPIDEMIOLOGY The incidence of HAPE varies from less than 1 in 10,000 skiers in Colorado to 2 to 3 percent of climbers on Mt. McKinley and was reported to be as high as 15 percent in some regiments in the Indian army that were airlifted to high altitude during the Indian-Chinese war. Women appear less susceptible than men. Risk factors include heavy exertion, rapid ascent, cold, excessive salt ingestion, use of sleeping medication, and a previous history indicating inherent individual susceptibility. Genetic factors include diminished lung epithelial sodium channel activity,⁷ excessive hypoxic pulmonary hypertension, and immunogenetic factors.⁸ Pulmonary hypertension of any cause greatly predisposes to HAPE. As a result, HAPE has been reported in patients with intracardiac shunts (atrial septal defect, patent ductus arteriosus [PDA], patent foramen ovale), drug-induced pulmonary hypertension (phentermine), and chronic venous thrombotic disease.^{9,10} Preexisting respiratory infection may predispose children to HAPE.¹¹

CLINICAL FEATURES Early in the course of illness, when the edema is still interstitial or localized, the victim develops a dry cough, decreased exercise performance, dyspnea on exertion, increased recovery time from exercise, and localized rales, usually in the right mid-

lung field. Late in the course of the illness, there develops tachycardia, tachypnea, and dyspnea at rest, marked weakness, productive cough, cyanosis, and more generalized rales. As hypoxemia worsens, consciousness becomes impaired. Victims usually become comatose and then die. Early diagnosis is critical, and decreased exercise performance and dry cough are enough to raise the suspicion of early HAPE. The typical victim is strong and fit and may or may not have symptoms of AMS before the onset of HAPE. The condition typically worsens at night and is noticed most commonly on the second night at a new altitude. Unfortunately, rales may not be audible in 30 percent of persons with HAPE at rest but can be elicited immediately after a short bout of exercise. Low-grade fever is common, and tachycardia and tachypnea generally correlate with the severity of illness. On cardiac auscultation, a prominent P₂ and right ventricular heave may be appreciated. Electrocardiogram generally reveals right-axis deviation and a right ventricular strain pattern consistent with acute pulmonary hypertension. Chest x-ray findings progress from interstitial to localized alveolar to generalized alveolar infiltrates as the illness progresses from mild to severe.

PATHOPHYSIOLOGY HAPE is a noncardiogenic, hydrostatic edema; left ventricular function is normal. Left ventricular end-diastolic pressure, wedge pressures, and left atrial pressures are low to normal, cardiac output is low, and pulmonary vascular resistance and pulmonary artery pressure are markedly elevated. The culprit in HAPE is high microvascular pressure (see Figure 207-1). Pulmonary hypertension is an essential component, but not all persons with pulmonary hypertension develop HAPE. Other factors that play a role include pulmonary venous constriction and uneven arterial vasoconstriction, leading to overperfusion of some areas of the lung vasculature. Inflammation was not present early in the course of HAPE, as measured by chemical composition of bronchoalveolar lavage fluid, but appears

to be a secondary finding later in the illness.¹² Predisposed individuals have a low hypoxic ventilatory response, an abnormal pulmonary circulation response to hypoxia, and tend to suffer HAPE on repeated exposures.

TREATMENT The key to successful treatment of HAPE (see Tables 207-2 and 207-3) is early recognition, because the condition in its early stage is easily reversible. The optimal therapy depends on the environmental setting, evacuation options, availability of oxygen or hyperbaric units, and ease of descent. **Immediate descent is the treatment of choice, but this is not always possible.** During descent, exertion by the victim must be minimized. Reports of victims dying during descent probably are related to overexertion offsetting the benefit of lower altitude. Oxygen provides excellent results and can completely resolve the pulmonary edema without descent to a lower altitude, but it may require 36 to 72 h to do so. Such quantities of oxygen are rarely available to trekking, mountaineering, and skiing groups, but they may be available at ski resorts or medical facilities. Oxygen immediately lowers pulmonary artery pressure and improves arterial oxygenation. Its use is lifesaving when descent is not an option; in such cases, rescue groups should make delivery of oxygen to the victim the highest priority. As in the treatment of AMS and HACE, the portable hyperbaric bag is a very useful adjunct to therapy when immediate descent is not possible.

Bed rest may be adequate for very mild cases, and bed rest with supplemental oxygen may suffice for moderate illness, as long as the safety of the patient can be ensured by the presence of a medical facility, adequate oxygen, or immediate descent capability should the patient's condition deteriorate.¹³ Because cold stress elevates pulmonary artery pressure, the patient should be kept warm. The use of an expiratory positive airway pressure (EPAP) mask has been shown to increase arterial oxygen saturation by 10 to 20 percent in HAPE patients by enhancing alveolar recruitment. The mask is lightweight, well tolerated, and may be a useful adjunct to descent.

Because oxygen and descent are so effective, experience with drugs has been limited. Several studies have demonstrated that nifedipine, either a 10-mg capsule or the 30-mg extended-release formulation, PO was of clinical benefit in reducing pulmonary artery pressure by 30 to 50 percent but increased arterial oxygen saturation only slightly. Nifedipine, at a dose of 20 mg (slow-release preparation) every 8 h while ascending, also was an effective prophylactic agent in those who have had previous episodes of HAPE.¹⁴ Nitric oxide also lowers pulmonary artery pressure and redistributes blood away from edematous areas.¹⁵ Nitric oxide, however, is difficult to administer. Sildenafil nearly completely blocks hypoxic pulmonary hypertension and therefore should prevent HAPE, although the study documenting this has yet to be done. Theoretically, it also should be useful for the treatment of HAPE.

None of these agents is as effective as oxygen or descent, which still remain the treatments of choice.¹⁶ An interesting recent study showed that inhaled salmeterol twice a day reduced the incidence of HAPE by 50 percent in persons with previous repeat episodes of HAPE.¹⁷ The mechanism is presumed to be upregulation of the epithelial sodium channel and increased clearance of alveolar fluid, a known effect of β_3 -agonists. Although these agents have not yet been studied for the treatment of HAPE, given their likely benefit and safety and ease of use, treatment of HAPE with β_3 -agonists is reasonable.

Hospitalization may be warranted for severe cases that do not respond immediately to descent, especially if cerebral edema is present. Intubation, high F_{IO_2} , and positive end-expiratory pressure ventilation are rarely required. Antibiotics are indicated for coexisting infection when present. Occasionally, pulmonary artery catheterization is useful to exclude a cardiac component to the edema in persons with heart disease. The patient with HAPE who does not make the usual rapid improvement [or develops HAPE at altitudes of less than 2500 m (8200 ft)] should be evaluated for pulmonary emboli or other pul-

monary circulatory abnormalities, such as congenital absence of a pulmonary artery or intracardiac shunt. Echocardiography with bubble contrast material can assess presence or absence of shunting from a patent foramen ovale or other cardiac abnormality.

Adequate discharge criteria are progressive clinical and radiographic improvement and a P_{aO_2} of 60 mm Hg or an S_{aO_2} of greater than 90 percent. Residua such as fibrosis and impaired pulmonary function tests have not been reported. An episode of HAPE is not a contraindication to subsequent ascent, but patients should be advised on staged ascent, acetazolamide and/or nifedipine prophylaxis, and recognition of early signs and symptoms.

Peripheral Edema

Swelling of the face and distal extremities is common at high altitude. Peripheral edema was reported in 18 percent of trekkers at 4200 m in Nepal and was twice as likely in women. It often was associated with AMS but not necessarily. The presence of peripheral edema should raise suspicion of altitude illness and prompt a thorough examination for pulmonary and cerebral edema. The problem can be treated with diuretics, but if left untreated, it will resolve spontaneously with descent. The mechanism is presumably similar to that of the fluid retention of AMS but with edema formation peripherally rather than in the brain and lung.

High-Altitude Retinopathy

Retinal abnormalities described at high altitude include retinal edema, tortuosity and dilatation of retinal veins, disc hyperemia, retinal hemorrhages, and rarely, cotton-wool exudates. Retinal hemorrhages are asymptomatic, except for rarely occurring macular hemorrhages, and are not considered an indication for descent unless visual changes are present. They resolve spontaneously in 10 to 14 days. Hemorrhages are common above a sleeping altitude of 5000 m and occur at lower altitudes in persons with altitude illness.

High-Altitude Pharyngitis and Bronchitis

Most unacclimatized persons exercising at altitudes over 2500 m develop a dry, hacking cough. With exposure to extreme altitudes for prolonged periods of time, a purulent bronchitis and a painful pharyngitis become nearly universal. These problems may not be of an infectious nature; high volumes of dry, cold air through the lungs may induce respiratory heat loss and cause purulent secretions on that basis alone. Bronchospasm also may be triggered by respiratory heat loss. Severe coughing spasms can result in cough fracture of the ribs.

Pharyngeal membranes become dry, painful, and cracked because of the dehydration and high ventilation. Mucosal cracks may be an entry for pathogens, or the erythema and dryness may cause discomfort strictly on a mechanical basis. Antibiotics generally are not helpful, supporting the concept of a noninfectious etiology. Breathing of steam, hard candies or lozenges to increase salivation, and forcing hydration may provide some benefit, with systemic analgesics being used as necessary. A silk balaclava or a scarf of similar material across the nose and mouth that is sufficiently porous to allow large-volume ventilation but trap some moisture and heat helps ameliorate these bothersome high-altitude conditions.

Chronic Mountain Polycythemia (CMP)

Monge disease, also called *chronic mountain sickness* (CMS), has been recognized in all high-altitude locations of the world. Both long-term high-altitude residents and lowlanders who relocate to high altitude may develop this condition after variable lengths of residence. The incidence is much higher in males and increases with age. The disease is characterized by excessive polycythemia for a given altitude,

which causes symptoms such as headache, muddled thinking, difficulty sleeping, impaired peripheral circulation, drowsiness, and chest congestion. The diagnosis is made by the characteristic symptoms and a hemoglobin value greater than expected for the altitude, generally over 20 to 22 g/dL. Any problem causing hypoxemia at sea level causes greater hypoxemia at altitude, and the etiology of CMP can be traced to problems such as chronic obstructive pulmonary disease (COPD) and sleep apnea in 50 percent of patients. The etiology of pure CMP is attributed to idiopathic hypoventilation on the basis of diminished respiratory drive.

Therapy includes phlebotomy, relocation to a lower altitude, or home oxygen use. Respiratory stimulants such as acetazolamide (250 mg PO bid) and medroxyprogesterone acetate (20-60 mg PO per d) also have been employed successfully. The response to respiratory stimulants supports the role of hypoventilation in this disorder.

Ultraviolet Keratitis (Snow Blindness)

Ultraviolet light (UVA and UVB) penetrates the atmosphere to a greater degree at high altitude because of less cloud cover, less water vapor, and less particulate matter in the air. Radiation increases roughly 5 percent for every 300 m (1000 ft) gained, and it is exacerbated by reflection back from snow. UV radiation below 300 nm (UVB) is absorbed by the cornea, and high exposure levels can cause corneal burns in 1 h, although symptoms do not become apparent for 6 to 12 h. The typical symptoms of photokeratitis are severe pain, a foreign body or gritty sensation, photophobia, tearing, marked conjunctival erythema, chemosis, and eyelid swelling. UV keratitis generally is self-limited and heals within 24 h, but the condition is sufficiently painful to warrant systemic analgesics. Cold compresses also may provide some relief, and eye patches may be necessary for comfort. Prevention is obviously of great importance because this condition can be disabling, especially in hazardous terrain. Adequate sunglasses should transmit less than 10 percent of UVB light. Side shields are necessary if traveling on snow, and polarizing lenses help by absorbing glare. Makeshift protection can be fashioned by cutting narrow horizontal slits in cardboard, foam, or any available material ("Eskimo sunglasses").

ILLNESSES AGGRAVATED BY HIGH ALTITUDE

Chronic Lung Disease

COPD patients ascending to altitude often report increased dyspnea and reduced exercise ability. Those with hypoxemia, pulmonary hypertension, disordered control of ventilation, and sleep-disordered breathing at sea level may have greater problems at altitude because of the greater alveolar hypoxia. Such patients may require supplemental oxygen at altitude when they do not at sea level (and avoid having to descend), and oxygen-dependent patients at sea level may need to increase the F_{IO_2} . The required F_{IO_2} can be calculated by multiplying low-altitude F_{IO_2} by the ratio of low-altitude barometric pressure divided by high-altitude barometric pressure. This will ensure the delivery of the same partial pressure of oxygen as at low altitude. There are no data to suggest that persons with COPD are more likely to develop AMS or HAPE, although such persons may be self-selected to avoid travel to high-altitude locations. In fact, persons with mild to moderate COPD already are partially acclimatized and may do well at modest altitude. High altitude per se does not exacerbate asthma, and persons with chronic bronchospasm often report easier breathing at high altitude due to lower air density and/or cleaner air. Patients with allergic asthma do better at high altitude because of reduced allergens.

Arteriosclerotic Heart Disease (ASHD)

The healthy heart and cardiovascular system tolerate even extreme hypoxia very well. Numerous electrocardiographic (ECG) studies,

echocardiograms, heart catheterizations, and exercise tests do not demonstrate cardiac ischemia or cardiac dysfunction in healthy persons at high altitude, even when P_{aO_2} was less than 30 mm Hg. Those with arteriosclerotic disease may not have the same adaptive capabilities and intuitively seem more likely to suffer from acute cardiac events. Epidemiologic data, however, do not support this supposition. Morbidity and mortality from arteriosclerotic heart disease are reduced in persons with long-term residence at high altitude, and visitors apparently do not have increased risk of acute myocardial infarction. Recent work, however, suggested earlier onset of angina at high altitude compared with sea level during the first few days at 2500 m. After 5 days, an elderly group with coronary artery disease (CAD) acclimatized well and performed at sea-level exercise capacity without increased or early-onset angina.¹⁸ Even men with CAD and low left ventricular ejection fraction (mean 39 percent) but without overt heart failure tolerated exercise at 2500 m as well as at low altitude.¹⁹ Congestive heart failure (CHF) may worsen in tourists arriving at the medium altitude of ski resorts, and it is related apparently to fluid retention rather than depressed ventricular function from hypoxia. Patients with CHF therefore should maintain or increase their diuretic regimen during travel to high altitude, and clinicians may want to consider administering low-flow oxygen during sleep for CHF patients, at least for the first few nights. Individuals after coronary-artery bypass graft have trekked to altitudes over 5000 m without problems.

Ascent to altitude produces a mild increase in blood pressure in normotensive and hypertensive persons secondary to increased sympathetic tone. However, the magnitude of blood pressure response is quite variable and not predictable. Patients should continue hypertensive medications at altitude, and blood pressure monitoring might be prudent. No data suggest that hypertensives have a higher risk for any of the altitude illnesses, and in general, hypertension is not a contraindication to altitude exposure.¹⁰

Sickle Cell Disease

Even the modest simulated altitude of a pressurized aircraft (1500-2000 m) may cause persons with hemoglobin SC and sickle-thalassemia to have a vaso-occlusive crisis. Exposure to high altitude thus requires supplemental oxygen. Sickle cell trait is not considered an increased risk, although splenic infarction syndrome during heavy exercise at altitude has been reported in those with trait.

Pregnancy

Pregnant residents of high altitude have an increased prevalence of hypertension, low-birth-weight infants, and neonatal hyperbilirubinemia. However, an increased incidence of pregnancy complications in lowlanders who visit high altitude has not been reported. The normal P_{aO_2} of the fetus is 29 to 33 mm Hg, and the mild maternal hypoxia induced by traveling to resort-type altitudes does not generate significantly more hypoxic stress. The few studies available suggest that exercise in pregnant women at altitudes of 2500 m is safe for mother and fetus. Based on the available data, pregnant women should be advised to avoid altitudes at which arterial oxygen saturation falls below 85 percent, which would be a sleeping altitude of about 10,000 ft. Perhaps of more concern than mild hypoxia is the fact that high-altitude locations are often remote from medical facilities, and patients need to be aware that without access to sophisticated medical care, complications could have more serious consequences.

Antarctica, with its cold, dry, windy climate, photoperiodicity, and isolation, is one of the harshest environments on earth. Despite the improved technological changes in clothing, equipment, food, and shelter, the environment is no less challenging than it was to the early explorers and exploiters. Apart from water, which needs significant energy to be "mined" from the polar ice cap, all survival needs must be taken to Antarctica, including health care. The history of medicine in Antarctica is a most interesting one.¹ No Antarctic-specific disease or ailment has been found. Since many of the persons going south are highly mobile, exotic diseases contracted in tropical or temperate areas may occur in Antarctica, consistent with the age and sex of the individual. Antarctic medicine is therefore the practice of medicine in the Antarctic region, as varied as that practice is, and not a specialty of Antarctic-specific disease states.

This chapter discusses Antarctic medicine as currently practiced by the varied groups, with particular emphasis on emergencies that may occur, whether shipboard, station, or remote field location.

POPULATION

In 2001, 18 nations operated 36 winter stations south of 60 degrees S,² with around a thousand scientists and support personnel spending the austral winter there; the number increases three- or fourfold in summer. In summer, over 14,000 tourists and adventure seekers travel by ship, yacht, and aircraft to indulge in observing and photographing this largely pristine wilderness and its wildlife, mountain climbing, skiing, camping, trekking, diving, skydiving, parasailing, kayaking, and running marathons. Over 60 Antarctic tour companies operate. Tourist overflights, of some 12 h duration, operate from Australia and are very popular.

EPIDEMIOLOGY

Trauma and accidents are the most common conditions, although most of these are of a minor nature. Injuries can range from abrasions, lacerations, sprains, and other musculoskeletal injuries and burns to fractures and multiple injuries causing death. Not all emergencies are simple, as illustrated by serious cases of a polio-like illness,³ ruptured intracranial aneurysm,⁴ breast cancer,⁵ chest injuries, myocardial infarction,^{6a} abdominal pain, fractured cervical vertebrae, and cold injuries.⁶ After trauma and accidents, symptoms and ill-defined diseases, such as insomnia (endemic in Antarctica in the period of 24 h of sunshine in summer), dyspepsia, and headaches rate high, along with dental problems and skin diseases.

Cold-related injuries are uncommon, with most being recreational, such as snowmobiling and skiing.⁷ Other conditions related to the environment, such as snow blindness and sunburn, are of low incidence.⁸ Ozone depletion, known as the annual "ozone hole," is not thought to be a problem because of changed attitudes to exposing skin to sunlight, the use of goggles and sunscreen, and the presence of polar clothing covering most of the body.⁹

Diagnoses in Antarctica have included nutritional disorders (scurvy and hypervitaminosis A),¹ hepatitis, malaria, amoebic dysentery, pneumonia, anorexia nervosa, appendicitis, peptic ulcer, myocardial infarction, acute terminal ileitis, pyrexia of unknown origin, kidney stones, and gout. Mental disorders have low rates of occurrence in documented studies.^{8,10} Although suggestions are made that behavioral problems are underreported,¹¹ many consider that much of this behavioral category consists of nonpathologic, adaptive mechanisms to the isolation and confinement. The role of alcohol in Antarctic communities reveals both positive and negative aspects.¹¹ Alcohol abuse does occur, and alcohol has been implicated in accidents.

Deaths in Antarctica have always been highly publicized. In the heroic era, deaths such as those of Scott and his four colleagues on the return from the South Pole, Mawson's two sledging companions on the Australasian Antarctic Expedition in 1911-1914, and three members

ANTARCTIC MEDICINE

Desmond J. Lugg

Antarctica, the lands and ice sheets below the Antarctic Convergence (Antarctic Polar Front), where the cold waters from the Antarctic region meet and sink beneath the warm waters from the middle latitudes, has no indigenous population. Humans are transient visitors, spending from days to several years at a time. The first group wintered on the Antarctic Continent just over 100 years ago. Captain James Cook was most likely the first of the explorers to travel beyond the Polar Front and over the Antarctic Circle in 1773. Discoveries of seals and whales by Cook and others drew those keen to exploit the riches of the region. Scientific studies were performed in this heroic era, but it was not until the International Geophysical Year (IGY) 1957-1959 that multinational, multidisciplinary research programs burgeoned and have been maintained to the present. The advent of the Antarctic Treaty, signed in 1959 and entering into force in 1961, made Antarctica an international region; the later convention on living resources conservation and protocol on environmental protection curtailed exploitation and ensured the desirability of Antarctica as a tourist destination. The first shipboard tourist voyages came in the late 1950s.

of the Ross Sea Party of Shackleton's Trans-Antarctic Expedition in 1914-1917 took from months to years to reach the public press but are now classic descriptions of human endurance. In marked contrast are the recent real-time press releases of the crash of the Air New Zealand tourist flight on Mount Erebus in November 1979 with the loss of 257 lives, the deaths of 3 sky divers, and the death of a young woman from diabetes while traveling on a yacht in Antarctic waters. Deaths on national expeditions have resulted from myocardial infarction, appendicitis, perforated gastric ulcer, cerebral hemorrhage, alcohol poisoning, head injuries, hypothermia, drowning, crush injuries, falls into crevasses, burns, pulmonary embolism, and carbon monoxide poisoning. Most national programs have had deaths. Examples are 17 fatalities on the Australian National Antarctic Research Expeditions (ANARE) between 1947 and 2002 and 57 on the U.S. Antarctic program since 1946,²⁶ 3 in the last 10 years.²⁷ The case report of a recent tourist death probably from septic shock secondary to respiratory tract infection and suspected vertebral fracture illustrates that health risks are present even for those on cruise ships in Antarctica¹² (Table 208-1).

HEALTH CARE SERVICES

Each nation and group traveling to Antarctica has assessed the risks to their particular group and has developed health care services in response to the perceived needs. They range from multidisciplinary medical teams and elaborate medical suites and equipment at some stations to no medical or paramedical staff and very basic equipment and supplies at others. Each should be self-sufficient because of the cost in terms of both financial and the diversion of scientific and support personnel from their work. Countries involved in Antarctica have chosen different models of health care: civilian, military, contract, within the national polar organization, or combination of these. Determining factors include the number and skills of the medically trained staff, the degree of physical isolation, and medical logistics capabilities, especially the ability to provide medical evacuation by ship or aircraft.²⁷ Medical services for the younger, more adventurous tourists cater to traumatic injuries, whereas on traditional tourist ships, older passengers need support for age-related medical problems.^{12,13} The International Association of Antarctic Tour Operators (IAATO), the voluntary self-regulating body for Antarctic tourism founded in 1991, is currently developing standards for its members' medical services.¹⁴ Some Antarctic medical practices have an evidence base of over 50 years, with a resulting emphasis on preventive medicine.⁸ This is arguably the most important factor and has been the cornerstone of "best practice" services in Antarctica, where logistic constraints prevent timely evacuation and resupply. Physicians who have wintered over and been the sole medical providers consider that two-doctor teams

would be preferable. As well as having an "on the spot" second opinion, this also brings a wider range of skills and experience to medical management in isolation. Although a number of nations used two-doctor teams in the past, few continue this practice today. All doctors would prefer medical evacuation capability, but limited numbers of groups have this luxury, even in summer. Without such capability, the Antarctic physician must rely on his own skills, the supplies and equipment at hand, and the assistance of telemedicine. Specialist advisors in the home country must know the doctor's skills and capabilities, as well as the limitations of the pharmaceuticals and equipment, preferably having seen the medical facilities in Antarctica at first hand. Planning is very important, and the risk-benefit ratio of every potential procedure must have been assessed.

Predeparture Medical Screening

Predeparture screening was advocated in the heroic era.¹⁵ Nations practicing preventive medicine have a rigorous predeparture medical screening, some having psychological or psychiatric assessment. This contrasts with many tourist operations.^{12,13}

Guidelines for screening vary between groups, with the most rigorous rejecting persons with specific conditions such as asthma, coronary artery disease, diabetes, and epilepsy and those whose continuing good health depends on medications. Waivers are granted for some groups. Most standards or guidelines are under constant or annual review to guarantee that the latest medical knowledge is taken into account. Investigations vary between groups and may include blood donor screening, electrocardiogram (stress electrocardiogram for some above a certain age), chest x-ray, and laboratory tests.

Selection and Training of Medical Staff

In selecting a doctor for the austral winter-over, account must be taken of the likelihood and consequences of medical events and the needed medical skills. In addition, one must assess the physician's personality and ability to deal with the demands of the practice with its isolation, confinement, and separation from family, friends, and colleagues. No one medical specialty is considered best for the Antarctic because it is the combination of personal attributes for the environment as well as medical expertise and experience of the individual that is important—a true "supergeneralist."

Experience in a number of fields is desirable. With the possibility of cold injury and the presence of scientific chemicals and allied materials, many deemed hazardous, occupational and environmental skills are useful. Knowledge of nutrition is often needed and certainly public health principles if food poisoning or water pollution occurs. Emergency medicine skills prepare for the accidents and acute conditions, while diving and aviation medicine are an advantage for such programs. For stations and groups that are completely isolated, predeparture training of physicians in surgery, anesthesiology, radiology, dentistry, and laboratory techniques is desirable. Medical training of lay staff is also important. In locations that are accessible by sea or air, a lower level of skill may be acceptable. Medical handbooks and first aid manuals are particularly useful to assist in orientation processes.^{16,17} With many hazards confronting all groups, preventive aspects are important for all individuals. Predeparture training in both general medical and work-related areas is also important for all; for those spending larger periods of time in Antarctic isolation, reentry into society also should be covered.

One topic rarely discussed is what happens if the doctor becomes ill. This is important not only for the patient but also for the group, especially if evacuation cannot be accomplished. Such scenarios are vividly illustrated by the description by Rogozov of his self-operation for appendicitis in 1961¹⁸ and the difficulties and management of the highly publicized medical evaluation of doctors from the South Pole.^{56a} Evacuation of patients has been achieved in all months of the

TABLE 208-1 ANARE Health Register, 1988-1997

Disorder	Number	Percent
Injury and poisoning	3910	42.0
Respiratory	910	9.7
Skin, subcutaneous	899	9.6
Nervous system/sensory	702	7.5
Digestive	691	7.4
Infection/parasitic	682	7.3
Musculoskeletal	667	7.1
Ill-defined symptoms	335	3.6
Mental	217	2.3

year from the U.S. McMurdo Station and recently during winter-over from Pole Station.⁶⁵¹ Preventive principles have even been extended to predeparture prophylactic appendectomy for physicians.¹⁰

Telemedicine and Medical Informatics

Medical communications have always been of utmost importance both within Antarctica and to the outside world, allowing solo practitioners to advise patients remote from them, as well as giving them access to a range of skills, ideas, and experience of medical specialists. Despite communications being subject to radio blackouts of polar cap absorption (PCA), they were the cornerstone of many medical systems.¹⁹ Simple, cheap, and effective solutions allowed data, clinical and microscopic photos, x-rays, and electrocardiograms to be transmitted from Antarctica to the countries of origin of expeditions for over 50 years.^{46,19} Today, with satellite systems, medical imaging and the transmission of medical and biomedical data are daily occurrences, unaffected by PCA blackouts. Many groups have access to phone, fax, e-mail, data circuits, and the World Wide Web. The system, in addition to providing clinical and peer support, has been innovative in education and continuing training of doctors with access to databases, electronic journals, and universities.

Hand-written medical logs from the 1940s onward were surveyed in the 1970s for epidemiology. For the last 15 years, medical informatics has come to the fore, with health registers containing data on all health events; coded information relating to each consultation with diagnosis, treatment, procedure performed, and pharmaceutical prescribed is transmitted in real time from Antarctica.²⁰ This has enabled researchers to quantify the occurrence of injuries in Antarctica; to compare incidence rates; to assess temporal, seasonal, and occupational trends; and to identify high-risk groups.^{7,21} Accurate usage records also assist in inventory control and planning.

Laboratory and Diagnostic Equipment

Routine diagnosis and treatment present a challenge to physicians, and it is important that they have access to facilities that can assist. Diagnostic facilities range from the basic to more sophisticated laboratory tests. It is important that every piece of equipment is assessed for its usefulness and not for the fact that it is nice to have. A solo practitioner with a very ill patient does not have a lot of time to operate laboratory equipment that takes considerable time to arrive at a result. Considerable planning must go into the "ideal" diagnostic armamentarium, with emphasis on what will assist. Equipment that works in a major teaching hospital may not work in a small boat or ship in Antarctica. Dry-chemistry analyzers have increased laboratory services in Antarctica, but difficulties still exist for their operation in simple ways such as shelf life of components and storage temperatures.²²

UNIQUENESS OF PRACTICE

In most Antarctic groups, the doctor lives and works with the group. The potential patients therefore see their physician at close quarters and also the medical system and what it could provide should they become ill or injured. This often puts stress on both the doctor and the patient. Patients are aware of the difficulties of supply, the problems of storage of Pharmaceuticals (some do not survive freezing or dramatic temperature changes), the short shelf life of some Pharmaceuticals, and the lack of equipment and skills. In most cases this can be overcome by clear advice at the outset of what can be done and whether evacuation can be accomplished. Doctors, too, are well aware of perceptions of danger, risk taking, and outcomes in remote Antarctica.²³ In addition, most staff are very perspicacious patients.²⁴

Doctors in Antarctica must be past masters of improvisation in managing health and related issues. The successful use of cyanoacrylate tissue adhesive for the painful spontaneous skin disorder "polar

hands,"²⁵ the manufacture of glasses from perspex, the manufacture of toothpaste, the unconventional repair of dentures and equipment, and the disassembly of an x-ray machine so that it could be flown by helicopter to a tourist ship to confirm a suspected diagnosis¹³ are a few of the documented cases.

RESEARCH

In Antarctic medicine there has always been a close association between clinical practice and research. The prime responsibility of doctors is health care, and they are in a unique position to integrate clinical and evidence-based observation of their colleagues, especially during winter. The multidisciplinary research has centered on human interaction with the Antarctic environment.¹⁰ Despite the inability to replicate space-specific effects of radiation, altered atmosphere, and weightlessness in Antarctica, the isolation, confinement, and total reliance on technology make Antarctica an excellent analogue for studies on long-duration space missions. The finding of an altered immune status in Antarctic wintering personnel, although not associated with any specific disease, has important health implications should viral disease occur. Further studies, however, have given evidence that such subjects have normal antibody production.²⁶ These studies illustrate the close nexus between Antarctic medicine and research.

INTERNATIONAL COLLABORATION

There has always been excellent collaboration in Antarctica, especially with medical evacuations.⁸ The Scientific Committee on Antarctic Research (SCAR) has had an active Working Group on Human Biology and Medicine for nearly 30 years. The continuing process of physicians of different national Antarctic programs sharing data, diagnostic dilemmas, management of difficult cases, experiences of pharmaceuticals, and equipment has led to improved standards of care. The decades of collective experience of the working group has greatly assisted nations establishing health care for the first time. The SCAR working group has been particularly active since 1974 in guidelines for Antarctic predeparture screening for national groups.

GUIDELINES FOR HEALTH CARE SERVICES IN ANTARCTICA

The following guidelines on staffing, training, facilities, medical equipment, and pharmaceuticals are not definitive. Organizers of health care must take into account the following:

1. Area of Antarctica—isolation factor
2. Numbers of people, their ages, sex, and medical status
3. Length of stay (winter, summer, ship visit, overflight)
4. Presence of medical practitioner(s), paramedical staff
5. Facilities available
6. Communications
7. Risk factors
8. Medivac capability and plan efficiently and effectively to cover all contingencies

Staffing and Training

Ideally, a medical practitioner should accompany all groups and should have the skills and adequate predeparture training to manage all medical, surgical, and dental emergencies to the level of care decided on. A doctor is a must for a wintering group. Additional personnel should receive training in assisting in emergency care and, if surgery is contemplated, maintenance of anesthesia and sterile operating theater techniques to assist the doctor. If paramedics are used instead of doctors, they should be adequately briefed and trained. In the case of small, isolated summering or wintering groups, predeparture training for all should include first aid and occupational health and safety.

Facilities

An adequate medical area should be provided to cope with the needs of each group. If a doctor is present, serious consideration should be given to operating facilities. Such facilities are vital for initial management of burns and much of the trauma sustained, even if the patient is ultimately evacuated. All vessels, both national expedition and tourist, require adequate facilities.

Equipment

The following list is an *aide memoire* for equipment selection. The amount and sophistication depend on factors mentioned earlier, as well as on the skills of the staff.

1. Medical library
2. Examination equipment
3. Ward equipment (suction, nasogastric tubes, Foley catheters, etc)
4. Emergency and resuscitation equipment including stretcher, defibrillator/electrocardiograph, and transfusion supplies
5. Instruments for surgical, orthopedic, obstetrics/gynecology, and dental procedures
6. Suture material
7. Sterilizing equipment (autoclave)
8. Laboratory and diagnostic equipment
9. Anesthetic equipment (including a pulse oximeter)
10. X-ray equipment and supplies, ultrasound
11. Operating theater equipment, including soft goods
12. Dressing, bandages, etc.
13. Splints and traction equipment
14. Physiotherapy and rehabilitation (ultrasound)
15. Medical gases
16. Training equipment
17. Telemedicine equipment

Pharmaceuticals

A complete range of Pharmaceuticals should be selected to cover the following:

1. Cardiovascular system
2. Respiratory system
3. Alimentary system
4. Analgesics, anti-inflammatory (nonsteroid), etc.
5. Narcotics, hypnotics, psychotropics, anticonvulsants
6. Antidotes
7. Antiallergics
8. Endocrine drugs
9. Vitamins and minerals
10. Hematopoietic system
11. Urinary system
12. Gynecologic drugs
13. Sera, vaccines
14. Dermatologic preparations
15. Ophthalmic preparations
16. ENT preparations
17. Intravenous fluids
18. Anesthetics and allied drugs
19. Diagnostic and laboratory agents
20. Antibiotics and allied drugs

MEDICOLEGAL

This is a complex issue and far beyond the Good Samaritan principle and the extent of national expeditions providing medical care for nongovernment activities.¹¹ This starts in the country of origin of the groups and extends to disability legislation and whether medical

selection legally can disqualify those with preexisting conditions. Many groups face the dilemma by giving waivers instead of arguing a case that Antarctica is different. A number of countries have legislation covering areas of Antarctica (the so-called Frozen Claims of the Antarctic Treaty), but whether this pertains only to citizens of the claimant nation or beyond probably will require legal testing in the courts.

Despite increasing standards of health care in Antarctica, which are in part a reflection of community attitudes and the expectations of groups in Antarctica and their families at home, it is unrealistic to expect the standard to be that of best practice in teaching hospitals. Availability of and short shelf life of Pharmaceuticals; levels of skills, equipment, and diagnostic and laboratory tests; correct servicing of equipment; and status of medical assistants, especially if dispensing drugs in the absence of a doctor, are but some of the areas that prevent Antarctic medicine from reaching the standard of teaching hospitals. When one adds international patients, issues of medical confidentiality in isolated small groups, the status of walking blood banks, the ability to screen adequately for all viruses, the potential sexual misconduct of a sole doctor who enters a relationship with a fellow member of the group (all of whom are potential patients), issues of pregnancy and management, and who doctors the doctor, then there is a medicolegal situation beyond belief. It is considered that common sense will prevail and that many of these will become nonissues in the situation of Antarctic medicine and its rather basic nature. However, in this litigious society, one cannot be certain, and the next decade therefore will be interesting because already government agencies and doctors have been sued.

SPACE MEDICINE David Williams

When once you have tasted flight, you will forever walk the earth with your eyes turned skyward, for there you have been, and there you will always long to return,

Leonardo da Vinci

INTRODUCTION

Space flight confronts some of the most challenging clinical, engineering, and technological problems of our time. Space medicine has grown significantly since the Mercury program, when the primary focus was on medical selection of astronauts, into an area of clinical practice requiring a unique set of knowledge, judgment, and clinical skills. Currently the delivery of health care in space is a combination of preflight medical selection of astronauts, wellness programs to optimize crew readiness for flight, health stabilization programs prior to launch, on-orbit countermeasures and conditioning programs, a system of clinical care provided by crew medical officers (CMOs) supported by flight surgeons (FS) in mission control, and postflight rehabilitation programs.

For the purposes of human space travel, the border to space has been set at 80 km (50 miles). In the United States, the term *astronaut* is used for individuals who have traveled above this altitude. Aerodynamic aircraft control is no longer effective beyond approximately 80 km above the earth's surface, and the vacuum and temperature extremes of space require complex environmental control and life support systems (ECLSS) for crew survival. Microgravity affects virtually every organ system. There are three primary sources of ionizing radiation that exist in the space environment: galactic cosmic rays (GCR), trapped belt radiation, and solar particle events (SPE). As mission duration and altitude increase, radiation shielding and specific radiation countermeasures become necessary.

Early in the history of human space exploration, a life science research program was implemented to study the physical challenges of space flight and physiologic adaptations that would occur in microgravity. The term *bioastronautics* was initially used to describe the study of the biological and medical effects of space flight on living organisms, with a particular focus on human adaptation to space. Prior to the first human space flights, the primary clinical question dealt with the survivability of space flight. Concerns were expressed about a number of issues ranging from cardiovascular, neurovestibular, and musculoskeletal changes to fears that astronauts would aspirate saliva and be unable to swallow in microgravity. The first human flights in

1961 demonstrated that humans could survive short-duration space travel with minimal adverse effects. This information was critical to the later declaration that the National Aeronautics and Space Administration (NASA) would land humans on the moon and safely return them to earth.

SPACE PROGRAMS

Early spacecraft from Mercury through Apollo-Soyuz were based on a ballistic capsule design with thermal barriers to protect the vehicle during reentry, and a series of parachutes to slow the vehicle for landing in the ocean. During the Mercury and Gemini programs, an environmental control system (ECS) was designed to maintain pressurization and thermal control of the capsule with crew members wearing space suits. Later in the Apollo, Skylab, and Apollo-Soyuz programs, crew wore space suits only for the launch and re-entry phases of space flight.

Mercury

The Mercury spacecraft provided a 28-h flight capability based on an oxygen consumption of 500 mL per min at standard temperature and pressure. Cabin pressurization was maintained at 5.1 psi. This pressure was chosen as the best compromise to provide necessary oxygen partial pressure, efficient use of the oxygen supply for emergency modes of operation, a pressure offering small differential change during sudden decompression emergencies, and a level at which decompression sickness would be minimal. The astronauts breathed 100 percent oxygen for 2 h prior to launch to reduce the risk of decompression sickness while transitioning from an ambient pressure of 14.7 psi at the launch site to 5 psi in the spacecraft in orbit.

A heat exchanger was designed as part of the suit pressure control system to accommodate astronaut metabolic heat production of 500 BTU per h. Potable water consisted of a flexible water pouch containing 2.7 kg of water with a flexible hose and drinking tube.

The primary medical conclusions from Project Mercury revealed few areas of significant clinical concern.¹ There was no evidence of deterioration in pilot performance and all measured physiologic functions remained within normal limits during the mission. An orthostatic rise in heart rate and fall in blood pressure were noted postflight and it persisted for 7 to 19 h after landing. There was no evidence of abnormal sensory or psychological response in any phase of flight and the radiation dose received was considered medically insignificant.

Still, many questions needed to be answered about the ability of astronauts to perform complex tasks on longer-duration missions, to pilot and dock spacecraft on orbit and perform spacewalks or extravehicular activities (EVAs).

Gemini

A new spacecraft that accommodated two astronauts was developed for the Gemini program with enhanced ECS capabilities to support longer missions.² The longest Gemini mission lasted close to 14 d, compared to the single-crewman Mercury missions that lasted a maximum of a day and a half.

The Gemini spacecraft ECS maintained a 100 percent oxygen atmosphere, controlled the temperature of the crew and spacecraft equipment, and provided a drinking water supply and means of disposing of waste fluids. Clinical studies showed no oxygen toxicity with exposure of humans for 14 d to the 100 percent oxygen at 5 psi. Gemini introduced a flight crew equipment system to support the longer missions. A food system consisting of vacuum packed freeze-dried rehydratable foods and beverages were provided to maintain between 2000 and 2500 calories per day. A urine collection system consisting of a portable receiver with a latex condom catheter and a defecation system consisting of individual plastic bags with adhesive-lined circular

tops and a disinfectant packet to eliminate bacterial growth were flown. In-flight use required considerable care and effort. The personal hygiene system included tissues in fabric dispenser packs, fabric towels, wet cleaning pads, and toothbrushes and chewing gum for oral hygiene.

The first NASA EVAs were performed in the G4C suit during the Gemini 4 mission.³ EVAs were accomplished on five of the ten Gemini missions, with important findings that facilitated the development of the more complex Apollo EVAs that would later be done in space and on the lunar surface. A small chest pack called the *ventilation control module* was developed for control of the space suit pressurization and ventilation, and suit pressure was maintained at 4.2 psi. The 100 percent oxygen environment of the spacecraft and the small change in cabin pressure from 5.1 to 4.2 psi minimized the risk of decompression sickness. During the initial egress activities and during ingress, the oxygen flow in the space suit did not keep the EVA pilot cool and overheating and visor fogging occurred.

Preflight quarantine was rejected as impractical in the Gemini program and a number of the astronauts developed short-lived flu-like syndromes; one was exposed to mumps and there was one incident of streptococcal pharyngitis that developed in the immediate preflight period. A drug kit was made available for in-flight prescription and aspirin was used in-flight for occasional mild headaches and for relief of muscular discomfort. Decongestants were used to relieve nasal congestion and alleviate the necessity for frequent clearing of the ears prior to reentry. Motion sickness medication was taken in one instance prior to reentry to reduce motion sickness resulting from motion of the spacecraft in the water. An inhibitor of gastrointestinal motility was prescribed when necessary to assist in avoiding in-flight defecation.

The medical findings from the Gemini Program extended the Project Mercury findings that humans can tolerate exposure to the space environment quite well.⁴ No significant performance detriment was noted. Once again, postflight orthostatic hypotension persisting for some 50 h was observed during tilt table tests. A decrease in red cell mass of the order of 5 to 20 percent was noted, and bone demineralization was observed as a percentage change in the density of the calcaneus. No adverse psychological reactions were observed even during 14 days' confinement in a restrictive cabin environment, and no vestibular disturbances were reported.

Apollo

The Apollo Program accomplished the goal of landing humans on the moon and safely returning them to earth less than a year after the first manned flight test of the Apollo vehicle.⁵ The three-person Apollo spacecraft consisted of a command module (CM), service module (SM), and lunar excursion module (LEM). The SM was mounted below the CM and contained the main propulsion system and stowage for most of the consumables. The SM was jettisoned prior to reentry into the earth's atmosphere at the end of the mission. The LEM was a two-staged vehicle with the ascent stage made up of three sections: the crew compartment, midsection, and aft equipment bay.

The Apollo CM ECS was composed of the oxygen subsystem, pressure suit circuit subsystem, water subsystem, coolant subsystem, and waste management subsystem. As in Mercury and Gemini, a 100 percent oxygen atmosphere was used with a cabin pressure of 5 psi and normal shirtsleeve environment except for launch and entry. Tragically, this environment led to the catastrophic loss of the Apollo 1 vehicle and crew in a fire on the launch pad during vehicle testing. This led to a redesign of the ECS such that the CM was launched with 60 percent oxygen/40 percent nitrogen gas composition that was eventually raised to 100 percent oxygen during the mission. The atmospheric pressure and composition after launch remained between 4.71 and 5.1 psi, including the time in the lunar module.

Carbon dioxide levels in the spacecraft were regulated to 3.8 mm Hg with a maximum limit of 7.6 mm Hg and an emergency limit of

15.0 mm Hg. Carbon dioxide levels recorded by sensors in the CM and LEM remained well below these limits except for the return flight of the Apollo 13 spacecraft, when they rose to a maximum of 14.9 mm Hg in the LEM. Temperature and humidity in the Apollo CM was regulated to between 70° and 80°F with a relative humidity of 40 to 70 percent. During the Apollo 13 mission the LEM ECS provided a habitable environment for approximately 83 h, after which cabin temperatures ranged between 49° and 55°F.

The primary medical objectives of Apollo were to ensure crew safety and health by identifying, minimizing, or eliminating potential crew health hazards. An important additional objective was to prevent terrestrial contamination from material brought back from the lunar surface. Supplemental objectives included continuing research to understand the biomedical changes affecting the body during space flight. A preflight medical program was implemented during the Apollo missions with the implementation of a health stabilization program and other preventive measures after Apollo 13. Determination of individual drug sensitivities to the contents of the Apollo medical kits was performed on all astronauts and a baseline data collection program was implemented to compare with postflight data for determination of the effects of space flight.

Significant in-flight medical observations⁶ from the Apollo program included upper respiratory tract infections (prior to preflight quarantine), space motion sickness, skin and eye irritation from fiberglass insulation, contact dermatitis, facial and inguinal rashes, cardiac dysrhythmias, fatigue, dehydration, anorexia, urinary tract infection, shoulder strain from drilling for lunar specimens, and possible mild decompression sickness. A number of factors predisposed to sleep disruption, including noise from thruster firings or communication with the ground, staggered sleep periods, excitement, the unfamiliar sleep environment, and the command pilot syndrome reported by some of the command pilots when alone in lunar orbit awaiting the return of the LM.

Crew nutrition was a concern due to inadequate food consumption to maintain metabolic balance during some of the missions (caloric intake was less than calories expended, with loss of tissue fluid and electrolytes). Meal preparation and consumption required too much time and effort relative to other mission tasks. Reconstitution of dehydrated foods affected its taste, and in some cases it contained large quantities of undissolved hydrogen and oxygen gas. Weight losses of 2 to 3 kg were observed. Dehydration was an issue after the explosion of the SM oxygen tank during the flight of Apollo 13 that required the crew to use the LEM as a lifeboat to return from the aborted lunar mission.

Despite the complexity of the CM EVAs and the 14 lunar surface EVAs, no problems were experienced by any of the astronauts.

Skylab

The successful conclusion of the Apollo program represented a tremendous technological and human achievement. Space medicine had evolved significantly over a period of 10 years, yet the discipline was still in its infancy. The major focus of space biomedical research following Apollo was on the physiologic adaptation of humans to space in both short- and long-duration missions. Long-duration missions are defined as those lasting longer than 30 days. By the end of the Apollo program, the longest NASA missions were 2 weeks.

Skylab was developed as an orbiting space station to provide a research platform to extend human capability during long-duration space flight. Launched to an altitude of 270 miles, it provided a shirtsleeved environment pressurized to 5 psi: 3.7 psi oxygen and 1.3 psi nitrogen. It was equipped to house three astronauts for up to 3 months in a volume of 294 cubic meters.⁷ This was huge in comparison to the Mercury, Gemini, and Apollo spacecraft, whose volume ranged between 1 and 8 cubic meters. The mission duration for Skylab-2 was 28 days, Skylab-3 59 days, and Skylab-4 84 days.

The biomedical objectives of Skylab included determining human physiologic responses and behavioral performance in space and during

the postflight readaptation to the terrestrial environment, after a series of progressively longer missions. Enhanced clinical capability was provided during the mission with the in-flight medical support system (IMSS). The IMSS consisted of diagnostic and therapeutic equipment to optimize the capability for mission completion in the event of an illness or injury by diagnosing and treating the affected astronaut in space. For diagnostic purposes, the standard clinical tools (stethoscopes, sphygmomanometers, thermometers) were provided, in addition to lab equipment for blood analysis, urinalysis, and microbiological work. For therapeutic purposes the IMSS was supplied with an assortment of drugs, both oral and injectable, for the treatment and prevention of infection, disease, and allergies. The IMSS was also outfitted with a surgery kit for the care of minor injuries.

Space motion sickness was reported by some of the astronauts and was treated with prophylactic medication early in the flight. Symptoms were reported to last up to 4 days, but typically resolved within 48 h of being in space. Anecdotal reports from the Skylab crews suggested that space motion sickness could not be predicted with the usual ground-based tests, but could be alleviated somewhat by prophylactic administration of medications early in the mission.

The cardiovascular response of the astronauts to provocative orthostatic stress was examined for the first time on orbit. The crews were tested using a lower-body negative pressure (LBNP) device before, during, and after all Skylab missions. LBNP during the mission imposed a negative 50 mm Hg orthostatic stress for 25 min. This provided an orthostatic challenge similar to standing in a 1 G environment and showed the familiar indices of reduced cardiovascular efficiency. This was found to stabilize after 4 to 6 weeks with no apparent impairment of crew health or performance. Bone density studies did not show mineral losses in the upper extremities, but bone loss occurred in the lower extremities at a rate of approximately 1.5 percent per month, comparable to rates observed in bed rest studies. Evidence of muscle loss was obtained from anthropometric studies, revealing a marked loss in leg volume, most of which was restored within 21 days of landing. One-third of the loss was attributed to partial atrophy of the leg muscles, while the remainder was attributed to fluid loss.

As in the case of Apollo, fatigue was an issue for some of the Skylab crews. Sleeping compartments were not sufficiently isolated from each other and from the waste management compartment for optimum noise control. Mobility and restraint systems were also found to be major factors in the perceived habitability of the station and suggested that further research on human factors would help improve performance in microgravity. The Skylab program conclusions suggested that with sufficient attention to such issues as food service, waste management, and sleep arrangements, a spacecraft can provide satisfactory living and working quarters for long periods of time.

Space Shuttle

Following completion of Skylab, attention shifted to developing a new launch vehicle. The space shuttle, or space transportation system (STS), was developed as a multipurpose vehicle to deliver crew and payloads to low earth orbit, to rendezvous and dock with orbiting space stations, and to function as an autonomous microgravity research platform. The maximum G forces during the launch are limited to 3 G's and occur in the last minute of powered flight.

The shuttle atmosphere is maintained at 14.7 psi, with a P_{O_2} of 3.2 ± 0.25 psi (165 mm Hg) and a P_{CO_2} below 7.6 mm Hg (0.15 psi). Mission rules require that oxygen masks be donned if oxygen pressure falls below 2.34 psi (121 mm Hg) or if carbon dioxide levels exceed 15 mm Hg. Water vapor pressure of 10 mm Hg is optimal for habitability and is controlled between 6 and 14 mm Hg. Ambient temperatures within the shuttle range from 18° to 27°C. The crew members wear launch and entry suits during the dynamic flight phases of the mission to support crew escape in the event of emergency.

The shuttle has sophisticated systems including onboard computers, communications capability, electrical systems, guidance, navigation and control systems, mechanical systems, orbital and aerodynamic maneuvering systems, and robotic and rendezvous/docking systems. The aviation skills required of the shuttle commander and pilot during all phases of flight are significant, but entry and landing are most critical, in part due to the physiologic deconditioning that occurs even on short-duration missions.

Biomedical research on the shuttle was organized to develop a series of countermeasures to prevent the deleterious effects of space flight. The research capability of the shuttle was augmented by the Spacelab and SpaceHab modules that could be installed in the payload bay of the orbiter. The additional workspace provided by these modules turns the shuttle into an orbiting laboratory for short-duration microgravity research. A number of shuttle missions have focused on space life science research, including SLS1 and SLS2, the International Microgravity Laboratory missions, the Life and Microgravity Science mission, and more recently Neurolab.

From 1990 to 1995 a robust research program⁷ to evaluate extending the duration of shuttle flights was implemented. Forty-six different experiments were flown on 42 different shuttle flights with 133 astronauts participating in the research protocols. The results of these studies, when combined with previous physiologic research, helped develop and evaluate a series of new countermeasures.

Mir

Eight flights between 1995 and 1998 were conducted to send and return seven NASA astronauts to the Russian Mir space station. The average mission duration was 131 days and 25 experiments were conducted in phase 1A and 26 experiments in phase 1B. Data were collected from both astronaut and cosmonaut participants. Many benefits arose from the program in addition to the life science research objectives. NASA gained further rendezvous, docking, and long-duration operational experience that would help reduce the risks associated with developing and assembling the International Space Station (ISS).

PHYSIOLOGIC ADAPTATIONS TO MICROGRAVITY

Cardiovascular Responses

Cardiovascular studies documented the prevalence of a number of benign atrial and ventricular dysrhythmias and helped establish normative values for heart rate and blood pressure on missions lasting 10 days or less. Extensive postflight studies of orthostatic intolerance were conducted, and the results suggested that decreased plasma volume plays a role, but decreased total peripheral resistance is an important determinant of pre-syncope.⁸ Use of a liquid-cooled garment as part of the launch and entry suit was found to be critical in preventing peripheral vasodilatation, and fluid-loading protocols were developed and utilized prior to reentry to maintain preload. Early inflation of G suits during entry was also found to be very helpful as the gravitational vector (+Gz) runs from head to toe when the crew are seated for entry and landing.

Aerobic and Muscular Capacity

Functional performance assessments revealed decreased (10 to 20 percent) aerobic capacity for all subjects, with a protective benefit documented for subjects who exercise for 20 min or more at 60 to 80 percent preflight maximum work levels at least three times per week. Decreases in muscle strength ranging from 10 to 20 percent were noted in the legs and postural muscles of the trunk. Muscle morphology changed rapidly in response to microgravity, with decreases noted in both type 1 and type 2 fibers.

Neurovestibular Adaptations

Neurovestibular and neuromuscular assessments revealed that experienced astronauts with multiple space flights had better adaptation to space and better postflight performance, suggesting retained learning.⁹

Metabolic Adaptations

Total energy requirements were documented to be similar for short-duration flight and a normal terrestrial activity level. Energy intake decreased in flight, partly due to space motion sickness, and most subjects lose body mass to some degree. All subjects were noted to lose 1 to 2 L of total body water, and it was felt that the renal stone risk increased immediately in flight and postflight due to decreased fluid intake.

Infections and Environmental Hazards

Changes in the shuttle environment were documented, revealing a moderate increase in bacterial levels during the mission. Fungal levels generally decreased due to the relatively low humidity of the shuttle. Although volatile organic hydrocarbons were generally below required levels, the necessity for monitoring real-time levels of combustion products led to the development of a combustion product analyzer.

Countermeasures

The Extended Duration Orbiter Medical Project (EDOMP) program demonstrated the need for a comprehensive countermeasures program that would include at least the following protocols: fluid/salt loading; pharmacologic, aerobic and resistive exercise; and nutritional, environmental, mechanical, and special countermeasure training for crews. Important lessons were learned about the need to monitor and maintain an appropriate cabin atmosphere, levels of potentially toxic environmental contaminants, the acoustic environment, the radiation environment, water quality, flight crew equipment, clothing, sleep quarters, exercise equipment, food, family support, and behavioral support. These lessons were not only important in extending the duration of shuttle missions; they helped prepare for the NASA/Mir long-duration missions. Current countermeasures are often specifically developed for each crew member to optimize their efficacy for astronauts of both genders and different ages. Although preliminary data suggests that the efficacy of these countermeasures is considerably improved over those in previous use, further research to improve efficacy will be critical to minimize the risk of long-duration space travel beyond low earth orbit.¹⁰

ILLNESS AND INJURY IN SPACE

Many of the deleterious physiologic changes associated with the transition to microgravity cause clinical conditions that are similar to terrestrial diseases. The bone loss and muscle wasting induced in long-duration space travel are similar to those noted in patients during prolonged bed rest, immobilization, or those with spinal cord injuries. The combination of increased calcium turnover and dehydration seen in astronauts increases the risk of kidney stones.

Once the physiologic adaptations to space have stabilized, it is not known if these adaptations alter the pathophysiology and clinical course of a particular illness. For instance, it has been suggested that a transient increase in intracranial pressure associated with the cephalad fluid shift early in flight results in the characteristic headache, nausea, and vomiting associated with space motion sickness. The combination of such physiologic changes with those associated with a significant closed head injury could be significant. Similarly, the hemodynamic response to blood loss may be altered by the cardiovascular and hematologic changes that have been described in both short- and long-duration crews.

Decompression illness (DCI) in a terrestrial environment is caused by rapid changes in ambient pressure, resulting in the formation of bubbles from gases saturated in the tissue. Preparation for EVA involves transitioning from the ambient pressure of the shuttle or ISS to the final 4.3 psi suit pressure. To prevent DCI, astronauts prebreathe 100 percent oxygen for up to 4 h, depending on the protocol used. It is of interest that the protocols evaluated for use in space have been associated with up to a 20 percent incidence of DCI in terrestrial studies, yet no DCI has been reported in space. The relative absence of tissue bubble micronuclei in microgravity has been proposed as a possible explanation. In a terrestrial gravitational environment, moving the extremities against the resistance of gravity will cause small tissue gas micronuclei that can produce evolved tissue gas when subjected to sufficient decompression stress. In the absence of gravity, these micronuclei are either less frequent or do not exist, a phenomenon that would protect against developing DCI. This has been referred to as the *adynamia model*¹¹ and is currently an area of great research interest due to the large number of EVAs required to build the ISS.

The biomechanics of blunt trauma may also be affected in space, depending on whether the astronaut is inside the spacecraft or performing an EVA. Typically, blunt trauma results from the dissipation of force and transfer of energy to tissue following impact with a fixed or moving object. Objects in space have no weight, yet they still possess mass, an important point when moving a 400-kg object in space with one hand. Significant crushing injuries are a major concern as astronauts move large objects with significant mass within the space station. During an EVA, whether in microgravity or on the surface of another planetary body, crew members wear protective space suits. It is unknown to what degree the space suit would help dissipate force, although their resemblance to an exoskeleton suggests there may be some protective effect.

HEALTH CARE SYSTEM IN SPACE

The delivery of health care in space^{12,13} is a team effort. All crew members have sufficient first aid training to act as first responders, and extended medical training is provided to the crew medical officers (CMOs). The majority of CMOs are not health care professionals, although when a career astronaut that is also a physician is assigned to a crew, they are automatically designated the CMO for the flight. CMOs are supported by flight surgeons (FS) sitting on console in mission control and are an important link in the chain of clinical care from space to terrestrial definitive medical care facilities. In the event of significant illness or injury in one of the astronauts on a space station or spacecraft in low earth orbit, the CMO would perform a focused history and physical examination, arrive at a primary diagnosis, and begin treatment as required. The CMO communicates his or her findings to the FS as soon as possible, and may initiate further diagnostic or therapeutic procedures at the request of the FS. Consultative support is available to the FS if necessary.

Some clinical conditions may require mission termination to return the crew member if consumables are depleted in treating the patient, if the treatment is not possible in space, or if the clinical condition of the patient warrants evacuation. Preparation of the shuttle and patient for reentry and landing results in a transport time of between 6 and 24 h to landing at the Kennedy Space Center. Upon landing the patient would be reassessed, treated, and stabilized by the medical support team, and transferred to a definitive medical care facility.

Shuttle On-Board Medical System

The shuttle on-board medical system (SOMS) includes two kits designed to support the delivery of basic life support, first aid, and ambulatory medical care. The emergency medical kit and the medications and bandages kit are stowed on the mid-deck for each orbiter flight. The two soft stowage kits are similar to the jump packs used by many

prehospital personnel and include a number of pallets that may be attached with Velcro to the medical worksite. Six pallets are included in the two kits, including injectable drugs, emergency items, diagnostic and therapeutic items, oral drugs, bandage items, and topical medications. The kits can be taken to the location of the ill crew member in the event of a serious injury or illness requiring immediate resuscitation. As in a terrestrial environment, ambulatory patients would be brought to a medical facility, in this case the mid-deck area, for definitive diagnosis and treatment.

One of the unique challenges in providing medical care in a microgravity environment is the need to restrain the patient, CMO, and medical supplies. The configuration of each of the pallets is designed to facilitate their use in microgravity, with extensive use of Velcro and individual pouches for restraint of instruments. Injectable medications are provided in preloaded syringes, and oral medications are stowed in single-dose dispensers.

Advanced cardiac life support (ACLS) capability was developed for the phase 1 NASA-Mir program and has also been flown on dedicated life sciences shuttle flights.¹⁴ The additional equipment includes an advanced airway management kit, defibrillator, and crew medical restraint system. Numerous flights on the KC-135 training aircraft were used to develop and validate procedures to implement resuscitation protocols in microgravity.

ISS Crew Health Care System

The medical capability of the ISS was designed to support the health care needs of long-duration missions. The three main subsystems of the crew health care system (CHCs) provide physiologic countermeasures, environmental monitoring capability, and a clinical capability to prevent, diagnose, and treat illnesses and injuries during a mission. The countermeasures system (CMS) provides a capability to evaluate crew fitness, implement exercise countermeasures, and monitor crew response to the countermeasures during the mission. The environmental health system (EHS) monitors air and water quality for chemical and microbial contaminants, and monitors radiation levels as well as surface microbial contamination. The health maintenance system (HMS) enables the FS to periodically assess crew health, provides resuscitative and ambulatory care in the event of illness or injury, and is the first link in the chain of clinical care to stabilize and medically evacuate crew to a terrestrial definitive medical care facility.

The primary purpose of the CMS is to prevent the cardiovascular deconditioning, disuse bone loss, and muscle atrophy associated with long-duration space flight. Prescribed exercise protocols are individually developed and performed daily by all ISS crew members except on the day of an EVA or within 24 h of a periodic fitness assessment. The CMS exercise equipment includes a vibration-isolated treadmill and cycle ergometer as well as a resistive exercise device. Heart rate, blood pressure, and electrocardiographic monitoring are provided to evaluate the efficacy of the exercise protocols. Treadmill exercise seems to provide additional benefit in promoting gaze stability and lower extremity proprioceptive training, facilitating neurovestibular readaptation that helps astronauts ambulate after landing.

The closed loop life support systems used in spacecraft are very reliable and provide a shirt-sleeved environment for crew members to live and work in. However, qualitative and quantitative monitoring are crucial to monitor potential toxicologic and microbial contamination of the environment. Periodic water sampling for onboard microbial and toxic contaminants is performed. Samples are obtained for return on the shuttle for terrestrial analysis to validate the data obtained in flight. Kits have been designed for collection of surface samples from different locations throughout the ISS for determination of microbial and fungal contamination. A microbial air sampler is used to record airborne microbial contaminants in the different modules of the ISS.

Radiation monitoring consists of area and personal dosimeters to document dose variation in different areas of the ISS, as well as indi-

vidual mission doses. Postflight biodosimetry is performed on long-duration astronauts to determine the biological consequences of the prolonged low-dose radiation exposure characteristic of space flight.

The HMS provides a clinical capability similar to that found in many primary care clinics. It is routinely used to prevent, diagnose, and treat minor medical problems, and could be instrumental in saving the life of an acutely ill or injured astronaut. There are five components to the HMS: the ambulatory medical pack (AMP), crew contamination protection kit (CCPK), the advanced life support (ALS) pack, crew medical restraint system (CMRS), and respiratory support pack. The AMP contains individual diagnostic and therapeutic pallets, including a stethoscope, sphygmomanometer, and portable clinical blood analyzer, in addition to medications, bandages, minor surgical instruments, and suture materials. Crew protection from toxic and nontoxic particulates and liquids is provided in the CCPK. The most frequently used item is the space station eyewash system for removal of ocular foreign bodies. In the absence of gravity, small airborne particles are present that can injure the eye. The CCPK also includes goggles, masks, gloves, and multiple waste bags for containment of contaminated material.

The ALS pack, defibrillator, and respiratory support pack provide limited resuscitative capability to manage life-threatening medical and surgical problems. The crew medical restraint system is an integral component of the suite of critical care hardware on the ISS, as it is required to isolate the spacecraft from electrical shocks during defibrillation. It can be deployed within 2 min and provides additional restraints for the CMO. The combined defibrillator and transcutaneous pacer is interfaced through a data interface module to downlink ECG and heart rate data to the FS in mission control.

In addition to the diagnostic capability provided in the HMS, the CMO may use equipment from the human research facility (HRF) for diagnostic purposes. An ultrasound with color Doppler capability is one of many biomedical research devices on the ISS and provides an important noninvasive diagnostic capability to the CMO. Due to the limited imaging capability on the ISS, terrestrial evaluations of non-standard uses of ultrasound to augment on-orbit diagnostic capabilities have revealed potential value in diagnosing extremity trauma,¹⁵ pneumothoraces,¹⁶ and dental abscesses.

Medical Events in Space Flight

The combined space flight experience of Russian cosmonauts and NASA and international astronauts has been 25,265 person-days in space by 418 people over 40 years. Up to STS-108, there were 5496 person-days on the shuttle (1981 to 2001) in comparison to the long-duration Skylab experience (504 person-days) and the NASA Mir program (849 person-days). Considering the risks associated with training astronauts and the potential for illness and injury during short- and long-duration missions, it is not surprising that a number of medical events have been reported.

Training for space flight occurs in a wide range of environments, including high-performance jets, simulators, and underwater. It includes extensive physical training and survival training in extreme terrestrial environments. Fatalities have occurred in high-performance jets and during development testing of spacecraft. Successful ejections from the lunar landing research/training vehicle occurred during the Apollo program, and other aviation incidents have included ejections from high-performance jet aircraft, and in one case minor injuries associated with a helicopter crash in flight training. Cases of soft tissue injury, minor extremity trauma, overuse syndromes, and barotrauma have occurred during shuttle and ISS training. The rigorous attention given to safety and training as well as the excellence of facilities, aircraft, and hardware have all been critical in preventing further significant training-related injuries.

Medical events related to space flight may be categorized based upon their occurrence during a particular phase of flight. Events during

ascent and re-entry, the dynamic phases of flight, range from relatively insignificant to catastrophic. Fatalities have occurred in both the Russian and U.S. space programs during the launch, ascent, or entry phases of flight. These fatalities have resulted from the failure of specific spacecraft systems that led to either destruction of the vehicle or loss of environmental control. The probability of such events is as low as reasonably achievable due to the appropriate attention given to safety and risk reduction. Improvements in spacecraft design, redundancy, mission support, and flight rules have played key roles in continuing to optimize the safety of human space travel.

Medical events in space are frequent, usually minor, self-limited medical problems. In a review of shuttle missions from 1981 to 1998,¹⁷ 439 male and 69 female astronauts participated in 89 missions, accumulating 4443 days of space flight experience. Overall, 98 percent reported some type of medical problem during the mission, with space motion sickness (79 percent) and headache (67 percent) being the most frequent. The remaining symptoms reported involved respiratory complaints (64 percent), facial fullness (59 percent), gastrointestinal problems (32 percent), and musculoskeletal problems (26 percent). Ocular foreign bodies have been a problem during short-duration missions and were readily treated with the emergency eye-wash kit.

Clinical experience from the NASA Phase 1 Mir program documented skin rashes and infections, crew fatigue, sleep disorders, urinary retention, dental problems, back pain, temporary hearing threshold shifts due to the acoustic environment, minor musculoskeletal injury, and benign dysrhythmias.¹⁸ A fire on the Mir station led to thermal injuries in some of the crew and the collision with the Progress spacecraft resulted in sudden decompression of a module.¹¹ These environmental hazards and the associated risk of trauma are of significant clinical concern and re-emphasize the need to ensure optimum crew safety at all times.

Resuscitation in Microgravity

Electric shock, anaphylaxis, cardiac dysrhythmia, **DCI**, toxic exposures, trauma, and clinical deterioration of medical or surgical events could all result in situations requiring some degree of resuscitative support. Procedure validation on the KC-135 has documented successful animal resuscitation using a porcine model in microgravity. End-tidal CO₂ measurements during CPR documented the efficacy of chest compressions in producing blood circulation in these trials. Limitations exist in extrapolating this data to space due to the potential impact of the physiologic changes associated with short- and long-duration missions on the efficacy of resuscitation.

In most circumstances the patient would be brought to the HMS where the CMRS, ALS pack, and defibrillator could be readily deployed. It is possible to establish unresponsiveness, open the airway, and verify respiratory and circulatory activity quite readily in any location on the space station. Moving the patient in microgravity to the medical work site is analogous to performing an aquatic rescue on a drowning victim, without the need to move against the resistance of the water. To perform CPR and defibrillate the patient, the CMRS must be deployed with the patient and CMO restrained. The CMO gets into position to perform cardiac compression with the feet pushing against the opposite surface of the module to provide the appropriate body positioning for performing chest compressions.

Rapid sequence defibrillation, intubation, and intravenous access are performed in the CMRS if required, it is anticipated that performing these medical procedures in microgravity will be associated with additional delays due to the difficulty manipulating the patient and equipment. Depending upon the ACLS protocol and the time to establish intravenous access, initial endotracheal drug administration will be followed by subsequent intravenous doses. A constant infusion pump is used to administer the intravenous fluids and volume replacement if required. Limited consumables can be a significant constraint

to resuscitation in space. This limitation may be mitigated by the ready availability of a crew return vehicle with medical evacuation capability. Blood loss on orbit presents a unique clinical challenge²⁰ in the absence of blood replacement products, relatively prolonged transport times in comparison to terrestrial prehospital care, and limited capability for volume replacement. Hemorrhagic shock would most likely occur following blunt trauma, although gastrointestinal bleeding and uncontrolled epistaxis could present significant clinical challenges to the CMO and FS.

Surgery in Microgravity

Experience performing surgical procedures in microgravity is limited. The KC-135 has been used to demonstrate the efficacy of a wide range of surgical procedures, including laparoscopic surgery,^{21,22} yet caution must be used in applying the results to the space environment. Animal dissections have been performed on a number of life science missions, including the successful reversible administration of a general anesthetic to perform research protocols.²³ The lessons learned reaffirm KC-135 findings documenting the need for patient, operator, and instrument restraint. A number of techniques have been proposed to restrain instruments in microgravity, including Velcro, magnets, and customized minor surgical trays. Customized kits with individual pockets for each surgical instrument were used successfully on the **Neurolab** mission.

Hemostasis in space does not present any different challenges than those confronting terrestrial surgeons.²⁴ Direct pressure, cauterization, and wound repair are all equally effective in space. Small or moderate amounts of blood form a dome on adjacent tissues in the absence of gravity. Profound venous and arterial bleeding rapidly produces large domes of blood that temporarily obscure the operative field until hemostasis is achieved and the blood is removed with gauze squares or suction. Uncontrolled arterial bleeding travels in a straight line until hitting a surface. Personal experience performing complex animal dissections, both on the KC-135 and in space, has confirmed that hemostasis does not pose any unique problems in microgravity. Anecdotal data suggest that clotting and wound healing appear normal in space, although confirmatory studies are required.

EVA Medical Support

The medical issues associated with astronauts performing spacewalks fall into several categories: pressure related, suit related, or task related. The transition from 14.7 psi to 4.3 psi in the NASA space suit or 5.7 psi in the Russian space suit is associated with a risk of DCI. A number of different prebreathing protocols exist for the NASA space-suit, and are chosen for operational reasons, while a 30-min 100 percent oxygen prebreathing protocol is used for the Russian Orlan space-suit. Barotrauma and DCI are the two pressure-related clinical concerns during spacewalks. Difficulty equalizing pressure in the ears or sinuses may be encountered and is often prevented by the prophylactic use of oral and nasal decongestants. There have not been any cases of DCI formally reported in either the NASA or Russian space program, although there is one anecdotal mention of isolated joint pain unrelated to an EVA in an Apollo astronaut that was described in a lay publication. To date it has not been possible to objectively validate the efficacy of prebreathing protocols in space. New noninvasive Doppler bubble detection devices may prove useful in this area, but must be certified for use in the 100 percent oxygen environment found in the spacesuit.

Some astronauts have reported minor symptoms related to pressure points in the spacesuit. Considerable effort is spent preflight to optimize suit fit and provide padding in potential areas of irritation. Eye irritation from the anti-fog compound used on the suit helmet visor has also been reported. This typically arises if the mouth seal of the **in-suit** drink bag leaks and water droplets contact the visor and then enter the

astronaut's eyes. Nonirritating anti-fog compounds eliminate this problem.

Astronauts perform a wide range of servicing and construction tasks during a spacewalk. It is not unusual to move large objects that weigh hundreds of kilograms manually while performing EVA tasks. In fact, three astronauts on an early shuttle mission were positioned in the payload bay of the shuttle to manually retrieve a satellite after rendezvous with the shuttle. Despite the evident skill of the astronauts, working with massive payloads introduces the risk of musculoskeletal injury, crushing injuries, and overuse syndromes. Extensive training and crew experience in managing massive payloads has played a critical role in preventing these injuries to date.

Spacewalks during the Apollo program were performed both in space and on the lunar surface. The potential for trauma related to working in a space suit while in the partial gravitational environment of another planet is another area of concern. Minor shoulder strain was reported by one of the Apollo astronauts on the lunar surface while drilling for lunar specimens. Astronauts successfully explored the lunar surface both on foot and in the lunar rover without difficulty.

FUTURE OF SPACE MEDICINE

Space medicine has undergone a gradual evolution from developing and implementing selection and retention standards to minimize the probability of disease in astronauts in space, to providing clinical support for short-duration missions in and beyond low earth orbit, and most recently to supporting a permanent human presence in space on the ISS.²⁵ The space station not only serves as an orbiting laboratory and technology development platform, it provides clinicians with a unique opportunity to conduct research to optimize crew safety, health, and performance that will be critical in reducing the biomedical risk of extended missions of human space exploration. Space-faring nations worldwide have sought to extend the accessibility to space for the purposes of research and technological development, commercial utilization, educational outreach, transportation, and exploration. While medical certification standards for professional astronauts and cosmonauts are extremely rigorous, less stringent standards have been developed for space flight participants to enable greater accessibility to space for lay people. Space medicine practitioners will play a critical role in helping engineers optimize the design of space planes to minimize the physiologic challenges experienced by travelers during short episodes of microgravity.

Dr. Williams flew on the STS-90 in April-May 1998. He was also on the first NASA Aquarius mission. He is currently training for his next shuttle flight.

ENDOCRINE EMERGENCIES

HYPOGLYCEMIA

William J. Brady Richard
A. Harrigan

Although there is no universally accepted definition of hypoglycemia, it is generally defined as: 1) symptoms consistent with the diagnosis, that 2) usually occur with a serum glucose level of less than 50 to 60 mg/dL, and (3) resolve following glucose administration. Up to 20 percent of patients with diabetes mellitus using insulin or oral hypoglycemic agents (OHAs) will experience symptoms of hypoglycemia in their lifetime, requiring ED evaluation and therapy.^{1,2} If one considers all patients with altered mentation arriving at the ED, hypoglycemia is the underlying process in approximately 7 percent. From the perspective of the diabetic patient, hypoglycemia occurs frequently within this population; approximately 25 percent of diabetes patients will experience hypoglycemia on a regular basis.⁴ In addition to diabetes, other clinical settings associated with hypoglycemia include sepsis, liver disease, alcohol intoxication, starvation, and certain toxic ingestions. Hypoglycemia should be considered in the differential diagnosis in any patient with altered mental status or focal neurologic signs.

PATHOPHYSIOLOGY

Blood glucose homeostasis involves complex neural, metabolic, and hormonal interactions. The central nervous system (CNS) requires a continuous supply of carbohydrate fuel for normal function and uses approximately 150 g/d of glucose. The CNS has a small reservoir of glucose that is sufficient for only a few minutes of normal brain function. Despite these stringent demands, the body normally functions quite well in maintaining plasma glucose levels within a narrow range despite constant changes in glucose intake and/or utilization.

The primary glucoregulatory organs are the liver, the pancreas, adrenals, and pituitary gland. These organs maintain glucose control by the release and interaction of various hormonal agents, including insulin, glucagon, the catecholamines epinephrine and norepinephrine, cortisol and other glucocorticoids, and growth hormone. Insulin is the major metabolic regulatory factor, acting predominantly on the liver, skeletal muscle, and adipose tissue. Insulin suppresses endogenous glucose production, stimulates glucose use, and increases glucose storage in the form of glycogen, thus lowering the plasma glucose concentration.

The first defense against the development of hypoglycemia is a decrease in insulin secretion. Glucagon and epinephrine are also important for the acute protection against hypoglycemia. Both of these counterregulatory hormones are the only agents capable of stimulating hepatic glucose production within minutes of their release into circulation, primarily by glycogenolysis—the release of glucose from its intracellular storage, depot glycogen. The effect of these two hormones beyond the immediate period after their release—ranging from several hours to several days—is felt predominantly through their effect on gluconeogenesis—the production of glucose from other metabolic substrates. Glucagon is thought to be the major counterregulatory hormone while epinephrine is important under certain conditions, especially during glucagon deficiency and in the generation of warning symptoms of hypoglycemia. Epinephrine also stimulates hepatic glucose production, and also limits glucose use. In contrast to glucagon and epinephrine, glucocorticoid and growth hormone responses are largely involved in the protection against prolonged hypoglycemia over days to weeks.

Hormonal responses are largely determined by glucose intake and vary between the fed and the fasting states. The fed state extends for up to 3 h after the ingestion of food. In the fed state, glucose absorption from the gut stimulates the release of insulin from the pancreas, causing a shift of carbohydrate from the circulation into the various tissues for either consumption or storage. In certain cases, after entry into the cell, glucose is immediately used for energy production by glycolysis, with the glycolytic products proceeding on to the tricarboxylic acid cycle and down the electron transport chain, generating additional ATP. If the glucose is destined for fuel storage, it may take various forms, depending on the host tissue location: glycogen in the liver, triglycerides in adipose tissue, and protein in muscle. Insulin also acts on the liver to decrease glucose output by inhibiting glycogenolysis and gluconeogenesis. It inhibits lipolysis and promotes lipogenesis in adipose cells, and encourages the uptake of amino acids and inhibits proteolysis.

The fasting period is the interval between feedings, beginning approximately 4 h after eating and extending up to the next meal. In fasted individuals, the maintenance of normal blood glucose levels depends on an adequate supply of endogenous gluconeogenic substrates (amino acids, glycerol, and lactate), functionally intact hepatic glycogenolytic and gluconeogenic enzymatic systems, and normal endocrinologic function for integrating and modulating these processes. Hypoglycemia may result if any part of this system is disrupted. During fasting, relatively low insulin levels initiate the mobilization of these various stored fuels from host tissue sources. The most readily and rapidly available source of glucose is hepatic glycogen. Glucose is formed by glycogenolysis, which is potentiated in the liver by glucagon and epinephrine. The glycogen reserve is limited and will be depleted after 24 to 48 h of fasting in healthy patients, and possibly earlier in malnourished individuals. With continuation of fasting (approximately 4 to 6 h), gluconeogenesis becomes the primary source of blood glucose required for CNS metabolism and other bodily processes. Gluconeogenesis, occurring primarily in the liver, uses various metabolic substrates to generate an additional glucose supply. Amino acids are mobilized from muscle tissue by proteolysis, which is facilitated by low insulin levels and mediated by cortisol and glucagon. Lactate, from recycled glucose, and glycerol, from lipolysis, are minor yet important substrates for gluconeogenesis. During non-prolonged overnight fasting, 90 percent of gluconeogenesis occurs via proteolysis with conversion of amino acids to glucose.

If fasting is prolonged beyond the functional capabilities of both gluconeogenesis and glycogenolysis, the mobilization of other fuel stores is initiated with a decline in plasma insulin levels, thus removing the insulin-mediated inhibitory action on lipolysis and proteolysis; alternative fuel stores are then mobilized. Fat stores in the form of triglycerides are a major source of energy. Lipolysis, potentiated by a relative decline in serum insulin levels and the presence of both epinephrine and growth hormone, produces free fatty acids and glycerol. Most tissues, except the CNS and cellular blood elements, use free fatty acids as a source of energy, simultaneously allowing the body to conserve glucose for brain metabolism and sparing protein from catabolism for gluconeogenesis. The released glycerol may also be converted to glucose in the liver.

Hypoglycemia unawareness—the development of low serum sugar values without the physiologic ability to react—places individuals at greater risk for coma and other neurologic sequelae. Extremes of age, comorbidity, medications, autonomic neuropathy, and the degree of serum sugar control are some factors affecting awareness of hypoglycemia. It has been suggested that elderly patients are more likely to

experience hypoglycemia without an awareness of the event. As an example, the presence of previous stroke in older patients could increase the chance of unrecognized hypoglycemia. (3-Adrenergic receptor antagonists block the effects of epinephrine, therefore contributing to patient unawareness of hypoglycemia. Furthermore, patients with diabetes mellitus and autonomic neuropathy demonstrate blunted counterregulatory responses to hypoglycemia.^{5,6} Although somewhat counterintuitive, increasingly rigid control of the serum glucose in patients with diabetes mellitus without neuropathy may also have reduced responsiveness of the counterregulatory hormones, potentiating an unawareness of hypoglycemia.⁷ Such a clinical unawareness may result from either a lack of CNS recognition of hypoglycemia or impaired autonomic response to low serum sugar.

CLINICAL FEATURES

Common underlying etiologies among adults likely to be encountered in an ED are diabetic medical therapy, ethanol use, and sepsis.

Common scenarios in diabetic patients include inadequate food intake, increased physical exertion, incorrect medication dosing, or drug interactions. The characteristics of diabetic patients who are more likely to experience hypoglycemia include male gender, adolescent and very elderly age groups, African American heritage, a past history of hypoglycemia, "intensive" diabetic medical therapy, insulin use [compared with oral hypoglycemic agent (OHA) therapy], polypharmacy (more than five agents), and recent hospitalization.^{1m3} A recent report notes that insulin therapy, lower hemoglobin A_{1c} levels, younger patient age, and report of past hypoglycemia are also associated with increased prevalence of hypoglycemia.⁴

Table 210-1 compares diabetic medical therapies and their propensity for hypoglycemia. Metformin, a biguanide, improves the end-organ sensitivity to insulin and acts by a number of mechanisms in diabetic patients, including a reduction in hepatic glucose output and enhanced peripheral glucose uptake. Metformin is considered an antihyperglycemic drug rather than a hypoglycemic agent such as the sulfonylureas (OHA) and insulin. Hypoglycemia is rarely, if ever, encountered in patients using only metformin. Three other new classes of medications, which are uncommonly associated with hypoglycemia, include the nonsulfonylurea secretagogues (repaglinide, nateglinide), the α -glucosidase inhibitors (acarbose, miglitol), and the thiazolidinediones (troglitazone, rosiglitazone, pioglitazone). The nonsulfonylurea secretagogues repaglinide and nateglinide increase pancreatic insulin secretion and target postprandial hyperglycemia; they are frequently used either as monotherapy or in combination with metformin. These

agents are associated with hypoglycemia—though less often as compared to the OHAs. The α -glucosidase inhibitors acarbose and miglitol decrease gut absorption of carbohydrate; hypoglycemia has not been reported in association with either agent. The thiazolidinediones rosiglitazone and pioglitazone increase use of peripheral glucose; they are not associated with the development of hypoglycemia.

The nonselective (J-blocker) agents impair glycogenolysis and the hyperepinephrinemic response to lowered serum sugar levels, thus predisposing individuals to hypoglycemia. Hypoglycemia resulting from the sole ingestion of such adrenergic-blocking agents is rare.

At least one study in the past showed that approximately 50 percent of patients treated for hypoglycemia in an urban ED were acutely intoxicated with ethanol or were chronic alcohol abusers. Alcohol inhibits hepatic gluconeogenesis, which becomes problematic when a patient has not eaten for a prolonged period and the glycogen stores have been depleted by glycogenolysis. A 12-h fast is often sufficient for severely malnourished alcoholics to become hypoglycemic. Hypoglycemia has also been produced in healthy adults by infusing 75 g of alcohol after a 36-h fast. Rapid bedside serum glucose determinations should be performed on all patients with any mental status abnormality or evidence of alcohol use.

Sepsis may cause hypoglycemia by inhibition of gluconeogenesis and by increased responsiveness to insulin. Systemic hypoperfusion, often associated with sepsis, increases peripheral glucose use while metabolic acidosis decreases gluconeogenesis. The multiorgan failure associated with the sepsis syndrome not infrequently includes hepatic dysfunction and an increased potential for hypoglycemia.

Patients with hypoglycemia may have a wide array of symptoms and signs. The clinical manifestations of hypoglycemia are divided into two broad categories: *neuroglycopenic* and *hyperepinephrinemic* (also known as the autonomic or sympathomimetic findings). As glucose is the main energy source for CNS function, it is not surprising that most episodes of symptomatic hypoglycemia include neurologic dysfunction. With a decline in serum sugar, the brain quickly exhausts its reserve supply of carbohydrate fuel, resulting in CNS dysfunction. This manifests most commonly by alterations in consciousness, lethargy, confusion, combativeness, agitation, and unresponsiveness. Other neuroglycopenic manifestations include seizures and focal neurologic deficits.

A rapid fall in blood glucose levels or the hypothalamic sensing of neuroglycopenia causes the release of the counterregulatory hormones, primarily the catecholamines epinephrine and norepinephrine. Their release is responsible for the hyperepinephrinemic findings, including anxiety, nervousness, irritability, nausea, vomiting, palpitations, and tremor.

TABLE 210-1 Diabetic Medical Therapy, Mechanism of Action, and Expected Glycemic Response

Agent (Examples)	Mechanism of Action	Expected Glycemic Response
Insulin (Regular, NPH, Lente, Ultra-lente)	Direct tissue effect	Hypoglycemia
Sulfonylurea (OHA) First generation: chlorpropamide, tolbutamide, tolazamide Second generation: glyburide, glipizide, glimepiride	Increased pancreatic insulin secretion	Hypoglycemia
Nonsulfonylurea secretagogues (repaglinide, nateglinide)	Increased pancreatic insulin secretion	Hypoglycemia (less than OHAs)
Biguanides (metformin)	Decreased hepatic glucose production	No hypoglycemia
α -Glucosidase inhibitors (acarbose, miglitol)	Decreased gastrointestinal tract glucose absorption	No hypoglycemia
Thiazolidinediones (troglitazone,* rosiglitazone, pioglitazone)	Increased peripheral tissue glucose use	No hypoglycemia

*Removed from the market because of idiosyncratic hepatocellular injury.

Abbreviation: OHA = oral hypoglycemic agent.

The term "hyperepinephrinemic" is a misnomer in that cholinergic factors resulting from autonomic nervous system stimulation are also noted in certain patients. Stimulation of the cholinergic nervous system also occurs and may result in manifestations such as sweating, changes in pupillary size, bradycardia, and salivation.

The rapidity of onset of the hypoglycemic event determines in part the presentation. A gradual onset of hypoglycemia results from a relatively slow decrease in the serum glucose and the development of the neuroglycopenic signs and symptoms. Conversely, a sudden drop in the blood sugar level will produce anxiety, diaphoresis, tremor, and the other hyperepinephrinemic findings. In most cases of hypoglycemia, however, CNS dysfunction predominates with some degree of alteration in the level of awareness, accompanied by diaphoresis and tachycardia.

DIAGNOSIS

Hypoglycemia should always be considered early (including the pre-hospital setting) as a potential cause of altered mentation. Failure to determine the blood glucose level early in the evaluation can result in a delayed or missed diagnosis with associated morbidity because of CNS injury or unnecessary invasive procedures and therapies. A recent investigation of children requiring advanced resuscitation on ED arrival reported that 18 percent of these patients had hypoglycemia.⁸ Hypoglycemia has been misdiagnosed as stroke, transient ischemic attack, seizure disorder, traumatic head injury, brain tumor, narcolepsy, multiple sclerosis, psychosis, sympathomimetic drug ingestion, hysteria, altered sleep patterns and nightmares, and depression.^{5,7} Although uncommon, bradycardia has also been reported.

The use of bedside testing is preferred in that the result is immediately available to the clinician and as such may alter therapeutic and diagnostic plans. The accuracy of bedside reflectance tests is acceptable though less reliable at extremely low and high glucose levels. If possible, immediately prior to intravenous dextrose therapy, a serum sample should be obtained and sent to the lab for confirmation. Glucose values of whole blood are approximately 15 percent less than that of serum or plasma. This discrepancy is a result of the relatively low glucose concentration in red blood cells—with storage, equilibration occurs. Venous blood has a 10 percent lower glucose concentration when compared with either capillary or arterial blood. Finally, the collecting tube should contain fluoride to inhibit *in vitro* glycolysis before the sample is assayed.

TREATMENT

Initial management is the administration of 1 g/kg body weight dextrose, as D50W in adults. This can be followed by the infusion of D10W at a rate to maintain the serum glucose above 100 mg/dL. Repeat bedside glucose determination should be done every 30 min for the first 2 h, to detect rebound hypoglycemia. Oral replacement is best, however. A total of 300 g (1200 cal) of carbohydrate should be given PO, as sodas, juices, sandwiches, or snacks. A total of 50 mL of D50W contains only 100 cal. Whereas some suggest that each ampule of glucose (50 g of a D50W solution) will raise the serum glucose by 60 mg/dL,⁹ others feel that prediction of pre- and posttreatment levels is impossible.¹⁰

Glucagon, 1 mg IM or IV, can be used in diabetics or in those in whom intravenous access is not readily obtainable. Response to glucagon therapy is generally slower when compared with intravenous dextrose, requiring 7 to 10 min prior to normalization of mental status; additionally, the response to glucagon administration may be short-lived. **The condition of alcoholics, the elderly, and others with depleted glycogen stores will generally not improve with glucagon.** Fructose and lactose should not be used to correct hypoglycemia in that these sugars do not cross the blood-brain barrier effectively and require extensive metabolic conversion.

If hyperglycemia is maintained by slow administration of dextrose, the infusion may be reduced and eventually withdrawn. Failure to re-

spond to parenteral glucose administration should prompt consideration of other causes of hypoglycemia, such as sepsis, toxin, insulinoma, hepatic failure, or adrenal insufficiency.

Octreotide, a synthetic analogue of somatostatin, inhibits the release of insulin and has been used in the treatment of sulfonylurea-induced hypoglycemia. One recent report describes the use of octreotide in patients who ingested excessive amounts of sulfonylurea OHA.¹¹ These patients, prior to octreotide administration, had experienced recurrent hypoglycemia. Soon after the initiation of octreotide therapy, serum sugar levels stabilized with a significant reduction in recurrent hypoglycemia. It is administered subcutaneously at an initial dose of 50 to 125 μ g. Constant infusions (125 μ g/h) and repeat dosing (50 to 100 μ g at 6- to 12-h intervals) have been employed successfully. The optimal dose, frequency of administration, and duration of therapy have not been defined. Intravenous glucose is still the most appropriate therapy for hypoglycemia. **Octreotide is only recommended after initial glucose therapy has been initiated in the sulfonylurea ingestion.** It should be considered when OHA induced hypoglycemia is not responding to dextrose therapy. It is primarily designed to reduce the chance of recurrent hypoglycemia.

A total of 100 mg parenteral thiamine should be given in conjunction with glucose, because, historically, the administration of glucose without thiamine in severe nutritional deficiency states could precipitate Wernicke encephalopathy. Today, this is rare. Thiamine acts as a coenzyme in several reactions in intermediary metabolism, specifically in the conversions of pyruvate to acetyl coenzyme A (linking glycolysis to the tricarboxylic acid cycle) and α -ketoglutarate to succinate (a reaction in the tricarboxylic acid cycle). As thiamine reserves disappear, the reactions halt, removing the CNS's main source of ATP and causing the acute development of Wernicke syndrome. Steroid administration should be considered for hypoglycemia that is either resistant to aggressive glucose replacement therapy or associated with the signs of adrenal insufficiency (see Chap. 217). The dose is 100 to 200 mg hydrocortisone intravenously in adults.

Studies in the early 1980s suggested that hyperglycemia at the time of hospital admission is associated with poor neurologic recovery in stroke patients¹² and survivors of out-of-hospital cardiopulmonary arrest.¹³ Similar concern has been voiced regarding the association of worsened neurologic outcome and hyperglycemia in patients with acute head injury.^{14,15} It is theorized that hyperglycemia accentuates local tissue damage by continued or increased anaerobic metabolism, lactate production, and intracellular acidosis. Acidosis may trigger a cascade that includes calcium entry into cells, lipolysis, and cytotoxic fatty acid release, culminating in neuronal death. The clinical significance of this issue has not yet been demonstrated; it is a known fact, however, that **untreated hypoglycemia is deleterious to the medically or traumatically injured brain.** Information from these retrospective studies should not alter the management of hypoglycemia at this time.

DISPOSITION

Factors affecting disposition (Table 210-2) include:

1. The patient's current mental status as well as the level of consciousness during observation in the ED;
2. Serial determinations of the serum glucose;
3. Both the timing and extent of the response to resuscitative therapy;
4. The need for additional replacement therapy;
5. Comorbidities;
6. The patient's social situation;
7. Any psychiatric issues;
8. The agent ingested; and
9. Cause of hypoglycemia.

Either continued or recurrent mental status alteration, recurrent hypoglycemia, or a downward trend in serial glucose values during ED

TABLE 210-2 Admission Guidelines in the ED Hypoglycemic Patient

Issue Under Consideration	Indication (Relative/Absolute)	In-patient Location (Noncritical Care Setting vs Critical Care Setting)
Medication etiology: non-short-acting insulins and all OHA	Absolute	Variable
Continued/recurrent mental status change	Absolute	Critical care setting
Continued/recurrent hypoglycemia	Absolute	Likely critical care setting
Requirement for frequent/continuous glucose administrations	Absolute	Critical care setting
Etiology of event: sepsis, severe malnutrition, toxicologic response to ingestion with other body system failures	Absolute	Critical care setting
Psychiatric (i.e., intentional ingestion) etiology	Absolute	Variable
Lack of 1) responsible adult supervision, 2) motivated patient or caretaker, and 3) identified physician care as outpatient	Absolute	Likely noncritical care setting
Patient age: neonate/infant and very elderly	Relative	Variable
Lack of "reactive" hyperglycemia despite adequate glucose replacement therapy	Relative	Variable
Significant comorbidities (renal, hepatic failure)	Relative	Variable
History of hypoglycemia	Relative	Variable

observation despite adequate replacement therapy demands admission to the hospital. Also, any patient requiring large doses of dextrose as both bolus and infusion should be admitted. An inpatient disposition in a critical care setting is likely warranted in cases involving the following etiologies: massive insulin or OHA ingestion, marked malnutrition, sepsis, acute liver failure, or any other event associated with the tendency toward profound hypoglycemia. Furthermore, patients without proper outpatient supervision should be admitted for observation.

The case suitable for outpatient observation is characterized by a responsible adult who will monitor the patient's mental status frequently on a regular basis, coupled with a motivated patient who will perform serum glucose determinations frequently and who can maintain oral feeding. Patients managed in a chronic care facility with adequate nursing supervision may also be managed out-of-hospital in such a setting, assuming that they have remained stable during ED observation. The use of this option is at the discretion of the treating physician's review who has reviewed all facets of the clinical presentation. The suspected or known *intentional* ingestion of either insulin or OHA must be admitted for ongoing medical and psychiatric care.

The particular medication agent ingested must be considered in disposition decisions as well. Short-acting insulin preparations do not always demand hospitalization, whereas intermediate- and long-acting preparations likely will require admission for ongoing observation and, at times, continued supportive care. Care must be exercised in large short-acting insulin exposures in that the pharmacodynamics of such insulin preparations are altered with massive doses. The expected short half-life may not be encountered. OHAs also represent a possible indication for hospitalization due to relatively long serum half-life with a prolonged tendency toward the development of hypoglycemia. Patients with OHA excess and end-stage renal disease may experience prolonged periods of hypoglycemia and therefore warrant inpatient management.¹⁶ Low serum glucose may develop as long as 16 h after ingestion, although the majority of patients will become symptomatic within 8 h of exposure. A single tablet ingestion by a child can produce significant hypoglycemia. Finally, if any doubt exists as to the need for inpatient observation, admission for short-term observation is justified. If a patient is discharged, follow-up should be provided within a reasonably short period of time with the primary care physician.

The above recommendations are largely based on retrospective data, practice patterns, anecdote, and medical "common sense"; they

lack significant support in the medical literature. One recent investigation, which compared the outcome of diabetic hypoglycemic patients who refused emergency medical services (EMS) transport with those individuals transported to the ED, does support the contention that many patients with hypoglycemia experience prompt, rapid return to the nonhypoglycemic state. Of 517 instances, 374 patients, the vast majority (72 percent), refused EMS transport. The rates of relapse did not differ between those patients refusing and accepting EMS transportation to the ED, and the nontransported patients did not suffer significant morbidity or mortality after termination of prehospital medical care. While the out-of-hospital treatment of hypoglycemic patients may be safe and effective,¹⁷ it should be noted that patients refusing transport may self-select for lower likelihood of adverse outcome. The treating clinician must weigh numerous factors and exercise medical judgment in arriving at the appropriate, safe disposition for the patient.

DIABETIC KETOACIDOSIS

Michael E. Chansky
Cary L. Lubkin

Diabetic ketoacidosis (DKA) is an acute, life-threatening complication of diabetes mellitus. DKA occurs predominately in patients with type I (insulin-dependent) diabetes mellitus but is also well described in type II (non-insulin-dependent) diabetes mellitus.¹ DKA accounts for 24 percent of all diabetic admissions and has an incidence among diabetics in the United States of 15 episodes per 1000 patients.² Europe has a comparable incidence. Between 20 and 30 percent of cases oc-

cur in patients with new-onset diabetes. Better understanding of pathophysiology and an aggressive, uniform approach to diagnosis and management have reduced mortality to less than 5 percent of reported episodes.³ However, mortality is higher in the elderly due to underlying renal disease or coexisting infection.

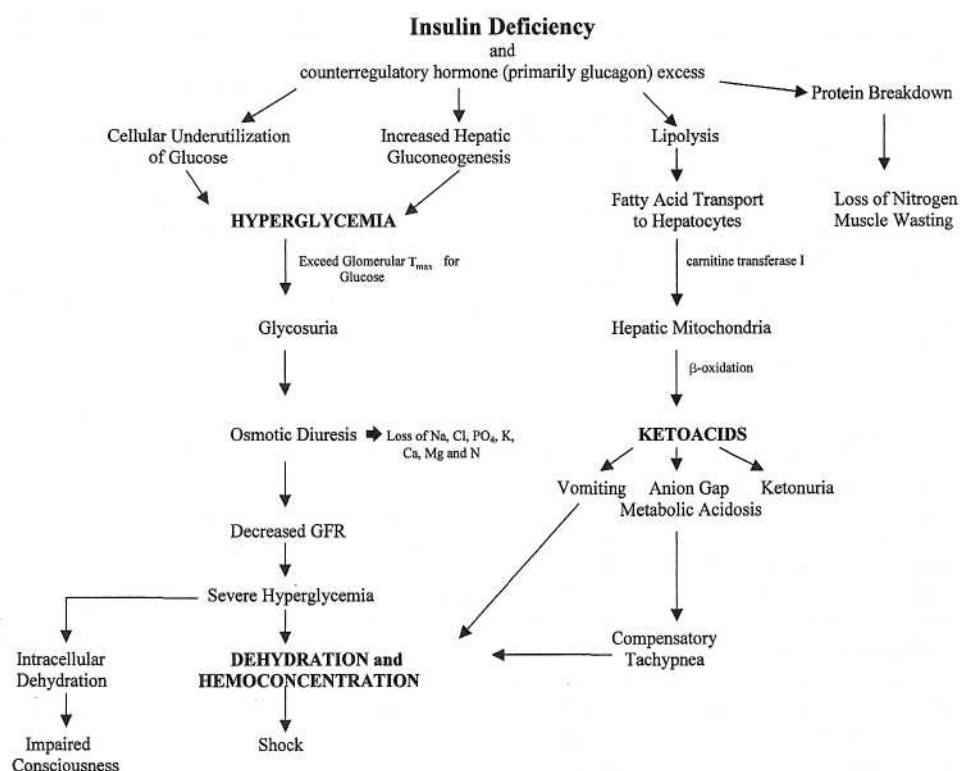

PATHOPHYSIOLOGY

In simplest terms, DKA represents the body's response to cellular starvation brought on by relative insulin deficiency and counterregulatory or catabolic hormone excess (Figure 211-1). Insulin is the only anabolic hormone produced by the endocrine pancreas and is responsible for the metabolism and storage of carbohydrates, fat, and protein. Counterregulatory hormones include glucagon, catecholamines, cortisol, and growth hormone. The lack of insulin and the excess counterregulatory hormones result in hyperglycemia (due to excess production and underutilization of glucose), osmotic diuresis, prerenal azotemia, ketone formation, and a wide-anion gap metabolic acidosis.^{3,4}

Insulin

Ingested glucose is the primary stimulant of insulin release from the β -cells of the pancreas. Insulin's main action occurs at the three principal tissues of energy storage and metabolism (i.e., liver, adipose tissue, and skeletal muscle). Insulin acts on the liver to facilitate the uptake of glucose and its conversion to glycogen while inhibiting glycogen breakdown (glycogenolysis) and suppressing gluconeogenesis. The net effect of these actions is to promote the storage of glucose in the form of glycogen. Insulin's effect on lipid metabolism is to increase lipogenesis in the liver and adipose cells by the production of triglycerides from free fatty acids and glycerol while inhibiting the breakdown of triglycerides. Insulin stimulates the uptake of amino acids into muscle cells with subsequent incorporation into muscle protein while preventing the release of amino acids from muscle and hepatic protein sources.

FIG. 211-1. Pathogenesis of DKA secondary to relative insulin deficiency and counterregulatory hormone excess.

Deficiency in insulin secretion due to loss of islet cell mass is the predominant lesion in diabetes mellitus, and it may be partial or total. In the initial stages of diabetes mellitus, the secretory failure of β cells impairs fuel storage and may be evident only during a glucose-tolerance test. As the disease progresses and levels of insulin decrease, fuel stores are mobilized during fasting, resulting in hyperglycemia. When pancreatic (3-cell reserve is present, hyperglycemia may trigger an increase in insulin and a return to normal glucose concentration. With further disease progression, hyperglycemia can no longer trigger an increase in insulin activity. Despite the presence of elevated intravascular glucose, in the absence of insulin, the cells are unable to use glucose as a fuel source. The body responds by breakdown of protein and adipose stores to try to produce a usable intracellular fuel. Loss of the normal physiologic effects of insulin leads to secretion of catabolic hormones and resulting hyperglycemia and ketonemia.

Counterregulatory Hormones

The response to cellular starvation seen with insulin insufficiency is increased levels of glucagon, catecholamines, cortisone, and growth hormone. Glucagon is the primary counterregulatory hormone. The catabolic effects of these hormones include increased gluconeogenesis and glycogenolysis, breakdown of fats into free fatty acids and glycerol, and proteolysis with increased levels of amino acids. Increased levels of glucogenic precursors, such as glycerol and amino acids, facilitate gluconeogenesis, worsening hyperglycemia.

Free fatty acids released in the periphery are bound to albumin and transported to the liver, where they undergo conversion to ketone bodies. The primary ketone bodies β -hydroxybutyric acid (pHB) and acetoacetic acid (AcAc) account for the metabolic acidosis seen in DKA. The two are in equilibrium: $\text{AcAc} + \text{NADH} = \text{pHB} + \text{NAD}$. AcAc is metabolized to acetone, another major ketone body. Depletion of baseline hepatic glycogen stores tends to favor ketogenesis. Low insulin levels decrease the ability of the brain and cardiac and skeletal muscle to use ketones as an energy source, also increasing ketonemia. The persistently elevated serum glucose level eventually causes an osmotic diuresis. The resulting volume depletion worsens hyperglycemia and ketonemia.

The renin-angiotensin-aldosterone system, activated by volume depletion, exacerbates renal potassium losses already occurring from osmotic diuresis. In the kidney, chloride is retained in exchange for the ketonions being excreted. This loss of ketonions represents a loss of potential bicarbonate. In the face of marked ketonuria, a superimposed hyperchloremic acidosis is also present. The presence of a concurrent hyperchloremic metabolic acidosis can be detected by noting a $[\text{HCO}_3^-]$ lower than explainable by the amount the anion gap has increased (see Chap. 25). As adipose tissue is broken down, prostaglandins PGI_2 and PGE_2 are produced. Both account for the paradoxical vasodilation that occurs despite profound levels of volume depletion. They may be responsible for the fact that acute renal failure and extremity gangrene rarely develop in DKA despite volume depletion.

DKA in Pregnancy

Several physiologic changes in pregnant patients make them more prone to DKA. Maternal fasting serum glucose levels are normally lower, which leads to relative insulin deficiency and an increase in baseline free fatty acid levels in the blood. Pregnant patients normally have increased levels of counterregulatory hormones. In addition, the chronic respiratory alkalosis seen in pregnancy leads to decreased bicarbonate levels due to a compensatory renal response, resulting in a decrease in buffering capacity. Pregnant patients also have an increased incidence of vomiting and infections (e.g., urinary tract infections, sinusitis, and otitis media), which are frequent precipitants of DKA. In addition, DKA is triggered at lower sugar levels in the pregnant population.⁵ Maternal acidosis causes fetal acidosis, decreases

uterine blood flow and fetal oxygenation, and shifts the oxygen-hemoglobin dissociation curve to the right. Maternal hypokalemia also can lead to fetal dysrhythmias and death.

Causes of Diabetic Ketoacidosis

Factors known to precipitate DKA include omission of daily insulin injections and a variety of stressful events, such as infection, stroke, myocardial infarction, trauma, pregnancy, hyperthyroidism, pancreatitis, pulmonary embolism, surgery, and steroid use. Studies have shown that errors in insulin usage are a much more common precipitant than previously thought, especially in the younger population.⁶ In approximately 25 percent of patients, no clear precipitating cause is found.⁷

CLINICAL FEATURES

The clinical manifestations of DKA are related directly to the three primary metabolic derangements—hyperglycemia, volume depletion, and acidosis. Hyperglycemia causes an increased osmotic load with movement of intracellular water into the vascular compartment. The ensuing osmotic diuresis gradually leads to volume loss in addition to renal losses of sodium, chloride, potassium, phosphorus, calcium, and magnesium. Initially, patients may compensate by increasing their fluid intake. In this initial period, polyuria and polydipsia are usually the only symptoms until ketonemia and acidosis develop. As acidosis progresses, the patient develops a compensatory augmented ventilatory response. Increased ventilation is stimulated physiologically by acidemia to diminish the Pco_2 and thus counters the metabolic acidosis. The acidosis combined with the effects of PGI_2 and PGE_2 lead to peripheral vasodilation despite profound levels of volume depletion. Prostaglandin release is also felt to play a role in the often unexplained nausea, vomiting, and abdominal pain that are seen frequently at presentation, especially in children. Vomiting, which may be a maladaptive physiologic response to diminish the acid load, unfortunately exacerbates the potassium losses and contributes to rapidly progressive volume loss, weakness, and weight loss. As volume depletion progresses, poor absorption of subcutaneous insulin renders its administration ineffective. Mental confusion or coma may be apparent at the time of presentation; these symptoms are much more likely with a serum osmolality of greater than 340 mosm/L. If the serum osmolality is less than 340 mosm/L in a comatose patient, another cause of the coma should be sought.

Abnormal vital signs may be the only significant physical findings at the time of presentation. Tachycardia and either significant orthostasis or hypotension are usually present. Poor skin turgor denotes significant volume depletion. With severe acidemia, Kussmaul respirations may be observed. Acetone produces the characteristic fruity odor on the breath found in some patients. The absence of fever does not exclude infection as a source of the patient's ketoacidosis. Hypothermia is present occasionally because of the aforementioned peripheral vasodilation.

Abdominal pain and tenderness can be due to gastric dilatation, ileus, or pancreatitis. Due to the frequency of abdominal pain and the presence of an elevated serum amylase level in both DKA and pancreatitis, distinguishing the diagnoses may be difficult. An elevated serum lipase level is more specific to pancreatitis and should be used to differentiate the two conditions.

ANCILLARY TESTS

When DKA is suspected, initial steps should include a test-strip glucose determination, a urine test strip, an electrocardiogram (ECG), venous blood gas determinations, and a normal saline intravenous drip. Almost all patients with DKA present with a blood glucose level greater than 300 mg/dL. Patients who present just after receiving insulin or who have impaired gluconeogenesis (e.g., in alcohol abuse or liver failure) may have lower initial serum glucose levels.⁴ Elevated

serum levels of (3HB and AcAc cause acidosis and ketonuria. The **nitroprusside** reagent normally used to detect urine and serum ketones **only detects AcAc**. Acetone is only weakly reactive and (3HB not at all. NADH accumulation in mitochondria, as may occur with lactic acidosis or alcohol metabolism, favors the (3HB side of the equation noted earlier. The enzymatic test for PHB is reliable but not widely available. Paradoxically, as the patient is being treated and clinically improves, measured ketone levels will increase as the body converts the more acidic (JHB to AcAc. Therefore, ketones need only be checked initially in the urine. Serum electrolytes should be examined carefully for multiple metabolic abnormalities. Elevated serum ketone levels lead to a wide-anion-gap metabolic acidosis. Hyperchloremic acidosis also occurs on the basis of ketoanion exchange for chloride in the urine; this is especially true in patients who maintain good hydration status and glomerular filtration rate despite ketoacidosis. Metabolic alkalosis also can occur secondary to vomiting, osmotic diuresis, and concomitant diuretic use. Some patients with DKA may present with normal-appearing $[\text{HCO}_3^-]$ or even alkalemia if these other alkalotic processes are severe enough to mask the acidosis. In such situations, **an elevated anion gap may be the only clue to the presence of an underlying metabolic acidosis** otherwise masked by the concomitant volume contraction-related metabolic alkalosis.

Arterial blood gases (ABGs) have been used traditionally to help determine precise acid-base status in order to direct treatment, but venous pH is just as helpful. A decreased Pco_2 determination usually reflects respiratory compensation for metabolic acidosis. If it is lower than explained by the degree of acidosis, as indicated by the $[\text{HCO}_3^-]$, a primary respiratory alkalosis exists, which may be an early indication of pulmonary disease (e.g., pneumonia, pulmonary embolus) as a possible trigger of the DKA or associated sepsis. (Chap. 25 details how compensatory changes in Pco_2 can be distinguished from a primary respiratory alkalosis.) Recent studies have shown a strong correlation between venous and arterial pH in patients with DKA.⁸ Venous pH obtained during routine phlebotomy potentially can be used to avoid ABGs, which are painful and may cause arterial vascular complications. Also, serial venous blood draws, should they be necessary to follow acid-base status, are more easily tolerated.

Total body potassium is depleted by renal losses. However, the measured serum potassium level is normal or elevated in most patients³ because of two important factors: extracellular shift of potassium secondary to acidemia and increased intravascular osmolarity caused by hyperglycemia.⁹ Prerenal azotemia also contributes by interfering with kaliuresis. Osmotic diuresis leads to excessive renal losses of sodium chloride in the urine. However, the presence of hyperglycemia tends to artificially lower the serum sodium levels. The standard teaching is that 1.6 mEq should be added to the reported sodium value for every 100 mg of glucose over 100 mg/dL. However, the correction factor is probably 2.4, especially for blood glucose levels over 400 mg/dL.¹⁰ Osmotic diuresis also causes urinary losses and total-body depletion of phosphorous, calcium, and magnesium. Be aware that hemoconcentration frequently leads to initially elevated levels of these electrolytes in serum. As therapy progresses, lower serum levels of each will be evident.

Serum creatinine frequently may be elevated factitiously if the laboratory assays for creatinine and AcAc interfere. Some elevation in creatinine is expected due to prerenal azotemia. Liver function studies may be elevated because of fatty infiltration of the liver, which gradually corrects as the acidosis is treated. Creatine phosphokinase (CPK) and amylase are also frequently elevated at the time of presentation. Leukocytosis is often present because of hemoconcentration and stress. However, an absolute band count of 10,000 μL or more has been shown to reliably predict infection in this population.¹¹

ECG changes of hyperkalemia or hypokalemia may be seen. These changes are often transient because of the rapidly changing metabolic status. The ECG also should be evaluated for ischemia because myocardial infarction may precipitate DKA. The underlying rhythm is usually sinus tachycardia.

DIFFERENTIAL DIAGNOSIS

Although the exact definition of DKA is variable, most experts agree that a blood glucose level greater than 250 mg/dL, a bicarbonate level of less than 15 mEq/L, and an arterial pH of less than 7.3 with moderate ketonemia constitute the diagnosis.^{3,4}

The differential diagnosis of metabolic coma in a diabetic patient includes hypoglycemia, nonketotic hyperosmotic coma, alcoholic ketoacidosis, lactic acidosis, and other causes of wide-anion gap acidosis. A rapid differentiation can be made in the ED using a glucose reagent strip, a urine test strip for ketones, and blood gas analysis. As an initial rapid diagnostic step, the finding of an elevated glucose level with the concomitant detection of ketones (by point-of-care testing methods) and the presence of metabolic acidosis on venous or arterial blood gas analysis have few rival diagnoses other than DKA. Evaluation of the anion gap is usually superior to pH or $[\text{HCO}_3^-]$ determination alone because "widening" of the anion gap is independent of potentially masking effects of concurrent acid-base disturbances. The clinician who is not well acquainted with the nuances of blood gas interpretation (see Chap. 25) will be confused when the pH and $[\text{HCO}_3^-]$ are close to normal. Although the pH and $[\text{HCO}_3^-]$ are usually examined in addition to the anion gap, both of the former can be affected by concurrent acid-base disturbances such as a metabolic alkalosis or respiratory alkalosis. Patients with hyperosmolar, nonketotic coma tend to be older, have a more prolonged course, and have prominent mental status changes. Their serum glucose levels generally are much higher (>600 mg/dL), and they have little to no anion-gap metabolic acidosis.³

The differential diagnosis of DKA (see Table 211-1) includes any entity that causes a high-anion-gap metabolic acidosis. These include alcoholic or starvation ketoacidosis, uremia, lactic acidosis, and various ingestions (e.g., methanol, ethylene glycol, and aspirin). The ketosis in alcoholic ketoacidosis and starvation ketosis tends to be milder, and the serum glucose level is usually low or normal. PHB predominates in alcoholic ketoacidosis, so the urinary ketone test may be negative. If an ingestion cannot be excluded, serum osmolality or drug-level testing is required. Depending on the hemodynamic status, lactic acidosis (poor perfusion) may occur simultaneously with DKA; in these cases, determination of the serum lactate level is indicated. Patients on metformin with new-onset renal insufficiency are at risk for developing type B (aerobic) lactic acidosis. The absence or presence of only moderate ketonemia should elicit a search for lactic acidosis because its presence favors the undetected PHB as the predominant ketone.

TREATMENT

The diagnosis of DKA should be suspected at triage, and aggressive fluid therapy should be initiated prior to receiving the laboratory results³ (Figure 211-2). Patients should be placed on a monitor in an acute care setting immediately and have at least one large-bore (16- to 18-gauge) intravenous line of NS running, a second intravenous line of jNS at minimal rate to keep the intravenous line open. Obtain a rapid bedside glucose determination, a urine test strip, and an ECG. A complete blood count (CBC); determination of electrolyte, phosphate, magnesium, and calcium levels; blood cultures; and other

laboratory tests should be done as indicated. Arterial blood gas determinations are optional and are only required for the diagnosis and monitoring of critically ill patients. Consider using venous pH determinations (approximately 0.03 lower than arterial pH)⁸ for monitoring critically ill patients. The goals of therapy include volume repletion, reversal of the metabolic consequences of insulin insufficiency, correction of electrolyte and acid-base imbalances, recognition and treatment of precipitating causes, and avoidance of complications. Metabolic disturbances should be corrected at the rate of occurrence or over 24 to 36 h.

Meeting the goals of safely replacing deficits and supplying missing insulin requires frequent (every 1-2 h) monitoring of electrolytes (glucose, potassium, and anion gap), vital signs, level of consciousness, and volume input/output until recovery is well established. Resolving hyperglycemia alone is not the end point of therapy. Con-

comitant resolution of the metabolic acidosis (or inhibition of ketoacid production) signifies resolution of DKA. Normalization of the anion gap usually requires 8 to 16 h and reflects clearance of ketoacids. **The order of therapeutic priorities is volume first and foremost** and then insulin and/or potassium, phosphate, magnesium, and bicarbonate.

Fluid Administration

Rapid fluid administration is the single most important initial step in the treatment of DKA.³ Fluid helps restore intravascular volume and normal tonicity, perfuse vital organs, improve glomerular filtration rate (GFR), and lower serum glucose and ketone levels. The average adult patient has a water deficit of 100 mL/kg (5-10 L) and a sodium deficit of 7 to 10 mEq/kg.³ NS is the most frequently recommended fluid for initial volume repletion, even though the extracellular fluid of

the patient is hypertonic initially. NS does not provide "free water" to correct intracellular fluid loss, but it does prevent an excessively rapid fall in extracellular osmolarity and the resulting devastating transfer of excessive water into the central nervous system (CNS). After initial resuscitation with NS, most authors favor alternating the administration of NS with $\frac{1}{2}$ NS³ or using two intravenous lines—one with NS and the other with $\frac{1}{2}$ NS.

Based on clinical suspicion alone and prior to initial electrolyte results, the first liter of NS should be administered well within the first 30 min unless there are mitigating circumstances. In general, the first 2 L are administered rapidly over 0 to 2 h, the next 2 L over 2 to 6 h, and then 2 L more over 6 to 12 h. This replaces approximately 50 percent of the total water deficit over the first 12 h, with the remaining 50 percent water deficit to be replaced over the subsequent 12 h. The blood glucose and ketone body concentrations begin to fall after fluid administration and before implementation of any other therapeutic modality. Hydration alone will reduce the glucose concentration somewhat over 12 to 14 h.⁴ Tissue perfusion is restored with volume repletion, improving the effectiveness of insulin. The subsequent rise in GFR allows for glucose and ketone body clearance, lowering serum glucose concentration and osmolarity. The patient's blood glucose level needs to be monitored carefully, and D5 is added to the rehydration solution when the glucose level is 250 to 300 mg/dL.

The fluid should be changed to a hypotonic solution ($\frac{1}{2}$ NS or D5 $\frac{1}{2}$ NS if blood glucose level is less than 300 mg/dL) after initial replacement of intravascular volume with NS. Patients presenting without extreme volume depletion can be managed safely with a modest fluid replacement regimen (500 mL/h for 4 h).¹² Monitoring central venous pressure or pulmonary artery wedge pressure should be considered during fluid replacement in elderly patients or in those with heart disease. Although a common pitfall is failure to give adequate volume replacement, excess fluid may contribute to the development of adult respiratory distress syndrome and cerebral edema.¹³

Insulin

Initial volume repletion reduces the level of counterregulatory hormones, replaces vital fluid and electrolytes, and more important, makes cells more responsive to insulin. It is generally accepted that the "ideal way" to administer insulin is by continuous intravenous infusion of small doses of regular insulin through an infusion pump.^{3,14} This approach appears to be more physiologic, helps produce a more linear fall in serum glucose and ketone body levels, and is associated with less severe metabolic complications (hypoglycemia, hypokalemia, and hypophosphatemia).

Low-dose regular insulin administration by an infusion pump is simple and safe, ensures a steady blood concentration, and allows flexibility in adjusting the insulin dose. Insulin inhibits gluconeogenesis, lipolysis, catabolic hormone secretion, and the production of ketoacids, in addition to promoting potassium, glucose, and phosphate uptake in tissues. After the initial fluid bolus, insulin is administered at 0.1 unit/kg per h. The effect of insulin begins almost immediately after initiation of the infusion. A loading dose has not been proven necessary. The desired gradual decrease in serum glucose level is secondary to improved renal perfusion as fluids are administered and insulin receptors become saturated. Recent reviews have different recommendations regarding the use of an insulin loading or priming dose.^{3,4,7} An intravenous loading dose is not recommended in children and is optional in adults. The half-life of insulin given IV is 4 to 5 min, with an effective biologic half-life at the tissue level of approximately 20 to 30 min. Because insulin binds to plastic tubing, the first 25 mL of a prepared insulin solution (100 units of regular insulin in 100 mL of NS) should be discarded, and the drip should be placed into an established intravenous line on an infusion pump at the port closest to the skin. Serious complications with continuous intravenous

low-dose insulin infusions are minimal. Frequent monitoring is required to ensure that insulin is being administered in the desired amount.

Intramuscular or subcutaneous administration of regular insulin in DKA is to be avoided.¹⁵ Insulin absorption may be erratic in the volume-depleted, vasoconstricted patient, delaying the achievement of adequate insulin levels. Furthermore, delayed absorption can produce deposits of insulin that may be absorbed later, causing hypoglycemia.

The incidence of nonresponse to low-dose continuous intravenous insulin administration is 1 to 2 percent. Infection is the primary reason for failure to respond. If the patient fails to respond to low-dose insulin therapy, i.e., a decrease of the serum glucose level by 50 to 70 mg/dL in the first hour (assuming adequate hydration), the infusion rate should be doubled or an intravenous bolus (0.2-0.4 units/kg) administered.³

The insulin infusion should continue until ketonemia has cleared and the anion gap has normalized. As noted previously, there is conversion from (3HB to AcAc, with "increasing ketones" measurable in the serum and urine. Therefore, the anion gap is the most accurate determinant of ongoing recovery. Resolution of hyperglycemia usually occurs earlier than the anion gap, and it may be necessary to administer glucose from the beginning of insulin therapy or shortly after its institution. In most patients, continuous intravenous insulin therapy should continue for at least 12 h (or until resolution of the anion gap), and an overlap period in which subcutaneous insulin is initiated should precede discontinuation of the insulin.

In the rare patient with initial hypokalemia (<3.3 mEq), insulin can precipitate life-threatening hypokalemic effects.³ While there are no studies supporting the administration of potassium prior to insulin therapy, the American Diabetes Association (ADA) suggests that parenteral potassium should be administered (10-15 mEq/h) 30 min prior to insulin.³

Potassium

Patients in DKA usually present with profound total-body potassium deficits in the range of 3 to 5 mEq/kg.³ This deficiency is created by insulin deficiency, metabolic acidosis, osmotic diuresis, and frequent vomiting. Only 2 percent of total-body potassium is intravascular. The initial serum concentration is usually normal or high because of the intracellular exchange of potassium for hydrogen ions during acidosis, the total-body fluid deficit, and the diminished renal function. Initial hypokalemia indicates severe total-body potassium depletion, and large amounts of potassium are necessary for replacement in the first 24 to 36 h.

The goals of potassium replacement are to maintain a normal extracellular potassium concentration during the acute phases of therapy and to replace the intracellular deficit over a period of days. During initial therapy for DKA, the serum potassium concentration may fall rapidly, primarily due to the action of insulin promoting reentry of potassium into cells and, to a lesser degree, the dilution of extracellular fluid, correction of acidosis, and increased urinary loss of potassium. If these changes occur too rapidly, precipitous hypokalemia may result in fatal cardiac arrhythmias, respiratory paralysis, paralytic ileus, and rhabdomyolysis. The development of severe hypokalemia is potentially the most life-threatening electrolyte derangement during the treatment of DKA.³

Early potassium replacement is now a standard modality of care. Potassium is not added blindly to the first liter of NS administered to restore circulation because giving potassium rapidly to a patient in a hyperkalemic potentiating state (i.e., acidemia, insulin deficiency, renal insufficiency), may dangerously increase the extracellular potassium level and precipitate fatal ventricular tachycardia or fibrillation. The patient's initial ECG often provides early evidence of hyperkalemia: progressively manifested by peaked T waves, a prolonged PR interval, an absent P wave, an increasing QRS interval, and lastly, a sine-wave

pattern. The initial measurement of serum electrolytes and the presence of urine output determine initial potassium therapy. As a general guideline, an initial serum potassium level greater than 3.3 mEq/L and less than 5.0 mEq/L (prior to fluid resuscitation and insulin) coupled with urine output calls for 10 mEq KCl per hour replacement in intravenous fluid for at least 4 h. Because the most rapid changes occur during the first few hours of therapy, the plasma potassium level initially is measured every 1 to 2 h. If oliguria is present (fortunately, this is rare secondary to the protective osmotic diuresis), renal function must be evaluated and potassium replacement must be decreased. An initial serum potassium level greater than 5.0 mEq/L usually reflects a more profound acidemia. Intravenous potassium replacement is withheld until the serum potassium level is documented to be below 5.0 mEq/L and urine output is established. Fluid and insulin therapy alone usually will lower the serum potassium level rapidly. Correction of the acidosis predicts a change in serum potassium concentration. For each 0.1 change in pH, serum the potassium concentration changes approximately 0.5 mEq/L inversely. This can be used as a guide for estimating the serum potassium concentration when pH balance is restored.

Initial hypokalemia (<3.3 mEq/L) necessitates more aggressive replacement prior to insulin therapy.³ In this setting, potassium should be given IV at 15 to 20 mEq/h, with insulin initiated 30 min later. There is no documented advantage to using potassium phosphate over potassium chloride; excessive use of potassium phosphate may result in metastatic precipitation of calcium phosphate in tissues.

The goal is to maintain serum potassium levels within the normal range of 4 to 5 mEq/L and avoid life-threatening hyper- or hypokalemia. Oral potassium replacement is safe and effective and should be used as soon as the patient can tolerate oral fluids. During the first 24 h, potassium chloride 100 to 200 mEq is usually required. Occasionally, as much as 500 mEq is necessary.

Phosphate

Phosphate plays an integral role in the conversion of energy from adenosine triphosphate (ATP) and in the delivery of oxygen at the tissue level through 2,3-diphosphoglyceric acid (2,3-DPG). In addition, many important enzymes, cofactors, and biochemical intermediates depend on phosphate. Phosphate is primarily intracellular, and it shifts to the extracellular compartment during DKA. Serum levels often are normal or increased on presentation and do not reflect the total-body phosphate deficits secondary to enhanced urinary losses.⁷ Phosphate (similar to glucose and potassium) reenters the intracellular space during insulin therapy, resulting in low phosphate concentrations. Hypophosphatemia is usually most severe 24 to 48 h after the start of insulin therapy. Acute phosphate deficiency (<1.0 mg/dL) has been associated with a variety of clinical disorders, including hypoxia, rhabdomyolysis, hemolysis, respiratory failure, and cardiac dysfunction. Fortunately, all are extremely rare during therapy of DKA.¹⁵

The role of phosphate replacement during the treatment of DKA remains controversial. No clinical trial has demonstrated significant benefits from routine intravenous phosphate therapy.^{3,7} In general, intravenous therapy should be withheld unless the serum phosphate concentration is less than 1 mg/dL. Hypophosphatemia can be corrected safely and effectively with oral replenishment, which may cause diarrhea.

There is no established role for initiating intravenous potassium phosphate in the ED. Significant hypo-phosphatemia tends to develop many hours into therapy, after the patient is already admitted. Several undesirable side effects from intravenous phosphate administration have been reported. These include hyperphosphatemia, hypocalcemia, hypomagnesemia, metastatic soft tissue calcifications, and hypernatremia and volume loss from osmotic diuresis. If deemed necessary (a phosphate level of less than 1.0 mg/dL early in therapy and/or patient vomiting), intravenous phosphate replacement should be done by or in consult with experienced physicians in an intensive care

unit (ICU) setting. Serum phosphate, calcium, and magnesium levels should be monitored during therapy of DKA, but again, the case for routine early parenteral phosphate replacement in the ED has not been made.

Magnesium

Ongoing osmotic diuresis may cause significant depletion of magnesium stores (from bone) and hypomagnesemia. Hypomagnesemia may inhibit parathyroid hormone secretion, causing hypocalcemia and hyperphosphatemia. Symptomatic hypomagnesemia in DKA (hyperreflexia, positive Chvostek or Trousseau signs) is rare, as is the need for intravenous therapy. If the serum magnesium concentration is less than 1.2 mg/dL or symptoms are suggestive of hypomagnesemia, magnesium can be given orally in the form of magnesium oxide or parenterally as magnesium sulfate. Serum magnesium and calcium concentrations should be monitored on presentation and 24 h into therapy unless symptoms suggestive of hypomagnesemia or hypocalcemia occur.

Bicarbonate

The role of bicarbonate in DKA has been debated for decades. Arbitrary initial pH levels to use bicarbonate are still currently recommended in many texts. To date, not a single study clearly demonstrates improved clinical outcome using bicarbonate in the treatment of DKA. Acidotic patients routinely recover from DKA without alkali therapy. **Routine use of supplemental bicarbonate in the treatment of DKA is not recommended.**^{7,16,18}

Severe metabolic acidosis is associated with numerous cardiovascular (impaired contractility, vasodilation, hypotension) and neurologic (cerebral vasodilation and coma) complications.¹² Theoretical advantages of bicarbonate include improved myocardial contractility, elevated ventricular fibrillation threshold, improved catecholamine tissue response, and decreased work of breathing.¹⁶ These theoretical advantages are outweighed by the possible disadvantages of bicarbonate administration in DKA: severe and worsening hypokalemia, paradoxical CNS acidosis, worsening intracellular acidosis, impaired (shift to left) oxyhemoglobin dissociation, hypertonicity and sodium overload, delayed recovery from ketosis,¹⁷ elevation of lactate levels,¹⁶ and possible precipitation of cerebral edema.¹³ During routine therapy of DKA, hydrogen ion production ceases when ketogenesis stops; excessive hydrogen ions are eliminated through the urine and respiratory tract. Ketone body metabolism results in the endogenous production of alkali. Children with initial pH values as low as 6.73 have been shown to recover promptly from DKA without bicarbonate.¹⁶

Severe acidosis (pH <7.0) and worsening pH despite aggressive therapy for DKA should prompt the clinician to rule out other causes of metabolic acidosis (i.e., lactate from sepsis, bowel infarction, metformin or methanol ingestion, etc.). The potential benefits of bicarbonate in the elderly with cardiovascular instability and DKA must be balanced against the potential disadvantages.^{3,7}

OUTCOMES, COMPLICATIONS, AND MORTALITY

Complications Related to Acute Disease

A critically ill, lethargic patient is at risk for aspiration, and airway protection should be instituted. In general, the greater the presenting serum osmolality, blood urea nitrogen, and blood glucose concentrations, the greater is the mortality. There is also increased mortality for patients presenting with a serum bicarbonate level of less than 10 mEq/L.

Of the factors responsible for precipitating DKA, infection and myocardial infarction are the main contributors to high mortality. The

mortality rate of DKA is high when myocardial infarction is the precipitating event. Additional factors that reduce the chances of survival include old age, severe hypotension, prolonged and severe coma, and underlying renal and cardiovascular disease. Severe volume depletion leaves the elderly at risk for vascular stasis and deep venous thrombosis. Prophylactic heparin should be instituted in high-risk patients.

Complications Related to Therapy

Major complications related to therapy of DKA include hypoglycemia, hypokalemia, hypophosphatemia, adult respiratory distress syndrome (ARDS), and cerebral edema. The goal of therapy, i.e., a gradual return to normal metabolic balance, will mitigate these possible outcomes to some extent.

ARDS is a rare complication of therapy. Aggressive fluid therapy decreases plasma oncotic pressure and raises left atrial end-diastolic pressure, favoring a shift of fluid across the pulmonary capillary membrane. Elderly patients with rales on chest examination may be at increased risk and should be monitored closely for this complication with continuous pulse oximetry and serial examinations; they also should receive lower rates of fluid administration.

Cerebral edema tends to occur between 4 and 12 h after the start of therapy but may develop as late as 48 h after.¹⁹ It is often seen when the patient appears to be improving clinically and biochemically.^{7,19} The true incidence of clinically apparent cerebral edema is unknown but estimated to be 0.7 to 1.0 per 100 episodes of DKA in children.⁷ Cerebral edema complicating DKA has a reported mortality of 70 percent. One hypothesis is that the osmotic diuresis promotes loss of water and sodium from both intra- and extracellular spaces. Hyperglycemia leads to a hyperosmolar extracellular state. Brain cells enzymatically produce osmotically active particles or idiogenic osmoles that protect cells from further loss of water and shrinkage. During therapy with intravenous fluid and insulin, water moves into brain cells faster than idiogenic osmoles can dissipate, promoting cellular swelling.^{7,13,19} Subclinical brain swelling has been reported in asymptomatic children during treatment of DKA.¹³

Multiple studies and reviews have found no specific presentation or treatment variables that predict or contribute to the development of cerebral edema.^{13,19} Young age and new-onset diabetes are the only identified potential risk factors. Excessive initial fluid administration of greater than 4 L/m² of body surface area per day has been associated with cerebral edema.^{13,19} Initial "corrected" hyponatremia may be a risk factor in children as well. Recent data suggest that children who develop cerebral edema initially may have a relatively normal serum osmolality and subsequently develop progressive hyponatremia and/or a trend toward a declining serum sodium level before developing cerebral edema.²⁰ Approximately one-half of the patients who developed cerebral edema had premonitory symptoms of severe headache, incontinence, change in arousal or behavior, pupillary changes, blood pressure changes, seizures, bradycardia, or disturbed temperature regulation. Any change in neurologic function early in therapy should prompt the clinician to immediately administer mannitol (1-2 g/kg), which should be at the bedside of high-risk patients. Mannitol should be given prior to obtaining confirmatory computed tomographic (CT) scans^{7,19} because serious morbidity and mortality may be prevented. Other aggressive measures such as intubation, hyperventilation, and fluid restriction may be necessary. Gradual replacement of water and sodium deficits and slow correction of hyperglycemia may lessen the risk.

Late Complications

Metabolic acidosis refractory to routine therapy may be secondary to unrecognized infection (lactic acidosis), insulin antibodies, or improper preparation or administration of the insulin drip. Shock that is unresponsive to aggressive fluid therapy suggests gram-negative bacteremia or silent myocardial infarction. Hyperchloremic non-anion-

gap metabolic acidosis develops in virtually every patient during therapy due to rapid volume expansion in the face of reduced bicarbonate. In addition, bicarbonate equivalents are excreted in the urine as ketones and replaced with chloride provided by the NS. This emphasizes the importance of monitoring the anion gap during therapy, not the bicarbonate concentration. The non-anion-gap metabolic acidosis (should it be present) resolves during recovery as bicarbonate is regenerated and excess chloride excreted in the urine.

Late vascular thrombosis may occur in any muscular artery, although the cerebral vessels appear to be most susceptible.¹⁵ Volume depletion, low cardiac output, increased blood viscosity, and underlying atherosclerosis may predispose the elderly to this rare complication. Thrombosis may occur several hours or days after institution of therapy and after resolution of ketoacidosis.

Mortality in DKA results mainly from sepsis or pulmonary and cardiovascular complications in the elderly and fatal cerebral edema in children and young adults (<28 years old).⁷ Age-adjusted death rates per 100,000 diabetic population for DKA and DKA-related deaths declined between 1980 and 1996. Overall, both the age-adjusted DKA death rate and the DKA-related death rate were 34 percent lower in 1996 than in 1980. This trend was seen in all age groups except in those aged less than 45 years. The highest death rates were among persons aged 75 years and older, followed by persons aged less than 45 years. Among race-sex groups, DKA death rates were highest among black males, followed by black females and then by whites. In 1996, the age-adjusted DKA death rate for black males was almost twice that for white males.²

DISPOSITION

The great majority of patients require hospitalization in a monitored setting where there is nursing experience with insulin drips. In many institutions, patients are cared for initially in an ICU or intermediate care unit. A select group of patients with an anion gap of less than 25, a glucose level of less than 600 mg/dL, and no comorbidity at the time of disposition decision may be managed safely on an inpatient unit with nursing expertise using insulin drips and managing diabetic patients. Patients presenting early in the course of their illness who can tolerate oral liquids may be managed safely in the ED or observation unit and discharged after 4 to 6 h of therapy. The anion gap on discharge should be less than 20.

DIABETES MELLITUS

Micheal D. Rush Sonia

Winslett Kimberley Dawn \fy

Diabetes mellitus is a group of metabolic diseases characterized by deficiency of insulin production, deficiency of insulin action, or a combination of the two deficiencies resulting in hyperglycemia. Chronic hyperglycemia resulting from all forms of diabetes is a final common precipitant of long-term complications involving the eye, the nervous system, the kidneys, and the immune system that collectively can be grouped as microvascular sequelae. These microvascular sequelae are leading causes of blindness, chronic renal failure, and lower extremity amputation. Hyperglycemia and diabetes, along with obesity, hypertension, and dyslipidemia, collectively known as the *dysmetabolic syndrome* or *metabolic syndrome X*, also predispose individuals to accelerated atherogenesis and endothelial damage. These effects are integral to the macrovascular complications of diabetes: cardiovascular, cerebrovascular, and peripheral vascular disease. Emergency physicians are called on frequently to evaluate and treat the complications of diabetes and may in some cases make the initial diagnosis. Early diagnosis and treatment are essential in preventing long-term complications of the disease.

CLASSIFICATION/DEFINITIONS

Diabetes can be grouped into four major categories.¹ *Type 1 diabetes* [older terminology: *insulin-dependent diabetes mellitus* (IDDM) or *juvenile-onset diabetes mellitus* (JODM)] is defined by a deficiency of insulin secretion. The disease is believed to be caused by autoimmune-mediated destruction of pancreatic β -cells in the islets of Langerhans, or it may be idiopathic. There is a genetic predisposition to autoimmune type 1 diabetes and possible links with viral infections or other environmental factors (such as absence of breast-feeding, diet, and factors related to low socioeconomic status). Rates of β -cell destruction vary, and some patients may retain some residual β -cell function throughout their lives. Individuals with type 1 diabetes frequently

require insulin therapy to sustain life and are prone to diabetic ketoacidosis (DKA).

Type 2 diabetes [older terminology: *non-insulin-dependent diabetes mellitus* (NIDDM) or *adult-onset diabetes mellitus* (AODM)] is defined as a combination of resistance to the action of insulin by the target organs and tissues with a relative inadequacy of compensatory insulin secretion and, in many cases, eventual **(β -cell failure)**. Type 2 diabetes is also believed to have a strong genetic predisposition. However, lifestyle issues such as a diet low in fiber and high in fat and simple carbohydrates (sugars, processed starches) combined with lack of exercise and obesity, also can have an impact on the development and severity of the disease and likely account for the alarming increase in both developed and developing countries. Patients with type 2 diabetes can have a variety of initial presentations such as life-threatening hyperglycemic, hyperosmolar, nonketotic syndrome (HHNS) or microvascular (retinopathy, nephropathy, neuropathy) or macrovascular complications (heart disease, cerebrovascular disease). Patients may have type 2 diabetes for years prior to having clinical symptoms. Type 2 patients often require insulin at some point in their course for adequate glycemic control. Therapy of type 2 diabetes typically is initiated stepwise from diet/exercise to oral agents to insulin or combination oral agent—insulin therapies. Data from the United Kingdom Prospective Diabetes Study (UKPDS) suggests that up to 75 percent of patients will need multiple steps of therapy by 9 years' disease duration to maintain glycemic control (i.e., glycosylated hemoglobin A_{1C}) < 7 percent.²

Unlike type 1 diabetes, type 2 diabetes can be prevented or delayed. A lifestyle intervention involving a low-fat, low-calorie diet high in fiber and low in simple carbohydrates, regular exercise up to 2.5 h weekly, and as little as a 7 percent weight reduction reduced the incidence of new cases of type 2 diabetes in prediabetes patients at high risk [impaired fasting glucose (IFG) or impaired glucose tolerance (IGT)] by 58 percent over a mean follow-up period of approximately 3 years.³

The third category represents *secondary* causes for diabetes, which are listed in Table 212-1. Collectively, patients with secondary diabetes represent only about 1 percent of all diabetes cases.

The fourth group, *gestational diabetes mellitus* (GDM), is present only during pregnancy and complicates about 4 percent (about

EPIDEMIOLOGY

It is estimated that 100 million people worldwide have diabetes, with 85 to 90 percent of cases being type 2. It is projected that by the year 2010, this number will increase to 215 million. In most developed countries, diabetes is one of the five leading causes of death.⁴

According to data collected from 1997 to 1999 by the National Health Information Survey (NHIS), approximately 17 million Americans, or 6.2 percent of the total U.S. population in year 2000, have diabetes mellitus, with 90 to 95 percent of cases classified as type 2 (NIDDM). Of these, 11.1 million have had their diabetes diagnosed by a physician, whereas 5.9 million are undiagnosed and do not know they have the disease. Approximately 1 million new cases of diabetes of all types were diagnosed each year in the United States from 1997 to 1999, with 90 to 95 percent diagnosed as type 2 diabetes.⁴ Prevalence of diabetes rose approximately 33 percent from 1990 to 1998 in the United States. In part, this was due to an increase in the population older than age 65, the group with highest diabetes prevalence, but was related most strongly to the epidemic levels of obesity.⁵ An additional 6.9 percent, or 13.4 million people in the U.S. population, has IFG (newer terminology: *prediabetes*) and is at high risk to develop the disease.⁶

Incidence rates for type 1 diabetes worldwide range from less than 0.1 per 100,000 per year in China to a high of 36.5 per 100,000 per year in Finland. Scandinavian/European countries tend to have much higher incidence rates for type 1 diabetes versus Asian and South American countries, with the rest of the world in the intermediate range. North Americans with ancestry in these ethnic groups likely would exhibit similar trends.⁷

In the United States, the prevalence of type 1 diabetes is slightly higher among men than among women. For type 2 diabetes, prevalence is roughly equal between sexes. For type 1 diabetes, non-Hispanic whites are affected most commonly, followed by African-Americans and Hispanic Americans. For type 2 diabetes, Americans of African, Mexican, Japanese, and Native American ethnicity are at higher risk than non-Hispanic whites.

In 1999, diabetes was estimated to account for 19 percent of all deaths in the United States in people aged 25 or older. The overall risk of death from diabetes is about twice that of people without diabetes, with a much higher risk ratio of 3.6 in people aged 25 to 44 years versus 1.5 in those aged 65 to 74 years. Ischemic cardiovascular disease is the most common cause of death in type 2 diabetes, and a person with diabetes has a two- to fourfold greater chance of death from cardiovascular disease than adults without diabetes.^{4,8} Generally, a middle-aged person with type 2 diabetes can expect 5 to 10 years of decreased life expectancy because of the disease. African, Hispanic, and Native American ethnicity increase the risk of death from diabetes versus non-Hispanic whites. DKA and coma are the most common causes of death in the early years of type 1 diabetes, with renal disease becoming more common up to age 30 and cardiovascular disease more common after age 30. Diabetes ranks sixth in the leading underlying causes of death listed on death certificates in the United States.^{4,8}

RISK FACTORS

Type 1 Diabetes

There is a genetic predisposition for type 1 diabetes, particularly if the father (three times more likely than if the mother) has type 1. Certain HLA antigens (HLA-DR3 and HLA-DR4) located on chromosome 6 are present in 95 percent of type 1 diabetics. Type 1 diabetes patients also have a higher prevalence of islet cell cytoplasmic antibodies

(ICAs), antibodies to insulin, and antibodies to the enzyme glutamic acid decarboxylase. Since concordance of type 1 diabetes occurs in only about 36 percent of monozygous twins, environmental factors also must play a role in the development of type 1 disease.

Dietary factors—such as breast-feeding for less than 3 months or not breast-feeding at all; exposure to cow's milk proteins, casein, and bovine serum albumin at age younger than 3 months; and exposure to food additives such as nitrates and nitrosamines—also have been associated with increased risk for development of type 1 diabetes.

Viral infections, especially coxsackie B group, are strongly associated with type 1 diabetes. Coxsackie B virus is isolated routinely from the sera of patients newly diagnosed with type 1 disease. Other viral infections with possible epidemiologic associations with type 1 diabetes include congenital rubella, cytomegalovirus (CMV), and mumps.

Older maternal age, birth order, and lower socioeconomic status also may contribute to development of type 1 diabetes, but results of studies are conflicting.

Type 2 Diabetes

Twin studies in type 2 diabetes establish a strong genetic link, with concordance rates of 34 to 100 percent for monozygous twins. Risk factors for type 2 diabetes are presented in Table 212-2.

PATHOPHYSIOLOGY

Type 1 diabetes results from destruction of insulin-producing pancreatic beta cells and absolute insulin deficiency. Type 2 diabetes begins with the development of insulin resistance and increased insulin production.

The organs and tissues that are most affected by diabetes—the retina, the kidney, and the nerves—all readily take up glucose, leading to its intracellular accumulation and subsequent metabolic end products. Two major mechanisms leading to microvascular complications from hyperglycemia are the increased formation and accumulation of sorbitol and other polyols by the aldose reductase pathway, and the formation of advanced glycosylation end products (AGEs) due to reactions of excess glucose with various cellular proteins.

Sorbitol formed from glucose through the aldose reductase pathway competitively inhibits myo-inositol formation, which causes a decrease in uptake of phosphoinositides into cell membranes, which in turn decreases Na⁺K⁺ATPase activity. The ultimate clinical effect is slowed nerve conduction. This decrease in the synthesis of myo-inositol may be the common metabolic link to membrane damage in neuropathy, retinopathy, and nephropathy.

Glycosylation and the subsequent formation of AGEs is another major explanation for diabetic microvascular pathology. Chemical cross-links form between excess glucose and various cellular proteins, altering their structure and function; most notable of these is glycosy-

TABLE 212-2 Risk Factors for Type 2 Diabetes

Pre-diabetes: IFG (FPG > 110 mg/dL <126 mg/dL) or IGT (plasma glucose 2 h following 75-g glucose load of > 140 mg/dL but <200 mg/dL)
Prior gestational diabetes or giving birth to infant >9 lb
Hypertension >: 140/90 mm Hg
Dyslipidemia: HDL <35 mg/dL and/or triglycerides ≥250 mg/dL
Sedentary lifestyle, lack of regular physical activity
Diet: High fat, high calorie, high simple carbohydrates (sugars, simple starches), low fiber
Overweight/obesity: BMI >25 kg/m ²
Centripetal obesity
Low birth weight
Low socioeconomic status

Abbreviations: BMI = body mass index; FPG = fasting plasma glucose; IFG = impaired fasting glucose; IGT = impaired glucose tolerance.

lated hemoglobin (HbA_{1c}), which forms proportional to glucose concentrations in the blood over time and is now used as a measure of glucose control in diabetes therapy. AGEs are thought to play a role in diabetic microvascular complications by effects on the structure and function of extracellular matrix and its interaction with the cell. An example of this is AGE formation on collagen, which, by trapping low-density lipoproteins, may be a contributor to accelerated atherogenesis seen in diabetes clinically.⁹ A second potential mechanism for the pathogenesis of AGE formation from hyperglycemia is by action on AGE-specific receptors, which alters levels of various hormones and cytokines, such as nitric oxide, ultimately leading to vascular proliferation and decreased elasticity in existing vessels. Intracellularly, AGE formation on DNA molecules leads to subsequent mutations and other harmful effects on gene expression in mammalian cell cultures *in vitro*. Ongoing clinical trials using aminoguanidine, an inhibitor of AGE formation, show promise in the prevention and treatment of microvascular complications of diabetes.

Accelerated atherogenesis in diabetes is multifactorial and is related to hyperglycemia, hyperlipidemia, insulin resistance, formation/activation of AGE, modification/oxidation of lipoproteins, platelet/coagulation factor activation, and endothelial injury (Figure 212-1).

CLINICAL FEATURES

Type 1 diabetes frequently presents as DKA, often associated with an acute infection or other significant physiologic stress, in children, adolescents, or young adults. Type 2 diabetes can be present for years prior to the onset of clinical symptoms. It also may present suddenly with HHNS or DKA. Frequently, type 2 diabetes is only diagnosed concurrently with the initial presentation of a macrovascular, microvascular, or infectious complication of the disease.

Classic diabetes signs and symptoms may include polyuria, polydipsia, fatigue, polyphagia, unexplained weight loss, poor wound healing, blurred vision, and a higher prevalence of certain infections, especially candidal vaginitis and balanitis, recurrent/severe urinary tract infections, recurrent skin and skin structure infections, and malignant otitis externa. The presence of any of these symptoms or infections should lead an emergency clinician to check the patient's blood glucose level.

Documentation of the medical history of patients with diabetes in the emergency department should be complaint-directed but generally

also should include questions on access to and frequency of home blood glucose monitoring, frequency and causes, if known, of recent hyperglycemia or hypoglycemia, recent glycosylated hemoglobin A_{1c} values, presence of and therapy for microvascular and macrovascular complications of diabetes, recent adjustments by the patient or the patient's physician in their glycemic control regimen, any problems with adherence to therapy, and symptomatology suggestive of complications.

Symptoms suggestive of potential complications or poor glucose control include visual changes, neurologic symptoms (especially numbness, dizziness, and weakness), chest pain, gastrointestinal symptoms, and genitourinary symptoms (especially overflow incontinence, changes in amount of urine, and sexual dysfunction). A thorough history of any recent or concurrent chronic medical illness, injury, or infection should be obtained. Current medications, diet and exercise history, and social history are also important components of the evaluation of diabetes patients. Medications such as diuretics or β -adrenergic agonists may adversely affect glycemic control, and (3)-adrenergic blockers may adversely affect awareness of hypoglycemia. Poor living conditions or the inability to afford home blood glucose monitoring or medications affect treatment compliance. Psychiatric disorders and substance abuse should be considered. Finally, diabetic patients should be fed according to schedule, and they should receive their diabetic medication while being evaluated in the emergency department if they are not metabolically decompensated.

Key elements of the physical examination of patients with diabetes are presented in Table 212-3. Physical examination should be tailored to the patient's chief complaint. However, it generally should include blood pressure measurement, funduscopy (to look for hemorrhage or proliferative retinopathy), cardiovascular examination (including auscultation of the carotids and abdomen for bruits and assessment of peripheral pulses), extremity examination (especially the feet for signs of skin breakdown, acute vascular disease, or infection), skin examination (including intertriginous areas to assess for irritations and infections, especially around peripheral insulin injection sites, and in the hands to assess lancet puncture sites), and a neurologic examination (to screen for neuropathy). In children, measurements of height,

TABLE 212-3 Key Elements of Physical Examination in Patients with Diabetes

Vital Signs

Temperature—fever, hypothermia (sepsis, hypoglycemia)
Pulse—tachycardia or bradycardia
Respirations—Kussmaul, tachypnea
Blood pressure—hypertension or hypotension

HEENT

Visual acuity—decreased acuity may be early retinopathy or detachment, may affect ability to dose insulin and other medications, have low threshold to measure intraocular pressures as incidence/prevalence of glaucoma is increased in diabetes
Funduscopy—vessel proliferation/hemorrhage, cotton wool exudates

Cardiovascular

Auscultation for bruits over carotids and abdomen
Assessment of peripheral pulses and adequacy of circulation

Extremities
Thorough extremity exam—especially the feet focusing on signs of abnormal wear/skin breakdown, abnormal sensation (proprioception and light touch), acute vascular disease, and infection (tinea, cellulitis, ulcers)

Examine hands at sites of lancet punctures for glucose checks

Skin

Insulin injection sites—lipodystrophy, scars, infection
Skin structures—folliculitis, cellulitis, intertrigo, tinea, nonhealing wounds
Pediatric considerations:

Height, weight, and measures of sexual maturity should be obtained and compared with normal individuals for age

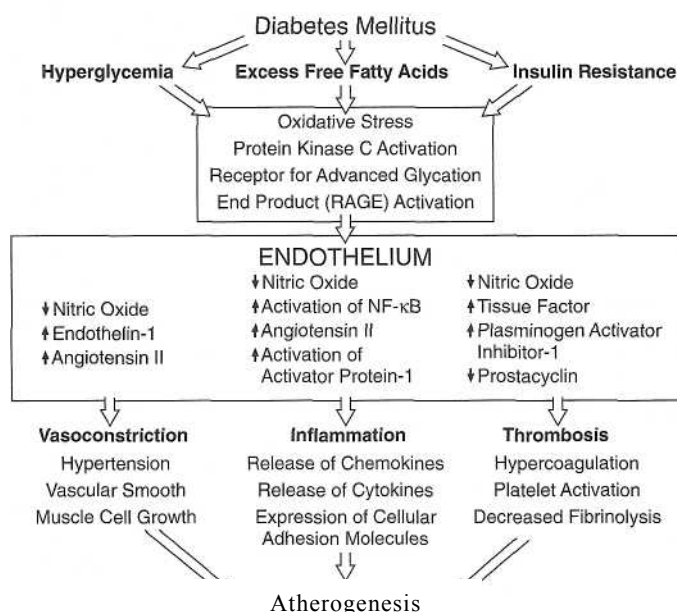

FIG. 212-1. Endothelial dysfunction in diabetes.

weight, and sexual maturity should be obtained and compared with normal children for age.¹⁰ **Testing of visual acuity may reveal the patient's inability to measure a self-administered insulin dose.**

DIAGNOSIS

The diagnostic criteria for diabetes have been revised recently, lowering the serum glucose values at which the diagnosis can be made, and include an intermediate category for patients whose glucose levels do not meet criteria for diagnosis of diabetes but which are significantly abnormal. These changes reflect advances in knowledge of what levels constitute abnormality significant enough to produce the complications of diabetes. Replacing the old term of *borderline* diabetes are IFG (newer terminology: *prediabetes*; fasting plasma glucose level > 110 but <126 mg/dL) and IGT, which constitute a group of patients who are generally euglycemic in everyday life but manifest hyperglycemia on oral glucose tolerance tests (fasting plasma glucose level > 140 but <200 mg/dL) 2 h after an oral 75-g glucose load. In non-pregnant patients, these categories are not diagnostic entities in themselves but represent a group of patients at high risk of developing diabetes.

The diagnosis of diabetes can be established in three ways. Two of these may be feasible in the ED, and the methods are summarized in Table 212-4.¹ It is not unreasonable to test blood glucose in the emergency department in patients with certain presentations such as unexplained cellulitis, foot ulcers, frequent candidal infections, and unexplained neuropathy.

THERAPY

Therapy for diabetes can best be divided into acute therapy of severe hyperglycemia and life-threatening metabolic decompensation, and the day-to-day prevention of hyperglycemia through insulin, oral agents, or combination therapy.

DKA and hyperosmolar hyperglycemic nonketotic syndrome (HHNS) are the acute life-threatening entities involving metabolic decompensation, with primarily type 1 diabetes in the case of DKA and type 2 diabetes with HHNS. DKA and HHNS, however, can be seen in either type of diabetes. Acute hyperglycemia and chronic hyperglycemia represent intermediates between good glycemic control and the development of life-threatening metabolic decompensation, as well as macrovascular and microvascular complications of diabetes. DKA and HHNS are discussed elsewhere in this book (Chaps. 211 and 214, respectively).

TABLE 212-4 Criteria for the Diagnosis of Diabetes Mellitus

Symptoms of diabetes plus casual plasma glucose concentration >200 mg/dL (11.1 mmol/L). *Casual* is defined as any time of day without regard to time since last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.

or

FPG a 126 mg/dL (7.0 mmol/L). *Fasting* is defined as no caloric intake for at least 8 h.

or

2-h PG >200 mg/dL (11.1 mmol/L) during an OGTT. The test should be performed using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.

Note: In the absence of unequivocal hyperglycemia with acute metabolic decompensation, these criteria should be confirmed by repeat testing on a different day. OGTT is not recommended for routine clinical use. *Abbreviations:* FPG = fasting plasma glucose; PG = plasma glucose; OGTT = oral glucose tolerance test.

ACUTE HYPERGLYCEMIA

Acute hyperglycemia, defined as a blood glucose level of greater than 300 mg/dL, can represent impending metabolic decompensation. High glucose levels, if present chronically, represent high risk for development of both macrovascular and microvascular complications of diabetes. Acute hyperglycemia and associated electrolyte abnormalities should be treated, and precipitating causes identified.

Clinical Features

The history and physical examination should focus on finding an underlying cause for the hyperglycemia and include a thorough medication history to ascertain the potential contributions of glucose-altering medications, most commonly corticosteroids, sympathomimetics, diuretics, anticonvulsants, salicylates, and (3-adrenergic receptor agonists. A thorough evaluation for infections is indicated, with pneumonia, urinary tract, and foot/skin structure infections being the most common. Acute coronary or CNS ischemia is also a common cause of acute hyperglycemia. In sexually active females, a pelvic examination should be performed to rule out cervicitis or pelvic inflammatory disease as an occult precipitating factor. Finally, and only after the above precipitants have been excluded, changes in or noncompliance with insulin or oral hypoglycemic therapy may be the etiology for the hyperglycemia.

Younger adults may complain only of polyuria and/or polydipsia as symptoms, whereas elderly diabetics may present severely volume depleted, with acute mental status changes, hypovolemic shock, and acute renal insufficiency or failure.

Determination of serum electrolyte, blood urea nitrogen, and serum creatinine levels is indicated in the clinical assessment of acute hyperglycemia. Clinicians experienced in acid-base interpretation should be able to diagnose abnormalities based on venous electrolyte and bicarbonate levels and anion gap, only using respiratory rate and pulse oximetry to guide the rare need for arterial blood gas determination. Capillary blood glucose measurement is indicated every 1 to 2 h during therapy, with the caveat that capillary blood glucose (glucometer) determination may be inaccurate at low (<30 mg/dL) or high (>400 mg/dL) levels. Coefficients of analytic variation within glucometer systems have been found to range from 4 to 33 percent. Ideally, analytic and user errors should be no more than 10 percent.¹¹

Therapy

Therapy for simple acute hyperglycemia is similar to that for DKA and HHNS and includes volume repletion, intravenous regular insulin therapy, correction of electrolyte imbalance, and specific therapies directed toward any identified underlying cause of hyperglycemia.

The cornerstone of therapy for acute hyperglycemia is restoration of intravascular volume and reperfusion of vital organs, especially the kidneys. Infusion of NS at a rate of 500 to 1000 mL/h should be initiated as soon as possible unless specific entities such as myocardial infarction with cardiogenic shock, acute renal failure, or stroke with cerebral edema contraindicate aggressive volume resuscitation. More moderate intravenous fluid infusion rates actually have been shown to improve hyperglycemia and metabolic acidosis faster and with fewer complications in the setting of DKA.¹² If the patient is hypotensive, 1 to 2 L of NS may be infused wide open to restore blood pressure. The use of two intravenous lines, 18 gauge or larger, is advisable to facilitate fluid resuscitation and correction of electrolyte imbalance. Volume resuscitation should be geared to the end point of lowering the serum glucose level, restoring organ perfusion, and replacing extracellular volume depletion. In patients with a history of congestive heart failure or chronic renal insufficiency, reassessment of status and need for further therapy should occur more frequently (approximately every hour or every 500 mL of intravenous fluid). Once improvement

is noted in vital signs and hyperglycemia (~250 mg/dL or less) and adequate urine output of at least 30 to 50 mL/h is ensured, intravenous fluids may be reduced to maintenance levels with D5¹NS or discontinued if the patient is taking oral fluids well.

Regular human insulin is administered IV because absorption of subcutaneous insulin in a volume-depleted patient can be erratic and unpredictable. Subcutaneous administration of insulin in non-volume-depleted patients is acceptable. Pharmacology of regular human insulin and insulin lispro is nearly identical except that insulin lispro has a significantly shorter onset of action and duration of action when compared with regular insulin and may lower glucose levels more rapidly.¹³ Insulin lispro would appear to be an excellent alternative to regular human insulin; however, insulin lispro does not currently have Food and Drug Administration (FDA) approval for intravenous administration, although many clinicians do use it.

It should be noted that there are currently no randomized clinical trials comparing route, type of insulin, or type and rate of intravenous fluids used in the treatment of acute hyperglycemia in the emergency department setting. Thus recommendations are based on available laboratory studies, clinical studies of related entities (DKA, HHNS), and clinical experience. Typically, an initial bolus dose of 0.1 to 0.15 units/kg IV or SC of regular human insulin or insulin lispro is given, which may be repeated in 1 to 2 h if glucose levels have not fallen at least 50 to 75 mg/dL in the first hour. While an intravenous bolus priming dose of insulin may speed the onset of ketone body metabolism and may be advantageous in overcoming the lag time for the low volumes delivered in insulin infusions reaching the patient, no advantage in the outcome of patients with DKA or HHNS has been demonstrated. Thus a patient simply may be started on a regular human insulin infusion of 0.1 to 0.15 units/kg of ideal body weight per hour, with hourly capillary blood glucose monitoring to assess therapy. The blood glucose level generally will decrease much more rapidly in patients with type 2 diabetes than in those with type 1. Once the capillary blood glucose level reaches 250 mg/dL or less and there is significant improvement of symptoms, patients are at low risk for acute metabolic decompensation, assuming treatment of any underlying cause for hyperglycemia has been initiated.

The most significant electrolyte disorder in acute hyperglycemia is hypokalemia. There is frequently a total-body deficit of potassium secondary to severe extracellular volume loss. Appropriate volume therapy further promotes urinary losses. The presence of metabolic acidosis, which elevates the serum potassium level, may mask true potassium deficits, leading to nearly normal serum potassium levels initially. While fluid administration should be aggressive, rapid correction of metabolic acidosis with large volumes of intravenous fluids and sodium bicarbonate may drop serum potassium levels precipitously, and in particular bicarbonate should be avoided. However, potassium replacement should remain a priority as soon as the potassium level is at or below 5.5 mEq/L if renal function is ensured. Potassium levels of less than 3.3 mEq/L represent severe deficit and need emergent supplementation even in the face of compromised renal function to prevent lethal dysrhythmias. Total-body potassium deficits in the range of 3 to 5 mEq/kg are typical for DKA. Potassium repletion should be geared to serum potassium levels and usually can be accomplished by adding 20 to 30 mEq potassium chloride (KCl) per liter to the intravenous infusion if the $[K^+]$ level is 3.3 to 5.0 mEq/L. Potassium also can be replaced orally with multiple doses of 20 to 40 mEq KCl if the patient is not vomiting. In the presence of severe hypokalemia, 10 mEq of KCl per 50 mL of NS may be administered IV every 15 min. Plan for approximately 100 mEq of KCl supplementation for each 1 mEq/L deficit. Measure serum potassium every 2 h during the initial 8 h of therapy. An electrocardiogram also may be useful in assessing for severe hypo- or hyperkalemia if the serum potassium level is not immediately available.

Phosphate therapy is not without complications, and **there is no routine indication for phosphate supplementation** in the treatment

of acute hyperglycemia, DKA, or HHNS. Patients with hyperglycemia refractory to therapy, severe electrolyte disturbance, significant prerenal azotemia or increase in baseline blood urea nitrogen and creatinine, or a serious underlying cause should be admitted to the hospital for further workup and therapy.

PRINCIPLES OF LONG-TERM THERAPY FOR HYPERGLYCEMIA

The general guiding principle of diabetes therapy is to lower glucose levels on a consistent basis to normal or near normal. Keeping glucose levels at or near normal in patients with type 1 diabetes (HbA_{1c} \leq 7.0 percent; normal: 4.0-6.0 percent) dramatically reduces the risk of developing both the microvascular and macrovascular complications of diabetes.¹⁴ Intensified hypertension control, glycemic control, and serum cholesterol control in type 2 diabetes are cost-effective in reducing morbidity and mortality from cardiovascular disease. Intensified blood pressure control actually reduces health care costs in patients with type 2 diabetes.¹⁵

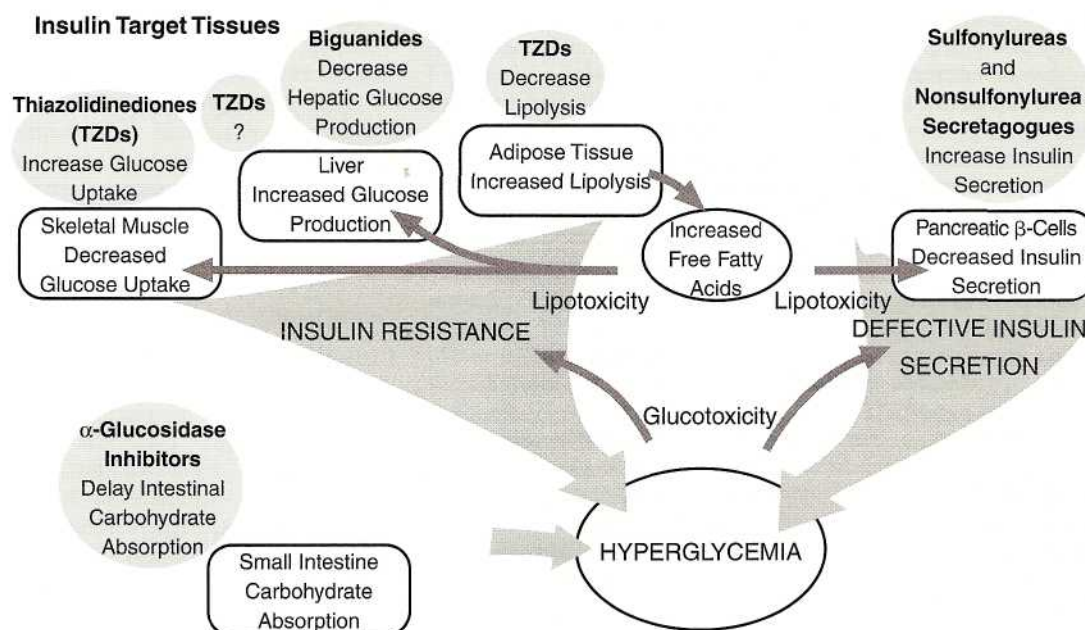

Intensive insulin therapy is indicated for well-motivated patients who administer multiple daily injections, usually as a single injection of a basal long-acting insulin such as ultralente or insulin glargine at bedtime coupled with short-acting lispro, aspart, or regular insulin injections before meals. Insulin also can be administered as a continuous subcutaneous insulin infusion (CSII) by means of a small pump that delivers insulin subcutaneously into the abdominal wall through a butterfly needle. Insulin usually is infused at a continuous basal rate, with preprogrammed or patient-initiated boluses given just before meals. Both hypoglycemia and ketoacidosis are more frequent in patients with CSII. For emergency department patients with CSII who develop hypoglycemia, marked hyperglycemia, or DKA, it is best to shut off the pump in the ED while standard glucose or insulin therapy is administered.

Intensive therapy generally is not indicated for patients with autonomic insufficiency, adrenal or pituitary insufficiency, and atherosclerotic coronary or cerebrovascular disease; for patients taking β -blocker medication; for patients with counterregulatory hormone deficiency; for the elderly or small children; for patients with psychiatric disorders; and for unreliable, chronically noncompliant patients.¹⁴

Glycemic control in type 2 patients is staged. Stage 1 is diet modification and weight reduction. Stage 2 includes various oral antidiabetic medications. Figure 212-2 represents the various pharmacologic approaches to therapy of type 2 diabetes.¹⁶ Stage 3 represents insulin requirement resulting from (3-cell failure, alone or in combination with oral agents. The indications for insulin therapy in type 2 diabetes are presented in Table 212-5.¹⁷ Initiating this therapy in patients who are failing oral agent therapy involves continuing the oral agent at the usual dose and adding an evening subcutaneous injection of 5 to 10 units of NPH insulin in lean patients [≤ 25 kg/m² body mass index (BMI)] and 10 to 15 units in obese patients.¹⁷ Caution should be used in prescribing oral agents to the elderly or to patients with impaired renal or hepatic function. Once the symptoms of acute hyperglycemia are controlled and underlying causes or exacerbating factors are sought out and treated, initiation of oral hypoglycemic and/or insulin therapy in patients with new-onset type 2 diabetes usually can be left to the primary care provider at 24 to 48-h follow-up if admission was not warranted. If the patient is overweight/obese (BMI ≥ 25 kg/m²) and renal function is adequate (serum creatinine level < 1.4 mg/dL), metformin, which inhibits hepatic gluconeogenesis and confers little risk of hypoglycemia, may be initiated safely at a dosage of 500 mg PO once a day, increasing by 500 mg each week until the maximum of 500 mg four times a day has been reached. This is until the patient can receive a diabetes education session, learn to test their his or her glucose, and recognize symptoms of hypoglycemia prior to starting an oral hypoglycemic agent, insulin, or a combination regimen.

A working knowledge of the pharmacology, including time to peak effect and duration of action of the various insulin and oral hypo-

FIG. 212-2. Pharmacologic approaches to the major metabolic defects of type 2 diabetes mellitus.

glycemic preparations, should enable the emergency physician to make adjustments in a patient's usual insulin or oral hypoglycemic regimen, especially if the patient arrives with a home blood glucose diary. Table 212-6 presents the various forms of insulin commonly prescribed, time to onset of action, time to peak effect, and their durations of action when given SC. **It is a good general rule not to change the total number of units of insulin by more than a 10 percent increase or decrease in a single day.** Adjustment of oral agent dosage generally can be left to the primary care provider because it requires careful and close monitoring. If this option is not readily available, oral hypoglycemic agent dosing generally should not exceed a 20 percent increase or decrease. If the patient is not doing regular home glucose monitoring, be sure that he or she has the equipment and the knowledge to test regularly during the adjustment period to avoid severe hypoglycemia or hyperglycemia. When the availability of a primary physician is in question, some EDs are able to provide a home health nurse for teaching and assessment.

Self-monitoring of blood glucose is recommended for all patients whose diabetes is managed with insulin and may be indicated for patients with type 2 diabetes who are initiating or changing their oral therapeutic regimens. Glucose measurements are indicated prior to meals and at bedtime at a minimum to guide intensive management regimens.

If a patient is unwilling or unable to test his or her blood glucose regularly during an adjustment and is not at high risk for metabolic decompensation, any adjustment of regimen and further education should be left to a primary care provider or endocrinologist.

TABLE 212-5 Indications for Insulin Therapy in Type 2 Diabetes

FPG consistently ≥ 300 mg/dL with ketonuria or ketonemia.
Temporary 6-8 week therapy for FPG ≥ 300 mg/dL and symptoms such as polyuria, polydipsia, weight loss at onset of type 2. Many patients can then be converted to oral therapy or continue insulin if comfortable and compliant. Patient desires insulin as initial therapy after reviewing available options with
PCP. In women whose gestational diabetes is not controlled with diet or in
women with type 2 diabetes who become pregnant. <i>All oral antidiabetic medications are contraindicated in pregnancy.</i>

COMPLICATIONS OF DIABETES MELLITUS

Cardiovascular Complications

Heart disease is the leading cause of diabetes-related deaths, accounting for approximately 40 percent of deaths in men with diabetes and nearly 32 percent in women.¹⁸ A diabetic is two to four times more likely to have ischemic heart disease or stroke than a nondiabetic, and the risk of a first myocardial infarction in a study that compared incidence rates of myocardial infarction in control versus patients with diabetes over 7 years was six times that of patients without diabetes.¹⁹ Odds ratios for stroke in patients with diabetes are increased 3.3 to 23.1 times, with the worst odds ratios noted in younger patients.²⁰

Factors contributing to cardiac dysfunction in diabetes are increased incidence of atherosclerosis of the coronary arteries, autonomic neuropathy, and microvascular disease (associated with hypertension and renal disease). Diabetics are prone to "silent" (pain-free) myocardial infarction or infarction associated with atypical symptoms, such as weakness. Even in the absence of vascular disease and hypertension, some diabetic patients develop cardiomegaly, with systolic and diastolic ventricular dysfunction that may evolve into congestive heart failure. Diabetic cardiomyopathy may be a direct effect of insulin deficiency or resistance on myocardial cell function. The detrimental effects of diabetes mellitus on the heart are more prominent in young diabetics and women. Women usually have a lower risk of coronary artery disease, but diabetes renders them more vulnerable to reinfarction and death after myocardial infarction and congestive heart failure. Vascular disease in patients with diabetes may be either nonspecific (atherosclerosis of large vessels) or specific (microangiopathic disease in

TABLE 212-6 Common Insulin Preparations: Onset, Peak, and Duration

Preparation	Onset of Action	Peak	Duration
Lispro/Aspart	5-15 min	1-2 h	4-6 h
Regular human	30-60 min	2-4 h	6-10 h
NPH/Lente	1-2 h	4-8 h	10-20 h
Ultralente	2-4 h	Variable	16-20 h
Glargine	1-2 h	No peak/flat	Approx. 24 h

small vessels) for diabetes.¹⁴ Therapy to reduce cardiovascular risk in type 1 and especially type 2 diabetic patients also must involve aggressive blood pressure control to 130/80 mm Hg or less, reduction of serum cholesterol to less than 200 mg/dL, and antiplatelet therapy with aspirin or clopidogrel (if the patient is aspirin-allergic or aspirin-sensitive), in addition to excellent glycemic control ($HbA_{1c} < 7$ percent if possible). Angiotensin-converting enzyme inhibitors (ACEIs) have been shown to slow the progression of diabetes-related nephropathy and reduce cardiovascular events and mortality in patients with diabetes at high risk for heart disease.²¹ Aspirin therapy is indicated in type 1 or 2 diabetic patients over 30 years of age as a primary prevention therapy for ischemic heart disease and as secondary prevention for patients with a history of macrovascular complications. It should not be used in anyone younger than 21 years of age because of the risk of Reye syndrome.²²

There is a risk for intraocular bleed from thrombolytic administration (for cardiac events) to a diabetic with proliferative retinopathy. Even though the risk of intraocular bleed is low, **proliferative retinopathy is an absolute contraindication to thrombolytic therapy.** The challenge to the emergency physician is expedient evaluation for proliferative retinopathy while simultaneously evaluating the need for thrombolytics.

Retinopathy

Diabetic retinopathy is the leading cause of new cases of blindness in patients aged 25 to 74 in the United States. Patients with this complication are 29 times more likely to become blind than those without retinopathy. Glaucoma and cataracts, also more common in diabetes, can contribute to new cases of blindness. An estimated 97 percent of diabetics taking insulin (types 1 and 2) and 80 percent of diabetics who do not take insulin (type 2 only) who have had their diabetes for 15 years or longer have some diabetic retinopathy. Among those with this complication, 40 percent of insulin-using and 5 percent of non-insulin-using diabetics have the most severe form—proliferative retinopathy—that frequently leads to blindness. In diabetes patients without eye disease, intensive glucose control lowers the risk of developing proliferative retinopathy by more than 75 percent compared with patients who do not practice intensive glucose control. Among patients with mild retinopathy, the risk for sustained retinopathy, progression to proliferative retinopathy, or need for laser photocoagulation can be reduced by more than 50 percent.

In the ED, history of any visual changes, low visual acuity, and the presence of visual field defects should arouse suspicion for retinopathy. A nondilated retinal examination frequently can reveal "cotton wool" exudates, microaneurysms, and vascular proliferation consistent with diabetic retinopathy (Table 212-7). A red and/or painful eye in association with headache or simply unexplained headache in patients with diabetes should prompt measurement of intraocular pressure to rule out acute glaucoma. The presence of these findings should prompt an immediate referral to an ophthalmologist for further examination and therapy. A baseline dilated funduscopic examination is in-

dicated 5 years after onset if age of onset is below 30 years and yearly thereafter. Those over age 30 at diagnosis should be examined at the time of diagnosis and yearly thereafter.

Laser photocoagulation of proliferative retinopathy has been proven to be efficacious in preventing blindness from proliferative retinopathy, particularly in patients with macular edema. Vitrectomy may be necessary to preserve vision in patients with severe proliferative retinopathy with vision loss secondary to retinal hemorrhage and detachment or vitreous hemorrhage.

Nephropathy

Diabetic nephropathy is one of the leading causes of end-stage renal disease. Approximately 43 percent of new cases of renal failure each year are due to diabetic nephropathy.⁴ Incidence approaches 40 percent lifetime in type 1 diabetes and 4 to 20 percent in type 2 diabetes. Since the overwhelming majority of diabetics are type 2, most patients with nephropathy will have this form of the disease. Hyperglycemia leads to glomerular hypertension and hyperfiltration, which in turn lead to deposition of protein in the mesangium. These protein deposits ultimately lead to sclerosis of the glomerulus and renal failure. The most useful clinical marker for nephropathy is the presence and degree of microalbuminuria. Patients with albumin excretion rates of as little as 30 mg/d are at high risk for developing diabetic nephropathy and subsequent renal failure. (Unfortunately, standard urine test strips do not give positive results until the urinary excretion of albumin has reached extremely high levels.) A special, more costly test strip and/or radioimmunoassay must be used to test for microalbuminuria. All diabetes patients should be screened for microalbuminuria at diagnosis and at least yearly thereafter. In addition to being a marker for nephropathy, microalbuminuria also has been shown to be associated with high risk for coronary ischemic events. Intensive insulin therapy reduces the likelihood of developing microalbuminuria, the clinical herald of diabetic nephropathy, by 60 percent. This benefit is maintained for at least 4 years.²³ Each point of reduction in HbA_{1c} when above normal represents a decrease in the risk of microvascular complications by 35 percent.¹⁴ ACEIs have been shown to delay both the onset and the progression of diabetic nephropathy independent of their effect on controlling blood pressure. Overall prevention of nephropathy involves a combination of glycemic control, effective treatment of hypertension to 130/80 mm Hg or less, restriction of dietary protein, and avoidance of nephrotoxic drugs or dyes.

Blood pressure control, ideally to 130/80 mm Hg or less, is crucial to slowing the progression of nephropathy. Nondihydropyridine calcium channel blockers (e.g., diltiazem, verapamil) and ACEIs are the best agents to begin therapy in patients with diabetes. (3-Blockers also may be a good choice if balancing the tendency toward hyperglycemia with cardioprotective and renal protective effects or if CHF with an ejection fraction of greater than 25 percent is present. Thiazide diuretics have side effects such as hyperglycemia, hypokalemia, and hyperlipidemia that make them unattractive. Dihydropyridine calcium channel blockers such as nifedipine and amlodipine actually may increase proteinuria and are best avoided in patients with diabetes. Patients with nephropathy are encouraged to eat a lower-protein diet (0.6-0.8 g/kg ideal body weight per day). Drugs with nephrotoxic potential, such as the nonsteroidal anti-inflammatory drugs (NSAIDs), should be avoided. NSAIDs should be used sparingly and in short courses in diabetic patients without evidence of nephropathy.

Neuropathy

Neuropathy can be divided into peripheral neuropathy and autonomic neuropathy. The degree of functional and structural neural damage is related directly to the degree and duration of hyperglycemia. Approximately 42 percent of patients with type 2 diabetes will develop symptomatic polyneuropathy in the 10 years after diagnosis.²⁴ Symptomatic peripheral neuropathy results from loss of both myelinated and un-

TABLE 212-7 Changes in the Diabetic Retina

Background (Simple)	Proliferative
Increased capillary permeability	New vessels
Capillary closure and dilation	Scars (retinitis proliferans)
Microaneurysms	Vitreous hemorrhage

Hemorrhages	
Cotton-wool spots	
Hard exudates	

myelinated nerve fibers and blunted nerve fiber reproduction, resulting in abnormal firing of sensory neurons. Usually bilateral, it often consists of symmetrical stocking/glove loss in the distal extremities. Symptoms run a spectrum from numbness to dysesthesias/paresthesias to constant burning pain. Physical examination also may demonstrate loss of vibratory sense and deep tendon reflexes.

Intensive glycemic control reduced the incidence of clinical neuropathy by 60 percent in the Diabetes Control and Complications Trial (DCCT) and approximately 35 percent with each 1 percent reduction in HbA_{1c} in the UKPDS.¹⁴ Drugs that have been proven effective in treating the pain associated with diabetic neuropathy include tricyclic antidepressants, especially amitriptyline, topical capsaicin, phenytoin, neurontin, and carbamazepine. Narcotic analgesics have a high abuse potential in this setting, so their use should be avoided. NSAIDs also should be avoided secondary to potential nephrotoxicity. Sensory nylon monofilament testing (Semmes-Weinstein) is a useful screening tool for early neuropathy.²⁵ Diabetic patients with depressed or absent Achilles' reflex or loss of vibratory sensation in the foot are at high risk for developing foot ulcers. Pain often subsides with time as neurons become destroyed.²⁴

Diabetic mononeuropathy usually affects a large peripheral nerve (femoral, obturator, sciatic, median, or ulnar) or an isolated cranial nerve (usually the third, fourth, or sixth). Patients present with sudden onset of symptoms related to the involved nerve. It may be difficult in the emergency department to differentiate the signs and symptoms of diabetic mononeuropathy from a transient ischemic attack or cerebrovascular accident.

Autonomic neuropathy represents the clinical entities of gastroesophageal reflux disease (GERD), gastroparesis, neurogenic bladder, impotence and sexual dysfunction, autonomic diarrhea (nocturnal, often with incontinence), and orthostatic hypotension. Symptoms of GERD include dysphagia, chest pain, and heartburn. GERD may be difficult to differentiate from acute coronary syndrome in the emergency department and usually will respond to antacids, H₂-receptor blockers, or proton pump inhibitors. Gastroparesis, which is associated clinically with nausea, vomiting, bloating, and easy satiety, has been shown to respond to erythromycin or metoclopramide, which decrease gastric emptying time. Severe cases may not respond to medication. Autonomic diarrhea, defined as at least 3 weeks of increased stool frequency and/or liquidity, usually will respond to traditional antidiarrheal medicines.

Constipation is probably the most common gastrointestinal symptom in diabetes patients. Treatment includes dietary fiber supplementation and stool softener. Neurogenic bladder, inadequate or spastic emptying of the bladder, may respond to bethanechol therapy. Erectile dysfunction may be treated successfully with the new oral agent, sildenafil, but this drug is contraindicated in patients using any form of organic nitrate therapy and should be used with caution in patients with known coronary artery disease. Symptomatic orthostasis can be treated by increasing salt intake (in the absence of hypertension) or by using elastic stockings (which should be fitted by a specialist), or the symptoms may respond to fludrocortisone, which increases arterial tone and expands intravascular volume.

Infections

Diabetic patients who achieve and maintain excellent glycemic control (HbA_{1c} < 7 percent) are probably not significantly more susceptible to infection than the general population. A number of factors related to both the associated defects in immunity and disease-specific effects may account for the increased prevalence of certain infections and poor wound healing in patients with diabetes.

There are possible epidemiologic associations between diabetes and urinary tract infections (UTIs), candidal vulvovaginitis, cystitis, and balanitis, pneumonia, influenza, chronic bronchitis, pneumococcal bacteremia, primary and reactivation tuberculosis, rhinocerebral mucormycosis, malignant otitis externa, lower extremity skin and soft tissue structure infections, surgical wound infections, and Fournier

gangrene.²⁶ However, only a few of these conditions (UTI and other urogenital infections; staphylococcal, streptococcal and Candida skin infections) have been shown to be more frequent in diabetic patients than control groups in retrospective or prospective studies.

There are several impairments seen in polymorphonuclear leukocytes in diabetic patients, including impaired migration, phagocytosis, intracellular killing, and chemotaxis, that lead to an intrinsic decrease in immunity and in the ability to heal wounds properly. Disease-specific factors such as neuropathy, impairments in bladder emptying, and poor local circulation may further hinder the immune response. Although there are few controlled outcome studies, it is probably prudent to have a low threshold for initiating intravenous antibiotics and hospitalization of diabetic patients with upper urinary tract, lower respiratory tract, or skin (cellulitis/erysipelas) and skin structure (abscesses, furuncles, ulcers, and boils) infections. However, the availability of home intravenous infusion therapy and the development of oral antibiotics with excellent antimicrobial coverage provide outpatient alternatives for the management of uncomplicated infections.

Immunizations are recommended according to the Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices (ACIP; <http://www.cdc.gov/nip/recs/adult-schedule.pdf>) for patients with diabetes, especially those with evidence of complications, against influenza annually in the fall and once with the pneumococcal polyvalent vaccine. Repeat pneumococcal vaccination is indicated only for patients older than 64 years of age if their initial vaccination was more than 5 years ago.

There is little in the literature to guide the emergency physician when confronted with a febrile patient with diabetes and no obvious source of infection. Given the potential for problems with host defects in immunity in patients with poor glycemic control, and given that many infections associated with diabetes can be catastrophic, **fever without a clear source is a good reason to admit the patient.** Some serious diabetic infectious complications are discussed below.

RHINOCEREBRAL MUCORMYCOSIS Rhinocerebral mucormycosis is an invasive fungal infection of the nasal and paranasal sinuses; sometimes involving the palate and adjacent tissues. An estimated 70 percent of these infections occur in patients with DKA; the other 30 percent in immunocompromised patients without diabetes. The onset is sudden and rapidly progressive; patients present with periorbital or perinasal pain; blood-tinged nasal discharge; unilateral headache; increased tearing; swelling of eyelids and conjunctiva, and decreased vision. Physical signs can include black eschar on the nasal mucosa or hard palate due to ischemia, proptosis, and if the infection progresses, cranial nerve involvement or seizures. The organism has a propensity for vascular occlusion; therefore, cavernous sinus thrombosis, as well as brain abscesses, can occur.²⁶

Mortality is high (up to 50 percent); therefore, prompt diagnosis and immediate, aggressive therapy must be initiated. Acidosis must be corrected and an otolaryngologist consulted for extensive debridement of necrotic tissue and drainage of sinuses or abscesses. Computed tomography (CT) or magnetic resonance imaging (MRI) should be obtained to both determine the extent of the infection and rule out an intracranial process. Amphotericin B is the drug of choice. Even with aggressive therapy, only 50 to 85 percent of patients are cured.

MALIGNANT OTITIS EXTERNA Unlike other serious infections in patients with diabetes mellitus, well-controlled glucose levels are present in up to half, and systemic toxicity is often absent. Microangiopathy in the external auditory canal of diabetic patients is thought to be a predisposing factor. Patients present with unilateral otalgia, decreased hearing, purulent discharge, and sometimes fever (see Chap. 239). Examination finds a tender, inflamed external auditory canal, and almost all patients have a mass of granular-appearing tissue. The infection can progress to osteomyelitis of the mastoid, temporal bone, or base of skull and meningitis, venous sinus thrombosis, or subdural empysema. MRI or CT can define the extent of anatomic involvement.²⁶

Infection is frequently due to *Pseudomonas aeruginosa*, but staphylococci, fungi, and other gram-negative organisms have been isolated. Parenteral antibiotics, imipenem, meropenem, ciprofloxacin, or the combination of a third-generation cephalosporin (ceftazidime) and an antipseudomonal penicillin (ticarcillin) is indicated for 4 to 6 weeks. Early surgical debridement and frequent cleansing are critically important.²⁶

CHOLECYSTITIS Patients with diabetes have a predisposition to cholelithiasis. When acute cholecystitis develops in patients with diabetes, it is associated with higher morbidity and mortality rates. In addition, the greater chance (up to 25 percent) of developing emphysematous cholecystitis is associated with a higher incidence of gangrenous gallbladder that is more likely to perforate. Abdominal radiographs may reveal gas in the gallbladder and biliary tree. Unexplained fever, with or without abdominal pain, should be evaluated with ultrasound for cholecystitis. The causative agents are most frequently a *Clostridium* species in addition to streptococci, *Escherichia coli*, and *Pseudomonas*. Despite prompt treatment and surgery, the mortality rate (15 percent) is 3 to 10 times higher than that for ordinary cholecystitis.²⁶

PYELONEPHRITIS, PERINEPHRIC ABSCESS, AND PAPILLARY NECROSIS Diabetics are at increased risk for two serious renal infections: emphysematous pyelonephritis and perinephric abscess. Emphysematous pyelonephritis is a rare, life-threatening infection with gas production in and around the kidney. Over 70 percent of these patients will have diabetes. Patients with emphysematous pyelonephritis are ill with fever, flank pain, and sometimes a palpable mass. Bacteremia is often present. Aggressive treatment with parenteral antibiotics and nephrectomy is required. Even then, the mortality rate is still about 40 percent. Patients presumed to have pyelonephritis but who fail to respond to parenteral antibiotics should be evaluated for renal papillary necrosis and perinephric abscess. Symptoms of flank pain suggesting renal colic always should be evaluated fully to exclude infection or papillary necrosis. Thirty-five percent of patients with perinephric abscess will have diabetes. Patients usually do not respond completely to parenteral antibiotics, and surgical drainage often is required. Even with surgical drainage, mortality is about 20 percent.

About 50 percent of patients who develop renal papillary necrosis have diabetes. Patients may be asymptomatic and not notice the sloughed papillary tissue excreted in their urine, or they may present with symptoms similar to acute pyelonephritis. Renal infection with ureteral obstruction may develop into sepsis and septic shock in these diabetic patients. Necrotic tissue fragments, when seen in the urine along with red and white blood cells and bacteria, are suggestive of the diagnosis. Ureteral obstruction can be detected with ultrasound and helical CT. An intravenous pyelogram should be avoided, especially in cases of preexisting renal disease. Treatment consists of aggressive intravenous antibiotics, urinary drainage, and if the condition is severe, surgery to remove necrotic tissue.²⁶

Diabetes-Related Foot and Lower Extremity Ulcers

Foot and lower extremity ulcers and associated infections are a major source of morbidity in the diabetic population, affecting some 15 percent of diabetic patients during their lifetime. The complications account for 20 percent of diabetes-related admissions and nearly 60 percent of all lower extremity amputations in the United States. A pathologic triad of neuropathy, premature atherosclerotic vascular disease, and impaired immunity combines to make diabetic foot ulcers a multidisciplinary treatment challenge.

Peripheral neuropathy predisposes the foot to ulceration, infection, and joint degeneration (Charcot joints) through the mechanisms of lack of sensation, diminished or absent proprioception, anhidrosis, and poor circulatory and thermal regulation. Risk factors for foot and lower extremity ulcers include high HbA_{1c} levels, older age, longer

duration of diabetes, foot deformities, smoking, retinopathy, peripheral neuropathy, albuminuria, and low diastolic blood pressure. Preventing foot ulcers involves education on foot care and proper fitting of footwear, combined with good glycemic control to limit development of neuropathy and premature vascular disease.

A thorough clinical examination of the diabetic patient's feet should be performed during all emergency department visits even for unrelated complaints. Hair and nail growth, calluses, corns, deformities, erythema, swelling, sensation, and vascular function should be assessed. Any ulcerations found should be unroofed surgically and probed using a blunt-ended rigid probe to determine the depth and possible bone, joint, or tendon involvement and rule out deep abscess. The ability to probe to bone through the ulcer suggests the strong possibility of osteomyelitis and deep-space soft tissue infection.

Foot ulcers can be classified into non-limb-threatening, limb-threatening, and life-threatening infections. *Non-limb-threatening infection* is defined as small (under 2 cm of cellulitis or inflammation), does not involve deep structures or bone, and is the result of recent injury to a well-perfused limb. *Limb-threatening infection* (more than 2 cm of cellulitis or inflammation) with associated ascending lymphangitis, deep ulceration or abscess, large area of necrotic tissue, involvement of deep structures or bone, gangrene, or critical lower extremity ischemia is defined by the absence of palpable pulses. *Life-threatening infection* has clinical signs of sepsis, including fever, leukocytosis, hypotension, tachycardia, tachypnea, altered mental status, and metabolic abnormalities ranging from hypoglycemia to DKA and HUNS.

Management of foot ulcers that do not appear infected and do not expand to the deep structures or bone on exploration should include avoidance of weight bearing and nonadherent padded dressings. Follow-up referral with a specialist in diabetes-related foot care should occur within a few days to consider the need for debridement, full contact casting, further evaluation of any bony deformity or neuropathy, and evaluation for peripheral vascular disease. Constrictive dressings, such as an Unna paste boot (alkaline methylene blue), and tight-fitting

TABLE 212-8 Antimicrobial Therapy in Infected Diabetes-Related Lower Extremity Ulcers

Non-limb-threatening*

(May give initial dose as IV equivalent)

Cephalexin 500 mg PO qid, 10-day course (cefazolin 1 g IV) *or* Clindamycin 300 mg PO qid, 10-day course (clindamycin 900 mg IV) *or* Dicloxacillin 500 mg PO qid, 10-day course *or* Amoxicillin-clavulanate 875 mg PO bid, 10-day course

Limb-threatening*

More than 2 cm of cellulitis/inflammation

Ascending lymphangitis Deep structure

involvement Large areas of necrosis

Gangrene

Lower extremity ischemia with decreased or absent pulses

Oral regimen: Fluoroquinolone and clindamycin *Close follow-up!* IV regimens:

Ampicillin-sulbactam 3 g IV q6h *or*

Ticarcillin-clavulanate 3.1 g IV q8h *or*

Second-generation cephalosporin (cefoxitin, cefotetan) 1–2 g IV q12h *or*

Ciprofloxacin 400 mg IV q12h and clindamycin 900 mg IV q6h

Life-threatening* IV regimens:

Imipenem-cilastatin 1 g q6h *or*

Ampicillin-sulbactam 3 g q8h + antipseudomonal aminoglycoside

tobramycin 5–7 mg/kg qd *or*

Vancomycin 1 g q12h + metronidazole 500 mg q6h + aztreonam 2 g q8h

♦See text for definitions.

Note: Adjust all dosages for renal/hepatic function and monitor blood levels where appropriate.

Abbreviations: DKA = diabetic ketoacidosis; HHNS = hyperglycemic, hyperosmolar nonketotic syndrome.

TABLE 212-9 Disposition/Guidelines for Hospital Admission

Inpatient care for the diabetic patient is generally appropriate for the following clinical situation:
Life-threatening metabolic decompensation such as diabetic ketoacidosis or hyperglycemic, hyperosmolar, nonketotic syndrome.
Newly diagnosed diabetes in children or adolescents.
Chronic, poor metabolic control that necessitates close monitoring to determine the cause of the poor control, with subsequent modification of the therapeutic plan.
Severe chronic complications of diabetes, such as chronic renal insufficiency or failure, atherosclerotic cardiovascular disease, infected lower extremity ulcers, retinopathy with acute loss of vision, neuropathy with intractable pain or affecting ability to ambulate, and autonomic neuropathy, i.e., gastroparesis with intractable nausea and vomiting that require admission for intensive therapy or to prevent metabolic decompensation.
Conditions that impact adversely on diabetes control or are complicated by the presence of diabetes, such as acute asthma or chronic obstructive pulmonary disease exacerbations requiring high doses of corticosteroids as therapy.
Uncontrolled or newly discovered diabetes during pregnancy.
Institution of insulin pump or other intensive insulin regimens for glycemic control.
Hyperglycemia (>400 mg/dL) associated with severe volume depletion.
Hyperglycemia that does not respond to appropriate interventions or with associated metabolic deterioration.
Hypoglycemia with neuroglycopenia (altered level of consciousness, altered behavior, coma, seizure) that does not rapidly resolve with correction of hypoglycemia.
Hypoglycemia resulting from long-acting oral hypoglycemic agents.
Hyperglycemia with adequate resolution of symptoms but no responsible adult to be with the patient for the next 12 h.
Recurrence of hypoglycemia despite interventions.
Admissions for complications of diabetes should be driven by the appropriate care for the particular diagnostic entity, such as infected lower extremity ulcer, renal failure, congestive heart failure, or unstable angina.
Admissions for other medical conditions should be considered if rapid initiation of glucose control can improve outcome, such as in pregnancy, infections, or surgery. Also, consider admission if the medical illness can lead to acute onset of retinal, renal, neurologic, or cardiovascular complications of diabetes, for example, hypertensive urgency/emergency. These guidelines may result in admissions for diabetic patients for conditions that may be treated on an outpatient basis in the nondiabetic population.
Fever without an obvious source in patients with poorly controlled diabetes.

Source: Adapted from the American Diabetes Association,²⁸ with permission.

shoes should be avoided. Avoidance of weight bearing on the affected limb is critical to avoid progression to infection and for proper healing.

Radiographs of the foot are indicated for all ulcers to exclude subcutaneous gas, foreign bodies, osteomyelitis, and Charcot joints. Swab cultures of foot ulcers may provide misleading results. Culture of tissue excised from the base of the ulcer provides the most accurate identification of the bacteria involved. Commonly isolated organisms include *Bacteroides* species, *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Enterococcus*, *E. coli*, *Proteus mirabilis*, and *Pseudomonas aeruginosa*. Empirical antibiotic therapy should be directed against these organisms.

In choosing antibiotic therapy for these infections, severity should be taken into account²⁷ (Table 212-8). The use of aminoglycosides generally should be avoided whenever possible because of their associated nephrotoxicity. For limb-threatening and life-threatening infections, immediate surgical consultation is indicated for incision and debridement, possible revascularization, or amputation.²⁷

Skin and Soft Tissue Complications

Skin infections such as cellulitis, furuncles, and carbuncles and candidiasis occur more commonly in patients with diabetes. Serious infections usually develop due to the combination of poorly controlled

serum glucose, vascular insufficiency, and tissue hypoxia. These infections may spread rapidly with dramatic skin changes. The worst of these infections is necrotizing fasciitis.

NECROTIZING FASCIITIS Necrotizing fasciitis is a rapidly progressive infection of the skin and soft tissues that is more common in diabetic patients (see Chap. 152). It can occur anywhere on the body but is associated most commonly with the extremities and the abdominal wall. Fournier gangrene is a form of necrotizing fasciitis involving the male genitalia and perineum. On clinical evaluation, pain is usually severe and out of proportion to the visible degree of erythema, swelling, and palpable tenderness. Later skin changes include the formation of bullae and eschar. Crepitus is noted in up to half of patients. Radiographs may reveal gas in the tissues in up to 75 percent of patients. Necrotizing fasciitis has been classified as type 1, typically caused by a combination of anaerobe (usually *Bacteroides fragilis* or *Clostridium* sp.) and facultative aerobe (usually *E. coli*), or type 2, typically caused by group A streptococci with or without concurrent *S. aureus* infection. Treatment involves immediate surgical consultation for aggressive debridement of necrotic tissue and IV antibiotics: penicillin G 6 million units IV every 6 h plus clindamycin 900 mg IV every 8 h plus gentamicin 5 mg/kg IV every day. Synthetic penicillins plus P-lactamase inhibitors (ampicillin-sulbactam, ticarcillin-clavulanic acid) and third-generation cephalosporins also may be effective in combination with clindamycin. Vancomycin and/or fluoroquinolones may be reasonable alternatives in the penicillin-allergic patient.

Hemodynamic support and correction of ketoacidosis and/or hyperglycemia are required to create optimal conditions for healing postoperatively.²⁶

DISPOSITION AND INDICATIONS FOR HOSPITAL ADMISSION

Guidelines for admission considerations are listed in Table 212-9. These guidelines may result in admissions for diabetic patients for conditions that may be treated on an outpatient basis in the nondiabetic population.²⁸

Patients who present with new-onset type 2 diabetes or type 1 diabetes without evidence of metabolic decompensation, acute hypoglycemia, or hyperglycemia and do not meet the aforementioned criteria for admission should see their primary care provider within 24 to 48 h as a general rule to arrange for general education and dietary evaluation and to initiate appropriate therapy for glycemic control. General discharge instructions for all diabetic patients, new or established, are detailed in Table 212-10.

TABLE 212-10 Discharge Instructions and Follow-Up Care

Follow a healthy diet.
Self-monitor blood glucose regularly.
Take insulin or oral hypoglycemics as directed.
Reduce weight where appropriate.
Cease smoking where appropriate.
Exercise regularly in the absence of contraindications, such as foot ulcers.
Practice good general foot care (check regularly for minor trauma and hot spots, keep nails trimmed properly, and wear well-fitted shoes).
Wearing a Medic-alert bracelet or necklace.
Be able to recognize symptoms of high blood sugar, such as frequent urination, thirst, dizziness, headache, nausea or vomiting, abdominal pain, lethargy, or blurry vision.
Be able to recognize symptoms of low blood sugar, including fatigue, headache, drowsiness, agitation, pale or moist, visual changes, or loss of consciousness.
Know how to help yourself or others with low blood sugar by self-administering or giving an awake person (who can swallow without gagging or choking) candy, fruit juice, or sugar or by calling an emergency phone number (e.g., 911) if the affected person is not able to respond.

ALCOHOLIC KETOACIDOSIS

William A. Woods

Debra G. Perina

Alcoholic ketoacidosis (AKA) is a wide-anion-gap acidosis most often associated with acute cessation of alcohol consumption after chronic alcohol abuse. The metabolism of alcohol with little or no glucose sources results in the elevated levels of ketoacids that typically produce the metabolic acidosis present in this illness. Although usually seen in chronic alcoholics, ketoacidosis has been described in first-time drinkers who binge drink, particularly in association with volume depletion from poor oral intake and vomiting.

EPIDEMIOLOGY

There are no gender differences. The age of presentation is variable but usually between 20 and 60 years. Patients often experience repeated episodes of ketoacidosis, with 23 percent of patients having more than one episode of AKA in one series.¹ The true incidence of this illness is unknown but most likely mirrors the incidence of alcoholism in the population.¹ This illness may be more prevalent than previously suspected. One study indicated that analysis of serum chemistries of alcoholics arriving at emergency departments with complaints related to excessive alcohol intake incidentally found ketoacidosis in 25 percent of patients.² Although with proper treatment this illness is self-limited, poor outcomes can occur. Medical examiner literature notes that 7 to 25 percent of deaths in known alcoholics are from AKA.^{2,3}

PATHOPHYSIOLOGY

The pathophysiology of AKA is complex and not entirely understood. The key features of AKA are an ingestion of a large quantity of alcohol, relative starvation, and volume depletion. To begin to understand this disorder, it is necessary to understand ethanol metabolism (Figure 213-1). Ethanol metabolism requires nicotinamide adenosine dinucleotide (NAD) and the enzymes alcohol dehydrogenase and aldehyde dehydrogenase to convert ethanol to acetyl coenzyme A. Acetyl coenzyme A can be metabolized directly (resulting in ketone production), used as substrate for the Krebs cycle, or used for free fatty acid synthesis.

The pathologic state of AKA can occur when NAD is depleted, aerobic metabolism in the Krebs cycle is inhibited, glycogen stores are depleted, and lipolysis is stimulated. The lactate-pyruvate ratio is in the range of 20:1.⁵ All these conditions are met in the recently intoxicated, volume-contracted patient with underlying poor nutrition and liver disease. Ethanol metabolism results in a higher ratio of NAD to NADH. When glycogen stores are depleted in a patient stressed by concurrent illness or volume depletion, insulin secretion is suppressed. On the other hand, under these same conditions, glucagon, catecholamine, and growth hormone secretion are all stimulated. This hormonal milieu inhibits aerobic metabolism in favor of anaerobic metabolism and promotes lipolysis. Hence the acetyl coenzyme A is metabolized to ketones.

The relative deficiency of NAD has another effect. NAD is used in the conversion of (3-hydroxybutyrate (3HB) to acetoacetate. Acetoacetate is rapidly converted to acetone, which is excreted in the urine. Due to the imbalance of NAD and NADH, (3HB is the predominant ketone product formed. Normally, the ratio of acetoacetate to 3HB is 1:1, however, in AKA it is 1:7, although it can be higher.⁵

FIG. 213-1. Ethanol metabolism.

Ketone production can be further stimulated in malnourished, vomiting patients or in those who are hypophosphatemic. Both these conditions are seen commonly in alcoholic patients with AKA.

CLINICAL FEATURES

AKA typically occurs after an episode of heavy drinking followed by an acute decrease in alcohol and food intake and vomiting. The nausea, vomiting, and abdominal pain that may be associated with gastritis or pancreatitis may exacerbate the progression of this illness. As anorexia continues, the symptoms worsen, leading the patient to seek health care. Symptoms are nonspecific, making diagnosis difficult without laboratory studies as confirmation (Table 213-1).

There are no specific physical findings associated solely with AKA. The most common findings are tachycardia, tachypnea, and diffuse, mild to moderate abdominal tenderness. Volume depletion resulting from anorexia, diaphoresis, and vomiting may explain the frequently seen tachycardia and hypotension. Most patients are alert at presentation. Mental status changes in patients with ketoacidosis should alert clinicians to other potential causes, such as toxic ingestion, hypoglycemia, alcohol-withdrawal seizures, postictal state, or unrecognized head injury.

LABORATORY

Alcohol levels are usually low or undetectable at the time of presentation, but some patients may present with an elevated blood alcohol level, making diagnosis more challenging. An elevated anion gap caused by ketones is essential for diagnosing AKA. Since (3HB predominates, the degree of ketonemia may not be appreciated, depending on the method of ketone detection (see Chap. 211 for a complete discussion). The initial anion gap is usually 16 to 33, with a mean of 21.² Patients frequently have mild hypophosphatemia, hyponatremia, and/or hypokalemia. Severe derangements are rare but have been reported. Most patients also will have elevated bilirubin and liver en-

zyme levels due to liver disease from a long history of chronic ethanol use. Blood urea nitrogen and creatine kinase levels frequently are elevated due to relative volume depletion. Serum lactate levels can be mildly elevated. Glucose levels most often are only mildly elevated, but a subset of patients will have hypoglycemia. On rare occasions, the glucose level may be greater than 200 mg/dL.

Acid-Base Balance

Serum pH is typically acidemic, but the pH may be normal or even alkalemic early in the course of the illness.⁶ In one study, 15 percent of patients were alkalemic, 30 percent had normal pH, and 55 percent had acidemia.¹ The degree of acidosis is typically less than that seen in patients with diabetic ketoacidosis. If the acidosis is mild and the patient also has a primary respiratory alkalosis (i.e., due to fever, sepsis, or alcohol withdrawal), then the pH may be normal or even alkalemic. Similarly, contraction metabolic alkalosis may mask the presence of a concurrent wide-anion-gap acidosis and result in a "normal" or even elevated serum bicarbonate level, rendering the pH normal or alkalemic. Since volume loss, whether due to poor volume intake or vomiting, is virtually always present in AKA, some degree of metabolic alkalosis is present.

Without routine evaluation of the anion gap in every patient at risk for AKA, the diagnosis can be easily missed. An anion gap greater than the patient's baseline (or greater than 15 in any case) signifies the presence of a wide-anion-gap acidosis regardless of the actual [HCO₃⁻] or the pH, even if the patient is alkalemic. For example, a common serum chemistry result in a patient with AKA may be along the following lines: [Na⁺], 145; [Cl⁻], 95; [K⁺], 4.1; and [HCO₃⁻], 25 all in mEq/L. In this example, the anion gap (25, excluding K⁺) is elevated by at least 10, yet the [HCO₃⁻] and electrolyte levels are normal. The only explanation is that a mixed acid-base abnormality of approximately equal but opposing magnitudes exists. Arterial blood gas determination is not needed to arrive at the correct diagnosis for this relatively complicated acid-base disturbance. (For a more detailed discussion, the reader is referred to Chap. 25.)

Ketones

The standard test for ketone detection is the serum or urine nitroprusside test. While pHB is the predominant ketone present in AKA, acetoacetate is the only ketone normally detected by the nitroprusside test. Since patients with AKA may have only mildly elevated acetoacetate levels, it is important not to exclude the diagnosis of AKA with a negative or only weakly positive test. As treatment progresses and NAD is replenished, the acetoacetate levels actually may increase, and the nitroprusside test will reflect an increasingly positive reaction. This natural progression should be expected and does not indicate a worsening of the patient's condition. The clinical application of this test is thus quite variable. Most authors suggest measuring [3HB and acetoacetate levels only if the diagnosis is unclear or other ways are not available to follow the patient's response to therapy.⁶

TABLE 213-1 Common Symptoms and Signs in Alcoholic Ketoacidosis

Symptoms	%	Signs/Anion Gap	%
Nausea	76	Tachycardia	56
Vomiting	73	Tachypnea	49
Abdominal pain	62	Abdominal tenderness	43
Shortness of breath	20	Heme-positive stool	18
Tremulousness	20	Hepatomegaly	18
Hematemesis	19	Altered mental status	15

DIAGNOSIS

The diagnosis is easily established in the classic presentation of the chronic alcoholic with recent anorexia, vomiting, abdominal pain, unexplained metabolic acidosis with a positive nitroprusside test, elevated anion gap, and a low or mildly elevated serum glucose level. However, classic presentations are uncommon. Establishing this diagnosis can be difficult for several reasons. First, the blood alcohol level may be zero, and the patient may not voluntarily provide the history of alcohol consumption. Second, urine nitroprusside testing may be negative or weakly positive despite significant ketoacidosis. Finally, the pH may vary from significant acidemia to mild alkalemia. However, a widened anion gap is invariable.

Initial laboratory studies include determination of electrolyte, blood urea nitrogen (BUN), and creatinine levels; hepatic and pancreatic enzyme levels; white blood cell count; hematocrit; and urinalysis. The anion gap should be calculated. Determination of serum lactic acid level and serum osmolality also may be helpful if the diagnosis is in doubt. Further laboratory studies may be needed to delineate the cause of the increased anion-gap acidosis if other ingestions besides ethanol are suspected (see "Differential Diagnosis" below). An arterial blood gas determination is unnecessary unless a primary respiratory acid-base disturbance is suspected (Table 213-2).

Differential Diagnosis

The differential diagnosis for AKA is very broad. It is essentially the differential diagnosis of wide-anion-gap metabolic acidosis. Lactic acidosis, uremia, and other ingestions (particularly methanol and ethylene glycol) should be considered. A mild lactic acidosis is occasionally present in AKA related to ethanol metabolism, but it is comparatively inconsequential. Lactic acidosis related to anaerobic metabolism (e.g., hypotension, sepsis, or tissue ischemia or associated with methanol, ethylene glycol, and salicylic acid) is usually markedly more severe and less readily masked by concurrent metabolic alkalosis. Both salicylic acid poisoning and sepsis often present with triple acid-base disturbances (metabolic acidosis, metabolic alkalosis, and respiratory alkalosis). Other potential etiologies, such as renal failure or diabetic ketoacidosis, can be ascertained from the serum chemistries, with an elevated creatinine, BUN, or blood sugar level greater than 300 mg/dL, respectively. Differentiation of AKA from starvation ketosis is an academic exercise and unimportant because underlying pathophysiology, treatment, and implications are similar.

Differentiating AKA from other alcohol ingestions should not be difficult. Methanol and ethylene glycol ingestions do not produce ketosis, but acidosis tends to be severe. Since patients with AKA have a negative urine nitroprusside test in approximately 15 percent of cases,¹ **the absence of urinary ketones cannot be used to exclude a diagnosis of AKA** if concurrent methanol or ethylene glycol ingestion is suspected. Isopropyl alcohol ingestion results in production of ketones and is on occasion associated with a mild lactic acidosis. However, the presence of an osmolal gap (which is a feature of isopropyl, methanol, and ethylene glycol poisonings) may help in differentiating pure AKA from other concurrent mixed ingestions. Remember, ethanol is osmotically active and, if present, also will contribute to production of an os-

molal gap. If the blood alcohol level is known, then its contribution to any osmolal gap can be calculated. If the entire osmolal gap cannot be attributed to the ethanol level, then isopropyl alcohol (mild or no acidosis), methanol, or ethylene glycol (severe acidosis) may well be the explanation. Each 100 mg/dL of ethanol raises the osmolal gap by 22. (Details of osmolal gap are discussed in Chap. 27.)

Patients with AKA often have concurrent illnesses that may have promoted the alcohol cessation and anorexia. Thus a thorough investigation for underlying illnesses should be performed. Common concurrent illnesses are pancreatitis, gastritis or upper gastrointestinal bleeding, seizures, alcohol withdrawal, pneumonia, sepsis, and hepatitis.

TREATMENT

Therapy is aimed at both glucose administration and volume repletion. The fluid of choice is D5NS. Glucose stimulates insulin production, which stops lipolysis and halts the further formation of ketones. Glucose also increases the oxidation of NADH to NAD, thereby further stopping ketone production. Patients with AKA are not hyperosmolar, and unlike treatment of diabetic ketoacidosis, cerebral edema is of little concern with large volumes of fluid administration. Even with vigorous fluid resuscitation, no cases of cerebral edema have been reported among those being treated for AKA.

Insulin is of no proven benefit and can be dangerous because patients often have depleted glycogen stores and normal or low glucose levels. Sodium bicarbonate is not indicated unless patients are severely acidemic, with a pH of 7.1 or lower. As noted, this level of acidemia is unlikely to be explained by AKA alone. A vigorous search for an alternate explanation must be undertaken. Hypophosphatemia is seen frequently in chronic alcoholic patients and can retard the resolution of acidosis because phosphorus is necessary for mitochondrial utilization of glucose to produce NADH oxidation. However, phosphate replacement generally is unwarranted as part of this treatment in the emergency department unless very low levels are encountered (<1.0 mg/dL). Oral replenishment is safe and effective. Nitroprusside tests correlated with clinical status may be used to help guide therapy because an increasingly positive reaction signifies improvement. To prevent the theoretical precipitation of Wernicke disease, all patients should receive 50 to 100 mg of thiamine prior to the administration of glucose. Concomitant administration of magnesium sulfate and multivitamins should be considered and guided by laboratory results. Acidosis may clear within 12 to 24 h. Patients with an uncomplicated emergency department course may be safely discharged home if there is resolution of acidosis over time and the patient is able to tolerate oral fluids. Patients with a complicated course, underlying illnesses, or persistent acidosis should be admitted for further evaluation and treatment.

214 HYPEROSMOLAR HYPERGLYCEMIC STATE

Charles S. Graffeo

The disease process discussed in this chapter is frequently referred to as *nonketotic hyperosmolar coma* to characterize the syndrome of severe hyperglycemia, hyperosmolality, and a relative lack of ketonemia in patients with poorly controlled or undiagnosed type 2 diabetes mellitus. The literature is replete with a score of other acronyms for this syndrome. The nomenclature used by the American Diabetes Association, *hyperosmolar hyperglycemic state* (HHS) and *hyperosmolar hyperglycemic nonketotic syndrome* (HHNS) are both commonly used and more appropriate. This chapter uses the HHNS designation. Placing emphasis on the presence or lack of coma is likely to underestimate the severity of disease, and thus "coma" should be excluded from the nomenclature. In fact, less than 10 percent actually present with coma.¹

In general, HHNS is "defined" by severe hyperglycemia with serum glucose usually greater than 600 mg/dL, an elevated calculated plasma osmolality of greater than 315 mOsm/kg, serum bicarbonate greater than 15, an arterial pH greater than 7.3, and serum ketones that are negative to mildly positive in a 1:2 dilution.² These values, however, are fairly arbitrary. A profound metabolic acidosis and even moderate degrees of ketonemia may be found in HHNS. The importance of recognizing the potential for a variety of mixed acid-base patterns in patients presenting with HHNS cannot be overemphasized.

Many authors propose that HHNS and diabetic ketoacidosis (DKA) should be viewed as similar disease processes with the fundamental difference being in the metabolism of lipids during a period of relative insulin deficiency. Shared features of both include hyperglycemia, hyperosmolality, severe volume depletion, electrolyte disturbances, and sometimes acidosis. The acidosis associated with HHNS is more likely to be due to tissue hypoperfusion (lactic acidosis), starvation ketosis, and azotemia, in various combinations. In contrast, patients with DKA at similar levels of tissue perfusion have much higher levels of lipolysis with the release and subsequent oxidation of free fatty acids (FFA) to ketone bodies, P-hydroxybutyrate and acetoacetate, which contribute additional anions, resulting in a more profound acidosis. The inhibition of lipolysis and FFA metabolism characteristic of HHNS is poorly understood. A comparison of the laboratory features of DKA and HHNS is shown in Table 214-1.

Knowledge of the diagnostic criteria for diabetes can be an aid for identification of undiagnosed diabetes (Table 212-4).³ Early identi-

cation of those at risk for HHNS is the most effective means of preventing serious complications. Patients with any evidence of unexplained hyperglycemia should be made aware of this potentially significant finding and referred for further evaluation. Caretakers of those without easy access to water such as nonambulatory nursing home patients must be particularly vigilant of the hydration status of such individuals. It is impaired access to water that is the fundamental risk factor for developing HHNS.

EPIDEMIOLOGY

The basic epidemiology of diabetes is discussed in Chap. 212. Although HHNS occurs much less frequently than DKA, mortality rates are much higher. The reported range of mortality in HHNS is approximately 15 to 30 percent versus approximately 5 percent in DKA.⁴ However, mortality for HHNS increases substantially with advanced age and concomitant illness.

PATHOPHYSIOLOGY

The basic pathophysiology of diabetes is discussed in Chap. 212. The development of HHNS is attributed to three main factors: 1) decreased insulin utilization, 2) increased hepatic gluconeogenesis and glycogenolysis, and 3) impaired renal excretion of glucose.

During a state of poorly controlled type 2 diabetes mellitus, inadequate tissue utilization of glucose caused by insulin resistance results in hyperglycemia. In the absence of an adequate peripheral response to insulin, hepatic glycogenolysis and gluconeogenesis occurs, further elevating serum glucose. As serum glucose concentration increases, it creates an osmotic gradient, attracting water from the intracellular space and into the intravascular compartment. This initial increase in intravascular volume is accompanied by a temporary increase in the glomerular filtration rate (GFR). As serum glucose concentration exceeds approximately 180 mg/dL, the capacity of the kidneys to reabsorb glucose is exceeded, and glucosuria and a profound osmotic diuresis occur.

Patients with free access to water are often able to prevent profound volume depletion by replacing lost water with large free water intake. If this water requirement is not met (as may occur in a nonambulatory nursing home patient), volume depletion occurs. During osmotic diuresis, urine produced is markedly hypertonic. Still, significant urinary loss of sodium and potassium, as well as more modest losses of calcium, phosphate, magnesium, and urea, also occur. As volume depletion progresses, renal perfusion decreases and the GFR is reduced.

TABLE 214-1 Diagnostic Criteria for DKA and HHNS

	DKA			HHNS
	Mild	Moderate	Severe	
Plasma glucose (mg/dL)	>250	>250	>250	>600
Arterial pH	7.25-7.30	7.00-7.24	<7.00	>7.30
Serum bicarbonate (mEq/L)	15-18	10 to <15	<10	>15
Urine ketone*	Positive	Positive	Positive	Small
Serum ketones*	Positive	Positive	Positive	Small
Effective serum osmolality (mOsm/L) ^t	Variable	Variable	Variable	>320

Source: ADA,² with permission.

Renal tubular excretion of glucose is consequently impaired, which further worsens the hyperglycemia. A sustained osmotic diuresis may result in total body water losses that often exceed 20 to 25 percent of total body weight, or approximately 8 to 12 L in a 70-kg patient.

The reason for the absence of ketoacidosis in HHNS is not clearly understood. Though some degree of a starvation ketosis does occur, clinically significant ketoacidosis does not. This lack of ketoacidosis in HHNS has been attributed to three possible mechanisms: 1) lower levels of counterregulatory hormones, 2) higher levels of endogenous insulin, which strongly inhibits lipolysis, and 3) inhibition of lipolysis by the hyperosmolar state.

There is controversy about the role that counterregulatory hormones glucagon, cortisol, growth hormone, and epinephrine play in HHNS. When compared with DKA, glucagon and growth hormone levels have been shown to be lower, which may help prevent lipolysis. When compared with DKA, significantly higher levels of insulin are found in the peripheral and portal circulation in HHNS. Though these levels of insulin are insufficient to overcome hyperglycemia, they appear to be sufficient to inhibit lipolysis.⁵ Finally, there have also been limited experimental animal studies that have shown that both the hyperosmolar state and severe hyperglycemia inhibit lipolysis in adipose tissue.

CLINICAL FEATURES

The typical patient with HHNS is usually elderly, and is often referred by a caretaker for abnormalities in vital signs and or mental status. Patient complaints may include weakness, anorexia, fatigue, cough, dyspnea, or abdominal pain. Many will have either undiagnosed or poorly controlled type 2 diabetes that has been precipitated by an acute illness. Pneumonia and urinary tract infection account for 30 to 50 percent of cases. Noncompliance with or under-dosing of insulin has been identified as a common precipitant as well, at least in some populations.⁶ Those predisposed to HHNS often have some level of baseline cognitive impairment, such as senile dementia, and self-referral for medical treatment during early stages of illness is rare. In general, any patient with hyperglycemia, an impaired means of communication, and limited access to free water intake is at major risk for HHNS. The presence of hypertension, renal insufficiency, or cardiovascular disease is common in this patient population, and medications commonly used to treat these diseases, such as diuretics and β -blockers, predisposes to the development of HHNS.

Typically, an insidious state of progressive hyperglycemia, or hyperosmolality and osmotic diuresis develops, which usually goes unchecked. Alterations in vital signs and cognition follow and signal a severity of illness that is often advanced. A host of metabolic and iatrogenic causes have been identified (Table 214-2), including many commonly prescribed drugs that may predispose to hyperglycemia, volume depletion, or other effects leading to HHNS (Table 214-3).

Physical Findings

The physical manifestations associated with HHNS are nonspecific. Generally, clinical signs of volume depletion such as poor skin turgor, dry mucous membranes, sunken eyeballs, and hypotension will corre-

TABLE 214-3 Drugs That May Predispose Individuals to the Development of Hyperosmolar Hyperglycemic State

Lithium	Neuroleptics
β -Blockers	Phenytoin
Mannitol	Didanosine
Chlorpromazine	Calcium-channel blockers
Cimetidine	Pentamidine

late with degree of hyperglycemia and hyperosmolality and duration of physiologic imbalance.

A wide range of findings from subtle changes in vital signs and cognition to clear evidence of profound shock and coma may occur. Normothermia or hypothermia is common due to vasodilation. HHNS may unexpectedly be found in non-diabetics who present with an acute medical insult such as a cerebrovascular accident (CVA), severe burns, myocardial infarction, infection, pancreatitis, or other acute illness. Up to 15 percent may present with seizures. These are typically focal, though generalized seizures, which are often resistant to anticonvulsants, may occur.⁷

Other central nervous system (CNS) symptoms may include tremor, clonus, hyperreflexia or hyporeflexia, a positive plantar response, reversible hemiplegia, or hemisensory defects (without CVA or structural intracerebral lesion). The degree of lethargy and coma is proportional to the level of osmolality. Those with coma tend to have higher osmolality, hyperglycemia, and greater volume contraction.⁸ In view of the age of the patient population, it is not surprising that the misdiagnosis of stroke or organic brain disease is common.

Laboratory Tests

Essential laboratory tests should include serum glucose, electrolytes, calculated and measured serum osmolality, blood urea nitrogen (BUN), ketones, and creatinine, as well as complete blood count. In view of the frequency of precipitating causes and underlying medical conditions associated with HHNS, a broad range of ancillary studies should be considered. These should include blood cultures, sputum collection, urinalysis and culture, liver and pancreatic enzyme determinations, cardiac enzymes, thyroid function, coagulation profiles, chest x-ray, and electrocardiogram. Other ancillary studies such as computed tomography of the head, lumbar puncture, and toxicologic studies should also be considered. Arterial blood-gas determination is of added value only if there is suspicion of a respiratory component to the acid-base abnormality, as both P_{CO_2} and pH can be predicted from $[HCO_3^-]$ concentration obtained in venous electrolytes (see Chap. 25, "Acid-Base Disorders").

In general, electrolyte abnormalities initially reflect a contraction alkalosis due to profound water deficit. As many as 50 percent of patients with HHNS will have an increased anion gap metabolic acidosis (lactic acidosis, azotemia, starvation ketosis, severe volume contraction). Acute or concurrent illnesses, however, such as ischemic bowel, will contribute anions such as lactic acid, causing varying degrees of an anion-gap metabolic acidosis. Initial serum electrolyte determinations can be reported as seemingly normal because the concurrent presence of both metabolic alkalosis and acidosis may result in each cancelling out the other's effect. A lack of careful analysis of serum chemistries may lead to a delayed appreciation of the severity of the underlying abnormalities, including volume loss. Serum sodium is suggestive but not a reliable indicator of degree of volume contraction. Although the patient is certainly total body sodium depleted, the serum sodium (even corrected for the glucose elevation) may be low, normal, or elevated. Measured serum sodium, however, is often reported as factitiously low due to the dilutional effect of hyperglycemia. It is important to correct for this effect. Serum sodium decreases by approxi-

TABLE 214-2 Conditions That May Precipitate Hyperosmolar Hyperglycemic State

Diabetes	Infection

Pancreatitis	Peritoneal or hemodialysis
Heat-related illness	Cerebrovascular events
Mesenteric ischemia	Rhabdomyolysis

mately 1.6 mEq for every 100 mg/dL increase in serum glucose above 100 mg/dL or:

$$\text{corrected } [\text{Na}^+] = \text{measured } [\text{Na}^+] + \frac{1.6 \times [\text{glucose} - 100]}{100}$$

Elevated corrected serum sodium during severe hyperglycemia is usually explainable only by profound volume contraction. Normal sodium level or mild hyponatremia usually (but not invariably) suggests modest dehydration.

Serum osmolality has also been shown to correlate with severity of disease as well as neurologic impairment and coma.² A calculated effective serum osmolality excludes osmotically inactive urea, which is usually included in laboratory measures of osmolality. The formula for calculated effective osmolality (mOsm/L) is:

$$2[\text{Na}^+] + \frac{\text{glucose}}{18}$$

Normal serum osmolality range is approximately 275 to 295 mOsm/kg. Values above 300 mOsm/kg are usually indicative of significant hyperosmolality and those above 320 mOsm are commonly associated with alterations in cognitive function. Osmolality (mOsm/L) and osmolality (mOsm/kg) are discussed in detail in Chap. 27.

Hypokalemia probably poses the most immediate electrolyte-based risk and should be anticipated. Total body deficits of 500 to 700 mEq/L are not uncommon. Initial values may be reported as normal during a period of severe volume contraction and with metabolic acidosis when intravascular $[\text{H}^+]$ ions are exchanged for intracellular $[\text{K}^+]$ ions. The presence of acidemia may mask a potentially life-threatening $[\text{K}^+]$ deficit. As intravascular volume is replaced and acidemia reversed, $[\text{K}^+]$ losses become more apparent. Patients who have low serum $[\text{K}^+]$ during the period of severe volume contraction are at greatest risk for dysrhythmia. The importance of $[\text{K}^+]$ replacement during periods of volume repletion and insulin therapy cannot be overemphasized.

Both prerenal azotemia and renal azotemia are common, with plasma BUN:creatinine ratios often exceeding 30:1. Leukocytosis is variable and a weak clinical indicator. When present, it is usually due to infection or hemoconcentration. Hypophosphatemia may occur during periods of prolonged hyperglycemia. Acute consequences such as CNS abnormalities, cardiac dysfunction, and rhabdomyolysis are rare and usually associated with serum phosphate levels below 1.0 mg/dL. Routine replacement of phosphate or magnesium, unless severe, is usually unnecessary. Both electrolytes tend to normalize as metabolic derangements are addressed. When necessary, gradual replacement minimizes the risks of complications such as renal failure or hypocalcemia. Metabolic acidosis is of a wide-anion-gap type, often due to lactic acidosis from poor tissue perfusion, resulting in uremia, mild starvation ketosis, or all three.

TREATMENT

Improvement of tissue perfusion is the key to effective recovery in HHNS. Treatment includes correction of hypovolemia, identifying and treating precipitating causes, correcting electrolyte abnormalities, and gradual correction of hyperglycemia and osmolality. What cannot be overstated is the importance of a judicious therapeutic plan that adjusts for concurrent medical illnesses such as left ventricular dysfunction or renal insufficiency commonly found in this patient population. Due to the potential for complications (noted below), rapid therapy should be reserved for potentially life-threatening electrolyte abnormalities only. A protocol for treating severely ill patients likely requiring ICU-level care is shown in Figure 214-1.

Fluid Resuscitation

Initial fluid resuscitation should be aimed at reestablishing adequate tissue perfusion and decreasing serum glucose. Replacement of in-

travascular fluid losses alone can account for reductions in serum glucose of 35 to 70 mg/h on average, or up to 80 percent of the necessary reduction.

The average fluid deficit in HHNS is in the range of 20 to 25 percent of total body water (TBW) or 8 to 12 L. In the elderly, about 50 percent of body weight is due to TBW. By using the patient's usual current weight in kilograms, normal TBW and water deficit can be calculated. One-half of the fluid deficits should be replaced over the initial 12 h and the balance over the next 24 h when possible. The actual rate of fluid administration should be individualized for each patient based on the presence of renal and cardiac impairment. Initial rates of 500 to 1500 mL per h during the first 2 h, followed by rates of 250 to 500 mL per h are usually well tolerated. Patients with cardiac disease may require a more conservative rate of volume repletion. Renal and cardiovascular function should be carefully monitored. Central venous and urinary tract catheterization should be considered in patients with preexisting renal or cardiac disease.

However, rate of fluid administration may need to be limited in children. Historically, a limited number of reports of cerebral edema occurring during or soon after the resuscitation phase of patients with both DKA and HHNS have been described.⁹ Most cases have occurred in children with DKA, and the mechanism is unclear. In one review, cerebral edema was found with similar frequency before treatment with replacement fluids.¹⁰ In a more recent study of cerebral edema in children with DKA, rehydration during the first 4 h at a rate greater than 50 mL/kg was associated with an increased risk of brain herniation.¹¹ There is little credible data on incidence or clinical indicators that may predispose to cerebral edema in HHS patients. However, current recommendations based on available data include limiting the rate of volume repletion during the first 4 h to <50 mL/kg of NS. Mental status should be closely monitored during treatment and computed tomographic brain imaging should be obtained with any evidence of cognitive impairment.

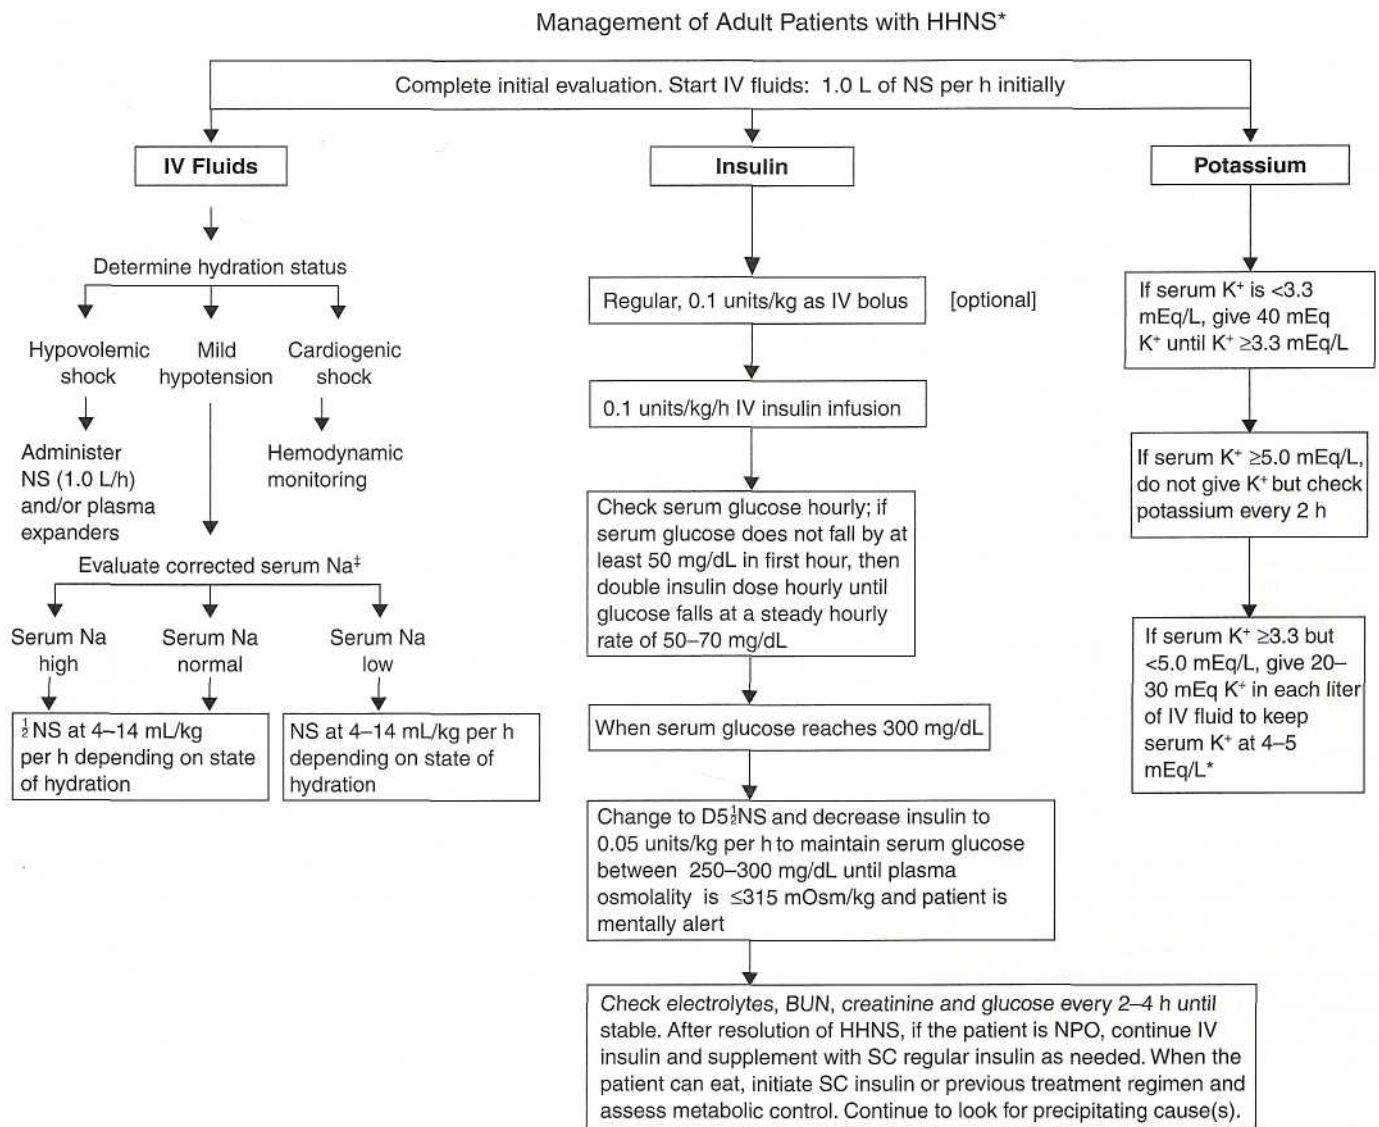

Most authors agree that the use of isotonic saline (NS) is the most appropriate initial crystalloid for the replacement of intravascular volume.² It is hypotonic to the patient's serum osmolality and will more rapidly restore plasma volume. Once hypotension, tachycardia, and urinary output improve, jNS can be used to replace the remaining free water deficit.

Electrolytes

Potassium deficits pose the most immediate electrolyte-based risk for a bad outcome. On average, potassium losses range from 4 to 6 mEq/kg, though deficits as high as 10 mEq/kg body weight have been reported. Despite these total body deficits, initial serum laboratory measurements may be normal or even high in the presence of acidemia. Patients whose initial serum potassium measurements are low (<3.3 mEq/L) are at highest risk for cardiac dysrhythmia and respiratory arrest and should be treated with urgency. Insulin therapy can precipitously lower intravascular potassium further and $[\text{K}^+]$ must be vigorously replaced.

When adequate urinary output is assured, potassium replacement should begin. In general, potassium should be replaced at a rate of 10 to 20 mEq per h, though life-threatening hypokalemia may warrant utilizing infusion rates of up to 40 mEq per h. (Rates over 20 mEq per h require central line administration.) Some authors feel that potassium infusion through a central venous catheter poses a risk for conduction defects and should be avoided although evidence for safe administration by this route exists.¹² If properly diluted, peripheral infusions of potassium through two peripheral intravenous lines are well tolerated. Monitoring of serum potassium should occur every hour until a steady state has been achieved.

Sodium deficits are replenished fairly rapidly, considering the amount of NS and jNS given during fluid replacement. Phosphate and magnesium levels should be measured. Current guidelines suggest

*Concentrations of K^+ > 20 mEq/L should be administered via central line.

FIG. 214-1. Protocol for the management of severely ill adult patients with HHNS. Diagnostic criteria for HHS: blood glucose >600 mg/dL, arterial pH >7.3, bicarbonate >15 mEq/L, mild ketonuria or ketonemia, and effective serum osmolality >320 mOsm/kg H_2O .

administering one-third of the $[K^+]$ replacement as potassium phosphate to avoid excessive chloride administration and to prevent hypophosphatemia. However, unless severe, alleviation of hypophosphatemia or hypomagnesemia should occur after the patient is admitted and usually in an ICU setting.

Insulin

Volume repletion should precede insulin therapy. If insulin is administered prior to fluids, intravascular volume may be further depleted. Insulin causes a shift of osmotically active glucose into the intracellular space, bringing free water with it. This fluid shift may further deplete the intravascular compartment and precipitate vascular collapse.

The absorption of insulin by the intramuscular or subcutaneous route is unreliable in patients with HHNS, and a continuous infusion of regular insulin should be given. While initiation of insulin therapy with a bolus (0.1 units/kg) is common, there is no proven benefit over a simple continuous infusion (0.1 units/kg). Insulin for infusion ideally should be mixed in a 1:1 ratio (e.g., 250 units of regular insulin in

250 mL of NS). Pump infusion rates will thus correlate exactly to the hourly rate of units of insulin required. Steady states utilizing infusion pumps occur within 30 min of infusion. This usually results in a decrease in the plasma concentration of glucose of 50 to 75 mg/dL per h, provided adequate hydration is being provided. With adequate hydration, the insulin infusion may be doubled every hour until a steady glucose decline between 50 and 75 mg per h is achieved. Some patients will demonstrate insulin resistance and require higher doses. Once serum glucose decreases to less than 300 mg/dL, the intravenous solution should be changed to D5 1/2 NS, and the insulin infusion should be reduced to half or 0.05 units/kg per h.

DISPOSITION

When considering the patient population likely to develop HHNS, most will require ICU monitoring for the initial 24 h of care. Patients without significant comorbid conditions, who demonstrate a good response to initial therapy as evidenced by documented improvement in vital signs, urine output, electrolyte balance, and mentation, may be

considered for step-down admission. Utilizing data flow sheets to track pH, vital signs, and key lab values is very useful for ED management and determining appropriate disposition.

cellular level and mediated by nuclear receptors for T_3 . Binding of these receptors modulates expression of specific target genes and subsequent protein synthesis. Thyroid hormone also may mediate cellular metabolism.

HYPERTHYROIDISM

Hyperthyroidism occurs at all ages but is less common under the age of 15. It is 10 times more common in women than in men, with an annual incidence of about 1 per 1000 women.¹ Causes of hyperthyroidism are shown in Table 215-1. Graves disease is by far the most common etiology, accounting for more than 80 percent of cases of hyperthyroidism in the United States. Toxic multinodular and toxic (adenoma) nodular goiters are the next most frequent etiologies. Graves disease is common in the third and fourth decades of age. It is characterized by hyperthyroidism due to an autoimmune thyroid-stimulating antibody that activates the thyrotropin receptor on thyroid cells. Graves disease also is associated with diffuse goiter, ophthalmopathy, and local dermopathy. In contrast, toxic multinodular goiter usually occurs in a somewhat older population, commonly with a previous history of simple goiter. Often these patients have milder symptoms of thyrotoxicosis. Less common etiologies of hyperthyroidism are thyroiditis, pituitary tumors, metastatic thyroid cancer, and dermoid tumors or teratomas of the ovary. Medication-induced hyperthyroidism may be due to iodine ingestion, lithium therapy, or thyroid medication (thyrotoxicosis facticia).

Amiodarone, an effective iodine-rich antiarrhythmic drug, may cause both hyper- and hypothyroidism.² Amiodarone-induced thyrotoxicosis (AIT) has proved to be difficult to treat until recently because of incompletely understood mechanism of AIT pathogenesis.³ There are two major forms of AIT. Type I occurs in an abnormal thyroid, while type II develops in an apparently normal thyroid. The treatment approach is different based on type (see below).

Classically, patients with hyperthyroidism may complain of heat intolerance, palpitations, weight loss, sweating, tremor, nervousness, weakness, and fatigue (Table 215-2).⁴ Sinus tachycardia (the most common rhythm disturbance), widened pulse pressure, and increased cardiac output resemble a state of increased adrenergic activity despite a normal or low serum concentration of catecholamines.⁵ An individual with hyperthyroidism exhibiting only mild symptoms may be safely referred for further evaluation as an outpatient. Clinical suspicion of hyperthyroidism is confirmed by thyroid function tests. An elevated free T_4 level and a low or undetectable TSH level are consistent with a diagnosis of hyperthyroidism. In some cases of Graves disease,

HYPERTHYROIDISM AND THYROID STORM

Liang

Hyperthyroid states may result from various disorders. Manifestation of disease may range from patients with subtle, nonspecific complaints to individuals presenting with life-threatening emergencies. Recognition and subsequent empirical treatment of thyroid storm are clinical decisions.

NORMAL THYROID STATE

Regulation of synthesis and release of thyroid hormone is under the control of the anterior pituitary gland via thyroid-stimulating hormone (TSH, thyrotropin). Regulation of TSH, in turn, is by hypothalamic thyrotropin-releasing hormone (TRH) and also by means of a feedback loop to the pituitary by circulating T_4 (thyroxine) and T_3 (triiodothyronine) levels. Thyroid hormone production depends on an adequate iodine intake and synthesis of thyroglobulin. Thyroid hormones, following release from the thyroid, are reversibly bound to various circulating plasma proteins, of which thyronine-binding globulin (TBG) is the major constituent. The free, unbound portions of the hormone are biologically active. Normally, T_4 is the predominant circulating hormone. T_4 is peripherally deiodinated to T_3 and is responsible for producing 80 percent of the circulating T_3 hormone. Free T_3 is biologically more active than T_4 but has a shorter half-life (1 day versus 1 week).

Thyroid hormone exerts its action on a wide host of metabolic processes. It appears that most actions of thyroid hormone are at the

T₄ may be normal and TSH decreased, but the patient appears to be thyrotoxic. A T₃ level should be determined to rule out T₃ toxicosis. Patients with hyperthyroidism secondary to pituitary adenomas will have elevated TSH level.

Palliative treatment for mild hyperthyroidism can be accomplished by using various β -blocker medications, the most common of which is propranolol. The goal of therapy includes decreased heart rate, decreased tremor, increased muscle strength, and an overall improvement in the patient's sense of well-being. Treatment of Graves disease may include long-term antithyroid medication (e.g., propylthiouracil, methimazole, or carbimazole), radioactive iodine (¹³¹I), or subtotal thyroidectomy.⁶ A successful regimen for type I AIT is methimazole (30 mg per d) and potassium perchlorate (1 g per d). Type II is treated with glucocorticoids.⁷ Thyrotoxicosis exacerbation is treated with (increasing) glucocorticoids for either type.² Toxic multinodular goiter and solitary adenomas also may be treated with radioiodine. Hyperthyroidism due to thyroiditis is usually self-limited, and therapy is rarely needed. Common etiologies of thyroiditis are subacute (painful) thyroiditis (due to viral etiologies), silent thyroiditis (due to lymphocytic infiltrates), and postpartum thyroiditis (due to transient immune destruction). Thyrotoxicosis factitia may be suspected with the absence of thyromegaly, a low serum thyroglobulin level, and decreased or absent radioactive uptake with thyroid scanning. Hyperthyroidism during pregnancy is almost always due to Graves disease. Often Graves disease will improve with progression of gestation. The lowest amounts of medication should be used in order to maintain the euthyroid state. Treatment options include propylthiouracil (fewer fetal anomalies than methimazole), although neonatal goiter has been reported with its use. Administration of radioiodine is contraindicated in pregnant women or those who are breast-feeding.⁸

THYROID STORM

The life-threatening hypermetabolic state due to hyperthyroidism is termed *thyroid storm*. This is a rare occurrence but constitutes a medical emergency. The diagnosis is based on clinical suspicion, treatment is initiated empirically, and the patient is admitted to an appropriately monitored setting. The differential diagnoses are listed in Table 215-3. Classically, thyroid storm occurs as a result of either previously unrecognized or poorly treated hyperthyroidism. Etiologies that precipitate thyroid storm are often recognized (Table 215-4), but the pathophysiology is not clearly understood. Most studies have not

demonstrated differences in thyroid hormone levels in patients with symptomatic, uncomplicated hyperthyroidism and thyroid storm. Some studies have noted higher levels of free T₄ in individuals who have presented with thyroid storm. Enhanced sympathetic nervous system activity explains many of the presenting clinical findings of thyroid storm. Mortality rates despite treatment are high (10-75 percent). The signs and symptoms of thyroid storm are listed in Table 215-5. The classic mark of this disease is fever, sinus or supraventricular tachycardia out of proportion to the fever, changes in normal mental status (e.g., confusion, delirium, or coma), and gastrointestinal symptoms.

Laboratory analysis is usually not helpful. Thyroid function tests are not routinely available to the emergency physician. Nonspecific laboratory findings may include leukocytosis, hyperglycemia, and increased transaminases and bilirubin. Further laboratory studies are aimed at potential underlying precipitants.

Treatment

Initial treatment of thyroid storm is stabilization, airway protection, oxygenation, intravenous fluids, and monitoring. Specific therapy is outlined in Table 215-6. β -Blockers are used to treat the severe adrenergic symptoms. Administration of propranolol has the additional benefit of inhibiting peripheral conversion of T₄ to T₃. If there is a contraindication to propranolol administration (e.g., asthma, congestive heart failure, chronic obstructive pulmonary disease), a selective β_1 medication (esmolol) may be substituted. Guanethidine (which inhibits norepinephrine release at the sympathetic junction) or reserpine (which depletes stored catecholamines both centrally and peripherally, including the adrenal medulla) may be considered as alternative therapy. Additional treatment goals are directed toward decreasing synthesis of additional hormone by the administration of propylthiouracil (PTU) or methimazole (MMI). PTU also decreases T₄-to-T₃ conversion.

After PTU administration has been initiated, treatment is then directed toward decreasing the release of preformed thyroid hormone by the administration of iodine. **It is important to not administer iodine until the synthetic pathway has been blocked.** Otherwise, the addition

of iodine will promote further hormone production. Various iodine-containing preparations, including iodine-containing radiographic contrast material [ipanoate (Telepaque) and iopodate (Oragrafin)] have been used for this purpose. Administration of lithium should be considered in patients with a prior history of iodine allergies. Note that many of the drugs used to treat thyroid storm are oral preparations and subsequently may need to be administered by naso- or orogastric tube. In cases where clinical deterioration occurs despite appropriate therapy, direct removal of circulating thyroid hormone has been accomplished by exchange transfusion, plasma transfusion, plasmapheresis, and charcoal plasmapheresis. Cholestyramine also has been reported to modestly decrease circulating thyroid hormone levels. Other therapeutic goals include treatment of hyperthermia with cooling blankets, ice packs, and antipyretics (acetaminophen). Avoidance of salicylates has been recommended because of displacement of T_4 from TBG, thereby increasing free T_4 . The empirical use of corticosteroids has been suggested to treat potential adrenal insufficiency that may occur with such a hypermetabolic state.

Comorbid factors that may have been a precipitant to thyroid storm also must be addressed. Electrocardiograms, chest radiographs, urinalysis, blood cultures, and administration of empirical antibiotics always should be considered in patients presenting in thyroid storm. Standard therapy for heart failure due to ischemic or hypertensive heart disease may be used. All patients should be admitted to an appropriately monitored setting for further evaluation and care. Definitive therapy is usually radioiodine administration once the patient is stable and euthyroid.

TABLE 215-6 Drug Treatment of Thyroid Storm

Decrease de novo synthesis:	
Propylthiouracil	600–1000 mg PO initially, followed by 200–250 mg q4h
Methimazole	40 mg PO initial dose, then 25 mg PO q6h
Prevent release of hormone (after synthesis blockade initiated):	
Iodine	Iopanoic acid (Telepaque) 1 g IV q8h for the first 24 h, then 500 mg IV bid <i>or</i> Potassium iodide (SSKI) 5 drops PO q6h <i>or</i> Lugol solution 8–10 drops PO q6h
Lithium carbonate	800–1200 mg PO per d
Prevent peripheral effects:	
β -blockade	Propranolol (IV) titrate 1 to 2 mg q5min prn (may need 240–480 mg PO per d) <i>or</i> Esmolol (IV) 500 μ g/kg IV bolus, then 50–200 μ g/kg per min maintenance
Guanethidine	30–40 mg PO q6h
Reserpine	2.5–5 mg IM q4–6h
Other considerations:	
Corticosteroids	Hydrocortisone 100 mg IV q8h <i>or</i> Dexamethasone 2 mg IV q6h
Antipyretics	Cooling blanket Acetaminophen 650 mg PO q4h

HYPOTHYROIDISM AND MYXEDEMA COMA

Horace K. Liang

Hypothyroidism arises from many etiologies. The severe manifestation of extreme hypothyroidism, myxedema coma, is a rare, potentially life-threatening illness. Correct diagnosis requires a high degree of clinical suspicion, and initiation of treatment is an empirical decision.

HYPOTHYROIDISM

Normal thyroid physiology was discussed in Chap. 215. Hypothyroidism occurs when there is insufficient hormone production or secretion. A general hypometabolic state is the principal feature of this disease. Hypothyroidism occurs more frequently in women than in men. The prevalence of hypothyroidism in women ranges from 0.6 to 5.9 percent.¹ The most common etiologies of hypothyroidism are primary thyroid failure due to autoimmune diseases (of which Hashimoto thyroiditis is most common), idiopathic causes, after ablative therapy, and iodine deficiency.² Hypothyroidism may be transient as in some cases of thyroiditis such as subacute or silent thyroiditis. The pathophysiology of this entity is unclear but may be viral in origin. Postpartum thyroiditis occurs within 3 to 6 months postpartum and reportedly occurs in 2 to 16 percent of women.¹ Secondary (due to pituitary tumors, infiltrative disease, or hemorrhage) or tertiary (hypothalamic disease) etiologies of hypothyroidism are less common (Table 216-1). Several medications have been reported to induce hypothyroidism. Amiodarone-associated hypothyroidism has been reported to occur from 1 percent to as high as 32 percent of patients.³ The mechanism is probably the large amount of iodine that is released by metabolism of the drug, which then inhibits thyroid hormone synthesis, release, and inhibition of triiodothyroxine (T_4) to triiodothyronine (T_3) conversion. Lithium acts similarly to iodine and decreases thyroid hormone release. When initiating lithium therapy, especially in patients with prior hypothyroidism, careful monitoring of thyroid function is required.

Primary hypothyroidism usually has an insidious onset (findings are shown in Table 216-2). Hemodynamic changes are opposite those of hyperthyroidism but are accompanied by fewer signs and symptoms.⁴ Patients with suspected uncomplicated hypothyroidism may be evaluated as outpatients. Typical laboratory findings in primary hypothyroidism include low T_4 and high thyrotropin [thyroid-stimulating

hormone (TSH)] levels. T_3 is an unreliable indicator of hypothyroidism and is not measured routinely. There is little urgent need for obtaining thyroid function tests, and typically they are not available during the emergency department visit. However, obtaining blood for testing in the emergency department may be helpful to the patient's health provider in follow-up care. In many cases, elderly patients with hypothyroidism may exhibit a paucity of symptoms. Because of the high prevalence of hypothyroidism in women over the age of 60 years of age, it is recommended that they be screened routinely with a serum TSH measurement.

Treatment

Treatment of primary uncomplicated hypothyroidism is with thyroxine administration. Initiation of oral therapy begins at a dose of 50 to 100 $\mu\text{g}/\text{d}$ and is increased gradually. The average daily adult dose is 75 to 150 μg . Elderly patients with underlying heart disease are treated with lower initial dosages. Monitoring of therapy is by achieving appropriate serum thyrotropin levels after 6 to 8 weeks of therapy. If hypothyroidism is due to less common secondary etiologies, initiation of thyroid hormone replacement may exacerbate preexisting adrenal insufficiency. Therefore, the etiology of hypothyroidism (primary versus secondary failure) should be determined prior to initiating thyroxine replacement. Initiation of therapy in the emergency department is rarely warranted. Clinical clues that may differentiate primary and secondary hypothyroidism are listed in Table 216-3.⁵

MYXEDEMA COMA

Myxedema coma is a rare clinical state in which an individual with long-standing preexisting hypothyroidism presents with life-threaten-

TABLE 216-2 Symptoms and Signs of Hypothyroidism

Symptoms	Signs
Fatigue	Hoarseness
Weight gain	Hypothermia
Cold intolerance	Periorbital puffiness
Depression	Delayed relaxation of ankle jerks
Menstrual irregularities	Loss of outer third of eyebrow
Constipation	Cool, rough, dry skin
Joint pain	Nonpitting edema
Muscle cramps	Bradycardia
Infertility	Peripheral neuropathy

Obese	Less obese
Hypothermia more common	Hypothermia less common
Voice course	Voice less course
Pubic hair present	Pubic hair absent
Skin dry and course	Skin fine and soft
Heart increased in size	Heart usually normal
Normal menses and lactation	Traumatic delivery, no lactation, amenorrhea
Sella turcica normal	Sella turcica may be increased in size
Serum TSH increased	Serum TSH decreased
Plasma cortisol normal	Plasma cortisol decreased
No response to TSH	Good response to TSH
Good response to levothyroxine without steroids	Poor response to levothyroxine without steroids

Source: From Senior et al.⁵

ing decompensation. In reality, few patients present comatose with severe myxedema. Affected patients are commonly in the geriatric population. Various etiologies that may precipitate this syndrome include infection, cold exposure, drugs (sedatives, lithium, amiodarone), trauma, stroke, congestive heart failure (CHF), inadequate thyroid hormone replacement, and previously undiagnosed hypothyroidism. The clinical presentation is one of a severe decompensated metabolic state that may include an alteration in mental status, hypothermia, bradycardia, hypoventilation, and even cardiovascular collapse (Table 216-4). These findings are not only secondary to a decline in metabolic function but also due to neurovascular and cardiovascular adaptations. Some of these adaptations are similar to those which occur in euthyroid patients exposed to a cold environment (decline in oxygen consumption and heat generation and redistribution of blood flow centrally). In addition, there is a change in end-organ responsiveness to catecholamines and a decline in cardiac performance. This is due to an absolute diminution in β -adrenergic receptors (decreased inotrope and chronotrope activity). There is also relatively increased α -adrenergic responsiveness resulting in mild diastolic hypertension. Increased CO_2 retention occurs because of decreased respiratory muscle strength and diminished ventilatory drive in response to hypercapnia. There is also decreased free-water clearance, resulting in a dilutional hyponatremia, impaired gluconeogenesis, and decreased drug clearance that predisposes patients to drug toxicity from medication.

Diagnosis of myxedema coma requires high clinical suspicion. A patient suspected of presenting with myxedema coma commonly has a prior history of primary hypothyroidism or previous thyroid surgery.

TABLE 216-4 Clinical Presentation of Myxedema Coma

Decreased mental status
Hypothermia
Bradycardia
Hypoventilation
Periorbital edema
Nonpitting edema
Delayed deep tendon reflexes
Hypoglycemia
Hyponatremia

Medication noncompliance or coexisting stressors such as cold exposure, severe infection, or the addition of new medications may precipitate the onset of myxedema coma. The decline in function is usually gradual and insidious in onset. The physical examination may confirm a history of long-standing hypothyroidism. In addition, there also may be clinical findings of hypothermia, hypoventilation, hypotension, bradycardia, and alteration or deterioration of the patient's mental status. Laboratory evaluation of the patient with suspected myxedema coma may reveal anemia; hyponatremia; hypoglycemia; elevated transaminases, creatine phosphokinase (CPK), and lactate dehydrogenase (LDH); hypercholesterolemia; and arterial blood gas abnormalities (decreased Po_2 and increased Pco_2). The electrocardiogram may demonstrate sinus bradycardia, prolongation of the QT interval, and low voltage with flattening or inversion of T waves. A chest radiograph may demonstrate an increased cardiac contour due to the presence of a pericardial effusion.

Treatment of Myxedema Coma

There are no prospective studies on the optimal therapy for patients in myxedema coma. Therefore, treatment recommendations are not uniform.⁶ However, initial therapy is directed toward stabilization. The patient may require endotracheal intubation and mechanical ventilation for airway protection and correction of hypoventilation, hypercapnia, and hypoxia. Correction of hypothermia is directed toward decreasing further heat loss. Cautious use of gentle passive external rewarming should be initiated. Hypotension due to reversal of the patient's hypothermic vasoconstriction should be avoided.

Specific therapy includes intravenous levothyroxine, which is recommended by most authors. An initial intravenous bolus of levothyroxine (Table 216-5) is administered and followed by a reduced daily dose until the patient can take oral medication. This has the advantage of replenishing the thyroxine pool and allowing the hormone to slowly enter tissues. Other authors suggest that in ill patients there may be decreased T_4 -to- T_3 conversion, and thus they recommend T_3 as the initial replacement hormone.

Routine administration of glucocorticoid is recommended to avoid the potential of precipitating adrenal crisis in patients with unrecognized adrenal insufficiency or hypothyroidism secondary to hypopituitarism. If possible, a baseline cortisol level should be sent to the laboratory prior to initiating therapy. Correction of hyponatremia is by means of fluid restriction. Severe hyponatremia has been treated successfully with hypertonic saline administration.

A search for a precipitating etiology must be initiated, and any such disorder should be treated aggressively. Infection is a common precipi-

itant of myxedema coma. If possible, appropriate cultures should be obtained prior to initiating empirical antibiotic therapy.

All patients presenting with a suspected diagnosis of myxedema coma should be admitted to an appropriately monitored inpatient bed for further evaluation and treatment.

ADRENAL INSUFFICIENCY AND ADRENAL CRISIS

Charles N. Schoenfeld

The adrenal glands are divided into the medulla and cortex. The medullary portion is controlled by the nervous system and, when stimulated, secretes epinephrine and norepinephrine into the adrenal veins.

The adrenal cortex secretes steroids that contribute to the control of glucose, protein, and fat metabolism; act to maintain vascular tone and cardiac contractility; aid in the maintenance of total-body water and sodium-potassium balance; and provide androgenic effects. In steady-state conditions, this secretion is cyclic and controlled by a complex series of interactions involving the time of day, the hypothalamic-pituitary-adrenal (HPA) axis, the renin-angiotensin system, and serum potassium levels. During times of stress (e.g., sepsis, trauma, major surgery, hypoxia, hypoglycemia, and burns), the basal secretion of glucocorticoids and, to a lesser extent, mineralocorticoids is increased by as much as 5 to 10 times. While the exact mechanisms by which stressful events stimulate the HPA axis are unknown, the effect is nearly immediate, occurring in minutes.

Failure of the adrenal glands to produce the essential basal secretion of these steroids results in *adrenal insufficiency* (AI), an insidious wasting disease. Failure to respond to the increased demands created by stress or the sudden inability to secrete these essential steroids results in the life-threatening condition of *adrenal crisis* (AC). Of the three types of steroids normally secreted, the absence of glucocorticoids is the most critical in adrenal crisis—making their repletion the mainstay of therapy.

CORTICOSTEROIDS

The adrenal gland produces more than 50 different steroids, grouped into three classes according to their effects. These are glucocorticoids, mineralocorticoids, and androgenic steroids.

Glucocorticoids

Cortisol, the most abundant steroid produced by the adrenals, is representative of this class. The glucocorticoids are involved in the regulation of glucose, protein, and fat metabolism. They are active in the synthesis of medullary catecholamines as well as (3-adrenergic receptors and thus play an important role in the maintenance of vascular tone and cardiac contractility. Other hemodynamic effects include maintaining endothelial integrity and controlling vascular permeability.

axis. In the nonstressed state, the hypothalamus secretes corticotropin-releasing (CR) hormone and arginine vasopressin (AV) in a circadian rhythm, with maximal secretion occurring between 2 and 4 A.M. This stimulates the anterior pituitary to release adrenocorticotropic hor-

none (ACTH), which causes the adrenal cortex to produce and release cortisol, with peak cortisol levels occurring around 8 A.M. and declining throughout the day. Total daily production of cortisol is approximately 25 mg in the nonstressed state, of which only 5 to 10 percent is free and physiologically active. The remainder is bound to plasma proteins, principally (80 percent) cortisol-binding globulin. There is evidence that this bound cortisol is uncoupled from these proteins during times of serious illness, increasing the availability of the active form of cortisol.¹

Cortisol, as well as exogenous corticosteroids, is involved in a negative feedback loop with the hypothalamus. Rising levels of cortisol inhibit the release of CR and AV, thus reducing the release of ACTH from the pituitary. This mechanism plays a crucial role in the development of secondary adrenal insufficiency (see below).

Mineralocorticoids

Aldosterone is the principal mineralocorticoid produced by the adrenals. While ACTH has a minor influence on its secretion, the primary regulators are the renin-angiotensin system and serum potassium levels. The juxtaglomerular apparatus, stimulated by the diminished glomerular filtration seen in volume depletion, releases prorenin. This ultimately causes the release of aldosterone from the adrenals, which results in the resorption of sodium and water in the distal tubules at the expense of potassium loss. Minor degrees of hyperkalemia directly stimulate the adrenals to secrete aldosterone. The net result is to increase serum volume while depleting potassium.

Adrenal Androgens

Adrenal androgens are under the control of ACTH and exhibit the same diurnal rhythm as cortisol. While they are a minor contributor to total androgen levels in the male, they are a significant source in the female—leading to some of the signs of adrenal insufficiency in these patients (see below).

ADRENAL INSUFFICIENCY

The signs and symptoms of adrenal insufficiency may occur because of failure of the adrenal glands (primary AI) or failure of the HPA axis (secondary AI), the latter most commonly due to suppression of the HPA axis by the chronic administration of exogenous glucocorticoids. Some authors divide secondary AI into that caused by pituitary failure (secondary AI) and that caused by hypothalamic dysfunction (tertiary AI). For the purposes of this chapter, any failure of the HPA axis will be considered secondary AI.

Primary Adrenal Insufficiency

Because of the functional reserve of the adrenals, 90 percent of the glands must be destroyed in order for AI to become manifest clinically. It is characterized by the loss of all three types of adrenal steroids. Table 217-1 lists the principal causes of primary AI.

The spectrum of causes of primary AI is changing. Addison disease, once considered idiopathic, is now recognized as being most commonly the result of autoimmune disorders.² This may occur as an isolated process or as a component of autoimmune polyglandular syndrome types I and II.

Worldwide, tuberculosis is the most common infectious cause of primary AI. In the United States, however, infection with the human immunodeficiency virus (HIV) is the most common cause.¹ While 50

Adrenoleukodystrophy

percent of HIV-infected patients show some degree of destruction of the adrenals, less than 5 percent will have clinical AI.³ HIV may cause AI via opportunistic infections (principally cytomegalovirus), the use of medications such as ketoconazole, or by inhibition of the HPA axis by cytokines released by macrophages.

Thrombosis and/or hemorrhage of the adrenals may occur as a complication of anticoagulation therapy, sepsis, or disseminated intravascular coagulation or in antiphospholipid syndrome. Infiltrative diseases such as amyloidosis and hemosiderosis are uncommon causes of primary AI, as is bilateral metastasis from cancer. Adrenoleukodystrophy is an inherited disorder of very-long-chain fatty acid metabolism. It is an X-linked disorder and is characterized by AI and progressive neurologic symptoms caused by demyelination.

Secondary Adrenal Insufficiency

Secondary AI occurs when the HPA axis fails to secrete corticotropin and/or ACTH. This causes a deficiency of glucocorticoids and adrenal androgens. The secretion of mineralocorticoids is unaffected, however. Table 217-2 lists the principal causes of secondary AI.

By far the most common cause of secondary AI is the chronic administration of exogenous glucocorticoids.^{2,4} This suppresses the diurnal hypothalamic release of CR and AV, leading to failure of the anterior pituitary to secrete ACTH, which in turn results in adrenal atrophy. As a result, the adrenals cannot respond to acute stressful events. This HPA axis suppression appears to be both time- and dose-related and usually is reversible, although recovery may take up to a year. It is generally believed that a short course (<2 to 3 weeks) of supraphysiologic doses of glucocorticoids is unlikely to suppress the HPA axis. Doses of less than 5 mg of prednisone (or its equivalent) daily are also unlikely to cause secondary AI.⁴

Less commonly, secondary AI is caused by infiltrative diseases or tumors that involve the hypothalamus or pituitary. Postpartum necrosis (Sheehan syndrome), hemorrhage into an adenoma, or head

trauma may abruptly destroy the pituitary. These forms of secondary AI generally are associated with focal neurologic findings, visual field cuts, diabetes insipidus, or findings of panhypopituitarism.

CLINICAL PRESENTATION

Adrenal insufficiency may present as a slowly progressive wasting disease (chronic AI) or as an acute life-threatening illness (adrenal crisis). The clinical manifestations of each are remarkably different.

Chronic Adrenal Insufficiency

The signs and symptoms of chronic AI are nonspecific and may mislead the clinician into an incorrect diagnosis. Fatigue, anorexia, weight loss, and loss of libido are common and may lead to a diagnosis of depression. Abdominal pain, nausea, vomiting, and diarrhea are also seen frequently, suggesting a primary gastrointestinal disorder. Fortunately, there are other findings that should raise the suspicion of chronic AI. Indeed, for the observant physician there are clues that suggest whether the AI is primary or secondary.

Hyperpigmentation is seen in primary AI due to elevated levels of ACTH and its effect on melanocytes. It may be particularly noticeable over pressure points and in the axillae, palmar creases, perineum, and oral mucosa. It characteristically develops early in the course of AI. In contrast, patients with secondary AI commonly exhibit a pallor out of proportion to their degree of anemia.

Low blood pressure and orthostasis are common findings. The habitus of patients with chronic AI generally is cachectic. In women, the loss of adrenal androgens results in thinning of axillary and pubic hair.

Hyponatremia, usually mild but occasionally marked (serum $\text{Na}^+ < 120 \text{ mEq/L}$), may be seen in both primary and secondary AI. In primary AI it is due to the lack of aldosterone and sodium wasting. In secondary AI it is due to increased vasopressin secretion and water retention.

Hyperkalemia, due to a loss of aldosterone, is seen in primary AI and generally is mild. This also may be associated with a mild azotemia and metabolic acidosis. Since aldosterone secretion is maintained in secondary AI, hyperkalemia does not occur.

Normocytic anemia, lymphocytosis, and eosinophilia are seen in both primary and secondary AI. Similarly, hypoglycemia is seen in both types of AI.

Secondary AI is commonly associated with other neurologic signs and symptoms. Headaches, visual field cuts, diabetes insipidus, or other signs of hypopituitarism may occur.

Adrenal Crisis

In contrast to the indolent and progressive course of chronic AI, AC presents as a life-threatening emergency in which the primary manifestation is hypotension. It can occur in either primary or secondary AI. The hypotension in AC typically is resistant to catecholamine and IV fluid administration and, if the missing cortisol is not replaced, will lead to death.

Adrenal crisis occurs when the body undergoes a significant stress and the adrenals are unable to respond by increasing cortisol secretion. It may be seen in a patient with known chronic AI or unrecognized chronic AI or in whom the adrenals or HPA axis fails abruptly.

Abrupt failure of the adrenals usually occurs as a consequence of hemorrhage or thrombosis of the glands. This may occur as a complication of anticoagulant therapy, disseminated intravascular coagulation, sepsis (Waterhouse-Friderichsen syndrome), or other overwhelming stress. Patients generally have abdominal and flank pain in addition to resistant hypotension, mimicking the presentation of ruptured abdominal aortic aneurysm.

Catastrophic failure of the HPA axis may occur as a result of head trauma, hemorrhage of a pituitary adenoma, or in the postpartum period (Sheehan syndrome). Patient's generally will have other neurologic deficits, headache, visual field cuts, and diabetes insipidus.

DIAGNOSIS

Adrenal crisis is relatively rare, and few emergency physicians have recognized experience with such patients. A multitude of diagnostic studies are used to confirm the presence of AI, but the results are rarely available to the emergency physician and thus of little utility in the management of these patients.

Measurement of plasma cortisol levels between 8 and 9 A.M. can rule in (level $< 83 \text{ nmol/L}$) or rule out (level $> 525 \text{ nmol/L}$) AI.² The short corticotropin stimulation test is the most commonly used test to assess for AI. After measuring plasma cortisol levels, 250 g of cosyntropin is injected (IM or IV), and plasma cortisol levels are measured at 60 min. AI is excluded if the basal or poststimulation level exceeds 550 nmol/L. Other studies include the insulin-induced hypoglycemia test, the short metyrapone stimulation test, and the CR hormone test.

TREATMENT

Stable Patient

Emergency department management of patients with known or suspected AI varies according to the clinical situation. Hemodynamically stable patients in whom the diagnosis of AI is to be excluded are best

TABLE 217-3 Guidelines for Adrenal Supplementation Therapy

Medical or Surgical Stress	Corticosteroid Dosage
Minor	
Inguinal hernia repair	25 mg hydrocortisone or 5 mg methylprednisolone IV on day of procedure only
Colonoscopy	
Mild febrile illness	
Mild-moderate nausea/vomiting	
Gastroenteritis	
Moderate	
Open cholecystectomy	50–75 mg hydrocortisone or 10–15 mg methylprednisolone IV on day of procedure
Hemicolectomy	
Significant febrile illness	Taper quickly over 1–2 days to usual dose
Pneumonia	
Severe gastroenteritis	
Severe	
Major cardiothoracic surgery	100–150 mg hydrocortisone or 20–30 mg of methylprednisolone IV on day of procedure
Whipple procedure	
Liver resection	
Pancreatitis	
	Rapid taper to usual dose over next 1–2 days
Critically ill	
Sepsis-induced hypotension or shock	50–100 mg hydrocortisone IV q6–8 h or 0.18 mg/kg per h as a continuous infusion and 50 $\mu\text{g/d}$ fludrocortisone until shock resolves
	May take several days to a week or more
	Then gradually taper, following vital signs and serum sodium

managed by an internist. A short corticotropin stimulation test could be performed, but it is most reliable if done before 10 A.M., and the results will not be available to the emergency physician. Other tests of adrenal function are much too time-consuming and cumbersome to warrant their use in the ED.

Stress or Rescue Management

Consideration of stress or rescue doses of corticosteroids is mandatory in patients with known or strongly suspected (e.g., chronic high-dose steroid use) AI when they are acutely stressed or about to undergo various procedures. Traditionally, these patients received corticosteroids in dosages similar to those used in the treatment of AC. However, there is evidence that this is both unnecessary and potentially harmful.⁴ A more physiologic approach (Table 217-3) is to base the dose of supplemental therapy on the severity of the stressful event. Patients receiving 5 mg/d of prednisone (or its equivalent) do not require additional corticosteroids regardless of the degree of stress because the HPA axis is not suppressed at this dose.

The treatment of AC, whether primary or secondary, requires only the use of glucocorticoids. Mineralocorticoids are not needed. Intravenous hydrocortisone is given as a 100-mg bolus, and then an infu-

sion of 200 mg is given over the next 24 h. Several liters of D5NS may be required to correct hypovolemia and hypoglycemia.

Any patient in whom AC is suspected should receive 100 mg hydrocortisone intravenously. The presence of unexplained hyponatremia and hyperkalemia in the setting of hypotension unresponsive to catecholamine and fluid administration is strong evidence of AC. Two decades ago, dexamethasone was proposed for all patients in cardiac arrest, but it was not shown to be of clear benefit.

HEMATOLOGIC AND ONCOLOGIC EMERGENCIES

EVALUATION OF ANEMIA AND THE BLEEDING PATIENT Robin R. Hemphill

EVALUATION OF THE PATIENT WITH ANEMIA

Anemia is a common problem, affecting an estimated one-third of the world's population. By itself, anemia is not so much a disease as a symptom of an underlying process. Worldwide, the most common causes of anemia include iron deficiency, thalassemia, hemoglobinopathies, and folate deficiencies. Within the United States, the most common causes are iron deficiency, thalassemia, and anemia of chronic disease. Not only is anemia common in the general population, the prevalence of anemia increases with age. Given the ubiquity of this entity, patients with anemia will present to the ED, some of whom will be symptomatic from their anemia, while in others this will be a spurious finding.

Pathophysiology

Anemia is defined as a reduced concentration of red blood cells (RBCs).¹ In healthy persons, normal erythropoiesis ensures that the number of RBCs present is adequate to meet the body's demand for oxygen and that RBC destruction equals production. The average life span of the circulating erythrocyte is approximately 120 days. Any process or condition that impairs the production, increases the rate of destruction, or increases the loss of erythrocytes will result in anemia if the body cannot produce enough new RBCs to keep up with the loss. More than one mechanism may be present in a single patient.

Quantification of the RBC concentration is reflected in the RBC count per μL , hemoglobin concentration, or hematocrit (percentage of RBC mass to blood volume). Normal RBC values for adults vary slightly between males and females (Table 218-1). Based on pathophysiologic mechanisms, there are three categories of anemia (Table 218-2).

Compensatory Mechanisms in Anemia

The body may respond to the development of anemia in several ways. These compensatory mechanisms vary dependent upon the rapidity of

onset, the degree of anemia, and the underlying condition of the patient. In acute onset anemia, if there is loss of intravascular volume, then peripheral vasoconstriction and central vasodilatation will help preserve blood flow to vital organs. As the anemia worsens, systemic small-vessel vasodilatation allows increased blood flow to tissues. Both of these compensatory actions result in decreasing systemic vascular resistance, increasing cardiac output, and tachycardia. Along with these changes, the RBCs enhance their ability to release oxygen to the tissues. If the anemia is more chronic in nature, there should be an increase in plasma volume that will maintain the total blood volume at a constant level. Finally, anemia will result in the stimulation of erythropoietin that should stimulate new erythrocyte production. New reticulocytes should begin to appear in the blood within 3 to 7 days.

Clinical Features

Regardless of the cause of anemia, many of the clinical manifestations are the same. The severity of symptoms and signs related to anemia depend on several factors: the rate of development of anemia, the extent of anemia that is present, the age of the patient, the general physical condition of the patient, and other existing comorbid illnesses that may be present.

Patients with chronic and slowly developing anemia may have almost no complaints even with hemoglobin levels as low as 5 to 6 g/dL. More typically, people will begin to be symptomatic at about 7 g/dL. Patients with chronic anemia may complain of weakness, fatigue, lethargy, dyspnea with minimal exertion, palpitations, and orthostatic symptoms. Physical examination findings that may be present in patients with significant chronic anemia include orthostatic hypotension; tachycardia; skin, nail bed, and mucosal pallor; systolic ejection murmur; bounding pulse; and widened pulse pressure. Evidence of jaundice and hepatosplenomegaly should lead one to consider a hemolytic anemia as the cause of symptoms. Unusual skin ulcerations or evidence of peripheral neuropathy may be evidence of nutritional abnormality. Additional manifestations may depend upon comorbid illnesses. Thus, a patient with preexisting angina may find that these symptoms are markedly worsened when anemia is present.

Patients who develop anemia in a rapid fashion may have all of the symptoms mentioned above, but frequently these symptoms will be more pronounced. Additionally, these patients may have hypotension; resting and exertional dyspnea; palpitations; diaphoresis; anxiety; severe weakness that may progress to lethargy; and altered mental status. They may also complain of thirst and will usually have decreased urine output. Again, comorbid illnesses may be worsened. Loss of more than 40 percent of blood volume leads to severe symptoms that are due more to intravascular volume depletion than to anemia. In healthy patients, coronary artery blood flow usually is not limited until

the hemoglobin is 50 percent or less of normal. Keep in mind that the hemodynamic response to anemia may be altered by the use of ethanol, prescription drugs, or recreational drugs.

Diagnosis

The diagnosis of anemia is established by the finding of a decreased RBC count, hemoglobin, and hematocrit on the routine complete blood count (CBC).³⁻⁴ Other than in patients who are acutely hemorrhaging, it is rarely essential that a specific cause of anemia be established in the ED. However, appropriate workup can be initiated in the ED to help expedite a diagnosis and should be started before the transfusion of packed red blood cells (PRBCs).

The basic evaluation of a patient newly diagnosed with anemia includes the following: review of the RBC indices provided with the CBC, reticulocyte count, and review of the peripheral blood smear (Table 218-3). The mean cellular volume (MCV) is the most useful guide to the possible etiology of an anemia. The reticulocyte count reflects activity in the bone marrow and, along with the MCV, can help classify an anemia quickly and helps provides an initial approach to the differential diagnosis (Figure 218-1). The red cell distribution width (RDW) measures the size variability of the RBC population and in early deficiency anemias (iron, vitamin B₁₂, or folate), may be increased before the MCV becomes abnormal. If not already done as part of the general evaluation, questions should be asked and findings sought for the two most common sources of blood loss: gastrointestinal (e.g., checking the stool for occult blood) and uterine bleeding.

Treatment

The treatment of anemia depends on the etiology, the symptoms, and the clinical status of the patient. In the ED, anemia that requires the most urgent attention results from acute blood loss. All patients who have ongoing blood loss and anemia should have blood typed and cross-matched so that it is available for transfusion if needed. The decision to transfuse PRBCs has to be individualized for each patient with consideration of clinical symptoms, objective signs, age of the patient, presence of comorbid disease, and the likelihood of further blood loss^{5,6} (see Chap. 223). In general, patients who are symptomatic and hemodynamically unstable and have evidence of tissue hy-

poxia and/or limited cardiopulmonary reserve should have PRBCs transfused. In most settings, patients with anemia resulting from acute blood loss are transfused at hemoglobin levels of 7 g/dL, if not at higher levels, as dictated by patient considerations discussed earlier.

ED patients with chronic anemia or a newly diagnosed anemia of uncertain etiology not caused by acute blood loss may not require immediate transfusion unless they are hemodynamically unstable, hypoxic, or have acidosis or ongoing cardiac ischemia. In a patient with newly diagnosed anemia of uncertain etiology, it is important that laboratory studies required for hematologic evaluation are obtained prior to transfusion. Consultation with a hematologist may be beneficial to guide this evaluation. The evaluation of some patients with chronic anemias or anemias of uncertain etiology can be made more difficult by transfusion, so transfusion should not be undertaken unless specifically indicated.

Disposition

Any patient with anemia from ongoing blood loss should be admitted to the hospital for further evaluation and treatment. Patients with isolated anemia that is chronic or newly diagnosed and not related to blood loss do not necessarily require admission if they are asymptomatic, hemodynamically stable, have minimal comorbid disease, and close follow-up can be arranged. Patients newly diagnosed with anemia who also have abnormalities in the white blood cell or platelet count should have immediate hematologic consultation and probable admission.

THE BLEEDING PATIENT

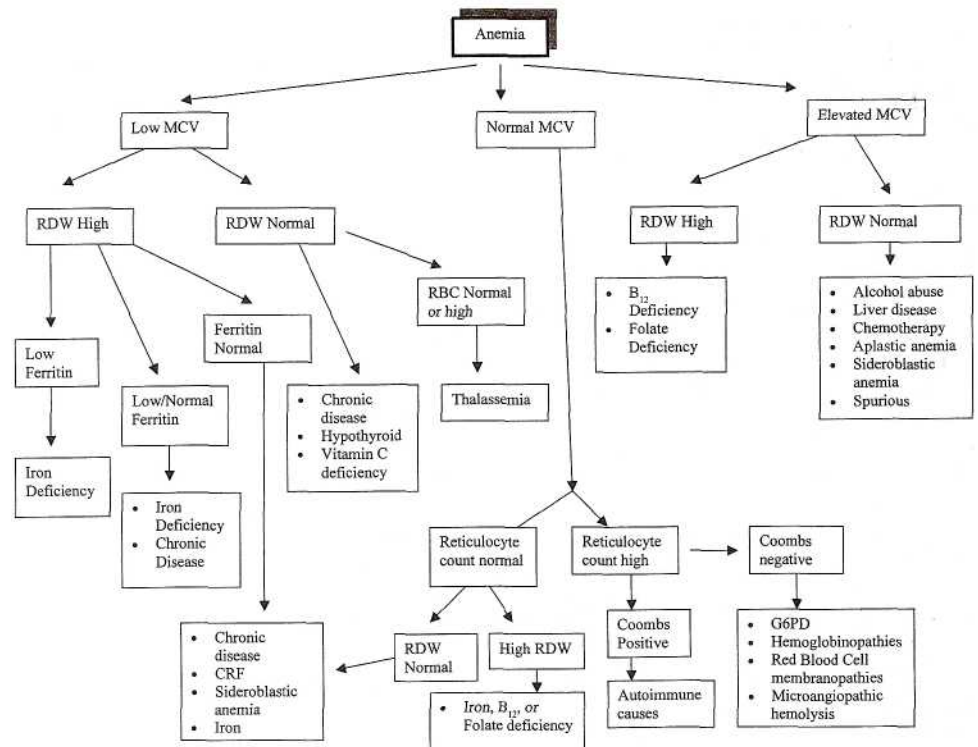

Most bleeding that is seen in the ED is a result of trauma—local wounds, lacerations, or other structural lesions. The majority of traumatic bleeding occurs in patients with normal hemostasis. With careful attention to the history and physical findings, patients with pathologic bleeding often can be readily identified.⁷ Generally speaking, patients who manifest spontaneous bleeding from multiple sites, bleeding from untraumatized sites, delayed bleeding several hours after trauma, and bleeding into deep tissues or joints should have the possibility of a bleeding disorder considered.

Important historical data for the presence of a congenital bleeding disorder include the presence or absence of unusual or abnormal bleeding in the patient and other family members and the possible occur-

TABLE 218-3 Tests in the Evaluation of Anemia

Test	Interpretation	Clinical Correlation
MCV (mean corpuscular volume)	Measure of the average red blood cell size	Decreased MCV (microcytosis) is seen in chronic iron deficiency, thalassemia, anemia of chronic disease Increased MCV (macrocytosis) is seen in B ₁₂ or folate deficiency, alcohol abuse, liver disease, disease, phenytoin, some HIV drugs
MCH (mean corpuscular hemoglobin)	Measure of the amount of hemoglobin in average red blood cell	
MCHC (mean corpuscular hemoglobin concentration)	Measure of hemoglobin concentration in average red blood cell

Peripheral blood smear	Allows visualization of the red blood cell morphology Allows evaluation for abnormal cell shapes Allows examination of the white blood cells and platelets	
Direct and indirect Coombs test	Direct Coombs test is used to detect antibodies on red blood cells Indirect Coombs test is used to detect antibodies in the sera	Direct Coombs test is positive in autoimmune hemolytic anemias, transfusion reactions, and some drug-induced hemolytic anemias Indirect Coombs test is routinely used in compatibility testing prior to transfusion

FIG. 218-1. Flow chart for the evaluation of anemia.

rence of excessive bleeding after dental extractions, surgical procedures, or trauma. Many patients with abnormal bleeding have an acquired disorder. Questioning about liver disease and drug use (particularly ethanol, aspirin, nonsteroidal anti-inflammatory drugs, warfarin, antibiotics, and other aspirin-containing products) may be helpful.

The site of bleeding may provide an indication of the hemostatic abnormality. Mucocutaneous bleeding, including petechiae, ecchymoses, epistaxis, gastrointestinal, genitourinary, or heavy menstrual bleeding is characteristic of qualitative or quantitative platelet disorders. Purpura is often associated with thrombocytopenia and commonly indicates a systemic illness. Bleeding into joints and potential spaces, such as between fascial planes and into the retroperitoneum, as well as delayed bleeding, is most commonly associated with coagulation factor deficiencies. Patients who demonstrate both mucocutaneous bleeding and bleeding in deep spaces may have disorders such as disseminated intravascular coagulation, where both platelet abnormalities and coagulation factor abnormalities are present.

Review of Normal Coagulation

The normal hemostatic system consists of a complex process that limits blood loss by the formation of a platelet plug (primary hemostasis) and the production of cross-linked fibrin (secondary hemostasis), which strengthens the platelet plug. These reactions are counterregulated by the fibrinolytic system, which limits the size of fibrin clot that is formed, thereby preventing excessive clot formation. Congenital and acquired abnormalities occur in all these systems. The affected patients may have excessive hemorrhage, excessive thrombus formation, or both.

PRIMARY HEMOSTASIS Primary hemostasis is the platelet interaction with the vascular subendothelium that results in the formation of a platelet plug at the site of injury. Required components for this to occur are normal vascular subendothelium (collagen), functional platelets, normal von Willebrand factor (connects the platelet to the endothelium via glycoprotein I_B), and normal fibrinogen (connects the platelets to each other via glycoprotein II_B-III_A) (Figure 218-2).

SECONDARY HEMOSTASIS Secondary hemostasis describes the reactions of the plasma coagulation proteins by a tightly regulated mechanism.

The final product is cross-linked fibrin, which is insoluble and strengthens the platelet plug formed in primary hemostasis (Figure 218-3).

THE FIBRINOLYTIC SYSTEM This complex system regulates the hemostatic mechanism by limiting the size of fibrin clots that are formed (Figure 218-4). The principal physiologic activator is tissue plasminogen activator (tPA), which is released from endothelial cells. Tissue

FIG. 218-2. Primary hemostasis. See text for details, pit = platelet; vWF = von Willebrand factor.

SECTION 18 • HEMATOLOGIC AND ONCOLOGIC EMERGENCIES

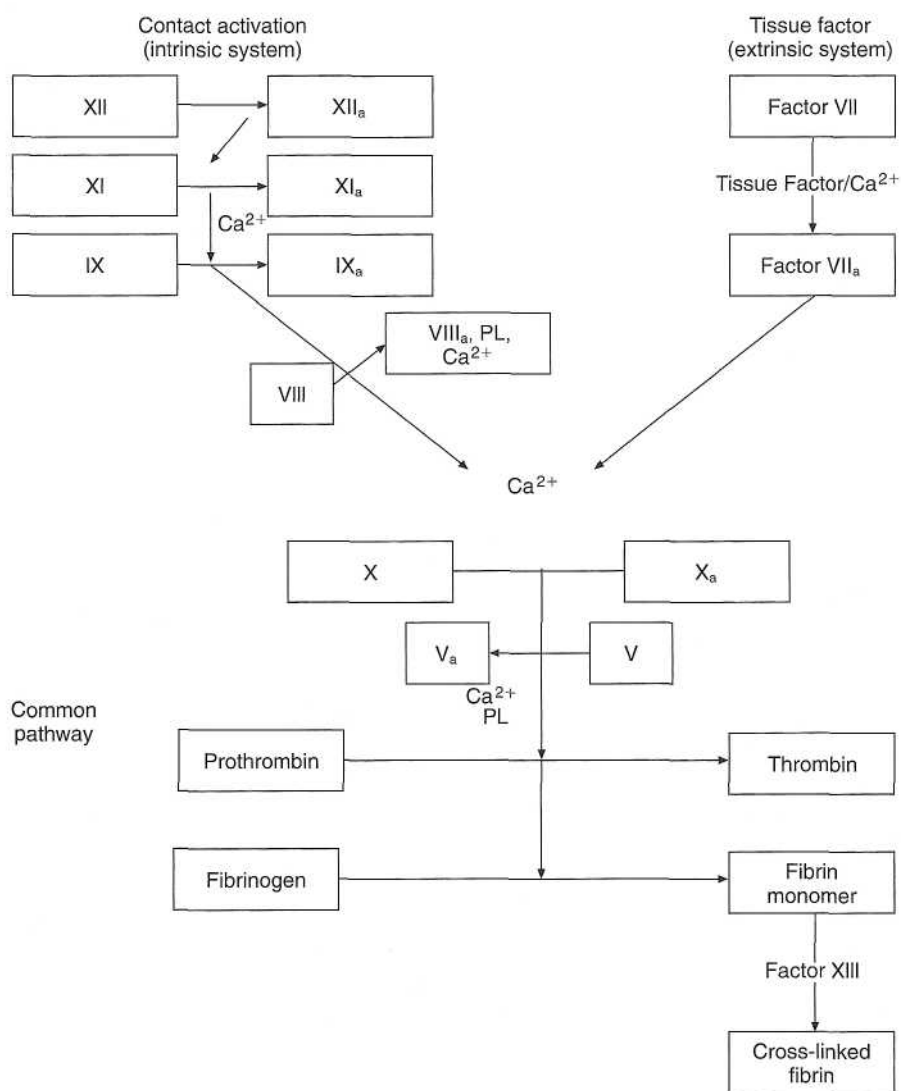

FIG. 218-3. Secondary hemostasis, also known as the coagulation cascade. The inactivated coagulation proteins (factors) are indicated by roman numerals; after the reaction occurs, the factor is activated and designated by subscript a. There are two independent activation pathways. The contact system is known as the *intrinsic pathway*, and the tissue factor system is known as the *extrinsic pathway*. The pathways merge at the point of activation of factor X. This begins the common pathway that generates the final product, cross-linked fibrin. Ca²⁺ = calcium; fibrinogen is factor I; PL = phospholipid surface (often platelets); prothrombin is factor II.

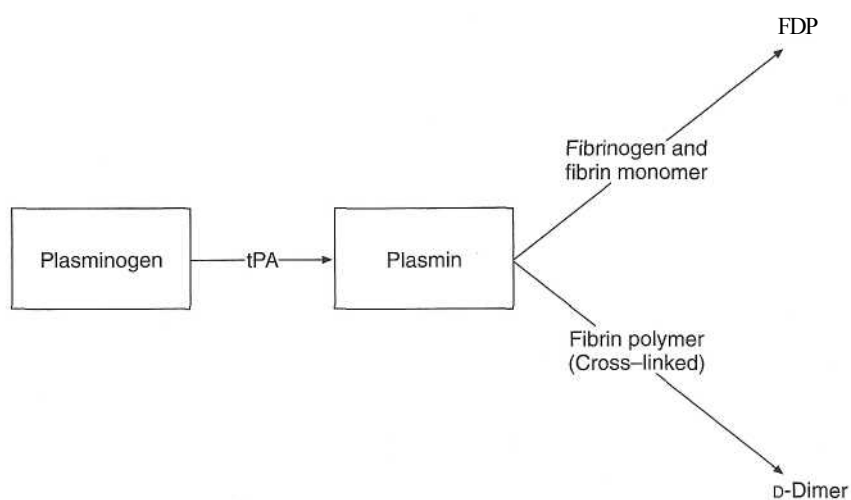

FIG. 218-4. The fibrinolytic pathway. See text for details. FDP = fibrin degradation product; tPA = tissue plasminogen activator.

plasminogen activator converts plasminogen, which is synthesized in the liver and adsorbed in the fibrin clot, to plasmin. Plasmin degrades fibrinogen and fibrin monomer into low-molecular-weight fragments known as fibrin degradation products (FDPs) and cross-linked fibrin into D-dimers.

Other physiologic inhibitors of hemostasis with clinical relevance include antithrombin III and the protein C-protein S system. Antithrombin III is a protein that forms complexes with all the serine protease coagulation factors (factors XII_a, XI_a, IX_a, and thrombin), thereby inhibiting their function. Heparin potentiates this interaction, and this is the basis for its use as an anticoagulant. Proteins C and S are vitamin K-dependent factors

that are produced in the liver. Activated protein C binds to the cell-surface-bound protein S and this complex is capable of inactivating the two plasma cofactors factors V_a and VIII_a, and inhibiting their participation in the coagulation cascade. Deficiency or defects in antithrombin III, protein C, and protein S produce a potentially hypercoagulable condition and predispose the patient to arterial and venous thromboses.

Diagnosis

The basic laboratory parameters that should be obtained in a patient with a suspected bleeding disorder are a complete blood count and

Screening Tests	Normal Value	Measures	Clinical Correlations
PRIMARY HEMOSTASIS			
Platelet count	150,000–300,000/ μ L	Number of platelets per μ L	Decreased platelet count (thrombocytopenia)—bleeding usually not a problem until platelet count <50,000/mL; high risk of spontaneous bleeding including CNS with count <10,000/ μ L; usually due to decreased production or increased destruction Elevated platelet count (thrombocytosis)—commonly reactive to inflammation or malignancy, or in polycythemia vera; can be associated with hemorrhage or thrombosis
Bleeding time (BT)	2.5–10 min (template BT)	Interaction between platelets and the subendothelium	Prolonged BT caused by: Thrombocytopenia (platelet count <50,000/ μ L) Abnormal platelet function (vWD, ASA, NSAIDs, uremia, liver disease)
SECONDARY HEMOSTASIS			
Prothrombin time (PT) and International Normalized Ratio (INR)	11–13 s, depending on reagent; INR 1.0	Extrinsic system and common pathway—factors VII, X, V, prothrombin, and fibrinogen	<i>Prolonged PT</i> —most commonly caused by: Use of warfarin (inhibits vitamin K-dependent factors II, VII, IX, and X) Liver disease with decreased factor synthesis Antibiotics, some cephalosporins, (moxalactam, cefamandole, cefotaxime, cefoperazone) that inhibit vitamin K-dependent factors
Activated partial thromboplastin time (aPTT)	22–34 s Depends on type of thromboplastin used; “activated” with Kaolin	Intrinsic system and common pathway including factors XII, XI, IX, VIII, X, V, prothrombin, and fibrinogen	<i>Prolongation of aPTT</i> most commonly caused by: Heparin therapy Factor deficiencies; factor levels have to be >30% of normal to cause prolongation
Thrombin clotting time (TCT)	10–12 s	Conversion of fibrinogen to fibrin monomer	<i>Prolonged TCT</i> caused by: Low fibrinogen level (DIC) Abnormal fibrinogen molecule (liver disease) Presence of heparin, FDPs or a paraprotein (multiple myeloma); these interfere with the conversion Very high fibrinogen level (acute phase reactant)
“Mixes”	Variable	Performed when one or more of the above screening tests is prolonged; the patient’s plasma (“abnormal”) is mixed with “normal” plasma and the screening test is repeated	<i>If the “mix” corrects the screening test</i> , one or more factor deficiencies are present. <i>If the “mix” does not correct the screening test</i> , an inhibitor is present
OTHER HEMOSTATIC TESTS			
Fibrin degradation products and D-dimer (evaluate fibrinolysis)	Variable	<i>FDPs</i> measure breakdown products from fibrinogen and fibrin monomer; normal <2.5 μ g/L <i>D-Dimer</i> measures breakdown products of cross-linked fibrin; normal <500 μ g/L	Levels of these are elevated in DIC, thrombosis, pulmonary embolus, liver disease
Factor level assays	60–130% (0.60–1.30 units/mL)	Measures the percent activity of a specified factor compared to normal	Used to identify specific factor deficiencies and in therapeutic management of patients with deficiencies
Inhibitor screens	Variable	Verifies the presence or absence of antibodies directed against one or more of the coagulation factors	<i>Specific inhibitors</i> —directed against one coagulation factor, most commonly against factor VIII; can be in patients with congenital or acquired deficiency <i>Nonspecific inhibitors</i> —directed against more than one of the coagulation factors; example is lupus-type anticoagulant

Abbreviations: ASA = aspirin; CNS = central nervous system; DIC = disseminated intravascular coagulation; FDPs = fibrin degradation products; NSAIDs = nonsteroidal anti-inflammatory drugs; vWD = von Willebrand disease.

platelet count, prothrombin time, and activated partial thromboplastin time (Table 218-4).^{7,8} The results of these tests coupled with clinical evaluation should enable one to formulate a differential diagnosis. Additional coagulation studies are ordered as indicated (see Table 218-4). Hematologic consultation should be sought if the differential diagnosis or the laboratory approach is unclear.

ACKNOWLEDGMENT

Thank you to the previous author, Mary Eberst, for her work.

TABLE 219-1 Pathophysiology of Acquired Thrombocytopenia

Mechanism	Associated Clinical Conditions
Decreased platelet production	Marrow infiltration (tumor or infection) Aplastic anemia Viral infections (measles) Drug (thiazides, estrogens, ethanol, interferon- α , chemotherapeutic agents) Radiation Vitamin B ₁₂ and/or folate deficiency
Increased platelet destruction	Idiopathic thrombocytopenic purpura Thrombotic thrombocytopenic purpura Hemolytic uremic syndrome Disseminated intravascular coagulation Viral infections (HIV, mumps, varicella, EBV) Drugs (heparin, protamine)
Splenic sequestration	Hypersplenism Hypothermia
Platelet loss	Excessive hemorrhage Hemodialysis Extracorporeal circulation

Abbreviations: EBV = Epstein-Barr virus; HIV = human immunodeficiency virus.

A complete blood cell count (CBC) will establish whether a low platelet count is present. The CBC will also determine whether other hematologic cell lines are affected. Platelet clumping can occur in some individuals, yielding a falsely low platelet count. In vitro platelet clumping results from cold-dependent or ethylenediaminetetraacetic acid (EDTA)-dependent agglutinins. This can be detected by examining the peripheral smear, which will show clumps of platelets. A correct platelet count can be obtained by collecting the blood in a citrated or heparin-anticoagulated sample tube. A peripheral smear should be done to evaluate the morphology of the platelets as well as the other cell lines.

Thrombocytopenia from Decreased Platelet Production

Neonatal infections, such as cytomegalovirus (CMV) or rubella, may include thrombocytopenia, but generally infants with these disorders have other problems as well. In the older child or adult, if multiple cell lines are affected, the differential diagnosis includes aplastic anemia, marrow infiltration from lymphoma or leukemia, or myelofibrosis. A drug history is important as many medications have been implicated as impairing platelet production (Table 219-2).³ Chronic alcohol use is a common cause of thrombocytopenia and will generally resolve if the patient abstains from drinking for 7 days. Usually the history and physical examination will determine the most likely source of thrombocytopenia; however, a bone marrow biopsy may be needed if no immediate cause is identified.

Thrombocytopenia from Increased Platelet Destruction

IMMUNE CAUSES OF PLATELET DESTRUCTION Antibody-mediated platelet destruction can be related to medications, infections, or autoimmune diseases. A review of the patient's age, prior medical history, medications, and concurrent symptoms may suggest an immune-mediated cause. Two of the more common antibody-mediated thrombocytopenic disorders are idiopathic thrombocytopenic purpura (ITP) and drug-induced immune thrombocytopenia.^{3,4}

Idiopathic Thrombocytopenic Purpura ITP is an acquired autoimmune disease that results in the rapid destruction of platelets. It is characterized by thrombocytopenia, the presence of purpura or petechiae, a normal bone marrow, and no other identifiable cause for the

ACQUIRED BLEEDING DISORDERS

Mary A. Wittier
Robin R. Hemphill

ACQUIRED PLATELET DEFECTS

Acquired platelet defects can be either quantitative or qualitative. Quantitative defects, resulting in thrombocytopenia, are caused by decreased production, increased destruction, splenic sequestration or a combination of the three (Table 219-1).¹ A decreased platelet count is commonly manifested by the presence of nonpalpable petechiae. These are most prominent in the lower extremities and in areas where blood flow is restricted. Other findings typical of thrombocytopenia include purpura, mucosal bleeding, hemoptysis, hematuria and hematochezia, whereas deep tissue bleeding is less common.

When platelet levels decrease to below 10 to 20,000/ μ L, the risk of spontaneous bleeding becomes concerning, particularly for intracranial bleeding. Additional risk factors for bleeding include age, comorbid illnesses (i.e., renal disease, liver disease, connective tissue disease, peptic ulcer disease, hypertension), fall risk, and lifestyle activity. With the exception of a few disease processes, platelet transfusion should be considered when counts fall below 10,000/ μ L (higher if other comorbid illness are present).² The cause of the platelet deficiency may also influence the risk of bleeding. At a given platelet level, patients with idiopathic thrombocytopenic purpura bleed less than patients with aplastic anemia. Research suggests that the younger platelets present in idiopathic thrombocytopenic purpura are more effective in hemostasis due to increased metabolic activity.

During the initial evaluation of a patient who exhibits signs of bleeding the circulatory stability should be assessed and secured. Once this is done, the history and physical examination, along with directed laboratory testing, may help limit the differential. Family history is important, but recent illness, current complaints and recent medications are likely of greater relevance in the patient who appears to have a platelet disorder. Physical examination should evaluate for additional bleeding sites, the type of bleeding, and assess the size of the spleen.

TABLE 219-2 Drugs Which Produce Thrombocytopenia or Impair Platelet Function

Produce Thrombocytopenia	Impair Function (Prolong Bleeding Time)
Heparin 4+	Aspirin
Gold salts 4+	Nonsteroidal anti-inflammatory drugs
Sulfa-containing antibiotics 4+	Antiplatelet agents: ticlopidine and clopidogrel
Quinine and quinidine 4+	Penicillins and cephalosporins
Ethanol (chronic use) 4+	Calcium channel blockers
Aspirin 3+	Propranolol
Indomethacin 3+	Nitroglycerin
Valproic acid 3+	Antihistamines
Heroin 3+	Phenothiazines
Thiazides 2+	Tricyclic antidepressants
Furosemide 2+	
Procainamide 2+	
Digoxin 2+	
Cimetidine and ranitidine 2+	
Phenytoin 1+	
Penicillins/cephalosporins 1+	

Note: 4+ to 1+ indicates relative incidence, from more frequent to less frequent, based on case reports.

thrombocytopenia.^{4,5} Platelet destruction is mediated by the production of autoantibodies that attach to circulating platelets and the antibody-coated platelets are removed by the reticuloendothelial system. The bone marrow will usually respond by increasing platelet production. However, in some cases, the same antibodies that bind to the platelets will also bind to the megakaryocytes, limiting the bone marrow response. Despite the presence of antibodies, the circulating platelets function properly and many people with ITP may not have significant bleeding despite very low platelet counts.

ITP presents in all age groups and may have an acute or chronic course. Acute ITP is more common among younger children, affects males and females equally, and typically resolves in 1 to 2 months. Chronic ITP lasts more than 3 months, is more common in adults, has a female predilection, and rarely remits spontaneously or with treatment. Additionally, patients with chronic ITP are more likely to exhibit an underlying disease or autoimmune disorder, such as Hiy systemic lupus erythematosus (SLE), Graves' disease, Hashimoto thyroiditis, or antiphospholipid antibody syndrome.

The most common sign of ITP is the development of petechiae. Mild epistaxis, gingival bleeding, and menorrhagia in women of child-bearing age may also be seen. Except for the petechiae and bruising, the patient should have a normal physical examination. The presence of lymphadenopathy, hepatosplenomegaly, pallor, or hyperbilirubinemia should suggest an alternative diagnosis such as leukemia, lymphoma, systemic lupus erythematosus, infectious mononucleosis, or hemolytic anemia.

Laboratory testing includes a CBC with platelets and a peripheral blood smear. The CBC should demonstrate normal cell lines except for the platelets. In some patients with bleeding, a mild anemia may be present, but the red cell indices should be normal. The peripheral blood smear should show large, well-granulated platelets, although few in number. The diagnosis of ITP is based primarily on the history, physical examination, CBC, and peripheral smear. If the evaluation supports the diagnosis of ITP and there are no atypical findings suggesting a different disease, then additional testing in the ED is not required.

For all patients with ITP, bleeding risks should be minimized, including: avoiding the use of antiplatelet medications [i.e., aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs)]; avoiding unnecessary invasive procedures; maintenance of good blood pressure control; treatment of exacerbating comorbid conditions (i.e., liver disease, renal disease); and addressing fall risks. Treatment of ITP depends upon severity, age, and presence of bleeding.^{5,6} **Asymptomatic patients**

who are otherwise healthy with platelet counts >50,000/fJIL require no treatment. Patients with platelet counts < 20,000 to 30,000/fJIL and patients with platelet counts <50,000/xL with bleeding or significant risk factors for bleeding require treatment.

Initial therapy in adults with ITP is prednisone started at 60 to 100 mg/d and tapered after the platelet count reaches normal.⁶ Steroid treatment failure is defined by 1) treatment with steroids for a period of 4 to 6 weeks without the return of platelets to >30,000 to 50,000/^L; 2) platelet counts that have not normalized after 6 to 8 weeks of treatment; or 3) falling platelet counts after tapering the steroid dose. For these patients, the main alternative therapy is splenectomy, which produces long-standing remission in approximately 65 percent of patients.

For life-threatening bleeding, stabilization and control of local bleeding should be implemented. In addition, the current recommendation is to initiate high-dose steroid therapy (methylprednisolone 1 to 2 g/d IV for 2 or 3 days). Intravenous immunoglobulin may be given alone or in combination with steroids. Platelets should be transfused as needed following the first dose of methylprednisolone or immunoglobulin; holding the platelet transfusion until the first dose of either is completed generally results in a greater rise in the platelet count. Red cells should be transfused as needed. Conjugated estrogen, 25 mg intravenously once, can be given for severe uterine bleeding.

Hospitalization is required for ITP-related bleeding. However, outside of this obvious indication, the necessity for hospitalization is less clear. Hospitalization is generally not required for asymptomatic patients with platelet counts >20,000 to 30,000/xL. Hospitalization is prudent when arranging patient follow-up is difficult, when compliance is in doubt, or when significant additional bleeding risk factors are present.

Drug-Related Causes of Thrombocytopenia Multiple medications have been implicated in causing immune mediated destruction of platelets.³ While the exact mechanisms have not always been determined, certain medications appear to bind to the platelet membrane causing a structural change that then stimulates an immune response (see Table 219-2). Presentation is identical to ITP.

NONIMMUNE CAUSES OF PLATELET DESTRUCTION Increased platelet destruction can occur from nonimmune mediated causes (see Table 219-1). In thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS), thrombotic microangiopathy occurs when vessel injury results in the deposition of platelet-fibrin thrombi.⁷ Disseminated intravascular coagulation (DIC) is a well-described cause of platelet destruction. Additionally, certain bacterial, rickettsial, and viral infections can cause direct toxic effects on platelets. Thrombocytopenia specific to pregnancy may be a result of the HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome, preeclampsia, or gestational thrombocytopenia.⁸ Gestational thrombocytopenia occurs in 5 to 8 percent of pregnancies and is generally benign.

Platelet Sequestration

The last major cause of thrombocytopenia is platelet sequestration. In patients with marked splenomegaly, platelet counts as low as 40,000 /xL are common. However, isolated splenomegaly rarely results in clinically significant hemorrhage without the presence of another concomitant hemorrhagic disorder, and splenectomy is rarely indicated.

Qualitative Platelet Abnormalities

Several disease processes can cause acquired qualitative or functional abnormalities of platelets (Table 219-3). In the myeloproliferative diseases, platelets are often dysfunctional, even if the platelet count is elevated. Patients can develop prolonged bleeding times or clinically significant bleeding. To control acute bleeding, transfusion should be

TABLE 219-3 Clinical Conditions Associated with Qualitative Platelet Abnormalities

Uremia
Liver disease
Disseminated intravascular coagulation
Antiplatelet antibodies (UP, SLE)
Cardiopulmonary bypass
Myeloproliferative disorders (PCV, CML)
Dysproteinemias (multiple myeloma, Waldenstrom macroglobulinemia)
Preleukemias, AML, ALL
von Willebrand disease (congenital or acquired)

Abbreviations: ALL = acute lymphocytic leukemia; AML = acute myelogenous leukemia; CML = chronic myelogenous leukemia; ITP = idiopathic thrombocytopenic purpura; PCV = polycythemia vera; SLE = systemic lupus erythematosus.

considered to raise the level of normal platelets to 50,000 / μ L. In macroglobulinemia and related disorders, the elevated level of viscous proteins interferes with platelet function. Patients with clinically significant bleeding may require plasmapheresis to reduce the protein level and correct hemostatic function.

Many commonly used drugs can influence platelet function and should be avoided in clinical conditions characterized by altered platelet function (see Tables 219-2, and 219-4). Of these, the most commonly used are aspirin—which produces an irreversible impairment in platelet aggregation—and the NSAIDs, clopidogrel, and ticlopidine—which produce temporary impairment in platelet adhesion and aggregation (see Chap. 224).

Thrombocytosis, a platelet count above 500,000 / μ L, can be seen in many disorders, including inflammatory reactions, malignancy, polycythemia, and postsplenectomy. Platelet function can be normal or abnormal depending upon the underlying condition. With abnormal platelet function, thrombocytosis can be associated with bleeding (mucosal, ecchymoses, gastrointestinal) or thromboembolic (deep vein thrombosis, portal or mesenteric thrombosis, splenic vein thrombosis) manifestations. However, these events are unusual, even with platelet counts in excess of 1 million/ μ L.

ANTICOAGULANTS AND FIBRINOLYTICS

These agents are discussed in detail in Chap. 224. Patients with acquired bleeding disorders should be carefully assessed before administration of anticoagulants or fibrinolytics.

LIVER DISEASE

Acute and chronic diseases of the liver can be associated with many hemostatic abnormalities.⁹ Hepatocytes synthesize all of the coagulation factors and related regulatory proteins, with the exception of factor VIII. Diseases affecting the hepatic parenchyma may result in a decreased synthesis of these factors, including the vitamin K-dependent carboxylation of factors II (prothrombin), VII, IX, and X. Because vitamin K is a fat-soluble vitamin, malabsorption can occur with processes that interfere with the absorption of fat-soluble vitamins, including impaired bile acid metabolism (i.e., primary biliary cirrhosis), intrahepatic or extrahepatic cholestasis, and treatment with bile acid binders.

TABLE 219-4 Duration of Antiplatelet Activity

Drug	Onset	Duration of Effect
Aspirin	1 h	Platelet life span (8 d)
Most NSAIDs	1 h	1 d
Piroxicam	1 h	2 d
Ticlopidine or clopidogrel	1–2 d	4–10 d

Thrombocytopenia in severe liver disease is most often caused by portal hypertension, which leads to congestive hypersplenism and splenic sequestration. Splenic sequestration decreases the effective circulating platelet number. Alone, this thrombocytopenia is not usually clinically significant, but can have additive effects to other hemostatic abnormalities present in liver disease. Patients with significant liver disease have increased fibrinolysis as a result of decreased synthesis of α_2 -plasmin inhibitor, which is produced by the liver. As α_2 -plasmin inhibitor is the major inhibitor of plasmin, a deficiency results in unregulated plasmin activity and increased fibrinolysis. Characteristics of increased fibrinolysis include low fibrinogen levels and a mild elevation of fibrin degradation products (FDPs) and D-dimers. In some patients with liver disease, abnormal fibrinogen molecules are synthesized. These abnormal fibrinogen molecules are converted to abnormal fibrin molecules that do not polymerize correctly.

Distinguishing DIC from the coagulopathy of severe liver disease is difficult. Abnormal laboratory values, including decreased platelets, decreased coagulation factors, and hypofibrinogenemia can be present in both conditions. The D-dimer assay should be normal in liver disease (see DIC discussion below). Patients with mild to moderate hepatic dysfunction frequently have subclinical hemostatic abnormalities. Those with severe liver disease may have life-threatening bleeding. Laboratory studies that should be obtained include a hematocrit, prothrombin time (PT), aPTT, and platelet count. Fibrinogen levels and measurement of FDP and/or D-dimers may also be considered. In general, prolongation of the PT and hypofibrinogenemia with a plasma fibrinogen level <100 mg/dL are poor prognostic signs in patients with liver disease.

Patients who have liver disease and laboratory abnormalities without clinically significant bleeding usually require only close observation. If there is clinically significant bleeding or a pending invasive procedure or surgery, the coagulopathic state will need to be treated. Packed red blood cells should be transfused to maintain an adequate hemoglobin level and to maintain hemodynamic stability. Oral or intravenous vitamin K should be given to all patients with liver disease and active bleeding. For patients with prolonged PT and aPTT and active bleeding or pending procedure, FFP can be used to temporarily replace coagulation factors. The volume needed to completely replenish the coagulation factors may limit the use of FFP. Each FFP unit is 200 to 250 mL and contains approximately 200 to 250 units of each coagulation factor. Because the half-life of several of the clotting factors is 12 h or less, additional doses of FFP may be required. Cryoprecipitate may be used to replace fibrinogen in patients with active bleeding and fibrinogen levels < 100 mg/dL. Platelet transfusions may be appropriate if bleeding is present with low counts. Desmopressin (DDAVP), a synthetic analogue of vasopressin, shortens the prolonged bleeding time in some patients with liver disease. Although controlled trials are lacking, there appear to be few side effects. The dose is 0.3 μ g/kg (maximum 20 μ g) SC or IV every 12 h up to three doses. Intranasal desmopressin may also be effective in this setting at a dose of 3 μ g/kg (maximum 300 μ g).

RENAL DISEASE

Hemostatic abnormalities are commonly present in patients with renal disease related to multiple abnormalities in hemostasis, including quantitative and qualitative platelet abnormalities and clotting factor abnormalities.¹⁰ Platelet counts are usually normal, although mild thrombocytopenia may occur. Clinically significant bleeding may occasionally occur with dialysis-induced thrombocytopenia. Retention of uremic toxins causes inhibition of platelet aggregation.

Management of these hemostatic defects is aimed at both prevention and directed at treatment of acute bleeding. Preventative measures include optimizing nutrition; folate, vitamin B₁₂ and iron repletion; optimizing dialysis; and correction of anemia with recombinant human erythropoietin (rHuEPO). Acute bleeding can be treated with

dialysis, transfusion of red blood cells, DDAVP, conjugated estrogens, cryoprecipitate transfusion, and (rarely) platelet transfusion. Dialysis improves platelet function transiently for 1 to 2 days. Optimally, patients are well dialyzed three times per week. In uremic patients with prolonged bleeding times, most will have shortening or normalization of the bleeding time when treated with desmopressin. Side effects associated with desmopressin are generally mild and include headache, flushing, minor hypotension, tachycardia, nausea, abdominal cramps, and local site reaction. Conjugated estrogens also improve both the bleeding time and clinical bleeding in more than 80 percent of uremic patients treated. Platelet transfusions are not routinely used in this setting because the infused platelets quickly acquire the uremic defect. Cryoprecipitate and platelet infusions are only indicated for life-threatening bleeding used in combination with packed red blood cells, desmopressin and conjugated estrogens.

DISSEMINATED INTRAVASCULAR COAGULATION

DIC is an acquired syndrome characterized by activation of the coagulation system resulting in fibrin formation.¹¹ Activation of the fibrinolytic system also occurs, resulting in the breakdown of fibrin clots, consumption of coagulation factors, and bleeding. DIC is associated with a wide variety of disorders and may be acute and life-threatening, or chronic and compensated (Table 219-5).

Pathogenesis

Although the diseases triggering DIC are diverse, the commonality of these illnesses is the activation of tissue factor, a substrate in the extrinsic pathway of the coagulation cascade. The deregulated formation of thrombin is central to the pathogenesis of DIC (Figure 219-1). Thrombin generation results in small fibrin clots formed and deposited in the microcirculation, thereby leading to the thrombotic occlusion of vessels and eventually end-organ dysfunction. Widespread activation of the coagulation system leads to consumption of circulating platelets and coagulation factors. Production of thrombin and

fibrin indirectly activates tissue plasminogen activator (tPA) and the counterregulatory fibrinolytic system. Plasmin is produced from plasminogen, which then degrades fibrin and results in the generation of FDR. Normally, the fibrinolytic system plays a homeostatic role and is balanced with the coagulation system, but in DIC, the degree of fibrinolytic activation is excessive and can result in pathologic bleeding.

Clinical Features

Clinical features of DIC vary with the underlying precipitating medical illness. The clinical complications of DIC are bleeding, thrombosis, purpura fulminans, and multiple organ failure. Although hemorrhage and thrombosis may occur simultaneously, in an individual patient, one usually predominates and the most common manifestation is bleeding. Bleeding can range from petechiae and ecchymoses to widespread bleeding from the gastrointestinal tract, genitourinary tract, surgical wounds, mucocutaneous sites and venipuncture sites. Intravascular coagulation and fibrin deposition can cause multiple organ failure. Clinical signs of this include mental status changes, focal ischemia or gangrene, oliguria, renal cortical necrosis and adult respiratory distress syndrome (ARDS). Purpura fulminans occurs when there are widespread arterial and venous thromboses and is most commonly seen with significant bacteremia. In chronic DIC, the pathophysiology of disease is essentially the same, but the consumption of coagulation factors and platelets is balanced by hepatic production.

Laboratory

The typical laboratory results in acute DIC include prolonged PT, low platelet count, and/or low fibrinogen level (Table 219-6). The most commonly observed abnormality is thrombocytopenia; a progressive drop in the platelet count is sensitive, although not specific, for DIC. Depletion of coagulation factors is reflected by prolonged clotting times. Fibrinogen levels may remain normal because fibrinogen is an acute-phase reactant. A fibrinogen level <100 mg/dL is associated

TABLE 219-5 Common Conditions Associated with Disseminated Intravascular Coagulation

Clinical Setting	Comments
Infection	Probably the most common cause of DIC; 10–20% of patients with gram-negative sepsis have DIC; endotoxins stimulate monocytes and endothelial cells to express tissue factor; Rocky Mountain spotted fever causes direct endothelial damage; DIC more likely to develop in asplenic patients or those with cirrhosis; septic patients are more likely to have thrombosis than bleeding.
Bacterial	
Viral	
Fungal	
Carcinoma	Malignant cells may cause endothelial damage and allow the expression of tissue factor as well as other procoagulant materials; most adenocarcinomas tend to have thrombosis (Trousseau syndrome), except prostate cancer tends to have more bleeding; DIC is often chronic and compensated.
Adenocarcinoma	
Lymphoma	
Acute leukemia	DIC most common with promyelocytic leukemia; blast cells release procoagulant enzymes, there is excessive release at time of cell lysis (chemotherapy); more likely to have bleeding than thrombosis.
Trauma	DIC especially with brain injury, crush injury, burns, hypothermia, hyperthermia, rhabdomyolysis, fat embolism, hypoxia.
Liver disease	May have chronic compensated DIC; acute DIC may occur in the setting of acute hepatic failure, tissue factor is released from the injured hepatocytes.
Pregnancy	Placental abruption, amniotic fluid embolus, septic abortion, intrauterine fetal death (can be chronic DIC); can get DIC in HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome.
Vascular disease	Large aortic aneurysms (chronic DIC can become acute at time of surgery), giant hemangiomas, vasculitis, multiple telangiectasias.
Envenomation	DIC can develop with bites of rattlesnakes and other vipers; the venom damages the endothelial cells; bleeding is not as bad as expected from laboratory values.
Adult respiratory distress syndrome (ARDS)	Microthrombi are deposited in the small pulmonary vessels, the pulmonary capillary endothelium is damaged; 20% of patients with ARDS develop DIC and 20% of patients with DIC develop ARDS.
Transfusion reactions	DIC with severe bleeding, shock, and acute renal failure.
Acute hemolytic reaction	
Massive transfusion	

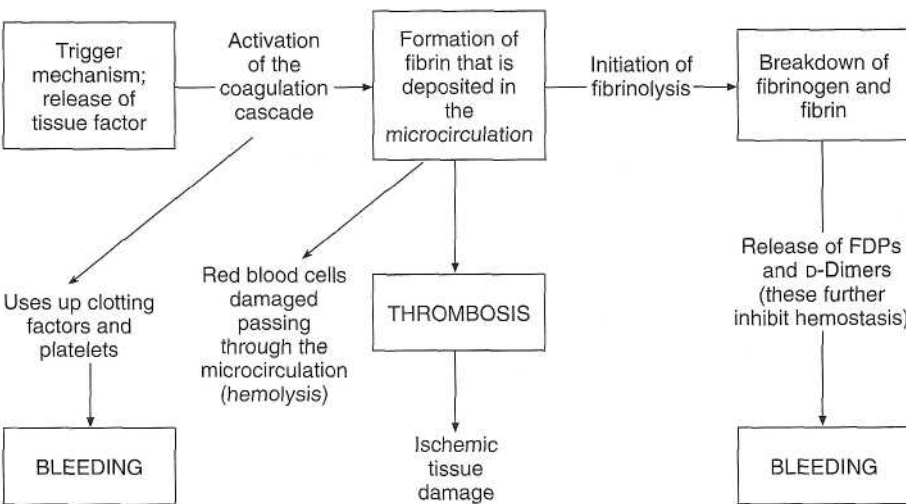

FIG. 219-1. Pathophysiology of disseminated intravascular coagulation. Refer to text for details. FDPs = fibrin/fibrinogen degradation products.

with increased bleeding manifestations. FDP and D-Dimer may help differentiate DIC from other causes of prolonged coagulation times and low platelets. D-Dimer is a test that indicates excessive cross-linked fibrin breakdown and may be more specific in diagnosing DIC than FDP. Additional laboratory findings include increased lactic acid dehydrogenase, decreased haptoglobin levels, and a peripheral smear with schistocytes. Chronic DIC will have minor abnormalities of the screening assays, reflecting the limited consumption of coagulation factors that are being replaced by hepatic synthesis.

TABLE 219-6 Laboratory Abnormalities Characteristic of Disseminated Intravascular Coagulation

Studies	Result
MOST USEFUL	
Prothrombin time	Prolonged
Platelet count*	Usually low
Fibrinogen level†	Low
HELPFUL	
Activated partial thromboplastin time	Usually prolonged
Thrombin clot time‡	Prolonged
Fragmented red blood cells§	Should be present
FDPs and D-dimers¶	Elevated
Specific factor assays**	
Factor II	Low
Factor V	Low
Factor VII††	Low
Factor VIII‡‡	Low, normal, high
Factor IX	Low (decreases later than other factors)
Factor X	Low

*Platelet count usually low, most important that it is falling if it started at an elevated level.
 †Fibrinogen level correlates best with bleeding complications; it is an acute phase reactant so it may actually start out at an elevated level; fibrinogen level <100 mg/dL correlates with severe DIC. ‡Not a sensitive test, prolonged by many abnormalities. §Fragmented red blood cells and schistocytes are not specific for DIC. ¶Levels may be chronically elevated in patients with liver or renal disease. **The factors in the extrinsic pathway are most affected (VII, X, V, and II). ††Factor VII is usually low early because it has the shortest half-life. ‡‡Factor VIII is an acute phase reactant so its level may be normal, low, or elevated in DIC.
 Abbreviations: DIC = disseminated intravascular coagulation; FDP = fibrin degradation products.

Differential Diagnosis

Primary fibrinolysis is a rare syndrome whereby plasmin and fibrinolysis are independently generated without the production of thrombin. Severe liver disease will also manifest with coagulation abnormalities and low platelets. These two entities can be differentiated from DIC on the basis of clinical history and laboratory tests. The hematologic abnormalities in liver disease should be relatively stable in contrast to the worsening abnormalities associated with acute DIC. Additionally, the o-dimer assay will usually be normal or minimally elevated in both primary fibrinolysis and liver disease, but elevated in DIC.

Treatment

Treatment of DIC rests on supportive measures and management of the underlying illness.¹¹ Circulatory stabilization requires fluid, red cells, and, sometimes, inotropic agents. If possible, the underlying cause of the DIC needs to be treated. Secondary treatment involves replacement therapy with platelets, fibrinogen, and coagulation factors. Many patients with DIC require no specific therapy if evidence of bleeding or thrombosis is lacking and laboratory studies are not deteriorating. Replacement therapy should only occur in patients with documented DIC with bleeding or an impending invasive procedure. Fibrinogen repletion should be considered in the patient who has hypofibrinogenemia and significant bleeding. The goal of treatment is to raise the plasma fibrinogen level to 100 to 150 mg/dL with cryoprecipitate. Each unit of cryoprecipitate contains approximately 200 to 250 mg of fibrinogen and is usually transfused in 10-unit increments. Platelet repletion should be considered in the patient with a platelet count less than 50,000/μL with bleeding, or with a platelet count less than 20,000/μL without bleeding. Typically, 6 units of random donor platelets (or one apheresis unit) are given at a time. FFP is used to replace clotting factors for DIC-associated bleeding with prolonged PT and aPTT. Each unit of FFP contains 200 to 250 units of each factor. A patient is usually transfused with 10 to 15 mL/kg, or in increments of 2 to 4 units of FFP. Patients with DIC also should be given vitamin K and folate.

Heparin administration usually has a limited role in the treatment of acute DIC, and it is usually considered in patients with documented DIC in whom thromboembolic complications predominate the clinical picture (i.e., purpura fulminans). The role of heparin in treatment of acute promyelocytic leukemia and advanced liver disease remains controversial. Heparin should also be considered in patients with chronic DIC and thrombosis (i.e., solid tumors). Low-molecular-weight heparin may be just as efficacious as unfractionated heparin. Antifibrinolytic agents, including ε-aminocaproic acid (EACA), are used with

great caution in DIC. Although these drugs may reduce bleeding, their use is associated with serious and/or fatal thromboembolic complications. Antifibrinolytic agents should be restricted to patients who have documented hypofibrinogenemia and fibrinolysis. When used, antifibrinolytic agents are given together with heparin or after heparin infusion to minimize the potential for thrombosis. Because several of the regulatory pathways of anticoagulation are dysfunctional and/or ineffective in DIC, current research is focusing on the use of antithrombin III concentrate replacement, protein C concentrate replacement, and tumor factor inhibitors.

INFECTION WITH HUMAN IMMUNODEFICIENCY VIRUS

The more common hemostatic abnormalities observed in patients infected with HIV-1 are thrombocytopenia and acquired circulating anticoagulants.^{12,13}

Thrombocytopenia is one of the earliest findings in asymptomatic HIV-1-infected individuals.¹² For patients with fully developed AIDS, 30 to 45 percent will have mild to moderate thrombocytopenia at some time during the course of their illness. Clinically significant bleeding is unusual, with the common manifestations being easy bruising, petechiae, and mucosal bleeding. The thrombocytopenia is secondary to increased peripheral platelet destruction and decreased platelet production. The increased platelet destruction is likely immune mediated. HIV-1 also directly infects bone marrow megakaryocytes, resulting in decreased thrombopoiesis. Additionally, drugs used to treat HIV-related illnesses can contribute to thrombocytopenia, including trimethoprim-sulfamethoxazole, ganciclovir, and fluconazole. TTP is an uncommon but well-described complication of HIV-1 infection and may be the initial manifestation of infection. It is characterized by the pentad of fever, thrombocytopenia, neurologic symptoms, renal insufficiency, and microangiopathic hemolytic anemia (see Chap. 222).

Antiphospholipid antibodies, including lupus anticoagulant and anticardiolipin antibodies, are a common hemostatic abnormality in HIV-1-infected patients.¹³ Patients with lupus anticoagulant will have a prolongation of the aPTT that does not correct after mixing with normal plasma. Often a transient defect, the lupus-type anticoagulant may appear with an acute opportunistic infection and disappear when the infection is treated. Anticardiolipin antibodies are detected by enzyme-linked immunosorbent assay (ELISA) and do not affect the basic hemostatic screening tests. One or both of these antibodies occur in 22 to 82 percent of patients with HIV-1 infection. While these antibodies do not predispose a patient to clinical bleeding, concomitant hemostatic abnormalities such as platelet dysfunction or hypoprothrombinemia (associated with the lupus-type anticoagulant) may lead to bleeding manifestations. Whereas HIV-negative patients who have antiphospholipid antibodies are predisposed to thrombosis, HIV-positive patients with antiphospholipid antibodies rarely manifest thrombosis.

CIRCULATING ANTICOAGULANTS

Acquired inhibitors of blood coagulation, also known as circulating anticoagulants, are antibodies directed against one or more of the coagulation factors.¹⁴ While inhibitors may develop spontaneously in previously healthy patients with normal hemostasis, most inhibitors develop in patients with hereditary bleeding disorders who receive transfusion of plasma products. Inhibitors have been described for most of the coagulation factors; the two most common inhibitors are factor VIII inhibitors and antiphospholipid antibodies. Factor VIII inhibitors are "specific" inhibitors, directed only against factor VIII as opposed to antiphospholipid antibodies, including lupus anticoagulant and anticardiolipin antibodies, which are "nonspecific" inhibitors directed against several of the coagulation factors.

Factor VIII Inhibitors

Factor VIII inhibitors most commonly develop in patients with hemophilia A (Chap. 220), but can also develop spontaneously in patients with previously normal hemostasis. This latter group includes the development of inhibitors in the elderly having no underlying disease, postpartum patients, and patients with autoimmune disorders or underlying disease processes. The incidence of spontaneously arising inhibitors is estimated at 0.2 to 1.0 per 1 million persons per year. Although uncommon, it is important to recognize this clinical entity because the mortality rate approaches 22 percent. Inhibitors can develop in association with autoimmune disorders [systemic lupus erythematosus (SLE), rheumatoid arthritis, ulcerative colitis], lymphoproliferative disorders (multiple myeloma, Waldenstrom macroglobulinemia, benign monoclonal gammopathy of uncertain significance), and in patients with allergic drug reactions (penicillins, sulfonamides, phenytoin).

Patients without a prior bleeding history who develop factor VIII inhibitors can present with massive spontaneous bruises, ecchymoses and hematomas. Laboratory studies classically show a normal PT, normal thrombin clotting time (TCT), and a greatly prolonged aPTT that does not correct with "mixing." A factor VIII-specific assay will show very low or absent factor VIII activity. Other factor specific assays should be normal or only slightly decreased. Quantitative measurement of the inhibitor by the Bethesda Inhibitor Assay is important for the emergency management of bleeding episodes. Treatment of factor VIII inhibitors focuses on using long-term management to suppress antibody production and treatment of acute bleeding episodes. Long-term management is directed at the suppression of antibody production via steroids, intravenous immunoglobulin, or cytotoxic agents. A hematologist should direct the management of an acute, clinically significant bleeding episode. Conservative therapies should be considered, including compression and immobilization of the bleeding site and possible administration of ϵ -aminocaproic acid. Additionally, the use of aspirin, NSAIDs, and intramuscular injections should be avoided. Other treatment options include factor VIII concentrates (porcine factor VIII, human purified factor VIII, recombinant factor VIII), factor IX complex concentrates, purified prothrombin complex concentrates, recombinant factor VIII concentrates, and plasmapheresis.

Antiphospholipid Antibody Syndrome

The antiphospholipid antibody syndrome is defined by the presence of the lupus anticoagulant or anticardiolipin antibodies plus one or both of the following clinical criteria: thrombosis (arterial or venous) and/or complications with pregnancy (recurrent fetal loss or recurrent premature births at <34 weeks estimated gestational age).¹⁵ The lupus anticoagulant is an antiphospholipid antibody that, in vitro, prolongs many of the coagulation reactions. In vivo, the lupus anticoagulant inhibits anticoagulant pathways, resulting in thrombosis. **Lupus anticoagulant is a misnomer because the majority of affected patients do not have lupus (it is present in only 5 to 15 percent of patients with SLE) and the majority of patients develop thrombosis rather than bleeding.** Aside from SLE, other conditions associated with the development of lupus anticoagulants include other autoimmune disorders, drug reactions (especially procainamide and phenothiazine), malignancies, and patients with HIV-1 infection.

Primary antiphospholipid syndrome includes affected patients who have no underlying disease state. Secondary antiphospholipid syndrome includes affected patients with an underlying autoimmune process or other disease state. Frequently, patients who have lupus anticoagulant also have anticardiolipin antibodies, which, like lupus anticoagulant, is an antiphospholipid antibody that, in vitro, prolongs many of the coagulation reactions. Although frequently present simultaneously, lupus anticoagulant and anticardiolipin antibodies may occur independently of each other. Therefore, both should be tested when evaluating for an antiphospholipid syndrome.

Laboratory studies of patients with the lupus anticoagulant typically show a normal or slightly prolonged PT (0.5 to 3.0 s), prolongation of the aPTT (not usually more than 10 to 15 s prolonged), and a normal TCT. The prolonged aPTT will not correct with mixing equal parts of the patient's plasma with normal plasma. Some patients with lupus anticoagulant develop antibodies that bind to prothrombin, resulting in a hypoprothrombinemia (factor II deficiency). Excessive prolongation of the PT (i.e., 18 to 20 s) is suggestive of a concomitant hypoprothrombinemia. Factor-specific assays will show a decrease in all the factor levels, although none are extremely low. There are multiple tests available to detect the presence of the lupus anticoagulant, including the dilute Russell viper venom time (dRVVT), the kaolin clotting time, the dilute phospholipid time, and the tissue thromboplastin inhibition test. Multiple tests should be employed to increase the number of patients identified. Patients suspected of having lupus anticoagulant should also be tested for anticardiolipin antibodies as measured by an ELISA.

Many patients with lupus anticoagulant and anticardiolipin antibodies are asymptomatic, with abnormalities discovered only on routine coagulation screening tests. If symptomatic, the major clinical manifestations are thromboembolism, pregnancy complications, and thrombocytopenia. Patients are more likely to develop venous as opposed to arterial thrombosis. Additionally, patients may develop non-bacterial aortic or mitral valvular lesions with resulting systemic embolization. Patients who remain positive for lupus anticoagulant have a 50 percent recurrence of arterial or venous thrombosis within 2 years. Complications during pregnancy include recurrent fetal loss and premature labor. Recurrent fetal loss usually occurs at an estimated gestational age >10 weeks, but can occur earlier. The likely mechanism for recurrent fetal loss is thrombosis of placental vessels and placental infarction. Additionally, premature delivery at <34 weeks is thought to be secondary to uteroplacental insufficiency. Approximately 40 to 50 percent of patients develop thrombocytopenia. Bleeding is rare, and if present, it is usually secondary to another process, such as hypoprothrombinemia (usually patients with SLE), significant thrombocytopenia, or uremia.

Asymptomatic patients diagnosed with the lupus anticoagulant or anticardiolipin antibodies require no treatment. However, risk factors for the development of thromboembolism, including vascular stasis, vessel injury, and hypercoagulable states should be minimized. Additionally, treatment of concurrent underlying disorders or autoimmune diseases may result in the reduction or disappearance of the antiphospholipid antibody. Corticosteroids are not recommended unless there is an associated autoimmune disorder. Patients who sustain a thrombotic event, whether arterial or venous, are managed with long-term anticoagulation by using oral anticoagulants. Aspirin alone fails to prevent recurrent thrombosis. Pregnant patients with the lupus anticoagulant or anticardiolipin antibody can be treated with low- or intermediate-dose heparin with or without daily aspirin. LMWHs are likely to be as efficacious as unfractionated heparin and a safe, convenient alternative.

ACKNOWLEDGMENT

We wish to recognize the contributions of Mary Eberst, MD, for chapter content in previous editions.

HEMOPHILIAS AND VON WILLEBRAND DISEASE Robin R. Hemphill

Hemophilias are bleeding disorders due to deficiency or defect in one of the factors present in the clotting cascade.¹ The most common factor abnormalities are of factor VIII (hemophilia A or classic hemophilia) or factor IX (hemophilia B or Christmas disease), von Willebrand disease is a related hereditary deficiency, a defect in a portion of the factor VIII complex.²

The hereditary disorders typically appear early in life and adult patients will usually be able to relate a history of a bleeding disorder in themselves or their family. However, patients with mild forms of inherited disease may be unaware of a bleeding disorder until stressed by significant trauma or development of another hemostatic problem. Because of new mutations, patients with congenital coagulopathies may not have a family history of bleeding.

Systemic bleeding disorders should be suspected in patients with severe bleeding related to trivial trauma or minor surgery, or spontaneous bleeding, particularly when the bleeding occurs in joints or muscle. Unusual bleeding or bruising at multiple areas should also raise concern about a coagulopathy. Medications can be responsible for unmasking a mild bleeding diathesis and a complete inquiry of current and recent medication use is warranted.

The pattern of bleeding can suggest a likely etiology. For example, patients with easy bruising, gingival bleeding, epistaxis, hematuria, gastrointestinal bleeding, or heavy menses are more likely to have a deficiency or dysfunction of the platelets. Conversely, patients with spontaneous deep bruises, hemarthrosis, retroperitoneal bleeding, or intracranial bleeding are more likely to have a coagulation factor deficiency. In factor-deficient patients, bleeding associated with trauma may be delayed. This is presumed to be due to the instability of the initial platelet thrombus that is inadequately stabilized by fibrin clot formation. Patients with von Willebrand disease may present with features of both platelet and clotting factor problems.

HEMOPHILIA

Hemophilia is a disorder of coagulation caused primarily by a deficiency or defect in one of two circulating plasma proteins.^{1,2} Hemophilia A or "classic" hemophilia is caused by a deficiency of factor VIII and is the most common cause of hemophilia in the United States, affecting 1 in 10,000 males. Hemophilia B or Christmas disease is caused by a deficiency of factor IX and is less common, affecting approximately 1 in 25,000 to 35,000 males. Together these forms of

hemophilia make up about 99 percent of patients with inherited coagulation factor deficiencies. Hemophilia A and B are clinically indistinguishable from each other, and specific factor testing must be done to identify the specific type of hemophilia.

Both hemophilia A and B are X-linked recessive disorders, therefore this is overwhelmingly a disease of men with women being asymptomatic carriers. However, approximately one-third of new cases of hemophilia A and one-fifth of new cases of hemophilia B arise from a spontaneous gene mutation.

Bleeding manifestations in patients with all forms of hemophilia are directly attributable to the decreased plasma levels of either factor VIII or IX. Individuals with factor levels below 1 percent of normal are classified as having severe disease, and these people will experience severe spontaneous bleeding episodes and difficult-to-control bleeding related to traumatic events. Patients with levels of 1 to 5 percent of normal are classified as having moderate disease. They may bleed spontaneously, but most commonly their bleeding is related to a traumatic event. Patients with factor levels of 5 to 25 percent of normal are classified as having mild disease. They will usually bleed only after trauma. Those with factor levels of 25 to 50 percent may never be aware that they have hemophilia, or they might manifest unusual bleeding only after major surgery or severe trauma. Unless there is another underlying disease, patients with hemophilia do not have problems with minor cuts and abrasions. Treatment of patients with hemophilia relies on either the replacement of missing factors, or for those who have mild factor VIII deficiency, stimulating the body to secrete additional clotting factor from intracellular stores.

Bleeding is the major complication of hemophilia, but as a result of exposure to blood products, many hemophiliacs have chronic viral hepatitis or are infected with the human immunodeficiency virus (HIV). Fortunately, as a result of newer viral inactivation procedures, there have been few seroconversions resulting from the use of currently available factor replacement products.

Clinical Manifestations

Depending on the severity of the disease, both types of hemophilia are characterized by easy bruising and recurrent bleeding into the joints and muscles. While the joints and muscles are the most common areas into which bleeding occurs, hemorrhage may also occur in the abdomen, retroperitoneum, or the central nervous system (Table 220-1). Any trauma or surgical procedure can result in prolonged and difficult-to-control bleeding.

TABLE 220-1 Common Bleeding Manifestations in Patients with Hemophilia

Site	Comments
Hemarthroses	Leads to joint destruction and chronic arthropathy if not treated aggressively
Hematomas	Bleeding into soft tissues or muscle; this bleeding can dissect along fascial planes; most dangerous near in the neck (airway compromise), limbs (compartment syndromes), and retroperitoneum (massive blood loss)
Mucocutaneous bleeding	Spontaneous bleeding uncommon from the oropharynx, gastrointestinal tract, epistaxis, or hemoptysis; delayed bleeding after dental extractions is common
Central nervous system	Intracranial bleeding is the most common cause of hemorrhagic death in hemophiliacs with a reported 34% mortality; subdural hematomas occur spontaneously or with minimal trauma
Hematuria	Common, usually not serious, and the source is rarely found
Pseudotumor	Bone cysts that result from unresolved hematomas; usually have to be removed surgically

While adults often know that they have hemophilia, young children may not have been diagnosed at the time that they present to the ED. A family history may reveal bleeding disorders. Hemophilia should be suspected in any infant or child that presents with excessive bruising or with significant bleeding into the joints, muscles, or central nervous system that is spontaneous or out of proportion to the history of trauma. Because factor level determines the severity of disease, those with mild hemophilia may come to medical attention only when they have a significant surgical procedure or trauma or have started a medication with antihemostatic effects. In addition, excessive bruising and bleeding out of proportion to the described trauma should raise consideration of child abuse, a condition much more common than hemophilia.

Laboratory Testing

In patients with hemophilia, the prothrombin time (PT), which measures the extrinsic coagulation cascade, will be normal, while the activated partial thromboplastin time (aPTT), which measures the intrinsic coagulation cascade, will be abnormal. However, if the factor VIII level in hemophilia A or factor IX level in hemophilia B is greater than 30 percent of normal activity (mild hemophilia), the aPTT may be normal. **Bleeding time in both forms of hemophilia will be normal.** Specific factor assays can be done to help determine the exact nature of the clotting deficiency if the diagnosis is new. Coagulation studies are unlikely to yield new information in the known hemophiliac and are not routinely indicated when the patient presents with mild to moderate bleeding episodes.

Initial Assessment

A general principle in managing major or life-threatening bleeding in a hemophilic patient is early and complete factor replacement, before or at the same time as other resuscitative and diagnostic maneuvers. Spontaneous or traumatic bleeding into the neck, tongue, retropharynx, or pharynx has a high potential for airway compromise. Airway management, including oral intubation, is appropriate if there is the potential for airway compromise. Bleeding into the central nervous system (CNS) can occur spontaneously as well as after trauma. Any patient with hemophilia who complains of a new headache, localizing neurologic symptoms, or a blunt head injury requires immediate factor replacement therapy followed by urgent computed tomographic (CT) scanning of the head. If the neurologic deficit localizes to a region within the spinal cord, magnetic resonance imaging (MRI) is appropriate. Hemophilic patients with complaints of back, thigh, groin, or abdominal pain may have bleeding into the retroperitoneum. Again, immediate factor replacement and CT scanning are indicated. If a hemophiliac patient requires transfer, factor replacement should be initiated before transfer and not be delayed by attempts to obtain imaging. Even in the patient who initially appears well, transport to specialized centers should be considered for intracranial, intrathoracic, retroperitoneal, or intraabdominal bleeding.

At times the initial manifestations of bleeding can be subtle. Simple injuries such as ankle and wrist sprains may at first appear benign but can be complicated by bleeding. Compartment syndromes can result from muscle bleeds within the fascial compartments of the extremities, both spontaneously and after minimal trauma to an extremity. If compartment syndrome is a concern, the compartment pressures can be safely measured after the patient has received factor replacement.

One of the most common manifestations of hemophilia is hemarthrosis. There may or may not be clinical evidence of an acute hemarthrosis, but patients can reliably report when bleeding is occurring. Prompt treatment of hemarthroses can prevent or reduce the long-term sequelae of hemophilic arthropathy. If a large hemarthrosis is already present, consultation with an orthopedist for appropriate splinting and rehabilitation may improve the outcome once the bleeding has been controlled. Infants with hemophilia are difficult to evaluate. If

an infant is irritable and no other source is found, there should be a presumption of occult bleeding.

Many patients and their families have a very sophisticated understanding of their disease. Patients will know to seek treatment at the first symptom when there may initially be little outward evidence of pathology. Despite minimal findings, patient concerns should be taken seriously. Many will have a detailed management plan for acute bleeding episodes in the medical record that should be consulted. A specific point needs to be made about pain management. Many of the above conditions are terribly painful. Pain control needs to be aggressively addressed. Even with a history of opiate abuse, if there is an obvious site of contained bleeding, the patient should receive analgesics.

When treating patients with hemophilia for other reasons, certain principles need to be kept in mind. Central lines, including femoral lines and external jugular lines, should not be placed in patients with hemophilia without factor replacement therapy. Similar rules apply to arterial blood gases or lumbar puncture. Patients with hemophilia should never receive intramuscular injections unless factor replacement is given and maintained for several days. Patients undergoing invasive procedures will also require factor replacement. Do not give compounds that contain aspirin or nonsteroidal anti-inflammatory agents for pain relief. If there is ever doubt or concern about the need for factor replacement in a hemophiliac, a hematologist should be consulted.

Treatment

Factor replacement therapy is effective in controlling hemorrhage in hemophilia.³ There are now two different treatment options: recombi-

nant factor replacement or plasma-derived and purified factor replacement (Table 220-2). The highest level of purity comes from the recombinantly produced factors. However, the cost of these products is high and they are not available everywhere. While the purity of the plasma-derived factors has improved, it does remain possible for even the treated plasma-derived products to potentially transmit viruses such as hepatitis A and the highly heat resistant parvovirus. Another concern with the plasma-derived factors is that some of the preparations may contain other coagulation factors. Prolonged use of the less pure concentrates may increase the risk of DIC, or in some cases cause paradoxical clotting.

The choice of which product to use in replacement therapy is dependent on considerations of safety, the cost, and the availability.⁴ The recombinant forms cost two to three times as much as the plasma-derived factors and occasionally there are shortages of these factors. However, because the recombinant forms are perceived to be safer, approximately 60 percent of patients with severe hemophilia in the U.S. receive these preparations.

The dosing regimen used in the hemophilic patient is based on the clotting factor volume of distribution, the half-life of the factor, and the hemostatic level of factor required to control the bleeding (Table 220-3).⁵ Clotting factor is dosed in units of activity. One unit of factor represents the amount of factor present in 1 mL of normal plasma. In the case of hemophilia A, one unit of factor VIII per kg of body weight raises the plasma level by approximately 0.02 U/mL (2 percent). The half-life of factor VIII is approximately 8 to 12 h. For hemophilia B, one unit of factor IX per kilogram of body weight will raise the plasma level by approximately 0.01 U/mL (1 percent). The half-life of factor IX

TABLE 220-2 Available Products for Hemophilia Treatment

Hemophilia Type	Available Products	Comments
Hemophilia A	<i>Human plasma-derived factor VIII products</i> Koate-HP (gel chromatography, solvent and detergent purified) Humate-P (heat treated) Alphanate (solvent and detergent purified)	All have a low risk of HIV and hepatitis transmission
	<i>Human plasma-derived factor VII with immunoaffinity purification</i> Hemofil M (monoclonal, solvent and detergent purified) Monoclote-P (monoclonal and heat treated)	Both have reduced amounts of vWF; Monoclote-P is highly purified source of factor VIII
	<i>Recombinant factor VIII products</i> Recombinate (recombinant DNA product) Gelixate (recombinant DNA product) Bioclote (recombinant DNA product) Kogenate (recombinant DNA product)	Low to no risk of HIV and hepatitis transmission
	<i>Porcine factor VIII products</i> Antihemophilic factor (cryoprecipitate fractionation, screened for porcine viruses) Hyate C (cryoprecipitate fractionation, screened for porcine viruses)	No evidence that human viral infection occurs
Hemophilia B	<i>Factor IX complex products</i> Koyne-80 factor IX complex (heat treated) Proplex T factor IX complex (heat treated) Profilnine SD (solvent and detergent purified) Bebulin VH (two-step vapor heat treatment)	Proplex T: HIV seroconversion has occurred Other products have low risk of HIV and hepatitis transmission
	<i>Activated factor IX complex products</i> Autoplex T (heat treated) Feiba VH (two-step vapor heat treatment)	Low risk of HIV and hepatitis transmission
	<i>Purified factor IX products</i> Alpha Nine SD (solvent and detergent purified, polysorbate) Mononine (monoclonal antibody purification, ultrafiltration)	Low risk of HIV and hepatitis transmission
	<i>Recombinant factor IX products</i> BeneFIX (recombinant DNA product)	No known risk of transmission

Abbreviation: vWF = von Willebrand factor.

TABLE 220-3 Initial Factor Replacement Guidelines in Severe Hemophilia

Site	Minimum Initial Factor Level	Hemophilia A Initial Dose	Hemophilia B Initial Dose	Details
Deep muscle	40–50%	20–40 U/kg	40–60 U/kg	Admit, monitor total blood loss, watch for compartment syndrome Duration of replacement: 1–3 days
Joint	30–50%	20–40 U/kg	30–40 U/kg	Orthopedic consult for splinting, physical therapy, and follow-up Duration of replacement: 1–3 days
Epistaxis	80–100%	40–50 U/kg	80–100 U/kg	Local measures should be used Replacement is given until bleeding resolves
Oral mucosa	50%	25 U/kg	50 U/kg	Local measures and antifibrinolytic therapy will decrease need for additional factor replacement Duration of replacement: 1–2 days
Gastrointestinal bleeding	100%	40–50 U/kg	80–100 U/kg	Consultation with a gastroenterologist for endoscopy to locate potential lesion is appropriate Duration of replacement: 7–10 days
Central nervous system	100%	50 U/kg	100 U/kg	Neurosurgical consultation should be done early Lumbar puncture requires factor replacement

is approximately 16 h. Calculation of the amount of factor needed can be done using the patient's weight and the desired increase in factor:

Factor VIII required = weight in kg x 0.5 X (% change in factor activity needed) **Factor IX required = weight in kg X 1.0 x (% change in factor activity needed)**

To avoid wasting factor, round off all doses to the closest vial.

When major bleeding occurs in the central nervous system, gastrointestinal tract, neck, throat, in a large muscle, or when a severe injury is present, factor replacement levels between 80 and 100 percent are necessary. In these cases therapy will need to continue for days or weeks. Factor replacement can be given as bolus therapy or as a continuous therapy. Continuous therapy may help decrease the total amount of factor required, but is best administered by those familiar with this method.⁶

When less severe bleeding occurs in soft tissue, muscle, or joints, the appropriate factor replacement level is from 30 to 50 percent. Usually three doses over 1 to 2 days are sufficient to control bleeding and prevent additional bleeding, although the clinical picture should be reassessed to ensure that the expected improvement is seen. In addition to factor replacement, extremity and joint bleeding may benefit from splinting followed by physical therapy.

There may be rare instances in which a patient presents with what appears to be a previously undiagnosed bleeding disorder. In these cases the use of a specific factor may not be possible, and the emergency physician may need to use fresh-frozen plasma (FFP) or cryoprecipitate (contains factor VIII and vWF; use is only appropriate if there is strong suspicion that the bleeding presentation is due to hemophilia A or von Willebrand disease) to control bleeding until definitive studies can be done. As is true of the other replacement factors, the measures used to purify FFP and cryoprecipitate have improved, and the risk of transmitting diseases such as HIV and hepatitis is far less than in the past. Each bag of cryoprecipitate contains about 100 units of factor VIII and variable amounts of von Willebrand factor (vWF). FFP contains all of the plasma clotting factors with an average concentration of 1 U/mL. However, one unit of FFP will only raise the factor levels by 3 to 5 percent, so volume overload can complicate extensive factor replacement using FFP. FFP is the most appropriate choice if there is no family history to suggest the type of bleeding disorder.

Specific Problems

ORAL AND MUCOSAL BLEEDING Bleeding from the mouth is common in hemophiliacs, particularly children. This bleeding is wors-

ened by the fact that saliva contains fibrinolysins. For an oral bleed, the area should be identified and then cleaned of inadequate clot, and a dry topical thrombin placed on the bleeding site. Initial factor replacement should be 80 to 100 percent. However, additional therapy may still be needed to prevent bleeding when the clot falls off. For oral or mucosal bleeding, antifibrinolytic agents such as epsilon-aminocaproic acid (EACA) and tranexamic acid are useful adjunctive therapy to factor replacement. For very superficial mucosal injuries, it may be possible to manage the bleeding with antifibrinolytic therapy alone. Patients should be closely monitored to ensure response. The dose of EACA is 75 to 100 mg/kg q6h for children, and 6 g q6h for adults, given PO or IV. Topical hemostatic agents used to help control oral or nasal bleeding include microfibrillar collagen hemostats, thrombin, and absorbable gelatin sponges.

MILD HEMOPHILIA A Patients with mild hemophilia A (factor levels of 5 percent of normal or greater) who have mild bleeding may not always require factor replacement. Rather, they may be given desmopressin (DDAVP).⁷ Desmopressin is believed to cause release of von Willebrand factor from endothelial storage sites. The increased amount of vWF is capable of carrying additional amounts of factor VIII in the plasma. This medication is well tolerated and patients can administer it at home by the subcutaneous route. When giving intravenous desmopressin, the dose is 0.3 (xg/kg (maximum dose 20 |xg) over 30 min. A concentrated intranasal form of desmopressin is also an option for use in hemophilia. For children older than age 5, a single spray in a single nostril (150 |xg total dose) is adequate. For adolescents and adults, a single spray in each nostril is used (300 |xg total dose). This dose of intranasal DDAVP will increase the factor VIII level by 2 to 3 times. This treatment can be repeated in 8 to 12 h, but the patient's stores of factor VIII will become depleted, and subsequently the effect will be less. DDAVP is an antidiuretic agent, and fluid restriction may be needed during use.

INHIBITORS Inhibitors, antibodies against replacement factors, tend to occur most commonly in severe hemophiliacs because of frequent factor replacement. Inhibitors not only interfere with the effectiveness of factor replacement therapy but can cause anaphylaxis during factor administration in patients with hemophilia B.⁸ Inhibitors occur in 10 to 25 percent of those with hemophilia A and 1 to 2 percent of those with hemophilia B. The use of factor replacement in hemophilic patients with inhibitors is guided by the concentration of inhibitor [measured in Bethesda inhibition assay (BIA) units] and the type of response the patient has to factor concentrates.

Patients with inhibitors are more difficult to treat during bleeding episodes, but options do exist (Table 220-4).⁹ In patients with an inhibitor titer less than 5 BIA and who are not vigorous antibody responders, an increased dose of factor can be given in an attempt to overwhelm the existing antibody. Alternative therapies include porcine factor VIII, prothrombin complex concentrates that circumvent the factor deficiency, activated prothrombin complex concentrates, and recombinant activated factor VII (rFVIIa). The rFVIIa is thought to act by competing against normal plasma-nonactivated factor VII for tissue binding, thus enhancing thrombin generation, and by binding to activated platelets, thereby activating factors IX and X on the platelet surface in the absence of tissue factor. Given the complexity of treating these patients, consultation or transfer to a hemophiliac center is recommended.

Indications for Hospital Admission

Hemophilic patients with bleeding episodes will require hospital admission in these situations:

Bleeding involving the CNS, neck, pharynx, retropharynx, or retroperitoneum

Potential compartment syndrome

Treatment requiring more than three doses (relative indication)

Inability to use or lack of access to factor replacement Inability to control pain with oral analgesics

VON WILLEBRAND DISEASE

von Willebrand disease (vWD) is the most common congenital bleeding disorder, present in 1 percent of the population.¹⁰ This disease is a group of disorders caused by abnormalities of vWF. The disease is heterogeneously inherited and expressed and, although there are multiple subtypes, can be classified into three major groups (Table 220-5). Type I is the most common and is a partial quantitative disease, type II is qualitative (abnormal function), and type III is a severe and almost complete deficiency of vWF (this type is a rare autosomal recessive form). vWF is a glycoprotein that unlike most other coagulation factors, is synthesized, stored, and then secreted by the vascular endothelial cells.

von Willebrand factor serves two key roles in normal hemostasis.¹¹ It is a cofactor for platelet adhesion as well as the carrier protein for factor VIII. Circulating vWF does not bind directly to platelets, but when exposed to the subendothelial matrix, vWF undergoes a structural change, allowing it to bind to platelet glycoprotein Ib. This inter-

action between vWF and platelet glycoprotein Ib leads to platelet activation and adhesion to other platelets, as well as to the damaged endothelium. The vWF is also a carrier protein for factor VIII. When vWF is absent, the half-life of factor VIII will decrease because vWF protects the factor VIII from proteolytic degradation within the plasma. If vWF fails to bind factor VIII due to defect or severe deficiency, the clinical presentation is similar to hemophilia A.

Clinical Manifestations

Skin and mucosal bleeding symptoms are common in people with vWD, particularly in children and adolescents. This includes recurrent epistaxis, gingival bleeding, unusual bruising, gastrointestinal bleeding, and menorrhagia in young women. Hemarthrosis is not typical unless severe disease is present. In mild cases of vWD the patient may be unaware of the disease until they have a surgical procedure or traumatic event and unexpected bleeding occurs.

Laboratory Tests

Diagnostic tests used to diagnose von Willebrand disease include bleeding time, aPTT, factor VIII coagulant activity, vWF antigen, and vWF activity. It is possible for some laboratory tests to be normal even in those with disease. However, the common abnormalities include prolonged bleeding time, low or normal vWF antigen, and low vWF activity. The PT should be normal and about half of patients have a mildly prolonged aPTT. Variability in vWF levels can sometimes make vWD difficult to differentiate from mild hemophilia A. The patient's blood type also affects the vWF, with blood type O having as much as a 30 percent reduction in vWF levels compared to the other blood types.

Treatment

von Willebrand disease is relatively common, and in addition to bleeding episodes, the presence of vWD has influence on treatment for other medical problems.¹² Medications with known antiplatelet effects should be avoided, including aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), antiplatelet agents, heparin, and some antibiotics.

NONTRANSFUSIONAL THERAPIES Desmopressin (DDAVP) has become a mainstay of therapy for many patients with type I vWD.^{7,12} For the other types of vWD, DDAVP may still work in conjunction

TABLE 220-4 Replacement Therapy for Hemophilia A and B in Patients with Inhibitors

Type of Product	Hemophilia A Dose	Hemophilia B Dose	Comments
Factor VII concentrates	5000–10,000 unit bolus followed by a continuous infusion	Not applicable	
Prothrombin complex concentrates (PCCs), contain factors II, VII, IX, X	75–100 U/kg	75–100 U/kg	Risk of DIC, thromboembolic disease, and low risk of hepatitis transmission
Activated prothrombin complex concentrates (aPCCs), contain factors II, VII, IX, X, with variable amounts of activated factors VIIa, IXa, and Xa	75–100 U/kg	Approximately 75 U/kg	Similar risks as with the PCCs
Recombinant factor VIIa (NovoSeven)	Variable	Variable	No risk of viral transmission
Porcine factor VIII (Hyate C)	Variable	Not applicable	Patients may develop inhibitors
Highly purified factor IX concentrates	Not applicable	Variable	

Abbreviation: DIC = disseminated intravascular coagulation.

TABLE 220-5 Simple Classification and Treatment of von Willebrand Disease

Type	Frequency	Defect	Treatment
I	70–80% of cases	All the multimeric forms are present, but in decreased quantity (about 20–50% normal levels)	Desmopressin (DDAVP) and if no response, consider the measures below
II	10–15% of cases	The von Willebrand molecule is abnormal and dysfunctional	Factor VIII concentrates or cryoprecipitate
III	Less than 10% of cases	Almost no von Willebrand factor present	Factor VIII concentrates or cryoprecipitate

with plasma products that contain vWF. Desmopressin induces the release of vWF from storage sites within the endothelium. In responsive individuals it causes a transient two- to fourfold increase in vWF. Desmopressin also seems to have an effect on the endothelium that promotes hemostasis. The dose is 0.3 [xg/kg (maximum 20 [xg] of body weight, administered SC or IV every 12 h to a total of three or four doses; after four doses, tachyphylaxis develops. A concentrated form of desmopressin is also available as an intranasal spray. For children older than age 5, a single spray in a single nostril is adequate (150 [xg total dose). For adolescents and adults, administer a single spray in each nostril (300 [xg total dose). Again, the number of times this can be used is limited.

TRANSFUSIONAL THERAPIES Plasma derivatives that contain vWF are used for those type I patients that do not (or no longer) respond to DDAVP or have type II or III vWD.¹² The chosen product needs to have vWF in the high-molecular-weight form to be effective. Cryoprecipitate meets this objective (contains factor VIII and vWF), but there is concern about the potential for viral transmission. The administration of 10 bags of cryoprecipitate every 12 to 24 h will usually control bleeding. Because of the risk of viral contamination, factor VIII products that contain multimeric vWF and have undergone viral inactivation processes are preferred. Humate-P is an intermediate-purity factor VIII concentrate that has significant amounts of vWF, and can be used to treat bleeding episodes. Cryoprecipitate from a limited number of donors is another possibility. Platelet transfusions may benefit patients with certain types of vWD (type III) who do not respond to vWF-containing plasma products.

ADDITIONAL THERAPY Patients with a history of vWD and have significant epistaxis should receive the normal measures taken to control bleeding. If these are not successful, intranasal application of porcine strips (Surgicel) or porcine strips sprinkled with microfibrillar collagen (Avitene) may help control bleeding. Caution is necessary in some cases.

Menorrhagia is a common complaint in young women with vWD. Birth control pills can help raise vWF levels and limit the degree of menstrual bleeding. DDAVP may also be used in responsive individuals.

For dental injury or planned procedures in the oral cavity, an antifibrinolytic agent should be used. EACA can be taken orally and tranexamic acid can be made into a mouthwash. These may be used for 5 to 10 days after the injury or surgical procedure.

ACKNOWLEDGMENT

Thank you to the previous author, Mary Eberst, for her work.

HEREDITARY HEMOLYTIC ANEMIAS Robin R. Hemphill

The hereditary hemolytic anemias are characterized by defects of hemoglobin or the red cell membrane that result in premature destruction of red cells. These disorders include hemoglobins that tend to gel or crystallize, unstable hemoglobin with abnormal oxygen-binding properties, hemoglobin that is readily oxidized to methemoglobin, and hemoglobin chains that are synthesized at unequal rates. This chapter discusses the common inherited hemolytic anemias: sickle cell anemia and its variants, thalassemia, glucose-6-phosphate dehydrogenase deficiency, and hereditary spherocytosis.

SICKLE CELL ANEMIA (SCA)

Pathophysiology

The normal adult red blood cell (RBC) contains three forms of hemoglobin (Hb): HbA, HbA₂, and HbF (fetal hemoglobin) (Table 221-1). Normal hemoglobin consists of a tetramer of four polypeptide chains: two α -globin chains and two non- α -globin chains. Hemoglobin A accounts for about 96 to 98 percent of adult hemoglobin and consists of two α - and two β -globin chains ($\alpha_2\beta_2$). HbA₂ accounts for about 2 to 3.5 percent of adult hemoglobin and is composed of two α - and two δ -globin chains ($\alpha_2\delta_2$). Fetal hemoglobin is composed of two α - and two γ -globin chains ($\alpha_2\gamma_2$). HbF production peaks in utero and starts declining just before birth and continues to decline, reaching a baseline at about 48 weeks of age. Because of the 120-day life span of the normal RBC, HbF is the predominant hemoglobin in the circulation for about the first 4 months of life. The α -globin chains are coded by four genes on chromosome 16, whereas the β -, γ -, and δ -globin chains are coded by two genes each on chromosome 11. A *hemoglobinopathy* is an inherited disease resulting from the presence of one or more abnormal hemoglobins.

TABLE 221-1 Composition of Normal Human Hemoglobin and Hemoglobin Variants

Syndrome	Types of Hemoglobin Present	Percent	Hemoglobin Tetramer Composition (Globin Chains)
Normal adults	HbA	96-98%	aa/pp
	HbA ₂	3-3.5%	aa/55
	HbF	0.5-0.8%	aa/77
Sickle cell trait (heterozygous)	HbA	60-65%	aa/pp aa/pP-
	HbAS	35-40%	sickle aa/77
	HbF	0.5-0.8%	
Sickle cell disease (homozygous)	HbSS	80-90%	aa/p-sickle p-sickle
	HbA ₂	2-4%	aa/55 aa/77
	HbF	20%	

SCA is caused by the substitution of the amino acid valine for glutamine at position 6 in the (3-globin chain).¹ This is the most common variant of hemoglobin and is known as *hemoglobin S* (HbS). As a result of this mutation, deoxygenated HbS polymerizes, deforming the RBC and producing the characteristic sickled appearance. The distorted cell results in premature RBC destruction and also increases the viscosity of blood, leading to obstruction within the microvasculature.² The overall effect is chronic ongoing hemolysis and episodic periods of vascular occlusion, resulting in tissue ischemia affecting most organ systems.

This defect is inherited as an autosomal recessive trait, and disease is seen in patients who are homozygous for the sickle gene (*HbSS*). **People with sickle cell trait** (*HbAS*, heterozygous with one gene for normal [3-globin chain and one gene for a [3-globin chain with the sickle mutation) **have a normal life span and usually are asymptomatic**, except in rare cases of severe physiologic stress, when they may suffer an acute pain crisis, splenic infarction, or cerebrovascular complications. Approximately 8 percent of the African-American population carries sickle cell trait (heterozygous for the sickle cell gene), and approximately 0.15 to 0.2 percent of African-American newborns have sickle cell disease (SCD) (homozygous for the sickle gene). A lesser percentage of individuals of Middle Eastern, eastern Mediterranean, and Indian descent may have the HbS gene. While sickle cell anemia accounts for the majority of disease, other sickle cell disorders can result from the coinheritance of a sickle cell gene and α -thalassemia or other hemoglobin abnormality.

The pathophysiologic effects of SCD are due to the polymerization of deoxygenated HbS that deforms the red cell into a sickled shape that causes microvascular sludging and obstruction (vasoocclusion). This obstruction worsens hypoxia and causes acidosis in the microcirculation that contributes to further sickling. The sickling process is reversible initially when the HbS is reoxygenated, but with repeated episodes of sickling, the red cell membrane is permanently damaged, and the cell remains irreversibly sickled. Anywhere from 5 to 50 percent of the circulating erythrocytes in a patient with SCD can be irreversibly sickled cells (ISCs). The sickling process is inhibited by the presence of fetal hemoglobin (HbF) and other hemoglobin variants. Structural and antigenic changes on the RBC membrane cause an increased abnormal tendency for the RBC to catalyze plasma coagulation factors and adhere to vascular endothelium in sickle cell disease. Paradoxically, ICSS lose this heightened ability for vascular endothelial adherence, and patients with high levels of circulating ICSS have fewer vasoocclusive crises. As stated earlier, the abnormal shape of the RBCs causes a decreased life span and yields a chronic hemolytic anemia. The combination of hemolytic anemia and recurrent vasoocclusive events provides the basis for this chronic disease.

Patients with SCD have a significantly decreased life span that in the past was predominately due to early death from infection. Prevention

TABLE 221-2 Emergencies in Sickle Cell Disease

but complications related to the disease continue to reduce life span.

Clinical Presentations

Because newborn screening takes place in the United States and most developed countries, most patients that present to the ED will already know that they have sickle cell trait or disease. Infants are protected from sickle cell complications during their initial six months of life largely due to the continuing presence of significant amounts of HbF. The continued presence of HbF in adults with SCD is protective, and the level of HbF inversely correlates with the frequency and severity of SCD complications. SCD should be considered in any child of African, Middle Eastern, or Indian descent with a presentation of unexplained pain or swelling in the extremities, anemia, or splenomegaly. The peripheral smear can be normal, and absence of anemia does not exclude the diagnosis in children younger than 4 years of age. Screening tests (such as hemoglobin solubility or sickle cell preparation) are not reliable before 6 months of age, may be falsely negative with severe anemia, and will not distinguish sickle cell trait from SCD. Accurate diagnosis requires hemoglobin electrophoresis. SCD patients typically present to the emergency department because of complications, most commonly vasoocclusive painful crisis (Table 221-2).

VASOOCCLUSIVE PAIN CRISIS Acute painful sickle crisis is a common problem, and the average patient with SCD will have one to four severe attacks per year. The initiating event may not be identifiable, but stressors such as infection, cold, dehydration, and altitude have been implicated. As a result of intravascular sickling and small vessel occlusion, infarction of bone, viscera, and soft tissue occurs. This is manifested as diffuse bone, muscle, and joint pain and, in some cases, symptoms related to a specific affected organ. Initial management of these patients includes aggressive pain management and hydration and an assessment of the cause of the current crisis as well as a search for additional complications.¹

Supplemental oxygen is used commonly for painful crises, but unless the patient is systemically hypoxemic, it has not been proven to be of routine benefit. Treatment of acute pain requires opioids, and severe pain should be treated with parenteral agents, commonly intravenously in the United States and subcutaneous in the United Kingdom.^{3,4} A potent opioid, such as morphine or diamorphine, is recommended, and meperidine, with the potential for neurotoxicity from the metabolite normeperidine, is not recommended. Some patients, because of prior opioid treatment, may be very tolerant, and large doses may be required. Regular doses of analgesics for a few hours to several days typically are required. Patient-controlled analgesia can be used in selected patients. Nonsteroidal anti-inflammatory drugs can be used for their additive effect in pain management of sickle cell crisis.⁴ SCD patients with a painful crisis have an absolute or relative hypovolemia due to

Vasoocclusive crises	Musculoskeletal pain (typical painful crisis)
	Dactylitis (hand-foot syndrome)
	Acute chest pain syndrome
	Stroke
	Priapism
Hematologic crises	Splenic sequestration
	Aplastic crisis
	Hemolytic crisis
Infections	Pneumonia
	Meningitis
	Sepsis
	Osteomyelitis
	Urinary tract infections

their disease (deficient renal concentrating ability) or crisis (anorexia, vomiting, fever), so aggressive oral or intravenous rehydration is done commonly. Research into therapies to shorten the duration or severity of painful crises has found small but statistically significant benefit with induced hyponatremia and purified poloxamer 188.^{5,6} However, no current approach to shortening the duration and severity of a painful sickle cell crisis has proven reliable, safe, and appropriate for routine use. A common and recommended practice is to develop an individualized assessment and treatment protocol for specific patients who frequently present to the emergency department with painful crises.⁷

Simple or exchange transfusion to reduce the concentration of HbS-containing RBCs to below 30 percent can prevent or reverse the vasoocclusive process.⁸ Transfusion should avoid raising the hematocrit above 36 percent in sickle cell patients. However, transfusion carries significant expense, the risk of blood-borne disease transmission, and the potential for iron overload and exposes the patient to the minor RBC antigens with the potential to induce antibodies that prevent or complicate future transfusions. Transfusion for sickle cell crisis or complications is reserved for specific indications, such as aplastic crisis, pregnancy, stroke, respiratory failure, general surgery, and priapism.^{8,10}

Hydroxyurea has been used to reduce the frequency and severity of painful crises.¹¹ The major side effect is bone marrow, hepatic, and renal toxicity. Hydroxyurea has not been approved for use in children. Daily prophylactic penicillin V reduces the incidence of infections and reduces mortality from sepsis in children.¹² A number of emerging therapies are being studied for prevention and treatment of SCD crises and complications.¹³

Generally, a complete blood count and reticulocyte count help to assess the degree of anemia and ensure that the marrow is still producing red cells. If the reticulocyte count is not available, the presence of polychromasia in the peripheral blood smear can be used to provide evidence of continued RBC production. It is not uncommon for the sickle cell patient to have a low-grade temperature as well as an elevated white blood cell (WBC) count. This combination can make it difficult to differentiate whether an infection is present during a crisis. If the WBC count has a left shift and is elevated above 20,000/ \times L, a potential infection should be considered. Because of the chronic hemolysis, mild elevations in bilirubin and serum lactate dehydrogenase (LDH) levels are common.

Specific issues with an acute vasoocclusive crisis include the following:

Bone Pain Bone pain is common during a sickle cell crisis and may include the back and the extremities.¹⁴ Usually the pain will be diffuse, and there will be no physical findings. However, redness, warmth, or swelling suggests infection (cellulitis or osteomyelitis). The complaint of localized pain to the hip with difficulty ambulating raises the possibility of aseptic necrosis of the femoral head, and approximately 30 percent of SCA patients develop hip pathology by age 30. Bone infarctions may cause symptoms similar to osteomyelitis.¹⁵ Joint effusions are seen occasionally as a complication of sickle cell crisis, but arthrocentesis is often necessary to determine if the joint is infected. Plain radiographs may show evidence of aseptic necrosis or osteomyelitis, whereas bone infarcts usually are not visible on radiographs. A bone scan or magnetic resonance imaging (MRI) may be necessary to differentiate infection from infarction.

In young children, an early manifestation of SCD is dactylitis (hand-foot syndrome). The syndrome is thought to be due to infarction of the red marrow with associated periosteal inflammation. The syndrome manifests as fever and painful swelling of the hands, feet, or both, and some redness and warmth may be present. As the child grows, the hematopoietic tissue in the metacarpal and phalangeal marrow is replaced by fatty tissue, making this entity less likely.

Chest Syndrome The acute chest syndrome is used to describe a sickle cell crisis with pulmonary symptoms and a new pulmonary infiltrate found on radiograph.¹⁶ The patient may have pleuritic chest

pain, shortness of breath, fever, nonproductive cough, and tachypnea. The exact etiology of the chest syndrome is unclear, but infection, infarction (ribs and/or lung), and pulmonary fat embolism (from ischemic marrow fat necrosis) all have been implicated. It can be difficult to distinguish pneumonia from pulmonary infarction. A chest radiograph is not required routinely in all patients with painful sickle cell crisis but is indicated in those with pulmonary symptoms, decreased Sao_2 , or signs of fever.¹⁷ The onset of acute chest syndrome may be associated with a fall in hemoglobin level from the normal baseline. Pulmonary infiltrates may be present in one lobe or be diffuse and bilateral, and pleural effusions also may be present. Severe cases may progress rapidly to respiratory failure. The initial chest radiograph may be normal, so the patient with pulmonary symptoms may require serial radiographs.

Treatment involves close monitoring of fluid status, oxygen, and pain control. Therapy should assume the cause to be both pulmonary infarction from microvascular occlusion and infection.¹⁸ Broad-spectrum antibiotics to cover *Streptococcus pneumoniae* and *Mycoplasma pneumoniae* are recommended. In severe cases, simple transfusion or exchange transfusion can be done. The acute chest syndrome is currently the leading cause of death from SCD in the United States.

Abdominal Crisis Generalized and constant abdominal pain is a common complaint during an acute sickle cell crisis, and it may be difficult to distinguish between infarction of the abdominal and retroperitoneal organs associated with a sickle cell crisis versus a focal abdominal problem such as cholecystitis or appendicitis. Frequently the patient can determine that the pain is similar to prior episodes. If there is doubt, repeated abdominal examinations should be done to assess for progression of tenderness and peritoneal signs (e.g., rebound). Patients with a typical vasoocclusive episode should not have evidence of peritonitis.

Hepatic infarction may cause the acute onset of jaundice and abdominal pain and can be difficult to distinguish from hepatitis or cholecystitis. Biliary disease is common because pigment-related cholelithiasis is seen in 30 to 70 percent of sickle cell patients. Both hepatic infarction and biliary obstruction should show elevations of liver enzymes and bilirubin. Severe right upper quadrant pain and marked elevations of bilirubin may be due to intrahepatic cholestasis, which rarely may progress to hepatic failure. When there is a concern for biliary disease or other intra-abdominal pathology, ultrasound or computed tomographic (CT) scanning of the abdomen and pelvis is useful.

Genitourinary System Vasoocclusive events involving the kidneys are common but often asymptomatic.¹⁹ Infarction in the renal medulla may cause flank pain, renal colic-type pain, and costovertebral angle tenderness, mimicking pyelonephritis. Papillary necrosis may result in either gross or microscopic hematuria, but RBC casts are uncommon. Renal imaging studies generally are necessary for correct diagnosis. Both renal medulla infarction and papillary necrosis are treated with intravenous fluids and close monitoring of hemoglobin levels to ensure that anemia does not worsen. Priapism occurs in up to 30 percent of males with SCD. Initial treatment is fluid hydration, pain control, and transfusion (see Chap. 95). Early involvement of the urologist is important. Urinary tract infections are more common in SCD patients, and urinalysis is recommended when these patients present to the emergency department.

Additional Systemic Manifestations of SCD

SPLenic INFARCTION The spleen is particularly susceptible to the effects of sickled cells. Over time, microinfarctions result in a spleen that is essentially nonfunctional. The Cooperative Study for Sickle Cell Disease demonstrated that the proportion of children with sickle

cell disease who are functionally asplenic is 14 percent at 6 months and 94 percent by the age of 5 years. This renders these patients at risk for serious infections and sepsis from encapsulated organisms. Therefore, immunizations, prophylactic penicillin therapy, and parental education are critical to minimize the risk of infection and prompt early evaluation of fever in these patients.^{12,20} As sickle cell patients age, their risk of overwhelming sepsis decreases, but they remain predisposed to infection.

SPLENIC SEQUESTRATION Splenic sequestration is more common in children than in adults and remains an important cause of morbidity and mortality. This syndrome manifests by the sudden enlargement of the spleen with an acute fall in the hemoglobin level due to sequestration of the blood volume within the spleen. Symptoms include tachycardia, hypotension, pallor, lethargy, and abdominal fullness. Left upper quadrant pain may or may not be present. The spleen is usually enlarged and firm. Platelets also may be sequestered, resulting in moderate thrombocytopenia. Reticulocyte count should remain elevated.

Therapy includes volume resuscitation, which may mobilize some of the RBCs trapped within the spleen. Transfusion or exchange transfusion may be necessary. Rarely, splenectomy is necessary. Search for a precipitating infection should be done. Unfortunately, recurrence of this syndrome is common.

HEMOLYTIC ANEMIA Patients with SCD have a chronic hemolytic process due to the shape of the red cells. The baseline hemoglobin level is often between 6 and 9 g/dL, and the reticulocyte count is between 5 and 15 percent. With infections, the hemolytic process may worsen, and hemoglobin may drop from the previous baseline. Typically, reticulocytosis will increase in response to the increased RBC destruction, but it may not be enough to compensate for the increased hemolysis. Acutely, the patient may notice symptoms of worsening fatigue, shortness of breath, dyspnea on exertion, and scleral icterus. These symptoms may be worsened if other comorbid diseases are present. It is uncommon for the hemolysis to be so severe as to require transfusion.

APLASTIC CRISIS Generally, the increased production of RBCs by the bone marrow is able to compensate for the increased rate of destruction. Aplastic crisis results when the production of RBCs declines significantly, producing a rapid decrease in the hemoglobin level with reticulocytopenia. The most common cause of aplastic crisis appears to be infection, specifically parvovirus. Folate deficiency and bone marrow necrosis also may play a role. Aplastic crisis is more common in pediatric patients than in adults. Patients generally will present with increasing fatigue and pallor and no evidence of increased hemolysis. The hemoglobin level will be unusually low, and few or no reticulocytes will be present (reticulocyte count typically <0.5 percent). The WBC and platelet levels are usually normal. Generally, this syndrome is self-limiting, and the marrow will begin producing RBCs spontaneously within a week. Transfusion may be required in the interim.

NEUROLOGIC DISORDERS Complications of SCA include stroke, subarachnoid hemorrhage, and isolated functional loss.²¹ Strokes usually develop abruptly with little warning but may occur during episodes of vasoocclusive pain. In some cases, vague symptoms consistent with a transient ischemic attack may be present and should be assumed to be potential warnings of impending stroke. The cause of stroke in most patients is cerebral infarction due to occlusion or narrowing of large cerebral vessels. The exact mechanism by which SCD causes endothelial damage in these large vessels is not clear. Approximately 10 percent of patients with SCA experience a stroke before age 20. Acute treatment is emergent simple or partial exchange transfusion. Cerebral aneurysms are also more common in sickle cell patients, perhaps due to local vessel occlusion or ischemia. Therefore, if symptoms of stroke due not improve with transfusion or the history

suggests that subarachnoid hemorrhage may be present, head CT scanning followed by lumbar puncture (if the head CT scan is normal) is indicated. Unfortunately, children who suffer a stroke are at 70 to 90 percent risk for recurrence. Chronic transfusion therapy is indicated to prevent recurrent stroke after the initial event.¹⁰

INFECTIONS Patients with SCA are functionally asplenic after early childhood, making them susceptible to infections from encapsulated organisms, such as *Haemophilus influenzae* and *Streptococcus pneumoniae*. Other common infections associated with SCA include pneumonia caused by these organisms as well as *Mycoplasma pneumoniae*, meningitis, and osteomyelitis due to *Salmonella typhimurium*, *Staphylococcus aureus*, and *Escherichia coli*. While low-grade fever is not uncommon during an acute crisis, unexplained fevers of 38°C (101°F) or higher require evaluation for bacterial infection and consideration for early treatment with broad-spectrum antibiotics. In addition to *H. influenzae* immunization, patients with SCD should be encouraged to receive yearly influenza vaccinations and remain up to date with the pneumococcal immunization, and children should be on prophylactic penicillin.^{12,20}

CARDIAC Cardiomegaly is common and correlates with the degree of chronic anemia. Additionally, cardiac dysfunction may occur from microinfarcts and hemosiderin deposition from hemolysis and blood transfusion. Because of the chronic anemia, enhanced cardiac contractility is present to maintain adequate systemic oxygen delivery, producing a widely radiating systolic ejection murmur.

DERMATOLOGIC Chronic, poorly healing leg ulcers around the malleoli are common in older sickle cell patients. Minor injury, impaired microcirculation due to repeated sickling episodes and microinfarcts, and infections all contribute to the development and persistence of these ulcers.

Disposition

Most painful crises last 2 to 3 days. Patients with an adequate clinical response and no indications for hospital admission can be discharged with oral pain medications and referred for follow-up with their primary care physician in the next 24 to 48 h. Patients also should receive instructions to return for the recurrence of severe pain, inability to take in fluids, fever, or other new and concerning symptoms. The following are some guidelines for hospital admission for sickle cell patients:

Patients with pulmonary or neurologic manifestations of their disease
Patients with evidence of significant bacterial infection
Patients with splenic sequestration or aplastic crisis
Patients in whom pain remains poorly controlled
Patients who are unable to maintain adequate hydration

VARIANTS OF SICKLE CELL DISEASE

Sickle Cell-Hemoglobin C (HbSC) Disease

Hemoglobin C results from a single point mutation in the P-chain gene; lysine is substituted for glutamic acid at the sixth position. The prevalence of the HbC gene is approximately 0.02 percent in African-Americans and 0.03 percent in northern Africans. Deoxygenated HbC has the tendency to precipitate inside the RBC, forming crystals that decrease cell deformability and increase blood viscosity. Patients with HbC trait (heterozygous for the HbC gene, or *HbAC*) are asymptomatic, and those with HbC disease (homozygous for the HbC gene, or *HbCC*) typically have a mild hemolytic anemia, abundant target cells, sporadic episodes of musculoskeletal pain, splenomegaly, dental infarctions, and angiod retinopathy. The heterozygous sickle cell variant, HbSC, results when the gene for HbS is inherited from one parent

and the gene for HbC is inherited from the other parent. These individuals have almost equal amounts of HbS and HbC but no HbA. Because HbC does not polymerize as readily as HbS, HbSC disease generally has less severe clinical consequences, and patients with HbSC disease live, on average, 20 years longer than those with SCD. These patients have less severe hemolytic anemia and, as a consequence, milder reticulocytosis. The peripheral smear shows abundant target cells and a few sickle cells, and HbC may be seen precipitated as a rhomboid crystal in the RBCs. The complications of HbSC disease are similar to SCD, although usually less severe. As opposed to SCD, adult patients with HbSC disease often have splenomegaly. HbSC disease patients are susceptible to a proliferative retinitis that may lead to loss of vision.

Sickle Cell-Hemoglobin D (HbSD) Disease

There are a number of hemoglobins termed HbD based on their migration location on hemoglobin electrophoresis. The most common form, HbD-Los Angeles (also called D-Punjab) has substitution of glycine for glutamic acid at position 121 in the (3-chain. By itself, HbD is of no clinical consequence; patients with HbD trait (heterozygotes, *HbAD*) are normal, and homozygotes (*HbDD*) have some decreased RBC osmotic fragility and target cells on peripheral blood smear but normal hemoglobin levels and no clinical symptoms. Patients with the heterozygous sickle variant, HbSD disease, are usually clinically similar to patients with SCD, having chronic hemolytic anemia, recurrent painful crises, and susceptibility to splenic sequestration and infections.

Sickle Cell-Hemoglobin O-Arab (HbSO-Arab) Disease

Hemoglobin O-Arab is a hemoglobin variant found in the Balkans and the Middle East and occasionally in African-Americans with a substitution of lysine for glutamic acid at position 121 of the P-chain. Patients heterozygous for hemoglobin O-Arab (HbAO-Arab) have no clinical problems. Patients homozygous for hemoglobin O-Arab (*HbOO-Arab*) or heterozygous for sickle cell-hemoglobin O-Arab (*HbSO-Arab*) are clinically similar to patients with SCD, having severe hemolytic anemia and recurrent vasocclusive crises, and children have the potential to develop sickle cell dactylitis and splenic sequestration crises.

THALASSEMIAS

The thalassemias are a diverse group of disorders characterized by defective synthesis of globin chains that results in the inability to produce normal adult hemoglobin.²² The hallmark of these disorders is a microcytic, hypochromic, hemolytic anemia. These disorders are most common in those of Mediterranean, Middle Eastern, African, and Southeast Asian descent. Like sickle cell trait, the abnormalities found in thalassemia trait are thought to be protective against malaria.

The (3-thalassemias have diminished production of the (3-globin chain, which allows unmatched a-globin chains to accumulate as α_4 tetramers in the immature RBC. These tetramers are very insoluble, and their precipitation damages the developing erythroid precursor cells, resulting in early death. The cells that are produced have decreased hemoglobin, which accounts for the hypochromia and target cell formation. Patients with a thalassemia develop an excess of 3-globin chains that accumulate as α_4 tetramers called *hemoglobin H* (HbH). HbH is more soluble and stable so that in severe a thalassemia, ineffective erythropoiesis is less of a problem, and increased destruction of the cells due to the structural abnormality is more prominent.

Both forms of thalassemia are characterized by differing extremes of anemia depending on the amount of ineffective erythropoiesis and premature destruction of the circulating RBCs. The hypoxia associated with severe anemia triggers compensatory mechanisms in an attempt to increase RBC production. This causes enlargement of the reticuloendothelial organs and expansion of the bone marrow cavity, leading to osteopenia. The complications of increased RBC production are

compounded by the complications that result from the chronic destruction of peripheral RBCs.

The β -thalassemias have two clinical syndromes representing mutations in one or both (3-globin genes: β -thalassemia major (Cooley anemia) and β -thalassemia minor. Because there are four a-globin genes, two each inherited from the parents, the genetics and clinical consequences of the a-thalassemias are determined by five genotypic possibilities: Normal is aa/aa, the silent carrier is a-/aa, the homozygous a-thalassemia trait is a-/a-, and the heterozygous a-thalassemia trait is -/aa. Hemoglobin H disease is a-/— and homozygous a-thalassemia is --/--. The most severe form of a-thalassemia occurs when there is a defect in all the a-globin chain genes, called *hemoglobin Bart's*, that is incompatible with life, producing stillborn or severely distressed infants. Outside of this most severe form, individuals with either a or 3-thalassemia can be minimally to severely affected due to the specific genotype and whether the mutation produces complete or partial reduction in globin chain production.

a-Thalassemia Carrier and Trait

These patients have no clinical symptoms or physical findings. Patients with a-thalassemia trait are detected by the finding of microcytic RBCs and a normal hemoglobin level.

Hemoglobin H Disease

This is a disorder in which one a-globin chain gene is still functional. Hemoglobin H disease usually presents in the neonatal period with a severe hypochromic anemia. Later in life the clinical picture includes a hypochromic, microcytic anemia with jaundice and hepatosplenomegaly. These patients may not require regular transfusions, but in conditions of increased oxidative stress (that may cause precipitation of the unstable hemoglobin H, resulting in hemolysis) or infection, a transfusion may be necessary. Most of these people will know their diagnosis, and the emergency physician need only provide supportive care and blood transfusion when necessary. Medications that may precipitate hemolysis should be avoided in this population (Table 221-3).

TABLE 221-3 Drugs That Produce Oxidative Stress on Red Blood Cells

Sulfonamides	Sulfacetamide Sulfamethoxazole Sulfanilamide Sulfapyridine
Antimalarials	Primaquine Chloroquine Pamaquine Pentaquine
Urinary agents	Nitrofurantoin Nalidixic acid Phenazopyridine
Miscellaneous antibiotics	Ciprofloxacin niridazole Norfloxacin Chloramphenicol
Mothballs	Naphthalene
Miscellaneous	Vitamin K analogues Methylene blue Acetanilid Doxorubicin Isobutyl nitrite Phenylhydrazine

P-Thalassemia Minor (p-Thalassemia Trait)

Patients with this form of thalassemia are heterozygous for the (3-globin mutation and have only mild microcytic anemia. Splenomegaly may be present but is not common. On blood smear, these patients may have microcytosis and hypochromia as well as basophilic stippling. An elevated HbA₂ level, typically 4 to 6 percent, confirms the diagnosis. These patients generally will not have clinical manifestations and may only come to attention during an evaluation for a mild anemia.

P-Thalassemia Major (Cooley Anemia)

In this disorder, both p-globin genes are defective, and production of P-globin chains is severely impaired.²³ P-Thalassemia major is characterized by a severe anemia that begins within the first year of life. These children develop hepatosplenomegaly, jaundice, expansion of the erythroid marrow (causing bone changes and osteoporosis), and increased susceptibility to infection. The anemia is severe and requires regular and lifelong blood transfusions. These transfusions and enhanced iron absorption eventually cause iron overload, which, if untreated, results in hemochromatosis with cardiac, hepatic, and endocrine dysfunction.

The RBCs of these children show a low mean corpuscular volume with microcytic and hypochromic cells. Variation in size and shape of the RBCs will be notable (increased red blood cell distribution width), as will be the presence of nucleated cells. This diagnosis should be considered in any child with a severe microcytic anemia and the appropriate ethnic background. For those with a known diagnosis who present to the emergency department with significant symptoms related to anemia or hemolysis, transfusion should be considered along with a search for precipitating events.

Sickle Cell-P-Thalassemia Disease

This heterozygous sickle cell variant occurs when the gene for sickle hemoglobin is inherited from one parent and the gene for (3-thalassemia is inherited from the other parent. The frequency of sickle cell-P-thalassemia disease is 2 per 3200 African-American births. The severity of the disease depends on the type of (3-thalassemia gene that is inherited. Between 80 and 90 percent of affected individuals have a P-thalassemia gene that results in the production of some normal beta chains; thus some normal HbA is made. These patients have a mild hemolytic anemia with near-normal hemoglobin levels, few crises, and minimal organ damage. Those 10 to 20 percent of patients who inherit a p-thalassemia gene that produces no beta chains and therefore no normal hemoglobin have severe hemolytic anemia and vasoocclusive symptoms comparable with patients with SCD.

GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

Glucose-6-phosphate dehydrogenase (G6PD) is an enzyme responsible for the production of nicotinamide adenine dinucleotide phosphate (NADPH), a required cofactor for maintaining glutathione in its reduced state.²⁴ RBCs rely on G6PD activity because it is the only source of NADPH that prevents oxidative damage to intraerythrocytic hemoglobin. There are over 300 variant mutations described for G6PD, with the highest prevalence in individuals of African, Asian, or Mediterranean descent. The gene for G6PD is carried on the X chromosome, so males are affected when they are hemizygous. Females must carry two defective genes to be severely affected, but because expression of this gene is variable, women with even one gene may still show some symptoms. The severity of G6PD disease is related to the magnitude of enzyme deficiency; severe cases have less than 10 percent of normal enzyme activity, and moderate cases have 10 to 60 percent of normal activity. G6PD deficiency is seen in approximately 10

to 15 percent of black males in the United States and a lesser percentage of those of Mediterranean descent.

G6PD-deficient RBCs are susceptible to oxidative stress; oxidation of the hemoglobin sulfhydryl groups causes hemoglobin to precipitate within the cell. The precipitated hemoglobin is recognized by the presence of Heinz bodies on the peripheral blood smear. The affected RBC is removed from the circulation by the spleen. Oxidant damage also occurs at the RBC membrane, producing both extravascular and intravascular hemolysis.

A history of neonatal jaundice 1 to 4 days after birth is common. In severe variants, the patient may have a severe chronic hemolytic anemia. In the more common variants of G6PD deficiency, the patient is usually asymptomatic, except for acute hemolytic crises that occur due to bacterial and viral infections, exposure to oxidant drugs, metabolic acidosis (such as diabetic ketoacidosis), renal failure, and in some patients, ingestion of fava beans²³ (see Table 221-3). These episodes are usually self-limited and well tolerated because only the older RBCs will hemolyze. There is an increased incidence of pigmented gallstones and splenomegaly in patients with G6PD deficiency.

The diagnosis of G6PD deficiency can be established by the demonstration of decreased enzyme activity through quantitative assay. Treatment for this disease is supportive and preventative. In patients with known G6PD deficiency, infections should be treated aggressively and oxidant drugs avoided. The drugs most commonly associated with oxidant stress are sulfonamides, antimalarials, and nitrofurantoin. HIV-positive patients should be screened for this defect because of the common use of sulfamethoxazole for the treatment and prophylaxis of *Pneumocystis carinii* pneumonia.

HEREDITARY SPHEROCYTOSIS

Hereditary spherocytosis (HS) is the result of an erythrocyte membrane defect and is the most prevalent hereditary hemolytic anemia among people of northern European descent.²⁵ The disease typically is inherited in an autosomal dominant pattern, although a less common autosomal recessive variant exists, and up to 20 percent of HS patients are the result of an apparent spontaneous mutation. The abnormal shape of the RBC results from molecular abnormalities in the cytoskeleton of the cell membrane, most commonly from mutations in the genes for the proteins spectrin and ankyrin. These abnormalities result in RBCs with a microspherocytic shape, which is not pliable enough to pass through the spleen. This results in an increased rate of destruction and a compensatory increase in RBC production. The clinical spectrum of HS is divided into those with 1) mild disease, occurring in 20 to 30 percent with an autosomal dominant inheritance, 2) moderate disease, occurring in 60 to 75 percent with primarily autosomal dominant inheritance, and 3) severe, occurring in about 5 percent with an autosomal recessive inheritance.

Neonatal jaundice during the first week of life occurs in 30 to 50 percent of HS patients. After the neonatal period, the symptoms and signs depend on the severity of ongoing hemolysis. Patients with mild disease usually have a normal hemoglobin level and little or no splenomegaly but are susceptible to hemolytic or aplastic episodes triggered by infection. Patients with moderate disease have mild to moderate anemia, modest splenomegaly, periodic episodes of hemolysis with jaundice, and an increased incidence of pigmented gallstones. The rare patient with severe HS has significant hemolytic anemia requiring episodic blood transfusions, chronic jaundice, and an enlarged spleen.

The peripheral blood smear shows spherocytes with a normal to low mean corpuscular volume and increased mean corpuscular hemoglobin concentration (>36 percent). The diagnosis of HS is established by the osmotic fragility test. In severe cases, splenectomy generally will reverse the anemia, except in the unusual cases of autosomal recessive variants. After splenectomy, spherocytes are still present.

anemia can exist in isolation or as part of a larger clinical syndrome. The hemolytic process can be idiopathic, triggered by sundry precipitants, present as a complication of known systemic illness, or herald systemic illness that has yet to be diagnosed. The patient with hemolytic anemia requires timely clinical and laboratory diagnosis, rapid determination of related pathology as part of a known clinical syndrome, initiation of cause-specific treatment made with specialty consultation, and likely hospital admission to carry out treatment and pursue the possibility of underlying illness. Acquired causes of hemolysis can be categorized according to mechanism (Table 222-1).

Presenting symptoms and signs of hemolytic anemia can include weakness or fatigue, dizziness, dyspnea on exertion, tachycardia, new or accentuated cardiac murmur, abdominal pain, pallor, and jaundice. When fever and lymphadenopathy are prominent, an underlying systemic disease should be suspected. Splenomegaly in the setting of hemolysis suggests that RBC destruction has been ongoing for weeks to months. Hepatomegaly may occur with significant hemolysis. Darkening of the urine is caused by intravascular hemolysis and hemoglobinuria.

The diagnosis of hemolytic anemia requires interpretation of laboratory data (Table 222-2). In general, hemolysis is corroborated by spherocytes or schistocytes on peripheral smear, a decreased hematocrit indicating anemia, an increased reticulocyte count indicating enhanced RBC production, increased unconjugated (indirect) bilirubin secondary to excessive hemoglobin breakdown, increased serum lactate dehydrogenase (LDH) as a nonspecific marker of RBC destruction, and decreased haptoglobin, a serum protein that binds free hemoglobin and serves as a sensitive marker of intravascular hemolysis.

TABLE 222-1 Etiologies of Acquired Hemolytic Anemia

Immune-mediated
Autoimmune
Warm-type antibody
Cold-type antibody
Cold agglutinin syndrome (CAS)
Paroxysmal cold hemoglobinuria (PCH)
Mixed-type (warm and cold antibody)
Alloimmune
Hemolytic disease of the newborn

March hemoglobinuria (exertion-related)

ACQUIRED HEMOLYTIC ANEMIA

Patty Chu

Robin R. Hemphill

Acquired hemolytic anemia is characterized by the destruction of red blood cells (RBCs) not due to a genetic or congenital disorder of hemoglobin synthesis or RBC membrane. The acquired hemolytic anemia disorders can produce disease of varying severity from asymptomatic, mild illness to fulminant, potentially fatal hemolysis. Hemolytic

TABLE 222-2 Ancillary Tests Used in the Evaluation of Hemolytic Anemia

Test	Finding	Interpretation
WBC	Leukocytosis thrombocytopenia	Common finding in hemolysis Leukocytosis <i>and</i> Consider Evans syndrome (idiopathic thrombocytopenic purpura and AIHA)
Platelet count	Thrombocytopenia	TTP and HUS <20,000 / μ L HELLP <100,000 / μ L Consider Evans syndrome
Hematocrit	Anemia	Expected with significant hemolysis
Reticulocyte count	Elevated Decreased	Expected bone marrow response to hemolysis Bone marrow suppression (hyperhemolytic transfusion reaction, early hemolysis, HIV-associated hemolysis)
Mean corpuscular volume	Elevated	Juvenile RBC population (reticulocytosis) Vitamin B ₁₂ or folate deficiency
WBC differential	Lymphocytosis Eosinophilia Neutrophilia or bandemia Atypical lymphocytosis	Lymphoproliferative disorder (secondary HA) Inflammatory or infectious condition (secondary HA) Infectious disorder (secondary HA) CMV or EBV infection (secondary HA)
Peripheral smear	Spherocytes Schistocytes Agglutination	RBC membrane destruction (probable immune HA) RBC fragmentation MAHA or macrovascular HA IgM Ab present (CAS)
Direct antigen (direct Coombs) test	Positive	IgG or complement present on RBC surface, consistent with AIHA, does not test for IgM on RBC surface
Indirect antibody (indirect Coombs) test	Positive	Anti-RBC IgG antibodies found in serum or eluted off red cells
Haptoglobin	Decreased Increased	Binds to free hemoglobin, indicates intravascular hemolysis Acute phase reactant
Lactate dehydrogenase (LDH)	Increased	Elevated in hemolysis Isoenzyme LDH-1 found in RBCs
Unconjugated (indirect) bilirubin	Increased	Indicates enhanced hemoglobin catabolism
Coagulation studies: PTT, PT/INR, fibrinogen, fibrin split products, D-dimer	Elevated Normal	Coagulopathy DIC TTP/HUS
Free serum hemoglobin	Increased	Intravascular hemolysis
Urine hemoglobin	Present	Intravascular hemolysis
ESR	Elevated	Systemic inflammatory or infections condition (secondary HA) Elevated in severe anemia
C-reactive protein	Elevated	Acute phase reactant Systemic inflammatory or infectious condition (secondary HA)

Abbreviations: CAS = cold agglutinin syndrome; CMV = cytomegalovirus; DIC = disseminated intravascular coagulation; EBV = Epstein-Barr virus; ESR = erythrocyte sedimentation rate; HA = hemolytic anemia; HUS = hemolytic-uremic syndrome; MAHA = microangiopathic hemolytic anemia; TTP = thrombotic thrombocytopenic purpura.

IMMUNE-MEDIATED

The immune-mediated hemolytic anemias traditionally have been divided into three categories: autoimmune, alloimmune, and drug-related (see Table 222-1).

Autoimmune Hemolytic Anemia

Individuals with autoimmune hemolytic anemia (AIHA) make antibodies against their own RBCs or against the body's higher-incidence antigens.^{1,2} AIHA is thought to occur because of generalized immune system dysfunction. The overall incidence of AIHA is approximately 1 to 3 cases per 100,000 people per year. The incidence of AIHA in infants and children is less, approximately 0.2 cases per 100,000 per year in those under age 20 years. AIHA in children is commonly associated with viral or respiratory infections, is mediated by IgG, and causes acute, fulminant hemolysis. Pregnancy carries a five times

greater risk of developing autoantibodies, but significant RBC destruction is not common.³

Diagnosis of AIHA requires evidence of an autoantibody on the patient's RBCs in the form of a positive direct antigen test (DAT or direct Coombs test) *and* identification of an autoantibody, either after elution (washing off) of the antibodies from a patient's RBCs or detecting the autoantibodies in the patient's serum (indirect Coombs test). The DAT is performed by combining the patient's anticoagulated RBCs with anti-IgG and anti-C3d (complement) antibodies to detect the presence of IgG and/or complement on the RBC surface. The DAT itself is not specific for AIHA (Table 222-3). The indirect Coombs test looks for the presence of antibodies in the patient's serum, testing against normal RBCs bearing specific surface antigens. Serologic evidence of autoantibodies should be correlated with clinical and other routine laboratory evidence of hemolytic anemia, including decreased hematocrit, decreased haptoglobin in the setting of intravascular hemolysis, elevated reticulocyte count, elevated unconjugated (indirect)

bilirubin, elevated LDH, and/or hemoglobinuria, to make the diagnosis of AIHA.

AIHA can be divided into primary and secondary varieties. Primary refers to cases without an underlying etiology (idiopathic), and secondary refers to cases of AIHA seen with an underlying disorder. Primary AIHA is more common in women, with peak incidence during the fourth and fifth decades. Many cases initially labeled idiopathic are found later to be associated with significant underlying pathology, such as a lymphoproliferative or autoimmune disorder. Thus all patients with AIHA, especially of the chronic variety, need regular follow-up. The hemolytic process in AIHA can take place within the vascular space or in the liver or spleen. AIHA is also divided into autoantibody type: warm-type, cold-type, and mixed-type.

WARM ANTIBODY AIHA Warm-type AIHA comprises 70 percent of AIHA cases and is usually mediated by an IgG antibody directed against surface antigens of the Rh-erythrocyte system. Autoantibodies of the warm type react most strongly near 37°C, with less affinity for RBC antigens at lower temperatures. These autoantibodies, when eluted or washed off the patient's RBCs, usually are panreactive with RBC panels. Thus these autoantibodies hemolyze not only the patient's own RBCs but also transfused RBCs from another individual (allogenic). Alloimmune-mediated hemolytic anemia, as described below, is characterized by specific autoantibodies triggered by and only reactive against allogeneic RBCs and their antigens; the patient's own RBCs are not damaged. In distinction, warm-type autoantibodies produce hemolysis in both the patient's RBCs and the transfused RBCs. Warm-type autoantibody-mediated hemolysis is predominantly extravascular, occurring in the spleen.

Warm-type AIHA carries a 2:1 female preference but has no racial predilection. About half of warm-type AIHA cases can be labeled as primary or idiopathic, but as mentioned earlier, an initial designation as primary may later be revised on discovery of an associated disease process. Secondary cases most often are associated with lymphoproliferative disorders (in about half) or a systemic autoimmune disease (Table 222-4).

Chronic lymphocytic leukemia is the most common lymphoproliferative disorder associated with warm-type AIHA, accounting for up to 25 percent of patients affected. Hemolytic anemia can precede the development of other systemic effects and diagnosis of lymphoma, Hodgkin disease, and systemic lupus erythematosus (SLE) by up to 3 years. Up to 4 percent of Hodgkin patients will have DAT-positive hemolytic anemia. Warm-type AIHA is seen uncommonly in patients with ulcerative colitis, most often occurring during or after a flare of colitis. Viral-induced warm-type AIHA is often mild and self-limited. Infection may produce warm- or cold-type AIHA as well as mixed-type. Warm-type AIHA associated with human immunodeficiency virus (HIV) infection is uncommon but likewise mild.

TABLE 222-4 Causes of Warm Antibody Hemolytic Anemia

Lymphoproliferative disease
Chronic lymphocytic leukemia
Lymphoma/Hodgkin disease
Waldenstrom macroglobulinemia
Multiple myeloma
Autoimmune disease/collagen-vascular disease
Systemic lupus erythematosus
Rheumatoid arthritis
Polyarteritis nodosa
Pernicious anemia
Scleroderma
Ulcerative colitis/Crohn disease
Infection (can be associated with warm or cold or often both)
Infectious mononucleosis
CMV
Viral hepatitis
Malaria
Pediatric viral respiratory illness
Immunodeficiency syndrome
HIV
Congenital syndromes
X-linked agammaglobulinemia
Common variable immunodeficiency
IgA deficiency
Wiskott-Aldrich syndrome
Dysglobulinemia
Nonlymphoid tumors
Ovarian carcinoma and dermoid cysts
Teratomas
Kaposi sarcoma
Thymoma

High-dose corticosteroids constitute first-line therapy for patients with warm-type AIHA. The initial dose typically is oral prednisone 1 to 1.5 mg/kg per d for 1 to 3 weeks.⁴ Improvement usually is noted within 1 week of initiating treatment, and 70 to 80 percent of patients are better within 3 weeks. Once the hemoglobin level stabilizes, the steroids can be tapered. Complete remission is achieved in 15 to 20 percent of new-onset cases of warm-type AIHA, and about half of patients will need low-dose prednisone for several months. If no improvement is noted within 3 weeks of initiating steroid therapy or if a chronic prednisone dose of more than 15 mg/d is needed to maintain a hematocrit of greater than 30 percent, the case should be deemed a steroid failure and alternative therapies considered. Between 10 and 20 percent of steroid-treated patients either will fail to respond adequately or will require unacceptably high doses to maintain the desired response. Such patients are treated with either splenectomy or cytotoxic drugs.

Splenectomy removes both the main site of extravascular hemolysis in IgG-mediated AIHA and a major site of general autoantibody production. Splenectomy produces a 65 to 70 percent response rate and has the potential for long-term remission or a complete cure. At the very least, if incomplete remission is achieved or if relapse occurs, patients after splenectomy may require lower doses of corticosteroids. The most feared complication of splenectomy is overwhelming postsplenectomy infection (OPSI) with encapsulated bacteria. **Splenectomized patients should receive pneumococcal and meningococcal vaccinations** and should be considered for daily penicillin prophylaxis.

Cytotoxic drugs produce a 40 to 60 percent response rate and have been used both for patients who have failed steroids and for those who have failed splenectomy. Some sources suggest saving cytotoxic agents for those who have failed a second trial of lower-dose steroids after splenectomy. The cytotoxic drugs may be used with or without steroids. Once the desired response is achieved, the steroids once again can be tapered slowly, followed by tapering the cytotoxic agent as tolerated. Cytotoxic drugs have significant side effects, including bone marrow suppression, gastrointestinal intolerance, secondary malignancy

development, hemorrhagic cystitis, alopecia, and sterility. Conflicting reports exist as to the efficacy of using cyclosporine, and its use requires careful monitoring for the development of nephrotoxicity. Rituximab, a genetically engineered chimeric murine-human anti-CD20 monoclonal antibody, is useful in severe, refractory cases of both warm- and cold-type AIHA, but the associated side effects can be serious or even fatal.

Severe hemolysis in cases of warm-type AIHA may be treated with plasma exchange as a transient stabilizing measure while waiting for steroids or cytotoxic agents to take effect. Intravenous immunoglobulin may be used as adjunctive treatment in children who cannot tolerate the side effects of chronic high-dose steroids or cytotoxic agents. Danazol, an attenuated androgen with fewer side effects than glucocorticoids, can produce remission in occasional patients. Vincristine-loaded platelets may bring about selective splenic macrophage injury, preventing the extravascular hemolysis that defines warm-type AIHA.

For patients with life-threatening anemia or for those at high-risk for cardiac or cerebrovascular ischemic complications, RBC transfusion of the *least incompatible* units may be transfused slowly with close monitoring. Transfusion may precipitate further production of autoantibodies as well as introduce a source for the production of allogeneic antibodies. In both warm- and cold-type AIHA, secondary cases may not respond to aggressive therapy unless the underlying illness is treated appropriately.

COLD ANTIBODY AIHA In cold-type AIHA, the autoantibodies produced are usually IgM and most strongly hemolytic at 0 to 4°C. The presence of cold-type autoantibodies leads to clumping or agglutination of RBCs on peripheral smear at cooler temperatures. This IgM-mediated disease is associated with the complement fixation on the RBC surface and the subsequent triggering of the complement cascade. Hemolysis occurs in both the extravascular and intravascular spaces after massive autoantibody production and complement activation. Instead of splenic macrophages, Kupffer cells in the liver are responsible for most of the extravascular RBC destruction. The two common cold-type AIHA disorders are cold agglutinin syndrome and paroxysmal cold hemoglobinuria. Fifty percent of secondary cold-type AIHA cases are associated with lymphoproliferative disorders, with infection the next leading secondary cause.

Cold Agglutinin Syndrome (CAS), accounting for up to one-third of all AIHA cases, is typically IgM-mediated but rarely has been found to be IgG- or IgA-mediated. Autoantibodies in the CAS are directed against the I/i blood group antigens, which are related to ABO antigens. CAS autoantibodies bind to RBC surface antigens in the cooler peripheral circulation and initiate the steps of the complement cascade. During the early phases of complement cascade activation, extravascular hemolysis takes place in the Kupffer cells, and during terminal stages of complement cascade activation, intravascular hemolysis occurs.

Primary CAS is seen in older adults, particularly females, with a peak incidence at age 70. The hemolysis associated with the primary and chronic secondary forms of CAS tends to be mild and stable with hemoglobin levels of 9 to 12 g/dL, and symptoms typically are mild. Secondary CAS also can present as an acute attack, such as that seen in patients who have preceding infectious illnesses, including *Mycoplasma pneumoniae*, Epstein-Barr virus (EBV), adenovirus, cytomegalovirus (CMV), influenza, varicella-zoster virus (VZV), HIV, *Escherichia coli*, *Listeria monocytogenes*, and *Treponema pallidum*. Symptom onset corresponds with the peak antibody response to infection, usually 2 to 3 weeks after the onset of illness. As the original illness itself resolves, the triggered cold-type AIHA resolves approximately 2 to 3 weeks later. In cases of severe hemolysis, pallor, jaundice, hemoglobinuria, and/or renal failure can occur. Chronic cold-type AIHA associated with lymphoproliferative diseases, such as chronic lymphocytic leukemia (CLL), lymphomas, and Waldenström macroglobulinemia, produces high autoantibody levels with the potential for significant hemolysis.

Cold weather exacerbates CAS; more episodes of acute hemolysis are seen during winter. Patients are apt to develop acrocyanosis because the peripheral circulation typically is cooler than the central circulation. Raynaud phenomenon, vascular occlusion, and tissue necrosis may complicate CAS. Clumping of cold agglutinins will elevate the mean corpuscular volume (MCV) and decrease the RBC count. Peripheral smear findings include the spherocytosis caused by RBC membrane destruction, as well as anisocytosis, poikilocytosis, polychromasia, and agglutination. As with other forms of hemolytic anemia, patients will have elevated LDH and unconjugated bilirubin levels with moderate disease and decreased haptoglobin, hemoglobinemia, and hemoglobinuria with severe, intravascular hemolysis.

In primary and chronic CAS with mild anemia, treatment is symptomatic and involves simply keeping the extremities as well as the nose and ears warm in cold weather. Patients with CAS should take a daily folate supplement. Treatment for severe hemolysis has been successful with immunosuppressive or cytotoxic agents, such as chlorambucil, cyclophosphamide, interferon- α , and fludarabine. The major side effect with such treatment is bone marrow suppression. Plasmapheresis, as in warm-type AIHA, may prove helpful as a temporizing measure by removing autoantibodies, particularly because auto-IgM has an intravascular distribution, but such therapy should be combined with immunosuppressive agents. Unlike warm-type AIHA, CAS rarely responds to steroids, although such treatment may be considered in atypical cases. Because splenic macrophages play a lesser role in IgM-mediated cold antibody disease, splenectomy is not particularly helpful for cold antibody-mediated extravascular hemolysis.

Treatment of secondary CAS depends on the underlying illness, whether it is chemotherapy for lymphoproliferative disease or antibiotics for a nonviral infection. Infection-related cold antibody disease does not require immunosuppressive therapy because the hemolytic anemia is usually self-limited. As with warm-type AIHA, rituximab may prove helpful.

RBC transfusion can be performed for patients at risk for significant cardiac or cerebrovascular ischemia, but transfused blood should be kept at 37°C using a blood warmer. Transfusions should be limited because they may worsen ongoing hemolysis; in addition to the risk of producing alloantibodies to transfused RBCs, most cold antibodies act against the I group antigens, which are found on most donor RBCs. Donor complement in the transfused product also may exacerbate ongoing hemolysis. There is limited experience using intravenous immunoglobulin in the treatment of CAS.

Paroxysmal Cold Hemoglobinuria (PCH) is caused by a biphasic IgG autoantibody called the *Donath-Landsteiner antibody*.⁵ The PCH autoantibody is directed against the P antigen system found on most RBCs. On binding, this potent autoantibody fixes complement not only at low temperatures, but it also can bind certain complement components at normal physiologic temperatures, causing clinically significant hemolysis at low autoantibody titers. Thus hemolysis may occur at both cold and normal temperatures. Symptoms include high fever, chills, headache, abdominal cramps, nausea and vomiting, diarrhea, and leg and back pain that develops with cold exposure. Cold urticaria also may develop, as well as extremity paresthesias and Raynaud phenomenon.

Primary PCH and PCH secondary to congenital or late-stage syphilis are characterized by chronic disease with cold-induced relapses; patients with chronic, relapsing disease should be tested for syphilis. Secondary PCH caused by other infectious agents is most common in children and is one of the more common causes of childhood hemolytic anemia. Postinfection PCH is usually seen after a preceding upper respiratory infection (URI) and has been associated with measles, mumps, EBV, CMV, VZV, adenovirus, influenza A, *M. pneumoniae*, *Haemophilus influenzae*, and *E. coli*. Most cases of postinfectious PCH are self-limited, but severe cases may take weeks to resolve. With severe hemolysis, hemoglobinuria is common, and methemoglobinuria may be seen. Acute renal failure may develop as a complication of PCH.

Patients with PCH should be kept warm. Steroids can be considered in children with severe hemolytic anemia, but since infection-related PCH tends to be self-limited, benefit is uncertain. PCH secondary to syphilis responds to effective antibiotic treatment. Splenectomy is not helpful, and plasmapheresis should be used only as a temporizing measure in life-threatening cases. RBC transfusion should be limited to cases of severe hemolysis because most donor units are P antigen-positive and may stimulate further production of PCH autoantibodies. Transfusion in cases of cold-type AIHA, whether CAS or PCH, always should be performed using a blood warmer.

MIXED-TYPE AIHA Mixed-type AIHA presents as primary or secondary disease—most commonly lymphoproliferative and autoimmune diseases. The course of illness is usually chronic with severe exacerbations. Like warm-type AIHA, mixed-type AIHA is steroid-responsive, can be treated with splenectomy, and responds to cytotoxic therapy. Relapses are not triggered by cold exposure, so acrocyanosis and Raynaud are not seen characteristically. As with any secondary AIHA, treatment of the underlying disorder will reduce hemolytic activity.

Alloimmune Hemolytic Anemia

Alloimmune hemolytic anemia requires exposure to allogeneic RBCs with subsequent alloantibody formation. In the laboratory, alloantibodies react specifically with the allogeneic RBCs that triggered their production; these antibodies do not react against a patient's own RBCs.

A well-known example of this is when the RhD-negative maternal immune system develops IgG alloantibodies on exposure to RhD-positive fetal RBCs.⁶ The maternal alloantibodies can then cross the placenta to inflict fetal RBC destruction in a condition termed *hemolytic disease of the newborn* (HDN). Anemia can range from mild to potentially fatal, producing intrauterine fetal death. The term *hydrops fetalis* has been used to describe the anatomic changes seen in severe HDN. Transplacental or fetomaternal hemorrhage, the inciting stimulus for maternal alloantibody formation, may occur during amniocentesis, chorionic villus sampling, delivery, or abortion (threatened or otherwise) or even during external cephalic version. By still uncertain mechanisms, administration of anti-D IgG (RhoGAM) with any fetomaternal hemorrhage event and soon after delivery will suppress maternal alloantibody formation and prevent HDN. Treatment of established HDN employs intrauterine and intravascular fetal transfusion and may include plasma exchange and/or intravenous immunoglobulin therapy.

Most adults who develop alloimmune hemolytic anemia have a history of RBC transfusion, which sensitizes patients to allogeneic RBC antigens. A subsequent transfusion can result in immediate alloantibody production, resulting in the fever, chest and flank pain, tachypnea, tachycardia, hypotension, hemoglobinuria, and oliguria seen in the hemolytic transfusion reaction. In patients with high alloantibody titers, the hemolytic reaction can be immediate. Delayed alloantibody-mediated hemolysis is possible, with hemolytic transfusion reaction (HTR) symptoms presenting 3 to 7 days after transfusion (see Chap. 223).

DRUG-RELATED

Drug-related hemolytic anemia can be divided into three types: autoimmune, drug adsorption, and neoantigen. Steroids can be used in cases of drug-related severe hemolysis. RBC transfusion will aggravate hemolysis if the recipient's serum contains antibodies against antigens found on the transfused RBCs.

Autoimmune Drug-Related Hemolytic Anemia

In autoimmune drug-related hemolytic anemia, the offending drug triggers formation of autoantibodies that bind with self RBC antigens,

leading to a hemolytic process serologically indistinct from that seen in warm-type AIHA.⁷ The diagnosis is proven when the hemolytic process abates on withdrawal of the offending drug. The classic and first example of autoimmune-type drug-related hemolytic anemia was discovered in the mid-1960s, when alpha-methyldopa was found to stimulate production of autoantibodies. Other drugs implicated in the formation of autoantibodies against RBCs include levodopa, mefenamic acid, procainamide, diclofenac, quinidine, phenacetin, and the second- and third-generation cephalosporins (particularly cefotetan and ceftriaxone). Up to 71 drugs have been associated with development of a positive DAT (direct Coombs test); however, significant hemolysis is seen only occasionally. An extended drug exposure usually is required for autoantibodies to form. Importantly, a positive DAT (direct Coombs test) does not indicate that hemolysis will occur or that a drug must be discontinued. Within days of stopping the offending drug, hemolysis usually stops, although it may take months to see full resolution of the process.

Drug Adsorption-Type Hemolytic Anemia

Drug adsorption-type hemolytic anemia requires that the drug incite the formation of antidrug antibodies and that the drug bind to the RBC with significant affinity. Antibodies formed against the drug will in turn react against the drug-bound RBCs, producing hemolysis. This type of hemolysis also has been called *drug-requiring* because the absence of the offending drug eliminates the hemolytic reaction completely.

Neoantigen-Type Drug-Related Hemolytic Anemia

Neoantigen-type drug-related hemolytic anemia involves weak binding of the offending drug to normal RBCs. The body's immune system, seeing the formed immune complexes as foreign, will generate an immune response, which then produces hemolytic disease. The classic causative agent is penicillin. Isolated cases of diphtheria-tetanus-pertussis (DTP) vaccination in children have been associated with hemolysis, possibly via this neoantigen mechanism.⁸

MICROANGIOPATHIC SYNDROMES: THROMBOTIC THROMBOCYTOPENIC PURPURA (TTP) AND HEMOLYTIC UREMIC SYNDROME (HUS)

Both TTP and HUS involve platelet aggregation in the microvascular circulation via the mediation of von Willebrand factor (vWF), leading to thrombocytopenia, often with platelet counts of less than 20,000/ μ L. Microangiopathic hemolytic anemia (MAHA) or schistocyte-forming hemolysis develops as RBCs are fragmented during travel through these occluded arterioles and capillaries.⁹ TTP and HUS are clinical syndromes with characteristic features, but overlap does occur, making differentiation sometimes difficult. TTP is traditionally more common in adults, whereas HUS is more common in children. TTP typically induces more prominent neurologic deficits with deposition of platelet aggregates in a broader, systemic distribution, whereas HUS more specifically impairs the renal system. However, TTP may present with significant renal compromise, whereas HUS can cause important extrarenal complications, obscuring the line between the two. In general, adults presenting with clinical and laboratory evidence of MAHA accompanied by thrombocytopenia should be treated as though they have TTP once other diagnoses have been excluded (Table 222-5) because untreated TTP has a 80 to 90 percent mortality.

Because of the significant hemolytic anemia, pallor, jaundice or scleral icterus, fatigue, and dyspnea on exertion are common. With significant thrombocytopenia, purpura or mucosal bleeding may be evident. Focal neurologic deficits (often vacillating), aphasia, seizure, coma, visual disturbance, chest pain, cardiac conduction disorders, abdominal pain, oliguria, and hypertension indicate end-organ involvement.

Evans syndrome
Heparin-induced thrombocytopenia with thrombosis
Malignant hypertension

Thrombotic Thrombocytopenic Purpura

TTP is classically comprised of the following pentad: 1) thrombocytopenia, 2) MAHA, 3) fever, 4) renal impairment, and 5) neurologic impairment.¹⁰ It is uncommon to see all five features in any one patient, but if present, severe end-organ ischemia or damage likely has taken place. Thrombocytopenia and MAHA are the most common features, and fever is the least frequent finding.

A key pathophysiologic role in TTP is played by the vWF-cleaving metalloprotease ADAMTS-13.¹¹ Endothelial cells and megakaryocytes normally make monomers of vWF that are joined to form larger vWF multimers. Under usual conditions, ADAMTS-13 cleaves these multimers before being allowed to enter the circulation or rest on the surface of endothelial cells. In cases of familial TTP or Upshaw-Schulman syndrome, a severe deficiency in ADAMTS-13 activity has been found to promote the adherence of unusually large vWF multimers to the surfaces of endothelial cells. These large vWF multimer strings attract circulating platelets, resulting in the formation of platelet thrombi; the larger the multimers, the greater is the affinity for platelets. The normal process of cleaving multimers is key to maintaining laminar microvascular blood flow. Microvascular platelet thrombi generate turbulent RBC flow through occluded vessels with subsequent RBC shear or hemolysis (MAHA). Tissue ischemia and necrosis follow, causing end-organ damage.

About 50 to 80 percent of patients with acquired TTP have presumed autoantibodies against ADAMTS-13. In those without autoantibodies, altered enzyme production, survival, or activity is presumed to produce TTP. Patients with many disorders associated with TTP or MAHA have been identified as having lower levels of ADAMTS-13 activity: liver disease, metastatic cancer, chronic metabolic disease, chronic inflammatory disease, pregnancy, and the neonatal period. Overall, ADAMTS-13 deficiency has been shown to play a definitive role in the pathogenesis of familial-type TTP and is suspected to play a central role in cases of acquired TTP.

Pregnancy is the most common precipitating event for TTP. Preeclampsia has some features similar to TTP, but because delivery is the treatment for preeclampsia but fails to alter the course of TTP, it is important to distinguish between the two entities. TTP usually presents earlier during pregnancy, around 23 to 24 weeks, whereas preeclampsia more commonly presents in the third trimester. Second-trimester preeclampsia is associated with molar pregnancies. The maternal mortality rate in cases of TTP has been reduced significantly with the use of plasma-exchange therapy, but fetal mortality has remained high secondary to placental microvascular occlusion and resulting infarction. TTP may relapse with a subsequent pregnancy, so affected women should be counseled accordingly.

Other triggers of TTP include infection (particularly HIV), vaccination, and autoimmune disorders such as SLE. Several drugs have been associated with TTP, including quinidine, cyclosporine, and tacrolimus.¹² Ticlopidine and clopidogrel, two thienopyridine antiplatelet agents commonly used in patients with cardiac and cerebrovascular disease, have received attention for their TTP-inciting potential, presumably due to the ability of either drug to incite the development of autoantibodies against ADAMTS-13 within 2 weeks of starting treatment. Most patients with thienopyridine-associated TTP have developed the illness within 1 month of drug initiation. TTP

has been seen more commonly with ticlopidine than with clopidogrel, with an incidence between 1 in 1600 and 1 in 5000. Thus clopidogrel has become the thienopyridine of choice.

A particularly refractory form of TTP has been linked with the post-bone marrow transplant (BMT) and postchemotherapy settings. As opposed to most other patients with TTP, post-BMT or postchemotherapy TTP patients have not been shown to have ADAMTS-13 deficiency, so the mechanism of disease may be immune-mediated or cytotoxic endothelial damage. Patients undergoing BMT are exposed to many known triggers of TTP, including infection and drugs, as well as endothelial damage from both chemotherapy and graft-versus-host disease. The chemotherapeutic agents mitomycin, cisplatin, gemcitabine, and bleomycin also have been associated with TTP.

TTP is still a clinical diagnosis, but characteristic laboratory findings include severe anemia, thrombocytopenia of less than 20,000/ μ L, schistocytes or helmet cells on peripheral smear, decreased haptoglobin, elevated reticulocyte count, and elevated unconjugated (indirect) bilirubin seen with intravascular hemolysis. The DAT (direct Coombs test) is characteristically negative because the hemolysis seen in TTP does not involve anti-RBC autoantibodies. TTP thrombi do not involve fibrin, so TTP is distinguished from DIC based on normal coagulation studies.¹³ Preeclampsia is associated with a reduced plasma AT III level as opposed to TTP. Renal function should be assessed, and cultures should be obtained as appropriate. ADAMTS-13 activity measurement is still too time- and labor-intensive for general use and is only available in specialty laboratories.

Familial-type TTP can be prevented with a periodic infusion of platelet-poor fresh frozen plasma (FFP), cryoprecipitate-poor plasma (from which vWF has been removed; also known as *cryosupernatant*), or plasma pretreated with detergent and solvent. All these products contain the ADAMTS-13 metalloprotease. An acute attack also can be treated with an infusion of one of these products; an ADAMTS-13 level of 5 percent of normal is sufficient to thwart an attack of TTP.

Acquired TTP is treated with daily plasma exchange consisting of 1) plasmapheresis to remove large vWF multimers and autoantibodies and 2) plasma infusion to give the patient back one calculated daily volume of FFP or cryosupernatant. Cryosupernatant may prove more advantageous to use due to its lack of vWF. Infusion can be initiated with FFP and then converted to cryosupernatant in refractory cases, or treatment can employ cryosupernatant initially. The use of plasma exchange has decreased TTP mortality rates from 90 percent down to 10 to 20 percent. Plasma exchange, presumably by removing vWF multimers and autoantibodies, is superior to plasma infusion alone, with improved response and lower mortality rates. If plasmapheresis cannot be performed immediately, initial FFP infusion should be started, but infusion should never replace exchange. Plasma exchange is performed daily until several days after remission is achieved, usually seen within 1 week, but it may require up to 4 weeks. Remission is defined by normalization of the platelet count and LDH combined with clinical resolution of tissue ischemia and thrombosis. Plasma exchange requires the placement of a central venous catheter and thus carries the same risks: hemorrhage, line-site thrombosis, line sepsis, and pneumothorax. Infusion of plasma carries a small risk of blood-borne pathogen transmission.

Corticosteroids, usually prednisone 1 to 2 mg/kg per d, may be helpful in the presence of a high autoantibody titer and if plasma exchange does not provide the desired response. Splenectomy can induce long-term remission or cure in cases of plasma-exchange failure by removing a site of autoantibody production and removing a site of microvascular occlusion mitigating MAHA. In post-BMT and postchemotherapy patients, running the patient's plasma through a staphylococcal protein A column, known as *immunoadsorption*, can remove immune complexes from patients with immune-mediated TTP. Post-BMT patients often change immunosuppressive drugs when TTP is considered drug-related. Vincristine, intravenous immunoglobulin, azathioprine, cyclosporine, and rituximab have been investigated as possible therapies.

Supportive measures may be needed to address systemic complications associated with TTP, including RBC transfusion in the setting of significant MAHA, anticonvulsants for seizures, antihypertensives for hypertension, and hemodialysis in cases of severe renal insufficiency. Platelet transfusions should be avoided, except for life-threatening bleeding or intracranial hemorrhage, because thrombosis may worsen acutely, leading to rapid renal failure and potentially death. Aspirin can worsen hemorrhagic complications in the setting of severe thrombocytopenia and also should be avoided. Heparin has not been shown beneficial in TTP or HUS. Relapse after appropriate treatment may be as high as 30 percent, and maintenance therapies have not been shown to prevent relapse.

Hemolytic Uremic Syndrome

HUS is a disease primarily of early childhood, with a peak incidence between 6 months and 4 years of age.¹⁴ The adult form of HUS may be very difficult to distinguish from TTP. Overall mortality rate is 5 to 15 percent, with a worse prognosis in older children and adults. HUS is one of the most common causes of acute renal failure in childhood and is characterized by acute renal failure, microangiopathic hemolytic anemia, fever, and thrombocytopenia.

In children, HUS often follows a viral or bacterial illness. Although several infectious agents have been implicated, infection with *Escherichia coli* serotype O157:H7 is a well-recognized agent associated with HUS. On ingestion, *E. coli* O157:H7 produces a toxin that is absorbed into the systemic circulation. The toxin then binds with greatest affinity to receptors found on the surfaces of glomerular and renal tubular epithelial and endothelial cells and to a lesser extent to receptors lining cerebral and colonic epithelial and endothelial cells. The result is targeted renal microvasculature damage leading to the formation of platelet thrombi, mediated by vWF multimers (as in TTP), with subsequent MAHA via shear mechanism and renal tissue ischemia and necrosis. The toxin also potentiates release of the large vWF multimers and upregulates high-affinity receptors to continue the cycle of thrombosis and hemolysis. Onset of HUS is typically 2 to 14 days after diarrhea develops. Between 20 and 40 percent of *E. coli* O157:H7-infected patients will have bloody diarrhea, whereas 15 percent of children and 5 percent of adults will go on to develop HUS. Other organisms implicated in HUS include *Shigella*, *Yersinia*, *Campylobacter*, *Salmonella*, *Streptococcus pneumoniae*, varicella, echovirus, and coxsackieviruses A and B.

Like TTP, HUS is pathologically identified by microthrombi consisting of platelet aggregates that occlude the arterioles and capillaries. In HUS, the microthrombi are confined mostly to the kidneys; in TTP, they occur throughout the microcirculation. Like TTP, HUS is a clinical diagnosis. Laboratory studies reflect the presence of MAHA. Thrombocytopenia may be present but generally not to the degree seen in TTP. The serum creatinine level may be markedly elevated, and urine, if present, will contain protein and red blood cells (although the urine can be normal). Coagulation studies usually are normal.

Mild HUS with less than 24 h of urinary symptoms requires only fluid and electrolyte correction and supportive care. Steroid therapy may be beneficial. In the setting of more severe disease, plasma exchange or infusion has been performed with equivocal results. Patients whose disease resembles TTP may respond to plasma therapy. The overall low mortality of HUS makes use of plasma exchange questionable. Hemodialysis may be required in the setting of acute renal failure, especially in adults, in whom acute renal failure tends to be more severe. A shorter duration of dialysis therapy is associated with increased likelihood of recovery from HUS. Infection with *E. coli* O157:H7 should not be treated with antimotility drugs because these agents appear to increase the risk of developing HUS. The use of antibiotics for treatment of *E. coli* O157:H7 is controversial. A recent meta-analysis found no evidence that antibiotic treatment increased or decreased the risk of developing HUS.¹⁵

PREGNANCY-ASSOCIATED HEMOLYSIS

HELLP Syndrome

A complication of preeclampsia known as the HELLP syndrome is comprised of hemolysis, elevated liver tests, and low platelets.¹⁶ The incidence of HELLP is about 1 in 1000 pregnancies.¹⁷ Endothelial cell dysfunction resulting from the release of vasoactive agents leads to the formation of microvascular platelet-fibrin thrombi in the preeclamptic patient and subsequent MAHA as RBCs pass through occluded vessels. Initially, pathologic changes occur predominately in the liver, as opposed to pathologic changes predominately seen in the CNS and kidneys from TTP and HUS, respectively. In the HELLP syndrome, widespread vascular occlusion may produce systemic end-organ damage, and excess coagulation cascade stimulation may progress to DIC. Right upper quadrant or epigastric pain may be seen in up to 90 percent of patients with HELLP syndrome and indicates the potential for hepatic rupture, the most ominous complication of HELLP.

Diagnosis of HELLP is made based on laboratory data. A decreased serum haptoglobin level (see Table 222-2) is the most sensitive marker for MAHA in the setting of HELLP.¹⁸ A decreased serum haptoglobin level may precede the onset of thrombocytopenia by 1 to 2 days, making it that much more valuable a marker to monitor in the HELLP syndrome.¹⁹ Unfortunately, classic markers of hemolysis such as schistocytes on the peripheral smear, elevated indirect bilirubin and LDH levels, hemoglobinemia, and hemoglobinuria are less reliable in the setting of the HELLP syndrome and may be seen only in late-stage or severe cases; their absence does not rule out hemolysis.

Timely delivery is the definitive treatment for the HELLP syndrome.¹⁷ Medical treatment of the HELLP syndrome includes supportive measures for complications such as seizures and hypertensive crisis. Steroids may be of use beyond inducing fetal lung maturity, but their use in the HELLP syndrome is still investigational and the mechanism is uncertain. The clinical and laboratory findings of the HELLP syndrome may extend up to 6 days postpartum.¹⁷

Pregnancy-Associated TTP

Pregnancy-associated TTP usually occurs in the antenatal period. As mentioned earlier, it is important to distinguish between preeclampsia/HELLP and TTP because the course of TTP is not altered by delivery but can be improved dramatically by initiation of plasma exchange therapy. Onset of TTP in the postpartum period requires a search for retained products of conception.

Pregnancy-Associated HUS

Pregnancy-associated HUS usually occurs during the postpartum period and is characterized by abrupt onset of acute renal failure, MAHA, and hypertension after a usually normal, complication-free delivery. Coagulation studies in both TTP and HUS should be normal, distinguishing these disorders from DIC.

MALIGNANCY-ASSOCIATED HEMOLYSIS

Patients with widely disseminated cancer may develop MAHA. Those at particular risk include patients with gastric cancer, followed by, in no particular order, patients with lung, breast, colon, prostate, and hepatic neoplasms. Malignancy-associated MAHA is attributed to microvascular fibrin deposition and resulting RBC shear-injury as blood passes through occluded arterioles and capillaries. In contrast to other forms of MAHA, malignancy-associated hemolysis may target the pulmonary circulation, with intimal proliferation in the pulmonary microvasculature leading to elevation in pulmonary artery pressures. Up to half of malignancy-associated MAHA cases may be associated with DIC. MAHA itself portends a poor prognosis for the cancer patient,

and the only known treatment for such cases is chemotherapy to treat the underlying malignancy.

HEMOLYSIS AND IMMUNE-COMPLEX DISEASE

Immune-complex deposition in the setting of collagen-vascular disease triggers the coagulation cascade, creating fibrin in the systemic microvasculature. The result is endothelial damage and RBC shear producing MAHA. SLE, polyarteritis nodosa, Wegener granulomatosis, and scleroderma may be complicated by MAHA.

HEMOLYSIS IN MALIGNANT HYPERTENSION

MAHA in the setting of malignant hypertension occurs via poorly understood mechanisms. The process has been attributed largely to fibrinoid necrosis occurring in systemic arterioles as a result of severely elevated blood pressure. MAHA abates with normalization of blood pressure.

MACROVASCULAR HEMOLYSIS

The presence of a prosthetic heart valve sets the stage for turbulent blood flow with high shear-stress across the prosthetic valve.²⁰ Intravascular hemolysis occurs in up to 85 percent of people with normally functioning mechanical prosthetic valves, although it is less frequent in patients with bioprosthetic compared with mechanical heart valves. Stentless aortic prosthetic valves produce less hemolysis, encouraging researchers that prosthetic valves can be modified even further to reduce the incidence of hemolysis and its resulting complications. Severe hemolysis may require replacement of an implicated prosthetic valve. Macrovascular hemolysis also may be seen after intracardiac patch repair, aortofemoral bypass, in patients with coarctation of the aorta, in patients with severe aortic valve disease, and with extracorporeal circulation, as in cardiopulmonary bypass or hemodialysis.²¹ Patients with ongoing mild hemolysis should receive supplemental iron and folate.

DIRECT TOXIC EFFECTS CAUSING HEMOLYSIS

Infections

Destruction of RBCs commonly occurs in the course of many infectious diseases. Malaria is the world's most common cause of hemolytic anemia, with RBC hemolysis resulting from direct parasitization of the RBCs. Hemolysis also results from direct parasitization of RBCs in babesiosis and infection with *Bartonella henselae*. *H. influenzae* type b infection can produce hemolysis by altering the RBC surface; the capsular polysaccharide of the bacterium binds to the RBC surface, and then antibodies destroy the bacterium as well as the RBC. *Clostridium perfringens* (*welchii*) infection can result in severe hemolysis by direct lysis of red blood cells. The organism releases enzymes that acutely degrade the phospholipids of the RBC membrane bilayer and the proteins in the structural membrane. Many viral infections can be accompanied by hemolytic anemia, including measles, CMV, herpes simplex virus, VZV, coxsackievirus, and HIV.

Toxin-Induced Hemolysis

Acute intravascular hemolysis can occur following bites/stings of bees, wasps, the southern black widow spider, and the brown recluse spider. American pit vipers and coral snake bites are known to cause coagulation abnormalities but rarely cause hemolysis. Conversely, the bite of the cobra snake does cause intravascular hemolysis.

MECHANICAL DAMAGE CAUSING HEMOLYSIS

Uncommonly, march hemoglobinuria occurs predominantly in young males after significant exertion against a hard surface, such as concrete. Damage to RBCs from direct impact causes transient red or dark

urine lasting up to a few hours after exercise. Runners, particularly beginners and those with a heavy stride, as well as soldiers, karate participants, and conga drummers, may develop march hemoglobinuria. Anemia is not usually seen because less than 1 percent of the body's RBCs are damaged. Patients are advised to wear thick-soled shoes and change exercise style to prevent further episodes.

ACKNOWLEDGMENT

Thank you to the previous author, Mary Eberst, for her work.

TRANSFUSION THERAPY

Sally A. Santen

Effective and safe blood transfusion began in the early to middle twentieth century when preservative solutions were developed and blood group types were identified. Continued advances in transfusion medicine have improved our understanding of the benefits and risks of blood component replacement.¹ Currently available products are puri-

fied so that precise factor or component replacement is common practice. While there have been significant advances in individual factor and component replacement, development of hemoglobin substitutes has been less successful.

Transfusion in the emergency department typically is done for acute blood loss and circulatory shock. As medical care is moved to outpatient settings and emergency departments become more crowded, emergency physicians may be responsible for transfusion therapy that was once relegated to inpatient settings. An understanding of the available blood products, their indications, and potential complications of transfusions is important for safe and effective transfusion practice (Table 223-1).

TRANSFUSION OF AVAILABLE BLOOD PRODUCTS

Packed Red Blood Cells (PRBCs)

An adult's total blood volume is estimated to be 2.5 L/m², 75 mL/kg, or approximately 5 L in a 70-kg person. Fresh whole blood transfusion would be ideal to replace acute blood loss; however, during the storage of whole blood, platelets and other factors become inactive. In addition, the storage life of whole blood is less than that individual components. Therefore, by necessity and convenience, whole blood is fractionated to its components for storage and transfusion.

PRBCs are prepared by the centrifugation of whole blood to remove about 80 percent of the plasma; then a preservative solution is added, most commonly citrate-phosphate-dextrose (CPD) with additional nutrients adenosine, glucose, and mannitol. Each unit of PRBCs has a hematocrit of 55 to 80 percent and a volume of approximately 250 mL (see Table 223-1). Transfusion of 1 unit of PRBCs into a typical adult will increase the hematocrit by 3 percent or the hemoglobin by 1 g/dL.

The primary reason for transfusion of PRBCs is to increase oxygen-carrying capacity. The two indications for emergency PRBC transfusion are acute blood loss and profound anemia with impaired oxygen delivery. It is difficult to set a transfusion threshold that holds true for all patients.³⁻⁷ Based on animal and human studies, lactic acid production increases, oxygen extraction ratio exceeds 50 percent, and the mortality rate starts to increase in otherwise stable patients with hemoglobin levels of 3.5 to 4.0 g/dL. In an animal model of coronary stenosis, adverse cardiac effects are seen with hemoglobin levels of 6.0 g/dL. Therefore, practice guidelines often use this level as a threshold for PRBC transfusion. However, there are reports of Jehovah's Witnesses who tolerate surgery with hemoglobin levels below 6.0 g/dL provided that intravascular volume is maintained.

The American College of Surgeons classifies hemorrhage according to estimated blood volume loss correlated with clinical findings. *Class II hemorrhage* corresponds to an estimated 15 to 30 percent blood volume loss with clinical manifestations of tachycardia, decreased pulse pressure, restlessness, and anxiety. While young, healthy patients can tolerate blood loss of up to 25 to 30 percent or 1500 mL when treated with crystalloid, older patients and patients with chronic illness such as cardiac diseases may not tolerate similar blood loss without cardiac or neurologic decompensation. Additionally, patients at most risk for end-organ damage are likely to have complicating factors such as medications (3-blockers), pacemakers that may alter the body's usual response to hypovolemia, and decreased oxygen-carrying capacity related to other comorbid conditions. *Class III hemorrhage* is an estimated 30 to 40 percent blood volume loss with clinical manifestations of tachycardia, tachypnea, systolic hypotension, and mental status changes. During hemorrhage, hematocrit values or hemoglobin levels lag behind the clinical signs or physiologic parameters in assessing the adequacy of oxygen-carrying capacity and delivery. Therefore, patient status is more useful than hemoglobin level to determine if crystalloid resuscitation alone is effective or if PRBC replacement is needed.

The second indication for transfusion is anemia.² The use of PRBCs to treat anemia depends on the severity, duration, and rate of change of the anemia, as well as the patient's ability to compensate for the diminished oxygen-carrying capacity. Patients with chronic anemia have developed compensation mechanisms so that chronic anemia is better tolerated than acute anemia. The threshold for transfusion in anemia is inexact, although various consensus panels have recommended transfusion for hemoglobin levels of less than 7 g/dL, whereas patients with hemoglobin levels greater than 10 g/dL rarely will benefit from transfusion.^{4,6} In intermediate ranges, patients with cardiac or vascular diseases may benefit from transfusion at a higher threshold. Transfusion thresholds for children may be higher and depend on the etiology of their anemia.

Red blood cell replacement usually is done with PRBCs. Depending on the urgency of transfusion, most patients can be typed (ABO and RhD blood group type) and cross-matched against the blood intended for transfusion. The blood type can be determined in about 15 min, whereas to perform a type and cross-match, it takes approximately 1 h. In critical patients, type O RhD⁻ (universal donor) may be transfused because the red cells do not contain blood group antigens. Type O RhD⁺ blood also may be used if type O RhD⁻ is not available but is not the blood of choice for women of child-bearing potential. If an RhD⁻ patient is transfused with 1 unit of RhD⁺ PRBCs, approximately 80 percent will develop anti-D antibodies. Because the effect

TABLE 223-1 Characteristics of Blood Products and Doses

Component	Shelf Life	Volume/Unit	Approximate Content/Unit*	Typical Dose	Dosage Effect
PRBC	21–42 days	250–350 mL	Red cells 65–80% Plasma 20–35%	2 units or 15 mL/kg	Raises hemoglobin concentration about 2 g/dL
Platelets (random donor platelet concentrate)	5 days	50–60 mL	Platelets 7.5×10^{10}	6 units or 5 mL/kg	Raises platelet count about 50,000/ μ L
Platelets (apheresis collected single donor platelet concentrate)	5 days	250–300 mL	Platelets 3 to 6×10^{11}	One unit	Raises platelet count about 50,000/ μ L
FFP	1 year frozen and 24 h thawed	200–250 mL	Each coagulation factor 200–250 units and fibrinogen 400–500 mg	4 units or 15 mL/kg	Raises most coagulation factors levels about 20%
Cryoprecipitate	1 year frozen	20–50 mL	Factor VIII 80 units, fibrinogen 225 mg, and von Willebrand factor variable amounts	10 units or 1 unit/5 kg	Raises fibrinogen 75 mg/dL

*Blood-derived components often contain WBCs, RBCs, platelets, and plasma unless they have been specially prepared.

of 1 unit of PRBCs is small (increase in hematocrit of 3 percent and hemoglobin of 1 g/dL) and clinically inconsequential, it is standard practice to transfuse a minimum of 2 units and raise the hematocrit by 6 percent and hemoglobin level by 2 g/dL. In children, 15 mL/kg of PRBCs will raise the hematocrit 6 percent and hemoglobin level by about 2 g/dL.⁸

PRBCs may be further treated to meet specific uses: leukocyte-reduced PRBCs, irradiated PRBCs, washed PRBCs, and frozen PRBCs. Leukocyte-reduced PRBCs have had 70 to 85 percent of the leukocytes removed. The advantages of leukocyte-reduced PRBCs is 1) to prevent or avoid nonhemolytic febrile reactions due to antibodies to white blood cells (WBCs) and platelets if the patient has been exposed to previous transfusions or pregnancies, 2) to prevent sensitization in patients who may be eligible for bone marrow transplantation, and 3) to minimize the risk of virus transmission such as human immunodeficiency virus (HIV) and cytomegalovirus (CMV). The leukocytes can be reduced by filtration or other methods before storage of the PRBCs or during transfusion. Irradiation of PRBCs eliminates the capacity of T cells to proliferate, thereby preventing the donor's T cells from reacting to the recipient's cells and causing graft-versus-host disease. Irradiated cells should be considered in transplant patients, neonates, and immunocompromised patients. Washed PRBCs are indicated in patients who have a hypersensitivity to plasma, such as IgA deficiency. For rare blood types, PRBCs may be frozen and saved for up to 10 years for later use.¹ This is more expensive than normal storage, and once thawed, the blood must be washed and transfused within 24 h.

One unit of PRBCs, about 250 mL in volume, generally is transfused over 1 to 2 h. However, blood may be transfused more rapidly in patients with hemodynamic instability. During standard transfusions, the initial rate is slower over the first 30 min so that if there is incompatibility, the transfusion may be stopped.

Platelet Transfusion

Platelet transfusions may be used either prophylactically to prevent bleeding or therapeutically when patients with thrombocytopenia are actively bleeding.^{9,10} Platelets are collected from whole blood donations or from single donors using apheresis techniques. One random-donor platelet concentrate prepared from 500 mL of donated whole blood contains an average of 7.5×10^{10} platelets (see Table 223-1). One apheresis-collected single-donor platelet concentrate generally contains 3 to 6×10^{11} platelets depending on local collection practice. Platelets should be given according to ABO compatibility, if available. A dose of one random-donor platelet concentrate per 10 kg (approximately six to eight random-donor platelet concentrates for an adult) or one apheresis—collected single—donor platelet concentrate in an adult will increase the platelet count by about 50,000/ μ L. Response to platelet transfusions is variable; therefore, platelet levels should be checked at 1 and 24 h. Failure of platelets to rise appropriately may be due to increased consumption of platelets from an underlying process, destruction due to platelet antibodies, or sequestration due to hyper-splenism. Transfused platelets should survive 3 to 5 days unless there is a consumptive process.

The etiology of thrombocytopenia is important in the decision to transfuse platelets.^{9,10} With idiopathic thrombocytopenic purpura, an antiplatelet antibody-mediated consumptive process, the platelets are larger, younger, and more functional, so prophylactic transfusion is rarely indicated despite very low platelet counts. However, with platelet hypoplasia, platelet function is impaired, making the risk of bleeding greater. Patients with comorbid diseases such as infection, fever, medications, and central nervous system (CNS) involvement may be more likely to bleed or be at higher risk if they bleed; therefore, the threshold for platelet transfusion is higher. The dose of platelets should reflect the indication. In general, spontaneous bleeding is possible, and prophylactic transfusion is indicated with platelet

counts of less than 10,000/ μ L. Platelet counts of greater 50,000/ μ L rarely cause significant bleeding.

Indications for platelet transfusions include:

- Platelet count <10,000/ μ L in asymptomatic patients
- Platelet count <15,000/ μ L with a coagulation disorder or minor bleeding
- Platelet count <20,000/ μ L with major bleeding
- Platelet count <50,000/ μ L with an invasive procedure (thoracentesis, paracentesis) or general surgery required or during massive transfusion (1 to 2 blood volumes)
- Platelet count <100,000/ μ L with neurologic or cardiac surgery

It is not possible to provide clear recommendations for patients with nonfunctioning platelets (antiplatelet medications, uremia, von Willebrand disorder, or hyperglobulinemia) and active bleeding. In von Willebrand disorder, normal platelets can deliver von Willebrand factor to the bleeding site. Conversely, in uremic patients, the transfused platelets may not function better than native platelets. In these complex cases, it is helpful to consult with a hematologist for the best recommendations.

Like PRBCs, platelets can be leukocyte-reduced or washed. Patients who have had repeated transfusions may become alloimmunized and refractory to platelet transfusion, noted by the lack of expected rise of platelet count after transfusion. Such patients need HLA- or cross-matched platelets. Other disorders may affect the efficacy of platelet transfusion, including duration of platelet storage, bacterial sepsis, antibiotics, graft-versus-host disease, disseminated intravascular coagulation (DIC), and splenomegaly.

Relative contraindications to the transfusion of platelets are disorders associated with platelet activation, such as thrombotic thrombocytopenic purpura (TTP) or heparin-induced thrombocytopenia, where transfusion may worsen thrombosis. In these diseases, procedures may necessitate platelet transfusion but should be performed in consultation with hematology.

Fresh Frozen Plasma Transfusion

Fresh frozen plasma (FFP) is plasma obtained after the separation of whole blood from RBCs and platelets and then frozen within 6 h.¹¹ Each unit of FFP is 200 to 250 mL and contains about 1 unit of each coagulation factor and 2 mg of fibrinogen per milliliter (see Table 223-1). FFP is appropriate for rapid replacement of multiple coagulation deficiencies such as in liver failure, warfarin overdose, DIC, and massive transfusion in bleeding patients. It should be considered when there is bleeding and the standard coagulation tests [prothrombin time/International Normalized Ratio (PT/INR) or activated partial thromboplastin time (aPTT)] are elevated 1.5 times control. Administration of FFP prophylactically to nonbleeding patients is not indicated, and prophylaxis is not always needed for some procedures in patients with a coagulopathy. For example, patients undergoing paracentesis and thoracentesis are not at increased risk of bleeding until the PT, INR, or aPTT are greater than 2 times control. During massive transfusions, replacement of an entire blood volume leaves only about one-third of normal factors, and although PT and aPTT may be abnormal, clinical coagulopathy does not always occur. Indications for FFP transfusion include: Rapid reversal of warfarin over-anticoagulation

Bleeding and multiple coagulation defects as evidenced by prolonged PT/INR/aPTT greater than 1.5 control (liver disease, DIC)

Correction of coagulation defects for which no specific factor is available (Table 223-2) (Specific factor replacement is safer and better but may not always be available.)

Transfusion of more than a total of one blood volume with evidence of active bleeding and prolonged PT/aPTT

Other possible indications for FFP in consultation with a hematologist include TTP, antithrombin III deficiency, and hereditary angioedema (FFP contains C1 esterase).¹²

TABLE 223-2 Replacement Therapy for Congenital Factor Deficiencies

Coagulation Factor	Incidence*	Replacement Therapy
Factor I (fibrinogen)	150 cases	Cryoprecipitate
Factor II (prothrombin)	>30 cases	FFP for minor bleeding episodes Prothrombin complex concentrate† for major bleeding
Factor V	150 cases	FFP
Factor VII	150 cases	FFP for minor bleeding episodes Prothrombin complex concentrates for major bleeding Recombinant factor VII _A (experimental)
Factor VIII	1 in 10,000 males	Factor VIII concentrates (cryoprecipitate or FFP if not available) Desmopressin for those with mild hemophilia
von Willebrand disease	up to 1 in 100 persons	Desmopressin (or some factor VIII concentrates or cryoprecipitate)
Factor IX	1 in 30,000 males	Factor IX concentrates
Factor X	1 in 500,000	FFP for minor bleeding episodes Prothrombin complex concentrates for major bleeding
Factor XI§	3 in 10,000 Ashkenazi Jews 1 in 1,000,000 in general	FFP
Factor XII	Several hundred cases	Replacement not required
Factor XIII	>100 cases	FFP or cryoprecipitate

*Incidence as of 1998.

†See Chap. 220 for details concerning prothrombin complex concentrates.

‡See Chap. 220 for detailed management recommendations for patients with hemophilia A and hemophilia B.

§Factor XI levels correlate poorly with bleeding complications; many patients have low levels, but no bleeding complications.

Abbreviation: FFP = fresh frozen plasma.

The efficacy of transfused coagulation factors varies, so the increase in specific coagulation factors seen after FFP infusion also varies. In general, 1 unit of FFP will increase most coagulation factors by 3 to 5 percent in a 70-kg adult. The common adult dose of 7 to 8 mL/kg (or 2 units of FFP in a 70-kg individual) will only increase coagulation factors by 10 percent, a clinically inconsequential benefit in most circumstances. For clinically relevant correction of coagulation factor deficiencies, a dose of 15 mL/kg (or 4 units in a 70-kg adult) is required (see Table 223-1). As indicated by the name, FFP is stored frozen, and there may be a delay while it is thawed. FFP should be ABO-compatible. After transfusion, bleeding and coagulation studies should be reevaluated. If coagulation factor consumption is present, repeated FFP transfusion should be guided by the PT/TNR/aPTT response.

Cryoprecipitate Transfusion

Cryoprecipitate is the cold insoluble protein fraction of FFP. Each unit of cryoprecipitate is about 20 to 50 mL and contains about 225 mg of fibrinogen and 80 units of factor VIII and von Willebrand factor (vWF). It also contains some factor XIII and fibronectin. With the de-

Y

velopment of recombinant factor VIII products for use in hemophilia, the primary role of cryoprecipitate is now replacement of fibrinogen or vWF. Bleeding patients with fibrinogen levels below 100 mg/dL due to severe liver disease, DIC, and dilutional coagulopathy may benefit from cryoprecipitate, although there is little evidence of improved clinical outcomes. The dose of cryoprecipitate is 1 unit of cryoprecipitate per 5 kg, which will raise the fibrinogen level by about 75 mg/dL. Usually 10 units are given at a time.

Indications for cryoprecipitate transfusion include:

Bleeding with a fibrinogen level of less than 100 mg/dL Bleeding in some subtypes of von Willebrand disease that are unresponsive to desmopressin (DDAVP)

Other Plasma-Derived Products

Immunoglobulin for intravenous administration (IVIG) is a pooled IgG product that has been virally attenuated. Labeled indications for IVIG are idiopathic thrombocytopenic purpura, pediatric HIV infection, primary humoral immunodeficiency, and several new and off-label treatments such as Kawasaki disease and autoimmune disorders. Dose and administration vary by indication. Adverse reactions include anaphylaxis, especially in IgA deficiency (rare); febrile reactions; headache; and renal failure. Some patients develop transient positive serology to hepatitis C and cytomegalovirus.

Albumin is a virally inactivated purified plasma protein that normally accounts for 50 percent of circulating protein and 75 percent of plasma oncotic pressure. Albumin transfusion in patients with decreased oncotic pressures may transiently increase oncotic pressure, but the albumin rapidly distributes to extravascular spaces. Therefore, due to the cost and the lack of proven efficacy over crystalloid, there is no advantage to using albumin for volume resuscitation.^{13,14}

Antithrombin III (AT III) is a coagulation inhibitory protein. Deficiency can be acquired or congenital and usually is associated with difficult-to-treat thrombosis. AT III replacement is indicated in AT III deficiency-related thrombosis and for thrombosis prophylaxis. This product should be considered in AT III-deficient patients when difficulty is encountered in achieving adequate heparinization or recurrent thrombosis is observed despite adequate anticoagulation. It is also reasonable to treat AT III-deficient subjects with concentrate before major surgeries or in obstetric situations where the risks of bleeding from anticoagulation are unacceptable. Currently, AT III therapy is under investigation in sepsis, DIC, and other thrombotic diseases. The dose depends on the indication. An infusion of 50 units (1 unit is the amount of AT III in 1 mL of pooled plasma) of AT III concentrate per kilogram usually will raise the plasma antithrombin III level to about 120 percent of normal in a congenitally deficient individual. Plasma AT III levels should be monitored to ensure that they remain above 80 percent. Subsequent administration of AT III at 60 percent of the initial dose at 24-h intervals is recommended to maintain AT III levels in the normal range.

Massive Transfusion

Massive transfusion is defined as the replacement of one blood volume or about 10 units of PRBCs within a 24-h period. Patients receiving less than one blood volume rarely need hemostatic factor (FFP, platelets) replacement. In patients receiving two blood volumes or more than 20 units of PRBCs, transfusing coagulation factors and platelet may be empirically helpful. For patients who receive one to two times total blood volume, hemostatic factor replacement should be guided by the considerations noted above: 1) if the platelet count is below 50,000/ μ L, platelet transfusion is warranted; 2) if the INR is greater than 1.5, FFP may be given; and 3) if the fibrinogen level is below 100 mg/dL, it may be replaced with cryoprecipitate.

In massive transfusion, hypothermia is a risk, and blood and crystalloid as well as the patient should be warmed. Hypocalcemia from

the preservative citrate chelating calcium is rare but should be considered in massive transfusion and symptoms or signs of hypocalcemia.

COMPLICATIONS OF BLOOD TRANSFUSIONS

The need for blood transfusions in the emergency department is common. Many are emergent due to hemorrhage, whereas others are less urgent and occur in the setting of an observation unit or prolonged emergency department stays. Up to 20 percent of all transfusions may lead to some type of adverse reaction.¹ Although most of these reactions are minor, some are life-threatening (Table 223-3). In critically ill patients, transfusion reactions may be difficult to identify; therefore, attention should be paid to unexpected changes in patient status during a transfusion.

Infectious Complications of Blood Transfusion

Improved blood donor screening, serologic testing, safer handling of blood products, and viral inactivation of many blood products have reduced the risk of infection from blood transfusion.^{1,15} However, risks remain, and patients need to be informed of the hazards associated with transfusions.

Donor blood is screened for the most concerning viral agents (Table 223-4). However, there is still a small risk of viral transmission^{1,15} (Table 223-5). Most cases of transmission are thought to occur during the window period between infection and antibody production in the donor. This window is reduced by the use of antigen testing but is still not eliminated completely.

The prevalence for CMV antibodies in the general population is between 50 to 80 percent. Therefore, blood is not tested routinely for CMV unless the recipient is seronegative and either pregnant, a potential or present transplant candidate, immunocompromised, or a premature infant. Use of leukocyte-reduced blood components further decreases the risk of CMV transmission to susceptible populations because most of the virus resides in the leukocytes.

Many other infections also can be transmitted by blood transfusion, including the hepatitis viruses, West Nile virus, and other bacteria (occurs if the donor was bacteremic during donation). Additionally, blood can become contaminated during storage or processing. Bacterial sepsis that results from RBC transfusion is most commonly due to *Yersinia enterocolitica*, which is able to grow easily in refrigerated blood.¹⁶ The risk of bacterial sepsis is estimated to be 1 in 500,000 units of PRBCs transfused and 1 in 40,000 units for random-donor platelet concentrates.¹

Hemolytic Transfusion Reactions

Hemolytic transfusion reactions occur when the recipient's antibodies recognize and induce hemolysis in the donor's RBCs. The reaction is usually acute when antibodies already exist but can be delayed when there is an anamnestic response to a transfused RBC-antigen to which the recipient is already sensitized. Immediate transfusion reactions are caused most commonly by ABO incompatibility and usually are the result of technical errors made during the collection of blood, in pretransfusion testing, or in patient identification. The majority of transfusion fatalities are acute hemolytic reactions due to human error of incorrect cross-matching or inadvertent administration of the wrong blood. The risk of acute hemolytic transfusion reaction due to incompatible blood is 1 to 4 per 1 million units transfused and has a high fatality rate.¹

With acute hemolytic reaction, most of the transfused cells are destroyed, which may result in activation of the coagulation system with DIC and release of anaphylotoxins and other vasoactive amines. Evidence of this type of reaction includes back pain, pain at the site of the transfusion, headache, alteration of vital signs (fever, hypotension, dyspnea, tachycardia), chills, bronchospasm, pulmonary edema, bleeding due to developing coagulopathy, and evidence of new or worsening renal failure. Recognition of transfusion reactions in critically ill patients who already may be hypotensive and tachycardiac is difficult and requires a high degree of suspicion.

TABLE 223-3 Acute Transfusion Reactions: Recognition, Management, Evaluation

Reaction Type	Signs and Symptoms	Management	Evaluation
Acute intravascular hemolytic reaction	Fever, chills, low back pain, flushing, dyspnea, tachycardia, shock, hemoglobinuria	Immediately stop transfusion IV hydration to maintain diuresis; diuretics may be necessary Cardiorespiratory support as indicated Can be life threatening	Retype and crossmatch Direct and indirect Coombs tests CBC, creatinine, PT, aPTT Haptoglobin, indirect bilirubin, LDH, plasma free hemoglobin Urine for hemoglobin
Acute extravascular hemolytic reaction	Often have low-grade fever but may be entirely asymptomatic	Stop transfusion Rarely causes clinical instability	Hemolytic workup as above to rule out the possibility of intravascular hemolysis
Febrile nonhemolytic transfusion reaction	Fever, chills	Stop transfusion Manage as in intravascular hemolytic reaction (above) because cannot initially distinguish between the two Can treat fever and chills with acetaminophen and meperidine Usually mild but can be life threatening in patients with tenuous cardiopulmonary status Consider infectious work-up	Hemolytic workup as above because initially cannot distinguish the etiology
Allergic reaction	If mild, urticaria, pruritus If severe, dyspnea, bronchospasm, hypotension, tachycardia, shock	Stop transfusion If mild, reaction can be treated with diphenhydramine; if symptoms resolve, can restart transfusion If severe, may require cardiopulmonary support; do not restart transfusion	For mild symptoms that resolve with diphenhydramine, no further workup is necessary, although blood bank should be notified For severe reaction, do hemolytic workup as above because initially will be indistinguishable from a hemolytic reaction

Abbreviations: aPTT = activated partial thromboplastin time; CBC = complete blood count; LDH = lactate dehydrogenase; PT = prothrombin time.

TABLE 223-4 Required and Optional Laboratory Testing of Donated Blood Required

ABO antigens
RhD antigens
RBC antibody screen
Serologic tests for syphilis (RPR), not that syphilis is thought to be transmitted by blood transfusion, but that it is a marker for other sexually transmitted bloodborne infections. If RPR is positive, then FTA-ABS is run. RPR positive, blood not used; FTA positive, then donor notified.
Hepatitis B surface antigen (RIA or ELISA, RPHA)
Anti-hepatitis B core antibody
Hepatitis C antibody
HIV-1,2 antibody
HIV-1 p24 antigen
HTLV (human T-cell lymphotropic virus) type I and II antibody
Optional
CMV antibody
HLA antibody
Other RBC antigens

Ongoing transfusion should be stopped immediately on first indication of potential problems. While laboratory confirmation is being performed, the sequelae of hemolysis are treated supportively. Renal function (serum creatinine, urinalysis), electrolytes, and coagulation status (PT/INR/aPTT) should be checked. It is critical to maintain renal blood flow with fluids, mannitol, and furosemide as needed. Shock should be treated with volume and vasopressors to support blood pressure. Coagulopathy should be treated with FFP. Heparin or steroids may be helpful.

The remaining donor blood should be sent, along with a posttransfusion blood specimen from the recipient, to the blood bank. Diagnosis is made by evidence of hemolysis (hemoglobinuria or hemoglobine-mia) and by blood incompatibility. In rechecking the blood type and cross-match, the patient's serum is tested for blood group alloantibodies, and the donor's plasma is tested for the presence of antibodies that react with the patient's blood. In transfusion reactions, serum haptoglobin will be decreased, serum lactate dehydrogenase will be elevated, and a direct antigen (Coombs) test usually will be positive. The blood bank will be able to test the blood, review records, confirm blood types, and determine if the patient's syndrome is from a transfusion reaction.

Risk of morbidity and mortality is proportional to amount of blood received prior to recognition of the transfusion reaction. Therefore, **in nonemergent blood transfusions, the initial rate of blood transfusion is low for the first 30 min to allow for identification of a transfusion reaction** while minimizing the volume of blood transfused. The best medicine is prevention by strict adherence to detail in obtaining blood for cross-match and initiating transfusion.

Extravascular delayed hemolytic reactions occur in about 1 per 1000 PRBC units transfused.¹ Hemolysis most commonly occurs in

TABLE 223-5 Risk of Infections from Transfusion of Blood Products

Etiology	Estimated Frequency: One Infection per Number of Units Transfused (95% CI)
HIV-1	1:1,000,000 (200,000-2,000,000)
HIV-2	Unknown
HTLV-I/II	1:500,000 (250,000-2,000,000)
Hepatitis B	1:40,000 (30,000-250,000)
Hepatitis C	1:40,000 (30,000-150,000)
Parvovirus B19	1:10,000
Bacterial contamination	1:12,000 random-donor platelet concentrates 1:500,000 PRBCs

the spleen and occasionally in liver and bone marrow. This type of reaction is less serious and rarely fatal. It may be determined by a positive Coombs test, elevated unconjugated (indirect) bilirubin level, and poor response to transfusion. Treatment is supportive.

Febrile Transfusion Reactions

Febrile transfusion reactions are characterized by onset of fever during or within a few hours of a blood transfusion.¹⁷ This type of reaction is one of the more common transfusion-related complications and is more common in multiparous women or multiply transfused patients. The clinical presentation can range from a mild elevation in temperature to fever along with rigors, headache, myalgias, tachycardia, dyspnea, and chest pain. Initially, it may be difficult to differentiate a febrile reaction from the more serious hemolytic transfusion reaction or sepsis.

Febrile transfusions result from a combination of recipient antibody against donor leukocytes and the release of cytokines that are produced during storage. For non-leukocyte-reduced platelets, the risk of fever during transfusion is about 20 percent, and with leukocyte reduction, the incidence of febrile reactions is about 2 percent. For the first-time febrile reaction or in any severe reaction, the transfusion should be stopped and the product returned to the blood bank. Laboratory investigation similar to that done for possible hemolytic transfusion should be done, and blood cultures should be obtained.

The febrile transfusion reaction is usually self-limited and will respond to antipyretics. Premedication with diphenhydramine and acetaminophen may help prevent these reactions. For patients with recurrent febrile reactions, the use of leukocyte-reduced blood products may be helpful, as well as pretreatment with antipyretics.

Allergic Transfusion Reactions

Allergic transfusion reactions are associated with the onset of urticaria and pruritus during the transfusion and occur in approximately 1 percent of transfusions. Fortunately, only a small percentage of patients will have more severe reactions, such as bronchospasm, wheezing, and anaphylaxis. These reactions are caused by an immune response to plasma proteins.

Conservative therapy with an antihistamine usually will control the symptoms. The transfusion usually does not have to be stopped. For more severe symptoms, the transfusion may need to be stopped and more aggressive management initiated. In patients with IgA deficiency, more severe anaphylactoid reactions can occur in response to exposure to the IgA in donor products. Washing the plasma from the cells minimizes this type of reaction.

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury is an uncommon but complex process that is thought to be due to granulocyte and antibody deposition within the lung.¹⁸ This injury results in the appearance of bilateral pulmonary infiltrates due to noncardiogenic pulmonary edema, usually within 4 h of transfusion. The presentation will be similar to a patient with adult respiratory distress syndrome and diagnosed by diffuse patchy infiltrates on chest radiograph and then excluding other etiologies. By itself, this lung injury is self-limiting and generally resolves spontaneously with only supportive care.

Hypervolemia

Transfusion of blood products can cause rapid volume expansion that patients with limited cardiovascular reserve such as infants, severe chronic compensated anemia, and the elderly may have difficulty managing. Patients may develop dyspnea, hypoxia, and pulmonary edema. Recognition of the potential for volume overload is the best

prevention so that blood can be transfused slowly, the patient monitored carefully, and treatment with diuretics may be initiated when necessary. The usual rate of transfusion is 2 to 4 mL/kg per h, but it can be slowed to 1 mL/kg per h in more delicate patients.

Electrolyte Imbalance

Electrolyte imbalances of hypocalcemia, hyperkalemia, or hypokalemia due to large-volume transfusions or altered excretion are uncommon. The anticoagulant citrate chelates calcium and is a component of many blood preservatives. Rarely with massive transfusions, hypocalcemia will develop. In patients with normal hepatic function, the infused citrate is metabolized to bicarbonate. Rarely, the excess bicarbonate causes alkalemia, driving potassium into the cells and causing hypokalemia. The potassium content in stored blood products increases during storage, and uncommonly, patients with renal insufficiency or neonates can develop hyperkalemia.

Delayed Complications

Many of the preceding complications can have delayed presentations. Furthermore, in patients with impaired immune systems, alloimmunization to class I HLA antigens can occur, having an impact on treatment and later transfusions. Immunocompetent T lymphocytes of donor blood can identify recipient cells as foreign and cause GVH disease, but this can be prevented by irradiation of blood products prior to transfusion.

ACKNOWLEDGMENT

We would like to acknowledge Mary Eberst for her contribution to these chapters in previous editions.

ANTICOAGULANTS, ANTIPLATELET AGENTS, AND FIBRINOLYTICS

Jim Edward Weber F.
Michael Jaggi Charles
V. Pollack, Jr.

Antithrombotic therapy is standard for numerous arterial and venous thromboembolic conditions, including acute myocardial infarction (AMI)—both ST-segment elevation MI (STEMI) and non-ST-segment elevation MI (NSTEMI)—unstable angina pectoris, deep venous thrombosis (DVT), pulmonary embolism (PE), and transient ischemic attack (TIA) or cardiovascular accident (CVA). Moreover, antithrombotic agents help prevent occlusive vascular disease in patients at risk for thrombosis. These agents, however, also have the potential to cause life-threatening complications, primarily uncontrolled hemorrhage. This chapter provides an overview of antithrombotic agents, including mechanisms of action, indications, and contraindications, as well as evaluation and management of acute bleeding complications. Detailed management of thromboembolic disorders is discussed in their respective chapters.

Hemostasis is initiated by platelet interaction with the vascular subendothelium and continues with a series of plasma coagulation proteins reactions that generate the final product of cross-linked fibrin, an insoluble protein, meshed with the initial platelet plug (see Chap. 218). Arterial thrombi, composed primarily of platelets bound by thin fibrin strands, develop under high-flow conditions, especially at sites of ruptured atherosclerotic plaques. Both anticoagulants and platelet-inhibiting drugs may effectively prevent and treat arterial thrombosis. In contrast, venous thrombi form in areas of sluggish blood flow, and are composed mainly of red blood cells and large fibrin strands. Anticoagulant drugs are effective in preventing and treating venous thromboembolism, while platelet-suppressing agents are less useful.

Both arterial and venous thrombi may result in local vascular obstruction or distant embolization. Antithrombotic agents interfere with these processes either by preventing formation of the platelet-fibrin net (blocking thrombin activation or platelet function) or by accelerating clot breakdown (fibrinolysis). Antithrombotic agents are classified by mechanism of action. Anticoagulants block the synthesis and activation of clotting factors, interfering with the coagulation cascade at one or more steps. Antiplatelet agents interfere with platelet activation or aggregation. Fibrinolytics (often but inaccurately referred to as thrombolytic agents) enzymatically dissolve the fibrin component of thrombi.

ANTICOAGULANTS

Warfarin

PHARMACOLOGY OF WARFARIN Oral anticoagulants are used to 1) stop further thrombosis when the condition already exists (e.g., DVT), 2) reduce the risk of embolism in patients with thrombotic disease (e.g., DVT or left ventricular mural thrombus), and 3) prevent thrombi from forming in patients with risk factors for their development (e.g., prolonged immobilization or venous disease) (Table 224-1). Sodium warfarin, a hydroxycoumarin compound, is the most

TABLE 224-1 Antithrombotic Therapy Guidelines

Clinical Indication	Comments
Treatment of DVT and PE	
Unfractionated heparin: 80 U/kg IV bolus, then 18 U/kg per h continuous infusion, with the aPTT checked after 6 h and the infusion adjusted to maintain the aPTT 1.5–2.5 times control <i>with</i> concurrent institution of warfarin.	In most cases, heparin and warfarin can be started simultaneously, with an overlap of 3–5 days.
Enoxaparin: 1 mg/kg SC bid or 1.5 g/kg SC per d	Warfarin should be continued for at least 3 months.
SK: 250,000 units IV bolus, then 100,000 U/h continuous infusion for 1–3 d	
Alteplase: 15 mg bolus, then 0.75 mg/kg over 30 min (maximum 50 mg), then 0.50 mg/kg over 60 min (maximum 35 mg)	
Urokinase: 4400 U/kg IV bolus then 4400 U/kg per h continuous infusion for 1–3 d	
Prophylaxis of DVT and PE	
Unfractionated heparin: 5000 units SC bid or tid	
Ardeparin: 50 U/kg SC bid	
Dalteparin: 2500 to 5000 units SC per d	
Enoxaparin 30 mg SC bid or 40 mg SC per d	
STEMI	
Aspirin (nonenteric coated): 160–325 mg PO per d	All postmyocardial infarction patients should receive aspirin 160–325 mg/d for an indefinite period (unless contraindicated or if on warfarin).
Unfractionated heparin: 60 U/kg IV bolus, then 12 U/kg per h continuous infusion adjusted to keep aPTT 1.5–2.5 times control <i>or</i> 17,500 units SC bid	Optimal strategies are unclear. Research is evolving rapidly.
Enoxaparin: 1 mg/kg SC bid	
Patients at high risk for mural thrombosis or systemic embolism: heparin, then warfarin for 1–3 months (INR 2.0–3.0)	
Streptokinase: 1–1.5 million units IV over 60 min	
Alteplase: 15 mg bolus, then 0.75 mg/kg over 30 min (maximum 50 mg), then 0.50 mg/kg over 60 min (maximum 35 mg)	
Retepase: 10 units IV bolus, then a second dose at 30 min	
Tenecteplase: weight-tiered single bolus (approximately 0.5 mg/kg with maximum of 50 mg) over 5 s	
Unstable angina or NSTEMI	
Aspirin: 162 mg PO per d	
Clopidogrel: 75 mg PO per d	
Heparin: 60 U/kg IV bolus, then 12 U/kg per h continuous infusion to keep aPTT 1.5–2.5 times control	
Enoxaparin 1 mg/kg SC bid	
Glycoprotein IIb/IIIa inhibitor depending upon risk and whether PCI is planned	
Peripheral vascular disease	
Aspirin: 160–325 mg/d for all patients with peripheral vascular disease	
Acute stroke	
Alteplase: 90 mg over 1 h, with 0.9 mg/kg as initial bolus, if within 3 h of symptom onset and no intracranial hemorrhage on brain CT	Use of fibrinolytics in acute CVA requires <i>strict</i> adherence to national guidelines and should be done with informed consent.
Heparin: for acute cardioembolic stroke, small to moderate size, no hemorrhage on CT or MRI	Adjunctive use of anticoagulants must be avoided for 48 h.
Delay anticoagulation: for large-size stroke or poorly controlled hypertension	Some evidence suggests that clopidogrel may be the preferred agent in patients with completed stroke.
Aspirin: 81 mg PO per d for completed stroke	
Clopidogrel: 75 mg PO per d	
Ticlopidine: 250 mg PO per bid	
TIA	
Aspirin: 81 mg PO per d	Use clopidogrel or ticlopidine if “aspirin-failure” or aspirin allergic.
Clopidogrel: 75 mg PO per d	
Ticlopidine: 250 mg PO bid	

Abbreviations: aPTT = activated partial thromboplastin time; AMI = acute myocardial infarction; CT = computed tomography; CVA = cerebrovascular accident; DVT = deep venous thrombosis; INR = International Normalized Ratio; MRI = magnetic resonance imaging; NSTEMI = non-ST-segment elevation myocardial infarction; PCI = percutaneous coronary intervention; PE = pulmonary embolism; SK = streptokinase; STEMI = ST-segment elevation myocardial infarction; TIA = transient ischemic attack.

widely used oral anticoagulant in North America. Readily absorbed from the gut, it reaches peak blood concentrations in 90 min and has a circulating half-life of 36 to 42 h. Warfarin is bound to albumin, metabolized by the liver, and excreted in the urine. Warfarin blocks activation of vitamin K and thereby interferes with hepatic carboxylation of coagulation factors II, VII, IX, and X. Without these vitamin K-dependent cofactors, the extrinsic coagulation pathway is blocked. Warfarin also blocks the synthesis of the antithrombotic proteins C

and S; proteins that inhibit the function of factors V and VII in the coagulation cascade.

Warfarin dosing is guided by measurement of the International Normalized Ratio (INR), a standardized measurement of prothrombin time (PT), with a desired therapeutic range of 2 to 3 in most cases.¹ Drugs and food that interfere with warfarin absorption, binding to albumin, or hepatic metabolism can have a profound effect on warfarin activity (Table 224-2). Warfarin is contraindicated in pregnancy

TABLE 224-2 Warfarin Interactions

Consideration	Prothrombin Time (PT) or INR*
Major	
Vitamin K malabsorption or dietary deficiency	↑
Excess vitamin K	↓
Reduced gut bacteria (antibiotics)	↑
Decreased warfarin absorption	↓
Altered warfarin metabolism (cytochrome P450)	↑ or ↓
Drug effects	↑ or ↓
Other	
Decreased clotting factor production (liver disease)	↑
Increased metabolism of clotting factors (fever)	↑
Confounding technical or laboratory factors (e.g., phlebotomy, handling in transport, thromboplastin reagents)	↑ or ↓

*t = Prothrombin time (PT) or International Normalized Ratio (INR) prolonged; ↓ = PT or INR decreased.

because it is teratogenic (especially during the sixth to twelfth week of gestation) and causes fetal hemorrhage.

Protein C has a short half-life (8 h), and its plasma level falls quickly after starting warfarin. The coagulation factors have variable half-lives; from about 7 h for factor VII to about 60 h for prothrombin (factor II). The phase delay between the fall in protein C (an antithrombotic protein) and the fall in the affected four coagulation factors (prothrombotic proteins) results in a transient state of increased thrombogenesis at the start of warfarin therapy that lasts for about 24 to 36 h. This potential hypercoagulable state is reduced but not eliminated by initiating warfarin therapy with 5 mg/d doses.² For patients in whom sudden intravascular thrombosis can be fatal (e.g., those with a prosthetic heart valve), anticoagulation should be ensured with a heparin product (unfractionated or low molecular weight) before starting oral warfarin. Thus, a noncompliant patient with a prosthetic heart valve who has stopped oral anticoagulants should not simply be discharged with instructions to restart warfarin.

There is also a prothrombotic rebound during warfarin withdrawal. During the first 4 days after cessation of therapy, factors VII and IX increase more rapidly than proteins C and S, resulting in an imbalance between provokers and inhibitors of coagulation.³ This potential hypercoagulable condition appears to exist biochemically, although prospective studies have shown no increased incidence of clinical episodes of thrombosis with sudden termination of warfarin therapy compared to gradual tapering during this interval. Thromboembolic events that occur in patients after warfarin discontinuation are related more to the underlying condition than to the method of termination.

COMPLICATIONS AND MANAGEMENT The two major complications of warfarin therapy are major bleeding episodes and skin necrosis. The most important factor influencing the risk of bleeding is the intensity of anticoagulant therapy. For most purposes, the target INR is 2.0 to 3.0, except for patients with mechanical heart valves and antiphospholipid antibody syndrome, who require more intense anticoagulation with an INR of 2.5 to 3.5. The risk of clinically significant bleeding is increased when the INR is in the 3.0 to 4.5 range, and an exponential increase in bleeding events occurs when the INR is >5.0. Reversal with vitamin K₁ or factor replacement may be necessary for major hemorrhage. Skin necrosis occurs primarily in patients with protein C deficiency. This complication usually develops 3 to 8 days after starting treatment and is caused by thrombosis of small cutaneous vessels. Treatment includes discontinuation of warfarin, administration of UFH or LMWH, vitamin K₁ administration, and screening for protein C and S deficiencies.

Bleeding is the most common complication of warfarin treatment. Risk factors for bleeding include hypertension, anemia, prior cerebrovascular disease, gastrointestinal lesions, and renal disease. Medications that increase warfarin activity and antiplatelet medications can also increase bleeding risks (see Table 224-2). The relationship be-

tween advanced age and warfarin-associated bleeding is controversial. Elderly individuals who are otherwise good candidates for anticoagulant therapy should not have it withheld because of their age. However, elderly patients require more frequent and careful monitoring.

Two general principles are important when warfarin-treated patients bleed with a prolonged INR: 1) attempt to identify and attenuate the cause of bleeding, and 2) lower the intensity of the anticoagulant effect. In patients with a high INR *without* clinically evident bleeding, cessation of warfarin, careful observation, and periodic monitoring is the safest course.⁴ With clinically significant bleeding, however, reversal may be required, but the speed and extent of reversal must be balanced against the risk of recurrent thromboembolism in patients who require therapeutic anticoagulation. For example, an over-anticoagulated patient with a prosthetic mitral valve may develop fatal thrombosis if rapidly and fully reversed.

Three approaches can be taken to reverse warfarin-induced coagulopathy. The first is to stop warfarin therapy; the second is to administer vitamin K_j (PO, SC, or IV); the third is to administer fresh-frozen plasma (FFP) or prothrombin concentrate (see Table 224-3). One mg of oral vitamin K_j decreases the INR faster than 1 mg of subcutaneous vitamin K_i in asymptomatic patients with elevated INR values while receiving warfarin. To reduce the risk of hemorrhage, 1 mg of oral vitamin K_j should be considered for asymptomatic patients who are receiving warfarin and who present with an INR of 4.5 to 9.⁵ Reversal is significant by 16 h, and the INR is within the therapeutic range by the second day. While subcutaneous vitamin K_j (1 to 2 mg) reverses warfarin, with a measurable effect on the INR usually by 8 to 12 h, the response may be less predictable and delayed when compared to oral administration. At least some normal liver function is required for vitamin K_i to be effective and to reverse the coagulopathy associated with warfarin. Low-dose oral and subcutaneous vitamin K_j carry a small risk for patients who require therapeutic anticoagulation, and it is recommended that the emergency physician consult an appropriate specialist before using either approach.

Intravenous vitamin K_j carries a rare but serious, non-dose-dependent risk of anaphylaxis, and should not be used for routine reversal of therapeutic over-anticoagulation. For patients who require continued anticoagulation, intravenous administration carries the risk of overcorrection not associated with oral or subcutaneous use. Intravenous vitamin K_i should be restricted to those patients with life-threatening bleeding or with an INR >20, and for symptomatic patients poisoned by an ingestion of warfarin (suicidal overdose) or a rodenticide (brodifacoum). Generally, such patients do not require therapeutic anticoagulation, and reversal does not carry the risk of recurrent thrombosis. Because of the long half-life of these superwarfarin rodenticides, significantly poisoned patients may require treatment with high doses of vitamin K_i, up to 125 mg/d, for several weeks.

From the standpoint of the risk of recurrent thrombosis, the safest method of reversing therapeutic over-anticoagulation is with coagula-

TABLE 224-3 Emergency Treatment of Bleeding Complications of Antithrombotic Therapy

Agent	Management
Warfarin	
INR <5.0 without clinically evident bleeding	Cessation of warfarin administration and observation with serial PT/INR
INR 5–9 and no significant bleeding	Hold warfarin, may resume at lower dose once INR therapeutic Oral vitamin K ₁ 1–2 mg if patient at increased bleeding risk
INR >9 and no significant bleeding	Hold warfarin and monitor INR frequently Oral vitamin K ₁ 2–4 mg
INR >20 or clinically significant bleeding (major or life-threatening)	FFP: 10–15 mL/kg to acutely restore coagulation factors to ≥30% of normal Vitamin K ₁ : 5–10 mg slow IV infusion Vitamin K ₁ therapy requires 12–24 h for full effect and may require >1 treatment Vitamin K ₁ may induce unwanted thrombosis and/or overcorrection
Heparin	
Clinically significant/bleeding	Immediate cessation of heparin administration Supratherapeutic aPTT not always present Anticoagulation effect lasts up to 3 h from last dose
Minor bleeding	Observation with serial aPTT may be sufficient
Major bleeding	Protamine: 1 mg per 100 units of heparin, given slowly IV over 1–3 min to a maximum of 50 mg over any 10-min period Protamine may need to be repeated Protamine has anaphylaxis risk Protamine does not reverse LMWH (e.g., enoxaparin)
Aspirin and NSAID	
Clinically significant bleeding: correlates poorly with BT	Cessation of aspirin or NSAID administration Platelet transfusion to increase count by 50,000 (typically requires at least 6 units of random donor platelets)
Other Antiplatelet Agents	Aspirin inhibition lasts for life of affected platelets so repeat platelet transfusions sometimes required NSAID platelet inhibition typically lasts less than 1 day
Fibrinolytics	
Minor external bleeding	Manual pressure
Significant internal bleeding	Immediate cessation of fibrinolytic agent, antiplatelet agent, and/or heparin Reversal of heparin with protamine as above Typed and cross-matched blood ordered with verification of aPTT, CBC, TCT, and fibrinogen level Volume replacement with crystalloid and PRBC as needed
Massive bleeding with hemodynamic compromise	All measures listed for significant internal bleeding, above Cryoprecipitate: 10 units and recheck fibrinogen level If fibrinogen level <100 mg/dL, repeat cryoprecipitate If bleeding remains after cryoprecipitate or despite fibrinogen level >100 mg/dL: administer 2 units of FFP If bleeding continues after FFP: check BT If BT <9 min: give ε-aminocaproic acid 5 g IV over 60 min, then 1 g/h infusion for 8 h or until bleeding stops or tranexamic acid 10 mg/kg q6–8h If BT >9 min: give ε-aminocaproic acid or tranexamic acid as above with 10 units of random donor platelets
Intracranial hemorrhage	All measures listed for significant internal and massive bleeding Immediate neurosurgery consultation.

Abbreviations: aPPT = activated partial thromboplastin time; BT = bleeding time; CBC = complete blood count; INR = international normalized ratio; LMWH = low-molecular-weight heparin; FFP = fresh-frozen plasma; NSAID = nonsteroidal anti-inflammatory drug; PRBC = packed red cells; PT = prothrombin time; TCT = thrombin clotting time.

tion factor infusion using either FFP or factor concentrates. A dose of FFP 10 to 15 mL/kg (typically 3 to 4 units) will acutely restore coagulation factor levels to at least 30 percent of normal in most adults, and will control most bleeding without undue risk. Reversal of anticoagulation with FFP is usually safe for short periods, regardless of indication for anticoagulant therapy.⁶ For patients with life-threatening hemorrhage and who require rapid, complete reversal, coagulation factor concentrates are more reliable and preferred.⁷

Heparin

PHARMACOLOGY OF UNFRACTIONATED HEPARIN Unfractionated heparin (UFH) is a heterogeneous mixture of polysaccharides ranging in molecular weight from 2000 to 40,000 Da. The anticoagulant effect of UFH requires binding to antithrombin **III** (ATIII). The heparin-ATIII complex is capable of inhibiting multiple steps in the extrinsic and common coagulation pathways, including factors Xa,

IXa, XIa, and XIIa, and thrombin (factor IIa). UFH inhibition of thrombin is dependent upon saccharide chain length, with shorter chain lengths (<18 saccharide units) possessing greater anti-Xa activity and longer chain lengths having greater antithrombin activity. These wide variations in chain lengths in UFH likely contribute to the unpredictable nature of its dose-response relationship.

UFH must be given parenterally (IV or SC). Its half-life (30 to 150 min) depends on the dose and route. Weight-based intravenous heparin-dosing protocols are the most reliable approach for achieving a therapeutic effect and preventing further thrombosis during acute thromboembolic events. The subcutaneous method is not recommended for the treatment of acute thromboembolic disease because the bioavailability of subcutaneous UFH ranges from 10 to 90 percent, depending on the dose. However, subcutaneous UFH can be used to prevent thromboembolism with a 60 to 70 percent risk reduction for DVT and fatal PE (see Table 224-1). Because UFH interferes with most laboratory investigations for hypercoagulable states, these tests should ideally be ordered before the patient is anticoagulated. Neither UFH nor low-molecular-weight heparin (LMWH) crosses the placenta; consequently, both are safe to use in pregnancy.

Despite extensive use in clinical practice over several decades, UFH continues to possess several important limitations. UFH has an unpredictable anticoagulation effect, requires frequent monitoring, and is inactivated by plasma proteins and platelet factor-4 (PF₄). The unpredictable inhibition of thrombin by UFH is attributable to a low bioavailability from extensive nonspecific binding to serum proteins, macrophages, and endothelial cells. The anticoagulant effect of heparin can be monitored with the activated partial thromboplastin time (aPTT), which is widely available from clinical laboratories (see Table 224-1).⁸ There is not a linear relationship between heparin concentration, the anticoagulant activity of heparin (as measured by its antifactor Xa activity), and the aPTT. For most purposes, a therapeutic range for heparin can be either an aPTT of 1.5 to 2.5 the "normal" value, a heparin level of 0.2 to 0.4 U/mL when assayed by protamine titration, or 0.3 to 0.7 U/mL when assayed for anti-Xa activity.⁸ UFH can increase the PT and FNR by a variable amount, depending on the heparin concentration and the thromboplastin reagent used in the assay. Typically, therapeutic concentrations of heparin increase the PT by approximately 1 to 5 s.

PHARMACOLOGY OF LOW-MOLECULAR-WEIGHT HEPARIN FRACTION The LMWH has made a significant contribution to the advancement of anticoagulation therapy. Both UFH and LMWH exert their anticoagulant effect by activating ATIII.⁹ Their interaction with ATIII is mediated by a unique pentasaccharide sequence that is randomly distributed along the heparin chains. When ATIII interacts with the pentasaccharide sequence on the heparin molecule, it undergoes a conformational change that allows it to bind thrombin 1000 times faster. This coupling with thrombin requires an additional 13-saccharide group that brings the key binding regions of ATIII and thrombin into contact. However, only the specific pentasaccharide sequence is necessary to bind to ATIII for effective inhibition of factor Xa. UFH binds factor Xa and thrombin in roughly equal proportions (anti-Xa: anti-IIa ratio = 1.0) because chains of at least 18 residues predominate. In contrast, LMWH are manufactured from UFH through depolymerization using either a chemical or an enzymatic process. This results in a smaller molecule (4000 to 5000 Da) with less than half containing the required 13-saccharide residues to bind ATIII and thrombin. The shorter chains results in a reduced ability to inactivate thrombin and enhanced affinity for inactivating factor Xa.

There are many clinical advantages associated with the use of LMWH (Table 224-4). The plasma half-life of LMWH is two to four times as long as UFH, allowing for once- or twice-daily dosing. LMWH has a decreased binding to plasma proteins, endothelial cells, and macrophages, thus yielding a more predictable anticoagulant and dose-response relationship. This allows for subcutaneous administra-

TABLE 224-4 Advantages of LMWH Over Unfractionated Heparin

Pharmacologic Effects	Clinical Benefit
Quick and predictable SC absorption	More reliable level of anticoagulation
stable dose response	Eliminates need for monitoring
inhibition by PF ₄	Decreased incidence of thrombocytopenia
Decreased antiheparin antibody production by 70%	Greater anti-Xa antithrombotic effects
Greater anti-Xa activity	Potential to reduce bleeding
Less antithrombin activity	Absence of "rebound"
Ease of administration	Outpatient therapy

Abbreviations: LMWH = low-molecular-weight heparin; PF₄ = platelet factor-4.

tion of fixed dosages. Laboratory monitoring of these agents is generally unnecessary except in patients with renal insufficiency and obesity. LMWH is cleared by the kidneys, and toxicity can occur in patients with significant renal impairment. LMWH therapy may be monitored by anti-Xa activity.¹⁰ Anti-Xa activity and half-life is prolonged with decreasing renal function, resulting in a higher tendency for hemorrhagic complications. Because of the lack of clear dosing guidelines, these agents should be dosed with caution in patients with renal impairment. LMWH dosing in obese patients has not been specifically addressed in large clinical trials. Safety data in the obese population are thus derived from studies in the ACS population.¹¹ In these trials, LMWH dosing was based on total body weight up to a maximum of 160 kg. In patients over 160 kg, the use of anti-Xa activity should be considered.

Enoxaparin, dalteparin, and ardeparin are the most widely available of the LMWH products. Current indications for LMWH use are treatment of DVT, PE, unstable angina, and AMI. Only enoxaparin is approved for outpatient management of DVT. Although acquisition costs of LMWH are higher than for UFH, formal studies of cost-effectiveness suggest that LMWH use pays for itself, and may ultimately be cost-saving. This cost benefit can be magnified if patients with DVT are treated primarily in the outpatient setting.

COMPLICATIONS AND MANAGEMENT

Unfractionated heparin The two major complications of UFH are major bleeding episodes and HIT. Up to one-third of patients receiving heparin develop some form of bleeding complication, with a 2 to 6 percent risk for major bleeding. An increased risk (up to 20 percent) for major bleeding is associated with a number of comorbid conditions, including recent surgery or trauma, renal failure, alcoholism, malignancy, liver failure, and gastrointestinal bleeding, as well as the concurrent use of warfarin, fibrinolytics, steroids, or antiplatelet drugs.

Bleeding in patients being treated with UFH is treated according to the clinical severity and aPTT level.¹² Unfortunately, heparin-associated bleeding is not always reflected by a supratherapeutic aPTT. If bleeding develops during UFH therapy, UFH administration should be stopped immediately. While UFH half-life is dose dependent (30 to 150 min), its anticoagulation effect can last up to 3 h. Thus, observation may be appropriate in less-severe cases, with serial aPTT used to determine when therapy may be resumed. While protamine can reverse the anticoagulant effect of UFH (a ratio of 1 mg intravenous protamine neutralizes 100 units of UFH administered in the prior 4 h), the adverse effects of protamine are significant. **Protamine should be given slowly intravenously over 1 to 3 min and should not exceed 50 mg in any 10-min period.** However, because the half-life of protamine is short, a heparin rebound may occur, requiring a second treatment. Allergic reactions are possible, and **approximately 0.2 percent of patients receiving protamine develop anaphylaxis, which has a**

30 percent mortality rate. Thus, protamine should be reserved for major bleeding complications.

There are two types of HIT: type I and type II. HIT type I is the more common type, and is caused by UFH-induced direct platelet aggregation. It occurs early (1 to 5 days) and is usually transient and benign. HIT type II is caused by IgG or IgM autoantibody formation directed against both heparin and PF₄. Thus platelet activation occurs, producing both thrombocytopenia and a tendency for thrombosis. Thrombosis may involve the skin (similar to warfarin-induced cutaneous necrosis), major arteries (e.g., ischemic limbs), or the veins (e.g., recurrent DVT or PE). The onset of HIT type II is usually 5 to 12 days after UFH treatment is started, but may be sooner for patients who developed the antibody from a previous exposure. Overall, the incidence of HIT type II is between 1 and 3 percent in patients treated with UFH, but is significantly less in patients treated with LMWH products. The platelet count nadir is often modest, typically 20,000 to 150,000/ \times L. However, a drop of 50 percent from baseline is concerning, even if the platelet count is normal. It is important to assess for recent use of UFH or LMWH before instituting therapy for a new DVT that may in fact be a thrombotic complication of HIT.

In HIT type II, UFH therapy must be stopped as soon as the condition is recognized. Protamine is not effective against the immune-mediated response. The platelet count generally returns to normal in 4 to 6 days. During the recovery phase, however, the risk of arterial or venous thrombosis is substantially elevated, and the potential complications include gangrene, stroke, and death. It is unclear whether such patients should ever be exposed to UFH again. Thrombocytopenia appears to be less common with porcine UFH than with bovine UFH. LMWH are not recommended for use in treating HIT because of cross-reactivity between LMWH and the antiplatelet antibody. Additionally, warfarin should not be started until the patient is sufficiently anticoagulated by an alternative measure to avoid precipitating arterial or venous thrombosis or producing skin necrosis. Prophylactic transfusion of platelets is not indicated because bleeding is not usually a manifestation of HIT type II, and platelet transfusion may precipitate thrombosis. Anticoagulation with a DTI should be considered in patients with clinically suspected HIT type II, even in the absence of symptomatic thrombosis.

Low-molecular-weight heparins In general, LMWH preparations cause less bleeding than does UFH. Reported side effects of LMWH include bleeding, HIT, local skin reaction, pruritus, and rare skin necrosis. Protamine will neutralize the antithrombin effect of LMWH, but incompletely reverses factor Xa inhibition. In the event of bleeding, 1 mg of protamine can neutralize 1 mg of enoxaparin and 100 units of dalteparin. The use of FFP and packed red blood cells should be considered in patients with ongoing or life-threatening bleeding.

Hirudin and Analogues

PHARMACOLOGY OF HIRUDIN AND HIRUDIN ANALOGUES Direct thrombin inhibitors (DTIs), hirudin and hirudin analogues, have several potential advantages over heparin. Unlike heparin, DTIs are capable of inhibiting both circulating and clot bound thrombin, do not inhibit other coagulation pathway or fibrinolytic enzymes, do not require ATIII as a cofactor, and are not inactivated by PF₄ or plasma proteins. Therefore, DTIs have a more predictable anticoagulant effect than UFH. Hirudin is a 65-amino-acid polypeptide, originally derived from the salivary gland of the medicinal leech *Hirudo medicinalis*. It is now prepared by recombinant technology. Recombinant hirudin has been modified into a number of available analogues. Currently, hirudin, lepirudin, and argatroban are currently FDA-approved for anticoagulation in patients with HIT. In the setting of AMI, unstable angina, or primary coronary intervention (PCI), hirudin reduced the incidence of death and reinfarction at 24 h, but not at 30 days postadmission. Although there were no significant differences in the inci-

dence of serious or life-threatening hemorrhagic complications, hirudin was associated with a higher incidence of moderate bleeding.¹³ Currently, hirudin is approved only for patients with history of or at risk for HIT.

Synthetic analogues of hirudin are currently being studied as alternatives to heparin for the treatment of unstable angina, post-PCI use, postsurgical DVT prevention, and as an adjunct to fibrinolytic therapy. Currently, bivalirudin and argatroban are approved for use in the catheterization laboratory as an anticoagulant during PCI. In addition to hirudin, lepirudin and argatroban are used for antithrombotic treatment in patients with HIT.

COMPLICATIONS AND MANAGEMENT The primary adverse effect of DTIs is bleeding and the majority of bleeding events occur at invasive sites. Because the half-life of hirudin and its analogues is relatively short (<2 h), and an antidote is not currently available, management of DTI-related hemorrhage may require only stopping the intravenous infusion and waiting, with coagulation factor replacement using FFP or prothrombin concentrates if bleeding persists.

ANTIPLATELET AGENTS

Aspirin and NSAIDs

PHARMACOLOGY Aspirin irreversibly blocks cyclooxygenase, an enzyme that in the platelet catalyzes the conversion of arachidonic acid to thromboxane A₂, and in the blood vessel wall promotes prostacyclin synthesis. The net effect of aspirin in ischemic arterial beds depends on the balance between thromboxane A₂, a potent vasoconstrictor and platelet-aggregation agent, and prostacyclin, a vasodilator and platelet-aggregation inhibitor. An antithrombotic effect can be seen with doses as low as 30 mg. Because prostacyclin synthesis is stimulated at lower aspirin levels than is thromboxane A₂ conversion, treatment plans often use low-dose strategies (e.g., 81 to 162 mg/d). For more rapid antiplatelet effect, a medium or higher initial dose (e.g., 162 to 325 mg) is indicated (see Table 224-1).

Aspirin is quickly absorbed in the upper gastrointestinal tract, reaches peak blood concentrations in 15 to 20 min, and circulates with a half-life of 30 to 60 min. However, its antiplatelet effect is irreversible and lasts for the life span of the platelet (about 10 days).

Side effects of aspirin use are mainly gastrointestinal and dose related, and may be reduced with concomitant use of antacids, enteric coating, and buffering agents. Aspirin should be avoided in patients with known hypersensitivity and used cautiously in those with bleeding disorders or severe hepatic disease. Active gastrointestinal hemorrhage (e.g., bleeding peptic ulcer) is a contraindication to aspirin use. However, in AMI and unstable angina with occult gastrointestinal bleeding (e.g., guaiac-positive stool), most experts favor aspirin use with careful monitoring. Non-enteric-coated aspirin should be considered when prompt onset of action is necessary, as in patients with ongoing chest pain. Aspirin therapy is also associated with a slightly increased risk of hemorrhagic stroke (12 per 10,000 over 3 years), but this risk is balanced by a tenfold reduction in the risk of myocardial infarction and a threefold reduction in the risk of ischemic stroke.¹⁴

Nonsteroidal anti-inflammatory agents reversibly inhibit platelet cyclooxygenase and inhibition of platelet aggregation usually lasts less than 24 h. The exception is piroxicam, which has a 2-day half-life.

COMPLICATIONS AND MANAGEMENT Upper gastrointestinal irritation is the most common side effect of aspirin therapy, while life-threatening gastrointestinal bleeding is uncommon.¹⁵ As noted earlier, intracranial hemorrhage, the most feared complication of anticoagulation and antithrombotic therapy, appears to occur rarely with aspirin alone.¹⁴ Some patients are markedly sensitive to aspirin, such that even low doses lead to markedly prolonged bleeding times and risk of

severe clinical hemorrhage, particularly related to surgery or trauma. Uremic patients are especially sensitive to bleeding induced by aspirin. The combination of alcohol and aspirin can also prolong a patient's bleeding time (BT).

Unfortunately, the BT is a poor test to confirm bleeding complications of aspirin. If aspirin-associated bleeding is suspected [e.g., persistent oozing after tooth extraction despite normal platelet count ($>100,000/\text{xL}$) and coagulation studies], further workup should include obtaining a careful history for ingestion (significant unintentional ingestion may occur because some 300 over-the-counter medications contain aspirin), and confirmed with a salicylate level if needed. Management of acute aspirin-induced or NSAID-induced hemorrhage involves the transfusion of enough normal platelets to increase the platelet count by $50,000/\text{xL}$. Because of the irreversible effect of aspirin on platelets, the hemostatic compromise might last for 4 to 5 days after aspirin has been discontinued, and platelet transfusions may have to be repeated daily, whereas NSAID-induced platelet dysfunction typically resolves within 1 day after halting use.

Clopidogrel and Ticlopidine

PHARMACOLOGY OF PLATELET MEMBRANE ALTERING AGENTS During platelet aggregation, fibrinogen forms a bridge between adjacent platelets by binding to the glycoprotein platelet-surface receptor, labeled IIb-IIIa. A variety of agents that interfere with the platelet membrane and the glycoprotein (GP) IIb-IIIa receptor have been introduced into clinical practice during the past few years.

Clopidogrel and ticlopidine selectively inhibit platelet aggregation induced by adenosine diphosphate (ADP). Specifically, they appear to irreversibly inhibit the binding of ADP to the receptor mediating inhibition of platelet adenylate cyclase, thereby deforming the region of the platelet membrane next to its fibrinogen receptor and rendering it ineffective. Clopidogrel has been approved for the treatment of unstable angina, NSTEMI, secondary prevention of AMI and CVA, and in established peripheral artery disease.¹⁶ Although clopidogrel is generally well tolerated, side effects include dyspepsia, rash, and diarrhea. Ticlopidine is associated with hematologic problems, such as neutropenia, idiopathic thrombocytopenic purpura, and, rarely, thrombotic thrombocytopenic purpura (TTP). Ticlopidine-related TTP occurs most often during the first 2 weeks of therapy. Clopidogrel should be considered for administration in hospitalized patients with NSTEMI or unstable angina who have a history of ASA hypersensitivity or major gastrointestinal intolerance.

COMPLICATIONS AND MANAGEMENT TTP has rarely been reported, even after as little as 2 weeks of exposure. If quick reversal of pharmacologic effects is needed, platelet transfusion should be considered.

Abciximab, Eptifibatide, and Tirofiban

PHARMACOLOGY OF GLYCOPROTEIN IIb-IIIa RECEPTOR INHIBITORS Damaged platelets activate several receptor sites, most notably the GP IIb-IIIa receptors. Once activated, a single fibrinogen molecule is capable of binding two GP IIb-IIIa receptor sites on adjacent platelets. Thus, GP IIb-IIIa receptors represent the final common pathway for platelet activation and aggregation.

Three parenteral GP IIb-IIIa receptor inhibitors are currently available for the treatment of unstable angina, NSTEMI, and high-risk patients undergoing PCI. Abciximab (a monoclonal antibody), eptifibatide (a synthetic peptide), and tirofiban (a nonsynthetic peptide) inhibit platelet aggregation, prevent thrombosis, and may augment thrombolysis. These agents are administered as an initial loading-dose bolus for abciximab and eptifibatide, and as a 30-min infusion for tirofiban, followed by a constant intravenous infusion. Abciximab is a

noncompetitive GP IIb-IIIa inhibitor with a much longer platelet effect than its plasma half-life of 10 min; platelet function will return to normal within 48 h after discontinuing the infusion. Eptifibatide is a competitive GP IIb-IIIa inhibitor with a plasma half-life of approximately 2.5 h. Tirofiban is also a competitive GP IIa-IIIb inhibitor with a plasma half-life of approximately 2 h. Platelet functional recovery after stopping either eptifibatide or tirofiban infusion is seen in 3 to 5 h. Improved outcome has been demonstrated in high risk unstable angina and NSTEMI patients with GP IIb-IIIa blockade who undergo PCI.¹⁷ Glycoprotein IIb-IIIa antagonists are recommended for such patients when catheterization and PCI are planned.¹⁸ Although a "time-dependent benefit window" for GP IIb-IIIa therapy has not been clearly established for unstable angina or NSTEMI, in patients undergoing PCI, a time-to-treatment benefit has been demonstrated with prompt initiation of eptifibatide and in the ED setting. The 2002 American College of Cardiologists (ACC)/American Heart Association (AHA) Guidelines state that the GP IIb-IIIa agent may "also be administered just prior to PCI."¹⁸ In institutions with ready access to a catheterization laboratory, emergency physicians can expedite definitive management by initiating aggressive medical therapy in consultation with interventional cardiologists. In institutions without an on-site catheterization laboratory, emergency physicians should initiate medical therapy and transfer arrangements in collaboration with the accepting interventional cardiologist. In patients not undergoing PCI, GP IIb-IIIa antagonists are appropriate for high-risk patients, but are not recommended for low-risk patient groups.¹⁸

COMPLICATIONS AND MANAGEMENT Patients receiving GP IIb-IIIa inhibitors have increased risk for bleeding complications (particularly if heparin is also used and usually related to catheterization or coronary artery bypass surgery) but have no increased risk of intracranial hemorrhage. Treatment of major hemorrhage in patients on GP IIb-IIIa inhibitors requires red cell and platelet transfusions, and replacement of coagulation factors as needed.

FIBRINOLYTICS

Although mechanisms vary, each fibrinolytic agent eventually converts plasminogen to plasmin, which then enzymatically breaks apart the fibrin component of thrombi. Currently approved fibrinolytic agents include streptokinase, anistreplase, alteplase, reteplase, and tenecteplase.

Streptokinase and Anistreplase (First Generation)

Streptokinase (SK), derived from P-hemolytic streptococci, binds to and activates circulating plasminogen, converting it to plasmin, which in turn attacks fibrin, leading to thrombus dissolution. Circulating fibrinogen also undergoes plasmin-induced lysis, producing a state of "systemic fibrinolysis." SK is administered as a slow infusion (usually 1.0 to 1.5 million U IV over 60 min) and has a serum half-life of approximately 23 min, but in most patients systemic effects persist for up to 24 h. Because of the prolonged fibrinolytic state and increased risk of hemorrhage, anticoagulation with heparin is usually delayed following treatment with SK. Anistreplase, a modified active plasminogen-streptokinase complex, has an effect similar to that of SK, but its chief advantage is that it can be administered as a slow bolus (usually 30 mg IV over 5 min) and has a serum half-life of approximately 90 min. Anistreplase has similar benefits and adverse effects compared to SK. Both SK and anistreplase are antigenic, and allergic reactions occur in approximately 6 percent of patients treated with SK and subcutaneous heparin. Antibodies to SK develop approximately 5 days after treatment and persist for 6 months; retreatment with SK or anistreplase is not advised during this interval. In addition, SK or anistreplase should not be administered within 12 months of a streptococcal infection.

Alteplase or Tissue Plasminogen Activator (Second Generation)

Alteplase or tissue plasminogen activator (tPA) is a naturally occurring enzyme in vascular endothelial cells that directly cleaves a specific peptide bond in plasminogen, converting it to active plasmin, with subsequent fibrinolysis. Alteplase has binding sites for fibrin, which would suggest specificity for activity in the thrombus and less systemic fibrinolysis. Despite the *in vitro* clot specificity of alteplase, its clinical side-effect profile is comparable to that of other fibrinolytics. The serum half-life of alteplase is less than 5 min, and it produces a shorter fibrinolytic state than does SK. Heparin is commonly administered shortly after the completion of alteplase infusion. Unlike SK and anistreplase, alteplase is not antigenic; allergic reactions occur in fewer than 2 percent of patients treated with alteplase and intravenous heparin. Depending on the indication, alteplase is given as a weight-based dose via an intravenous infusion over 60 to 90 min.

Retepase and Tenecteplase (Third Generation)

Both reteplase and tenecteplase (TNK) were created from modifications of the parent alteplase molecule, with the intent of improving both efficacy and safety. Reteplase is a deletion mutant of tPA in which the fibronectin finger (high-affinity fibrin binding), epidermal growth factor (EGF), and kringle-1 (receptor binding) regions of the wild-type tPA molecule have been deleted. These modifications prolong the half-life of reteplase to 18 min, nearly fourfold longer than alteplase, allowing for bolus administration of reteplase as opposed to infusion administration of alteplase. The double-bolus reteplase regimen results in superior coronary blood flow compared to the accelerated alteplase regimen, although mortality rates are similar.

TNK resulted from creating amino acid substitutions in four different regions of the tPA molecule, with the intention of producing a molecule with an extended half-life, higher level of fibrin specificity, and superior potency. The long half-life of TNK (approximately 20 min) allows for single-weight tiered bolus dosing over 5 to 10 s. The specific amino acid substitutions also resulted in a molecule with 14-fold greater fibrin specificity than alteplase in an effort to reduce systemic plasmin generation. Point mutations in the TNK molecule have resulted in plasminogen activator inhibitor-1 resistance 80 times greater than alteplase, thus allowing for longer association of TNK with the fibrin-rich clot. In addition, no increase in thrombin-antithrombin complex was seen following administration of TNK, in contrast to a fourfold increase following administration of streptokinase and a twofold increase after administration of alteplase.¹⁷

Despite theoretical advantages associated with genetic modification, neither reteplase nor tenecteplase demonstrate an absolute mortality benefit in AMI. However, bolus-dose fibrinolytics result in significantly fewer medication errors, when compared to more complicated regimens.¹⁹

Indications for Fibrinolytic Therapy

ACUTE MYOCARDIAL INFARCTION The National Heart, Lung, and Blood Institute has established the principle that routine STEMI patients should receive emergency reperfusion therapy, either fibrinolytic therapy initiated within 30 min or PCI within 90 min after arrival in the emergency department. There are four general criteria for emergent fibrinolytic therapy in AMI: 1) clinical presentation consistent with AMI within 12 h of symptom onset; 2) an electrocardiogram showing ST-segment elevation in two or more contiguous leads or new-onset left bundle-branch block; 3) absence of contraindications (Table 224-5); and 4) absence of cardiogenic shock. PCI, if available within 60 to 90 min of presentation, is preferred over peripheral fibrinolytic therapy for AMI with cardiogenic shock. Important additional considerations, however, include patient age, location of the infarct, relative contraindications to fibrinolysis, and duration of symptoms within the 12-h criterion.

TABLE 224-5 Contraindications to Fibrinolytic Therapy

Absolute
Active or recent internal bleeding (<14 d)
CVA <2-6 months or hemorrhagic CVA
Intracranial or intraspinal surgery or trauma <2 months
Intracranial or intraspinal neoplasm, aneurysm, or arteriovenous malformation
Known severe bleeding diathesis
On anticoagulants (warfarin with PT > 15 s, heparin with increased aPTT)
Uncontrolled hypertension (i.e., blood pressure >185/100 mm Hg)
Suspected aortic dissection or pericarditis
Pregnancy Relative*
Active peptic ulcer disease
Cardiopulmonary resuscitation >10 min
Hemorrhagic ophthalmic conditions
Puncture of noncompressible vessel <10 d
Advanced age >75 years
Significant trauma or major surgery >2 weeks and <2 months
Advanced kidney or liver disease

*Concurrent menses is *not* a contraindication.

Abbreviations: aPTT = activated partial thromboplastin time; CVA = cerebrovascular accident; PT = prothrombin time.

Patients who do *not* meet all four eligibility criteria (e.g., because symptoms have been present for > 12 h or relative contraindications to fibrinolytic therapy are present) may still derive benefit from fibrinolytic therapy provided that no absolute contraindications are present and the differential diagnosis does not include disorders in which fibrinolytic therapy is harmful (e.g., aortic dissection). Under such circumstances, consultation with the physician who will assume continued definitive care of the patient (e.g., a cardiologist or internist) is reasonable and appropriate before initiating fibrinolysis.

The rapid administration of fibrinolytic therapy is of greater importance than the specific agent used. Bolus-dose fibrinolytics have the added benefit of reducing medical errors. However, despite early studies that demonstrated improvement in patient survival, recent trials investigating newer fibrinolytic agents have not achieved significant improvement in 30-day mortality and stroke rates. Defining additional mortality benefit is the subject of much debate. Most clinicians in the United States accept a 1 percent absolute difference as clinically relevant; the level of benefit found favoring alteplase versus SK. Fibrinolytic studies underscore the important relationship between restoration of normal coronary flow and survival benefit. However, an additional 1 percent mortality benefit would require near-normal coronary blood flow [Thrombolysis in Myocardial Infarction (TIMI)-3 grade] rates after fibrinolytic therapy to approach 80 percent. Most new fibrinolytic agents are only capable of generating TIMI-3 flow rates of approximately 60 to 70 percent, suggesting that additional mortality reduction is unlikely with fibrinolytics alone.

Prehospital fibrinolytic administration has a sound theoretical basis, given the critical relation between time to successful reperfusion and outcomes. Nonrandomized trials comparing prehospital administration of reteplase to hospital administration for STEMI have found the prehospital group is more likely to receive their first bolus within 30 min and achieve complete ST-segment resolution sooner.²⁰ Although such studies have been underpowered to determine a mortality benefit, there is a trend for lower mortality at 7 days or hospital discharge favoring prehospital fibrinolytic therapy. A prehospital strategy of electrocardiography, confirmation of fibrinolytic eligibility and administration of bolus-dose lytic appears feasible in accelerating the time to reperfusion in patients with STEMI. Although prehospital fibrinolytic therapy for AMI remains investigational, in rural and remote communities, such therapy seems medically reasonable when excessive delays (>30 min) until arrival at the hospital may occur.

DEEP VEIN THROMBOSIS OR PULMONARY EMBOLISM

Although DVT and PE are a continuum of one disease, venous thromboembolism (VTE), management options are discussed separately. Therapy for VTE should start with an agent that has immediate anticoagulant effect (either UFH or LMWH) and it should be given at adequate dosage. Failure to reach the prescribed intensity of anticoagulation in the first 24 h of treatment is correlated with an increased risk of VTE recurrence during the next 3 months.

DVT In a patient with DVT, the goals of therapy are the prevention of pulmonary embolism and the restoration of venous patency and valvular function in order to prevent the postphlebotic syndrome. Anticoagulation, with the dose adjusted for body weight, using intravenous UFH with aPTT monitoring or subcutaneous LMWH, are both suitable options. LMWH preparations are as safe and as effective as standard heparin for the treatment of acute DVT, with a lower incidence of bleeding complications. Alternatively, recent well-controlled studies demonstrated that selected patients with DVT may safely and effectively be treated entirely at home or after a brief hospitalization. Therapeutic anticoagulation with either agent along with initiation of a vitamin K antagonist (e.g., warfarin) on the first day of treatment is standard practice. The INR should be therapeutic (target INR 2.0 to 3.0) for 2 consecutive days before the discontinuation of the UFH or LMWH. The duration of warfarin therapy following an acute DVT is typically 3 months.

The risks and benefits of fibrinolytic therapy in DVT remain uncertain. Systemic fibrinolytic therapy for DVT has shown some promise in reducing the incidence and morbidity of postphlebotic syndrome. Catheter-directed fibrinolysis has also shown some promise in the hands of highly skilled interventional radiologists. Controlled trials are lacking, and thus no formal guidelines exist regarding the use of fibrinolytic agents when treating patients with DVT.

PE Antithrombotic drugs, mechanical devices, and fibrinolytics are all used to some extent in treating this life-threatening condition. The goals of treatment are to prevent death from the embolus and to prevent any further recurrence. Occasionally, empiric therapy may be initiated based on clinical suspicion alone before diagnostic testing.

Both UFH as well as LMWH are indicated for the treatment of pulmonary embolism. A number of studies have found that LMWH is at least as effective and as safe as UFH in the treatment of PE. As with DVT, recent studies suggest that outpatient treatment of PE in a highly selective patient population is possible. Regardless of which heparin product is used, timely administration and adequate dosing are essential to good patient outcomes. Provided the patient is hemodynamically stable, adequate anticoagulation with UFH or LMWH, along with a vitamin K antagonist (e.g., warfarin), initiated during the first 24 h is standard practice. Warfarin is continued for a minimum of 3 months. The total duration of therapy is dependent upon the etiology of the thrombus.

Thrombolytic agents provide a more rapid lysis of pulmonary emboli and reduction of pulmonary hypertension than heparin.²¹ Whether or not these advantages result in improved clinical outcomes and outweigh the increased risk of bleeding complications is controversial. No conclusive clinical outcome studies aimed at comparing thrombolysis with standard treatment in patients with pulmonary embolism are available. A recent meta-analysis concluded that in patients with pulmonary embolism, thrombolysis had a lower composite end point of death/reoccurrence than did heparin treatment.²¹ However, the risk of intracerebral hemorrhage and other serious bleeding complications were significantly higher in patients treated with thrombolytic therapy. Other opinions suggest that there was no evidence that thrombolytic therapy decreases the mortality or the rate of reoccurrence of PE.²² Advocates for the more liberal use of thrombolytic therapy suggest that in the presence of right ventricular strain as evidenced by echocardiography, patients may achieve better outcomes. As published in the American Col-

lege of Chest Physicians (ACCP) guidelines, the use of thrombolytic agents in treating VTE is highly individualized.²³ However, most authorities agree that thrombolytic therapy may play a role in patients with massive PE complicated by hemodynamic collapse.

Currently approved fibrinolytic agents for PE include alteplase, streptokinase, and urokinase. The antigenicity and high incidence of bleeding complications associated with the 24-h infusion of SK make it a less-attractive alternative. Full anticoagulation with UFH or LMWH is not a contraindication to fibrinolysis for PE.

Vena cava filter devices are indicated for patients with contraindications to anticoagulation therapy, patients who have failed anticoagulation therapy, and patients who are at high risk of mortality from recurrent pulmonary embolism. There are a number of different devices available and most are placed percutaneously. Complications include filter migration, thrombosis, and perforation of the inferior vena cava. Anticoagulation therapy is recommended whenever possible as an adjunctive therapy with filters to help prevent thrombosis of the filter and further DVT.

ISCHEMIC STROKE The use of fibrinolytics for acute ischemic stroke to restore cerebral blood flow and to improve neurologic outcome is controversial. Only alteplase has been shown to benefit carefully selected patients with acute ischemic stroke if given within 3 h of the onset of stroke symptoms. The benefit was greater if alteplase was given within 90 min from stroke onset as measured by 24-h and 3-month outcomes.²⁴ Benefits are sustained up to 1 year in treated patients.²⁵ Conversely, there is no reduction in mortality.²⁵ One reason for this lack of mortality reduction is that alteplase increases the absolute risk of conversion to intracerebral hemorrhage by 6 percent, and the majority of these patients died.²⁶ Currently, alteplase can be recommended only if the protocol used in the National Institutes of Neurological Disorders and Stroke Tissue Plasminogen Activator Stroke Trial is strictly followed. Physicians are advised to obtain informed consent from patients or their proxies in all cases. It is best to have an emergency department policy developed in cooperation with neurologists concerning the administration of alteplase for acute CVA.

Contraindications to the use of alteplase for acute stroke include patients with rapidly improving neurologic signs or minor symptoms, significant pretreatment hypertension (blood pressure > 185/110 mm Hg or requiring aggressive therapy to control), seizure at onset, or symptoms suggestive of subarachnoid hemorrhage.

Complications and Management

Compared with fibrinolytic therapy, PCI (angioplasty and/or stent placement) are the favored reperfusion strategies for high-risk patients presenting with STEMI. Unfortunately, not all patients have expeditious access to PCI. In such cases, thrombolytic therapy remains a good alternative for most patients. The most significant complications of fibrinolytic therapy are hemorrhagic, and the most catastrophic complication is intracranial hemorrhage, seen in at least 1 to 3 percent of patients.²⁷ Fibrinolytics should not be given to any patient with an absolute contraindication (see Table 224-5). In patients with a relative contraindication, careful weighing of potential risks and benefits of fibrinolysis in consultation with the physician who will assume in-hospital care of the patient is indicated.

Allergic reactions and anaphylaxis from SK and anistreplase should be treated with diphenhydramine 50 mg and methylprednisolone 125 mg IV. Hypotension occurs in up to 10 percent of patients treated with either SK or tPA, and is treated by slowing the fibrinolytic infusion rate and administering intravenous crystalloid, paying close attention to the patient's volume status.

To minimize the bleeding risks associated with fibrinolytic therapy, the following precautions should be observed: 1) avoid all unnecessary needle sticks; 2) avoid any arterial punctures; 3) limit venous access to easily compressible sites (e.g., avoid central lines, especially the

jugular or subclavian veins); and 4) avoid both nasogastric tubes and nasotracheal intubation.

Careful monitoring of the patient is crucial. The hematocrit should be checked every 4 to 6 h after fibrinolytic therapy is initiated. A fall in hematocrit of greater than 2 percent should prompt a search for the source of blood loss. Most bleeding episodes (more than 70 percent) occur at vascular puncture sites, but intracranial, intrathoracic, retroperitoneal, gastrointestinal, genitourinary, or soft tissue extremity hemorrhage may occur.

External bleeding at any site should be controlled with prolonged manual pressure. Significant bleeding, especially from an internal site, mandates discontinuation of the fibrinolytic agent, antiplatelet agent, and heparin. Volume replacement using NS or LR solution should be provided as necessary and supplemented with red blood cell transfusions if clinically indicated. The thrombin time, aPTT, platelet count, and fibrinogen level should be checked. Heparin administered within 4 h of the onset of bleeding can be reversed with protamine.

Massive bleeding with hemodynamic compromise necessitates coagulation factor replacement in addition to the interventions recommended above. Ten units of cryoprecipitate (rich in fibrinogen) should be administered and the fibrinogen level rechecked. If the fibrinogen level is less than 100 mg/dL, the dose of cryoprecipitate should be repeated. If bleeding continues after cryoprecipitate or if bleeding persists despite a fibrinogen level above 100 mg/dL, 2 units of FFP should be given. If bleeding persists after appropriate cryoprecipitate and FFP treatments, a BT should be checked. If it is more than 9 min, 10 units of random donor platelets should be administered, followed by an antifibrinolytic agent (e.g., ϵ -aminocaproic acid or tranexamic acid); if the BT time is less than 9 min, platelets are unnecessary, but an antifibrinolytic agent should still be administered for continuing hemorrhage.

Fibrinolytic-associated intracranial hemorrhage requires an aggressive response. Immediately discontinue the fibrinolytic agent, antiplatelet agent, and heparin. Administer protamine in the dose outlined above if the patient received heparin. The patient should also receive cryoprecipitate, FFP, platelet transfusion, and an antifibrinolytic agent (e.g., ϵ -aminocaproic acid or tranexamic acid).

EMERGENCY COMPLICATIONS OF MALIGNANCY

Paul Blackburn

Most cancer patients experience at least one emergency during the course of the disease, and emergency physicians are increasingly being confronted with complications related to cancer or its treatment. The approach to the patient with potential complications may be confounded by many variables. Patients may be uncomfortable discussing their disease or its extent or may not be knowledgeable concerning the condition or its therapy. The emergency physician may be unfamiliar

with the large number or combinations of chemotherapeutic agents or with the complex classification and staging of malignancies. The biologic variation in cancer progression and response to treatment makes for imprecise prognostic predictions in individual patients.

Trends in cancer management include an aging population with a concomitant increased prevalence of malignant disease, aggressive chemotherapeutic regimens with broader applications, and longer patient survival. All place demands on the ability of the emergency physician to recognize and treat a broad spectrum of oncologic emergencies.

Emergencies related to cancer or its therapy can be broadly categorized into those created by local tumor effects, due to biochemical derangement, from hematologic derangement, or related to therapy (Table 225-1).

RELATED TO LOCAL TUMOR EFFECTS

Pathologic Fractures

Anatomic disruption of diseased bone resulting from normal but stressful activity is termed a *pathologic fracture*. The skeleton is most commonly affected by metastases, mostly in the axial skeleton and proximal aspect of the limbs, where the red marrow is located.¹ Patients present with bone pain and history of a primary cancer. Only rarely will the fracture represent the first evidence of malignancy. Plain radiographs are usually sufficient for initial imaging. Computed tomography evaluates the three-dimensional bone integrity and soft tissue extension, whereas magnetic resonance imaging delineates soft tissue and bone marrow involvement.²

The goals of treatment are pain relief and restoration of ambulation or function, through IV narcotics and fracture immobilization. Nondisplaced fractures in non-weight-bearing bones are occasionally managed conservatively, but most are treated surgically. Criteria for hospitalization include those with neurologic deficits, fractures through lesions of unknown origin involving the hip or femur (the most disabling fractures), comminuted or irreducible fractures, and those with hemodynamic compromise.²

Acute Spinal Cord Compression

Up to 20 percent of patients with neoplastic involvement of the vertebral column and 5 to 10 percent of all patients with cancer will develop spinal cord compression. Patients present with unrelenting, progres-

sive back pain that usually worsens when supine, unlike most other musculoskeletal cases of back pain. The thoracic vertebrae are most often involved. Weakness is most apparent in the proximal extremity musculature and may progress to complete paralysis. Sensory changes initially may be confined to a band of hyperesthesia around the trunk at the involved spinal level or eventually become anesthetic distal to the level. Urinary retention (with overflow incontinence), fecal incontinence, and impotence are late manifestations.²

Plain films may identify the level of vertebral collapse and deformity. Magnetic resonance imaging is the imaging tool of choice to define the site and degree of cord compression and to identify the presence of additional vertebral lesions. Computed tomography with or without myelography is used when magnetic resonance imaging is contraindicated or inaccessible.²

Initial pain control is done with narcotic analgesics. Definitive pain control is achieved through the use of corticosteroids, radiation therapy, surgery, or a combination of modalities and will depend on the life expectancy of the patient, extent of disease, and degree of motor impairment (ambulatory vs. nonambulatory vs. paraplegic status). The usual steroid dose is dexamethasone 10 mg IV bolus, followed by 4 mg PO or IV every 6 h.²

Upper Airway Obstruction

Malignancy-related airway obstruction is insidious, rarely an emergent problem, and due to tumors arising in the oropharynx, neck, and superior mediastinum. Acute compromise may occur due to supervening infection, hemorrhage, or inspissated secretions. Soft tissue plain films may assist in defining the soft tissue architecture. Due to the distortion of local anatomy, fiberoptic laryngoscopy is often necessary to evaluate the airway lumen size. If immediate airway control is required, options include cricothyrotomy, jet insufflation, or emergency tracheostomy.

Malignant Pericardial Effusion with Tamponade

The most common sources of malignant pericardial effusions are breast and lung cancer, although other malignancy-related etiologies include mediastinal radiation, infection, and certain chemotherapeutic agents. Symptoms of pericardial effusion are a function of accumulation rate and total volume. Collections greater than 500 mL may be well tolerated with gradual development. Sudden accumulation or hemorrhage may cause dyspnea, chest pain, or hypotension.

Classic features of cardiac tamponade are 1) hypotension and narrowed pulse pressure, 2) jugular venous distention, 3) diminished heart sounds, 4) pulsus paradoxus greater than 10 mm Hg, 5) low QRS voltage on the electrocardiogram, and 6) cardiomegaly without radiographic evidence of congestive heart failure. Diagnosis of the pericardial effusion can be confirmed with echocardiography or bedside transthoracic ultrasound. Although sonographic features of pericardial tamponade may be seen, the absence of these features does not exclude tamponade, and the decision to emergently intervene is made by evidence of inadequate cardiac output.

Emergency pericardiocentesis can be lifesaving, although classic blind pericardiocentesis has been associated with mortality rates of up to 6 percent. Echo-guided pericardiocentesis is safe, effective, and well tolerated, and Doppler mode allows evaluation of the hemodynamic effects of the effusion and treatment.³ Care of the stable patient should include discussion with an oncologist. The tumor type, symptom severity, and prognosis are considered in determining a treatment plan that might include systemic chemotherapy, intrapericardial chemotherapy or sclerotherapy, or creation of a pleuropericardial window.

Superior Vena Cava Syndrome

Superior vena cava (SVC) syndrome occurs by compression of the thin-walled SVC carrying blood at low pressure through the nondis-

Abbreviation: SIADH = syndrome of inappropriate antidiuretic hormone.

tensible mediastinum by primary tumor or superior mediastinal nodes. Up to 97 percent of patients with SVC syndrome have a malignant cause, with lung cancer accounting for 65 to 80 percent of cases. Those diagnosed with SVC syndrome usually do not die of the syndrome itself but of the underlying disease.⁴

Symptoms are usually easy to recognize, the most common being facial swelling, with venous engorgement of the trunk, upper extremities, and neck. The skin may have a slightly violet hue, mimicking cyanosis. Dyspnea, orthopnea, and cough are common complaints, as are headache, nausea, dizziness, and visual disturbances. Neurologic involvement with obtundation, seizures, or coma may be secondary to metastatic disease and cerebral edema from venous occlusion. The more rapid the compression onset, the more severe the symptoms due to lack of time for collateral vessel development. Histologic diagnosis is desirable before definitive treatment is initiated, if possible. Sputum cytology is the simplest method and can yield a diagnosis in two-thirds of patients.

Initial management is head elevation, rest, cautious administration of fluids, and supplemental oxygen. Diuretics (furosemide 40 mg IV) for temporary relief of symptoms and glucocorticoids (methylprednisolone 125 mg IV, or dexamethasone 16 to 20 mg IV) are often recommended, but their roles are unclear. Most patients with SVC syndrome are treated nonoperatively with radiotherapy, chemotherapy, or both. In addition, vena caval stents, adjuvant therapy with anticoagulants, and surgical procedures may be considered after stabilization.

RELATED TO BIOCHEMICAL DERANGEMENT

Hypercalcemia

Hypercalcemia is one of the most common metabolic complications of malignancy, occurring in 20 to 30 percent of patients at some time during the course of their disease and more commonly in patients with advanced disease.^{5,6}

Symptoms are referable to almost any organ system and depend on the level of plasma calcium, the rate of rise, and the general medical condition of the patient. Gastrointestinal symptoms such as anorexia, nausea, vomiting, and constipation are early, frequent features that may be mistakenly attributed to underlying disease or therapy. Neurologic manifestations occur in more than 50 percent of patients, including cognitive and behavioral changes, altered mental status, and neuromuscular disturbance. Psychiatric symptoms may resemble schizophrenia or mania. Renal involvement includes polydipsia and polyuria due to interference with antidiuretic hormone (ADH) action at the distal nephron, causing a diabetes insipidus-like syndrome. The resulting dehydration further exacerbates the existing dehydration.⁵

Normal calcium regulation is through the interaction of parathyroid hormone (PTH), calcitonin, and 1,25(OH)₂ vitamin D. In malignancy, the breakdown of normal regulation leads to increased bone resorption in all cases and occasionally to decreased renal excretion of calcium. The most common cause of hypercalcemia of malignancy is by production of a PTH-related peptide that is structurally similar to PTH. The PTH-related peptide binds to PTH receptors, thereby mobilizing calcium from bones and increasing renal reabsorption of calcium.^{5,6} Some malignancies, such as multiple myeloma, secrete a factor or factors that stimulate osteoclasts to resorb bone.⁵

Significant hypercalcemia is a true metabolic emergency. Due to the invariable dehydration present, continuous administration of intravenous isotonic saline at a rate based on severity of hypercalcemia, degree of dehydration, and ability to tolerate volume expansion is initiated and will result in a modest decrease in the plasma calcium. Clinical improvement will improve over 24 to 48 h but rarely normalizes the level. Forced saline diuresis with large doses of furosemide 80 to 100 mg IV every 2 h, increases renal excretion of calcium, but only after adequate hydration. Calcitonin 4 to 8 U/kg SC or IM every 6 to 12 h, lowers plasma calcium within 2 to 4 h. It may cause a hypersensitivity response, and tachyphylaxis develops within 3 days.^{5,6} Glucocorticoids may

blunt the tachyphylaxis and may be helpful in the short term in and of themselves, especially with sensitive tumors such as lymphoma and myeloma.^{5,7} Bisphosphonates are potent inhibitors of bone resorption and produce a sustained decrease in calcium for approximately 2 to 4 weeks beginning 12 to 48 h after administration. Bisphosphonate is given slowly to prevent precipitation of bisphosphonate-calcium complexes in the kidney and subsequent renal failure. Gallium nitrate, mithramycin, and plicamycin are used infrequently due to their toxicity.^{5,6} Dialysis is indicated for those with profound mental status changes, renal failure, or unable to tolerate a saline load.^{6,8}

Syndrome of Inappropriate ADH, Hyponatremia

Ectopic secretion of ADH may be present with a variety of malignancies or from stimulation of ADH release from chemotherapy, narcotics, carbamazepine, and selective serotonin reuptake inhibitors.⁸ Regardless of the etiology, the syndrome of inappropriate ADH consists of hyponatremia, less than maximally dilute urine, excessive urine sodium excretion ($U_{Na} > 30$ mEq/L), and decreased serum osmolality, all in the presence of euolemia, absence of diuretic therapy, and normal renal, adrenal, and thyroid function (see Chap. 27).

Hyponatremia is the most common electrolyte abnormality in cancer patients. Signs and symptoms are primarily neurologic and correlate with severity and with rapidity of development. Anorexia, nausea, and malaise are the earliest findings, followed by headache, confusion, obtundation, seizures, and coma. Seizures are tonic clonic and, if recurrent, require treatment with hypertonic saline. Focal seizures require more in-depth evaluation. Life-threatening symptoms are nearly invariably present with sodium concentrations below 105 mEq/L.⁸

Water restriction is the mainstay of treatment. Patients with sodium levels above 125 mEq/L are generally asymptomatic and can be managed with water restriction of 500 mL per d and close follow-up. More severe symptoms may require furosemide (0.5 to 1.0 mg/kg) administration, with concomitant administration of NS to maintain euolemia and effect a net free water clearance. Demeclocycline (300 to 600 mg bid) is a tetracycline derivative that will induce a drug-induced diabetes insipidus, allowing continued water intake and improvement in sodium level. Three percent hypertonic saline (51 mEq sodium/dL) can be given, with or without furosemide, for rapid correction. The hypertonic saline amount must be carefully calculated to avoid volume overload or too rapid correction, with subsequent osmotic demyelination syndrome (central pontine myelinolysis). The rate of correction of hyponatremia is controversial, but a rate of 0.5 mEq/L per h, with not more than a 12- to 15-mEq increase in the first 24 h, is recommended (see Chap. 27). Coincident hypokalemia requires repletion, because plasma potassium elevation can raise the serum sodium concentration.⁸

Adrenal Insufficiency

Adrenal insufficiency may be related to adrenal gland replacement by metastases or suppression from glucocorticoid administration, with adrenal function insufficient to support the patient stressed by infection, metabolic disruption, or surgery. Adrenal crisis with vasomotor collapse may be sudden and fatal. Clues to possible adrenal insufficiency may include mild hypoglycemia, hyponatremia, hyperkalemia, and eosinophilia. The stressed and steroid dependent patient empirically should be given intravenous steroids with glucocorticoid and mineralocorticoid effects. Appropriate emergency stress doses of hydrocortisone hemisuccinate are 200 to 500 mg IV (see Chap. 217). In suspected cases of adrenal insufficiency, a serum cortisol should be drawn before steroid treatment.

Tumor Lysis Syndrome

Tumor lysis syndrome is a set of metabolic abnormalities resulting from acute destruction of neoplastic cells, with release of intracellular

contents into the circulation overwhelming the body's homeostatic mechanisms for handling potassium, calcium, phosphorus, and uric acid. Abnormalities may occur individually or in combination. It is more common with hematologic malignancies and may occur spontaneously or after cytotoxic therapy. Morbidity (primarily renal failure) depends on the type and extent of tumor, treatment type, and pre-existing renal function. Prophylaxis with intravenous fluids and allopurinol has greatly reduced the incidence of tumor lysis syndrome.

Catabolism of DNA and RNA produces uric acid, which may precipitate in the renal tubules. Malignant cells may contain up to four times the amount of phosphorus as normal cells. As phosphate increases, it combines with calcium and precipitates in soft tissue and renal tubules, leading to hypocalcemia and renal failure. Hyperkalemia is the most life-threatening derangement of tumor lysis syndrome. The sudden increase in potassium results in the well-described presentation of cardiac arrhythmias and death.^{6,8}

Treatment of hyperuricemia includes urine alkalinization through addition of sodium bicarbonate to intravenous fluids or administration of acetazolamide, with a goal of urine pH at or above 7.0. Excessively alkaline urine increases the likelihood of calcium phosphate precipitation in the renal tubules. Hyperkalemia is treated with the usual regimen of β -adrenergic agonists, glucose, insulin, and sodium-potassium exchange resin (see Chap. 27). Calcium administration is to be avoided unless there is evidence of cardiovascular instability (electrocardiographic changes) or neuromuscular irritability (Chvostek or Trousseau sign), because supplemental calcium may cause metastatic precipitation of calcium phosphate. Hyperphosphatemia is managed with phosphate binders (limited effect) or by the administration of glucose and insulin. Hemodialysis is effective in correcting all abnormalities of tumor lysis syndrome, although the large phosphate burden may require repeat dialysis at 12- to 24-h intervals.⁸

RELATED TO HEMATOLOGIC DERANGEMENT

Granulocytopenia and Infection

A febrile, neutropenic patient is an absolute medical emergency. Neutropenia, or an absolute neutrophil count of fewer than 500/ μ L, is the most frequent factor predisposing patients with cancer to infection, especially bacteremia. If untreated, the mortality rate of a neutropenic patient with a bacteremic infection is about 50 percent.⁶ The most common presenting symptom is fever, defined as a temperature of 38.3° C on one occasion or 38.0° C for longer than 1 h.

Due to an impaired inflammatory response and granulocytopenia, the usual findings of infection may be muted or masked. Signs of infection, such as purulence, may not develop, and erythema or pain may be the only findings. During the physical examination, all portals of entry, including mucosal surfaces, must be inspected. Funduscopic examination may show evidence of disseminated infection or papilledema. Manifestations of pneumonia may be auscultatory only, because granulocytopenia may preclude development of a visible infiltrate on chest radiograph. A detailed skin examination, in particular the perirectal area of acute leukemia patients, is important. **Digital rectal examination is relatively contraindicated in neutropenic patients and should be withheld until after initial antibiotic administration.** Clotted catheters represent a high risk of infection due to bacterial colonization, and central venous catheters may be associated with the development of endocarditis.⁹

To evaluate for occult infection, ancillary tests include blood and urine cultures and chest radiograph. Sputum, stool, and wound drainage Gram's stain and culture should be obtained if productive cough, diarrhea, or wound drainage is present. Lumbar puncture is not routine, because the incidence of meningitis is not increased with neutropenia.

The choice of initial empiric antimicrobial therapy should be broad spectrum to cover the range of potential bacterial pathogens. There are

several combination regimens in use. Bacteremia is most frequently due to aerobic gram-positive cocci (coagulase-negative staphylococci, viridans streptococci, or *Staphylococcus aureus*) or aerobic gram-negative bacilli (*Escherichia coli*, *Klebsiella pneumoniae*, or *Pseudomonas aeruginosa*). An aminoglycoside combined with an antipseudomonal (3-lactam has become standard for empiric treatment. Vancomycin should be added if the following are present: severe mucositis, catheter infection, quinolone prophylaxis, hypotension, institutions with methicillin-resistant *S. aureus*, or known colonization with resistant gram-positive organisms.^{6,9} Fungi are common secondary infections in those who have received courses of broad-spectrum antibiotics.⁹

Hyperviscosity Syndrome

Hyperviscosity syndrome describes a group of pathologic conditions in which blood flow is impaired due to abnormal blood characteristics. The flow properties of blood are dependent on its fluid and cellular contents. Abnormal plasma contents are most commonly Waldenström macroglobulinemia, followed by immunoglobulin A myeloma. Hyperproduction of any cell line can lead to hyperviscosity.¹⁰ Polycythemia (with a hematocrit >60 percent) and leukemias (with a white blood cell count >100,000/ μ L or a leukocrit >10 percent) often are associated with clinically significant hyperviscosity. Dehydration will exacerbate the effects of all hyperviscosity syndromes.

Initial symptoms are vague and may include fatigue, abdominal pain, headache, or, most commonly, altered mental status. Thrombosis may occur, with the creation of focal or unusual findings. Specific physical findings other than retinal hemorrhages, exudates, and "sausage-linked" vessels are rare. The diagnosis depends on a high index of suspicion coupled with laboratory findings. The peripheral blood smear may reveal *rouleaux* formation (red cells stacked like coins). The laboratory may be unable to perform serological testing due to serum stasis in the analyzers. Serum viscosity and protein electrophoresis can be diagnostic.

Initial therapy consists of intravascular volume repletion, early involvement of a hematologist, and emergency plasmapheresis. When coma is present and the diagnosis established, a temporizing measure can be a two-unit (1000 mL) phlebotomy with concomitant volume replacement with 2 to 3 L of NS.

Thromboembolism

Thromboembolism occurs with all tumor types and is the second leading cause of death in cancer patients. Symptomatic deep venous thrombosis (DVT) occurs in approximately 15 percent of all patients with cancer and up to 50 percent of those with advanced malignancies.¹¹ A hypercoagulable state, decreased proteins C, S, and antithrombin III, the effect of metastases on activation of the coagulation pathway, chemotherapy, invasive procedures, and long-term venous catheterization increase thromboembolism risk.¹²

Coagulation activation may contribute to the tumor progression; as such, anticoagulants may have anticancer activity. Treatment with low molecular weight heparin (LMWH) or unfractionated heparin as a bridge to chronic warfarin therapy is appropriate for most newly diagnosed cases of DVT, although some recommend the use of LMWH in view of data suggesting a survival advantage for cancer patients receiving LMWH. **Cancer patients do not appear at increased risk for anticoagulant-related bleeding complications, including those with brain metastases.** More frequent monitoring of the International Normalized Ratio is required, because warfarin is more difficult to control than in other patients.¹¹ Thrombolytic therapy for treatment of DVT is not indicated, because anticoagulant therapy alone is generally successful.

A pulmonary embolus with hemodynamic stability is treated with unfractionated heparin or LMWH. Because of the high mortality rate for pulmonary embolus and hemodynamic instability, right ventricular fail-

TABLE 225-2 Antiemetic Agents (Adult Dosages)

Class and Agent	Dose	Comments
opamine receptor antagonists Metoclopramide Promethazine	10 mg IV or IM 25 mg IV	Dose-related extrapyramidal side effects IV use common but not approved
erotonin (5-HT ₃) antagonists Dolasetron Granisetron Ondansetron	1.8 mg/kg up to 100mg IV 10 ng/kg IV over 5 min 32 mg IV over 15 min	Constipation, headaches (all)
corticosteroids Dexamethasone	20 mg IV	Mechanism unknown, no immunosuppression
enzodiazepines Lorazepam	1-2 mg IV	Sedation, anxiolysis
histamine receptor antagonists Diphenhydramine	50 mg IV or IM	Minor therapeutic effect

ure, or thrombus in the right atrium or ventricle, thrombolytic therapy is recommended. Of the available agents, no agent or dosing range has currently been shown to be superior to another. Less ill patients should not receive thrombolytic therapy, because major bleeding can occur in 20 percent of patients, and there is no improvement in mortality. However, a blocked indwelling catheter due to catheter tip thrombosis can be treated with a local infusion of low-dose thrombolytic therapy.¹² This is best done with the approval of the local specialist.

RELATED TO THERAPY

Chemotherapy-Induced Nausea and Vomiting

Nausea and vomiting can be debilitating to an already compromised patient. Commonly used antiemetics include benzodiazepines, corticosteroids, dopamine antagonists, neuroleptics, and serotonin (5-HT₃) receptor antagonists (Table 225-2). Although there is no definite superiority for any group or combination of agents, the most common regimens are a combination of metoclopramide or a 5-HT₃ receptor antagonist plus dexamethasone. Although lorazepam has no direct antiemetic efficacy, its addition will provide sedation and anxiolysis and a measurable decrease in emesis.¹³

Pain Control

The pain associated with cancer requires aggressive treatment and avoidance of "oligoanalgesia," a term describing the underuse of analgesics. Physicians are generally poor at adequately treating pain, with the usual reasons given as fear of adverse effects, such as respiratory depression or addiction with prolonged courses of treatment. The concern of causing addiction in the patient with significant cancer-related pain should be disregarded. First-line therapy should be parenteral opioids, which allows for a more rapid onset of action and titratability. Nonopioid analgesics (aspirin, acetaminophen, other nonsteroidal agents) may act as adjuvants, allowing lower narcotic dosages, and should be concomitantly administered if there are no contraindications.¹⁴ Corticosteroids also can be used as opioid adjuvants, usually in patients in the terminal phases of cancer, although drug, dose, route, and schedule are not standardized.⁷

Systemic Therapy Emergencies

The two emergencies related to systemic therapy are drug extravasation and hypersensitivity reactions. Most chemotherapeutic agents cause different degrees of local tissue injury when extravasated. If extravasation occurs through a peripheral line, the infusion is stopped and aspiration through the line is attempted. If an antidote exists, it is administered

through the original line while avoiding pressure to the area to prevent further dispersion of material (Table 225-3). Conservative measures include rest and elevation. There are no indications for corticosteroids or the use of bicarbonate to alter local pH. Hyaluronidase injected locally has been shown to enhance absorption of some drugs. Topical dimethyl sulfoxide has been proposed as an antidote, because of its potent free radical-scavenging properties, plus its possible capacity to hasten the removal of drug from tissue. Hypersensitivity reactions are treated in the usual manner with epinephrine, H₁ and H₂ blockers, intravenous fluids, nebulized albuterol, and steroids as needed.¹⁵

Renal and Urologic Syndromes

Urologic emergencies in cancer patients are common and consist of bladder hemorrhage, obstruction, and infection.

Bladder hemorrhage may be a presenting sign of malignancy or secondary to tumor invasion, chemotherapy, radiation therapy, or infection. It can evolve into a life-threatening emergency, with clot retention, obstruction, or hemodynamic instability. Initial treatment is a multiple-hole bladder catheter with continuous saline lavage and, occasionally, endoscopic clot evacuation in the operating room, if required. Methods of controlling bleeding have included intravesicular agents (alum, prostaglandins, phenol, and silver nitrate), iced saline lavage, and oral or parenteral aminocaproic acid, all with different degrees of success.

TABLE 225-3 Antidotes for Extravasated Cytotoxic Drugs

Drug	Antidotes	Comments
Anthracyclines	Dimethyl sulfoxide	Apply topically, allow to dry, repeat
	Ice packs	Repeat every 6–8 h
Mitomycin	Dimethyl sulfoxide	Apply topically, allow to dry, repeat
Cisplatin, mechlorethamine	Sodium thiosulfate	Prepare 0.17 mol/L solution: mix 4 mL 10% wt/vol sodium thiosulfate with 5 mL sterile water, inject into extravasation site
Vinca alkaloids	Hyaluronidase	Reconstitute with normal saline, inject 150–900 U into extravasation site
	Warm packs	
Paclitaxel	Hyaluronidase	Reconstitute with normal saline, inject 150–900 U into extravasation site
	Ice packs	

SECTION 18 • HEMATOLOGIC AND ONCOLOGIC EMERGENCIES

Obstruction of the ureters may be due to direct tumor invasion or compression, retroperitoneal lymph node encasement, or, rarely, by direct metastases. Surgery, chemotherapy, or radiation therapy may cause retroperitoneal fibrosis with compression. Clinically, acute unilateral obstruction will appear identical to ureterolithiasis, whereas chronic unilateral obstruction is a silent event incidentally discovered as hydronephrosis on computed tomography. Bilateral chronic ureteral obstruction will present with decreased urine output and uremia. Urologic consultation for relief of obstruction is required.

Lower tract obstruction can be caused by mechanical or neurophysiologic factors. The combination of antiemetic and pain medications with hydration may precipitate urinary retention in those with pre-existing prostatism. Relief is obtained with bladder catheters, with a coude tip if passage of standard catheters cannot be accomplished.

THE NEUROLOGIC EXAMINATION IN THE EMERGENCY SETTING J. Stephen Huff Andrew D. Perron

The key to evaluation of patients with neurologic problems is the medical history; in most patients, the physical examination confirms thoughts formulated during history taking. Time of onset, symptom progression, associated symptoms, and exacerbating factors are key historical points. Another axiomatic point is that the neurologic examination does not exist in isolation from the general physical examination or imaging procedures. Rarely does the neurologic examination delineate a problem not suggested by the patient's history or general physical examination. Few findings of the neurologic examination are pathognomonic of clinical conditions or sufficiently specific that examination alone secures the diagnosis. Further complicating the value of the neurologic examination are that the sensitivity and specificity of different examination techniques have not been rigorously investigated and the degree of interobserver variability is not known.

The idea of performing a "complete" examination in the emergency department is misleading, because most frequently a "complete" examination is neither required nor appropriate. An adequate examination is one that is sufficient for the task at hand. The examination detailed in this chapter is arbitrarily divided into eight sections, and basic and advanced levels are described for each section. Much of this information should be a review for the reader, but it is hoped that this simple framework will help with organization and in the approach to the patient.

Examination of children follows the same framework as that for adults, but even more information is gathered indirectly by observation. For example, interacting with a child playing with a toy or other object allows the examiner to assess vision, extraocular motion, coordination, and strength as the child reaches for and grasps the toy.

Traditional neurologic formulation follows a three-tiered approach: 1) Is there a lesion of the nervous system? 2) Where is the lesion? 3) What is the lesion? History is the key to answering these questions, with the physical examination useful for confirmation. Findings should be clearly documented without the use of ambiguous terms or abbreviations. After data gathering by history and physical examination, the clinician might formulate possible answers to these questions by integrating historical information and physical examination findings. There may very well be only tentative answers, but formulation will guide the tempo of workup and follow-up. The brevity of this chapter allows only an introduction to problem formulation, but more information is available in chapters on specific disease processes in this book and in other references listed at the end of this chapter.

ORGANIZATIONAL FRAMEWORK

Organization of the neurologic examination along a framework of subsections is a convenient technique. At the bedside, the clinician can mentally review the framework as he or she examines the patient and selects additional tests to explore possibilities suggested by the history. Some of the tests grouped in a section test several aspects of the nervous system function, and listing of tests in a particular section is for organizational convenience. The clinician should keep this organization in mind while at the bedside. For example, visual field testing, although technically a test of higher cortical function, is listed with cranial nerve testing, because the examining physician may find it easier

to evaluate visual fields during that portion of the examination dealing with cranial nerve function. One organizational scheme divides the examination into eight elements:

1. Mental status testing
2. Higher cerebral functions
3. Cranial nerves
4. Sensory examination
5. Motor system
6. Reflexes
7. Cerebellar testing
8. Gait and station

Mental Status Testing

BASIC A mental status examination, however informal, is part of every patient encounter. The observation may be brief and descriptive, such as, "The patient is awake, alert, and conversant," or it may be quite detailed. Mental status assesses the emotional and intellectual functioning of the patient. It is quite important to make some assessment of mental status, because the patient with an abnormal mental status cannot be relied on for an accurate history of the medical problem.

Major elements of mental status testing are assessment of appearance and assessment for thought disorders or abnormal thought content, such as hallucinations, mood, insight, and testing of the sensorium. *Sensorium* is a term for the appropriate awareness and perception of consciousness. Mental status testing is covered more fully in Chap. 229.

One key element in mental status testing is attention and memory assessment. Attention testing is best performed with digit repetition. The average adult of normal intelligence should be able to repeat six or seven digits forward and four or five digits backward. Failure to do so may suggest confusion, delirium, or a problem with language perception. Often this represents a problem with attention rather than with memory. Memory is a complex process but is often simply broken into long-term and short-term activities. *Long-term memory* is recall of events of some months or years ago. *Short-term memory* is assessed by asking about events of the day or by three-object recall at 5 min. The patient is verbally presented with three items in a neutral tone and asked to repeat; reassessment at 5 min gives a gross assessment of short-term memory function. Failure to repeat the items immediately after presentation is likely an indication of an attention problem rather than of a memory problem.

ADVANCED Evaluation by screening tools, such as the Mini-Mental State Examination and the Quick Confusion Scale, are described in Chap. 229. Other screening tests for depression, substance abuse, and other problems are outside the scope of this chapter.

SPECIAL CIRCUMSTANCES In general, patients with abnormal mental status, in particular attention problems or disorientation, are more likely to have "organic," i.e., medical, problems than "functional," i.e., psychiatric etiologies.

Higher Cerebral Functions

Higher cerebral functions concern maneuvers that test neurologic functions that are thought to reside in the cerebral cortex. Language defines dominant hemisphere function. The majority of the population is right-handed; for 90 percent of these patients, the left hemisphere is

where language functions reside; hence, they are referred to as left-hemisphere dominant. Even in left-handed patients, most have the left hemisphere dominant for speech. Thus, a large cortical stroke affecting the cortex of the dominant hemisphere (the left hemisphere in most patients, whether they are left- or right-hand dominant) likely will affect language functions.

The nondominant hemisphere is concerned with spatial relationships. Often a nondominant hemispheric problem is suspected in the ED when the patient has consistent visual inattention to a care provider approaching from one side (usually the left, because most patients are left-hemisphere dominant).

Higher cerebral function pragmatically involves the assessment of language. For a patient with speech that is difficult to understand, a fundamental distinction must be made between the presence of *dysarthria* and a *dysphasia* (aphasia and dysphasia are often used interchangeably in clinical practice). A dysarthria is a mechanical disorder of speech resulting from difficulty in the production of sound from weakness or incoordination of facial or oral musculature; this may result from a motor system problem (cortical, subcortical, brainstem, cranial nerve, or cerebellar), but it does not represent a disorder of higher cerebral function. Dysphasia is a problem of language resulting from cortical or subcortical damage; the portion of the brain concerned with comprehension, processing, or producing language is impaired.

There are many different types of aphasia, but a simplified scheme is sufficient for assessment. A descriptive scheme that discriminates aphasia into fluent, nonfluent, and mixed patterns is adequate for testing in the ED and for communicating with other physicians.

BASIC Normal conversation monitoring for correct responses is the common screening examination for a language disorder. If suspicion of a language disorder exists, a series of assessments allows confirmation and categorization of the aphasia.

Comprehension is tested initially by the ability to follow simple commands. Asking the patient to identify common objects may be part of the assessment. Objects commonly available, such as a watch, a pen, or a glass, may be used as a stimulus. The patient may be queried regarding the names of different parts of the objects. The inability to name objects is of little localizing value other than to note a dominant hemisphere problem. The patient also may be asked to demonstrate how an object is used in the case of a pen or watch. The inability to show how an object is used, assuming hearing and motor functions are intact, may represent an apraxia, defined as the inability to perform a willed act.

In a nonfluent aphasia (a rough synonym is motor or expressive aphasia), the speed of language and the ability to find the correct words may be impaired. A common type of nonfluent motor aphasia is known as *Broca aphasia*, from localization to the eponymous portion of the dominant cortex. Speech is halting and slow, with stops between words or word fragments.

In a fluent aphasia (a rough synonym is auditory or receptive aphasia), the quantity of word production is normal or even increased. Sentences may have normal grammatical structure with normal rhythm, and intonation may be clearly articulated. However, language is impaired and the listener is struck by peculiarities of conversation that may lack content. Incorrect words may be substituted within sentences that may be sound-alike words or words with similar yet incorrect meanings. A global or mixed aphasia involves elements of fluent and nonfluent aphasia and is the most common type encountered in clinical practice.

Nondominant hemisphere problems may show problems of higher function, such as sensory discrimination, or auditory or visual inattention.

ADVANCED Testing of mental status and cognitive function may require appreciation of cultural context and language barriers. Further

assessment of comprehension may involve showing the patient a picture (there are some standard stimuli, but almost any magazine photo will suffice for testing) and asking for the patient's interpretation of the picture while noting if the content is correctly described and if the sentence structure and word selection of the descriptions are correct.

Assessing the ability of the patient to repeat a phrase may be a key point in delineating some types of fluent aphasia. Typically, the ability to repeat short words is more impaired than the ability to repeat longer words. A classic test involves the patient repeating the phrase, "No ifs, ands, or buts." In one type of fluent aphasia, Wernicke aphasia, comprehension is impaired, as is repetition.

Paraphasic errors may be further characterized in patients with fluent aphasia. A literal paraphasic error is one in which part of a word is replaced by an incorrect sound. The use of *spool* when *spoon* is meant is an example of this type of literal paraphasic error. At times the errors may reach the point when the substitutions are not understandable and a neologism is produced, i.e., a meaningless collection of syllables that takes the place of a word in conversation. Verbal paraphasic errors involve substitution of one correct word for another; for example, a patient may wish to use *spoon* in a sentence and substitute *fork* or even *bike*; the word is a correct word, but the meaning of the sentence is transformed erroneously.¹

A patient who is aphasic in speaking also will be aphasic in written communication. Writing and drawing simple constructions may be revealing in selected patients. A sequence of simple commands such as requesting the patient to draw a circle and then placing numbers correctly on it as if placing numbers on a clock may reveal constructional errors. A response consistent with a problem in the nondominant hemisphere might be to number half the clock face and stop or to place all the numbers around one-half of the circle.

Impairment of sensory perception on a cortical level may involve the inability to distinguish objects by feeling alone. Implied in this testing is that the primary sensory modalities (sharp, light touch, etc.) are intact. In cases of nondominant hemisphere lesions, the ability to identify objects placed in a hand, such as a coin, may be impaired.

SPECIAL CIRCUMSTANCES Fluent aphasia at times so impairs communication that the patient is thought to be intoxicated or psychotic from severe psychiatric illness. Attention to the speech may give a first clue and then further constructional or language testing may reveal the aphasia.

Cranial Nerves

BASIC A survey of the cranial nerves is part of the neurologic examination. Much information may be gathered informally. Facial asymmetry (cranial nerve VII) at rest or with movement may be observed. Lingual movement (XII) and other facial movements may be inferred during conversation if articulation is good. However, a more formal approach often is used in assessment. Most examiners start sequentially with cranial nerve II in testing; cranial nerve I (olfactory) testing has infrequent application in emergency medicine.

Cranial nerve II is the optic nerve with afferent function of light and visual perception. The optic nerve head is visible with direct ophthalmoscopy and may be inspected for any abnormalities. Common tests for optic nerve function include visual acuity and stimulation for pupillary reactivity. The response to bright light stimulation involves direct and indirect (consensual) pupillary responses. This is a reflex arc, with the afferent limb being cranial nerve II and brainstem interneurons and the efferent limb of the arc being cranial nerve III, which carries the pupilloconstrictors. A bright light shone into one eye should cause a brisk constriction of equal magnitude in both pupils. In the swinging flashlight test, the pupils are observed as the light is slowly moved from one pupil to the other. A seemingly paradoxical dilation of one pupil as the light is moved onto that pupil may indicate

optic nerve dysfunction of that eye; this is referred to as an *afferent pupillary defect*.

Cranial nerves III, IV and VI are concerned with extraocular eye movements. Tracing an object through a full-H pattern allows assessment of the different cranial nerves. Cranial nerve VI innervates the lateral rectus muscle, which abducts the globe moving it laterally away from the midline; this lateral movement will be impaired or lost in the case of a cranial nerve VI palsy. In fact, the unopposed adduction movement of medial rectus muscle innervated by cranial nerve III may result in the globe being adducted. Cranial nerve III innervates the extraocular muscles that adduct each eye and those that elevate and depress the globe. Impairment of cranial nerve III will reveal several abnormalities of extraocular movement, reflecting weakness in the innervated muscles. A complete paresis of cranial nerve III will show a dilated pupil in a globe deviated downward and outward. An isolated cranial nerve IV weakness may be hard to detect; cranial nerve IV supplies the superior oblique muscle that elevates and intorts the globe. Often, only subtle abnormalities of elevation are present.

Cranial nerve III also carries the parasympathetic pupilloconstrictors to the eye; a lesion of cranial nerve III may impair those fibers, resulting in unopposed dilatation (by functioning sympathetic fibers reaching the eye by a circuitous path) and a pupil larger than in the unaffected eye. Ptosis from levator paralysis is another finding of cranial nerve III paresis.

Cranial nerve V has motor and sensory functions. It supplies the muscles of mastication and is assessed by appreciating the masseter bulk. The sensory component of cranial nerve V supplies the cornea; the corneal reflex is a reflex arc of cranial nerves V to VII. Cranial nerve VII supplies the muscles for facial movement.

Cranial nerve VIII has auditory and vestibular afferent components. Cranial nerves IX and X are tested by observing pharyngeal musculature and gag reflexes. Cranial nerve XII controls lingual movement and can be assessed by asking the patient to stick out the tongue and observing for any asymmetry of motion. Cranial nerve XI is assessed by a shoulder shrug.

ADVANCED In about 20 percent of the population, some degree of physiologic anisocoria is present. Small differences in pupillary size in otherwise asymptomatic patients likely represent this normal variant. A peripheral lesion of cranial nerve VII will cause complete facial paralysis on the same side as the lesion. A cortical lesion (often stroke) results in weakness of the lower and mid-face, with preservation of motor function in the upper face ("central seventh pattern"), because of the bilateral cortical upper motor neuron innervation of the forehead musculature present in most patients.

SPECIAL CIRCUMSTANCES In the comatose patient, a unilaterally dilated pupil that is unreactive or reacts sluggishly to light may represent third nerve dysfunction or paresis from impingement of the oculomotor (III) nerve at the tentorium; this finding is consistent with the uncal herniation syndrome.

Sensory Examination

BASIC The sensory examination may be the most time-consuming portion of the overall examination, but it is key in some patients with sensory complaints. The primary sensory modalities are light touch, pinprick, position, vibration, and temperature sense. Because of variability in neuroanatomy, at times dissociation of these modalities occur and allow localization of problems to anatomic areas within the central nervous system.

Practically, in the screening examination, establishing that touch or pinprick is perceived in all extremities is often the only sensory examination assessment needed. However, if this is not intact or if peripheral nerve or spinal cord injury is suspected, additional examination is necessary.

Position testing is best used for the detection of peripheral neuropathy or if posterior column spinal cord disease is suspected. Position and vibration sensations are conveyed in the posterior columns of the spinal cord, so that there is little utility in testing both modalities.

ADVANCED Spinal cord dermatome levels are illustrated in Figure 226-1. If sensory alteration conforms to a level or selectively involves specific dermatomes, further localization to the peripheral nerve or nerve root may be possible.

If primary sensory modalities have been demonstrated to be intact, then testing of higher sensory functions may be pursued; these are covered in the section on higher cerebral functions.

SPECIAL CIRCUMSTANCES A few patterns of sensory loss are worthy of special mention. In cervical spinal cord injury or compression, an area of apparent sensory demarcation often appears to be just above the nipples. This transverse sensory level suggests a spinal cord lesion in the low cervical to high thoracic area. Most cervical dermatomes are represented in the upper extremity and not in the trunk (see Figure 226-1), and further testing is necessary to delineate the sensory level.

With suspected spinal cord injury, it is important to test the area of the perineum for sensation. The sacral dermatomes are distributed in an onion skin pattern around the perineum and represented only in that region. **The demonstration of a preserved island of sensation around the perineum may be the only sign of an incomplete spinal cord injury, which has a different prognosis than a complete spinal cord injury.**

Some general comments may be made about patterns of sensory alterations. In general, a hemi-body sensory loss or alteration suggests that cortical or subcortical lesions may be present. A localized problem in one limb suggests a peripheral nerve or nerve root problem, although there are other possible locations of abnormalities in the central nervous system. More information may be found in a recent monograph on new-onset sensory alteration.²

Motor System

There is more to evaluation of the motor system than simple assessment of strength. Muscle bulk and muscle tone are basic areas of assessment. The presence of any tremor should be noted and described. Is the tremor fine or coarse? Is it worse with activity?

BASIC Muscle tone may be characterized as normal, decreased, or increased. Movement of muscle groups and appreciating any resistance to movement comprise the process of assessing tone. The patient is requested to relax and not resist. Increased tone may be appreciated by greater than normal resistance to passive motion. At times the resistance will be increased, seemingly with the muscle transiently catching and then releasing to the movement (cogwheeling). Axial or truncal tone may be assessed by standing behind the patient, grasping the shoulders, and gently moving the shoulders forward and then backward. A patient with normal tone will offer little resistance to repeated motions, and some spontaneous swing of the arms will be noted. A patient with increased axial tone (e.g., Parkinson disease) may turn en bloc without the arm swing.

Simply having the patient hold the arms outstretched with palms upward and observing for any inward rotation or downward drift is a very sensitive sign for weakness (pronator drift); this also may be assessed in unresponsive patients (Figure 226-2). If both arms are held outright at the same time, comparison is easy, with observation of the upper extremity of one side as opposed to the other. A similar maneuver may be performed in the lower extremities. Another sensitive test for a subtle hemiparesis is the forearm rolling technique; the patient is asked to move the arms around each other in a tight circle in front of the trunk; the movements should be small and rapid. Asymmetry or slowness with one arm suggests a weak limb.³

FIG. 226-1. Sensory dermatomes. (Reproduced with permission from DeMyer W: *Technique of the Neurologic Examination: A Programmed Text*. New York, McGraw-Hill, 1994.)

Assessment and recording of other motor strength is best done by description of the stimulus and response. For example, the fact that the patient is able to strongly resist elbow extension or elbow flexion against the examiner is an appropriate notation.

ADVANCED Observation of the muscles at times may be very informative. Muscle mass or bulk should be comparable with muscle groups of the extremities. If weakness or paralysis has been present for some time, muscle wasting or atrophy may be present. Brief, rapid twitches of small parts of a muscle may represent fasciculations; fasciculations may indicate a process involving the lower motor neurons.

A formal rating scale for muscle strength exists but is not straightforward to apply. A rating of five is assigned for normal strength, and a rating of four indicates weakness and the ability to contract the muscle against some resistance. Thus, a tremendous range of strength is covered within the range of the four rating; rating is often further roughly quantified by adding 4+ and 4- to that rating range. A rating of zero represents complete paresis, and a rating of one indicates a minimal flicker of contraction. A rating of two is assigned for active movement of a muscle with gravity eliminated by limb repositioning, e.g., so that elbow flexion and contraction are demonstrated by a horizontal rather than by a vertical movement. A value of three is assigned to a muscle able to voluntarily demonstrate full motion against gravity only. It is better for the examiner to describe the strength of a muscle by noting the amount of resistance than by invoking what may be a little-used scale and erroneously applying a rating.

Listings of some muscle innervations, actions to test, and dermatomal representations may be found in Tables 226-1 and 226-2.

FIG. 226-2. Testing for weakness in the comatose patient; diagram illustrates assessment of muscular tone in a patient with a right hemiplegia. A similar maneuver may be used in the conscious patient. (Reproduced with permission from DeMyer W: *Technique of the Neurologic Examination: A Programmed Text*. New York, McGraw-Hill, 1994.)

TABLE 226-1 Muscle Innervation: Shoulder and Upper Extremity

Nerve	Action to Test	Muscle*

SPECIAL CIRCUMSTANCES Although not classically described as part of the motor system examination, information regarding bladder tone and function is at times vital to the examiner. In patients with complaints of incontinence and low back pain, for example, discovery of a probable neurogenic bladder by demonstrating large postcatheterization residual urine volume might be a key to diagnosis of spinal cord compression. A normal value is less than 75 mL.

Reflexes

Elicitation of muscle stretch reflexes is arguably the least important part of the neurologic examination and offers little value when used in isolation. Correctly termed *muscle stretch reflexes*, the jerk or involuntary motor movement follows the stretching of intrafusal muscle spindle fibers by the strike of the reflex hammer and the involuntary muscle contraction that follows. Muscle stretch reflexes serve mainly to weight evidence collected in other parts of the history or physical examination.

Depending on the force of the reflex hammer strike and local impact factors, an elicited reflex may seemingly change from moment to moment. The patient should be relaxed, and the muscle tested should be relaxed. Often several reflex strikes are performed. The best response is the value recorded.

BASIC Muscle stretch reflexes are graded on a scale from one to four that is not rigorously defined, with zero representing the absence of reflex, two or three being normal, and four representing hyperactive reflexes. Patterns of reflex abnormalities, e.g., upper versus lower extremity, left versus right, may suggest a location of a problem within the central or peripheral nervous system.

A toe that moves upward in response to a mildly noxious stimulation applied to the lateral plantar or lateral aspect of the foot defines Babinski response. The application of stimuli should not be hard or forceful. In adults, the normal response of the toe is to move downward to plantar stimulation.

ADVANCED Clonus is the rhythmic oscillation of a body part, typically the ankle, elicited by a brisk stretch (Figure 226-3). It may be thought of as one sign of a spasticity in addition to Babinski response, increased muscle tone, and hyperactive muscle stretch reflexes. It may be seen in conditions of metabolic disturbance and primary neurologic dysfunction.

SPECIAL CIRCUMSTANCES Principles of interpretation are that disease processes involving upper motor neurons or their processes (cortical or spinal cord injuries) result in hyperactive reflexes, Babinski response, and clonus. Processes injuring lower motor neurons,

TABLE 226-2 Muscle Innervation: Hip and Lower Extremity

Nerve	Action to Test	Muscle*

1374 SECTION 19 • NEUROLOGY

their axons, peripheral nerve roots, peripheral nerves, or the muscles themselves may result in hypoactive reflexes. However, in spinal cord injury or stroke, reflexes may take several hours or even days to become hyperactive, so the absence of these signs is not valuable in excluding acute spinal cord injury.

Spinal cord emergencies are high-risk clinical scenarios. A recent report noted that emergency physicians erroneously derive false reassurance from the absence of pathologic reflexes.⁴ Although the presence of Babinski signs and hyperreflexia are understood to be cardinal signs of upper motor neuron syndrome, the absence of these signs does not reliably exclude a diagnosis of spinal cord compression, and the diagnosis should be pursued if historical or other physical examination findings suggest the possibility of this critical diagnosis.

Cerebellar Testing

The cerebellum is concerned with involuntary activities of the central nervous system and may be simply thought of as a structure that helps with smoothing muscle movements and aiding with movement coordination. Very simply, the central cerebellar structures may be thought of as controlling coordination of posture and truncal movements, i.e., *axial coordination*. The lateral cerebellar structures are more coordinated with movements of the extremities, i.e., *appendicular coordination*.

BASIC Rapidly alternating movements may be assessed by a variety of maneuvers. Hand-slapping tests, asking the patient to rapidly pronate and then supinate the forearm, and slapping the thigh with each movement is a commonly used test. The movements are normally small, and the hand slapping should be symmetric. Rapid pronation and supination of the hands is another test for dystaxia and dysmetria; the movements should be equal with both hands (Figure 226-4).

ADVANCED Although usually included in cranial nerve testing, eye movements are useful in assessing cerebellar function, and abnormalities in their movements may suggest cerebellar dysfunction. Tracking an object slowly should show smooth, slow eye movements; breakup of the smooth movement may be evident and is analogous to the decompensation of movements that may occur in isolated cerebellar impairment. Similarly, if a patient is asked to look back and forth between two objects (finger-to-nose testing involves the patient looking back and forth quickly between the examiner's outstretched finger and nose), the eyes should quickly and conjugately look at the target without overshoot. These faster, or saccadic, movements are, at least in part, reflective of cerebellar function. *Nystagmus* refers to rapid involuntary movements of the eyes that may be present with primary (straight-ahead) gaze or provoked by looking at extremes of gaze. Course nystagmus or other abnormalities of eye movements are at times present with cerebellar problems (see Chap. 238 for a discussion of nystagmus).

FIG. 226-4. Pronation and supination test: cerebellar testing. (Reproduced with permission from DeMyer W: *Technique of the Neurologic Examination: A Programmed Text*. New York, McGraw-Hill, 1994.)

Gait and Station

BASIC It has been said that, if only one neurologic test could be performed, observation of the patient walking would be the most informative. The posture that the patient assumes when stationary defines the station of the patient. A variety of abnormal gaits and postures are discussed further in Chap. 230, "Ataxia and Gait Disturbances," as are different techniques of physical examination.

SPECIAL CIRCUMSTANCES Cerebellar infarction or hemorrhage is a true emergency, because expanding lesions in the posterior fossa may rapidly compress the brainstem, causing apnea and death. However, rapid recognition and surgical intervention have been shown to have good outcomes, unlike most other intraparenchymal brain hemorrhages. Patients with cerebellar hemorrhage may have severe nausea and vomiting and be massively diaphoretic. Their clinical condition is such that fine neurologic examination is simply not possible. One feature common in many patients with cerebellar hemorrhage is the sudden inability to walk. The examiner should keep the possibility of cerebellar injury in mind when evaluating a patient with sudden onset of symptoms that include the inability to walk.

ACKNOWLEDGMENTS

The authors acknowledge the work of Dr. Greg Henry and Dr. Hugh S. Mickel, authors of chapters on this topic in previous editions of the study guide. Their chapters served as a check for completeness and provided some tabular information. J. Stephen Huff also thanks Dr. William DeMyer of Indiana University whose instruction in the neurologic examination years ago stimulated an interest in this area.

HEADACHE AND FACIAL PAIN

Christopher J. Denny

Michael J. Schull

HEADACHE

Headache represents up to 4 percent of all emergency department visits.¹ Emergency physicians generally are concerned with identifying those patients whose headaches are caused by life-threatening conditions. Most patients, however, have benign primary headache syndromes and are concerned with receiving rapid and effective treatment for their headaches.

Epidemiology

Migraine headaches have prevalence rates of approximately 17 percent in women and 5 percent in men. Most emergency department patients have benign primary headache syndromes, but approximately 3.8 percent have serious or secondary pathology.¹

Classification

For practical purposes, headaches generally are divided into primary headache syndromes, including migraine, tension-type, and cluster headaches, and secondary causes. The most common causes are listed in Table 227-1.

Pathophysiology

The brain parenchyma is largely insensate to pain. Pain may originate from large cranial vessels, proximal intracranial vessels, and the dura mater. Anterior vessels are innervated by branches of the ophthalmic division of the trigeminal nerve, whereas contents of the posterior fossa are innervated by branches of the C2 nerve roots.²

Approach to Patients with Headache in the Emergency Department

The 1996 American College of Emergency Physicians' (ACEP's) Clinical Policy for Adults with Headache groups all causes of headache into four broad categories³ (Table 227-2). Evaluation of the headache patient has four essential objectives:

1. To appropriately select patients for emergency investigation and treatment of suspected critical secondary headache causes
2. To diagnose and effectively treat patients with generally benign and reversible secondary headache causes
3. To provide effective treatment for primary headache syndromes
4. To provide appropriate disposition and follow-up (including outpatient investigations and referral as necessary) for all discharged patients

The central role played by the history in the evaluation of the headache patient is emphasized in the guidelines published by ACEP and those of other groups. Patients with an atypical history, a substantial change from a previous headache pattern, or certain high-risk features, as summarized below, require emergency department evaluation.^{3,4}

HISTORY

Headache Pattern Important features include: first severe headache, worst headache ever, steady worsening over several days, or significant differences from prior headaches in terms of duration, severity, or associated symptoms.³

Onset Sudden-onset headache, especially if it begins during exertion (including coughing, defecation, etc.), is an independent predictor of

ness, persistent visual disturbance, fever, or seizure(s).³ The history also should include a search for symptoms of nonneurologic conditions causing headache, such as visual change and eye pain, suggestive of glaucoma or iritis; jaw claudication, suggestive of temporal arteritis; or congestion and facial pain, suggestive of sinusitis.³

Other History Medications [e.g., nitroglycerin, chronic analgesic use, monoamine oxidase inhibitors (MAOIs), or anticoagulants], a remote history of trauma, or toxic exposures (e.g., carbon monoxide) may be important causes. Prior headache history, results of any previous neuroimaging, and comorbid conditions such as malignancies, AIDS or HIV seroconversion, coagulopathy, and hypertension should be sought.³

Family History Migraine headaches occur more commonly in patients with a family history of migraines or motion sickness.² Headache patients should be asked about relatives with SAH because the risk of ruptured intracranial aneurysm in first- and second-degree relatives is up to four times higher than in the general population.⁶

PHYSICAL EXAMINATION Aspects of the general appearance and vital-sign abnormalities are warning signs of a possible serious cause. Fever suggests infection, such as meningitis or sinusitis, but also can occur in SAH. Marked hypertension should raise suspicion of a hypertensive urgency or emergency.

A focused examination looking for important nonneurologic causes of headache should be undertaken. In the head and neck, the sinuses should be examined for evidence of sinusitis; the temporal arteries palpated for tenderness or reduced pulsation, suggestive of temporal arteritis; and the dentition and temporomandibular joints examined for tenderness.³ An eye examination should be carried out to exclude acute glaucoma, visual field defects, or iritis. Funduscopy may reveal papilledema or the absence of venous pulsations, both signs of raised intracranial pressure (ICP) or subhyaloid hemorrhage (gravity-dependent venous hemorrhage between the retina and vitreous membrane, convex at the bottom and flat at the top when the patient is examined sitting), which is highly suggestive of SAH.

Finally, a careful neurologic examination is mandatory, focusing on the mental status, cranial nerves, motor and sensory examinations, reflexes, gait, and cerebellar testing. Evidence of meningeal irritation should be assiduously ruled out. Papilledema, altered mental status, or focal neurologic deficits are predictive of raised ICP. An abnormal neurologic examination in the setting of a headache requires emergent neuroimaging.

SPECIAL CONSIDERATIONS

Women Migraine headaches are more common in women and are influenced by hormonal factors. Menarche, menstruation, oral contra-

intracranial pathology, and up to 25 percent of such headaches are caused by subarachnoid hemorrhages (SAHs).¹

Headache Location The location of the headache is nonspecific and should not be relied on for diagnosis. Migraines are most commonly unilateral and tension-type headaches bilateral, but the reverse also may be true.⁵ Occipitotemporal location of headache among emergency department patients is an independent predictor of intracranial pathology, although its positive predictive value is only 16 percent.¹ It is, however, the most common location for the headache of an acute SAH.

Associated Symptoms Other important features include a history of syncope, altered level of consciousness, confusion, neck pain or stiff-

ceptive use, pregnancy, and menopause all may affect migraine. Higher estrogen levels generally are associated with improved symptoms.

Pregnancy Preeclampsia should be considered in pregnant women. Pregnancy improves migraine symptoms in 60 to 70 percent of patients.

Older Age New onset of headaches in patients over 50 years of age is worrisome and may herald the presence of a secondary cause.¹ However, one study of new-onset headache in older patients still found primary headache syndromes to be the most common diagnosis.

Children (See Chap. 130)

HIV and Other Causes of Immunosuppression Specific consideration of space-occupying lesions such as toxoplasmosis and central nervous system (CNS) lymphoma is prudent in the immunosuppressed patient. Altered mental status, new seizure activity, and greater than 3 days of headache are high-risk criteria.⁷

USING CLINICAL DATA TO GUIDE DECISION MAKING (SEE ALSO CHAP. 237) Data obtained from the history and physical examination allow patients to be classified according to the ACEP groupings (see Table 227-2). Patients suspected of having critical secondary causes of headache (see Table 227-1) should undergo emergent investigations, as outlined below, and have appropriate consultation and treatment initiated. Those with a benign and reversible secondary cause or an urgent but not emergent secondary etiology can have diagnostic tests and specific treatments initiated in the ED or as outpatients, as appropriate.

The 2002 ACEP Clinical Policy on Acute Headache differentiates between the use of neuroimaging for the identification of life-threatening etiologies versus its use in diagnosis for disposition.⁸ The policy grades these recommendations based on the quality of evidence for or against an intervention. There were no level A recommendations (i.e., those which reflect a high degree of certainty). Level B recommendations are for emergent neuroimaging of new focal deficits, acute sudden onset of headache, and in HIV-positive patients presenting with a new headache. In patients older than 50 years of age with new headache and a normal neurologic examination, there are level C recommendations for consideration of urgent neuroimaging. The largest group of emergency department headache patients has assessments that suggest a benign primary headache syndrome, and the objective for these patients is to provide effective therapeutic relief.

Appropriate follow-up should be ensured for all discharged patients. Outpatient investigation and referral may be required, especially in cases such as poorly controlled primary headache syndromes or occasionally a patient with a suspected critical secondary cause not needing emergent investigation (e.g., suspected brain tumor without raised ICP). In cases such as the latter, outpatient workup is appropriate only if the physician is confident that the patient will not be lost to follow-up.

Diagnostic Adjuncts

COMPUTED TOMOGRAPHY The emergency department patient whose headache requires emergent investigation usually begins with a non-contrast-enhanced computed tomographic (CT) scan.³ The use of contrast material increases the time, expense, and risk of adverse effects (minor 10 percent, severe 0.1 percent),⁴ and the non-contrast-enhanced CT scan usually adequately excludes critical lesions or mass effects requiring emergent interventions. In particular, the non-contrast-enhanced CT scan is the best neuroimaging test for diagnosing an acute SAH, although a negative CT scan alone cannot exclude SAH. When there is strong suspicion of small lesions likely to be missed without contrast (e.g., in an AIDS patient suspected of cerebral

toxoplasmosis or suspected small brain mass), then a CT with intravenous contrast material or magnetic resonance imaging (MRI) may be needed.⁴ Chap. 237 provides a detailed review of the various neuroimaging techniques and their indications.

LUMBAR PUNCTURE (LP) See Chap. 235 for a description of this procedure. LP is required in cases such as suspected meningitis or suspected SAH with a normal CT scan.⁹ Contraindications to LP include the suspicion of raised ICP, which can be excluded by a combination of the absence of papilledema, normal level of consciousness, and normal findings on neurologic examination. **Absence of papilledema by itself is unreliable** because papilledema may not be apparent in rapidly developing ICP. Venous pulsations seen at the disc margins on fundoscopic examination with the patient upright reliably insures a normal ICP. If these conditions are met, then a CT scan is not required prior to LP, especially if the CT scan is likely to be delayed.

MAGNETIC RESONANCE IMAGING (MRI) The cost and restricted availability of MRI limit its utility in the emergency investigation of headache. MRI is more sensitive than CT scanning in evaluating brain injuries, such as diffuse axonal injuries, small parenchymal contusions, isodense subdural hemorrhages, and most tumors.⁴ In acute SAH, however, MRI is no more sensitive than CT scanning in the first few days following a bleed. CT scanning and LP are adequate for the large majority of emergency department headache patients requiring emergent investigation.

Life-Threatening Causes of Headache

SUBARACHNOID HEMORRHAGE

Epidemiology SAH (see Chap. 228) has an annual incidence of approximately 1 per 10,000 in the United States.⁶ Of all sudden, severe headaches presenting to the ED with a normal neurologic examination, 12 percent have SAH.¹⁰ SAH occurs in young people, with a median age of 50 years. Mortality rates from SAH are high; 50 percent of patients die within 6 months.

Clinical Features At the time of presentation, almost half of patients with SAH have normal findings on neurologic examination, including normal vital signs, normal level of consciousness, and no neck stiffness. The headache of SAH is most commonly severe and of sudden onset, but it also may be more subtle. The most common location for the headache is occipitotemporal. Many presentations are atypical and may mislead the clinician. For example, sudden-onset intense neck pain may be mistakenly attributed to radiculopathy. Also, resolution of the pain even without treatment does not exclude the diagnosis. Beware of radiation of pain down along the cervical spine because this suggests tracking of subarachnoid blood down the spinal canal.

Diagnosis Investigation of suspected SAH usually begins with a plain CT scan of the head. Retrospective studies suggest that the sensitivity of newer-generation CT scans may be in excess of 93 percent for the detection of SAH when symptom presentation is within 24 h and may be even higher if performed within 12 h of symptom onset.¹¹ However, no study has convincingly shown that CT scanning alone can exclude SAH, even within 12 h.¹² The sensitivity of CT scanning falls to slightly over 80 percent after 24 h and decays rapidly thereafter. Older-generation CT scanners were less sensitive among patients who were alert compared with those with an altered sensorium. It remains unclear whether this finding holds with new-generation scanners.¹³

Most authorities consider an LP to be mandatory following a negative CT scan. An alternate view suggests that LP may be unnecessary when the pretest probability is very low. However, this view has itself been challenged on the basis that so-called low-probability patients

(isolated severe headache and absence of neurologic findings) may still have up to a 12 percent chance of SAH and that CT scanning may be less sensitive in these patients.¹⁴ Thus, given the potential for catastrophic outcome, it remains prudent to perform an LP on all patients suspected of SAH in whom the CT scan was negative.

The "gold standard" for the diagnosis of SAH is the presence of xanthochromia in the cerebrospinal fluid (CSF) supernatant. If LP is performed 12 h or longer after onset of headache (allowing sufficient time for xanthochromia to develop) and spectrophotometry is used for CSF analysis, then xanthochromia is nearly 100 percent sensitive for up to 2 weeks following a bleed. Naked-eye detection of xanthochromia may yield a false-negative result in 50 percent of cases, yet this remains the laboratory standard in many hospitals across North America. If a patient presents to the emergency department less than 12 h after the onset of headache, some authors argue that LP should not be delayed.¹⁰ Others suggest that delaying LP optimizes the detection of xanthochromia, which simplifies interpretation of CSF results. Traumatic taps occur in up to 20 percent of LPs. In LPs with questionable red blood cell counts, the presence of xanthochromia suggests a SAH, whereas its absence in a delayed LP suggests the blood may be due to the procedure itself. Regardless of LP timing, persistently bloody CSF or the presence of xanthochromia mandates CNS vascular imaging.

Treatment Treatment for SAH diagnosed as a "stroke syndrome" is discussed in Chap. 228. Neurosurgical consultation is appropriate. The Hunt and Hess classification (Table 227-3) is one of several scales that can be used to assess prognosis and determine eligibility for surgery. Patients presenting with headache and without major neurologic complaints or findings are likely to be of grade I or II severity and thus are appropriate candidates for angiography and surgical intervention. However, the Glasgow Coma Scale (see Figure 255-2) and the World Federation of Neurological Surgeons (WFNS) scale can also be used to predict mortality.^{15,16}

Nimodipine (60 mg PO q6h) appears to decrease incidence and severity of vasospasms that may cause cerebral ischemia. If the patient cannot take oral medications, initiation of this medication is delayed.

Prophylactic phenytoin loading is recommended to avoid seizures, which can cause increased intracranial pressure. For similar reasons, nausea and vomiting should be treated with standard antiemetics.

MENINGITIS (SEE ALSO CHAP. 235) All forms of meningitis can cause headache. In viral or bacterial meningitis, the headache may be severe and of rapid onset, and it is usually accompanied by fever and meningismus. Opportunistic infections in immunocompromised patients, such as cryptococcal meningitis, may present with a more insidious onset of headache, and fever and neck stiffness may be absent. An LP is required if there is any suspicion of meningitis, and it need not be preceded by a CT scan in patients with normal findings on neurologic examination, a normal level of consciousness, and no papilledema. If the LP must be delayed for any reason and bacterial meningitis is suspected, antibiotics should be started immediately.

TABLE 227-3 Hunt and Hess Classification of Subarachnoid Hemorrhage

Classification	Symptoms
Grade I	Asymptomatic or minimal headache and mild nuchal rigidity
Grade II	Moderate to severe headache, nuchal rigidity, no neurologic deficit other than cranial-nerve palsy
Grade III	Drowsiness, confusion, or mild focal deficit
Grade IV	Stupor, moderate to severe hemiparesis, possible early decerebrate rigidity, vegetative disturbance
Grade V	Deep coma, decerebrate rigidity, moribund appearance

Source: Hunt WE, Hess RM: Surgical risk as related to time of intervention in the repair of intracranial aneurysms. *J Neurosurg* 28:14, 1968.

INTRAPARENCHYMAL HEMORRHAGE AND CEREBRAL ISCHEMIA About 55 percent of patients with intraparenchymal hemorrhage report headache at the onset of their symptoms. Only 17 percent of ischemic stroke patients and 6 percent of patients with transient ischemic attacks (TIAs) complain of headache. Other neurologic signs and symptoms are present in most patients.

SUBDURAL HEMATOMA (SDH) A history of remote trauma in a patient with a headache should raise suspicion of a subacute or chronic subdural hematoma. A low threshold for initiating investigations is appropriate for high-risk patients, including patients on anticoagulants, chronic alcoholics, and the elderly, in whom there may be no clear history of trauma.³ If a plain CT scan of the head appears normal yet the clinician has grounds to suspect a subacute or chronic SDH (which may appear isodense to brain parenchyma), then a contrast-enhanced CT scan or MRI of the head should be considered.

BRAIN TUMOR Up to 70 percent of patients with brain tumors complain of headache at the time of diagnosis, and only about 8 percent have abnormal findings on neurologic examination. The headache may be unilateral or bilateral, intermittent or continuous. The classic headache of brain tumors (worse in the morning, associated with position and nausea and vomiting) occurs in only a few. If headache is suspected of being due to a tumor and 24-h follow-up can be ensured, a reliable patient with normal findings on neurologic examination, including absence of papilledema, can be investigated as an outpatient.³

Secondary Causes of Headache

TEMPORAL ARTERITIS

Epidemiology Temporal arteritis (TA) occurs almost exclusively in patients over 50 years of age. In this age group, there is an annual incidence rate of 15 to 30 cases per 100,000 persons, and it occurs more commonly in women.¹⁷

Pathophysiology TA is a systemic panarteritis that selectively involves arterial walls with significant amounts of elastin.

Clinical Features Headache is the most common symptom of TA, reported in 60 to 90 percent of patients. The headache is most often severe and throbbing and usually located over the frontotemporal region. Other strongly suggestive features include jaw claudication or evidence of polymyalgia rheumatica, with which TA is strongly associated. The involved temporal artery may be nonpulsatile or tender or have a diminished pulse. The most serious complication is loss of vision, usually due to ischemic optic neuritis.¹⁷

Diagnosis The diagnosis is established by fulfilling three of the five following criteria: age over 50 years, new-onset localized headache, temporal artery tenderness or decreased pulse, erythrocyte sedimentation rate over 50 mm per h, and abnormal arterial biopsy findings.¹⁷

Treatment In order to prevent loss of vision, treatment should begin immediately with 40 to 60 mg PO per d of prednisone when TA is suspected clinically. Patients should be referred urgently for definitive diagnosis and follow-up.¹⁷

OPHTHALMIC DISORDERS (SEE ALSO CHAP. 238) Acute glaucoma may present with headache, and in other eye disorders, such as iritis or optic neuritis, some patients may describe eye or supraciliary pain as headache. These conditions usually can be distinguished by a careful history and eye examination, including measurement of intraocular pressure when necessary.³

HYPERTENSION (SEE ALSO CHAP. 57) Hypertension may cause headaches, with higher diastolic pressures generally associated with more severe headaches. Physicians should be cautious prior to making this diagnosis, however, because hypertension also may occur as a sign of other secondary headache conditions (e.g., stroke, pheochromocytoma, or preeclampsia) or simply may be secondary to the pain and anxiety associated with a primary headache syndrome.³ When other secondary causes of headache, including hypertensive emergency, have been excluded, reduction of the blood pressure should result in improvement or resolution of the headache. While some consider isolated headache associated with hypertension as evidence of possible end-organ involvement, most such patients can be discharged following complete resolution of symptoms and blood pressure reduction if follow-up in the next 24 to 48 h can be arranged.

SINUSITIS (SEE ALSO CHAP. 241) Infection of the sinuses may result in facial pain or headache. Maxillary sinusitis, by far the most common type, causes pain over the anterior aspect of the face rather than headache. Involvement of other sinuses can cause headache: frontal sinusitis over the forehead, ethmoid sinusitis behind and between the eyes, and sphenoid sinusitis cause a diffuse headache. The headache frequently varies with head position. Symptoms predictive of sinusitis include colored nasal discharge, maxillary toothache, and poor response to decongestants, while reliable signs include purulent nasal discharge and abnormal transillumination (not easy to do properly in the ED). Regardless of plain sinus x-ray findings, patients with four or more of the above-mentioned features have a very high likelihood of sinusitis, while those with fewer than two features are very unlikely to have sinusitis.

DRUG-RELATED AND TOXIC OR METABOLIC HEADACHES Various drugs, such as nitrates, MAOIs, or chronically used analgesics, may cause headache. Metabolic conditions such as hypoxia, hypercapnia, and hypoglycemia and toxins such as monosodium glutamate and carbon monoxide may cause headache as well. Withdrawal from alcohol also may result in headache. Such headaches can be identified either in the history or through appropriate laboratory testing (glucometer, arterial blood gases, and carboxyhemoglobin levels).³

BENIGN INTRACRANIAL HYPERTENSION (PSEUDOTUMOR CEREBRI) A rare entity, benign intracranial hypertension (BIH), should be considered in a young, obese patient presenting with longstanding headaches. Nausea, vomiting, and visual disturbance also may be present. While its cause is unknown, BIH has been linked to the use of oral contraceptives, vitamin A, and tetracycline and to thyroid disorders. BIH is characterized by papilledema, a normal level of consciousness, normal CT scan findings, and markedly elevated CSF pressure on LP. The only serious adverse outcome is the potential for visual loss. Initial treatment is usually with acetazolamide or steroids. When these fail, repeated LPs to drain CSF or surgery (CSF shunts or optic nerve sheath fenestration) may be tried.

INTERNAL CAROTID AND VERTEBRAL ARTERY DISSECTION While rare, dissection of the internal carotid or vertebral artery is frequently associated with headache. Dissection may be spontaneous or the result of trauma and generally occurs in younger patients (median age 40 years). Internal carotid artery dissection may be suspected in a patient with unilateral anterior neck pain or headache, usually around the eye or frontal area. Most patients present with or eventually develop neurologic signs, such as TIA, stroke, Horner syndrome, transient monocular blindness, or cranial nerve palsies. Vertebral artery dissection typically presents with marked occipital or posterior neck pain associated with signs of a brainstem TIA or stroke. Diagnosis is usually made by angiography. Duplex scanning and MRI also may identify vessel abnormalities. SAH may be caused by dissection through the adventitia of the vessel, and this must be excluded prior to initiating anticoagulant therapy.

POST-LUMBAR PUNCTURE HEADACHE Between 10 and 36 percent of patients who undergo LP develop a headache within 24 to 48 h due to a persistent CSF leak from the dura. The incidence of post-LP headaches can be minimized through the use of smaller-bore needles with noncutting tips in order to spread, rather than cut, dural fibers. Post-LP headache can be treated with simple analgesics, intravenous fluids, and intravenous caffeine. If this treatment fails, a blood patch may be required. This procedure involves an epidural injection of autologous blood at the level of the LP to "patch" the CSF leak.

Primary Headache Syndromes

The term *primary headache* includes all forms of migraine, tension-type, and cluster headaches. There is considerable clinical overlap in primary headache syndromes, and it has been suggested that they share a pathophysiology and represent different ends of a clinical spectrum.⁵

MIGRAINE

Epidemiology Migraine headaches are common, with onset usually in the early teens or even younger. Prevalence is estimated at approximately 5 percent for males and 15 to 17 percent for females. Prevalence peaks in both sexes at around 40 years of age and then declines gradually.¹⁸

Pathophysiology Early theories postulated abnormal vasculature as the root cause of migraine headaches, with vasoconstriction being responsible for the aura and rebound vasodilatation the cause of the pounding headache. It now seems clear that migraines are a primary response of brain tissue to some trigger, resulting in dysfunction of brainstem pathways that normally modulate sensory input, whereas the disordered activity of blood vessels is secondary.²

Auras are thought to be due to primary neuronal dysfunction, with the neurologic symptoms resulting from a slowly spreading wave of neuronal hypoactivity traveling across brain tissue. There is a corresponding decrease in local blood flow where neuronal activity is reduced. This reduction in blood flow does not follow vascular territories, which makes it unlikely to be vasospastic in origin.²

Animal models suggest that the headache of migraine is related to activation of sensory axons, leading to the release of various peptides. This causes sterile neurogenic inflammation in pain-sensitive arteries, the dura, and meningeal tissues and promotes local vasodilatation. The release of these peptides and the resulting inflammation and plasma extravasation can be blocked by sumatriptan, a selective agonist of 5-HT_{1D} (serotonin) receptors, as well as by ergots, indomethacin, and others. Sumatriptan also has direct vasoconstricting effects. Both mechanisms may explain its efficacy at revealing migraine headache. The neurophysiologic pathways linking auras and headaches are still poorly understood.

The actual triggers for these complex mechanisms are unknown, although enhanced excitability of occipital cortex neurons in migraine patients has been proposed.²

Clinical Features Migraine without aura accounts for most migraines. The headache generally is slow in onset and lasts from 4 to 72 h. It is typically unilateral and pulsating or worsened by physical activity. Nausea, vomiting, and photo- or phonophobia frequently accompany the headache. The scalp may or may not be tender. These features, however, are not entirely sensitive (migraines need not be unilateral or pulsating) or specific (the same features can be present in tension-type headaches).³ Suspicion that a different etiology may be underlying should be raised when a patient presents with a "migraine" that is significantly different from prior headaches. The headache in migraine with aura is similar but is preceded or accompanied by an aura that develops gradually over minutes, usually lasts 60 min, and is fully reversible.

Visual auras are the most common, usually consisting of scintillating scotomata (i.e., dark spots) or flashing lights, but virtually any neurologic symptom or sign can occur. Other "typical" auras include hemiparesthesia, hemiparesis, aphasia, or other speech difficulties. Rarer types of auras include those with brainstem symptoms (basilar migraine), those lasting longer than 60 min (migraine with prolonged aura), and aura without accompanying headache (migraine aura without headache). Auras should be distinguished from migraine prodromes, which occur many hours prior to the headache and can consist of lethargy, hyperactivity, yawning, depression, food craving, polyuria, or rarely fluid retention.

Other, less common forms of migraine include *ophthalmoplegic migraine*, in which headache overlaps with paresis of one or more of cranial nerves III, IV, and VI, or retinal migraine, with sudden monocular scotoma or blindness associated with headache. Rarely, migrainous infarction may occur (previously called *complicated migraine*), characterized by an aura lasting more than 7 days or neuroimaging evidence of cerebral infarction.

Clearly, in a patient who presents with a focal neurologic deficit and headache, migraine of any sort must be a diagnosis of exclusion unless the patient has a clear history of previous similar migraines, including the neurologic deficit, and normal results of prior investigations. Given that they rarely last more than 60 min, the aura and deficits would be expected to resolve in migraine patients prior to discharge from the emergency department.

Treatment There is a wide spectrum of clinical practice and no clear consensus on the best therapy for migraine. This reflects the fact that, to date, no migraine treatment has been shown to be superior in all respects. Although there is ongoing use of opiate medications as abortive migraine therapy in the emergency department, several guidelines suggest instead using more migraine-specific therapy.²

At present, several nonopioid abortive therapeutic options are available (Table 227-4) based on a review of emergency department randomized, controlled trials (RCTs) and consensus guidelines. Dihydroergotamine (DHE), a 5-HT_{1B/1D} (serotonin) receptor agonist, is highly effective in relieving headaches and is an appropriate first-line therapy for migraine. However, DHE causes vomiting in a significant proportion of patients, probably due to its affinity for other serotonin and dopamine receptors. Patients therefore should be pretreated with an antiemetic, such as metoclopramide or prochlorperazine.

The triptans (e.g., sumatriptan) are more selective 5-HT_{1D} agonists than DHE and cause less nausea and vomiting.¹⁹ These agents have three potential mechanisms of action: cranial vasoconstriction, peripheral neuronal inhibition, and inhibition of transmission through second-order neurons of the trigeminocervical complex.² However, emergency department-based studies have shown that subcutaneous sumatriptan results in frequent but short-lived minor adverse effects (e.g., sensations of heat, tingling, chest discomfort, and injection-site reactions), is more costly, and has a higher 24-h recurrence/relapse rate than treatment with DHE.¹⁹ While sumatriptan still may be useful for migraines unresponsive to other medications, it should not be given within 24 h of the administration of DHE or other ergots because both cause vasoconstriction.

Other migraine drugs studied in emergency department-based RCTs and shown to be effective include several dopamine-antagonist antiemetics: metoclopramide, chlorpromazine, prochlorperazine, ketorolac, and droperidol²⁰ (see Table 227-4). Regardless of the medication chosen, patients should be placed in a darkened, quiet area in order to lessen the associated phono- and photophobic symptoms. Given that patients may have been vomiting and had poor oral intake for hours or days prior to their arrival in the emergency department, intravenous rehydration is also frequently of benefit.

Dexamethasone has been touted as effective in reducing the rate of recurrent migraine following standard treatment. In one emergency department-based RCT, patients received either 20 mg intravenous dexamethasone or placebo after standard migraine therapy. A signifi-

TABLE 227-4 Treatment Options for Migraine Headache

Drug	Dosing and Adjuncts	Contraindications (CI), Precautions (PC), and Notes
Dihydroergotamin (DHE)	1 mg IV over 3 min; pretreat with metoclopramide or chlorpromazine or prochlorperazine to reduce nausea and vomiting	CI: Pregnancy, hypertension (uncontrolled), coronary artery disease, recent sumatriptan use, hemiplegic or basilar migraine PC: May cause nausea, vomiting, diarrhea, abdominal pain
Sumatriptan (Initrex)	6 mg SC	CI: Pregnancy, hypertension (uncontrolled), coronary artery disease, ergot use in past 24 h, MAOI use, hemiplegic or basilar migraine PC: Minor adverse effects; rarely, coronary artery spasm, myocardial infarction, dysrhythmias
Ketorolac	30 mg IV or 60 mg IM	CI: History of peptic ulcer disease (especially in the elderly) PC: Class B in pregnancy, avoid in third trimester
Chlorpromazine	Pretreat with NS bolus to minimize hypotension; 7.5 mg IV	PC: Class C in pregnancy, may cause hypotension, drowsiness, dystonic reactions. Note: effective antiemetic
Prochlorperazine	5-10 mg IV or PR	PC: Class C in pregnancy, may cause drowsiness, dystonic reactions Note: effective antiemetic
Metoclopramide	10 mg IV	PC: Class B in pregnancy, may cause drowsiness, dystonic reactions Note: effective antiemetic
Droperidol	2.5 mg IV slow, or 2.5 mg IM	PC: Cases of QT-interval prolongation and/or torsades de pointes have been reported
Magnesium sulfate	2 g IV over 30 min	Note: nonvalidated but occasionally useful therapy
Methylprednisolone	125 mg IV or IM	Note: nonvalidated but occasionally useful rescue therapy

Abbreviation: MAOI = monoamine oxidase inhibitor.

cant reduction in the rate of 48- to 72-h recurrent migraine was found in the dexamethasone group as compared with the placebo group.²¹

Special mention is reserved for the use of opioid analgesics in migraine. Meperidine is still used as an acute migraine treatment despite several studies that have shown it to be less effective than other agents.²² The frequent use of opioids in chronic and recurrent headache conditions may lead to adverse effects and may even exacerbate headaches. Today the indications for opioid use in the treatment of migraine are declining.

Special Considerations

PREGNANT WOMEN Migraines generally improve during pregnancy, especially after the first trimester. Nonpharmacologic therapy,

such as rest and ice, should be tried first, but in patients with intractable headache or nausea and vomiting, medications may be used. Acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) are considered class B by the U.S. Food and Drug Administration (i.e., no evidence of risk in pregnant women, but there are no controlled trials) and can be used. However, NSAIDs should not be used in the third trimester because they inhibit labor and decrease amniotic fluid volume. Metoclopramide, another class B drug, can be very useful, especially if there is significant nausea and vomiting. Akathisia is a potential side effect of metoclopramide.

PREVENTIVE THERAPY Nonpharmacologic therapies include education of the patient about the disorder, its mechanisms, approaches to treatment, and changes in lifestyles involved in the avoidance of triggers of migraine.² Initiating pharmacologic preventive therapy is best done in collaboration with the family physician and/or the patient's neurologist.

TENSION-TYPE HEADACHES Previously, extracranial muscle tension was thought to be a causative factor in tension-type headaches. However, this relationship has been questioned, given the problem of demonstrating muscle tension and the difficulty of determining whether it is a cause or merely an epiphenomenon. More recent theories suggest that tension-type headaches and migraines may share a common pathophysiology and that they represent different ends of a clinical spectrum.⁵

Tension-type headaches are defined in such a way as to distinguish them from migraines. Therefore, they are described as bilateral, non-pulsating, not worsened by exertion, and not associated with nausea or vomiting. However, patients with severe tension-type headaches may indeed have nausea and vomiting, and mild migraine easily may fit the description of a tension-type headache.⁵

Treatment for mild headaches consists of simple analgesics or NSAIDs. For severe tension-type headaches, treatment is the same as for migraines, given the difficulty of distinguishing between the two entities.

CLUSTER HEADACHES Cluster headaches are generally rare (prevalence rates of 0.4 percent of the general population), and they are very short-lived, even without treatment. Unlike other primary headaches, they are more common in men, and onset is usually after 20 years of age.

Dysfunction of the trigeminal nerve is believed to cause cluster headaches, and the fact that they respond to 5-HT_{1D} agonists suggests a common mechanism with migraines.

Cluster headaches are characterized by very severe unilateral orbital, supraorbital, or temporal pain lasting 15 to 180 min. The pain is such that patients rarely can lie still, and most are pacing and restless. The headaches are associated with at least one of the following signs on the ipsilateral side: conjunctival injection, lacrimation, nasal congestion, rhinorrhea, facial swelling, miosis, or ptosis. They tend to occur in clusters, i.e., daily on the same side of the face for several weeks, before remitting for anywhere from weeks to years.

Given the short duration of cluster headaches, any medication used in their treatment must act very rapidly. High-flow oxygen is effective in up to 70 percent of patients, and DHE and sumatriptan also have been shown to be rapidly effective. Oral agents are unlikely to be effective for acute attacks, given the long time for absorption and the short duration of cluster headaches, but NSAIDs may be useful in reducing the frequency and severity of future attacks.

Disposition of Patients with Primary Headache Syndromes

Regardless of the type of primary headache, poor response to treatment should heighten suspicion of a secondary cause and prompt emergent investigations. However, improvement of a presumed pri-

mary headache as a result of treatment does not exclude secondary causes.³ Patients who respond well to emergency department management usually can be discharged with appropriate follow-up. Occasionally, a patient with intractable migraine may require admission for more aggressive pain control.

CRANIAL AND FACIAL PAIN DISORDERS

Temporomandibular Disorder

Temporomandibular disorder (TMD) refers to persistent discomfort due to dysfunction of the temporomandibular joint (TMJ), surrounding muscles, and ligaments. Symptoms include TMJ noise and pain on movement, limited jaw movements, locking of the jaw on opening, bruxism, and tongue, lip, or cheek biting. Headache may be associated with TMD as well, but in patients with headache and bruxism, it is often not clear which is cause and which is effect. Patients with TMD usually can locate their pain in the TMJ area. It is usually acute and associated with jaw movement. More diffuse symptoms may be the result of dysfunction of the muscles and ligaments used for mastication. Effective management of TMD often requires a multidisciplinary team, and improvement usually occurs with conservative measures. Simple radiographs of the TMJs are of little use in the emergency department because the diagnosis of TMD frequently requires more sophisticated imaging techniques. Simple analgesics or NSAIDs can be tried as an initial treatment.

Trigeminal Neuralgia (Tic Douloureux)

Trigeminal neuralgia is characterized by paroxysms of severe unilateral pain in the trigeminal nerve distribution lasting only seconds, with normal findings on neurologic examination. There is no pain between paroxysms. Treatment can be medical or surgical. Carbamazepine is a very effective treatment. If it fails, the patient is unlikely to have trigeminal neuralgia. Patients with trigeminal neuralgia may present to the emergency department because symptoms are of recent onset or recurrent, and they should be started or restarted on carbamazepine. Pain control is rarely an issue because the paroxysms are so brief. Patients with intractable symptoms despite medical therapy should be referred to a neurologist or neurosurgeon.

STROKE, TRANSIENT ISCHEMIC ATTACK, AND OTHER CENTRAL FOCAL CONDITIONS Phillip A. Scott Caroline A. Timmerman

Stroke is the third leading cause of death and the leading cause of disability in the United States. More than 700,000 Americans are afflicted yearly; of these, almost 20 percent will die within the first year. Although stroke is considered to be a disease of the elderly, one third of patients are younger than 65 years of age.¹ Research suggests early diagnosis and management of patients arriving with stroke at the emergency department may lessen the impact of this disease.

STROKE TYPE

The term "stroke" refers to any disease process that disrupts blood flow to a focal region of brain and that may be ischemic or hemorrhagic in nature. Approximately 80 percent are ischemic in nature with the remainder caused by hemorrhage within the cranial vault. Injury is dependent on the mechanism and is related to the loss of oxygen and glucose substrates necessary for high-energy phosphate production and the presence of mediators of secondary cellular injury. Subsequent factors, such as edema and mass effect, may exacerbate the initial insult.

Ischemic Stroke

Ischemic stroke can be subdivided into three major etiologies: thrombosis, embolism, and hypoperfusion. *Thrombosis* is the most common and occurs as a result of narrowing of the vascular lumen, with subse-

quent platelet adhesion and clot formation. Narrowing because of atherosclerotic disease is the most common cause of thrombotic stroke in the United States, and results from plaque development following vascular injury, with resultant arterial hyperplasia and fibrous deposition in the subintimal region. Other causes of thrombotic stroke include vasculitis, dissection, polycythemia, and hypercoagulable states. Less common effectors of vessel injury and narrowing are infectious diseases, such as HIV, syphilis, tuberculosis, aspergillosis, and trichinosis.

The signs and symptoms of thrombotic stroke usually develop gradually over minutes to hours and may wax and wane in severity. Often there is a history of similar but transient symptoms that have occurred in the past, suggesting a transient ischemic attack (TIA) in the same vascular distribution.

One-fifth of ischemic strokes are due to *embolism*. Intravascular material from a proximal source is released, subsequently occluding a distal vessel. In contrast to thrombotic stroke, there is no intrinsic vascular disease in the occluded vessel. Thus, emboli are less adherent and more likely to fragment or move distally than thrombotic occlusions. Cardiac sources of emboli include valvular vegetations, mural thrombi (caused by atrial fibrillation, myocardial infarction, or dysrhythmias), paradoxical emboli (caused by an atrial or ventricular septal defect), or cardiac tumors (myxomas). Artery-to-artery emboli occur when a platelet-fibrin clump is dislodged from a tight stenotic lesion or from a large-vessel atherosclerotic plaque. Rarer causes of embolic stroke include fat emboli, particulate emboli from intravenous drug injection, and septic emboli.

Systemic *hypoperfusion* is a less common mechanism of ischemic stroke and is typically caused by cardiac failure. Hypoperfusion leads to a more diffuse injury pattern compared to thrombosis or embolism and is typically located in watershed regions at the periphery of the cerebral vascular supply territories. Clinical findings often wax and wane with hemodynamic parameters.

Hemorrhagic Stroke

Hemorrhagic strokes are typically divided into two subtypes: intracerebral (ICH) and nontraumatic subarachnoid (SAH) hemorrhage. In ICH, which is the more common form, bleeding occurs directly into brain parenchyma from small arterioles previously weakened by elevated blood pressure. Increasing age and a history of prior stroke are leading risk factors for developing ICH. Race also plays a prominent role, with Asians and blacks having a higher incidence relative to whites. Tobacco and alcohol abuse are additional risk factors. Amyloidosis is another major cause of ICH, especially among elderly patients with lobar or multiple hemorrhages. Other causes of ICH include bleeding diathesis because of anticoagulant or thrombolytic use, vascular malformations, and cocaine use.

In SAH, blood leaks from a cerebral vessel into the subarachnoid space. SAHs result from berry aneurysm rupture, most commonly occurring at arterial bifurcations, or rupture of an arteriovenous malformation.

PATHOPHYSIOLOGY

Anatomy

The vascular supply to the brain is divided into anterior and posterior circulations. The anterior circulation, supplying blood to four-fifths of the brain, originates from the carotid system. The common carotid arteries divide into the right and left internal and external carotid arteries at the level of the angle of the mandible. The internal carotid arteries then course intracranially along the sella turcica within the cavernous sinus. The first branch off the internal carotid artery is the ophthalmic artery, supplying the optic nerve and retina. Sudden onset of painless monocular blindness (amaurosis fugax) identifies the stroke as involving the anterior circulation (specifically, the carotid ar-

tery) at or below the level of the ophthalmic artery. The internal carotid arteries terminate by branching into the anterior and middle cerebral arteries at the circle of Willis. The anterior circulation supplies blood to the optic nerve, retina, and frontoparietal and anterotemporal lobes of the brain.

The posterior circulation is derived from the two vertebral arteries that ascend through the transverse processes of the cervical vertebrae. The vertebral arteries enter the cranium through the foramen magnum, supplying the cerebellum via the posteroinferior cerebellar arteries. They join to form the basilar artery, which branches to form the posterior cerebral arteries. The posterior circulation supplies the brainstem, cerebellum, thalamus, auditory and vestibular functions of the ear, medial temporal lobe, and the visual occipital cortex.

The anterior and posterior circulations join at the circle of Willis, potentially allowing collateral flow around an area of occlusion. A patient with excellent collateral blood flow from the contralateral hemisphere may have minimal clinical deficits despite a complete carotid occlusion. In contrast, a patient with poor collateral flow may be hemiplegic with the same lesion.

Ischemic Stroke

Neurons are exquisitely sensitive to changes in cerebral blood flow and die within minutes of complete cessation. Despite complete occlusion of a cerebral vessel during an ischemic stroke, some perfusion may remain due to collateral flow and variations in local tissue pressure gradients. Cells vary from irreversibly injured neurons in the center of the ischemic region to reversibly injured neurons in the periphery (the penumbra). The degree and duration of occlusion determine the viability of the cells in the penumbra. Theoretically, the earlier reperfusion occurs, the greater the chance of survival. The use of intravenous and intraarterial thrombolytic therapy and the use of neuroprotective agents, are based on this rationale.

Hemorrhagic Stroke

In ICH and SAH, intracranial pressure (ICP) rises following vascular rupture with a corresponding short-term decrease in global perfusion. After these immediate changes, ICP and perfusion gradually improve, although they do not return to baseline. A marked reduction in perfusion occurs near the hematoma in ICH and is probably a result of local compression. Areas of the brain remote from the hemorrhage also have alterations in perfusion, thought to be secondary to vasoconstriction mediated by blood breakdown products or neuronal mechanisms (diaschisis).

CLINICAL FEATURES

The clinical presentation of stroke is often subtle and varied. Armed with an understanding of the various stroke types and anatomy, the history taking and physical examination should be aimed at diagnosing stroke, and determining the underlying cause and the location of the lesion. For example, strokes within the middle cerebral artery (MCA) distribution have the potential for benefit from early treatment with intraarterial thrombolysis (discussed later). Also newer approaches that use mechanical clot disruption catheters (e.g., jet-pulse venturi effect, ultrasound, vacuum, rotation) are in clinical trial, and are directed at larger MCA territory infarcts. Proximal MCA strokes have a higher likelihood of developing cerebral edema.

History

A history of hypertension, coronary artery disease, and diabetes mellitus are all suggestive of underlying atherosclerotic disease and vessel thrombosis. In contrast, atrial fibrillation, valvular replacement, or recent myocardial infarction suggest embolism.

Patients should be thoroughly questioned regarding recent history of TIAs, because this can help differentiate stroke types. A transient neurologic deficit in the same vascular distribution is suggestive of underlying vascular disease consistent with a thrombotic stroke, in contrast to multiple TIAs involving different vascular distributions, which suggest embolism.

Sudden onset of symptoms suggest an embolic or hemorrhagic stroke, whereas a stuttering or waxing and waning deficit suggests a thrombotic or hypoperfusion related stroke. Concomitant complaints such as headache, vomiting, or recent trauma should be recorded. Headache occurs in the majority of patients with hemorrhage but in a minority of those with ischemic stroke. A recent history of neck injury, such as in a motor vehicle accident, chiropractic manipulation or a sports-related injury, suggests a carotid dissection. A history of straining or coughing immediately preceding symptoms suggests ruptured aneurysm.

Physical Examination

If a patient is febrile, a potential infection should be investigated. An infection may be the cause of a patient's deterioration or may be a complication of the stroke (e.g., aspiration pneumonia). The skin should be examined for signs of emboli (Janeway lesions and Osier nodes) or bleeding dyscrasia (ecchymosis or petechiae). A fundoscopic examination should be completed to identify signs of papilledema (suggesting a mass lesion, cerebral vein thrombosis or hypertensive crisis), pre-retinal hemorrhage (consistent with SAH), or evidence of hypertensive retinopathy. Findings suggestive of possible cardiac or vascular disease such as rales, an S3 gallop, or carotid bruit should be identified.

Neurologic Examination

The goal of the neurologic examination is to localize the central nervous system (CNS) lesion and exclude other neurologic disease processes. The National Institutes of Health (NIH) stroke scale is a 15-item neurologic evaluation (range 0-42) that is reproducible and correlates to infarct volume (Table 228-1).^{2,3} It allows a serial, standardized neurologic evaluation of a patient by either a nurse or a physician. The basic neurologic assessment can be broken down into six major areas: 1) level of consciousness; 2) visual assessment; 3) motor function; 4) sensation and neglect; 5) cerebellar function; and 6) cranial nerves. Many of these elements are contained in the NIH stroke scale.

LEVEL OF CONSCIOUSNESS A patient's level of alertness should be evaluated by asking simple questions (birth date or month of the year) and by having the patient follow simple commands (close their eyes, make a fist, show me two fingers).

VISUAL ASSESSMENT Evaluation of visual fields and extraocular movements can provide information regarding occipital lobe or brainstem lesions. Visual fields can be tested by confrontation, using finger counting or visual threat as appropriate. Gaze palsy can be assessed by evaluating both voluntary and reflex eye movements (oculocephalic maneuver).

MOTOR FUNCTION Upper extremity motor weakness is best determined by testing for pronator drift. The test is considered positive if one arm pronates or drifts lower than the other within 10 s. Lower extremity strength can be similarly evaluated by a patient's ability to elevate each leg 45 degrees individually for 5 s while lying in bed. For subtle signs of lower extremity weakness, observe the patient's gait or have patients walk on their toes and then on their heels.

CEREBELLAR FUNCTION Cerebellar function is tested by observing a patient's gait, finger-to-nose and/or heel-to-shin testing. These

Articulation	Normal Mild Severe	0 1 2
Language	Normal Mild aphasia Severe aphasia Mute or global aphasia	0 1 2 3

*Items deleted from the modified NIHSS.

tests are all performed with the patient's eyes open and then closed to differentiate from posterior column disease (see Chap. 226).

SENSATION AND NEGLECT Sensory deficits and neglect should be evaluated by pinprick testing, having the patient identify numbers gently written on the palm (graphesthesia), and by double-simultaneous extinction (the physician touches the patient's right and left limbs individually and then simultaneously). The double-simultaneous extinction test is positive if the patient feels the sensation in either limb individually but only on one side when touched simultaneously. Neglect can be further confirmed by having the patient draw a box or house. Patients with neglect will often omit figures on one side of the drawing.

LANGUAGE *Dysarthria* is a disturbance in articulation and is caused by paralysis or incoordination of muscles used for speech. Dysarthric speech is often slurred. Repetition of simple phrases may identify subtle cases. In contrast, *aphasia* is caused by a disturbance in processing language (either written or spoken) and can be receptive (difficulty in comprehension), expressive (difficulty in communicating thoughts), or both. Receptive aphasia can be tested by having patients follow simple commands (either vocal or written). Having patients identify simple objects or describe what is happening in a magazine picture assists in evaluating an expressive aphasia. Patients with expressive aphasia will use inappropriate words or use nonfluent sentences, whereas the words of patients with dysarthria will be slurred.

CRANIAL NERVES Cranial nerves should be individually tested in all patients to identify possible brainstem involvement. Anterior circulation strokes, which cause contralateral motor deficits, while brainstem involvement causes ipsilateral cranial nerve deficits with contralateral motor weakness. In facial nerve weakness caused by a CNS lesion, the patient retains the ability to wrinkle the forehead. Inability to move the upper and lower face can be a result of Bell's palsy or Genu VII palsy (see Chap. 238). Genu VII palsy is a stroke involving Cranial Nerve VI and VII as it "genoflects" around the sixth nerve nucleus. The upper and lower face are paralyzed but there is also inability to abduct the ipsilateral eye.

STROKE SYNDROMES

Physical findings often follow classic patterns that can assist in localizing the lesion.

Transient Ischemic Attack

A TIA is a neurologic deficit that resolves within 24 h (although most resolve within 30 min) and is most commonly associated with thrombotic strokes. The incidence of prior TIAs ranges from 50 to 75 percent in patients with subsequent thrombotic, extracranial carotid artery strokes, but only 10 percent in all other stroke types. Many clinical TIAs may in fact be associated with computed tomography (CT) findings of infarction. Recent data suggest that more than 10 percent of patients with TIA may return to the ED with a stroke within 90 days, with half of these in just 2 days.⁴

Ischemic Stroke Syndromes

ANTERIOR CEREBRAL ARTERY INFARCTION Lesions of the anterior cerebral artery cause contralateral leg weakness greater than arm weakness with mild cortical sensory deficits. Patients may perseverate with speech or motor actions and respond slowly. Anarthria (speechlessness) with paraplegia may occur in a bilateral parasagittal infarct if the anterior cerebral arteries originate from an occluded common trunk.

MIDDLE CEREBRAL ARTERY INFARCTION A stroke involving the MCA territory presents with contralateral weakness and numbness variably affecting the face and arm greater than the leg. If the dominant hemisphere is involved, aphasia (receptive, expressive, or both) is often present. In right-handed patients, and in up to 80 percent of left-handed patients, the left hemisphere is dominant. Inattention, neglect, or extinction on double-simultaneous stimulation localize the lesion to the nondominant hemisphere. Constructional apraxia in these patients can be demonstrated by the inability to draw a clock and fill in the appropriate numbers. Patients may be dysarthric but typically are not aphasic. A homonymous hemianopsia and gaze preference toward the side of the infarct may also be found.

POSTERIOR CEREBRAL ARTERY INFARCTION Patients with posterior cerebral artery (PCA) infarcts may be unaware of their deficits until formally tested. Motor involvement is minimal, and visual cortex abnormalities may go unrecognized. Light-touch and pinprick sensory modalities, however, may be significantly reduced. The anastomoses of branches of the PCA with arteries from the anterior cerebral artery and MCA territories are common locations of watershed infarcts in hypotensive states.

VERTEBROBASILAR SYNDROME The posterior circulation supplies blood to the brainstem, cerebellum, and visual cortex. Signs and symptoms attributable to a stroke in this distribution may be subtle. They include findings such as dizziness, vertigo, diplopia, dysphagia, ataxia, cranial nerve palsies, and bilateral limb weakness, singly or in combination. **The hallmark of posterior circulation stroke is crossed neurologic deficits (i.e., ipsilateral cranial nerve deficits with contralateral motor weakness).**

The lateral medullary (Wallenberg) syndrome is a specific posterior circulation infarct involving the vertebrobasilar arteries and/or the posterior inferior cerebellar artery. In its pure form, it has a good prognosis. Presenting signs include ipsilateral loss of facial pain and temperature sensation with contralateral loss of these senses over the body, and gait and limb ataxia. Partial ipsilateral loss of cranial nerves V, IX, X, and XI in varying combinations are also present. Ipsilateral Horner syndrome (ptosis, miosis, and anhidrosis) may be present from disruption of the reticulospinal tracts to the sympathetic outflow.

BASILAR ARTERY OCCLUSION Occlusion of the basilar artery causes severe quadriplegia, coma, and the *locked-in syndrome*. The locked-in syndrome occurs with lesions in the pontine tectum with complete muscle paralysis except for upward gaze.

CEREBELLAR INFARCTION An important subset of posterior circulation strokes involve the cerebellum. Patients commonly present following a "drop attack" with the sudden onset of inability to walk or stand. This is often accompanied by vertigo, headache, nausea, vomiting, and neck pain. Cranial nerve abnormalities are often present. Bone artifact on CT imaging of the posterior fossa can obscure imaging, and an MRI or MRA should be obtained for diagnosis. Typically, after a delay of 6 to 12 h, cerebral edema will develop with subsequent increased brainstem pressure and decreased level of consciousness. Treatment of elevated ICP and emergent surgical decompression may be lifesaving.

LACUNAR INFARCTION Lacunar infarcts are pure motor or sensory deficits caused by infarction of small penetrating arteries and are commonly associated with chronic hypertension. Lesions are primarily located in the pons and the basal ganglia.

ARTERIAL DISSECTION Dissections are often associated with severe trauma but can occur from such mild events as turning the head sharply. Hypertension is a risk factor in spontaneous dissection. Patients may complain of severe neck pain or headache hours to days prior to onset of neurologic deficits. Dissections may occur in the carotid or vertebral circulation. Diagnosis is difficult as the extracranial vessels may not be well visualized on CT scans.

Hemorrhagic Stroke Syndromes

INTRACEREBRAL HEMORRHAGE ICH may be clinically indistinguishable from cerebral infarction. Headache, nausea, and vomiting often precede the neurologic deficit and the patient's condition may quickly deteriorate necessitating emergent intubation. Bleeding is usually localized to the putamen, thalamus, pons, or cerebellum (in order of decreasing frequency) in patients with hypertensive ICH. Lobar

hemorrhages are suggestive of amyloid angiopathy and are associated with a better prognosis.

CEREBELLAR HEMORRHAGE A patient presenting with sudden onset of dizziness, vomiting, marked truncal ataxia, and inability to walk must be immediately suspected of having a cerebellar infarction or hemorrhage. These findings may be associated with gaze palsies and increasing stupor. Patients may rapidly progress to coma and herniation unless surgical decompression and/or hematoma evacuation are quickly initiated. However, with appropriate surgical treatment, the prognosis is good.

SUBARACHNOID HEMORRHAGE SAHs frequently develop focal findings, possibly related to location of an aneurysm, but often there is no adequate explanation. Overall, SAH occurs more commonly in women, however men have a higher incidence in the under-forty population. Patients typically present with a severe, constant headache often occipital or nuchal in location. A recent history suggestive of a "sentinel hemorrhage" can be obtained in many cases. Vomiting often presents with the onset of headache, and patients may have a decreased level of consciousness. Presentation is usually sudden, and a careful history may reveal activities associated with elevated blood pressures such as defecation, intercourse, or coughing at stroke onset. Occasionally, the pain is only nuchal, misleading clinicians to consider only musculoskeletal etiologies. See Chap. 227 for detailed discussion regarding diagnostic approach.

DIAGNOSIS

Critical Pathway

Specific critical pathways similar to those used for AMI (door, data, decision, drug) should be used to speed the evaluation of patients with suspected acute stroke. Triage personnel should be educated to identify patients with symptoms of acute stroke and initiate standing orders. These include electrocardiogram; CBC; coagulation profile; type and screen; serum electrolytes, glucose, and renal function studies. An emergency noncontrast CT of the head should be ordered. The emergency physician should be notified of a potential acute stroke, and the acute stroke team notified if available.

There must be careful identification of the time of symptom onset, defined as *the last moment the patient was known to be normal*. Taking the patient and family chronologically through the events immediately prior to the stroke is a particular help in unclear cases. Thrombolytic use in stroke is not recommended when the time of onset cannot be reliably ascertained. Strokes recognized upon awakening should be timed from when the patient was last known to be without symptoms. A review of alteplase (rtPA) inclusion and exclusion criteria (Table 228-2) should be completed. Relative exclusion and inclusion criteria for rtPA administration based upon CT findings are shown in Table 237-2.

Diagnostic Tests

An emergent noncontrast CT of the head is essential to quickly differentiate hemorrhage from ischemia. **Most acute ischemic strokes will not be visualized by routine CT for at least 6 h**, depending on the size of the infarct. However, hypodensity indicating infarct should appear within 24 to 48 h. CT identifies almost all parenchymal hemorrhages greater than 1 cm in diameter and up to 95 percent of subarachnoid hemorrhages (if obtained within 12 h of symptom onset). This information is crucial for subsequent therapeutic decisions. If subarachnoid hemorrhage is still strongly suspected after a nondiagnostic CT scan, lumbar puncture is indicated. CT can also identify other life-threatening intracranial processes, such as abscess, tumor, and subdural or epidural hematoma.

TABLE 228-2 Criteria for Intravenous Thrombolysis in Ischemic Stroke

Inclusion	Exclusion*
Age 18 years or older	Minor stroke symptoms
Clinical diagnosis of ischemic stroke	Rapidly improving neurologic signs
Time since onset <i>well established</i> to be less than 3 h	Prior intracranial hemorrhage
	Blood glucose <50 mg/dL or >400 mg/dL
	Seizure at onset of stroke
	GI or GU bleeding within preceding 21 days
	Recent myocardial infarction
	Major surgery within preceding 14 days
	Sustained pretreatment SBP >185 mmHg or DBP >110 mmHg
	Previous stroke within preceding 90 days
	Previous head injury within preceding 90 days
	Current use of oral anticoagulants or PT >15 s or INR >1.7
	Use of heparin within preceding 48 h and a prolonged PTT
	Platelet count <100,000/μL

*Caution is advised before giving rtPA to persons with severe stroke (NIH Stroke Scale Score greater than 22).

Abbreviations: DBP = diastolic blood pressure; GI = gastrointestinal; GU = genitourinary; INR = international normalized ratio; PT = prothrombin time; PTT = partial prothrombin time; SBP = systolic blood pressure.

Source: Adams HP, Brott TG, Furlan AJ, et al: Guidelines for thrombolytic therapy for acute stroke: A supplement to the guidelines for the management of patients with acute ischemic stroke. *Circulation* 94:1167, 1996.

An electrocardiogram should be obtained in all patients with suspected stroke to identify atrial fibrillation or acute myocardial infarction. Patients with untreated chronic atrial fibrillation have an associated 6 percent risk of stroke per year. In the first month following a myocardial infarction, the risk of stroke is 2.5 percent.

Blood tests that may be helpful include a complete blood count with platelet count, coagulation studies, toxicologic screen, and cardiac enzymes. A hematocrit can identify polycythemia, which can affect blood flow by increasing viscosity. A platelet count can identify thrombocytosis or thrombocytopenia that may precipitate thrombosis or hemorrhage, respectively. Coagulation studies are especially helpful in patients with hemorrhagic stroke to exclude coagulopathy or excessive anticoagulation with warfarin. A toxicologic screen for cocaine or amphetamine use should be obtained in patients with either ischemic or hemorrhagic stroke in which substance abuse is suspected, particularly young adults with stroke. Serum electrolytes are necessary to detect hyponatremia. Determination of cardiac enzymes will assist evaluation for a possible myocardial infarction.

Other diagnostic tests that may be of assistance, depending on the circumstances, include an echocardiogram, carotid duplex scanning, angiogram, and magnetic resonance imaging (MRI) or magnetic resonance imaging angiography (MRA). Few of these help with ED evaluation or treatment. An echocardiogram can identify a mural thrombus, tumor, or valvular vegetation in patients with a suspected

cardioembolic stroke. Carotid duplex scanning may be helpful in patients with worsening neurologic deficit or crescendo TIAs with known or suspected high-grade carotid stenosis. Such patients may be candidates for emergent carotid endarterectomy or consideration of anticoagulation. Angiography is the definitive test to demonstrate stenosis or occlusion of both large and small blood vessels of the head and neck. It can detect subtle arterial abnormalities, such as dissection, which may be missed with other imaging techniques. Angiography remains the "gold standard" for demonstrating the cause of SAH and for defining the anatomic relationships of aneurysms.

MRI currently has a limited role in the emergency department evaluation of stroke because of access issues, delays for patient screening, and patient ability to cooperate. MRI will visualize ischemic infarcts earlier than CT and is more effective than CT at identifying acute posterior circulation strokes. Previously, MRI was considered less accurate at differentiating ischemia from hemorrhage, but new data suggests T2-weighted MRI sequences may be superior in detecting microbleeds, although this remains to be confirmed.⁵ Emergent MRI should be considered when a dural sinus thrombosis is suspected or confirmation of a brainstem lesion is required. MRA enables demonstration of large vessel occlusions at the base of the skull, but small intracranial vascular occlusion may not be readily apparent. Improvement in MRA speed and resolution may allow greater use of this technology, and MRAs may replace the need for angiograms in the future.

Differential Diagnosis

Although strokes are the most common cause of focal neurologic deficits, other causes must be considered (Table 228-3). All patients with neurologic deficits should have their blood glucose checked for hypoglycemia. Bell palsy usually occurs in younger patients, is associated with upper and lower facial paralysis has no associated extraocular muscle involvement, and does not involve the extremities. Epidural or subdural hematoma can mimic an acute stroke and are usually associated with trauma. However, minor traumatic events may be overlooked, especially in those at risk (e.g., alcoholics). Although stroke can present with marked hypertension, one can usually differentiate stroke from hypertensive encephalopathy by history and physical examination. Unlike stroke, the onset of hypertensive encephalopathy is more gradual, and focal neurologic deficits, if present, are superimposed upon global cerebral dysfunction. Other diseases mimicking stroke include meningoencephalitis and hyperosmotic coma. Diabetic ketoacidosis (DKA), may be associated with infarction and arterial thrombosis, but also may rarely mimic stroke. Another stroke mimic is Wernicke encephalopathy, with its triad of ataxia, ophthalmoplegia, and confusion, typically found in chronic alcoholics. Multiple sclerosis, presenting commonly in the third and fourth decades of life, with a female predominance, may present with focal deficits, depending on the area of demyelination. The onset of symp-

toms, however, is more gradual than those in acute stroke. Meniere disease may be distinguished by its paroxysmal course of vertigo, tinnitus, and deafness. Drug toxicity may also masquerade as acute stroke, with lithium toxicity inducing dysarthria, cranial nerve deficits, and confusion. Phenytoin and carbamazepine toxicity may present with ataxia, vertigo, nausea, and abnormal reflexes.

SPECIFIC ISSUES THAT IMPACT EVALUATION AND TREATMENT

Sickle Cell Disease

Stroke occurs by age 20 years in more than 10 percent of patients with sickle cell anemia, and is the most common cause of ischemic stroke in children. The risk is inversely proportional to age, with the highest incidence noted between ages 2 and 5 years. Symptoms are similar to those in patients without sickle cell disease and range from brief TIAs to hemiparesis, depending on the vascular territory involved and duration of ischemia. Cerebral aneurysms also occur with increased frequency in patients with sickle cell anemia, and careful evaluation for SAH is mandated for patients presenting with headache and neurologic findings.

Emergent management of stroke in patients with sickle cell anemia includes supportive care with oxygen, intravenous fluids, and immediate CT scanning to evaluate for ruptured cerebral aneurysm or ICH. Initial laboratory studies should include a type and cross-match. Lumbar puncture is indicated in patients with suspected SAH and a nondiagnostic CT. If SAH is established, it is recommended delaying arteriography until hemoglobin S levels are below 30 percent of the total hemoglobin concentration and generous hydration is established. This may avoid increased sickling as a result of vasospasm from hyperosmolar contrast media.

In sickle cell patients with ischemic stroke, emergent simple or exchange transfusion should begin as soon as blood is available to reduce hemoglobin S to less than 30 percent. This is targeted toward improving blood flow and oxygen delivery to the infarct zone. The same therapy is indicated in hemorrhagic stroke in order to reduce vasospasm and secondary ischemic infarction. The efficacy of aspirin or warfarin therapy following ischemic stroke in this population has not been established. Early consultation with a hematologist and a neurologist are in order, and admission to an intensive care unit (ICU) setting indicated for close neurologic monitoring. Patients with TIA should also undergo similar exchange transfusion to the same target hemoglobin S levels.⁶

Young Adults with Stroke

Particular care should be exercised when evaluating the young adult (ages 15 to 50 years) with acute stroke. In this group, arterial dissection accounts for 20 percent of all ischemic strokes and may often be preceded by only minor trauma. The young adult with a cardioembolic event may have mitral valve prolapse, rheumatic heart disease, or paradoxical embolism as the originating cause. Migrainous stroke (infarction associated with typical migraine attack, among those with established recurrent migraines) in this age group is also a possibility. Air embolism should be considered in patients with a history of recent scuba diving or an invasive medical procedure. Such patients should be placed in a supine position and also placed on 100 percent oxygen. Emergent recompression in a hyperbaric chamber is indicated. Finally, some members of this population are at risk for ischemic stroke from substance abuse, with heroin, cocaine, amphetamines or other sympathomimetic drugs often implicated.

Pregnancy

While early pregnancy itself has not been associated with an increased risk of stroke, the peripartum and postpartum periods (up to 6 weeks

after birth) have been identified as having an increased incidence of both ischemic and hemorrhagic stroke. Potential contributors to this increased risk include the presence of preeclampsia/eclampsia and the decrease in blood volume and alterations in hormonal status following birth.⁷ Treatment should be targeted toward the underlying etiology.

The Elderly

The fastest growing population in the United States are those aged 85 years and older. The Census Bureau estimates a fivefold increase in this group to 18.2 million by 2050. There are no age-related limitations on the use of thrombolytic therapy.⁸ In elderly patients with ICH, particular consideration should be given to amyloid angiopathy as a pathologic cause because of its increased incidence in the elderly.

Medicolegal Issues

At the time of this writing, initiation of anti coagulation in ischemic stroke or TIA is without a uniform consensus and is a matter of individual physician preference. With FDA approval of alteplase for the treatment of acute (0 to 3 h from symptom onset) ischemic stroke, the need for early identification of stroke in the emergency department has assumed increased importance. Delays in patient evaluation may prevent use of thrombolytic therapy when appropriate and place the physician at potential medicolegal risk. The development of ED systems to coordinate care of these patients is strongly recommended.

TREATMENT OF ISCHEMIC STROKE

General Management

Upon entry of patients with ischemic stroke into the emergency medical services (EMS) or emergency department setting, priority should be given to airway management and oxygenation. Generally, all patients should be placed on oxygen. The head of the bed should be slightly elevated, and a cardiac monitor and intravenous access established. Unless there is hypotension, fluids should be administered judiciously to prevent cerebral edema. Volume depletion in patients with ischemic stroke deserves prompt treatment, as it may contribute to decreased cerebral blood flow in the ischemic region. Careful examination of the scientific evidence for avoidance of glucose containing fluids is weak, and no causation of effect has been shown. Still, general practice is to avoid glucose-containing solutions except in those with proven hypoglycemia. Patients with fever should have antipyretics promptly administered. Experimental studies suggest hyperthermia increases CNS metabolic demands, whereas hypothermia has demonstrated neuroprotective effects.

The use of anticonvulsants is not recommended for seizure prophylaxis in ischemic stroke. If seizures occur, the patient should be treated acutely with benzodiazepines (e.g., lorazepam 2 to 4 mg IV or diazepam 5 to 10 mg IV) and then given a loading dose of fosphenytoin (18 mg/kg IV at 25 mg/min).

Hypertension

A cautious approach to the management of elevated blood pressure is recommended in acute ischemic stroke. In general, frequent monitoring of blood pressure in hypertensive stroke patients is indicated and only persistent, severe hypertension (greater than 220 mm Hg systolic or more than 130 mm Hg mean arterial pressure) should be considered for treatment. Pharmacologic lowering of systemic blood pressure may reduce perfusion to the penumbra, converting an area with reversible injury to an area of infarction. Recommended agents include parenteral drugs that are easily titrated and that have minimal effects on cerebral blood vessels, such as labetalol or enalaprilat. Sublingual use of calcium-channel antagonists should be avoided.⁹

In hypertensive patients being considered for thrombolytic stroke therapy, the use of nitroglycerin paste or labetalol is acceptable to reduce blood pressure below 185/115 mm Hg to allow treatment. **Requirements for more aggressive treatment exclude the use of tissue plasminogen activator** in stroke patients. Following the use of recombinant tissue-type plasminogen activator (rtPA) in acute stroke, however, aggressive treatment with the aforementioned agents or, if control is inadequate, nitroprusside is warranted to maintain the blood pressure below 185/115 mm Hg. Hypertension is a significant cofactor in the risk of ICH in patients treated with thrombolytics.¹⁰

Thrombolysis

BAC KG ROU N D The NIH/National Institutes of Neurological Disorders and Stroke (NINDS) study was a randomized, double-blind, placebo-controlled trial conducted at 40 geographically diverse hospitals (30 community and 10 university settings) comparing intravenous rtPA against placebo in 624 patients meeting specific enrollment criteria, including treatment within 3 h of symptom onset. Neurologists in private practice treated many patients in the trial, and some were evaluated and treated by emergency physicians. At 3 months, patients treated with rtPA were at least 30 percent more likely to have minimal or no disability as measured by four different neurologic outcome scales, with an absolute increase in favorable outcome of 11 to 13 percent. Benefit was found regardless of ischemic stroke subtype and has been demonstrated to continue for up to 1 year following therapy. Symptomatic ICH attributable to drug occurred in 6.4 percent of treated patients compared with 0.6 percent in the placebo group. The mortality rate at 3 months was not significantly different between treatment and placebo groups (17 percent, rtPA patients; 21 percent, placebo; $p = 0.3$), but the percentage of patients left severely disabled was lower in those receiving rtPA.¹¹

Four other trials of intravenous thrombolysis have been published, and their conflicting results have generated debate over the role of thrombolysis in stroke. One of these, the European Cooperative Acute Stroke Study (ECASS), also evaluated the use of rtPA, although at a higher dosage (1.1 mg/kg; maximum dose, 100 mg) and longer time window (0 to 6 h). Although this study failed to demonstrate a difference in its primary end points between treatment and placebo groups, it must be considered that 109 of the 620 enrolled patients had major protocol violations. After excluding protocol violators, neurologic recovery at 3 months was significantly better for patients treated with rtPA.¹² The three trials of intravenous streptokinase in ischemic stroke were all halted prematurely for safety considerations. Potential explanations of the increased risk include the use of streptokinase itself, the high dosage used (1.5 million units), the allowance of concurrent heparin and aspirin use, and the time to treatment (the majority of patients were treated within 3 to 6 h).^{13–15}

The FDA approved the use of intravenous rtPA in acute ischemic stroke in 1996 and approval was granted in Canada in 1999. The American Heart Association and the American Academy of Neurology support its use under appropriate conditions. The American College of Emergency Physicians has endorsed the principle that "intravenous tPA may be an efficacious therapy for the management of acute ischemic stroke if properly used incorporating the guidelines established by the NINDS," but did not endorse its use where systems are not in place to meet those guidelines.¹⁶ The time-critical nature of thrombolytic therapy highlights the need for the involvement of emergency medicine in a coordinated, multidisciplinary approach to the treatment of stroke patients.

The use of intraarterial delivery of thrombolytics remains investigational. Advantages include specific evaluation of the occluded vascular territory, use of lower total doses of thrombolytic drugs, and the possibility of mechanical clot disruption. Studies evaluating prouroki-

nase given within 6 h of symptom onset found superior recanalization compared with placebo but with high rates of hemorrhagic complications.¹⁷ Intraarterial thrombolysis may have a unique role in the treatment of patients with acute or subacute brainstem infarcts. Numerous cases have been reported where late intraarterial thrombolysis in the posterior circulation successfully restored function, suggesting this region may tolerate longer periods of ischemia.

DOSE AND COMPLICATIONS The total dose of rtPA is 0.9 mg/kg, with a maximum dose of 90 mg; 10 percent of the dose is administered as a bolus, with the remaining amount infused over 60 min. Blood pressure and neurologic checks should be assessed every 15 min for 2 h after starting the infusion. Table 228-4 outlines the emergent management of hypertension following thrombolytic administration. **No aspirin or heparin is given in the initial 24 h following treatment.** Patients should be admitted to an ICU setting familiar with the use of thrombolytic drugs and neurologic monitoring. Intracerebral bleeding should be suspected as the cause of any neurologic worsening until repeat CT imaging is obtained.

If bleeding is suspected, a CBC with platelet count, coagulation studies, fibrinogen and type- and cross-match for packed red blood cells, cryoprecipitate or fresh-frozen plasma, and platelets should be obtained. An emergent hematology and neurosurgical consultation, as necessary, is appropriate. Patients may be cared for at hospitals without in-house neurosurgical availability as long as access, or transport, to neurosurgical care can be arranged while a patient is stabilized. Chap. 224 discusses treatment of bleeding complications in detail.

Antiplatelet Agents

For the majority of stroke patients thrombolytic treatment will not be a consideration. In these patients, and those with TIAs, *antiplatelet strategies form the cornerstone for secondary stroke prevention*. Aspirin is the prototypical agent, decreasing the synthesis of thromboxane A₂ by irreversibly inhibiting cyclooxygenase for the life of the platelet, causing decreased platelet aggregation. Both the International Stroke Trial (IST) and Chinese Acute Stroke Trial (CAST) studies

TABLE 228-4 Emergent Management of Hypertension Following the Use of rtPA in Acute Stroke

Monitor arterial blood pressure during the first 24 h after starting treatment.

Every 15 min for 2 h after starting the infusion, then every 30 min for 6 h, then every 60 min for 24-h total

If SBP is 180–230 mm Hg or DBP is 105–120 mm Hg for two or more readings 5–10 min apart:

Give IV labetalol 10 mg over 1–2 min; the dose may be repeated or doubled every 10–20 min up to a total dose of 150 mg Monitor blood pressure every 15 min during labetalol treatment and observe for hypotension

If SBP is >230 mm Hg or if DBP is 121–140 mm Hg for two or more readings 5–10 min apart:

Give IV labetalol 10 mg over 1–2 min; the dose may be repeated or doubled every 10–20 min up to a total dose of 150 mg Monitor blood pressure every 15 min during labetalol treatment and observe for hypotension If no satisfactory response, infuse sodium nitroprusside (0.5–1.0 µg/kg per

min); continuous arterial monitor advised If DBP is >140 mm Hg for two or more readings 5–10 min apart:

Infuse sodium nitroprusside (0.5–1.0 µg/kg per min); continuous arterial monitor advised

Abbreviations: DBP = diastolic blood pressure; SBP = systolic blood pressure.

demonstrated significant reduction in mortality rates and stroke recurrence in aspirin treated patients. Aspirin reduces stroke risk 20 to 25 percent compared to placebo.^{18,19} No dose-effect response has been identified,²⁰ suggesting lower doses may be equally effective and better tolerated. Thus, initiation of aspirin therapy with doses of 50 to 300 mg in the ED is reasonable and offers a substantial cost advantage compared to other antiplatelet agents, and will not interfere with subsequent thrombolytic consideration.

Dipyridamole acts by phosphodiesterase inhibition thereby increasing cyclic adenosine monophosphate and inhibiting platelet function. Dipyridamole alone (200 mg PO bid) reduces the risk of stroke or death by 15 percent, as compared to placebo in patients with prior stroke or TIA. When combined with aspirin (50 mg PO per d), a 37 percent relative risk reduction compared to placebo can be expected.²¹

Clopidogrel acts via inhibition of adenosine diphosphate-dependent platelet activation and is, at best, marginally superior to aspirin with fewer side effects than its pharmacologic predecessor, ticlopidine. The use of clopidogrel (75 mg PO per d) in patients with atherosclerotic vascular disease resulted in a statistically significant but minimal (0.5 percent absolute) reduction in the annual risk of ischemic stroke, myocardial infarction, or vascular death when compared with aspirin (325 mg PO per d).²² No combination studies have been reported. The use of clopidogrel is ideal for those patients who cannot tolerate, or fail, aspirin therapy. The selection of a particular antiplatelet regimen is a multifactorial decision based on comorbid conditions, prior drug use and cost. Aspirin remains a reasonable initial choice in the patient with a first-ever stroke or TIA.

Anticoagulants

Often, in the emergent setting, the etiology of a presenting stroke is unknown and the clinician must treat based on their best presumption as to etiology. The goal in treating these patients is to limit stroke progression and/or recurrent thromboembolism. Although used in this role, benefits of unfractionated heparin (UFH) in any stroke patient population remains unproven. Indeed, recently published studies have called into doubt its effectiveness. Although patients receiving heparin can expect significantly fewer recurrent ischemic strokes, this benefit is offset by an increased intracranial hemorrhage.⁴ Thus, a decrease in death or nonfatal recurrent stroke is inapparent.

Multiple studies of low-molecular-weight heparin (LMWH) and heparinoids have found similarly disappointing results as with UFH. As of this writing, **the use of UFH, LMWH, or heparinoids to treat a specific stroke subtype or TIA cannot be recommended based on available evidence** and its use is at the discretion of the treating physician, preferably within the context of a clinical trial. In patients with atrial fibrillation and TIA, adjusted-dose oral anticoagulation with warfarin is the therapy of choice for stroke prevention.

Cerebellar Infarction

Early neurosurgical consultation is needed in the treatment of all patients with cerebellar infarction. Cerebellar swelling can lead to rapid deterioration with herniation, and consultation is required to determine the need for emergency posterior fossa decompression in these patients.

Transient Ischemic Attack

Patients with new onset TIAs should be admitted for evaluation of cardiac sources of emboli or high grade stenosis of the carotid arteries. Heparin is not recommended as routine therapy, either acutely or long term, for patients with TIAs. Some suggest UFH use may be considered in patients with recent TIAs who are at high risk for recurrence. These include patients with 1) known high-grade stenosis in the ap-

propriate vascular distribution for the symptoms, 2) a cardioembolic source (except infective endocarditis), 3) TIAs of increasing frequency (crescendo TIAs), and 4) TIAs despite antiplatelet therapy. No conclusive data exist to support or refute this practice and its use is at discretion of the admitting physician. Urgent carotid endarterectomy should be considered for TIAs that resolve within the first 6 h and are associated with greater than 70 percent stenosis of the carotid artery. Endarterectomy has been shown to significantly reduce the risk of future strokes in these patients.²³ The role of angioplasty and cerebral artery stenting are unclear at this time.

TREATMENT OF INTRACEREBRAL HEMORRHAGE

To date, there are no large randomized studies evaluating the appropriate management of blood pressure in ICH. Current recommendations are that only severe hypertension (i.e., greater than 220 mm Hg systolic or more than 120 mm Hg diastolic) be treated. When treated, blood pressure should be lowered gradually to prehemorrhage levels using either labetalol or nitroprusside. The exceptions to this rule are cases of ICH associated with cardiac failure or arterial dissection, in which more rapid reduction is required. If a patient is known to have chronic hypertension, the blood pressure should not be lowered to normotensive levels but rather to an approximation of the patient's usual hypertensive blood pressure.

The patient's head should be elevated 30 degrees to the horizontal. The use of hyperventilation and osmotherapy with mannitol (0.25 to 1.0 g/kg IV), and furosemide (10 mg IV) is recommended in patients with evidence of increased intracranial pressure with features such as mass effect, midline shift, or herniation. The target $Paco_2$ is 30 to 35 mm Hg, while the target serum osmolality is <310 mOsm/kg. Steroids are not indicated. ICP monitors should be considered in (but not limited to) patients with a Glasgow Coma Scale score of <9, and in all patients whose condition is thought to be deteriorating because of elevated ICP. Intraventricular devices allow direct reduction of ICP by cerebrospinal fluid drainage. Seizure prophylaxis with phenytoin should also be considered.

The role of acute surgical intervention remains controversial and depends on the neurologic status of the patient as well as the size and location of the hemorrhage. Surgical decompression and hematoma evacuation may be lifesaving in patients with cerebellar hematomas greater than 3 cm in diameter or those near the brainstem.

TREATMENT OF SUBARACHNOID HEMORRHAGE

Rebleeding and vasospasm are the major complications in SAH. Risk of rebleeding is greatest in the first 24 h. In patients with elevated blood pressures, lowering systolic blood pressure to 160 mm Hg and/or maintaining a mean arterial pressure of 110 mm Hg is associated with lower risk of rebleeding and a decreased mortality rate. Current recommendations are that blood pressure should be maintained at prehemorrhage levels.

Cerebral ischemia caused by vasospasm occurs from 2 days to 3 weeks after aneurysm rupture. Nimodipine, given PO 60 mg every 6 h, reduces the incidence and severity of vasospasm and should be given to all patients with SAH. In patients who have difficulty swallowing, it may be advisable to delay initiation of this medication, although if there are no contraindications it may be started in the ED.

Seizures and persistent vomiting can cause elevations in systemic and intracranial pressure. Prophylactic phenytoin loading is recommended. Nausea and vomiting should be promptly treated with antiemetics. Pain should be appropriately managed.

Usually, candidates for early angiography and surgical intervention are stable patients with good neurologic condition (Hunt and Hess grades 1 to 3). However, there is little published evidence that this regimen reduces the long-term morbidity or mortality rates. Alternative

approaches for patients with appropriate aneurysms include endovascular obliteration through the use of intraluminal platinum coils or detachable balloon embolization.

ALTERED MENTAL STATUS AND COMA J. Stephen Huff

Disorders of consciousness may be divided into processes that affect either arousal functions, content of consciousness functions, or combinations of both functions. Arousal behaviors include wakefulness and basic eyes-open, alerting functions. Anatomically, neurons responsible for these arousal functions reside in the reticular activating system, a collection of neurons scattered through the midbrain, pons, and medulla. Content of consciousness includes self-awareness, language, reasoning, spatial relationship integration, emotions, and the myriad complex integration functions that we regard basic to being human. The neuronal structures responsible for the content of consciousness reside in the cerebral cortex. Dementia is failure of the content portions of consciousness with relatively preserved alerting functions. Delirium is an arousal system dysfunction, and content of consciousness is affected as well. Coma is failure of both arousal and content functions. Psychiatric disorders and altered mental states may share features such as hallucinations or delusion; some distinctions between the different states are summarized in Table 229-1.¹

Mental status is the clinical state of emotional and intellectual functioning of the individual. The mental status evaluation may be divided into six categories (Table 229-2). Testing the mental status is done both formally and informally during patient evaluation. The higher mental or cognitive functions need specific tests for assessment; screening tests are described in the following section.

DELIRIUM

Delirium, acute confusional state, acute cognitive impairment, acute encephalopathy, and other synonyms refer to a transient disorder with impairment of attention and cognition. Delirium represents a form of brain failure, but the patient is more alert than in coma. Alerting functions are working, perhaps overworking. The patient may have difficulty in focusing, shifting, or sustaining attention. The formal definition also includes disturbed wake-sleep cycles and a fluctuating course of confusion (see Table 229-1).

The incidence of delirium in emergency department populations is not clear. It is estimated that 10 to 25 percent of elderly hospitalized patients have delirium at the time of admission.³ Recent literature suggests that up to one-quarter of all emergency department patients aged 70 or older have impaired mental status or delirium, and notes that routine evaluation is not satisfactory to identify many of these patients.^{4,5}

Pathophysiology

Delirium always has an organic cause. Pathologic mechanisms are complex and are thought to involve widespread neuronal or neurotransmitter dysfunction. There are four general causes:

1. Primary intracranial disease
2. Systemic diseases secondarily affecting the central nervous system (CNS)
3. Exogenous toxins
4. Drug withdrawal¹

Clinical Features

Delirium or acute confusional state develops quickly, generally over days. Attention, perception, thinking, and memory are all distorted to varying degrees. Alertness is reduced as manifested by difficulty maintaining attention and focusing concentration. The patient may appear quite awake, but attention is impaired. Activity levels may be either increased or decreased. Three variants are described: hypoalert-hypoactive, hyperalert-hyperactive, and mixed. The patient with the mixed variety may fluctuate rapidly between hypoactive and hyperac-

TABLE 229-1 Features of Delirium, Dementia, and Psychiatric Psychosis

Characteristic	Delirium	Dementia	Psychiatric
Onset	Over days	Insidious	Sudden
Course over 24 h	Fluctuating	Stable	Stable
Consciousness	Reduced	Alert	Alert
Attention	Disordered	Normal	May be disordered
Cognition	Disordered	Impaired	May be impaired
Orientation	Impaired	Often impaired	May be impaired
Hallucinations	Visual and/or auditory	Often absent	Usually auditory
Delusions	Transient, poorly organized	Usually absent	Sustained
Movements	Asterixis, tremor may be present	Often absent	Absent

Source: Modified from Lipowski.

tive states. Symptoms may be intermittent and it is not unusual for different caregivers to witness completely different behaviors within a brief time span.³ The sleep-wake cycles are often disrupted with increased somnolence during the day and agitation at night. The increased nocturnal agitation is commonly referred to as "sundowning." Evidence of organic disease such as tremor, asterixis, tachycardia, sweating, hypertension, or emotional outbursts may be present. Hallucination, delusions, and illusions may be present. Hallucinations tend to be visual, though auditory hallucinations can also occur.

Diagnosis

Both historical and physical findings are necessary to confirm the diagnosis of delirium. The history is needed to confirm the acuity of the change in behavior and reveal the fluctuating confusion consistent with the delirium. The history from caregivers, spouse, or other family members is the primary method for diagnosing delirium.³ The acute onset of attention deficits and cognitive abnormalities with fluctuating severity through the day and worsening at night is virtually diagnostic of delirium. Medication history, including over-the-counter medications, should be examined in detail. In the elderly, medication side effects or toxicity may be observed in what are ordinarily regarded as therapeutic and safe doses. General physical examination is directed at discovering the underlying process, such as pneumonia. Ancillary testing, should include serum electrolytes hepatic and renal studies; urinalysis; blood count; and a chest radiograph. Cranial CT should be done followed by lumbar puncture if meningitis or subarachnoid hemorrhage is in consideration.

TABLE 229-2 Six Elements of Mental Status Evaluation

Appearance, behavior, and attitude
Is dress appropriate?
Is motor behavior at rest appropriate?
Is the speech pattern normal?
Disorders of thought
Are the thoughts logical and realistic?
Are false beliefs or delusions present?
Are suicidal or homicidal thoughts present?
Disorders of perception
Are hallucinations present?
Mood and affect
What is the prevailing mood?
Is the emotional content appropriate for the setting?
Insight and judgement
Does the patient understand the circumstances surrounding the visit?
Sensorium and intelligence
Is the level of consciousness normal?
Is cognition or intellectual functioning impaired?

Source: Modified from Zun and Howes.²

One key tool for detecting delirium is the mental status examination. The Mini-Mental State Examination (MMSE) is probably the most widely used test, though frequently only parts are administered in ED (Table 229-3).⁶ This test is valuable in directing the physician to study aspects of attention and memory that might not otherwise be formally tested. Age, education, chronic cognitive impairment, and verbal abilities may all affect scores. Several other shorter evaluation systems have been proposed. The Quick Confusion Scale (QCS) has been tested in ED patients, correlates well with the MMSE, and takes less time to administer (Table 229-4).⁷

Depression may resemble a hypoactive delirium, with withdrawal, slowed speech, and poor results in cognitive testing present in both conditions. However, rapid fluctuation of symptoms is common in delirium but absent in depression. Additionally, clouding of consciousness is absent in patients with depression; usually testing will find patients oriented and able to perform commands.³

Treatment

Treatment is directed at the underlying cause. Common medical causes of delirium are listed in Table 229-5, and multiple causes may be present in a patient.

Environmental manipulations such as adequate lighting and psychosocial support may be helpful in enhancing the patient's ability to interpret the surroundings correctly.³ Sedation may be needed at times to relieve severe agitation. Haloperidol is a frequent initial choice at a dose of 5 to 10 mg PO, IM, or IV; 1 to 2 mg in the elderly. This may be repeated at 20- to 30-min intervals as the clinical situation indicates. Benzodiazepines such as lorazepam 0.5 to 2 mg PO, IM, or IV may be used in combination with haloperidol in doses of 1 to 2 mg, the dose varying widely because of the age and size of the patient and the degree of agitation. Any institutional confinement or restraint policies should be appropriately addressed. Sedation or restraint is no substitute for diagnostic activities and specific illness-targeted therapy.

Disposition

Unless a readily reversible cause for the acute mental status change is discovered, treatment initiated, and improvement is seen, the majority of patients will be hospitalized for further treatment and possibly additional diagnostic testing. This decision will be individualized to the patient, the resources in the home or health care facility, and the safety of the patient.

DEMENTIA

Dementia implies a loss of mental capacity. The individual who once functioned at a certain psychosocial level with certain cognitive abilities

3	()	Name 3 objects; ask patient to repeat.
		ATTENTION AND CALCULATION
5	()	The serial 7 test; 1 point for each correct. Stop after 5 answers. Option: spell "world" backwards.
		RECALL
3	()	Ask for the 3 objects repeated above. 1 point scored for each correct object recalled.
		LANGUAGE
9	()	Name a pencil and watch (2 points)
		Repeat the following, "No if's, ands, or buts." (1 point)
		Follow 3 stage command: "Take a paper in your right hand, fold it in half, and put it on the floor." (3 points)
		Read and follow the following printed command:
		"Close your eyes" (1 point)
		Write a sentence (1 point)
		Copy design (1 point)

SCORING: A score of 23 or less may indicate the presence of dementia or another cognitive disorder and suggests the need for further testing and evaluation.

Instructions for Administering the Mini-Mental State Examination

Orientation: Ask for the date. Specifically ask for any omitted information. One point for each correct answer.

Registration: Ask permission to test memory. Name 3 unrelated objects clearly and slowly about 1 s apart. After you have said all 3, ask the patient to repeat. The first repetition determines the score. In order to test recall (discussed below) the examiner should repeat the items in order up to 6 times, until the patient can repeat all 3. If the patient is unable to do this, recall can't be tested.

Attention and calculation: Ask the patient to begin with 100 and count backwards by 7. Stop after 5 subtractions and score correct answers. If the patient cannot calculate, ask him or her to spell "world" backwards. The score is the number of letters in correct order.

Recall: Ask the patient if he or she can recall the 3 words previously asked to remember. Score 0-3.

Language: Naming: Show the patient a wristwatch and pencil and ask name. Score 0-2.

Repetition: Ask the patient to repeat a sentence. Allow one trial. Score 0 or 1.

3-Stage command: Give the patient a piece of paper and repeat the command. Score 1 point for each portion of the command correctly performed. Reading:

Print clearly on a piece of paper in large letters the command, "Close your eyes." Ask the patient to read and perform the command. Score 1 point

if the eyes are closed. Writing: Give the patient a blank piece of paper and ask him or her to write a sentence of his or her own choosing. It must contain a subject and a verb to be

scored 1 point. Punctuation does not matter for scoring purposes. Copying: On a clean piece of paper, draw intersecting pentagons, each side 1 inch, and ask the patient to copy exactly. All 10 angles must be present and the

2 figures must intersect to score 1 point. Any rotation of the figures or tremor is ignored.

Source: Modified from Folstein and Folstein.⁶

is now failing and behavioral problems have developed. Most dementias are idiopathic and are termed *dementia of the Alzheimer disease* (DAT). The other large category is vascular dementia. However, many other disorders more treatable than Alzheimer disease (AD) or vascular dementia may also cause dementia or simulate dementia. The largely untreatable dementias are thus diagnoses of exclusion.

The typical course of dementia is slow with insidious symptom onset; the abrupt onset of symptoms or rapidly-progressing symptoms should prompt a search for another organic process. Presentation to the ED is usually precipitated by some sentinel occurrence or event. Patients may be brought to the ED as a consequence of caregiver burn-out. The behavioral symptoms of patients with Alzheimer may be disruptive to the home environment and distressing to the patient and caregivers. Hallucinations, delusions, repetitive behaviors, and depression are all common. Patients may misidentify other people and family members may be regarded as strangers, sometimes with apparent great fear.

Pathophysiology

The majority of cases of dementia in the United States are due to AD. Alzheimer is a neurodegenerative disorder of unknown etiology. The pathophysiology is complex, with a reduction in neurons in the cere-

bral cortex as well as increased amyloid deposition and the production of neurofibrillary tangles and plaques. Other neurodegenerative diseases have their own unique pathologies.

Vascular dementia accounts for the next largest number of individuals with dementia. The pathology is that of cerebrovascular disease with multiple infarctions. A listing of different dementias is provided in Table 229-6.

Clinical Features

Impairment of memory, particularly recent memory, is gradual and progressive. Remote memories are often preserved. Impairment of memory and orientation with preservation of motor and speech abilities is said to be characteristic of the onset of AD. Degenerative dementias such as AD may be divided into early, middle, and late stages. Early in the disease, complaints of memory loss, naming problems, or forgetting items are common. The middle stage shows progression of these problems plus loss of reading, decreased performance in social situations, and losing directions. The late stage of the illness may include extreme disorientation, inability to dress and perform self-care, and personality change. Typically, the onset of symptoms is slow and gradual; if the onset of symptoms is acute, the possibility of a reversible process is increased. Clinical features of AD or other dementias

TABLE 229-4 The Quick Confusion Scale

Item	Score (Number Correct)	X (Weight)	(Total)
What year is it now?	Oor 1 (Score 1 if correct, 0 if incorrect)	X 2	=
What month is it?	Oor 1	X 2	=
Present memory phrase: "Repeat this phrase after me and remember it: John Brown. 42 Market Street. New York."			
About what time is it? (Answer correct if within 1 hour)	Oor 1	X 2	=
Count backwards from 20 to 1	0, 1, or 2	X 1	=
Say the months in reverse	0, 1, or 2	X 1	=
Repeat memory phrase (each underlined portion correct is worth 1 point)	0, 1,2, 3,4, or 5	X 1	=
Final Score is the Sum of the Totals			=

15 is the top score; a score less than 15 may indicate the need for additional assessment.

Scores highest number in category indicates correct response; lower scoring indicates increased number of errors.

Item 1. "What year is it now?"

Score 1 if answered correctly, 0 if incorrect.

Item 2. "What month is it?"

Score 1 if answered correctly, 0 if incorrect.

Item 3. "About what time is it?"

Answer considered correct if within 1 hour; score 1 if correct, 0 if incorrect.

Item 4. "Count backwards from 20 to 1"

Score 2 if correctly performed; score 1 if one error, score 0 if 2 or more errors.

Item 5. "Say the months in reverse"

Score 2 if correctly performed; score 1 if one error, score 0 if 2 or more errors.

Item 6. Repeat memory phrase

"John Brown, 42 Market Street, New York"

Each underlined portion correctly recalled is worth 1 point in scoring; score 5 if correctly performed; each error drops score by one.

Final score is sum of the weighted totals; items one, two, and three are multiplied by 2 and summed with the other item scores to yield the final score.

Source: From Huff et al.⁷

tias may include affective symptoms such as depression and anxiety, behavioral disorders, and speech difficulties.

Vascular or multi-infarct dementia has symptoms similar to AD, but may have findings on physical examination of exaggerated or asymmetric deep tendon reflexes, gait abnormalities, or weakness of an extremity.

Diagnosis

The history of memory problems is usually one of slow progression without landmark occurrences. If specific dates of worsening are noted, the possibility of a vascular dementia increases. Family history may be significant. One inherited dementia, Huntington disease, has a clear autosomal dominant pattern of inheritance.

General physical examination does not determine the diagnosis of dementia, but may be helpful in identifying associated causes.⁸ The presence of focal neurologic signs may suggest vascular dementia or a mass lesion. Increased motor tone and other extrapyramidal signs such as rigidity or a movement disorder may suggest Parkinson disease. Mental status testing should be performed as outlined above and summarized in Tables 229-2, 229-3, and 229-4.

For diagnosis, the American Academy of Neurology practice parameter⁹ in 1994 recommends complete blood count, serum electrolytes, calcium, glucose, BUN, creatinine, and liver function tests. However, no studies have been done to evaluate these recommendations. In 2001, an evidence-based review suggested the use of thyroid function tests, serum vitamin B₁₂, and serology for syphilis (only if at risk).¹⁰ Other laboratory tests that are optional and may be helpful in certain circumstances include erythrocyte sedimentation rate, serum folate level, HIV testing, chest x-ray, urinalysis. Neuroimaging such as

CT or MRI should be considered in every patient at some point in the diagnostic evaluation. Lumbar puncture should be performed if the diagnosis is not readily apparent.

Diagnosis of probable vascular dementia again requires signs of cerebrovascular disease. The relationship between stroke and cognitive decline must be temporally related, with dementia within 3 months of the stroke or abrupt deterioration in memory and other cognitive abilities. A fluctuating, stepped course suggests vascular dementia.¹¹

The possibility of a comorbid condition suddenly worsening cognitive functioning should be strongly considered and often is the thrust of investigation in the ED. Urinary tract infection, congestive heart failure, or hypothyroidism are just a few of the conditions that may cause a mildly demented but functioning individual to rapidly deteriorate. The symptoms overlap with those of delirium as discussed above. The differential diagnosis is particularly important for consideration of depression imitators, the so-called treatable causes of dementia (see Table 229-6).

Depression may coexist with dementia; however, depression imitating dementia (pseudodementia) should also be considered. Appropriate inpatient or outpatient follow-up may be arranged for further psychiatric evaluation. If the patient is thought to be seriously depressed, consideration should be given to hospital admission.

Treatment

All types of dementia are treatable at least to some degree by environmental or psychosocial interventions. Antipsychotic drugs have been used for management of the psychotic and nonpsychotic behaviors, but treatment remains problematic because of adverse drug effects. Use of these drugs should be selective and reserved for patients with

TABLE 229-5 Important Medical Causes of Delirium in Elderly Patients

persistent psychotic features or those with extreme disruptive or dangerous behaviors.¹² Treatment is best coordinated with caregivers that are in a position to monitor the patient's behavior patterns over time.

Treatment of vascular dementia is limited to treatment of risk factors including hypertension.

Normal-pressure hydrocephalus (NPH) is suggested by the presence of excessively large ventricles on head CT and can prompt consideration of a trial of ventricular shunting. The clinical suspicion of NPH should be increased with the presence of urinary incontinence and gait disturbance at a relatively early point in the disease. Improvement in some individuals may be striking, but controversies remain on patient selection and the duration of improvement.

Disposition

A new diagnosis of dementia may be entertained in the ED, but the decision making and depth of the diagnostic evaluation will usually exceed the time available during the ED stay. A decision to admit or arrange an outpatient diagnostic plan is the usual course in the ED after the major differential diagnostic possibilities have been eliminated. Attention should be directed toward the presence of delirium or a treatable cause of dementia. The existence of comorbid medical problems, a rapidly progressive or atypical clinical course, or an unsafe or uncertain home situation should prompt consideration for admission.

COMA

Introduction

Coma is a state of reduced alertness and responsiveness from which the patient cannot be aroused.¹³ The Glasgow Coma Scale (see Table 255-2) is a widely used clinical scoring system for alterations in con-

sciousness. Advantages are a simple scoring system and assessment of separate verbal, motor, and eye-opening functions. Disadvantages include lack of acknowledgement of hemiparesis or other focal motor signs and lack of testing of higher cognitive functions. Causes of coma likely to be encountered in the ED are noted in Table 229-7.

Pathophysiology

The pathophysiology of coma is complex for clinical purposes. Coma can result from deficiency of substrates needed for neuronal function (as with hypoglycemia or hypoxia). With systemic causes, the brain is globally affected and signs that localize dysfunction to a specific area of the brainstem or cortex will usually be lacking. In primary CNS causes, coma may result from brainstem disease such as hemorrhage or from bilateral cortical dysfunction. Signs localizing to specific areas of CNS dysfunction such as hemiparesis or cranial nerve abnormalities may be present. Unilateral hemispheric disease, such as stroke, should not by itself result in coma. The function of either the brainstem and/or both hemispheres must be impaired for unresponsiveness.

A traditional view of reduced consciousness from mass lesions invokes secondary compression of the brainstem by physical shifting of brain tissue. In the uncus herniation syndrome, the medial temporal lobe shifts to compress the upper brainstem, resulting in progressive drowsiness followed by unresponsiveness. The ipsilateral pupil will be sluggish, eventually becoming dilated and nonreactive on the postulated basis of third cranial nerve compression by the medial temporal lobe. Other signs of progressive third nerve dysfunction include loss of extraocular movements. Hemiparesis may develop ipsilateral to the mass from compression of the descending motor tracts in the opposite cerebral peduncle. A central herniation syndrome is also described

TABLE 229-7 Differential Diagnosis of Coma

Nonconvulsive status epilepticus
Postictal state

characterized by progressive loss of consciousness, loss of brainstem reflexes, decorticate posturing, and irregular respirations.

The herniation syndromes serve as models, but their exact mechanism has been questioned. The amount of midline shift of structures as evaluated by neuroimaging seemingly correlates with the level of consciousness without invoking physical herniation. For example, given an acute lesion, the patient may be awake with up to 3 to 4 mm of pineal shift with unresponsiveness deepening as the pineal shift increases to 10 mm.

Ischemia from vascular compression is undoubtedly a factor in cerebral edema and increased intracranial pressure (ICP). Increased ICP may be localized to specific regions of the brain, perhaps initiating a herniation syndrome or midline shift as described above. Increased ICP may also occur diffusely, resulting in diffuse CNS dysfunction. Cerebral blood flow (CBF) is constant at mean arterial pressures (MAPs) of 50 to 100 mm Hg through the process of cerebral autoregulation. At MAPs outside this range, CBF will be reduced and ischemia may develop. Cerebral perfusion pressure (CPP) is equal to the MAP minus the intracranial pressure ($CPP = MAP - ICP$). It follows that in extreme uncontrolled elevation of the ICP, cerebral perfusion pressure is lost as the ICP approaches the MAP, and ischemia will develop.

Clinical Features

The clinical features of coma vary both with the depth of coma and the etiology. For example, a patient in coma with a hemispheric hemorrhage may still have some muscle tone; careful examination may allow detection of decreased muscle tone on the side of the hemiparesis. The eyes may conjugately deviate toward the side of the hemorrhage. With expansion of the hemorrhage and surrounding edema, increase in ICP, or brainstem compression, unresponsiveness may progress to a complete loss of motor tone and loss of the ocular findings as well.

A variety of abnormal breathing patterns may be seen in the comatose patient. They are of interest, but offer little information in the acute setting. Pupillary findings, the results of other cranial nerve evaluation, hemiparesis, and response to stimulation are all part of the clinical picture that need to be assessed. These findings help the clinician sort the cause of the coma into a likely large general category—diffuse CNS dysfunction (toxic-metabolic coma) or focal CNS dysfunction (structural coma). A further division of structural coma is into hemispheric (supratentorial) and posterior fossa coma, and is often possible at the bedside.

Toxic and metabolic causes of coma result from a wide range of clinical conditions. In general, the diffuse CNS dysfunction is reflected by the lack of physical examination findings that might point to a specific region of dysfunction within the brain. For example, in toxic-metabolic coma, if the patient is having either spontaneous movements or reflex posturing, the movements are symmetric without evidence of hemiparesis. Muscle stretch reflexes, if present, are symmetric. Pupillary response is generally preserved in toxic-metabolic coma; typically the pupils are small but reactive. If extraocular movements are present, again they are symmetric. However, if extraocular movements are absent, this sign is of no value in differentiating toxic-metabolic from structural coma. A notable exception is severe sedative poisoning as with barbiturates; the pupils may be large, extraocular movements absent, muscle tone flaccid, and the patient apneic simulating the appearance of brain death.

Coma from lesions of the hemispheres, or supratentorial masses, may present with progressive hemiparesis or asymmetric muscle tone and reflexes. The hemiparesis may be suspected with asymmetric responses to stimuli or asymmetric extensor or flexor postures. The uncus herniation syndrome, as described above, is an example of a supratentorial syndrome. Frequently, however, large acute supratentorial lesions are seen without the features consistent with temporal lobe herniation. Coma without lateralizing signs may result from decreased cerebral perfusion secondary to increased intracranial pressure. Reflex changes in blood pressure and heart rate may be observed with increased ICP or brainstem compression. Hypertension and bradycardia in a comatose patient may represent the Cushing reflex from increased ICP.

Posterior fossa or infratentorial lesions comprise another structural coma syndrome. An expanding mass, such as cerebellar hemorrhage or infarction, may cause abrupt coma, abnormal extensor posturing, loss of pupillary reflexes, and loss of extraocular movements. The anatomy of the posterior fossa leaves little room for accommodating an expanding mass. Early brainstem compression with loss of brainstem reflexes may develop rapidly. Another infratentorial cause of coma is pontine hemorrhage, which may present with the unique signs of pinpoint-sized pupils.

Pseudocoma or psychogenic coma is occasionally encountered and may present a perplexing clinical problem. Adequate history and observation of responses to stimulation will reveal findings that differ from the syndromes described above. Pupillary responses, extraocular movements, muscle tone, and reflexes will be shown to be intact on careful examination. Tests of particular value are observing the response of the patient to manual eye-opening (there should be little or no resistance in the truly unresponsive patient) and extraocular movements. Specifically, if avoidance of gaze is consistently seen with the patient always looking away from the examiner, or if nystagmus is demonstrated with caloric vestibular testing, this is strong evidence for nonphysiologic or feigned unresponsiveness.

Diagnosis

In the approach to the comatose patient, stabilization, diagnosis, and treatment actions overlap and are often performed simultaneously. Examination, laboratory procedures, and neuroimaging allow determination of the cause of coma in almost all patients in the ED. As with any

patient, airway, breathing, and circulation need to be immediately addressed. Reversible causes of coma, such as hypoglycemia or opiate overdose, should always be considered. Exploit all possible historical sources (EMS personnel, caregivers, family, witnesses, medical records, etc.) to aid in diagnosis.

The tempo of onset of the coma is of great diagnostic value. Abrupt coma suggests abrupt CNS failure with possible causes such as catastrophic stroke or seizures. A slowly progressive onset of coma may suggest a progressive CNS lesion such as tumor or subdural hematoma. Metabolic causes such as hyperglycemia may also develop over several days.

General examination and vital signs (including oxygen saturation and temperature) should receive special attention following stabilization and resuscitation. General examination may reveal signs of trauma or suggest other diagnostic possibilities for the unresponsiveness. For example, a toxidrome may be present that suggests diagnosis and therapy, such as the hypoventilation and small pupils found with opioid overdose.

Neurologic testing deviates from the standard examination. Fine tests of weakness in the alert patient, such as testing for pronator drift of the outstretched upper extremities, are not possible in the unresponsive patient. However, assessment of cranial nerves through pupillary examination, corneal reflexes, and oculovestibular reflexes may suggest focal CNS lesions. Observation for abnormal extensor or flexor postures are nonspecific for localization or etiology of coma, but suggest profound CNS dysfunction. Again, asymmetric muscle tone or reflexes raise the suspicion of a focal lesion. The goal of the physician is to rapidly determine if the CNS dysfunction is from diffuse impairment of the brain or if signs point to a focal (and perhaps surgically treatable) region of CNS dysfunction.

CT scanning is the neuroimaging procedure of choice. Acute hemorrhage is readily identified as are midline shifts and mass lesions. Lumbar puncture should be done if CT scan is negative, to identify CNS bleeding or infection. Basilar artery thrombosis should be suspected in the comatose patient with a "normal" head CT, where the only finding may be a hyperdense basilar artery. MRI or angiography are needed to make the diagnosis.

Specific Issues

Airway issues of importance in the comatose patient include concerns for cervical spine injury and increased intracranial pressure. If trauma is suspected, stabilization of the cervical spine during the diagnostic process must be maintained. Issues of intubation in the head-injured patient or other comatose patient with suspected increased intracranial pressure need modification of rapid sequence intubation techniques that are discussed at length in Chap. 19. If protection of the airway is at all in doubt, seizure is a possibility, or the coma state is likely prolonged, it may be prudent to intubate the patient.

In the pediatric patient, causes of coma differ from the adult. Toxic ingestions, infections, and child abuse all assume a greater frequency and importance.

Nonconvulsive status epilepticus or subtle status epilepticus is an area of increasing interest. Patients who have had generalized seizures and remain unresponsive may be in a continuing state of electrical seizures without corresponding motor movements. This has been termed *electromechanical dissociation of the brain and body*. If the motor activity of the seizure has been stopped and the patient is not awakening within 30 min, the existence of this subtle status epilepticus should be considered and urgent EEG or neurologic consultation sought.

Treatment

Treatment of coma involves identification of the etiology of the brain failure and initiation of specific therapy directed at the underlying

cause. Brain-saving procedures should be performed while diagnostic steps are taking place. Again, stabilization with attention to airway, ventilation, and circulation assume priority. Attention to readily reversible causes of coma such as hypoglycemia and opioid toxicity demand priority.

The "coma cocktail" that was routinely given to all comatose patients has come under scrutiny. While hypoglycemia is common, with rapid glucose determinations, empiric administration of dextrose is not always necessary. It has been axiomatic that thiamine should be administered before glucose infusions, and this certainly is true of the patient with a suspected history of alcohol abuse or malnutrition, but this may not be necessary in all patients. Some suggest that naloxone, an opiate antagonist, need not be administered if clinical signs of the opiate are not present. Routine use of flumazenil in unknown coma is not recommended.¹⁴

Several rapid decisions face the emergency physician. An early decision involves assigning the patient into probable structural coma etiology versus toxic-metabolic etiology. History and physical examination will allow that initial categorization with many patients, but liberal use of CT scanning is encouraged since exceptions to the tentative clinical diagnosis are frequent.

If history, physical examination, or neuroimaging suggests increased intracranial pressure, specific steps may be indicated to reduce or ameliorate any further rise in ICP. Any noxious stimulus including "bucking" the ventilator will increase ICP; paralysis and sedation should be liberally used. A general recommendation is to keep the head elevated about 30° and midline to aid in venous drainage. Osmotic diuretics such as mannitol (0.5 to 1 g/kg) will decrease intravascular volume and brain water and may transiently reduce ICP. In cases of brain edema associated with tumor, steroids such as dexamethasone will reduce edema over several hours. Hyperventilation with reduction of $Paco_2$ will reduce cerebral blood volume and transiently lower ICP. Current recommendations are to avoid prophylactic hyperventilation ($Paco_2$ =s 35 mm Hg) during the first 24 h after brain injury. Brief hyperventilation may be necessary for refractory intracranial hypertension. Data to recommend specific therapy is lacking and preferences among individuals and institutions vary greatly; early communication is encouraged with consultants and admitting physicians.

Disposition

Patients with readily reversible causes of coma, such as insulin-induced hypoglycemia, may be discharged if home care and follow-up care are adequate and a clear cause for the episode is suspected. For patients with enduring altered consciousness, admission will be necessary. Most systems depend on emergency physicians to stabilize the patient and correctly assign a tentative diagnosis so the patient may be admitted to the proper specialty service. If the appropriate service is not available, transfer should be considered after stabilization.

	Conditions affecting predominantly the peripheral nervous system	
	Peripheral neuropathy	Vestibulopathy

clinical picture of motor- or cerebellar-like ataxia with hemisensory loss. These effects are seen contralateral to the lesion.² Lesions affecting the frontal lobe, such as tumor or hydrocephalus, may cause a motor ataxia of the contralateral extremities through poorly understood mechanisms.³

Sensory ataxia occurs with a failure in transmission of proprioception or position sense information to the central nervous system (CNS). This may arise from disorders affecting the peripheral nerves, spinal cord, or cerebellar input tracts. Coordinated motor performance is faulty even though motor systems and the cerebellum are intact. Sensory ataxia may be compensated to a degree, consciously with visual sensory information. Loss of this visual information leads to the observation that symptoms of sensory ataxia often worsen in poor lighting conditions and may be brought out during examination (see below).

CLINICAL FEATURES

Historical information should be collected about the entire symptom constellation in addition to any complaints of headache, nausea, fever, weakness, or numbness. A history of febrile illness, medication history, or family history may be a key element leading to a correct diagnosis in individual cases. The nature of onset of symptoms and the time course of the process guide the pace of investigations. For example, abrupt onset of gait difficulty in a patient with severe headache, drowsiness, nausea, and vomiting should suggest an acute process within the CNS, possibly a hemorrhage into the cerebellum. The possible consequences of that diagnosis are severe and may require immediate attention. At the other extreme, a patient without significant medical history who is brought to the emergency department with a stumbling gait after an episode of binge drinking requires examination but may need nothing other than observation unless history or

230 ATAXIA AND GAIT DISTURBANCES

J. Stephen Huff

Ataxia and gait disturbances may be symptoms of a variety of disease processes and generally are not diagnoses themselves. Ataxia is the failure to produce smooth intentional movements. Gait disorders include ataxic gait, as well as a variety of other conditions. The presenting complaint may be articulated by the patient or family as weakness, dizziness, stroke, falling, or another nonspecific or even inaccurate chief complaint. These symptoms must always be viewed in the context of the patient's overall clinical picture. For example, in a patient with the inability to walk, hemiplegia would not be considered primarily a gait disturbance. However, if the intraparenchymal hemorrhage were in the cerebellum, the inability to walk may be one of the dominating signs and symptoms. In this chapter, acute ataxia and disorders of gait are emphasized; chronic or progressive forms are covered only in a list.

PATHOPHYSIOLOGY

Ataxia or gait disturbances may result from many conditions that affect different elements of the central and peripheral nervous systems as well as systemic conditions (Table 230-1). Clinicians tend to think that these disorders result primarily from cerebellar lesions. Cerebellar lesions may indeed cause ataxia, but isolated lesions of the cerebellum are not the most common cause of these complaints.

Ataxia may be roughly categorized into two types. *Motor ataxias* (also referred to as cerebellar ataxia) are usually caused by disorders of the cerebellum; the sensory receptors and afferent pathways are intact, but integration of the proprioceptive information is faulty. Involvement of the lateral cerebellum (one of the cerebellar hemispheres) may lead to a motor ataxia of the ipsilateral limb. Lesions affecting primarily the midline portion of the cerebellum often cause problems with axial muscle coordination reflected in difficulty maintaining a steady upright standing or sitting posture.

There are many reports of lesions in what would seem to be unlikely locations producing motor ataxia. Supratentorial infarctions, particularly small deep infarctions or lacunae of the posterior limb of the internal capsule, have been reported to cause isolated hemiataxia. It is postulated that interruption of either ascending or descending cerebellar to cortical pathways are the cause of this motor-type ataxia.¹ Small infarctions or hemorrhages in thalamic nuclei may produce a

physical examination suggest trauma or some alternative cause for the symptoms.

The following discussion of the neurologic examination assumes that the gait disorder is the dominating abnormality, but examination including testing of cranial nerves, mental status, sensation, or the motor system is necessary and may yield findings that lead to an unanticipated diagnosis.

General physical examination of a patient with ataxia or gait disturbance should include determination of orthostatic vital signs; besides hypovolemia, orthostatic hypotension may be present in patients with diabetic neuropathy and other neurologic syndromes. Especially in the elderly, volume replacement for simple hypovolemia may correct many symptoms of unsteadiness.

Gait testing is one of the most important parts of the directed neurologic examination. Observing the patient sit upright in the stretcher, rise, stand, walk, and turn gives information about many parts of the nervous system. The patient should be asked to walk at a normal speed, then walk on the heels, and then toes. Tandem gait is toe-to-toe walking and also tests many elements of the nervous system. Do not assume a normal examination without observing ambulation.

Cerebellar functions are tested by asking the patient to perform smooth voluntary movements and rapidly alternating movements; dyssynergia (breakdown of movements into parts), dysmetria (inaccurate fine movements), or dysdiadochokinesia (clumsy rapid movements) may be indicative of a problem in the lateral cerebellum. The rapid thigh-patting test particularly examines rapidly alternating movements. This is correctly performed by asking the patient to pat the thigh with the palm then the back of the same hand in alternating fashion, making a sound with each rapid slap. The maneuver is performed with each hand in turn. The familiar finger-to-nose test (*dyssynergia*) may be helpful in distinguishing between cerebellar and posterior column lesions. Performing this test with the eyes closed tests proprioception in the upper extremity. A test for cerebellar function that emphasizes the lower extremities (and another part of the cerebellum) is the familiar heel-to-shin test (also *dyssynergia*). In cerebellar disease, the knee may initially overshoot. In posterior column disease, there may be difficulty locating the knee, but the movement down the shin typically weaves from side to side or falls off. Another test commonly used for cerebellar function is the *Stewart-Holmes rebound sign* (sudden release of the flexed forearm may rebound back and forth in several cycles).

The *Romberg test* is primarily a test of sensation and, if positive, may distinguish sensory from motor ataxia. With the patient standing with arms outstretched and the eyes open, the patient is observed for signs of unsteadiness. The feet should be narrowly spaced, and the posture should be easily maintained. The inability to maintain a steady standing posture (or, in extreme cases, a seated position) confirms that an ataxia is present but does not yet give any information about the type of ataxia. The patient is then asked to close the eyes with the resulting loss of visual orienting information. If the ataxia worsens with this loss of visual input, then the Romberg sign is present or positive, suggesting sensory ataxia with a problem of proprioceptive (posterior column, vestibular dysfunction), or a peripheral neuropathy. In patients who show little or no change in their unsteadiness with eye closure (Romberg test-negative), a motor ataxia is suggested with possible localization of that problem to the cerebellum. Note that many normal individuals will have some small increase in unsteadiness with eye closure. Further neurologic examination is indicated to confirm the suspicion of sensory etiology of the ataxia.

In the last century, *tabes dorsalis* (neurosyphilis) was a common cause of sensory ataxia. In *tabes dorsalis*, the posterior columns and posterior spinal roots degenerate, primarily in the lumbosacral region. The loss of proprioceptive information from the lower extremities renders the patient dependent on visual cues for correct gait. The classic description paints the picture of a patient who walks slowly with wide gait while staring at the ground. In darkness or with interruption of vi-

sion, the patient is unable to walk. The gait in this condition is peculiar with the foot first raised and then slapped to the ground with each step. These abnormalities reflect the loss of proprioceptive information from the posterior roots and posterior columns. The possibility of vitamin B₁₂ deficiency should be a consideration in patients with evidence of posterior column disease. If left untreated, an initial unsteady gait may progress to weakness, spasticity, and ataxia. The finding of a megaloblastic anemia may be a clue, but the neuropathy may precede the anemia.

Sensory examination in a patient with unsteady movements should include position or vibration testing (posterior columns), as well as testing sensation to pinprick. Testing of the deep tendon reflexes will serve largely to discover asymmetry or spasticity that might suggest an alternative diagnosis. Acute cerebellar injury may result in muscle hypotonia for a few days or weeks.⁴

Nystagmus is seen in many different disorders due to lesions in a variety of different locations of the CNS, but the presence of nystagmus does suggest that the pathologic process is intracranial and not in the spinal cord or peripheral nervous system (see Chap. 231).

No organized classification scheme exists for gait disorders, and different authors categorize abnormal gaits in descriptive terms. A brief summary of some of the more commonly used terms follows. A *cerebellar* or *motor ataxic* gait is wide-based with unsteady and irregular steps; compensation to barriers in the environment may be lacking. The gait of sensory ataxia resulting from loss of proprioception is notable for abrupt movement of the legs and slapping impact of the feet with each step.

An *apraxic* gait is one in which the patient seemingly has lost the ability to initiate the process of walking, a sort of "ignition failure." Apraxia describes the inability of a patient to perform a voluntary act even though the motor system and understanding are intact. This may occur with right or nondominant hemispheric lesions. Frontal lobe dysfunction may result in a similar gait. This may be seen in normal pressure hydrocephalus.

Footdrop from peroneal muscle weakness is reflected in an *equine* (high-stepping) gait. The high stepping from hip flexion is necessary for the foot to clear the ground.

The term *festinating* gait is used to describe narrow-based minia-ture shuffling steps. Once the walk begins, the steps may become more rapid. This is common in Parkinson disease and may be accompanied by other elements of Parkinson disease, such as increased muscle tone, lack of facial expression, slow movements (bradykinesia), and tremor.

An abnormal gait with outward swinging or circumabduction of the leg suggests a mild hemiparesis reflecting the asymmetric weakness of the proximal lower extremity muscles. The examination should then be directed to find other signs of hemiparesis. Bilateral weakness of the trunk and pelvic girdle muscles may result in a waddling gait from failure to maintain the normal position of the pelvis relative to the lower extremities.

A *functional* gait disorder is one in which the patient is unable to walk normally, though all motor pathways, sensory pathways, and cerebellar functions may be demonstrated to be functioning normally. The underlying problem is often a conversion disorder. These gaits may be bizarre, at times resembling a person balancing on a tightrope and seemingly threatening to fall but not falling. The wildness of flailing movements without falling actually demonstrates that the strength, balance, and coordination are intact. This dramatic functional gait is termed *astasia-abasia*.

A unifying concept defines gait disorders according to the level of processing of neurologic information (Table 230-2).⁵ Low-level gait disturbance refers to disorders of proprioception or dysfunction of the musculoskeletal system. Middle-level gait disturbance causes distortion of appropriate interaction of postural and motor processes or synergies. This might include stroke with paralysis, cerebellar dysfunction, or diseases of the basal ganglia such as Parkinson disease. On

TABLE 230-2 Classification of Gait Disorders

Low-level gait disorders
Musculoskeletal problems
Arthritic gait or other joint or skeletal problems
Muscle weakness
Peripheral sensory problems
Sensory ataxic gait
Vestibular problems
Middle-level gait disorders
Hemiplegia
Paraplegia
Motor or cerebellar ataxia
Parkinson disease
Dystonia, chorea, other movement disorders
High-level gait disorders
Senile gait (cautious gait)
Frontal ataxic gait
Apraxic gait (gait ignition failure)
Frontal disequilibrium

Note: "Level" refers to the level of processing of sensorimotor information.

examination, patients might have findings of spasticity, muscular tone, paralysis, or abnormal movements. High-level gait disturbances seemingly involve structures or processes that choose the appropriate responses for the support surface, body position in space, and intention of the patient. Cautious gait, apraxic gait, and the frontal gait disorder conceptually fall into this group with pathology that correlates with lesions in the frontal cortex or thalamus. This latter group is the least understood and the source of clinical confusion. This classification scheme is not ideal but does allow a thoughtful approach to patient diagnosis.

DIAGNOSIS

Assuming a primary complaint of ataxia, the first task is to determine whether the ataxia is sensory or motor and whether the primary process is systemic or within the nervous system. If within the nervous system, the next question is one of localization to the peripheral nervous system versus the CNS and perhaps to a more specific anatomic location. Finally, the tempo of the illness, comorbid diseases, and other clinical findings guide investigations and may allow a disease-specific diagnosis.

A patient with acute gait failure over hours to days needs thorough evaluation in the emergency department, consultation if available, and possible admission, in contrast to a patient with gradual loss of abilities over weeks or months where outpatient referral and evaluation may be appropriate.

SPECIFIC ISSUES THAT IMPACT EVALUATION AND TREATMENT

The Geriatric Patient

The gait changes with advancing age. A typical constellation includes gait slowing, shortening of the stride, and widening of the base. This results in the appearance of a guarded gait, that is, the gait of someone about to slip and fall. Many patients are aware of the loss of speed and adaptive balance and acknowledge the need to be careful. The nature of this *senile* gait is not fully understood but may represent a mild degree of neuronal loss, failing proprioception, slowing of corrective responses, or weakness of the lower extremities. Senile gait disorder is thought to exist in up to one-quarter of the elderly population. Some authorities divide this disorder into components of gait ataxia with

mild truncal instability and widened gait, and gait slowing with diminished spontaneous arm swing and bradykinesia.⁶ However, elements of the senile gait are also found in neurodegenerative diseases, and caution is urged to consider the possible presence of a neurodegenerative disorder such as Parkinson disease in elderly patients with gait impairment.⁶ Patients unable to walk or care for themselves need admission for supportive care.

The Alcoholic Patient

A history of alcoholism or malabsorption problem in the patient with ataxia or gait disorder should raise the possibility of a potentially remedial nutritional problem. If acute motor ataxia is present with confusion or eye movement abnormalities, the possibility of *Wernicke disease* should be considered and intravenous thiamine administration should be initiated promptly. The entity of alcoholic cerebellar degeneration (sometimes referred to as *rostral vermis syndrome*, since a portion of the cerebellar vermis is preferentially affected) may represent the same nutritional deficiency and not direct toxic effects of alcohol.

Children

In evaluating children with acute ataxia or gait disorder, examination must exclude weakness and musculoskeletal disorders. The child may be awake, alert, and playful but is visibly unsteady or wobbly sitting on a stretcher. The differential diagnosis is extensive (Table 230-3). Acute or deteriorating presentation generally mandates aggressive search for underlying etiology and likely inpatient management.

Intoxications are a cause of ataxia in children, and the ingestion may be surreptitious. Though ethanol may be suspected by odor, other drugs such as phenytoin or carbamazepine will not be detected in that

TABLE 230-3 Causes of Acute Ataxia in Children, Roughly in Order of Frequency

Cause	Example
Drug intoxication	Ethanol Isopropyl alcohol Phenytoin Carbamazepine Sedatives Lead, mercury
Infection and inflammation	Varicella Coxsackievirus A and B Mycoplasma Echovirus Postinfectious inflammation Postimmunization
Neoplasm	Neuroblastoma Other central nervous system tumors
Trauma	Subdural or epidural posterior fossa hematoma
Congenital or hereditary	Pyruvate decarboxylase deficiency Friedreich ataxia Hartnup disease

Source: Modified from Belcher RS: Preemptive cerebellar ataxia in varicella. *Ann Emerg Med* 27:511, 1996, and Chutorian AM, Pavlakis SG: Acute ataxia, in Pellock JM, Myer EL (eds): *Neurologic Emergencies in Infancy and Childhood*. Boston: Butterworth-Heinemann, 1993, p. 208, with permission.

manner. History should include queries about any medications in the household.

Unusual metabolic disorders such as pyruvate decarboxylase complex deficiency may present with ataxia. Family history may or may not suggest a metabolic disorder. Typically, the onset is gradual, but abrupt decompensations may occur. Other systemic or CNS abnormalities will be present.

Posterior fossa mass lesions and other CNS masses may present with ataxia, though usually some abnormality of cranial nerves or strength will be discovered with careful examination. Attention is needed to exclude abnormalities on physical examination that might suggest problems not localized to the cerebellum. Abnormal ocular movements should increase the suspicion of a mass lesion.

Rarely, acute ataxia may follow immunizations, viral illnesses, or varicella but also has been rarely reported in the preeruptive phase of varicella.⁷ Most children are in the 2- to 4-year-old range. The onset of gait ataxia is abrupt, and only occasionally is fever present at the time ataxia begins. The latency from the prodromal illness to the onset of ataxia is from 2 days to 2 weeks. Other neurologic findings encountered included truncal ataxia, dysmetria, and, uncommonly, cranial nerve abnormalities. Varicella patients appear to have uniform excellent recovery compared with patients with acute cerebellar ataxia from other causes that may have some residual problems.⁸ Little workup is needed if the ataxia occurs in the convalescent phase of varicella, and antiviral medications are not indicated. Otherwise, neuroimaging, lumbar puncture, and consultation are advisable. One study showed that while roughly half of the patients had cerebrospinal fluid inflammatory changes with pleocytosis or elevated immunoglobulin G index, magnetic resonance imaging (MRI) identified inflammatory changes in the cerebellum in only a minority of cases.⁸ Another small report noted MRI abnormalities not only in the cerebellum, but also in other areas of the CNS. This "syndrome" may in fact consist of several subgroups, some of which involve transient demyelination.⁹

covery. *Near-syncope* is defined as light-headedness signifying an impending loss of consciousness. *Psychiatric dizziness* is defined as a sensation of dizziness not related to vestibular dysfunction that occurs exclusively in combination with other symptoms as part of a recognized psychiatric symptom cluster.² *Disequilibrium* refers to a feeling of unsteadiness, imbalance, or a sensation of "floating" while walking.

PATHOPHYSIOLOGY

The central nervous system (CNS) coordinates and integrates sensory input from the visual, vestibular, and proprioceptive systems. The three streams of information help form an impression of the orientation of the head and body as well as the perception of motion. Vertigo arises from a mismatch of information from two or more of the involved senses, which, in turn, can be caused by dysfunction in the sensory organ or its corresponding pathway.

Visual inputs provide spatial orientation. Proprioceptors help relate body movements and indicate the position of the head relative to that of the body. The vestibular system (via the otoliths) establishes the body's orientation with respect to gravity. The cupulae contain sensors that track rotary motion. The presence of embedded otoconia or particles on the cupulae may transform them into linear motion sensors capable of sensing gravity. The three semicircular canals sense orientation to movement and head tilts and are filled with a fluid called *endolymph*. The endolymphatic sac produces glycoproteins that create an osmotic sink necessary to maintain flow. The movement of fluid in the semicircular canals causes specialized hair cells inside the canals to move, causing afferent vestibular impulses to fire. Sensory input from the vestibular apparatus travels to the nucleus of the eighth cranial nerve (Figure 231-1).

The CNS structures involved in integrating sensory input from all three sensory modalities include the medial longitudinal fasciculus, the red nuclei, the cerebellum, and the parietal lobes and superior temporal gyrus of the cerebral cortex. Connections between these structures and the oculomotor nuclei that drive the vestibuloocular reflex (VOR) complete the system. The VOR prevents retinal slip and thus visual blurring that otherwise would result from head movements and body sway.

Ordinarily, there is balanced input from the vestibular apparatus on both sides of the body. Asymmetrical activity may result in vertigo. Causes of asymmetrical activity include unilateral lesions of the vestibular apparatus as well as excessive unilateral firing due (for instance) to abnormal motion of the endolymph. Rapid head movements induce vertigo by accentuating the imbalance. Symmetrical bilateral damage does not usually produce vertigo but may lead to truncal or gait instability.

FIG. 231-1. Vestibular innervation.

VERTIGO AND DIZZINESS Brian Goldman

Recent evidence suggests that as many as one in five adults aged 18 to 64 years reported dizziness during the past month.¹ To patients, dizziness may mean vertigo, syncope, presyncope, weakness, giddiness, anxiety, or a disturbance in mentation.

Vertigo is the perception of movement (rotational or otherwise) where no movement exists. *Syncope* is a transient loss of consciousness that is accompanied by loss of postural tone with spontaneous re-

The most striking clinical sign associated with vertigo is nystagmus. *Nystagmus* is a rhythmic movement of the eyes that has both a fast and a slow component, with direction named by its fast component. The slow component is due to the vestibuloocular reflex and is generated by excitation of the semicircular canal, producing eye movement away from that canal. The fast component of nystagmus is caused by the cortex, which exerts a quick corrective movement in the opposite direction. With disorders of the vestibular apparatus, the sensation of vertigo is usually associated with nystagmus. The nystagmus of vestibular injury or dysfunction is provoked when the affected side is in the dependent position, and the characteristic pattern is vertical and rotational or horizontal. When horizontal nystagmus is present, its slow-beating component points to the injured labyrinth. Vertical nystagmus by itself (and not associated with a rotational component) usually indicates a brainstem abnormality. However, an atypical pattern of nystagmus in the absence of other signs of CNS disease does not necessarily indicate central pathology.¹

The prevalence of vertigo and dizziness is greatest in the elderly. Decreases in visual acuity, proprioception, and vestibular input often occur with aging. The risk of near-syncope also increases with age due to causes such as dysrhythmias, orthostatic hypotension, and autonomic dysfunction. In addition, as people age, they are more likely to have free-floating otoconia within the semicircular canals, a condition that is believed to increase the risk of benign paroxysmal positional vertigo (BPPV).⁴ The elderly are also more likely to be taking medications, many of which, alone or in combination, can cause "dizziness."

Physiologic Vertigo

Physiologic vertigo is vertigo not caused by disease of the cochleo-vestibular system. It results from a mismatch among visual, proprioceptive, and vestibular input. This may be the pathogenesis of motion sickness as well as the transient vertigo associated with watching a film that captures the visual sensation of motion without the corresponding vestibular or proprioceptive input (*visual vertigo*). Visual vertigo can be triggered by complex visual environments such as shopping malls (due in part to the ceiling height of shopping malls as well as the large number of objects in motion) and by viewing complex floor or wallpaper patterns.

CLINICAL FEATURES

The conditions that cause vertigo are summarized in Table 231 -1. Vertigo is usually categorized into peripheral and central causes. There is no valid measurement of the severity of vertigo. Peripheral vertigo is caused by disorders affecting the vestibular apparatus and the eighth cranial nerve, whereas central vertigo is caused by disorders affecting central structures, such as the brainstem and the cerebellum. The classic characteristics distinguishing peripheral and central vertigo are found in Table 231-2 and in reality are not so distinct. For example, vertigo due to stroke or cerebellar hemorrhage certainly would have an acute (rather than insidious) presentation yet be of central origin. Similarly, severity and even accentuation with certain head positions, while suggestive, does not uniformly distinguish underlying pathology. Figure 231 -2 shows how the nystagmus pattern itself may help to differentiate peripheral and central vertigo. Peripheral nystagmus is increased by removal of fixation, but central nystagmus generally (though not always) decreases with fixation.

Although disorders causing peripheral vertigo tend to produce more distressing symptoms, they are seldom life-threatening. Disorders causing central vertigo may produce less distressing symptoms and have a slower onset than those due to peripheral vertigo, but they are generally of a more serious nature, requiring urgent or semiurgent diagnostic imaging or consultation with a neurologist or neurosurgeon.

TABLE 231-1 An Etiologic Classification of Vertigo

Vestibular/otologic	Benign paroxysmal positional vertigo Traumatic: after head injury Infection: labyrinthitis, vestibular neuronitis, Ramsay Hunt syndrome
Syndrome	Ménière syndrome Neoplastic Vascular Otosclerosis Paget disease
Neurologic	Toxic or drug-induced: aminoglycosides Vertebrobasilar insufficiency Lateral Wallenberg syndrome Anterior inferior cerebellar artery syndrome Neoplastic: cerebellopontine angle tumors Cerebellar disorders: hemorrhage, degeneration Basal ganglion diseases Multiple sclerosis Infections: neurosyphilis, tuberculosis Epilepsy Migraine headaches Cerebrovascular disease
General	Hematologic: anemia, polycythemia, hyperviscosity syndrome Toxic: alcohol Chronic renal failure Metabolic: thyroid disease, hypoglycemia

DIAGNOSIS

History

An approach to vertigo is shown in Figure 231-3. A key portion of the history is the unprompted description of what the patient means by "dizziness." It is important to avoid leading questions because they may bias the patient's responses. If patients have difficulty describing the dizziness, it is useful to ask them to describe the initial episode in detail. Often this is the most vivid episode, and the patient is more likely to recall key precipitants. Further history taking depends on how the dizziness is categorized.

If the patient has experienced true vertigo, the next step is to determine whether the vertigo is of peripheral or central origin. Although the symptoms of central vertigo may not be severe, they are more likely to indicate potentially life-threatening disorders. The temporal pattern and precipitating causes can help to distinguish the different etiologies of vertigo (Table 231-3). Peripheral vertigo is more likely

TABLE 231-2 Differentiating Peripheral from Central Vertigo

	Peripheral	Central
Onset	Sudden	Sudden or slow
Severity of vertigo	Intense spinning	Ill defined, less intense
Pattern	Paroxysmal, intermittent	Constant
Aggravated by position/movement	Yes	Variable
Associated nausea/diaphoresis	Frequent	Variable
Nystagmus	Rotatory-vertical, horizontal	Vertical
Fatigue of symptoms/signs	Yes	No
Hearing loss/tinnitus	May occur	Does not occur
Abnormal tympanic membrane	May occur	Does not occur
CNS symptoms/signs	Absent	Usually present

FIG. 231-2. Schematic drawing of peripheral and central vestibular nystagmus with and without visual fixation. The direction of the arrows indicates the horizontal direction of the fast phase of the nystagmus (a torsional component is not shown). The thickness of the arrows represents the relative intensity of the nystagmus. **A.** Findings typical of peripheral nystagmus, which remains in the same direction when the direction of gaze changes, and central nystagmus, which changes direction when the direction of gaze changes. Removal of visual fixation increases the intensity of peripheral nystagmus but not of central nystagmus. **B.** Removal of fixation helps to differentiate peripheral from central nystagmus when the nystagmus is predominantly in one direction of gaze during fixation. With removal of fixation, peripheral nystagmus may increase in intensity and become apparent in more than one direction of gaze. (Reprinted with permission from Hotson JR, Baloh AW: Acute vestibular syndrome. *New Engl J Med* 339:680, 1998. © 1998 Massachusetts Medical Society. All rights reserved.)

than central vertigo to be intense and to be associated with nausea, vomiting, diaphoresis, tinnitus, hearing loss, and photophobia. Central vertigo is more likely to be associated with neurologic symptoms and signs such as diplopia, dysarthria, and bilateral visual abnormalities. An associated headache or history of headache suggests migraine or a space-occupying lesion. Inquiry into history of head trauma and medications is required because these can precipitate episodes of dizziness or interfere with central adaptation. **Again, while these classic differentiations are useful, they are not invariable, and thus the clinician should not be reassured that a central cause is not present when symptoms appear more consistent with benign peripheral etiology.**

Physical Examination

Patients with vertigo should have ear, neurologic, and vestibular examinations. The external auditory canal and tympanic membrane should be examined for evidence of otitis media, cholesteatoma, and other pathology. Insufflation of air by use of a pneumatic otoscope that precipitates a burst of vertigo with nystagmus is diagnostic of an inner ear fistula. Hearing should be screened by whispering questions to the patient in one ear while lightly covering or rubbing one's fingers in front of the contralateral ear. Webber and Rinne testing also should be done if indicated. Other cranial nerves should be examined in detail as appropriate. Where central vertigo is considered, note abnormalities such as absent corneal reflex, facial paresis, difficulty swallowing, dysphonia, and depressed gag reflex. Test for limb as well as truncal ataxia. The vestibulospinal system and cerebellum are tested by tandem gait and Romberg testing. Proprioception and vibration also should be tested.

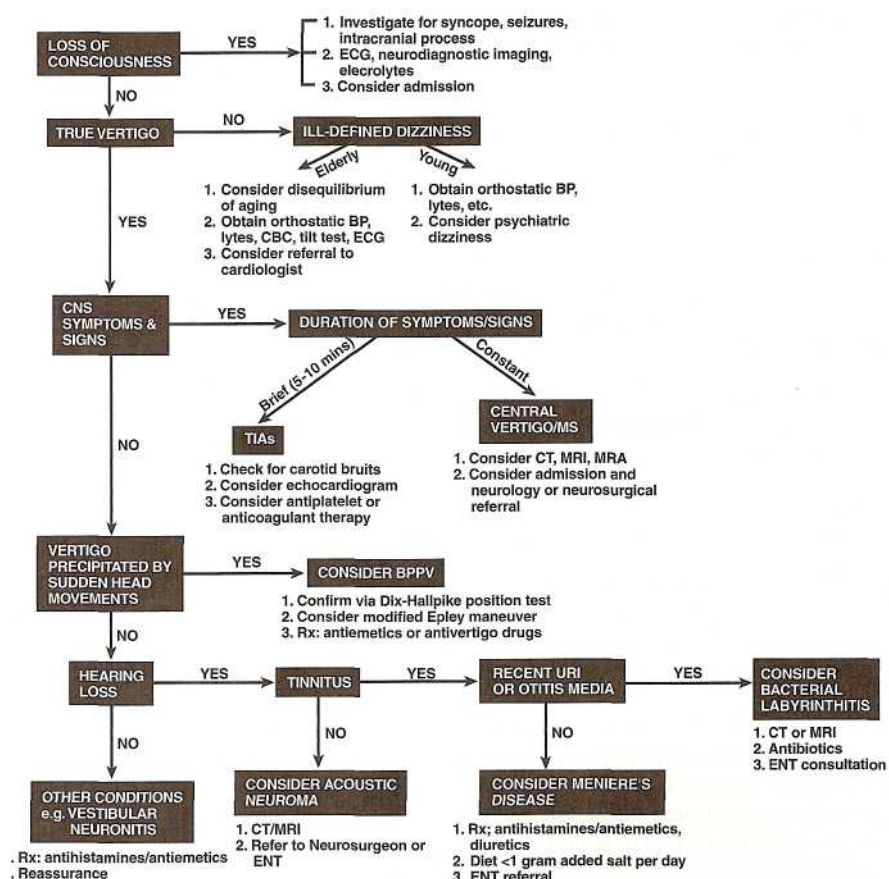

Nystagmus is the principal objective sign of vertigo. The eyes should be examined for spontaneous nystagmus, and the direction of such nystagmus should be noted. Because visual fixation can suppress nystagmus, the patient ideally should be wearing a pair of Frenzel

glasses, which are high-diopter lenses in a frame equipped with a light source. Examine for nystagmus while testing extraocular movements to 40 degrees from the midline. Note that several beats of nystagmus at the extremes of lateral gaze are a normal finding. Nystagmus on gaze testing suggests peripheral or central vertigo. The nystagmus pattern and behavior can assist in determining whether the lesion is central or peripheral (Figure 231-2).

The diagnosis of BPPV is aided by the Dix-Hallpike position test. This test should not be performed on patients with carotid bruits. It may be performed on patients with cervical spondylosis, provided that the neck is not hyperextended. The patient should be cautioned that the test might provoke vertigo. Pretreatment with 50 mg dimenhydrinate IM or IV may make the test more tolerable but will not obliterate nystagmus. Patients should keep their eyes open at all times and stare at the examiner's nose or forehead. The initial position of the patient on the examining table is upright and seated, close enough to the head of the table so that when the patient lies down, the head will be able to extend backward an additional 30 to 45 degrees. To test the right posterior semicircular canal, the head is initially rotated 30 to 45 degrees to the right. Keeping the head in this position, the patient is rapidly brought to the recumbent position until the head is 30 to 45 degrees below the level of the stretcher or examining table. A positive test is indicated by rotatory nystagmus following a latency of 1 to 5 s; the nystagmus exhibits rapid eye torsions toward the affected ear and lasts for 10 to 40 s. The patient is then returned to the upright sitting position, and the test is repeated on the left side. The side exhibiting the positive test is the side of the lesion.

Patients with suspected near-syncope should be tested for orthostatic hypotension. This maneuver is not definitive because orthostatic blood pressure measurements are notoriously unreliable, especially in elderly patients and even in patients with documented blood pressure changes. On cardiac examination, note the heart rate and rhythm, and evaluate the patient for evidence of valvular disease.

FIG. 231-3. Guideline approach to vertigo. MS = Multiple sclerosis; URI = Upper respiratory infection.

Ancillary Tests

Most patients with peripheral vertigo do not require emergent laboratory investigations. For suspected bacterial labyrinthitis, obtain a complete blood count (CBC) and blood cultures. Vertigo associated with a closed head injury warrants a computed tomographic (CT) scan or magnetic resonance imaging (MRI) to exclude intracranial bleeding. Patients with near-syncope should have an electrocardiogram (ECG) and cardiac monitoring as well as a CBC if anemia is suspected. Ambulatory Holter monitoring is indicated for suspected cardiac dysrhythmias. Emergent echocardiography generally is not indicated unless symptomatic valvular heart disease (such as aortic stenosis) or conditions causing compromised cardiac output are suspected. Electrolytes, glucose, and renal function tests are occasionally of value in patients with nonvertiginous dizziness, such as disequilibrium of aging. Outpatient thyroid testing may be of use if anxiety due to thyrotoxicosis is suspected.

Patients with suspected central vertigo may require more urgent investigations. If a cerebellar hemorrhage, infarction, or tumor is suspected, a CT scan or MRI should be obtained immediately. In the case

of suspected vertebral artery dissection, magnetic resonance angiography (MRA) may be superior to conventional angiography. Patients with suspected vertebrobasilar insufficiency (VBI) require an ECG, cardiac monitoring. Echocardiography is appropriate if cardiac emboli are suspected although this need not be performed in the ED. With VBI, it is sufficient to leave investigations such as duplex ultrasound of the carotids and MRI with MRA to the consulting neurologist. A psychiatric assessment for consideration of panic and/or mood disorders may be warranted in patients with persistent unexplained dizziness. In addition, patients with agoraphobia suggestive of space and motion discomfort (SMD) might warrant a full neurologic assessment. Detailed testing of cochleovestibular function can be left to the otologist or ear, nose, and throat (ENT) specialist.

SYMPTOMATIC TREATMENT

In general, short-term treatment with pharmacotherapy is the mainstay for patients with peripheral vertigo (Table 231-4). However, prolonged treatment with such medications may exacerbate symptoms in patients with nonvertiginous dizziness. Specific treatment varies somewhat with the etiology of peripheral vertigo.

Drug Therapy

The goals of pharmacotherapy are the reduction or elimination of vertigo, the enhancement or noncompromise of vestibular compensation, and the reduction of accompanying symptoms such as nausea, vomiting, and anxiety. Many of the agents used in the treatment of vertigo may suppress both vertigo and vestibular compensatory mechanisms. Drugs with anticholinergic effects can be quite effective in the treatment of vertigo. The current agent of choice is transdermal scopolamine.

TABLE 231-3 Temporal Patterns Seen in Vertigo

Pattern	Conditions
Seconds	BPPV,* postural hypotension
Minutes	TIAs†
Hours	Meniere disease
Days	Viral labyrinthitis
Constant	Nonspecific dizziness

*Benign paroxysmal positional vertigo.

†Transient ischemic attacks.

TABLE 231-4 Pharmacotherapy of Vertigo and Dizziness

Category	Drug	Dosage	Indications	Advantages	Disadvantages
Anticholinergics	Scopolamine	0.5 mg transdermal patch (behind ear) q3–4d	Vertigo, nausea	Useful if patient is vomiting	Sometimes difficult to obtain
Antihistamines	Dimenhydrinate	50-100 mg IM, IV, or PO q4h	Vertigo, nausea	Inexpensive	Drowsiness/anticholinergic effect
	Diphenhydramine	25-50 mg IM, IV, or PO q4h	Vertigo, nausea	Inexpensive	Drowsiness/anticholinergic effect
	Meclizine	mg PO q6-12h	Vertigo, nausea		Drowsiness/anticholinergic effect
Antiemetics	Hydroxyzine	25-50 mg PO q6h	Vertigo, nausea	Inexpensive	Drowsiness/anticholinergic effect
	Metoclopramide	10-20 mg PO q8h	Vertigo, nausea	Effective, versatile	Occasional extrapyramidal effect
	Promethazine	25 mg IM, PO, or PR q6-8h	Vertigo, nausea	Useful if vomiting	Occasional extrapyramidal effect
Benzodiazepines			Central vertigo, anxiety related to peripheral vertigo		Dependency, may impair vestibular compensation
	Diazepam	2-5 mg PO q6-12h	Central vertigo, anxiety related to peripheral vertigo	Inexpensive	Dependency, may impair vestibular compensation
	Clonazepam	0.5 mg PO q12h		Inexpensive	
Calcium antagonists	Cinnarizine	150 mg PO od	Peripheral vertigo, migraine	Nonsedating	Lesser clinical experience
	Nimodipine	30 mg PO tid	Peripheral vertigo	Nonsedating	Lesser clinical experience
	Flunarizine	20 mg PO tid	Meniere	Well tolerated	Not available in United States
Vasodilators	Betahistine	8-16 mg PO tid	Peripheral vertigo	Well tolerated	Little evidence of efficacy

Antihistamines are the most commonly prescribed drugs for the treatment of vertigo. Such agents possess anticholinergic effects. Some antihistamines such as astemizole (see Table 231-5) have antivertigo properties without appreciable anticholinergic effects, suggesting a unique central action. H₁ antihistamines are considered effective against vertigo, but H₂ antihistamines are not. Calcium channel blockers such as cinnarizine and nimodipine (see Table 231-5) have been shown to be useful in the treatment of peripheral vertigo. Calcium channel blockers are known to possess antihistaminic and antidopaminergic activity. They also may act by suppressing sensory input from the vestibular apparatus. Calcium channel blockers are indicated for the symptomatic relief of vertigo in patients not responding to scopolamine or antihistamines or for whom such drugs are contraindicated. Calcium channel blockers are also useful in managing vertigo in association with migraine headaches. Antidopaminergic (neuroleptic) agents such as promethazine and metoclopramide are indicated as second-line treatment for patients who fail to respond to transdermal scopolamine and antihistamines. They also have been shown to be effective in the treatment of vertigo. Such agents reduce neurovegetative symptoms such as nausea and vomiting by blocking dopaminergic receptors in the area postrema of the brainstem. They also possess antihistamine and anticholinergic effects. Prochlorperazine and chlorpromazine should not be used in the management of vertigo because they tend to cause excessive orthostatic hypotension, which can exacerbate symptoms. Ondansetron, a serotonin 5-HT₃ receptor antagonist, has not been shown to be effective in the management of nausea related to motion.^{5,6} Small doses of benzodiazepines such as diazepam and clonazepam may be used sparingly in the management of severe anxiety

accompanying vertigo. Benzodiazepines bind to "γ-aminobutyric acid (GABA) receptors in the brainstem, and thus may act centrally to suppress vestibular responses and to impair vestibular compensation.

There are several recognized complications of symptomatic therapy. Antihistamines can cause sedation and anticholinergic adverse effects. Antidopaminergic neuroleptic agents can induce or exacerbate orthostatic hypotension. These drugs also can cause somnolence and acute dystonia and can exacerbate anticholinergic adverse effects. Because of overlapping anticholinergic and antidopaminergic effects, anticholinergic, antihistaminic, and neuroleptic drugs should never be used in combination.

Patients with nonvertiginous dizziness and disequilibrium of aging should not be treated with antivertigo medication.

Vestibular Rehabilitation Exercises

Vestibular exercises are indicated for patients with BPPV, chronic vertigo, and psychiatric dizziness.⁷ They are relatively simple to teach and can be quite helpful in giving patients a measure of control over their own symptoms. The principle behind vestibular exercises is the fatiguing response observed with Dix-Hallpike testing. Exercises developed by Brandt and Daroff have been shown to be efficacious.⁸ Such exercises can be repeated by the patient at 3-hourly intervals at home.

DISORDERS CAUSING PERIPHERAL VERTIGO

Peripheral vertigo is noted for its abrupt (often explosive) onset. It is an intense sensation of spinning or hurtling toward the ground or surrounding walls. It is typically worsened by rapid movement and by changes in head position. It is frequently associated with nausea, often severe vomiting, diaphoresis, and bradycardia and hypotension.

Benign Paroxysmal Positional Vertigo

BPPV is a frequent diagnosis for patients presenting to dizziness clinics. The incidence of BPPV is conservatively estimated at 64 patients per 100,000 per year.⁹ BPPV is defined as a mechanical disorder of the inner ear causing transient vertigo (with autonomic symptoms) and associated nystagmus that is precipitated by certain head movements. The condition was described first by Barany in 1921; most of the essential clinical features were described by Dix and Hallpike in 1952.¹⁰

TABLE 231-5 Supportive Findings in Benign Paroxysmal Positional Vertigo

Latency period of 1-5 s between the provocative head position and onset of nystagmus.
The intensity of nystagmus increases to a peak before slowly resolving. Duration of vertigo and nystagmus ranges from 5-10 s. If nystagmus is produced in one direction by placing the head down, then the nystagmus reverses direction when the head is returned to the sitting position. Repeated head positioning causes both the vertigo and accompanying nystagmus to fatigue and subside.

The most widely accepted hypothesis to explain BPPV is known as *canalolithiasis*. According to this hypothesis, BPPV is caused by inappropriate activation of the posterior semicircular canal (typically unilateral) by the presence of free-floating particles or otoconia. The otoconia become displaced from the utricular macula by aging, head trauma, or labyrinthine disease. Because the particles are heavier than the surrounding endolymph, they tend to collect in the long arm of the posterior semicircular canal, the most dependent part of the endolymph system. Once the particles clump in sufficient mass, changes in head position cause gravitation of the particles, which creates a hydrodynamic drag (or plunger effect) on the endolymph, causing the cupula to be displaced. This results in inadvertent neural firing, causing both vertigo and nystagmus.

BPPV can occur at any age, but the average age of onset is in the midfifties. Women are twice as likely to be affected as men. The onset is sudden, and an attack typically is precipitated by rolling over in bed, assuming a supine position, leaning forward, looking up at the sky or ceiling, or turning the head. Nausea is often present. Because the symptoms fatigue, they tend to be worse in the morning and become less pronounced as the day progresses. Patients may eliminate the offending activities. There is no associated hearing loss or tinnitus and no physical findings on examination of the external auditory canal.

Several findings support a diagnosis of BPPV (Table 231-5). There is a latency period of 1 to 5 s between assuming the offending head position and onset of vertigo and nystagmus. Both the vertigo and nystagmus crescendo to a peak of intensity and then subside within 5 to 40 s. BPPV is diagnosed using the Dix-Hallpike position test described earlier.¹⁰ The response to repeated provocative testing fatigues, causing the vertigo and nystagmus to disappear.¹¹

Some patients with BPPV have a negative Dix-Hallpike test. Instead, they have anterior semicircular canalolithiasis and may exhibit positional down-beating nystagmus when the head is lowered as described earlier but not turned to one side or the other (the so-called straight head-hanging maneuver).¹²

The treatment of BPPV includes the use of transdermal scopolamine as well as antihistamines. In addition, the particle-repositioning maneuver (or Epley maneuver) may be attempted by emergency physicians, but few have any experience with this, and the diagnosis is rarely established conclusively in the emergency department. The principle behind the particle-repositioning maneuver is to use gravity to induce the particles to move along the semicircular canals until they end up inside the utricle, where they are unlikely to cause vertigo. The maneuver is indicated in patients who have a history suggestive of BPPV plus a positive Dix-Hallpike position test. The affected ear is determined by the side on which the Dix-Hallpike position test is positive. An antihistamine or antiemetic should be administered prior to the maneuver for the patient's comfort. The patient is seated as in the Dix-Hallpike position test, and the head is turned 45 degrees toward the affected ear. The patient is gently brought to the recumbent position with the head hanging 30 to 45 degrees below the examining table. The head is gently rotated 45 degrees to the midline. The head is then rotated a further 45 degrees to the unaffected side. The patient rolls onto the shoulder of the unaffected side, at the same time rotating the head a further 45 degrees. The patient is returned to the sitting position, and the head is returned to the midline.

Each portion of the maneuver should be done slowly (about 5 min) and evenly to permit the particles to traverse their intended course. If the maneuver is done correctly, nystagmus in the same direction as that observed during Dix-Hallpike position testing may be observed. If nystagmus in the opposite direction is observed, then the particles have moved back toward the cupula; this portends an unsuccessful maneuver. The maneuver is repeated several times until both the vertigo and the accompanying nystagmus have disappeared. A Cochrane Review concluded that the Epley maneuver is a safe and effective treatment for posterior canal BPPV. However, there is no good evidence to conclude that the maneuver provides long-term resolution of symptoms.¹³

Adverse effects include light-headedness and exacerbation of vertigo (caused by backsliding of the particles). The Epley maneuver should not be performed on patients with cervical spondylosis or back pain that might be exacerbated.

Most episodes of BPPV resolve spontaneously after a few days. Patients with persistent symptoms should be referred to an otolaryngologist.

Meniere Disease

Meniere disease is a disorder associated with an increased endolymph within the cochlea and labyrinth. It occurs equally in men and women. The first attack of Meniere disease usually occurs in patients aged 65 years and older. Rarely, the disease may begin in childhood. The disease is usually unilateral initially but often becomes bilateral over time. The precise pathogenesis is unknown, but evidence suggests that patients have difficulty regulating the volume, flow, and composition of endolymph. Histologic studies have demonstrated that the endolymphatic sac contains immunologically active tissue, raising the possibility of an autoimmune mechanism. As with BPPV, the onset of vertigo is usually sudden. However, the duration of vertigo ranges from 20 min to 12 h (typically 2 to 8 h). It is associated with nausea, vomiting, and diaphoresis. The frequency of attacks can vary from several times per week to several times per month. Other associated symptoms include roaring tinnitus, diminished hearing, and fullness in one ear. Between attacks, the patient is usually well, although deafness may persist. Increasingly, the diagnosis of Meniere disease is confirmed by the introduction of glycerol, an osmotic agent, into the inner ear. A positive glycerol test is heralded by temporary improvement in postural control as well as a decrease in vertigo.¹⁴

Patients with Meniere disease usually are managed by an otolaryngologist. Meniere disease is managed symptomatically with antihistamines as well as with a combination of the diuretics triamterene and hydrochlorothiazide (the latter two drugs are used in confirmed cases only). Flunarizine, a calcium channel blocker (not available in the United States at the time of this writing) is second-line treatment in the management of vertigo associated with Meniere disease (see Table 231-4). Betahistine, a structural analogue of histamine, has been used widely in Europe for the treatment of vertigo due to Meniere disease. Betahistine is believed to act by reducing the asymmetrical functioning of sensory vestibular organs as well as by increasing vestibulocochlear blood flow. The dosage of betahistine is 8 to 16 mg PO three times daily. None of these drug treatments improves hearing. A salt-restricted diet (<1 g/d of added salt) is recommended for patients with a confirmed diagnosis. Intratympanic steroid injections, as well as transtympanic gentamicin administered via round-window microcatheter, also can offer significant relief to symptomatic patients.

Perilymph Fistula

A perilymph fistula is an opening in the round or oval window that permits pneumatic changes in the middle ear to be transmitted to the vestibular apparatus. Trauma, infection, or a sudden change in the pressure inside the ventricular system may cause the tear. The diagnosis is suggested by the sudden onset of vertigo associated with flying, scuba diving, severe straining, heavy lifting, coughing, or sneezing. Associated symptoms may include hearing loss. The diagnosis is confirmed by nystagmus elicited by pneumatic otoscopy (Hennebert sign). Hearing loss is confirmed by audiology testing.

Perilymph fistula is managed with symptomatic treatment and bed rest, with referral to an ENT specialist for surgical repair. Fistulas associated with hearing loss of less than 14 days' duration may benefit from rapid surgical intervention.

Vestibular Neuronitis

Vestibular neuronitis is a disorder of suspected viral etiology. Unlike BPPV and Meniere disease, vestibular neuronitis typically lasts several

days and does not recur. The onset is usually sudden, and the patient is otherwise well except for possible symptoms of a viral illness. The vertigo is often so intense that the patient requires several days of bed rest; symptoms usually decrease dramatically, with complete resolution over several weeks. Elderly patients may have persistent unsteadiness of gait. Unilateral loss of hearing and tinnitus may occur. Up to one-third of patients have positional nystagmus.

Vestibular neuronitis is treated symptomatically. Antihistamines and antiemetic drugs should be used at the outset and withdrawn after several days, if possible.

Vestibular Ganglionitis

This disorder is believed to be caused by a neurotrophic virus such as varicella zoster that can be reactivated years following an initial infection. Typical histopathologic changes associated with a viral inflammatory process have been identified in the vestibular ganglion. This disorder may be mistaken for more commonly diagnosed conditions such as BPPV and Meniere disease. Multiple ganglia may be involved. Herpes zoster oticus, also known as the Ramsay Hunt syndrome, is a neuropathic disorder thought to be associated with vestibular ganglionitis. It is characterized by deafness, vertigo, and facial nerve palsy. The diagnosis is confirmed by the presence of grouped vesicles on an erythematous base inside the external auditory canal. Patients with this disorder are managed with a combination of symptomatic treatment and antiviral therapy (if diagnosed within 72 h of the appearance of vesicles).

Labyrinthitis

Labyrinthitis is an infection of the labyrinth that produces peripheral vertigo associated with hearing loss. The infection may be viral, in which case the clinical course is similar to that of vestibular neuronitis. Cases reportedly have been associated with measles and mumps. Bacteria also may cause labyrinthitis. Although unusual, an infection within the labyrinth can develop from otitis media, in which bacteria and toxins diffuse across the membrane of the round window. A cholesteatoma can erode into the inner ear, creating a portal of entry for bacteria. Other possible antecedents for bacterial labyrinthitis include otitis media with fistula, meningitis, mastoiditis, and dermoid tumor. The hallmarks of this disease include sudden onset of vertigo with associated hearing loss and middle ear findings. Serous labyrinthitis occasionally may produce vertigo.

Patients with bacterial labyrinthitis may benefit from symptomatic treatment but also require antibiotics (see Chap. 235) and referral to an otologist or ENT specialist for likely admission and possible surgical drainage.

Ototoxicity

Aminoglycoside antibiotics produce hearing loss and peripheral vestibular dysfunction by accumulating inside the endolymph, where they cause the death of cochlear and vestibular hair cells. However, since both inner ears are affected, vertigo is uncommon. Typical clinical manifestations include ataxia and oscillopsia, which is defined as an inability to maintain visual fixation while moving. The damage is irreversible but is dose- and duration-dependent. Loop diuretics (furosemide and ethacrynic acid) also cause irreversible vestibular and ototoxicity. Cytotoxic agents associated with vestibular damage include vinblastine and cisplatin. Recent evidence suggests that the topical administration of D-methionine to the round window membrane may protect against the ototoxic effects of cisplatin. Newer platinum compounds such as carboplatin have been shown to induce less ototoxicity than cisplatin. The antiarrhythmic drug quinidine and antimalarial drugs derived from quinine, such as chloroquine and mefloquine, also can cause vestibular symptoms that may be irreversible (Table 231-6). In

TABLE 231-6 Ototoxic and Vestibulotoxic Agents

Agent	Dose Dependent	Reversible
Aminoglycosides	Yes	No
Erythromycin	No	Yes
Minocycline	No	Yes
Fluoroquinolones	No	Yes
NSAIDs, salicylates	Yes	Yes
Loop diuretics	No	Can be irreversible
Cytostatic drugs	Yes	No
Antimalarials	No	Yes

one study, 96 percent of healthy adults had vertigo while taking mefloquine. However, the symptoms resolved within 3 weeks of cessation of therapy in 77.3 percent of patients.¹⁵

Reversible causes of vestibular damage and ototoxicity include NSAIDs, salicylates, minocycline, erythromycin, and some fluoroquinolones. Tinnitus as well as alterations in the perception of sounds have long been known to be associated with salicylate ingestion. There have also been rare case reports of sudden hearing loss associated with the use of NSAIDs including ketorolac, naproxen, and piroxicam. In the cases of naproxen as well as piroxicam, tinnitus has been associated with hearing loss.^{1,18} Isolated cases of unsteady gait have been observed with antiviral drugs such as abacavir, as well as antiparasitic agents.

Numerous solvents and other chemicals can cause both peripheral and central vestibular symptoms. These include propylene glycol, mercury, and hydrocarbons. Drugs that sometimes induce a central vestibular syndrome include anticonvulsants, tricyclic antidepressants, neuroleptics, opiates, and alcohol.¹⁹ Phencyclidine is a recreational drug that causes central vestibular symptoms, including nystagmus and ataxia. Drugs causing irreversible cerebellar toxicity include phenytoin and toluene, as well as cancer chemotherapeutic agents. In general, most patients adapt to vertigo that is chronic by relying on increased sensory input from unaffected modalities such as proprioception and vision. However, certain drugs that are used as antivertigo therapy may exacerbate preexisting chronic vertigo by delaying or inhibiting such compensation. These drugs include alcohol, benzodiazepines, barbiturates, and neuroleptics. Thus, with chronic vertigo, antivertigo therapy should not be used on a long-term basis. Patients with suspected ototoxicity should be referred to an otolaryngologist.

Eighth-Nerve Lesions

Lesions of the eighth cranial nerve may produce mild vertigo. Meningiomas and acoustic schwannomas are typical causes. The onset of vertigo is usually gradual, remaining constant until central compensation can take place. The vertigo is usually preceded by hearing loss. Such patients require urgent diagnostic imaging as well as referral to a neurosurgeon.

Cerebellopontine Angle Tumors

Vertigo is sometimes associated with tumors of the cerebellopontine angle. Such tumors include acoustic neuromas, meningiomas, and dermoids. They usually present with a cluster of findings including deafness and ataxia as well as ipsilateral facial weakness, loss of the corneal reflex, and cerebellar signs. Such patients require urgent diagnostic imaging as well as referral to a neurosurgeon.

Posttraumatic Vertigo

Vertigo and gait unsteadiness are common complaints following a head injury. Acute posttraumatic vertigo is caused by a direct injury to

the labyrinthine membranes. The onset of vertigo is immediate and is accompanied by nausea and vomiting. Such patients may have sustained a concomitant fracture of the temporal bone. Vertigo associated with a closed head injury warrants a CT scan or MRI to exclude an extradural or intradural hematoma. Vertigo due to direct labyrinthine trauma tends to resolve within several weeks. Closed head trauma also can displace otoconia from the utricular maculae, precipitating an attack of BPPV. Some patients with a history of a closed head injury develop a postconcussive syndrome that can be associated with unsteadiness of gait and a vague sense of dizziness. Patients with this condition usually are treated symptomatically. Those who fail to improve usually are referred to a neurologist or neurosurgeon.

Vertigo Following Cochlear Implantation

As many as three-quarters of adults who undergo cochlear implantation experience vertigo postoperatively. Such patients generally respond to symptomatic therapy as well as vestibular rehabilitation exercises.²⁰

DISORDERS CAUSING CENTRAL VERTIGO

Central vertigo is caused by disorders affecting the cerebellum and the brainstem. Central vertigo is gradual in onset and mild in intensity; the symptoms are not provoked by changes in position. Central vertigo is unlikely to be associated with nausea, vomiting, or diaphoresis. Unlike conditions causing peripheral vertigo, both tinnitus and hearing impairment are unlikely. Nystagmus is more likely to be vertical than horizontal or rotatory and may be present in the absence of vertigo. However, a finding of vertical nystagmus does not necessarily imply a central etiology unless accompanied by signs of brainstem disease, such as ataxia, blurred vision, long tract signs, dysphagia, dysarthria, and diplopia.

Cerebellar Hemorrhage and Infarction

Cerebellar hemorrhage typically causes symptoms such as acute vertigo and ataxia. Headache, nausea, and vomiting may or may not be present. Instead of intense vertigo, patients tend to complain of a sense of side-to-side or front-to-back motion. Patients may have truncal ataxia and may not be able to sit without support. Romberg testing and tandem gait will be abnormal. Occasionally, there may be a sixth cranial nerve palsy or conjugate eye deviation away from the side with the hemorrhage. Cerebellar infarction has a similar clinical presentation. When suspected, both conditions require urgent diagnostic imaging as well as referral to a neurosurgeon or neurologist as appropriate.

Wallenberg Syndrome

A lateral medullary infarction (Wallenberg syndrome) of the brainstem can cause vertigo as part of its clinical presentation. Classic ipsilateral findings include facial numbness, loss of corneal reflex, Horner syndrome, and paralysis or paresis of the soft palate, pharynx, and larynx (causing dysphagia and dysphonia). Contralateral findings include loss of pain and temperature sensation in the trunk and limbs. Occasionally, lesions of the sixth, seventh, and eighth cranial nerves can occur, causing vertigo, nausea, vomiting, and nystagmus. Such patients usually require urgent diagnostic imaging and referral to a neurologist.

Vertebrobasilar Insufficiency

Transient ischemic attacks (TIAs) of the brainstem due to vertebrobasilar insufficiency (VBI) can produce vertigo. Such patients have typical risk factors for cerebrovascular disease. Orthostatic signs should be determined, as orthostasis can worsen symptoms of VBI. As

with TIAs in general, the vertigo may be of sudden onset and typically lasts from minutes to hours. By definition, the episode should resolve completely within 24 h. VBI-induced vertigo can present by itself or be accompanied by diplopia, dysphagia, dysarthria, bilateral long-tract signs, and bilateral loss of vision. **Unlike other causes of central vertigo, VBI may be provoked by position.** Turning the head partially occludes the ipsilateral vertebral artery. If the contralateral artery is stenotic, head turning could cause transient ischemia to the brainstem, resulting in VBI. A sufficient loss of brainstem circulation caused by a head turn could affect the reticular activating system, causing near-syncope or syncope. Patients with VBI should have diagnostic imaging in the emergency department, as well as referral to a neurologist for investigation and treatment of TIAs.

Vertebral Artery Dissection

Vertebral artery dissection can lead to strokes involving the posterior circulation. Symptoms of vertebral artery dissection include headache, vertigo, and a unilateral Horner syndrome. Sudden (and often violent) rotation or extension of the neck may precipitate a dissection of the vertebral artery in susceptible patients. Such injuries reportedly have occurred following high-velocity motor vehicle accidents, diving injuries, coughing, sneezing, and chiropractic neck adjustments.²¹ Such patients require urgent diagnostic imaging plus referral to a neurosurgeon.

Multiple Sclerosis

Demyelinating disease can present with vertigo that tends to last several hours to several days or weeks and is usually nonrecurrent. The vertigo is not usually intense; the nystagmus is often more prominent than the vertigo reported by the patient. Ataxia or optic neuritis may be present or may have occurred previously. The diagnosis usually is made using MRI as well as vestibular evoked myogenic potentials. Patients with vertigo due to demyelination require urgent referral to a neurologist.

Neoplasms

Neoplasms of the fourth ventricle can cause brainstem signs and symptoms, including vertigo. Such tumors include ependymomas in younger patients and metastases in older patients. Obviously, these patients require diagnostic imaging while in the emergency department and should be referred to a neurosurgeon.

Migraine-Related Dizziness and Vertigo

Vertigo can be a symptom of an aura, an analogue or equivalent of the headache phase itself, or as an associated symptom with the migraine prodrome. Basilar migraine is a migraine headache in which the aura is associated with clinical manifestations similar to those of VBI. The etiology of migraine-related vertigo remains somewhat unclear. The International Headache Society's diagnostic criteria for basilar migraine²² are shown in Table 231-7. Vertigo as an aura should develop over 5 to 20 min and should subside within 60 min. Vertigo as a symptom of a migraine aura may precede the headache or may occur in the absence of a headache.

A strong association has been found between migraine and cochleovestibular disturbances. Such patients may complain of episodes of constant vertigo, positional vertigo, or nonvertiginous dizziness. In cases of true vertigo, the vertigo may accompany the headache or may occur independently. Some patients complain of vertigo lasting from several minutes to 2 h, whereas others experience vertigo lasting longer than 24 h. The diagnostic criteria for migraine-related vertigo include a history of vertigo not attributable to other known conditions and a present or past history of migraine or a strong

TABLE 231-7 Diagnostic Criteria for Basilar Migraine*

Bilateral visual symptoms in both the nasal and temporal fields
Vertigo
Tinnitus
Decreased hearing
Diplopia
Dysarthria
Ataxia
Bilateral paresis
Bilateral paresthesias
Decreased level of consciousness

family history. Often it is difficult to distinguish vertigo associated with migraine and vertigo associated with Meniere disease. Frequently, patients who fail to respond to therapy specific for Meniere disease may benefit from therapy for vertigo associated with migraine headaches.

Patients with vertiginous migraine headaches are managed symptomatically with antivertigo therapy; migraine prophylactic agents such as (3-blockers and calcium channel antagonists may be instituted as well (see Chap. 227). Patients with migraine-related vertigo and dizziness can be managed symptomatically. However, ergotamine preparations or sumatriptan should not be used in basilar migraine. They should be referred to a neurologist for definitive management.

OTHER CONDITIONS

Disequilibrium of Aging

Disequilibrium of aging is a condition manifesting as ill-defined dizziness and gait unsteadiness. It is associated with age-related loss of hearing, balance, proprioceptive input, and vision. Other factors include a decline in central integration and processing, as well as a decrease in motor responses. Approximately 50 percent of individuals over the age of 70 experience imbalance and frequent falls. Symptoms may be precipitated or exacerbated by diminished ambient light (with worsening of symptoms at night), unfamiliar surroundings, and the use of benzodiazepines and drugs with anticholinergic effects such as tricyclic antidepressants and neuroleptic agents. Such patients should be referred to an internist or gerontologist.

Near-Syncope

Near-syncope is a feeling of light-headedness that, in its most severe form, leads to loss of consciousness (syncope). The most common categories of near-syncope include vasovagal, situational, and orthostatic hypotension; drug-induced syncope; and cardiac causes (cardiac dysrhythmias and valvular heart disease). The cause of near-syncope is not determined in a significant percentage of patients. Recent evidence suggests that most patients with unexplained presyncope may have subclinical vasovagal presyncope. Positive upright tilt testing, in which the patient is placed in the passive upright position at 60 degrees for 45 min, generally is recommended. The end points of a positive tilt test include the development of syncope or presyncope associated with hypotension, bradycardia, or both. In normal subjects, tachycardia usually results from a passive tilt test.²³

Syncope and near-syncope in the elderly may be associated with micturition, defecation, postural changes, meals, laughing, coughing, and swallowing. Orthostatic hypotension is extremely common in the elderly and is associated with volume depletion, venous insufficiency, poor conditioning, polyneuropathy, preganglionic autonomic dysfunction (Shy-Drager syndrome), and the use of such medications as va-

sodilating drugs, diuretics, other antihypertensive agents, and antiparkinsonian and anticholinergic medications; polypharmacy is a relatively common factor.

Orthostatic tachycardia syndrome is a relatively mild disorder associated with a fall in blood pressure in which patients experience near-syncope, nonvertiginous dizziness, and symptoms suggestive of a TIA. The pathogenesis is thought to be mild autonomic dysfunction. Findings on tilt testing include an increase in heart rate of 30 beats/min over baseline within the first 10 min of testing (unassociated with profound hypotension) along with recurrence of the symptom complex.²⁴ Unless debilitated, such patients should be referred to a cardiologist, internist, or gerontologist for outpatient management.

Convulsive Disorders

Nonconvulsive status epilepticus (NCSE) is characterized by altered mental status without loss of consciousness or tonic-clonic phenomena yet associated with electroencephalographic (EEG) evidence of seizure activity. Some patients with NCSE may complain of nonvertiginous dizziness. Symptoms may last for hours to days. The diagnosis is made by electroencephalography as well as by determining the underlying mechanism for the seizure. Patients with suspected convulsive disorders should be treated symptomatically while in the emergency department and referred to a neurologist for further assessment.

Hyperventilation Syndrome

Patients with primary hyperventilation may experience nonvertiginous dizziness or near-syncope during an episode. Such symptoms usually can be reproduced by asking the patient to hyperventilate. Such patients are managed by the emergency physician.

Psychiatric Dizziness

Psychiatric dizziness is dizziness that presents as part of a recognized psychiatric disorder or symptom complex that is not related to known vestibular disorders. Dizziness is the second most common symptom reported by patients with panic disorder.²⁵ In the emergency setting, a diagnosis of psychiatric dizziness should only be made when the evidence is overwhelming and when other more serious causes of dizziness have been ruled out.

DISPOSITION

In general, patients with peripheral vertigo may be discharged from the emergency department, once symptoms are controlled. All patients with a first episode of peripheral vertigo should be referred to their primary care physician or an otolaryngologist for further testing. Patients with BPPV who have had a particle-repositioning maneuver should be referred to an otologist or ENT specialist for follow-up.

Patients with suspected central causes of their vertigo almost always require urgent diagnostic imaging and neurologic or neurosurgical consultation while in the emergency department. Patients in whom less urgent causes of central vertigo remain within the differential diagnosis (such as multiple sclerosis and migraine headache) may be referred for neurologic consultation on an outpatient basis. Patients with near-syncope should be referred on an outpatient basis to a cardiologist for tilt testing, an echocardiogram, and Holter monitoring. Elderly patients should be referred for admission to a cardiologist if they have symptomatic coronary artery or valvular disease, exhibit a potentially life-threatening dysrhythmia, or have a past history of syncopal episodes.

Outpatient psychiatric consultation may be considered for patients with dizziness not related to vestibular dysfunction that occurs exclusively in combination with other symptoms as part of a recognized psychiatric symptom cluster or for patients in whom dizziness appears to be amplified by psychogenic overlay.

tic" electroencephalographic (EEG) discharges may not experience any overt clinical symptoms. Conversely, some seizure-like clinical episodes may be due to causes other than abnormal brain electrical activity; such attacks, however impressive, are not true seizures (see below).

Epilepsy is a clinical condition in which an individual is subject to recurrent seizures; it implies a more or less fixed condition of the brain responsible for the seizures. Ordinarily, the term *epileptic* is not used to refer to an individual with recurrent seizures caused by reversible conditions such as alcohol withdrawal, hypoglycemia, or other metabolic derangements.

Seizures referred to as *primary* or *idiopathic* occur in patients who are otherwise normal and in whom no evident cause for the attacks can be discerned. Seizures that occur as a consequence of some other identifiable neurologic condition, such as a mass lesion, are referred to as *secondary* or *symptomatic*. Any individual can have a seizure under appropriate conditions. Electrical stimulation of the brain, convulsant potentiating drugs, profound metabolic disturbances, or a sharp blow to the head may induce seizures (termed *reactive seizures*) in otherwise normal individuals. Such attacks are generally self-limited, and such persons are not considered to have a seizure disorder or epilepsy.

There are approximately 100,000 new cases diagnosed in the United States each year. An estimated 6 to 10 percent of individuals will experience at least one seizure during their lives, and 1 to 2 percent of persons are subject to recurrent seizures. Hauser and Hesdorfer¹ from the Epilepsy Foundation of America analyzed reports of incidence and prevalence of seizures and epilepsy worldwide and deduced an overall age-adjusted incidence of 30.9 to 56.8 per 100,000. Incidence rates are highest among people less than 20 years old, with a second peak in incidence in those older than 60 years, reflecting a difference in seizure etiology between these two groups. There is a slightly higher male predominance (estimated 1.1 to 1.7 greater incidence).

The mechanisms involved in generating clinical seizures appear to be multifactorial, requiring intense and prolonged neuronal electrical discharges, and failure or inhibition of normal protective mechanisms. Scars from previous insults, such as penetrating head trauma or stroke, can act as epileptogenic foci. Factors such as medical noncompliance, fever, sleep deprivation, convulsant drugs, alcohol withdrawal, and infection can lower the seizure threshold.

SEIZURE CLASSIFICATION

Many attempts have been made to provide a clinically useful classification of seizure types, both to facilitate communication among physicians and to provide a basis for treatment decisions. Formerly, seizures were identified using the terms grand mal, petit mal, and psychomotor. The International League Against Epilepsy² recommends dividing seizures into two major groups: *generalized seizures* and *partial seizures* (Table 232-1). When there is inadequate data to categorize the seizure, the seizure is considered *unclassified*.

TABLE 232-1 Classification of Seizures

Generalized seizures (consciousness always lost)
Tonic-clonic seizures (grand mal)
Absence seizures (petit mal)
Myoclonic seizures
Tonic seizures
Clonic seizures
Atonic seizures Partial
(focal) seizures
Simple partial (no alteration of consciousness)
Complex partial (consciousness impaired)
Partial seizures (simple or complex) with secondary generalization
Unclassified (due to inadequate information)

SEIZURES AND STATUS EPILEPTICUS IN ADULTS

Christina L. Catlett

INTRODUCTION

A seizure is an episode of abnormal neurologic function caused by an inappropriate electrical discharge of brain neurons. The seizure is the clinical attack experienced by the patient; some patients with "epilep-

Generalized Seizures

Generalized seizures are thought to be caused by a nearly simultaneous activation of the entire cerebral cortex, perhaps caused by an electrical discharge originating deep in the brain and spreading outward. The attacks begin with abrupt loss of consciousness. This may be the only clinical manifestation (as in absence attacks), or there may be a variety of motor manifestations (myoclonic jerks, tonic posturing, clonic jerking of the body and extremities, etc.).

Generalized tonic-clonic seizures (grand mal) are the most familiar and dramatic of the generalized seizures. They begin with abrupt loss of consciousness; there is usually no warning or aura. In a typical attack, the patient suddenly becomes rigid, trunk and extremities are extended, and the patient falls to the ground. Patients are often apneic during this period and may be deeply cyanotic. They often urinate and may vomit. As the rigid (tonic) phase subsides, there is increasing coarse trembling that evolves into a symmetrical rhythmic (clonic) jerking of the trunk and extremities. As the attack ends, the patient is left flaccid and unconscious, often with deep, rapid breathing. Typical attacks last from 60 to 90 s (occasionally longer). Bystanders generally overestimate the duration of the seizure. Consciousness returns gradually, and postictal confusion and fatigue may persist for several hours or longer.

Absence seizures (petit mal) are very brief, generally lasting only a few seconds. The patients suddenly lose consciousness without losing postural tone. They appear confused, detached, or withdrawn, and current activity ceases. They may stare and have twitching of their eyelids. They do not respond to voice or to other stimulation, exhibit voluntary movements, or lose continence. The attack ceases abruptly, and the patients are able to resume their previous activity with no postictal symptoms. Both the patients and witnesses may be unaware that anything has happened. Classic absence seizures are limited to school-aged children and are often attributed by parents and teachers to daydreaming or not paying attention. The attacks may be very frequent, sometimes occurring 100 or more times daily, and may result in poor school performance. Petit mal attacks may occur alone or in association with other kinds of seizures. They usually resolve as the child matures. Similar attacks in adults are more likely to be minor complex partial seizures and should not be called absence. The distinction is important, because the causes and treatment of the two seizures are quite different.

There are four less-common seizure classifications with which the clinician should be familiar. *Myoclonic seizures* are characterized by brief, shock-like muscular contractions that may be generalized or limited to one or more extremities. *Clonic seizures* involve repetitive clonic jerks without the tonic element. *Tonic seizures* have a prolonged, strained contraction of the body with deviation of the head and eyes. The patient becomes pale, flushed, then cyanotic, and the body may rotate around in position. *Atonic seizures* are characterized by a sudden loss of postural tone in the head, trunk, and/or limbs, which may be associated with a brief loss of consciousness.

Partial (Focal) Seizures

Partial seizures are due to electrical discharges, which begin in a localized region of the cerebral cortex; the discharge may remain localized or may spread to involve nearby cortical regions or the entire cortex. Focal seizures are generally thought to be *secondary* seizures, their occurrence implying a localized structural lesion of the brain.

In *simple partial focal seizures*, the seizure remains localized, and consciousness and mentation are not affected. It is possible to deduce the likely location of the initial cortical discharge from the clinical features at the onset of the attack. Unilateral tonic or clonic movements, often limited to one extremity, suggest a focus in the motor cortex, while tonic deviation of the head and eyes suggests a frontal lobe focus. Sensory hallucinations (e.g., paresthesias or numbness) suggest a

discharge in the sensory cortex. Visual symptoms, especially flashing lights or distortions of vision, suggest an occipital focus. Bizarre olfactory or gustatory hallucinations suggest a focus in the medial temporal lobe. Such sensory phenomena, known as *auras*, are often the initial symptoms of attacks that then become more widespread, and that are termed *secondary generalization*.

Complex partial seizures are focal seizures in which consciousness and/or mentation are affected. They are often caused by a focal discharge originating in the temporal lobe and are sometimes referred to as *temporal lobe seizures*. Because of their alterations of thinking and behavior, they are occasionally called *psychomotor seizures*. As such seizures may originate from brain regions other than the temporal lobes, and to avoid any confusion with psychiatric illness, the term complex partial seizures is preferred. Often thought to be rare, they are in fact quite common.

Because of their frequently bizarre symptoms, complex partial seizures are commonly misdiagnosed as psychiatric problems. Their symptoms may include automatisms, visceral symptoms, hallucinations, memory disturbances, distorted perception, and affective disorders. Automatisms are typically simple, repetitive, purposeless movements such as lip smacking, fiddling with clothing or buttons, or repeating short phrases. More complex behaviors may occur, but well-organized, purposeful activity is unlikely. Visceral symptoms often consist of a sensation of "butterflies" rising up from the epigastrium. Hallucinations may be olfactory, gustatory, visual, or auditory. There may be complex distortions of visual perception, time, and memory. Affective symptoms may include intense sensations of fear, paranoia, depression, or rarely, elation or ecstasy.

As noted, a focal seizure discharge may spread to involve both hemispheres, mimicking a typical generalized seizure. This is termed *secondary generalization*. For the purpose of classification, diagnosis, and treatment, such attacks are regarded as focal seizures. In some patients, the discharge may spread so rapidly that no focal symptoms are evident, and the correct diagnosis may depend on demonstration of the focal discharge on an EEG recording.

CLINICAL EVALUATION OF SEIZURE PATIENTS

History

When a patient presents after an event, the first step is to determine whether the attack was truly a seizure. A careful history of the details of the attack should be obtained from the patient, if possible, and from any bystanders who actually witnessed the attack. Only a physical description of the attack should be sought as witnesses, even physicians, may mislabel the activity and mistake nonseizure activity as a seizure.

Important avenues of inquiry include preceding aura, abrupt or gradual onset, progression of motor activity, loss of bowel or bladder control, and whether the activity was local or generalized, symmetrical or not. Finally, the duration of the attack and any postictal confusion or lethargy should be sought. The patient should be asked whether he or she has any recollection of the attack.

Next, the clinical context in which the attack occurred should be determined. If the patient is a known epileptic, the baseline seizure pattern should be established. In patients presenting with an attack consistent with their previously documented seizures, the history should be directed toward factors that may have precipitated epileptic activity. Missed doses of antiepileptics or recent alterations in medication, including dosage change or conversion from brand name to generic formulation, may be the inciting element. Other possible factors that might provoke a seizure include sleep deprivation, alcohol withdrawal, infection, electrolyte disturbances, and use or cessation of other drugs.

If there is no previous history of seizures, a more detailed inquiry is needed. Symptoms that might suggest previous unwitnessed or unrecognized seizures, such as blank or staring spells in school, involun-

tary movements, unexplained injuries, nocturnal tongue biting, and enuresis may be clues to a more longstanding problem. A history of recent or remote head injury should be sought. Persistent, severe, or sudden headache should prompt a search for intracranial pathology. Concurrent pregnancy or recent delivery suggests the possibility of eclampsia. A history of metabolic derangements or electrolyte abnormalities, hypoxia, systemic illness (especially cancer), coagulopathy or anticoagulation, drug ingestion or withdrawal (licit and illicit), and alcohol use may help identify factors that predispose patients to seizures (Table 232-2).

Physical Examination

The general physical examination should be directed toward discovering any injuries, especially to the head or spine, that might have resulted from the seizure. Seizures may cause injuries such as fractures, sprains, and bruises; posterior dislocations of the shoulder can occur and may be overlooked. Tongue lacerations and pulmonary aspiration are frequent sequelae. A search for any systemic illness or derangements (see Table 232-2) that may have caused the attack should be undertaken. Temperature should be noted, and a bedside glucose determination should be obtained.

A directed neurologic examination should be performed with subsequent serial examinations as appropriate. Level of consciousness and mentation should be followed closely. Profound obtundation that improves steadily is likely benign. Progressive deterioration is not an expected sequela of any benign process and requires prompt intervention. Signs of increased intracranial pressure should be sought. Any focal neurologic deficit should be noted. A transient focal deficit (usually unilateral) following a simple or complex focal seizure is referred to as *Todd paralysis*, and should resolve within 48 h. If the patient's symptoms cannot be readily attributed to a benign cause, further urgent evaluation (see below) is warranted.

Differential Diagnosis

Many episodic disturbances of neurologic function may be mistaken for seizures (Table 232-3). A complete review of these conditions is too lengthy for inclusion here, but several of the more important entities should be mentioned. Of these, syncope is clearly of the highest order for consideration.

TABLE 232-2 Causes of Secondary Seizures

Trauma (recent or remote)
Intracranial hemorrhage (subdural, epidural, subarachnoid, intraparenchymal)
Structural abnormalities
Vascular lesion (aneurysm, arteriovenous malformation)
Mass lesions (primary or metastatic neoplasms)
Degenerative diseases
Congenital abnormalities
Infection (meningitis, encephalitis, abscess)
Metabolic disturbances
Hypo- or hyperglycemia
Hypo- or hypernatremia
Hyperosmolar states
Uremia
Hepatic failure
Hypocalcemia, hypomagnesemia (rare)
Toxins and drugs (many)
Cocaine, lidocaine
Antidepressants
Theophylline
Alcohol withdrawal
Drug withdrawal
Eclampsia of pregnancy (may occur up to 8 weeks postpartum)
Hypertensive encephalopathy
Anoxic-ischemic injury (cardiac arrest, severe hypoxemia)

TABLE 232-3 Paroxysmal Disorders: Differential Diagnosis

Seizures
Syncope
Pseudoseizures
Hyperventilation syndrome
Migraines
Movement disorders
Narcolepsy/cataplexy

Syncope usually is attended by premonitory symptoms such as dizziness, diaphoresis, nausea, and "tunnel vision." Patients often are aware that they are going to faint and can clearly describe the onset of the attacks. Cardiac syncope, however, may occur suddenly without any warning. Injury or incontinence may attend syncope; in addition, some patients may experience brief tonic-clonic activity. Recovery is usually rapid, with few or no postictal-like symptoms.

Pseudoseizures, or nonepileptic seizures, are common and may be extremely difficult to distinguish from true seizures in the emergency department. They may occur as well in a patient who has a documented seizure disorder. They are psychogenic, rather than neurogenic, in origin, and are not accompanied by an alteration in brain activity. They are often associated with a conversion disorder, panic disorder, psychosis, impulse control disorder, Munchausen syndrome, or malingering. The patients are usually female, and there may be a history of physical or sexual abuse. The diagnosis of pseudoseizures should be suspected when seizures occur regularly in response to emotional upset or when seizures only occur with witnesses present. The attacks are often very bizarre and highly variable. Patients often are able to protect themselves from noxious stimuli during the attack. Characteristic movements include side-to-side head thrashing, rhythmic pelvic thrusting, and clonic extremity motions that are alternating rather than symmetric. Incontinence and injury are uncommon, and there is usually no postictal confusion. The examiner may be able to provoke or arrest the seizure by suggestion (through injection of saline, for example). Accurate diagnosis of pseudoseizures may require prolonged EEG or video monitoring to demonstrate the presence of normal EEG activity during an attack. The lack of lactic acidosis, as evidenced by the presence of an anion gap acidosis on serum electrolytes drawn within 10 to 15 min of the cessation of seizure-like activity, makes generalized seizures unlikely.

Hyperventilation syndrome is common and is often misdiagnosed as a seizure disorder. A careful history will reveal the gradual onset of the attacks with shortness of breath, anxiety, and perioral numbness. Such attacks may progress to involuntary spasm (especially carpopedal) of the extremities and even loss of consciousness. The episodes often are reproduced easily by asking the patient to hyperventilate.

Movement disorders, such as dystonia, chorea, myoclonic jerks, tremors, or tics, may occur in a variety of neurologic conditions. Consciousness is always preserved during these movements. Though involuntary, the movements can often be temporarily suppressed by the patient.

Migraines may be preceded by an aura similar to that seen in some partial seizures. The most common migraine aura is the scintillating scotoma. Migraines may also be accompanied by focal neurologic symptoms such as homonymous hemianopsia and hemiparesis. However, there is no active movement disorder seen.

Narcolepsy is characterized by brief attacks of uncontrollable daytime sleepiness. Patients are able to feel their attacks coming on and can sometimes control them with judiciously timed naps. Other symptoms of narcolepsy include vivid dreams, often at the onset of sleep or immediately upon awakening, and attacks of sleep paralysis. An associated symptom is *cataplexy*, characterized by a sudden brief loss of postural muscle tone that is often triggered by emotional upset, laughter, or crying. The patient collapses but remains fully conscious; there are no involuntary movements.

Clinical features that help to distinguish seizures from other kinds of mimicking attacks include:

1. Abrupt onset and termination. Although some focal seizures are preceded by auras that last 20 to 30 s (or more), most attacks begin abruptly. Attacks reported to develop over several minutes or longer should be regarded with suspicion. Most seizures last only 1 or 2 min, unless the patient is in status epilepticus.
2. Lack of recall. Except for simple partial seizures, patients usually cannot recall the details of an attack.
3. Movements or behavior during the attack generally are purposeless or inappropriate. Rare exceptions have been described.
4. Most seizures, except for simple absence attacks (*petit mal*) or simple partial seizures, are followed by a period of postictal confusion and lethargy.

Although a clinical diagnosis of seizures often can be made with a high degree of certainty, there are occasions when the presentation is not convincing. In such cases it is better to admit uncertainty and provide follow-up to determine the exact diagnosis, and not to use the term seizure or begin inappropriate and potentially hazardous treatment. Multiple EEG recordings, prolonged EEG monitoring, and neurologic evaluation may be necessary.

Laboratory Examination

The need for laboratory studies must be assessed on an individual basis. In a patient with a well-documented seizure disorder who has had a single unprovoked seizure, the only test that may be needed is an anticonvulsant level.

In the case of a patient with a first seizure or when the history is unclear, more extensive studies may be helpful. A serum glucose should be obtained, and serum electrolytes, blood urea nitrogen (BUN), creatinine, calcium, magnesium, a pregnancy test, and a toxicology screen may be indicated depending on the clinical context. If the patient's urine is positive for hemoglobin, but there are no red cells in the urine, a CPK should be done to rule out rhabdomyolysis.

If blood is drawn soon after the event, the patient should demonstrate a wide anion gap metabolic (lactic) acidosis following a major seizure, which should correct spontaneously within 1 h.³ The majority will clear within 30 min and some will clear in as little as 15 min. If the diagnosis is in doubt, serum lactate can be drawn within 15 min of the episode. The blood prolactin level may also be elevated for a brief period (15 to 60 min) immediately following a seizure and may be helpful in distinguishing a true seizure from a pseudoseizure;⁴ a normal prolactin level, however, is not helpful.

The presence of anticonvulsant drugs in the blood of a patient from whom no history is available suggests (but does not prove) the presence of a seizure disorder. Anticonvulsant drug levels must be interpreted with caution, as the time the last dose was taken needs to be known to properly interpret levels. The usual therapeutic and toxic levels indicated in laboratory reports are helpful only as rough guides. **The therapeutic level of a drug is that level that provides adequate seizure control without unacceptable side effects.** A phenytoin level of 15 $\mu\text{g/mL}$ may be toxic in a given patient; conversely, a phenytoin level of 24 $\mu\text{g/mL}$ in another may result in excellent seizure control and be well tolerated. A marked change in previously stable drug levels may indicate noncompliance, a change in medication (e.g., from one brand name or generic to another), malabsorption of a drug (as in severe diarrhea or vomiting), or ingestion of a potentiating or competing drug. Minimal amounts of a standard seizure medication most likely indicates a compliance problem.

Radiographic Studies

The issue of neuroimaging following seizures remains controversial. In 1996, the American College of Emergency Physicians (ACEP)⁵ in

conjunction with a panel of neurologists, neurosurgeons, and neuroradiologists, developed a practice parameter outlining the role and timing of neuroimaging following seizures. In patients with a febrile seizure or seizure typical of their documented epilepsy, radiographic studies usually are not indicated. However, for patients with a first seizure or a change in their established seizure pattern, CT scanning of the head is appropriate to identify a structural lesion. Table 232-4 lists guidelines for emergent CT scanning following a seizure. Noncontrast CT is an appropriate screening tool.⁶

If the patient does not meet the criteria in Table 232-4, has recovered from the seizure, and no metabolic cause for the seizure has been identified, a head CT may be obtained in the outpatient setting in conjunction with close follow-up with a neurologist.

Because many important processes, such as metastatic or primary tumors or vascular anomalies, may not be evident on noncontrast studies, a follow-up enhanced CT or MRI may be arranged. MRI is more sensitive than CT in detecting subtle alterations of brain structure and is often the study of choice in the evaluation of patients with seizures. In patients with an uncomplicated first seizure, it is reasonable to omit the CT scan and obtain an MRI instead. Consultation with a neurologist or radiologist may be helpful in choosing the best approach and avoiding unnecessary examinations.

Other radiographic studies may be indicated in some cases. Radiographs of the cervical spine or neck should be obtained if there is suspicion for head or neck trauma. Chest radiographs may reveal primary or metastatic tumors. There may be evidence of aspiration, although related radiographic findings are usually delayed. Skull x-rays are generally not indicated. Special examinations, such as cerebral angiography, are rarely part of the emergency department evaluation.

ELECTROENCEPHALOGRAPHY

While EEG may be very helpful, it is not readily available in most emergency departments. Emergency EEG can be considered in the evaluation of a patient with persistent, unexplained, altered mental status to rule out nonconvulsive status epilepticus; to evaluate a paroxysmal attack when a seizure is suspected; or in status epilepticus to detect ongoing seizures after paralysis for intubation or induction of general anesthesia. Patients in whom an EEG is warranted emergently should be admitted to the appropriate service and setting, and the EEG should be performed there if possible.

In the outpatient setting, the EEG may be used to distinguish specific epileptic syndromes. The diagnostic yield of EEG recordings can be increased by appropriate patient preparation (especially sleep deprivation) or by activation techniques such as hyperventilation, photic stimulation, and sleep recordings. More elaborate examinations, such as 24-h recordings or video-EEG recordings, may also be used. Consultation with a neurologist ensures that the appropriate studies are chosen.

TREATMENT

Certain general measures should be taken for any seizure patient. A patent airway must be assured and vital signs should be stabilized. Initial

TABLE 232-4 ACEP Recommendations for Obtaining Emergent Neuroimaging Following a Seizure⁵

HiV-positive/immunosuppression
Meningismus
Alcoholism
Change in seizure pattern

interventions should include an intravenous line, oxygen, pulse oximetry, bedside glucose determination, and a cardiac monitor if warranted. Intubation should be considered for prolonged seizures, persons that require GI decontamination, and patients who may need to be transferred off site. In and of themselves simple seizures do not usually warrant intubation. Standard measures for management of any unconscious patient should be employed (see Chap. 229). The likelihood of trauma should be assessed. Care should be taken to identify and treat any underlying metabolic disorder.

The first objective is to make an accurate diagnosis; only in patients with status epilepticus is it necessary to initiate specific treatment (for seizures) before diagnostic evaluation has been completed.

Specific management is reviewed below for four clinical situations: the patient who is actively seizing; the patient with previous epilepsy who has a seizure; the patient with a first seizure; and status epilepticus.

The Active Seizure

Usually, little is required during the course of an actual seizure other than to protect the patient from injury. Gentle but firm restraint should be used to prevent falls. If possible, the patient should be turned to one side to reduce the risk of aspiration. It is usually not possible to insert a bite block between the teeth without using considerable force and risking damage to teeth. It is usually not necessary or even possible to ventilate a patient effectively during a seizure, but once the attack subsides, ensure a clear airway. Suction and airway adjuncts should be readily available. Seizure activity should be observed to determine if it is focal. **There is no indication for intravenous anticonvulsant medications during the course of an uncomplicated seizure.** Expectant treatment is best. Unnecessary sedation at this point will complicate evaluation and result in a prolonged decrease in level of consciousness. Seizures that fail to abate are considered status epilepticus (see below).

Patients with Previous Seizures

Proper management of a patient with a well-documented seizure disorder who presents after one or more seizures depends on the particular circumstances of the case. Potential precipitants that may lower seizure threshold should be sought. Many such seizures occur because of failure to take anticonvulsant medication as prescribed. Some anticonvulsants have short serum half-lives (Table 232-5), and missing even a single dose may result in a sharp drop in serum levels.

If anticonvulsant levels are very low, supplemental doses may be appropriate, and the patient may be restarted on their regular regimen or require adjustment. Without a loading dose, the patient may not achieve anticonvulsant effects for 2 d to 3 weeks (see Table 232-5). An oral loading dose of phenytoin (usually 18 mg/kg PO, divided into three doses given q2h) will achieve therapeutic serum concentrations

in 2 to 24 h. Alternatively, 10 to 20 mg/kg of intravenous phenytoin (no faster than 25 mg/min) achieves anticonvulsant effects in 1 to 2 h. The dose of fosphenytoin is 10 to 20 mg phenytoin equivalent (PE) at a maximum IV rate of 150 mg per min. Loading doses of carbamazepine are not generally given.

In the known or suspected noncompliant patient, it is common practice for some clinicians to initiate antiepileptic loading (in full or half dosing) prior to, or in lieu of, a serum anticonvulsant level. This has the advantage of potentially shortening the length of stay of the patient in the ED, but could result in toxic levels of anticonvulsant if indeed the patient has some medication in their system.

If anticonvulsant levels are adequate and the patient has had a single attack, specific treatment may not be needed if the pattern and frequency of occurrence falls within the expected range for the patient. Even well-controlled patients may have occasional breakthrough seizures. Any precipitants that have lowered the seizure threshold should be identified. If there has been a recent change in the frequency or pattern of breakthrough seizures, conditions affecting the seizure threshold should be sought. If none is found, a change in or adjustment of medication may be needed. The patient's primary care physician or neurologist should be made aware of the situation and participate in decision making.

If a medication's maintenance dose is increased, only very small increments should be made, and follow-up within 1 to 3 d should be provided, because even small dose changes may result in dramatic increases in serum levels.

The Patient with a First Seizure

There has been considerable controversy about the appropriate management of a patient who has experienced an apparent first seizure. The decision to begin outpatient treatment with antiepileptics depends on the risk of recurrent seizures weighed against the risk/benefit ratio of anticonvulsant therapy. Previous studies have suggested a risk of recurrence ranging from 23 to 71 percent. The most important predictors of the risk of recurrence were the etiology of the seizure and the results of the EEG.⁷ In patients with idiopathic seizures and a normal neurologic examination, the risk of a recurrent seizure within 2 years is 24 percent if the EEG was normal and 48 percent if the EEG is abnormal. In patients with previous neurologic injury or illness, the risk is 48 percent if the EEG was normal, and 65 percent if the EEG is abnormal. Neither family history, age, sex, nor the presence of status epilepticus at the time of the first seizure was a strong predictor of the risk of recurrence. Unfortunately, EEG results are often not available to the emergency physician who must make a treatment decision.

A randomized multicenter clinical trial of 397 patients demonstrated that treatment of first unprovoked seizures appears to reduce the risk of recurrent seizures from 51 to 25 percent during 2 years of follow-up.⁸ Some general recommendations can be made based on these studies.^{7,8} Patients with secondary seizures due to an identifiable

TABLE 232-5 Properties of Commonly Used Anticonvulsant Drugs

Drug	Oral Dose, mg per d*	Therapeutic Level, μ g/mL†	Days to Reach Steady Stated	Serum Half-Life h
Phenytoin	300-600 divided tid	10-20	5-10	7^2
Carbamazepine	400-1200 divided tid or qid	6-12	2-4	12-17
Phenobarbital	60-200 qd	10^0	14-21	48-144
Primidone	750-2000 divided tid or qid	5-12	4-7	10-21
Valproic acid	15-60 mg/kg per d divided bid or tid	50-150	2-4	12-18

*Average therapeutic dose. Initiation dosing may be different. Daily dose is individualized. Drug-drug interactions may dramatically change daily doses in patients receiving multiple drugs. †See text for definition of therapeutic and toxic levels. % Indicates time required to establish stable serum levels after any change in dose.

neurologic condition should generally be treated, as their risk of recurrence is quite high (48 to 65 percent). In patients with idiopathic seizures, the decision is less clear. Their risk of recurrence may be as low as 24 percent if the EEG is normal. Given the expense, inconvenience, and potential side effects, initiation of treatment in the ED should be made on consultation with a neurologist.

The ideal initial antiepileptic regimen is a single-drug therapy that controls seizures with minimum toxicity. If treatment is initiated, drug selection is based on the type of seizure. For generalized or partial seizures, either phenytoin or carbamazepine would be an appropriate choice for most adults (see above for dosing information). Both drugs are equally efficacious and have similar side effect profiles. Valproic acid, phenobarbital, and primidone may also be used.

Determining Need for Consultation and Admission

ACEP guidelines⁶ recommend *neurologic consultation* in the emergency department (or urgently on the floor if the patient is admitted) in certain situations (Table 232-6). Hospital admission recommendations are shown in Table 232-7. Alcohol- or drug-related seizures do not necessarily require admission, although detoxification or withdrawal should be addressed.

Disposition

There are no evidence-based rules for how long a patient must be observed prior to discharge. Some clinicians discharge patients with nontherapeutic anticonvulsant levels after administration of a loading dose of an anticonvulsant if vital signs are normal and the mental status is at baseline. Peak effect can be expected soon after intravenous loading of phenytoin and thus it is preferred. While there is no proscriptio regarding oral loading of medication, time to peak effect compared to intravenous loading is considerably delayed. If the patient has a subsequent seizure in the next few hours, it will be unclear if an inadequate level remains an issue, or whether the patient is seizing despite adequate levels. Those given oral loading doses should be warned of continued risk for seizures until anticonvulsant effect has been achieved. Such patients should be discharged with a reliable family member or friend, with imperative medical follow-up arranged within a week.

Patients should be instructed to take precautions to minimize the risks for injury from further seizures. Swimming should be avoided. Working with hazardous tools or machines and working at heights should be avoided. The emergency physician should be familiar with driving regulations and reporting requirements, which vary from state to state. Regardless of local laws, it is prudent to advise patients against driving and other hazardous activity until they have stabilized and have been seen in follow-up. The emergency department record should reflect the precise instructions given to the patient.

SPECIAL CONSIDERATIONS

Seizures in the HIV-Positive Patient

Seizures are a common manifestation of CNS disease in patients infected with HIV, although the etiology of seizures in this population dif-

fers somewhat from immunocompetent patients (Table 232-8). Mass lesions, HIV encephalopathy, and meningitis are seen more frequently.⁹ The most common mass lesion is caused by toxoplasmosis, followed by lymphoma. Cryptococcal, bacterial, or aseptic meningitis, or encephalitis due to herpes simplex, varicella zoster, or cytomegalovirus may cause seizures. HIV encephalopathy or AIDS dementia complex is an underrecognized etiology of seizures for HIV-infected patients. Other etiologies to consider are progressive multifocal leukoencephalopathy, CNS tuberculosis, cysticercosis, and neurosyphilis.

While the evaluation of seizures in HIV-positive patients should include a search for metabolic or toxicologic causes, there is also a high incidence of space-occupying lesions. If no space-occupying lesion is identified on noncontrast head CT scan, and there is no evidence of increased intracranial pressure, a lumbar puncture should be performed to exclude meningitis. Finally, if the initial head CT scan is negative or no other explanation for seizures is found, a contrast-enhanced head CT or an MRI should be obtained on an urgent basis, either on the floor if the patient is admitted, or arranged by the primary physician as part of the disposition. Some HIV patients will have no discernible cause for seizures after a thorough evaluation, particularly if the neurologic examination in the interictal period is normal.

Treatment of the first-time seizure in the HIV patient is controversial. Most authorities recommend treatment with phenytoin or phenobarbital because the seizure recurrence rate in this population is high, but there is a 10 percent incidence of hypersensitivity reactions to phenytoin in patients with HIV.

Seizures and Neurocysticercosis

Neurocysticercosis is caused by CNS infection with the larval stage of the tapeworm *Taenia solium*. It is the most common cause of secondary epilepsy in the developing world. Cases in the United States are increasing, with over 1000 cases diagnosed each year, due to immigration from endemic areas, particularly Latin America.¹⁰

ideation, or delirium may occur, in the symptom complex of *delirium tremens* (DTs). If left untreated, approximately 5 percent of patients who withdraw from alcohol will proceed to DTs, which usually begin 3 to 5 days after cessation of alcohol (see Chap. 295). Prior to the advent of intensive care settings and benzodiazepines, mortality from DTs was as high as 35 percent; currently, with advanced treatment modalities, mortality estimates are from 5 to 15 percent.

Classic *alcohol withdrawal seizures* usually occur within 6 to 48 h after reduction or cessation of alcohol, but may occur up to 1 week later. The seizures are generalized, and the interval EEG is usually normal. There may be several seizures occurring over several hours.

The alcohol-abusing patient with a first seizure should be evaluated and treated as any patient with a first-time seizure (see previous discussion), with additional evaluation for toxic-metabolic abnormalities and intracranial bleeding. Cervical spine precautions may be appropriate. Head CT should be considered when the diagnosis is in doubt, or there are concurrent considerations such as trauma, focality, or persistent depressed sensorium.

Most authorities agree that patients with alcohol withdrawal seizures usually do not require chronic anticonvulsant therapy. Acute or chronic treatment with phenytoin is neither necessary nor effective.¹⁶ Use of benzodiazepines such as valium (5 to 10 mg IV then q5 to 15 min as needed) or lorazepam (2 to 4 mg IV then q5 to 15 min as needed), in doses sufficient to manage withdrawal symptoms will usually afford adequate protection from acute seizures. The exception is withdrawal that is complicated by status epilepticus, which requires prompt treatment. Patients with epilepsy exacerbated by alcohol withdrawal should be managed as any other seizure patient with recurrent seizures.

If the clinical presentation and evaluation are consistent with alcohol withdrawal seizures, and the patient remains stable and seizure-free for several hours, the patient may be discharged and referred for detoxification. Outpatient detoxification with a benzodiazepine regimen is most appropriate for patients with mild to moderate withdrawal symptoms, no significant medical or psychiatric problems, no concurrent drug use, and no history of DTs. Since 90 percent of patients with alcohol withdrawal seizures have one or two seizures within a 6-h window, patients with more than two seizures should be admitted for observation and further investigation.

STATUS EPILEPTICUS

There are an estimated 120,000 to 200,000 cases of status epilepticus per year in the United States, with 55,000 deaths. In 12 to 30 percent of these, status epilepticus is the first epileptic event.^{17,18} Estimations of acute mortality range from 1 to 10 percent.

In the past, status epilepticus was defined as either continuous seizure activity for 30 min or more, or two or more seizures that occur without full recovery of consciousness between the attacks. Recently, Lowenstein and colleagues have recommended revising the time frame of status epilepticus to 5 or more mins of seizure activity.¹⁹ It remains unclear how long a seizure can continue before permanent neurologic sequelae ensue. Although this question has never been satisfactorily answered, it does appear that the longer seizures are allowed to continue, the more likely that permanent CNS injury will result. Thus treatment should be initiated as soon as possible in all patients with continuous seizure activity lasting more than 10 min. The longer the seizure is allowed to continue, the more difficult it will be to control.

The diagnosis of status epilepticus is usually obvious in patients with continuous tonic-clonic movements. However, convulsive activity may gradually lessen over time or with partial treatment, giving the impression that the seizures have been controlled. This is known as *nonconvulsive status epilepticus*. The incidence of nonconvulsive status epilepticus is unknown, as the condition is probably underrecognized. Nonconvulsive status epilepticus should be suspected in a critically ill patient with altered mental status of unknown etiology,

especially if the patient has subtle motor activity (nystagmus, or twitching of the face, hands, or feet). An EEG is confirmatory.

Any type of seizure may occur continuously or in rapid succession, fulfilling the criteria for status epilepticus. *Epilepsia partialis continua* is repeated partial seizures without loss of consciousness and often with one's ability to follow simple commands retained. Altered mentation, diminished responsiveness, confusion, amnesia, or dream-like states without motor symptoms suggest continuous absence seizures.

Treatment

The goal of treatment of convulsive status epilepticus and *epilepsia partialis continua* is seizure control within 30 min of presentation (see Figure 232-1). Morbidity is due to hypoxemia, hyperthermia, circulatory collapse, and eventual neuronal injury.

A brief history and physical examination should be directed toward discovery of the cause of the seizures and to any injury that may have resulted. Any of the causes of seizures (see Table 232-2) may result in status epilepticus; in many patients, no specific etiology is found.

A large-bore IV line should be established and a bedside glucose determination made. Use of an IV fluid without glucose will facilitate administration of anticonvulsant drugs (glucose is not compatible with phenytoin). The patient should be placed on oxygen, a cardiac monitor, and a pulse oximeter.

Endotracheal intubation is recommended when status epilepticus is diagnosed. If a paralytic agent is used to assist with intubation, a short-acting agent such as vecuronium should be used so the physician can monitor ongoing seizure activity.

Initial laboratory evaluation should include blood glucose, a metabolic panel including calcium and magnesium, and if appropriate, a pregnancy test, a toxicology screen, and anticonvulsant levels.

Thiamine (100 mg) and glucose (25 to 50 g) should be given IV if hypoglycemia is suspected or confirmed. There is no benefit to giving additional glucose to normoglycemic patients. Rectal temperature should be monitored, and hyperthermia should be treated with passive cooling. A urinary drainage catheter should be placed to monitor urine output and a nasogastric tube to minimize aspiration.

If ingestion is suspected as the cause of seizures, GI decontamination (as appropriate) should ensue. Emergency lumbar puncture should not be attempted during status epilepticus. If bacterial meningitis is suspected, empiric antibiotic therapy should be started. It should be noted that status epilepticus can induce a brief peripheral leukocytosis as well as a mild CSF pleocytosis. Radiographic studies (such as a CT scan) will usually need to be delayed until the seizures are controlled.

Anticonvulsant Drugs in Status Epilepticus

The drugs most often used in the therapy of status epilepticus are the benzodiazepines (diazepam or lorazepam), phenytoin or fosphenytoin, and phenobarbital (see Figure 232-1).

Benzodiazepines are used in patients with continuous or very frequent seizures to temporarily control the seizures until more specific agents can be given. **Intravenous lorazepam** (4 to 8 mg) and IV diazepam (10 to 20 mg) have equal efficacy in controlling status epilepticus.²⁰ Although diazepam has a slightly faster onset, (2 min vs. 3 min), lorazepam has a significantly longer duration of action (12 to 24 h vs. 15 to 30 min), is associated with fewer seizure recurrences, and **is thus considered the initial agent of choice**. Lorazepam is also more effective than phenytoin or phenobarbital as the initial drug.²¹ Respiratory depression and hypotension may occur when benzodiazepines are used, especially in young children and in patients who have taken alcohol, barbiturates, narcotics, or other sedatives. Although diazepam enters the brain readily, it is redistributed quickly to fatty tissues, so serum concentrations fall rapidly. Therefore a longer-acting agent such as phenytoin should follow diazepam.

Phenytoin is the most important drug used in the management of status epilepticus. It may be given immediately after a benzodiazepine or may be used as primary therapy in patients whose seizures are less frequent. The recommended loading dose is 18 to 20 mg/kg IV; note that doses well in excess of the usual 1000 mg are required for many adults. A smaller loading dose (15 mg/kg) may be used in the elderly, but the loading dose is not reduced in patients with renal or hepatic disease. Due to myocardial depression effects, phenytoin should be infused at a rate of 25 mg per min. Phenytoin should not be mixed with any glucose-containing intravenous fluid and should not be given intramuscularly due to erratic absorption. The drug is contraindicated in the presence of second- or third-degree AV block. Adverse effects include significant infusion-site reactions, hypotension, and cardiac dysrhythmias, so continuous cardiac monitoring is needed. If side effects develop, the infusion should be stopped and may be restarted at a lower rate when the side effects have resolved; in some cases, patients are unable to tolerate the drug.

Fosphenytoin is a water-soluble prodrug of phenytoin that is rapidly converted to phenytoin in the plasma. In status epilepticus, fosphenytoin has similar time of onset, effectiveness, and cardiac effects as phenytoin. Its advantages include fewer infusion-site reactions due to the lack of propylene glycol and ethanol as the diluents. Secondly, fosphenytoin may be infused at a faster rate. Fosphenytoin dosing is expressed as "phenytoin equivalents (PE)" to prevent confusion. The loading dose is 15 to 20 mg PE per kg, which can be infused at 100 to 150 mg PE per min. Unlike phenytoin, fosphenytoin can be given intramuscularly, which is useful if the patient is not in status epilepticus. The only apparent drawback is the cost. Fosphenytoin can cost 10 to 60 times more than phenytoin.

Phenobarbital (up to 20 mg/kg IV) can be used as a third-line drug in patients who are unable to tolerate phenytoin or in patients whose seizures are not controlled despite full loading doses of benzodiazepines and phenytoin. However, patients who do not respond to lorazepam and phenytoin are unlikely to respond to phenobarbital.²² Because of very slow elimination, large doses of phenobarbital may result in prolonged obtundation. Respiratory depression and hypotension are common, especially at higher doses or when diazepam or lorazepam is also given.

In some patients, seizure control is not obtained with these regimens and further treatment is needed.

Refractory Status Epilepticus

The standard regimens of benzodiazepines, phenytoin, and phenobarbital suffice to control status epilepticus within 30 min of presentation in most patients. In some (generally patients with structural lesions, anoxic injuries, metabolic encephalopathy, or CNS infections), seizures continue for more than 60 min despite first- and second-line treatment. In one study, 31 percent of patients with status epilepticus developed refractory status epilepticus (RSE).²²

Various approaches to refractory status epilepticus have been advocated, including intravenous infusions of midazolam, propofol, or barbiturates to induce anesthesia (see Figure 232-1).²³⁻²⁶ These modalities are best used in an intensive care setting, as advanced respiratory and cardiovascular support, as well as continuous EEG and invasive hemodynamic monitoring, may be needed. Consultation from an anesthesiologist and neurologist should be obtained.

Anesthesia may be induced to treat RSE by administering infusions of midazolam or propofol for 12 to 24 h. General anesthesia may also be obtained with intravenous barbiturates such as thiopental and pentobarbital. Midazolam and propofol have the advantage over barbiturates of having a short half-life and rapid clearance, allowing for earlier extubation and earlier clinical assessment; midazolam also causes less hypotension.^{22,24} Intravenous valproate has also been advocated as a treatment modality.²⁶

Neuromuscular blocking agents (usually pancuronium or vecuronium) are sometimes helpful. These drugs will abolish tonic-clonic movements and may facilitate ventilation and other measures, but they have no effect on abnormal neuronal activity. EEG monitoring is necessary to assess the effectiveness of anticonvulsant therapy when neuromuscular blockers are utilized.

ACUTE PERIPHERAL NEUROLOGIC LESIONS

Michael M. Wang

When confronted with a patient with neurologic complaints, one should first localize the problem anatomically based on the history and physical examination. An initial distinction that should be made is whether the pathologic process involves the peripheral or central nervous system. Sometimes, the distinction is not clear.

HALLMARKS OF PERIPHERAL NERVOUS SYSTEM DISORDERS

The peripheral nervous system serves sensory, motor, and autonomic functions. The patient with a peripheral nerve problem thus may have symptoms reflecting disorder of any or a combination of these functions. Sensory symptoms may include numbness, tingling, dysesthesias, pain, or ataxia caused by proprioceptive dysfunction. Motor symptoms are predominantly weakness. Autonomic disability can include orthostatic symptoms, bowel or bladder dysfunction, gastroparesis, or sexual dysfunction.

On physical examination, the most important finding in a peripheral nerve process is reduction or absence of reflexes. The sensory examination, which includes tests of proprioception, vibratory sensation, and pain and temperature sensibility, is also often abnormal. When the motor system is involved, wasting and fasciculations may be seen in addition to weakness. Autonomic dysfunction can cause hair loss, anhidrosis, pupillary dysfunction, orthostatic hypotension, and tachy- and bradyarrhythmias.

Similar symptoms and signs may be seen in disorders of the central nervous system (CNS). Weakness and numbness can be seen in both peripheral and central disorders. Hyporeflexia sometimes occurs with acute central lesions, but hyperreflexia and spasticity invariably develop later. Peripheral nervous system disorders, like CNS diseases, can affect bulbar structures, resulting in diplopia, dysarthria, or dysphagia. Nevertheless, CNS disorders frequently have other features that are not seen in peripheral diseases. For example, aphasia, apraxia, and visual loss are hallmarks of cortical disease. Signs on examination, such as hyperreflexia and clear lateralization of weakness, should prompt evaluation for CNS disorders.

LOCALIZATION OF NEUROLOGIC DISEASE

Once a peripheral disorder has been established, it is necessary to determine which part of the peripheral nervous system is involved. A localized process, such as numbness and tingling of the fifth and half of the fourth digits of one hand, strongly suggests a focal lesion (ulnar nerve). The lesion may involve the nervous system at a number of locations: the nerve, plexus, or root. Basic knowledge or the aid of an anatomy text or neurology handbook should be sufficient to accurately localize focal lesions of these types. Figure 233-1 shows a schematized view of the peripheral nervous system and illustrates the signs associated with disease of specific parts of the neuromuscular system. Most muscle-related processes result in weakness of large proximal muscles, and patients may have a difficult time lifting their arms over their heads or arising from a seated position. Pain and tenderness of the muscles occur commonly in muscle disorders (although usually these are not predominant symptoms and if not accompanied by weakness rarely indicate myopathy), and creatine kinase (CK) is usually elevated, sometimes dramatically. Diseases that affect other components of the peripheral nervous system seldom cause muscle tenderness and elevations in CK. Neuromuscular junction processes also affect large proximal muscles and frequently affect the bulbar musculature, resulting in pupillary dysfunction, diplopia, dysarthria, or dysphagia. Unlike muscle and neuromuscular junction disorders,

neuropathies frequently affect both the motor and sensory systems; because these diseases most severely affect longer nerves, distal power is reduced most dramatically. Polyradiculopathy, which frequently follows a progressive and stepwise course, usually results in electrical pain sensations, assorted sensory abnormalities, areflexia, and weakness.

Once localization of the peripheral problem is accomplished, efforts should be made to pinpoint the etiology. Specific historical points that always should be addressed include the time course of the illness, diurnal fluctuations (if any), other systemic symptoms or conditions, a review of medications, and antecedent illnesses. A serum chemistry and metabolic profile and CK are useful blood tests in the ED. Further testing is usually deferred in the acute setting, but may include a variety of blood tests, nerve conduction studies, electromyography, lumbar puncture, and nerve/muscle biopsy.

TREATMENT: GENERAL CONSIDERATIONS

Management of peripheral nervous system disorders depends on the specific diagnosis. However, a few general remarks about care should be made. When a peripheral disorder is suspected or diagnosed in the ED, one should arrange for neurologic consultation for further specific treatments. Many neuromuscular disorders are difficult to diagnose and require complex treatments such as immunomodulation with intravenous immunoglobulin, immunosuppressive drugs, and plasmapheresis.

Careful supportive care is mandatory for severe, life-threatening neuromuscular diseases and should begin in the ED. Patients with the potential for respiratory failure, aspiration, and cardiac dysrhythmias should be monitored appropriately. Where the presentation warrants, baseline forced vital capacity or negative inspiratory pressure should be measured in the ED to assess whether there is need for imminent respiratory support or admission to an intensive care unit.

With few exceptions, admission to the hospital is generally required for acute peripheral neurologic conditions in which there is danger of respiratory or autonomic compromise, or in cases of debilitating or rapidly progressing weakness. Specific indications for hospital admission are discussed below for individual diseases.

SPECIFIC NEUROMUSCULAR DISORDERS

The number of neuromuscular disorders is extensive and cannot be discussed fully in this text; consequently, this section covers the most common and most important disorders to recognize and the diseases that have acute therapies available.

Myopathies

Polymyositis is an inflammatory myopathy that affects individuals older than age 30 years, with a slight propensity for women. Usually, patients present with chronic complaints of proximal symmetric weakness, although the disorder occasionally presents subacutely. Some patients will have dysphagia, and a few will progress to respiratory failure. There may be muscle pain and tenderness. On examination, there is reduced proximal strength, which may best be tested by asking the patient to arise from a chair with his or her arms crossed or to lift a light object over his or her head. There is no sensory loss, and unless weakness is profound, reflexes should be intact. If deep tendon reflexes are diminished, neuropathy should be considered. Laboratory testing may reveal an elevated erythrocyte sedimentation rate (ESR), leukocytosis, and CK. The differential diagnosis includes Lambert-Eaton myasthenic syndrome, inclusion body myositis, toxic myopathies, dermatomyositis, endocrinopathies, and an assortment of muscular dystrophies.

Patients with newly suspected polymyositis should be assessed for potential respiratory compromise and aspiration risk in the ED. Ad-

FIG. 233-1. Schematic of the neuromuscular system and typical findings with disease of each component of the system. DRG = dorsal root ganglion; NMJ = neuromuscular junction.

mission is usually warranted in newly suspected cases. Further diagnostic studies likely pursued under the direction or consultative advice of a neurologist typically include electromyography (EMG) and muscle biopsy. Long-term treatment consists of immunosuppressive agents such as steroids and methotrexate.

Dermatomyositis, unlike polymyositis, can affect children and, like polymyositis, affects mostly women. The clinical manifestations of dermatomyositis are similar to those of polymyositis, except for the usual appearance of a violaceous rash typically over the face and hands. The neurologic examination shows a myopathic distribution of weakness without sensory or reflex abnormalities in most cases. The laboratory findings are also similar, with an elevated ESR and CK in most instances. Despite similarities in the clinical presentation compared with polymyositis, the pathology and pathophysiology of the two disorders are quite distinct.¹ Treatment is aimed at immunosuppression.

OTHER MYOPATHIES A large number of substances, including environmental (alcohol), occupational, and pharmacologic agents [steroids, cholesterol-lowering drugs, AZT (azidothymidine)], can cause myopathy. Table 233-1 summarizes several important medication-induced myopathies. Although usually chronic, some present subacutely and cause a predominantly proximal pattern of weakness with normal sensation and preserved tendon reflexes (except with severe weakness). CK is usually elevated. Viral myositis causes an acute myopathy, occasionally involving the heart, and is usually associated with a febrile illness, myalgia, and elevated CK levels. An important cause of both acute and chronic myositis is HIV infection (see below). Trichinosis should be suspected in patients with myalgias, bulbar and proximal muscle weakness, facial edema, and eosinophilia; symptoms occur within days of ingesting undercooked pork. Definitive diagnosis is made on visualization of parasitic cysts on muscle biopsy.

TABLE 233-1 Some Drugs That Cause Myopathy

Chloroquine	ε-Amino-caproic acid	Thiazides
Emetine	D-Penicillamine	Amphotericin
Corticosteroids	Chlorpromazine	Amphetamines
Amiodarone	Zidovudine	Toluene
Adriamycin	Colchicine	Ethanol
Procainamide	Vincristine	Phencyclidine
Perhexilene	Clofibrate	
Imipramine	Lovastatin

Disorders of the Neuromuscular Junction

Myasthenia gravis is discussed in Chap. 234.

BOTULISM Ingestion of foods contaminated with *Clostridium botulinum* toxin causes botulism, an acute disease marked by weakness and gastrointestinal slowing. Adults whose disease is caused not by bacterial infestation but by ingestion of botulinum toxin may report exposure to foods such as home-canned vegetables in the preceding 1 to 2 days. Unlike adults, infants, whose guts are not colonized fully, are susceptible to infection with viable bacteria that elaborate toxin. Parents of infants should be questioned for possible ingestion of *C. botulinum* spores, commonly transmitted by feeding honey. Infants may present with poor sucking. Botulism caused by infection through a wound is rare. With botulism, mentation is normal, but there may be bulbar weakness. The extraocular movements are sometimes abnormal, and an important diagnostic clue is the absence of the pupillary light reflex, which distinguishes this disorder from myasthenia gravis. There is proximal limb weakness, sensation is intact, and reflexes generally are normal except in the case of severe weakness.

Botulism is treated with antibiotics (infants only) and immune serum (adults and infants), which is obtained from the Centers for Disease Control and Prevention (Atlanta). The serum, derived from immunized horses, is first used in skin tests to exclude hypersensitivity. The antiserum is generally available at quarantine sites at major U.S. airports. Patients should be admitted to the hospital for treatment, monitoring, and testing. In cases where the diagnosis is not clear, treatment with immune serum, which has potential morbidity, should be withheld until electrodiagnostic studies are performed. Nerve conduction studies show an incremental response on repetitive nerve stimulation.

Acute Peripheral Neuropathies

Guillain-Barre syndrome (GBS) affects individuals of all ages and is the most common form of acute generalized neuropathy. Frequently, patients report an antecedent viral illness, especially gastroenteritis. There is an association between acute *Campylobacter jejuni* infection and development of GBS. Sometimes the patient first notices numbness and tingling of the lower extremities. This is followed by weakness of thighs, legs, and then arms. There are numerous variants of the syndrome, and some patients may experience facial weakness, which can mimic Bell palsy, ophthalmoparesis, severe shooting pains, or ataxia caused by proprioceptive difficulty. In most, but not all, cases, GBS is caused by an autoimmune attack on myelinated motor nerves. In classic cases, there is symmetric extremity weakness, more pronounced in the legs. Despite subjective sensory disturbances, sensation on examination is usually normal. The hallmark finding in GBS is the lack of deep tendon reflexes. In variant cases, there may be ophthalmoplegia and pupillary disturbances. Occasionally, there may be facial weakness involving the forehead. Autonomic instability, marked by brady- and tachycardia or blood pressure fluctuation, may be apparent in a few cases. Where ophthalmoparesis is present, there may be a marked limb ataxia, and the patient may not be able to walk or stand despite reasonable strength. In all forms of the disease, there is a chance of developing respiratory failure and lethal autonomic fluctuations.

Lumbar puncture should be performed when acute disease is suspected. The classic laboratory finding in GBS is a high cerebrospinal fluid (CSF) protein with normal glucose and cell count. However, the protein will not be elevated until after the first week of symptoms and may not be elevated even after 1 week. Although many patients will have a modest CSF pleocytosis (up to 100 lymphocytes/ μ L), the presence of cells in the CSF should prompt consideration of other systemic diseases sometimes associated with GBS, such as HIV infection, lupus, and lymphoma.

Lyme disease can present with a clinical picture similar to GBS and would be suggested by a CSF pleocytosis in combination with a history of tick bites or the presence of CSF Lyme antibodies. Carcinomatous meningitis also can present with similar symptoms but will be evident with malignant cells in the CSF or extremely high protein or low glucose levels. *Tick paralysis* mimics GBS, and all patients with suspected GBS should be examined thoroughly for ticks. Acute intermittent porphyria (discussed below) and spinal cord compression should be considered in the differential diagnosis; the presence of upper motor neuron signs and bowel and bladder incontinence would suggest the latter.

Patients with GBS should be admitted to the hospital for monitoring and treatment. When forced vital capacity (FVC) is under 1 L, the patient should be intubated. No specific treatment is warranted in the ED; treatment is composed of plasma exchange or intravenous immunoglobulin, which both have been shown in controlled studies to shorten the duration of the illness.²

Acute intermittent porphyria is a rare autosomal dominant condition in which patients suddenly experience the symptom triad of weakness, psychosis, and abdominal pain. Seizures can occur. The three occasionally occur together, but in many cases occur independently. The disease activates acutely in flares that are usually precipitated by medications such as barbiturates, phenytoin, sulfonamides, and estrogen.

The major neurologic findings are weakness and diminished reflexes, particularly of the lower extremities, which are the direct consequence of an acute peripheral neuropathy. There may be sensory findings such as diminished pain and temperature sensation, although these signs are usually outweighed by motor deficits. In the acute setting, basic ancillary laboratory studies may be normal. Further testing reveals elevation in urine 8-aminolevulinic acid and porphobilinogen.

The key management issue is recognition of the disorder and identification and discontinuation of the offending drug. Care also must be taken to avoid overtreatment of symptoms such as pain and seizures with medications that may exacerbate the illness. Other treatment modalities include supportive care, glucose infusions to prevent heme biosynthesis, vitamin B₆, and heme (4 mg/kg IV daily for 1 to 2 weeks). The differential diagnosis includes other disorders that cause pain and lower extremity weakness. Spinal cord compression causes back pain, which frequently radiates around the trunk and is followed by lower extremity weakness, but reflexes in this situation are brisk with upgoing toes (positive Babinski reflex). An aortic aneurysm or dissection also can cause abdominal pain and lower extremity weakness if spinal arteries are occluded by the expanding aneurysm.

Focal Neuropathies

The most common entrapment neuropathies are discussed below. For the most part, the nerve damage is reversible, and referral to the appropriate specialist for relief on entrapment is necessary.

Carpal tunnel syndrome (CTS) is the most commonly seen entrapment neuropathy. Patients describe intermittent pain and/or numbness in the thumb and first two fingers, prominently at night. Symptoms frequently awaken the patient from sleep, occur in both hands independently, and may be poorly localized (i.e., numbness is often described going up to the elbow). The symptoms usually can be reproduced by compression of the nerve over the carpal tunnel or by tapping

on the nerve, although these signs are neither sensitive nor specific. Occasionally, these symptoms are mistaken for cerebrovascular disease until a history of bilateral, repeated, and stereotypical nocturnal occurrence is obtained. When symptoms become long-standing and severe, weakness of the thenar musculature develops. Wrist splints worn at night are useful in the conservative management of CTS. Patients should be referred to a hand surgeon as an outpatient for further diagnostics and management. A carpal tunnel release may be performed in patients who fail to respond to conservative management.

Ulnar nerve entrapment, usually occurring at the elbow, produces numbness in the fifth digit and medial half of the fourth finger, but symptoms are frequently poorly localized. Weakness and wasting of the hypothenar muscles occur very late in the course. The patient should be referred to a specialist for electrodiagnostic confirmation because occasionally, C8 radiculopathy can mimic this common condition. Severe cases are treated surgically with ulnar nerve transposition.

Entrapment of the deep peroneal nerve at the fibular head can cause footdrop and numbness of the web between the great and second toes. This condition occurs in the setting of injury to the leg, rapid weight loss, or habitual crossing of the legs. Peroneal entrapment should be confirmed by EMG to be differentiated from lumbar root disease or motor neuron disease. Almost all cases are treated conservatively and improve without specific therapy.

Meralgia paresthetica is entrapment of the lateral cutaneous nerve of the thigh. The diagnosis is often overlooked in the ED, being mistaken for a hip-related orthopedic disorder. Patients describe numbness and dysesthesias of the lateral aspect of the upper leg. This occurs after weight loss and notably following pelvic surgery or obstetric procedures where the legs are abducted and flexed for a prolonged period of time. Tricyclic antidepressants (TCA) are useful in the management of the dysesthesias associated with meralgia paresthetica. The condition resolves without sequelae and requires no specific therapy.

Mononeuritis multiplex is a syndrome of multiple nerve dysfunctions caused by a vasculitis. Patients experience multiple deficits in a stepwise fashion, usually involving both sides of the body. For example, a patient may experience wristdrop on the right, followed by footdrop on the left, and then footdrop on the opposite side a few weeks later. This condition requires urgent referral to a neurologist to determine the etiology and initiate treatment, usually in collaboration with a rheumatologist. Frequently this disorder is caused by a systemic vasculitis, and a thorough serologic examination and nerve biopsy are required to establish specific treatment plans. The condition must be differentiated from multiple compression neuropathies and from multifocal motor neuropathy.

Bell palsy should be viewed as a diagnosis of exclusion. It is the most common cause of acute facial paralysis but is similar to other processes that are important to recognize. Patients with Bell palsy complain of sudden facial weakness, difficulty with articulation, problems keeping an eye closed, or inability to keep food in the mouth on one side. Because the seventh cranial nerve also serves other functions, the patient may have variable degrees of dry eye, metallic taste of the mouth, and facial pain, commonly around the ear. The examination is notable for one-sided weakness of the face involving the forehead. There may be decreased sensation along the external acoustic meatus (Hitselberger sign). Other cranial nerves are normal. Diminished reflexes suggest a different diagnosis.

Several alternative diagnoses should be considered. Stroke can lead to sudden facial weakness that involves only the lower face but also leads to neurologic involvement below the neck or other cranial neuropathies. Lyme disease and GBS can cause facial paralysis, as discussed elsewhere in this chapter. In patients with cancer, facial weakness may herald the metastatic spread of malignancy. The ear should be inspected carefully to rule out ulcerations caused by cranial herpes-zoster activation (Ramsay Hunt syndrome), which should be treated with oral acyclovir. Facial paralysis also can be seen in sarcoidosis, collagen vascular disease, and polio. All patients with facial weakness

should be screened for HIV risk factors, since seventh nerve palsy can occur at the time of seroconversion.

The treatment of Bell palsy with steroids is controversial. Most neurologists argue in favor of a short course of prednisone in individuals with low risk for complications from corticosteroids. The recommended dose is 50 mg PO per d for 7 days. More recent studies³ suggest that steroids in combination with acyclovir (200 mg PO five times a day for 10 days) leads to better outcomes. If the patient is seen more than a week after paresis began, steroids generally are not given.

Eye care must be meticulous to avoid corneal abrasions. Patients are instructed to tape the affected eye so that the palpebral fissure is narrowed to prevent drying of the cornea. Patients should apply ocular lubricants and patch the eye before sleeping.

Lyme disease affects individuals exposed to the tick-borne pathogen *Borrelia burgdorferi*. Although its neurologic manifestations are multiple, one of the most common sites of involvement is the peripheral nervous system. A comprehensive discussion of Lyme disease can be found in Chap. 145. Neurologic complications ensue the weeks following initial manifestations such as fatigue and arthralgias. A common neurologic sign is seventh nerve palsy, which should not be confused with Bell palsy. Lyme disease affects the peripheral nerves and the nerve roots. The patient may describe the acute or subacute progression of weakness and sensory loss, sometimes associated with radicular pain. On examination, the patient will have one of several signs. Unless there is encephalitis (a rare complication of Lyme disease), mental status will be normal. Apart from seventh nerve involvement, there may be weakness in the limbs, and if there is localized radicular inflammation, there will be a patchy myotomal pattern. Similarly, depending on the regional involvement of the disease, selected deep tendon reflexes will be diminished. Laboratory features suggestive of Lyme disease include serum and CSF Lyme antibodies. A CSF pleocytosis and increased protein with a normal glucose is the most common abnormality. When the diagnosis is made with confidence and other entities such as syphilis, carcinomatous meningitis, and sarcoidosis excluded, a minimum 3-week course of intravenous antibiotics, either ceftriaxone or doxycycline, is given.

Plexopathies

Brachial neuritis is an acute condition that tends to affect younger individuals, with a slight male predominance. Patients report excruciating shoulder, back, or arm pain followed by weakness of the arm or shoulder girdle. In a third of cases, it is bilateral. The cause is idiopathic, but cases have been reported following immunizations or viral infections. On examination, the patient has weakness in various distributions of the brachial plexus. The upper trunk is the preferred site of involvement, affecting strength of proximal arm and shoulder musculature. The anterior interosseous nerve is also affected preferentially, causing inability to form a pincer with the index finger and thumb. Sensory abnormalities are found but are not as profound as the motor dysfunction. Reflexes are diminished in the affected limb.

The differential diagnosis includes multiple cervical radiculopathies, Pancoast tumors, and neoplastic or inflammatory infiltration of the plexus. The diagnosis is usually clear, because a history of pain followed by weakness that plateaus in a week or two makes other diagnoses unlikely. A chest radiograph should be performed to look for mass lesions involving the brachial plexus. CSF analysis is required if there is a suspicion of other etiologies. Spine imaging and EMG may be performed outside the ED setting.

The management of brachial plexitis is conservative, and no therapies have been shown to affect the course of the illness. The prognosis is good, with most patients experiencing full recovery in months. If careful follow-up with a neurologist can be arranged and other causes or symptoms are excluded, admission to the hospital is elective.

Lumbar plexopathy, or diabetic amyotrophy, occurs in diabetic patients and presents with back pain followed by weakness. Patients

TABLE 233-2 A Framework to Approach Chronic Neuropathies

Etiologies	PREDOMINANT SYMPTOMS			
	Sensory	Motor	Sensory and Motor	Autonomic
Infectious	HIV Leprosy	Lyme	Syphilis Lyme	Chagas disease (<i>American trypanosomiasis</i>)
Medications	Cisplatin	Dapsone	INH	Vincristine
Toxins	Arsenic Alcohol	Lead	Alcohol	
Nutritional	Beriberi		B12 deficiency	
Metabolic	Diabetes		Uremia	Diabetes
Neoplastic	Paraneoplastic ganglionopathy		Paraneoplastic polyneuropathy	
Hereditary	Hereditary sensory neuropathy		Charcot-Marie-Tooth	Amyloidosis Riley-Day
Inflammatory	Sjogren disease	CIDP	Mononeuritis multiplex	
Paraproteinemias, dysproteinemias	Anti-MAG sensory neuropathy	Anti-Gjvii motor neuropathy	Waldenstrom macroglobulinemia	Amyloidosis

Note: Examples of a variety of causes of chronic neuropathy. This table is meant to illustrate the major classes of etiologies and the usefulness of classifying neuropathy by symptom complex. Syndromes of pure symptomatology (e.g., pure motor neuropathy) are rare but suggest a small number of potential causes. Note that the table is incomplete and does not necessarily list the most common neuropathies in each class. Many neuropathies present with distinct symptoms from those described above. Para- and dysproteinemias are assumed, but have not been proven, to be causative etiologies of nerve dysfunction.

report the acute onset of ipsilateral back pain, followed within days by progressive leg weakness. Sensory findings are absent. The examination reveals decreased leg power in a variety of patterns reflecting impairment of plexus function with relatively symmetric sensation. There may be muscle wasting in affected limbs in long-standing disease. Deep tendon reflexes may be diminished on the affected side. Bowel and bladder functions are not affected.

Laboratory studies are generally not helpful in the emergency setting. In the ED, routine plain films of the lumbar spine are useful to screen for spine compression from degenerative or neoplastic disease, and MRI is usually ultimately needed. The differential diagnosis also includes the cauda equina and conus medullaris syndromes and compression from arteriovenous malformations. Computed tomography (CT) scanning of the abdomen is useful to exclude aortic aneurysm and psoas muscle masses, which also lead to asymmetric lower extremity weakness. Patients with acute weakness from lumbar plexopathy should be admitted to the hospital for testing and rehabilitation to definitely determine the cause of weakness.

HIV-Associated Peripheral Neurologic Disease

HIV infection, its complications, and its pharmacologic treatments are associated with a number of peripheral neurologic disorders. Fortunately, the most common of these, HIV neuropathy and drug-induced neuropathy, are chronic processes that do not cause sudden disability or symptoms. HIV-infected patients also have a higher rate of mononeuritis multiplex and an inflammatory myopathy resembling polymyositis.

Occasionally, patients will complain of weakness that progresses over the course of days. Patients in the early stages of HIV infection have greater susceptibility to GBS. The presentation is similar to that of the non-HIV-infected patient, except that a CSF pleocytosis is seen commonly. Such patients should be treated as discussed earlier.

CYTOMEGALOVIRUS RADICULITIS In the latter stages of AIDS, patients may suffer from an acute radiculitis caused by cytomegalovirus (CMV) infection. These patients almost always have

evidence of CMV infection elsewhere in the body and may have ongoing CMV retinitis. Patients become acutely weak, with primarily lower extremity involvement, and may have variable degrees of bowel and bladder dysfunction. The examination shows primarily lower extremity weakness and hyporeflexia, with decreased sensation in the lower extremities and groin. Rectal tone may be impaired. Lumbar puncture reveals a pleocytosis with predominantly polymorphonuclear cells and modestly increased protein; viral DNA is detected by polymerase chain reaction in most patients and is highly specific. MRI of the lumbosacral spine demonstrates swelling and clumping of the cauda equina. Imaging of these patients is mandatory to exclude mass lesions of the lower spine or nerve roots. The treatment of CMV radiculitis is intravenous ganciclovir, started at 5 mg/kg every 12 h for 3 to 6 weeks, which may be initiated prior to definitive diagnosis.

CHRONIC CONDITIONS

Neuropathies can also be chronic or subacute associated with an underlying medical disorder. A detailed discussion of neuropathies associated with underlying medical illness is worthy of an entire text. The interested reader is referred to standard neurology texts.⁴ Table 233-2 shows the expected presentations for some diseases associated with peripheral neuropathies.

CHRONIC NEUROLOGIC DISORDERS

Edward P. Sloan

AMYOTROPHIC LATERAL SCLEROSIS

Amyotrophic lateral sclerosis (ALS), often referred to as Lou Gehrig disease, causes rapidly progressive muscle atrophy and weakness resulting from the degeneration of both upper and lower motor neurons. ALS causes varying degrees of spasticity, hyperreflexia, and muscle paralysis, eventually leading to pulmonary complications and the need for mechanical ventilatory support. Because there is no curative therapy for this disease, symptomatic management is directed at preventing pulmonary infections and forestalling terminal respiratory failure.

Epidemiology

There are two forms of ALS, the most common of which is sporadic ALS (sALS). The worldwide annual incidence rate for sALS is 0.6 to 2.0 per 100,000, and the prevalence is 4 to 6 per 100,000.¹ In the United States, 5600 new cases are diagnosed each year, causing an estimated prevalence of 30,000 U.S. ALS patients. The mean age of onset for sALS is 56 years, with a slightly higher incidence in men. Familial ALS (fALS) is genetically present in only 149 patients from 53 families worldwide (including a rare juvenile form), and there is an endemic focus of ALS in the western Pacific, especially Guam. The incidence of fALS is only 10 percent of that of sALS, with a 1.5-fold higher disease rate for men. In fALS patients, 20 percent have a change in the superoxide dismutase (SOD1) gene, which suggests the ability to test for the disease prior to symptom onset. There are no race differences with either of the forms of ALS. There is a higher prevalence of ALS in individuals older than age 60 years, and the annual worldwide ALS mortality rate is 1 per 100,000.

Pathophysiology

The most likely cause of ALS is a genetic superoxide dismutase dysfunction causing an abnormal response to a variety of environmental insults. Current theories of cell death in ALS include excitotoxins such as glutamate, free radicals, heavy metals, viral agents, and autoimmune reactions to tissues such as spinal cord collagen. Programmed cell death as a result of apoptosis is also being studied as a possible cell death etiology.

Gross central nervous system (CNS) pathology includes frontal cortical atrophy, degeneration of the corticospinal and spinocerebellar tracts, a reduction in large cervical and lumbar motor neurons, and cranial nerve nuclei degeneration. Both motor and sensory peripheral nerves are noted to undergo axonal degeneration and segmental demyelination, including motor end plate and axon terminal involvement.

Clinical Presentation

Upper motor neuron dysfunction causes limb spasticity, hyperreflexia (including Babinski sign and a brisk jaw-jerk reflex), and emotional lability. Lower-motor-neuron dysfunction causes limb muscle weakness, atrophy, cramps, fasciculations, dysarthria, dysphagia, and difficulty in mastication. At the time of initial presentation, asymmetric extremity cramping, fatigue, weakness, muscle fasciculations, and atrophy can be seen, especially in the upper extremities.² Patients with fALS more often present with isolated lower-extremity weakness and atrophy at the time of diagnosis. Despite these profound motor findings, sensory and cognitive function is usually spared. Regardless of the initial symptoms, widespread motor and respiratory dysfunction

progresses within weeks to months. Significant extremity atrophy occurs, as well as fasciculations, hyperreflexia, foot drop, and claw deformity of the hand. Patients also may develop monotonous speech caused by tongue atrophy, despite the relative sparing of facial and eye movements. Some patients eventually diagnosed as having ALS present initially with cervical or back pain consistent with an acute compressive radiculopathy. Despite successful operative intervention, these patients develop significant muscle wasting consistent with motor neuron dysfunction shortly after the procedure.³

Progressive respiratory muscle weakness initially causes exertional dyspnea and eventual dyspnea at rest. Dementia and parkinsonism also may occur in up to 15 percent of patients, especially those with fALS. Other cognitive problems such as apathy, poor attention and motivation, and altered social skills may be noted in ALS patients.

Clinical Diagnosis

The clinical diagnosis of ALS is suggested when there are signs of both upper and lower motor neuron dysfunction without other CNS dysfunction. ALS-like symptoms can be seen with other systemic illnesses such as diabetes, dysproteinemia, thyroid and parathyroid dysfunction, vitamin B₁₂ deficiency, heavy metal toxicity, and vasculitis, as well as CNS and spinal cord tumors. The diagnosis of ALS also requires that other inflammatory neuropathies such as myasthenia gravis be excluded. The World Federation of Neurology developed the El Escorial criteria for the diagnosis of ALS.⁴

Electromyography (EMG) demonstrates decreased muscle action potential amplitude and decremental responses to repetitive nerve stimulation, making it the most useful diagnostic test. Nerve conduction velocity studies, magnetic resonance imaging (MRI), spinal fluid analysis, and neuromuscular biopsies are also useful diagnostic studies.

Disease Management

Therapy is designed to enhance muscle function, especially those that support breathing, swallowing, and speech, in order to avoid malnutrition, recurrent aspiration, or choking. Riluzole is a drug that delays disease progression by preventing cell toxicity through modulation of the excitotoxin glutamate.⁵ It is most useful in patients with a clear diagnosis of ALS whose symptoms have been present for less than 5 years, with a forced vital capacity (FVC) >60 percent of predicted, without tracheostomy. An FVC below 25 mL/kg or a 50 percent FVC decrease increases the risk of aspiration pneumonia and respiratory failure. Optimizing pulmonary function, including the eventual use of long-term assisted ventilation, is an important part of enhancing the quality of life as diaphragm weakness progresses.⁶

Emergency Diagnosis and Management

Patients with ALS most often will not present to the ED undiagnosed unless there is extremely rapid disease progression or a long period without medical care. Emergency management usually is required for acute respiratory failure, aspiration pneumonia, choking episodes, or trauma related to extremity weakness. **Blood gas determination does not reliably predict impending respiratory failure**, because mild hypoxia and hypercarbia may exist throughout the disease course. Although no acute therapies exist for worsening ALS, therapies that optimize pulmonary function (e.g., nebulized medications, steroids, antibiotics, assisted ventilation, intubation) are indicated. Because the need for long-term ventilatory assistance rarely reverses, it is important to establish the patient's preference regarding intubation via a living will or the power of attorney for health care. Hospitalization is indicated with impending respiratory failure, pneumonia, the inability to control secretions, or a worsening overall status that requires social service intervention for long-term placement.

Long-Term Outcome

ALS causes a consistent, predictable deterioration in motor function, leading to tracheostomy in most patients within 2 to 4 years. ALS leads to complete respiratory failure in 80 percent and complete limb paralysis in 45 percent of patients. Although early diagnosis and aggressive management have increased the median survival of sALS, 50 percent of patients die within 3 years of diagnosis, and only 10 percent survive beyond 10 years. The use of riluzole in the ALS patients described above increased 12-month survival from 58 to 74 percent, with the greatest survival improvement seen in those with extensive bulbar symptoms (as opposed to those with primary limb symptoms). Patients diagnosed prior to age 40 years may survive up to four times than those diagnosed after age 60 years, especially if swallowing and airway control are spared. Survival in fALS is shorter, with a median survival of 2 years and a 23 percent 5-year survival rate. Long-term outcome is currently being followed in a longitudinal European survey termed the European ALS Health Profile Study.

MYASTHENIA GRAVIS

Myasthenia gravis (MG) is an autoimmune disease characterized by muscle weakness and fatigue, seen especially with repetitive use of voluntary muscles. Acetylcholine receptor (AChR) antibodies impair receptor function at the neuromuscular junction, causing muscle weakness, most often in proximal muscles. This weakness is generally relieved by rest, and requires long-term immunotherapy. Because the mechanism and optimal therapies for MG are well understood, much of the morbidity and mortality associated with the disease can be minimized. The diagnosis of cholinergic and myasthenic crises, and the aggressive management of respiratory complications associated with a myasthenic crisis are the most important issues for MG patients and emergency physicians.

Epidemiology

The incidence of MG is 0.4 per 100,000, and the prevalence is estimated to be 10 to 15 per 100,000.⁷ There are approximately 25,000 cases in the United States and 100 million cases worldwide. The most common age of onset for females is in the second and third decades. In males, the peak onset age is in the seventh and eighth decades. Although females were believed to have up to fourfold higher disease prevalence, as the population has aged, the higher prevalence has shifted to males. There is a slightly higher prevalence in the African American population. Although family members of patients with MG are much more likely to develop MG, the disease is not transmitted by traditional Mendelian inheritance.

Pathophysiology

MG is the most well understood of the human autoimmune disorders. In the normal neuromuscular junction, acetylcholine (ACh) release by the nerve fiber causes a localized end-plate potential that leads to muscle fiber contraction. In MG there is a marked decrease in the number and function of the muscle fiber AChR, despite normal nerve anatomy and function. Failure to respond to ACh stimulation causes decreased muscle fiber potential amplitudes, causing some fibers to fail to function and leading to decreased muscle strength. The autoimmune etiology of MG is demonstrated by the consistent presence of AChR autoantibodies in nearly all MG patients. These antibodies react to the AChR, can be transferred and cause the disease, and can be induced by immunization with AChR proteins. Similarly, disease severity can be correlated with AChR autoantibody levels. These autoantibodies cause accelerated AChR degradation, as well as receptor dysfunction and blockade, through complement activation.

The etiology of the pathologic autoimmune response is believed to be caused by dysfunction of either the thymus gland or the immune re-

sponse to exogenous infectious antigens. The thymus is found to be abnormal in 75 percent of MG patients, most often with hyperplasia or the presence of a thymoma. Thymectomy resolves or improves the symptoms in most MG patients, especially those with a thymoma. It is likely that the AChR autoantibodies arise following exposure to similar antigens, such as those caused by herpes simplex virus or bacteria infection, causing a pathologic attack on the AChR proteins.

Clinical Presentation

The symptoms of MG can mimic the symptoms seen in many other chronic neurologic disorders, such that some call it "the great imitator." Prior to the establishment of a definitive diagnosis, most MG patients have general weakness, especially of the proximal extremities muscle groups, neck extensors, and facial or bulbar muscles. Although ptosis and diplopia are the most common presenting symptoms, limb weakness and oropharyngeal symptoms such as dysphagia and dysarthria also can be seen initially or occur over time. These symptoms can fluctuate throughout the day, usually worsening as the day progresses or with prolonged muscle group use, such as with prolonged reading or prolonged chewing during a meal. The maximum extent of this weakness usually becomes manifest within the first year after the time of diagnosis. Despite the presence of profound muscle weakness, there usually is no deficit in sensory, reflex, or cerebellar functioning. MG in elderly patients can be misdiagnosed as ischemic stroke, especially when new-onset facial weakness is seen.⁸

Although the weakness seen in MG patients is focal and mild to moderate in severity, in rare instances undiagnosed MG patients may present with extreme weakness in the muscles of respiration, resulting in respiratory failure. This life-threatening situation, termed *myasthenic crisis*, can be seen prior to MG diagnosis or as a result of inadequate drug therapy or drug tolerance. The complications associated with the respiratory failure seen in acute myasthenic crisis are the leading cause of death in MG patients, but are fortunately rare, given the understanding of the disease and the available therapies.

Clinical Diagnosis

The diagnosis of MG should be considered in any patient who complains specifically of ocular disturbances or proximal limb muscle weakness not associated with systemic causes of generalized fatigue. Involvement of the facial muscles, muscles of mastication, and those that facilitate swallowing all may suggest MG, as well as the observations that the symptoms worsen as the day progresses and that rest alleviates the symptoms. Other causes of symptoms that suggest MG include congenital MG, Lambert-Eaton syndrome (seen with small cell lung tumors), drug-induced myasthenia (e.g., penicillamine, procainamide, quinines, aminoglycosides), botulism, thyroid disorders, and other causes of ocular disorders, such as progressive external ophthalmoplegia or intracranial mass lesions.

The diagnosis of MG is established through the administration of edrophonium chloride (an acetylcholinesterase inhibitor), EMG, and serologic testing for AChR antibodies. In the presence of abnormal neuromuscular transmission, edrophonium or neostigmine is expected to improve muscle strength in objectively weak limb, ocular, and pharyngeal muscles. Because these drugs can actually cause profound weakness in the presence of other disorders that impair neuromuscular transmission, one must be ready to provide ventilatory support or intubation as a complication of pharmacologic testing. EMG testing with repetitive nerve stimulation demonstrates a rapid reduction in the size of the muscle action potential, a finding that correlates with the clinical observation of enhanced weakness with prolonged or repetitive muscle use. AChR antibody testing is the most specific test for MG, but up to 15 percent of MG patients may have undetectable AChR antibody titers, especially those who have isolated ocular disturbances. Other useful tests in the diagnosis of MG include mediastinum thymus

imaging, laboratory testing for lupus, thyroid disorders, and tuberculosis, as well as pulmonary function testing.

Disease Management

The management of MG includes the administration of acetylcholinesterase inhibitors, thymectomy, chronic immune suppression, and acute immune modulation using plasma exchange or intravenous immunoglobulin, when indicated. MG patients, especially those with a thymoma, show a favorable response to thymectomy.⁹ Most show improvement with oral corticosteroids, although some patients initially become weaker prior to symptom improvement when high-dose steroids are administered. The use of azathioprine with oral prednisolone provides for fewer treatment failures and complications, longer remissions, and the need for a lower overall steroid dose.¹⁰ Severe MG symptoms, such as those that would require hospital admission, might require the use of intravenous immunoglobulins or a combination of high-dose steroids and plasma exchange.

Muscle weakness usually does not return to normal even with the use of these immunomodulators, and there can be great temporal variability in the nature and amount of MG patient muscle weakness. Variability in the amount of muscle weakness can be seen in response to asthma exacerbations, infections, menstruation, pregnancy, emotional stress, hot weather, and other disorders that alter the response to medication, such as pulmonary, renal, and gastrointestinal disease.

Emergency Diagnosis and Management

Several drugs used in the ED are known to affect neuromuscular function, and caution must be exercised with their use in MG patients (Table 234-1). If a drug is absolutely necessary, such as steroids for status asthmaticus, equipment for emergency endotracheal intubation should be immediately available because respiratory failure can develop rapidly. MG patients being treated in the ED for other conditions should receive their usual dose of cholinergic inhibitors such as pyridostigmine. The suggested dose is often 60 to 90 mg PO every 4 h. If a dose has been missed, the next dose is usually doubled. If the patient cannot take oral medications or is intubated, one-thirtieth the oral dose of pyridostigmine is given by slow intravenous infusion. Neurology consultation generally is needed to determine the optimal intravenous dose, rate of infusion, and timing of repeat doses.

The most significant ED complication of MG is respiratory failure, which is usually precipitated by infection, surgery, or the rapid tapering of immunosuppressive drugs. Although intubation should be considered in patients with a low FVC or in the presence of abnormal blood gas analysis, this decision is made primarily on clinical grounds. Because of the increased sensitivity of MG patients to neuromuscular junction inhibitors, **if avoidable, patients preferably should not receive either depolarizing or nondepolarizing paralytic agents** in preparation for intubation. Patients with myasthenia are extremely sensitive to these agents, and the paralytic effects can be expected to persist at least two to three times longer than in normal patients. Short-acting agents such as etomidate, fentanyl, or propofol can be used instead of these agents, and can be used in smaller doses.¹¹ If paralytic agents are necessary, some authors recommend using one-half the dose of these agents, although there are no clinical studies supporting this recommendation.

Myasthenic crisis, which occurs because of disease exacerbation or inadequate drug therapy, must be distinguished from cholinergic crisis, which is caused by excessive cholinergic drug therapy. This differentiation can be made in the emergency department by the use of the Tensilon test. Edrophonium chloride (Tensilon) is used for this purpose because of its rapid onset (30 s) and the short effects duration (5 to 10 min). A positive result, one that suggests that the symptoms are caused by a myasthenia exacerbation, is characterized by the resolution of muscle weakness within a few minutes. To ensure that the patient does not react adversely to the edrophonium test (as a result of excessive baseline cholinergic effects), 1 to 2 mg IV should first be injected. The occurrence of muscle fasciculations, respiratory depression, or cholinergic symptoms within a few minutes of this test dose of edrophonium suggests that the baseline muscle weakness is related to a cholinergic crisis and that further edrophonium administration is contraindicated. If there is no evidence of adverse cholinergic effects, up to 10 mg of edrophonium can then be administered in order to demonstrate benefit in the face of a presumed myasthenic crisis.

If muscle weakness is improved with the edrophonium, the Tensilon test is considered positive, indicating a myasthenic crisis. Neostigmine can then be given parenterally or PO. Intramuscular or subcutaneous neostigmine is given in 0.5 to 2 mg doses, with clinical effectiveness by 30 min, lasting for up to 4 h. Alternatively, 15 mg neostigmine tablets can be given, each having a clinical effect comparable with that of a 0.5 mg parenteral neostigmine injection.

TABLE 234-1 Drugs That Should Be Used With Caution in Myasthenia Gravis

Steroids	Kanamycin*	Amitriptyline	Lidocaine	Others
ACTH*	Gentamicin	Droperidol	Dilantin	Amantadine
Methylprednisolone*	Tobramycin	Haloperidol	Trimethaphan	Diphenhydramine
Prednisone*	Dihydrostreptomycin*	Imipramine		Emetine
Anticonvulsants	Amikacin	Paraldehyde	Local Anesthetic	Diuretics
Dilantin	Polymyxin A	Trichlorethanol	Lidocaine*	Muscle relaxants
Ethosuximide	Polymyxin B		Procaine*	CNS depressants
Trimethadione	Bacitracin	Antirheumatics		Respiratory depressants
Paraldehyde	Sulfonamides	D-Penicillamine	Analgesics	Sedatives
Magnesium sulfate	Viomycin	Colchicine	Narcotics	Procaine*
Barbiturates	Colistin	Chloroquine	Morphine	Tranquilizers
Antimalarials	Colistimethate*	Cardiovascular	Dilaudid	
Chloroquine*	Lincomycin	Quinidine*	Codeine	Neuromuscular blocking agents
Quinine*	Clindamycin	Procinamide*	Pantopon	Tubocurarine
IV Fluids	Tetracycline	Beta blockers	Meperidine	Pancuronium
Na lactate solution	Oxytetracycline	Propranolol		Gallamine
Antibiotics	Rolitetracycline	Oxprenolol	Endocrine	Dimethyl tubocurarine
Aminoglycosides	Psychotropics	Practolol	Thyroid replacement*	Succinylcholine
Neomycin*	Chlorpromazine*	Pindolol	Eyedrops	Decamethonium
Streptomycin*	Lithium carbonate*	Sotalol	Ecothiopate	

*Case reports implicate drugs in exacerbations of myasthenia gravis.

Source: This table is a modified version of the table from Adams SL, Matthews J, Grammer LC: Drugs that may exacerbate myasthenia gravis. *Ann Emerg Med* 13:532, 1984, with permission.

In children, the total edrophonium intravenous dose is 0.15 mg/kg, not to exceed 10 mg. To test hypersensitivity in children, an initial intravenous edrophonium dose one-tenth that of the total dose can be given. For children weighing up to 75 lb (34 kg), a test dose of 1 mg is appropriate, and a total dose of 5 mg can be used in 1-mg increments. In infants, or when intravenous access is not available in children up to 75 lb, an intramuscular edrophonium test dose of 0.5 to 2 mg can be given.

Caution should be exercised when administering edrophonium to patients with cardiac disease, because it may cause bradycardia, atrioventricular (AV) block, atrial fibrillation, and **cardiac** arrest. Although atropine will counteract these muscarinic effects of edrophonium, it is ineffective in reversing the nicotinic effects, such as skeletal muscle paralysis, that can occur in the face of a cholinergic crisis.

Acute respiratory failure can result from either acute myasthenic or acute cholinergic crisis. Cholinergic crisis patients who fail the Tensilon test may require immediate intubation and management of excessive secretions and acute bronchospasm. When determining final disposition, the emergency physician also must consider other complications of muscle weakness in MG patients, such as impaired swallowing, aspiration pneumonia, dehydration, and decubitus ulcers.

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is a neurologic disorder that causes variable motor, sensory, visual, and cerebellar dysfunction as a result of multifocal areas of CNS myelin destruction. Paresthesias, gait difficulty, extremity weakness, poor coordination, and visual disturbances occur most often with a relapsing and remitting clinical course. Despite the lack of a definitive cure, immunosuppression and immunomodulation provide adequate symptomatic relief in the majority of MS patients, such that most sustain only mild to moderate lifetime morbidity without a reduction in overall life expectancy.

Epidemiology

Three clinical courses are noted in patients with MS. Up to 80 percent of MS patients have a relapsing and remitting course, with relapses lasting weeks to months. The remaining patients have either a relapsing and progressive course or a chronically progressive clinical course, the latter of which is more common with advanced age. The incidence of MS is 3.2 to 8 per 100,000, and the prevalence may be greater than 200 per 100,000.⁷ In the United States, the peak age of onset for either sex is during the third decade of life. Females are two to three times more likely to contract MS, and they do so at a younger age than do men. Males, however, are more likely to have a chronically progressive disease course from the time of symptom onset. MS is two times more likely in whites than in blacks, and is rare in Asian populations. There is a geographic MS distribution, with temperate climates of economically developed countries experiencing a higher prevalence. Communities of northern Europe and the United States have prevalence rates of up to 173 per 100,000 in the white population. In the northern hemisphere there is a diminishing MS prevalence gradient that runs from north to south, while the opposite is true in the southern hemisphere. In general, 5 to 10 percent of MS patients will sustain a malignant course, and 20 to 35 percent will have a very benign disease course. Although pregnancy reduces the MS relapse rate by 50 percent, relapse risk increases up to sixfold during the postpartum period.

Patho physiology

Although the etiology of MS is unknown, it is best described as an inflammatory disorder resulting in scattered neuron demyelination. The most frequently postulated theory for MS is a genetic predisposition triggered by a virus (such as herpes or human T-cell leukemia virus

type I), heavy metals, or other environmental toxins that induce an immune-mediated neuronal inflammation and demyelination. MS causes a dysfunction in oligodendrocytes such that the axonal myelin sheaths are damaged, slowing nerve impulse conduction. These scattered cerebral and spinal plaques cause gliosis primarily in the white matter, with relative axon sparing.

These plaques occur in multiple areas, including the cerebrum, brainstem, spinal cord, and cranial nerves. The brain may have variable amounts of atrophy and ventricular dilatation. Nerves in the corticospinal tracts, posterior columns, and spinothalamic tracts will cause upper motor neuron, proprioception/vibration, and pain/temperature dysfunction, respectively. Cranial nerve dysfunction most often causes optic neuritis, as well as facial motor and sensory deficits.

Clinical Presentation

MS is suggested when a young person presents multiple times with neurologic symptoms that suggest different areas of pathology, often with resolution of the prior symptoms. Most MS patients will have more severe lower extremities symptoms as compared with the upper extremities. For example, a young person might complain of an inability to walk on a street without tripping over a curb or a sense of clumsiness with physical **activity**.

The physical examination may reveal decreased strength, increased tone, hyperreflexia, clonus, Babinski reflex, a decrease in both vibration sense and joint proprioception, as well as a reduction in pain and temperature sensation. Although sensory and motor deficits are present initially in only one-third of patients, all patients will experience these findings at some point during the disease course. Patients describe these deficits as a heaviness, weakness, stiffness, or extremity numbness. *Lhermitte sign* is commonly experienced during the course of MS and is described as an electric shock sensation, a vibration, or a pain radiating down the back and often into the arms or legs resulting from the flexion of the neck. Rarely, patients with established MS may present with complete or near-complete loss of motor function, termed *acute transverse myelitis*. Cerebellar lesions may cause a kinetic tremor, dysmetria, or truncal ataxia. Vertigo may be seen as a result of brainstem MS lesions.

Optic neuritis, which usually causes acute or subacute central vision loss, may be the initial sign of MS in up to 30 percent of patients. The loss, which occurs over several days and is usually unilateral, often is preceded by retrobulbar pain or extraocular muscle pain that may be reproduced with periorbital palpation. Optic neuritis may cause an afferent pupillary defect, or Marcus Gunn pupil. Although funduscopy is most often normal in the acute setting, the optic disk may be noted to have pallor due to axonal loss and gliosis. Although the ocular pain most often resolves over several days, it may take up to months for the visual disturbances to resolve. Most MS patients at some time experience blurred vision, compromised color vision, and/or eye pain due to optic neuritis. In fact, visual acuity may worsen due to increases in body temperature, known as *Uhthoff phenomenon*. Nystagmus and diplopia are often seen in MS, as is internuclear ophthalmoplegia. Internuclear ophthalmoplegia usually causes abnormal adduction bilaterally and horizontal nystagmus. When bilateral internuclear ophthalmoplegia is seen acutely in an otherwise healthy young person, it is highly suggestive of MS.

Dysautonomias can cause vesicourethral dysfunction, resulting in urinary retention, urgency, frequency, detrusor-external sphincter dyssynergia, and stress or overflow incontinence. Gastrointestinal dysfunction can cause constipation and fecal incontinence in MS patients. Sexual dysfunction, especially in males, may be the presenting MS symptom and is correlated with other types of urologic dysfunction. Cognitive and emotional changes, including dementia, decreased motivation, depression, and bipolar mood disorders occur in most MS patients. Cerebral MS, which affects only 5 percent of MS patients, can cause a severe, disabling decrease in intellect as well as focal seizures.

MS symptoms often will worsen with increases in body temperatures, as seen with exercise, fever, or even hot baths. Most initial MS attacks or exacerbations will progress over several days, peaking at about 1 week, with resolution over several weeks to months. Complete recovery from an acute attack or exacerbation occurs more commonly early in the course of the disease.

Clinical Diagnosis

The diagnosis of MS is clinically based, relying heavily on the neurologic history and physical examination. The diagnosis is suggested when a patient has either two or more prolonged or worsening episodes of neurologic dysfunction that suggest distinct white matter pathology or spinal cord dysfunction in two or more distinct locations.¹⁴ Optic, cerebrospinal fluid (CSF), and neuroimaging findings, as well as typical features such as dysautonomias all suggest the diagnosis of MS. Symptoms that mimic MS are seen with systemic lupus erythematosus, Lyme disease, neurosyphilis, HIV disease, and Guillain-Barre syndrome, which is associated with peripheral nervous system demyelination.

Nearly all MS patients will demonstrate some CNS pathology by MRI. T2-weighted scans demonstrate either discrete lesions in the supratentorial white matter or homogeneous borders surrounding the ventricles. Although computed tomography (CT) is not as sensitive as MRI, it may show cerebral atrophy, ventricular enlargement, and low-density focal lesions in the cerebrum, brainstem, or optic nerves. CSF protein and gamma-globulin concentrations are elevated in many MS patients. A slight increase in CSF white blood cells (up to 25/xL) is also seen, most of which are T lymphocytes. Evoked potentials demonstrate scattered slowing in CNS pathway conduction in the majority of MS patients.

Disease Management

The long-term management of MS is directed at slowing the progression of the disease and providing symptomatic relief during exacerbations. In order to modify the frequency and severity of MS exacerbations, immunomodulation with glucocorticoids, interferon- β , and glatiramer, as well as immunosuppression with mitoxantrone are recommended for subsets of MS patients.¹⁵ High-dose methylprednisolone therapy shortens the duration of exacerbations, and may be most effective early in the disease course.¹⁶ Diets high in fruits, vegetables, and grains may protect against the development of MS symptoms. Because relapses are less common during pregnancy, the use of the pregnancy hormone estriol has preliminarily been shown to be beneficial in female MS patients.¹⁷

Emergency Diagnosis and Management

Emergency therapy is directed at minimizing the complications of acute MS exacerbations, such as respiratory distress, optic neuritis, pulmonary infections, severe constipation, and worsening muscle weakness. Airway management with endotracheal intubation should use rapid sequence induction and the Sellick maneuver because of an increased aspiration risk as a consequence of decreased gastric motility. Also, because many MS patients have labile autonomic nervous system function, they are at greater risk of developing hypotension in the settings of rapid sequence induction, emergent intubation, and surgical anesthesia. Seizures can be treated with the standard benzodiazepine and phenytoin drugs. Fever must be reduced in order to minimize the weakness caused by elevated temperature. Urinary tract infections and pyelonephritis must be excluded during any MS exacerbation, especially in patients with residual urine volumes greater than 100 mL. A postvoid residual urine determination, a urine culture, and antibiotic therapy all should be provided whenever there is clinical evidence of an urinary tract infection or significant bacteriuria.

When feasible, discharged patients should manage elevated residual urine volumes with intermittent sterile catheterization as opposed to placement of a urinary drainage catheter.

Hospitalization is indicated for any exacerbation that puts the MS patient at risk of further complications or when intravenous antibiotic or steroid therapy needs to be initiated. Admission is also indicated when depression and a significant risk of suicide require inpatient management.

LAMBERT-EATON MYASTHENIC SYNDROME

Lambert-Eaton myasthenic syndrome (LES), like myasthenia gravis, is an autoimmune disorder that causes fluctuating weakness and fatigue, especially of the proximal limb muscles. It is 100 times less common than MG, and unlike patients with MG, LES patients may show some improvement in strength with sustained or repeated exercise. For example, when an LES patient is asked to grasp the examiner's hand, the squeeze becomes more forceful over several seconds, termed *Lambert sign*. Patients often complain of myalgias, muscle stiffness, paresthesias, metallic tastes, and autonomic symptoms (e.g., dry mouth and impotence) caused by muscarinic cholinergic insufficiency. Although eye movements are unaffected, the pupillary reaction can be abnormal, and the reflexes can be diminished. The sensory examination can be normal, but because LES is associated with malignancy, paraneoplastic or chemotherapy-induced neuropathy can lead to a superimposed sensory deficit. LES is predominantly a disease associated with older men with a history of cigarette smoking and lung cancer, although it can occur in younger women without an associated neoplasm. When seen with a neoplasm, it can precede detection of the malignancy by several years. EMG and single-fiber EMG examinations are abnormal in LES patients as a result of diseased calcium channels at the cholinergic nerve terminals. Serum tests are highly specific for antibodies to the voltage-gated calcium channels.

Only in rare cases does LES progress to respiratory or bulbar failure, such that the acute treatment of LES patients, as with the other chronic neurologic disorders, is mainly supportive. Treatment of the neoplasm can markedly improve LES symptoms, as can treatment with cholinesterase inhibitors such as pyridostigmine. Neuromuscular transmission can also be enhanced with 3,4-diaminopyridine (DAP). Immunosuppression with corticosteroids and azathioprine also can be used to reduce symptom severity.¹⁸ Hospital admission is required when infectious complications occur or when severely disability requires inpatient immunotherapy with IV immunoglobulin or plasma exchange.

PARKINSON DISEASE

Parkinson disease (PD) is the most common of the chronic neurodegenerative diseases. It is an extrapyramidal movement disorder characterized by the presence of a resting tremor, cogwheel rigidity, bradykinesias or akinesias, and impaired postural reflexes. Although the exact disease etiology is unknown, PD patients consistently have a reduced number of functional dopaminergic receptors in the substantia nigra. Drug therapy is designed to enhance central dopaminergic activity, thus decreasing the relative excess in central cholinergic activity. Even though multiple drug and surgical therapies can be used to minimize PD symptoms, the disease still progresses without symptom remission in most patients.

Epidemiology

Epidemiologic studies suggest that PD is caused primarily by environmental factors in patients who possibly may have a genetic predisposition to the disease. The overall U.S. incidence is 16 cases per 100,000 persons and is as high as 200 per 100,000 in patients in their seventh and eighth decades of life, affecting up to 1.5 million Americans.¹⁹

The average onset age is between 55 and 60 years, with the peak age of onset between 70 and 79 years.

Pathophysiology

PD is characterized by consistent CNS changes, including the presence of cellular cytoplasmic inclusions termed *Lewy bodies*, and extracellular pigment granules that stimulate macrophage activity. An oxidative phosphorylation disturbance and free radical formation is thought to be one possible mechanism for these changes. In the pigmented areas of the midbrain, especially the substantia nigra, there is depigmentation, dopaminergic neuron loss, and gliosis. These cellular changes result in the loss of functional dopaminergic receptors, causing a decrease in the overall level of striatal dopamine.

Clinical Presentation

The clinical diagnosis of PD is based on the presence of one or more of four hallmark neurologic signs identified in the mnemonic *TRAP*: resting *tremor*, cogwheel *rigidity*, bradykinesia or *akinesia*, and impairment in *posture* and equilibrium. Besides these signs, there also may be facial and postural changes, voice and speech abnormalities, depression, and muscle fatigue. Prior to the diagnosis of PD, most patients will have symptoms for months to years, including a general feeling of slowness or stiffness and/or difficulties with handwriting and other skills that require manual dexterity.

Most often patients will complain initially of a unilateral resting tremor of the upper extremity. The tremor is a repetitive low amplitude movement of the fingers and thumb that occurs five or more times per minute, described as "pill rolling." These tremors, which also can be seen in the legs or face, most often dissipate when intentional movement is performed, which differentiates it from the kinetic tremor of other neurologic disorders. The resting tremor of PD will become less prominent as the patient performs the finger-to-nose test and resumes once this purposeful movement is ended and the limb is supported and at rest. Cogwheel rigidity is elicited by causing passive movement of the limb through a full range of motion. As the limb is moved, the muscles will develop an increased tone, and a ratchet-like movement is noted. Bradykinesia, the general sense of slowness of voluntary movement, is often felt to be the most debilitating symptom of PD. The most severely affected PD patients can develop akinesia, the inability to perform the movements necessary for daily living, such as turning over in bed, rising from a seated position, or walking. When PD impairs postural reflexes, patients may have an impaired ability to turn or change direction while walking or may lose their balance and fall.

Clinical Diagnosis

The clinical diagnosis of PD is easy to recognize, given the presence of the TRAP symptoms. Once noted, the patient should be questioned about any family history of neurologic disorders, a prior history of encephalitis or other CNS infections, concurrent drug use, and any exposure to toxins or street drugs. The symptoms of PD also can be seen in postencephalitis patients and those with other infections such as neurosyphilis, subacute spongiform encephalopathy, and AIDS. Parkinsonism also can occur as a result of street drugs, toxins, neuroleptic drugs, hydrocephalus, head trauma, and with more rare and complex neurologic disorders.

Although once thought to be a common cause of parkinsonism, cerebral infarction is now considered an unusual cause of these symptoms.

In drug-induced PD, akinesia is the most common sign, with resting tremor less commonly observed. Other characteristics of drug-induced parkinsonism include a history of drug ingestion known to interfere with central dopamine activity, short interval between symptom onset and maximal disability, bilateral presentation of motor dysfunction, and the presence of other drug-related motor abnormalities.

There is no definitive laboratory or neuroimaging study that is pathognomonic for PD. Although positron emission tomographic (PET) scans may be useful in demonstrating this CNS pathology, CT and MRI most often only show CNS atrophy.

Disease Management

Although currently available therapies do not change the underlying pathology of PD, their use can significantly reduce symptoms. These drugs include anticholinergics such as trihexyphenidyl and benzotropine; drugs that increase central dopamine levels such as amantadine, levodopa, and carbidopa; and dopamine receptor agonists such as bromocriptine and pergolide. When PD symptoms cause severe motor dysfunction, the monoamine oxidase inhibitor selegiline and the catechol methyltransferase inhibitors entacapone and tolcapone may be effective through beneficial dopamine metabolism.

Levodopa, which is converted into dopamine by decarboxylases that are present peripherally, can cause symptoms such as anorexia, nausea, and vomiting due to increases in peripheral dopamine levels. When levodopa is combined with carbidopa, a peripheral decarboxylase inhibitor, smaller doses of levodopa are required for effectiveness, reducing side effects. Over time, the effectiveness of levodopa will diminish, requiring the additional use of dopamine receptor agonist therapy. PD patients who are fully mobile, in the "on" state, can suddenly convert to the "off" state and become akinetic, especially in the morning shortly after rising and prior to taking the initial daily dose. This "on-off" phenomenon is treated by the use of controlled-release preparations of the combined carbidopa-levodopa therapy.

When drug therapy effectiveness diminishes over time, or when significant motor or psychiatric complications occur, a "drug holiday" lasting about 1 week is often attempted. Despite the fact that withdrawal of dopaminergic therapy can worsen PD symptoms, functioning actually can improve once therapy is resumed, lasting weeks to months.

The treatment for drug-induced parkinsonism, which most often causes akinesia, is termination of the causative agents, which presumably either acts to block central dopamine receptors (neuroleptics, metoclopramide) or reduce central dopamine levels (reserpine). Patients who are refractory to optimal drug therapy for all types of PD may benefit from pallidotomy, a stereotactic neurosurgical procedure that enhances medical therapy effectiveness and reduces dyskinesia severity.^{20,21} Thalamic stimulation or thalamotomy are useful for PD patients with severe tremor.

Emergency Diagnosis and Management

Although most PD patients present to the ED already diagnosed, some might present undiagnosed with motor or sensory symptoms that may not be related immediately to the diagnosis of PD. Patients may experience motor symptoms such as freezing episodes, dysphagia, or abnormalities of whole-body movement. Sensory complaints may include akathisia, paresthesias, muscle aches, or extremity pain. Although severe pain is usually related to the loss of medication efficacy, it can be the prominent symptom of undiagnosed PD.

Complications related to the motor, gait, and truncal disabilities of PD include deep venous thrombosis, pulmonary embolism, aspiration pneumonia, compressive neuropathies, and trauma related to falls. Autonomic disturbances such as orthostatic hypotension, intestinal motility disorders, and bladder dysfunction can occur, as well as facial seborrhea. Behavior abnormalities caused by frontal lobe dysfunction and dementia also are seen.

Dyspnea, respiratory distress, and pneumonia are more likely during the "off" periods, when drug efficacy is reduced. The most common cause of death in severe PD is respiratory failure.

Dopaminergic therapy toxicities can include cardiac dysrhythmias, orthostatic hypotension, dyskinesias, and dystonias. Psychiatric and

sleep disturbances, including nightmares, auditory and visual hallucinations, paranoia, and frank psychosis, is related to the treatment dose and duration, and can be improved by a reduction in dosage or a drug holiday. Depression and panic attacks are common, and can occur in PD patients independent of dopaminergic therapy.

Psychotropics that are known to cause tardive dyskinesia, such as haloperidol, must be used cautiously in patients with PD because of an increased risk of this complication. Patients may manifest lingual, facial, or buccal dystonias and choreic movements similar to those seen with Huntington chorea or tardive dyskinesia. These drug effects unfortunately are relatively common but can also be alleviated with a drug holiday or a decrease in levodopa dosage. Adjustment of chronic PD therapies should be done in consultation with the patient's primary care physician, who can often help to determine which symptoms reflect dopaminergic excess and whether prior drug holidays have improved the patient's symptoms.

POLIO MYELITIS AND POSTPOLIO SYNDROME

Poliomyelitis is a neurotropic enterovirus that causes paralysis through motor neuron destruction, muscle denervation, and atrophy. Indigenously acquired wild poliovirus was eradicated from the United States in 1979, and from the Western Hemisphere in 1991. However, the disease is occasionally still seen among those originating from other populations. Postpolio syndrome, termed *postpoliomyelitis progressive muscular atrophy* (PPMA), is an important sequelae of acute poliomyelitis. This disorder is characterized by the recurrence of motor symptoms following a latent period of several decades after the resolution of the motor symptoms caused by the initial infection.

Epidemiology

Poliomyelitis, an infection caused by a group of enteroviruses, leads to significant striated muscle paralysis in less than 5 percent of infected patients.²³ Prior to mass immunization, virtually all children were exposed to and developed antibodies to this enterovirus infection by age 4 years. A 1952 polio epidemic caused 14 new cases of paralytic polio per 100,000 persons, a rate similar to that seen in developing countries that are unable to provide mass immunization. Polio rates as high as 600 cases per 100,000 were seen as recently as the early 1980s in India. Mass immunization with the inactivated poliovirus vaccine or attenuated oral poliovirus (OPV) has dramatically reduced the incidence of polio, which was 0.003 cases per 100,000 persons in the United States in 1981. Polio outbreaks still occur in populations that are not consistently immunized, such as were seen in the 1979 U.S. Amish epidemic, which was caused by the wild poliovirus type 1. Outbreaks also have been seen in association with inadequate immunization with modified poliovirus type 3, as was seen in the Finland outbreak in 1984-1985. With the use of OPV, some immunized children will develop polio, as will some young adults who are exposed to children who have been vaccinated with the OPV vaccine. Immunocompromised patients are at greater risk for contracting polio after exposure to children who were vaccinated with the OPV vaccine. In developing countries, recent intramuscular injections, tonsillectomy, and strenuous exercise all are associated with increased polio infection severity.

The prognosis for most enteroviral CNS infections is favorable with the exception of paralytic poliomyelitis and those enteroviral infections which occur during the first year of life.

PPMA is expected to afflict up to 100,000 of the 250,000 U.S. adults with a prior history of polio. Because the majority of these polio cases occurred prior to mass immunization, these patients most likely will be older than age 50 years. There is no gender predisposition for PPMA. Although PPMA most often occurs after a stable, disease-free period of 20 to 30 years, there are risk factors that predict an earlier onset of postpolio syndrome. These include greater age at the time of initial polio infection, greater residual motor disability,

residual bulbar or respiratory signs, and the occurrence of recent injuries that require limb immobilization.

Pathophysiology

In developed countries the viral transmission is oral to oral, whereas in developing countries where the sanitation is poor the transmission is fecal to oral. Acutely, the polio enterovirus enters the body via the gastrointestinal tract and reproduces in the gastrointestinal lymphoid tissue, termed *gut-associated lymphoid tissue*. Oral secretion of the virus takes place for several days and stool excretion for several weeks.

At a critical concentration, the virus spreads to the large motor nuclei of the spinal cord, the brainstem, and the reticular formation. The vestibular and brainstem motor nuclei, hypothalamus, thalamus, cerebellum, and the precentral motor cerebral cortex also can be infected by the poliovirus. The infected neurons sustain Nissl granule dissolution and disruption, causing neuronal loss and gliosis. Most affected neurons have an altered morphology, and half are destroyed during the first week of acute paralysis. Neuron loss then causes a cycle of muscle denervation and reinnervation, resulting in lost muscle function.

The pathology of the postpolio syndrome remains unclear. The motor neuron degeneration seen in PPMA is thought not to be a result of the loss in whole motor neurons, as is seen in ALS, but rather a result of a dysfunction in the individual nerve axons in surviving motor neurons. It is suggested that postpolio fatigue is similar to that seen in chronic fatigue syndrome, both of which may cause fatigue by causing a relative depletion of central dopamine.²⁴ Although bromocriptine, amantadine, and pyridostigmine all have been studied in PPMA, none have been shown to be effective in minimizing patient symptoms.^{25,26}

Clinical Presentation

Polio infection remains asymptomatic in more than 90 percent of cases. The majority of symptomatic polio infections involve only a minor viral illness that causes no paralysis, termed *abortive polio*. After an incubation period of a few days, symptoms may include fever, malaise, headache, sore throat, and gastrointestinal symptoms. Some of the patients who experience the minor viral illness, especially young children, may develop aseptic meningitis as the infection resolves. Only 1 to 2 percent of all poliovirus infections result in the major illness associated with neurologic involvement. Often there is resolution of the minor viral illness symptoms prior to development of neurologic symptoms, such that it is difficult to identify the preceding minor viral illness. Muscle pain, stiffness, and weakness during the early viral syndrome may suggest the later occurrence of paralysis. Because exercise can exacerbate the severity of the subsequent paralysis, patients with these symptoms suspected of having polio should be advised to avoid exercise.

When the major illness occurs, most commonly the spinal cord anterior horn cells are affected, causing asymmetric proximal limb weakness, especially in the lower extremities. Flaccid and weak muscles, absent tendon reflexes, and fasciculations, characterize spinal polio. Although polio patients note pain, paresthesias, and transient sensory abnormalities, sensory deficits are usually not found on clinical examination. Maximal paralysis usually occurs within five days, and muscle wasting then occurs over several weeks. Autonomic dysfunction, including sweating disturbances, urine retention, delayed gastric emptying, and constipation, is commonly found. Most spinal polio patients will demonstrate improved motor function, with resolution of the paralysis occurring within the first year after the acute infection.

Up to 20 percent of polio patients with paralysis will develop bulbar polio, which can cause speech, swallowing, facial muscle, and extraocular muscle dysfunction. Acute polio infection also can cause encephalitis and can disturb the reticular formation, resulting in cardiac dysrhythmias, blood pressure alterations, hypoxia, and hypercarbia. Patients who survive the acute episode of encephalitis normally will recover without residual affects.

Patients who present with postpolio syndrome complain of muscle fatigue, joint pain, worsening of skeletal deformities, or weakness in muscles that were spared during the initial viral infection.²⁷ These complaints occur on average 30 years after maximal resolution of the neurologic symptoms caused by the initial polio infection. When muscle weakness is observed, atrophy, pain, and fasciculations may be noted both in previously unaffected muscle groups and in those previously involved. Patients with PPMA also may present with new bulbar, respiratory, or sleep difficulties. For example, laryngeal muscle weakness can cause progressive dyspnea, dysphagia, and/or hoarseness. Some patients complain of abnormal movements in sleep that disturb normal sleep, requiring therapy with benzodiazepines or dopaminergic drugs.²⁸ These symptoms occur independent of any concurrent neurologic, orthopedic, psychiatric, or systemic medical illness.

Clinical Diagnosis

Acute paralytic poliomyelitis should be considered whenever an at-risk patient (see above) presents with an acute febrile illness, aseptic meningitis, and asymmetric flaccid paralysis associated with the loss of deep tendon reflexes and normal sensation. As with other causes of aseptic meningitis, the CSF reveals pleocytosis during the first week after paralysis onset. The CSF white cell count can elevate into the hundreds, with a predominance of neutrophils early in the disease course. These cells allow noninflammatory causes of paralysis to be excluded from the differential diagnosis. Although the poliovirus can be cultured from the CSF early in the disease course, throat and rectal swabs will provide a greater yield. When a particular viral serotype is identified, serial serum antibody titers can be used to verify the cultures.

The most important cause of paralysis that must be excluded is Guillain-Barre syndrome, which, unlike the acute polio infection, causes more symmetric muscle weakness. Acute paralysis can result from peripheral neuropathies caused by infectious mononucleosis, Lyme disease, or porphyria. Paralysis also can result from inflammatory myopathies, electrolyte abnormalities, toxins, or other viruses, such as coxsackieviruses, mumps, echoviruses, and nonpolio enteroviruses. Paralysis also can result from acute spinal cord compression, vascular lesions, and transverse myelitis, all of which should produce a sensory level and sphincter disturbances. In children, it is necessary to exclude spinal muscular atrophy, which can be undiagnosed until it is manifested by dramatic limb weakness caused by an acute febrile illness.

To diagnose postpolio syndrome, the patient should have a history of acute paralytic poliomyelitis with stable recovery of motor function associated with residual muscle atrophy, weakness, and areflexia with normal sensation in at least one limb. Additionally, there should be new muscle symptoms or weakness not attributable to an acute injury, neuropathy, radiculopathy, or systemic, neurologic, or psychiatric illness.

Disease Management

Treatment of the new muscle weakness seen with postpolio patients is primarily symptomatic, with the use of analgesic and anti-inflammatory medications. The onset of new weakness that is severe enough to cause the complications seen with the other chronic neurologic disorders such as ALS, MG, or MS is not to be expected. However, dyspnea, respiratory dysfunction, sleep disorders, and psychiatric disorders all must be addressed in patients with worsening PPMA.²⁹

the predominant causes of meningitis in children 1 month of age or older.² Antibiotic resistance of *S. pneumoniae* to penicillins and ceftriaxone is becoming more prevalent in the United States. While such resistance has been encountered to date mostly in children, the clinician should consider modifying antibiotic selection for both children and adults with suspected pneumococcal meningitis (Table 235-1). The following discussion focuses on bacterial meningitis in adults.

Pathophysiology

Bacterial meningitis begins with the entry of organisms into the well-defended subarachnoid space. The ability to infect the subarachnoid space is not shared equally by all bacteria. The dominance of three organisms—*S. pneumoniae*, *H. influenzae* type b, and *N. meningitidis*—that cause over two-thirds of bacterial meningitis is not accidental. These encapsulated organisms share the ability to invade the host through the upper airway, survive dissemination through the bloodstream, and then gain access to the subarachnoid space. The subcapsular constituents of these organisms are a strong trigger of inflammatory cascades in the host. Inflammation produces the clinical picture of fever, meningismus, and eventually altered mental status that are the hallmarks of the disease. Stimulation of pain-sensitive structures in meninges and posterior spinal roots leads to headache and meningeal signs. The brain and meninges, encased in the fixed-volume skull, become edematous. Cerebrospinal fluid (CSF) drainage is reduced by interference with its flow in the subarachnoid pathways as well as its absorption by the arachnoid granulations. Hence the quantity of CSF increases, causing communicating or noncommunicating hydrocephalus. Intracranial blood vessels expand initially, increasing the volume occupied by that compartment. The brain itself swells by several mechanisms. Disruption of the blood-brain barrier allows entry of protein and ultimately water (vasogenic edema), simultaneously hydrocephalus forces CSF into the periventricular parenchyma (interstitial edema). Eventually, cell membrane homeostasis may be compromised, leading to increased intracellular water (cytotoxic edema).

The sum of these expanded volumes overwhelms the compensatory displacement of CSF into the more compliant spinal compartment, and intracranial pressure rises as a result. Since brain perfusion depends on arterial pressure exceeding tissue pressure (in this case, intracranial pressure), ischemia may develop. Diminished perfusion is all the more likely because the vascular supply is burdened with an inflammatory infiltrate whose functional and structural consequences include faulty autoregulation, inflammatory narrowing, and a prothrombotic milieu. There are some variations on the pathophysiologic

235 CNS INFECTIONS Keith E. Loring BACTERIAL MENINGITIS

In cases of bacterial meningitis, the two most critical actions in the emergency department are to suspect it and to begin empirical treatment promptly. In the emergency department it is often impossible to distinguish with certainty bacterial meningitis from meningitis due to viruses, fungi, and other organisms or those due to neoplastic, toxic, and autoimmune processes from bacterial meningitis on the basis of clinical findings and sometimes even lumbar puncture (LP) results. If the clinical situation and the emergency physician's practice environment permit, the diagnostic groundwork can be laid for establishing alternative diagnoses. Prompt initiation of therapy must take priority over all diagnostic maneuvers when bacterial meningitis is part of the differential diagnosis.

Epidemiology

Attack rates of meningitis are age-specific, ranging from almost 400 per 100,000 in neonates to 1 to 2 per 100,000 in adults. Two-thirds of cases are in children.¹ Long-term complications, such as cognitive deficits, epilepsy, hydrocephalus, and hearing loss, affect about a quarter of survivors. Prior to 1985, three species accounted for the majority of bacterial meningitis: *Haemophilus influenzae* (45 percent), *Streptococcus pneumoniae* (18 percent), and *Neisseria meningitidis* (14 percent). However, the specific cause of bacterial meningitis has changed dramatically in the era of vaccination against *H. influenzae* type b. From 1991 to 1996 alone, the incidence of *H. influenzae* meningitis in children younger than 5 years of age dropped from a rate of 100 per 100,000 to less than 0.3 and has remained at that level through 2000. Hence *S. pneumoniae* and *N. meningitidis* have become

TABLE 235-1 Guidelines for Empirical Treatment of Bacterial Meningitis* with No Organisms on Gram Stain

Patient Category	Potential Pathogens	Empirical Therapy
AGE		
18–50 years	<i>S. pneumoniae</i> , <i>N. meningitidis</i>	Ceftriaxone 2 g IV q12h plus vancomycin or rifampin if <i>S. pneumoniae</i> resistance possible
Older than 50 years	<i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>L. monocytogenes</i> , aerobic gram-negative bacilli	Ceftriaxone 2 g IV q12h plus ampicillin 2 g IV q4h plus vancomycin or rifampin if <i>S. pneumoniae</i> resistance possible
SPECIAL CIRCUMSTANCES		
CSF leak with history of closed head trauma	<i>S. pneumoniae</i> , <i>H. influenzae</i> , group B streptococcus	Ceftriaxone 2 g IV q12h
History of recent penetrating head injury, neurosurgery, CSF shunt	<i>S. aureus</i> , <i>S. epidermidis</i> , diphtheroids, aerobic gram-negative bacilli	Vancomycin 25 mg/kg IV load (max infusion rate 500 mg per h), then 19 mg/kg at intervals dictated by Matzke nomogram plus ceftazidime 2 g IV q8h†
Immunocompromised host	<i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>L. monocytogenes</i> , aerobic gram-negative bacilli	Vancomycin 25 mg/kg IV load (max infusion rate 500 mg per h), then 19 mg/kg at intervals dictated by Matzke nomogram plus ampicillin 2 g IV q4h plus ceftazidime 2 g IV q8h†

themes just described. For example, organisms sometimes gain entry to the CSF not by hematogenous seeding but through direct contiguity. Such direct spread may be from infected parameningeal structures (e.g., brain abscess, otitis media, and sinusitis), traumatic or congenital communications with the exterior, or neurosurgery. The bacteriologic characteristics of these infections may vary. Immunologic deficiency states are increasingly common and predispose to yet other organisms. The clinical and pathophysiologic effects of organisms other than *S. pneumoniae*, *H. influenzae* type b, and *N. meningitidis* depend on their capacity to stimulate the host's immune processes and the host's response.

Clinical Features

SIGNS AND SYMPTOMS About 25 percent of adult cases are classic and fulminant, and there is little diagnostic challenge. The patient presents with rapidly developing fever, headache, stiff neck, photophobia, and altered mental status. Seizures occur in 25 percent of adults and in at least that proportion of children. In some patients, typically the very young and the elderly, the clinical features may be nonspecific.

Certain historic data should increase the suspicion of meningitis and suggest specific pathogens. Several areas deserve special attention: living conditions, trauma, immunocompetence, immunization history, and antibiotic use. Army barracks and college dormitories are typical environments in which clusters of cases due to *N. meningitidis* occur. Day-care centers may become a source for multiple cases due to *H. influenzae* type b. A history of head trauma (*S. pneumoniae*) or neurosurgery (staphylococcal species or gram-negative rods) may be significant. Conditions that affect immunocompetence (e.g., history of surgical or functional splenectomy, glucocorticoid therapy, and HIV infection) should be sought. On the other hand, a history of immunization to *H. influenzae* type b in the past will make meningitis due to this organism unlikely. It is important to inquire about recent exposure to antibiotics, which may influence the clinical course and CSF findings.

Examination must include assessment for meningeal irritation with resistance to passive neck flexion, Brudzinski sign (flexion of the hips and knees in response to passive neck flexion), and Kernig sign (contraction of the hamstrings in response to knee extension while the hip is flexed). Examination of the skin is also crucial for seeking the purpuric rash characteristic of meningococcemia and, less commonly, other pathogens. Cutaneous stigmata suggesting microembolization (e.g., petechiae, splinter hemorrhages, and pustular lesions) should be aspirated when possible for Gram stain and culture. Paranasal sinuses should be percussed, and the ears should be examined for evidence of primary infection. Fundi must be assessed for papilledema or absence of venous pulsation (patient should be sitting upright), indicating increased intracranial pressure. Neurologic examination should seek evidence of focal neurologic dysfunction, such as disordered eye movements, homonymous visual field deficits, facial asymmetry, and hemiparesis.^{3,4}

Diagnosis

The differential diagnoses may be categorized into parenchymal or meningeal disorders. When fever and focal neurologic symptoms and signs predominate, parenchymal central nervous system (CNS) infections are concerns (e.g., brain abscess, viral encephalitis, cerebral toxoplasmosis, and other parenchymal processes). When meningeal signs predominate, other infectious meningitides, meningeal neoplasm, CNS vascularity, and subarachnoid hemorrhage are possible.

For evaluation of parenchymal brain infections, LP is unhelpful and potentially dangerous because it can lead to transtentorial or tonsillar herniation. A cranial computed tomographic (CT) scan should be

done first if the patient exhibits papilledema or focal neurologic signs. A cranial CT scan is also the preferred initial mode in diagnosing subarachnoid hemorrhage.

For meningeal disorders other than subarachnoid hemorrhage, CSF examination is most helpful. LP should be carried out as soon as it is deemed safely possible; however, its timing should not impede the early administration of empirical antibiotic therapy. Appropriate sequencing of LP, cranial imaging studies, and initiation of empirical antibiotics are discussed further below. Blood cultures (two specimens drawn 15 min apart) yield the responsible organism in only around 50 percent of cases of bacterial meningitis. Thus, for bacteriologic diagnosis, CSF analysis is paramount.

Typical CSF findings for bacterial, viral, neoplastic, and fungal meningitides are displayed in Table 235-2, but there is considerable overlap in findings. Some infectious agents (e.g., *Mycoplasma*, *Listeria*, spirochetes, syphilis, *Leptospira*, and *Borrelia*) produce CSF alterations that are less pronounced than those outlined for bacteria in Table 235-2. An aseptic profile, suggesting viral infection, is typical of partially treated bacterial infections (one-third or more of pediatric cases have received antimicrobial treatment before presenting with meningitis). The same is true of untreated bacterial infections adjacent to but not communicating with the subarachnoid space, such as abscesses of the brain and subdural or epidural spaces. The percentage of polymorphonuclear cells may be higher in early viral meningitis, and glucose levels may be reduced in some viral cases.

Additional testing can include viral cultures in suspected viral meningitis, tests for *Borrelia* antibodies in patients with possible Lyme disease, india ink or serum cryptococcal antigen in immunocompromised patients, acid-fast stain and culture for mycobacteria in tuberculous meningitis, and latex agglutination or counterimmune electrophoresis for bacterial antigens in potentially partially treated bacterial cases. Assays are most widely available for *S. pneumoniae*, other group B streptococci, *H. influenzae* type b, and *N. meningitidis*. Rarely, CSF may be normal or nearly so in very early bacterial meningitis, especially during meningococcemia. Empirical antibiotic treatment, admission, and repeated LP are appropriate if clinical suspicion is great despite negative initial CSF results.

LUMBAR PUNCTURE LP can be performed safely if intracranial mass lesions and coagulopathy are unlikely on historical or clinical grounds (Table 235-3). Coagulopathy is considered a relative contraindication to LP. At least one major authority asserts that LP may be performed even in the presence of known coagulopathy when the results are felt to provide essential information, as may be the case in suspected meningitis.⁵ Infusion of clotting factors in the hemophiliac patient is desirable if conditions permit and appears to mitigate related complications.⁶ There is no standard agreement regarding safe performance of lumbar puncture based on a given platelet level. Again, if the clinical situation allows, infusion of platelets may be desirable in cases of severe thrombocytopenia.⁵ Lumbar puncture is contraindicated if there is infection in the overlying skin.

If a delay is anticipated for any reason, then blood cultures should be obtained, and empirical antibiotic therapy should be instituted promptly. LP can then proceed if no intracranial mass lesion and no mass effect are found on CT scan. Antibiotic therapy given up to 2 h prior to LP will not decrease the diagnostic sensitivity if CSF bacterial antigen assays are obtained along with CSF culture. However, at 2 h after antibiotic administration, the CSF likely will be sterilized in meningococcal disease but not until 4 h after antibiotic administration in pneumococcal disease.^{7,8}

Local anesthetic should be used to improve patient comfort, relaxation, and cooperation. Anxiolytics such as benzodiazepines, which are helpful adjuncts in the performance of painful procedures, can cloud the patient's sensorium and confuse subsequent clinical assessment. The L3-L4 interspace should be punctured (L4-L5 in newborn infants) while the patient is curled as tightly as possible in a fetal position. In

TABLE 235-2 Typical Spinal Fluid Results for Meningeal Processes

Parameter (Normal)	Bacterial	Viral	Neoplastic	Fungal
OP (<170 mmCSF)	>300 mm	200 mm	200 mm	300 mm

adults, a line drawn between the iliac crests crosses the spine at the L3-L4 interspace. Alternatively, the patient may be seated on the edge of a bed or cart leaning over a tray stand. The latter technique is particularly useful when landmarks are uncertain, as they may be in an obese patient. The site should be prepared with povidone-iodine and allowed to dry thoroughly to avoid introduction of bacteria by puncture and the production of chemical arachnoiditis. A 24-in. 22-gauge needle should be used in children and a 3H-in. 20-gauge needle in adults. The use of larger-gauge needles will greatly increase the risk of post-LP CSF leak and resulting headache. Although useful, the opening pressure is not critical for interpretation of the procedure. To obtain meaningful results, the pressure must be measured with the patient lying extended on his or her side. Pressures measured with the patient still curled in extreme flexion or while sitting will be artificially elevated. Normal pressure is less than 170 mm CSF. Careful repositioning (straightening the curled patient or helping the seated patient to a lying position on his or her side) is performed safely with the needle in situ.

Four tubes, each containing at least 1 mL of CSF, typically are obtained. More volume—up to 5 mL—may be preferable in patients who are immunocompromised. Red and white blood cell counts with differential counts are requested for tubes 1 and 4. The two-tube assessment helps detect a traumatic tap because the rate of bleeding changes rapidly, causing a difference in red blood cell count between the two tubes. Tube 4 also may be used for culture and Gram stain. Tube 2 is sent for determination of protein and glucose levels. Tube 3 should be saved for other studies, discussed below, if necessary. Closing pressure determination is not routinely necessary.⁹

Treatment

Ideal management has several goals. The first priority is the rapid administration of a bactericidal antibiotic that gains rapid entry to the subarachnoid space. A secondary priority in some cases is use of an anti-inflammatory agent to suppress the normal inflammatory processes, which are amplified by antibiotic-induced bacteriolysis. A

final concern is to counter the adverse effects of increased intracranial pressure and vasculopathy, which may lead to brain ischemia. Agents to which local bacterial resistance has developed should be avoided. Currently, for example, about 30 percent of *H. influenzae* type b isolates are resistant to ampicillin. **Bacteriostatic agents should not be used alone or in combination with a bactericidal agent because they are antagonistic.** Agents of current choice for given bacterial meningitides are indicated in Table 235-1.

Empirical treatment for bacterial meningitis is based on the likelihood of certain pathogens (see Table 235-1) and results of CSF Gram stain, the patient's age, and certain risk factors, if available.^{10,12} For patients aged 18 to 50 years with no organisms evident on Gram stain, ceftriaxone 2 g IV every 12 h is the current recommendation.

For patients with Gram stain suggestive of *S. pneumoniae* (gram-positive cocci in clusters), a broad-spectrum cephalosporin and vancomycin should be given to ensure coverage of resistant organisms. For patients >50 years or the immunosuppressed, ampicillin should be given to treat against *Listeria monocytogenes*. For gram-negative cocci, presumed *N. meningitidis*, penicillin G is still effective. For gram-positive rods, *Listeria monocytogenes* is the presumed agent, and the recommended regimen is ampicillin and gentamicin. For gram-negative rods, the recommendation is ceftazidime and an aminoglycoside. If herpes simplex is suspected, acyclovir 10 mg/kg ideal body weight (IBW) is given every 8 h. Dosage should be decreased in renal insufficiency.

A number of inflammation suppressants have been shown to improve outcome in experimental bacterial meningitis, but only glucocorticoids, and specifically dexamethasone, have been tested in clinical trials. The use of steroids in pediatric meningitis is discussed in Chap. 116.

The question of steroid use for adults in the emergency department is inadequately answered.^{13,14} Dexamethasone given to adults with bacterial meningitis (10 mg IV 15 min prior to antibiotic administration) appears to decrease the morbidity and mortality of meningitis due to *S. pneumoniae*, but not for *N. meningitidis*. The problem in the emergency department, however, is that because administration of antibiotics usually appropriately precedes diagnosis, we rarely deal with known bacterial meningitis. As noted antibiotic administration should never be delayed in suspected bacterial meningitis, especially in cases where neurologic decompensation or clear toxicity is present. Additionally, many patients ultimately prove to have a viral etiology and potentially may be harmed by the administration of steroids.

Also important in management is surveillance for and correction of complications, including seizures, hyponatremia, hydrocephalus, and cerebrovascular accidents. General treatment measures include maintenance of normal blood volume. Hypotonic fluids should be avoided. The serum sodium level should be monitored serially to detect the syndrome of inappropriate antidiuretic hormone or cerebral salt wasting. Hyperpyrexia should be treated. Coagulopathies should be corrected using specific replacement therapies. Phenytoin loading is indicated in

TABLE 235-3 Considerations for Lumbar Puncture without Neuroimaging*

Age <60
Immunocompetent
No history of CNS disease
No recent seizure (<1 wk)
Normal sensorium and cognition
No papilledema
No focal neurologic deficits

*Coagulopathy is a separate consideration for lumbar puncture. Source: From Hasbun R, Abrahams J, Jeel J, et al: Computed tomography of the head before lumbar puncture in adults with suspected meningitis. *New Engl J Med* 345:1727, 2001.

patients who develop seizures. For marked cerebral edema, as evidenced by clinical or CT findings, the following are indicated: head elevation, hyperventilation to a Paco_2 of 25 to 30 mm Hg, and use of mannitol. Measurements of intracranial and systemic arterial pressure are useful in severe cases to enable monitoring of cerebral perfusion pressure.

Chemoprophylaxis is indicated for high-risk contacts of patients with documented *N. meningitidis* or *H. influenzae* type b infection, including household contacts; school or day-care contacts in the previous 7 days; those who have had direct exposure to the patient's secretions through kissing, shared utensils, or shared toothbrushes; and those who have performed mouth-to-mouth resuscitation or have intubated the patient while unprotected with a face mask. Other health care providers do not require prophylaxis. First-line treatment is with rifampin 10 mg/kg (to a maximum of 600 mg per dose) every 12 h for four doses. Alternatives are ceftriaxone, ciprofloxacin, and sulfisoxazole. High-risk contacts should be instructed to return at once if they develop symptoms. For moderate- to low-risk contacts, single-dose ciprofloxacin 500 mg is recommended."

VIRAL MENINGITIS

A number of viruses can cause aseptic meningitis, including nonpolio enteroviruses, mumps, cytomegalovirus, herpes simplex virus (HSV), lymphocytic choriomeningitis, adenovirus, and HIV. Specific diagnosis depends on isolation of the virus or positive results on immunoassay of the CSF. Nonpolio enteroviruses (echovirus, coxsackievirus, and enterovirus) account for about 85 percent of all cases of viral meningitis in the United States.

While the diagnosis of viral meningitis is often straightforward (see Table 235-2), there can be overlap of CSF findings with early bacterial meningitis and partially treated bacterial meningitis, making specific diagnosis for some cases difficult in the emergency department. Neutrophils may predominate in the CSF for the first 24 h in viral meningitis. Standard references report up to a 10 percent incidence of lymphocytic predominance in CSF with bacterial meningitis, more common with *L. monocytogenes* and in neonatal meningitis. Depending on clinical diagnostic certainty, a range of approaches can be employed in the management of presumed viral meningitis, from admission with empirical antibiotic therapy until culture results return to discharge from the emergency department with follow-up in 24 h.

VIRAL ENCEPHALITIS

Viral encephalitis is a viral infection of brain parenchyma that produces an inflammatory response. It is distinct from, although often coexists with, viral meningitis, in which the infectious agent and inflammatory response are in the subarachnoid space. Clinically, the distinction is made by the presence of neurologic abnormality in encephalitis, whereas only meningeal symptoms and signs (e.g., photophobia, headache, and stiff neck) occur in meningitis. The true incidence of viral encephalitis is difficult to estimate because of the variability of clinical expression, ranging from profound neurologic involvement to clinically silent cases, as well as variability in reporting policies. Several thousand cases are reported yearly in the United States.

Epidemiology

The incidence of the various types of viral encephalitis varies from year to year, depending on whether sporadic or epidemic outbreaks occur. In relative terms, the incidence is about one-tenth that of bacterial meningitis. In North America, viruses that cause encephalitis include the arboviruses, HSV-1, herpes zoster, Epstein-Barr virus (EBV), cytomegalovirus (CMV), and rabies. Arboviruses account for 10 percent of cases during times of sporadic, isolated cases but can ac-

count for up to 50 percent of cases during epidemic outbreaks. Historically, the four most common arboviral encephalitides in the United States have been La Crosse encephalitis (LAC), St. Louis equine encephalitis (SEE), western equine encephalitis (WEE), and eastern equine encephalitis (EEE). However, after the 1999 outbreak of the West Nile virus (WNV) in New York State—its first appearance in the western hemisphere—this pathogen has become widely recognized as part of the differential diagnosis. Of these viruses, LAC is diagnosed most frequently, with a reported average annual incidence of 75. It is seen in the midwestern and eastern United States exclusively. Ninety percent of reported cases occur in children. SEE is seen throughout the United States in periodic outbreaks, with the yearly incidence ranging from 20 reported cases to 2000. It is seen primarily in young children and the elderly and has a 20 percent mortality rate in the latter. WEE prevails in the western United States and Canada. Disease is most severe in the very young, causing seizures in 90 percent of affected infants and permanent neurologic deficits in 50 percent. EEE, the most devastating of these arboviral infections, is prevalent in the Atlantic and Gulf Coast regions. It tends to occur in sporadic epidemics and has a mortality rate of nearly 70 percent. WNV, only under surveillance since 1999 and then initially found only in New York, spread to 27 states in 2002. It leads to clinical disease in roughly 20 percent of those infected, the majority of these suffering a mild febrile illness. Neurologic sequelae are relatively uncommon, but it can lead to significant morbidity in the extremes of age.¹⁵

HSV-1 and HSV-2 encephalitides occur in 1 in 250,000 to 1 in 500,000 cases annually in the United States, respectively. HSV-1 disease typically is seen in older children and adults as reactivation disease, whereas HSV-2 disease is seen in neonates as a result of perinatal transmission and generally leads to devastating neurologic outcomes.

Pathophysiology

Entry portals are highly specific for the encephalitis-producing viruses. The arboviruses (*arbo* meaning "arthropod-borne") are transmitted by mosquitoes and ticks, and rabies is transferred by the bite of an infected animal. Impaired immune status may play a role in herpes zoster and CMV encephalitis. Common to all is preliminary viral invasion of the host at a site where replication takes place that is outside the CNS. Most viruses then reach the nervous system hematogenously during viremia. However, at least three important viruses—rabies, HSV and herpes zoster virus (HZV)—reach the spinal cord and eventually the brain by traveling backward within axons from a distal site where they have gained access to nerve endings.

Once in the brain, the virus enters neural cells. Neurologic dysfunction and damage are caused by the disruption of neural cell functions by the virus and by the effects of the host's inflammatory responses. Gray matter is predominantly affected, resulting in cognitive and psychiatric signs, lethargy, and seizures. Multifocal white matter damage occurs predominantly in postinfectious encephalomyelitis and rarely during acute encephalitis. Sensorimotor deficits referable to one hemisphere or to the spinal cord are more typical of this immune-mediated pathologic process, which may follow viral encephalitis and meningitis of any type.

Clinical Features

Encephalitis should be considered in patients presenting with the following clinical features singly or in combination: new psychiatric symptoms, cognitive deficits (e.g., aphasia, amnesic syndrome, or acute confusional state), seizures, and movement disorders. Features of meningeal involvement, such as headache and photophobia, are usually but not invariably present. The same is true for fever.

Patients with HZV EBV or CMV encephalitis (lymphadenopathy and hepatosplenomegaly) often will have a history of and/or show signs typical of clinical syndromes caused outside the CNS by these

viruses. Other circumstances of the case may suggest both the broad diagnosis of encephalitis and a specific viral cause (Table 235-4). For example, a late-summer encephalopathy suggests the possibility of an arbovirus encephalitis, and an animal bite for which no antirabies treatment was obtained has obvious relevance.

Signs of meningeal irritation and increased intracranial pressure should be sought. Neurologic findings reflect the areas of involvement. A careful assessment of cognition is crucial. Sensorimotor deficits are not typical. Encephalitides may show special regional tropism. HSV involves limbic structures of the temporal and frontal lobes, with prominent psychiatric features, memory disturbance, and aphasia. Some arboviruses predominantly affect the basal ganglia, causing choreoathetosis and parkinsonism. Involvement of the brainstem nuclei that control swallowing leads to the hydrophobic choking response characteristic of rabies encephalitis.

Diagnosis

Diagnosis rests on imaging studies using magnetic resonance imaging (MRI) or CT scan if MRI is not reasonably available, electroencephalography (EEG), and LP. Imaging not only excludes other potential lesions, such as brain abscess, but also may display findings that are highly suggestive of HSV encephalitis, a treatable infection, with involvement of medial temporal and inferior frontal gray matter. MRI is more sensitive than CT scan in this regard. EEG is quite useful in establishing the broad diagnosis as well. Almost by definition, the EEG findings are abnormal in encephalitis, in contrast to isolated viral meningitis or to a primary psychiatric disorder. Furthermore, HSV produces an almost pathognomonic picture, with the EEG showing periodic, usually asymmetric, sharp waves in the setting of acute febrile encephalopathy. These findings can be present before any abnormality is visible on MRI. Realistically, LP is the most useful diagnostic procedure in the emergency department once imaging studies, if clinically indicated and available, rule out the risk of uncal herniation. Findings of aseptic meningitis are typical on CSF examination. It is at least theoretically possible to have encephalitis without meningitis, but it is quite rare.

The differential diagnosis depends on the nature of the presentation. When fever and meningeal symptoms predominate, bacterial meningitis is suspected. In less fulminant meningeal cases, Lyme disease; tuberculous, fungal, and neoplastic meningitis; and subacute subarachnoid hemorrhage are part of the differential diagnosis. When parenchymal features are prominent, brain abscess, bacterial endocarditis, postinfectious encephalomyelitis, and toxic or metabolic encephalopathies should be considered.

The clear diagnostic imperative in the emergency department is to exclude the most immediately life-threatening alternative processes

requiring immediate treatment. The two most important are bacterial meningitis and acute subarachnoid hemorrhage. Once this is accomplished satisfactorily, the mandate is less definite. Of the viruses causing encephalitis, only HSV has been shown by clinical trial to be responsive to antiviral therapy at this time. HSV can be isolated in as many as 50 percent of neonatal infections but is found rarely in older children and adults. The polymerase chain reaction (PCR) analysis of CSF has 95 percent sensitivity and 100 percent specificity in the diagnosis of HSV infection with respect to brain biopsy. Regardless of diagnostic approach, because current antiviral treatment is relatively free of risk and side effects, empirical therapy is recommended in cases of clinical encephalitis.¹⁶ Of the other viral encephalitides, CSF culture results are positive for 50 to 70 percent of patients with enteroviral meningitis but for a much smaller percentage of those with isolated enteroviral encephalitis. The use of PCR techniques for the enteroviruses is also showing promise for CNS diagnosis in the future.

Treatment

The agent of choice for HSV disease is acyclovir 10 mg/kg every 8 h for 14 to 21 days. Based on anecdotal data, patients with HZV and CMV encephalitis also may benefit from antiviral therapy: acyclovir for HZV and ganciclovir for CMV encephalitis.

Prognosis depends on the virus and host. Rabies encephalitis, while rare, continues to be neurologically devastating and usually fatal. EEE and HSV encephalitis also have high mortality rates and frequently produce residual deficits. For the others, adverse outcome is seen mainly in elderly patients or in those with compromising preexisting systemic or neurologic conditions.

Disposition

Patients with encephalitis in general should be admitted. The outcome in cases of HSV encephalitis is related to the neurologic condition at the time that antiviral therapy is initiated. Patients who are already in coma do very poorly, making timely diagnosis and therapy priorities for this form of encephalitis. Empirical initiation of acyclovir 10 mg/kg in the emergency department in encephalitis suspects should be highly considered.

BRAIN ABSCESS

A brain abscess is a focal pyogenic infection. When fully developed, it is composed of a central pus-filled cavity ringed by a layer of granulation tissue and an outer fibrous capsule. Surrounding this is edematous brain tissue infiltrated with inflammatory cells. It is a pathologic

TABLE 235-4 Viral Pathogens Causing Encephalitis in North America

Virus	Clinical Clues	Diagnosis	Prognosis
HSV-1	"Psychiatric" presentation	MRI, EEG, PCR of CSF, biopsy	30% die, 30% have deficits
Herpes zoster	Shingles, chickenpox, immunosuppressed state	Skin vesicle or CSF culture, serology	10–20% die
EBV	Mononucleosis	Serology	5–10% die
Rabies	Animal bite	Saliva or CSF culture, biopsy, serology	90% die
Arboviruses	Seasonal		
La Crosse	Midwest, children	CSF or blood culture, serology	Good
St. Louis	Midwest, older urban dwellers	As above	5–10% die
Western equine	West, outside workers	As above	5–10% die
Eastern equine	Southeast, outside workers	As above	50% die
WNV	East, urban dwellers	CSF or IgM serology	15% mortality among hospitalized patients

Abbreviations: CSF = cerebrospinal fluid; EBV = Epstein-Barr virus; EEG = electroencephalogram; HSV-1 = herpes simplex virus 1; MRI = magnetic resonance imaging; PCR = polymerase chain reaction; WNV = West Nile virus. **Source:** From Bale JR Jr: Viral encephalitis. *Med Clin North Am* 77:25, 1993, with permission.

response typical of a relatively competent immune system against a bacterial invader. Focal brain infections due to other organisms, such as granulomas due to tuberculosis, necrotic lesions of toxoplasmosis in immunocompromised patients, or cystic lesions of cysticercosis, are not abscesses in the pathologic sense. These nonpurulent focal lesions are not considered here.

Epidemiology

Brain abscess is rather uncommon. The rate has fallen gradually over the past century, probably reflecting the effect of antibiotics on predisposing conditions such as otitis media. Mortality rates for diagnosed cases also have fallen.

Age distribution corresponds to the various predisposing conditions. Most patients with brain abscess related to a paranasal sinus focus are in the 10- to 30-year-old range. When the source is otic, a bimodal incidence occurs in ages younger than 20 and older than 40 years. Twenty-five percent of cases occur in children under 15 years of age, with the majority occurring in the 4- to 7-year-old range. Pockets of higher incidence occur along the lines of age, origin of initial infection, and in some cases, gender.

Pathophysiology

Organisms reach the brain by one of three known routes: hematogenously (one-third of cases); from contiguous infections of middle ear, sinus, or teeth (one-third of cases); or by direct implantation by neurosurgery or penetrating trauma (about 10 percent of cases). The route is unknown in about 20 percent. Circumstances that reduce oxygenation of brain parenchyma are important predisposing factors for bacterial invasion. For example, spread from a contiguous infection usually involves intervening cerebral thrombophlebitis, with congestive ischemic hypoxemia of tissue destined to become infected. Hematogenous seeding is facilitated by systemic hypoxemia, as in congenital heart diseases with right-to-left shunt and chronic pulmonary suppuration. This is demonstrated by the prominent role of anaerobic bacteria in brain abscesses. The source of brain abscess should be identified for the dual purpose of eliminating the source itself and gaining insight into the probable bacteriologic characteristics of the abscess. For example, gram-negative rods, especially *Bacteroides*, are the usual pathogens in otogenic brain abscesses, which are typically single and located in the adjacent temporal lobe or cerebellum. Anaerobic and microaerophilic streptococci are the most common pathogens in sinogenic and odontogenic abscesses and are located more typically in the frontal lobes. Abscesses formed from hematogenous spread are often multiple and polymicrobial, with anaerobic and microaerophilic streptococci commonly represented. Staphylococci are typical pathogens in abscesses due to direct implantation. Gram-negative rods are also suspected in cases related to a neurosurgical procedure.

Clinical Features

Presenting features of brain abscess are notoriously nonspecific. Patients rarely appear acutely ill, and the classic triad of headache, fever, and focal neurologic deficit is present in less than one-third of all patients. As a result, the diagnosis is often delayed. Symptoms reflect the infectious and neurologic (focal and mass effect-producing) aspects of the disease. The most common symptom is headache, which is a complaint in almost all cases. Fever is present in about half of all cases, and neck stiffness occurs in fewer than half. Toxic appearance is rare until late in the disease process. Focal neurologic symptoms, such as hemiparesis or seizures, are present in about a third. Other symptoms of increased intracranial pressure, such as vomiting, confusion, or obtundation, are present in about half of cases. The presentation may be dominated by the origin of the infection (e.g., ear or sinus pain).

Meningeal signs and papilledema are uncommon. Focal neurologic signs reflecting the site of the lesion (e.g., frontal lobes, hemiparesis; temporal lobes, homonymous superior quadrant visual field deficits or aphasia; or cerebellum, limb incoordination or nystagmus) are present in about 60 percent of patients on careful examination. Discovery of potential sites of origin may raise suspicion of brain abscess when the presentation is otherwise nonspecific (e.g., otitis media, sinus tenderness, evidence of pulmonary suppuration, or right-to-left shunting) in a patient with subacute headache and lethargy.

Diagnosis

Brain abscess is diagnosed by imaging studies. CT scan with contrast infusion classically demonstrates one or several thin, smoothly contoured rings of enhancement surrounding a low-density center and surrounded by white matter edema. Early in the course, a ring may be thicker and less well defined, with the only CT finding being an area of focal hypodensity. Suspected brain abscess is one of the rare instances in the emergency department when a contrast-enhanced study is preferred over a non-contrast-enhanced study. MRI usually demonstrates a ring even without gadolinium enhancement. Both types of studies are highly sensitive, and one imaging modality has no real advantage over the other except that CT scans usually are more readily available in the emergency department. Other studies, such as blood analysis, EEG, and CSF examination, are too nonspecific for definitive diagnosis, and LP is contraindicated when suspicion is high and when focal neurologic signs are present. Cultures of blood or other sites of infection may guide future management and always should be obtained.

Differential diagnosis of the clinical presentation is broad because of its nonspecific and variable nature. A sudden onset with focal features may suggest cerebrovascular disease. Prominent fever, stiff neck, and confusion may suggest meningitis. A protracted course with features of increased intracranial pressure may suggest neoplasm. Brain neoplasm, subacute brain hemorrhage, other focal lesions, and other focal brain infections, such as toxoplasmosis, may mimic the imaging findings of brain abscess. Biopsy or aspiration for confirmation of diagnosis as well as for bacteriologic studies is necessary in most cases.

Treatment

The cornerstone of early emergency department treatment of brain abscess is administration of antibiotics (Table 235-5). The susceptibility of the likely pathogen and the penetration of the agent into the lesion should be considered when choosing an antibiotic. The bacteriologic characteristics of the lesion may be inferred if the origin is obvious. Initial empirical antibiotic choice should take advantage of such information. Initial treatment in a suspected otogenic case is with a third-generation cephalosporin such as cefotaxime (2 g IV every 6 h) or trimethoprim-sulfamethoxazole with metronidazole or chloramphenicol. For presumed abscess of sinogenic or odontogenic origin, high-dose penicillin and metronidazole is a good choice (see Table 235-5). Penicillin is also appropriate for an abscess of hematogenous origin. Chloramphenicol or metronidazole, which by virtue of their lipophilic nature penetrate abscesses very well, can be added to penicillin. When communication with the exterior is suspected, as in penetrating trauma or after neurosurgery, nafcillin or vancomycin are indicated. Addition of ceftazidime may be required if gram-negative aerobes are suspected. For patients in whom no mechanism is apparent or suspected, the combination of a third-generation cephalosporin such as cefotaxime and metronidazole provides good coverage.

Most patients require a neurosurgical procedure for diagnosis and bacteriologic analysis, if not for definitive treatment. Total excision has become necessary less often with the availability of imaging techniques for following the course of abscesses treated medically after surgical aspiration. In patients in whom intracranial pressure is high,

TABLE 235-5 Guidelines for Empirical Treatment of Brain Abscess Based on Presumed Source

Presumed Source	Primary Empirical Therapy	Alternative Therapy
Otogenic	Cefotaxime 2 g IV q8h	TMP-SMX* 5 mg/kg IV q6h based on TMP and metronidazole 1 g IV load then 500 mg IV q6h or chloramphenicol
Sinogenic or odontogenic	Penicillin 24 million units/day IV divided q4h and metronidazole 1 g IV load then 500 mg IV q6h	Penicillin (same dose) and chloramphenicol 100 mg/kg per d divided q6h
Penetrating trauma or neurosurgical procedures	Nafcillin 2 g IV q4h and ceftazidime 2 g IV q8h if gram-negative aerobes suspected	Vancomycin 15 mg/kg IV q6h (max 1 g/dose; monitor serum levels) and ceftazidime 2 g IV if gram-negative aerobes suspected
Hematogenous	Penicillin 24 million units/day IV divided q4h and metronidazole 1 g IV load then 500 mg IV q6h	Penicillin (same dose) and chloramphenicol 100 mg/kg per d divided q6h
No obvious source	Cefotaxime 2 g IV q6h and metronidazole 1 g IV load then 500 mg IV q6h	No recommendation

*Trimethoprim-sulfamethoxazole.

excision is still carried out. The role of glucocorticoids is controversial. Steroids may produce temporary improvement of increased intracranial pressure.¹⁷⁻¹⁸

COMPLICATIONS OF CENTRAL NERVOUS SYSTEM DEVICES

Joseph Pagane Jay Ladde

CEREBROSPINAL FLUID SHUNTS

Hydrocephalus has an incidence of 3 cases per 1000 live births. Mechanical shunting is the primary treatment as there is usually no alternative corrective surgical or medical therapy for this disorder. The shunting of cerebrospinal fluid (CSF) was first described in 1895, but it was not until the 1950s that shunting ventricular CSF became a routine procedure.^{1,2} Each year there are approximately 18,000 CSF shunts inserted, making it the most common pediatric neurosurgical procedure performed in the United States.¹ The CSF shunt is also the neurosurgical procedure with the highest incidence of postoperative complications,^{1,2} with a 39 percent 1-year and a 52 percent 2-year failure rate being reported following initial shunt placement.³ Many types of CSF shunt systems exist (Figures 236-1 and 236-2). Most systems consist of three components beginning with a silastic tube passed into the ventricle via a burr hole. This tubing is tunneled subcutaneously to a valve chamber. The valve chamber, the second component, establishes a pressure gradient that ensures drainage of fluid away from the ventricle. The valve chamber, or in some cases a separate reservoir, allows access to the shunt system for patency testing, pressure measurement, CSF sampling, medication injection (e.g., chemotherapy, antibiotics), or contrast administration. Distal tubing, which is the third component, connects the valve chamber to a drainage point. The most common drainage site is the peritoneal cavity. Other drainage sites include the right atrium, gallbladder, pleural cavity, and ureter.

Shunt Malfunction

Shunt malfunctions are the most common complications encountered with CSF shunts, occurring in up to 67 percent of patients during their lifetime. Obstruction is the most common type of shunt malfunction and most commonly occurs in the proximal tubing followed by the distal tubing, and, finally, the valve chamber. Proximal obstructions usually occur within the first 2 years after shunt insertion. Causes include tissue debris, choroid plexus, clot, infection, catheter-tip migration, or following a localized immune response to the tubing. Kinking or disconnection of the tube, pseudocyst formation, or infection can cause distal obstruction. Distal obstruction is the most frequently encountered obstruction in shunts in place for longer than 2 years.^{1,2}

FIG. 236-1. Example of shunt kit. Circular objects on the left are a locator and a pressure/performance indicator. Circular object on right is an adjustment tool. All three are needed to adjust the settings. Two sizes of valves are shown in the middle.

SLIT VENTRICLE SYNDROME

Overdrainage and the slit ventricle syndrome are seen in approximately 5 percent of shunted patients. Because of overdrainage, the tissues actually occlude the orifices of the proximal shunt apparatus. As intracranial pressure increases, the same occluding tissue is disengaged, allowing drainage to resume. This phenomenon is cyclical and is responsible for the episode or waxing and waning aspect of the presenting complaint. Patients present with episodes of elevated intracranial pressure caused by a transient obstruction of the ventricular catheter from a collapsed ventricle. De-

creased cerebral compliance may prevent the ventricles from fully expanding as intracranial pressure and volume increase, further contributing to ventricular collapse. Currently used shunt systems with antisiphon devices and improved shunt valves have a lower rate of this complication.^{1,2}

CLINICAL PRESENTATION Symptoms of shunt malfunction usually develop over several days although rapid deterioration within 24 h has been reported. Clinical features include mental status changes; headache; nausea; vomiting; abdominal pain; lethargy; decreased intellectual performance; ataxia; coma; and autonomic instability. Often, the presenting complaint is vague. No single sign or symptom is accurate in predicting shunt malfunction. Recent analysis of signs and symptoms demonstrated that a decrease in level of consciousness and erythema at the surgical site had the highest correlation with shunt malfunction and infection.³ As intracranial pressure increases, paralysis of upward gaze or sundowning, dilated pupils and papilledema may develop. "Sundowning" is caused by impingement of the brainstem by the third ventricle as it engorges. Symptoms of slit ventricle syndrome are exacerbated or precipitated by standing or exercise caused by excessive CSF drainage and relieved by lying down or the Trendelenburg position.

SHUNT EVALUATION Identification of shunt type is important although frequently difficult. Many different types exist and appropriate assessment is dependent on the apparatus implanted. Shunt function is evaluated by manual testing and radiologic studies. Palpation of the shunt allows the physician to locate the valve chamber. Shunt patency is evaluated somewhat differently for each type of device depending on such features as valves, dome or cylinder-shaped reservoirs. Generally, testing follows intuitive expectations but may yet prove perplexing to inexperienced clinicians. For a simple device, once the chamber is located, it is gently compressed and observed for refill. Difficulty compressing the chamber indicates distal flow obstruction, while slow refill, defined as greater than 3 s, following compression indicates a proximal obstruction. Clinicians should realize that **compression is inaccurate in identifying shunt obstruction** as up to 40 percent of obstructed shunts have normal refill during manual palpation.² In any case, further evaluation is required.

FIG. 236-2. Typical ventriculoperitoneal shunt.

A shunt series of plain films includes an anteroposterior and lateral radiographs of the skull, and an anteroposterior view of the chest and abdomen (for ventriculoperitoneal shunts). While plain radiography will identify kinking, migration or disconnection of the shunt system, computed tomography (CT) is required to evaluate ventricular size. Comparison to previous CT scans is needed as many shunted patients have an abnormal baseline ventricular size. In one series, using CT, or both CT and plain films, 25 percent of patients with documented shunt malfunction had no radiologic evidence of shunt malfunction.⁴ Therefore, in patients with suggestive clinical features, unimpressive CT and/or shunt series cannot be relied on to exclude shunt obstruction. In this instance, neurosurgical consultation should be obtained whenever shunt malfunction is suspected.

A shunt tap may need to be performed to make the diagnosis of shunt malfunction, exclude infection, or to alleviate life threatening increased intracranial pressure. The shunt tap should be performed by a neurosurgeon if available. Emergency physicians should be prepared to perform a shunt tap if a neurosurgeon is unavailable or if a shunt tap is needed to control life-threatening increased intracranial pressure.

To perform a shunt tap, locate and sterilize the site over the valve system or reservoir. Shave the scalp. A 23-gauge needle or butterfly attached to a manometer is inserted into the reservoir. If no fluid returns or flow ceases, a proximal obstruction is likely. The opening pressure should be measured while occluding the reservoir outflow. An opening pressure of 20 cm H₂O or greater indicates a distal obstruction, while low pressures indicate a proximal obstruction. The normal basal intracranial pressure is around 12 ± 2 cm H₂O.

MANAGEMENT Surgical intervention is generally required for shunt obstruction. As a temporizing measure intracranial pressure can be lowered by standard methods-hyperventilation and osmotic diuresis (mannitol). If these measures fail and surgical intervention is not immediately available, one can lower intracranial pressure when the malfunction is distal by removing CSF via the reservoir as previously described. To prevent choroid plexus bleeding, CSF is removed slowly, and the process is discontinued when intracranial pressure reaches 10 to 20 cm H₂O. Stable patients with suspected obstruction require admission and neurosurgical consultation. Patients should be observed for any neurologic changes, abdominal complaints, or development of fever.

Shunt Infection

With improved techniques and shunts, infection rates have decreased to 5 to 8 percent per procedure.² The highest rates of infection are found in the very young and old, and in patients who have had multiple shunt revisions. There is no association between shunt type and infection rates.

Half of all shunt infections present within the first 2 weeks of placement, 70 percent present within 2 months, and 80 percent within 6 months of placement. CSF shunt infections can be categorized into internal and external infections. External infections involve the subcutaneous tract around the shunt, which is usually tender and there is often an associated fluid collection within the skin. An internal infection involves the shunt and the CSF contained within that shunt. Patients with CSF shunts have a higher risk of developing meningitis from typical pathogens (e.g., *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Neisseria meningitidis*) as compared to the general population. This increased risk may be due to disruption of the blood-brain barrier by foreign material.

If diagnosed and treated in a timely fashion, mortality from shunt infections is low. However, if ventriculitis develops, mortality is 30 to 40 percent, underscoring the need for prompt diagnosis and aggressive management.^{1,2}

BACTERIOLOGY CSF shunt infections are typically caused by low-virulence organisms. The most commonly cultured agent is *Staphylo-*

coccus epidermidis, which accounts for 50 percent of all shunt infections; *S. aureus*, the next most commonly cultured agent, accounts for 25 percent of all shunt infections. Gram-negative, anaerobic, and mixed infections account for approximately 5 to 10 percent of shunt infections. Gram-negative infections are associated with the highest mortality.

CLINICAL FEATURES The clinical presentation varies with the virulence of the organism and the severity of the infection. Typically, patients will present with obstructive and possibly meningeal symptoms, including mental status changes, headache, nausea, vomiting, and irritability. Fever, meningismus and abdominal pain may also be present. Unfortunately, these signs are not universally present. In fact, the finding of fever is highly variable and meningismus may only be present in only a third of patients with shunt infection.² Abdominal pain may be the predominant symptom in patients with ventriculoperitoneal shunts. Swelling, erythema, and tenderness along the site of the shunt tubing are highly suggestive of external shunt infection.

EVALUATION To exclude CSF shunt infection, a shunt tap is required (Figure 236-3) (see "Shunt Malfunction: Shunt Evaluation" above). This procedure should be performed by a neurosurgeon or by an emergency physician only after consultation with a neurosurgeon. **A traditional lumbar puncture often misses CSF shunt infection** and has no meaningful role in the evaluation when shunt infection is suspected.

Analysis of fluid from infected CSF shunts usually reveals an elevated leukocyte count, elevated protein, and normal glucose. Almost one-fifth of patients evaluated for shunt malfunction may have positive CSF culture despite normal CSF analysis. Other (non-CSF) lab values are rarely helpful in diagnosing CSF shunt infection. CT scan and plain radiographs of the shunt (shunt series) are required to exclude mechanical shunt malfunction, which often coexists with shunt infection.⁴ Abdominal ultrasonography or CT scan are indicated if an abdominal fluid collection, pseudocyst, or abscess is suspected.

FIG. 236-3. Ventriculoperitoneal shunt system.

MANAGEMENT All patients with CSF shunt infection or suspected shunt infection require emergent neurosurgical consultation and admission. Most neurosurgeons advocate replacement of the infected shunt, external CSF drainage, and administration of intravenous and intrathecal antibiotics. This combination of therapy has a 96 percent success rate. Until the infecting agent is identified, broad-spectrum antibiotics effective against typical pathogens are recommended (e.g., intravenous third-generation cephalosporin and aminoglycoside, plus intravenous or intrathecal vancomycin). Meningitis caused from typical pathogens has been successfully treated with antibiotics alone.

CHANGES IN AVAILABLE TECHNOLOGY

Many new types of shunts are being clinically tested and some have received FDA approval. Among these, are shunts with magnetically adjustable valves and antimicrobial impregnated shunt systems.

The adjustable valve allows for non-invasive adjustments to valve pressure/performance levels. The valve can be adjusted/tested using a locator and indicator tool to determine the pressure programmed into the valve. An adjustment tool can then be used to dial up or down the valves pressure/performance as needed. Typical nonadjustable pressure type valves are available in low, medium and high settings. These valves open at a pressure gradient of 2 to 4, 4 to 6, and 8 to 10 cm F₂O for the low, medium, and high settings, respectively. The adjustable valves will typically have five preset pressure settings that can be selected or adjusted as clinically warranted. The patient/family should be given a card that will report initial setting and any subsequent adjustments. Pressure setting can also be confirmed by radiography as the dials on the valve are radiopaque.

Exposure to strong magnetic fields and **some magnetic resonance imaging (MRIs) can change the valve pressure setting**, so all patients should have the setting verified after any exposure to strong magnetic fields.

Antimicrobial impregnated catheter systems are being produced to prevent bacterial colonization of newly implanted systems. These systems can diffuse some combination of antimicrobials (clindamycin and rifampin) to reach concentrations high enough to prevent colonization for up to a 1-month period.

Efficacy and complication rates for these new systems are not yet available.

HALO DEVICES

The halo vest provides one of the most rigid types of cervical immobilization available. The halo vest consists of a lightweight radiolucent ring attached to a lightweight adjustable vest. Current vests allow adjustment of the cervical spine in multiple planes. Titanium pins that do not interfere with MRI are stronger, lighter, and more expensive than older stainless steel pins. Pins are usually tightened to 6 to 8 lb.^{5,6}

Indications

Halo devices are indicated for stabilization of an unstable cervical spine, including fractures, dislocations, subluxations, and alignment of severe kyphotic and scoliotic spines. A halo is not applied if there is a sensory deficit that extends beneath the halo vest as this leads to a higher risk of skin breakdown and infection. Pin sites are chosen to avoid nerve, vessels, and muscle while attempting to place the pins in the thickest area of calvaria possible. Four pins are usually used. The anterior pins are placed in the frontal or temporal regions. Posterior pins are placed relatively opposite to the anterior pin sites.

Complications

Pin loosening is the most common complication encountered in the emergency department. It occurs in 36 to 60 percent of patients with

halo devices.⁵⁻⁷ Neurosurgical consultation should be obtained, and infection of the pin site excluded. If resistance is met within the first rotations, the pin can usually be retightened to 6 to 8 lb. If no resistance is met, the pin has to be removed. This is usually done by the neurosurgeon after placement of a new pin is completed to avoid any loss of stability in the halo device.

If pin loosening has caused movement of the halo device, assume that the cervical spine is unstable, immobilize the cervical spine using an alternate technique, and obtain plain radiographs to assess for proper alignment. Tangential plain radiographs, CT, or MRI can be used to exclude penetration of a pin through the inner table of the skull.

Pin-site infection is the second most frequently encountered complication. It occurs in approximately 20 to 22 percent of patients with halo devices.^{5,7} Careful examination is required to differentiate a localized pin-site infection from less common, more serious infection, such as cellulitis, osteomyelitis, and abscess formation. Patients with cellulitis often have fever, and systemic signs and symptoms of infection. Patients with osteomyelitis usually have a prolonged infection, pin-site loosening, and radiologic abnormalities. Patients who develop an abscess usually have neurologic changes and evidence of intertable penetration (CSF leak, trauma), although cases of asymptomatic brain abscess associated with pin-site infection or pin tightening after late pin loosening have been reported.⁸ Local pin-site infections are commonly managed with local wound care. The skin around the pin site must be pulled away to allow thorough cleaning of the skin beneath the pin and skin-pin interface with soap and water four times a day. Culture the wound site. If antibiotics are administered, agents effective against skin pathogens (e.g., *Staphylococcus* and *Streptococcus* species) are used. If local infection does not respond to treatment, or if cellulitis, osteomyelitis, or abscess is suspected, neurosurgical consultation is required for admission, intravenous antibiotics, and possible surgical intervention.

Pin-site discomfort occurs in 18 percent of patients.^{5,7} It is most commonly a result of local inflammation. However, infection (localized or systemic) must be considered in each patient. Sensory and motor deficits or paresthesias indicate nerve damage or pressure, while painful mastication indicates temporalis muscle inflammation. If infection is excluded, a short course of analgesics is recommended. Neurosurgical consultation is required if pain continues or a serious complication is suspected.

Ring migration and/or loss of immobilization occurs in 10 to 13 percent of patients.^{5,7} Suspect loss of immobilization in patients complaining of neck pain and or mobility, and change in fit or position of the ring or vest. Immediately immobilize the cervical spine using an alternative technique (e.g., hard collar plus backboard). Obtain plain films to assess for changes in alignment and neurosurgical consultation for reapplication of the halo device.

Skin breakdown and pressure sores occur in 4 to 11 percent of patients.^{5,7} If present, the vest should be inspected for adequate padding and strap position. Urgent referral to a neurosurgeon for refitting may be required.

Dysphagia occurs in 2 percent of patients.^{5,7} Immobilization holding the head in exaggerated extension is the usual cause of the dysphagia. Halo adjustment will remedy this problem. Alternatively, dysphagia can occur following anterior displacement of a bone graft. This diagnosis can be made by plain films and/or a swallowing study and will require emergency surgical intervention.

Dural punctures occur in 1 percent of patients and are a result of halo system trauma.^{5,8} Symptoms include headache, malaise, or visual changes. Physical exam may reveal a CSF leak or evidence of skull fracture. All patients require admission and neurosurgical consultation. Treatment includes elevation of head, intravenous antibiotics, and pin removal.

Cardiopulmonary resuscitation is rarely required in patients with halo devices. To perform chest compressions, remove the anterior por-

tion of the vest. Instructions for removing the halo vest are printed on the front of most vests. Intubation is performed with the halo in place. If orotracheal intubation is unsuccessful, attempt nasotracheal intubation (if respirations are present) or cricothyrotomy.

OTHER CENTRAL NERVOUS SYSTEM DEVICES

Intrathecal Baclofen Infusions

Generalized dystonia occurs in 15 to 25 percent of patients with cerebral palsy. These patients typically respond poorly to medical and surgical treatment plans aimed at controlling their dystonia. Baclofen, a 7-aminobutyric acid agonist that acts at the level of the spinal cord by impeding the release of excitatory neurotransmitters, decreases spasticity. Oral baclofen offers patients only mild relief because of its inability to cross the blood-brain barrier and because it is poorly lipid soluble. Intrathecal administration is more effective, requires lower doses, and leads to higher CSF levels. Intrathecal baclofen reduces spasticity, improves gait, sitting ability, and upper extremity function in most patients.^{9,12} Complications observed in patients receiving continuous intrathecal baclofen include hypotension; bradycardia; apnea; oversedation; respiratory depression; pump pocket effusions; mechanical failure; catheter extrusion; kinking; dislodgement; local infection; meningitis; and CSF fistula formation. Newly available intrathecal catheters cause fewer complications compared to original catheters. More experience is needed with continuous intrathecal baclofen to determine the long-term benefits. Complication occur in approximately 20 to 38 percent of cases, while infection requiring removal occurs in approximately 5 percent of cases.^{9,13} Concerns about baclofen pumps should always be directed to the neurologist.

Implantable CNS Stimulators

The pathogenesis of Parkinson disease is thought to involve unregulated activity of the subthalamic nucleus and globus pallidus intermedius. Neurophysiologists have shown that high-frequency stimulation can reversibly inactivate nerve conduction in these areas.^{14,15}

High-frequency stimulation with implantable CNS devices are being used for suppression of parkinsonian and essential tremors. Neurostimulation is typically used if drug therapy has failed to control tremors. Neurostimulation is as efficient at controlling tremors as classic thalamotomy, but is less invasive.

Limited studies suggest that neurostimulation has a lower risk of physical or cognitive impairment compared to thalamotomy. Reported complication rates range from 7 to 65 percent, with a decline in the number of reported complications as user experience increases.¹⁶ Patients may present to the emergency department with varied complaints including problems related to the subcutaneous pulse generator, temporary or permanent paresthesias, dysarthria, dysequilibrium, or failure of the neurostimulator to suppress tremors. Neurosurgical consultation is needed as these complaints may represent lead displacement or migration requiring surgical correction or replacement. If the diagnosis remains uncertain, observation may be required with the stimulator in the off position to help differentiate mechanical failure from an acute neurologic deficit.^{14,16}

Spinal Cord Stimulation

Spinal cord stimulation is an established modality for treating chronic back pain, angina pectoris, and the pain syndromes associated with vascular disease. Multicontact electrodes are placed in the epidural space, and the distal end of the electrode is connected to an internalized pulse generator. The therapeutic response is thought to be a result of stimulation of one of several dorsal tracts. Reported complications include the need for surgical revision and infection. Surgical revisions

have been reported to be as high as 50 percent within 3 years of implantation.¹⁷ The most common reasons for revision include electrode replacement or repositioning, generator replacement, cable failure, and implant removal. Infection at either the generator, cable, or electrode are reported to be as high as 8.6 percent.¹⁷

APPROACH TO NEUROIMAGING IN THE EMERGENCY DEPARTMENT

Maria G. Matheus Norman J.
Beauchamp, Jr.

GENERAL OVERVIEW OF COMMON TECHNIQUES

Although a more thorough discussion of techniques is provided in other chapters of this textbook, a brief introduction to the more common techniques will be beneficial to understanding the optimal approach to cranial neuroimaging.

Plain films remain the first-line imaging technique. X-rays generate two-dimensional images based on attenuation of a collimated beam. The attenuation is proportional to the electron density of the structures through which it passes, with the final image reflective of tissue density. This results in high spatial resolution and thus sensitivity for the detection of fractures. However, detection of abnormalities requires that there be no obscuration of the region of interest by overlying bone or other dense material. Thus whereas a skull fracture of the

calvaria is often readily detected, a fracture involving the skull base is typically obscured due to overlying bone. Plain films also provide a coarse view of the extracranial soft tissues, but intracranial soft tissues are obscured. Because the primary goal of ED neuroimaging is the detection of intracranial soft tissue abnormalities, the role of plain films is largely limited to the primary assessment of spinal trauma, the assessment of some facial fractures, assessment of some subtle, linear skull fractures oriented in the axial plane of acquisition, or as part of the skeletal survey for child abuse.

Computed tomography (CT) has largely supplanted plain films for neuroimaging. CT images are generated using a rotating x-ray tube that projects a collimated beam through the brain with resultant attenuation of the beam proportional to the electron density (tissue density) of the tissue through which it passes. Thus rather than interrogating the tissue of interest from one direction (as in conventional x-rays), computerized processing of the circumferentially projected attenuated rays enables reconstruction of tissue maps largely unobscured by overlying tissues. Differentiation of adjacent tissues such as bone, gray and white matter, and cerebrospinal fluid (CSF) is possible due to perceptible differences in tissue density. Vasogenic and cytotoxic edema and hemorrhage alter the density of the tissue affected, making CT highly sensitive in the detection of disease. Further, the fine anatomic detail enables detection of morphologic alterations such as fractures and parenchymal swelling.

Magnetic resonance imaging (MRI) involves placing a patient inside an externally applied magnetic field. The nuclei of the tissues are aligned by the powerful magnetic field. Due to its odd number of nucleides and its abundance in our bodies, hydrogen is the major element responsible for the signal production in MRI. The "magnetized" hydrogen atoms are "energized" by the input of an applied radiofre-

quency pulse, and the pattern of energy released provides information about the biophysical properties of the tissue being evaluated. Depending on the way that the radiofrequency pulse is applied, different sequences in an MRI are generated. The different MR sequences allow the characterization of shifts in water (hydrogen) distribution. All pathologic processes alter the biophysical properties (shift in water distribution of the affected tissue). Detectable changes in the biophysical properties occur prior to a detectable change in tissue density. Thus MRI is more sensitive than CT in detecting parenchymal pathologic processes such as cerebral ischemia, infection, or metastases. Equally important is that the presence of certain blood products (deoxy- and methemoglobin, hemosiderin) develops over time postbleeding. These cause a detectable alteration in local magnetic field. MRI and CT thus are nearly equivalent in the detection of fresh bleeding, but MRI is much more sensitive in the detection of static blood. Blood becomes CT isodense with the brain parenchyma around 7 to 10 days postbleed, but can generate an abnormal magnetic field for months to years. Lastly, MRI enables multiplanar acquisition while the patient remains supine. In the majority of the available CTs, imaging requires patient positioning specific for the plane of interest. This can be difficult for the very young, the elderly, and for trauma patients. Multi-detector CT can acquire the images in an axial plane and reconstruct the images in a multiplanar isotropic fashion.

Notably, cortical bone is relatively depleted of hydrogen. Thus the cortex of bone is nearly invisible on MRI. Although this is of benefit in that parenchyma can be assessed without compromise from adjacent dense bone (e.g., infratemporal region and posterior fossa assessment is slightly limited in CT due to artifact from the adjacent skull base) (Figures 237-1A and 237-1B), MRI is inadequate for the assessment of bone integrity. Compared to CT, MRI may not be available to

FIG. 237-1. A. Axial CT obtained in a patient presenting with a left cerebellar infarct. Initial CT demonstrates a focal area of decreased attenuation in the left cerebellar hemisphere that is difficult to detect due to artifact generated by adjacent bone (arrow). Incidental note is made of similar obscuration of the inferior temporal lobe by artifact (arrowheads). B. Axial MRI clearly demonstrates an area of infarction in the left cerebellum. Visualization is clear with no artifact generated despite proximity to bone.

many emergency departments. MRI is also contraindicated in the presence of devices such as pacemakers, cochlear implants, and metallic foreign matter near vital structures; requires greater patient cooperation; and prevents monitoring of critically ill patients. As a result, despite its superior sensitivity to most pathologic processes, MRI plays an important but more limited role when compared to CT in the ED.

Ultrasound generates images based on transmittance of sound waves. In general, sonographic imaging enables evaluation of soft tissue structures provided that air or bone does not obscure the area of interest. In neuroimaging, most of the structures of interest are obscured by the calvaria. However, in infants, patency of the fontanelle provides an adequate sonographic window, enabling high sensitivity for the detection of intracranial masses, hemorrhages, or hydrocephalus. In infants and very young children, ultrasound is the study of choice for intracranial assessment. Ultrasound can also be used to assess traumatic globe injury or masses. However, this technique is highly operator-dependent, is limited in the assessment of the orbital apex, and is typically performed by an ophthalmologist. Finally, ultrasound images can be generated in which flowing blood produces color images scaled to flow velocity. These images give information on lumen caliber and hemodynamic alterations (such as occur with a distal occlusion or proximal stenosis). Ultrasound has become the screening technique of choice in assessing common carotid bifurcation atherosclerotic disease. Transcranial Doppler and power Doppler ultrasound enable assessment of the most distal aspects of the internal carotid arteries, the proximal cerebral arteries, the circle of Willis, and the superficial parenchyma. Assessment of the posterior circulation and deeper parenchyma remains limited.

The vasculature can also be assessed noninvasively with CT angiography (CTA) or MR angiography (MRA). CTA and MRA are appealing techniques because they are noninvasive and can be incorporated into a comprehensive CT or MR examination with minimal

additional time or difficulty (Figures 237-2A and 237-3B). MRA utilizes a gradient echo pulse sequence that results in increased intravascular signal intensity with normal flow. CTA is performed following the peripheral venous administration of iodinated contrast. An image similar to a conventional arteriogram can be reconstructed from the axial images. Both are sensitive to large vessel occlusion or narrowing in the internal carotid, vertebral, basilar, and first and second segments of the anterior, middle, and posterior cerebral arteries. Furthermore, both techniques can be modified to look at venous structures (i.e., CT venography or MR venography). CTA requires less patient cooperation, with an assessment of the vasculature complete in approximately 30 s. However, vascular detail is limited when vessels are in direct apposition to bone. Vascular assessment with MRA is not limited in the presence of bone. It is useful for assessing the vertebral arteries as they course through the bony transverse foramina and skull base, and in assessing the cephalad course of the internal carotid artery.

Both CTA and MRA techniques have greatly improved in the last decade, but resolution is still considered inferior to catheter angiography. Both noninvasive methods approach 90 percent accuracy for detection of aneurysms larger than 3 mm, but for small aneurysms (less than 3 mm) the sensitivity of these methods drops sharply to 61 percent and 38 percent for CTA and MRA, respectively.¹ CTA can assess the neck of the aneurysm, enabling appropriate planning for endovascular therapy. The primary use of both techniques is as a screening tool for vascular occlusion, and generally they should be supplemented with catheter angiography when clinical suspicion remains (see Figures 237-3A and 237-3B).

Catheter angiography utilizes plain x-rays in conjunction with administration of intraarterial contrast through a catheter placed in the femoral artery and positioned proximal to the vasculature to be assessed. The intraarterial contrast delineates vascular anatomy and

FIG. 237-2. A. MR angiogram demonstrates occlusion of the right internal carotid artery. B. MR diffusion-weighted image of the same patient, less than 6 h after the onset, demonstrates conspicuous high signal intensity in right frontotemporal region and basal ganglia corresponding to an infarcted area with restriction of the water's random motion. The image has low resolution but high contrast and the lesion is easily seen.

FIG. 237-3. A. Oblique view from a catheter angiogram demonstrates a small anterior communicating artery aneurysm less than 3 mm in diameter (arrow). B. In the same patient, CT angiogram shows a small irregularity in the anterior communicating artery (arrow). The small size of the aneurysm, the overlapping of the vessels, and its proximity with the clinoid process and sphenoid bone made the assessment of the aneurysm on the CTA image difficult.

detects pathologic changes such as narrowing and occlusion. It is the definitive procedure for assessment of the intra- and extracranial vasculature. However, there is a 1 to 2 percent risk of stroke associated with catheter angiography.

Near-infrared spectroscopy (NIRS) measures changes in absorbance of an infrared light beam projected transcranially. Specifically, near-infrared light (700 to 1000 nm) has relatively good transcranial penetration, and hemoglobin (Hb) has characteristic absorption spectra. The absorbance of light is dependent on the presence of Hb and the oxygen content of the Hb. Thus this technology can be used to assess for the presence of hemorrhage and to assess the oxygen state of the superficial microcirculation. For example, in one investigation, 24 of 27 patients with delayed traumatic intracranial hemorrhages demonstrated increases in the NIRS absorbance.² NIRS units are portable and relatively inexpensive, but the role for NIRS remains to be determined.

Radioisotope scans are performed following the administration of radioisotopes that emit photons. Photon imaging studies can be used to assess ventriculoperitoneal shunt patency, CSF leaks, hydrocephalus, Ommaya reservoirs, and brain death. Anatomic scans can also be performed that enable detection of space-occupying lesions. In general, nuclear medicine neuroimaging studies are infrequently utilized in the ED setting due to the superior resolution, increased availability, and expedience of CT and MR.

The remainder of this review focuses on guiding principles for the assessment of the most common emergency neurologic complaints.

HEADACHE

Subarachnoid Hemorrhage

Recommendations for which subset of patients with acute headache requires some form of neuroimaging are as varied as they are numerous. However, neuroimaging has been accepted as the standard of care

in specific clinical situations (Table 237-1). In addition to atypical headache (associated with neurologic signs), severity of headache is an indicator for imaging. Specifically, acute onset of the "worst headache of my life" raises concern for subarachnoid hemorrhage. Identification is essential because rupture of an intracranial aneurysm is the most common cause of nontraumatic subarachnoid hemorrhage. Furthermore, if subarachnoid hemorrhage (SAH) remains undetected, there is a 50 percent 2-week risk of rebleeding with an associated 50 percent mortality. In this instance, nonenhanced head CT is the recommended study (Figure 237-4). Its sensitivity in the detection of SAH is within 93 to 100 percent if performed within 12 to 24 h of the event.³ In addition to the demonstration of high-density acute blood in the subarachnoid spaces, it also demonstrates other manifestations of SAH, including intraventricular and intraparenchymal hemorrhage and hydrocephalus. With small amounts of acute hemorrhage, SAH can be overlooked and the sensitivity of CT decreases to about 80 percent after 24 h,¹ and continues to diminish significantly over time to less than 30 percent 3 days postrupture.

Conventional MRI technique (conventional gradient and spin-echo T1- and T2-weighted images) does not demonstrate SAH well. FLAIR sequence (fluid attenuation inversion recovery sequence) is an MRI technique that enables identification of SAH in subacute and even in acute periods, because the CSF signal becomes brighter in the presence

TABLE 237-1 Considerations for Nonenhanced Head CT

1 for	Unexplained mental status change or focal neurologic signs "Worst headache of life" of sudden onset
	Unexplained fever Meningismus
	Extremes of vital signs (blood pressure, bradycardia, or respiratory rate, although seldom an isolated finding)

FIG. 237-4. Axial CT demonstrates areas of increased density compatible with subarachnoid hemorrhage (SAH) (*straight arrows*). There is also early hydrocephalus with the temporal horns dilated (*curved arrow*).

of blood. Unfortunately FLAIR imaging is somewhat limited in the posterior fossa and around the circle of Willis because of motion artifact. FLAIR is useful for SAH surrounding the hemisphere.⁴ If the CT is negative and FLAIR is not available, lumbar puncture is necessary. A positive CT or lumbar puncture requires conventional angiography.

Headache and Fever

Headache associated with unexplained fever is also an indication for neuroimaging, particularly when there is associated meningismus and photophobia. Although diagnosis is made by lumbar puncture, imaging is typically recommended to exclude mass effect or hydrocephalus. Despite the absence of scientific validation, it has become the standard of care to precede lumbar puncture with nonenhanced CT (NECT) of the head. Secondary hydrocephalus tends not to obviate performing lumbar puncture, but it will lead the physician to performing a low-volume lumbar puncture. Further, it can alert to the possible need for shunt placement.

Hydrocephalus

Acute or recurrent hydrocephalus can present with headache as well as nausea, incontinence, and ataxia. There is generally an increase in the intraventricular volume. Hydrocephalus can be caused by a number of processes, including prior subarachnoid hemorrhage, prior trauma, meningitis, masses obstructing the ventricular system, or masses external to the ventricles but causing obstructing compression due to size or edema. In the evaluation of patients with suspected hydrocephalus, NECT is an adequate evaluation. It will enable detection of patients requiring emergency placement of intraventricular shunt catheters. If hydrocephalus is identified and the etiology remains undefined, a contrast-enhanced MRI examination with its superior ability to image

in multiple planes should be performed. Lastly, in examining patients with an intraventricular shunt catheter and suspected recurrent hydrocephalus, the NECT should be accompanied with a plain film shunt series. The latter will detect possible kinks or disruptions of the catheter (see Chap. 236 for detailed discussion).

Mass CNS Lesion

Generally, an intraparenchymal mass large enough to cause headache will be associated with neurologic signs prior to, or concurrent with, the development of headache. Thus in instances in which tumors are associated with headache, they are large and readily detectable on NECT; indirect effects, such as obstruction of CSF outflow, will also be evident on NECT.

MENTAL STATUS CHANGE

The issue of whether to image patients under the influence of alcohol or other substances in order to consider other etiologies as a possible explanation for mental status change frequently arises in ED practice. The approach is discussed in detail in Chap. 229. Generally, patients with a Glasgow Coma Scale (GCS) score of 13 or less, those that fail to improve with time, or those in whom alcohol or drug levels are not in keeping with the clinical findings, require imaging.

CNS Tumor

An initial NECT can be performed in patients with mental status changes who also have a known primary tumor, or who have a suspected metastasis or primary brain tumor. This will suffice to detect lesions resulting in mental status change, such as marked cerebral edema, herniation, and intracranial hemorrhage, that require emergent intervention. However, the optimal choice of imaging is based on the availability of imaging resources as well as the clinical suspicion. For example, contrast MRI is the more sensitive test and is typically required for patients in whom clinical concern persists, even if the initial CT is normal. However, if MRI resources are immediately available and the patient is stable, it could be more appropriate in some instances of high suspicion to proceed directly to MRI and avoid unnecessary time delay and additional imaging costs to the patient. Contrast-enhanced CT subjects patients to the small but unnecessary risk of iodinated contrast and is less sensitive than MRI.

Encephalitis

Proceeding directly to imaging with MRI when available is also indicated with certain cerebral infections. Encephalitis presents as acute mental status change and fever. Herpes encephalitis from HSV-1 is a particularly devastating form, but it can have a good clinical outcome if diagnosed and treated early in the course of the disease. Herpes often has a characteristic appearance in which the temporal lobes are first affected (Figure 237-5). Due to the difficulties assessing parenchyma in direct apposition to bone structures, detection of the subtle early findings of cytotoxic edema involving the temporal lobes can be difficult when utilizing NECT in the first 3 days. Sensitivity is not increased by the addition of intravenous contrast. Conversely, MR is highly sensitive to the early manifestations of encephalitis. It is often positive in the first 24 h and can be helpful in expeditious diagnosis.

HIV-Positive Patient

The approach to imaging the HIV-positive patient with mental status change is greatly debated. There is a tendency to provide an emergent screening examination with NECT followed by nonemergent performance of contrast-enhanced MRI as indicated. Using this approach, processes creating vasogenic edema and those requiring immediate intervention, such as toxoplasmosis and lymphoma, will undoubtedly be

FIG. 237-5. Axial CT scan demonstrates decreased attenuation in the right temporal lobe (*straight arrow*). In a young patient with acute-onset mental status change, this is highly suggestive of herpes encephalitis. Note the normal left temporal horn (*curved arrow*) as compared to the effaced right temporal horn.

detected. However, further investigation using contrast MRI is often requested to better characterize these lesions and for the detection of HIV encephalopathy and progressive multifocal leukoencephalopathy. A cost-effective approach of proceeding directly to MRI has also been recommended. This largely depends on the institutional availability of MRI and the management practices of clinicians.

SEIZURES

In recurrent seizures, determination of a sole cause such as noncompliance typically eliminates the need for imaging. Similarly, neuroimaging is not indicated for the evaluation of children with simple febrile seizures. However, the optimal approach for the evaluation of first-time seizures is debated.⁵⁶ The American College of Emergency Physicians Special Panel suggests CT scanning for first-time seizures. CT is nearly 100 percent sensitive for etiologies of seizures that require emergent intervention, such as brain abscesses, hemorrhage, or other space-occupying lesions. However, the neurologist may additionally request multiplanar MRI emergently or electively, depending on the clinical situation, although not necessarily while the patient is in the ED.

STROKE

Determining the optimal approach to imaging cerebral infarction is becoming increasingly complex, and is thus relevant to the discussion of modality selection in neuroimaging.

U.S. Food and Drug Administration (FDA) guidelines require performance of a NECT prior to the institution of thrombolytic therapy.

Intravenous contrast administration is of limited value in the CT evaluation of acute stroke. Contrast enhancement is generally not seen during the first 3 days. Experience from the European Cooperative Acute Stroke Trial (ECASS) has demonstrated that efficacy of treatment is contingent on accurate CT interpretation.⁷ Specifically, treated patients who had evidence of infarction on CT had a worsened outcome. Such patients should be excluded from treatment. However, identifying this contraindication can be challenging because the signs of infarction initially are quite subtle. For example, trained readers did not detect 12 percent of areas of advanced infarction in the ECASS study.⁷ Optimal treatment is most likely to occur when all members of the treatment team are familiar with the early signs of infarction (Table 237-2). Briefly, the presence of hemorrhage or evidence of progressive infarct are contraindications to treatment (Figure 237-6). The sensitivity of CT for the detection of hemorrhage has been previously discussed. An important sign of acute stroke is the hyperdense middle cerebral artery sign (HMCAS). This may correspond to a thrombus. The early CT findings of infarction are due to cytotoxic edema—cellular injury with influx of fluid in the intracellular space. The four CT signs that can be seen in the acute period are: 1) blurring of the clarity of the internal capsule; 2) loss of distinctness of the insular ribbon cortex; 3) loss of differentiation between the cortical gray and the subjacent white matter; and 4) swelling of the cortical gray matter resulting in effacement of interposed sulci. In addition to the attenuation changes, morphologic changes occur due to the accumulation of intracellular fluid, causing swelling of the cortical gyri. This results in effacement of the spaces demarcated by the gyral infoldings (sulci) and is referred to as "sulcal effacement." The extent of these changes determines whether treatment with thrombolysis is indicated.

MR has a greater sensitivity and specificity than CT for the acute changes of stroke. In the first 24 h, over 80 percent of MR scans are positive as compared to 60 percent of CT scans. MR is particularly superior for the detection of stroke in the posterior fossa, where CT is limited due to a beam-hardening artifact from the adjacent skull base (see Figure 237-1). The earliest MR changes are morphologic swelling of the gray matter, increased signal intensity on the T2-weighted images and spin density-weighted images (referred to as T2 hyperintensity), and loss of normal intravascular flow voids (see Chap. 305 for details on the physics of MR). More importantly, MRI can be combined with MRA for the detection of large-vessel occlusion (see Figure 237-2A).

Newer MRI techniques can provide physiologic information about brain tissue. Diffusion-weighted sequences (MRD) are pulse sequences sensitive to small-scale water-molecule motion (i.e., diffusion). The principle is to apply sequential gradient pulses to a spin-echo sequence. Image construction is based on the degree of signal

TABLE 237-2 CT Appearance Exclusion and Inclusion Criteria for the Administration of Recombinant Tissue Plasminogen Activator (rtPA) in Patients Presenting within 3 Hours of Ictus

Grade 0—Normal CT

Grade 1—Possible early signs of infarction: May still give rtPA depending on the clinician's judgment

Vague blurring of gray-white boundaries

Slight attenuation of the insular ribbon

Slight indistinctness of basal ganglia gray matter

Suggestion of crowding of sulci Grade 2—Subtle but definite signs of early infarction: likely will not treat

Same as above except findings are distinct Grade 3—Prominent signs of early infarction: contraindication to treatment

Mass effect—i.e., ventricular effacement, subfalcine or uncal herniation

Clearly-demonstrated hypodensity

Intracranial hemorrhage

Note: In the ECASS study, the major early signs of infarction included: diffuse swelling of the affected hemisphere and effacement of the cerebral sulci in more than 33% of the middle cerebral artery territory.

Note: Based on recommendations by the American Heart Association and experience from the NINDS and ECASS Trials.

FIG. 237-6. Axial CT demonstrating clear evidence of decreased attenuation compatible with infarction (*straight arrow*). Also, there is a focal area of hemorrhage (*curved arrow*), which further obviates thrombolysis.

drop, proportional to microscopic water motion (Brownian motion). Areas with restricted motion, such as areas of acute infarction, undergo loss of signal at a slower range than does normal tissue. These changes can be detected within the first hour of infarction as conspicuous high signal intensity in diffusion-weighted sequences (see Figure 237-2B). Mathematical tools can create an ADC map (apparent diffusion coefficient map), which compares normal and affected tissue and highlights the area of infarction as dark.⁸

The mechanism of abnormal diffusion is thought to be due to: 1) alterations in the sodium/potassium pump that lead to increased intracellular water accumulation and restriction of normal random motion; or 2) a decrease in the extracellular space with increased tortuosity of the extracellular compartment.

MR perfusion is a physiologic imaging method useful to demonstrate hyperacute cerebral infarction. It is performed following the bolus administration of intravascular contrast, with changes in signal intensity that can reflect the status of the cerebral microvasculature.⁹ Perfusion can be combined with echo planar spin-echo and gradient echo-techniques and can improve vessel visualization. Diffusion and perfusion MR techniques together can dramatically improve the ability to determine extent of infarction and thus should improve the safety profile of recombinant tissue-type plasminogen activator (rtPA) administration.

Neither clinical examination nor conventional CT or conventional MRI techniques provide information on the ischemic penumbra. MR perfusion, CT perfusion, and MR spectroscopic (MRS) imaging appear capable of providing this information (see Chap. 305). When ischemia is present, MR perfusion imaging shows a delay in peak signal loss in the affected area. The region with hypoperfusion does not necessarily correspond in size with the infarcted area. The mismatch in size between the area with cytotoxic edema (visualized in the diffusion-weighted images) and the hypoperfused area may correlate with the penumbra area (tissue that could be saved with early reperfusion). CT perfusion correlates the early stroke signs visualized by NECT with the perfusion maps acquired after contrast injection to assess penumbra area.¹⁰

MRS generates maps of hydrogen spectra containing major resonances from TV-acetyl aspartate (NAA), choline, creatine, and lactate." Signals from lactate are not normally detected, but are demonstrated in the presence of ischemia and acute infarction, possibly due to a conversion of aerobic to anaerobic glycolysis in the infarcted tissue. Clinical MRS can demonstrate low or normal levels of metabolites (NAA, choline, and creatine) and elevated lactate in the infarcted area. Peripheral areas which demonstrate low levels of metabolites without lactate buildup are felt to be the penumbra.

HEAD TRAUMA

Debate remains whether imaging is required for patients with a GCS of 15. Clear indications for neuroimaging include GCS less than 15; unexplained transient or persistent loss of consciousness; other forms of altered sensorium; focal neurologic signs; depressed skull fractures; seizure; persistent variations; progressive headache; and penetrating injuries.¹² In these instances, NECT plays an essential role for diagnosis and for detecting processes that require emergent intervention, such as epidural and subdural hematomas, increased intracranial pressure, and depressed skull fractures. Although discussed elsewhere, a number of points related to optimal imaging are worthy of emphasis.

The differential density of blood facilitates the detection of intraparenchymal and extraaxial hemorrhage. Density is displayed on a relative scale referred to in Hounsfield units (HU). For example, water or CSF is assigned a value of zero, bone or metal varies between 100 and 1000 HU (hyperdense), fat is approximately -100 HU (hypodense), and air is -1000 HU. Further, acute blood has a density of 60 to 100 HU, and normal brain parenchyma has a density of approximately 35 (white matter) to 40 HU (gray matter). This differential density enables the increased density of blood or the decreasing density with accumulating edema to be detectable. Images are filmed in a manner that accentuates differences in the parenchymal range of densities. To optimize sensitivity for detecting parenchymal injuries, a gray scale is assigned such that regions of higher density are not easily differentiated. As such, blood in proximity to bone can be difficult to detect using parenchymal windows (Figures 237-7A and 237-7B).

When evaluating for the presence of subdural and epidural collections, it is important that images are formatted in a fashion so that the high densities are also distinguishable (i.e., blood windows). At many institutions it may not be routine to print these windows due to associated added film costs, but at a minimum, images should be reviewed on the CT console to exclude small blood collections. This is particularly true in children, in whom subdural hematomas can be a marker of intentional trauma. Detection is also facilitated by attention to the subtle secondary signs of extraaxial blood, including loss of sulcal demarcation, mass effect on a ventricle, or displacement of the gray-white junction from the inner table (see Figure 237-7). These secondary signs are also important because not all acute blood is hyperdense. In anemic patients (hemoglobin level 8 to 10 g/dL) or patients with a coagulopathy, acute blood may be isodense and thus difficult to visualize.

Occasionally, MRI can be of value in assessing trauma patients. For example, in assessing for small acute subdural hematomas or for subacute/chronic hematomas, CT may be limited due to the hematoma's proximity to bone or because over time the density of blood becomes isodense to normal brain (subacute) or to normal CSF (chronic) (see Figure 237-7B). However, these blood products will remain abnormal with MRI for months to years. This can be of value in children when new and old coexistent extraaxial hematomas are essentially pathognomonic for child abuse.

MRI is also more sensitive in detecting diffuse axonal injury in which differential movement of parenchyma results in neuronal shearing. Diffuse axonal injury should be suspected when coma occurs immediately after severe injury and the degree of compromise is out of proportion to the CT findings. MRI may be beneficial in that it will show multiple punctate areas of blood products below the threshold of CT detection. Specific anatomic structures that tend to be involved

FIG. 237-7. A. Axial CT demonstrates a somewhat subtle left subdural hematoma (curved arrows). Note secondary signs of mass effect with the contralateral sylvian fissure detectable but compressed on the side of the subdural hematoma (straight arrow). B. Axial MRI demonstrating the increased conspicuity of blood due to the lack of obscuration by adjacent bone.

include the corpus callosum, adjacent to the superior cerebellar peduncle, the internal capsule, and gray-white matter junction.¹³

Intra- or extracranial arterial dissection may be the result of trivial trauma, blunt trauma, or penetrating injury. MRI can detect the presence of an acute dissection with T1 hyperintense blood seen in the vessel wall. In combination with MR angiography, it provides a fairly sensitive screening for a dissection. It enables an adequately sensitive but noninvasive method for vascular assessment and simultaneous assessment of the brain parenchyma and the extraaxial spaces. Other vascular lesions associated with trauma are pseudoaneurysms, which may occur in any dissected vessel, both intracranially and extracranially, and are prone to bleed. Catheter angiography remains the gold standard, but should be restricted to those patients with equivocal or abnormal MRA or CTA findings or a high level of clinical suspicion.

Catheter angiography is also recommended in all patients with penetrating injuries to zone 1 and zone 3 of the neck, although assessment of zone 3 injuries is slightly more equivocal.¹⁴ Angiography is needed to evaluate vessels of the thoracic inlet and those above the mandible, because they are not accessible to visual inspection. Further, when indicated, surgical exploration will require a vascular road map. Zone 2 injuries can be observed without angiography, but angiography is recommended for expanding hematomas or where there is the development of respiratory or neurologic compromise.¹⁵

EYE, EAR, NOSE, THROAT, AND ORAL SURGERY

OCULAR EMERGENCIES John

D. Mitchell

A wide range of ocular emergencies, conditions, and manifestations of systemic illness are encountered regularly in the ED. The emergency physician should be comfortable with the use of a slit lamp, Tonopen or Schiatz tonometer, and direct ophthalmoscope and be familiar with ocular anatomy (Figures 238-1 and 238-2) and basic neuro-ophthalmology. The approach to the patient should proceed in typical fashion with a good history and physical examination, with treatment of life-threatening conditions taking priority.

EYE EXAMINATION

History

A detailed history of the chief complaint and circumstances surrounding the onset should be obtained. The past ocular and medical history will provide additional information and help focus the physical examination so as to arrive at the differential diagnosis. For example, a history of sudden, painless monocular visual loss associated with a history of atrial fibrillation or carotid stenosis would suggest a central retinal artery occlusion, whereas a history of eye pain occurring while hammering metal on metal would suggest a projectile corneal or intraocular foreign body. Past visual acuity and the need for glasses or contact lenses provide information on acuity testing expectations. Use of soft contact lenses, especially the extended-wear type, is associated with a higher incidence of corneal ulceration from microbial infection. "Flashing lights" and a "curtain or veil" obstructing a portion of the visual field suggests a retinal detachment. A history of diabetes or chronic hypertension and acute isolated sixth-nerve palsy suggests an ischemic cranial neuropathy.

Physical Examination

The physical examination typically proceeds in a sequential fashion unless the circumstances require otherwise (i.e., chemical ocular injuries require intervention *prior* to assessment of visual acuity). The glossary of terms and abbreviations in Table 238-1 is useful in documenting the findings. The typical eye examination sequence is as follows: Visual acuity, external eye, visual fields, pupils, ocular motility, anterior pigment, fundus, and intraocular pressure.

VISUAL ACUITY An attempt should be made to assess visual acuity in each eye individually in all conscious and alert patients. If the patient uses glasses or contacts but the glasses are not available, pinhole testing can be performed to obtain an estimate of corrected visual acuity. The pinhole allows only parallel rays (collimated light) to fall on the macula, thereby reducing the refractive error and allowing an estimate of the person's corrected visual acuity.

Distance charts are preferable but are not practical with patients confined to a stretcher. Nearsighted patients and those under age 45 can use a near card to test their visual acuity. Patients in their midforties or older may require reading glasses or bifocals to read a near card because of presbyopia. If the bifocals are not available, again, a pinhole occluder can be used with a near card. Corneal abrasions or foreign bodies can cause severe photophobia, pain, and tearing, so a top-

ical anesthetic can reduce discomfort sufficiently to allow a more accurate assessment of visual acuity. Documentation of best acuity in each eye and whether prosthetic devices were used (glasses, pinhole) should be noted. If the patient cannot read the chart or near card, ask how many fingers you are holding up, and record the furthest distance at which the fingers can be counted correctly (e.g., at 4 ft). If the patient is unable to count fingers, assess ability to detect hand motion 1 to 2 ft in front of the eye. If the patient is unable to detect hand motion, turn off all the lights in the room, fully occlude the contralateral eye, and test for light perception. In recording the results of visual acuity testing, refer to Table 238-1.

EXTERNAL EYE Examine the periorbital skin and lids for trauma, infection, dysfunction, deformity, crepitus, or proptosis. Subcutaneous emphysema can be found with blowout fractures of the medial orbital wall (ethmoid). The orbital rims should be palpated for step-off deformities in trauma cases.

CONFRONTATION VISUAL FIELDS Test the gross confrontation visual field of each eye with all visual complaints, including "blurred" vision. Bitemporal hemianopia can occur in pituitary adenoma, homonymous hemianopia is associated with some cerebrovascular accidents (CVAs), and monocular field cuts are sometimes seen with large retinal detachments.

PUPILS Pupil assessment should be performed under slightly dim light to test for an afferent pupillary defect (Figure 238-3). A positive afferent pupillary defect indicates an optic nerve disorder. It is important to note that the pupils will be equal in size *prior* to testing because of the consensual light response. Therefore, an afferent pupillary defect does not cause a baseline anisocoria and will be discovered only if specifically tested for. Causes of unequal pupils (anisocoria) can range from an acute emergency (posterior communicating artery aneurysm) to chronic baseline conditions such as previous intraocular trauma or surgery, or can be idiopathic. A careful history is important to determine whether anisocoria is preexisting. Ocular medications such as pilocarpine can cause extreme miosis, resulting in small, non-reactive pupils. Some patients with uveitis will be using a cycloplegic agent (scopolamine, cyclopentolate, or atropine) and have a chemically dilated, unreactive pupil. **It is not worthwhile to attempt to "reverse" a chemically altered pupil in the ED as a diagnostic test because the results are variable and unreliable.**

OCULAR MOTILITY Eye movements are controlled by the six extraocular muscles attached to each eye (Figures 238-4 and 238-5). These muscles are innervated by cranial nerves III, IV, and VI. Cranial nerve IV controls the superior oblique muscle, cranial nerve VI controls the lateral rectus muscle, and all other extraocular muscles are controlled by cranial nerve III. Ocular motility can be impaired by restriction, interrupted or decreased innervation, or trauma. Examples of restriction include thyroid orbitopathy, myositis, and mechanical entrapment of a muscle secondary to an orbital blowout fracture. Cranial nerve palsies or paresis may be caused by stroke, myasthenia gravis, diabetes, hypertension, tumors, aneurysms, infections, and trauma. Penetrating or blunt traumatic injury to an extraocular muscle also can result in motility disturbance. Diplopia may develop, especially when the patient is attempting to look in the direction of the malfunctioning muscle. Ocular alignment should be evaluated in primary gaze initially (looking straight ahead), followed by testing in all fields of gaze.

FIG. 238-1. Anatomic diagram of eye and adnexa.

ANTERIOR SEGMENT The conjunctiva, cornea, anterior chamber, iris, lens, and ciliary body make up the anterior segment. All these structures except the ciliary body can be inspected directly by slit-lamp examination. A slit lamp is a biomicroscope that affords an excellent view of these structures and should be used whenever possible (Figure 238-6). The conjunctiva should be inspected for hemorrhages, discharge, inflammation, trauma, and foreign bodies. The upper lid always should be everted anytime a foreign-body sensation or abrasion is present. The cornea should be assessed by narrowing the light source to produce a slit beam and optically sectioning the cornea (Figure 238-7), which allows an oblique section to be seen and facilitates evaluation of the entire corneal thickness. This is a particularly important technique when one is trying to determine if a corneal foreign body has caused a full-thickness penetration.

Fluorescein dye should be instilled and the cobalt-blue filter used to identify corneal abrasions, dendrites, and perforations. The *modified Seidel test* is useful in identifying corneal perforations. The eye is anesthetized and held open, and the cobalt-blue filter is used to observe the eye while a moistened fluorescein strip is "painted" across the suspicious site. Leakage of aqueous humor through a penetrating

FIG. 238-2. Horizontal cross-sectional diagram of eye.

TABLE 238-1 Glossary of Terms, Abbreviations, and Notations

AC:	Anterior chamber, the first portion of the anterior segment.
Anisocoria:	Unequal pupil size under equal lighting conditions.
Anterior segment:	Consists of the anterior chamber and posterior chamber.
Aqueous humor:	Is produced in the posterior chamber of the anterior segment and circulates through the pupil into the anterior chamber of the anterior segment.
APD:	Afferent pupillary defect (see Figure 238-3).
CF:	Counting fingers (visual acuity assessment).
CVF:	Confrontation visual fields.
EOM:	Extraocular muscle.
HM:	Hand motion (visual acuity assessment).
Hyphema:	Red blood cells in the anterior chamber.
Hypopyon:	White blood cells in the anterior chamber.
INO:	Internuclear ophthalmoplegia.
IOFB:	Intraocular foreign body.
IOP:	Intraocular pressure (mm Hg).
Limbus:	Circumferential border where clear cornea ends and white sclera begins.
NLP:	No light perception (blind).
OD:	Oculus dexter (right eye).
OS:	Oculus sinister (left eye).
OU:	Oculus uterque (each eye).
PH:	Pinhole visual acuity.
RD:	Retinal detachment.
Tonopen:	A handheld, pen-shaped device for measuring intraocular pressure.
Tono-	Tension (IOP) with subscript representing method used (tono = Tonopen, S = Schiottz, A = applanation).
V_{Ao} :	Visual acuity with correction (glasses or contact lenses).
V_{As} :	Visual acuity without correction.

Note: By convention, in documenting the visual acuity (V_A) or IOP, the right eye is listed above the left, as follows:

$V_{A_s} <$	20/20
	20/30
This represents a visual acuity <i>with</i> glasses/contacts of 20/20 right eye and 20/30 left eye.	
$V_{A_s} <$	20/400 → 20/30
	CF at 8 ft → 20/40
This represents a visual acuity <i>without</i> glasses/contacts of 20/400 in the right eye, improving to 20/30 with pinhole testing; counting fingers at 8 ft in the left eye, improving to 20/40 with pinhole testing.	
$T_{ono} <$	14
	15
This represents an IOP of 14 mm Hg in the right eye and 15 mm Hg in the left eye measured by Tonopen.	

wound will appear as a lime-green fluid oozing onto the dark violet corneal surface (Figure 238-8, **Plate 3**).

The anterior chamber should be checked for clarity and the presence of a hyphema (Figure 238-9, **Plate 4**) or hypopyon (Figure 238-10, **Plate 5**). Cell and flare may be present in acute injuries or in chronic uveitis/iritis conditions and should be checked for as follows: The slit beam should be shortened to about 1 mm, and all the room lights should be out. The high-magnification position should be selected. The incident light source should create an angle of 45 to 60 degrees with the objective (similar to optical sectioning). The light beam should be focused on the pupillary margin. Then pull back on the joy stick to focus on the cornea. Then move the focus inward halfway between the iris and cornea, with the pupillary aperture as a dark backdrop. This will place your focus in the center of the aqueous humor, and the light beam will illuminate cells slowly drifting up and down in the aqueous convection currents. Flare typically is described as the appearance of "headlights in a fog" and represents the ability to see the course of the normally transparent light beam through the aqueous hu-

FIG. 238-3. A. "Swinging-flashlight test" revealing an afferent pupillary defect (Marcus-Gunn pupil) of the left eye. C. The test is positive when the affected pupil dilates in response to light. Conditions with an afferent pupillary defect (AFD) include optic neuritis and central retinal artery occlusion.

mor. This is caused by increased aqueous protein content, which is common with inflammatory conditions.

The iris should be inspected for tears and foreign bodies if trauma occurred. The lens likewise should be inspected for injury, subluxation, and foreign bodies.

FUNDUS The optic nerve, macula, and retina can be viewed with a direct ophthalmoscope in the emergency department. A dilated pupil makes it easier to see these structures, and unless the patient has a rare

FIG. 238-4. Extraocular muscles of the eye.

contraindication (narrow angles without a previous peripheral iridectomy), dilation can be performed if a posterior segment view is needed. Dilation can be achieved by using one drop of 1% tropicamide (Mydracyl) in Caucasians and one drop each of 1% tropicamide and 2.5% phenylephrine (Neo-Synephrine) in all others. A dilated examination is particularly important if an intraocular foreign body, central retinal artery occlusion (CRAO), or retinal detachment is suspected. A vitreous hemorrhage from diabetes or trauma can obscure or significantly reduce the view of the posterior pole. In these patients, an ophthalmologist may need to perform an ultrasound-B scan to evaluate the posterior segment. An indirect ophthalmoscope provides an excellent three-dimensional view of the optic nerve and retina but requires extensive practice to use and generally is not a tool for the non-ophthalmologist.

INTRAOCULAR PRESSURE The eye remains consistently "inflated" because of a delicate balance between intraocular aqueous fluid production and outflow. Intraocular pressure (IOP) or tension can decrease due to reduced ciliary body production (some cases of iritis and uveitis) or loss of globe integrity (perforating injury). An increase in IOP occurs when intraocular fluid production exceeds outflow (glaucoma, hyphema). The normal IOP is 10 to 21 mm Hg, and three main methods are used to achieve a measurement. Applanation tonometry is the method preferred by ophthalmologists and physicians trained in using this slit-lamp attachment. Practice and previous experience are recommended, however. The Tonopen, a handheld instrument for measuring IOP, has gained popularity because it is easier for a non-ophthalmologist to use and has reasonable accuracy for identifying elevated IOP. The Schiøtz tonometer is another instrument that can be used readily if a Tonopen is not available. All methods require an anesthetized cornea and a cooperative patient. Avoid any pressure on the globe with your fingers when holding the lids open because this will cause a falsely high reading. The lids should be held open, with the fingers compressing the lids against the bony rims of the orbit. The method used always should be recorded. In recording the IOP, refer to Table 238-1.

INFECTIONS

Lids

STYE (EXTERNAL HORDEOLUM) A sty is an acute staphylococcal infection of an oil gland associated with an eyelash. It is located at the lash line and has the appearance of a small pustule. Warm compresses and erythromycin ophthalmic ointment twice daily for 7 to 10 days is usually sufficient treatment.

CHALAZION (INTERNAL HORDEOLUM) A chalazion is an acute or chronic inflammation of the eyelid secondary to blockage of one of the meibomian oil glands in the tarsal plate. A reddened, tender lump develops in the lid or at the lid margin. Initial conservative treatment:

1. Warm, moist compresses three to four times a day
2. Erythromycin ophthalmic ointment applied to lid margins four times daily
3. Consider doxycycline 100 mg PO twice daily for 14 to 21 days if chronic and recurrent
4. Ophthalmology referral after 4 to 6 weeks, earlier if it worsens

Chronic inflammation will induce a cystic wall, and a discrete lump develops that is usually both palpable and visible in the lid. Chalazions can cycle between being quiet or acutely inflamed. The patient with a chronic, recurrent chalazion should be referred to an ophthalmologist for surgical excision and curettage, which is the definitive procedure.

SECTION 20 . EYE, EAR, NOSE, THROAT, AND ORAL SURGERY

FIG. 238-5. Arrows indicate direction of ocular movement by each muscle. Cranial nerve IV, superior oblique muscle; cranial nerve VI, lateral rectus muscle; cranial nerve III, superior rectus, inferior rectus, inferior oblique, and medial rectus muscles.

Conjunctivitis

BACTERIAL CONJUNCTIVITIS Bacterial conjunctivitis generally presents with a mucopurulent discharge and inflammation of the conjunctiva. Often the eyelids are stuck together on awakening. The condition can be monocular or binocular. The cornea is clear *without* fluorescein staining. Frequently there is a history of recent exposure to someone with "pink eye." Treatment consists of a topical ocular antibiotic four times daily for 5 to 7 days. Treatment with a broad-spectrum agent is safe for patients 2 months of age and older; Polytrim (trimethoprim and polymyxin B), for example, is very effective and avoids potential allergies to sulfa and neomycin preparations. Wearers of soft contact lenses should be treated with a fluoroquinolone (Ciloxan, Ocuflax) or aminoglycoside (Tobrex) to treat *Pseudomonas*. With the expanding choices of well-tolerated topical antibiotic drops, gentamicin is now seldom used by ophthalmologists because of the high incidence of ocular irritation. Treatment:

1. Fluorescein stain of the cornea (especially infants) to avoid missing a corneal abrasion, ulcer, or dendrite
2. *Non-contact lens wearer*: broad-spectrum topical antibiotic (Polytrim or erythromycin), one drop four times daily for 5 to 7 days

3. *Contact lens wearer*: fluoroquinolone (Ciloxan or Ocuflax) or aminoglycoside (Tobrex) for *Pseudomonas* coverage, one drop four times daily for 5 to 7 days

VIRAL CONJUNCTIVITIS Viral conjunctivitis tends to follow an antecedent upper respiratory infection and often will have a palpable preauricular node, which aids in confirming the diagnosis. Generally, one eye will be involved initially, with the other eye becoming involved within days. The discharge tends to be watery, and the conjunctiva is reddened and edematous (chemosis). The cornea is clear, with occasional punctate staining with fluorescein dye (multiple tiny dots of stain uptake seen only on slit-lamp examination). It is important to stain the cornea to avoid missing a herpes dendritic keratitis. Treatment consists of cool compresses; Naphcon-A, one drop three times daily and as needed for redness and conjunctival congestion; and artificial tears five or six times a day. Viral conjunctivitis can take 1 to 3 weeks to run its course and is highly contagious. The physician examining a patient with possible conjunctivitis should wear gloves in order to avoid self-contamination. If, after a history and physical examination, it is still uncertain if the conjunctivitis is viral or bacterial, it is not unreasonable to add an antibiotic eyedrop until the patient can be reexamined by an ophthalmologist.

FIG. 238-6. A. The slit lamp provides a magnified view of the eye. B. A thin slit can demonstrate the cornea (C), iris (I), and lens (L).

FIG. 238-7. Optical sectioning. By creating an angle of 45 to 60 degrees between the slit-beam light source and the observer's biomicroscope objective, the cornea can be optically "sectioned" obliquely. This allows a cross-sectional view of the cornea and is helpful in ascertaining depth of penetration of corneal foreign bodies and injuries.

Treatment:

1. Fluorescein stain the cornea to avoid missing a herpes dendrite
2. Cool compresses four times daily
3. Naphcon-A one drop three to four times daily or as needed for conjunctival congestion/itching
4. Consider a topical antibiotic if there is uncertainty as to whether an infection is viral or bacterial
5. Ophthalmology follow-up in 7 to 10 days if cornea is clear

ALLERGIC CONJUNCTIVITIS Allergens can cause ocular discharge, redness, and itching. Itching is a very common and consistent symptom seen with allergic conjunctivitis. Treatment consists of cool compresses four times daily, antihistamine/decongestant drops (Patanol, Zaditor, or Alocril twice daily or Naphcon-A four times daily), and artificial tears as needed.

NEONATAL CONJUNCTIVITIS (OPHTHALMIA NEONATORUM) THIS CONDITION IS DISCUSSED IN CHAP. 117.

Herpes Simplex Virus (HSV)

HSV can affect the eyelids, conjunctiva, and cornea. Skin involvement has typical vesicular eruptions, and the conjunctiva also can become inflamed. Ocular HSV alternately can present with only corneal findings on physical examination. The dendrite of herpes keratitis is an ep-

FIG. 238-8. (PLATE 3). Positive Seidel test showing aqueous leaking through a full-thickness corneal wound. Aqueous will turn fluorescein lime-green under a cobalt-blue light as it oozes through the wound while being observed at the slit lamp.

ithelial defect that can be seen with fluorescein staining and has a linear branching pattern with terminal bulbs (Figure 238-11, **Plate 6**). An initial outbreak of HSV involving the lids and conjunctiva can be treated with an oral acyclovir derivative such as Zovirax or Famvir and topical antiviral drops (Viroptic five times a day without corneal involvement, nine times a day with corneal involvement). Erythromycin ophthalmic ointment can be added to prevent secondary infection of the vesicular eruption. HSV keratitis can progress to corneal scarring and requires prompt treatment with topical antiviral agents. Viroptic—one drop nine times a day—represents standard treatment, and Vira-A ointment five times a day or Stoxil can be substituted for those who are allergic to Viroptic. Topical steroids should be strictly avoided, and all patients should be referred to an ophthalmologist for outpatient follow-up. Treatment:

1. If the initial outbreak is less than 3 to 4 days old, consider oral acyclovir-class medications.
2. Erythromycin ophthalmic ointment four times daily to skin and conjunctival lesions to avoid secondary bacterial infection
3. HSV *without* corneal involvement: Viroptic one drop five times a day
4. HSV *with* corneal involvement: Viroptic one drop nine times a day
5. Ophthalmology follow-up in 1 to 3 days

Herpes Zoster Ophthalmicus

Herpes zoster ophthalmicus (HZO) represents shingles in the trigeminal nerve distribution with ocular involvement. When the cutaneous lesions include the tip of the nose (Hutchinson sign), the nasociliary nerve is involved, and the eye frequently becomes inflamed. An iritis can occur with photophobia and pain. Cutaneous lesions and conjunctival involvement are treated with erythromycin ointment to prevent secondary bacterial infection. The cornea can have a pseudodendrite, which is a poorly staining mucous plaque with no epithelial erosion (unlike HSV, which has a true dendrite with epithelial erosion and staining). The anterior chamber on slit-lamp examination can show manifestations of iritis (cell and flare). Iritis can be treated with topical steroids such as prednisolone acetate 1% (Pred Forte) one drop four to five times a day, and pain reduction can be achieved with topical cycloplegic agents (scopolamine 0.25% one drop three times daily or cyclopentolate 1% one drop three times daily). If HZO is diagnosed, admission and intravenous acyclovir should be considered, especially if any intracranial symptoms are present.

FIG. 238-9. (PLATE 4). Hyphema secondary to blunt trauma. Note the blood filling the lower half of the anterior chamber and hazy appearance of cornea suggesting increased IOR

Treatment:

1. Erythromycin ophthalmic ointment to lesions to prevent secondary infection
2. Oral narcotic analgesia if necessary
3. Prednisolone acetate (1%) (Pred Forte) one drop five times a day if iritis is present and *no corneal epithelial defect* is seen on fluorescein staining and slit-lamp examination
4. Cycloplegic pain reduction with 0.25% scopolamine or 1% cyclopentolate one drop three times daily
5. Consideration for admission and intravenous acyclovir; dosage 30 mg/kg per d divided in three doses if creatinine is below 2 mg/dL

Preseptal Cellulitis (Periorbital Cellulitis)

Preseptal cellulitis is a periocular superficial cellulitis that has not breached the orbital septum. The eyelids become edematous, warm, and red. The eye itself is not involved, with *acuity and pupillary reaction maintained* and *full ocular motility preserved*. The majority of cases occurring in children and adults are the result of inoculation sec-

FIG. 238-10. (PLATE 5). Corneal ulcer with hypopyon. The ulcer is seen as a shaggy white corneal infiltrate surrounding the borders of the epithelial defect. The hypopyon represents the accumulation of white cells layering out in the lower one-sixth of the anterior chamber.

FIG. 238-11. (PLATE 6). Herpes simplex corneal dendrite seen with fluorescein staining and cobalt-blue light.

ondary to skin infection or trauma (see Chap. 122). The offending agent is usually *Staphylococcus aureus*. Oral antibiotics can be adequate if there is no orbital involvement, but if the latter is suspected, then intravenous antibiotics, computed tomographic (CT) scanning, and possible admission should be considered.

Preseptal cellulitis in children under 5 years of age is a special circumstance due to the association with bacteremia, septicemia, and meningitis and warrants a complete diagnostic evaluation, including blood cultures and intravenous antibiotics. Although *S. aureus* is still the most common organism, often the cause is bacteremic spread of *H. influenzae* from otitis media or pneumonia. The incidence of *H. influenzae* preseptal cellulitis has been decreasing with the use of *H. influenzae* type b vaccine. Consultation with a pediatrician is recommended for consideration of admission.

Treatment:

1. Ascertain no restriction of ocular motility, no proptosis, no pain with eye movement, and preserved pupillary response and acuity
2. *Children older than 5 years of age:* Amoxicillin/Clavulanate 20 to 40 mg/kg per d orally divided into three doses
3. *Adults:* Amoxicillin/Clavulanate 500 mg PO three times daily
4. Regarding those younger than 5 years of age or in severe cases, admit for IV antibiotics and systemic workup
5. *Children:* Ceftriaxone 100 mg/kg per d IV divided into two doses plus vancomycin 40 mg/kg per d IV divided three doses
6. *Adults:* Ceftriaxone 1 to 2 g IV every 12 h plus vancomycin 0.5 to 1.0 g IV every 12 h

Orbital Cellulitis (Postseptal Cellulitis)

Orbital cellulitis is an *orbital* infection; therefore, it is deep to the orbital septum. This is a serious ocular infection that has the potential to be life-threatening. *S. aureus* is the most common pathogen; however, *H. influenzae* should be considered in young children and mucormycosis in diabetics and immunocompromised patients. Polymicrobial infection is common. Orbital extension of paranasal sinus infection (especially ethmoid sinusitis) is the most frequent source. Orbital and sinus CT scans should be performed in the ED. If the CT scan is negative, an enhanced CT scan should be performed looking for a subperiosteal abscess. Diagnostic clinical findings that help distinguish this infection from preseptal cellulitis include extraocular muscle (EOM) motility impairment, pain, fever, and occasionally, proptosis. Decreased visual acuity is a late finding. Cavernous sinus

thrombosis also can occur. Patients require a full workup, admission, and intravenous antibiotics. Treatment:

1. Intravenous cefuroxime alone or intravenous penicillin plus nafcillin or chloramphenicol plus nafcillin. In penicillin-allergic patients vancomycin or a cephalosporin can be substituted.
2. Contrast-enhanced CT scans of the orbits and paranasal sinuses and admission.

Corneal Ulcer

A corneal ulcer is a serious infection involving multiple layers of the cornea. Corneal ulcers develop secondary to breaks in the epithelial barrier, allowing infectious agents to gain access to the underlying corneal stroma. The initial disruption of the epithelial layer can be due to desquamation, trauma, or direct microbial invasion. Exposure keratitis from incomplete lid closure secondary to Bell palsy can cause corneal desiccation and sloughing of the epithelium, allowing bacteria to gain access to the underlying stroma and create an ulcer. Trauma can also breach the epithelium and inoculate the cornea. Wearing of soft contact lenses is a very common cause of corneal ulcers, and the incidence increases dramatically in those who use extended-wear lenses and wearers who sleep with them in place.

Typically, the patient will have a painful red eye, with tearing and occasionally photophobia. Examination reveals a staining epithelial defect and a white, hazy infiltrate underlying the defect and spreading into adjacent stroma. Occasionally, a hypopyon is also present on slit-lamp examination (see Figure 238-10), signifying an intraocular inflammatory response. Corneal ulcers need to be treated aggressively with topical antibiotics. A fluoroquinolone such as ciprofloxacin (Ciloxan) or ofloxacin (Ocuflox), one drop every hour in the affected eye, is the recommended treatment. A topical cycloplegic agent such as cyclopentolate 1% (Cyclogyl), one drop three times daily, also can help with pain control. The eye *should not be patched* because of the risk of *Pseudomonas* infection, which can cause rapid, aggressive ulceration with corneal melting and perforation. All corneal ulcers should be referred to an ophthalmologist to be seen within 12 to 24 h.

Treatment:

1. Ciloxan or Ocuflox, one drop every hour
2. No patching
3. Topical cycloplegic (1% cyclopentolate or 0.25% scopolamine) three times daily
4. Ophthalmology referral within 24 h

TRAUMA

Superficial Trauma

SUBCONJUNCTIVAL HEMORRHAGE The fragile conjunctival vessels can rupture from trauma, sudden Valsalva pressure spikes (sneezing, coughing, vomiting, straining), hypertension, or spontaneously with no discernible etiology. No treatment is necessary, and the hemorrhage usually resolves within 2 weeks. If multiple recurrent episodes occur, coagulation studies and further investigation are warranted.

CONJUNCTIVAL ABRASION Superficial conjunctival abrasions without any other associated ocular injury only require erythromycin ointment twice daily for 2 to 3 days or no treatment if very small. The lid should be everted and the fornix inspected under magnification for any residual particulate matter or organic debris.

CORNEAL ABRASION Abrasions of the cornea are associated with pain, photophobia, and tearing. They can be the result of trauma or contact lens wear. Visual acuity assessment can be difficult because of the patient's extreme discomfort. A drop of a topical anesthetic often will reduce the discomfort temporarily and facilitate visual acuity testing. A corneal epithelial defect will be present and is best seen with fluorescein staining and examination with a cobalt-blue light. The eyelid should be everted and inspected for foreign bodies. Examine the cornea for possible full-thickness injury (optical sectioning), and assess the anterior chamber with the slit lamp, looking for any associated injury. Adequate and persistent cycloplegia is essential to controlling pain. Reduction of ciliary spasm contributes significantly to pain relief and in most cases eliminates the need for narcotic pain medication. By the same token, inadequate cycloplegia almost mandates the need for oral analgesics. If an abrasion is larger than 2 mm or very painful, consider having the patient instill a cycloplegic agent (cyclopentolate 1%, homatropine 5%, or scopolamine 0.25%) one drop every 6 to 8 h at home to help control discomfort. Scopolamine dilates the pupil for several days and usually is reserved for very large, painful abrasions. Cyclopentolate 1% (Cyclogyl) one drop three times daily does an excellent job of providing cycloplegia and wears off within 24 h of discontinuation. Erythromycin ophthalmic ointment should be instilled and an eye patch may be placed, if desired, provided that the abrasion was not from an organic source or from the wearing of soft contact lenses. Abrasions will heal with or without a patch, and ophthalmologists will treat patients either way. Some patients appear to be more comfortable with an eye patch for the first 12 to 18 h, but this is not uniform, and the physician can make an individual decision with the patient. **Abrasions from organic sources have for fungal infections potential and should not be patched. Abrasions related to the wearing of soft contact lenses pose a risk of *Pseudomonas* infection and likewise should not be patched.** These patients should be treated with tobramycin ointment four times daily, followed by a fluoroquinolone (Ciloxan, Ocuflox) drop or tobramycin drop four times daily once the epithelial defect starts to close. Do not prescribe a topical anesthetic for pain relief as most anesthetics cause corneal toxicity when dosed recurrently and can lead to visual loss.

Documenting the Dimensions of a Corneal Abrasion Some slit lamps (Haag-Streit) have a measuring dial attached to the mechanism that varies the length of the slit beam. If your slit lamp is equipped with this feature, you can vary the length of the slit beam on the cornea until it corresponds to the length or width of the abrasion. The reading on the wheel equals the length of the slit beam in millimeters. This additional feature allows you to document the dimensions of the abrasion precisely, thereby enabling subsequent examiners to evaluate the wound's healing response objectively. Treatment:

1. Identify the source of the abrasion if possible.
2. Cycloplegia (cyclopentolate 1%, or homatropine 5%) one drop now and repeat every 6 to 8 h as needed for pain. Warn the patient that the pupil will dilate and lose its ability to focus at near and that the drop will burn for 10 to 15 s when placed in the eye.
3. *Not related to contact lens wear:* Erythromycin ophthalmic ointment and eye patch, or no patch and erythromycin ointment four times daily.
4. *Related to contact lens wear:* Tobramycin ophthalmic ointment four times daily. *No patch.*
5. *Organic source:* Erythromycin ophthalmic ointment four times daily. *No patch.*
6. Ophthalmology referral or reexamine next day.

CONJUNCTIVAL FOREIGN BODIES Conjunctival foreign bodies usually can be removed with a moistened cotton-tipped applicator

after anesthetizing the eye with a topical anesthetic. The upper eyelid should be everted and inspected under the highest magnification available to avoid missing any additional foreign bodies. Frequently, small wooden particles such as sawdust will blend into the conjunctiva when moistened by the tears and be difficult to find without slit-lamp magnification. Small, fine vertical corneal abrasions seen only with fluorescein staining often will alert the physician to the presence of a foreign body embedded in the tarsal conjunctiva of the upper lid.

CORNEAL FOREIGN BODIES Foreign bodies should be removed carefully under the best magnification available. The slit lamp provides sufficient magnification and allows both hands to be free for use. A history consistent with high-velocity ocular impact (i.e., hammering metal on metal) should alert you to the possibility of a penetrating injury. The cornea should be inspected using "optical sectioning" (see Figure 238-7) to assess depth of penetration *prior* to removal. **Full-thickness corneal foreign bodies should not be removed in the ED and require an ophthalmology consult.** Fortunately, most corneal foreign bodies are superficial and can be removed easily and safely. A "golf-club spud" is a handy tool for this task, but a small 30- to 25-gauge needle under slit-lamp magnification or a moistened cotton-tipped applicator will work most of the time. A topical anesthetic should be instilled prior to removal, and it is helpful to also instill an anesthetic drop in the unaffected eye to suppress reflex blinking during removal. Many slit lamps have an attached "fixation light" that is mobile and can be moved in front of the unaffected eye to give the patient a steady target to concentrate on. This reduces the random movements that can occur when you are trying to remove the foreign body. The eyelids can be held open with your fingers, or a wire eyelid speculum can provide excellent support during the procedure.

Metallic foreign bodies can create rust rings that are toxic to the corneal tissue. If a rust ring is present, the spud or an ophthalmic burr can be used to remove superficial rust. Even if a thorough job is done initially, the next day more rust often can be seen, requiring additional burring. It is therefore not necessary to remove all the rust aggressively in the emergency department if the patient can be seen by an ophthalmologist the next day. The rust-ring area can soften overnight and be removed in the office the next day. The deeper the stromal involvement, the higher is the risk of corneal scarring; therefore, only a superficial burring should take place in the emergency department. **No emergency department drill burring should take place if the rust ring is located in the visual axis (pupil) owing to the risk of causing visually significant scarring.** Such conditions require that an ophthalmologist remove the stromal rust in the office within 24 h. As with any foreign body of the eye, the lid should be everted and inspected under magnification to ensure that no additional foreign bodies are present. The corneal abrasion that will be present after removal of a foreign body should be treated as discussed previously with adequate cycloplegia, antibiotic ointment, and optional patching.

Treatment:

1. Instill topical anesthetic in *both eyes* to suppress the blink reflex.
2. Test visual acuity (sometimes easier after an anesthetic drop is administered).
3. Assess if this is a full-thickness or penetrating injury.
4. Remove the foreign body under slit-lamp magnification, and remove superficial rust if possible.
5. Use a burr if available, but avoid burring in visual axis, and avoid removal of deeply lying rust.
6. Evert the lid to rule out additional foreign bodies.
7. Treat resulting corneal abrasion with topical cycloplegia, erythromycin ointment, and optional patching (see "Conjunctival Abrasion" above).
8. Referral to an ophthalmologist, to be seen the next day.

Lid Lacerations

Full-thickness lid lacerations should be repaired by an ophthalmologist, if at all possible, within 24 h. Proper alignment of the lid margin during repair under magnification (loupe or microscope) is essential to preserve proper lid function and even corneal wetting with each blink. Notching of the lid can result in improper lid closure. Very small lacerations (< 1 mm) at the lid edge only, do not need suturing and can heal spontaneously. Any laceration > 1 mm needs repair. Notching of the lid can result in improper lid closure. If there is no opportunity for the patient to see an ophthalmologist, repair should be performed as in Figure 238-12. One 6-0 silk vertical mattress suture, using the meibomian gland orifices as a landmark, or two 6-0 silk sutures (one approximating the anterior and the other the posterior lamella) are used to repair the lid margin. The ends of the silk sutures should be left long enough to tuck under the more distal skin sutures to avoid corneal irritation. The tarsus should be repaired with 5-0 Vicryl from the external side so as to approximate the wound without the need for sutures on the conjunctival side of the lid (which would abrade the cornea with each blink). Skin closure can be performed with 6-0 or 7-0 monofilament or silk suture. Deep lacerations medial to the punctum potentially can transect the canalicular system. These injuries need to be seen by an ophthalmologist for evaluation of the nasolacrimal duct system's integrity. If a canalicular laceration is discovered, the patient will need to go to the operating room within 24 to 36 h for repair and Silastic tube stenting (Figure 238-13). Because a meticulous repair by an experienced eye surgery team is preferable, it is not unreasonable for the ophthalmologist to discharge a patient seen late in the evening or on the weekend with arrangements for surgical repair to take place within the next 36 h. Patients discharged pending repair should be placed on oral and topical antibiotics and told to use cold compresses. Oral cephalexin (Keflex) 500 mg twice or four times daily and topical erythromycin ophthalmic ointment four times daily are reasonable choices.

FIG. 238-12. Full-thickness lid repair. 6-0 silk is used for lid margin. 5-0 Vicryl is used to approximate the tarsal plate. The Vicryl sutures should not pass through the conjunctiva on the inside of the eyelid to avoid mechanical abrasion of the cornea during blinking. 7-0 Nylon is used for skin closure, and the lid margin silk suture tail can be incorporated into these sutures to avoid corneal irritation.

FIG. 238-13. Traumatic canalicular laceration repair requires microsurgical stenting to reestablish patency.

Partial-thickness lid lacerations can usually be repaired in the ED with referral for ophthalmologic evaluation in 2 to 3 days. It is important to have the suture ends closest to the cornea tucked under more distal sutures to avoid corneal irritation (see Figure 238-12).

Blunt Trauma

After sustaining blunt trauma, the eyelids frequently are swollen shut, and the globe is difficult to visualize. Trying to pry the eyelids open with your fingers can be frustrating; it increases the IOP and usually results in obtaining an unsatisfactory view of the globe. A wire or adjustable eyelid speculum can help tremendously. Insertion of the eyelid speculum provides a significantly improved view of the cornea and anterior chamber and allows your hands to remain free for examination of the globe at the slit lamp. If a speculum is not available, try your best to assess the patient's visual acuity and the integrity of the globe and anterior chamber. If the anterior chamber is flat, a ruptured globe is certain, and no further attempts to assess the eye should be made. A metal shield should be placed and an ophthalmologist consulted. A hyphema is also evidence of significant ocular trauma and necessitates an ophthalmology consult. If the globe appears intact and vision is preserved, next check ocular motility. Restricted upgaze or lateral gaze suggests a blowout fracture with entrapment (see "Blowout Fractures" below). Feel the orbital rim above and below for step-off deformities. Test for cutaneous sensation along the distribution of the inferior orbital nerve (below the eye and ipsilateral side of the nose). Perform a slit-lamp examination with fluorescein staining to check for abrasions, lacerations, foreign bodies, hyphema, iritis, and lens dislocation. Traumatic iritis is common, causing cell and flare to be seen on slit-lamp examination. If no corneal epithelial defect is

seen, iritis can be treated with one drop of Pred Forte four to five times a day. The pupil can be constricted or dilated after sustaining trauma. It is important to look for pupillary irregularity because the pupil often will peak toward the site of a penetration or rupture. If the anterior chamber is of normal depth and not shallow, one drop of Mydracyl 1% will dilate the pupil and allow an easier funduscopy view. Non-Caucasian brown-eyed individuals frequently will require an additional drop of phenylephrine 2.5% to achieve adequate dilation. If vision and ocular anatomy and function are preserved, outpatient follow-up by an ophthalmologist in the next 48 h should be planned. If a ruptured globe is suspected (blind eye, flat anterior chamber, obvious full-thickness laceration, intraocular foreign body), no attempts at eye manipulation or IOP measurement should take place, and an ophthalmologist should be consulted. Treatment:

1. Assess globe integrity and vision.
2. If a ruptured globe is suspected, do not attempt to check IOP; place a protective metal eye shield, check tetanus status, administer intravenous cephalosporin, let the patient take nothing by mouth, and call ophthalmology.
3. If a ruptured globe is not suspected, proceed with the following.
4. Check eye motility and cutaneous sensation.
5. Obtain a facial/orbital CT scan if a blowout fracture or orbital/intraocular foreign body is suspected. Treat accordingly.
6. Slit-lamp examination of corneal, conjunctival, scleral, and anterior chamber structures.
7. Dilate if anterior chamber depth is normal for funduscopy view.
Caucasians: Mydracyl 1 %, one drop.
All others: Mydracyl 1%, one drop, plus phenylephrine 2.5%, one drop.
8. Ophthalmology referral within 48 h if no injuries are found.

HYPHEMA Blood in the anterior chamber is referred to as a *hyphema* (see Figure 238-9). Hyphemas generally can be classified as either traumatic or spontaneous. Traumatic hyphemas usually are the result of bleeding from a ruptured iris root vessel. Both blunt and penetrating trauma can cause hyphemas. Spontaneous hyphemas frequently are associated with sickle cell disease. All hyphemas, regardless of etiology, should be seen by an ophthalmologist. ED management consists of assessing concomitant injury (ruptured globe, intraocular foreign body) and managing rises in IOP. The patient's head should be elevated to promote settling of suspended red blood cells inferiorly so as not to clog the entire 360 degrees of trabecular meshwork. The pupil should be dilated to avoid "pupillary play" (constriction and dilation movements of the iris in response to changing lighting conditions). Because an iris vessel is usually involved, pupillary activity can put the vessel on stretch, promoting additional bleeding. Pupillary dilation *does not* compromise the angle and aqueous outflow in normal individuals, and many ophthalmologists choose to dilate hyphemas for the preceding reasons. IOP control is important and consists of topical (3-blockers, intravenous mannitol, topical adrenergic agonists (apraclonidine), and oral, topical, or intravenous carbonic anhydrase inhibitors (CAIs) such as Diamox and Trusopt. **In patients suspected of having sickle cell disease (either by history or if the hyphema was spontaneous), carbonic anhydrase inhibitors should be strictly avoided.** CAIs will lower the aqueous pH in the anterior chamber, causing the red blood cells to sickle and become less flexible, thereby clogging outflow through the trabecular meshwork and increasing IOP.

Rebleeding can occur 3 to 5 days later in up to 30 percent of cases, sometimes causing potentially blinding elevations of IOP and necessitating surgical anterior chamber "washouts." Because of this risk, some ophthalmologists believe in admitting all patients with hyphe-

mas, whereas others will choose to follow them closely as outpatients. Generally, those with hyphemas occupying one-third or less of the anterior chamber can be followed closely as outpatients. Because of the variance in treatment philosophy, the emergency physician should not assume responsibility for disposition. This decision should be made by the ophthalmologist on call after he or she has examined the patient. Treatment:

1. Elevate the patient's head.
2. Administer atropine 1% one drop three times daily.
3. Administer prednisolone acetate 1% (Pred Forte) one drop four times daily.
4. If the globe is intact, measure IOP.
5. If IOP is greater than 30 mm Hg, administer topical (3-blocker (Timoptic 0.5%), one drop. Give oral or intravenous acetazolamide (Diamox) 500 mg and add mannitol 1 to 2 g/kg IV if there is no response to the preceding.
6. If IOP is greater than 24 mm Hg and the patient is sickle cell trait-positive, treat as above *except avoid Diamox*.
7. Arrange for an ophthalmology consult.

BLOWOUT FRACTURES The most frequent sites of orbital blowout fractures are the inferior wall (maxillary sinus) and medial wall (ethmoid sinus). A Waters' view x-ray frequently will show a cloudy maxillary sinus on the side of the trauma. This represents blood and fluid in the maxillary sinus from fracture of the orbital floor. Fractures of the medial wall can be associated with subcutaneous emphysema, sometimes exacerbated by sneezing or blowing the nose. Fractures of the inferior wall with entrapment of the inferior rectus muscle can cause restriction of upgaze and diplopia (Figure 230-14). Isolated blowout fractures with or without entrapment do not require immediate surgery and can be referred to ophthalmology, plastic surgery, oral maxillofacial (OMF) surgery or otolaryngology (depending on the local referral patterns) for repair within the next 3 to 10 days. CT scanning with 1.5-mm cuts of the orbit should take place, and oral antibiotics (Cephalexin 250 to 500 mg four times daily for 10 days) are often recommended because of the presence of sinus wall fractures. **All blowout fractures with normal initial eye examination in the emergency department should be referred to an ophthalmologist for an outpatient full dilated examination to rule out any unidentified retinal tears or detachments.** About one-third of blowout fractures are associated with ocular trauma (abrasion, traumatic iritis, hyphema, lens dislocation/subluxation, retinal tear or detachment); therefore, a

FIG. 238-14. Inferior wall blowout fracture of the left eye with entrapment of the inferior rectus muscle. The patient's left eye is unable to look upward, causing diplopia on upgaze.

careful eye examination in the ED and referral to an ophthalmologist are essential.

Penetrating Trauma/Ruptured Globe

Penetrating ocular trauma can occur from numerous sources (BB pellets, lawn mower projectiles, hammering, knife and gunshot wounds). Any projectile injury has the potential for penetrating the eye. Any lid laceration from a sharp object, especially if it involves the upper and lower eyelid, has the potential to have lacerated the globe and requires a slit-lamp examination. Clues to a ruptured globe or intraocular foreign body include shallow anterior chamber, hyphema, irregular pupil, significant reduction in preinjury visual acuity, and poor view of the optic nerve and posterior pole on direct ophthalmoscopy. It is not unreasonable to dilate the eye with Mydracyl 1% and phenylephrine 2.5% to obtain a better view of the posterior segment of the eye, facilitating identification of an intraocular foreign body or retinal detachment. A modified Seidel test is helpful in identifying wound leaks (see Figure 238-8). Any penetrating injury is considered a ruptured globe and mandates an eye shield and ophthalmology consultation. Tetanus status should be determined and intravenous cephalosporin administered. Do not attempt to measure IOP if a ruptured globe is suspected. A Waters view x-ray, orbital CT scans or ultrasonography can be helpful in locating and confirming the presence of orbital and intraocular foreign bodies. Treatment:

1. If a ruptured globe is suspected, do not attempt to check IOP; place a protective metal eye shield, check tetanus status, administer intravenous cephalosporin, caution the patient to take nothing by mouth, and call ophthalmology.
2. Obtain a Waters' view x-ray and/or orbital CT scans if foreign bodies are suspected.

Chemical Trauma

CHEMICAL OCULAR INJURY A chemical injury to the eye is a true ocular emergency. The potential for chemical injury requires immediate recognition and treatment in the field and by the triage nurse. Immediate intervention consists of copious irrigation with at least 1 to 2 L of saline. Topical anesthesia and placement of a Morgan lens allow the irrigation to be delivered effectively and directly to the corneal surface. **This is one situation where a delay even to assess visual acuity is inappropriate.** Litmus paper or the pH portion of a urine dipstick can be used to assess the pH of the tears in the lower cul-de-sac. Irrigation should continue until pH testing improves to the range of 7.5 to 8 (see Chap. 181 for details). Both acid and alkali burns can be blinding; however, the majority of acid burns tend to coagulate proteins, thereby limiting the depth of penetration. Alkali burns (lye, ammonia) can rapidly penetrate the cornea, and aqueous pH can rise within minutes of exposure, causing damage to intraocular structures such as the iris and lens. After copious irrigation has been administered and the pH of the tears is close to normal, the eye should be inspected for any particulate matter, and visual acuity should be assessed. A topical cycloplegic agent such as 0.25% scopolamine or 1% cyclopentolate should be used three times daily for pain reduction if an epithelial defect is present. Erythromycin ophthalmic ointment should be instilled four times daily if both eyes are affected. If only one eye is affected and an epithelial defect is present, adding a pressure patch for the first 12 to 24 h sometimes will make the eye more comfortable. **Any patient with corneal clouding or an epithelial defect after irrigation should receive prompt ophthalmology referral.**

Patients with chemosis (edema of the bulbar conjunctiva overlying the white sclera) and no corneal or anterior chamber findings should be treated after irrigation with erythromycin ointment four times daily and referred for an ophthalmologic examination in the next 48 h. These patients are considered to have "chemical conjunctivitis."

Treatment:

1. Immediate copious irrigation with a minimum of 1 to 2 L of saline or until tear pH is 7.5 to 8.
2. If there is no corneal epithelial defect and the anterior segment is normal, administer erythromycin ointment four times daily.
3. If there is a corneal epithelial defect or there is clouding, administer erythromycin ointment, cycloplegia (cyclopentolate 1% or scopolamine 0.25%), and optional eye patching.
4. Provide for ophthalmology referral in the ED or within 24 h.

CYANOACRYLATE (SUPER GLUE/CRAZY GLUE) Cyanoacrylate adhesives are commonplace and often easily accessible to children. Accidental instillation into the eye and adnexa can cause the lids to adhere and adhesive clumps to form on the cornea. Most of the time these accidental instillations are not permanently harmful to the eye. Medicinal-grade cyanoacrylates are used occasionally directly on the cornea to seal corneal perforations and are not considered toxic to the cornea. The only concern is the mechanical abrasive effect of hard, irregular glue aggregates rubbing against the cornea with eye movement and blinking. Erythromycin is instilled heavily into the eye and on the surface of the eyelids to moisten, lubricate, and provide antibiotic coverage. Initial debridement of the surface glue clump should be limited to easily removable pieces. The glue will loosen and become easier to remove in a few days. Referral to an ophthalmologist should take place within 24 to 48 h. **Treatment:**

1. Moisten the glue with erythromycin ointment, and remove as much as can be removed easily without causing damage to underlying tissue.
2. Apply erythromycin ointment heavily into eye (if not glued completely shut) and eyelids five or six times a day.
3. Refer to ophthalmologist in the next 24 to 48 h.

ULTRAVIOLET KERATITIS ("WELDER'S FLASH") Pain, tearing, photophobia, and foreign-body sensation typically occur 6 to 12 h after unprotected ocular exposure to welding or sun-tanning lights. The history is diagnostic in these cases. Slit-lamp examination with fluorescein staining shows superficial punctate keratitis; this appears as numerous small microdots of staining on the corneal surface seen under high magnification using the cobalt-blue light. Treatment consists of cycloplegia, erythromycin ointment, and pressure patching overnight. Oral narcotic analgesia sometimes is necessary. **Treatment:**

1. Instill cycloplegic agent: 1% cyclopentolate or 0.25% scopolamine, one drop in each eye; this may be repeated by the patient every 6 to 8 h if needed for pain reduction.
2. Erythromycin ophthalmic ointment now, then four times daily once the patch is removed.
3. Pressure patching for comfort for the first 24 h; bilateral is preferable but seldom practical.
4. Consider oral narcotic analgesia if pain is severe.
5. Ophthalmology referral within 48 h (this condition is usually self-limited, with complete recovery).

ACUTE VISUAL REDUCTION/LOSS

Painful Visual Reduction/Loss

ACUTE ANGLE-CLOSURE GLAUCOMA Acute angle-closure glaucoma presents with cloudy vision, eye ache and/or headache, increased IOP, and frequently, nausea and vomiting. Abdominal symptoms sometimes can be misleading and delay the diagnosis. Acute angle closure typically occurs in a patient with *no* previous history of glaucoma, but with undiagnosed narrow anterior chamber angles.

When the pupil becomes mid-dilated and the iris leaflet touches the lens, "pupillary block" suddenly develops. This prevents circulation of the aqueous humor from the posterior chamber (where it is produced by the ciliary body) through the pupil and into the anterior chamber (where it is filtered out of the eye through the trabecular meshwork located in the angle). The continuous production of aqueous humor in the posterior chamber is trapped, and the increasing hydrostatic pressure bows the iris forward, further compromising the angle and inhibiting outflow (Figure 238-15). IOP rises and eventually exceeds the capacity of the corneal pump mechanism, causing the cornea to become edematous and less transparent. This explains the foggy vision or halos patients complain of and the hazy appearance of the cornea on physical examination. The pupil is *mid-dilated and nonreactive* (Figure 238-16). Pressures as high as 50 mm Hg and greater are not uncommon. Treatment, aimed at pressure reduction, consists of using suppressants of aqueous humor production such as topical (3-blockers, α -adrenergic agonists (apraclonidine), and oral or intravenous CAIs (acetazolamide). Because patients frequently are nauseated, intravenous CAIs are preferable to oral ones. Intravenous mannitol is very good at quickly lowering IOP and should be considered an adjunct to treatment if there are no contraindications. Pilocarpine frequently will not cause the iris to constrict during the acute attack until the pressure is reduced. This is due to pressure-induced ischemic paralysis of the iris. Pilocarpine 1% or 2% should be added once the pressure is reduced to make the pupil miotic, thereby pulling the peripheral iris away from the angle. This maneuver will help protect against recurrence until an ophthalmologist can perform the definitive treatment procedure of creating a peripheral laser iridectomy. **Treatment:**

1. Identify mid-dilated, nonreactive pupil with increased IOP.
2. Topical P-blocker (Timoptic 0.5%), one drop.
3. Topical α -agonist (Iopidine 0.1%), one drop.
4. Topical steroid (Pred Forte 1%), one drop every 15 min for four doses, then hourly.
5. CAI (acetazolamide) 500 mg IV or PO.
6. Mannitol 1 to 2 g/kg IV
7. Recheck IOP hourly.

FIG. 238-15. A. Normal flow of aqueous from ciliary body, through the pupil and out through the trabecular meshwork and Schlemm's canal located in the anterior chamber angle. B. Angle-closure glaucoma with pupillary block. Iris leaflet bows forward, blocking the chamber angle and prohibiting aqueous outflow. Meanwhile, aqueous production continues and IOP rises.

FIG. 238-16. Acute angle-closure glaucoma. Pupil is mid-dilated and nonreactive. The cornea is hazy due to stromal edema.

8. Topical pilocarpine 1% to 2%, one drop four times daily once IOP is below 40 mm Hg.
9. Consult ophthalmology.

3. Discuss with ophthalmologist or neurologist whether to treat with intravenous steroids or discharge without treatment. *Steroid regimen*: methylprednisolone 250 mg IV four times daily for 3 days followed by oral prednisone 1 mg/kg per d for 11 days.

OPTIC NEURITIS Optic neuritis is the most common cause of acute reduction of vision due to optic nerve dysfunction in patients 20 to 40 years of age. Women are affected more frequently than men. Reduction of vision is rapid and frequently painful (especially with eye movement). Color vision is affected commonly more than visual acuity. The red desaturation test is helpful in identifying optic neuropathies. (Have the patient look with one eye at a dark red object; then test the other eye to see if the object looks the same color. The affected eye often will see the red object as pink or lighter red.) An afferent pupillary defect (APD; see Figure 238-3) is commonly present. Visual acuity can range from mildly reduced to no light perception (NLP). If the optic disc is swollen and edematous on the affected side (papillitis), the patient is said to have anterior optic neuritis. If the head of the optic nerve is normal in appearance, the patient is said to have retrobulbar neuritis. The Optic Neuritis Treatment Trial (ONTT) showed that 1 year after an attack of optic neuritis, there was no difference in visual outcome between the patients treated with intravenous steroids and those given a placebo. Treatment with intravenous steroids, however, was associated with a slightly lower 2-year risk of subsequent development of multiple sclerosis, especially in patients whose MRI showed periventricular white matter lesions. For this reason, some physicians will consider intravenous steroids for any attack of optic neuritis, although no treatment is also acceptable. *Initial treatment with oral steroids is contraindicated* and, for unexplained reasons, had the least favorable outcome in the ONTT. Children can develop optic neuritis with similar initial findings, except that the majority of them tend to have bilateral optic nerve swelling (simulating papilledema) and a viral illness is frequently associated with an attack. Subsequent development of multiple sclerosis occurs less frequently in children. Treatment:

1. Check visual acuity, do red desaturation test, APD, eye pain with movement.
2. Check optic nerve head for papillitis (usually unilateral), may be bilateral in children or normal in retrobulbar neuritis.

Painless Visual Reduction/Loss

CENTRAL RETINAL ARTERY OCCLUSION Sudden, profound, painless, monocular loss of vision is characteristic of a central retinal artery occlusion (CRAO). The event is often preceded by episodes of amaurosis fugax. The first branch off the internal carotid artery is the ophthalmic artery, which supplies the central retinal artery, which in turn, provides the blood supply to the inner retina. If the central retinal artery becomes occluded, the retina will infarct and become pale less transparent, and edematous. The macula is the thinnest portion of the retina, and the intact underlying choroidal circulation remains visible through this section of retina, creating the illusion of a "cherry red spot." In fact, the macular area tends to maintain its normal color whereas the surrounding ischemic retina turns pale, thus causing this classic finding on funduscopy (Figure 238-17, **Plate 7**). An APD is a common finding associated with a CRAO. Causes include embolus (carotid and cardiac), thrombosis, giant cell arteritis, vasculitis (lupus), sickle cell disease, and trauma. Often the patient will have atrial fibrillation. The retina will sustain irreversible damage within 90 min of total occlusion, so treatment should begin immediately. Unfortunately, response to therapy is rare, but because the visual loss is usually so profound, every attempt should be made to reestablish circulation to the retina. Treatment in embolic cases (the majority) is aimed at trying to convert a CRAO into a branch retinal artery occlusion (BRAO). In the attempt to dislodge the embolus from the central artery and into one of its retinal branches, the other retinal branches may become reperfused, thereby reducing the size of the infarct. Maneuvers include digital massage, IOP-lowering drugs, and vasodilation techniques (breathing into a paper bag to increase $Paco_2$). An ophthalmologist should be consulted immediately to evaluate the patient and decide whether performing an IOP-lowering anterior chamber paracentesis is indicated. Treatment:

1. Consult ophthalmology the moment the diagnosis is made.

FIG. 238-17. (PLATE 7). Central retinal artery occlusion. Note macular "cherry red spot" and retinal pallor between macula and disc. The retinal veins appear normal size, but the arteries are barely visible and attenuated.

FIG. 238-18. (PLATE 8). Central retinal vein occlusion "blood and thunder fundus." Note diffuse retinal hemorrhages in all retina quadrants and blurred disc margins.

2. Administer ocular massage: firm, steady digital pressure on the globe through closed lids for about 15 s, followed by sudden release of pressure. This may be repeated several times.
3. Administer topical P-blocker (Timoptic 0.5%), one drop.
4. Give acetazolamide 500 mg IV or PO.
5. Consider having the patient breathe into a paper bag for 5 to 10 min if there are no respiratory contraindications.

CENTRAL RETINAL VEIN OCCLUSION Thrombosis of the central retinal vein causes retinal venous stasis, edema, and hemorrhage. Loss of vision is variable, painless, monocular, and rapid. Funduscopic examination typically reveals optic disc edema and diffuse retinal hemorrhages in all quadrants ("blood-and-thunder fundus") (Figure 238-18, Plate 8). The contralateral optic nerve and fundus generally are normal, which helps distinguish central retinal vein occlusion (CRVO) from papilledema, and the diffuse retinal hemorrhages help distinguish it from optic neuritis (the peripheral retina is normal in optic neuritis). Typically patients have a history of hypertension, although hypercoagulable disorders, vasculitis, and glaucoma also may be associated. No specific treatment is available, although the addition of aspirin 60 to 325 mg daily is reasonable. Patients should be referred to an ophthalmologist for confirmation of the diagnosis and monitoring of ischemia-induced neovascularization. Treatment:

1. Ophthalmology referral.
2. Consider aspirin 60 to 325 mg/d PO.

FLASHING LIGHTS (PHOTOPSIAS) AND FLOATERS Complaints about new onset flashing lights and/or floaters commonly cause patients to seek urgent medical attention. The first distinction to make is if the symptoms are monocular or binocular. Binocular complaints are almost always intracranial (i.e., ophthalmic migraines) whereas monocular complaints are almost always related to the symptomatic eye.

The posterior segment of the eye is a large cavity filled with vitreous gel. As a person ages, this gel eventually contracts centrally and separates from the posterior wall of the eye. The vitreous is very sticky and tugs on the retina prior to separation. The mechanical traction stimulates the retina and the brain perceives this stimulation as light. This process takes place in every one eventually. The average age of onset is 55 years of age, but can occur as early as the twenties in se-

verely nearsighted people. If the vitreous gel separates successfully, then floaters occur. These may persist for years until the gel liquefies enough for the floaters to sink below the visual axis. If the gel creates enough traction on the retina prior to separation that it tears a hole in the retina, then fluid can go through the retinal hole and start to peel the retina off like wallpaper. In this case a dark veil or curtain will be perceived by the patient, blocking a segment of their visual field in the affected eye. This is an emergent condition requiring a retina specialist to evaluate and treat the patient.

Diagnosing a retinal detachment or tear requires a dilated indirect ophthalmoscopic evaluation by an ophthalmologist. It is very difficult for a non-ophthalmologist to comprehensively examine the retina. A retinal tear will be almost impossible for an emergency physician to see. A large retinal detachment will appear as a pale billowing parachute on dilated funduscopic examination. The history and symptoms are the most useful.

1. Ascertain if symptoms are monocular.
2. Assess visual acuity in the affected eye and ask about subjective changes.
3. If the visual acuity is baseline and the patient only perceives flashes and floaters and no sectoral vision loss is present, then dilate and view posterior pole to rule out hemorrhages, papilledema, or overt pathology. If it appears normal then contact ophthalmology to arrange a full evaluation with 24 h.
4. If the patient has a definite monocular visual field cut, then a retinal detachment is highly suspected and ophthalmology should be consulted. Most diagnosed retinal detachments are repaired within 24 h, unless the macula has detached. If the macula has come off and the vision is CF or HM, then the repair is less urgent.

GIANT CELL ARTERITIS (TEMPORAL ARTERITIS) Giant cell arteritis (GCA) is a systemic vasculitis involving medium-sized arteries in the carotid circulation and can include the aorta and its primary branches. GCA can cause a painless ischemic optic neuropathy with devastating visual consequences and rapid contralateral involvement if not diagnosed and treated promptly. Patients are generally over 50 years of age and frequently have a history of polymyalgia rheumatica. Women are affected more commonly than men. Symptoms may include headache, jaw claudication, myalgias, fatigue, fever, anorexia, and temporal artery tenderness. Up to 33 percent may have associated neurologic

symptoms such as transient ischemic attacks or stroke. The patient can develop rapid and profound visual loss, with the contralateral eye becoming involved within days to weeks. The physical examination frequently will reveal an APD if the optic nerve circulation is involved. An elevated Westergren sedimentation rate is usually present, with the majority of biopsy-proven cases in the range of 70 to 110 mm/h. The added presence of an elevated C-reactive protein also suggests the diagnosis. Treatment consists of several doses of intravenous steroids followed by oral steroids. Steroids should not be delayed while waiting for a temporal artery biopsy to be performed. Biopsies will still be positive a week after initiation of steroid therapy. Treatment:

1. Order sedimentation rate and C-reactive protein.
2. Consult patient's personal physician.
3. If highly suspicious or any visual loss, admit for methylprednisolone 250 mg IV every 6 h for 3 days and temporal artery biopsy.
4. If not suspicious and no visual involvement, prednisone 80 to 100 mg/d PO and close outpatient monitoring.

NEURO-OPHTHALMOLOGY

Approximately 38 percent of all the neurons in the brain have some association with the visual system; therefore, an understanding of neuro-ophthalmology is essential.

Bell Palsy

Bell palsy is a dysfunction of peripheral cranial nerve (CN) VII commonly of viral origin. It is palsy of the ipsilateral upper and lower face. The orbicularis muscles are involved frequently, resulting in incomplete closure of the eyelids on the affected side. If the eye rolls up under the upper lid on attempted blinking (*Bell phenomenon*), the cornea will be moistened, and the risk of corneal exposure keratitis and subsequent ulceration will be less. These patients should still use viscous topical wetting agents, such as Celluvisc or Lacrilube, to keep the corneal epithelium from breaking down. Ophthalmology referral for outpatient monitoring of the cornea is warranted. Etiology and treatment of Bell palsy is discussed in Chap. 143.

Genu VII Bell palsy is a CVA masquerading as a peripheral seventh-nerve Bell palsy. It is a stroke involving CN VI and the ipsilateral CN VII as it "genuflects" around the sixth nerve nucleus. This results in a CN VII palsy identical to a typical Bell palsy (affecting the upper and lower face ipsilaterally) but with the added finding of the patient's inability to abduct the ipsilateral eye (CN VI palsy). This underscores the importance of EOM testing in all Bell palsy patients to avoid misdiagnosis of a CVA.

Treatment:

1. Test ipsilateral abduction (rule out genu VII Bell palsy).
2. Have the patient use eye lubricants every 2 h (Celluvisc or artificial tears) and ointment at bedtime.
3. Consider oral steroids and acyclovir.
4. Refer to ophthalmology for outpatient monitoring of cornea.

Diabetic/Hypertensive Cranial Nerve Palsies

Chronic diabetes and hypertension eventually can create vascular compromise to the vasa nervorum of any cranial nerve. Frequently, the patient will present with new-onset diplopia, and an isolated CN III or VI palsy will be found on physical examination. The cranial nerve palsy can be painful or painless. The *pupil is spared* in acute diabetic CN III palsy due to vascular compromise of the central nerve fibers (the efferent pupillomotor fibers run in the periphery of the nerve) (Figure 238-19). EOM testing will reveal an inhibition of ipsilateral medial gaze, upward gaze, and downward gaze as well as ptosis in an

acute CN III palsy. Lateral gaze (abduction) will be preserved, and diplopia will be worse when the patient attempts to look toward the contralateral side due to the inability to adduct the eye (medial rectus dysfunction). In an acute CN VI palsy, lateral gaze will be diminished (abduction) on the ipsilateral side, and diplopia will be worse when the patient is trying to look to the affected side (lateral rectus dysfunction). If no other associated neurologic symptoms or findings are present and the blood sugar and blood pressure are under control, the patient can be discharged with ophthalmology and/or neurology follow-up. Many palsies will resolve or improve over the following 3 months. Neuroimaging is generally done in the ED to rule out an intracranial lesion.

Posterior Communicating Artery (PCA) Aneurysm

Acute CN III palsy with ipsilateral pupillary dilatation is a PCA aneurysm until proven otherwise. Concomitant headache is a frequent but not absolute finding. Expansion of an aneurysm of the posterior communicating artery frequently causes compression of the outer fibers of CN III. The pupillomotor fibers are located in the outer portion of CN III; therefore, the pupil becomes dilated on the affected side (see Figure 238-19). These patients require emergent blood pressure reduction, neuroimaging, and neurosurgical consultation.

Internuclear Ophthalmoplegia (INO)

A stroke or demyelinating disease involving the medial longitudinal fasciculus (MLF) will cause the patient to experience diplopia, most noticeable when he or she attempts to look to the side opposite the lesion. EOM testing reveals an ipsilateral adduction weakness (medial rectus muscle only—not a CN III palsy).

For example, if a patient has experienced a right (MLF) stroke, the right medial rectus muscle will not function when he or she attempts a leftward gaze, and the patient will not be able to adduct the right eye. The left eye will abduct but may experience some nystagmus on leftward gaze. The patient will be able to look to the right without difficulty unless there is bilateral involvement. The patient also will be able to look up and down, revealing that the superior and inferior rectus muscles are functioning and that this is not a CN III palsy.

Treatment:

1. Same as with any newly diagnosed CVA.
2. Consider demyelinating disease if the patient is young.

FIG. 238-19. Posterior communicating artery aneurysm compresses the peripherally located pupillomotor fibers of CN III, causing a nerve palsy and pupillary dilatation. Diabetes and hypertension can cause microvascular compromise of the central nerve fibers causing a nerve palsy with pupil sparing.

FIG. 238-20. Horner syndrome. Note ptosis and miosis of the right eye. This patient sustained an acute right carotid artery dissection after being hit in the neck with a football.

Horner Syndrome

The physical findings of ipsilateral ptosis and miosis and anhydrosis are characteristic of Horner syndrome (Figure 238-20). Interruption of the sympathetic nerve impulses controlling the Mueller muscle in the upper eyelid and the iris dilators causes these classic findings. Interruption can occur anywhere along the pathway from the brainstem to the sympathetic plexus surrounding the carotid artery (Figure 238-21). It is very important to determine whether this syndrome is acute or chronic. Patients with chronic disease can be evaluated on an outpatient basis, but all cases of acute disease require a full emergent evaluation. Workup includes a chest x-ray, CT scan of the brain and cervical region, and a carotid angiogram if a carotid dissection is suspected (acute Horner syndrome with neck pain).

Causes of Horner syndrome include, in adults, CVA, tumors, internal carotid dissection, herpes zoster, and trauma. In children, the causes include neuroblastoma, lymphoma, and metastasis. Neck pain and acute Horner syndrome suggest carotid dissection and can occur spontaneously (usually above age 30) or as a result of blunt or penetrating neck injury.

Treatment:

1. Determine whether the condition is chronic or acute.
2. *Chronic:* Outpatient workup by personal physician.
3. *Acute:* Evaluate for CVA, tumor, or carotid dissection.

Papilledema

Papilledema generally is defined as bilateral edema of the head of the optic nerve due to increased intracranial pressure (ICP). It is a common finding in malignant hypertension, pseudotumor cerebri, intracranial tumors, and hydrocephalus. Any disease process that increases the ICP and thereby inhibits vascular or axoplasmic flow in the optic nerve causes congestion and edema of the nerve head. When only one nerve head is involved, it generally is not related to increased ICP (except in the rare Foster-Kennedy syndrome). Monocular optic nerve edema or binocular involvement not associated with increased ICP is usually referred to as *optic nerve edema* or, if inflammatory in origin, *papillitis* (i.e., optic neuritis). Frequently, the term *papilledema* has been used interchangeably in the literature to refer to monocular or binocular nerve head edema; however, most neuro-ophthalmologists reserve the term *papilledema* for bilateral nerve involvement due to increased ICP. Regardless of the etiology, the clinical

FIG. 238-21. Sympathetic nerve pathway of the eye. An interruption anywhere along this pathway can cause Horner syndrome.

findings on ophthalmoscopy of papilledema and papillitis are identical: The disc margins are blurred, the cup is diminished or absent, and the nerve head is elevated with vascular congestion (Figure 238-22, **Plate 9**). Frequently, flame-shaped hemorrhages are seen on or adjacent to the nerve head. A distinguishing feature of papilledema is prolonged preservation of visual acuity (frequently patients are visually asymptomatic). In this respect they differ markedly from patients with optic neuritis, who generally present with decreased visual acuity.

Pseudotumor Cerebri (Idiopathic Intracranial Hypertension)

Increased ICP, papilledema, normal CSF, and normal CT/MRI characterize pseudotumor cerebri. Most patients are 20- to 30-year-old obese women, although this condition can occur at any age. Patients complain of nausea, vomiting, headaches, and transient visual obscurations. They can develop CN VI paresis, causing horizontal diplopia (double vision on lateral gaze). A number of conditions (pregnancy) and exogenous agents (oral contraceptives, vitamin A, tetracycline,

FIG. 238-22. (PLATE 9). Optic nerve head edema. Vascular congestion, elevation of the nerve head, and blurred disk margins are characteristically seen in papilledema, papillitis, and compressive lesions of the optic nerve.

nalidixic acid, and corticosteroid withdrawal or prolonged use) have been associated with this poorly understood disease. It can be self-limited, but the recurrence rate can be as high as 40 percent, and permanent loss of visual field can occur. Treatment is aimed at weight reduction and use of diuretics. Serial lumbar punctures sometimes are performed to reduce ICP. Treatment:

1. Identify papilledema.
2. Perform neuroimaging of brain (CT/MRI).
3. If CT/MRI is normal, perform lumbar puncture and record opening pressure; send CSF for routine diagnostics.
4. If ICP is elevated and scans and CSF are normal, discuss with ophthalmologist/neurologist institution of diuretics (acetazolamide 500 mg PO twice daily) and outpatient visual field monitoring.

COMMON DISORDERS OF THE EXTERNAL, MIDDLE, AND INNER EAR

Anne Tintinalli
Michael Lucchesi

NORMAL ANATOMY

External Ear

The auricle, or pinna, is the visible external portion of the ear, whose trumpet shape enables it to collect air vibrations. It consists of a thin plate of elastic cartilage with a tightly adherent covering of skin. The external auditory canal (EAC) is an S-shaped skin-lined tube that extends from the auricle to the tympanic membrane. The outer one-third of the EAC is composed of an incomplete cartilaginous tube. Its thick skin contains hair follicles and apocrine and sebaceous glands. The inner two-thirds of the canal is composed of bone covered by a thin layer of tightly adherent skin, which is easily torn by minimal trauma.

The blood supply to the external ear is derived from the posterior auricular, superficial temporal, and deep auricular arteries. Venous drainage of the external ear is into the superficial temporal and posterior auricular veins and then into the external jugular vein. The posterior auricular vein frequently connects to the sigmoid sinus, providing a route for extension of infection into the intracranial cavity.

Middle Ear

The middle ear is an air-containing cavity in the petrous temporal bone. It contains the auditory ossicles, which transmit vibrations of the tympanic membrane (TM) to the perilymph of the internal ear. It communicates with the nasopharynx anteriorly via the eustachian tube and with the mastoid air spaces posteriorly via the aditus ad antrum (Figure 239-1).

The TM is a thin, pearly gray, fibrous membrane, which, when illuminated, produces a cone-shaped light reflex anteroinferiorly. Superiorly, the pars flaccida is the relatively slack portion of the membrane between the malleolar folds; the remainder of the membrane is tense and is called the pars tensa. The auditory ossicles are the malleus, incus, and stapes. Both the incus and the handle and lateral processes of the malleus are typically visible through the TM (Figure 239-2). Figure 239-1 shows the relationships of the facial nerve, sigmoid sinus, and internal carotid artery to the middle ear.

FIG. 239-1. Sagittal section of the middle ear and related structures.

~Cone of light

FIG. 239-2. Right tympanic membrane as seen through the otoscope.

Inner Ear

The inner ear consists of the cochlea, which contains the auditory sensory receptors, and the vestibular labyrinth, which contains balance receptors. Cristae in the semicircular canals detect angular acceleration and maculae detect linear acceleration. Afferent nerves from the vestibular labyrinth connect to brainstem nuclei to maintain smooth movement of the eyes during head movement and to the cerebellum to control oculomotor and postural functions. Blood supply is from the vertebrobasilar system (Figure 239-3). The otolithic organs (utricle and saccule) lie in the vestibule. The internal auditory artery divides into the common cochlear artery and the anterior vestibular artery. The anterior vestibular artery provides the blood supply to the anterior and horizontal semicircular canals but not to the cochlea. Isolated occlusion of the anterior vestibular artery may therefore cause acute ves-tibular syndrome without hearing loss.

COMMON EAR COMPLAINTS

Otalgia

Primary otalgia is caused by auricular and periauricular disease, while referred otalgia is caused by disease originating from remote structures. Referred otalgia is common because of the multiple cranial nerves and branches of the cervical plexus that supply sensory innervation to both the ear and other structures of the head and neck. The sensory innervation of the ear is mediated by the fifth, seventh, ninth, and tenth cranial nerves, as well as by the cervical plexus, with much overlapping and variability. Table 239-1 lists common causes of primary and referred otalgia.

PRIMARY OTALGIA The mandibular division of the trigeminal nerve mediates sensory innervation from the anterior outer ear: the au-

	Neoplasm	

ricle, tragus, EAC, and external surface of the TM. The facial nerve carries sensory innervation from the EAC and the skin behind the auricle. The glossopharyngeal nerve and the auricular branch of the vagus nerve (the Arnold nerve) carry sensory input from the medial ear structures. Branches of the second and third cervical nerves form the greater auricular and lesser occipital nerves, which receive input from the skin over the parotid gland and behind the ear, respectively.

Disease from any portion of the ear or its surrounding skin and structures may result in primary otalgia. A history and physical examination of the external ear, EAC, and TM will usually identify the cause of primary otalgia, with specific therapy as appropriate.

REFERRED OTALGIA The maxillary and mandibular divisions of the trigeminal nerve receive sensory input from the nasopharynx, paranasal sinuses, teeth, parotid gland, and muscles of mastication. The facial nerve carries sensory innervation from the nasal mucosa and the ethmoid and sphenoid sinuses. The glossopharyngeal nerve carries sensory innervation from the nasopharynx, eustachian tube, soft palate, posterior pharynx, and tonsils. The vagus nerve mediates sensation from the valleculae and piriform sinuses, from the larynx via the superior laryngeal nerve, and from the cervical esophagus and trachea via the recurrent laryngeal nerve.

Abscessed and impacted teeth, usually mandibular molars, frequently cause ear pain. Malocclusion, bruxism, mandibular trauma, temporomandibular joint (TMJ) disorders, and ill-fitting dentures are frequent causes of otalgia.¹ Trigeminal neuralgia, or tic douloureux, causes severe unilateral facial pain. Herpetic geniculate neuralgia, or Ramsay Hunt syndrome, is herpes zoster of the EAC and auricle with facial palsy, which may persist long after the disappearance of the vesicles (postherpetic neuralgia).

The diagnosis of the source of referred otalgia requires a history and physical examination that encompasses the nasal and oral cavities, nasopharynx, oropharynx, throat, and neck. Again, further evaluation and treatment depend upon diagnosis.

Tinnitus

Tinnitus is the perception of sound without external stimulation. It may be constant, pulsatile, high- or low-pitched, hissing, clicking, or ringing. It is most prevalent between the ages of 40 and 70 years and has no gender predominance.²

Tinnitus is divided into two types: objective and subjective. Objective tinnitus may be heard by the examiner. Subjective tinnitus is more

common. Its exact mechanism is unknown, although it is believed to result from damage to cochlear hair cells. Table 239-2 outlines causes of tinnitus.²

Pharmacologic side effects are the cause of tinnitus in at least 10 percent of cases.² The most commonly implicated drugs are aspirin (which may produce tinnitus in doses as low as 1.5 g per d) and aspirin-containing compounds, nonsteroidal anti-inflammatory drugs, and antibiotics, particularly aminoglycosides. (See Table 239-3 for a list of common ototoxic agents.)

Accurate diagnosis usually requires referral to an otolaryngologist. Many medications have been suggested as therapies, but antidepressants are currently the only class of drug found to be useful in alleviating tinnitus for which no correctable cause can be found.

SUDDEN HEARING LOSS Sudden hearing loss (SHL) is hearing loss occurring over 3 days or less. The incidence increases with increasing age, and there is no gender predominance. Indicators of poor prognosis include more severe hearing loss on presentation and the presence of vertigo. Although most cases of SHL are idiopathic, other causes include infection, vascular causes, and trauma, as well as metabolic disturbances and ototoxic drugs (Table 239-4).³

Viral infections, most typically mumps, have long been associated with SHL. Because of the terminal branches and interosseous location of the blood supply to the inner ear, the ear is uniquely vulnerable to a variety of vascular and hematologic diseases. Cogan syndrome is an autoimmune disorder that presents with a bilateral hearing loss classically associated with tinnitus and vertigo. SHL may also be caused by rupture of the tympanic membranes.

Many common medications have been implicated in SHL (see Table 238-3).^{4,10} Although a variety of mechanisms are responsible for medication-induced SHL, a general rule is that risk of hearing loss increases with increasing dosage and length of use and is further aggravated by factors that impair drug metabolism and excretion, such as renal insufficiency.

The evaluation of SHL begins with a complete history and physical examination. Sudden conductive hearing loss results from obstruction of the EAC or from disturbances of the TM or ossicles. An evaluation of all current medications for possible ototoxic agents is necessary. A history of trauma or recollection of a "popping" noise preceding the hearing loss may indicate perforation of the TM. Coexistent tinnitus or vertigo may point to Meniere disease. Systemic illness should be considered.

The differential diagnosis includes both potentially reversible and potentially ominous causes (see Table 239-4). If the physical examination does not identify the cause, emergency otolaryngologic consultation is necessary.

TABLE 239-2 Common Causes of Tinnitus

Objective	Subjective
Vascular	Sensorineural hearing loss
AV malformations	Hypertension
Arterial bruits	Conductive hearing loss
Mechanical	Head trauma
Enlarged eustachian tube	Medication
Palatomyoclonus	TMJ disorders
Stapedial muscle spasm	Depression, stress

Carboplatin	
Vinblastine	
Vincristine	

Abbreviation: NSAID = nonsteroidal anti-inflammatory drug.

INFECTIONS

Otitis Externa

Otitis externa includes infections and inflammation of the EAC and auricle. It is divided into acute diffuse and malignant types.

ACUTE DIFFUSE OTITIS EXTERNA

Definition and Diagnosis Also known simply as otitis externa (OE) or swimmer's ear, this infection is characterized by pruritus, pain, and tenderness of the external ear. Physical signs include erythema and edema of the EAC, which may spread to the tragus and auricle. Other signs are clear or purulent otorrhea and crusting of the EAC. As the disease progresses, the pain may become intolerable and occur with mastication or any movement of the periauricular skin. Increasing edema eventually narrows the EAC lumen and may cause hearing impairment. In severe cases, infection may spread to the periauricular soft tissues and lymph nodes, and there may be lateral protrusion of the auricle secondary to inflammation.

Pathophysiology Predisposing factors for the development of OE are trauma to the skin of the EAC and elevation of the local pH. Constant contact with water, from swimming or bathing in hot tubs, pools, or freshwater lakes is associated with the development of OE, as is living in a humid environment. Trauma is most commonly caused by scratching or by overzealous disimpaction of cerumen. Cerumen is an

acidic mixture of sebaceous and apocrine gland secretions and desquamated epithelial cells. It forms a physical barrier that protects the EAC skin from violation, while the acidic pH has antimicrobial properties.

Microbiology The most common organisms implicated in OE are *Pseudomonas aeruginosa* and *Staphylococcus aureus*,¹¹ although one study found a polymicrobial etiology in one-third of patients and an anaerobic bacterial etiology in one-quarter, with *Bacteroides* species predominating. Interestingly, the microbial pathogen is often not isolated from suspect water samples.¹²⁻¹⁴

Otomycosis, or fungal OE, accounts for approximately 10 percent of cases, with a high percentage found in tropical climates. A history may reveal the presence of diabetes, HIV or other immunocompromised states, or previous long-term therapy with antibiotics. Most (80 to 90 percent) of otomycosis is caused by *Aspergillus* species, and physical examination may reveal a black, blue-green, or yellow discoloration of the EAC. The second most common fungal pathogen is *Candida*.⁵

Noninfectious causes include contact dermatitis from topical medications or resins in hearing aids, seborrhea, and psoriasis. Although not generally an occupational disease, OE resulting from mite infestation has been reported in poultry workers.¹⁶

Treatment The treatment of OE involves analgesia, cleansing of the EAC, acidifying agents, topical antimicrobials, and sometimes steroids. Cleansing may be done with gentle irrigation using hydrogen peroxide, and gentle debridement by the physician with a suction aspirator such as a Frazier suction.

A variety of topical agents exist that combine an antimicrobial agent with either an acid and/or a steroid. Table 239-5 lists the components of many otic preparations. No single agent is more effective than the others, and there are many considerations to guide the choice of agent, including the risk of ototoxicity, cost, and compliance. A commonly prescribed agent, Cortisporin, is a combination of neomycin (an aminoglycoside), polymyxin B, and hydrocortisone. Although there are few established cases of ototoxicity, there is a theoretical risk of both auditory and vestibular toxicity with the use of aminoglycosides, polymyxin, and acetic acid preparations.^{3,4,17} Although this risk appears to be negligible in the presence of an intact TM, there is evidence of systemic absorption of topical aminoglycosides.^{18,19} A consensus panel of the American Academy of Otolaryngology-Head and Neck Surgery has concluded that nonototoxic ototopical antibiotics should be considered as first-line therapy in the treatment of OE, particularly when the integrity of the TM is unknown or in the presence of a known TM perforation or tympanostomy tubes. Both available ototopical quinolones, ofloxacin and ciprofloxacin, have both antistaphylococcal and antipseudomonal activity, and have

been shown to be as effective at treating OE as Cortisporin. In addition, topical ofloxacin has been approved by the Food and Drug Administration (FDA) for use in infants and children, and is the only ototopical antibiotic approved by the FDA for use with an open middle ear.¹⁷

The burning associated with the acidic preparations may reduce compliance. Patients unable to tolerate the low pH of otic preparations may instead use the slightly more alkaline ophthalmic drops.

If cost is a factor and there are no known contraindications, Cortisporin drops may be used as they are less expensive than the quinolones. In this case, Cortisporin Otic *Suspension* should be used and not the solution; theoretically, this has less chance of middle ear penetration and resultant ototoxicity.

The medication should be instilled into a cleansed ear while it is facing up, with this position held for 3 min. If edema of the EAC obstructs the lumen, a commercial wick or piece of gauze may be inserted into the EAC and kept moist with the otic drops.

Bacterial and fungal cultures may guide treatment of nonresponsive cases. Oral antibiotic therapy should be reserved for febrile patients and those with periauricular extension. All patients with OE should be taught to avoid predisposing factors in order to eliminate recurrences. Strategies include ear plugs while swimming or bathing (cotton wool impregnated with petroleum jelly or commercial ear plugs), brief use of a hair dryer to remove EAC water, and avoidance of cotton-tipped applicators or other devices to remove cerumen.

Specific treatment of otomycosis consists of antifungal agents such as clotrimazole. *Aspergillus* is not sensitive to most oral antifungals with the exception of itraconazole.¹¹ With noninfectious OE, removal of the offending agent is the first step in treatment. Topical steroid drops may be used for seborrhea and psoriasis.

Finally, all patients should be instructed to follow up with their primary physician or an otolaryngologist if the condition worsens at any time or does not respond to treatment in 1 week, to be evaluated for the more serious disease of malignant otitis externa.

MALIGNANT OTITIS EXTERNA

Definitions Malignant otitis externa (MOE) is a potentially life-threatening infection of the EAC with variable extension to the skull base. It is almost always caused by *P. aeruginosa*. The term *MOE* actually refers to a spectrum of disease. When it is limited to the soft tissues and cartilage, it is called necrotizing otitis externa (NOE). When there is involvement of the temporal bone or skull base it is called skull-base osteomyelitis (SBO).

Pathophysiology MOE begins as a simple otitis externa that then spreads to the deeper tissues of the EAC and infects cartilage, periotum, and bone, with the normal anatomy of the ear serving as the conduit for the spread of infection. The cartilaginous floor of the EAC has clefts, known as the fissures of Santorini, through which the infection may spread to deeper structures. The parotid gland and TMJ are anterior, the mastoid air cells are posterior, and the skull base, carotid artery, jugular bulb, and sigmoid sinus are inferomedial. Infection may spread to any of these structures as well as to the seventh cranial nerve as it exits the stylomastoid foramen and the ninth, tenth, and eleventh cranial nerves at the jugular foramen.

The typical patient with MOE is the elderly diabetic, although it is now seen more often in the patient with HIV. The presence of an impaired immune response, which is further compromised in the elderly, may predispose to the onset of pseudomonal infection. Furthermore, the cerumen of diabetic patients has been found to have a higher pH than that of normal controls; this represents an additional breakdown in local defense mechanisms. Finally, the small blood vessel disease of diabetics may lead to cartilaginous degeneration, further promoting the spread of infection.

TABLE 239-5 Some Common Topical Otic Preparations

Preparation	Constituents	Comments
CiproHC Otic	Ciprofloxacin Hydrocortisone	Not safe with perforation
Cortisporin Otic	Neomycin Polymyxin B Hydrocortisone	Use suspension* only theoretical potential for ototoxicity
Floxin Otic	Ofloxacin	Safe with perforations; 5 drops bid
Otic Domeboro	2% Acetic acid solution	pH 4.5-6.0
VoSol HC Otic	Acetic acid Hydrocortisone	pH 3.0

*Solution is thinner and more easily absorbed through the round window or a perforation.

Microbiology The most common causative organism of MOE is *P. aeruginosa*. *Aspergillus* has been reported to cause SBO, usually in patients who are immunosuppressed because of AIDS or other causes. *Aspergillus* SBO also has a different presentation than typical pseudomonal SBO in that the infection generally begins in the middle ear rather than in the EAC.

Diagnosis Any elderly, diabetic, HIV, or otherwise immunocompromised patient presenting with OE or any person with persistent OE despite 2 to 3 weeks of topical antimicrobial therapy should be suspected of having MOE. The typical presentation is similar to that of OE: otalgia and edema of the EAC with or without otorrhea. The otalgia may be out of proportion for routine OE. Granulation tissue may be evident on the floor of the EAC near the bone-cartilage junction.

The history and physical examination should also be directed toward determining the extent of progression of the disease by identifying involvement of nearby structures. Parotitis may be present, and trismus indicates involvement of the masseter muscle or TMJ. Cranial nerve involvement is a serious sign. The history and examination should specifically rule out facial palsy and hoarseness or dysphagia. The seventh cranial nerve is usually the first affected, and the presence of dysfunction of the ninth, tenth, or eleventh cranial nerve implies even more extensive disease. Lateral or sigmoid sinus thrombosis and meningitis are also possible complications.

Certain patients may have an atypical clinical presentation and require special mention. MOE in children tends to be rapidly progressive, so children may be ill appearing upon presentation, with fever, leukocytosis, and even bacteremia. Also, the TM, middle ear, and facial nerve are more likely to be involved in children than in adults. AIDS patients with MOE tend to be younger, have etiologic organisms other than *Pseudomonas*, and tend to have a worse prognosis than patients without AIDS.

Diagnosing MOE depends first on having a high index of suspicion. Emergent otolaryngologic consultation is necessary. The next step involves radiographic confirmation and staging of the disease with computed tomography (CT) of the head, focusing on the EAC and temporal bone.

Treatment Once the diagnosis of MOE has been made, the patient should be admitted to the hospital for parenteral antibiotics. Therapy with an aminoglycoside and antipseudomonal penicillin, or cephalosporin, or quinolone is standard, and should be initiated in the ED. Selected cases may be managed with oral quinolones, depending on the otolaryngologist's preference.

The ultimate prognosis of MOE is primarily based on the stage of disease at presentation. Earlier stages are likely to completely resolve with a single course of antibiotic therapy, while more advanced stages may require surgical debridement and may ultimately prove fatal.

Otitis Media

EPIDEMIOLOGY Otitis media (OM) is primarily a disease of infancy and childhood (see Chap. 121). Although adults may present with OM, its incidence and prevalence peak in the preschool years and then decrease with increasing age. There is little or no literature to suggest that the diagnosis or management of OM in adults differs from that in children. The decrease in incidence of OM from childhood through adolescence is thought to be due to the changing anatomy of the eustachian tube. Between infancy and adulthood the eustachian tube angle and length both increase, promoting drainage of the middle ear and offering a greater physical barrier to the migration of bacteria from the nasopharynx to the middle ear.

MICROBIOLOGY The most common bacterial pathogens in acute OM are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and

Moraxella catarrhalis. The predominant organisms involved in chronic OM are *Staphylococcus aureus*, *P. aeruginosa*, and anaerobic bacteria.²⁰ This pattern may change, however, with increasing use of pneumococcal vaccines. The heptavalent pneumococcal vaccine recently approved for use in the United States may provide protection against *S. pneumoniae* serotypes responsible for up to 86 percent of bacterial isolates causing OM, including >95 percent of drug-resistant isolates.²¹ Viruses probably play a role in the pathogenesis of OM in that they may promote bacterial superinfection by impairing eustachian tube function and other host defense mechanisms. They may also interfere with host response to antimicrobial drugs.

DIAGNOSIS The patient with OM presents with otalgia with or without fever. Otorrhea and hearing loss are variably present, while tinnitus, vertigo, and nystagmus are uncommon. The TM may be retracted or bulging. It may be red in color, indicating inflammation, or it may be yellow or white, as a result of middle ear fluid. Pneumatic otoscopy demonstrates impaired mobility. The facial nerve should always be assessed because of its proximity to the middle ear.

TREATMENT There are no treatment guidelines specifically for adults, and recommendations for children are commonly used. Amoxicillin has been effective against all three major pathogens, but currently approximately 30 percent of *H. influenzae* and up to 80 percent of *M. catarrhalis* have developed p-lactamase, conferring resistance to amoxicillin. In all, resistant strains account for approximately 10 percent of all cases of acute OM.^{21,23}

The preferred initial treatment is still amoxicillin. The dose in adults (weighing >40 kg) is 500 to 875 mg PO every 12 h, or 250 to 500 mg PO every 8 h, for 7 to 10 days. Alternative agents include trimethoprim-sulfamethoxazole, azithromycin, or cefuroxime (second-generation cephalosporin). For OM unresponsive to initial therapy after 72 h, cefuroxime or amoxicillin-clavulanate may be given.

Because pain usually continues for 8 to 24 h after the initiation of antibiotics, the addition of acetaminophen or ibuprofen analgesia is appropriate. OM with effusion requires treatment with the same antimicrobials, but for 3 weeks, and prednisone may be added.²⁰

Adults with simple acute OM should receive follow-up to assess treatment efficacy and to ensure that there is no anatomic obstruction to the eustachian tube, as for example, from occult neoplasm. Any patient who presents with complications of OM or who appears septic should have urgent consultation for diagnostic and therapeutic tympanocentesis and possible admission for intravenous antibiotics.

Complications

Complications of OM can be divided into intratemporal and intracranial types. Perforation of the TM is a common intratemporal complication and most often occurs in the pars tensa from the increased pressure of middle ear secretions, with resultant otorrhea. Healing usually occurs in 1 week, although a chronic perforation may result. A temporary conductive hearing loss may occur with OM secondary to fluid in the middle ear. The hearing loss resolves as the fluid is resorbed. Acute serous labyrinthitis may occur when bacterial toxins enter the inner ear via the round window. Facial nerve paralysis is an uncommon complication but requires emergent otolaryngology consultation.

ACUTE MASTOIDITIS One of the most serious complications of acute OM is acute mastoiditis. This occurs as infection spreads from the middle ear to the mastoid air cells via the aditus ad antrum. When this opening becomes blocked, the mastoid cavity becomes a closed space, and the mastoid air cells become filled with fluid and inflamed. Spread through venous channels to the overlying periosteum is referred to as *acute mastoiditis with periostitis*. In addition to otalgia and fever, patients with mastoiditis will have postauricular erythema, swelling, and tenderness, with protrusion of the auricle and obliteration

tion of the postauricular crease. Although the diagnosis can usually be made based on the history and physical examination, certain radiographic tests are indicated. Mastoid radiographs will demonstrate mastoid clouding because of fluid accumulation, and CT may delineate the extent of bony involvement. Mastoiditis requires admission for intravenous antibiotics, tympanocentesis, and myringotomy. Cefuroxime is frequently chosen as an initial empiric agent.²⁴ Incision and drainage of subperiosteal abscess or mastoidectomy may ultimately be indicated.

INTRACRANIAL COMPLICATIONS Intracranial complications of OM are more likely with chronic than with acute OM and are, in general, decreasing with the widespread use of antibiotics in the treatment of OM. However, suppurative intracranial extension is a severe complication, and suggestive signs and symptoms should be investigated appropriately. Meningitis and brain abscess are the most common intracranial complication of OM; the most prevalent causative organisms are *S. pneumoniae* and *H. influenzae* type b. Extradural abscess and subdural empyema are also potential complications.

LATERAL SINUS THROMBOSIS Lateral sinus thrombosis (LST) is another ominous complication of acute OM. It arises from extension of infection and inflammation in the mastoid, with eventual inflammation of the adjacent lateral or sigmoid sinus. Reactive thrombophlebitis with mural clot formation, intraluminal empyema, or perforation of the venous wall may occur. A high index of suspicion is necessary to diagnose LST because the common clinical findings are similar to those found in acute OM or mastoiditis.

Headache is the most common symptom, with papilledema, sixth-nerve palsy, and vertigo being less frequently present. Angiography with venous phase and magnetic resonance imaging (MRI) are more sensitive than CT in diagnosing LST. Although in the majority of cases of LST no bacterial isolates are recovered, antibiotic therapy is the initial treatment of choice. The agent should cover *Staphylococcus*, *Streptococcus*, and upper respiratory anaerobes, and have good penetration of the blood-brain barrier. A combination of intravenous penicillin or nafcillin, ceftriaxone, and metronidazole has been recommended as an initial empiric regimen.²⁵ Most patients will also require surgical intervention.

CHOLESTEATOMA A serious complication associated with chronic OM is cholesteatoma. Aural cholesteatoma is composed of epidermis and exfoliated keratin within pneumatized spaces of the temporal bone. It is an erosive, expanding lesion originating within the middle ear or mastoid air cells. As the cholesteatoma expands, it may erode the ossicular chain, bony labyrinth, or facial nerve canal. Cholesteatomas are often infected and their intracranial extensions may be life-threatening.

Bullous Myringitis

DEFINITION Bullous myringitis is a painful condition of the ear characterized by bulla formation on the TM and deep EAC. Its epidemiology, etiology, and pathology are poorly understood. It may occur at any age, frequently after an upper respiratory tract infection.

PATHOPHYSIOLOGY The blisters are believed to occur between the highly innervated outer epithelium and the inner fibrous layer of the TM, explaining the severe otalgia. The blisters may be blood-filled, serous, or serosanguineous. Middle ear effusions may be present, either sympathetic in origin or as a result of medial rupture of bullae. Otorrhea as a result of ruptured bullae is short-lived. A reversible hearing loss is commonly associated with the condition and may be conductive, sensorineural, or mixed.

MICROBIOLOGY Although bullous myringitis was originally associated with influenza epidemics, since then numerous pathogens have been implicated in its etiology, including *Mycoplasma pneumoniae*, *Chlamydia psittaci*, and numerous viral pathogens. Herpes simplex has not been implicated as a causative agent.²⁶

DIAGNOSIS Patients with bullous myringitis typically present with severe, throbbing otalgia, often with hearing loss. Otoscopy reveals multiple fluid-filled blisters, which may be yellow to red in color. There may be bloody otorrhea or hemotympanum.

TREATMENT As the etiologic agent of bullous myringitis remains elusive, treatment of the condition consists of warm compresses and systemic analgesia with acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs). Oral antibiotics may be added in cases with an associated middle ear effusion, because some of these may represent a concomitant otitis media.

TRAUMA TO THE EAR

Although trauma to the ear is rarely life-threatening, its associated morbidity is significant and includes hearing loss and poor cosmetic outcome.

Abrasions can cause partial loss of the covering epidermis. Abrasions that do not penetrate to the underlying perichondrium should be thoroughly irrigated with normal saline. If there are any embedded foreign bodies, they should be meticulously removed to prevent infection and "tattooing" of the wound. A topical antimicrobial ointment with a contoured nonpressure dressing should be applied. The wound should be reevaluated in 24 h. Lacerations of the auricle require delicate closure with careful realignment to maintain the natural contour (see Chap. 42). Prior to closure, a thorough examination is required to determine the magnitude of the injury, followed by cleansing and irrigation with normal saline. Further exploration can be done with a sterile cotton swab to determine the actual extent of the injury and explore for any remaining foreign bodies. In simple lacerations not involving the perichondrium or cartilage, the skin can be approximated with everting nylon sutures. In lacerations involving the cartilage, the perichondrium should be sutured using 5-0 or 6-0 absorbable sutures. If debridement is necessary, the otolaryngologist may be consulted. After skin closure, an antimicrobial ointment and a firm, contoured, non-pressure dressing should be applied. Complete or partial avulsion injuries, especially those involving tissue loss exposing large areas of cartilage, should be referred to an otolaryngologist or plastic surgeon.

Thermal Injuries

FROSTBITE With its position of prominence and large surface area, the auricle is extremely susceptible to extremes in temperature. The thin subcutaneous tissue makes the auricle particularly susceptible to cold-induced injury. In frostbite, the ear will initially appear pale. In superficial frostbite injuries, the underlying tissue remains soft and pliable. In deep injuries, the underlying tissue is very hard. With rewarming, the ear may become painful, with edema and blister formation. If blisters do form, they should be allowed to reabsorb spontaneously. The ear should be aseptically and quickly rewarmed with saline-soaked gauze that has been warmed to 38° to 40°C (100.4° to 104°F). The rewarming process may be very painful and analgesics will be necessary.

BURNS Burns of the upper body occur frequently, with burns of the face and neck representing approximately 30 percent of all burn injuries. In one study of patients sustaining significant facial burns, 42 percent suffered burns to the ears. Direct thermal burns may be severe enough to cause necrosis and sloughing of the entire external ear. Even

with lesser injury, disruption of the auricular skin can lead to damage of the underlying cartilage, which, once damaged, is particularly susceptible to infection. Factors that affect the healing of burn injuries include the depth of the burn, development of infection, and external pressure or friction on the burned auricle.

Burns more severe than first-degree should be seen in consultation with a burn unit or an otolaryngologist. If the burn is an isolated injury and a mild second-degree type, treatment in the ED should consist of meticulous cleaning and irrigation with normal saline, application of a non-sulfa-containing antimicrobial ointment, and a non-pressure dressing. Silver sulfadiazine ointment can cause skin pigmentation changes and for cosmetic reasons should not be used above the clavicles. Referral should be made within 24 h. Substantial second-degree burns with blistering or any third-degree burns should be referred to a burn center for further management.²⁷

Osteochondritis is a potentially disfiguring complication of otic burns. Chondritis may occur in up to 20 percent of significant otic burns and may appear anywhere from 2 to 5 weeks after the injury. The hallmarks of chondritis consist of helical dull pain followed by erythema, edema, exquisite tenderness to palpation, and an increase in the auriculocephalic angle (lateral protrusion of the ear from the head). Once chondritis is present, treatment must be aggressive to preserve ear architecture; it usually consists of surgical debridement. Systemic antibiotics alone are generally considered ineffective.

Heraatoma

A hematoma can develop from almost any type of trauma to the ear. As a result of the lack of subcutaneous fat on the anterior surface of the auricle, blunt force applied to this area tends to shear the perichondrium from the underlying cartilage and tear the adjoining blood vessels. The cartilage depends on the perichondrial blood vessels for viability. Any separation can result in necrosis. In addition, a subperichondral collection can lead to stimulation of the overlying perichondrium, which can result in an asymmetrical formation of new cartilage and deformity of the auricle. The resultant deformed auricle has been referred to as "cauliflower ear," which is commonly associated with boxers. The auricular hematoma itself presents as a painful swelling after trauma, which obscures the normal contour of the ear. The hematoma may accumulate immediately or several hours after injury. In the past, the advised treatment was aspiration of the hematoma. More current literature suggests that aspiration alone does not completely evacuate the clot and therefore leads to deformity and increased morbidity. The goal of treatment is to remove the fluid collection and maintain pressure in the area for several days to prevent reaccumulation of fluid. After local anesthesia, and using sterile technique, a semicircular incision should be made through the skin with caution not to violate the underlying perichondrium. The incision should be the minimal necessary to drain the underlying hematoma and positioned in an area with the least exposure (the inner curvature of the helix or anthelix). The hematoma can then be removed by gentle suction or curettage.^{28,29}

A dental roll or a firm sterile pledget can then be placed over the resutured site with through-and-through sutures connected to a similar bolster on the opposite side. A nonpressure dressing with antibiotic ointment should then be applied and the patient given instructions as to reevaluation within 24 h to assure there has been no reaccumulation. Prophylactic antibiotics can be reserved for immunocompromised patients and should cover *P. aeruginosa* and *S. aureus*, the two likely participants in posttraumatic chondritis.

Foreign Bodies

Foreign bodies in the external canal are commonly seen in the emergency department. Variations can include anything from cotton, pencil erasers, or pieces of toys to illicit drugs and insects. Organic materials

such as beans, seeds, and vegetable matter may conform to the contour of the canal or expand if moistened, complicating the process of removal. Insects that crawl into the ear can actually survive for a long period of time, causing a local inflammation and a great deal of distress to the patient.

The evaluation of a patient with a foreign body in the ear should begin with calming the patient and placing the patient in the reclined position. Occasionally, the complaint may be sudden pain while in the recumbent position, as in the case of an embedded insect. Most of the time, the history will reveal the type of material in the ear. A thorough examination and visualization of the complete tympanic membrane is mandatory. Inability to visualize the entire canal, contact of the foreign body with the tympanic membrane, or the presence of a perforation mandates the use of an operative microscope and speculum, with obvious consultation. Foreign bodies in children medial to the bony isthmus often require conscious sedation or even general anesthesia for safe extraction. Cerumen loops, a right-angle hook, and alligator forceps are the instruments of choice for the removal. Live objects should be drowned with a 2 percent lidocaine solution or viscous lidocaine, which immediately paralyzes the bug and provides modest topical anesthesia. The liquid can then be suctioned out with butterfly tubing and the insect removed with gentle suction or forceps under direct visualization. Care must be taken to assure that no debris of the insect remains in the canal. Irrigation with room-temperature water is adequate for small particles such as hard sand or cerumen and can mobilize distally positioned objects. Irrigation should not be used unless the tympanic membrane is completely visualized and free of perforation, and it can be used only for nonorganic matter, which will not expand when moistened.

Complete inspection of the ear canal after removal of the foreign body is important to exclude more significant injury to the canal skin, tympanic membrane, and ossicles caused by the foreign body or its extraction. Small abrasions heal spontaneously. Topical antibiotics should be considered in cases where there was more serious cutaneous damage or where the foreign body consisted of organic material (see Table 239-5).

Cerumen Impaction

Occasionally, the diagnosis is made as patients present with unrelated complaints, but more often, patients complain of decreased hearing, a sensation of pressure or fullness in the ear, dizziness, tinnitus, or pain. The symptoms are often precipitated by the use of cotton-tipped applicators. Most of the time, cerumen loops can be used. In the particularly difficult cases, or where cerumen is completely occluding the canal, softening of the cerumen can be accomplished with half-strength hydrogen peroxide, sodium bicarbonate drops, mineral oil, or over-the-counter preparations such as Debrox or Cerumenex for 30 min. If irrigation is the treatment of choice, it can usually be accomplished with a metal ear syringe, a flexible 18-gauge IV catheter, or a syringe attached to the tubing of a butterfly infusion catheter. Body-temperature irrigant is the solution of choice. The catheter should be inserted into the cartilaginous canal (distal third) and a gentle, pulsatile flow should be inserted along the superior portion of the external auditory canal; in this way the pressure of the stream is directed toward the wall of the canal and not the TM. Irrigation of the canal when the middle ear is not infected often causes a temporary redness of the tympanic membrane; therefore, the subsequent diagnosis of otitis media should be made with caution.

The most common iatrogenic injury associated with syringing of the ear is traumatic TM perforation. Predisposing factors include previous ear surgery, a previous or current history of OM, and severe OE. When in doubt, it is safer to defer the procedure to an otolaryngologist. When determining if a perforation has occurred, it is important to rely on symptoms (sudden hearing loss, severe otalgia, or vertigo) rather than signs, as visualization of the TM may be impaired by the

irrigating fluid and debris. In case of suspected perforation, reassurance, analgesia and otolaryngology referral in 1 to 2 weeks are indicated. Prophylactic antibiotics are not necessary.³⁰ If injury to ossicles is suspected, emergency consultation is needed.

Tympanic Membrane Perforation

Tympanic membrane perforations can occur as a result of blunt, penetrating, acoustic, or baro- trauma. When it is secondary to blunt or noise trauma, the perforation almost always occurs in the pars tensa, usually anteriorly or inferiorly. The pars tensa, the largest area of the tympanic membrane, is only a few cell layers thick.

The patient usually complains of an acute onset of pain and hearing loss, with or without bloody otorrhea. There may also be associated vertigo and tinnitus, but this is usually transient unless there has been injury to the inner ear or rupture of the round or oval windows. In evaluating these injuries, the canal must be cleared of blood and debris. The tympanic membrane should be completely visualized. Most tympanic membrane perforations heal spontaneously. Patients with perforations secondary to blunt or noise trauma that are isolated injuries can be safely discharged and referred to a specialist for further evaluation and a formal audiogram as soon after the injury as possible. Patients should be instructed not to allow water to enter the canal of the ear. They do not need topical or systemic antibiotics. Perforations in the posterosuperior quadrant or those secondary to penetrating trauma have a greater likelihood of damaging the ossicular chain or, in the case of the latter, a retained foreign body and should be referred to an otolaryngologist within 24 h.

Lightning fatally strikes approximately 600 persons annually in the United States and leaves thousands more survivors with permanent sequelae. Although the blast effect associated with a lightning strike plays a part in perforations, conducted electrical current from cutaneous sites via the external auditory canal and into the middle or inner ear structures is another hypothesized mechanism for lightning-induced otologic injuries.²⁹ Tympanic membrane perforation is the most common sequela.

Barotrauma

Barotrauma to the middle ear, also called barotitis media, is discussed in Chap. 196.

FACE AND JAW EMERGENCIES

Robert Haddon
W. Franklin Peacock IV

FACIAL INFECTIONS

Facial infections can be organized from most superficial to most deep. A given infection may traverse more than one layer or space depending on its source, duration, and host. Further, infections of the upper and lower face form distinct clinical groups.¹ Sinusitis and periorbital and orbital cellulitis are covered in Chaps. 241 and 238, respectively.

Impetigo

Impetigo is a superficial epidermal infection characterized by amber crusts at the sites of minor skin trauma. *Streptococcus pyogenes* (group A 3-hemolytic streptococci) predominates, often mixed with *Staphylococcus aureus*. *S. aureus* is the sole isolate in 10 percent of cases. Treatment should cover both pathogens and includes topical mupirocin ointment either alone or in combination with cephalexin, amoxicillin-clavulanate, dicloxacillin, cefuroxime, or clindamycin.^{2,3} Lesions should be cleaned and, if practical, covered. The importance of handwashing should be emphasized to the patient and family members.

Erysipelas

Erysipelas involves both the epidermis and dermis, usually on the face. Classically, it has a red, raised, puffy appearance with a sharply defined, palpable border that advances rapidly. Erysipelas is usually caused by *S. pyogenes*. First-line treatment is either amoxicillin-clavulanate or ampicillin-sulbactam. If these cannot be used, use cefuroxime (PO or IV), vancomycin with ceftriaxone IV, or gatifloxacin, gemifloxacin, or moxifloxacin.^{2,3}

Cellulitis

Cellulitis is a diffuse, spreading infection of the skin.⁴ Other definitions include subcutaneous tissue as well,² but the general sense is of a superficial soft tissue infection that lacks either vertical or horizontal constraint. Because this infection evolves, its precise definition may hinge on the time of its diagnosis.

PATHOPHYSIOLOGY Bacteria may enter the soft tissues from any skin violation. The patient's risk for cellulitis is increased by immunosuppression, systemic disease (e.g., diabetes), or vascular compromise such as that caused by past radiation treatment. Medical appliances and foreign bodies impair local defenses. Decorative facial piercing combines a foreign body with a renewable source of bacteria. Facial cellulitis is caused most commonly by *S. pyogenes* and *S. aureus* and in children may be caused by *Haemophilus influenzae* and *S. pneumoniae*. Less commonly, cellulitis may represent extension from deep-space infections (see "Masticator Space Infections" below).

CLINICAL FEATURES The history should address events and exposures, both recent and remote, that predispose to cellulitis. Ask about chronic illness, trauma, arthropod bites, allergen exposure, dental caries, painful mastication, surgical history, and radiation exposure. Obtain an occupational history, which may help identify unusual pathogens. Perform a thorough head and neck examination. Check for prostheses, nasal drainage, and changes in vision or phonation. Be alert for signs of systemic, occult, or invasive disease, including fever, headache, vomiting, trismus, draining sinus tracts, and airway compromise.

DIAGNOSIS Cellulitis is diagnosed clinically, defined by pain, erythema, edema, warmth, and diminished function. The differential diagnosis includes insect envenomation, trauma, dental caries with abscess formation, occult head and neck infection, orbital or periorbital cellulitis, sinusitis with erosion of the bony cortex, otitis externa, impetigo, erysipelas, viral exanthems (e.g., erythema infectiosum or "fifth disease"), parotitis, systemic lupus erythematosus, herpes zoster, dermatitides, angioneurotic edema, contact dermatitis (e.g., cosmetics or poison ivy), allergy,¹⁻⁵ vancomycin flushing reaction, and occupational or recreational ultraviolet radiation burns.

Anthrax infections of the face and hands have been reported and are expected when the rare occupational case occurs.⁶ In the 2001 bioterror attack victims, cutaneous lesions occurred on forearm, neck, chest, and fingers.⁷ Cutaneous anthrax appears as a papule that becomes a vesicle in 1 to 2 days. The vesicle ulcerates and forms the classic black eschar early in the second week of illness. Especially on the face, anthrax lesions are surrounded by a suprisingly large area of edema.⁸ The absence of these features and an implausible exposure history are useful in reassuring anthrax-fearing patients with minor skin infections.

TREATMENT Administer analgesics and antipyretics as needed. Select antibiotics to cover staphylococcal and streptococcal species. When possible, remove foreign bodies and appliances from the affected area. Amoxicillin-clavulanate or ampicillin-sulbactam are the first-choice antibiotics (Table 240-1). Vancomycin and/or cephalosporins also may be used.² If there is not an obvious point of entry, evaluate the patient for an abscess or other deep infection. Hos-

TABLE 240-1 Antibiotic Therapy for Facial Infections

Impetigo	Topical mupirocin ointment alone or in combination with cephalexin, amoxicillin-clavulanate, dicloxacillin, cefuroxime, or clindamycin
Erysipelas	Amoxicillin-clavulanate or ampicillin-sulbactam; if these cannot be used, use cefuroxime (oral or IV), vancomycin with ceftriaxone IV, or gatifloxacin, gemifloxacin, or moxifloxacin
Cellulitis	Amoxicillin-clavulanate or ampicillin-sulbactam; vancomycin and cephalosporins are alternatives
Suppurative parotitis	Amoxicillin-clavulanate or ampicillin-sulbactam; if penicillin-allergic, clindamycin or the combination of cephalexin with metronidazole, or vancomycin with metronidazole; if hospitalized or nursing home patients, consider vancomycin
Masticator space infection	Inpatient: intravenous clindamycin is recommended; alternatives include ampicillin-sulbactam, cefoxitin, or the combination of penicillin with metronidazole; outpatient: oral clindamycin or amoxicillin-clavulanate for 10 to 14 days

pitalization should be considered for the following conditions: systemic signs of sepsis; antibiotic intolerance for any reason, including emesis; immunosuppression; extensive areas of erythema or induration; unremovable appliances or foreign bodies; or inability to comply with the outpatient regimen. Patients at the extremes of age should be hospitalized more readily.

Otherwise, outpatient therapy is appropriate. Instruct the patient to return to the emergency department for fever, difficulty swallowing or breathing, inability to take or to tolerate the antibiotic, or any worsening of the condition. If the cellulitis progresses, admission for inpatient antibiotic therapy is warranted.

SALIVARY GLANDS

There are three groups of salivary glands: the parotid, the submandibular, and the sublingual. The facial nerve passes through the superficial portion of the parotid gland, and the parotid (Stensen) duct opens into the mouth opposite the upper second molar. The submandibular and sublingual glands lie below the plane of the tongue. The submandibular ducts open into the mouth at either side of the frenulum of the tongue. The multiple sublingual ducts open into the sublingual fold or directly into the submandibular duct.

Disorders of the salivary glands may be infectious, neoplastic, immunologic, or traumatic. Only the most common disorders are discussed here. It is important initially to answer several questions:

1. Which glands are involved, and are single or multiple glands affected (multiple gland involvement suggests infection)?
2. What is the location of pain and tenderness, and is there a palpable mass (palpable mass suggests tumor or obstruction by stone)?
3. What is the acuity of symptoms and their precipitants (suppurative parotitis and obstruction have an acute onset)?
4. Are symptoms persistent or recurrent?
5. Are there associated problems such as dry mouth or eyes, joint symptoms, diabetes, or orchitis?

Viral Parotitis

Mumps is caused by the paramyxovirus and is most common in children under the age of 15 years. Vaccination has reduced its incidence substantially.^{9,10} The virus is spread by airborne droplets, incubates in the upper respiratory tract for 2 to 3 weeks, and then spreads systemically. At this stage, one-third of patients experience a prodrome of fever, malaise, headache, myalgias, arthralgias, and anorexia during a 3- to 5-day period of viremia.⁹ The classic salivary gland swelling then follows. Bilateral parotid involvement occurs in 75 percent. The gland

is tense and painful, but erythema and warmth are notably absent.⁹ Mumps is diagnosed clinically. Amylase levels will be elevated, and cell counts show leukocytopenia with lymphocytosis.⁹ Viral serology can be obtained but routinely will not affect management. Treatment is supportive, and salivary gland swelling typically lasts from 1 to 5 days. The patient is contagious for 9 days after the onset of parotid swelling, and children with mumps should be excluded from school or day care for this interval. Viral parotitis may be caused less commonly by influenza, parainfluenza, coxsackieviruses, echoviruses, lymphocytic choriomeningitis virus, and even HIV⁹

Mumps is usually benign in children but can be severe in adults. Unilateral orchitis affects 20 to 30 percent of males, whereas oophoritis affects only 5 percent of females. Other mumps complications include mastitis, pancreatitis, aseptic meningitis, sensorineural hearing loss, myocarditis, polyarthritis, hemolytic anemia, and thrombocytopenia.⁹

Suppurative Parotitis

Suppurative parotitis is a potentially fatal bacterial infection that occurs in patients with compromised salivary flow. It is caused by the retrograde migration of oral bacteria into the salivary ducts and parenchyma.⁹ In contrast to mumps, the onset is rapid, and the skin over the parotid gland is red and tender. Also in contrast to mumps, pus may be expressed from Stensen duct. There is often fever and trismus.

There are many predisposing factors to suppurative parotitis. These include recent anesthesia, dehydration, prematurity or advanced age, sialolithiasis, oral neoplasms, salivary duct strictures, tracheostomy, and ductal foreign body.⁹ Medications that cause either systemic dehydration or decrease salivary flow specifically can cause parotitis. These include diuretics, antihistamines, tricyclic antidepressants, phenothiazines, beta blockers, and barbiturates.⁹ Several chronic illnesses also predispose patients to suppurative parotitis. These are HIV infection, hepatic failure, renal failure, diabetes mellitus, hypothyroidism, malnutrition, Sjogren syndrome, depression, anorexia, leukemia, hyperuricemia, and cystic fibrosis.⁹

The diagnosis of parotitis is clinical. Parotitis can be distinguished from cellulitis by the drainage from Stensen duct. Lymphangitis usually has a source distinct from the salivary gland. Imaging is not needed unless the patient fails to improve after 48 h of treatment.⁹ If at that point computed tomographic (CT) scan or ultrasound reveals an abscess, consult an ear, nose, and throat (ENT) specialist to consider surgical drainage. The serum amylase level typically is normal, and a peripheral smear shows a neutrophilic leukocytosis.⁹

Suppurative parotitis is usually caused by *S. aureus* and less often by *S. pneumoniae*, *S. pyogenes*, and *H. influenzae*.²⁰ Anaerobes such as *Bacteroides* species, peptostreptococci, and fusobacteria are found in up to 43 percent of isolates. Accordingly, antibiotics effective against both staphylococci and anaerobes are needed (see Table 240-1). The first choice is amoxicillin-clavulanate or ampicillin-sulbactam.²⁰ In penicillin-allergic patients, use clindamycin or a combination of cephalexin with metronidazole or vancomycin with metronidazole. In hospitalized or nursing home patients, the possibility of methicillin-resistant *S. aureus* (MRSA), for which vancomycin is appropriate,⁹ must be considered. In the compromised host, gram-negative organisms such as *Escherichia coli* and *Pseudomonas* may be seen. Cultures of Stensen duct drainage can guide therapy in the patient not responding to first-line antibiotics.⁹

Since suppurative parotitis is caused by states of decreased salivary flow, treatment should optimize salivary flow. Hydrate the volume-depleted patient. Massage and apply heat to the affected gland. Stimulate salivation using sialogogues such as lemon drops. When possible, discontinue drugs that cause dry mouth, and attempt to correct underlying medical problems.

Outpatient treatment is appropriate if the patient is hemodynamically stable, able to take oral liquids and antibiotics, and can comply with the treatment regimen.

Sialolithiasis

Salivary calculi can be seen at any age but usually are symptomatic in men between the third and sixth decades.¹¹ More than 80 percent of stones occur in the submandibular gland, with most of the remainder in the parotid. Submandibular sialoliths are more common in the submandibular (Wharton) duct because of both its more viscous secretions and its uphill course.¹¹ Sialoliths develop when an organic matrix begins to gel in a relatively stagnant duct and is then seeded with calcium carbonate and calcium phosphate.

The symptoms of pain, swelling, and tenderness may resemble those of parotitis. It may be hard to distinguish the two, and at times they may coexist. However, the pain and swelling of ductal obstruction is exacerbated by meals and may develop over the course of minutes when eating.

The diagnosis of sialolithiasis is usually clinical. Predominately unilateral, the stone may be palpated within the duct, and the gland will be firm.¹¹ Intraoral radiographs are more sensitive than extraoral films in identifying salivary calculi. Sialography is highly sensitive for stones but is contraindicated when infection is possible. Ultrasound and thin-cut CT scans also will identify sialoliths but are not necessary emergently. A conservative course of treatment should precede imaging studies.

The initial management of sialolithiasis consists of analgesics, antibiotics if there is concurrent infection, massage, and sialogogues such as lemon drops.¹¹ Outpatient management is the rule. Palpable stones in the distal duct may be digitally "milked" from the duct. They also may be removed electively either by dilation or by incision of the ductal orifice.

Complications of salivary duct obstruction include recurrent or persistent obstruction, strictures, infection, and gland atrophy.¹¹

Salivary Gland Enlargement

Salivary gland enlargement can result from a large number of conditions. Beyond those already covered, additional causes include infections such as HIV, tuberculosis, actinomycosis, cat scratch disease, and branchial cleft cyst abscess.¹² Nutritional, toxic, and metabolic causes include malnutrition with vitamin deficiency, phenothiazine use, alcoholism, diabetes mellitus, hypothyroidism, pregnancy, and obesity.¹² Neoplastic lesions may present with enlarged salivary glands. Less than 3 percent of all head and neck tumors are found in the salivary glands. Most salivary neoplasms occur in the parotids, and 75 percent of these are benign.

Most cases of salivary gland enlargement do not require emergency intervention. However, the patient should be directed to appropriate follow-up for definitive diagnosis and treatment, based on the suspected underlying cause.

MASTICATOR SPACE INFECTION

Pathophysiology

The masticator space consists of four potential spaces bounded by the muscles of mastication (Figure 240-1). These spaces include the masseteric (or submasseteric), superficial temporal, deep temporal, and pterygomandibular spaces.¹³ Since they are contiguous, it is rare for one to be infected alone.

The masseteric space is bounded by the masseter muscle and the ascending ramus of the mandible. Infection of the masseteric space arises most frequently from soft tissue infection around the third molar. It also may follow third molar surgery and mandibular fractures.¹³

The pterygomandibular space is bounded by the medial pterygoid muscle and the medial aspect of the ascending ramus of the mandible. It is bounded superiorly by the lateral pterygoid. Again, common sources of infection in this space are third molar disease and mandibular

FIG. 240-1. Masticator space.

block injections.¹³ Infections within this space may spread to the lateral pharyngeal space, which can then be complicated by airway compromise.

The temporal spaces lie between the temporal fascia and the temporal bone and are divided into superficial and deep by the plane of the temporalis muscle. Maxillary molar infections may spread to the deep temporal (infratemporal) space, or it may become infected by extension from elsewhere within the masticator space. The deep temporal space is one of the potential sources of cavernous sinus thrombosis. Because all the subordinate spaces of the masticator space communicate and ultimately communicate with the tissue planes that extend down the neck to the mediastinum, the extent of the infection should be defined efficiently and treatment begun promptly.

Infections of the masticator space are polymicrobial and generally anaerobic, although aerobic oral streptococcal species may predominate briefly.^{2,13} Typical organisms include species of *Streptococcus*, *Peptostreptococcus*, *Bacteroides*, *Prevotella*, *Porphyromonas*, *Fusobacterium*, *Actinomyces*, *Veillonella*, and anaerobic spirochetes.^{2,13}

Clinical Features

The most frequent acute clinical findings are facial swelling, pain, erythema, and trismus. In chronic infection, the patient can be afebrile but may complain of variable trismus.¹⁴ Constitutional signs may include fever, malaise, dehydration, dysphagia, nausea, or vomiting. In more advanced cases, systemic signs of sepsis are present.

History and physical examination features are variable. When infection occurs in the masseteric space, there is posteroinferior facial swelling with mild to moderate trismus. If the temporal space is infected, there is soft tissue swelling over the temporalis and significant trismus. Trismus without swelling suggests pterygomandibular space abscess.

Contrast-enhanced CT scanning is the preferred imaging tool for masseteric and related deep space infections.^{13,14} Not only can the extent of an abscess be seen, but CT scan can distinguish more reliably between cellulitis and abscess in all spaces except the retropharyngeal.¹³ The differential diagnosis includes other sources of lateral jaw pain such as angina, masticator space neoplasm, temporomandibular joint (TMJ) dysfunction, referred dental pain, pharyngeal infection, tonsillitis or peritonsillar abscess, and otitis media or externa. History and physical examination usually will exclude these clinically.

Treatment

The patient's condition determines therapy. Airway compromise is rare in unilateral masticator space infection but should be considered. Emergent ENT consultation is required with airway compromise, severe trismus, abscess or phlegmon visible on CT scan, vomiting, palpable abscess, large or diffuse areas of cellulitis, large areas of induration, or systemic signs of sepsis.

Antibiotics should be administered in the emergency department (see Table 240-1). For patients requiring hospitalization, intravenous clindamycin is recommended. Alternatives include ampicillin-sulbactam, cefoxitin, or the combination of penicillin with metronidazole.^{2,13} For outpatient management, oral clindamycin or amoxicillin-clavulanate is appropriate. Antibiotics should be continued for 10 to 14 days. Because of increased resistance, the macrolides (e.g., erythromycin) are generally no longer used for masticator space infections.¹³

Stable afebrile patients with minimal symptoms, only slight trismus, no palpable abscess or induration, and without vomiting or systemic signs of infection may be considered for discharge on oral antibiotics and analgesics. Follow-up should be arranged in 24 h.

TEMPOROMANDIBULAR JOINT DYSFUNCTION AND FRACTURE

The TMJ combines both a hinge and gliding action. The articular surfaces are separated by the articular disk, or meniscus, which assists in the hinge action between the mandibular condyle and the disk and in the gliding action between the disk and temporal bone. The masseter, temporalis, and medial pterygoid close the mandible. The jaw is opened by forward traction on the mandibular neck by the lower portion of the lateral pterygoid, with assistance from the digastric, mylohyoid, and geniohyoid muscles.¹⁵

Anatomic internal derangement may occur as the result of intracapsular disk displacement. This may be the result of a direct blow to the jaw or secondary to jaw hypermobility with chronic injury. The TMJ always should be assessed in patients who have direct jaw trauma or acute dental injury.

Chronic TMJ dysfunction probably results from a variety of causes, either singly or in combination, and includes neuromuscular disturbance, anatomic deviations as a result of trauma or congenital formation, dental abnormalities, or TMJ manifestations of systemic disease.¹⁷ Most studies have found no significant correlation between occlusal parameters or bruxism and signs or symptoms of TMJ disorders.^{16,18} Degenerative joint disease may result from chronic internal derangement or secondarily as the result of a systemic disease such as rheumatoid arthritis or systemic lupus erythematosus.

The patient's chief complaint is usually of pain localized to one of the muscles of mastication. The masseter is the most frequently identified painful area, followed by the temporalis, sternocleidomastoid, splenius capitis, and trapezius.¹⁶ Physical findings may include limitation in the range of motion of the mandible. Isolated clicking without pain or other dysfunction is not diagnostically sufficient.¹⁶ Palpate the muscles of mastication to find areas of sensitivity, induration, rigidity, and swelling. The condylar heads may be palpated just anterior to the tragus with the teeth together and then with the teeth apart. Perform a careful head and neck examination to exclude more serious causes of facial pain.

In the setting of acute trauma, the panoramic x-ray view of the mandible is usually the initial radiographic evaluation of the TMJ. This also provides information about the teeth and other parts of the jaw that may be contributing to pain.¹⁹ The panoramic view, combined with a frontal projection, can identify medial displacement of a condylar fracture.¹⁹ CT scanning is appropriate in the assessment of potentially complex fractures, infections, and neoplastic disease. For chronic conditions, there is no acute need for x-rays. TMJ disk condition and position are best evaluated in a nonemergency setting using magnetic resonance imaging (MRI).¹⁹

Acute fracture is managed by the oral maxillofacial surgeon. For chronic conditions, the patient should be advised to eat soft foods until follow-up and more definitive treatment can be provided.

DISLOCATION OF THE MANDIBLE

The mandible can be dislocated in an anterior, posterior, lateral, or superior direction. Anterior dislocation is most common and occurs when the mandibular condyle is forced in front of the articular eminence. Muscular spasm then traps the mandible in anterior dislocation. The following factors predispose patients to symptomatic anterior dislocation: a shallow glenoid fossa, increased muscle tone, and a loss of joint capsule tone from previous trauma. Spasm of the temporalis and lateral pterygoid muscles tends to prevent reduction once dislocation has occurred. Dislocations are usually bilateral, but unilateral dislocations are seen.¹⁵

Anterior dislocations are classified as acute, chronic recurrent, or chronic.¹⁵ Patients usually present quickly after an anterior dislocation occurs because of pain. When presented with a chronic recurrent dislocation, look for predisposing factors such as dystonic reactions and hypermobility syndromes (e.g., Marfan's or Ehlers-Danlos syndromes). Chronic dislocations, where the condyle remains displaced from the fossa for an extended time, occur in patients who do not obtain prompt medical treatment.¹⁵

Posterior dislocations are rare. They follow a direct blow to the chin that does not break the condylar neck. In this dislocation, the mandibular condyle is thrust up against the mastoid, and the condylar head may prolapse into the external auditory canal.¹⁵

Lateral dislocations are often associated with mandibular fracture. With a lateral dislocation, the condylar head is forced laterally and then superiorly into the temporal space. Superior dislocations occur from a blow to the partially open mouth that forces the condylar head upward. Associated injuries include cerebral contusions, facial nerve palsy, and deafness.

Clinical Features

Patients with acute jaw dislocation usually present with severe pain, difficulty in speaking or swallowing, or malocclusion. There may be loose or missing teeth and areas of sensory deficit at the chin or mouth.

With anterior dislocation, pain is localized anterior to the tragus. Frequently, the symptoms are reported to have begun acutely following extreme mouth opening. Anterior dislocation has been reported to have occurred after laughing, yawning, vomiting, taking a large bite, trauma, oral sex, dental extraction, general anesthesia, and tonsillectomy.¹⁵ In contrast to anterior dislocation, all other types of mandibular dislocation tend to require significant trauma.

All patients with possible mandibular dislocation should have a good head, neck, and dental examination. With anterior dislocations, there is a visible and palpable preauricular depression from the displacement of the mandibular condyle. There also will be difficulty with jaw movement. If the dislocation is unilateral, there is deviation of the jaw away from the dislocation.

When a posterior dislocation is considered, examine the external auditory canal. Confirm that hearing is at baseline. With lateral dislocations, the condylar head is palpable in the temporal space, and there are always signs of jaw fracture (e.g., malocclusion). When a superior dislocation is suspected, a thorough examination is needed, especially focusing on the head, neck, and nervous systems.

In the cooperative patient with a spontaneous nontraumatic anterior dislocation, the diagnosis is based on clinical grounds. In other dislocations, radiographs may be needed to confirm the clinical suspicion. With significant trauma, radiographs should be obtained to exclude fracture. The panoramic view usually demonstrates the pathology and excludes other mandibular injury. In patients with more serious

trauma, where there may be a superior dislocation or intracranial injury, a CT scan will provide more information.

The differential diagnosis of jaw dislocation includes mandibular fracture, traumatic hemarthrosis, acute closed locking of the TMJ meniscus, and TMJ dysfunction.¹⁵

Treatment

Reduction may be attempted in closed anterior dislocations without fracture. Most attempts are made easier with analgesia. A short-acting intravenous muscle relaxant (e.g., midazolam) helps to decrease muscle spasm.²¹ Appropriate airway and hemodynamic monitoring is required. Consider using narcotic analgesia. Conscious sedation also has been used successfully.²⁰ Alternatively, local anesthetic can be placed into the joint space. Using aseptic technique, place a 21-gauge needle into the preauricular depression just anterior to the tragus and inject 2 mL of 2% lidocaine¹⁵ (Figure 240-2).

There are two methods for reducing an anterior mandibular dislocation.¹⁵ The most commonly used technique requires the patient to be firmly seated with the head against the wall or chair back, positioned so that the examiner's flexed elbow is at the level of the patient's mandible. Facing the patient, the examiner places his or her gloved thumbs in the patient's mouth, over the occlusal surfaces of the mandibular molars, as far back as possible. The fingers should curve beneath the angle and body of the mandible. Using the thumbs, the examiner applies pressure downward and backward. Slightly opening the jaw may help disengage the condyle from the anterior eminence (Figure 240-3). When the dislocation is bilateral, it may be easier to relocate one side at a time. Some suggest that the examiner wear gauze over the thumbs for protection, should the mandible snap closed after reduction.¹⁵

The second technique requires the examiner, standing behind the recumbent patient, to place the thumbs on the molars and to apply downward and backward pressure.¹⁵

The patient should be able to close his or her mouth immediately after a successful reduction. Postreduction radiographs usually are not required unless the procedure was difficult or traumatic or there is significant postreduction pain. Complications from the reduction itself are unusual but can include iatrogenic fracture or avulsion of the articular cartilage.²⁰

Disposition

Patients with dislocations that are open, superior, associated with fracture, have any nerve injury, or are unreducible by closed technique should be referred emergently to a head and neck or oral surgeon.

FIG. 240-2. Site for injection of local anesthesia for reduction of dislocated mandible.

FIG. 240-3. Maneuver for mandibular relocation in a seated patient. The examiner should wear gloves for this procedure.

Following successful reduction of an acute dislocation, patients are placed on a soft diet and cautioned against opening their mouths more than 2 cm for the following 2 weeks.²¹ They should be instructed to support the mandible with a hand when they yawn. Nonsteroidal analgesics may help the initial discomfort. After reduction, elective referral to an oral maxillofacial surgeon is recommended. In severe cases, intermaxillary fixation may be required to control jaw motion during healing. Chronic dislocations may require operative intervention.

NASAL EMERGENCIES AND SINUSITIS Thomas A. Waters W. Franklin Peacock IV

EPISTAXIS

Introduction

Because the blood supply of the nasal mucosa ultimately originates from the carotid arteries, acute epistaxis is potentially very serious, especially when the patient is frail or elderly. Up to 60 percent of patients may experience at least one episode of epistaxis in their lifetimes.¹ Still, most cases of epistaxis are self-limited and can be managed conservatively.

Epistaxis has an increased incidence during the dry, cold winter months,^{2,*} due to abrupt temperature changes and exposure to dry heat.

The origin of epistaxis can be broadly divided into anterior and posterior categories. Anterior epistaxis is more common in the young, while posterior is most common in the older patient. Determining the site of bleeding helps guide treatment.

The nose functions to warm and humidify air and therefore requires a vigorous blood supply (Figure 241-1). Its blood supply originates from both the internal and external carotid arteries. The posterior and inferior aspects of the nasal cavity are supplied by the sphenopalatine artery, which is a branch of the maxillary artery. The internal carotid artery gives rise to the ophthalmic artery, which supplies the anterior-superior nasal cavity by the anterior and posterior ethmoidal arteries. The nasal septum receives its blood supply from multiple arteries. The superior labial branch of the facial artery supplies the vestibule and inferior-anterior septum. The posterior and superior septum is supplied by branches of the sphenopalatine, anterior ethmoidal, and posterior ethmoidal arteries. These all join to form Kiesselbach plexus (Little area).

Anterior Epistaxis

Anterior epistaxis represents 90 percent of all nosebleeds, with the majority originating from Kiesselbach plexus.⁵ This area has been referred to as the picking zone, and is also the area most prone to drying and cracking from the environment. Anterior nosebleeds can result from any process that causes mucosal hyperemia. Hereditary hemorrhagic telangiectasia (HHT), or Osler-Weber-Rendu disease, is an unusual but severe cause of recurrent anterior nosebleeds. HHT is an autosomal-dominant disorder, characterized by mucosal telangiectasia throughout the airway and gastrointestinal tract.

FIG. 241-1. Arterial blood supply to the nasal cavity. The most common site of nasal hemorrhage is at Little area, located on the nasal septum. The most common origin of posterior epistaxis is from the sphenopalatine artery.

Anterior epistaxis is fairly common in children. In a study of 1218 children aged 11 to 14, 6 percent had experienced epistaxis. The most common cause is idiopathic or related to upper respiratory infections. Treatment is by direct pressure. In the rare case when packing is required, conscious sedation may be needed.

Clinical Features

The history can provide valuable insight as to the location of the epistaxis. Questions that are important to ask include:

1. Is one side bleeding, or both? (anterior epistaxis is usually unilateral)
2. Do you have a sensation of blood in the back of the throat? (more often associated with posterior epistaxis)
3. Do you have a history of previous epistaxis, trauma, head/neck tumor, radiation therapy, or head/neck surgery? (suggests the need for otolaryngologic consultation)
4. Is there a family history of bleeding disorders? (clotting studies may be needed)
5. Are you using anticoagulants, nonsteroidal anti-inflammatory drugs (NSAIDs), or aspirin? (clotting studies or medication change may be needed)

In anterior epistaxis one can often directly visualize the area of bleeding. However, proper lighting and suction are essential. Adequate lighting is best achieved by the use of an ENT headlamp or by a head mirror. Universal precautions must be observed by the examiner and the patient's clothing should also be protected. The patient should be seated in a chair leaning forward with the head inclined anteriorly. This helps to visualize the nasal cavity and minimizes retropharyngeal blood flow, which decreases gagging. The assessment of the patient must include complete vital signs, as well as a thorough examination of the oropharynx and nasopharynx. Additionally, a general physical overview is necessary to evaluate for signs of systemic coagulopathy. Laboratory investigation is not routinely required, unless there are multiple or prolonged episodes of hemorrhage, if there is clinical suspicion of anemia, or if coagulopathy is suggested by history or physical examination.

Treatment

The treatment of anterior epistaxis includes direct pressure, vasoconstrictive agents, nasal packing, and cautery. Even though the blood pressure may be elevated with acute epistaxis, stabilization should focus on direct hemorrhage control. Once bleeding has been stopped and

patient anxiety is relieved, elevated blood pressure usually spontaneously resolves. Persistent or extremely high elevations of blood pressure can then be addressed (see Chap. 57).

Most episodes of anterior epistaxis can be managed by direct pressure to the nose. This is achieved by compressing the elastic areas of the nose between the thumb and middle phalanx of the index finger. Pressure must be continuously maintained for 10 to 15 min, and confirmed with a clock, as patients frequently underestimate the amount of time that has elapsed. Premature release of pressure to see if the bleeding has stopped will not allow adequate clot formation and may result in continued bleeding. At least two adequate attempts at direct pressure should be made before moving to cautery or packing.

Vasoconstrictive agents may be used with all other treatment modalities and should be instilled into the nose before pressure is applied. Table 241-1 lists the common agents. These compounds can be instilled into the nasal cavity by a spray bottle, atomizer, or cotton swab. Have the patient completely blow out the nose to remove any clot before instillation of vasoconstrictors, to ensure that the medication reaches the nasal mucosa.⁴ If the area of bleeding can be visualized, the vasoconstrictor can be topically applied with cotton swabs or pledgets using gentle direct pressure.

If the source of bleeding is easily visualized anteriorly, careful cautery using silver nitrate sticks can be attempted. After bleeding has stopped, the tip of the silver nitrate stick is gently and briefly applied to the bleeding site. Chemical cautery can lead to septal perforation if used overzealously. **Electrical and thermal cautery are best left for the otolaryngologist.** It is difficult to control or estimate the depth of cautery achieved with the battery-powered cautery devices available. Significant trauma can occur to the nasal mucosa, septal cartilage, and the skin surrounding the nares.

Anterior Nasal Packing

Anterior nasal packing is performed on any patient in whom direct pressure, vasoconstrictors, or silver nitrate application are unsuccessful in controlling epistaxis. Either nasal tampons or an anterior gauze pack can be used.

Preformed nasal tampons or sponges made of synthetic material that expands to many times its original size after hydration are generally used (Figure 241-2). They are commercially available in 5- and 10-cm lengths, for anterior and posterior packing, respectively. A drawstring at the distal end is taped to the face to secure the tampon and prevent inadvertent aspiration. Insertion of the device can be facilitated by coating the tampon with water soluble antibiotic ointment, and by mucosal pretreatment with a topical anesthetic and vasoconstrictor. The ointment decreases the number of nasal bacteria,⁵ and will also help delay tampon expansion until after the tampon is in place. The nasal tampon is then inserted along the floor of the nasal cavity against the septum. If the tampon has not expanded within 30 s of placement, it should be gently irrigated (while in place) with 10 mL of normal saline in order to promote expansion. The drawstring should then be taped to the face or nose.

Placement of a traditional anterior nasal pack may be considered when the bleeding is difficult to control or other methods fail. The technique detailed in Figure 241-3 is preceded by preparing the nasal mucosa as before placement of the nasal tampon (see above).

TABLE 241-1 Vasoconstrictive and Anesthetic Agents Used in Epistaxis

Phenylephrine 0.5-1.0% concentration mixed with 4% lidocaine*
Oxymetozaline 0.05% concentration mixed with 4% lidocaine*
Epinephrine 0.25 mL of 1:1000 concentration mixed with 20 mL of 4% lidocaine*

*The maximum dose of lidocaine applied to the nasal mucosa should not exceed 4 mg/kg.

FIG. 241-2. The Merocel nasal sponge in its desiccated (*left*) and hydrated (*right*) forms.

Even a properly placed anterior nasal pack may fail to control bleeding. If bleeding continues or recurs, the pack should be replaced. If after replacement bleeding still persists, a posterior nosebleed must be considered and a posterior pack applied (see below). For refractory epistaxis, otolaryngologic consultation should be obtained.

Complications associated with anterior nasal packing include: dislodgment of the pack, persistent bleeding, sinusitis, septal necrosis, and rarely, toxic shock syndrome (see Chap. 142). Patients may also experience reflux of blood through the lacrimal puncta and need to be warned about this. No specific therapy is needed.

Disposition

Discharge instructions should include the following:

1. Do not manipulate the external nares or insert any foreign object into the nasal cavity. An exception is made for patients with no packing, in which case the patient may apply petrolatum jelly or triple antibiotic ointment to the nasal mucosa twice daily for 3 to 4 days to prevent mucosal drying.
2. **Do not use aspirin or NSAIDs for 3 to 4 days.**
3. If bleeding recurs where no packing has been inserted, home measures may be tried before returning to the ED. Patients may be advised to use an over-the-counter vasoconstrictor nasal spray (such as phenylephrine or oxymetazoline) and pinch their nose, using proper technique, for 10 to 15 min. If the bleeding continues, compression may be repeated. If after three attempts the bleeding continues, the patient should return to the ED. Patients with an anterior pack should return if bleeding occurs around it, or if there is a sensation of blood trickling down the back of the throat. They should be advised to leave the pack in place.

Any patient who has undergone nasal packing may be considered for prophylaxis against staphylococcal or streptococcal infections and for sinusitis. Coating the pack with antibiotic ointment before placement can decrease the amount of nasal bacteria and the frequency of bacteremia.⁵ Cephalexin (250 or 500 mg PO qid) or amoxicillin-clavulanate (250 or 500 mg PO tid) can be given. In the penicillin-allergic patient, clindamycin (150 to 300 mg PO qid) or trimethoprim-sulfamethoxazole DS (1 tablet PO bid) can be used as a second choice.⁵ Nasal packing should be removed after 2 to 3 days. When nasal tampon removal is planned, the pack should first be rehydrated with 10 mL of NS. The drawstring is then grasped and the tampon gently removed.

POSTERIOR EPISTAXIS

Posterior epistaxis is far less common than anterior epistaxis.⁶ It is more common in the elderly and is believed to be due to arteriosclerosis of the large posterior nasal cavity vessels and underlying hypertension.

FIG. 241-3. The key to placement of an anterior nasal pack that will control epistaxis adequately and stay in place is to lay the packing into the nasal cavity in an accordion-like manner, so that part of each layer of packing lies anteriorly, preventing the gauze from falling posteriorly into the nasopharynx. A. The first layer of 14-in. petrolatum-impregnated gauze strip is grasped approximately 2 to 3 cm from its end. B. The first layer is then placed on the floor of the nose through the nasal speculum (not pictured here). The bayonet forceps and nasal speculum are then withdrawn. C. The nasal speculum is reintroduced on top of the first layer of packing, and a second layer is placed in an identical manner. After several layers have been placed, it is often useful to reintroduce the bayonet forceps to push the previously placed packing down onto the floor of the nose, making it tighter and more secure. D. A complete anterior nasal pack can tamponade a bleeding point anywhere in the anterior nasal cavities and will stay in place until removed by the physician or patient.

The most common site of bleeding is posterior to the inferior turbinate, about 6 to 7.5 cm posterior to the vestibule, and emanates from branches of the sphenopalatine artery. The actual bleeding site can only be visualized with a nasopharyngoscope.

Bleeding is typically more profuse than with anterior epistaxis, and may be more difficult to control because the site of hemorrhage is closer to the choanae and blood is more likely to reflux to the unaffected side. Blood can often be seen flowing down the posterior oropharynx or from both nares. A complete set of vital signs, a thorough head, neck, and naso- and oropharyngeal examination, and general physical examination to search for evidence of systemic coagulopathy should be performed. An intravenous line and laboratory studies including complete blood count, blood type, and antibody screening, and coagulation studies are often warranted.

Posterior Nasal Packing

The treatment of posterior epistaxis is posterior nasal packing. Direct pressure is ineffective, and blind attempts at chemical, heat, or electrocautery can cause injury and more bleeding. The application of vasoconstrictors and anesthetic agents in the treatment of posterior epistaxis is the same as for anterior bleeding.

Posterior nasal packing is most often accomplished by the use of commercial devices, such as 10-cm nasal sponges, the Nasostat epistaxis balloon (Sparta Surgical Corp., Hayward, CA), or the Storz epistaxis catheter (Storz Instrument, St. Louis, MO). The use and insertion of the nasal tampons in posterior epistaxis is the same as discussed above for anterior epistaxis. A 10-cm sponge is utilized to obtain both anterior and posterior tamponade.

The procedure for insertion of a commercial nasal catheter for posterior epistaxis control is as follows:

1. The nasal cavity is prepared using vasoconstrictors and anesthetic agents.
2. A test is performed for leakage by filling the anterior balloon with 25 mL of water and the posterior balloon with 8 mL of water. If no leak is detected, the water is removed.
3. The device is lubricated with 4 percent lidocaine jelly and inserted into the nasopharynx. The patient opens his or her mouth, and the catheter is advanced until the distal balloon tip is visible in the posterior pharynx.
4. The posterior balloon is slowly filled with 4 to 8 mL of water, and the device is pulled anteriorly so that it wedges in the posterior nasopharynx.
5. While gentle traction is maintained, the anterior balloon is slowly inflated with 10 to 25 mL of water, providing anterior tamponade. Inflation should be stopped immediately if the patient complains of significant pain. However, some discomfort is usually present.
6. Bilateral packing may be necessary to control hemorrhage.
7. Analgesics are usually required.

If a commercial device is not available, a Foley catheter can be used to construct a posterior pack. The placement of the Foley catheter is similar to the procedure described above, but with slight differences. The tip of the Foley catheter must be trimmed off to avoid stimulation of the posterior pharynx. The Foley catheter must be pulled anteriorly and held in the forward position by a transverse clamp across the catheter, external to the nasal septum. Ensure that alar necrosis does not result by inserting padding between the nasal alae and the clamp. After placement of a Foley catheter, the anterior nasal cavity is packed to prevent accumulation of a large clot that would represent an aspiration risk.

The procedure of inserting a posterior nasal pack is very uncomfortable and stressful to the patient. After placement, the patient often continues to have significant discomfort and may require analgesia and sedation. Complications of posterior nasal packs include difficulty swallowing, eustachian tube dysfunction, otitis media, sinusitis, nasal synechiae, cardiac arrhythmias, cardiac arrest, accidental dislodgment into the airway, or aseptic necrosis of the nasal alae, columella, palate, and nasal mucosa. In patients with altered mental status, severe chronic obstructive pulmonary disease, or severe congestive heart failure, posterior nasal packing can result in hypoxia. Therefore, **admission should be considered for patients with significant comorbidities and posterior epistaxis.**

If epistaxis is refractory to the above, otolaryngologic consultation is needed. If packing by the consultant is ineffective, arterial ligation or embolization may be necessary.

Disposition

Because of the potential for serious morbidity and mortality associated with posterior packing, patients are usually admitted for observation. They may need sedation secondary to severe discomfort and require monitoring for hypoxia. Prophylactic antibiotics are generally given (see anterior packing, above).

NASAL FRACTURE

Any significant central midface trauma should be considered highly suspicious for the presence of a nasal bone fracture. A direct impact is most likely to cause a fracture because there is no soft tissue to dissipate the force of the blow. The pathomechanics of the resulting fracture vary according to the site, direction, and intensity of impact, as well as the characteristics of the bone that is struck. In younger patients, bones are denser and more elastic, whereas in older patients, bones are less dense and more brittle.

A careful history can usually ascertain the severity of trauma incurred. In cases in which the forces involved are severe, suspicion of cervical spine injury or closed-head injury takes precedence over any concurrent nasal fracture. Findings suggestive of a nasal fracture include swelling, tenderness, crepitance, ecchymosis, or nasal deformity. Indirect evidence of nasal fracture includes periorbital ecchymosis, epistaxis, and rhinorrhea. A general physical examination, specifically focused on the head, neck, and neurologic system, is necessary to exclude associated injury. After spraying the nasal mucosa with a vasoconstricting agent, search for defects in the mucosa, septal hematoma, and bony displacement. Finally, palpate the injured nose, checking for crepitance, stepoffs, and instability that suggest orbital or midface fracture.

The diagnosis of nasal fracture is clinical. Nasal radiographic studies are usually not required for either diagnosis or management. If there is associated facial bone injury, radiographic imaging selection may be driven by the requirements of collateral testing (e.g., facial bone CT scan to exclude orbital fracture).

Complications

The complications of a nasal fracture include nasal deformity, deviated nasal septum, septal hematoma, cribriform plate fracture, and associated facial, head, or spinal injuries. A septal hematoma is a rare complication. It is a collection of blood beneath the septal perichondrium. Easily visualized using an otoscope, it appears as a bluish, fluid-filled sac overlying the septum. The hematoma is easily managed by making an incision for drainage, followed by packing the nasal cavity to prevent reaccumulation (see Figure 241-3). If undiagnosed or left untreated, it may progress to an abscess or result in avascular necrosis of the cartilaginous septum within several days. Septal avascular necrosis is associated with the cosmetic complications of saddle nose deformity, retraction, and changes in phonation.

Fracture through the cribriform plate of the ethmoid bone is associated with a cerebrospinal fluid (CSF) leak via torn meninges. It represents a violation in the integrity of the subarachnoid space. Although rare, CSF rhinorrhea is suspected when there is a clear nasal discharge following facial injury. In major trauma, it is usually seen within the first week as cerebral edema resolves, but it may be delayed days to weeks. If untreated, possible sequelae include meningoenitis or brain abscess.

The identification of CSF rhinorrhea can be difficult in nasal injuries because it is not unusual for there to be a clear transudate from the traumatized nasal mucosa. One method of detecting CSF is to put a drop of the suspected liquid on a piece of filter paper and see if a clear area surrounds a central blood stain. **The glucose content of both CSF and nasal secretions can be similar.** All patients with suspected CSF rhinorrhea should undergo a head CT scan and urgent neurosurgical consultation. If a fracture of the cribriform plate is clinically suspected, the patient should be placed in an upright position, intranasal packing avoided, and immediate neurosurgical consultation obtained. Furthermore, the patient should be instructed to avoid coughing, sneezing, nose blowing, and straining.

Other injuries often seen with nasal trauma are fractures of the orbital wall, sinuses, and zygoma. Be suspicious of cervical spine damage or closed head injury in any patient with significant facial trauma.

Treatment and Disposition

A simple, minimally or nondisplaced nasal fracture requires no specific treatment other than analgesia, nasal decongestants, and protection from further injury. If significant epistaxis occurs, nasal packing can be placed as previously discussed, but is usually unnecessary. For extreme nasal displacement, emergency consultation is needed for realignment.

Discharge instructions include intermittent ice application for 24 to 48 h, elevation of the head (even while sleeping), and over-the-counter decongestants as needed. Patients may require head-injury instructions and advice to be alert for CSF rhinorrhea. Patients are also offered follow-up with an appropriate specialist at about 1 week, after edema has subsided. Although nondisplaced fractures rarely need further treatment, follow-up can address the cosmetic importance of the injury.

NASAL FOREIGN BODIES

Children frequently insert foreign bodies that may require removal into their nares. Items placed in the nasal cavity are limited only by the child's imagination, and are most often food, paper, and pieces of toys.⁷ Dried beans and vegetable matter are particularly concerning because they tend to absorb fluid and swell, increasing discomfort and making removal difficult. Other common foreign bodies include rocks, buttons, and small batteries.

Many children are reluctant to admit to placing a foreign body in their nose for fear they will elicit displeasure from their parents or the physician. In most cases, the insertion of the foreign body is actually observed by the caregiver, or the child reports the presence of a foreign body.⁸ Suspect a nasal foreign body in the following circumstances:

1. Sensation of unilateral nasal obstruction
2. Persistent, foul-smelling rhinorrhea despite proper antibiotic treatment
3. Persistent unilateral epistaxis

In addition to a nasal examination, a complete head and neck physical examination is performed. The ears are also carefully checked for foreign bodies, and the lungs auscultated for wheezing.

Treatment

If the child is cooperative and the foreign body visible, it is possible to remove the object in the ED. In small or uncooperative children, a papoose board may be used for restraint. The nasal mucosa is generally prepared with vasoconstrictors and anesthetics (1 mL of phenylephrine mixed with 3 mL of 4 percent xylocaine). In uncooperative children, aerosolized adrenaline (racemic epinephrine) can be used to decongest the nasal mucosa and loosen the foreign body.⁹ When administered in the aerosolized form by the parent, it causes little or no distress to the child. Following this, visualization with an appropriately sized nasal speculum is attempted.

If the object appears loose after vasoconstriction, an attempt to remove it can be made using a number of different techniques including:

1. Positive pressure technique
2. Removal by a suction catheter
3. Grasping the object with bayonet or alligator forceps
4. Passing a curette beyond the object, rotating the instrument, and pulling the foreign body out
5. Passing a Fogarty vascular catheter past the foreign body, inflating the balloon, and removing the catheter and foreign body

The latter four techniques are all acceptable, but require a cooperative child, physical restraint, or conscious sedation to prevent damage to the nasal mucosa. Regardless of the technique utilized, the airway must be protected and appropriate material for managing airway ob-

struction should be immediately available. The examiner should be careful not to advance the foreign body deeper into the nasopharynx.

POSITIVE PRESSURE TECHNIQUE The successful use of this method is well documented.^{9,11} It can be performed in both cooperative and uncooperative patients, and is the least invasive. After vasoconstrictors, positive pressure can be applied by the patient if cooperative (i.e., blow the nose) or the caregiver. If the caregiver is performing the removal, they are instructed to give a puff of air to the mouth of the child while occluding the unobstructed nare with a finger. The foreign body is usually expressed from the nose onto the cheek of the caregiver. Repeated attempts may be necessary.

Despite anxiety generated in the mind of the parent, most patients with nasal foreign bodies can be discharged home even if removal attempts are unsuccessful. Admission need only be considered if the patient exhibits constitutional symptoms such as fever, malaise, or lethargy. If attempts to remove the foreign body are unsuccessful, the patient should follow-up with an otolaryngologist the next day. If foreign body removal was successful, no further follow-up or treatment is required.

SINUSITIS

Pathophysiology

There are six nasal sinuses: two maxillary, two frontal, one sphenoidal, and the ethmoidal air cells. Sinusitis occurs when there is an acute obstruction of the normal drainage mechanisms of the sinuses. Efficiency of sinus drainage consists of three elements: ostial patency, ciliary apparatus function, and the quality of the nasal secretions. Inflammatory edema causes obstruction or mucociliary drainage at the osteomeatal complex, followed by reabsorption of the air in the sinus, resulting in negative pressure. Negative pressure causes a collection of transudate within the sinus cavity. If bacteria are present, suppuration results.

Acute sinusitis is acute inflammation of the paranasal sinuses of less than 3 weeks duration. Viral upper respiratory tract infections and allergic rhinitis are the most common initiating factors in acute sinusitis.¹² Bacterial sinusitis is most commonly caused by *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*.¹³ Immunocompromised patients may be infected with the usual pathogens, opportunistic bacteria, or fungi.

Chronic sinusitis results from unresolved acute sinusitis of more than 3 weeks duration. In chronic sinusitis, polymicrobial anaerobic species are found in most cases.

Clinical Features

The consensus definition of acute bacterial sinusitis is as follows:¹² (1) symptoms for 7 days or more; (2) sinus pain or tenderness in the face or teeth; and (3) purulent nasal secretions.

Ethmoidal sinusitis usually causes a dull, aching sensation behind the eye. Infection of the frontal and maxillary sinuses generally causes pain over the affected sinus. Ethmoidal sinusitis can spread to the orbit, retro-orbital area, and central nervous system. The headache of sinusitis may be aggravated by bending forward, coughing, or sneezing.

On physical examination, there may be tenderness to palpation and percussion over the involved sinus, and direct visualization of the nasal cavity may show swollen, erythematous mucosa with purulent exudate draining from the ostia. Diminished transillumination of the affected sinus can also be seen. The physical examination should be directed to specifically exclude indications of infectious spread beyond the sinus cavity, as well as complications and confounders in the differential diagnosis.

Diagnosis

Radiography is not recommended for diagnosis in routine cases.¹² Physical examination has moderate ability to identify patients with positive radiographs [summary receiver operating characteristic (SROC) area, 0.74].¹⁴ The radiographic signs of sinusitis are sinus opacity or fluid, with a sensitivity of 0.73 and specificity of 0.80 for radiography when compared to sinus puncture/aspiration as the gold standard.¹⁴ Computed tomography (CT) has a greater ability to define physical characteristics, but its primary role is to diagnose sinusitis when the differential diagnosis is unclear and to define anatomy before surgery.¹⁵ Not all patients with sinus-related symptoms will have CT evidence of abnormality,¹⁶ and conversely, a small number of patients without sinus-related symptoms have abnormalities on CT.¹⁶ Therefore, CT is not routinely indicated for diagnosis, but could be considered in the immunosuppressed or where the diagnosis is not clear.

Cultures of nasopharyngeal secretions are not routinely recommended.¹³ However, they can be considered in the immunosuppressed, those who demonstrate any signs of infectious spread external to the sinus cavity, or in those who are systemically toxic.

Differential Diagnosis

The most important points to consider are those diagnoses arising as complications from sinusitis. These include any evidence of infectious extension from the sinus cavity, such as periorbital cellulitis, brain abscess, subdural empyema, meningitis, or cavernous sinus thrombosis. Such patients are usually febrile, extremely ill, may have unstable vital signs, and can demonstrate altered mental status, meningismus, and focal neurologic findings.

The differential diagnosis of patients with signs and symptoms of facial pain include tension headache, migraines, and cluster headache (see Chap. 227). While history and physical examination can usually differentiate these disorders from sinusitis, occasionally they can coexist with sinusitis, making diagnosis more difficult. Dental pain is usually localized to a single tooth, and is exquisitely sensitive to percussion, with few other symptoms to support the diagnosis of sinusitis. History taking should differentiate rhinitis symptoms from mucosal engorgement due to rebound following excessive topical decongestant use.

Treatment

For acute sinusitis with mild symptoms of less than 7 days' duration, symptomatic treatment is recommended.¹² Antibiotics should not be given unless symptoms persist for more than 7 days, or unless symptoms are severe (unilateral facial pain or purulent nasal secretions), regardless of duration of illness.¹² The most narrow-spectrum agent active against the likely pathogens should be selected.

Antimicrobial therapy shortens the symptomatic period by several days¹³ and decreases the incidence of respiratory complications.¹³ The most cost-effective initial antibiotic choices are amoxicillin or trimethoprim-sulfamethoxazole.^{17,18} Cefuroxime or azithromycin are also commonly prescribed. In patients with suspected streptococcal antibiotic resistance, then amoxicillin-clavulanate, or a "respiratory" fluoroquinolone (levofloxacin, gatifloxacin, moxifloxacin, or gemifloxacin) can be considered.^{19,20} In chronic sinusitis, recommended antibiotics include amoxicillin-clavulanate, cefuroxime, gatifloxacin, moxifloxacin, gemifloxacin, or clindamycin.

Over-the-counter nasal spray decongestants or antihistamines such as pseudoephedrine, phenylephrine, or oxymetazoline, are commonly used to alleviate symptoms of sinusitis. If topical decongestants are prescribed, they are for limited duration due to rebound mucosal congestion and edema if their use exceeds 5 to 7 days.^{21,23} Oral antihistamines may be of use in allergic rhinosinusitis.^{21,22} However, in sup-

purative sinusitis, they may result in thickening of secretions with crust formation at the osteomeatal complex.²²

Steroid nasal sprays, used twice daily, can improve symptoms of acute sinusitis compared to antibiotic treatment alone.^{24,25}

Complications

Persistent sinusitis can result in extension of the infectious process into the surrounding tissues. Bony destruction, originating from the frontal sinus, can extend anteriorly. This leads to the development of a doughy, edematous forehead called Potts puffy tumor. If a frontal bone osteomyelitis extends posteriorly, a frontal brain abscess, meningitis, subdural empyema, and epidural abscess can develop. Extension from the ethmoid sinus can result in orbital or periorbital cellulitis. Finally, direct extension from the paranasal sinus to the venous or lymphatic system can cause cavernous sinus thrombosis. All patients suspected of having any extension of infection beyond the paranasal sinuses needs immediate CT or MRI scanning, intravenous antibiotic therapy, and emergent consultation with the appropriate specialist.

Disposition

Most patients with acute sinusitis can be treated as outpatients. Hospitalization is required if there is evidence of infectious spread beyond the sinus cavity, or if there is systemic toxicity. Discharged patients should receive follow-up in 5 to 7 days, with instructions to return to the ED for persistent fever, severe or worsening headache, visual changes, or vomiting.

FIG. 242-1. Normal eruptive patterns of the primary and permanent dentition.

ORAL AND DENTAL EMERGENCIES

Ronald W. Beaudreau

Oral emergencies generally can be divided into three categories: 1) orofacial pain, 2) orofacial trauma, specifically dentoalveolar trauma, and 3) hemorrhage. Early manifestations of many systemic illnesses are evident in the oral environment and may provide clues to the diagnosis of systemic illnesses. Oral lesions may cause pain or anxiety, and it is important that the emergency physician be familiar with common oral pathology and its management.

ORAL AND DENTAL ANATOMY

The normal adult dentition consists of 32 permanent teeth. The adult dentition has four types of teeth: 8 incisors, 4 canines, 8 premolars, and 12 molars. The primary or deciduous dentition consists of 20 teeth of three types: 8 incisors, 4 canines, and 8 molars. Figure 242-1 shows the eruptive pattern of both the primary and permanent dentition. Each tooth type is designed for a specific function in the process of mastication. Incisors are used for biting and cutting, canines and premolars for ripping, and molars for grinding. Figure 242-2 illustrates one commonly used tooth numbering system; however, description by the emergency physician of the tooth type and location is appropriate. Mastication is an important initial step in the digestive process and thus nutrition. The dentition is also important in the development of the mandible and maxilla and aesthetic development of the midface.

Anatomy of the Teeth

Table 242-1 lists commonly used dental nomenclature. A tooth consists largely of *dentin*, which surrounds the *pulp*, or neurovascular supply of the tooth (Figure 242-3). Dentin is a homogeneous material produced by pulpal odontoblasts throughout life. It is deposited as a system of micro tubules filled with odontoblastic processes and extracellular fluid. The *crown*, or the visible portion of tooth, consists of a thick *enamel* layer overlying the dentin. Enamel, the hardest substance in the human body, consists largely of hydroxyapatite and is produced by ameloblasts prior to eruption of the tooth into the mouth. The *root* portion of the tooth extends into the alveolar bone and is covered with a thin layer of *cementum*.

The Normal Periodontium

The periodontium, or attachment apparatus, is essential for maintaining the integrity of the dentoalveolar unit. The attachment apparatus consists of a gingival component and a periodontal component. The gingival component includes the junctional epithelium, gingival tissue, and gingival fibers. The periodontal component includes the periodontal ligament, alveolar bone, and cementum of the root of the tooth. The periodontal ligament consists of collagen fibers that extend from the alveolar bone to the root of the tooth, adhering to the cementum via a hemidesmosomal attachment. The latter component forms the majority of the attachment apparatus, and the former aids primarily in maintaining the integrity of the periodontal ligament. Disease states such as gingivitis and periodontal disease weaken and destroy the attachment apparatus, resulting in tooth mobility and tooth loss.¹

Gingival tissue is keratinized stratified squamous epithelium. It can be divided into the free gingival margin and the attached gingiva. The free gingiva is the portion that forms the 2- to 3-mm-deep *gingival sulcus* in the disease-free state. The attached gingiva adheres firmly to the underlying alveolar bone. The nonkeratinized alveolar mucosa extends from the attached gingiva to the vestibule and floor of the mouth. The mucosal tissue of the cheeks, lips, and floor of the mouth is also comprised of nonkeratinized squamous epithelium.¹

OROFACIAL PAIN

Pain of Odontogenic Origin

TOOTH ERUPTION Discomfort is commonly associated with the eruption of primary or deciduous teeth in infants. Irritability, drooling, and decreased intake are commonly associated findings. An associated low-grade fever (37.9°C/100.2°F) and diarrhea are more controversial findings. No scientific data support an association of teething, fever, and diarrhea. One must be careful in attributing either to tooth eruption. Other sources for fever must be carefully sought.² Table 242-2 lists common causes of orofacial pain.

As with the primary dentition, eruption of permanent teeth, especially third molars, or *wisdom teeth*, may result in significant pain. Gingival irritation and inflammation associated with tooth eruption

FIG. 242-2. Identification of teeth.

are common and must be distinguished from *pericoronitis*. Pericoronitis is inflammation of the *operculum*, or the gingival tissue overlying the occlusal surface of an erupting tooth. Impaction of food and debris beneath the operculum results in a severe inflammatory response. Without intervention this progressive inflammatory process will result in frank infection. Because of the close proximity of the masticator space (comprised of the masseteric space, pterygomandibular space, and the superficial and deep temporalis space) to third molars, associated trismus is common and portends the potential for extension into the communicating parapharyngeal spaces. Treatment consists of appropriate antibiotic therapy with penicillin VK 500 mg PO qid, erythromycin 250 mg PO qid, or clindamycin 300 mg PO qid, local irrigation of food and debris from underneath the operculum, saline mouth

TABLE 242-1 Commonly Used Dental Terminology

Anatomically descriptive terms for tooth surfaces	
Interproximal	The surface between two adjacent teeth
Mesial	The interproximal surface facing anteriorly or toward the midline
Distal	The interproximal surface facing posteriorly or away from the midline
Occlusal	The chewing surface
Facial	Toward the face, a general term applicable to all teeth
Labial	Toward the lips, specific to the anterior teeth
Buccal	Toward the cheek, specific to the posterior teeth
Palatal	Toward the palate, specific to the maxillary teeth
Lingual	Toward the tongue, specific to the mandibular teeth
Apical	Toward the tip of the root of the tooth
Radicular	Associated with the root, especially the apical region
Coronal	Associated with the crown of the tooth
Incisal	Toward the biting edge of incisors
Cervical	Related to the junction of the crown and root of the tooth

rinses, and analgesic therapy with nonsteroidal anti-inflammatory drugs (NSAIDs) and opiate preparations as appropriate. Referral to a general dentist or an oral and maxillofacial surgeon within 24 to 48 h is essential. If pericoronitis is related to trauma from an opposing tooth during mastication, as is frequently the case with third molars, concomitant extraction of the opposing tooth and antibiotic therapy will bring marked relief within 24 h. Definitive treatment is extraction of the associated tooth by a general dentist or oral and maxillofacial surgeon.

TABLE 242-2 Differential Diagnosis of Orofacial Pain

Odontogenic origin	
Dental caries	Pericoronitis
Reversible pulpitis	Postrestorative pain
Irreversible pulpitis	Postextraction discomfort
Pulpal necrosis and abscess	Postextraction alveolar osteitis
Dental sensitivity	Bruxism
Tooth eruption	Cervical erosion
Periodontal pathology	
Gingivitis	Periodontal abscess
Periodontal disease	Acute necrotizing gingivostomatitis
Orofacial trauma	
Dental fractures	Facial fractures
Subtle enamel cracks	Alveolar ridge fractures
Ellis fractures	Soft tissue lacerations
Dental luxation and avulsion	Traumatic ulcers
Infection	
Oral candidiasis	Hand, foot, and mouth disease
Herpes simplex types 1 and 2	Sexually transmitted diseases
Varicella-zoster, primary and secondary	Mycobacterial infections
Herpangina	Mumps
Malignancies	
Squamous cell carcinoma	Leukemia
Kaposi sarcoma	Graft-versus-host disease
Lymphoma	Melanoma
Other etiologies	
Cranial neuralgias	Vesiculoulcerative disease
Stomatitis and mucositis	Lichen planus
Uremia	Cicatricial pemphigoid
Vitamin deficiency	Pemphigus vulgaris
Other	Erythema multiforme
Erythema migrans	Crohn disease
Pyogenic granuloma	Behçet syndrome

DENTAL CARIES AND PULPAL PATHOLOGY *Dental caries* represents the loss of integrity of the tooth enamel secondary to dissolution of hydroxyapatite from prolonged exposure to the acidic metabolic by-products of plaque bacteria. Caries most commonly occurs in areas where plaque accumulates such as pits and fissures of the occlusal surface, interproximally, and along the gingival margins. When a sufficient breach of enamel integrity has occurred, sensitivity to cold or sweet stimulus may result. With dentinal involvement, carious progression occurs more rapidly, spreading along dentinal microtubules. At this stage, direct communication between the oral environment and the vital dental pulp has been established, and inflammatory changes in the pulpal tissue are evident histologically.

The pulpal inflammatory process is initially reversible, but with continued stimuli, the pulp's ability to respond and repair is jeopardized. *Irreversible pulpitis* can be distinguished from *reversible pulpitis* by the duration of symptoms. Both require a stimulus to initiate a painful response; however, in reversible pulpitis, the duration of pain is short, lasting seconds, as compared with irreversible pulpitis, in which the pain may last for minutes to hours. The most common stimulus is thermal, although sweet or sour stimuli also can elicit a painful response. Spontaneous odontogenic pain most frequently represents pulpal death or necrosis. Pain elicited with heat stimulus is most commonly associated with pulpal necrosis. Determining a particular tooth's position in this continuum of disease is impractical for the emergency physician. Treatment focuses on providing adequate analgesia and referral to a general dentist. The definitive treatment for irreversible pulpitis and pulpal necrosis is root canal therapy or dental extraction.

PERIRADICULAR PATHOLOGY The most common cause of severe odontogenic pain is periapical pathology. *Periapical granuloma*, more appropriately termed *periradicular periodontitis*, is the most common periapical lesion. This lesion is not a true granuloma but rather slowly expanding granulation tissue associated with the root apex. Most commonly, periradicular periodontitis is a result of pulpal inflammation or necrosis, but it can be associated with trauma. *Periapical* or *radicular cyst* and *periradicular abscess* are clinically and radiographically indistinguishable from periradicular periodontitis, yet histologically separate entities. A periapical cyst has an epithelial lining originating embryologically from the rest of Malassez, and a periradicular abscess merely represents the accumulation of associated inflammatory cell. All three lesions are only associated with teeth with severely inflamed or necrotic pulps and may cause significant pain. Radiographically, these periapical lesions appear as a slight widening of the periodontal ligament space, a thinning of the lamina dura, or a frank radiolucent area associated with the root apex on a periapical dental radiograph (Figure 242-4). Radiographic evaluation with a Panorex panoramic x-ray machine is rarely useful for identification of all but the most extensive periradicular lesions, but can be important in identifying other more significant painful osseous pathology.

Pain of dental origin may be diffuse in nature, presenting as a headache, sinus pain, eye pain, or jaw or neck pain, or may be localized to a single tooth. One must remember to consider myocardial infarction as an etiology of jaw pain. Identification of the offending tooth is best accomplished by eliciting pain with percussion of the suspected teeth with a dental mirror handle or similar metallic object. A small swelling of the gingiva with a draining fistula adjacent to the affected tooth is known as a *parulis*, and can help identify the involved tooth. Erosion of a periradicular abscess through the cortical bone and subperiosteal extension results in intraoral or facial swelling and fluctuance that, if possible should be incised and drained intraorally. The emergency physician should treat dental abscesses or other periapical lesions with oral antibiotics such as penicillin VK 500 mg PO qid, clindamycin 300 mg PO qid, or erythromycin 500 mg PO qid, and should provide adequate analgesia with an NSAID. Opioid analgesia

FIG. 242-4. A. The radiographic appearance of a healthy tooth with a normal periodontal ligament space and distinct lamina dura compared with the radiographic appearance of a periapical abscess, periradicular periodontitis, and periradicular cyst. B. A periapical radiolucency. C. Subtle radiographic loss of the periapical lamina dura and widening of the periodontal ligament space. (Courtesy of Gary M. Beaudreau, DMD.)

may be indicated in the first 24 to 48 h. Prompt referral to a dentist for definitive treatment such as root canal therapy or extraction is indicated.

FACIAL CELLULITIS Spread of odontogenic infections into the various facial spaces is relatively common. Buccal extension of a periapical infection of the mandibular teeth will involve the buccinator space. Maxillary labial extension of infection primarily will involve the infraorbital space. Perforation through the lingual cortical bone of mandibular molars, particularly the second and third molars, usually occurs below the mylohyoid ridge and involves the submandibular space. Lingual spread of periapical infections associated with mandibular anterior teeth will affect the lingual space. The submandibular space and lingual space communicate with each other at the posterior border of the mylohyoid muscle.

Cellulitis of bilateral submandibular spaces and the lingual space is called *Ludwig angina* (see Chap. 243) and is potentially life-threatening. Clinically, Ludwig angina is a rapidly spreading cellulitis that results in brawny induration of the suprahyoid region and elevation of the tongue. Involvement of the floor of the mouth pushes the tongue posteriorly. As these spaces and the masticator spaces ultimately communicate, with the parapharyngeal space, involvement of the epiglottis is not uncommon. As a result, airway compromise is the immediate primary concern. The primary focus of initial management is maintenance of a patent airway. Timely intravenous administration of high-dose penicillin and metronidazole or cefoxitin is essential. An aminoglycoside may be added to extend coverage, and in the penicillin-sensitive person, clindamycin may be substituted. Immediate oral and maxillofacial surgical consultation and hospitalization for incision and drainage and intubation as indicated are necessary.

Infection of the infraorbital space may have a potentially devastating outcome if retrograde spread via the ophthalmic veins occurs, and the cavernous sinus becomes involved. *Cavernous sinus thrombosis* presents as an infraorbital or periorbital cellulitis with rapidly developing meningeal signs, sepsis, and coma. Early recognition and treatment with a high-dose IV antibiotic as above are essential in decreasing morbidity and mortality.
