EMERGENCY MEDICINE

A COMPREHENSIVE STUDY GUIDE

Editor-in-Chief

Judith E. Tintinalli, MD, MS

*Professor and Chair
Department of Emergency Medicine
Adjunct Professor
Department of Health Policy and Administration
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina*

Co-Editors

Gabor D. Kelen, MD

*Professor and Chair
Department of Emergency Medicine
Johns Hopkins University
Baltimore, Maryland*

J. Stephan Stapczynski, MD

*Professor and Former Chair
Department of Emergency Medicine
University of Kentucky College of Medicine
Lexington, Kentucky*

1 2 3 4 5 6 7 8 9 0 DOW/DOW 0 9 8 7 6 5 4 3 ISBN: 0-07-138875-3

This book was set in Times New Roman by ATLAS Graphics, Inc.

The editors were Andrea Seils, Nicky Fernando, and Michelle Watt.

The production supervisor was Catherine H. Saggese.

The cover designer was Aimee Nordin.

The index was prepared by Jerry Ralya.

RR Donnelley was the printer and binder.

This book is printed on acid-free paper.

LIBRARY OF CONGRESS CATALOGING-IN-PUBLICATION DATA

Emergency medicine : a comprehensive study guide / [edited by] Judith E. Tintinalli, Gabor D. Kelen, J. Stephan Stapczynski.—6th ed.

p. ; cm.

Includes bibliographical references and index. ISBN: 0-07-138875-3

1. Emergency medicine. I. Tintinalli, Judith E. II. Kelen, Gabor D. III. Stapczynski, J. Stephan.

[DNLM: 1. Emergency Medicine. 2. Emergencies. WB 105 E552 2004] RC86.7 .E57828 2004 616.02'5—dc21

To students and practitioners of Emergency Medicine around the world.
JET

To Laurie, Ardie and Mikey, whose love and support sustained me through this endeavor.
GDK

*To those who have taught me, my gratitude for their patience and wisdom; to those I have
taught, my encouragement for life-long learning.*
JSS

Section One Prehospital Care 1

- 1 [Emergency Medical Services](#) *G. Patrick Lilja* 1
- 2 [Prehospital Equipment and Adjuncts](#) *Daniel G. Hankins, Andy Boggust* 5
- 3 [Air Medical Transport](#) *C. Keith Stone, Stephen H. Thomas* 11
- 4 [Neonatal and Pediatric Transport](#) *Phillip V. Gordon, Carl Bose* 15
- 5 [Mass Gatherings](#) *Eric W. Ossmann, Arthur H. Yancey II* 21

Section Two Disaster Preparedness 27

- 6 [Disaster Medical Services](#) *Eric K. Noji, Gabor D. Kelen* 27
- 7 [Bioterrorism Response: Implications for the Emergency Clinician](#) *Anthony G. MacIntyre, Joseph A. Barbera* 35
- 8 [Disaster Management for Chemical Agents of Mass Destruction](#) *Suzanne R. White, Kelly R. Klein, Col. Edward M. Eitzen, Jr.* 42
- 9 [Blast and Crush Injuries](#) *John M. Wightman, Barry A. Wayne* 46
- 10 [Radiation Injuries](#) *Christina L. Catlett, Pamela L. Piggott* 50

Section Three Resuscitative Problems and Techniques 61

- 11 [Sudden Cardiac Death](#) *Joseph P. Ornato* 61
- 12 [Basic Cardiopulmonary Resuscitation in Adults](#) *Jon Mark Hirshon* 66
- 13 [Neonatal Resuscitation and Emergencies](#) *Eugene E. Cepeda, Mary P. Bedard* 71
- 14 [Pediatric Cardiopulmonary Resuscitation](#) *William E. Hauda II* 78
- 15 [Pediatric Airway Management](#) *Marcie Rubin, Nicholas Sadovnikoff* 88
- 16 [Resuscitation Issues in Pregnancy](#) *Elizabeth M. Datner, Susan B. Promes* 94
- 17 [Ethical Issues of Resuscitation](#) *Catherine A. Marco* 99
- 18 [Noninvasive Airway Management](#) *A. Michael Roman* 102
- 19 [Tracheal Intubation and Mechanical Ventilation](#) *Daniel F. Danzl, Robert J. Vissers* 108
- 20 [Surgical Airway Management](#) *David R. Gens* 119
- 21 [Vascular Access](#) *William A. Berk, Bharat Sutariya* 124
- 22 [Invasive Monitoring, Pacing Techniques, and Automatic and Implantable Defibrillators](#) *Edward S. Bessman* 132
- 23 [Cerebral Resuscitation](#) *Gary S. Krause, Blaine C. White* 138
- 24 [Newer Resuscitative Techniques](#) *James E. Manning, Christopher W. Barton, Laurence M. Katz* 141
- 25 [Acid-Base Disorders](#) *David D. Nicolaou, Gabor D. Kelen* 149
- 26 [Blood Gases: Pathophysiology and Interpretation](#) *Kelly L. Grogan, Peter Pronovost* 159
- 27 [Fluid and Electrolyte Problems](#) *Michael Londner, Darcie Hammer, Gabor D. Kelen* 167
- 28 [Disturbances of Cardiac Rhythm and Conduction](#) *Edmund Bolton* 179
- 29 [Pharmacology of Antidysrhythmic and Vasoactive Medications](#) *Elizabeth A. Clements, Bryan R. Kuhn* 202

Section Four Shock 219

- 30 [Approach to the Patient in Shock](#) *Emanuel P. Rivers, Ronny M. Otero, H. Bryant Nguyen* 219
- 31 [Fluid and Blood Resuscitation](#) *James E. Manning* 225
- 32 [Septic Shock](#) *Jonathan Jui* 231
- 33 [Cardiogenic Shock](#) *W. Franklin Peacock IV, Jim Edward Weber* 242
- 34 [Anaphylaxis and Acute Allergic Reactions](#) *Brian H. Rowe, Stuart Carr* 247
- 35 [Neurogenic Shock](#) *Brian Euerle, Thomas M. Scalea* 252

Section Five Analgesia, Anesthesia, and Sedation 257

- 36 [Acute Pain Management in the Adult Patient](#) *Gary D. Zimmer* 257
- 37 [Local and Regional Anesthesia](#) *Eric Higginbotham, Robert J. Vissers* 264
- 38 [Procedural Sedation and Analgesia](#) *David D. Nicolaou* 275
- 39 [Management of Patients with Chronic Pain](#) *David M. Cline* 280

Section Six Emergency Wound Management 287

- 40 [Evaluation of Wounds](#) *Judd E. Hollander, Adam J. Singer* 287
- 41 [Wound Preparation](#) *Susan Stone, Wallace A. Carter* 289
- 42 [Methods for Wound Closure](#) *Adam J. Singer, Judd E. Hollander* 292
- 43 [Lacerations to the Face and Scalp](#) *Wendy C. Coates* 298
- 44 [Injuries to the Arm, Hand, Fingertip, and Nail](#) *Fiona E. Gallahue, Wallace A. Carter* 305
- 45 [Lacerations of the Leg and Foot](#) *Earl J. Reisdorff* 312
- 46 [Soft Tissue Foreign Bodies](#) *Richard L. Hammers* 317
- 47 [Puncture Wounds and Mammalian Bites](#) *Robert A. Schwab, Robert D. Powers* 324
- 48 [Postrepair Wound Care](#) *Adam J. Singer, Judd E. Hollander* 328

Section Seven Cardiovascular Disease 333

- 49 [Approach to Chest Pain](#) *Gaty B. Green, Peter M. Hill* 333
- 50 [Acute Coronary Syndromes: Acute Myocardial Infarction and Unstable Angina](#) *Judd E. Hollander* 343
- 51 [Intervention Strategies for Acute Coronary Syndromes](#) *Judd E. Hollander, Deborah B. Diercks* 352
- 52 [Syncope](#) *Barbara K. Blok, Tina M. Newman* 359
- 53 [Congestive Heart Failure and Acute Pulmonary Edema](#) *W. Franklin Peacock IV* 364
- 54 [Valvular Emergencies](#) *David M. Cline* 373
- 55 [The Cardomyopathies, Myocarditis, and Pericardial Disease](#) *James T. Niemann* 378
- 56 [Pulmonary Embolism](#) *Jeffrey A. Kline* 386
- 57 [Hypertension](#) *Melissa M. Wu, Arjun Chanmugam* 394
- 58 [Aortic Dissection and Aneurysms](#) *Louise A. Prince, Gary A. Johnson* 404
- 59 [Thrombophlebitis and Occlusive Arterial Disease](#) *Anil Chopra* 409
- 60 [Cardiac Transplantation](#) *Michael R. Mill, Michelle S. Mill* 418
- 61 [Noninvasive Myocardial Imaging](#) *David A. Bluemke, Bennett Chin, Joao A. C. Lima, Malek Tebache* 424

Section Eight Pulmonary Emergencies 437

- 62 [Respiratory Distress](#) *J. Stephan Stapczynski* 437
- 63 [Bronchitis, Pneumonia, and Pleural Empyema](#) *Donald A. Moffa, Jr., Charles L. Emerman* 445
- 64 [Aspiration Pneumonia and Lung Abscess](#) *Eric Anderson* 453
- 65 [Tuberculosis](#) *Janet M. Poponick* 458
- 66 [Spontaneous and Iatrogenic Pneumothorax](#) *William Franklin Young, Jr., Roger L. Humphries* 462
- 67 [Hemoptysis](#) *William Franklin Young, Jr., Michael Stava* 465
- 68 [Acute Asthma in Adults](#) *Rita K. Cydulka* 467
- 69 [Chronic Obstructive Pulmonary Disease](#) *Rita K. Cydulka, Mohak Dave* 475
- 70 [The Lung Transplant Patient](#) *Thomas P. Noeller* 480
- 71 [Pulmonary Imaging](#) *Janet M. Poponick* 483

Section Nine Gastrointestinal Emergencies 487

- 72 [Acute Abdominal Pain](#) *E. John Gallagher* 487
- 73 [Abdominal Pain in the Elderly](#) *Robert McNamara* 501
- 74 [Gastrointestinal Bleeding](#) *David T. Overton* 505

- 84 [Jaundice](#) *Richard O. Shields, Jr.* 560

85	Cholecystitis and Biliary Colic	<i>William J. Brady, Thomas P. Aufderheide, Judith E. Tintinalli</i>	561
86	Hepatic Disorders and Hepatic Failure	<i>Joshua S. Broder, Rawden Evans</i>	566
87	Acute and Chronic Pancreatitis	<i>Robert J. Vissers, Riyad B. Abu-Laban</i>	573
88	Complications of General Surgical Procedures	<i>Edmond A. Hooker</i>	577
89	Complications of Gastrointestinal Devices	<i>Edmond A. Hooker</i>	583
90	The Liver Transplant Patient	<i>Steven Kronick</i>	585
91	Gastrointestinal Imaging	<i>Michael J. Bono</i>	590

Section Ten Renal and Genitourinary Disorders 593

92	Acute Renal Failure	<i>Richard Sinert, Peter R. Peacock, Jr.</i>	593
93	Emergencies in Renal Failure and Dialysis Patients	<i>Richard Sinert, Mark Spektor</i>	599
94	Urinary Tract Infections	<i>David S. Howes, Mark P. Bogner</i>	606
95	Male Genital Problems	<i>Robert E. Schneider</i>	613
96	Urologic Stone Disease	<i>Rakesh Engineer, W. Franklin Peacock IV</i>	620
97	Hematuria and Hematospermia	<i>David S. Howes, Mark P. Bogner</i>	625
98	Complications of Urologic Procedures and Devices	<i>Elaine B. Josephson, Jatinder Singh</i>	629
99	The Renal Transplant Patient	<i>Richard Sinert, Mert Eroglu</i>	633
100	Renal Imaging	<i>Daniel E. Wiener, Emily H. Sheffer</i>	640

Section Eleven Gynecology and Obstetrics 647

101	Vaginal Bleeding in the Nonpregnant Patient	<i>Laurie J. Morrison, Julie M. Spence</i>	647
102	Abdominal and Pelvic Pain in the Nonpregnant Patient	<i>Reb Close</i>	653
103	Ectopic Pregnancy	<i>Richard S. Krause, David M. Janicke</i>	658
104	Normal Pregnancy	<i>Christina E. Hantsch, Donna L. Seger</i>	664
105	Comorbid Diseases in Pregnancy	<i>Jessica L. Bienstock, Harold E. Fox</i>	670
106	Emergencies During Pregnancy and the Postpartum Period	<i>Gloria J. Kuhn</i>	676
107	Emergency Delivery	<i>Michael J. VanRooyen, Kimberly B. Fortner</i>	684
108	Vulvovaginitis	<i>Gloria J. Kuhn</i>	691
109	Pelvic Inflammatory Disease	<i>Amy J. Behrman, William H. Shoff, Suzanne M. Shepherd</i>	697
110	Breast Disorders	<i>Janet Simmons Young</i>	700
111	Urogynecologic Disorders and Gynecologic Oncology	<i>Michael Londner, Daniela Meshkat</i>	705
112	Complications of Gynecologic Procedures	<i>Michael A. Silverman, Karen M. Hardart</i>	710
113	Pelvic Ultrasonography	<i>Robert F. Reardon, Dietrich V.K. Jehle</i>	715

Section Twelve Pediatrics 727

114	The Normal Child	<i>Peter Mellis</i>	727
115	Fever	<i>Carol D. Berkowitz</i>	731
116	Bacteremia, Sepsis, and Meningitis in Children	<i>Peter Mellis</i>	735
117	Common Neonatal Problems	<i>Tonia J. Brousseau, Niranjana Kissoon</i>	742
118	The NICU Graduate	<i>Daniel G. Button</i>	752
119	SIDS (Sudden Infant Death Syndrome) and ALTE (Apparent Life-Threatening Event)	<i>Carol D. Berkowitz</i>	755
120	Pediatric Heart Disease	<i>C. James Corral</i>	758
121	Otitis and Pharyngitis in Children	<i>Kimberly S. Quayle, Susan Fuchs, David M. Jaffe</i>	769
122	Skin and Soft Tissue Infections	<i>Richard Malley</i>	778
123	Viral and Bacterial Pneumonia in Children	<i>Kathleen Brown, Willie Gilford, Jr.</i>	784
124	Pediatric Asthma and Bronchiolitis	<i>Maybelle Kou, Thorn Mayer</i>	789
125	Seizures and Status Epilepticus in Children	<i>Michael A. Nigro</i>	798
126	Vomiting and Diarrhea in Children	<i>Christopher M. Holmes, Summer A. Smith</i>	808
127	Pediatric Abdominal Emergencies	<i>Robert W. Schafermeyer</i>	813
128	Diabetic Ketoacidosis	<i>Frederick Place, Thorn Mayer</i>	821
129	Hypoglycemia	<i>Randolph Cordle</i>	825
130	Altered Mental Status and Headache in Children	<i>Nancy Pook, Natalie Cullen, Jonathan I. Singer</i>	831
131	Syncope and Sudden Death	<i>William E. Hauda II, Thorn Mayer</i>	838

132	Fluid and Electrolyte Therapy	<i>William Ahrens</i>	843
133	Upper Respiratory Emergencies	<i>Randolph Cordle</i>	848
134	Acute Pain Management and Procedural Sedation in Children	<i>Michael N. Johnston, Erica L. Liebelt</i>	858
135	Pediatric Exanthems	<i>Michael S. Weinstock, Alexander M. Rosenau</i>	869
136	Musculoskeletal Disorders in Children	<i>Courtney Hopkins-Mann, David Leader, Donna Moro-Sutherland, Richard A. Christoph</i>	876
137	Sickle Cell Disease	<i>Peter J. Paganussi, Thorn Mayer, Maybelle Kou</i>	890
138	Evaluating the Child with Special Health Care Needs	<i>Douglas R. Trocinski, Donna Moro-Sutherland</i>	895
139	Urologic and Gynecologic Problems in Children	<i>Samy Saad, Oily Duckett</i>	900
140	Pediatric Urinary Tract Infections	<i>Michael F. Altieri, Mary Camarca, Thorn Mayer</i>	905

Section Thirteen Infectious Diseases 909

141	Sexually Transmitted Diseases	<i>Joel Kravitz, Susan B. Promes</i>	909
142	Toxic Shock Syndrome and Streptococcal Toxic Shock Syndrome	<i>Shawna J. Perry, Ashley E. Booth</i>	913
143	Common Viral Infections: Influenzaviruses and Herpesviruses	<i>Robert A. Brownstein</i>	919
144	HIV Infection and AIDS	<i>Richard E. Rothman, Catherine A. Marco, Gabor D. Kelen</i>	925
145	Infective Endocarditis	<i>Richard E. Rothman, Samuel Yang, Catherine A. Marco</i>	937
146	Tetanus	<i>Donna L. Carden</i>	943
147	Rabies	<i>David J. Weber, David A. Wohl, William A. Rutala</i>	946
148	Malaria	<i>Jeffrey D. Band</i>	953

CONTRIBUTORS'

STEPHANIE B. ABBUHL, MD [304]

Associate Professor and Medical Director
Department of Emergency Medicine
Hospital of the University of PA
University of PA School of Medicine
Philadelphia, Pennsylvania

RIYAD B. ABU-LABAN, MD, MHSc [87]

Assistant Professor and Research Director
Division of Emergency Medicine University of
British Columbia Department of Emergency
Medicine Vancouver General Hospital
Vancouver, British Columbia, Canada

WILLIAM AHRENS, MD [132] Director
of Pediatric Emergency Medicine
University of Illinois Chicago, Illinois

MICHAEL F. ALTIERI, MD [140]

Associate Clinical Professor of Emergency Medicine
George Washington University
Washington, DC
Inova-Fairfax Hospital for Children
Department of Pediatrics
Falls Church, Virginia

ERIC ANDERSON, MD, MBA [64]

Associate Director of Operations Department
of Emergency Medicine The Cleveland Clinic
Foundation Assistant Professor of Emergency
Medicine The Ohio State University Cleveland,
Ohio

WILLIAM T. ANDERSON, MD [150]

Chief, Department of Emergency Medicine
William Beaumont Hospital Troy, Michigan

THOMAS P. AUFDERHEIDE, MD [85]

Professor of Emergency Medicine and Research Director
Medical College of Wisconsin Department of
Emergency Medicine Milwaukee, Wisconsin

CHENICHERI BALAKRISHNAN, MD [199]

Associate Professor of Surgery
Department of Emergency Medicine
Wayne State University Detroit
Receiving Hospital Detroit, Michigan

JEFFREY D. BAND, MD [148]

Director, Infectious Diseases and International Medicine
William Beaumont Hospital
Royal Oak, Michigan
Clinical Professor of Medicine
Wayne State University School of Medicine
Detroit, Michigan

JOSEPH A. BARBERA, MD [7]

Associate Professor of Engineering Management Clinical
Associate Professor of Emergency Medicine Co-Director,
Institute for Crisis, Disaster, and Risk Management The George
Washington University Washington, DC

ROBERTA. BARISH, MD [76]

Associate Dean for Clinical Affairs Professor of
Emergency Medicine and Surgery University of
Maryland School of Medicine Baltimore,
Maryland

BONNY J. BARON, MD [256, 258]

Associate Professor
Department of Emergency Medicine
State University of New York Downstate Medical Center
Director of Trauma, Emergency Department
Kings County Hospital Center
Brooklyn, New York

CHRISTOPHER W. BARTON, MD [24]

Clinical Professor of Medicine University of
California San Francisco Medical Director,
Emergency Services San Francisco General
Hospital San Francisco, California

DANIEL G. BATTON, MD [118]

Director, Neonatal Intensive Care Unit
William Beaumont Hospital Royal Oak,
Michigan

BRIGITTE M. BAUMANN, MD, DTM&H [306]

Head, Division of Clinical Research Department
of Emergency Medicine UMDNJ-Robert Wood
Johnson Medical School Cooper Health System
Camden, New Jersey

NORMAN J. BEAUCHAMP, JR., MD [237]

Professor and Chair University of Washington
Department of Radiology Seattle, Washington

RONALD W. BEAUDREAU, DMD, MD [242]

Doctor's Hospital
Department of Emergency Medicine
Augusta, Georgia
Medical Evacuation Services
SOS International
Shanghai, China

MARY HARKINS BECKER, MD [80]

Department of Emergency Medicine
Maine Medical Center Assistant
Clinical Professor Department of
Surgery University of Vermont Portland,
Maine

XVI CONTRIBUTORS

MARY P. BEDARD, MD [13]

Clinical Director, Neonatal Intensive Care Unit Medical Director, Transport Program Children's Hospital of Michigan Associate Professor of Pediatrics Wayne State University Detroit, Michigan

AMY J. BEHRMAN, MD [109]

Associate Professor Department of Emergency Medicine Director, Occupational Medicine Hospital of the University of Pennsylvania Philadelphia, Pennsylvania

WILLIAM A. BERK, MD [21,166, 295]

Associate Professor Department of Emergency Medicine Wayne State University Vice-Chief, Emergency Department Detroit Receiving Hospital Detroit, Michigan

CAROL D. BERKOWITZ, MD [115,119, 297]

Executive Vice Chair and Professor Department of Pediatrics Harbor-UCLA Medical Center David Geffen School of Medicine at UCLA Torrance, California

EDWARD BERNSTEIN, MD [295]

Professor and Vice Chair for Academic Affairs Department of Emergency Medicine Boston University School of Medicine Professor of Social and Behavioral Sciences Boston University School of Public Health Boston, Massachusetts

JUDITH BERNSTEIN, RNC, PhD [295]

Associate Professor Department of Maternal and Child Health Boston University School of Public Health Director, MCH Certificate Program Boston University School of Medicine Department of Emergency Medicine Boston, Massachusetts

HOWARD A. BESSEN, MD [192]

Professor of Medicine UCLA School of Medicine Los Angeles, California Director, Emergency Medicine Residency Program Department of Emergency Medicine Harbor-UCLA Medical Center Torrance, California

EDWARD S. BESSMAN, MD [22]

Assistant Professor Department of Emergency Medicine The Johns Hopkins University Baltimore, Maryland Clinical Director Department of Emergency Medicine Johns Hopkins Bayview Medical Center Baltimore, Maryland

MICHAEL B. BEUHLER, MD [180]

Medical Director Carolinas Poison Center Charlotte, North Carolina Adjunct Instructor of Emergency Medicine University of North Carolina at Chapel Hill Chapel Hill, North Carolina

JESSICA L. BIENSTOCK, MD [105]

Residency Program Director Assistant Professor Johns Hopkins Hospital Baltimore, Maryland

PAUL BLACKBURN, DO [225]

Residency Program Director Department of Emergency Medicine Maricopa Medical Center Phoenix, Arizona

BARBARA K. BLOK, MD [52]

Assistant Professor Department of Emergency Medicine Johns Hopkins Hospital Baltimore, Maryland

DAVID A. BLUEMKE, MD, PhD [61]

Associate Professor, Radiology Clinical Director, MRI Johns Hopkins University and Hospital Department of Radiology Baltimore, Maryland

ANDY BOGGUST, MD [2]

Department of Emergency Medicine Mayo Clinic School of Medicine Rochester, Minnesota

MARK P. BOGNER, MD [94, 97]

Assistant Clinical Professor Department of Emergency Medicine University of Wisconsin Medical School Madison, Wisconsin

EDMUND BOLTON, MD [28]

EM Healthcare Physicians Westmont, Illinois

MICHAEL J. BONO, MD [91]

Associate Professor Associate Residency Program Director Department of Emergency Medicine Eastern Virginia Medical School Norfolk, Virginia

ASHLEY E. BOOTH, MD [142]

University of Florida Health Sciences Center-Jacksonville Department of Emergency Medicine Jacksonville, Florida

CARL BOSE, MD [4]

Chief, Division of Neonatal-Perinatal Medicine Professor of Pediatrics University of North Carolina Chapel Hill, North Carolina

GEORGE M. BOSSE, MD [164]

Associate Professor of Emergency Medicine
Department of Emergency Medicine
University of Louisville
Medical Director-Kentucky Regional Poison Center
Louisville, Kentucky

SHARON A. BOSWELL, RN, BSN, CRNP [260]

Clinical Nurse Practitioner
R. Adams Cowley Shock Trauma Center
Baltimore, Maryland

JAMES K. BOUZOUKIS, MD [82]

Department of Emergency Medicine
Medical Center of Delaware Wilmington,
Delaware

WILLIAM M. BOWLING, MD [259]

Department of Surgery
Washington University School of Medicine
St. Louis, Missouri

WILLIAM J. BRADY, MD [85,161, 210, 245, 246]

Associate Professor
Vice Chair and Program Director of Emergency Medicine
Department of Emergency Medicine
University of Virginia School of Medicine
Charlottesville, Virginia
Medical Director
Charlottesville-Albemarle Rescue Squad
Charlottesville, Virginia

G. RICHARD BRAEN, MD [186]

Professor and Chairman Department of
Emergency Medicine State University of
New York at Buffalo Buffalo, New York

ANNE F. BRAYER, MD [204]

Assistant Professor of Emergency Medicine and Pediatrics
University of Rochester School of Medicine
Department of Emergency Medicine
Rochester, New York

JASON H. BREDENKAMP, MD [270]

Rockford Memorial Hospital Department of
Emergency Medicine Rockford, Illinois

JANE H. BRICE, MD, MPH [153]

Assistant Professor
Department of Emergency Medicine
Medical Director, Orange County Emergency Medical Services
University of North Carolina
Chapel Hill, North Carolina

JOSHUA S. BRODER, MD [86]

Assistant Professor Coordinator, International
Programs Department of Emergency Medicine
University of North Carolina at Chapel Hill
Chapel

*Deceased.

This is the seventh *Study Guide* since 1979, when the first edition was published by the American College of Emergency Physicians. The first McGraw-Hill edition was published in 1985.

The maturation of the *Study Guide* matches the development and maturation of the specialty of Emergency Medicine. As a matter of fact, the phrase 'study guide' was coined in 1979 because the scope of practice of emergency medicine was felt to be so large that no one text could possibly cover all of the conditions encountered in a busy emergency medicine practice.

Each successive edition has expanded in scope and depth. We three editors are active teachers and practitioners of emergency medicine.

We have tried to make sure that the likely, and unlikely, conditions encountered during a busy practice have been reflected in this text.

This book would not be possible without the contributions of more than 400 authors. They have incorporated evidence-based medicine into the text wherever possible. We editors have cross-checked references, and double checked drugs against standard pharmacological references.

We thank our readers who have corresponded with us to point out inconsistencies or omissions. And we thank the practitioners of emergency medicine around the world who have motivated us, and charged us with the responsibility of establishing high clinical standards for emergency medicine practice.

October 2003

ACKNOWLEDGMENTS

The authors wish to acknowledge Cinnamon Larson for her fine illustrations; David Nielsen, MD, Elizabeth Mejia-Millan, PharmD, and Kelly Summers, PharmD for helping us to review the accuracy of the manuscript; and Amy Ahlquist for her excellent administrative support.

EMERGENCY MEDICINE

A COMPREHENSIVE STUDY GUIDE

EMERGENCY MEDICAL SERVICES

G. Patrick Lilja

Emergency medical services (EMS) constitute the extension of emergency medical care into the community. Strong emergency physician leadership is essential to a safe and effective EMS system.

The current EMS system in the United States started with the 1966 National Highway Safety Act, which authorized the U.S. Department of Transportation (DOT) to fund ambulances, communications, and training programs for prehospital medical services. Coincidentally, in 1967, J. F. Pantridge began using a mobile coronary care unit in Belfast, Northern Ireland, to extend coronary care into the prehospital setting.

In 1973, Public Law 93-154 defined a goal of improving emergency medical care and EMS on a national scale. Although much has changed in EMS since passage of that initial act, the original definition of an EMS system is useful for understanding its functions. This law identified 15 elements of an EMS system: (1) personnel, (2) training, (3) communications, (4) transportation, (5) facilities, (6) critical care units, (7) public safety agencies, (8) consumer participation, (9) access to care, (10) transfer of care, (11) standardization of patients' records, (12) public information and education, (13) independent review and evaluation, (14) disaster linkage, and (15) mutual aid agreements. Thus an EMS system is the entire system in place to provide care to emergency patients from the initial call to definitive care.

In the United States, individual state EMS laws and regulations typically define levels of ambulance service capability, training requirements, equipment requirements, and requirements for physician leadership and accountability. In addition, the state health department may be the lead agency in promoting and funding EMS activity.

LOCAL ROLE IN EMERGENCY MEDICAL SERVICES

To be effective, an EMS system should be planned, organized, and operated at the local level. Local communities identify the needs and allocate resources to meet the demands for emergency care. The 15 elements of an EMS system defined by Public Law 93-154 can provide guidance in this process.

Personnel

In most urban areas, paid public safety and ambulance personnel provide prehospital medical care, but in rural or wilderness areas, citizen volunteers, park rangers, or ski patrols are commonly employed.

Training

Training begins with education of the private citizen in EMS system access, CPR, and other forms of first aid. Communications media can be used to reach large populations with the information necessary to educate citizens to respond to medical emergencies.

Currently, there are four DOT EMS training curriculum levels. These are first responder (FR), Emergency Medical Technician (EMT) basic (EMT-B), EMT intermediate (EMT-I), and EMT paramedic (EMT-P). The DOT FR course is designed primarily for individuals who may be the first to arrive at a medical emergency; typically police

officers, firefighters, first aid teams, and/or other community EMS re-ponders. This course provides instruction in CPR, spinal immobilization, bleeding control, and other basic emergency care procedures. The FR course is not designed for personnel working primarily on ambulances.

The three DOT EMT levels are designed for individuals who will function as members of an ambulance crew. Some states have additional EMT levels other than the three recognized by the DOT. The EMT-Bs have the necessary first aid skills to take care of immediately life-threatening prehospital emergency conditions. These skills include CPR, use of an automated external defibrillator (AED), and safe extrication, immobilization, and transportation of emergency victims. EMT-Bs are now being trained to assist patients in using their own nitroglycerin, epinephrine, and inhalers. There is an optional module in the DOT EMT-B curriculum on advanced airway techniques: endotracheal intubation or an advanced airway adjunct, such as a pharyngeal-tracheal lumen airway or laryngeal-mask airway. The decision to teach the optional airway module generally is made by the state EMS agency. EMT-I training includes additional skills in patient assessment but also adds such skills as intravenous therapy, defibrillation, basic electrocardiogram (ECG) interpretation, and the ability to give some cardiac medications. The EMT-I curriculum was changed recently to add medications. There are, however, some states that are still using the previous EMT-I curriculum that did not include delivery of medications. The highest level of EMT training, that of EMT-P, adds additional skills in patient assessment as well as additional background in basic medical physiology. Besides the skills of the EMT-I, the paramedics are trained in the ability to give additional medications and to have a better understanding of the pathophysiology and pharmacology needed for interventions in various medical conditions. Clearly, physicians need to be deeply involved in EMT training to ensure that knowledge and skills are being taught appropriately.

Communications

The universal emergency telephone number (e.g., 911 in the United States and Canada, 000 in Australia, 999 in the United Kingdom, and 112 in the European Union member countries) has greatly facilitated citizens' access to emergency medical care. In many systems, the answering centers have enhanced equipment (e.g., E-911) that provides automatic number and location identification as well as additional information to assist the responding personnel. However, the advent of cellular telephones has complicated this process. In some urban areas, up to 25 percent of all emergency calls are made from cellular phones. Technology is being developed to address this issue.

The emergency call is the essential front door of the EMS system; those answering the calls should have the knowledge and training to obtain initial medical information properly, dispatch appropriate personnel, and offer first aid information to the caller when appropriate. The training level for individuals answering emergency medical calls in dispatching ambulances is a curriculum called the Emergency Medical Dispatch (EMD) course. EMDs are trained to collect information in a structured manner in order to direct the most appropriate EMS response. This process is called *priority dispatch*. Information obtained by the EMD allows for the provision of basic instructions to help care for the patient prior to the arrival of EMS personnel. This process is called *prearrival instruction*.

Ambulance personnel should be able directly or indirectly to communicate with the hospital of destination. Most EMTs operate in the field under *offline* medical control, according to standing orders and

patient care protocols developed by physicians. However, there are times when EMS personnel may require *online* medical control, in which they talk directly with a physician for specific direction or orders. The EMS communications system should function to provide public access, prompt dispatch of the appropriate vehicles and personnel, timely hospital notification, and online medical control. The public should be encouraged to use the universal emergency telephone number rather than call a hospital or physician when life-threatening symptoms (e.g., acute chest pain, dyspnea, loss of consciousness, or focal weakness) occur.

Transportation

Ground ambulances have evolved from transport vehicles into sophisticated and efficient mobile patient care areas where lifesaving maneuvers can be performed. The most important aspect of ambulance design is that the attendants must be able to provide airway and venti-latory support while transporting the patient safely. Basic life support (BLS) ambulances carry equipment appropriate for attendants trained at the EMT-B level. Advanced life support (ALS) ambulances are equipped for EMT-Ps or other health care personnel capable of providing drug therapy and performing other advanced medical procedures. Ground transportation is appropriate for the majority of ill or injured patients, especially in urban and suburban areas. Air transport should be considered if the time elapsed before definitive care is important and air transport would shorten that interval.

Facilities

In general, emergency patients should be transported to the closest appropriate hospital or, if there are multiple hospitals within the same transport time, to the hospital of the patient's choice. However, if the EMS system has identified a specific hospital with better resources to treat seriously ill or injured patients (e.g., trauma center, cardiac center), the patient should be transported to that institution, bypassing closer hospitals. Several systems of categorizing hospitals exist, and this process should precede or coincide with the development of the EMS system. In a number of regions, the state has the statutory authority to designate certain specialty hospitals to receive a subset of patients (most commonly trauma patients) based on an objective review of the hospitals' capabilities. Some states and the American College of Surgeons also have developed a process to provide external verification of trauma centers. This process requires a review of hospital facilities, treatment processes, and patient outcomes to confirm that quality trauma care is in place. EMS systems are now also identifying hospitals as specialized receiving facilities that can provide emergency angioplasty for patients with acute myocardial infarction (AMI) or that have special expertise with thrombolytic therapy for acute stroke patients.

Decisions to divert patients to specialty centers have substantial health care and monetary implications. These decisions should be made in a collaborative manner for the EMS region based on clearly defined criteria.

Critical Care Units

Tertiary care facilities should be identified by every EMS system to provide specialty care that is not available in typical community hospitals. These facilities may be either within the EMS service area or, more commonly, outside the area. Usually, patients are transported initially to a local hospital for assessment and treatment and then transferred to a tertiary center. In some EMS regions, it may be possible to develop criteria for the transport of patients requiring tertiary specialty care directly from the scene to these centers. The most common reasons for tertiary care emergency transfer are trauma, neonatal inten-

sive care, high-risk obstetrics, burns, spinal cord injury, and neurosur-gical and **cardiac** care. It is not cost-effective or feasible for every community to support all these specialty services.

Public Safety Agencies

The EMS system should have strong ties with police and fire departments. Public safety agencies provide first-response services because their personnel are often the first on the scene of an emergency, and they are vital links in the delivery of emergency care. For example, police in some municipalities have begun carrying automatic defibrillators in order to improve outcomes for patients suffering cardiac arrest.¹ Conversely, EMS personnel often require support from police and fire departments to provide medical care in hazardous circumstances.

Consumer Participation

Laypersons should be represented on EMS councils. Public support, both political and financial, is necessary for a good EMS system. Two important components of a successful EMS system are lay public first aid training and the implementation of a universal telephone number system.

Access to Care

A successful EMS system ensures that all individuals have access to emergency care regardless of their ability to pay or type of insurance coverage. Often the EMS system is a patient's only point of entry into the health care system. In an effort to control health care costs, patients may be discouraged from accessing the EMS system for perceived emergencies. An important principle of EMS is that all individuals deserve timely access to the system when necessary.

A more difficult problem exists when population densities or terrain dictate longer response times for some citizens than others. EMS councils should address such inequities by providing accurate information and advice to local political entities responsible for EMS service.

Transfer of Care

Patients sometimes are transferred from one medical care facility to another either within or outside of the EMS service area. Safe transfer is an important concept, and many problems can be avoided if both the transferring and receiving medical facilities develop transfer agreements in advance. For example, the prospective agreement to accept a trauma patient decreases the time spent arranging for transfer of a critical patient. The receiving physician should be assured of receiving all relevant information about the patient on arrival. Having appropriate medical personnel accompany the patient ensures medical support during transfer.

Standardization of Patients' Records

Patient care often depends on good medical records, and prehospital records are no exception. It is desirable that all ambulance services within a specific region use a similar reporting form that can be interpreted quickly and easily by receiving nurses and physicians. It is more difficult to standardize emergency department records. However, flow sheets that are easily interpretable by receiving physicians and nurses can be used. Uniform data elements for EMS care have been developed by the NHTSA and are coming into common use.² Uniform data elements for emergency department care also have been developed by a cooperative effort among the NHTSA, the Centers for Disease Control and Prevention (CDC), and many emergency medical organizations. It is wise to design record systems that facilitate data

extraction for trauma registries, severity scoring, and cardiac arrest outcome studies.

Public Information and Education

In designing a public information program, the local EMS council should consider that the public (1) understands how the community stands to benefit from an excellent EMS system, (2) is prepared to render first aid care, (3) knows how to quickly access the EMS system, and (4) understands that patients may not be delivered to the hospital of their choice under life-threatening conditions.

Independent Review and Evaluation

Governing agencies should be assured that there is ongoing review of the EMS system. Monitoring of radio communications, review of response times, and review of patient care records are relatively mechanical methods of quality control that are implemented easily. Outcome studies of such entities as cardiac arrest and multiple trauma require considerable physician input and cooperation. The system medical director should require that mechanisms be in place to ensure and improve the quality of EMS care. EMS system access to hospital charts should be a requirement for participating hospitals, with proper controls to ensure patient confidentiality.

Disaster Linkage

The EMS system is an integral part of disaster preparedness and should be involved in planning and practice drills along with public safety agencies and others. Public safety agencies should keep the EMS system informed of potential disaster situations or hazards that may be present temporarily. Also, hospitals should be prepared to keep the EMS system informed of their capacity to receive certain kinds of patients under disaster conditions.

Mutual Aid Agreements

EMS services should develop mutual aid agreements with neighboring jurisdictions so that uninterrupted emergency care is available when local agencies are overwhelmed or unable to provide services.

Research

While not one of the original 15 elements of an EMS system, research is needed to determine which therapeutic interventions are beneficial and which are not. Unfortunately, much of what has been done in pre-hospital emergency care has been based on assumptions, many of which have not been subjected to scientific investigation. An investment in research is the key to improved EMS practice.³

MEDICAL CONTROL

A safe and effective EMS system requires considerable physician input and surveillance.⁴ Medical control can be either online (immediate and direct) or offline (indirect).

Online medical control is the provision of direct medical communication to personnel in the field either in person or by radio or phone communication. The EMS medical director may delegate this authority to other physicians who understand the protocols under which EMTs administer care. Also, the medical director may allow ambulance personnel to carry out certain standing orders when timely contact with the controlling physician is not feasible.

Offline medical control is the responsibility of the ambulance service medical director. Three main components of offline medical control are (1) development of protocols, (2) development of medical ac-

countability (quality assurance), and (3) development of ongoing education. Protocol development determines treatment procedures that prehospital personnel may perform under the medical license of the medical director. Protocols not only should address medical treatment but also should specify the use of medical devices and equipment. It is the medical director's responsibility to approve the medical devices used by EMS personnel. EMS medical protocols should be reviewed and revised to keep pace with current medical knowledge. Quality assurance requires ongoing surveillance and study of the system. Enlisting other physicians to review existing protocols and suggest improvement is recommended. Finally, the medical director is responsible for the ongoing educational needs of the prehospital care providers under his or her direction. The medical director is responsible for the quality and content of that training.

MEDICAL BASIS FOR EMERGENCY MEDICAL SERVICES

While a relatively small number of emergency physicians are involved in the direction and control of an EMS system, virtually every emergency physician deals with prehospital care in day-to-day clinical practice.

Emergency Cardiac Care

The impetus for starting paramedic ambulance programs in the United States grew out of the recognition that sudden cardiac death was the leading cause of out-of-hospital deaths in the United States. At the same time, J. F. Pantridge in Belfast, Ireland, investigated bringing the hospital to the patient's side in the form of a mobile coronary care unit to treat life-threatening cardiac arrhythmias and improve patient survival. Subsequently, it was recognized that rather than sending physicians and nurses to the patient's side, that ambulance technicians could be trained to appropriately recognize and treat many cardiac rhythm disturbances, particularly ventricular fibrillation (VF). This resulted in communities having over 20 percent of patients resuscitated successfully from an out-of-hospital cardiac arrest. Over time it became apparent that the most effective treatment for cardiac arrest was rapid electrical defibrillation for patients in VF.⁵ This observation led to the development of automated external defibrillators (AEDs) that could be used by individuals with as little as 2 to 4 h of training. Currently, the American Heart Association (AHA) recommends that AEDs be available for all individuals who may respond to cardiac emergencies and, in addition, has proposed that they be distributed widely in communities in a program known as Public Access Defibrillation. Observations from casinos and airports found that bystanders or trained security personnel could use a publicly accessible AED to obtain a survival rate of over 50 percent for victims of sudden cardiac arrest.^{6,7} With the advent of reperfusion therapy for AMI, EMS systems have attempted to identify patients in the field who may benefit from this intervention. Some systems perform 12-lead ECGs in the field and notify hospitals if the patient has ECG evidence of an AMI so that the hospital may prepare to intervene promptly on patient arrival, reducing the time needed to initiate reperfusion therapy.⁸ In addition, thrombolytic agents also may be given by paramedics; a meta-analysis of six studies indicated that prehospital thrombolytic administration decreases time to drug administration and in-hospital mortality.⁹ For patients with angina and unstable angina, there is evidence that prehospital drug therapy (nitroglycerin and aspirin) improves the patient's symptoms and reduces hospital use.¹⁰

Trauma Care

While the care of trauma patients is more controversial than cardiac care for EMS systems, there is widespread agreement that delivery of critically injured trauma patients to trauma centers

saves lives.¹¹

Trauma triage protocols are designed to bypass certain hospitals under predetermined protocols based on the mechanism of injury or the patient's physiologic status.

There is less agreement on what therapy should be given by EMS providers to trauma victims in the field and en route.¹² While the value of providing a secure airway is unarguable, the value of prehospital intravenous fluid administration has been challenged. A study from the Houston EMS system found that for hypotensive victims of penetrating truncal trauma who required surgical repair, withholding fluid and blood in both the prehospital and emergency department phases until arrival in the operating room improved survival rates, reduced the amount of blood loss, and shortened the overall hospital stay compared with patients who received fluid and blood in the field and emergency department.¹³ A case-control study from Pennsylvania for hypotensive blunt trauma victims found that prehospital fluid administration had no effect on survival or length of hospital stay.¹⁴ Thus, questions concerning the value of prehospital fluid therapy for trauma victims remain.¹⁵ Until further studies are done, emphasis remains on rapid transport and airway support of trauma victims, with intravenous fluid administration an unproven but commonly performed treatment.

Adult Medical Care

While much of initial EMS care centered on cardiac and traumatic emergencies, interest has evolved in the management of other emergencies by EMS providers as they have broadened their scope of practice.¹⁰ The management of airway obstruction and respiratory arrest is an important function of the EMS system. Paramedics can achieve airway control by endotracheal and nasotracheal intubation with a high success rate and an acceptable complication rate. Early advanced airway measures for upper airway obstruction from burns, trauma, foreign bodies, or allergic causes may be lifesaving. Neuromuscular paralytic agents, such as succinylcholine, may be used safely by paramedics in the field with appropriate instruction and close medical oversight.¹⁶

Respiratory distress in patients with chronic obstructive pulmonary disease (COPD) and asthma is a common clinical entity treated in EMS systems. Beta-2 agonists and ipratropium have been shown to be safe and effective bronchodilators for field use. Pulse oximetric studies for the evaluation of occult hypoxemia have become widely used. Devices capable of delivering continuous positive airway pressure (CPAP) have become available for use on ambulances.¹⁷ There are initial observations indicating that this treatment may add benefit to the care of patients with acute exacerbations of COPD and perhaps also for other disorders such as asthma.

Paramedics are commonly called to evaluate patients with altered mental status. Glucose is given routinely to hypoglycemic patients and naloxone to patients with suspected opioid overdose. Similarly, control of seizures with diazepam or lorazepam and airway support for status epilepticus are important EMS functions.¹⁸

Pediatric Care

With the development of pediatric emergency care as an area of interest, experts and organizations have started to review the care of children in EMS systems.¹⁹ It is estimated that 5 to 10 percent of an EMS system's volume consists of pediatric cases, and the most common pediatric emergencies are trauma, respiratory emergencies, and seizures. Cardiac arrest in children is rare (approximately 1 per 10,000 children per year in the United States), usually with a dismal outcome. The ability of paramedics to perform procedures to treat pediatric cardiac arrest, respiratory emergencies, and trauma is extremely variable and age-dependent. For most age groups, endotracheal intubation success rates are comparable with those for adults. As would be expected, endotracheal intubation and intravenous access have poorer success in infants and small children. Conversely, the benefit of these procedures

in the field for pediatric patients remains unproven. For example, a study of pediatric prehospital intubation in Los Angeles County found no increase in patient survival compared with bag-mask ventilation.²⁰

RURAL EMERGENCY MEDICAL SERVICES

Most EMS literature has been developed by urban and suburban systems, with little emphasis on rural EMS care. The rural environment provides a number of unique challenges to providers of emergency care. Long distances over which to reach and transport patients are the central issue. Specialized search and rescue capabilities may be needed for off-road and wilderness emergencies. Because of the low population density of rural areas, there is a decreased likelihood that an emergency will be witnessed and emergency aid summoned. Compared with urban and suburban populations, the population in rural areas tends to be less affluent, older, and less likely to request emergency aid unless it is truly needed.

Implementation of a universal emergency telephone number has not occurred in some rural communities. Enhanced emergency telephone service, which provides automatic location identifiers, may not be as useful in rural locations because there may not be addresses to guide emergency providers. The infrastructure for basic radio communications may not be as well developed or supported. The contraction of the health care system in the United States has caused the closure of a number of hospitals, most of them in rural areas. If an emergency facility exists, it may not have specialty or critical care services. Therefore, access to air or ground interfacility transport services is important.

Rural EMS systems face particular challenges in maintaining a cadre of EMS personnel. The volume of EMS responses in most rural communities is too low to allow for the employment of full-time EMS providers; thus rural EMS services often use volunteers or on-call part-time personnel who are paid only when called out. Volunteer and part-time personnel have limited time for initial training and continuing education and limited experience necessary for skill maintenance. Most, but not all, rural EMS services are provided at the EMT-B level. The DOT EMT-B curriculum now allows for an increased level of service by EMT-Bs that may be useful in rural areas. Some states have adopted rules allowing EMT-Bs to use certain medications such as nitroglycerin for chest pain, epinephrine for anaphylaxis, and β_2 agonists for asthma. These modifications allow a higher level of basic EMT service without having to commit rural providers to the much longer time required to obtain a higher level of certification. Innovative approaches to continuing education are also needed, particularly in isolated areas. Distance learning approaches, often in collaboration with local schools, are invaluable. Videotape conferences, satellite transmissions of lectures, and computer- and Internet-based education programs are all valuable adjuncts to rural EMS continuing education.

The provision of lifesaving services on a volunteer basis entails particular obstacles. Daytime coverage for service is a challenge because most volunteers or part-time personnel have other full-time employment. As a result, many services hire a cadre of full-time providers to respond during business hours. Dispatching volunteers from home or work directly to the scene may be one method of providing daytime coverage and reducing response times. Recruitment and retention of providers is an ongoing problem; incentives such as retirement benefits, death benefits, and scholarships for volunteers and their children are useful. Undoubtedly, the most powerful incentive for EMS volunteers is the fellowship bonds that develop within volunteer EMS agencies.

Medical leadership of any EMS system is crucial. Identification of a physician who is knowledgeable and experienced in emergency care and willing to take time away from his or her family and practice is a difficult problem for rural systems. Many systems depend on non-emergency physicians, such as family physicians

with an interest in community health or general surgeons with an interest in acute surgical care, to provide medical leadership.

PREHOSPITAL EQUIPMENT AND ADJUNCTS Daniel G. Hankins Andy Boggust

To a large extent, early emergency medical service (EMS) equipment began as hospital equipment that was extrapolated to the field; it was assumed that if something worked in the hospital, then it would work in the field. It soon became apparent that this hospital equipment did not always perform under the more rigorous conditions of out-of-hospital care. Over the last 30 years, equipment has evolved specifically for EMS that is better adapted to field use in terms of size, weight, and durability. This equipment is directed at resuscitating and packaging the patient for transport to the hospital and for maintenance of stability during emergency or interfacility transport. As the science of EMS continues to mature, more and more equipment will be scrutinized for effectiveness.¹ The four basic

questions regarding EMS equipment are: (1) Does it do the job? (2) Is it safe? (3) Does it do the job and is it safe in the field environment? and (4) Does it do the job and is it safe in the field environment in the hands of field personnel?

The nature of EMS equipment is changing due to expanded scope of practice by paramedics and the blurring of care levels between basic and advanced life support (BLS versus ALS) personnel. Equipment once considered only for ALS care is now being carried routinely on BLS ambulances (e.g., defibrillators and airway adjuncts).

VEHICLES

The equipment used in out-of-hospital care includes the vehicles and everything on them. The vehicles may be ground ambulances, helicopters, fixed-wing aircraft, or even first-response vehicles of every sort (fire engines, police cruisers, or pickup rescue vehicles). The most common vehicle used is the ground ambulance, categorized into three common varieties: (1) type I, a standard truck (e.g., pickup) chassis with a separate modular box to carry personnel, patient, and equipment; (2) type II, an enlarged van-type vehicle, and (3) type III, a van chassis with an integrated modular box on the back for medical care and equipment. In types II and III, there is physical access between the driver's and patient care compartments, as opposed to type I, where these spaces are separate.

Ground vehicles typically have warning devices (lights and siren) as part of their equipment. Unwarranted use of red lights and sirens is dangerous for the EMS crew, the patient onboard (if present), and the general public on the streets. Protocols or guidelines to limit the use of these devices only to times when they are medically indicated is important.

COMMUNICATIONS

The two-way radio is an important piece of equipment carried by prehospital providers. As the arena of wireless communication changes, EMS systems will need to adapt their communications system to best fit their needs. The spectrum of frequencies available for emergency services is limited and is shared with other industries that require wireless communications. In the United States, EMS services may use specific frequencies (*channels*) in the very high frequency (VHF, around 170 MHz), ultra high frequency (UHF, around 460 MHz), and public safety (around 800 MHz) bands. In an attempt to create more channels for users, the Federal Communications Commission (FCC) has decreased channel spacing from 25 to 12.5 kHz, and there is an FCC mandate to continue spacing down to 6.25 kHz. Although newer radio equipment can be reprogrammed to allow for the change in channel spacing, older equipment may not function correctly with this spacing. EMS systems in rural or suburban settings may have no difficulties with local communications; however, as they transport patients into urban settings and attempt to communicate with urban providers, the problem of compatible frequencies and channel congestion may develop. Urban systems may use *trunking*, where communications pathways are managed by a central processor between end users, allowing large numbers of users to share a relatively small number of communications frequencies. Trunked systems may be analog, VHF/UHF digital radio, or 800-MHz digital radio. An 800-MHz digital trunked system is popular because of the advantages of shared equipment between different providers (EMS, police, and fire), enhanced radio coverage, shared or lowered cost, and wide-area communications. The main disadvantage with all trunked systems is the cost necessary to upgrade the current system.

Many urban and suburban EMS providers are choosing cellular/personal communication systems (PCS) as a means of communications. These systems are abundant in urban settings because they are often inexpensive and easier to use. However, at times these PCS systems are congested, and there are still dead spots even in urban areas.

ELECTRONIC PATIENT RECORD

Although many vendors provide software to generate electronic medical records on different platforms (desktops, laptops, or handheld devices), there are no prospective or retrospective studies that support the use of any of these products on any given platform. This may be a catch-22 of EMS. It is difficult to do research in EMS because there are limited good data. However, platforms employing such software, which may help generate these data, are not used because there is no evidence to support their use.

Large systems with enough resources often have their own software specifically written for that system. However, smaller EMS systems often use off-the-shelf alternatives. Using one of these products may require either modification of a vendor's product (often costly) or modification of the EMS system to make the software fully functional.

Many states are in the process of or have already generated a common data set and are collecting statewide data. As noted before, these data are essential for prehospital research. Local EMS systems should have the ability to query their databases to provide the state with patient information for this common data set.

UNIVERSAL PRECAUTIONS

Every EMS provider must be protected against exposure to blood and other body fluids from patients. This includes masks, goggles, and gloves for routine use. On occasion, more protection may be needed, such as gowns or perhaps heavier gloves. This equipment should be carried on every EMS vehicle.

PERSONAL PROTECTIVE EQUIPMENT (PPE)

The equipment needed for universal precautions may not provide the protection necessary when personnel are exposed to hazardous material or biologic or chemical weapons of mass destruction. Minimum PPE for such exposure should include a filtered (HEPA, M95, N95, or chemical-specific) mask, goggles, gloves, and protective clothing. Protective clothing should be nonabsorbent and puncture-resistant (Figure 2-1).

FIG. 2-1. Personal protective equipment: filtered (HEPA, M95, N95, or chemical-specific) mask, goggles, gloves, and protective clothing.

A growing number of urban EMS providers wear soft body armor as a standard part of the uniform. Suburban and rural providers can be placed in situations that necessitate similar protection. With advances in soft-armor technology, there are now a variety of styles and levels of protection from which to choose. Although each service must consider such variables as comfort, heat, weight, and cost, for EMS providers, a combination of ballistic/stab protection is optimal.

RESUSCITATION EQUIPMENT AND THERAPEUTIC MODALITIES

Defibrillators

Defibrillators have been an essential part of prehospital care since Pantridge showed that defibrillation could be done in the field on the streets of Belfast in 1965. Early defibrillation is the most important factor in survival from a cardiac arrest. Because of this, defibrillators have gotten smaller and less costly in order to expand their use. Paramedic-staffed ALS services typically carry manual monitor/defibrillators, often with additional functions (e.g., 12-lead electrocardiogram, external cardiac pacing, and synchronized cardioversion). An increasing percentage of BLS services carry automated external defibrillators (AEDs). These devices are *shock advisory defibrillators*; AEDs analyze the patient's rhythm by computer algorithm, determines if the rhythm meets defibrillation criteria, informs the operator that a shock is advised, charges the capacitor, and delivers a defibrillation when the operator pushes the appropriate button. AEDs are designed only to shock ventricular fibrillation and very fast ventricular or supraventricular tachycardias (usually over 180 beats/min). AEDs have become so easy to use and are so effective that many health and medical organizations are promoting these devices for first-responder public safety personnel and for public-access defibrillation by laypersons.^{2^}

As mentioned earlier, AEDs are simple and relatively inexpensive. They often do not have monitor screens that display the patient's rhythm. This actually may be better because a rhythm on the screen may only serve to distract a non-ALS operator. The device should have recording capabilities in order that the cardiac arrest can later be reviewed for medical oversight and quality assurance reasons. The medical director should be involved in choosing such devices, training in their use, establishing protocols for their use, and reviewing their use afterwards for quality assurance reasons.

A defibrillator used by ALS personnel is typically a different, more sophisticated device, usually with additional functions. Defibrillation is facilitated using hands-off combination monitoring/defibrillation adhesive pads rather than with handheld paddles. These pads give better contact with the skin and decreased resistance of the skin to allow for a higher success rate of rhythm conversion. It is also safer for the operator who does not have direct contact with the patient when the shock is delivered. The ALS defibrillator has a screen for interpreting rhythms and so is also used for ongoing monitoring of patients' rhythms and may be used for countershocking rhythms other than lethal ones or pacing brady-asystolic rhythms. Additional critical-care patient monitoring can be incorporated into an ALS defibrillator: non-invasive blood pressure, pulse oximetry, end-tidal Pco₂ in intubated patients, as well as other physiologic parameters. ALS personnel can use these machines for closely monitoring very ill patients during emergent calls or interfacility transfers.

The most recent development in defibrillator technology is the development of biphasic waveforms for shock delivery (as opposed to the traditional monophasic waveform). It appears from preliminary data that these biphasic defibrillators may be more successful at lower energy levels for both defibrillation and cardioversion, but papers have been few as of yet.⁵ Every manufacturer is developing its own biphasic waveform for the defibrillatory shock. The debate and data may

become moot in the sense that soon only biphasic models may be available.

Airway and Ventilation Adjuncts

In a patient with acute respiratory failure or arrest, these devices maintain a patent airway that otherwise would have to be maintained by the paramedic. In addition, some airway adjuncts aid in preventing complications of airway management such as gastric distention or aspiration (Figure 2-2).

The simplest devices for airway management after manual airway maneuvers are the oropharyngeal and nasopharyngeal airways. These basic airway adjuncts usually are paired in the field with a simple bag-valve mask device for ventilation and will work quite well together. Ventilation with the bag-valve mask is deceptively complex and difficult for a single person to both attain a good seal with the mask and to compress the bag to produce an adequate tidal volume for the patient. It is probably more effective (especially for first-responder and ambulance personnel who do not perform the skill often) to make this a two-person task (one to maintain the seal and one to compress the bag to maintain tidal volume). Along with these adjuncts, effective portable suction devices are available to be carried to the patient's side to help clear the airway.

More advanced airway devices are used if the patient appears to need more prolonged airway management or is at greater risk for aspiration. At the BLS ambulance level, these more invasive airways include the pharyngeal tracheal lumen (PTL) airway, the esophagotra-cheal Combitube (or simply Combitube), and the laryngeal mask airway (LMA). Each of these is used in conjunction with a bag-valve mask for ventilation. These devices are great improvements over the old esophageal obturator airway (EOA) and esophageal gastric tube airway (EGTA), which both had unacceptably high complication rates and are no longer recommended for use. Both the PTL airway and the Combitube are for adult patients in full cardiac arrest. They improve the airway seal to promote better ventilation than the bag-valve mask with the oral airway and seal the esophagus off with a balloon to prevent aspiration. If either device goes into the trachea, which happens a small percentage of the time, it can function equivalently to an endo-tracheal tube. There is some evidence that the Combitube is a more reliable device than the PTL airway because the large PTL mouth balloon is more easily broken than the more robust Combitube balloon and the Combitube may be easier for basic EMTs to ventilate with.⁶

FIG. 2-2. Airway devices and adjuncts. A. Combitube. B. Pharyngeal tracheal lumen airway. C. Nasopharyngeal airway. D. Oropharyngeal airway. E. Tube exchanger. F. Laryngoscope. G. Magill forceps. H. Qualitative expiratory CO₂ detector. I. Stylets for endotracheal intubation. J. Endotracheal tube.

There are few data on use of the LMA for out-of-hospital care. It provides a seal for ventilation but may not prevent aspiration. One possible advantage of the LMA is that it is cheaper than the Combitube or the PTL airway. The PTL airway or Combitube are mostly used by BLS ambulance personnel but may be used by ALS personnel (or even by hospital personnel) as a fallback rescue device for a patient who has a difficult airway and cannot be intubated with an endotracheal tube.

The disadvantages of the PTL airway, Combitube, or LMA is that they cannot be used in small adults, children, or patients who are somewhat responsive with a gag reflex. Endotracheal intubation is the "gold standard" for airway management in all patients and is especially useful in patients in whom the other airways cannot be used. The majority of ALS systems use endotracheal intubation as the airway of choice for patients in respiratory failure or with an unprotected airway. Different-sized endotracheal tubes, laryngoscope blades with handles, stylets, lubricant, and Magill forceps should be carried in the airway kit to handle the variety of patients encountered. Tube-exchanger catheters or gum bougies also can aid in placing a difficult endotracheal tube.

The basic EMT curriculum has an optional module for endotracheal intubation training. Therefore, intubation equipment may be found on some BLS ambulances around the country. Increasing the number of ambulance personnel in need of endotracheal intubation training in an EMS system may cause logistic problems for the medical director. It is sometimes difficult to obtain adequate live intubation opportunities for the personnel in an EMS system in order to maintain skills. Some studies have shown that basic EMTs do not maintain endotracheal intubation skills and have low rates of successful completion.^{7,8} This would suggest that intubation remain an ALS skill.

Another intubation-related modality that has bearing on the equipment carried on an ambulance is rapid-sequence intubation (RSI). Critical-care transport services have been doing RSI for more than a decade, but now this is being done in some ALS systems as well with good success. RSI raises the level of training, judgment, and psychomotor skills needed by the paramedic but has the advantage of being able to secure more difficult airways. In addition to the usual equipment required for intubation, RSI requires these ALS services to carry the drugs needed for sedation and paralysis.¹¹ RSI increases the need for oversight and vigilance by the medical director if this treatment modality is added to the ambulance providers' armamentarium.⁹

Vascular Access Equipment

The equipment used to establish intravenous access is the same as at the hospital: tourniquets, cleaning agent, intravenous (IV) catheters, IV fluid bags, and IV tubing. ALS ambulances use this treatment modality for fluid resuscitation and for administration of drugs. In general, vascular access for drug administration is completed as soon as possible after the patient is assessed and it is determined that pharmacologic intervention is needed. For fluid resuscitation, usually in trauma patients, vascular access usually is started en route to the hospital after the patient is immobilized, unless there is prolonged scene time due to extrication. This is to avoid prolonged scene times that may be detrimental to a trauma patient who may need intervention in the operating room. In any event, the amount of fluid that can be administered during transport is modest and may not be physiologically significant. There is also evidence that aggressive fluid resuscitation of hypovolemic trauma patients is detrimental in that it may increase morbidity and mortality by enhancing exsanguination from vascular or organ injury requiring operative intervention. The difference between hospital and EMS usage of IVs is that the medical director must provide guidelines for when and how to institute vascular access to allow appropriate interventions at the appropriate time. Use of vascular access should be examined in the quality assurance process in an ongoing manner. Sternal interosseous devices for establishing vascular access in patients with no other sites have been developed recently; it is

too early yet to determine how useful these devices will be in out-of-hospital care.

Vascular access is also used by some U.S. BLS services for fluid resuscitation. Since BLS services are usually more rural and have longer transport times, fluid resuscitation may be more beneficial in these rural hypovolemic trauma patients who tend to have blunt rather than penetrating trauma.

Military Antishock Trousers (MASTs)

The MAST garment is a one-piece layered device made of polyvinyl fabric that encircles the legs and lower abdomen and can be inflated to apply external pressure to the enclosed body parts. The legs and lower abdomen are each enclosed separately, allowing access to the perineal area. The three compartments are fastened with Velcro. Some versions of the garment allow separate inflation and deflation of each compartment. The MAST is usually inflated with a foot pump, and some are equipped with an interposed inflation pressure monitoring gauge. Internal pressures of the suit are limited by a pressure-relief valve (set at 104 mm Hg) and the ability of the Velcro fastener to withstand stress. Pulmonary edema is an absolute contraindication to use of the MAST garment. Relative contraindications for MAST use are pregnancy, impaled objects, evisceration of the abdominal contents, and thoracic and diaphragmatic injuries.

The MAST garment has fallen into considerable disfavor because there is little evidence that it improves survival in hemorrhagic shock after trauma, and it may even be detrimental in penetrating thoracic trauma with short transport times. It is not clear whether MASTs may be useful in other situations or in disease entities other than trauma. For instance, they may be useful in blunt trauma patients with long transport times, in ruptured abdominal aortic aneurysms (AAA), and in pelvic fractures. A position paper from the National Association of EMS Physicians (NAEMSP) categorizes possible indications for MAST use into class I (useful and effective), class IIA (weight of evidence favors usefulness and efficacy), class IIB (may be helpful, probably not harmful), and class III (not indicated); the only class I intervention for MASTs was hypotension due to ruptured AAA.¹⁰ It may be reasonable to keep the MAST garment on ambulances for now, especially on rural services, with medical oversight on its use.

SPINAL IMMOBILIZATION

Preservation of the integrity of the spinal column and spinal cord is of paramount importance in the field. The first person to assess the patient should immobilize the cervical spine immediately and simultaneously perform a modified jaw thrust to open the airway, if necessary. Manual stabilization of the neck is not released until the patient has been transferred and securely strapped to a board. Short or long boards, either alone or in combination, are used to immobilize the spine depending on the initial position in which the patient is found by the EMT or first responder.

Carrying boarded patients takes a heavy toll on the backs of EMTs and paramedics. Evaluation of the boarded patient is more expensive and time-consuming in the emergency department because of the need to clear the cervical spine. A reasonable approach is to set criteria down in protocols/guidelines written by the medical director to clinically clear the spine in the field. A patient with no neck pain or tenderness (neck pain must be defined liberally and include stiffness or "feels funny"), not in the extremes of age (below age 10 or above age 65), no altered sensorium (no drugs or alcohol present, no head injury), and no distracting injuries (long bone fracture, abdominal or chest injury) may be cleared in the field because there is an extraordinarily low probability of neck injury.¹¹

Spinal Boards and Cervical Collars

Spinal boards, either short or long, are made from plastic or wood to provide a rigid surface on which to bind the patient to ensure that no move-

ment occurs in the cervical, thoracic, or lumbar spine. Straps are used to secure the patient for transport. Some boards are provided with firm rubber blocks on either side of the head and straps to go across these blocks to keep the head steady between them. Blanket rolls secured to the board with tape are also effective head blocks. A popular and effective variation of the short board is the Kendrick extrication device (KED board), which consists of slats of rigid material bound together by heavy cloth. This board immobilizes the cervical spine, wraps partly around the patient, and is then strapped the rest of the way around the thorax and around the thighs for secure immobilization. The patient can be lifted by the KED straps, allowing for easier and safer extrication from a vehicle upward, if this is the appropriate way to remove the patient.

Rigid cervical collars are more accurately called *cervical extrication devices*. Multiple types are used in the field, such as the Philadelphia collar, the Stiffneck, and the Neck-Loc. The collars come in two asymmetric pieces, which are used and marked for back and front, or as a single piece that is folded into the correct shape. By themselves, collars are not adequate for cervical immobilization but require additional lateral support to avoid movement in that direction. For adequate immobilization, the patient needs to be strapped on the back board and secured with head blocks and head straps. Once the patient is well secured to the board, the collar does not add a significant amount of stabilization and actually can be removed without compromise of the spine; however, it is often left in place for added protection. Patients with mandible or soft tissue neck injuries probably should not have a collar applied because of the potential for airway compromise, which could be masked by the collar. Newer collars have openings in the front to allow observation of the trachea and jugular veins, but this may not be adequate for observing other neck areas. Soft cervical collars are not adequate or appropriate for out-of-hospital care.

Sequence of Spinal Immobilization

Prehospital personnel are taught to have a high index of suspicion for spine trauma. If the patient is sitting in a car after an accident and is stable from respiratory and circulatory standpoints, the short spine board and rigid cervical collar or KED are first used to get the patient out of the vehicle safely and onto a long spine board. If the situation at hand is a critical one because of the patient's condition or the threat of hazards such as chemicals, fire, or water, the patient can be extricated more rapidly using only the cervical collar without the short board or KED. After applying the cervical collar, the patient is carefully rotated out and slid onto the waiting long board.

At a non-critical scene, when the patient is still sitting in the vehicle, one EMT secures the neck with his or her hands and applies the necessary airway maneuvers, while the second EMT applies the rigid cervical collar. The short board is then slid in behind the patient, and the patient is strapped to the short spine board. (Short boards are not used if the patient is not seated in a vehicle.) The first EMT maintains manual stabilization of the neck until the patient is secured to the short board. The patient's head and trunk can then be rotated around as one unit and slid directly on to the long board positioned on the car seat or on the ambulance cot. The MAST garment, if needed, is often already placed on the long board underneath the patient. The patient is then strapped to the long board and then to the cot. A properly boarded patient can be turned on the board or even stood on end if necessary to move the patient to the ambulance. If the patient vomits, for instance, the board can be partly log-rolled up to prevent aspiration.

Because of the difference in relative size and positions of head and body, adults and children need slightly different positioning on a backboard. An adult needs more padding under the head, whereas a child needs more padding under the body to maintain neutral neck position.

If a patient is walking at the scene when the paramedical personnel arrive but complains of neck pain, the patient can be boarded from a standing position. If the patient is lying on the ground when the EMTs arrive, the patient can be carefully log-rolled by several attendants onto a long backboard.

Immobilization on a rigid board produces midline cervical pain and tenderness, so examination and radiographs should be done promptly on arrival.¹² Radiographs can be done without difficulty through short and long boards. In general, patients should not be removed from immobilization until the spine has been cleared clinically and roentgenographically. Transfer from the hard out-of-hospital board to a padded board at the hospital is desirable if the patient may spend prolonged time immobilized.

Football Helmet Removal

The National Athletic Trainer's Association (NATA, www.nata.org) and the Inter-Association Task Force for the Appropriate Care of the Spine-Injured Athlete have developed guidelines for the prehospital care of athletes with potential spine injury. These guidelines recommend that the face mask of a football helmet should be removed at the earliest opportunity, before transportation and regardless of respiratory status. However, because a properly fitted football helmet with shoulder pads holds the head in position of neutral spinal alignment, field removal of these devices is not recommended. It is recommended that the helmet and shoulder pads remain on as the athlete is immobilized and transported on a rigid backboard. Simultaneous removal of the helmet and shoulder pads should be done after clinical assessment and radiographs at the hospital, although radiographs may have to be repeated after equipment removal.¹³

Removal of football shoulder pads and helmet requires at least four individuals to maintain spinal alignment.¹⁴ One individual stands at the head of the bed to stabilize the patient's head, neck, and helmet. All straps and laces that secure the pads to the torso and arms are cut, not unbuckled or unsnapped. The laces or straps over the sternum are cut, allowing the right and left anterior portions to be spread open exposing the chest. The posterior portion of the shoulder pads are kept in place to maintain spinal alignment with the helmet. Another individual cuts the chin strap from below while standing beside the patient's chest. Accessible internal padding should be removed from inside the helmet and any air bladders deflated. The individual standing alongside the patient's chest then reaches up into the helmet to stabilize the head by placing a hand with fingers and thumbs spread alongside the jaw, mastoid region, and occiput.

Two additional individuals stand alongside the patient's chest and place their hands directly on the skin in the thoracic region. On command, the patient is lifted slightly, with all four individuals maintaining spinal alignment. The individual standing at the head of the bed can remove the helmet by a slight forward rotation to slide it off the occiput. Slight traction or anteroposterior motion may be necessary, but care should be taken not to move the head and neck unit. Attempting to assist removal by pulling on the ear holes tightens the helmet in the forehead and occipital regions and does not help. The posterior portion of the shoulder pads is removed, and the patient is lowered. A rigid cervical collar can then be placed.

Other Athletic Helmets

Studies with standard lacrosse and ice hockey helmets also support the principle of maintaining spinal immobilization by leaving the helmet on and securing the patient to a rigid spine board for transport from the field to the hospital. Because of variations in helmet design, this principle cannot be extrapolated to other circumstances.¹⁵

Motorcycle Helmets

Because motorcycle helmets do not fit snugly on the head and are not worn with shoulder pads, they do not maintain a neutral spine position when the patient lays down on a flat surface. Therefore, motorcycle helmets should be removed in the field. The two-person technique, one above to remove the helmet and one below to reach up inside to stabilize the mandible and occiput similar to football helmet removal is recommended.

EXTREMITY IMMOBILIZATION

Most fractures encountered in the field are splinted for patient comfort and ease of transport. Air splints or circumferential bladders that are inflated by mouth are adequate for most distal fractures of the upper and lower extremities. In hot weather, air splints can be difficult to remove because they stick to the skin. It is better to use an air splint with a zipper and powder the inside for easy removal. The MAST garment can function as an air splint for one or both lower extremities. Other splinting possibilities include simple sling and swathe, tying the legs together with cravats to splint one injured leg with the other normal one, or using a pillow wrapped around an extremity and secured with tape. A pillow splint is comfortable and secure for the patient either out of hospital or in the emergency department. Other splints are available on the market, such as vacuum splints, but they add cost with perhaps no clearcut advantages over older, cheaper splinting methods.

Traction Splints

Pelvic fractures and fractures of the femoral shaft are potentially life-and limb-threatening. Field or emergency department stabilization of pelvic fractures is difficult; the only effective method is the MAST garment with all compartments inflated. Radiographs can be performed through the MAST garment.

Fractures of the femur can damage vessels and nerves when bony fragments move. Stabilization in the field is imperative to minimize blood loss and soft tissue damage. While MAST garments are used often to stabilize femur fractures, they do limit patient assessment and cannot reduce the fracture. The femoral traction splint is the preferred device for femur fractures.

Several leg traction splint variations are available for use. The two most commonly used types are the Hare (Dyna Med) splint and the Sager (Minto Research and Development, Inc.) splint. Other traction splints (Thomas Ring, Donway, and Klippel) are used less commonly. The underlying mechanism is the application of traction by a hitch on the ankle against resistance when the splint impinges proximally on the pelvis. The padded proximal end of the Hare splint abuts the is-chial tuberosity (Figure 2-3). The proximal end of the Sager splint (Figure 2-4) rests against the pubic symphysis. These splints cannot be used if a pelvic fracture is suspected because the pressure on the pelvis may further displace a fracture and cause more bleeding. Another contraindication to traction splint use is the presence of a hip dislocation.

Leg traction splints also may be used for tibial shaft fractures. Traction splints should not be used for fractures near the knee

FIG. 2-3. Hare traction splint.

because longitudinal traction may damage neurovascular structures in the

FIG. 2-4. Sager traction splint.

popliteal region. Traction splints for the tibia should be reserved for angulated or displaced fractures; otherwise, an air splint, a pillow splint, or a MAST garment would suffice.

At the scene, clothing is removed, and the extremity is assessed for injury and distal neurovascular function. If the Hare is used, the proximal half ring is placed in the crease of the buttocks against the ischial tuberosity. Traction is placed on the ankle with the padded ankle strap by one rescuer while the splint is strapped to the leg. The ankle strap is then attached to a ratcheting mechanism, and traction is tightened (see Figure 2-3). If a Sager splint (see Figure 2-4) is used, the splint is placed on the medial side of the limb up against the groin. The padded ankle hitch is applied, and traction is applied until malalignment is reduced and pain is relieved. Elastic straps are then applied to hold the splint to the leg.

The Hare splint can be longer than an ambulance cot when fully extended, and care needs to be taken when closing the rear door of the ambulance. The Sager splint is shorter than the Hare splint, and one Sager splint can be used to splint both legs simultaneously. The Sager splint is less bulky and therefore takes up less room in an ambulance or a helicopter, which can be very important in the latter.

PHARMACEUTICAL EQUIPMENT

Another area where practice is becoming blurred between BLS and ALS is in the realm of medications. The new basic EMT curriculum has modules on certain classes of pharmaceuticals to prepare basic EMTs for helping patients administer their medication in a limited fashion. These include such things as nitroglycerin for chest pain, inhaled beta agonists for bronchospasm, glucagon for hypoglycemia, and epinephrine-preloaded injections for anaphylaxis. These scenarios occur when the patient already has the medication and the EMT is simply assisting; the drugs are not carried on the ambulance. Some states have gone beyond this and allow limited carrying of medications on the BLS ambulance. The drugs carried by ALS services are more extensive, but it must be emphasized here that out-of-hospital pharmaceutical interventions are limited to a few that will make a real difference before the patient gets to the hospital. The drugs that can make a real difference when administered by a paramedic include oxygen for hypoxia; glucose for hypoglycemia; nitroglycerin for chest pain and to decrease afterload on the heart; inhaled beta agonists for bronchospasm; naloxone for suspected narcotic overdose; morphine for pain; benzodiazepines for seizures, extreme agitation, or intubation; furosemide for fluid overload; epinephrine for cardiac arrests and anaphylaxis; and lidocaine, magnesium, and amiodarone for cardiac arrest. Adenosine and diltiazem are useful for rate control of the various

tachycardias. Calcium and sodium bicarbonate are helpful for suspected or known hyperkalemia. In some systems, paralytic drugs (succiylcholine, vecuronium) are used for RSI along with sedating agents.

THE FUTURE OF EMS THERAPEUTIC MODALITIES

Small portable laboratories are already being used during critical-care transports. Most ALS services already use glucometers, but the portable laboratory or similar device would allow for other determinations in the field: low hemoglobins, high potassiums, high calciums, and high P_{CO_2} readings. Several companies are working on bloodless analyzers for glucose, electrolytes, and hemoglobin. While it is clear that these devices can be used in the field, it is not yet clear if the laboratory value obtained has any impact on out-of-hospital care or patient outcomes.

If proved safe and effective, oxygen-carrying resuscitation fluids (blood substitutes) may be used eventually in the out-of-hospital care arena. The roles of EMTs and paramedics are changing. Perhaps paramedics will be giving immunizations or suturing in the field. Different roles will require different equipment on the vehicle. The vehicle of the future may not look much like its current counterpart. Perhaps the paramedics will respond in a nontransporting vehicle such as a smaller truck, and the transporting vehicle will come to the scene only if asked to respond after the paramedics evaluate the situation. Digital video cameras can be used to send live visual information back to the medical control physician in those unusual complicated circumstances where the paramedics need acute advice. All these options for treatments, devices, and expanded scope of practice will need to be evaluated carefully, with physician participation, to determine their indications, usefulness, and mode of implementation.

AIR MEDICAL TRANJ

C. Keith Stone Stephen H.
Thomas

Air medical transport consists of helicopter (or rotor-wing) and airplane (or fixed-wing) transport serving as an important component of emergency medical service (EMS) systems for prehospital care and interfacility transport. Rotor-wing and fixed-wing aircraft have different capabilities and advantage/disadvantage profiles. These specialized vehicles offer fast speeds, ranging from 100 to 200 miles per h for helicopters to over 500 miles per h for airplanes, but planning for appropriate vehicle use involves many other logistic factors as well as speed. While many ill and injured patients can be transported safely by ground, air medical transport provides added medical assessment and care capabilities beyond those of the paramedic-staffed ground ambulance. Guidelines for the use of air medical transport exist, but field EMS personnel and physicians involved in transfer decision making should be able to consider situational circumstances to determine the appropriate transportation mode.

With the occasionally important exception of ground transport legs (e.g., from a landing zone to the patient or from an airport to the hospital), air transport modalities are not limited by traffic or road quality. Weather can be an operational limitation, particularly for helicopters. Service radii differ among various helicopters and between helicopters and fixed-wing craft, but as a general rule, fixed-wing transport is considered when weather is bad or when transport distances exceed 150 to 200 miles.

The complexity of air transport far exceeds the simple act of loading a patient onto an airborne vehicle. National organizations such as the Air Medical Physician Association (AMPA), the Committee on Accreditation of Medical Transport Systems (CAMTS), and the National Association of EMS Physicians (NAEMSP) have published texts, position statements, and guidelines covering aspects of air medical transport. The AMPA (www.ampa.org) *Air Medical Physician Handbook* is a particularly helpful resource for medical issues. The CAMTS (www.camts.org) accreditation standards address medical, aviation, organizational, and operational issues. NAEMSP (www.naemsp.org) has created detailed position statements and guidelines addressing helicopter EMS (HEMS) trauma and nontrauma triage criteria as well as training of physicians involved as air medical crew or medical directors.

The effectiveness of air medical services is enabled by attention to myriad factors that come into play before, during, and after actual patient transport. The transport service should disseminate protocols guiding appropriate triage, and the program's communications personnel (as well as its physician consultants) should be versed and available for rapid decision making as to appropriate vehicle use. Ongoing training of referring agencies should occur to ensure safe and efficient operations during air transport service arrival (e.g., securing of landing zones) and transition of patient care to the flight crew (e.g., loading of patients onto the aircraft). Rigorous training programs, covering both cognitive and procedural skills, enable flight crews to provide a high level of intratransport care. In-flight communications capabilities should include the ability of the air medical crew to speak with medical control physicians, as well as arrange for any change of plan (e.g., direct transport to the operating suite) necessitated by patient condition. Some posttransport issues include utilization review, continuous quality improvement, and flight crew participation in continuing medical education conferences in which their patients are discussed. In

terms of the "big picture," the air transport program should be integrated into the EMS system plans for both primary (i.e., scene response) and secondary (i.e., interfacility) missions. Because of their role in disaster operations, air medical services should be integrated into regional disaster plans.

HELICOPTER TRANSPORT History and Aviation Issues

The first use of rotor-wing aircraft for evacuation of wounded occurred in Burma during World War II, but large-scale use of helicopters commenced with the transport of 20,000 soldiers during the Korean War. The experience in Korea led to further development of rotor-wing evacuation techniques in Vietnam, with hundreds of thousands of soldiers airlifted to medical care. Inevitably, the success of military helicopter evacuation translated into enthusiasm for development of civilian HEMS programs with the founding of the first program in the United States in Denver in 1972. HEMS grew rapidly thereafter, with approximately 200 programs in the United States and over 500 programs worldwide by 2002.

Individual hospitals or hospital consortia run most U.S. civilian air transport programs. Since helicopters are expensive (ranging from \$750,000 to over \$5 million) and other aviation needs (e.g., maintenance, pilot training) are also resource-intensive, most programs lease their helicopters from vendors. The air medical program typically provides and equips communications and medical personnel, whereas the aircraft vendor supplies the helicopters, pilots, and maintenance personnel. Though costs vary depending on geographic region, patient case mix, equipment and aircraft used, and even the methods used for their calculation, annual operating costs for a rotor-wing service typically exceed \$2 million.

Safety is an overriding consideration for air transport. Optimization of safety begins well before an actual air transport, with training of the flight crew and of those who interact with them at scenes and hospitals. Training is especially important for scene responses, in which the helicopter may be landing in an unknown area with more nearby obstacles (e.g., wires, trees) than the hospital helipad. Scene setup (depending on the aircraft, an area of up to 100 X 100 ft is required) and demarcation, as well as safety of nearby personnel, must be taught to ground EMS services and others who call for HEMS transport. Some relevant rules include the following: (1) The aircraft always should be approached from the front, where the pilot can see approaching personnel and can then acknowledge their presence and motion them into the helicopter, (2) when rotors are turning, non-flight team personnel should approach the aircraft only with escort from a flight team member, (3) a rotor-wing aircraft should never be approached from the rear because the turning tail rotor is virtually invisible, and (4) since landings and takeoffs are the most likely times for adverse incidents to occur, ground personnel need to be well clear during these operations.

In addition to providing training for referring agencies, HEMS pilots and medical crew should undergo both initial and recurrent safety training. For added protection, most HEMS programs have followed the lessons of the military experience and adopted injury-prevention maneuvers such as the use of helmets and fire-resistant clothing. As another safety issue, the pilot should be "blinded" to the nature of the call during mission planning; this eliminates introduction of acuity-related subjectivity as the pilot considers whether the mission should be accepted. During a mission, the pilot has chief responsibility for safety, but the medical crew also should participate by maintaining a sterile cockpit (e.g., no nonaviation dialogue) at appropriate times and by pointing out obstacles or other aircraft.

Safety is partially behind the transition of HEMS programs from single-engine helicopters with visual flight rules (VFR) capability to

twin-engine helicopters that can fly under instrument flight rules (IFR) conditions. The latter aircraft have greater lifting capacity, range, and speed and usually can execute controlled landings in the event of failure of one engine. A VFR aircraft can fly only during good visibility, whereas IFR aircraft operate safely in poorer conditions; both comply with visibility limitations imposed by the Federal Aviation Administration (FAA), but the IFR helicopter has fewer restrictions. If the pilot unexpectedly encounters bad weather during a flight, an IFR helicopter (as compared with a VFR aircraft) has a better chance of completing the mission successfully and safely. Due to the complexity of IFR operations, some programs (especially those with frequent bad weather periods) have elected to use two-pilot IFR.

Air medical programs operate under rules established by the national aviation authority—in the United States, the FAA. Additionally, the industry itself has set forth stringent standards under the auspices of CAMTS. On request, CAMTS performs site visits of air medical programs to certify that they comply with strict safety and operational (as well as clinical) standards. As of 2002, nearly 100 U.S. transport programs (including both rotary- and fixed-wing services) were accredited by CAMTS.

The Air Medical Crew

The primary considerations with regard to medical members of the flight crew are background (i.e., crew configuration) and training. While there are few absolutes with regard to optimal configuration, it is clear that initial and recurrent training are at least as important as the credentials of the flight team members.

The air medical team can have multiple compositions: nurse-paramedic, nurse-nurse, nurse-physician, or nurse-respiratory therapist. Further subdivisions also can be made. For example, should transport nurse hiring focus on those experienced in emergency department care, intensive care unit practice, or both? Even within the physician crew category, there would appear to be a wide difference—without casting aspersions on either party—between the capabilities and expertise of an anesthesiologist on a German HEMS unit as compared with those of a junior emergency medicine resident in a U.S. service. These differences may be one reason that the literature has failed to answer definitively the seemingly simple question of whether a physician should be on board the helicopter. Though there are a few studies that suggest outcome improvement associated with physician staffing of HEMS programs, most experts (at least in the United States) agree that physicians are not a necessary component to HEMS crews, and individual program staffing configurations generally have remained stable during the ongoing debate on optimal team makeup.^{1,3}

For a number of reasons, it is unlikely that further efforts to define the optimal crew configuration will result in a consensus. The capabilities of most U.S. nonphysician crews represent an *extended scope of practice*. For instance, flight paramedics and/or nurses frequently are credentialed to perform such procedures as neuromuscular blockade-assisted endotracheal intubation and cricothyrotomy. This example of extended practice scope is important, given the importance of prehospital airway considerations and the fact that flight crews represent a highly trained group with particular expertise in this area. This level of achievement is reflected in part by the 98 percent success rate for airway establishment by the nonphysician personnel for one air medical program during a 6-year period.⁴ This ability of nonphysicians to perform advanced procedures—and to perform them well—blurs the procedural skills demarcation between physician and nonphysician crew. Thus crew configuration-based outcome analyses often emphasize assessment of a more subjective (e.g., cognitive) physician contribution; these contributions are inherently difficult to quantify or associate with patient survival.^{1,2}

At this time, the best recommendation with regard to crew configuration is for programs to continue to do what works for them; the rel-

evant literature is not of sufficient strength to prompt undertaking major changes toward any single model. With this in mind, some crew configuration guidelines have relatively widespread applicability. As a good starting place, the mission profile of the HEMS program should be a consideration in determining optimal staffing. The staffing needs of a program performing primarily interfacility cardiac transports differ from the needs of a program transporting mostly trauma scene patients. Most U.S. programs perform a variety of scene and interfacility missions for trauma and nontrauma indications, so the nurse-paramedic configuration, combining the complementary skills of prehospital and hospital-based practitioners, is most popular in this country. Some transport population heterogeneity can be addressed by the accommodation of extra crew members (e.g., neonatal nurses, intra-aortic balloon pump technicians) when logistics allow.

Regardless of the background of the air medical crew, initial and recurrent training in both cognitive and procedural skills is necessary to ensure an optimal level of care. Organizations such as CAMTS and NAEMSP have promulgated education and training guidelines for medical crew, as well as medical directors, of air transport programs. In addition to the considerations (e.g., airway management) applicable to acute-care provision in any setting, education of the air medical crew must address issues specific to transport in the helicopter (or fixed-wing) setting.

Environmental Factors of Air Transport

Patient care in any transport vehicle (including a ground ambulance) differs from that provided while the patient is on a hospital stretcher. Vehicle vibrations, bumpy rides, noise, physiologic stress, ergonomic constraints, and motion sickness are among the factors that can affect care. The higher acuity of air-transported patients, with the attendant need for more monitoring and interventions, is probably behind the increased focus on vehicle-related patient care limitations of air (as opposed to ground) vehicles. However, many of the same constraints probably apply to both types of transport, and even absent speed issues, there are some vehicle considerations in which helicopters may be preferable to ground ambulances (e.g., smoothness of the ride for a patient with a spinal column injury).

The impact of most vehicle-related issues in HEMS can be eliminated or at least reduced. Some solutions are easy (i.e., visual rather than aural alarms on ventilators), but flight crew must learn to "work around" other limitations (e.g., perform preflight intubation on patients who appear likely to deteriorate). Some problems will be specific to a service's particular aircraft, mission profile, or crew background; individual program patient care protocols thus should take into account the service's equipment and personnel-related capabilities and limitations.

One transport-related issue that cannot be avoided is the question of altitude and its potential effects on the patient and the crew. In the absence of unusual circumstances (i.e., ground transport over a mountain pass), these considerations are not problematic for ground transport. In fact, altitude considerations vary with location—a Denver-based program has concerns that are different from those of a Miami service. Environmental conditions also have an impact on altitude considerations, since aircraft operating under IFR frequently fly at higher altitudes than those operating under VFR. Of course, fixed-wing transports have more pronounced altitude considerations.

Helicopter (or fixed-wing) altitude and environment are known to have potential effects on patient pathology as well as the crew's ability to monitor and care for the patient. Helicopters generally transport patients at about 1000 to 3500 ft above ground level (not necessarily sea level), although sometimes these altitudes are increased for IFR flights or for clearing of obstacles or terrain. Therefore, the altitude-related problems tend to be mild, as is the case for hypoxemia, and/or relatively easily overcome, as are the cases with dehydration and cold temperatures. As noted previously, however, geographic differences are

important; some western U.S. programs fly with supplemental oxygen for the medical crews.

Pressure-related problems related to Boyle's law may represent the most important consideration for helicopter-transported patients. For example, even the relatively low transport altitude range for HEMS may affect patients with certain diagnoses (e.g., decompression sickness, cerebral arterial gas embolism) or instrumentation (e.g., tamponading devices for esophageal variceal hemorrhage). In some cases, understanding of altitude issues is important for provision of prophylactic care. To minimize aspiration risk, gastric intubation should be performed for unconscious patients transported by air. Alternatively, understanding of the relevant science can be employed to prevent over-reaction to potential barometric risks. The best example of this is the fact that not all patients with small pneumothoraces (i.e., who do not otherwise require tube thoracostomy) require pretransport chest decompression simply because they are to be transported by air.

CLINICAL USE OF HELICOPTERS

The roots of HEMS are clearly in the trauma arena, and trauma transports still constitute a major portion of helicopter transports for most programs. However, with more diagnoses becoming time-critical and in part due to medical care regionalization, helicopters are being used increasingly for noninjured patients. There are many logical schemes (e.g., adult/pediatric age group, scene/interfacility mission type) for categorization of HEMS transports, but an attempt to incorporate evidence-based information is perhaps best aided by parsing HEMS use into trauma and nontrauma diagnostic categories. Some issues, primarily logistic in nature, can be applied (at least in part) to both patient groups, and therefore, these are considered first.

Logistics and HEMS Utilization

Some general logistic factors have been mentioned already, but this type of detail is a prime example of information often best considered on a case-by-case basis. For example, if a mildly ill or injured patient requiring evacuation is miles away from road access, then HEMS is likely the best transport choice. This accessibility issue can be broadened to complications (e.g., traffic conditions) other than topography.

Time and distance factors, discussed earlier in relation to triage to rotary- or fixed-wing aircraft, come into play in determining whether air transport is indicated at all. A severe trauma or medical situation in an urban area, close to a major hospital, does not present the same vehicle triage implications as would the same situation occurring in a rural area—either at a small hospital or at a trauma scene—many miles from a major hospital.

A general logistic indication for helicopter use is whether delays involved in ground transport are likely to affect the patient adversely. Some logistic prompts for helicopter consideration, used primarily for scene trauma but also for other selected circumstances, include (1) lengthy transport time for ground ambulances to reach the tertiary center, (2) ground vehicle transport time to the local hospital exceeds the time required for helicopter transport to the tertiary center, and (3) for entrapped trauma patients, extrication time is expected to exceed 20 min. In some cases, HEMS is used because local ground EMS personnel lack the expertise requisite to providing the indicated level of intratransport care. Another important consideration is whether a region's ground EMS system can provide transport to the receiving tertiary center while still maintaining the ability to cover their base area with appropriate ALS care.

HEMS Use in Trauma Patients

There is no easy solution to the problem of designing helicopter trauma response guidelines that are sufficiently sensitive that nearly all appropriate patients are responded to, yet do not result in over-triage. Various anatomic, physiologic, and mechanism criteria

have been tested without agreement on any detailed protocol. National organizations have used the extant triage literature to generate consensus guidelines intended to aid localities in designing HEMS triage criteria optimally suited to their needs and resources. Reasonably appropriate triage is achievable when local ground EMS providers use such guidelines in addition to clinical judgment.⁵ Critical to the process, especially for trauma scene response, is retrospective utilization review, whereby ongoing educational efforts strive to maximize appropriate HEMS use while minimizing over-triage.

There is one group of trauma patients—those in traumatic cardiac arrest—for whom air medical scene response has shown a very low rate of resuscitation and essentially zero survival.⁶ Most HEMS programs have their crews accompany traumatic arrest patients by ground to the nearest facility. Outside sporadic clinical situations (e.g., hypothermic cold-water drowning in a child), there is no benefit to loading an asystolic trauma patient onto the aircraft.

After the initial triage response decision, the larger issue is whether HEMS actually improves outcome for *any* injured patients. Disagreement over this question is evidenced in the medical literature.

One tool commonly used to compare air and ground transport is the TRISS method. This methodology incorporates physiologic (Trauma Score), anatomic (Injury Severity Score, or ISS), and age (55 years as cutoff) as independent variables to predict mortality using the multivariate logistic regression model (with *p* coefficients derived from a large trauma database) that then can be compared with actual mortality. Studies assessing HEMS patients' survival versus that predicted by TRISS can incorporate a ground control group by simultaneously evaluating whether ground-transported patients' survival was equivalent to that predicted by TRISS.

TRISS methods have provided argument for blunt trauma mortality benefit associated with HEMS use, but there have also been no-benefit studies. The most commonly cited study that failed to identify a benefit associated with HEMS transport was conducted in London, England.⁷ The authors analyzed scene transports to either a specialized trauma center or one of 19 regional nontrauma centers and concluded that there was little, if any, HEMS-associated benefit. However, further study in the same transport service during the same era but assessing only patients transported to specialized trauma center care reached an opposite conclusion: 4.2 additional lives were saved per 100 HEMS transports.⁸ This difference in results likely was due to improved methodology and the use of *ofa.W* statistic that was standardized to account for the fact that the London case mix was different from that on which TRISS methodology was based.

There have been at least seven other TRISS studies examining adult and pediatric patients transported from scenes and community hospitals that have found mortality benefit to air transport.⁹ A pediatric trauma study of scene and interfacility transports concluded that for every 1000 patients flown (as compared with a control group transported by ground), 11 lives were saved.¹⁰ Two TRISS methodology papers focused on crew configuration but also suggested an HEMS-associated mortality benefit: a 30 to 45 percent reduction in patient deaths compared with TRISS-predicted mortality.¹⁻²

Two large-scale multivariate logistic regression design studies have found a reduction in blunt trauma mortality with HEMS use. HEMS transport produced improved survival for patients with moderate injury severity (ISS between 16 and 60).¹¹ HEMS was associated with a 24 percent reduction in mortality compared with ground transport in a large-sample study (*n* = 16,699 air and ground patients) using logistic regression analysis to control for demographic factors, ISS, mission type (i.e., scene or interfacility), and prehospital level of care (i.e., BLS or ALS).⁹

The small role of penetrating trauma in the HEMS outcomes literature is likely a reflection of the fact that most civilian HEMS programs transport few patients with this injury mechanism. Another shortcoming of the literature is that studies generally address only the hard end point of mortality, with little emphasis on either mechanisms

for survival improvement or on nonmortality end points. Regardless of these shortcomings, however, the primary issue for trauma HEMS is not whether some patients benefit, but rather how well those patients most likely to benefit from helicopter use can be identified by ongoing work on improved triage criteria.

HEMS Use in Nontrauma Patients

The reason that HEMS trauma literature is (relatively) abundant is that there are ready means for controlling for the differing acuities of air- and ground-transported patients. Unfortunately, there is no such easy methodology for patients with nontrauma diagnoses, and acuity scales for nontrauma patients generally have not been accepted for use in assessing association between transport mode and outcome.

As is the case with use of HEMS for trauma, some general guidelines are applicable, and the logistic considerations noted previously apply to nontrauma flights. Rural areas have more potential use for nontrauma scene flights (or modified scene flights, in which ground ambulances transporting deteriorating patients are intercepted by a helicopter). Also, patients who are in cardiac arrest generally are transported to the nearest hospital rather than loaded onto the aircraft. Conversely, cardiac arrest patients who have been resuscitated at community hospitals may benefit from interfacility HEMS transport.¹²

NAEMSP has developed criteria for use of HEMS in nontrauma diagnoses based on a literature that suggests that time savings and the high level of HEMS care are beneficial, especially in the critically ill. The relevant studies suggest utility of HEMS for a myriad of patients ranging from premature neonates to elderly stroke victims.¹³

In most HEMS programs, the largest single nontrauma diagnostic category is cardiac. Transport for primary or rescue coronary intervention is a frequent indication for helicopter use.¹⁴ Cardiac patients, including those with pacemakers or those who have received throm-bolytics, can be transported safely and effectively by HEMS.¹⁵

Obstetrics transports are a special consideration for air transport because many high-risk patients are best delivered at tertiary care centers. The question for this population is primarily one of safety during transport; in-flight deliveries of such patients would doubtless represent a major resuscitation problem for both mother and infant. Experience has provided some reassurance that the use of HEMS to transport high-risk obstetric patients did not result in deliveries in the back of the helicopter, and neonatal outcomes are not adversely impacted by transport. HEMS transport of obstetric patients in an urban area is a viable solution to the problem of traffic congestion, and helicopters reduce response times for patient transport. An important aspect is the pretransport screening for the appropriateness of HEMS use.

COST AND REIMBURSEMENT

Using only direct comparison of costs to perform a single transport, which can exceed \$4000 for a U.S. HEMS service, helicopters are clearly more expensive than ground ambulances. The fees charged by almost all U.S. programs include a base fee for liftoff plus a fee for loaded (one-way) mileage. Depending on staffing and local considerations, some programs charge for professional services and drugs or medical supplies used in flight.

Reimbursement by medical insurance companies for HEMS transport varies among companies and over time. Since helicopter transport services must respond when called, there is no prospective screening of ability to pay. Insurance reimbursement guidelines require adjustment to keep up with increasing calls on helicopter services to transport patients (e.g., with ischemic stroke) who historically have not warranted HEMS. Some states have regulatory guidelines for HEMS utilization and appropriateness, and there are ongoing efforts to revise the reimbursement adjudication process.

Fixed-wing transport reimbursement is less problematic than that for rotor-wing service. One reason is that fixed-wing

transports are more likely to be nonemergent. Time, regulatory, and ethical considerations dictate that HEMS must respond when called, without reference to ability of the transported party to pay. These considerations less commonly come into play for airplane transports. As a result, fixed-wing transport services often can ensure reimbursement before dispatching aircraft. There are important exceptions to this rule. For example, fixed-wing services may provide emergency evacuation in regions with considerable interhospital distances or in areas where weather situations such as fog sometimes preclude helicopter operations and surface transport is not an option.

Closely related to the issue of reimbursement is demonstration of favorable cost-benefit ratios associated with HEMS use. As noted, HEMS outcomes literature limitations (e.g., lack of nonmortality end points) preclude a definitive cost-benefit analysis. However, economic analysis of HEMS for trauma patients concluded that helicopter transport is at least as cost-beneficial as many other medical interventions commonly performed in the United States.¹⁶

The studies just mentioned do not completely account for all aspects pertinent to true analysis of cost-benefit analysis of helicopter as compared with ground transport. The costs of helicopter transport are compared with transport by a single ambulance unit only at the peril of neglecting important systems costs. Economic analyses and expert commentary suggest that there would be little (if any) savings if helicopter coverage in a specific geographic area were replaced with ground^{17,18} critical-care ambulances characterized by similar response times.

FIXED-WING AIR MEDICAL TRANSPORT

Fixed-wing aircraft can serve a wide variety of missions, from urgent to routine, over great distances. Since airplanes land only at airports, they cannot make scene flights, and they need ground ambulance connections at both ends of the flight to transport the patient between the hospital and airport. Because of these factors, fixed-wing flights generally take longer to arrange and are uncommonly used for truly emergent patients.

Unlike the situation with helicopters, which are virtually always dedicated as air medical transport vehicles when used by U.S. HEMS services, airplanes used for medical transport may have other roles. When such fixed-wing aircraft are to be used for air medical transport, their cabins must be reconfigured in a sometimes time-consuming step that may result in a transport vehicle not optimally suited for medical care. To aid with this potential problem and to ensure the presence of adequate medical equipment, vendors have developed removable medical equipment modules that can be placed relatively quickly in the aircraft cabin.

On a per-mile basis, fixed-wing transports are less expensive than HEMS transports. Excluding weather considerations, fixed-wing transfer generally becomes preferred when distances exceed 150 to 200 miles. However, the optimal transport radius for fixed-wing triage varies with regional and patient-specific considerations.

Airplanes vary in size and speed. Turboprop aircraft typically cruise at 200 to 300 miles per h; jets are twice as fast. The appropriate aircraft to use for any one mission depends on many factors: distance, the nature of the airport at the patient's pickup point, the condition of the patient, the amount of equipment, and the crew required in transport. The more critically ill the patient, the more equipment and crew may be needed and the larger the aircraft required. The choice of aircraft also must take into account the comfort of the crew and the patient for a trip of that distance (e.g., bathroom facilities for a plane making a 6 h cross-country trip). The cabins of fixed-wing aircraft are larger than those of rotor-wing craft, although the cabin's cylindrical build can be more of a constraint than its absolute volume. A larger plane that can be pressurized can fly above 3000 m (10,000 ft), which means that the aircraft can travel faster, farther, and more comfortably. At these higher altitudes, flight crews must have a deeper understand-

ing of altitude physiology issues. Cabin pressure (i.e., indicated altitude above sea level) should be recorded on medical records because of the importance of pressure issues to physiology, and crew safety training should include measures to take in case of inadvertent cabin depressurization.

All fixed-wing services must comply with civil aviation authority rules for airplanes. As is the case with helicopters used for medical transport, CAMTS has developed standards for air medical fixed-wing transport. These standards, which are also a useful primer for more detailed information about fixed-wing air medical transport, deal with aircraft configuration, medical equipment requirements, medical crew configuration and training, and medical director qualifications.

MEDICAL DIRECTION OF AIR MEDICAL SERVICES

Medical direction may be even more important with rotor- and fixed-wing services than with ground services; it is certainly more complicated because it involves most aspects of ground EMS in addition to vehicle-specific and altitude- and acuity-related issues. The medical director should be familiar with the physiology and stress of flight on patients and should oversee the teaching of these and other applicable principles to the air medical crew. Overall, a flight crew requires more initial and ongoing training than do most ground EMS personnel due to the higher patient acuity and extended practice scope. Because flight crews are often far from their base of operations and may be out of voice contact, they must be sufficiently trained that they can act independently when necessary. For nonphysician crew, standing orders or protocols (especially for advanced procedures such as cricothyrotomy) are needed. Periodic review and updating of these protocols, as well as close inspection of every transport record, are among the many responsibilities of the medical director. Information on the responsibilities and function of the air medical program physician director have been published by AMPA and NAEMSP.

NEONATAL AND PEDIATRIC TRANSPORT Phillip V. Gordon Carl Bose

Regionalized intensive care is a concept that has gained wide acceptance in neonatology and pediatric care.¹ This concept mandates that expensive, high-technology, labor-intensive therapies be limited to a few regional centers. Because patients in need of these services may initially present to other hospitals, interfacility transport has developed as a complement to regionalized intensive care.²

Either the referring hospital or, more commonly, the regional center may assume the responsibility for transport of a patient to a regional center. Because community emergency medical services (EMS) systems often are not equipped to transport critically ill children, the interfacility transport of pediatric patients frequently is conducted by specialized transport services.² Under these circumstances, the referring hospital and its medical care staff still have important responsibilities related to transport; emergency department personnel most often assume these responsibilities because the emergency department is the site of initial care.

THE TRANSPORT ENVIRONMENT

Moving critically ill patients between hospitals invariably adds to the risks of the illness or injury because of the hazards associated with the transport environment, particularly during the transport of neonatal and pediatric patients. An understanding of the transport environment is important for individuals who participate in the preparation of a patient for transport, as well as for those who conduct the transport.

Features

The features of transport that distinguish this environment from the inpatient setting and the effects of these features on patients and caretakers include the following:

1. **Excessive noise.** The acute effects of excessive noise on older pediatric and adult patients probably are minimal. By contrast, persistent sound in excess of 80 dB significantly increases the frequency of arterial oxygen desaturation in premature infants. In addition, excessive noise makes it virtually impossible to use the sense of hearing to evaluate patients during transport.
2. **Vibration.** The effects of vibration on patients are uncertain but probably are not of great significance. However, vibration may limit the reliability of transport equipment. Monitor artifact must be recognized, and alternative techniques for monitoring should be employed as needed.
3. **Inadequate lighting.** Inadequate lighting is rarely a problem during the transport of adult patients because EMS vehicles generally have lighting designed for adult patients on stretchers. However, task lighting for illuminating small areas and small patients is usually not available.
4. **Variable ambient temperature.** Although the range of ambient temperatures encountered during transport rarely influences the body temperature of adult patients, environmental conditions can markedly influence the body temperature of neonates and small children.

SECTION 1 • PREHOSPITAL CARE

5. *Changes in barometric pressure.* Changes in barometric pressure during ascent in nonpressurized aircraft cause expansion of gases in closed spaces (e.g., with endotracheal tube cuffs or pulmonary in terstitial emphysema) and a fall in the partial pressure of oxygen. These changes are rarely of sufficient magnitude to influence physiologic characteristics unless the change in altitude is greater than 1500 m (5000 ft).
6. *Confined space.* The confined space in transport vehicles is an obvious handicap because it limits the number of caretakers and the amount of support equipment.
7. *Limited support services and personnel.* Similarly, the extent and precision of care are limited during transport by the lack of support services (e.g., radiographic and laboratory services) and specialty personnel.
8. *Equipment failure.* Equipment failure during transport is common and is particularly problematic because replacement equipment is less likely to be available in the vehicle than in an inpatient setting. A common problem is the unexpected exhaustion of an oxygen tank.
9. *Motion-induced illness.* Many medical personnel develop motion-induced illnesses during transport. Symptoms often are categorized into one of two syndromes: the Sople syndrome, which is characterized by drowsiness and inability to concentrate, and the nausea syndrome. Either syndrome may impair the ability of personnel to provide skilled care.

Precautions

Suggested guidelines to minimize the impact of the handicaps inherent in a transport environment are

1. *Stabilize the patient carefully prior to transport.* Unless the immediate needs of the patient can only be met in the receiving hospital (e.g., severe trauma), ample time should be devoted to stabilizing the patient in the referring hospital.
2. *Anticipate deterioration.* Preparation of the patient should include not only care for the identified problems but also anticipation of problems that may arise during transport.
3. *Monitor as many physiologic parameters as possible electronically.* Because physical examination is nearly impossible during transport, and because pediatric patients often are transported during dynamic changes in their physiologic condition, electronic monitoring is essential. The following monitors are commonly used during transport:
 - a. *Heart rate and respiratory monitor.* All transported patients should be monitored with impedance electrocardiogram (ECG) and respiratory monitoring. The selection of a monitor should be based on its size, weight, battery life, and resistance to motion artifact. The monitor should include a screen with a graphic display of ECG and respiratory tracings. Ideally, the monitor should display pressure waveforms and digital readings of systolic, diastolic, and mean blood pressures from transduced intravascular catheters. It is not essential that the monitoring system include the capability of electrical cardioversion or pacing; the need for such a device in the care of pediatric patients is extremely rare. However, this capability should be available during the transport of patients with known arrhythmias or patients at risk for such problems (e.g., tricyclic antidepressant poisoning or complex heart disease).
 - b. *Pulse oximetry.* Continuous pulse oximetry is essential in patients with cardiorespiratory illness. Devices that display a plethysmographic waveform are ideal because they assist in identifying motion artifact.
 - c. *Body temperature monitor.* Continuous temperature monitoring is helpful in neonates and small infants because of their predisposition to hypothermia.
 - d. *Carbon dioxide monitor.* Continuous estimation of PacO_2 is helpful in patients with respiratory failure. Capnography, using con-

tinuous in-line infrared analysis to measure end-tidal carbon dioxide, is becoming increasingly popular as an alternative to transcutaneous carbon dioxide monitoring or arterial blood analysis. Colorimetric CO_2 detectors to confirm endotracheal tube placement in the airway are readily available and are especially helpful during transport when there is emergent concern of inadvertent extubation.

- e. *Blood pressure monitor.* Noninvasive blood pressure monitoring is advisable in children without indwelling arterial catheters. The cuff should cycle frequently enough to provide meaningful information about changes in hemodynamics. Arterial pressure can be monitored directly in patients with indwelling arterial catheters. Direct monitoring is preferable because it is more accurate and provides an alarm system in the event that arterial pressure suddenly falls (e.g., if the line becomes disconnected and the neonate suddenly has unimpeded arterial hemorrhage). Noninvasive blood pressure monitoring also may be useful in patients with direct monitoring to differentiate abnormal findings from technical artifacts.
- f. *Portable blood analyzer.* Small battery-powered devices are now available for the performance of blood gas analysis and measurement of selected blood chemistries (e.g., electrolytes and blood glucose). These devices are valuable for monitoring patients with dynamic diseases, particularly when the transit time between hospitals is long, and such devices are rapidly becoming the standard of care for neonatal transport teams.

4. *Prepare the transport vehicle.* If repeated transport of pediatric patients is anticipated, one or more vehicles should be prepared to meet the special needs of these patients (e.g., accessory lighting and a more precisely controlled thermal environment).

PREPARATION OF A PATIENT FOR TRANSPORT

Decision to Transport

A pediatric patient should be transferred to a regional center if the current or anticipated medical care needs of the patient exceed the resources of the local hospital. Arranging transfer to the regional center can occur simultaneously with assessment, resuscitation, and stabilization at the local hospital.

Basic Preparation

Extensive preparation and planning are required for transfer of a critically ill child from one institution to another. This preparation should be completed by the referring hospital personnel to the limits of their abilities and resources, regardless of whether they or a receiving hospital will perform the transport. Two of the most important aspects of care are airway management and vascular access.

AIRWAY MANAGEMENT Intubation and mechanical ventilation in a pediatric patient usually are done to (1) protect the airway from obstruction, (2) provide adequate oxygenation, or (3) ensure adequate ventilation. This principle applies to both inpatients and those being prepared for transport. However, the threshold for intervention is lowered for patients requiring transport.⁴ For example, an infant with a Paco_2 of 50 mm Hg might be observed without ventilatory support in the inpatient setting but probably should be intubated and ventilated in preparation for transport. In addition, children without respiratory failure but in whom deterioration is anticipated should be intubated in preparation for transport. This more aggressive approach to airway management is justified because the ability to identify respiratory failure and to intubate often is impaired during transport.

Emergency departments should be supplied with equipment to intubate and ventilate patients of all sizes (Table 4-1). A weight- and

TABLE 4-1 Intubation Guide for and Pediatric Patients Neonatal

Age/ Weight	Laryngoscope Blade	Tube Size (mm)*	Insertion Distance (cm)
<1 kg	Straight 0	2.5	6.0-7.0
1-2 kg	Straight 0	3.0	7.0-8.0
2-3 kg	Straight 0 or 1	3.0-3.5	8.0-9.0
3^ kg	Straight 1	3.5^0	9.0-9.5
0.5-3 years	Straight 1	4.0^1.5	X
3-5 years	Straight or curved 2	4.5-5.5	I
5-8 years	Straight or curved 2	5.5-6.5	
>8 years	Straight or curved 2 or 3	6.5-7.5	

* Cuffed endotracheal tubes should not be used in children <7 years of age. t Insertion distance is the distance from the tip of the tube to the lip. **X** See Chap. 15 for more details.

size-appropriate endotracheal (ET) tube should be used. In an observational study of pediatric air medical transports, about 15 percent of intubated patients had an inappropriate ET tube size, almost always too small.⁵ All nonneonatal patients should be medicated prior to intubation unless they are unconscious or in extreme distress. Neonatal patients should be premedicated only if they are alert and vigorous. An opiate analgesic (morphine or fentanyl) should be administered intravenously to patients less than approximately 3 months of age. Older children should be intubated following rapid-sequence anesthesia and paralysis.

Neonatal intubation may be challenging for personnel not experienced in airway management within this population. Attention to the following problems may increase the likelihood of success:

1. A common mistake made during neonatal intubation is to insert the blade into the esophagus and then fail to withdraw it far enough to visualize the glottis.
2. The glottis is in a more ventral position in infants than in older children; therefore, it is more difficult to visualize. This problem can be minimized by avoiding overextension of the neck and by applying gentle pressure to the cricoid. Too much pressure should be avoided because it can occlude the airway and prevent intubation.
3. Premature infants have very small mouths and upper airways, making insertion of an ET tube difficult. Gentle traction on the infant's mouth, pulled in a fishhook fashion on the right side by an assistant, often can augment the opening, allowing insertion of the ET tube just to the right of the blade. This maneuver also helps preserve the intubator's field of view.
4. Because the skin of newborns is usually moist, extra care must be taken during taping of the ET tube.

Because the distance between the thoracic inlet and the carina is extremely short in small children, the position of the tip of the ET tube should be confirmed with a chest radiograph as soon after insertion as possible. A radiograph should be obtained even when reassuring signs of a successful intubation are present (condensation on the wall of the tube, symmetric chest rise and breath sounds, and positive CO₂ detection). In the previously mentioned pediatric air medical transport study, 55 percent of intubated patients did not have the ET tube inserted to the recommended depth; almost always it was inserted too deep.⁵ Right mainstem intubation is common in neonates. Prolonged right mainstem intubation increases the likelihood of pneumothorax and is particularly hazardous in premature infants. Soon after the initiation of mechanical ventilation, arterial blood gas analysis should be performed to ensure appropriate ventilator settings. Overventilation is a common error that may have serious consequences in the preterm neonate.

VASCULAR ACCESS All patients should have intravascular access during transport. Critically ill children should have at least two lines in case one becomes dislodged or several drugs must be administered simultaneously. Access should be through a device that includes a non-metallic intravascular component. The metal butterfly needles previously used in pediatric inpatient units are not satisfactory during transport because they frequently perforate the vessel as a result of vibration and movement. Intraosseous cannulation is an alternative technique for fluid and drug administration when intravascular lines cannot be placed and the severity of illness demands immediate access.

In small children, intravenous lines should be infused with the use of pumps. Open "drips" should not be used, even with volumetric drip chambers, because of the risk of fluid intoxication from inadvertent administration of large boluses. The amount of fluid administered should be monitored and recorded carefully.

CONDUCT OF A TRANSPORT

The transport of a critically ill child from the emergency department in a community hospital to a regional center is facilitated by preestablished transfer protocols. These protocols should provide information about each regional center to which a patient might be referred, including (1) special services available, (2) criteria for referral, (3) telephone numbers for consultation, referral, and transport, (4) distance and usual response time, (5) type of transport personnel and their capabilities, (6) type of transport vehicles, and (7) protocols for preparation of patients. It is also advisable to establish formal agreements with regional centers that outline the circumstances under which patients can be transported without prior administrative approval.

Once the decision has been made to transport a child, the referring hospital has certain obligations in addition to medical care.⁶ In the United States, federal law specifies some of these responsibilities; the referring physician must obtain acceptance from a receiving physician, the patient must be stabilized to the best of the transferring hospital's ability prior to transport, and the patient must be transported using a medically appropriate transport vehicle.

In preparation for transport, the referring hospital should assemble all available information pertinent to the current illness. This generally includes a copy of the emergency department record, laboratory data, radiographs, and old medical records, if available. The referring physician should inform the parents of the need for transfer and discuss the mechanism by which the child will be transferred. Consent to transport should be obtained from a parent or other responsible individual.

Receiving physicians often make recommendations regarding stabilization of the patient, sometimes at the request of the referring doctor. However, referring physicians are not obligated to follow these recommendations if they are considered to be medically inappropriate or beyond the capabilities of the referring hospital. Under these circumstances, it is advisable for the referring and receiving physicians to develop an alternative plan.⁶

For most critically ill pediatric patients, ideal care is provided when the emergency department of the referring hospital devotes its energy to providing emergent short-term care and the responsibility for transport is left to the regional center. This is particularly true for neonatal patients because of the special equipment and expertise required for transport. It is rarely in the best interest of critically ill neonates to "pick them up and run." When transport services are not provided by the regional center or when time is critical, it may be appropriate for the referring hospital to provide transport. In these circumstances, it is the referring hospital's responsibility to ensure the adequacy of care during transport.

In many areas, physicians have a choice between air and ground transportation. Again, this decision should be made collaboratively.⁷ Air transport should be reserved for situations in which reduction of a critical period of time during transport is likely to reduce morbidity or mortality. In some emergencies, the critical period ends with arrival of

the receiving hospital's transport team because the team is able to administer a definitive intervention for most medical emergencies. Under these circumstances, the advantage of air compared with ground transport is related directly to the reduction in time between the referral and the arrival of the team at the referring hospital. Air transport may offer the greatest advantage when definitive therapy is available only in the receiving hospital (e.g., a surgical procedure) because the patient benefits from the reduction in transit time between the receiving and referring hospitals.

When the transport team arrives, the referring physician should be present to coordinate the transition of care. Under most circumstances, a transport team originating from a hospital other than the referring hospital does not receive a detailed history of the patient's illness prior to arrival. It is essential that the referring physician be available to provide this history and a brief review of recent events. In addition to the referring physician, one or two support personnel also should be available to aid the transport team with further stabilization.

SPECIAL PROBLEMS OF THE NEONATE

The stabilization and transport of critically ill neonates are complicated by their dependence on extrinsic factors to maintain homeostasis. This is particularly true when birth occurs prior to term. In fact, the complexity of care often is inversely related to birth weight and gestational age. Neonatal conditions and aspects of clinical care that deserve special consideration when preparing for a transport include the following:

Hypothermia

Humans conserve body temperature by several mechanisms: (1) shunting blood from the skin and periphery to the core, (2) increasing basal metabolic rate, (3) voluntary muscle activity, (4) shivering, and (5) nonshivering thermogenesis. With the exception of nonshivering thermogenesis, all these mechanisms are less effective in the neonate. Although older children and adults can maintain normal core body temperature when subjected to a wide range of environmental conditions, neonates, particularly premature infants, are very limited in this regard. In addition, even under conditions in which a neonate can maintain normal body temperature, this is often accomplished at the expense of increased oxygen consumption and carbon dioxide production. These consequences are particularly onerous in infants with respiratory failure.

Neonates should be cared for in a neutral thermal environment in which core temperature remains normal and oxygen consumption is minimized. Such an environment is best provided by treating a neonate on or within a thermo-controlled bed specially designed for neonates. Thermo-controlled beds come in two varieties: an open platform heated with an overhead radiant heat source and a closed plastic incubator heated with a convection heater. Although not satisfactory for transport, open incubators with radiant heaters are ideal for the care of critically ill neonates in the emergency department because they permit access by several caretakers. An alternative is the use of a portable overhead heat lamp and a standard crib. These devices should be used with extreme caution because they do not usually include a servo-control mechanism. The patient's body temperature should be monitored frequently to avoid hyperthermia. The neutral thermal environment is presumed when the infant's body temperature is normal and there is a minimal gradient between the core and the skin temperature.

Neonates, especially preterm infants, are particularly susceptible to heat loss because they have a relatively large surface-to-body-mass ratio when compared with older patients. Also, their skin is more permeable to water vapor, and they may have a paucity of subcutaneous tissue. In addition to providing a heat source, attempts to create a neutral thermal environment should include provisions to minimize heat loss.

1. Infants should be thoroughly dried to avoid evaporative heat loss. This is critical after an emergent delivery; drying should not be delayed under any circumstances. If emergent procedures are necessary, such as intubation, another caretaker should simultaneously dry the infant.
2. Whenever possible, infants should be placed on a prewarmed surface to avoid conductive heat loss. The temperature of these surfaces or auxiliary heat sources (e.g., hot water bottles) should not exceed 40°C (104°F) because of the risk of thermal injury.
3. When treating an infant in an open crib or platform warmer, the room temperature should be increased to avoid convective heat loss. The infant should be located away from drafts (e.g., heat and/or air-conditioning vents).
4. An infant should be clothed to the extent that it does not interfere with patient care and should not be placed near cold surfaces (e.g., exterior windows) to avoid radiant heat loss. At a minimum, a covering or hat should be placed on the infant's head.

Hypoxemia

Newborn infants delivered in an emergency department or those brought to the emergency department soon after delivery outside the hospital are most often healthy. However, some may have respiratory failure with severe hypoxemia. The disease that most often causes severe hypoxemia in newborns is respiratory distress syndrome (RDS). Persistent pulmonary hypertension of the newborn (PPHN) and cyanotic congenital heart disease (CHD) also may cause severe hypoxemia in this population. It is critical that the cause of hypoxemia be identified with accuracy so that specific therapies (e.g., surfactant therapy) can be initiated promptly and/or referral to centers with appropriate subspecialty support (e.g., pediatric cardiology) can be made.

RESPIRATORY DISTRESS SYNDROME (RDS) Premature infants with RDS present with progressively worsening retractions, tachypnea, and oxygen requirements because their lungs are too immature to synthesize surfactant (a lipid-protein complex that reduces the surface tension of the alveoli). This disease has a characteristic pattern on x-ray that includes "ground glass" opacity in the lung parenchyma and prominent air bronchograms (Figure 4-1). Two postnatal strategies are employed to minimize further lung damage and rescue the patient. First, the stenting of airways with continuous positive airway pressure (CPAP) reduces the collapse of the alveoli and thereby limits further damage. CPAP can be administered through specially designed nasal cannula-type devices (with a continuous pressure of 4 to 6 cmH₂O) in the nonintubated patient with mild respiratory distress. A similar strategy should be used as an adjunct therapy in the intubated patient by adjusting the ventilator to provide a positive end-expiratory pressure (PEEP) of 4 or 5 cmH₂O such that there is never a period of negative pressure during passive exhalation. The second intervention is administration of surfactant through the ET tube. This procedure can result in rapid changes in pulmonary compliance, can cause transient airways obstruction, and sometimes is associated with pulmonary hemorrhage. For these reasons, only experienced personnel should administer surfactant. When an infant needs surfactant but the referring institution is unable to administer it, transport always should be performed by the receiving hospital. This allows the transport clinicians to administer surfactant as soon as they arrive on site, thereby minimizing further treatment delay.

During transport, most neonates are ventilated with time-cycled, pressure-limited ventilators using intermittent mandatory ventilation. As with volume ventilation, the clinician determines the fraction of inspired oxygen (Fio₂) and the ventilator rate. In contrast to volume ventilation, the tidal volume is not set and, in fact, is not known with many infant ventilators. The volume of each breath is determined by setting a peak inspiratory pressure (PIP), a positive end-expiratory pressure (PEEP), and an inspiratory time (T_i) with suggested initial ventilator

FIG. 4-1. Chest x-ray of an intubated infant illustrating classic findings of respiratory distress syndrome (RDS). Note the granular or "ground glass" appearance of the lung parenchyma, the poor inflation, the lack of focal opacities (typically seen with pneumonia), and the prominent air bronchograms. These findings correlate clinically with moderate to severe retractions and oxygen dependence in premature infants with RDS.

settings for infants that vary according to the severity of lung disease (Table 4-2).

The adequacy of oxygenation and ventilation should be assessed immediately after initiation of ventilation by observing the degree of chest expansion, skin color, and oxygen saturation. Arterial blood gases are the best means to fine-tune ventilator settings, but capillary or venous blood is acceptable for measurement of the P_{CO_2} and pH in the absence of access to arterial blood. The target ranges for oxygenation and ventilation of neonates differ according to the disease process and gestational age (Table 4-3). The blending of oxygen and air to deliver the minimum F_{IO_2} required to achieve adequate oxygenation is highly desirable, particularly in premature infants, in whom hyperoxia may lead to retinopathy.

PERSISTENT PULMONARY HYPERTENSION (PPHN) Pulmonary circulation is attenuated in the fetus due to high intrinsic vascular resistance in the pulmonary arterioles and bypass shunting around the lungs via the ductus arteriosus. The rapid transition from fetal to newborn circulation includes a precipitous drop in pulmonary vascular resistance concomitant with lung expansion, followed by increased pulmonary blood flow in the first minutes of life and then a gradual closing of the ductus arteriosus over the next 48 h. Unfortunately, there

TABLE 4-3 Target Ranges for Oxygenation and Ventilation of Neonates

Oxygenation	Arterial Blood Gas	Pulse Oximetry
Premature infant with RDS	P_{aO_2} 50-70 mm Hg	S_{aO_2} 93-98%
Term infant (no lung disease)	P_{aO_2} 60-100 mm Hg	S_{aO_2} 96-100%
Infant with PPHN	P_{aO_2} 80-100 mm Hg	S_{aO_2} 100%
Infant with CHD	P_{aO_2} 35-50 mm Hg	S_{aO_2} 75-95%
Ventilation		
Premature infant with RDS	P_{aCO_2} 45-55 mm Hg	
Term infant (no lung disease)	P_{aCO_2} 35-50 mm Hg	
Infant with PPHN	P_{aCO_2} 30-35 mm Hg	
Infant with CHD	P_{aCO_2} 35-50 mm Hg	

Abbreviations: CHD = cyanotic heart disease; PPHN = persistent pulmonary hypertension; RDS = respiratory distress syndrome; S_{aO_2} = arterial oxygen saturation.

are several common conditions that can disrupt this progression, including infection, meconium aspiration, and asphyxiation. Infants with PPHN can be quite ill and require significant experience and expertise on the part of the caregivers to manage in the long term. Fortunately, the stabilization algorithm for PPHN is reasonably concise. The challenge comes in diagnosing PPHN early enough to prevent patient morbidity.

Infants with PPHN demonstrate labile oxygenation despite adequate ventilation due to right-to-left shunting of blood through the ductus arteriosus (Figure 4-2). This usually can be detected by placing a pulse oximetry probe on the right hand (preductal) and a second probe on a foot (postductal). If the preductal oximeter exceeds the post-ductal oximeter by more than 5 percent in a newborn, right-to-left

FIG. 4-2. Homunculus illustrating right-to-left shunting through the ductus arteriosus due to persistent pulmonary hypertension.

TABLE 4-2 Initial Ventilator Settings for Neonates

Severity of Respiratory Disease	Mild	Moderate	Severe
PIP (cmH ₂ O)	18	24	28
PEEP (cmH ₂ O)	4	4	5
$T_{I/S}$	0.5	0.4	0.4
Rate, breaths/min	20	24	30

Note: The appropriateness of initial ventilator settings should always be tested by blood gas analysis.

shunting is present. This finding, in combination with labile oxygenation, indicates a diagnosis of PPHN until proven otherwise with echocardiography.

Initial management of severe PPHN includes a variety of interventions designed to optimize pulmonary blood flow. These include intubation, administration of 100% oxygen (a pulmonary vasodilator), optimization of ventilation to promote lung expansion (see Table 4-3), maintenance of high-normal blood pressures to slow ductal shunting (with saline boluses and pressors if necessary), and sedation with paralysis (to minimize intrathoracic pressure). These therapies may transiently stabilize critically ill infants with PPHN but are damaging in the long term. Nitric oxide (NO) is a potent pulmonary vasodilator that has revolutionized the management of PPHN, and many neonatal transport teams now have portable NO tanks. When possible, transport of a neonate with PPHN should be performed by a team that can administer NO, thus minimizing the time to treatment. Infants that do not respond adequately to the preceding interventions are likely to require extracorporeal membranous oxygenation (ECMO) for survival. For this reason, infants with PPHN should be transported preferentially to ECMO centers.

CYANOTIC HEART DISEASE (CHD) Because fetal oxygenation occurs through the placenta, cyanotic heart lesions usually are asymptomatic in the fetus. Likewise, a large number of cyanotic heart lesions become dependent on the ductus arteriosus for pulmonary blood flow at birth but remain clinically silent until the time of ductal closure. This sequence of events can result in delayed diagnosis of CHD and a subsequent need for emergency management.

The classic emergency maneuver for confirming the suspected diagnosis of CHD in a newborn is to draw an arterial blood gas while the patient is on 100% oxygen. A P_{aO_2} of less than 100 mm Hg indicates the presence of right-to-left shunting. However, distinguishing CHD from PPHN requires additional assessments.⁸ Whenever possible, the diagnosis of CHD should be confirmed with an echocardiogram.

Emergent management of CHD relies on two strategies: (1) supportive interim management and (2) reopening and maintaining ductus arteriosus patency with a prostaglandin E₂ infusion (PGE₂). Supportive interim management may include administration of oxygen, mechanical ventilation, correction of acidosis, augmentation of cardiac contractility with pressors, and sedation. PGE₂ typically is started at 0.05 µg/kg per min and titrated according to oxygen saturation up to 0.1 µg/kg per min when trying to reopen the ductus in a severely ill patient. Mild hyperthermia and profound apnea are two side effects that are seen more commonly with the higher dosage.

Once stabilized, the primary issue for transport is typically retaining intravenous access and ensuring a continuous, steady flow of PGE₂. Patients with previously undiagnosed cyanotic heart lesions should be transferred to a tertiary facility that can perform pediatric cardiovascular surgery (preferably to a service that does at least 100 pediatric cases annually).

Hypoglycemia

During fetal life, the placenta and the maternal circulation closely regulate metabolic homeostasis. In healthy full-term neonates, homeostasis is maintained by the infant's autoregulatory mechanisms. Unfortunately, these mechanisms often fail during acute illness or after preterm birth.

The most common metabolic abnormality in newborns is hypoglycemia. At birth, blood glucose in the neonate is approximately 60 to 70 percent of the maternal level. Within 1 to 2 h, the level falls to approximately 40 mg/dL. This decline may be accentuated in premature infants, acutely ill infants of any gestational age, and certain other high-risk infants (e.g., infants of diabetic mothers).

Because of the risk of hypoglycemia, all neonates should receive glucose-containing fluids in preparation for and during transport. Thus

D10 infused at a rate of 80 mL/kg per d should be used in infants with birth weights greater than 1000 g. In infants smaller than 1000 g in weight, D5 infused at a rate of approximately 100 mL/kg per d should be used because of the risk of hyperglycemia using the more concentrated solution and the relatively larger fluid requirements of the smaller neonate. In all infants at risk for hypoglycemia, measurement of blood sugar should be repeated at frequent intervals, at least every 2 h.

Vascular Access

Peripheral venous access in the neonate may be technically challenging and usually is performed successfully only by caretakers skilled in this technique. Femoral line placement is difficult in neonates and should be considered rarely. Intravascular lines placed through the umbilicus are a simple and desirable alternative for both arterial and venous access in infants less than 1 week of age. The most rapid way to obtain vascular access is to temporarily place an umbilical venous catheter (UVC) 2 to 3 cm below the level of the skin. A UVC located in this position can be used to administer fluids and medications in emergency situations, but it is not a sufficiently stable form of access during transport. By contrast, UVCs with the tip located near the junction of the inferior vena cava and the right atrium are ideal for all infusions during both stabilization and transport. The position of the tip of the catheter should be determined radiographically prior to use to ensure that medications are not being infused into the liver. An umbilical artery catheter is desirable when frequent blood gas analysis is anticipated or central blood pressure monitoring is crucial. However, umbilical artery catheters generally should not be used for the administration of pressors.

Infection

Signs and symptoms of infection in a neonate are often nonspecific and may be indistinguishable from those associated with other diseases. Therefore, infection should be presumed as a cause of illness in any sick neonate. Broad-spectrum antibiotics should be administered unless the signs and symptoms can be attributed with reasonable certainty to a cause other than infection. Antibiotics also should be administered to premature infants because uterine and placental infection is a common cause of preterm labor. Antibiotics should be administered as soon as possible because early treatment decreases mortality and morbidity rates. It is preferable to collect a blood culture prior to the initiation of antibiotic therapy, but therapy should not be withheld because of difficulties in collecting a blood culture.

Viability

Delivery of premature infants who are at the limits of viability is not an uncommon occurrence in the emergency department. Under these circumstances, the first priority of the physician caring for the infant is to determine whether resuscitation is justified. In the United States, an infant born at a gestational age of less than 23 weeks, weighing less than 400 g, with gelatinous/translucent skin and fused eyes generally should not be resuscitated or transported. By contrast, infants born at 24 weeks or older are capable of relatively good outcomes and should be supported aggressively after birth. The decision to initiate support must be made immediately because any significant delay can worsen the child's prognosis dramatically. If the decision is not clear, proceed immediately with a full resuscitation. There is never a reason to do a "slow" code in a newborn.

The death of an infant judged to be nonviable often does not occur rapidly, even in the absence of spontaneous respiration. After a decision has been made to withhold interventional care, it is important that the staff remain supportive and available to the parents. If the parents desire, the child can be held in a quiet place with a physician checking

periodically to determine the time of death. This period, around the time of death, may be emotionally difficult for the staff as well as for the family. However, families often recall these irreplaceable moments (and the facility in which they occurred) with tenderness and gratitude. Futile efforts at resuscitation or interfacility transport should not be a substitute for compassionate support without medical intervention.

SPECIAL PROBLEMS ASSOCIATED WITH PEDIATRIC PATIENTS

Consent for Transport

In most of the United States, the legal age of majority is 18 years. However, mothers of younger ages have consenting authority for medical therapies for their offspring unless specifically prohibited by court order. Likewise, in many states, medical care to minors can be given without parental consent when it involves reproductive health (e.g., a teenager with a tubal pregnancy). Thus the definition of the age of majority is situational and must be addressed on an individual basis within the confines of both federal and state law.

In situations where transport of a minor patient is advisable and a parent or guardian is not available (such as is often the case with pediatric traumas in intercity areas), the minor patient can be transported under the philosophical auspices of beneficence. In these cases, legal authorization for interhospital transport requires documented consent from the referring physician explicitly stating that failure to transport would endanger the patient's well-being.

Stranger Anxiety

Young children often exhibit anxiety during contact with strangers. This behavior becomes especially significant when a child's condition is compromised by an unstable airway. In particular, patients with croup, epiglottitis, and inhaled foreign bodies can become acutely unstable when agitated. Sedation, which may reduce anxiety, may incur the risk of compromising respiratory drive and/or causing paradoxical agitation. Often the best adjunct to management of an anxious child with airway obstruction is to allow a parent to hold the child while treatment is administered (e.g., nebulized bronchodilators).

Respiratory Fatigue

Infants and small children have remarkable respiratory reserve. Infants in particular can maintain respiratory rates above 100 breaths per min for days without significant fatigue. Unfortunately, when infants or small children do experience respiratory fatigue, little time may elapse before they become apneic and unconscious. Therefore, caretakers need to be prepared for sudden respiratory failure. A laryngoscope, an appropriately sized ET tube, oxygen, and a bag-mask device should be readily available during the care of children in whom respiratory fatigue is a possibility. When respiratory fatigue appears imminent, a controlled rapid-sequence intubation is recommended prior to transport.

Transport Decisions in Children with Terminal Diseases

In the past decade, the deaths of children with terminal diseases have occurred more frequently in the home.⁹ In some regions, the role of hospice and physician-directed end-of-life care provides these patients with a desirable alternative to death in the hospital. These patients may have highly evolved plans and specific limitations on end-of-life care. To be valid, these documents must be signed by both the patient's legal decision maker and his or her primary physician. These documents typically are kept at the bedside or on the refrigerator door. Despite these measures, EMS personnel sometimes are requested because the

patient is experiencing intolerable discomfort or because caregivers become uncomfortable with the dying process. Under these circumstances, EMS personnel generally are obligated to take patients to the closest appropriate medical facility, placing them at risk for having to experience the very fate that the end-of-life directive was designed to avoid. In these instances, it is of paramount importance that the patient's end-of-life directives be honored.

MASS GATHERINGS

Eric W. Ossmann Arthur

H. Yancey II

Mass gatherings have been defined as any voluntary and temporary collection of greater than 1000 people at one site or location for a common purpose.¹ Gatherings can be short-term (for a few hours as in a sporting contest) or longer (for several days to weeks as in the Olympic games). The event can be held on one location (e.g., a stadium) or spread over different sites. While mass gatherings imply a sports or entertainment event, smaller gatherings have many similar characteristics for medical care. These smaller gatherings include commercial airliners, passenger trains, and offshore transportation modes, such as ferries or hydrofoils, that create a situation where varying numbers of people are crowded into a limited area.

A major sporting event in an outdoor stadium will typically involve 60 to 80,000 spectators, although some university stadiums can accommodate more than 100,000 fans. Indoor arenas for basketball, ice hockey, and concerts can seat up to 20 to 25,000 people. Outdoor music festivals or motor racing can have more than 300,000 people in attendance. Not included in these figures are the thousands who attend events as diverse as high school athletics, local and state fairs, air shows, parades, and religious, political, or professional gatherings. A common feature of all these gatherings is that the injury and illness rates of those present are greater than the average non-gathered population.

Several features of mass gatherings create unique medical treatment and transportation challenges not found in the general population.

Densely clustered crowds and physical barriers prevent access to, on-scene care of, and timely safe evacuation of patients. Exposure to the climatic elements and intentional injury can result in mass casualty incidents, quickly overwhelming dedicated, on-site resources. Distances within the site or between different venues, as well as interaction with public resource managers, require reliance on wireless communications. Medical care for mass gatherings represents an intersection of emergency medicine with public health and public safety, requiring working talents in business, logistics, disaster preparedness, telecommunications, and public relations.

The American College of Emergency Physicians (www.acep.org) and the National Association of Emergency Medical Service Physicians (www.naesmp.org) have developed recommendations for the provision of medical care at mass gatherings; relevant documents can be accessed through their websites. However, as noted in the NAESMP Position on Mass Gathering Medical Care, there is little scientific evidence to substantiate many of the recommendations stated in these documents.

EPIDEMIOLOGY

The modern era of mass gathering medical care began in 1965, when two spectators collapsed and died in the University of Nebraska Football Stadium. Staff or equipment to provide CPR was not available. To address this problem, personnel and equipment were placed within the stadium to provide emergency medical care. In the 8 years that followed, 18 spectators developed a cardiac or pulmonary emergency; 9 experienced cardiac arrest, 8 of whom were successfully resuscitated and discharged from the hospital. Since then, reported specific experiences on mass gathering medical care include professional and collegiate football, summer and winter Olympic Games; World's Fair Expositions; motor racing; and rock concert festivals.

Statistics generated from sporting events have shown the incidence of medical problems ranging from 0.12 to 17 per 1000 spectators and cardiac arrests ranging from 0.3 to 4.0 per 1,000,000 spectators.⁴⁵ Statistics from major rock concerts demonstrate a 3 to 10 times higher incidence for spectator medical care than at sporting events. For events with a large number of participants engaged in physical activity (e.g., biking, running, and walking marathons) the demand for medical care (24 per 1000) can far exceed that from events at which spectators are the majority of the event population. These numbers reflect the unique medical setting for which a medical care plan and program is indicated.

MEDICAL DIRECTION

The event medical director is ultimately responsible for the conduct of medical care provided at the event. The goal should be the provision of medical care to at least the standard of that in the surrounding community. To accomplish this goal, the directorship position should be integrated into the overall event administrative structure, with clear lines of responsibility and authority to event management and medical care providers. In addition to the requisite state licensure, the medical director must be knowledgeable and experienced in the care of acutely ill and injured patients. Further, the medical director should have education and experience in out-of-hospital [i.e., emergency medical services (EMS)] medical care. Emergency medicine is an ideal background for the medical director.

On-site medical direction has several advantages over off-site medical direction. Critical medical issues requiring the expertise of a physician can be addressed in the most appropriate and timely manner, including the perspective of both in-transit care level and destination facility capability. The quality of decisions about nontransport and triage is improved by on-scene evaluations. The credibility of care and disposition decisions is enhanced in circumstances where a physician-

spectator intercedes in event emergency care. Ultimately, the medical director's presence symbolizes organized medicine's commitment to the highest level of care possible at the event, an attribute likely to be appreciated by event management, as well as by patients. However, because of potential conflict with oversight duties, the medical director should avoid all but brief direct patient care responsibilities. When on-site, the medical director should be easily and readily identifiable by uniform or vest. In spite of these perceived benefits by those with mass gathering medical experience, physicians do not need to be on-site for events of low acuity, small to moderate size, with on-site patient times of less than 30 min.⁶

MEDICAL DIRECTOR AND EVENT MANAGER NEGOTIATIONS

The medical director should meet with the event managers during the planning phase to discuss the issues relevant to medical coverage. The medical director should inspect each event venue and anticipate medical demand based on either past experience or research of the literature. These findings should be discussed with the event managers. A final meeting should result in an agreement upon which the medical care plan is based. Elements to be addressed by the medical care plan include personnel issues covering medicolegal liability, credentialing, scope of practice, compensation, labor laws (uniformed medics); logistical support covering potable water, meals, sanitation facilities, parking, lodging, work-cycle assignments; communications system design for physician supervision of all event medical personnel and liaison to event managers responsible for functions impacting medical care; facility supplies, medical equipment, and Pharmaceuticals. The agreement should be documented and contractual because of the risk management and medicolegal implications of the anticipated duties.

EVENT RECONNAISSANCE

The Physical Setting

Preparation should begin with repeated reconnaissance of the event setting with respect to the event type and expected population. Will the participants be seated at a sports event in a stadium or a political rally at a convention center or arena? Or will they be ambulatory at a golf or racecourse, aviation exhibit, cross-country running, biking, or equestrian event? The extent of spectator mobility has important implications for the population density and expected morbidity. At events where spectators are predominantly ambulatory, especially on irregular terrain, lower extremity trauma should be anticipated. Reports from both the 1984 Los Angeles and 1996 Atlanta Summer Olympics revealed the highest medical care use in venues where spectators moved about during the events.^{7,8}

Internally, the medical director must investigate the total geographic area of medical responsibility, as well as the physical barriers to accessing potential patients. These factors can affect the ability to discover, locate, and extricate victims from a crowd as well as transport them to the most appropriate treatment site. Are on-site treatment facilities needed, or will on-scene stabilization and immediate patient evacuation off-site, or some combination of both be instituted? Externally, are dedicated public safety ingress and egress routes adequate to handle anticipated medical needs? What is the estimated transport time to the nearest hospital for noncritical patients and the nearest appropriate facility for critical patients? These factors hold profound implications for both the number and expertise of event medical care providers needed as well as their mode(s) of transportation within the venue.

For indoor events, adequate ventilation and access to exits are important issues, usually determined by jurisdictional fire codes. For outdoor events with climatic exposure, access to shelter and protection

from indigenous species must be anticipated. In both settings, access to potable water, adequate numbers and distribution of restrooms, and public address system geographic range must be investigated. The history of severe weather conditions during the time of the event should be researched in anticipation of resultant illness/injury such as heat syndromes or hypothermia-frostbite.

Expected Populations and Hazardous Exposures

The event attendance bears some relationship to the expected patient volume with implications for the numbers and type of medical staff needed. However, retrospective research has not yielded any universally acceptable mathematical relationship, and the event's hazardous exposures bear a much greater relationship to patient volume than to crowd size. In studying Syracuse University's rock concert, basketball, and football events for 7 years, De Lorenzo found a correlation of crowd size with patient volume only for the concerts.¹ Event duration also correlates with patient volume through time of exposure to event and population health risk factors; the 1982 U.S. Rock Music Festival experienced a significant increase in daily patient volume on the second day of the 3-day event.

Therefore, investigating expected population characteristics and hazardous exposures is crucial to planning for their medical care. The expected density and range of ambulatory movement within a venue may foretell the risk of heat exhaustion. Will this event attract an older population at risk for sudden cerebrovascular and cardiovascular events or one in which a younger population will likely be exposed to the attendant morbidity of street drugs? Children presenting the danger of separation from responsible adults can be tagged with identification upon entry to the event. Will alcohol be allowed and/or served, and if so, what is the history of its effect on participants' behavior and health at previous and similar events? Will food be offered at the event, and if so, what public health official(s) has responsibility for monitoring and enforcing its sanitation and disposal? Is the access to toilet facilities and potable water adequate, especially at outdoor and rural sites? What is the public address system range? Will VIPs (very important persons such as politicians, heads of state, diplomats, media personalities, and corporate heads) participate, and if so, what special health and medical care measures are planned? Who are the officials responsible for these measures?

INTERACTIONS

Plans for medical care should proceed simultaneously along interdisciplinary and intradisciplinary lines. Coordination with fire/rescue/hazardous material (HAZMAT), public health, and law enforcement/security is essential. What law enforcement agency and official(s) are responsible for precautions against terrorism and the coordinated response to it? What agency and official(s) are responsible for the jurisdictional disaster/multicasualty incident (MCI) plan? What is the communications path to officials responsible for initiating execution of the plan and what infra-venue officials are in the decision tree to trigger the request?

What EMS service is responsible for responding to emergency calls within the jurisdiction surrounding the venue? The patient transport capacity of that service should be determined. If the transport service becomes saturated, when is the MCI plan activated? The extra patient transport capacity afforded by any existing mutual aid agreements with other services should be examined. What potential patient capacities do the surrounding hospitals possess? Limited external medical facilities (i.e., rural setting) may force more advanced care to be performed on site, requiring more medical staff at a higher level of expertise, more supplies, and intravenue facilities. Both the medical and administrative directors of potentially affected EMS and hospital emergency services should be repeatedly updated on medical care plans for the event and their suggestions actively solicited.

RESPONSIBILITY FOR COVERAGE

The owner or promoter of any mass gathering has an obligation to provide for the safety and security of its participants, spectators, and workers. Very few venues have enough events on a regular basis to provide for permanent, in-house medical care without outside assistance. On-site emergency medical care is typically secured through an affiliation or contractual arrangement with an EMS system and/or a health care provider, such as a hospital. The goal of any venue should be to provide the same quality of health care and security one could reasonably expect as a normal citizen outside of the venue. Failure to provide this level of service could result in a significant liability for the venue owner or event promoter. Inappropriate and/or inadequate resources or care is also a liability to the medical director, EMS system, or hospital that is assisting with the medical services.

The medical director plays a key role in the planning of any on-site medical facility and the care it is to provide during a mass gathering. The medical director should be involved in the plan, setup, and maintenance of any medical facility; and the selection, training, and function of the medical team. This requires involvement not only in the event planning, but, if possible, during the design and construction of the facility.

Licensing and credentialing all medical personnel is important. Typical good Samaritan laws provide only limited protection to health care workers who provide emergency care on a voluntary basis and are not designed to cover medical personnel assigned specific responsibilities at a scheduled event. The relevant statutes and law should be investigated prior to the event.⁹ Health care providers should be licensed to perform their function during the event.

Liability insurance is also important for the medical director as well as the health care providers. The owner or promoter of the event may be able to obtain coverage for the medical care, or coverage may extend from the health care provider or their employer.

Several legal issues should be addressed in a contract between the medical director and event organizer/manager. A contract should give the medical director the authority to obtain whatever supplies or resources are appropriate prior to and during the event. The contract should specify financial responsibility for equipment, resources, and personnel. At a minimum, the contract should include start and end dates, fee structures, health department and medical license structures, equipment and personnel requirements, minimum medical care requirements, medical direction authority level, and emergency provisions for disaster or mass casualty situations. As much detail as possible should be listed with respect to the medical treatment facility size, location, and physical construction; the transportation of patients and personnel; the personnel's lodging, parking, food, and hygiene issues; and the communications system and devices.

ANATOMY OF A MEDICAL CARE SYSTEM

Planning

The first step in designing a mass gathering medical care system is to determine the sophistication of medical care that is needed or desired. On-site levels of care may be basic life support (BLS), on-site treatment with jurisdictional EMS transportation, advanced life support (ALS), or some combination thereof. The patient population for which medical direction is responsible should also be established; this may be participants or performers, spectators or employees. The goal is to provide the maximum care possible with the resources available. For events involving significant risk of injury to performers, separate medical personnel and resources should exist for both spectators and participants; so that care to one sector does not interrupt coverage to the other. This requires that the system be cooperative, adjustable, organized, intelligent, and prepared.

If possible, the design of a medical care system should be based on interventions that can positively affect patient outcome. For instance,

a response time of 3 to 5 min can positively influence the ability to successfully resuscitate a cardiac arrest victim. Rapid (optimally, bystander) CPR is the cornerstone of BLS care, as is airway management and early defibrillation for ALS care. Therefore, responders who are trained at least to a BLS level should be stationed within 3 min of anyone in the venue.

Medical personnel and supplies should be allocated based on the anticipated number of patients and the seriousness of the anticipated medical problems. The medical problems encountered at mass gatherings are often similar. The volume and complaints can depend to a large degree on the variables previously discussed. If possible, it is helpful to obtain pre-event medical intelligence from the records of previous and/or similar events or law enforcement agencies that have had experience with the particular event. This may give insight to the potential for violence, and alcohol and drug use.

Patient Care Path

The medical care plan should address the flow of patient care from the occurrence and possible scenes of the medical events to their definitive care. Ushers, volunteers, and security personnel should be equipped with adequate communications devices and trained to relay information concerning any individual in need of medical care. Those without communication devices should be informed of the location of the nearest security officer or device for contacting the command center. Training should include the ability to communicate the appropriate information in a clear, concise format. These individuals must also act as first responders in providing a path to the patient and when necessary, providing bystander CPR.

The command center or dispatch center is responsible for coordinating the response to a medical incident. Provision of a clear, concise chief complaint to the center is vital to coordinating an appropriate response. The command center should provide all the necessary medical and security resources for response. Command staff should include managers of facility maintenance to address plumbing and electrical mishaps, parking, public relations, security and ushers. The command center is also responsible for the flexibility of personnel duties and the positioning of the response teams within the facility to provide the best response time.

Once dispatched, the response team should locate the victim and initiate care. This is best accomplished by the rapid extrication of the patient from the crowd to the nearest space (tunnel, open entryway) isolated by security personnel. At this point, stabilization/treatment can be initiated by protocol or with on-line medical direction. The amount of treatment provided at this point depends on the medical condition of the patient and the layout of the facility. Transport to a designated on-site treatment facility or ambulance should occur as soon as possible so that a specialist can provide care at the highest level appropriate to definitive treatment.

Transportation from the event should be by the most efficient mode possible considering all factors. If no access roads are available, helicopter transport may be the most appropriate option. A medical care plan should integrate the local EMS system to allow for increased transport capabilities to external hospitals if needed. This can be done by dispatching units in service within the jurisdictional system to sites of medical occurrences at the event or to a site previously occupied by a unit transporting a patient.

MEDICAL CARE RESOURCES

Personnel

Often events are staffed by a combination of paid personnel and volunteers. The number of personnel is based on the layout of the facility, the size and characteristics of the crowd, the adequacy of EMS cover-

age, and the proximity to adequate off-site (hospital) facilities. These factors determine the level of intravenue care needed. Response teams should be located throughout the facility to keep response times within a 3- to 5-min time period needed to successfully resuscitate cardiac arrest victims. It is often very beneficial to couple security officers with medical personnel in order to provide a safer environment and a quicker response. In special situations, it may be necessary to add others to the response team, such as fire fighters or water rescuers. Each response team should be efficiently staffed and equipped to easily transport a nonambulatory patient.

Treatment facilities should be staffed with definitive emergency care-level personnel; usually a mixture of nurses, physician assistants, emergency medical technicians, paramedics, and physicians. It is the function of the medical director to determine how to best meet the demands of patient care in the context of the event budget dedicated to medical care. The appropriate expertise of nonphysician personnel varies greatly. Their availability can have a direct impact on the number of physicians required. The number of physicians recommended for on-site care ranges from 1 for every 5000 to 1 for every 50,000 people. These staffing requirements should be part of a formal contract with the facility management.

Equipment

It is the responsibility of the medical director to determine the supply level and type of equipment to be used within the facility, and to incorporate these specifications into both the contract and medical care plan.¹⁰ Often this is dictated by the local EMS system, which provides equipment for the event. Response teams should be equipped with basic airway and first aid equipment. The teams must also have adequate extrication and intravenue transportation modes (e.g., motorized carts) based on the layout and terrain of the facility. In the event of a cardiac arrest, a defibrillator should be available to be sent to the location of the patient along with ALS personnel with advanced airway equipment. This may not be necessary if an intravenue treatment facility is within a 3- to 5-min transport time under actual event conditions. The medical care system should have enough defibrillators to allow any location in the facility to have access to one in 5 min or less.

Equipment within the on-site treatment facilities should be based on the level of care provided, the number of patients anticipated, and the length of time each patient would be required to stay at the site awaiting disposition or transportation. Transportation, if not on-site, should be established in the plan to have the capabilities of transporting the patient to a hospital within 30 min of the request.

Communications

Audio communications represent the glue that joins not only the myriad of medical care and surveillance components into an efficiently functioning system, but also the venue health care system to the other systems vital to managing a mass gathering.

The spectator level presents the greatest challenge. The first "first responders" are always fellow performers or spectators. Upon entry to an event, they should be educated in how to link knowledge of an illness/injury occurrence to the venue's medical care system so that rapid assistance can be rendered. In preparation for the 1996 Olympics, health promotion brochures were mailed with ticket information. Concise information on ticket stubs accompanied by periodic public service announcements can serve the same purpose.

At the medical care system personnel level, every event official, from ushers, volunteers, security, and public relations personnel to the top rung of management, must be educated in and updated on the most expedient manner in which to obtain medical assistance. Because radios are expensive, for the most numerous event workers, usually ushers, alternatives such as flag systems have been organized. At the U.S. Open Tennis Tournament, Forrest Hills, New York, a flare system has

been organized. All event personnel should know the venue location of the nearest official who has a radio.

Among those officials with radios, frequencies and/or "talk groups" (e.g., 800 MHz trunking) can be organized to minimize interruptions and maximize effective radio traffic from incident discovery through responders to definitive caregivers. At the most highly evolved events, discovery of a victim(s) by the system usually proceeds from bystanders, ushers, or vendors to on-site security to a central communications or command center where the event medical director is based. Venue surveillance cameras can augment verbal reports on victim location as well as examine the scope of the incident. The medical director can then select and radio-dispatch the nearest most appropriate responders with adequate security and/or public relations assistance. Responding event field providers, dedicated event ambulance crews, on-site medical facilities, the medical director, and the medical command center should be able to communicate with each other. Additionally, medical command should have voice access to all area hospital emergency facilities.

RELATIONSHIP OF FUNCTIONAL AREAS

Optimally, a central location should be designated for stationing the directors of the following functions: medical emergencies, event management, logistics, facility maintenance, public relations, and security/law enforcement, ushers and event performers/athletes. If not within this immediate area, fire/rescue, public health, and public transportation and parking directors must be easily and reliably accessible by telephone and/or radio. From the medical care perspective, the leadership's close physical proximity is especially important if on-site care is provided, as it will allow for efficient information exchange and problem solving among the directors whose functional areas are integral to medical care delivery. A less-reliable alternative involves intra-venue radio links among the directors of these functional areas.

Internally, event management has to mediate issues at the interface of one functional area with another. Event management is the contact for accessing outside resources, a vital function in the management of multicasualty incidents. Whenever depletion of operational resources is threatened, logistics personnel should immediately access and deliver additional equipment and supplies as patient demand dictates. The medical director and logistics supervisor should prospectively determine a threshold level of each essential supply item, below which resupply is undertaken. Facility maintenance has a major public health role in providing and maintaining an adequate potable water supply, sanitary facilities, and the venue electrical system vital to operating the public address system, air conditioning/ventilation, and lighting. Public relations plays a crucial role in directing crowd control and informing the event population of preventive public health measures as well as the location of medical care. Security/law enforcement personnel serve the entire spectrum of illness/injury prevention. Their primary prevention role includes pedestrian safety in regulating the interface of vehicular and pedestrian traffic, clearance of emergency vehicle access routes and venue pedestrian entrances/exits, and surveillance for and investigation of terrorist threats. Their discovery of the ill/injured by direct sight or television surveillance, subsequent dispatch of medical care providers, then clearance of the path through crowds to gain access to patients represents their secondary prevention role. Similarly, ushers play a crucial role in the direct-sight discovery of victims and must know how to relay medical event information to the predesignated personnel responsible for dispatching medical response teams. Like security/law enforcement, their ubiquitous positioning make them invaluable in the delivery of response time-sensitive CPR.

Event participants or performers, be they athletes, politicians, musicians, or animals, represent a separate and distinct population requiring medical care specifically geared to their talent(s) and/or position in society; their care is best provided by a cadre of personnel most

familiar with their specific health care needs. When affordable, a separate medical care system and resources should be provided to ensure that care for performers and spectators do not interfere with each other.

QUALITY MANAGEMENT

Documentation

A medical record should be generated for each medical encounter, the type based on the severity of the complaint. An officially sanctioned event form should be used to record the encounter date and time, patient's name, sex, age, race, medical complaint, drug allergies, relevant medical history, and examination findings. The tentative diagnosis and treatment plan should be documented, complete with discharge instructions. Because most all patients provided ALS care will be transported to a hospital, the transporting EMS patient care report form can conveniently document the continuum of care provided at the scene and in transit.

Event Training

Event training represents prospective quality management. Optimally, all of the personnel functions described in the preceding relationship of the functional areas should be represented at event training sessions held on-site. Ironically, especially with regard to public safety, health, and medical care personnel, the major obstacle to their training participation in one place at the same time is their regularly scheduled duties, the skills from which will translate into their event duties. Possible alternatives to address this problem include videoconferencing and virtual-reality applications. However, both of these modes preclude a realistic grasp of time-space relationships (i.e., patient access obstacles) that are facilitated by drills at the venue.

A central goal of event orientation should include instruction in the following venue locations: the command center, medical care facilities, ambulance, radio-equipped security postings, and emergency ingress and egress routes. All personnel must know their geographic postings and coverage areas, receive instruction in communications equipment use, and practice the appropriate communications pathways to be used for medical care. Instruction in filling out a standardized medical care report form should be provided. Practice scenarios should include a mock MCI requiring designation of ambulance staging and contingent triage zones, and a request for outside intervention. Contingency plans for critical incident stress debriefing should be made and explained. Difficult access extrication, hyper- and/or hypothermia prevention and treatment, cardiac arrest, event player/performers) injury, and dignitary/VIP care should be rehearsed. Within each of these scenarios, communication (radio, cell phone) and physical routes to optimal care (ambulance evacuation, on-site facility care) should be tested.

Retrospective quality management can be done through instruments that document the quality of care (patient care report forms), measures of the public image of care rendered at the event (patient-targeted surveys), and management's degree of satisfaction with the results. The medical director should review all medical records. If the patient volume has been large or included a multicasualty incident, an audit and review committee should perform the review.

SPECIAL CONSIDERATIONS

Cardiac Arrests

As discussed, the incidence of cardiac arrests in mass gatherings is higher than in the normal population. It has been postulated that because of the natural excitement generated by competitive sports, individuals

who have cardiac disease are more likely to become symptomatic. However, medical systems at mass gatherings have demonstrated much higher success rates than even the most advanced EMS systems. This is primarily a result of the ability to provide early bystander CPR, airway control, defibrillation, and ALS care. Survival rates for hospital discharge have varied from 20 to 100 percent survival from documented cardiac arrest. This evidence would also support the use of automatic external defibrillators (AEDs) in mass gatherings where ALS support is not available in less than 5 min.

Positioning of emergency care providers with AEDs requires careful attention during the planning stages for any mass gathering. Optimally, BLS and AED should be available to all event participants within 3 min of collapse. Factors such as event layout, slope and crowd density all need to be evaluated when positioning AED-equipped first responders.

Commercial Airline In-flight Emergencies

The population density, temporary isolation, and common purpose on commercial airliners is one situation where many of the principles of mass gathering medical care applies.¹¹ Since 1986, U.S. airlines have been required to carry mandated emergency medical kits. In April 2001, the rule was changed to require all U.S. airlines to carry an enhanced emergency medical kit (accessible to the flight crew but to be used only by medical professionals) and an AED, plus providing the flight crew with appropriate AED and CPR training.

Medical problems encountered on board commercial airliners resemble those seen at ground-level mass gatherings. A survey of 5 U.S. domestic airlines between 1996 and 1997 found 1132 in-flight medical incidents with use of the medical kit in 47 percent of these events.^{12,13} A major airline can expect approximately three in-flight medical emergencies per day and one life-threatening (asthma, choking, cardiac arrest, heart attack, loss of consciousness, stroke) emergency every 2 to 3 days. The most frequent (in decreasing order) complaints were neurologic, syncopal, cardiac, psychiatric, and respiratory. Intentional injury of crews by unruly passengers has increased, with 174 incidents reported in 1995.

The airplane environment presents several unique aspects of medical emergencies and their treatment. Following discovery of a medical incident, the response time to on board care is minimal. Caregivers' access to victims is compromised by their seated position in a setting similar to that in a crowded stadium. The victim's safe, timely extraction to a secured space allowing the supine (left lateral decubitus for pregnant patients) position is a foremost priority but a formidable challenge in such a confined environment not dedicated to even provisional medical care. Oxygen sources are plentiful but their location is not configured for optimal patient care. At cruising altitude, despite cabin pressurization, ambient air oxygen availability is below that at sea level $f\text{Po}_2$ (partial pressure of oxygen) is typically 118 mm Hg while in-flight versus 159 mm Hg at sea level] and has the potential to cause respiratory problems in the marginally compensated patient.

Flight attendants receive basic first aid training to a degree that varies among airlines. A 2-year monitoring period following institution of the Federal Aviation Administration (FAA)-mandated basic medical kit in 1986, found that physicians responded in 85 percent of

the 2322 cases when it was used. A review of the kit contents supports the inclusion of bronchodilator inhalers, oral antihistamines and non-opioid analgesics.¹² The demonstrated efficacy of AEDs on commercial aircraft has prompted the FAA to require them on U.S. carriers.¹³ Recent reports document a survival-to-discharge rate of up to 40 percent for witnessed arrests in-flight when an AED is available.

When addressing in-flight medical emergencies, the issue of plane diversion arises. Diversion is considered when the patient is in immediate need of care and the expertise needed to provide that care is not available on board. The decision to divert a commercial aircraft rests ultimately with the pilot. However, in 2321 cases from U.S. domestic air carriers between 1990 and 1993, the crews complied with a physician's recommendation to divert 97 percent of the time. In addition to the time sensitivity of the patient's condition, diversion involves issues of proximity to an airport suitable for the aircraft versus the original destination port, availability of adequate EMS resources (ALS versus BLS) to meet the diverted craft, and proximity of appropriate hospital resources to the diversion airport. Many of the U.S. air carriers contract with in-flight medical consultation companies to assist crews and on-board medical personnel in making an appropriate diversion decision. Emergency physicians, by virtue of their expertise, have collaborated with the airlines to improve in-flight medical care.

DISASTER PREPAREDNESS

6

DISASTER MEDICAL SERVICES

Eric K. Noji Gabor D. Kelen

Natural disasters such as earthquakes, tornadoes, floods, and hurricanes have claimed approximately 3.5 million lives worldwide during the past 25 years, adversely affecting the lives of at least 1 billion more people, and have resulted in property damages exceeding \$50 billion. While past disasters have produced their share of mass casualty situations, the future appears to be even more bleak. Increasing population density in flood plains and seismic and hurricane-prone areas, the development and transportation of thousands of toxic and hazardous materials on the nations' roads, the potential risks that can occur from incidents at fixed-site industrial facilities, and the catastrophic possibilities from nuclear, explosive, biological, and chemical terrorism, all point to the probability of major emergencies in the future. Recent significant disasters have included Hurricane Mitch (1998); a series of devastating tornadoes in Oklahoma; record flooding in eastern Texas; a number of major earthquakes in India, Turkey, El Salvador, Taiwan, and southern Italy; the terrorist passenger plane attacks on the World Trade Center, followed by intentional anthrax releases up and down the East Coast; and, most recently, the deadly terrorist bombing of a crowded tourist venue on the island of Bali and the nightclub fire in Rhode Island.

The emergency physician has extensive responsibilities for community disaster preparedness and other disaster medical services. Since 1976, the American College of Emergency Physicians (ACEP) has taken the position that emergency medicine should assume a primary role in the medical aspects of disaster planning, management, and patient care. Despite efficient field management of disaster victims, a rapid flow of victims from a disaster scene can quickly overwhelm a hospital emergency department. The point at which the emergency department becomes overwhelmed often varies according to the time of day, the nature of the injuries, and the amount of preparation time prior to the arrival of victims.¹ When it appears that normal procedures will be overwhelmed, emergency departments must have a specific set of protocols that direct the mobilization of personnel and equipment outside of the emergency department and permit rapid assessment, stabilization, and triage to definitive care of victims of a mass casualty incident.²

DEFINITION OF DISASTER

A multivehicle crash involving four or five seriously injured persons, or a family presenting with carbon monoxide poisoning that would overwhelm the resources of a small rural community hospital may be a rather routine event at a large university teaching medical center. On the other hand, greater than 25 patients at one time will overwhelm even the best staffed trauma center. According to the World Health Organization, a disaster can be defined as a sudden ecologic phenomenon of sufficient magnitude to require external assistance. From the perspective of the emergency department, however, a disaster exists when the number of patients presenting in a given space of time are such that the emergency department cannot offer even minimal care for them without external assistance. Disasters that are characterized by the production of large numbers of deaths and injuries are also referred to as "mass casualty incidents."³ Note that disasters are not defined simply by a given number of victims. A single case of smallpox may paralyze an entire hospital let alone the ED. The arrival of one im-

portant political person or celebrity with severe injuries (e.g., the president of the United States, the Pope, a rock star) will completely disrupt normal operations of even the most efficient emergency department. Thus, the definition of disaster incorporates the concept of "massive disruptive impact."

The hospital and, more specifically, the emergency department should have a preestablished protocol for effectively dealing with such an extraordinary situation. These protocols (e.g., for intentionally infected, chemically contaminated patients or for the mobilization of appropriate outside assistance) should be instituted rapidly in order to prevent death or severe complications.

In many hospitals in the United States, disasters are often divided further into external or internal events. *External disasters* are events that occur physically outside the hospital (e.g., transportation accidents, industrial explosions, terrorist actions). Patients are brought to the hospital from the outside, usually to the emergency department. Unlike patients contaminated from a chemical, nuclear, or biologic contagion incident, the hospital and its staff, patients, and visitors are in no immediate physical danger from victims of explosives, blast, or other simple but devastating traumas.

Internal disasters are events that occur within the physical plant of the hospital itself (e.g., fire, laboratory accident involving radioactive material, power failure, contaminated water) that severely compromise the ability of the hospital to function.⁴ A disaster may be both internal and external; for example, an earthquake or explosion that severely damages the hospital.

CHARACTER OF MASS CASUALTY EVENTS INVOLVING EMERGENCY DEPARTMENTS

Extensive social and organizational research, conducted on the management of mass casualty events prior to September 11, 2001 (9/11), has shown that emergency departments experience great difficulty coping with even moderate numbers of patients following a disaster. The reasons for this difficulty include confusion, lack of planning, lack of training in principles of disaster management, and lack of practice drills. Hospitals are often not well integrated into the surrounding community's disaster planning efforts. Shortcomings of hospital disaster plans include:

- Delayed or improper notification
- Poor delineation of command structure
- Overloaded or broken communications networks
- Improper or incomplete identification
- Lack of supplies
- Lack of public relations

The World Trade Center and Pentagon attacks have forced virtually all public hospitals to focus on these issues.

In mass casualty events, the emergency medical services (EMS) protocols that call for transport of patients in equitable distribution to appropriate centers is easily foiled because of confusion, route obstacles, and difficulty in communications. This was quite evident in New York City on 9/11. As a result, the highly injured and ill are often transported to the nearest hospital ED, which often does not have appropriate facilities and expertise to best care for the seriously injured and ill. Unfortunately, the problem is compounded by the fact the "walking wounded" and "worried well," that is, those who need the least medical attention, also arrive at the nearby hospital(s); often in overwhelming numbers. In an urban setting, patients can be expected at the nearest hospital(s) within minutes, and peak volumes can be

SECTION 2 • DISASTER PREPAREDNESS

expected within 2 to 3 h.⁵ More than half of all patients likely to require or seek medical care within 48 h will be seen within 7 h of the event.⁵ During the World Trade Center disaster, 18 percent of the 790 injured survivors were admitted.⁵ The vast majority of patients are not transported by the EMS system. Announcements of numbers of patients to be brought to the ED by the local emergency communications center or by the on-site command will invariably underestimate the total number of patients who actually arrive.

Those with minor injuries travel by alternate means of transport (private automobiles, police vehicles, buses, cabs, and on foot),⁶ and are likely to arrive in great numbers, even before many of the seriously ill are transported via EMS. The more severely injured, who often need extrication (e.g., from collapsed buildings following earthquakes and explosive devices), arrive at a later stage. Thus, without careful planning, less-severely injured patients often tend to be treated before the more seriously injured.

Other factors that may hinder effective ED disaster management include:

- Poor communications with the scene and within the facility (often considered the greatest problem)
- Incident Command System not followed
- Convergence of rescuers, emergency medical technicians, and the media in the ED
- Convergence in the ED of other hospital physicians and nurses, who are unfamiliar with their roles and have little experience caring for traumatized or nuclear, chemical, or biologic agent-exposed patients.
- Convergence of friends and family searching for loved ones

It does not take a mass casualty event to essentially paralyze an ED. In the early phase of the anthrax release, even one case of possible exposure could paralyze an ED. In at least one major academic ED, local law enforcement, the FBI, hospital infection control, hospital corporate security, hospital safety officials, and city and state health departments all converged in various ways in the ED as part of the investigation (G. D. Kelen, personal communication, Nov. 21, 2002), illustrating clearly that a disaster is not defined by numbers, but by impact.

DISASTER PLANNING

Overview

Roles, responsibilities, and working relationships between those responsible for disaster operations should be clarified in the planning process to lessen the confusion that invariably occurs during a disaster event.⁷ Selected protocols should require personnel to perform functions that are relatively similar to their day-to-day activities.

The disaster planning process should begin by answering the following questions:

- What types of disasters are most likely to occur in the community (e.g., hazard analysis)?
- What are the disaster planning requirements of the Joint Commission on Accreditation of Healthcare Organizations (JCAHO),² as well as other accreditation bodies (e.g., local and state health agencies)?
- What are the capabilities and responsibilities of the hospital?

Hazard Analysis

Hospital disaster planners should plan for those disasters most likely to occur in their community. For example, hospitals in Hawaii and along the Gulf and Atlantic Coasts of the United States should plan for hurricanes, those in California should plan for earthquakes,^{8,9} and those near chemical industries should have facilities for decontamination. Regarding the latter, hospitals located near facilities using large amounts of hazardous materials are required by Title III of the Super-

fund Amendments and Reauthorization Act (SARA III) to participate in local emergency planning committees (LEPCs).¹⁰ Factors such as the presence of nearby transportation facilities (e.g., airports, harbors), festivals, stadiums, and amusement parks should be included within the risk assessment. Because different disasters are characterized by very different morbidity and mortality patterns, anticipation of health care requirements can be specific.¹¹ For example, earthquakes cause many deaths and severe injuries.^{12,13} Hurricanes cause mostly property damage; however, deaths are usually low and injuries minor.¹⁴ Pulmonary irritation may result from fires or hazardous chemicals, requiring large supplies of oxygen, as the 1984 Bhopal industrial accident demonstrated,¹⁵ or a specific antidote (atropine), as occurred following the Tokyo sarin chemical weapon attack in 1995.¹⁶

JCAHO Requirements for Hospital Disaster Planning

There are other motivations for hospitals to plan for potential disasters. The JCAHO requires that member hospitals have a written plan for the timely care of casualties arising from both external and internal disasters, and the hospital must document the rehearsal of these plans.²

Hospital-Community Cooperation in Disaster Planning

The Medical and Health Incident Management (MaHIM) System was recently developed as a model for planning a regional response that allows customizable organization of available assets for mass casualty response¹⁷ (more than 500 casualties). The health system and its component hospitals play a vital role. Every hospital should integrate its own disaster plan with those of community disaster management agencies. This is especially important regarding disaster notification and communications, transportation of casualties and provisions for dispatch of hospital medical teams to a disaster site. Strong relationships with community agencies (e.g., the fire department, the regional EMS system, local emergency management or civil defense agency) are important to ensure a coordinated disaster response. The number of community agencies that have some responsibility for disaster planning and response can be bewildering. Table 6-1 lists just a few.

TABLE 6-1 Key Agencies that May Play a Role in Health-Related Disasters

Community Agency	Responsibilities
FBI	Initial incident command if a federal crime may be involved
FEMA	Incident command in public health disaster
State governor	Authority to declare health emergency; requests federal assistance (e.g., from FEMA); responsible for public safety
State health department	Authorized by governor to coordinate disaster response
State emergency management association	State-level equivalent to FEMA
City/county health department	May have jurisdiction for local disasters
EMS service	Patient triage in the field, stabilization, and transfer to definitive care facility
Fire service	Overall scene command; victim rescue and hazard control
Police service	Traffic management and scene security
Public works	Support equipment and personnel; structural safety expertise

Abbreviations: EMS = emergency medical services; FBI = Federal Bureau of Investigation; FEMA = Federal Emergency Management Agency.

Other organizations that a hospital may interact with during the disaster planning process may include the military, local chapters of the American Red Cross, LEPCs, Citizens' Corps Councils, and other volunteer agencies, along with state and federal agencies [e.g., National Disaster Medical System, Metropolitan Medical Response System, Centers for Disease Control and Prevention (CDC)]. The CDC in and of itself is advisory and has no official jurisdiction.

Medical planning for disasters in the community is usually the responsibility of local EMS councils, health departments, or boards of health.

Each hospital should have mutual aid agreements or memoranda of understanding with hospitals outside the immediate area should hospital capacities be exceeded.

Hospital disaster planners should anticipate that information about specific hazards (e.g., chemicals, radiation), expert personnel (e.g., poison control), and special supplies (e.g., antidotes) not readily available may be needed in a particular disaster situation. Plans should consider how to rapidly access these resources. Plans for obtaining additional shelter, food, and water should also be considered.

INTEGRATION WITH OTHER RESPONSE ASSETS Some of the federal response resources with which the emergency clinician should have familiarity are listed below. They all are subsidiary agencies to the Department of Health and Human Services (DHHS), with the exception of the Federal Bureau of Investigation (FBI). During a response, these agencies may play pivotal roles and may interface and coordinate with hospitals and emergency medicine clinicians.

United States Public Health Service/Office of Emergency Response [formerly Office of Emergency Preparedness (USPHS/OER)] This agency is an office within the DHHS dedicated to the management and coordination of federal health and medical activities related to preparation, response, and recovery from major emergencies and Presidentially declared disasters. One of the most significant programs developed by the Office of Emergency Preparedness (OEP) is the Metropolitan Medical Response System (MMRS) (www.mmrs.hhs.gov). Initiated in 1996, MMRS was originally a program with a team-oriented approach to responding to weapons of mass destruction events including bioterrorism. Teams were hosted by local jurisdictions and then provided funding, equipment, and supplies by OEP to make them operational. The concept was developed on the basis that local responders would be more rapidly able to respond to incidents in an individual jurisdiction. Since then, the MMRS program has evolved to include a more primary focus of enhancing local emergency preparedness systems as opposed to developing stand-alone teams. The MMRS program promotes coordination between various types of local responders [police, fire, hazardous material (HAZMAT), EMS, hospital, law enforcement, and others] to affect an adequate community response system. This is accomplished through contractual requirements that prompt participating jurisdiction to meet in developing specific elements of their weapons of mass destruction response plans. By the end of 2002, it is expected that 120 U.S. cities will have funding in place for an MMRS.

OEP also manages and participates in other programs which could potentially play a role in a bioterrorist event. OEP is the principal coordinator of the National Disaster Medical System (NDMS). NDMS is an asset-sharing program between DHHS, the Federal Emergency Management Agency (FEMA), Department of Defense (DoD), Veteran's Health Administration (VA), and public/private organizations. Originally developed to provide surge capacity for injured victims of catastrophic natural disasters and for wartime military casualties, the system also has utility in a large-scale bioterrorist event. Key components of NDMS are the Disaster Medical Assistance Teams (DMATs), patient transport systems, and agreements with definitive care facilities across the United States to care for casualties. DMATs are teams comprised of physicians, nurses, medics, pharmacists, and logisticians that deploy in response to federally declared disasters and emergencies

to support a local jurisdiction's response. Several specialty teams, based on the DMAT concept, have been developed to respond to chemical, biological, and radiologic events (National Medical Response Teams or NMRTs). OEP has additional assets such as the Commissioned Corps Readiness Force (CCRF), which draws on volunteers from within the U.S. Public Health Service (USPHS) commissioned officers corp. Disaster Mortuary Operations Response Teams (DMORTs) are designed to handle the increased demands of processing the deceased after a disaster and could potentially be utilized as well.

Centers for Disease Control and Prevention The CDC is the lead federal agency in developing and applying disease prevention and control and also sits within the DHHS. Though responsible for diseases of all types, the traditional focus has been on infectious diseases, making the CDC a natural resource for bioterrorism response. Many programs managed by the CDC are related to bioterrorism response, and some of them are described below.¹⁸

Rapid Response Teams: These include CDC epidemiologists on standby to assist with local efforts in investigating potential outbreaks, confirmation of cases and exposures, and environmental clean-up. This, most likely, is the program with which emergency clinicians will have direct contact.

Laboratory Response Network (LRN): The CDC has developed a program designed to link state and local public health laboratories to advanced-capacity labs including military, clinical, veterinarian, agricultural, water, and food testing labs.

Rapid Response and Advanced Technologies lab (RRAT): The CDC has laboratory capability to provide diagnostic, confirmatory, and reference support to terrorism response teams.

National Electronic Disease Surveillance System (NEDSS): Using the development of standards to advance efficient and integrated surveillance systems, the CDC promotes a national surveillance system for health departments.

Health Alert Network (HAN): Health departments and others are connected via internet communications that allows for early warning broadcast alerts for potential emerging infectious diseases.

National Pharmaceutical Stockpile (NPS): The NPS is a two-part system designed to supply local jurisdictions with medications, vaccines, and equipment during response to a chemical or biological event. The first part of the system relies on prepackaged caches that can be delivered within 12 h in the United States. The second part relies on the vendor-managed inventory, which takes 36 h to arrive.

Federal Bureau of Investigation The FBI is designated as the lead federal agency for crisis management and, as such, has the authority to conduct law enforcement investigations into acts of terrorism. Clinicians may be approached by these persons during investigations.

THE HOSPITAL DISASTER PLAN

The Hospital Emergency Incident Command System (HEICS) was developed to mitigate confusion and chaos that can paralyze hospitals' response during a disaster. HEICS employs a clear management structure with defined responsibilities and mechanisms of reporting using a uniform nomenclature that allows clear communication and understanding between hospitals and with other emergency responders. HEICS has become the standard, and all hospitals should use this system. It includes the following components¹⁹:

- Common language
- Defined and predictable chain of management
- Flexible response
- Prioritized response
- Accountability of position function
- Documentation guidelines for accountability and cost recovery

Basic Requirements of Hospital Planning

Hospital disaster planning is the responsibility of administration, nursing, and the entire medical staff. It should provide for an organized response of the hospital for the management of casualties transported to the hospital from the disaster site. In addition, it should plan for disasters arising within or near the hospital that require hospital evacuation.²⁰

Disaster research has demonstrated that staff who perform most efficiently are those who are performing relatively familiar tasks. The disaster plan should take this into account by relying on standard operating procedures as much as possible.

The hospital plan should describe several key functions, including:

- Activation of the plan
- Assessment of the hospital's capacity
- Establishment of a disaster command
- Communications
- Supplies
- Hospital disaster administrative and treatment areas
- Training and drills
- Security and crowd control

Activation of the Disaster Plan

The plan should designate a (set of) individual(s) who can put the hospital's disaster plan into effect. This is not the equivalent of taking incident command. Situations that warrant activation of the plan should also be defined. Disaster protocols should define how it is determined to what degree to mobilize ED staff and staff from other departments. Following activation of the plan, there should be immediate mobilization of all disaster resources likely to be needed. These include personnel, supplies, equipment, communications, and transportation.

Assessment of the Hospital's Capacity

Before the hospital can receive casualties, it must be determined if the hospital itself has sustained any structural damage or loss of utility as a result of a disaster. These include blocked passageways or inoperable elevators; potential for fire, explosion, or building collapse; failure of any utility; loss of equipment and/or supplies including oxygen; contamination of water; and outside access problems. This damage assessment is usually the responsibility of the plant safety officer or hospital engineer. If the hospital's structural integrity has been compromised, it may be necessary to evacuate staff and patients.

Once it is determined that the hospital itself is safe, the hospital should determine how many casualties from the disaster site it can safely manage. This may be limited by available personnel, beds, operating room and intensive care unit (ICU) capacity, and supplies, as well as by the type of disaster and the availability of other community resources. At the time of disaster notification, it is necessary to know the status of many of the hospital's capabilities: how many beds are available; how much critical supplies and medications (including blood) are available; how many personnel are on duty; what damage has been done; how many operating rooms are in use; which doctors are present in the hospital; and so forth. Ideally, a mechanism to collect these data in short order is delineated in the plan.

Establishment of Disaster Command

A command site within the hospital should be established, preferably in a predesignated area (e.g., disaster control center). This center should be able to communicate with the patient-receiving area (triage site), patient care areas, and with regional EMS, police, fire, and government authorities. Provisions for multiple (redundant) modes of communication (cellular telephones, two-way radios, runners, etc.) should be made. The command personnel should include at least a physician, a nurse, and an administrator. The command structure itself should be clear.

Communication

Establishment of good communications is critical in any disaster or mass casualty situation. Without a clear method of communication, the best disaster plans fail. Unfortunately, experience shows that this essential function is difficult to achieve for a variety of reasons. Many communication modes become inoperative during a disaster. A major goal should be full use of all possible communication resources, including citizens' band groups, cellular phones, blackboards, e-mail, intercoms, closed-circuit television, shortwave radio, and radio-equipped individuals of all kinds, even messenger and courier services. Interhospital and intrahospital communication needs should be considered. It may be necessary because of shortages of life-saving supplies such as blood, antibiotics, and intravenous fluids; certain equipment, such as incubators and surgical instruments; or personnel, such as nurses, x-ray technicians, respiratory therapists, and physicians. Unfortunately, most hospitals in the United States today have limited "surge capacity" regarding both staff and stores of supplies and medications. An overloaded hospital may also wish to transfer patients to a prearranged receiving hospital. (Interestingly, during the World Trade Center disaster, ICU capacity was not stressed.²¹) Unfortunately, interhospital communications may present a weak link in the community's disaster response.

Supplies

During a disaster, necessary supplies and equipment must be ready for immediate distribution to appropriate locations in the hospital (e.g., stretchers and wheelchairs to the receiving area). Each hospital will need to estimate the amount of supplies that will be needed in stock over and above their regular hospital supply. Unfortunately, whereas 10 years ago many medical centers kept a month's supply of many items in stock, most now keep only 2 to 3 days' worth of consumable supplies and medications such as antibiotics. The CDC has arranged a series of medication push-packs throughout the United States that can be delivered to any area of disaster within 12 h. Unfortunately, it is up to each jurisdiction or state to determine how the contents will be distributed.

Hospital Disaster Administrative and Treatment Areas

As part of disaster planning, it is essential that certain areas of the hospital be designated for specific functions such as reception of casualties, treatment, and discharge of patients. The plan should be quite specific as to the function of these areas, staffing requirements, and basic supplies to be used. The areas to be incorporated in each plan are discussed below.

DISASTER CONTROL CENTER A disaster control center should be established remote from the ED. Apart from establishing a hospital-based incident command, the center coordinates hospital activities with those at the disaster site. Good communication is absolutely essential. Other responsibilities include opening up additional hospital wards or clinics, obtaining outside assistance, evacuation of endangered patients, assignment of staff to treatment areas, and revision of original job assignments.

TRIAGE To maximize efficiency, entry of all patients should be restricted to only one location, the triage area. The primary functions of a disaster triage area are rapid assessment of all incoming casualties or ill patients, the assignment of priorities for management, and classification of dispositions (i.e., distribution of patients to various other patient care areas in the hospital). Without a triage area to manage the patient flow, the major treatment area may become overwhelmed.

PATIENT CARE STATIONS One suggested method of organizing patient care stations includes major trauma and medicine and minor trauma-primary care.

Major Trauma and Medicine From the triage location, most, if not all, of the seriously injured patients will be sent to the major trauma-medicine area (e.g., trauma and cardiac resuscitation, treatment of hypovolemic or septic shock, severe respiratory distress). This is usually physically located in the emergency department.

Minor Trauma-Primary Care In most disaster situations, the majority of patients are not very seriously injured. A great percentage of these will be classified as the "walking wounded" or the "worried well." These low-priority patients can be sent to an "urgent care" area, often designated as the minor trauma-primary care area, for definitive care including splinting of fractures, primary closure of lacerations, and tetanus prophylaxis. This minor trauma-primary care area can be established in the hospital's outpatient clinics.

ADMISSION PRESURGICAL HOLDING Most trauma patients stabilized in the major trauma area (emergency department) will be sent to the admission presurgical holding area.

SURGERY The number of operating rooms that can be staffed is the main limiting factor in the provision of definitive care for a large number of severely injured casualties. The most experienced (not necessarily most senior) surgeon available should take the responsibility to prioritize cases and to assign surgeons to these cases as rapidly as possible.

MORGUE Many disasters can result in a large number of fatalities. This may require that present morgue capacities be expanded possibly to outside facilities such as a church, school auditorium, or stadium.²² Because the vast majority of patients reaching a hospital are salvageable, this is historically usually not an immediate concern for a given hospital.

DECONTAMINATION JCAHO requires hospitals to have provisions for emergency treatment and decontamination of individuals who are radioactively or chemically contaminated.² Some basic requirements for hospitals are:

- A safe area for decontamination

- A means of washing external contamination from the patients
- A method of containment of contaminated materials
- Adequate protection for persons handling the patient, and other hospital personnel
- Disposable/cleanable medical equipment

The goals are to reduce external contamination, contain the contamination that remains, and prevent further spread of potentially dangerous substances. The decontamination area should have the ability to provide major resuscitative efforts which are never subservient to decontamination itself.

PSYCHIATRY In the event of a disaster involving mass casualties, and even property damage with loss of possessions, it is common for patients to present with episodes of anxiety and depression, as well as psychotic episodes. Hysterical persons, whether patients, visitors, or staff, can be extremely disruptive to hospital disaster operations. A separate isolated area should be predesignated to receive individuals in need of psychological intervention. The issue of stress and the need for ongoing debriefing among all who provide assistance in a disaster (including hospital staff) is becoming increasingly recognized.

FAMILY WAITING AND DISCHARGE AREA As past experience in disasters has shown, families and friends will converge en masse to the hospital seeking information about victims. This convergence can seriously interfere with efforts of the hospital to respond effectively to the situation. For this reason, a separate area should be predesignated for family members seeking information. This area may also be utilized to discharge in-hospital patients and victims of the disaster.

VOLUNTEER PROGRAM In major disasters, the potential of large numbers of volunteers, including those wishing to donate blood, should be anticipated. While some of these may have appropriate clinical skills, they are unlikely to be familiar with the hospital functions and could be more hindrance than help.²¹ A separate place should be identified to handle these volunteers and if appropriate credential and decide how they may best be used.

Training and Drills

Regular training and drills help to familiarize staff with their disaster roles and responsibilities. They also serve to point out weaknesses or omissions in the plan that require additions or revisions. Drills can range from full-scale community-wide simulations with moulage victims, to tabletop triage scenarios, to mini-drills that test only certain components of the disaster plan, such as call-up of personnel, and test of communications. The JCAHO requires two drills a year; the scenarios should reflect incidents that are likely to occur in the community.²

CATASTROPHIC CASUALTY MANAGEMENT: DISASTER OPERATIONS

Field Medical Care

In the field, rescue personnel often use a simple triage and rapid treatment (START) technique that depends on a quick assessment of respirations, perfusion, and mental status (RPM).²³ Subsequently, determining how much and what type of care to administer at the disaster site depends on several factors. If the number of patients is small and there are sufficient prehospital personnel and transportation resources available, on-site medical care can proceed in a fairly normal manner, with rapid stabilization and transportation to nearby hospitals. When extrication will be prolonged, it is important that potentially life-saving interventions be instituted in the field, such as intravenous fluids for hypovolemic shock. On the other hand, early, rapid transportation with a minimum of treatment should be practiced when there is danger to rescuers and casualties from fire, explosion, falling buildings, hazardous materials, and extreme weather conditions.

When there is an overwhelming number of casualties that exceed transportation capacities, advanced field medical and surgical treatment may be beneficial because it may be hours before seriously injured patients can be evacuated. This may necessitate the establishment of field hospitals with operating theater capabilities. Such a field hospital may be set up in a large building such as a school gymnasium or church. Casualties are brought here from the disaster site for further assessment and initial treatment of their injuries. After a period of observation and stabilization, they are either sent home or transported to a hospital.

When local hospitals are likely to be, or are, overwhelmed prior to transporting victims, it may be better to treat victims in the field. To address these considerations, the "secondary assessment of victim endpoint" (SAVE) system of triage was proposed.²⁴ The SAVE triage system is designed to identify patients who are most likely to benefit from the care available under austere field conditions. When combined with the START protocol, the SAVE triage is useful for any scenario wherein multiple patients experience a prolonged delay in accessing definitive care. The SAVE triage methodology divides patients into three categories: (1) those who will die regardless of how much care they receive; (2) those who will survive whether or not they receive care; and (3) those who will benefit significantly from austere field interventions.

Incident Command System

The incident command system (ICS) is a standard emergency management system used throughout the country to provide a flexible

SECTION 2 • DISASTER PREPAREDNESS

command and control structure upon which to organize a response.²⁵ The ICS is generally used when there is an identifiable single scene for a disaster event such as the site of a plane crash. By standardizing an organizational structure and using common terminology, the ICS provides a management system that is adaptable to incidents involving a multiagency or multijurisdictional response. At the most basic level there are five main components to the organizational structure: (1) incident command; (2) operations; (3) planning; (4) logistics; and (5) finance. With this type of organizational infrastructure and the flexibility to expand and collapse as needed, an orderly and efficient response to any incident can theoretically be implemented.

Communication from Disaster Site to Hospital

The local emergency communications or disaster operations center should alert hospitals in the affected area of a possible mass or multiple casualty situation. Ideally, this report should include number of injured, specifically the number of seriously injured (who may need ICU capability) and number for whom ambulatory treatment is sufficient. Hospitals should report to the local emergency communications center the following information: bed availability, number of casualties received thus far, number of additional casualties that the hospital is prepared to accept, and specific items in short supply.

Distribution of Casualties to Receiving Hospitals

Victims of a mass casualty incident usually are distributed unequally as described above. However, to decrease the possibility of this occurring, good communications should be maintained between hospitals and on-site EMS command. The on-scene incident commander should be alerted immediately by a potentially overloaded hospital. In this situation, the less injured and more stable can be sent a further distance to outlying hospitals. Secondary triage from one hospital to another may also be necessary if the hospital's capability to handle victims has been exceeded.

Casualties with special problems, such as major burns, carbon monoxide poisoning, spinal cord injuries, or victims of chemical or biological terrorism may need to be transferred directly to specialized units, although it may not be possible for these units to accept a large number of ill or injured.

On-Site Disaster Medical Teams from Hospitals

On-site disaster medical teams dispatched from local hospitals may be of value in situations where victims require prolonged extrication; transportation routes are blocked, preventing easy evacuation to hospitals; or the number of casualties are of such magnitude that they exceed transportation capacities. Such a team should be dispatched with great caution. Most physicians and nurses function well in an in-hospital setting; few, however, are prepared to work under austere field conditions either by training, inclination, or experience. Such hospital-based teams should probably not come from the emergency department staff until backup staff has arrived to care for patients arriving from the disaster site or who are already present. How such personnel are placed in action should be explicitly described in the hospital disaster plan and should be coordinated with state and local agencies through memoranda of understanding.

The resources for such field response teams should be carefully planned on a regional basis. The capability to send hospital teams to a disaster site can be developed in a number of ways. For example, an on-site triage team of physicians and nurses can come from teaching hospitals or be created from a pool of volunteer medical staff in office practice. Ideally, at least one institution from each region should maintain such a capability. The designated hospital should store disaster triage kits containing essential resuscitation and stabilization equipment in the emergency department for such circumstances.

THE EMERGENCY DEPARTMENT

The emergency department is the most critical part of the hospital's initial response to virtually any type of external disaster. It is often the hospital department that usually receives first notification that a disaster has occurred, and it is usually the entry point for incoming victims.

Initial Response

When a call is made to the hospital informing them of a disaster or potential mass-casualty-producing event, the receiver of the call must have a procedure to follow for verification of the incident. A disaster notification form is usually used by some facilities to remind the staff of the questions they are to ask the caller.

The appropriate hospital official or administrator on duty is then given this information. When the emergency department is notified by hospital administration (now disaster control) that the external disaster plan is in effect, it sets in motion a series of activities. The information obtained from the call is given to the charge nurse; the nursing and medical personnel in the department are notified of the impending arrival of casualties; and the emergency department's plan for calling additional staff is activated. Many hospital plans call for specific action by other doctors and allied personnel that is department-specific (e.g., surgeons, ICU staff, respiratory therapy, operating room staff).

An initial needs assessment is conducted by the nurse and physician in charge, given the information available. They should evaluate the current status of the patients in the department and make the appropriate decisions concerning their care and disposition. The ED physician becomes the on-site incident commander until the plan-designated disaster control physician arrives on the scene. Among the decisions to be made are those related to the admission, discharge, or transfer of patients, and decisions about the priority of patient care. All nonemergency patients should be discharged from the emergency department with responsible individuals (e.g., friends and relatives).

Based on the initial assessment, the number of patients that the department can receive is determined and communicated to the prehospital disaster communications center. The nurse and the physician in charge then determine whether more physician and nursing coverage is required in the emergency department and assign staff to those areas in the department to be used during the disaster.

As predetermined by the plan, a designated waiting area for family members should be located away from the emergency department.

Personnel Notification

The director of the emergency department or the director's designee should have a phone list of appropriate personnel to be called in to work during a disaster. Lists of addresses and phone numbers of these individuals should be distributed to all key personnel should it be impossible to locate the director or his or her assistant. Every position, address, and telephone number listed should be updated at least quarterly.

If hospital telephone communications have been completely disrupted, ED personnel may have to be reached by radio, cellular phone, e-mail, or television announcement (if power lines are down). Alternatively, a calling station remote from the hospital, such as an administrator's, physician's, or nurse's residence, may be able to handle this extensive calling job without taxing the hospital's phone system.

Security and Traffic Control

Hospital security play a key role in the emergency department by diverting nonessential vehicles and ensuring a smooth, one-way flow of traffic to the ambulance entrance. Once patients, family, and media arrive, security is also responsible for protecting the treatment areas.

Reception of Patients

Many seeking help will arrive independent of the official or formal EMS system. They will be brought by neighbors or friends or even hitchhike. Plans should include appropriate triage of these patients so that they do not overwhelm the ED prior to the arrival of the more severely injured, who arrive at a later stage.

All available litters and wheelchairs should be taken to the ambulance ramp immediately on announcement of the disaster status. Patients from the disaster site are met at the receiving area by hospital escorts who assist the EMTs in transferring patients to wheelchairs or stretchers.

Essential equipment such as endotracheal tubes, intravenous solutions, cervical collars, splints, and bandages should be placed near to the ambulance entrance to permit convenient restocking of the ambulance and rapid return to the disaster site.

THERAPEUTIC MANAGEMENT DURING DISASTER SITUATIONS

Triage

PURPOSES In general, triage can be defined as the prioritization of patient care based on severity of injury/illness, prognosis, and availability of resources. For those responsible for the triage of patients arriving in the emergency department, the purpose of triage is to determine to which predesignated patient care area the patient should be sent. The location to which patients are "triaged" establishes priorities for care. For example, some patients may need immediate decontamination as they arrive, regardless of their severity of injury. Those needing immediate care (e.g., respiratory failure, shock) are taken to resuscitation areas ("crash" rooms), while the dead are moved directly to the morgue. The severely but less critically injured are taken to the major trauma-medical area described earlier, where they are further assessed and initial treatment commenced. The walking injured are directed to the minor surgery-primary care treatment area, often located in outpatient clinic areas.

PERSONNEL A team consisting of a physician (preferably an emergency physician or a surgeon), an emergency department nurse, and a medical records or admitting clerk should receive every patient. In extraordinary situations, several triage teams may be required to handle the casualty load. The physician performing hospital triage should be acknowledged as being in command of the triage area, should be clearly identified by a specially colored vest or other garment, and must understand all triage options.

If a physician is not available, an emergency nurse with training in the concepts of casualty triage and disaster patient assessment can be designated as the triage officer.

RESPONSIBILITIES Although likely triaged at the scene, patients should undergo a second process of triage upon arrival at the hospital, preferably at the ambulance entrance to the emergency department. Responsibilities of members of the triage team include:

- 1. Assigning disaster patients to appropriate treatment areas (e.g., resuscitation room, major surgical, minor surgical) according to the assessment of their immediate needs and the availability of resources.
- 2. Instituting the most basic of life-support measures, such as inserting oral airways, cardiopulmonary resuscitation, and the external control of hemorrhage.

Assessment of severity of injury should be accomplished by conducting a rapid primary survey supplemented by obtaining prehospital information from the patient or prehospital personnel. The triage team

communicates information on number of casualties, severity of injuries, and the need for additional resources to both the emergency department and the hospital disaster control center. If phones are tied up, this notification can be accomplished by using runners, cellular phones, or portable radios. Likewise, triage personnel need to be informed about the capability of the various treatment areas (e.g., major and minor surgery) to handle additional casualties or special problems such as eye injuries or burns. They also need to know about the establishment and location of patient overflow areas.

The triage physician should also be aware of the location of a family waiting and public relations area within the institution, because family, friends, and the media will otherwise attempt to enter the triage area.

The admitting clerk's role as part of the triage team is to complete tags, attach them to victims, and retrieve valuables and clothing for bagging. The admitting clerk then tags the bag and completes the triage area casualty log.

Principles of Triage

The approach to patient evaluation and treatment is quite different under disaster situations resulting in large numbers of casualties.²⁶ In mass casualty situations, one no longer has the luxury of concentrating all resources on the management of a single critical patient. To accomplish the most good for the most number of patients, the triage team should evaluate all patients arriving at the ED doors and classify their conditions with regard to severity of injury and need for treatment. Some principles of medical care must be altered to achieve the best overall result. There clearly is no role for resuscitation or definitive care at this stage. Care should be limited to manually opening airways, and controlling external hemorrhage.

The most common triage classification in the United States still involves assigning patients to one of four color-coded categories (red, yellow, green, or black), depending on injury severity and prognosis (Table 6-2). In addition to the nature and urgency of the patient's systemic condition, triage decisions should be sensitive to factors affecting prognosis, such as age, general health, and prior physical condition of the patient, and the qualifications of the responders and availability of key supplies and equipment.

TABLE 6-2 Triage Categories

Red	
First priority	
Most urgent	
Life-threatening shock or hypoxia is present or imminent, but the patient can likely be stabilized and, if given immediate care, will probably survive	
Yellow	
Second priority	
Urgent	
The injuries have systemic implications or effects, but patients are not yet in life-threatening shock or hypoxia; although systemic decline may ensue, given appropriate care, can likely withstand a 45- to 60-min wait without immediate risk	
Green	
Third priority	
Nonurgent	
Injuries are localized without immediate systemic implications; with a minimum of care, these patients generally are unlikely to deteriorate for several hours, if at all	
Black	
Dead	
No distinction can be made between clinical and biologic death in a mass casualty incident, and any unresponsive patient who has no spontaneous ventilation or circulation is classified as dead. Some place catastrophically injured patients who have a poor chance for survival regardless of care in this triage category	

SECTION 2 • DISASTER PREPAREDNESS

Catastrophically injured patients who have a minimal chance for survival despite optimal medical care should be classified as "expectant" (i.e., "black": e.g., burns involving 95 percent body surface area, patients in full cardiac arrest, anthrax-infected patients in septic shock). Spending time on patients who are not likely to live leaves other patients who are truly salvageable awaiting care. If too much time intercedes, these patients also may become nonsalvageable. The goal with these "expectant" patients should be adequate pain control and the opportunity to be with friends and family.

PATIENT CARE IN THE EMERGENCY DEPARTMENT

Mass casualty care cannot be covered appropriately here, but some concepts of care are not within emergency routine. For example, wound infections may occur in virtually all types of disasters. Infected wounds and gangrene were major problems following the earthquakes in Armenia (1988) and Turkey (1999) and tornadoes in Illinois (1991) and Oklahoma (2000). In hurricanes or tornadoes, persons may be cut by flying glass and other potentially highly contaminated material. Because of this, all wounds should be copiously flushed with saline. Primary closure of heavily contaminated wounds may result in major complications, as was the case following the Armero volcanic eruption in Colombia in 1985. If lacerations are old (more than 6 to 12 h) or appear contaminated, they should be treated by debridement and left open for primary delayed closure in a 3-day period. This will allow one an opportunity to observe the wound for the development of infection. Tetanus prophylaxis and tetanus immunoglobulin (TIG) should be administered as indicated.

Patients with blunt trauma, for example, victims of earthquakes who have been trapped by rubble for several hours or days, should be watched very closely for signs and symptoms of crush syndrome such as cardiac arrhythmias, hyperkalemia, and renal failure.²⁷ Fulminant pulmonary edema or pneumonia from dust inhalation may also be a delayed cause of mortality for victims of building collapse as with patients injured by blast waves from explosions ("white butterfly sign").²⁸

Radiographic and Laboratory Studies

Radiographic and laboratory studies should be used sparingly, if at all, in a mass casualty situation, and only if the results of such tests will change therapeutic intervention. For example, x-rays of closed, nonangulated potential fractures can be safely delayed for 24 to 48 h, during which time effective splinting, elevation, and ice can be used. A chest film may be appropriate in those patients complaining of chest pain, dyspnea, or abnormal chest wall motion, or who were potentially exposed to blast waves secondary to bombs. The abdominal film in most cases of trauma does not provide much useful information. Cervical spine films and pelvic and femur x-rays may be indicated, considering the potential seriousness of injuries thus detected (e.g., permanent neurologic impairment, potential blood loss from internal injuries). Ultrasonography for FAST examination and detection of pneumothorax can be both timesaving and cost-effective.

There are few indications for laboratory testing in disaster medicine (exception: patients suspected of exposure to biologic weapons). For example, in cases of hemorrhagic shock, obtain a baseline hematocrit in addition to type- and cross-matching for blood. Urine test strip for blood may be useful to detect kidney or urinary tract injuries. In patients who are short of breath, or who demonstrate ventilatory impairment, it may be useful to have baseline arterial blood gases. All other laboratory studies should be considered accessory and only ordered in specific circumstances (e.g., carboxyhemoglobin in cases of smoke inhalation).

Blood Bank

In a disaster situation involving many casualties, it is recommended that the blood bank have as many as 50 units of blood available. It is

also important that the blood bank have ready access to a source of volunteer donors who can be rapidly mobilized. Other potential sources of blood include friends and family members of patients, as well as the "walking wounded."

Patient Identification and Record Keeping

In past disasters ED records of disaster victims have usually been poor to nonexistent. The general absence of detailed and systematic record keeping in disasters, except for serious cases admitted to hospitals for surgery or to intensive care units, has many implications ranging from problems of cost of care, billings, reimbursement, and insurance collection to the difficulty of making any evaluations of the quality of medical care given and the possible efficacy of treatment procedures.²⁹

Documentation of the patient's hospital course starts in the triage area. Proper tagging with a hospital disaster tag is essential for proper identification, documentation of medical care rendered, and for supplying information for relatives and the news media.

One member of the triage team (admitting or medical records clerk) should be assigned the job of recording the victim's name on the disaster tag along with the triaged destination within the hospital. If identification of the patient is not available, ethnicity, gender, and approximate age should be noted on the tag. An initial diagnostic impression should also be registered on the tag. This information is entered into a department log and is also placed in a triage logbook.

Media Relations

In a disaster, the hospital may become inundated by more members of the media than by actual disaster victims. Witness the recent intense media coverage of anthrax cases in the autumn of 2001 and during the sniper attacks in metropolitan Washington, DC, in the fall of 2002. The unauthorized presence of the press in patient care areas can definitely impair the performance of an already stressed hospital staff. Members of the media should be directed to a room or office of the hospital away from the emergency department and closely supervised by a hospital administrator or public relations specialist. This person should be in direct contact with the disaster control center. Hospital staff should leave all communications with the press to this person and should direct any member of the media to the public relations area so as to have consistent information given out by the hospital.

Handling of Family Members

Similarly, a separate area should be predesignated for family members seeking information. Family members should not be allowed into patient care areas, unless to see patients who are critically ill or who have died. The hospital operator will also be inundated with calls of inquiry regarding the presence and status of individual patients from concerned family members. These calls should be directed to a single predesignated desk or office for handling them.

AFTERMATH OF DISASTER

As soon as possible, efforts should be directed toward returning the hospital to normal operations. Besides restocking and cleaning, consideration should be given to the emotional stress experienced by both prehospital EMS and hospital staff. Short- and long-term emotional problems, particularly among rescuers, have been reported on numerous occasions including posttraumatic stress disorder. All those involved should be encouraged to talk with one another and with counselors as needed. In an attempt to reduce the psychologic impact of these events on medical responders, a technique known as critical incident stress debriefing (CISD) was introduced in 1993.³⁰

The CISD is an important part of the overall disaster response. Implementation of this stress management strategy offers immediate

emotional support to health care workers. Data from previous experiences suggest that such intervention can assist providers in maintaining job performance and satisfaction, resulting in improved patient care.³¹

Deficiencies in a hospital's disaster plan that are revealed during a disaster should be carefully recorded, reviewed, and criticized. Immediate steps should then be taken to correct these flaws in the plan.

BIOTERRORISM RESPONSE: IMPLICATIONS FOR THE EMERGENCY CLINICIAN

Anthony G. Macintyre Joseph
A. Barbera

Of all the issues facing the modern emergency physician, the potential threat of bioterrorism is one of the most challenging. An adequate response to a bioterrorist event of any magnitude requires the effective coordination of many disparate health and medical entities beyond the emergency department. Although the emergency physician plays a critical role in these types of events, many other essential functions must be addressed by individuals and organizations representing public health, mental health, law enforcement, emergency management, and others. Emergency physicians may find themselves working closely with organizations that are not traditionally encountered in everyday emergency medical practice.

A bioterrorist event involves the release of a biological agent among a civilian population for the purpose of creating fear, illness, and death. In extreme instances, disruption of the social and economic infrastructure may result. Biological agents are classified into two groups: infectious agents and biologically produced toxins. In most circumstances, biological toxins act as chemical agents in their human impact. The response requirements for these are very similar to those for chemical terrorism incidents and therefore are not discussed in this chapter. Infectious agents may be subdivided into two categories: contagious (propagating person to person) and noncontagious.

The use of infectious agents has been an increasing concern of the U.S. federal government since the mid 1990s (after waning at the end of the Cold War). This concern has been due in part to the biological weapons development programs in existence in certain countries and the capabilities of transnational terrorism. Throughout history, biological agents have been investigated as potential weapons for military campaigns, but current realities raise the specter of attacks that primarily target noncombatants. A bioterrorist event in the civilian setting often has been described as a low probability, high impact event.

Until the fall of 2001, only two small events had occurred in recent U.S. history involving a biological agent deployed against civilians.^{1,2} These events might be more appropriately described as criminal rather than terrorist in nature, because there was no associated terror message aimed at a larger audience. Concern for bioterrorism grew more acute after the events of September 11, 2001. Public trepidation was validated by the subsequent anthrax dissemination incident, in which the U.S. Postal Service was used to deliver letters containing spores of *Bacillus anthracis*. Although the environmental contamination was widespread, only 22 diagnosed cases of anthrax infection occurred: 11 cases of inhalational and 11 cases of cutaneous anthrax. Five patients died as a direct result of the anthrax exposure.³ The limited numbers of actual diagnosed cases belies the fact that multiple communities on the eastern seaboard of the United States were severely

SECTION 2 » DISASTER PREPAREDNESS

affected, with thousands receiving prophylaxis for anthrax.⁴ The fear then spread across the entire nation as concern increased for a wider delivery of anthrax in mid-western and western locales. Much of this national concern may have been exacerbated by the perception of an inadequate public health response capability, with the deficiencies demonstrating a critical need to integrate acute care medicine and the public health response.

It is difficult to comprehensively cover the complex topic of bioterrorism in this limited format. General event characteristics are presented with focused information on specific biological agents of concern. References for more comprehensive information on specific agents are identified. Response to bioterrorism is a rapidly evolving discipline, with the U.S. response systems and the understanding of individual agents in constant transition.

AGENTS OF CONCERN

Many infectious biologic organisms have the potential to be used as bioterrorism agents. Certain characteristics, however, make individual organisms particularly attractive as weapons for generating widespread fear, illness, and death among civilian populations. In an effort to risk stratify agents of concern, the Centers for Disease Control and Prevention (CDC) convened a multidisciplinary working group to designate select organisms and the diseases they cause as the priority for focused preparation.⁵ Agent selection was based on four general criteria:

1. Potential for public health impact
2. Delivery potential (an estimation of the ease for development and dissemination, including the potential for person-to-person transmission of infection)
3. Public perception (fear) of the agent
4. Special requirements for public health preparedness (diagnostic, logistical, etc.)

The selected agents were then ranked in three categories, based on their overall potential for adverse public health impact (Table 7-1). Class A agents have the most severe potential and include viruses and bacteria such as *Variola major* (smallpox), *Bacillus anthracis* (anthrax), and *Yersinia pestis* (plague). Class B agents are considered to have less potential for causing widespread illness and death, and class C agents are those that, as technology improves, could emerge as future threats. It is important to recognize that many other, more common pathogens could be used to cause intentional injury, and the intentional etiology of the infections may be apparent only through epidemiologic cohort evaluation.

RECOGNITION OF A BIOTERRORIST EVENT

Unlike the more common scenario from terrorist bombings, a biological agent attack may not be immediately recognizable. Unless the release of an agent is openly announced or the terrorist is caught in the process of delivering the agent, initial indications of attack may be subtle. Recognition that a biological attack has caused a disease outbreak is complicated further by the fact that initial symptoms of most agents of concern are not readily distinguished from more common, less threatening illnesses. Fever, body aches, and malaise could be the initial presenting symptoms of a victim of bioterrorism (anthrax and others) or of influenza, parainfluenza, or many common illnesses. This is more than a theoretical risk, as demonstrated when some agents of concern have been documented to occur in the non-bioterrorism setting. For example, cases of human plague in the Southwest United States (where plague is endemic) initially were diagnosed as nonspecific viral illnesses and dismissed as benign. Only later, when symptoms became more severe, was bubonic plague diagnosed.⁶ During the anthrax dissemination event of 2001, several anthrax-infected postal workers were evaluated by physicians early in their illness, but their relatively nonspecific symptoms were attributed to other causes, and

they were discharged home without antibiotic therapy.⁷ Two postal workers in this cohort died from inhalational anthrax.

The actual recognition of any future, surreptitious biologic attack could occur through several pathways:

1. A patient presents with signs, symptoms, or immediately available diagnostic results that obviously indicate a suspect disease process.
2. A patient presents with protean symptoms, but an astute clinician establishes enough criteria (suspicious historical information, signs, symptoms, short turn-around laboratory results, public health corroborative information, etc.) to designate the patient as a presumptive case until diagnostic confirmation can be accomplished.
3. Patient presents, is evaluated and admitted or released, but not suspected as being a victim of bioterrorism. Diagnostic test results (blood cultures, immunoassays, etc.) subsequently establish a diagnosis, potentially even postmortem.
4. Multiple patients present over a defined period with similar symptoms or historical characteristics, raising the suspicions of a practitioner and causing that individual to report the concern. Further investigation with diagnostic testing and/or public health epidemiological investigation of the cohort establishes the cause.
5. Public health surveillance systems establish unusual patterns of signs, symptoms, or disease in the community and correlate with further investigation to establish the etiology.

Currently, the first three scenarios appear to be the most likely ways in which a bioterrorist event will be detected. Scenario 3 is how inhalational anthrax was initially diagnosed in Florida during the fall of 2001.⁸ The initial inhalational anthrax infection in a postal worker was recognized as in scenario 2. Thus, the emergency clinician, perhaps more than any other medical specialist, should have an operational knowledge of the biological agents of concern. This knowledge should include basic pathologic principles for each agent, modes of dissemination and transmission, disease signs and symptoms, recommended diagnostic testing, recommended therapy (medicines, immunizations, or prophylaxis), and infection control practices. For example, every emergency clinician should be capable of listing the distinguishing characteristics of the rash caused by smallpox and how to differentiate it from chickenpox or other pox viruses. Another example of diagnostically important knowledge was noted during the anthrax dissemination event of 2001. All symptomatic patients presenting with inhalational anthrax had abnormal chest x-rays and/or thoracic computed tomographic scans at presentation (most with a widened mediastinum), providing an important diagnostic indicator in suspicious cases.⁷

Enhanced knowledge among practitioners is currently the best method for improving the capability to detect a bioterrorist event. Some formalized education efforts are underway to address this,⁹ and changes to the curricula of emergency medicine residencies have been proposed.¹⁰ In addition, access to references for specific clinical information, such as distinguishing signs and symptoms for agents of concern, can be very useful in identifying suspect patients. Pictorial resources made widely available during the anthrax dissemination incident, for distinguishing between cutaneous anthrax and other cutaneous lesions, were exceptionally reassuring for clinicians in the national capital area.¹¹

Unfortunately, currently available technology for virtually all emergency clinicians does not provide real-time diagnostic studies to reliably confirm or exclude the presence of most potential agents of concern (which actually do not differ from most common infectious processes). Confirmatory tests, however, may not even be available at the individual hospital or even in the community, and may require specialized studies through state or federal laboratories. The clinician therefore should command sufficient knowledge of agent diagnosis to confidently order appropriate tests and provide appropriate medical interventions when *suspicious* of a patient's clinical presentation.

The emergency clinician also should be prepared to appropriately respond to notification of potential disease by another health or med-

TABLE 7-1 Agents of Concern as Defined by the Centers for Disease Control and Prevention

Biological Agent	Disease Caused	Incubation Period	Signs and Symptoms
Class A agents			
<i>Variola major</i>	Smallpox	12-14 d	Initially fever, severe myalgias, prostration; followed within 2 d by papular rash on the face spreading to extremities (affecting palms and soles) and then to trunk (lesser extent than chickenpox); lesions progress at same rate, becoming vesicular and then pustular with subsequent scab formation
<i>Bacillus anthracis</i>	Cutaneous anthrax GI	Usually < 1 d, up to 2 wk reported	Macule or papule enlarging into eschar with surrounding vesicles and edema; sepsis possible, less common
	anthrax	Usually 1-7 d	Abdominal pain, vomiting, GI bleeding progressing to sepsis; mesenteric adenopathy on CT
	Oropharyngeal anthrax	Usually 1-7 d	Sore throat, ulcers on base of tongue, marked unilateral neck swelling
	Inhalational anthrax	Usually < 1 wk, 43 d reported at Sverdlovsk*	First stage is nonspecific (fever, dyspnea, cough, headache, vomiting, abdominal pain, chest pain); second stage (dyspnea, diaphoresis, shock); hemorrhagic mediastinitis with widened mediastinum on x-ray
<i>Yersinia pestis</i>	Bubonic plague	2-8 d	Initially fever, chills, painful swollen lymph node(s); node progresses to bubo (sometimes suppurative)
	Pneumonic plague	2-3 d	Fever chills, cough, dyspnea, nausea, vomiting, abdominal pain; clinical condition consistent with gram-negative sepsis
	Primary septicemic plague	2-8 d	After bubo formation, the clinical condition is consistent with gram-negative sepsis, DIC
<i>Clostridium botulinum</i>	Food-borne botulism	1-5 d	GI symptoms followed by symmetric cranial neuropathies, blurred vision, progressing to descending paralysis
<i>Francisella tularensis</i>	Inhalational botulism† Tularemia	12-72 h 2-5 d	Symmetric cranial nerve palsies followed by descending paralysis
Filoviruses and arenaviruses (e.g., <i>Ebola virus</i>)	Viral hemorrhagic fevers	2 d—3 wk depending on virus	Abrupt nonspecific febrile illness progressing to pleuropneumonitis; may have mucocutaneous lesions
Class B agents			
<i>Coxiella burnetii</i>	Q fever	2-3 wk	Initial nonspecific febrile illness, sometimes with rash; progresses to bloody vomiting, diarrhea, shock.
<i>Brucella</i> spp.	Brucellosis	2-4 wk	Fever, myalgias, headache, 30% develop pneumonia, rarely lethal (2%) Fever, myalgias, back pain; CNS infections and endocarditis
<i>Burkholderia mallei</i>	Glanders	10-14 d	possible Local infection: ulcers, suppurative; pneumonia, pulmonic abscesses, sepsis possible Local infection: nodule; pneumonia, pulmonic abscesses, sepsis
<i>Brucella pseudomallei</i>	Melioidosis	2 d to years reported	
<i>Alphaviruses</i> (VEE, EEE, WEE)	Encephalitis	Variable	Fever, headache, aseptic meningitis, encephalitis, focal paralysis, seizures
<i>Rickettsia prowazekii</i>	Typhus fever	7-14 d	Fever, headache, rash
Toxins (e.g., Ricin, <i>Staphylococcus</i> , Enterotoxin B)	Toxic syndromes		
<i>Chlamydia psittaci</i>	Psittacosis	6-19 d	Fever, headache, dry cough, pneumonia, endocarditis
Food safety threats (e.g., <i>Salmonella</i> spp., <i>Escherichia coli</i> O157:H7) Water safety threats (e.g., <i>Vibrio cholera</i> , <i>Cryptosporidium</i> <i>parvum</i>)			
Class C threats			
Emerging threat agents (e.g., <i>Nipah virus</i> , hantavirus)			

*Data from Meselson M, Guillemin J, Hugh-Jones M, et al: The Sverdlovsk anthrax outbreak of 1979. *Science* 266:1202, 1994.

†Inhalational botulism may not be preceded by GI symptoms. Inhalational and food-borne botulisms are caused by botulinum toxin, not the bacteria itself.

Abbreviations: CNS = central nervous system; CT = computed tomography; DIC = disseminated intravascular coagulation; EEE = Eastern equine encephalitis; GI = gastrointestinal; VEE = Venezuelan equine encephalitis; WEE = Western equine encephalitis.

ical professional (laboratory technician, radiologist, pathologist, or medical examiner). Carefully querying the source for pertinent specific information, including methodology of the testing that produced the concern (specimen collection technique and the sensitivity and specificity of the test procedure), and time until confirmatory test re-

sults become available are important factors in considering further actions, such as those delineated below.

Situations that pose great challenge to emergency department operations are those in which patients present after having been exposed to an unidentified substance (e.g., white powder), with circumstances

that have raised suspicion for terrorism (threatening letter, high profile location, a "very important person," etc.). The source substance may not have been properly evaluated or secured, and any recommended treatment necessarily will involve coordination with outside agencies (public health and law enforcement). If no testing was performed, one may attempt to obtain confirmatory studies (through the local public health authorities) if the substance remains available. Otherwise, the difficult task of stratifying patient exposure risk is necessary, using arguably nonspecific factors such as patient demographics and the specific characteristics of the event (e.g., white powder found in a local business vs. a high-level federal official's office). The public health authorities with jurisdiction over the involved communities should be consulted early in this process, ideally by using preplanned notification processes and decision support tools (see Chap. 6). When testing has been performed by others, the emergency clinician should request specific information on the testing methodology and judge the reliability of the test procedure. For instance, anthrax environmental testing may be performed with a wide range of procedures, including immune-based assays, assays based on polymerase chain reaction, and confirmatory culture testing.¹² Numerous instances of false positive environmental tests, when reported in the press, have created serious public concern. Several widely used field tests for anthrax, long recognized as unreliable, have now been officially discredited.¹³

Currently, much effort in the United States is focused on developing broad-based public health surveillance systems for detection of disease. The surveillance systems currently in use or under development are based on collecting and analyzing public health information and/or patient diagnostic information in specific communities. Information is sought from many disparate sources, including hospitals, clinics, nursing homes, pharmacies, emergency medical service systems, independent laboratories, medical examiners, and general businesses (e.g., absenteeism rates). Information collected from emergency departments often is based on symptom complexes (syndromic surveillance). Proposed methods for detection of a biologic event include the recognition of unusual epidemiologic phenomena such as a high incidence of non-specific illness, clusters or large numbers of rapidly fatal cases, and steep infection curves.¹⁴ The City of New York's Department of Health has operated this type of surveillance system since the late 1990s.¹⁵

Even though modeling suggests earlier detection and recognition, it has not yet been proven that currently proposed syndromic surveillance systems are sensitive and specific enough to detect an anomaly at a sufficiently early stage and to recognize the anomaly as a bioterrorism event to allow the earliest possible response. Most new infectious events (e.g., hantavirus and West Nile virus) were noted first by astute practitioners evaluating the initial cases. However, public health surveillance systems may have an important role during an actual event, if they also can assist with defining the size and scope of the event, the at-risk population, the effects of response interventions, and other epidemiologic characteristics. Critical data likely will be generated from patients in emergency departments, so emergency physicians should participate in surveillance systems. Emergency medicine should, however, be involved in the design and implementation of their community surveillance systems to assure that the resulting system meets the following criteria that the author's propose:

1. Clinical duties are minimally affected (does not consume valuable clinician or support staff time and attention)
2. Financial investment is not carried by the hospital or professional staff (especially in the current fiscal environment)
3. Patient privacy and hospital proprietary issues are appropriately addressed
4. Participation in the system provides direct benefit to the acute care medical community (i.e., all pertinent epidemiologic information is disseminated in real time to the practitioners)

Past attempts at surveillance system development and implementation have occurred without adequately addressing these principles (e.g.,

temporary surveillance for a presidential inauguration).¹⁶ The resulting hospital and emergency department participation was limited.

INITIAL RESPONSE TO A POTENTIAL BIOTERRORIST THREAT

Every receiving facility and emergency department should have plans and policies to manage a bioterrorism threat. The initial response to a suspected or confirmed bioterrorist event should involve many different hospital departments and agencies outside the hospital. Initial actions taken by the emergency physician can be pivotal in the success of the hospital efforts and the overall community response.

If the emergency clinician has diagnosed a confirmed or probable victim of bioterrorism, a critical action is adequate initial notification and plan activation. Infection control procedures should be used as appropriate (see below). Within the hospital, administration should be notified, as should other departments such as infection control, infectious diseases, and laboratory services (if not already involved in the case). If contaminating bioagent is an issue, as may be the case with anthrax, security and environmental services should be notified. The plan should address efficient methods of information flow to all departments of the hospital regarding the suspected agent, its characteristics including potential for person-to-person transmission, and efforts to protect the staff. Consideration should be given to activating a facility's full emergency operations plan (EOP). Implementation of the EOP should provide a preplanned surge capacity configuration. Nonmedical departments that require special attention include security (to aid in protection of the facility and staff) and media relations. Media personnel for the hospital ideally should coordinate any information released in briefings with the department of public health to prevent the presentation of conflicting information. Ideally, the hospital EOP fully integrates the hospital into the community response, which is critical in any bioterrorist event.¹⁷

Depending on the details of the plan or the circumstances of the incident, the emergency clinician also may have the responsibility for notifying the respective jurisdictional public health department. This necessitates that a reliable 24-h contact method be established and regularly tested. The information should be provided to public health as soon as a presumptive diagnosis is made to aid in the community response. Information that should be conveyed includes:

1. Diagnosed or suspected agent of concern
2. Whether it is a presumed or definitive diagnosis (and how any "definitive" diagnosis was made)
3. Patient demographics (including occupation)
4. Recent history of travel or participation in special events (mass gatherings, high-profile events, or at-risk gatherings)
5. Patient condition
6. Initial testing performed and further diagnostic testing being conducted
7. Treatment being provided
8. Public health assistance required (including testing)
9. Preferred method of contacting hospital or treating physicians for follow-up

The local department of health then has the responsibility to notify regional or state public health departments (as applicable) and the CDC. With some agents, the CDC would notify the World Health Organization, because the potential impact could be global (e.g., smallpox). Public health (city or state) also would have the responsibility of notifying local law enforcement and the Federal Bureau of Investigation. Another critical initial action for the emergency clinician is to establish the appropriate infection control guidelines respective to the diagnosed or suspected agent. This is essential in protecting the clinician, hospital staff, and other patients present in the hospital. It is also critical in maintaining the ability of the hospital to continue its regular medical commitment to the community. In 1999, the Association for

Professionals in Infection Control and Epidemiology published guidelines for hospital infection control in response to a bioterrorist event.¹⁸ Fortunately, most agents of concern require only standard precautions (gloves, mucous membrane protection when potential for splashing exists, and gown when potential exists for soiling). The more troubling agents are those that are capable of airborne transmission. A case of pneumonic plague will require droplet protection and patient isolation, very similar to current procedures for active tuberculosis cases. Smallpox would require airborne and contact precautions and therefore full patient isolation. Appropriately fitting face masks should be protective against these agents. Adequately providing these types of protection can pose one of the greater challenges to hospitals when multiple patients are involved.

Aside from actual medical treatment of the individual patient, another important initial consideration is whether patient decontamination is indicated. Decontamination should be a consideration only if a patient presents shortly after acute exposure to a substance suspected or confirmed as a biologic weapon, in contrast to the presentation of the patient who has already developed symptoms of an infectious disease. Public health authorities consider the risk of secondarily cross contaminating hospital staff from resuspension of an agent on this type of patient as unlikely.¹⁹ If a realistic concern exists, simple disrobing of the patient and showering with soap and warm water should be adequate decontamination. Clothing and personal belongings may need to be secured to assist with the public health and law enforcement investigations. Decontaminants, such as diluted bleach, should be avoided, due to their potential for harm and the lack of any demonstrated clinical efficacy (hypochlorite requires prolonged contact time for its agent-cidal action and can in itself cause skin injury).

INTEGRATION WITH LOCAL DEPARTMENT OF HEALTH

In any suspected or confirmed case of bioterrorism, the emergency physician can expect to interface with multiple diverse agencies, the most critical of which is the local public health department. In most communities, public health epidemiologists are assigned the task of defining the size and scope of an incident, the at-risk population, and other incident parameters. This type of information becomes critical to acute care clinicians, other medical care providers, and hospitals in the evaluation and treatment of patients and in the anticipation of surge capacity requirements. Challenges, such as the evaluation of minimally symptomatic individuals or the evaluation of large volumes of patients, can be facilitated by the provision of clear and concise information from the public health department.

The most important assistance public health can provide to all clinicians is in the development of a communitywide patient evaluation and treatment protocol. Evaluation and treatment protocols provide a clear delineation of epidemiologic criteria that establish a patient's individual risk for exposure and, hence, how to further evaluate and treat the individual. This kind of tool is essential for the practitioner once an event has been recognized, because confirmatory testing will rarely be immediately available. It therefore assists the practitioner in risk stratifying a patient or groups of patients. The protocol also should include the recommended testing, treatment methodologies, and patient and public education. During the response to the anthrax event in the fall of 2001, initial epidemiologic investigations using nasal swabs were misunderstood by some practitioners and the public as having individual diagnostic utility. It was merely an epidemiologic surveillance tool. Anxiety and confusion, however, resulted when individuals received nasal swabbing at some health care locations and were told it was not useful for diagnosis at other locations.

During the initial stages of a biologic event, the screening criteria for potential exposure may be necessarily broad. As the epidemiologic investigation ensues, these criteria should rapidly become more conclusive. Information coordination between health care providers and

public health epidemiologists is necessary to rapidly accomplish an epidemiologic profile of the incident. Evaluation protocols may evolve during this epidemiologic investigation and will require reliable dissemination of the recommendations with regularly scheduled updates. Ideally, the medical community should receive incident updates and changes in recommendations before general release to the public. This allows clinicians time to respond to changes and to provide further explanation and reassurance to anxious inquiring patients.

An important advantage of a single evaluation and treatment protocol is that it provides a uniform method across a community to evaluate patients presenting with possible exposure. This is important not only for individual practitioners but also for the public. During the response to the anthrax dissemination event in the Washington-Baltimore corridor, no early standardized protocol was developed; instead, hospitals implemented their own protocols to limit variation of practice between clinicians at individual hospitals. The variability between each institution's approach caused great consternation for patients and, hence, for providers. The protocols used at George Washington University Hospital were modified daily, based upon updated information. The operationalization of the public health approach can be quite complex.

Critical information that the public health system should provide is a clear and concise case definition for the particular agent in question. A case definition provides clinical and diagnostic criteria for an individual patient to be considered as a definitive victim of the infectious agent in question. Within the case definition, criteria also should be supplied that define "suspicious" cases for patients awaiting confirmatory testing. This kind of tool is simple and allows practitioners to officially designate victims as confirmed or suspicious for infection. A similar "exposure" definition would be helpful for defining the criteria for confirmed or suspected exposure. In many cases, the epidemiologic investigation that can initially define and later refine these definitions requires close information sharing and collaboration between clinicians seeing cases and the public health authorities.

Other critical information for the clinician includes reporting requirements (surveillance) for suspected or diagnosed cases. Specific points as to what information should be reported and the method in which it should be conveyed are essential (phone, fax, or Internet). Contact methods should be provided that allow for 24-h access and for technical advice. Ideal reporting systems affect the clinician minimally (as described above) and provide confirmation of receipt of transmitted information. The reporting format should promote rapid processing of the communitywide data, with dissemination of composite information to the reporting sources. This demonstration of the value of the system will promote clinician participation and provide clear value in participating in a coordinated, overall incident management system.

Integration with Other Response Assets Requests for assistance or for assets not available within an individual hospital should be coordinated through hospital administration to the local department of health and/or the local emergency management agency. From there, requests may be transmitted to the regional, state, or federal level. Other response assets are discussed in Chap. 6.

TREATMENT, PROPHYLAXIS, AND IMMUNIZATION

General treatment principles for victims of bioterrorism should be understood by the practitioner. Specific therapies for individual class A agents are listed in Table 7-2. Limitations of morbidity and mortality are based on preventing exposure, providing prophylaxis and immunization (when available for the specific pathogen), and providing treatment to those infected. Treatment may involve specific pharmaceuticals or general supportive care. Depending on the agent involved, prophylaxis or immunization of the hospital staff may be warranted (e.g., smallpox). It is important to recognize that therapeutics may be

TABLE 7-2 Category A Agents: Treatment, Prophylaxis, and Vaccination

Biological Agent	Vaccination	Prophylaxis	Treatment
Class A agents			
<i>Variola major</i>	Vaccinia vaccination: currently not recommended for general public use because of its association with limited numbers of deaths and complications in immunocompromised individuals and those with eczema; useful in preventing disease if given within 4 d of exposure	Vaccinia immune globulin: best given within 2–3 d of exposure; limited supplies are available; consider giving to those exposed who have contraindications to vaccine	Mainly supportive; Cidovir has demonstrated some efficacy in monkey models
<i>Bacillus anthracis</i>	Anthrax vaccination: 6-part series vaccination at 0, 2, and 4 wk and then at 6, 12, and 18 mo; annual boosters required; currently not available to the public; efficacy in preventing inhalational anthrax demonstrated in animal models	Ciprofloxacin or doxycycline for 60 d (amoxicillin if strain not resistant); 60-d term established by using latency period for last infection occurring at Sverdlovsk*; consideration for concurrent vaccination Ciprofloxacin or doxycycline;	Ciprofloxacin or doxycycline (amoxicillin if strain not resistant) <i>in combination</i> with two others including clindamycin, rifampin, imipenem, aminoglycoside, chloramphenicol, vancomycin, streptomycin, and some macrolides
<i>Yersinia pestis</i>	Killed whole bacilli vaccine no longer available by producers; vaccine had efficacy in preventing bubonic disease but not the pneumonic form	alternative: chloramphenicol; prophylaxis for 7 d	Streptomycin or gentamicin preferred choices; alternatives: doxycycline, ciprofloxacin, chloramphenicol
<i>Clostridium botulinum</i>	Vaccine not available to the public: pentavalent toxoid of C botulinum toxin types A–E; 3-part series with yearly booster	Not applicable	Antitoxin: requires procurement through local public health agency (state or the CDC); antitoxin may preserve remaining neurologic function but does not reverse paralysis; may require prolonged, assisted mechanical ventilation and supportive care
<i>Francisella tularensis</i>	Live attenuated vaccine under investigation by FDA	Ciprofloxacin or doxycycline for 14 d	Streptomycin or gentamicin preferred choices; alternatives: doxycycline, ciprofloxacin, chloramphenicol
Filoviruses and arenaviruses (e.g., <i>Ebola virus</i>)	Not applicable	Not applicable	Supportive therapy; ribavirin may have applicability in arenaviruses

*Data from Meselson M, Guillemin J, Hugh-Jones M, et al: The Sverdlovsk anthrax outbreak of 1979. *Science* 266:1202, 1994.

indicated even without obvious signs of disease or definitive information about exposure. This makes the practitioner heavily reliant on the public health sector to stratify patient risk as to their exposure and to provide science-based prophylaxis and treatment recommendations.

One of the critical issues in providing treatment to victims of bioterrorism is the development of an adequate surge capacity. This issue is complicated by the current health care industry practice of minimizing staff and maintaining just-in-time inventory. For the individual practitioner, ideal surge capacity is provided by first maximizing health care facility response assets and coordinating with regional resources. State and federal assistance should be included in planning, but not relied on, for the initial stages of an event (up to at least 48 h).

General Emergency Operations Plans

Patients will self-refer to hospitals and emergency departments, even if instructed to do otherwise (as occurred in the anthrax dissemination event). All emergency department and hospital surge capacity should be based on a sound and well-practiced hospital EOP that can manage a large surge in general patient volume.

Specialty Requirements

Specialty needs also should be addressed for patients with unusual medical conditions and those who present contagion or contamination risks to staff and other patients. Separate treatment areas may need to be established within the health care facility to allow normal emergency department operations to continue. This also may be necessary if the potential agent is capable of person-to-person transmission.

Disease Containment

Isolation of large numbers of infectious patients may be necessary (e.g., smallpox). Adequate plans for this procedure should be investigated before an incident. Current hospital configurations often prohibit large-scale containment of patients in official isolation rooms, but entire wings could be adapted (using doors and ventilation re-routing) to serve as isolation wards. Plans to provide adequate separation from other, noninfected patients, to designate specific staff to care for these patients, and to furnish proper personal protective equipment should be accomplished.

Management of Personnel

Large numbers of patients require additional staff to manage them. Staff recruitment may be complicated by reluctance of staff to care for potentially infectious patients. Lack of training of temporary personnel from staffing agencies makes this more difficult and is addressed only through regionwide training efforts.

Logistics

Just-in-time inventory may limit the amount of Pharmaceuticals and supplies available for treating patients. Further, vendors for emergency backup supplies and equipment are commonly shared by multiple institutions, each counting the backup cache as their own. Having a communitywide mutual aid system between all the hospitals promotes sharing of critical supplies, equipment, and staff during an emergency. If prescriptions are being written for antibiotics, consideration must be

given to the supply local pharmacies have on hand (an issue during the anthrax incident in 2001). Integration of National Pharmaceutical Stockpile (NPS) supplies into a medical community has specific requirements that are available for review through the CDC, and that require specific planning by the community emergency management and public health agencies.

Patient Management

Addressing the requirements of each patient encounter can facilitate the overall processing of victims. For those patients who are potentially exposed but not physically ill, the patient interaction may require sophisticated explanations as to why the individual is or is not receiving a particular therapy. Preprinted instructions (indicating category of risk stratification and why the patient was placed in that category) can be helpful for patients being treated and released. These instructions should clearly indicate how the disease is transmitted, measures that prevent spread, and early signs and symptoms of disease, with appropriate steps if they should occur. Appropriate follow-up should be established (in a large-scale event, this may not be with a primary care physician but through public health avenues). It is important to note any change in the epidemiology of the event (e.g., new site tests positive for an agent) or if new information becomes available on the etiological agent (antibiotic resistance patterns, etc.), and patients may need to be contacted to change their therapy. Proper record keeping and organization of charts based on assigned risk category can assist with this process. Entering all patients into a reliable long-term surveillance data base should be a task for the public health agency, but hospitals and emergency departments could facilitate this process.

For agents of concern that have a vaccine (e.g., anthrax and smallpox), recommendations at the time of this writing are that they not be given in a pre-event setting to the general public. Anthrax vaccination requires a series of six injections followed by yearly updates. Smallpox vaccine has not been given to the general public for nearly three decades. Even those who received vaccine in the past are expected to have a waning immunity to the virus. At the time of writing of this chapter, recommendations are under review to re-introduce this vaccine. The risk of potential life-threatening side effects, such as generalized vaccinia, complicate the recommendations of smallpox vaccination in the absence of known disease.

Recommended therapies for some bioterrorism agents normally are not approved for children or pregnant or lactating women. In many instances, these recommendations have been relaxed where the risk of infection and its consequences exceeds the risks of the medications or vaccines. Examples include using ciprofloxacin in children for anthrax exposure. Preparation to explain this concept to patients is imperative.

Fatality Management

Large numbers of deceased patients can pose a burden on a health care facility, especially when death is caused by a contagious disease. In intentional events, the forensic requirements add complications, because the bodies are considered evidence and must be processed through an official medical examiner or coroner.

SOURCES OF EXPERT INFORMATION

There are many sources of expert information available on the World Wide Web that present specific knowledge on individual agents of concern. Some of these are listed below:

1. The Journal of the American Medical Association has published a series of articles on individual agents. These are available online at <http://jama.ama-assn.org>
2. The CDC provides individual agent information at: <http://www.bt.cdc.gov>

3. The Department of Defense has a military textbook available online that discusses biological and chemical agents. It is available at: <http://chemdef.apgea.army.mil/textbook/contents.asp>
4. The Association for Professionals in Infection Control and Epidemiology has infection control guidelines available at: <http://www.apic.org>

Information is also available through telephone resources. An individual practitioner should start by contacting the local department of public health for quick information reference. Certain poison control centers are now updating their databases to include information on biological agent and patient management. The CDC also may be contacted directly as a backup resource for information (after first contacting local public health). The CDC's emergency response center telephone number is 1-770-488-7100.

DISASTER MANAGEMENT FOR CHEMICAL AGENTS OF MASS DESTRUCTION

Suzanne R. White

Kelly R. Klein

Col. Edward M. Eitzen, Jr.

"... [T]he effect of chemical and biological weapons is so deadly to the unprepared that we can never afford to neglect the question."

General Pershing

INTRODUCTION

Chemical warfare is the intentional use of weapons (agents) designed to kill, injure, or incapacitate on the basis of toxic or noxious chemical properties. The battlefield use of chemical agents was first documented in 1000 B.C. in the form of Chinese arsenical smokes. Other notable military deployments included picric acid use during the 1899 Boer War, and the large-scale use of multiple agents such as chlorine, phosgene, cyanogen chloride, hydrogen cyanide, and, most significantly, the sulfur mustards during WWI. While both the U.S. and Germany had stockpiled nerve agents during World War II, the only chemical incident documented was the nautical release of mustard from an allied ship bombed in Bari, Italy. In the 1980s, Iraq allegedly used multiple agents against the Kurdish nationals and Iranians, resulting in thousands of fatalities. Following Desert Storm in the early 1990s, defectors ultimately disclosed the extent of the Iraqi arsenal and thousands of tons of chemical agents loaded into bombs were then located and destroyed. Current intelligence suggests that despite chemical weapons treaties, offensive programs are proliferating in at least 17 countries hostile to the U.S., many of whom are signatories to these agreements.

Recent terrorist events highlight the potential for chemical agent use extending beyond the war theatre. Specifically, chemical releases could be sponsored by parastate, paramilitary, militia, or extremist groups or by deranged individuals, for the furtherance of political or social objectives. For example, Aum Shinrikyo, a cult of educated, wealthy multinationals twice carried out the release of the nerve agent sarin. The first attack occurred in Matsumoto, Japan, in 1994, killing 7 and injuring more than 600 people. A larger scale release into the Tokyo subway system 1 year later caused 5510 people to seek medical attention. During this incident, 640 chemically contaminated patients arrived by private conveyance within the first few hours to a single health care facility. Twenty-three percent of the ED staff at that hospital became secondarily poisoned as the nerve agent was essentially transported via contaminated victims from the scene to the hospital.¹² Other chemical events around the same period included the aversion of a large-scale plot to release chlorine gas at Disneyland and the discovery that cyanide had been involved in the 1993 World Trade Center bombing in New York. As a recent example of nonbattlefield use,

the Russian military ended a hostage crisis in Moscow, in 2002, by deploying a potent "gas." More than 100 fatalities and more than 400 hospitalizations resulted. Definitive identification of the chemical is pending at this time, but based on clinical features that included a response to naloxone, an opioid derivative is suspected.

Chemical weapon disasters from terrorism are low-probability, high-impact events. Casualties are not only poisoned but may be contaminated. They may also have serious concomitant injuries, such as trauma, burns, or smoke inhalation. Those victims able to flee the scene are likely to seek their own transportation to the hospital, which then potentially becomes a crime scene and a secondary "hot zone." Other problems include communication breakdown and chaos among medical personnel who may be unfamiliar with the agents involved, unaware of available resources, or themselves secondarily contaminated. In addition, widespread or prolonged psychological impact may occur. As seen both in drill and in real-life scenarios, chemical disasters quickly overwhelm prehospital and hospital medical resources. The need for emergency medical planning and preparedness to mitigate the consequences of such events has become a priority for emergency physicians.

PLANNING AND PREPAREDNESS

Every hospital emergency department should be prepared to receive and treat contaminated victims who arrive unannounced. Survival of victims will largely be determined by awareness training and preeducation of emergency staff, the practice of contingency plans, and effective communication at the time of the incident. The following are planning priorities:

- Recognition that chemical terrorism has occurred;
- Rapid identification of the agent(s) involved;
- Information retrieval on the toxicity and secondary contamination potential of the agent; Proper protection of self, hospital personnel, already-hospitalized patients and the facility itself from secondary contamination or loss of serviceability to other patients; Decontamination and triage of victims; Stabilization and medical treatment of victims; and Protection of the community-at-large from secondary contamination.

A critical step in planning is the identification of those chemical agents that pose the greatest threat. Along these lines, the Centers for Disease Control (CDC) has established a list of agents of most concern for chemical terrorism (Table 8-1).³ The inclusive nature of this list illustrates the difficulty in performing a chemical-threat assessment. In reality, the specific agent used is limited only by the determination and creativity of the terrorist, with common industrial chemicals potentially representing a greater hazard than military agents. To this end, close integration of hospital planning committees with public agencies is essential. In the wake of the largest chemical disaster ever, in which 2500 fatalities resulted from the release of methylisocyanate in Bhopal, India, the Emergency Planning and Community Right-to-Know Act of 1986, also known as the Superfund Amendments and Reauthorization Act (SARA Title III) emerged. This law requires the establishment of State Emergency Response Commissions to oversee the activities of local emergency planning committees (LEPCs). LEPCs, in turn, are responsible for the development of comprehensive emergency response plans for community hazardous materials incidents. Active emergency physician participation in LEPC activities promotes medical community awareness of the major chemical hazards that exist at industrial and worksites nearby. Once community response plans are established, drills concentrating on the types of hazards likely to be encountered locally should be practiced annually. Finally, a formal critique of each drill, as well as each "live" incident, should be carried out with the involved medical personnel to allow for plan revision. Refer to Chap. 185 for a toxicologic review of important chemical agents.

TABLE 8-1 Chemical Agents

Chemical agents that might be used by terrorists range from warfare agents to toxic chemicals commonly used in industry. Criteria for determining priority chemical agents include:

Chemical agents already known to be used as weaponry; Availability of chemical agents to potential terrorists; Chemical agents likely to cause major morbidity or mortality; Potential of agents for causing public panic and social disruption; and Agents that require special action for public health preparedness (Box 4). Categories of chemical agents include: Nerve agents

tabun (ethyl N,N-dimethylphosphoramidocyanidate)
sarin (isopropyl methylphosphonofluoridate)
soman (pinacolyl methyl phosphonofluoridate)
GF (cyclohexylmethylphosphonofluoridate)
VX (o-ethyl-[S]-[2-diisopropylaminoethyl]-methylphosphonothioate)

Blood agents

hydrogen cyanide
cyanogen chloride

Blister agents

lewisite (an aliphatic arsenic compound, 2-chlorovinylchloroarsine)
nitrogen and sulfur mustards
phosgene oxime

Heavy metals

arsenic
lead
mercury

Volatile toxins

benzene
chloroform
trihalomethanes

Pulmonary agents

phosgene
chlorine
vinyl chloride

Incapacitating agents

BZ (3-quinuclidinyl benzilate) Pesticides, persistent and nonpersistent Dioxins, furans, and polychlorinated biphenyls (PCBs) Explosive nitro compounds and oxidizers

ammonium nitrate combined with fuel oil

Flammable industrial gases and liquids

gasoline
propane Poison industrial gases, liquids,

and solids

cyanides
nitriles
and Corrosive industrial acids and

bases

nitric acid
sulfuric acid

*www.cdc.gov/mmwr/preview/mmwrhtml/rr4904@l.htm.

A standard operating procedure for mass casualty decontamination should be developed as part of the hospital disaster plan. It should include a plan for outdoor hospital decontamination of patients, types and location of protective and decontamination equipment, designation of personnel responsibilities, medical treatment guidelines for expected toxic agents, and reference lists of information resources (Table 8-2). One excellent resource for designing such procedures is the Agency for Toxic Substances and Disease Registry's *ATSDR Medical Management Guidelines for Acute Chemical Exposures*.⁴ At the time of this writing, most hospitals in the United States are not adequately prepared to treat contaminated patients, many assuming that other local facilities or agencies will handle such events or that patients will undergo prehospital decontamination. It is true that Hazardous Materials Response (HAZMAT) Teams and some fire departments are trained and equipped to provide on-scene chemical decontamination; however, response times and availability of such resources vary

widely. In reality, typically less than 20 percent of contaminated victims receive decontamination and treatment at the scene. Furthermore, most victims of a chemical disaster, especially the "walking wounded," will flee the scene and seek out the closest hospital for their medical care regardless of that institution's capabilities.

In a chemical disaster situation, it is possible that first responders will not initially recognize a hazardous material situation and will transport contaminated victims to the ED, potentially contaminating the ED as well as themselves. Accidents occurring at industrial sites, on farms, or on freeways or railways are always suspect for a chemical involvement. Other clues are the presence of multiple victims, vapor clouds, fires or explosions, or patients with burns, unusual odors, colors, or patterns of skin irritation.⁵ The emergency physician's interface with a large cross-section of the community confers unique perspective and opportunity toward the early detection of illness from chemical hazards.

ACTIVATION OF THE RESPONSE PLAN

If prenotification allows, several steps should be taken to prepare for patient arrival. Communication with prehospital providers is desirable to ascertain the type of the incident, number of victims, signs and symptoms exhibited, nature of injuries, identification of chemical(s), presence of radioactive materials, prior decontamination, and estimated time of arrival. At this point, consideration should be given to the potential for a specific method of decontamination. Is there an antidote or distinct method of treatment for this exposure, and if so, what is its availability at the receiving and or surrounding institution(s)? Do hospital entrances need to be secured? A determination should be made as to whether the hospital's disaster plan should be activated and which community facilities in the area are prepared to assist with overflow of large numbers of victims. Examples of individuals to be pre-notified include the medical toxicologist, poison control center, industrial hygienist or occupational physician, safety officer, radiation safety officer, security, hospital administrator, and media relations representative.

ADVANCE INFORMATION RETRIEVAL

Detailed information about the chemical(s) involved is most helpful if received prior to patient arrival. Regional poison control centers (PCCs) are often already integrated into the emergency medical, hazardous materials, and Metropolitan Medical Response Systems (MMRS) and provide 24-h availability.⁶ Another information resource is the Material Safety Data Sheet (MSDS), a document that identifies health and safety information for any product containing hazardous chemicals.⁷ MSDSs may be obtained by facsimile from the work-site employer or safety officer, regional PCCs, Chemtrec, NRC, the Internet, and computer databases such as Dolphin. Included are chemical and physical hazard data as well as information regarding safe use, handling, and storage. Basic first aid procedures are outlined, but advanced medical information usually is not included. While the merit of MSDSs has been questioned,⁸ at the least they will assist with correct identification and spelling of the chemical agent(s) involved. Limitations of MSDS use are that they may not exist for all toxic substances, they are not always comprehensive with regard to ingredients listing or toxicity data, they may not be up to date, ingredients listed as inert may be toxic, and "trade secret" ingredients may be deleted (although trade secret toxicity data must be listed, and the treating physician is entitled to immediate identity on request). Other resources that may assist with hazard identification and determination of toxicity are listed in Table 8-2.

Ascertain the reason for the incident (explosion, spill, act of terrorism), the presence and status of other victims, the route of exposure, whether exposure was within a confined space, and the duration of exposure.

DECONTAMINATION ZONES

Patient decontamination ideally should occur outside the hospital. Hot, warm, and cold zones should be established and cordoned off with brightly colored tape. The *hot zone* is the area of the spill or chemical release (at the scene) or the hospital area where arriving patients with no prior decontamination are held. Therefore, only people who are trained and properly attired may enter. Only the most immediate life threats are addressed in the hot zone (opening of the airway, cervical spine immobilization, brushing off of gross contaminants, and application of pressure to stop arterial bleeding). The *warm zone* is an area where thorough decontamination and further medical stabilization occur. Theoretically, this area poses no risk of primary contamination (direct exposure to the toxin), but secondary contamination (transfer of the toxic material from the victim to personnel or equipment) may still occur. Access, therefore, is also restricted, and the use of protective clothing is required. The *cold zone* is the area to which fully decontaminated patients are transferred. There is no personnel flow between hot/warm or warm/cold areas.

PERSONAL PROTECTION

The various levels of personal protection are levels A through D. *Level A* attire [fully encapsulating chemical-resistant suit and self-contained breathing apparatus (SCBA)] is recommended when the highest level of eye, mucous membrane, skin, and respiratory protection is needed. Lower levels of protection include level B (splash protection with chemical-resistant clothing and an SCBA) and level C (splash protection with chemical-resistant clothing and a full-faced, air-purifying canister-equipped respirator). Level D protection is a standard work uniform and includes firefighter bunker gear. Military mission-oriented protective posture (MOPP) level IV gear, comprised of an air-purifying respirator, protective mask, hood, charcoal-impregnated suit, and butyl rubber gloves and boots, affords effective protection against the biochemical weapons of mass destruction.

While level A protection is recommended by the National Institute of Occupational Safety and Health (NIOSH) and the Environmental Protection Agency (EPA) in situations where the concentration or identity of toxins involved is unknown (i.e., most hazardous materials incidents), there is no consensus regarding the level of protection needed for health care workers decontaminating patients at the hospital.⁸ Only limited patient care can be rendered while wearing level A or level B gear, and air availability restricts its use to only short periods of time. Furthermore, specialized protective gear is only recommended for those with prior training and fitting, given the added level of physical and heat stress and false sense of security that its use may render. Despite these limitations, if level A or B protection is to be used by the emergency staff, it is recommended that the hospital coordinate equipment acquisition with the local fire departments or hazardous materials teams so that regulator fittings (replacement air bottles) are interchangeable. Practically speaking, most hospitals have only level C protection available to employees. Powered air-purifying respirators (PAPRs) allow for increased mobility and may be used for longer periods of time in oxygen-sufficient environments, such as most emergency departments. Ideally, persons responsible for selecting the personal protective equipment and decontamination process should be trained to the first-responder operations level under the Occupational Safety and Health Act (OSHA 29 CFR 1910.120).

TRIAGE

The first wave of minimally exposed victims arrives within 30 min of the incident and has the potential to overwhelm the emergency department and impede the care of sicker patients who arrive later.⁹ Emergency department triage must be efficient and should occur outdoors. **First and foremost, the contaminated patient should not be allowed to enter the ED.** Second, personnel who are not in an appropriate

level of protective gear must not be allowed in the triage/decontamination area. The incoming ambulance or ambulatory patients should be met by a triage officer, an individual in appropriate level of personal protective gear, to determine whether decontamination has been performed and, if so, its adequacy. The most difficult situations involve victims who are seriously injured and who have bypassed the field decontamination procedure. A management dilemma is created between immediate medical treatment and decontamination. While the appropriate response varies depending on the chemical(s) involved, many situations involve unknown chemicals and therefore unknown risk to personnel. **It is always prudent to err on the side of decontamination before treatment in unknown situations.** Examples of substances with little or no risk of secondary contamination include gases, vapors, and substances with no serious toxicity or skin absorption. Patients exposed to gases or vapors only, with no symptoms other than respiratory irritation and no signs of condensation of vapor on the clothing, do not require decontamination beyond clothing removal. This may not hold true, however, for large numbers of victims exposed to nerve agent vapor or for those exposed in confined spaces. Substances with high risk of secondary contamination include highly toxic substances that are readily absorbed dermally, radioactive agents, and certain biologic agents. Patient triage is covered in more detail in Chap. 6. Table 8-2 lists aids in chemical identification and hazard determination.

PATIENT DECONTAMINATION

Outside portable decontamination systems include portable showers, large inflatable heated tents, or a series of kiddie pools with privacy screens. Attempts to contain effluent should not delay patient decontamination. Disposable equipment should be used wherever feasible. Suggested equipment for outdoor hospital decontamination is listed in Table 8-3. Decontamination inside the hospital should only be done in a designated room with a separate entrance, separate ventilation, and ideally, a separate water drainage system.

The goal of decontamination is to decrease the absorbed dose for the victim and prevent secondary contamination of health care providers. Clothing should be removed quickly because this is thought to accomplish 80 percent of the decontamination. Particulate or radioactive matter should be removed by careful roll-down of clothing. Further particulate matter should be brushed away prior to showering because interaction of some dry chemicals with water may produce heat. All clothing should be double bagged and treated as toxic waste. All patient belongings and waste must be accounted for by a tracking log. Jewelry and valuables should be bagged separately from clothing, which may require disposal.

The critically ill, nonambulatory contaminated patient should have a patent airway ensured, the cervical spine immobilized, oxygen administered, ventilation assisted, and pressure maintained on arterial bleeding. Further medical care, such as intubation or intravenous line insertion, is delayed until gross decontamination has been completed and the patient has been transferred to the cold zone. Ocular exposures take precedence and should be treated first with immediate eye irrigation. Ideally, this should have begun in the prehospital phase. Wounds are the next decontamination priority and should be irrigated, debrided of gross contaminants, and then covered with a water-occlusive dressing to prevent recontamination during subsequent showering. Whole-body decontamination should begin with the head and proceed downward. Along with the hands, the face and head generally are the most heavily contaminated areas and should be washed or shampooed in the head-back position to avoid runoff onto other body parts and incorporation of toxic material. This may be best accomplished initially in the sitting position, prior to showering. Most agents are readily removed with copious amounts of water. A mild soap, shampoo, or detergent may be necessary for nonpolar, water-insoluble substances. Tincture of green soap has been recommended by some based on its small concentration of ethanol that enhances dissolution of certain agents such as hydrocarbons. Typically, 3 to 5 min of showering is recommended, although 15 min may be required for concentrated, strongly alkaline

TABLE 8-3 Suggested Equipment for Outdoor Hospital Decontamination

Biohazard/radiation hazard tape
Decontamination stretcher (alternative fiberglass backboard with sawhorses)
Hose with warm water and soft-stream shower head
Disposable butyl rubber, nitrile rubber, and neoprene rubber gloves in various sizes
Disposable chemical-resistant jump suits (Tyvek or Saranex) with hoods and boots
Rubber aprons
Mild soap/shampoo
Splash protective goggles
Plastic bags for clothing and waste container liners
Multiple wading pools for ambulatory patients (to contain runoff)
Adsorbent materials (for diking of waste water)
Oxygen tanks with delivery supplies
Disposable towels and gauze
Blankets and sheets for patient privacy
Portable privacy barriers

materials or oily, adherent substances. The use of abrasives, such as corn meal or scrub brushes, generally is not advised because abrading the skin may increase toxin absorption. New amphoteric decontamination solutions, such as Diphoterine or Hexafluorine, for specific acid, base, solvent, oxidizer, and reducing-agent exposures are under investigation. Water temperature should be tepid because heat potentially will increase dermal absorption of some toxins.

Certain agents may be removed more effectively with the use of specific decontamination solutions. Dilute household bleach solutions (9 parts water to 1 part bleach) will inactivate nerve agents and most biologic agents, but its use on patients is controversial. The use of neutralizing solutions for acid or alkaline exposures generally is not recommended. Other agents requiring targeted decontamination solutions include phenol and hydrofluoric acid and are discussed below. One should not delay decontamination if such solutions are not readily available but rather begin washing with deluge volumes of water in an attempt to prevent toxin absorption through massive dilution.

Certain metals such as sodium, lithium, and potassium react violently with water, releasing heat, hydroxide ion, and hydrogen gas and potentially causing thermal burns. Proper treatment of alkali metal burns involves clothing removal, covering the affected area with mineral or cooking oil, followed by removal of any remaining metal with dry forceps. Only then can wounds be copiously irrigated with water. Burning fragments should be extinguished by smothering or with a class D fire extinguisher. Again, in the absence of proper solutions, decontamination with deluge volumes of water may be considered. Other water-reactive chemicals are listed in Table 8-4. In contrast to water-reactive chemicals, white phosphorus ignites spontaneously on exposure to air. Burns from this agent must be kept continuously moist with water or saline dressings until adequate debridement is accomplished. Each phosphorus particle must be removed. The application of copper sulfate solution blackens the phosphorus to aid in visualization and provides neutralization. Alternatively, a Wood's lamp may be used. Some adherent toxins are extremely difficult to remove from the skin. Epoxy resins and cyanoacrylates (glues) may be removed by swabbing with acetone. Use of vegetable or mineral oil or saline-soaked gauze pads for the eyes and mucous membranes is safe. Hot tar, typically inflicting burns to the face and upper extremities, should be allowed to cool prior to removal. Effective tar removal has then been reported using Neosporin cream, Tween 80, plain Vaseline, Shur Clens, Desolv-It, or mayonnaise. No attempt should be made to remove tar by mechanical means because this may increase tissue destruction and result in hair follicle loss.

Nausea and vomiting are common following chemical exposures. These symptoms may indicate toxin ingestion with gastrointestinal irritation or, more commonly, systemic toxin effect or hysteria. Regardless of the cause, secondary contamination by toxic vomitus may occur, and the need for its containment should be anticipated. Furthermore, some materials may react with stomach acid to produce toxic gas (sodium azide \rightarrow hydrazoic acid, cyanide salts \rightarrow hydrogen cyanide gas). Suction with outdoor venting should be available to prevent secondary poisoning of personnel. If spontaneous emesis has not occurred already, gastric emptying or the administration of charcoal may be considered for certain large chemical ingestions. Induction of vomiting is not recommended. If an alkaline corrosive material is

TABLE 8-4 Water-Reactive Substances

Acetic anhydride, acetyl chloride
Alkali metals: lithium, sodium, potassium (also form caustic sodium and potassium hydroxides) calcium
Chlorosulfonic acid
Concentrated sulfuric acid (oleum), concentrated muriatic acid
Dry lime (calcium oxide), calcium carbide
Hydrides: boranes, silanes
Inorganic chlorides (some): titanium tetrachloride peroxides
Organometallics: alkylaluminums, zinc phosphide

ingested, 4 to 8 oz of water may be administered if the patient is conscious. Other decisions regarding gastrointestinal tract decontamination may be guided by the regional PCC.

Following decontamination, zipping patients into body bags or placing them into hooded Tyvek suits prior to transport to the support zone is no longer recommended. This technique is not effective in minimizing the transfer of toxin to hospital staff and poses the risk of increased toxin absorption by the patient. The patient simply should be wrapped in clean blankets or sheets prior to transfer to the cold zone.

Complete medical assessment and specific medical treatment can be carried out in the support zone (cold zone). **Emergency department personnel in this area should maintain protective gear (chemical-resistant gowns, latex gloves, eye protection) until the chemical has been definitively identified and the risk of secondary contamination is known.**

BLAST AND CRUSH INJURIES

John M. Wightman Barry
A. Wayne

Sudden force and rapid acceleration of body surfaces to high peak velocities, but relatively small amounts of actual displacement, characterize the interaction of blast waves with victims caught near explosions. Slower application of force, weaker acceleration, and lower peak velocity, but relatively greater surface displacement, are typical of crashing injuries.¹ Both can create internal tissue damage and pathophysiologic derangement, which may be clinically occult to providers managing patients soon after the time of injury. Stress waves are created by the brief acceleration of a surface, and are transmitted deep into the body through the fluid of the tissues akin to the sonic pressure wave produced by a high-velocity bullet. Damage occurs when the stress wave encounters tissues of different densities, thus creating differential pressure forces, motion, stretching, and eventual tearing. Shear waves are created by body deformation, which stretches tissues tangentially to the displaced surface. Primary blast injury (PBI) of the ears, lungs, and bowel are mostly caused by stress waves. Damage from blunt trauma and crushing injuries is mostly due to shear waves.

BLAST INJURIES

Intentional detonation of high explosives or accidental ignition of many explosive substances lead to virtually instantaneous release of

large amounts of energy in the form of expanding gasses.² These gases compress and superheat the surrounding air or water so rapidly that a shock wave is created. This wave (also called a blast wave) delivers high overpressures to surfaces it contacts. Solid surfaces such as concrete and glass are poorly compliant and tend to shatter. Body surfaces, accelerated through the force created by differentials in air or water pressure between the blast wave, ambient medium, and body surface, "spring back" to their original shape because they are more compliant. Unlike other internal organs, bone tends to shatter like other solids. Although applied for only milliseconds due to the supersonic speed of the shock wave passing a human body, extreme accelerations on the order of hundreds of km/s² can induce stress and shear waves, which can tear tissues by exceeding their tensile strengths.³

Pathophysiology

Stress waves propagated through solid organs of relatively homogeneous liquid densities generally do not cause significant effects until overpressures are high enough to cause multiple obvious external injuries. However, stress waves in hollow organs constantly encounter different densities at air-tissue interfaces, which result in macroscopic and microscopic distortions leading to tissue tearing. Bleeding and air escape are the two principal manifestations of PBI (i.e., damage caused by the blast wave itself).

EAR Bleeding of the tympanic membrane (TM) can be seen as petechiae or hemotympanum. More likely, however, the TM will rupture from even relatively low pressure differentials between the external canal and middle ear. Occasionally, the ossicles may be fractured or dislocated. Forces transmitted to the inner ear may cause temporary or permanent hearing loss.

SINUSES Sinus bleeding has been described, but unless their bony supports yield to the pressure differentials, there will not be significant injury at these air-tissue interfaces.

LUNGS Tearing of pulmonary tissue can result in blood or air escaping their normal confines into the parenchyma or pleural cavity or being exchanged between the respiratory tree and the pulmonary vascular circuit. A pulmonary laceration can cause hemo- or pneumothorax. Large tears of the bronchi or lungs may create bronchopleural fistulae with unilateral or bilateral tension pneumothoraces.⁴ Extreme tension pneumothorax can lead to tension pneumoperitoneum.⁵ Parenchymal hemorrhage results in pulmonary contusion, which may be localized, patchy, or diffuse. Blood in tissues and small airways impairs gas exchange between alveoli and pulmonary capillaries. Air escape into pulmonary tissues will result in pseudocyst formation called a pneumatocele. Blood entry into the larger bronchi may compromise airway patency and prevent oxygen from reaching many alveoli. Air entry into the pulmonary venous circuit can lead to systemic arterial air embolism (AAE) with impaction in any organ and subsequent distal ischemia.⁶ Two conditions that, alone or in combination, make AAE more likely are high airway pressures and low venous pressures.²

BOWEL Bleeding from the walls of the gastrointestinal tract can leak into the lumen, the bowel wall, the intraperitoneal cavity, or other extraperitoneal space. In addition to blood loss, transmural tears of the stomach, small bowel, or colon can result in peritonitis following spillage of intraluminal contents. Stretching of the bowel wall or in-

traparenchymal hemorrhage can result in ischemia with delayed perforation.⁷

OTHER Most of the injuries seen in survivors of explosions are from missiles, generally causing penetrating trauma to exposed body regions, particularly the eyes. Blunt trauma can also result from flying objects. The blast wind created by differentials in pressure between the shock wave and ambient air can be hundreds of mph, which is sufficient to throw or tumble people along the ground or into objects, also creating blunt and penetrating trauma. Miscellaneous injuries include burns, toxic inhalations, and traumatic amputations, as well as crushing injuries if victims are caught within a structural collapse.

Detection and Intervention

With the exception of ruptured TMs, the management of various PBIs may not be well known because they are not commonly encountered. Additionally, standard emergency interventions, useful for most trauma victims, may have to be altered in the presence of pulmonary PBI in order not to cause iatrogenic harm as discussed below.

AIRWAY COMPROMISE Selective bronchial intubation may be used for massive hemoptysis when there is more blood coming from one side than the other.^{2,8} Otherwise, airway patency is at risk from all of the usual mechanisms such as depressed level of consciousness, facial or neck trauma, and inhalational injury.

VENTILATORY INSUFFICIENCY High-flow oxygen should be administered to all victims with any period of dyspnea, evidence of hemorrhage, or obviously serious injuries. Continuous positive airway pressure (CPAP) has been used successfully. Positive-pressure ventilation (PPV) may be required for persistent hypoxemia or inability to exchange gasses. **However, PPV can increase the risk of AAE, so spontaneous (negative-pressure) respirations in victims with blast injuries are desirable whenever adequate.** In severe cases with marked lung stiffness, permissive hypercapnia⁹ or other ventilation strategies used for the acute respiratory distress syndrome (ARDS)² may be necessary.

EXTERNAL HEMORRHAGE Bleeding from external wounds is likely to be the most commonly encountered life-threatening finding based on military experience. Whether venous or arterial, blood loss from multiple wounds may have a cumulative effect (or be combined with internal hemorrhage) sufficient to cause hypovolemic shock. All external bleeding must be quickly controlled with direct pressure. Tourniquets should be considered for extremity hemorrhage whenever blood loss cannot be controlled with direct pressure or the resources required to maintain direct pressure are insufficient during either treatment or transportation.

TENSION PNEUMOTHORAX Asymmetrical breath sounds and any evidence of shock should mandate immediate performance of a needle thoracostomy on the side of decreased or absent breath sounds to relieve any potential tension pneumothorax. If there is no improvement in the patient's hemodynamic status, a tube thoracostomy should quickly follow. If a large-bore chest tube connected to an underwater seal and 20 cm H₂O of suction still does not evacuate sufficient air from the pleural space, the presence of a bronchopleural fistula should be assumed. At this stage, either more chest tubes must be placed or air should be prevented from entering the affected lung by selectively intubating the opposite mainstem bronchus.^{2,8}

SHOCK Shock, which persists after external hemorrhage, tension pneumothorax, and hypoxia have been addressed, could be due to internal blood loss; traumatic deep venous thrombosis (DVT) with pulmonary embolism following blunt trauma; crush syndrome; sepsis, if rescue and care were delayed; or AAE, causing brainstem stroke, myocardial infarction, or injury to the spinal cord. Plain chest and pelvis radiography and focused abdominal sonography for trauma (FAST) or diagnostic peritoneal tap and lavage (DPTL) are the most rapid studies used to exclude immediately life-threatening internal hemorrhage. There are no studies commonly available in the ED that are sufficiently

sensitive to rule out the other possibilities rapidly, so clinical suspicion and judgment must be used to determine their likelihood and priority for additional diagnostic testing. Perfusion of vital organs should be restored with small, repeated boluses of crystalloid fluids or blood products to avoid secondary injury of contused lungs or edematous brain.

ARTERIAL AIR EMBOLISM Although blunt trauma can cause many of the same manifestations, **AAE should be considered for any evidence of localized ischemia of the skin or mucous membranes, or such findings as altered mental status, seizures, focal neurologic deficits, chest pain, dysrhythmia, pulmonary edema, abdominal pain, or hematuria.**² AAE should also be considered when there is a sudden deterioration after an intervention such as intubation or change in altitude. Other clues may be an acute myocardial infarction in a young victim without evident chest trauma, paraplegia in absence of spinal cord injury, or focal neurologic deficits without head trauma. Pulmonary venous pressure must be maintained by correcting hypovolemia and PPV should be avoided whenever possible.⁶ Specific treatment involves hyperbaric oxygen (HBO) therapy. Since most centers do not have a hyperbaric chamber, risks related to transportation to the nearest accepting center would have to be considered.

Additional Evaluation

Classic descriptions of blast injuries are divided into primary, secondary, tertiary, and miscellaneous.² Secondary blast injuries are caused by flying objects, whereas tertiary blast injuries result from the victim's body being placed in motion by the blast wind associated with the high pressures of the blast wave. These clinical entities do not differ in their clinical presentation from those caused by different mechanisms, and most of these are obvious or easily detected during the normal evaluation of trauma victims. However, manifestations of pulmonary and gastrointestinal PBI are commonly occult.

PULMONARY PBI Symptoms of pulmonary PBI include dyspnea and chest pain. Pharyngeal petechiae or hemoptysis may be clinical predictors of possible pulmonary PBI,² but TM rupture probably is not.¹⁰ Plain chest radiography is the mainstay of the ED diagnosis of pulmonary injury. Hemo- and pneumothoraces, interstitial infiltrates representing pulmonary contusion, pneumatoceles, and manifestations of blunt and penetrating trauma can all be identified. Additionally, arterial blood gas analysis may be helpful as a predictor of which patients may require ventilatory assistance using the Pao₂/Fio₂ ratio (PFR).⁴ Table 9-1 shows how this ratio correlates with early requirements for standard and nonstandard PPV.² Computed tomography (CT) of the chest can identify smaller degrees of pneumothorax and pulmonary contusion, but is unlikely to be as helpful early in the course of ED care.

GASTROINTESTINAL PBI Symptoms of abdominal injury include abdominal or testicular pain, nausea or vomiting, and an urge to defecate. Hematochezia is a clinical sign predictive of gastrointestinal PBI. The evaluation for intra- and extraperitoneal injury should proceed as for blunt abdominopelvic trauma. However, each ED will have to assess how to best employ individual or combined tests such as physical examination, FAST, DPTL, and CT, given that the likelihood of injury to hollow organs is increased."

Management Caveats

Although the approach to patients with blast injuries is the same as for other victims of trauma, there are specific issues that require awareness: (1) External hemorrhage is much more likely than airway compromise,

TABLE 9-1 Severity Categories for Primary Blast Injury of the Lung

	Mild	Moderate	Severe
adiographic infiltrates	Unilateral	Asymmetrical	Diffuse
PFR (mm Hg)	>200	60-200	<60
ronchopleural fistula	No		Yes
PV requirement	Unlikely for respiratory problem	lightly likely but conventional methods usually	Universal and unconventional methods common
EEP requirement (cm H ₂ O)	<5 if PPV needed	-10 usually needed	>10 commonly needed

Abbreviation: PFR = P_{aO_2}/F_{iO_2} .

Source: From Wightman.²

and thus requires primary attention. (2) Trauma victims usually receive vigorous ventilatory assistance as per standard practice. However, risk of pneumothorax and air embolism is very high, and needs to be considered. In fact, air embolism from positive-pressure ventilation is the most common cause of early death among immediate survivors. (3) Ideal positioning of the patient may not be supine. The risk of AAE may be lower with the patient placed on the left side slightly forward prone. (4) Rapid infusion of crystalloid fluids as may occur in typical trauma patients may be harmful due to the high risk of pulmonary contusion. Small boluses with frequent assessment would be a better approach. (5) Casualties may attempt to assist rescue efforts in the field, but this should be prevented if possible. Exertion may worsen clinically occult blast lung injury.

Disposition

Patients with no chest or abdominal complaints, normal plain chest radiography, normal arterial blood gases, and no other indications for admission 4 h after injury may be candidates for discharge. Detailed instructions should be provided for follow-up care, as delayed manifestations of pulmonary contusion or bowel perforation would be the most likely late PBI complications in those discharged. All other victims should be admitted for management or observation in a facility with capabilities for surgery, pulmonology, and critical care.

CRUSH INJURIES

Blunt or compressive trauma may result from a great variety of mechanisms: industrial machinery accidents, building collapse following explosion or earthquake, combat injuries, drug overdose, mining accidents, torture,¹¹ and transportation and construction accidents. Apart from isolated limb entrapment, these mechanisms frequently result in multiple trauma and/or multiple victims. The term "crush injury" is imprecisely used in the literature, at times referring to the mechanism, and at others referring to the sequelae, such as "crush syndrome" or "compartment syndrome." The term *acute traumatic ischemia* (ATI) is preferable in the majority of these cases, particularly because it focuses attention on the underlying problem that is common to these injuries.

Pathophysiology

The basic cause of ATI is a disruption of adequate perfusion of the affected tissues by oxygenated blood. The underlying mechanisms fall into two broad categories (Figure 9-1). One is direct macroscopic muscular and vascular trauma, typically resulting from energy applied to the tissue in a brief but intense pulse. The other is microvascular trauma, which may

result from a less intense though prolonged application of compressive force, or from hypoperfusion or hypoxia alone. Hemorrhage, associated with either the specific injury or with other internal or external injuries, may also lead to hypoperfusion due to the anemia it produces. Hemorrhage into an intact compartment may lead to a compartment syndrome (see Chap. 278) and an ongoing cycle of increased pressure and decreased perfusion. Hypoperfusion may also be the result of tearing or compressive vascular trauma despite the presence of adequate total-body vascular volume. Microvascular trauma may lead to extracellular edema, and if this occurs in an intact compartment, a compartment syndrome as well. If neurologic structures are involved as they are in many myofascial compartments, the result may also be a Volkmann's contracture.¹²

The net result of hemorrhage, edema, and hypoperfusion is tissue hypoxia and ischemia. Capillary blood flow in muscular compartments is compromised at pressures exceeding 20 mm Hg and hypoxic injury results from tissue oxygen tensions below 30 mm Hg.¹² At the cellular level, this lack of substrate and oxygen translates into a decrease in available ATP and cellular acidosis. An inadequate level of energy results in decreased membrane sodium-potassium-ATPase pump activity and eventual bidirectional sarcolemma leakage. The derangement of intracellular organelles that results leads to an ever-increasing cycle toward cellular death and rhabdomyolysis.^{13,14} Upon cellular lysis, there is a release of mediators of inflammation that promotes vasoconstriction, platelet aggregation, and vascular permeability, which causes further edema and decreased tissue perfusion. Cellular death also results in the release of potassium, phosphate, and myoglobin—aspects of acute traumatic rhabdomyolysis that are responsible for the creation of a crush syndrome (see Chap. 279).

Clinical Approach

The standard approach to any trauma victim should be followed (see Chap. 251). Apart from those cases that result in clinically apparent compartment syndromes, or those that result in crush syndrome, there remains the significant clinical entity of ATI. While ATI may initially not cause compartment syndromes or systemically profound rhabdomyolysis, it does require appropriate intervention to prevent their development. Unfortunately, a history of a crushing mechanism or the time elapsed from the moment of injury may not be obtainable in many cases due to an obtunded patient or lack of witnesses. A disruption in the medical infrastructure or a large number of casualties may also delay care. Clues to the presence of ATI include: mechanisms of injury, prolonged immobilization following the injury, a history consistent with the possibility of a crush mechanism, and, in cases of a conscious patient, pain out of proportion to the apparent extent of the injury.

Although any tissue can be affected, nerve and muscle within myofascial compartments are at particular risk. The affected limb may not appear to be diffusely swollen or particularly painful until the onset of an actual compartment syndrome, though a tensely swollen limb with shiny overlying skin is an indication that a compartment syndrome has probably already developed. These relatively unyielding compartments may contain increased pressure without a marked change in the external appearance. It is essential that the skin be cleansed of dirt, soot, and debris in order to determine if there are any changes or asymmetries in skin color. Areas that are blanched, as well as areas of erythema, should prompt concern and an expanded evaluation. Palpation of the entire body should be done to determine if there are areas of crepitus, swelling, or tenderness. Although the utility of capillary refill has been called into question, it may provide a useful screening tool for detecting asymmetry and for serial checks.

Following a thorough neurologic examination, and removal of any clothing or jewelry, which may be potentially constrictive, any affected limbs should be immobilized with padded splints in a position that will enhance local circulation. Frequent neurologic and vascular checks are essential to detect developing processes that may have been occult to the examiner initially.

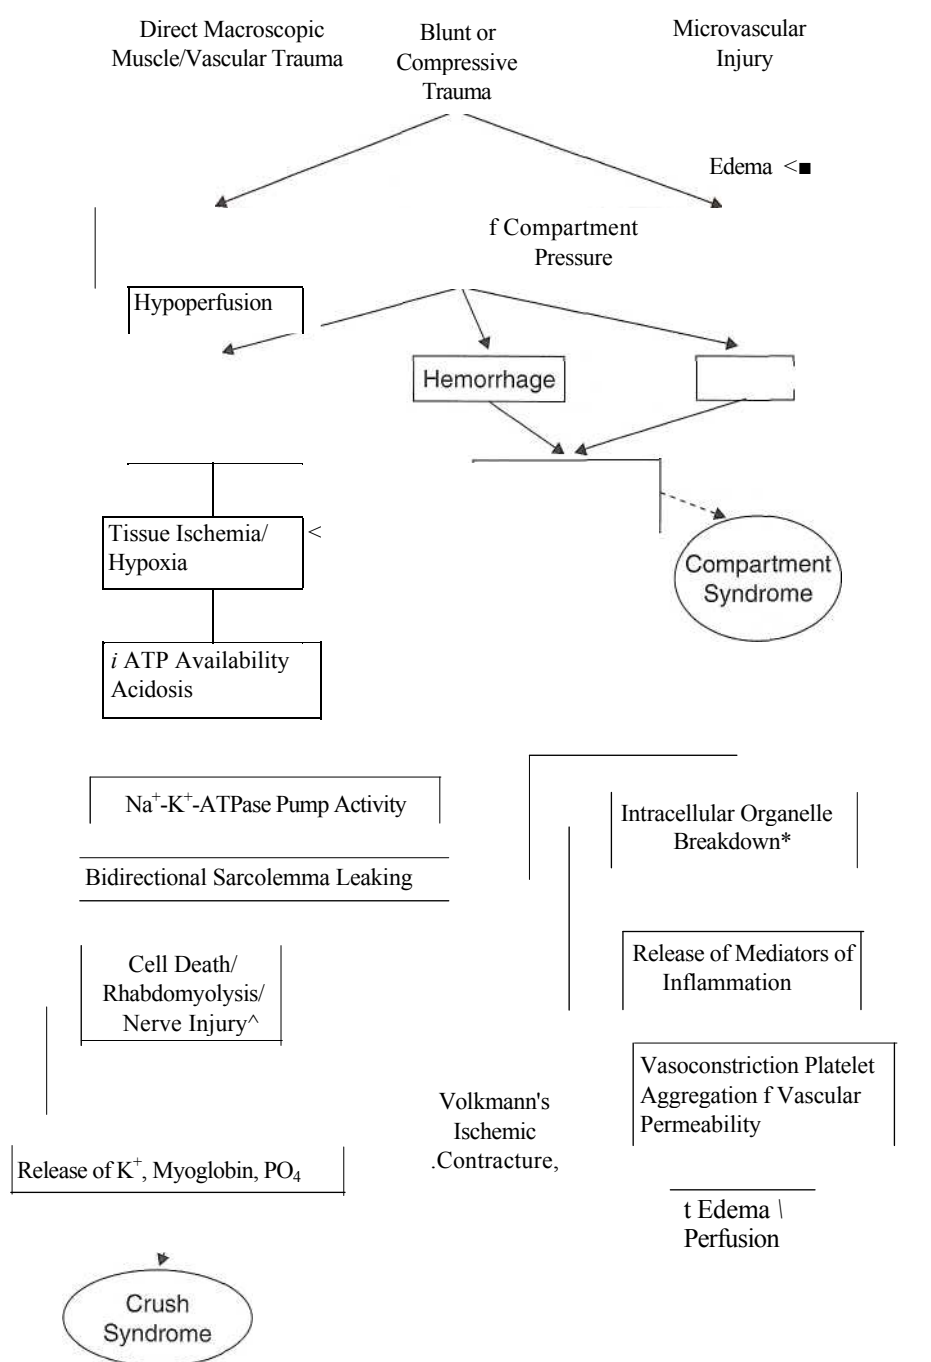

FIG. 9-1. Pathophysiologic cascade of acute traumatic ischemia (ATI). *The intracellular derangement includes swelling of the mitochondria, a breakdown in the endoplasmic reticulum, and gradual breakdown of the cell membrane, all leading to increased intracellular calcium, lysosome breakdown, and the release of multiple enzymes. These enzymes (lipase, protease, etc) further accelerate the autocatabolism and result in cell death.

Apart from any laboratory tests needed for concomitant injuries, blood should be drawn for CBC, BUN, creatinine, electrolytes, phosphorus, calcium, and creatine kinase (CK) activity. Urine should be sent for urinalysis and urine myoglobin concentration. Samples should be collected from freshly produced urine, not the pretrauma specimen that the bladder initially contains. Prior to results being returned, the presence of myoglobin can be assumed when a urine test strip is positive for blood but microscopic examination reveals no red blood cells. Serial laboratory examinations of serum potassium and CK, as well as urine myoglobin, should likewise be obtained, particularly if the initial results are normal in a clinical context that strongly suggests the possibility of ATI.

Management

Standard trauma protocols should be followed. Supplemental oxygen should be provided to keep the hemoglobin saturation greater than 95 percent, and blood transfused to keep the hemoglobin concentration greater than 10 g/dL. Continuous cardiac monitoring and pulse oximetry

should be performed. Initial fluid resuscitation should be done with 250-mL aliquots of NS every 15 min until urine is produced at a rate of 2 mL/kg per h. Large fluid boluses should be avoided. The goal is a resuscitated mean arterial pressure greater than 80 mm Hg. The use of furosemide and mannitol is controversial. Furosemide 40 to 120 mg IV may be given. Furosemide causes renal vasodilation, decreased oxygen demands by the kidney, and increased renal intratubular flow.¹⁴

It should be realized that, particularly in the case of mass casualty incidents or disasters, that amputation of a nonviable limb may be a life-saving procedure in terms of preventing the sequelae found in crush syndrome.

Disposition

All patients with suspected ATI require admission for intravenous hydration; serial monitoring of potassium, CK, and myoglobin; and close monitoring for the onset of compartment syndromes by performing

frequent neurologic and vascular examinations. The treatment of hyperkalemia, hypercalcemia, hypophosphatemia, and myoglobinuria associated with rhabdomyolysis is discussed in Chap. 279. HBO therapy has recently been demonstrated in a double-blind trial to be effective in extremity ATI,¹⁵ and could also be considered.

RADIATION INJURIES

Christina L. Catlett Pamela L. Piggott

INTRODUCTION

In the last 40 years, the public's concern with radiation injuries centered around nuclear power plant accidents and the threat of use of a nuclear weapon in a war setting. However, with today's widespread use of radiation technology in medicine, research, industry, power production, and national defense, there is a growing potential for radiation injuries. Of further concern is the potential for large numbers of casualties from a terrorist attack employing a nuclear weapon or radioactive material. As a front-line responder, the emergency physician must be prepared to recognize and treat injuries sustained in a radiation event.

RADIATION EVENT SCENARIOS

Radiation events may be accidental or intentional. Accidents may occur at any facility utilizing a radioactive source, or during transport of radioactive materials. Accidents can also occur in the medical setting, involving erroneous dosing of radiotherapy.

Nonmalevolent theft of radioactive sources for financial gain can result in accidental exposure to radiation. Sealed medical and industrial sources, such as cobalt-60, cesium-137, and iridium-192, could be targets for thieves. These sources can also be abandoned, lost, misplaced, or embezzled, thereby ending up in the wrong or unsuspecting hands.

Recently, the threat of a radiation event as a result of terrorist activity has arisen. A "dirty bomb" is one in which conventional explosives are linked to a radioactive source with the intention of dispersing radioactive particles over a large area. While this may not be likely to cause many radiation injuries, the ensuing panic and psychological distress would be devastating. Terrorists may also attempt to attack a nuclear installation (such as a power plant or waste repository) in an effort to disperse radioactive material. In the worst-case scenario, terrorists may manage to obtain a nuclear weapon for detonation.

Radiation injury can also occur if an individual has contact with a radiation source without being aware of its hazardous nature. Four major cases of this occurred in Thailand (2000), Egypt (2000), Estonia (1994), and Brazil (1987), in which unsuspecting villagers gained possession of lost or abandoned radioactive sources (scavenging scrap metal in two of the incidents) and were exposed to radiation. The average time from first exposure to diagnosis for these four events was 22 days.¹ The ability to recognize signs and symptoms of radiation injury will enable the physician to deliver more prompt and effective treatment to these types of patients.

INCIDENCE OF RADIATION EVENTS

The most recognized and comprehensive record of radiation accidents is the registry maintained by an asset of the U.S. Department of Energy, the Radiation Emergency Assistance Center/Training Site (REACTS). Since the inception of the registry in 1944, 426 radiation accidents have been recorded worldwide with a total of 133,811 victims; 3063 had significant exposure and there were 134 fatalities. The 1986 Chernobyl accident accounted for 116,500 individuals and 28 acute fatalities. The most frequent radiation accident is one of high-dose local exposure, usually to the hands, from a radiation device. The majority of these accidents have occurred in the industrial setting with inadvertent exposure from radiation devices used in radiography to verify integrity of metals such as pipe welds.²

FUNDAMENTALS OF RADIATION PHYSICS

An understanding of basic radiation physics and pathogenesis of injury will aid the emergency physician in the triage and initial management of radiation injuries.

Nonionizing and Ionizing Radiation

The electromagnetic radiation spectrum includes long-wavelength, low-frequency, low-energy forms of nonionizing radiation and progresses to short-wavelength, high-frequency, high-energy forms of ionizing radiation. *Ionizing* refers to the ability of high-energy radiation to displace electrons from atoms and cause matter through which it passes to become electrically charged. Alpha and beta particles, neutrons, x-rays, and gamma waves are ionizing forms of radiation. Nonionizing forms include ultraviolet rays, visible light rays, infrared rays, microwaves, and radio waves. Lasers, ultrasound, and nuclear magnetic resonance systems are other examples of devices that use nonionizing radiation in the medical field.

Types of Ionizing Radiation

Radiation is emitted as either particles or waves. Particulate radiation includes alpha, beta, and neutrons, whereas gamma and x-rays are electromagnetic waves (Table 10-1).

TABLE 10-1 Types of Radiation

Type (Symbol)	Mass*	Charge	Penetration	Shield	Hazard	Source
Alpha (α)	4	+2	Few cm in air	Paper, keratin layer of skin	Internal contamination only	Transuranic elements, i.e., plutonium found in nuclear weapons and isotope production facilities
Beta (β)	1/200	-1	~8 mm into skin	Clothing	Skin and internal contamination	Most radioisotopes decay by β followed by γ emission
Neutron (N)	1	0	Variable	Material with high hydrogen content	Whole-body irradiation	Nuclear power plants, particle accelerators, weapons assembly plants
Gamma (γ) and x-rays	0	0	Several cm in tissue	Concrete Lead	Whole-body irradiation	Most radioisotopes emit γ following β decay

*Approximate measurement in atomic mass units (AMU).

ALPHA PARTICLES Alpha radiation is a heavy, highly charged particle composed of two protons and two neutrons. Because of its large mass and charge, alpha particles travel at a low velocity and interact readily with matter. This form of radiation deposits a large amount of energy in a small volume of tissue; however, the energy dissipates quickly. Therefore, alpha radiation possesses a significant biological hazard only when internalized. Alpha radiation is easily shielded and cannot penetrate paper or the keratin layer of skin. Heavy radioisotopes with an atomic number above 82, such as uranium and plutonium, are sources of alpha particle emission. Specialized devices are required to detect alpha particles.

BETA PARTICLES Beta particles have a smaller mass and charge and generally have a greater velocity than alpha particles. Beta radiation can travel several meters in air and penetrates approximately 8 mm into exposed skin and can cause serious burns. Like alpha, beta is also a hazard if internally deposited, but to a lesser extent. Most radioisotopes decay by beta radiation followed by gamma emission.

NEUTRONS Neutrons are electrically neutral particles with a wide range of energy, velocity, and penetration power. Exposure to neutrons is unique. Unlike irradiation by other forms, high-level neutron exposure can induce radioactivity. That is, neutron irradiation can cause previously stable atoms of the absorbing material to become radioactive. In human tissue, the induced radioactive isotope is primarily Na-24, which can be detected in blood and urine specimens. In peacetime, neutron exposure is unlikely and sources of neutrons are limited primarily to nuclear power plants, particle accelerators, and weapon assembly sites.

GAMMA AND X-RAYS Gamma and x-rays are electromagnetic waves with no mass and no charge that travel at the speed of light. X-rays have longer wavelengths, lower frequency, and lower energy than gamma rays. Gamma rays are the most penetrating type of ionizing radiation and travel several meters in air and many centimeters into tissue; therefore dense materials are required to shield from gamma radiation. Exposure to an external source of gamma or high-energy x-rays presents a significant whole-body radiation hazard and high doses may result in acute radiation syndrome.

Units of Measure

Radiation can be measured as activity, exposure, or dose (Table 10-2). Conventional units include the curie, roentgen, rad, and rem. The International System (SI) is now more widely used and includes the becquerel, gray, and sievert.

The curie (Ci) and becquerel (Bq) are units of activity and describe the amount of radioactivity present, which is a function of the radioisotope's rate of decay or number of disintegrations per second. The roentgen (R) is a unit of exposure and measures the amount of x-ray or gamma radiation that produces a given number of ionizations in air. Many radiation survey instruments record exposure rate per h of x-ray or gamma radiation. The SI equivalent of roentgen is coulomb per kilogram (coul/kg). The rad (r) and gray (Gy) are units of absorbed dose and reflect the amount of energy that the radiation imparts to matter through which it passes.

Because the different types of radiation have different magnitudes of biological effect on humans, units of dose-equivalent are used to provide a common scale of measurement for the different types of radiation. The

TABLE 10-2 Radiation Units of Measure

Description	Conventional Units	SI Unit	Conversion
Activity Units of activity describe the amount of radioactivity present.	Curie (Ci)	Becquerel (Bq)	1 Bq $\sim 2.7 \times 10^{-11}$ Ci 1 Ci $\sim 3.7 \times 10^{10}$ Bq
Exposure Units of exposure measure the amount of x-ray or gamma radiation that produces a given number of ionizations in air.	Roentgen (R)	Coulombs per kg (coul/kg)	1 R = 2.58×10^{-4} coul/kg
Absorbed Dose Units of absorbed dose can be applied to any type of radiation and reflects the energy imparted to matter.	Rad (r)	Gray (Gy)	1 rad = 0.01 Gy 1 Gy = 100 rad
Dose Equivalent Units that provide a common scale of measure for the different types of radiation.	Rem	Sievert (Sv)	1 rem = 0.01 Sv 1 Sv = 100 rem
Internalized Radiation Term that reflects the amount of radiation that will be delivered to the body from internally deposited radioisotopes.	Body burden	N/A	

rem and sievert (Sv) are units of dose-equivalent and are obtained by multiplying the absorbed dose by modifying factors. Differentiation between units of absorbed dose and dose equivalent is most important with high-energy transfer radiation, particularly alpha radiation. Because of the large amount of energy that alpha particles deposit in a concentrated area, the potential of alpha particles to cause biological damage is greater. The dose equivalent of alpha radiation is approximately 20 times the absorbed dose. In other words, one rad (or gray) of alpha radiation is approximately equivalent to 20 rem (or sievert).

For beta, x-ray, and gamma radiation, the dose equivalent is essentially equal to the absorbed dose. In simplified terms, a rad (or gray) of beta, x-ray, or gamma radiation is roughly equivalent to a rem (or sievert). For these types of low-energy-transfer radiation, units of absorbed dose and dose-equivalent are often used interchangeably.

Body burden is used in reference to internally deposited radioactive material. Different radionuclides will deliver varying amounts of radiation to the body when internalized. The amount of radioactivity that may be present in the body for a working lifetime and pose no reasonable expectation of health risk is referred to as the maximum permissible body burden (MPBB). The amount of internally deposited radioactive material is quantified as a percentage of the MPBB that has been established for the particular radionuclide. The MPBB is based on continuous exposure in a working lifetime, thus the MPBB must be interpreted with caution in an accident setting involving acute exposure. Annual limit of intake (ALI) is a newer term that is also used to quantify internally deposited radioactive material.

Biologic Effect of Ionizing Radiation

The biologic effect of ionizing radiation occurs at the cellular level. DNA and other macromolecules of the cell may be directly ionized by radiation or indirectly damaged by highly reactive free radicals created by ionization of cellular water. High levels of radiation exposure may directly cause cell death. More commonly, lower levels of radiation interrupt the cell's reproductive process by damaging its mitotic capability, making it unable to divide. Injury occurs at the time of exposure, but the onset of clinical manifestations of radiation injury varies among cell types. Short-lived cells, such as blood cells, are quickly depleted and injury may become evident before new cells are generated. Longer-lived cells, such as in the lens of the eye, regenerate slowly and thus injury may not become apparent for years after the exposure.

Radiosensitivity is the response of cells to acute manifestations of radiation injury. In general, poorly differentiated cells and cells with a short lifespan and high turnover rate are most vulnerable to the detrimental effects of radiation. Rapidly proliferating cells, such as those of the hematopoietic, gastrointestinal, and reproductive systems, are more radiosensitive than the more slowly dividing cells of the nervous and musculoskeletal systems.

Radiation Monitoring Equipment

Common radiation monitoring equipment includes dosimeters and survey meters (Table 10-3). Dosimeters are small devices that are typically worn on the upper torso to record the cumulative amount of ra-

diation an individual receives while wearing the device. Survey instruments are rate meters that record the amount of radiation detected in an area per unit of time. Both of these monitoring devices should be available to the emergency department for use during a radiologic emergency. Survey meters should be used to monitor contamination of victims and staff, and personal dosimeters should be worn by personnel working in the radiation emergency area (see below).

PERSONAL DOSIMETERS A thermoluminescent dosimeter (TLD), or film badge, is used to provide permanent records of cumulative dose received. Most of these devices measure beta, x-ray, and gamma radiation. The dose is recorded in rem or sievert. Dose measurements are not immediately available to the wearer because these devices require processing. Self-reading pocket dosimeters may be used in addition to TLDs. These devices provide immediate estimates of cumulative exposure of x-ray and gamma radiation. Most pocket dosimeters can be directly read when held up to a light source. Estimates are typically recorded in milliroentgen (mR).

RADIATION SURVEY METERS Ion chambers are common types of survey meters for recording exposure rates of x-ray and gamma radiation. Some types of ion chambers are also equipped to detect beta radiation with a Mylar window beneath a removable shield. These instruments are usually calibrated in mR/h. Geiger-Mueller (GM) instruments are commonly used to perform surveys for external contamination. These instruments detect lower exposure rates of x-ray and gamma radiation, as well as beta radiation. With special instrument probes, alpha radiation can also be detected. The units recorded are typically counts per minute (cpm). For comparison, 2500 cpm is approximately equal to 1 mR per h.

Lethal Dose of Radiation

The LD50/60 from exposure to ionizing radiation is defined as the dose of penetrating ionizing radiation that will result in the deaths of 50 percent of the exposed population within 60 days. Three values are commonly cited regarding human survival. The most commonly cited value is LD50/60 of approximately 4.5 Gy (450 rad). This value assumes intensive medical therapy is provided, including antibiotics, blood products, and reverse isolation. With only minimal treatment, such as basic first aid, the LD50/60 falls to approximately 3.4 Gy (340 rad). Victims of the Chernobyl nuclear accident have demonstrated that humans can survive radiation doses greater than anticipated. Intensive medical support for Chernobyl victims allowed a high survival rate in individuals receiving less than 6 Gy (600 rad). With newer advances in medical treatment, such as stem cell transplantation and hematopoietic growth factor administration, it may be possible to raise the LD50/60 to 11 Gy (1100 rad).³

RADIATION EVENT MANAGEMENT

Advance Planning

Every EMS system should have a prehospital plan for the evacuation of victims from a radiation disaster. HazMat is often the responsible entity. In addition, every hospital is required by the Joint Commission

TABLE 10-3 Radiation Monitoring Equipment

Equipment Type	Device	Common Type of Measurement	Units Commonly Recorded
Dosimeter	Thermoluminescent dosimeter or film badge	Cumulative dose of beta, x-ray, and gamma	Rem or Sievert
Dosimeter	Pocket dosimeter	Cumulative exposure to x-ray and gamma	mR
Survey meter	Geiger-Mueller tube	Low exposure rates of x-ray, gamma, and betaf	cpm*
Survey meter	Ion chamber	Higher exposure rates of x-ray and gamma	mR per h

*2500 counts per minute (cpm) equal approximately 1 mR per h. ■(■With special instrument probes, alpha radiation can also be detected.

on Accreditation of Healthcare Organizations (JCAHO) to have a written protocol detailing instructions for receiving and treating radiation event victims. The initial medical evaluation and treatment of the victims often falls under the purview of the emergency department; therefore the emergency physician should take an active role in the development of the hospital's radiation event plan.⁴⁶⁵ Further, the hospital should stage regular disaster drills and train personnel in decontamination procedures, use of personal protective equipment, and radiologic monitoring.

Prehospital Emergency Medical Management

Emergency responders rapidly establish incident command in a situation involving radioactive materials. Responders secure the scene and attempt to identify the hazard. Personal protective equipment, respiratory protection, and turnout gear are used per protocols. Radiation dosimeters or survey meters are utilized, if available. Victims are extricated, and life-saving medical interventions are administered. Care and transportation of seriously injured victims should not be delayed, even if the patient is contaminated. In medically stable patients, radiation control measures will be undertaken at the scene, such as radiation monitoring, removal of the patient's clothing, covering of wounds, and transfer of the patient to a clean stretcher and ambulance if possible. First responders must communicate with hospitals prior to arrival to allow adequate preparation.

Emergency Department Notification and Preparation

When receiving notification of a radiation event, the emergency department should request information that will facilitate the necessary preparation, including:

1. Circumstances of the accident or event
2. Number of victims
3. Medical condition and physical injuries of the victims
4. Type and extent of radiologic insult: irradiated, externally contaminated, or internally contaminated
5. Identification of the radioactive material, if known
6. If victims were able to be surveyed in the field
7. Exposure to other hazardous material that may be chemically toxic or corrosive

If contamination of the victim is unknown, the patient should be assumed to be contaminated and undergo decontamination measures (see below).

Notification alone should serve to activate the radiation event protocol. Elements of the protocol include: clear identification of the members of the radiation emergency response team, individual responsibilities, location and type of radiation emergency supplies, specific details for physical preparation of the emergency department, and procedures to ensure ED staff and patient safety (Table 10-4).

Initial activation of the protocol should instruct ED personnel how to contact predetermined local radiation specialists, and ideally, health physics professionals. Radiation specialists may assist by monitoring radiation doses of personnel, surveying personnel and areas for contamination, directing contamination control and decontamination efforts, and disposing of contaminated wastes.

Triage and Treatment Philosophies

When there are multiple casualties, triage should be based on the patient's acute medical condition and not specifically on radiation exposure. Radioactive contamination (external or internal) is never immediately life-threatening. Therefore radiologic surveying or decontamination should never supersede life-saving medical interventions.

If all patients are medically stable, then the suggested priority of providing treatment is:

1. Externally contaminated patients (to prevent spread of contamination and internal contamination)

TABLE 10-4 Emergency Department Preparation

Establish the radiation emergency area (REA)

- Locate away from usual traffic or patient flow
- Establish "buffer zone"

Adequate size for anticipated number of victims Police or security strictly control access Boundaries identified with rope or signs Cover floors with plastic or paper secured with heavy tape Pregnant women, nonessential personnel not allowed

Obtain preassembled emergency kits

- Supplies for REA set-up and decontamination
- Personal dosimeters
- Radiation survey meters
- Specimen collection containers
- Resuscitation equipment (intubation equipment, IV supplies and fluids, drugs, etc.) and trauma supplies (chest tubes, dressings, etc.)

Portable ultrasound Don protective gear

- Water-repellent coveralls or aprons and shoe covers Surgical gown, mask, eye protection, cap Double pair of latex gloves, with inner glove taped in place, outer pair changed after contact with contamination Fasten dosimeter on torso, on outermost clothing layer
- Meet the patient(s)** At the ambulance if the ED has the capability to decontaminate patients prior to entry into the hospital At the entrance to the REA if the patient must be decontaminated within the ED

2. Internally contaminated patients
3. Externally irradiated patients

Additional precautions are required when managing radiation events, because unlike incidents involving hazardous material of other types, incidents that involve radiation and radioactive material can only be detected by monitoring devices. Contamination control is necessary in order to protect the safety of patients, health care providers, and the environment. The goal of treatment is to limit exposure of the patients and staff to the hazardous substance, thereby minimizing morbidity and mortality, and to contain the spread of the hazardous material.

TYPES OF RADIATION EXPOSURE

A radiation accident or event can expose a victim through several different means. *External contamination* occurs when radioactive materials are deposited on the skin. These patients require decontamination to prevent further exposure to the patient and hospital staff.

External irradiation occurs when all or part of the body is exposed to a penetrating radiation source. The irradiation may occur locally (i.e., to the hands) or diffusely, resulting in acute radiation syndrome. Localized injuries, which rarely cause systemic illness, are the most common type of radiation exposure.

Internal contamination can occur through an accidental or intentional ingestion of a radioactive source, or via absorption of radioactive materials through wounds or the lungs. Internal contamination can result in *incorporation*, or uptake of the radioactive material into cells, tissues, and organs such as bone, thyroid, liver, or kidneys.

CLINICAL PRESENTATION AND MANAGEMENT

The presentation, emergency management, and long-term care of a radiation victim varies based on the mechanism of exposure to radiation. For ease of discussion, the following four exposure scenarios will be addressed: externally contaminated patients; localized radiation injuries; whole-body irradiation; and internally contaminated patients. For each scenario, patient presentation, decontamination, emergency department treatment, and inpatient treatment shall be discussed. For

a summary of recommendations for the medical treatment of radiation victims, please refer to Table 10-5.

Externally Contaminated Patients

A patient is externally contaminated when radioactive materials are physically deposited onto the patient's skin or clothing. All victims of radiation events should be handled as if contaminated until known otherwise.

Upon arrival at the hospital, all patients should be surveyed for contamination. If radiation monitoring devices are not available, patients should be routinely decontaminated and then surveyed for contamination when monitoring equipment is obtained.

The dose from external contamination to either the patient or the medical staff is rarely significant. Spreading the contamination in the environment and the potential of internalization are the main hazards with external contamination. Thus special precautions are required for receiving and treating these patients. Specific contamination control principles, physical decontamination techniques, and personal protective equipment are required for the care of these patients (see Tables 10-4 and 10-6).

It is not immediately crucial to know the identity of the radionuclide; however, it is important to determine whether the nuclide emits beta-gamma radiation and/or alpha radiation. Commonly used radiation survey meters easily detect beta and gamma radiation. Detection of alpha radiation requires special instrument probes and careful monitoring techniques. Alpha radiation is shielded by any moisture, including perspiration and blood. Therefore only trained individuals should perform surveys for alpha-emitting contamination.

Local Radiation Injury

The majority of radiation accidents in the United States result in local radiation injury from partial-body exposure. In contrast to whole-body irradiation, partial-body irradiation rarely causes systemic manifestations. A rare exception is the development of acute radiation syndrome (see below) following partial-body irradiation that affects a significant amount of the bone marrow. Most commonly, a portion of the extremities is affected and the clinical picture consists of cutaneous changes. The extent and course of cutaneous involvement is dose dependent. Generally, within the first week following localized radiation exposure, the patient may be asymptomatic or experience some transient erythema, hyperesthesia, and itching. In the second week, true erythema develops along with progressive epilation. In week 3, the skin

becomes warm, painful, swollen, and pruritic. By the fourth week, dry or wet desquamation and/or ulceration ensues, depending on the radiation dose received (Table 10-7).⁶

These skin manifestations may appear similar to thermal burns. However, unlike thermal burns, cutaneous radiation injury may be associated with waves of transient erythema described above, as well as with a delayed onset of pain, followed by a more prolonged and severe pain. Another important distinction of radiation injury is that the clinical changes evolve over a more prolonged time period. The exception is very high doses on the order of 50 Gy (5000 rad), that result in prompt transdermal injury resembling a thermal third-degree burn. The pain is immediate and excruciating. Surgical resection and grafting may be required.

Emergency department care of cutaneous radiation injury is limited to analgesics, routine burn care, and if indicated, surgical referral. Inpatient treatment may not be required. However, close follow-up is essential. Physical therapy and splinting may be useful for preventing contractures and preserving joint range of motion. These patients should be carefully monitored for hemorrhage, infection, and necrosis. In addition, prolonged close follow-up is needed for later neoplastic changes of the skin.

Whole-Body Irradiation/Acute Radiation Syndrome

Characteristic and relatively predictable signs and symptoms develop when a significant portion of the body is exposed to a high level of penetrating radiation over a short period of time, typically less than 24 h. These signs and symptoms are collectively referred to as *acute radiation syndrome* (ARS) (Table 10-8). A whole-body gamma dose in excess of 2 Gy (200 rad) is the primary cause of acute radiation syndrome. Alpha and low-energy beta radiation lack sufficient energy to penetrate the skin and deliver a whole-body radiation dose. Neutron exposure is rare, but high-level neutron irradiation is also capable of producing ARS. Additionally, there are a few reports of ARS following significant amounts of internal radioactive contamination.

Four distinct phases are seen in the unfolding of ARS. The *prodromal phase* is a transient period of self-limiting symptoms that may occur within minutes, hours, or days after exposure. The acuity of onset and the duration of this phase are directly related to the dose received. The prodromal phase is an autonomic nervous system response that initiates gastrointestinal symptoms such as anorexia, nausea, vomiting, and with high doses, diarrhea. In addition, neuromuscular symptoms often accompany the autonomic response and may include hy-

TABLE 10-5 Medical Management of Radiation Event Victims

Radiologic Insult	Key Actions
External Contamination	Initiate contamination control practices and decontamination techniques described in Tables 10-4 and 10-6.
Localized Radiation Injury	Provide adequate analgesics. Routine burn care. Surgical referral as indicated.
Internal Contamination	After swabs have been obtained, irrigate wounds with normal saline. Begin collection of body excreta (sputum, urine, feces, emesis) for bioassay to identify and quantify radioisotopes. Continue collection of urine and feces for 4 days to monitor excretion rate. If ingestion is suspected, begin gut decontamination methods. If high levels of internal contamination are suspected, particularly radioiodine or alpha-emitting radiation, obtain expert consultation for assistance with decorporation procedures.
Whole-Body Irradiation	Obtain blood specimens for dose estimation and for cell and HLA typing. Document time of onset of all symptoms, i.e., anorexia, nausea, vomiting. Symptomatic treatment, i.e., antiemetics, pain management, anxiolytics. Supportive treatment, i.e., IV fluids, blood products, total parenteral nutrition. Consider prophylactic measures, i.e., reverse isolation, prophylactic antibiotics, and antifungals. If severe bone marrow suppression is anticipated, consider administration of hematopoietic growth factors. If neutron irradiation is a concern, obtain blood and urine specimens and monitor for induced radioactivity of Na-24. Monitor all metals on the patient's body for induced radioactivity.

TABLE 10-6 Key Decontamination Techniques

Remove the patient's clothing. This may remove as much as 90% of external contamination. Ideally, this is done at the accident scene prior to transport, or prior to entrance into the ED. Potentially contaminated items are placed in plastic bags and labeled for further management by the Radiation Safety Officer. Survey the patient for radiation. Document the location and level of contamination. Decontaminate the patient:

1. If the hospital has permanent showers or prefabricated (temporary) decontamination tents, the patient should be decontaminated prior to entrance into the hospital. Resuscitation and stabilization supplies should be available in the decontamination area. Management of decontamination run-off should be discussed with the state's Environmental Protection Agency (EPA) office prior to an actual event. If a patient still surveys positive for radiation following general decontamination, he or she should be brought into the REA for further decontamination.
2. If the hospital has an approved decontamination room(s) with water containment capability, this may be used.
3. If neither is available, the patient may be decontaminated in the REA (see Table 10-4). If contamination is localized, the area is irrigated and the washings are collected in a container. If contamination is generalized, the patient is cleansed with washcloths, warm water, and a mild soap. Washcloths should be placed in a plastic bag.

Wounds and body orifices are the first priority of decontamination because of the potential for systemic absorption. Intact skin with the highest level of surface contamination follows, progressing to the area of lowest contamination. Attention should be paid to skin folds, where contamination may collect.

Resurvey the patient after each decontamination attempt. Remaining contamination may be removed with mild soap and gentle scrubbing. Vigorous decontamination may damage the skin and thus facilitate absorption. Surgical debridement or excision may be necessary if contamination is embedded in a wound. Emergency procedures that must be performed immediately (e.g., intubation, relief of tension pneumothorax) may need to occur in the REA. Swab samples should be obtained (time and location noted) for contaminated areas of skin, wounds, nares and assessed by Geiger counter. If radioactivity persists, suspect skin folds or internal contamination (absorption, inhalation, or ingestion). Nasogastric suction may be appropriate of ingestions. If significant uptake is suspected, request assistance from expert consultants for management of internal contamination. All excreta should be collected, bagged,

labeled by site and time, and sent to the appropriate laboratory (per the Radiation Safety Officer or Health Physicist) for isotope analysis. Following decontamination (accomplished when the reading on the radiation monitor is at or below twice background level), a clean stretcher is rolled over plastic to the patient, and the patient is transferred to the clean stretcher for transfer out of the REA. Any patient, staff, supplies, and/or equipment leaving the REA are assessed for contamination by the Radiation Safety Officer or Health Physics personnel to prevent spread of contamination into the ED. Life-saving surgical procedures should not be delayed for decontamination. If necessary, the patient may be covered with clean sheets and transferred to the operating room. The operating room will require decontamination prior to further use.

potension, pyrexia, diaphoresis, cephalgia, and fatigue. The *latent phase* is a symptom-free interval that follows the resolution of the prodromal phase. Shorter latent phases correspond to higher levels of dose received. The latent period may last 1 to 3 weeks with a dose of less than 4 Gy (400 rad), but may last only a few hours when a dose above 15 Gy (1500 rads) is received.

The *manifest illness phase* is often divided into three dose-dependent subsyndromes. In ascending order of severity, these syndromes are clinically related to injury of the hematopoietic, gastrointestinal, and cardiovascular and central nervous systems. The toxic effects to these organ systems are not discrete. There is considerable overlap as well as additive detrimental effects among these syndromes.

HEMATOPOIETIC SYNDROME The hematopoietic system is the first organ system to manifest injury and symptoms are seen from doses above 1.5 to 2 Gy (150 to 200 rad). Self-limiting prodromal symptoms begin within several hours or days and typically resolve within 48 h. An asymptomatic latent period follows and typically lasts for 1 to 3 weeks. Radiation destroys circulating lymphocytes and damages stem cells in the bone marrow and lymphatic system. The rapid

decline in lymphocytes is a hallmark of the hematopoietic syndrome and is one of the best early indicators of the extent of radiation injury. Granulocytes, and to a lesser extent, platelet counts display an initial rise followed by an accelerated decrease, reaching a nadir at about 30 days. The red blood cell population also decreases in concentration with resultant mild anemia, but to a lesser extent than other blood cell lines (Figure 10-1). This syndrome results in pancytopenia and immunosuppression with subsequent hemorrhage and infection as the principal causes of morbidity and mortality. Survival is possible with extensive medical intervention.

GASTROINTESTINAL SYNDROME Gastrointestinal syndrome is the second subsyndrome of the manifest illness phase of ARS and may occur after doses above 6 to 7 Gy (600 to 700 rad) are received. This syndrome is distinguished from the hematopoietic syndrome by the onset of nausea, vomiting, and often diarrhea within hours after exposure. These prodromal symptoms are followed by a short latent period of 1 week or less. Reappearance of gastrointestinal symptoms then occurs with severe nausea, vomiting, diarrhea, and abdominal pain. There is damage of the intestinal mucosal barrier with massive fluid losses resulting in profound volume loss and electrolyte disturbances. The denuded gastrointestinal mucosa allows enteric flora to disseminate into the bloodstream. Declines in blood cell populations are similar to that which occurs with the hematopoietic syndrome, but abnormalities occur sooner and with greater magnitude. With the concurrent immunocompromised state, a fulminating enterocolitis follows. There are few documented cases of gastrointestinal syndrome in humans, all of which resulted in fatalities.

CARDIOVASCULAR AND CENTRAL NERVOUS SYSTEM SYNDROME The cardiovascular and central nervous system syndrome is the third subsyndrome of the manifest illness phase of ARS that occurs after doses above 20 to 30 Gy (2000 to 3000 rad) are received. This syndrome presents with immediate prostration, nausea, vomiting, and explosive bloody diarrhea as well as hypotension. Alterations in

TABLE 10-7 Deterministic Thresholds for Local Radiation Injury

Dosage	Cutaneous Manifestation	Time From Exposure
3 gy	Epilation	2—3 weeks
6gy	Erythema	First day Recurs in 2—3 weeks
10-15 gy	Dry desquamation	2—3 weeks
20-50 gy	Wet desquamation	2-3 weeks
>50gy	Overt radionecrosis and ulceration	1-2 weeks

Source: From Goans.¹

TABLE 10-8 Acute Radiation Syndrome

Approximate Dose	Onset of Prodrome	Duration of Latent Phase	Manifest Illness
>2 gy (200 rad)	Within 2 days	1–3 weeks	Hematopoietic syndrome with pancytopenia, infection, and hemorrhage; survival possible
>6 gy (600 rad)	Within hours	<1 week	GI syndrome with dehydration, electrolyte abnormalities, GI bleeding, and fulminant enterocolitis; uniformly fatal
>30 gy (3000 rad)	Within minutes	None	Cardiovascular/CNS syndrome with refractory hypotension and circulatory collapse; fatal within 24–72 h

consciousness including lethargy, disorientation, ataxia, tremors, and convulsions occur within hours after exposure. Hypotension is persistent and refractory to treatment. The lymphocyte count promptly falls to near-zero levels. This syndrome is universally fatal with death occurring within 24 to 72 h, predominately due to circulatory collapse. In addition to these organ system injuries of the manifest illness syndromes, radiation doses above 8 to 9 Gy (800 to 900 rad) may damage the pulmonary system with resulting pneumonitis, fibrosis, and interstitial edema.⁷

TREATMENT OF WHOLE-BODY IRRADIATION The patient who has been exposed only to an external source of penetrating radiation is not radioactive or contaminated and therefore requires no special precautions for handling or treating. A rare exception is exposure to high-level neutron irradiation, which can induce radioactivity. In the unlikely event of a nuclear plant accident, neutron exposure becomes a concern. Patient specimens of blood and urine should be collected and assayed for induced radioactivity in the body, predominately Na-24. In addition, all metal objects on the patient's body or clothing should be monitored for potential radioactivity, including jewelry, coins, dental fillings, wristwatches, and buttons.

Treatment of the irradiated patient in the emergency department is directed toward alleviating the symptoms of the prodromal phase. Although metoclopramide has been used to prevent nausea and vomiting with some success, studies show that 5-HT₃ receptor antagonists (e.g., ondansetron 10 mg IV q4 to 6 h, or 8 mg PO tid) are a more effective way to control nausea and vomiting.⁸ Anxiolytics or pain management may be required. Medical treatment has been unsuccessful in the few documented cases of high radiation doses that cause major damage to the GI or CV and CNS systems, but comfort care should be provided. Survival is possible for individuals with lower radiation doses resulting in the hematopoietic form of ARS.

The absence or time of onset of nausea and vomiting are useful for assessing the injury severity. Diarrhea is a less useful symptom unless

there is prompt, explosive, bloody diarrhea, which indicates a likely fatal outcome. Individuals who have received doses less than 1 Gy (100 rad) seldom experience nausea or vomiting. Less than 1 Gy is a reliable dose estimate for individuals who remain asymptomatic 24 h postexposure; further hospitalization of these individuals is generally unnecessary.⁹

Serial blood specimens should be obtained for hematologic and cytogenetic dose assessment. The earliest laboratory indicator of biological damage from radiation is a marked decrease in peripheral lymphocytes, often within 8 h postexposure. The more precipitous the decline in lymphocytes, the greater the dose received (Figure 10-2). The lymphocyte count 24 h postexposure is useful in predicting the patient's clinical course. If the lymphocyte count is maintained above 1200/ \times L, no clinical support is required. If the count falls below 500/ \times L, a severe clinical course can be anticipated. If the entire lymphocyte count is depleted within 6 h, a fatal outcome is likely.

Cytogenetic analysis of circulating lymphocytes is another method of dose estimation. Radiation induces some characteristic chromosome aberrations, particularly rings and dicentrics, in a dose-dependent manner. The frequency of these abnormalities can be scored in cytogenetic laboratories to obtain estimates of radiation dose received. This process is technically challenging, time consuming, and expensive, but is the most sensitive biologic measurement for quantifying dose from whole-body irradiation.¹⁰

Obtaining data and specimens for dose estimation is a crucial aspect of planning inpatient therapy and predicting the patient's clinical course. The time of onset of all clinical symptoms should be carefully observed and documented.

The ultimate long-term treatment goal is to provide support during the period of deficient defenses against infection and hemorrhage until marrow recovery occurs. Supportive treatment may include intravenous fluids, blood products, and total parenteral nutrition, as well as reverse isolation, prophylactic antibiotics, and antifungal medications.

Anemia, granulocytopenia and thrombocytopenia can be expected within a month following significant radiation exposure (see Figure

FIG. 10-1. Typical hematologic course and clinical stages after sublethal (~300 rad) exposure to total body irradiation. [Reprinted with permission from *Radiobiological Factors in Manned Space Flight*, © 1965 by the National Academy of Sciences. Washington: National Academy Press, 1965.]

FIG. 10-2. Estimated radiation dose and degree of injury from early changes in lymphocyte counts. Approximate whole-body dose: Curve A-3.1 Gy (310 rad); Curve B-4.4 Gy (440 rad); Curve C-5.6 Gy (560 rad); Curve D-7.1 Gy (710 rad). [Reproduced from *Health Physics* 72:514, 1997 with permission from the Health Physics Society. Figure has been modified from its original version.]

10-1). Therefore the patient, as well as family members who may be potential blood donors, should undergo HLA typing in preparation for white cell and platelet transfusions if marrow suppression becomes severe. The most severe marrow depression occurs at 2 to 3 weeks after exposure. Spontaneous recovery of granulocytes and platelets is quite rapid after the fifth week.

Two approaches have been used to combat bone marrow suppression in victims of radiation injury. Hematopoietic growth factors are cytokines such as erythropoietin, interleukins, and colony-stimulating factors, that have been shown to stimulate the proliferation and differentiation of the surviving stem cells and thus accelerate reconstitution of the bone marrow.¹² Hematopoietic stem cell transplants are also being studied to improve survival.

If significant radiation dose was received, the patient should have long-term periodic follow-up for potential delayed effects of radiation damage such as cataracts, infertility, thyroid dysfunction, leukemia, or other neoplasms.

Internally Contaminated Patients

Radioactive material gains entry into the body by three principal routes: inhalation, ingestion, or absorption from contaminated mucous membranes or abraded skin. Misadministration of a radiopharmaceutical is a potential source of internal contamination that can occur in the hospital setting. Internal contamination becomes a major concern if large amounts of radioactive material are released into the atmosphere as a result of nuclear weapon detonation, large-scale nuclear power plant accident, or even a volcanic eruption. Such events may result in inhalation of airborne radioactive material or ingestion of radioactive material deposited onto agricultural land with subsequent transfer into the food chain.

Internally deposited radioactive material will continue to irradiate tissues until it decays to a stable isotope or is biologically eliminated. The biochemical nature of the radionuclide determines if it is disseminated throughout the body or concentrated in a specific organ. Th

term *critical organ* is used to describe the organ that receives the highest dose of radiation or is the site of the most significant biologic damage.

In contrast to external contamination, identification of the specific radionuclides that become internalized is important for determining the method of treatment. When the substance is not known, laboratory identification is possible. Internally deposited radionuclides are identified by radioanalysis of swabs from the nares, oropharynx, and wounds, as well as sputum, urine, and fecal specimens. All body excreta from internally contaminated patients should be collected for several days because repeated measurements are used to monitor the elimination rates of the radionuclide.

Radioactivity within the body can also be measured *in vivo* by a device called a whole-body counter. These detectors predominately measure gamma-emitting radiation and some high-energy beta radiation. Internalized alpha and lower-energy beta-emitting radiation do not escape from the body and are not detected by these devices. Whole-body counters are very sensitive and give false measurements if external contamination is present on the body. For this reason and because these detectors are not readily accessible, whole-body counters are generally not practical in the acute setting of a radiation event.

TREATMENT OF INTERNAL CONTAMINATION When the contaminating radionuclide is not known, radiochemical laboratory identification of radioisotopes may take several days. Prior to obtaining identification, methods can be initiated for removal of the most commonly encountered radionuclides that are suspected for the particular radiation event. Treatment is aimed at reducing absorption or hastening elimination. After all swabs have been obtained, wounds should be irrigated with physiologic saline.

Pulmonary clearance of inhaled radioactive particles is not effectively enhanced by medications. If large quantities of insoluble radioactive material have been inhaled, bronchopulmonary lavage may be considered. This treatment carries the associated risk of general anesthesia and is performed more commonly in Britain than in this country.

In the emergency department, reduction in gastrointestinal absorption may be accomplished with gastric lavage, emetics, and purgatives. Additionally, antacids containing aluminum cause many metals to precipitate as insoluble hydroxides. Cathartics can then be administered to decrease the transit time of these precipitants.

Decorporation Treatment: Once the radioactive material crosses into the extracellular fluid, incorporation has occurred and elimination is more difficult. Methods of decorporation include blocking agents, isotopic dilution, displacement, mobilizing agents, and chelation.

Frequently treated causes of internal contamination are radioactive forms of iodine, plutonium, cesium, and hydrogen (Table 10-9). Of particular importance and effectiveness are the treatments discussed below for radioiodine and alpha-emitting contamination such as plutonium.

Radioiodine: Inhalation or ingestion of radioiodine is particularly hazardous to the thyroid with a potential risk of causing hypothyroidism or thyroid cancer. ¹³¹I is the predominant internal contaminant resulting from incidents that involve the release of nuclear fission products such as a nuclear reactor accident or nuclear weapons test. Studies on the health effects of the Chernobyl accident have shown that populations in heavily contaminated areas have an increase in thyroid cancer. The number of thyroid cancers reported in these areas continues to increase, with the highest prevalence in individuals who were under the age of 10 years at the time of the accident.¹³

Rapid detection of radioiodine uptake is essential because treatment is most beneficial when administered within 12 h. Radioiodine is a soluble nuclide that is detected in the urine immediately after exposure, allowing early identification of radioiodine uptake. A more rapid, but less sensitive, method is direct measurement with a survey meter held over the thyroid gland.

TABLE 10-9 Commonly Treated Forms of Internal Contamination

Radionuclide	Primary Route of Intake	Principal Hazard	Treatment Mechanism	Agent	Usual Administration*
I-131	Inhalation Ingestion Percutaneous absorption	Thyroid	Block thyroid uptake	KI	130 mg PO for adults ages 18^0 y, and pregnant or lactating women, dosed daily until significant risk of exposure to radioiodine no longer exists 65 mg a day for school-age children 32 mg a day 1 mo to 3 y 16 mg a day for 0 to 1 mo Adults >40 y need KI only when a large internal radiation dose a 5 gy is predicted 1 g/d for 5 d, IV or aerosol IV: 1 g in 250 mL NS or D5W over 30 min Aerosol: 1 g in nebulizer; inhale over 15 to 20 min
Pu-239	Inhalation Ingestion Absorption through wounds	Bone Liver Lung	Chelation Increase excretion	Ca-DTPA or Zn-DTPAt	
H-3	Inhalation Ingestion Percutaneous absorption	Whole-body dose	Isotopic dilution Increase excretion	Water	Oral: 3-4 liters a day for 2 wks
Cs-137	Inhalation Ingestion	Whole-body dose	Mobilization Decrease GI uptake	Ferric Ferrocyanide (Prussian blue)	Oral: 1 g in 100-200 mL water tid for several days

*Duration of therapy is based on dose estimations from radiochemical measurements of urine and fecal samples.

fCalcium and zinc salts of diethylenetriamine pentaacetic acid. *Abbreviation:* KI = potassium iodide.

Early administration of stable potassium iodine (KI) is recommended for high levels of radioiodine exposure. Realizing that it may be difficult to assess the risk or level of radioiodine exposure to the public, the FDA has recommended that the administration of KI should begin before or immediately coincident with the passage of a radioactive cloud. Oral administration of KI (see Table 10-9 for dosing) within 1 h of exposure is approximately 90 percent effective at blocking the thyroid uptake of radioiodine. KI administered 6 h after exposure reduces thyroid uptake by approximately 50 percent. Little protective effect is seen when KI is given after 12 h of exposure.¹⁴ KI should be continued daily until significant risk of exposure to radioiodine no longer exists. Administration of antithyroid medications, such as propylthiouracil or methimazole, may be considered if the time since exposure is more than 12 h.¹⁵ In the event of widespread release of radioiodine, the FDA has approved the use of nonprescription KI. State and local officials are responsible for the procurement and distribution of KI to the general public.

Alpha Contamination: Early treatment is recommended for contamination with alpha-emitting radionuclides such as Pu-239. Alpha radiation has potential for significant damage when internally deposited. This internal contamination hazard is a result of alpha's emission of large amounts of energy for a short range, thus causing intense ionization in a concentrated area. This potential damage is made worse by the fact that many of the radioisotopes that emit alpha radiation have very long half-lives.

Chelating agents such as calcium and zinc salts of diethylenetriamine pentaacetic acid (Ca-DTPA and Zn-DTPA, respectively) are effective treatments for contamination with heavy metals and rare earths that emit alpha radiation. If alpha-emitting contamination is detected in wounds or in the nares or oropharynx, treatment with DTPA should be initiated promptly, ideally within 1 to 2 h after contamination has occurred. Potential contraindications for the use of DTPA are severe renal dysfunction, thrombocytopenia, or leukopenia. DTPA is administered systemically by slow intravenous push or by aerosol administration. Ca-DTPA has been shown to be more effective in animal studies and is the preferred form of drug for the initial 1 to 2 d of treatment. Zn-DTPA is less toxic and recommended for treatments of longer duration and of pregnant females. For aerosol administration, Ca-DTPA is preferred because of the metallic taste associated with Zn-DTPA. Of note, most DTPA solutions in nuclear medicine depart-

ments are too dilute a concentration for effective decorporation. The success of decorporation techniques depends on early administration. The risks associated with therapy must be weighed against the risk of untreated internal radiation exposure. Assistance from expert consultants should be requested prior to beginning decorporation therapy.

Prenatal Exposures

When a pregnant female is exposed to ionizing radiation, special consideration must be given to the radiosensitive unborn child.^{16,17} Fetal cells are largely undifferentiated and highly proliferative and thus have increased radiosensitivity depending on the phase of gestation. At 0 to 2 weeks postconception, there is an all-or-none phenomenon. Irradiation during this time usually results in death with resorption of the conceptus or no observable damage. This phenomenon is a result of the pluripotential of the early blastomeres that allows injured cells to be replaced by remaining cells when the damage is not extensive. After 2 weeks' gestation, organogenesis begins and the embryo is at risk of congenital malformations. The risk of injury is greatest for the particular organ system that is under development at the time of radiation exposure. After 7 weeks, major organogenesis is complete, with the exception of the CNS. The CNS has continued susceptibility to radiation injury during the early fetal period.¹⁷

Data derived from Japanese atomic bomb survivors suggest the most common in utero injuries are related to the CNS, particularly microcephaly and mental retardation. Other malformations, such as growth restriction and ocular defects, have been reported less frequently.¹⁷

If a fetal dose is above 500 millirem (5 mSv), particularly during the vulnerable period of 8 to 15 weeks' gestation, risks such as CNS damage or growth defects must be considered. In such a case, a physician with expertise in radiation injury should be consulted to provide counseling to the expecting parents.

SOURCES OF ASSISTANCE

Emergency department personnel should be familiar with authorities that can provide advice and assistance when radiation accidents occur. Radiation emergency call lists may be prepared in advance and include the following contacts:

1. Local facilities which staff medical and health physics professionals trained in radiation accidents
2. Local civil defense or disaster offices
3. State radiologic health office (title may vary by state)
4. Federal Emergency Management Agency (FEMA)

In addition, there are two organizations that provide current medical advice for the treatment of radiation casualties. The first is the Radiation Emergency Assistance Center/Training Site (REACTS), sponsored by the Department of Energy and managed by the Oak Ridge Institute for Science and Education. REACTS provides training programs, consultation assistance, and treatment capabilities. It has the capability to dispatch an emergency response team of health professionals to assist at an accident site. After initial treatment and decontamination actions are complete, REACTS may also accept severely contaminated or irradiated patients for transfer to its facilities for more definitive care. REACTS contact information is:

Radiation Emergency Assistance Center/Training Site
Oak Ridge Institute for Science and Education P.O.
Box 117, MS 39, Oak Ridge, TN 37831-0117
(865)576-3131 (daytime phone) (865) 576-1005 (24-h
emergency number)

The second organization available for medical consultation is the Medical Radiobiology Advisory Team, sponsored by the Department of Defense and managed by the Armed Forces Radiobiology Research Institute. The contact information is:

Medical Radiobiology Advisory Team (MRAT)
Armed Forces Radiobiology Research Institute
National Naval Medical Center 8901 Wisconsin
Avenue, Building 42 Bethesda, MD 20889-5603
(301)295-0316

RESUSCITATIVE PROBLEMS AND TECHNIQUES

SUDDEN CARDIAC DEATH

Joseph P. Ornato

Sudden cardiac death (SCD) as a consequence of unexpected cardiac arrest claims the lives of more than 460,000 adult Americans each year and accounts for approximately 63 percent of all deaths from cardiovascular causes.¹ Despite advances in resuscitation and emergency medical services (EMS), only approximately 3 to 8 percent of all cardiac arrest victims survive to leave the hospital neurologically intact. However, there is substantial variability in the odds for survival among various geographic locations, with published survival to hospital discharge for patients with all initial rhythms ranging from 1 percent to 25 percent.^{2,*} This chapter reviews the epidemiology and pathophysiology of SCD in adults, and the strategies to prevent and treat the problem. Sudden infant death syndrome and cardiac arrest in children are discussed in Chaps. 13 and 14, respectively.

EPIDEMIOLOGY

Most episodes of unexpected SCD in adults occur in the home.⁵ The most common victim is a male who is 50 to 75 years of age. The majority of SCD victims have underlying structural heart disease, usually in the form of coronary atherosclerosis and/or cardiomegaly.⁶ A recent review surmised that structural coronary artery abnormalities and their consequences (e.g., myocardial ischemia and infarction) are associated with 80 percent of fatal arrhythmias.⁷ Dilated and hypertrophic cardiomyopathies are the next most common cardiac abnormalities causing SCD. Other cardiovascular disorders, including valvular or congenital heart disease, acquired infiltrative disorders, primary electrophysiologic abnormalities (e.g., hereditary prolonged Q-T interval syndromes), genetically determined ion-channel abnormalities (e.g., Brugada syndrome), account for only a small proportion of SCD cases.

Epidemiologic studies have identified both a circadian and a seasonal pattern of SCD and acute myocardial infarction (AMI), suggesting the presence of underlying biologic triggers of the onset of both disease processes.⁸ Both SCD and AMI are most likely to occur within the first few hours after awakening from sleep, at a time when there is increased sympathetic stimulation. (3-blockade appears to protect against SCD, particularly in patients with known coronary artery disease who have had an AMI and have a low ejection fraction. In addition, both SCD and AMI are much more likely to occur during climatic winter rather than summer.^{8,9} These and other epidemiologic and experimental findings suggest that neurophysiologic factors, such as autonomic tone, may alter the heart's propensity to develop and sustain a serious ventricular dysrhythmia. An alternative possibility is that there are factors external to the atherosclerotic plaque, such as triggers of plaque rupture or thrombus formation, which may affect the onset of ischemic cardiac events.

PATHOPHYSIOLOGY

Ventricular Tachyarrhythmias

Sudden cardiac death is usually caused by chance arrhythmic events that are triggered by an interaction between structural heart abnormalities and transient, functional electrophysiologic disturbances. In the majority of cases, the initiating event is a ventricular tachyarrhythmia,

either pulseless ventricular tachycardia (VT) that degenerates rapidly to ventricular fibrillation (VF) or "primary" VF.^{10**} From a public health standpoint, strategies for preventing and treating SCD in the community can be targeted primarily at VT and VF because these rhythms are not only the most frequent, but also the most potentially treatable, currently identified initiating event.

The mechanisms responsible for triggering fatal ventricular dysrhythmias are only partially understood. Frequent ventricular ectopy alone, in the absence of significant underlying structural heart disease, does not generally result in cardiac arrest. However, ventricular extrasystoles in the presence of transient myocardial ischemia, left ventricular dysfunction, and/or cardiomegaly may trigger runs of VT that may degenerate into pulseless VT or VF.

Many types of structural heart disease can predispose to SCD. One common denominator is dispersion of ventricular depolarization and/or repolarization, allowing "islands" of ventricular tissue to depolarize and repolarize at different rates. This lack of homogeneity in electrical activation and recovery fosters the development of circus movement reentry, which can initiate and sustain ventricular tachyarrhythmias. Myocardial ischemia and/or infarction can also diminish transiently the homogeneity of left ventricular depolarization and repolarization.

Left ventricular hypertrophy (often a result of hypertension and/or valvular heart disease) or conduction disturbances (left or right bundle-branch block or a nonspecific intraventricular conduction disturbance) can create similar functional disturbances on a more chronic basis. Preexcitation, such as the Wolf-Parkinson-White (WPW) syndrome, can trigger SCD if atrial fibrillation occurs and is conducted into the ventricles at a rate rapid enough to initiate VF. Other electrophysiologic mechanisms, such as Brugada syndrome [syncope with or without SCD caused by polymorphic ventricular tachycardia and associated with a distinctive electrocardiogram (ECG) pattern], can also cause SCD. Brugada syndrome is caused by an autosomal dominant, genetic defect resulting in total loss of function of the sodium channel or in acceleration of recovery from sodium channel activation.¹² It most commonly affects men and can be recognized by its pathognomonic ECG pattern (downsloping ST-segment elevation in leads V₁-V₃, often associated with a RBBB pattern) (Figure 11-1). It can be distinguished from benign early repolarization because Brugada syndrome causes right precordial ST-segment elevation that is downsloping and followed by a negative T wave, whereas early repolarization usually has ST elevation in V₂-V₆ with an upward concavity, a notched J point, and a positive T wave. Although its prevalence in the United States is unknown, Brugada syndrome accounts for 40 to 50 percent of idiopathic ventricular fibrillation cases in some countries in Southeast Asia. Current treatment includes implantation of a cardioverter-defibrillator.

The long QT syndrome, in which the corrected QT interval (QT_C) is prolonged pathologically, is also associated with SCD.¹² Prolongation of the QT_C probably represents dispersion in ventricular repolarization and can be congenital (with or without nerve deafness) or acquired (caused by hypokalemia, hypomagnesemia, hypocalcemia, anorexia, ischemia, central nervous system pathology, terfenadine-ketoconazole combinations, or certain antipsychotic or antiarrhythmic drugs). The "QT_C" can be calculated by Bazett's equation:

$$QT_C = \frac{QT_m}{\sqrt{R-R}}$$

where QT_C is the corrected QT interval in seconds, QT_m is the measured QT interval in seconds, and R-R is the interval between any two consecutive R waves on the ECG in seconds. Because the QT interval

FIG. 11-1. Twelve-lead ECG typical of Brugada syndrome shows characteristic downsloping ST-segment elevation in leads V₁ and V₂ and QRS morphology resembling a right bundle-branch block. (Reproduced with permission from *Ann Emerg Med* 36:157, 2000.)

is heart-rate dependent, the formula "corrects" the measured QT interval to a heart rate of 60 beats/min (at which the R—R interval is 1.0 s). Because the square root of 1 = 1, the QT_C equals the QT_m at a heart rate of 60 beats/min (at which the normal QT interval limits are 0.35 to 0.44 s).

Most SCD victims have cardiac abnormalities on postmortem examination. The most common autopsy findings in SCD victims are evidence of coronary atherosclerosis and its complications, cardiomegaly with left ventricular hypertrophy and contraction band necrosis. The latter appears to be a marker for catecholamine stimulation and occurs with high frequency regardless of whether CPR was performed.¹³

Factors affecting survival from out-of-hospital VF include witnessed collapse, prompt initiation of CPR, early defibrillation, younger age, and arrest occurring away from home.¹⁴ Comorbid illnesses, such as a history of congestive heart failure, contribute to hospital mortality following successful resuscitation but only account for one-fourth of the variation in survival from SCD. Cardiac arrest during AMI is associated with a significantly improved outcome compared to cases not occurring in the setting of AMI.¹⁵ Although the reason for improved long-term survival of AMI patients is not fully known, it probably occurs because such patients have *transient* electrical instability, unlike patients with chronic cardiomyopathy in whom there is a persistent vulnerability to VT or VF.

The outcome of resuscitation is influenced strongly by the patient's initial cardiac rhythm. The likelihood of survival is relatively high (up to 60 percent) if the initial rhythm is VT or VF (particularly if the VF is "coarse," the arrest is witnessed, and prompt CPR and defibrillation are provided). If the initial rhythm is not VT or VF, survival is typically less than 5 percent in most reported series. Asystolic patients whose cardiac arrest is unwitnessed rarely survive neurologically intact to hospital discharge. The only common exceptions are witnessed cardiac arrest patients whose initial asystole is a result of increased vagal tone or other relatively easily correctable factors, such as hypoxia of brief duration.

Bradyasystole

Although this chapter emphasizes VT and VF, an important minority of SCD events begin with a bradyarrhythmia¹⁶ or an organized rhythm without a pulse [e.g., pulseless electrical activity (PEA)]. Bradyasystole refers to a cardiac rhythm that has a ventricular rate below 60 beats/min in adults and/or periods of absent heart rhythm (asystole). Bradyasystolic states are clinical situations during which bradyasystole is the dominant heart rhythm.

Bradyasystolic rhythms other than asystole can either be accompanied by a pulse or there can be no discernible pulse with each QRS (PEA). Bradyasystole with a pulse is often accompanied by a significant decrease in cardiac output, leading to hypotension and/or syncope. Bradycardia with or without a pulse occurs frequently during cardiac arrest, either as the initial rhythm, during the course of resuscitation, or following electrical defibrillation. Obviously, asystole occurs eventually in all dying patients.

To ensure that VF is not masquerading as asystole, the American Heart Association recommends confirmation of asystole by switching to another lead whenever a "flat line" is recorded on the ECG during resuscitation. Although there are anecdotal case reports in the literature suggesting that this phenomenon can occur in humans, "masquerading" VF probably occurs rarely during clinical resuscitation and is not responsible for the misdiagnosis of large numbers of cases of asystole.¹⁷

Primary bradyasystole occurs when the heart's electrical system intrinsically fails to generate and/or propagate an adequate number of ventricular depolarizations per minute to sustain consciousness and other vital functions. Secondary bradyasystole is present when factors external to the heart's electrical system cause it to fail (e.g., hypoxia). It is unclear why conventional treatment of bradyasystolic cardiac arrest with atropine, epinephrine, or electrical pacemakers rarely results in survival to hospital discharge.

Cellular metabolic functions must be intact for normal electrical impulse generation and propagation to occur. Severe ischemia of the sinoatrial (SA) node can disable cellular metabolism, preventing pacemaker cells from actively transporting the ions necessary to control the transmembrane action potential. Proximal occlusion of the right coronary artery (RCA) can cause ischemia and/or infarction of both the SA and atrioventricular (AV) nodes, because in humans, the SA node is supplied by a branch from the proximal RCA in 55 percent, and the AV node receives its nourishment from a branch of the distal RCA 90 percent of the time. Ischemia or infarction of the AV node can disrupt normal conduction, causing bradycardia as a consequence of AV block. Because the bundle branches receive their blood supply from multiple coronary arteries, bradyasystole caused by ischemic bilateral bundle-branch block is rare and generally only occurs when there is extensive myocardial infarction caused by severe, multivessel coronary artery disease.

The spectrum of disorders affecting the heart's primary pacemaker, known as the *sick sinus syndrome*, can cause intermittent lightheadedness, syncope, or SCD. The disorder affects both men and women. Although it is more common with advancing age, primary electrical failure of the heart can occur in infants and children. The precise cause of

sick sinus syndrome is unknown. Pathologic studies usually reveal histologic degeneration of the SA node. In addition, the disorder often involves the AV node and the conduction tissue between the SA and AV nodes. Thus, sick sinus syndrome should be thought of as a diffuse degenerative disease of the heart's electrical generation and conduction system. Idiopathic sclerodegeneration of the AV node and the bundle branches (Lenegre disease) or invasion of the conduction system by fibrosis or calcification spreading from adjacent cardiac structures (Lev disease) can lead to bradysystolic heart block with or without cardiac arrest. In rare cases, a clinical presentation resembling the sick sinus syndrome can occur when the heart's electrical system is affected by systemic disease, vascular compromise, or tumor (e.g., melanoma metastatic to the AV node).

Atropine, transcutaneous pacing, dopamine, or epinephrine can be used to treat acute, symptomatic bradysystole (including cardiac arrest) that is caused by the sick sinus syndrome. Permanent ventricular or AV sequential pacing is usually necessary for patients with persistent symptomatic bradycardia. Patients who manifest the tachycardia-bradycardia variant (periods of supraventricular tachycardia followed by prolonged sinus arrest or bradycardia) may also require antiarrhythmic therapy or radiofrequency ablation.

Pacemaker cells and conducting tissue can be affected by a variety of endogenous chemical, hormonal, pharmacologic, toxicologic, and neurogenic influences. Hypoxia and hypercarbia, because of respiratory arrest, frequently cause bradysystole as a consequence of both a direct depressant effect on cardiac pacemaker cells and increased parasympathetic discharge. Common clinical conditions that often cause bradysystole include suffocation, near drowning, stroke, and opiate overdose. @-Adrenergic blocking agents, calcium channel blockers, digitalis glycosides, parasympathomimetic agents (e.g., edrophonium), hypoxia, hypercarbia, adenosine, and adenosine triphosphate can also cause bradysystole.

Endogenous adenosine that is released when there is myocardial hypoxia and ischemia relaxes vascular smooth muscle, decreases atrial and ventricular contractility, depresses pacemaker automaticity, and impairs AV conduction. During normal aerobic metabolism, adenosine is formed primarily by intracellular degradation of S-adenosyl-L-homocysteine (SAH), catalyzed by the enzyme SAH hydrolase (SAH pathway). During myocardial ischemia, adenosine is formed primarily by dephosphorylation of adenosine monophosphate (AMP), catalyzed by the enzyme 5' nucleotidase [adenosine triphosphate (ATP) pathway].

The cellular electrophysiologic effects of adenosine can be antagonized competitively by methylxanthines but not by atropine. A specific adenosine antagonist (BW-A1433U) reverses and prevents postdefibrillation bradysystole and hemodynamic depression in a domestic pig model. In small pilot studies, aminophylline, a competitive nonspecific adenosine antagonist, restored cardiac electrical activity within 30 s in more than half of the bradysystolic cardiac arrest patients who were refractory to atropine and epinephrine.^{18,19}

Myocardial ischemia excites cardiac vagal and sympathetic afferents, leading to vagally mediated depressor reflexes and/or sympathetic reflex cardioexcitation. In addition, myocardial infarction can interrupt afferent and efferent neural transmission, potentially triggering dysrhythmias. Autonomic disturbances have been documented in the majority of AMI patients, especially during the first 30 to 60 min after coronary artery occlusion. Stimulation of afferent vagal cardiac receptors, particularly those located in the posterior left ventricle, during ischemia or infarction can trigger sympathetic inhibition producing vasodilation, bradycardia, and hypotension (the Bezold-Jarisch reflex). Activation of this reflex may explain the higher incidence of nausea and vomiting in patients with inferior (69 percent) compared to anterior (29 percent) infarction. Bradysystole triggered by the Bezold-Jarisch reflex is usually short-lived and often responds to atropine.

One of the most baffling mysteries of bradysystolic cardiac arrest relates to myocardial mechanics. Bradysystole, unlike ventricular fibrillation, is accompanied by very little myocardial oxygen con-

sumption in animal models. Because of this, myocardial high-energy phosphate stores should decay relatively slowly during bradysystole. This should theoretically result in a high incidence of return of spontaneous circulation following restoration of a more normal rhythm (e.g., with the early use of electrical pacing). However, return of spontaneous circulation is infrequent, and long-term neurologically intact survival is rare in bradysystolic cardiac arrest.

These findings strongly suggest that other factors must play a determining role in the pathophysiology and subsequent outcome of bradysystolic cardiac arrest. Bradysystolic arrest is not just a disorder of rhythm generation or propagation; it is a perplexing syndrome characterized by such rhythm disturbances accompanied, in many cases, by profound depression of myocardial and vascular function. The causes of the latter derangements have yet to be elucidated. Suspected causes include endogenous myocardial depressants (including downregulation of catecholamine receptors and/or toxic influences of intense sympathetic stimulation), neurogenic influences, postischemic myocardial stunning, and/or free radical injury.

Pulseless Electrical Activity

Pulseless electrical activity can be caused by a variety of pathophysiologic conditions. The sine qua non of this syndrome is the presence of an organized rhythm without the presence of a detectable pulse in an individual who is clinically in cardiac arrest. The latter is important to differentiate conditions in which the rescuer is unable to detect a pulse, but there is unmistakable evidence that there is adequate blood pressure and cardiac output to maintain vital organ perfusion (e.g., a conscious patient with profound vasoconstriction caused by hypothermia, or "pseudo-PEA"). There is evidence that PEA encompasses a spectrum of pathophysiologic effects ranging from good left ventricular (LV) function with an empty ventricle or widely dilated arterial bed, to a stiff ventricle.

The underlying physiologic cause of PEA is a marked reduction in cardiac output that is a result of either profound myocardial depression or mechanical factors that reduce venous return or impede the flow of blood through the cardiovascular system. Common conditions that can cause PEA are shown in Table 11-1. In one recent analysis, PEA was present initially during resuscitation in 22 percent of cardiac arrest cases.²⁰ Compared to other patients, individuals with PEA were more likely to be women whose cardiac arrest was unwitnessed, at night, and without bystander-initiated CPR. Only 2 percent of these patients

survived to hospital discharge. The management of patients with PEA is directed at identifying and treating the underlying cause or causes.

SCD PREVENTION

Prediction of SCD

It is necessary to accurately predict who is at risk for SCD for any prevention strategy to be of value. Unfortunately, the majority of future SCD victims cannot be identified in advance. Prodromal symptoms in the days to weeks preceding cardiac arrest are common but usually too nonspecific to be of important predictive value. In one of the largest series in which survivors of SCD were questioned about events preceding their collapse, Goldstein et al²¹ found that 71 percent of SCD survivors reported no prodromal symptoms or symptoms of 1 h or less in duration. Prodromal symptoms were present for more than 1 h in only 29 percent of patients. The most common symptoms reported by SCD survivors or family members of SCD victims are chest pain, dyspnea, and palpitations.

Even aggressive attempts to predict SCD in high-risk patients, such as those who have suffered a prior AMI or those with a chronic cardiomyopathy, have been of limited value (Table 11-2). Various diagnostic techniques have been used to try to "risk stratify" these patients, including invasive and noninvasive assessment of left ventricular ejection fraction; coronary angiography; ambulatory ECG (Holter) monitoring; exercise testing; detection of ventricular late potentials by using signal averaging; programmed ventricular stimulation of the heart to test the inducibility of ventricular tachydysrhythmias; assessment of heart rate variability; and T-wave alternans (alternating T-wave amplitude from beat to beat on the ECG, which is only visible with special recording equipment).^{6,22} None of these tests, alone or in combination, has sufficient sensitivity and specificity to identify more than a small fraction of those who will develop SCD. For example, only 15 to 30 percent of even "high-risk" post-AMI patients identified by a variety of these screening tests will experience a sustained ventricular tachydysrhythmia over the next several years of follow-up.²³ Despite this reality, it is critically important for emergency physicians to recognize signs and symptoms of the syndromes that place a patient at higher SCD risk and to admit or refer such patients for proper evaluation and preventive intervention promptly.

Antidysrhythmic Drug Therapy

Results of large randomized, controlled, clinical trials of antidysrhythmic agents for primary and secondary prevention of VT and VF are changing traditional beliefs regarding the actions, efficacy, and risk of these agents. The Cardiac Arrhythmia Suppression Trial (CAST) showed that potent class I sodium channel-blocking antidysrhythmic drugs (encainide, flecainide, and moricizine) are proarrhythmic and paradoxically increase the odds of developing SCD, as compared to placebo, in patients at relatively low risk for death.²⁴ Conversely, Class III agents (amiodarone, sotalol) and/or (3-blockers may be of some protective value in patients at high SCD risk.

TABLE 11-2 Common Risk Factors for SCD in Adults Older than 35 Years of Age

Age
Male gender
Coronary artery disease (i.e., prior or acute myocardial infarction or unstable angina)
Cardiomegaly with left ventricular hypertrophy Impaired left ventricular function (i.e., ejection fraction <30% and/or congestive heart failure) Prolonged QT _C interval Ventricular arrhythmias, particularly sustained, inducible ventricular tachycardia

Implantable Cardioverter-Defibrillator Therapy

The benefits of [3-blockade, sotalol, and amiodarone in decreasing mortality from SCD pale in comparison to the protective effects of the implantable cardioverter-defibrillator (ICD) on high-risk patients.²⁵ Treatment with an ICD is more effective than antidysrhythmic agents at reducing mortality in patients at high risk for SCD, as defined by a reduced left ventricular ejection fraction, documented nonsustained VT, and/or inducibility of sustained VT during programmed electrical stimulation.^{26,27} Although these devices are expensive to insert, their effectiveness over conventional therapy results in a cost of less than \$30,000 per year of life saved, which is highly cost-effective.²⁸ At present, these devices are indicated for preventing SCD in high-risk patients, particularly those with clinically significant coronary artery disease, depressed left ventricular function, and spontaneous life-threatening and/or inducible ventricular dysrhythmias. However, in some patients with advanced coronary atherosclerosis and a low ejection fraction who are candidates for mechanical revascularization, effective revascularization may obviate the need for ICD therapy. Prophylactic ICD insertion does not appear to provide additional survival benefit beyond that achieved with effective coronary revascularization. Further research is ongoing to determine the value of ICD therapy in patients with nonischemic cardiomyopathy accompanied by reduced left ventricular function.

RESCUE FROM SCD

Emergency medical services and in-hospital resuscitation (also known as code blue or code 99) systems are the most effective means currently known to rescue patients from SCD. Survival from pulseless VT or VF is inversely related to the time interval between its onset and its termination. Each minute that a patient remains in VF, the odds of survival decrease by 7 to 10 percent. Survival is optimal when both CPR and advanced cardiac life support (ACLS), including defibrillation and drug therapy, are provided early.

The American Heart Association has introduced the "chain-of-survival" concept to represent a sequence of events that ideally should occur to maximize the odds of successful resuscitation from cardiac arrest." The links in the chain include early access (recognition of the problem and activation of the EMS system by a bystander), early CPR, early defibrillation for patients who need it, and early advanced cardiac life support.

Early Access and Early CPR

Bystanders who witness the event can improve a victim's chances for survival significantly by alerting the emergency response system promptly. Although the value of bystander CPR was once debatable, virtually all recent studies show that early initiation of CPR by a bystander improves survival from cardiac arrest significantly, and it also results in improved neurologic outcome of survivors." The presumed mechanism by which CPR by a bystander improves outcome is the preservation of flow to the heart, brain, and other vital organs, providing a "holding action" until other therapies (e.g., defibrillation) can result in restoration of spontaneous circulation.

Public CPR education can improve the behavior of bystanders significantly when a cardiac emergency occurs in the community. However, there are a number of problems associated with training the public to perform CPR. The typical cardiac arrest victim is male, age 50 to 75 years, and usually arrests at home, often in the presence of a spouse of similar age. Most citizens who have taken CPR training are younger than 30 years of age; typically, fewer than 10 percent live with family members known to have heart disease. Most citizens who have received CPR training never actually witness or participate in managing a cardiac arrest; conversely, bystanders who witness a cardiac arrest usually do not know how to perform CPR. Many laypersons who

attempt to perform CPR out of hospital are actually employed or volunteer their services as health professionals. The best solution to the problem is to target CPR training to "high-risk" individuals, such as middle-aged persons, senior center residents and staff, and family members (particularly the spouse) of patients who are survivors of AMI or cardiac arrest or who have other risk factors for SCD.

Skill retention is also a problem because CPR is a psychomotor technique that deteriorates rapidly over time unless practiced or used. In Belgium, 46 percent of bystanders who performed CPR forgot to perform mouth-to-mouth breathing; chest compressions were not done 17 percent of the time.²⁹ As important as it is to receive at least annual reinforcement, only about 20 percent of trainees return for annual training in the United States. Fear of communicable disease, particularly infection with the human immunodeficiency virus (HIV), that is disproportionate to the known minimal risk of disease transmission may decrease the likelihood that trained rescuers will actually perform mouth-to-mouth ventilation on strangers.³⁰

Early 1) i-fibrillation

The rationale for the use of early defibrillation stems from four observations: (1) ventricular tachyarrhythmias are the most common cause of SCD in adults; (2) defibrillation is the most effective treatment for VT and VF; (3) the effectiveness of defibrillation diminishes rapidly over time; and (4) unless treated promptly, VF becomes less coarse and eventually converts to the less treatable rhythm of fine VF or asystole.

Pulseless VT and VF in adults occur regularly in the electrophysiology laboratories. Prompt defibrillation (typically within 20 to 30 s of dysrhythmia onset) results in virtually 100 percent survival. Defibrillation, which can be performed within the first minute or two in cardiac rehabilitation programs, results in as many as 90 percent of patients resuscitated, with return to their prearrest neurologic status. Survival from out-of-hospital VT and VF treated by police officers equipped with automatic external defibrillators (AEDs) in Rochester, Minnesota, has averaged 50 percent resuscitation, with a median time from collapse to defibrillation of about 5 min. Outcomes in many locations with EMS systems that cannot provide defibrillation until 10 min or more after a patient's collapse typically yield survival rates of less than 10 percent."

The best survival is attained in EMS systems that can provide early defibrillation to a large percentage of patients. In most cases, this is most cost-effectively accomplished by a tiered response system, in which large numbers of rapid first-response firefighters or emergency medical technicians (EMTs) are trained and equipped to provide first aid, CPR, and early defibrillation using an AED. Unfortunately, not all communities in the United States have yet implemented a comprehensive, tiered EMS system. Many systems, particularly in suburban or rural areas, have EMTs who are neither trained nor equipped to defibrillate. For such areas, adding rapid defibrillation capability offers a cost-effective alternative that can significantly improve survival from out-of-hospital VF or pulseless VT.

The American Heart Association advocates the widespread implementation of rapid defibrillation programs throughout the nation, including the training of all emergency personnel (volunteer or professional) whose activities require response or competence in managing cardiac arrest. All emergency ambulances and other emergency vehicles that respond to or transport cardiac patients should be equipped with a defibrillator.³¹

More novel strategies have also been tried to increase the availability of rapid defibrillation in the community. There are many densely populated public areas in which conventional EMS systems *cannot* respond within an acceptable response time interval. The most innovative idea is termed *public access defibrillation* (PAD), so named because the intent is to have citizens from outside the health care fields perform early defibrillation using AEDs.

There are three "levels" of PAD based on the type of potential first responder expected to use the AED. There has been considerable ex-

perience demonstrating benefit with minimal risk for level 1 nontraditional responders (e.g., police, firefighters, security personnel, sports marshals, ski patrol members, ferryboat crews, flight attendants, airport personnel) who have a duty to respond as part of their everyday responsibilities.

Level 2 refers to targeted, trained "citizen responders" who may be employed by a worksite with a PAD program but who do not have an explicit duty to respond. There has been good experience with level 2 AED workplace use in British rail stations, oil platforms in the North Sea, electricity plants, passenger cruise ships, gambling casinos, and merchant marine vessels." Level 3 responders are trained family members and/or friends living with or visiting a person at high risk for SCD. There has been little experience thus far with level 3 AED use, and the few studies that have been reported have been somewhat disappointing. For example, Eisenberg et al. trained family members of 59 patients who had survived out-of-hospital cardiac arrest in King County, Washington.³² Only 6 of 10 cardiac arrests that occurred in these patients were defibrillated successfully, and only 1 patient survived for a few months with sustained new neurologic impairment. Further study is needed to determine the risks and benefits of AED use by the general public, and also to identify optimal locations for AED placement.

Early ACLS

Physicians provide prehospital ACLS by staffing specially equipped ambulances in many countries (e.g., Western Europe, Scandinavia, Czech Republic, and Canada). In the United States, "intermediate"-level EMTs or paramedics provide most prehospital ACLS intervention (e.g., defibrillation or synchronized cardioversion, endotracheal intubation, intravenous fluid therapy, or drug administration). Intermediate EMTs (often called cardiac technicians) typically receive several hundred hours of training; paramedics usually receive 1000 or more hours. Adding field ACLS capability appears to affect survival from out-of-hospital cardiac arrest favorably, although the degree of benefit is relatively minimal compared to the powerful effect of early defibrillation.¹¹

port should be initiated within 8 min of arrest. While basic life support alone may be lifesaving in some instances, in most cases advanced interventions such as the delivery of electric current for defibrillation and the addition of various pharmacologic therapies are required to maximize the likelihood of patient recovery. Without rhythm-specific interventions, recovery from cardiac arrest is highly unlikely.'

This chapter reviews basic CPR for adults (S8 years), including approach to an unresponsive patient, basic airway opening procedures including initial management of an obstructed airway, and the physiology and mechanics of closed-chest compression techniques.

Overview

As with all aspects of emergency medicine, it is important to approach basic CPR systematically. When someone is found unresponsive, the following should be performed rapidly and in sequence:

1. Assess responsiveness. If unresponsive, then
2. Obtain assistance and activate the local emergency medical service system, called "phone first" in American Heart Association Guidelines.'
3. Call for a defibrillator (if available).
4. Position the patient and open the airway (maintain cervical spine immobilization if trauma is potentially involved).
5. Assess breathing. If no breathing is noted, then
6. Give two slow breaths.
7. Assess circulation. If no pulse noted, then
8. Begin closed-chest compressions and continue ventilations. Use the defibrillator if available and indicated.

Initial Actions

Upon discovery of a collapsed individual, the first medical action should be to assess the victim and determine whether the person is unresponsive. However, prior to approaching a collapsed individual, the scene needs to be fully assessed for dangers to health care providers. Potential risks, whether from hazardous materials, an unstable physical environment, or personal violence should be considered. Once the patient is reached, the level of responsiveness to noxious stimuli can be determined quickly. If the individual is not responding, obtain help prior to starting ventilations and chest compressions. In a hospital, this may mean calling for the arrest team and requesting the arrest cart; outside the hospital, this is likely to involve activation of the local emergency medical services system or asking a bystander to do so. Additionally, efforts should be made to obtain a defibrillator. Rapid administration of rhythm-specific therapy, especially defibrillation for unstable ventricular tachycardia or ventricular fibrillation, is critical for the recovery of patients.

Open the Airway

The next step is to assess the upper airway of the victim. This usually requires positioning the individual supine on a flat, firm surface with arms along the sides of the body, followed by opening the person's airway. Unless trauma can be definitely excluded, any movement of the victim should take into account the potential of a spine injury; as the patient is placed supine, stabilize the cervical spine by maintaining the head, neck, and trunk in a straight line. If the neck is not already straight, then it should be moved the least possible that allows the establishment of an airway. If for some reason the patient cannot be placed supine, consider using the jaw-thrust maneuver (see below) from a lateral position to open the airway. Properly opening the airway is a critical and potentially lifesaving step. Common causes for airway obstruction in an unconscious patient are occlusion of the oropharynx by the tongue and laxity of the epiglottis. With loss of muscle tone, the tongue or the epiglottis can be forced back into the oropharynx upon inspiration. This can create the effect of a one-way valve at the entrance to

BASIC CARDIOPULMONARY RESUSCITATION IN ADULTS

Jon Mark Hirshon

CPR is a key part of emergency medical care designed to resuscitate individuals in cardiac arrest. The purpose of cardiopulmonary resuscitation is to temporarily provide effective oxygenation of vital organs, especially the brain and heart, through artificial circulation of oxygenated blood until the restoration of normal cardiac and respiratory activity occurs. The intended effect is to stop the degenerative processes of ischemia and anoxia caused by inadequate circulation and inadequate oxygenation. Quick initiation of cardiopulmonary resuscitation is critical to improve the likelihood of recovery; ideally, it should be started within 4 min of arrest, and advanced cardiac life sup-

the trachea, leading to airway obstruction manifesting as inspiratory stridor. After positioning the patient, the mouth and oropharynx should be inspected for secretions or foreign objects, including loose dentures. If secretions are present, they can be removed with the use of oropharyngeal suction if available; a foreign body may be dislodged by use of a finger sweep and then manually removed (see below).

Once the oropharynx has been cleared, two basic maneuvers for opening the airway may be tried to relieve upper airway obstruction. These are the head tilt-chin lift and the jaw thrust. These maneuvers help to open the airway by mechanically displacing the mandible and the attached tongue out of the oropharynx.

HEAD TILT-CHIN LIFT MANEUVER The head tilt-chin lift is usually the first maneuver attempted if there is no concern for cervical spine injury. The head tilt is performed by gently extending the neck. This is done by placing one hand under the patient's neck and the other on the forehead and extending the head in relation to the neck. This should place the patient's head in the sniffing position with the nose pointing up. In conjunction with the head tilt, the chin lift is performed. This is done by carefully placing the hand which had been supporting the neck for the head tilt under the symphysis of the mandible, taking care not to compress the soft tissues of the submental triangle and the base of the tongue. The mandible is then lifted forward and up until the teeth barely touch. This supports the jaw and helps tilt the head back.

JAW-THRUST MANEUVER The jaw thrust is the safest method for opening the airway if there is the possibility of cervical spine injury. It helps to maintain the cervical spine in a neutral position during resuscitation. The rescuer, who is positioned at the head of the patient, places the hands at the sides of the victim's face, grasps the mandible at its angle, and lifts the mandible forward (Figure 12-1). This lifts the jaw and opens the airway with minimal head movement.

Assess Breathing and Initiate Ventilation

Once the airway has been opened, assessment of respiratory effort and air movement should occur. The care provider should look for chest expansions and listen and feel for airflow. The simple act of opening the airway may be adequate for the return of spontaneous respirations. However, if the victim remains without adequate respiratory effort, then further intervention is required. If rescuers are reluctant to perform mouth-to-mouth ventilation, and the patient is in cardiac arrest, chest compressions alone can be effective (see Techniques of Closed-Chest Compressions below).

Two slow breaths over 2 s each should be given. At this point, if a foreign body obstruction is noted, as indicated by a lack of chest rise or airflow on ventilation, the obstruction requires removal (Figure 12-2). Agonal respirations in an individual who has just suffered a cardiac arrest are not considered adequate. Intermittent positive-pressure ventilation, if possible with oxygen-enriched air, should be initiated.

FIG. 12-1. Jaw-thrust maneuver.

FIG. 12-2. Determine breathlessness.

VENTILATION TECHNIQUES

Ventilation

Without Supplemental Oxygen

Rate: 10 to 12 per min

Amount: 10 mL/kg (700 to 1000 mL)

With Supplemental Oxygen (>40 percent)

Rate: 10 to 12 per min Amount: 6 to 7

mL/kg (400 to 600 mL)

There are a number of techniques for ventilating an individual, including mouth to mouth, mouth to nose, mouth to stoma, and mouth to mask. Rescue breaths with an inspiratory time of over 2 s each should be given at a rate of 10 to 12 per min, with a volume adequate to make the chest rise visibly (10 mL/kg; 700 to 1000 mL in adults). Expired air has a F_{iO_2} of 16 to 17 percent. Supplemental oxygen should be delivered as soon as possible. If supplemental oxygen (>40 percent) is available, a smaller tidal volume of 6 to 7 mL/kg (400 to 600 mL for adults) may be used.¹

Too large a volume or too rapid an inspiratory flow rate will likely cause gastric distention, which can lead to regurgitation and aspiration. If an additional trained rescuer is available, cricoid pressure may be applied in an attempt to limit gastric inflation and distention. This is done by applying a moderate amount of firm pressure on the cricoid cartilage, located directly below the thyroid cartilage.

Mouth to Mouth With the airway open, the patient's nose should be gently pinched shut with the rescuer's thumb and index finger (Figure 12-3). This prevents air escape. After taking a deep breath, the rescuer places his or her lips around the patient's mouth, forming an airtight seal. The rescuer slowly exhales. Release the seal and allow adequate time for passive exhalation by the victim, and then repeat the procedure. Protective devices such as face shields are commonly available to decrease the risks to the provider of contracting an infectious disease, and can be purchased from most medical equipment stores.

Mouth to Nose In some cases, as with severe maxillofacial trauma, mouth-to-nose ventilation may be more effective. With the airway open, the rescuer lifts the patient's jaw, closing the mouth. After a deep breath, the rescuer places his or her lips around the patient's nose, forming an airtight seal. The rescuer slowly exhales.

Mouth to Stoma or Tracheostomy After laryngectomy or tracheotomy, the stoma or tracheostomy becomes the patient's airway. As with the other techniques, a seal is made around the stoma or tracheostomy tube, and the rescuer slowly exhales.

FIG. 12-3. Mouth-to-mouth rescue breathing.

Mouth to Mask Placement of the mask properly and securely on a victim's face is important when using a mask for ventilation, either with a bag or via mouth to mask. The mask should be placed over the bridge of the patient's nose and around the mouth. The rescuer places the thumb on the part of the mask that is sitting on the patient's nose and places the index finger of the same hand on the part of the mask sitting on the patient's chin (Figure 12-4). The three other fingers of the same hand are then placed along the bony margin of the jaw. The mask can then be firmly sealed to the patient's face. Two hands may be used for this technique if a second rescuer is available. Ventilations are then performed through the mask; some masks also allow for supplemental oxygenation.

FIG. 12-4. Mouth-to-mask rescue breathing with proper mask placement.

Foreign Body Obstruction

It is important to recognize and be able to assist someone with an airway obstruction due to a foreign body. The National Safety Council reported that approximately 3200 deaths (1.2 per 100,000) were caused by foreign body airway obstruction in 1998.² An individual in distress from a compromised airway is likely to use the universal sign for an airway obstruction, which is for the individual to grab his or her neck with both hands. Foreign bodies can cause partial or complete obstruction. With a partial airway obstruction, air exchange may be adequate or inadequate. If the victim is able to speak, cough, and exchange air, then he or she should be encouraged to continue spontaneous efforts. Assistance, such as activation of the local emergency medical services system, should be obtained. No interference should be made with the patient's attempts to cough or expel the foreign body. If air exchange becomes inadequate, as indicated by an inability to speak, increased difficulty breathing, weak and ineffective cough, worsening inspiratory stridor, or cyanosis, immediate medical intervention should be performed. Inadequate air exchange from a severe partial or a complete airway obstruction should be managed the same way. In an unconscious person, the presence of airway obstruction may be ascertained by noting inadequate airflow and poor chest rise with efforts to ventilate.

OBSTRUCTION-RELIEVING MANEUVERS Maneuvers used to relieve foreign body obstructions include the Heimlich maneuver (subdiaphragmatic abdominal thrusts), chest thrusts, and the finger sweep. In a conscious individual, the Heimlich maneuver is the recommended maneuver in most adults for relieving airway obstruction due to a solid object. It is not useful for liquids. In an unconscious individual suspected of having an aspirated foreign body, the recommended first step is the finger sweep. Otherwise, in an unconscious patient the recommended sequence is to perform the Heimlich maneuver up to five times, open the mouth and perform a finger sweep, and then attempt to ventilate. This sequence may be repeated as often as needed until the patient recovers or additional assistance arrives.

HEIMLICH MANEUVERS Described by Dr. Heimlich in 1975, this maneuver creates an artificial cough by forcefully elevating the diaphragm and forcing air from the lungs.³ It may be repeated multiple times; each individual thrust should be performed with the intention of removing the obstruction. It can be performed with the victim standing, sitting, or lying down, or it can be self-administered (Figure 12-5). To perform the maneuver with the patient standing or sitting, the rescuer stands behind the patient and places the thumb side of a fist against the victim's abdomen midline just above the navel and well below the xiphoid process (Figure 12-5). Grasping the fist with the other hand, the rescuer presses the fist into the victim's abdomen with a quick upward thrust. This is repeated until the item is dislodged or the patient becomes unconscious. For an unconscious patient, the individual is placed supine on a firm surface with the rescuer sitting astride the victim's thighs (Figure 12-6). The heel of a hand is positioned midline just above the patient's umbilicus, and the second hand is placed directly on top of the first. The rescuer then delivers quick upward thrusts. To self-administer thrusts, the individual can either use his or her own fist to deliver the thrusts or lean forcibly against a firm object, such as a porch rail or the back of a chair. Potential complications of the Heimlich maneuver include injury or rupture of abdominal or thoracic viscera and regurgitation of stomach contents.

CHEST THRUSTS This maneuver is used primarily if someone is morbidly obese or in the late stages of pregnancy and the rescuer cannot reach around the patient's abdomen to perform abdominal thrusts (Figure 12-7). To perform chest thrusts with the patient standing or sitting, the rescuer stands behind the patient and places the thumb side of

FIG. 12-5. Standing Heimlich maneuver administered to conscious victim of foreign body airway obstruction.

a fist against the victim's sternum, avoiding the costal margins and the xiphoid process. Grasping the fist with the other hand, the rescuer presses the fist into the victim's chest with a quick backward thrust. This is repeated until the item is dislodged or the patient becomes unconscious. For an unconscious patient, the individual is placed supine on a firm surface with the rescuer kneeling close to the victim's side. The hands are placed in the same position as for chest compression (i.e., the lower sternum), and quick thrusts are delivered.

FINGER SWEEP This maneuver is used only in unconscious patients (Figure 12-8). Using the thumb and fingers of one hand, the rescuer grasps both the tongue and the mandible and lifts. This may partially relieve the obstruction by lifting the tongue away from the back of the throat. With the other hand, the rescuer then inserts his or her

FIG. 12-6. Prone Heimlich maneuver administered to unconscious victim of foreign body airway obstruction.

FIG. 12-7. Standing chest-thrust maneuver administered to conscious victim of foreign body airway obstruction.

index finger into the back of the throat and uses a hooking action in an attempt to dislodge the foreign body to move it into the mouth for manual removal. Care must be used so as to not push the foreign object deeper into the throat.

Assess Circulation and Initiate Compressions

The carotid artery is generally the most reliable and accessible location to palpate a pulse. The artery can be located by placing two fingers on the trachea and then sliding them down to the groove between

FIG. 12-8. Finger-sweep maneuver administered to unconscious victim of foreign body airway obstruction.

SECTION 3 • RESUSCITATIVE PROBLEMS AND TECHNIQUES

the trachea and the sternocleidomastoid muscle. Simultaneous palpation of both carotid arteries should not be performed because in low-pressure states this could obstruct cerebral blood flow and may interfere with the ability to detect a pulse. The femoral artery may be used as an alternative site to palpate a pulse. This can be found just below the inguinal ligament approximately halfway between the anterosuperior iliac spine and the pubic tubercle. If no pulse is felt after 5 to 10 s, chest compressions should begin.

PHYSIOLOGY OF CLOSED-CHEST COMPRESSIONS Since the technique of closed-chest compressions was put forth initially by Kouwenhoven and colleagues in the 1960s, there has been an active debate as to the exact mechanism that causes blood flow.^{4,5} In a closed system, liquid flows when pressure gradients develop. There are three basic theories for how pressure gradients and flow are produced during closed-chest cardiac massage.^{6,7} The conventional theory of blood flow during compressions is called the *cardiac pump theory*. This postulates that direct compression of the heart between the spine and the sternum leads to increased pressure in the ventricles. This causes closure of the mitral and tricuspid valves, leading to blood flow into the aorta and the pulmonary arteries. The *thoracic pump theory* postulates that compressions lead to an increase in pressure throughout the thoracic cavity, leading to a pressure gradient from intrathoracic to extrathoracic arteries. The third mechanism described is the *abdominal pump theory*, which has both an arterial and a venous component. The arterial component postulates blood flow into the peripheral arterial system from increased arterial pressure caused by abdominal compressions that forces blood from the abdominal aorta against the closed aortic valve. The venous component leads to blood return via the inferior vena cava from abdominal pressure. However, regardless of the mechanism, conventional chest compressions generate one-fourth to one-third of physiologic cardiac output. Lower ratios can be expected with delays in initiating compressions.

TECHNIQUES OF CLOSED-CHEST COMPRESSIONS

Closed-Chest Compressions:

1. Depth: $\frac{1}{2}$ - 2 in (3.8 to 5.1 cm)
2. Rate: Approximately 100 per min

Ventilations:

1. Single rescuer or two rescuer non-intubated patient: 2 ventilations after every 15 compressions
2. Two rescuer, intubated patient: 1 ventilation after every fifth compression

Upon confirmation that an individual is without a pulse, serial rhythmic closed-chest compressions should be initiated. The victim is placed supine on a firm surface with the rescuer at the side. The care provider places the heel of one hand midline on the lower half of the sternum, approximately 2 in. (5 cm) cephalad of the xiphoid process (Figure 12-9). The heel of the hand should be parallel with the long axis of the patient's body. The second hand is then placed on top of the first hand so the hands are parallel with each other. The fingers of the two hands may be interlaced if desired, but they should not be touching the chest. The arms should be straight and the elbows preferably locked. The vector of the compression force should start from the rescuer's shoulders and be directed downward; lateral forces will decrease efficiency of the compressions and increase the likelihood of complications. The sternum should be depressed $\frac{1}{2}$ to 2 in. (3.8 to 5.1 cm) in an adult at a rate of approximately 100 compressions per min. Rates lower than this are inadequate. The compression-release phases should be roughly equal in length. With a single rescuer or with two rescuers if the patient is not intubated, 2 ventilations should be given after every 15 compressions. With two rescuers assisting an intubated patient, a ventilation should be given after every fifth compression. Of

FIG. 12-9. Proper hand and rescuer positioning for chest compression.

note, while assisting ventilation is important, not everyone is willing to perform mouth-to-mouth breathing due to concerns over infectious disease transmission. Chest compressions alone can be effective and should be provided even if rescue breathing is not being performed.⁸

There are currently several experimental techniques for improving the effectiveness of closed-chest cardiac massage. In one method, circumferential chest compressions are performed by a pneumatic vest to more effectively increase intrathoracic pressure during chest compressions.⁹ In interposed abdominal compression CPR, abdominal compression occurs during the relaxation phase of chest compression, causing increased aortic diastolic pressure and leading to improved blood flow to organs above the diaphragm.¹⁰ In active compression-decompression CPR, a hand-held suction device is used to decrease intrathoracic pressure during the relaxation phase of chest compression and to improve ventricular filling.¹¹ Additionally, self-initiated cardiopulmonary resuscitation can be performed by forceful coughing. This increases intrathoracic pressure, leading to blood flow to the brain for as long as the patient remains conscious and able to cough.¹² Increased understanding of the physiology of cardiopulmonary resuscitation is leading to improved circulatory adjuncts, such as interposed abdominal compression CPR and active compression-decompression CPR, and may lead to improved CPR by experienced practitioners.^{13,14} Currently, however, availability of these adjuncts should not delay the initiation of closed-chest cardiac massage.

Open-chest cardiac massage is an additional alternative to standard CPR, and has been shown to improve blood flow in animal models. While there are no data showing improved clinical outcome with the use of open-chest cardiac massage versus closed-chest cardiac massage, this technique may be considered in a number of situations, including (1) after penetrating chest trauma; (2) the perioperative period

before or after cardiothoracic surgery; (3) cardiac arrest caused by hypothermia, pulmonary embolism, pericardial tamponade, or abdominal hemorrhage; (4) cases of chest deformity in which closed-chest CPR is ineffective; (5) penetrating abdominal trauma with deterioration and cardiac arrest; and (6) blunt trauma with cardiac arrest.¹⁴ However, the use of this technique requires a well-coordinated multidisciplinary team (see Chap. 259).

Complications of Cardiopulmonary Resuscitation

Ventilations can cause insufflation of the stomach, leading to regurgitation and aspiration and possibly to gastric rupture. Closed-chest compressions can lead to fractures of the sternum or the ribs, separation of the ribs from the sternum, pulmonary contusion, pneumothorax, myocardial contusion, hemorrhagic pericardial effusions, splenic laceration, or liver laceration. Proper techniques can minimize these complications but cannot totally prevent them. Late complications include pulmonary edema, gastrointestinal hemorrhage, pneumonia, and recurrent cardiopulmonary arrest. Anoxic brain injury can occur in a resuscitated individual subjected to prolonged hypoxia; it is the most common cause of death in resuscitated patients.

Terminating Resuscitation

Efforts at resuscitation should be continued until the patient recovers spontaneous respirations and cardiac output, the rescuer becomes exhausted, or the patient is pronounced dead. An atraumatic individual who recovers spontaneous respirations and circulation should be placed on their side—the *recovery position*. Recovery from cardiac arrest depends on time to CPR and rhythm-specific intervention. Resuscitation and long-term outcome in normothermic patients with arrest times of 20 min or more are very poor.

Ethical Considerations in Resuscitation (also see Chap. 17)

While resuscitation attempts are initiated, efforts should be made to discover whether or not the victim has advance directives that prohibit CPR,¹⁵ and these should be honored when possible. In addition, family members may wish to be present during resuscitation attempts.¹⁵ This often requires support from social services and clergy. However, whenever possible family members should be given this option.

NEONATAL RESUSCITATION AND EMERGENCIES

Eugene E. Cepeda
Mary P. Bedard

NEONATAL RESUSCITATION

Approximately 6 percent of all newborns require life support in the delivery room or nursery, and in those neonates whose birthweights are less than 1500 g, the need for resuscitation rises to 60 percent. Personnel skilled in neonatal resuscitation should be available at every delivery.¹

There are no guidelines available to assist in making the decision to resuscitate extremely premature infants in the emergency department. When in doubt, resuscitate. At the present time, survival at 22 weeks of gestation or younger is rare. However, an 11 to 30 percent survival rate is reported at 23 weeks' gestation, although often with severe resultant morbidity. About 30 to 50 percent of surviving children with birthweights less than 750 g or whose gestational age was younger than 25 weeks had moderate to severe disability including blindness, deafness, and cerebral palsy.²

The single most frequent reason for resuscitation of a newborn is prematurity. Factors associated with an increased risk for neonatal resuscitation are shown in Table 13-1. The following conditions should alert nursery personnel to the possibility that apnea may develop: previous need for resuscitation, prematurity, sepsis and/or meningitis, congenital abnormalities, respiratory distress, or seizures.

Normal newborns are equipped with physiologic, pharmacologic, and metabolic responses to enable them to survive the hypoxia that develops as a consequence of asphyxia. In general, brain injury occurs only when the asphyxia is severe enough to impair cerebral blood flow. Initially the injury is reversible, and only prolonged periods of ischemia lead to permanent damage. The pattern of injury is strongly influenced by the distribution of blood flow. During asphyxia, blood flow is redirected to the heart, brain, and adrenals at the expense of other organs, such as the kidneys and the gastrointestinal tract. Within the brain, flow is directed to the brain stem at the expense of the high cerebral structures, such as the cortex. In the preterm neonate, the periventricular white matter is susceptible to injury. In the full-term or post-term neonate, the gray matter regions, such as the overlying parasagittal "watershed" cortex, are more vulnerable to ischemic injury. When the asphyxial insult is severe or prolonged, hypoxic multi-organ dysfunction occurs, because of the redistribution of organ blood flow, and results in cardiopulmonary distress, renal failure, impaired

TABLE 13-1 Factors Potentiating the Need for Neonatal Resuscitation**Maternal factors**

Inadequate prenatal care
 Age <16 and >35 y
 History of previous perinatal morbidity or mortality
 Toxemia or hypertension
 Diabetes
 Chronic renal disease
 Anemia
 Drug therapy (e.g., reserpine, lithium, magnesium, adrenergic-blocking agents)
 Substance abuse
 Blood type or group isoimmunization
 Oligohydramnios

Intrapartum factors

Abnormal presentation
 Caesarean section
 Prolonged labor or precipitous delivery
 Prolonged rupture of membranes, chorioamnionitis
 Cephalopelvic disproportion
 Forceps delivery other than outlet or vacuum extraction
 Prolapsed cord
 Cord compression
 Maternal hypotension, shock
 Analgesic or sedative drugs given within 2 h of delivery

Fetal factors

Prematurity
 Postmaturity
 Intrauterine growth failure
 Multiple gestation
 Acidosis on fetal scalp capillary monitoring
 Abnormal fetal heart rate per monitor
 Thick meconium in amniotic fluid
 Congenital infection
 Fetal malformation or edema diagnosed by ultrasound

hepatic function, seizures and encephalopathy, gastrointestinal dysfunction, and coagulopathies.

PRINCIPLES OF RESUSCITATION

The Apgar score (Table 13-2) is assessed at 1 and 5 min of age for every newly delivered infant. Although the scoring system has been useful in evaluating the condition of the newborn, 1 min is too long to wait to make the decision to initiate resuscitation. If the 5-min score is less than 7, additional scores are obtained every 5 min for a total of 20 min.

Perinatal asphyxia is currently defined as the presence of umbilical artery acidemia (pH <7.00), 5-min Apgar score of 0 to 3, neonatal neurologic sequelae, and multiorgan dysfunction. Certain conditions require specific measures during resuscitation in addition to those outlined below. These conditions are discussed after the general principles.

TABLE 13-2 Apgar Score

Sign	0	1	2
Heart rate	Absent	<100/min	>100/min
Respiratory effort	Absent	Weak cry	Strong cry
Muscle tone	Limp	Some flexion	Good flexion
Reflex irritability (when feet stimulated)	No response	Some motion	Cry
Color	Blue, pale	Body pink, extremities blue	Pink

Infants who are successfully resuscitated at birth should have continuous monitoring of vital signs, blood gases, hematocrit, glucose levels, blood pressure, fluid status, and clinical condition. Complications associated with severe asphyxia are hypoxic-ischemic encephalopathy, seizures, intracranial hemorrhage, syndrome of inappropriate secretion of antidiuretic hormone, hypocalcemia, persistent pulmonary hypertension, ischemic cardiomyopathy, hypovolemia or shock, necrotizing enterocolitis, renal failure, and coagulopathy.

Equipment

Equipment necessary for resuscitation is listed in Table 13-3.

Resuscitation Steps

MAINTAIN BODY TEMPERATURE The infant should be maintained below the level of the placenta before clamping the cord. When the cord is clamped, the infant is blotted dry with a sterile towel and placed under a preheated radiant warmer on a sterile table. Neonates should be placed on the back or the left side, somewhat in the Trendelenburg position, with the neck in a neutral position.

CLEAR THE AIR WAY The nose and mouth are suctioned gently with a bulb syringe or mechanical suction apparatus with an 8-French suction catheter. A 5- to 10-s examination should be performed to determine the need for resuscitation. This examination should include an assessment of heart rate, respiratory effort, color, and muscular tone. If the infant has a lusty cry, is pink, has spontaneous respirations, and has a heart rate faster than 120 beats/min (Apgar >8), no further therapy is needed.

INITIATE BREATHING If the infant is apneic or the heart rate is slow and irregular (<100 beats/min) and the color is cyanotic (Apgar 4 to 7), positive pressure ventilation is administered with the mask over the infant's face with 100 percent oxygen. The respiratory rate should be maintained at 40 to 60 breaths/min, with enough pressure applied to gently move the chest wall. In an infant who has not yet taken a breath, pressure over 30 cm H₂O may be necessary to expand the lungs. In mildly depressed infants, this amount will produce a prompt increase in heart rate and the onset of regular spontaneous respirations. If no improvement is noted in 15 to 30 s or the condition deteriorates (Apgar s4), the trachea should be intubated and assisted ventilation continued.

MECONIUM STAINING Meconium staining of the amniotic fluid occurs in up to 20 percent of all births. Meconium aspiration syndrome is a cause of severe respiratory disease and often is associated

TABLE 13-3 Neonatal Resuscitation Equipment

Bag and mask with manometer attached, connected to a source of 100% oxygen (oxygen should be heated and humidified; bag should be a rubber anesthesia bag, a rebreathing bag of 500-mL capacity, or a self-inflating bag designed for newborns)
 Rubber face masks of different sizes, 1, 2, 3, and 4
 Wall suction, sterile catheters, and bulb syringes
 DeLee suction catheter with mucus trap
 Laryngoscope with 0 and 1 blades
 Oral endotracheal tubes with stylet, sizes 2.5, 3.0, 3.5, and 4.0 mm
 Radiant heater with servomechanism
 Sterile umbilical vessel catheterization tray
 Glucose blood test strips
 Heart rate monitor with easily applicable leads
 Intravenous infusion equipment
 Pulse oximeter
 Appropriate light
 Infant stethoscope
 Nasogastric tubes, 5 and 8 French
 Clock with sweep second hand

with persistent pulmonary hypertension of the newborn. With proper obstetric and pediatric management, the incidence and severity of the disease can be significantly decreased. When meconium staining of the amniotic fluid is present, the infant's nose, mouth, and pharynx should be thoroughly suctioned after delivery of the head and before delivery of the shoulders. If the infant is vigorous after delivery, the oropharynx should be suctioned again with a bulb syringe or large-bore catheter. No further intervention is necessary.

If the infant is depressed at birth, direct suctioning of the trachea should be performed. Free-flow oxygen should be given throughout the procedure. The infant's trachea is visualized with a laryngoscope, and the mouth and pharynx are cleared with a 12- or 14-French suction catheter. An endotracheal tube is inserted into the trachea and attached to a suction device. Suction is applied as the endotracheal tube is slowly removed. This procedure should be repeated until little additional meconium is recovered.³ If the heart rate remains slower than 100 beats/min, positive pressure ventilation and chest compressions should be initiated. If no suction device is available to attach to the endotracheal tube, a large-bore suction catheter can be inserted in the trachea and suction applied to remove meconium from the trachea. If the heart rate remains slower than 100 beats/min after suctioning, bag-and-mask ventilation should be done. If the heart rate does not respond, the infant should be intubated and given positive pressure ventilation. Chest compressions and epinephrine should be given, as outlined below, if bradycardia persists.

Endotracheal intubation of the neonate is not particularly different from other young pediatric patients. Details of this technique are discussed in Chap. 15.

CARDIAC MASSAGE If the heart rate is slower than 60 beats/min with assisted ventilation, cardiac massage should be initiated by placing both hands around the infant's chest with two thumbs over the mid-sternum, one finger's width below the intermammary line. The sternum is depressed one third of the distance to the vertebral column at 120 compressions per min. Chest compressions should be coordinated with ventilation at one breath for every three compressions. Cardiac massage may be stopped periodically to assess improvement. The chest should expand, bilateral breath sounds should be heard in the axilla, and heart rate should increase if the resuscitation is effective and the endotracheal tube is in good position. *In most instances* it is possible to obtain an adequate response with the use of external cardiac massage and assisted ventilation. If there is no response to these measures after 30 s, drug therapy should be considered. Any route of access to the circulatory system is acceptable, including a peripheral vein, the umbilical vein, or the endotracheal tube.

UMBILICAL VEIN CATHETERIZATION The most expedient procedure for obtaining vascular access is to insert the venous catheter through the umbilicus via the umbilical vein and the ductus venosus into the inferior vena cava (Figure 13-1). The venous catheter should be inserted 10 to 12 cm and anchored to the abdominal wall. Radiographs of chest and abdomen should be obtained to rule out other abnormalities and evaluate the position of the catheters.

UMBILICAL ARTERY CATHETERIZATION Umbilical artery catheterization is indicated for continuous monitoring of blood pressure and closer monitoring of arterial blood gases (Table 13-4). If the umbilical artery cannot be cannulated for a blood gas determination, the radial artery or warmed (arterialized) finger stick for capillary blood are alternatives.

Patency of the umbilical arterial line can be maintained by a continuous infusion of fluid. The catheter should be removed when the need for arterial blood gas monitoring is no longer necessary or complications occur.

Possible complications of umbilical artery catheterization are infection, thrombosis and vasospasm, and hemorrhage. Renal hypertension is a delayed complication.

FIG. 13-1. Umbilical vein catheterization. The large vessel is the umbilical vein. The two smaller vessels are the umbilical arteries.

DRUG THERAPY IN RESUSCITATION

There is a minor role for drug therapy in resuscitation. Most resuscitative efforts in the delivery room respond to adequate support of ventilation and circulation without drug therapy (Table 13-5).

DEXTROSE To provide metabolic substrate and expansion of plasma volume, D10W in water at 100 mL/kg a day or 6 to 8 mg/kg per min (0.06 to 0.08 mL/kg per min) should be infused. If the blood glucose is below 45 mg/dL, 2 mL/kg of D10W or D15W solution should be infused at a rate of 2 mL per min; 25 percent dextrose infusions should be avoided because of the risk of rebound hypoglycemia.

EPINEPHRINE To stimulate heart rate if it is slower than 60 beats/min, 0.1 to 0.3 mL/kg of a 1:10,000 solution may be given IV. Epinephrine may be administered down the endotracheal tube at a dose that is 2 to 2.5 times larger than the IV dose. Cardiac massage should continue after epinephrine administration.

VOLUME EXPANSION Infants who appear pale with weak pulses or who fail to respond to the above resuscitative measures may be hypovolemic and require volume expansion. The fluid of choice is an isotonic crystalloid solution, such as NS or LR. After intravenous access is established, administer 10 mL/kg of fluid by slow intravenous push over 5 to 10 min. If there is minimal response to the first dose, a second 10 mL/kg dose can be given. If acute blood loss is suspected, transfusion with 10 mL/kg of O-negative blood can be given.

BICARBONATE The use of sodium bicarbonate during neonatal resuscitation remains controversial. If possible, a blood gas should be obtained to check adequacy of ventilation before sodium bicarbonate is given. During a prolonged arrest, it can be given once adequate ventilation and circulation have been established. Sodium bicarbonate is caustic and should be given intravenously, not by the endotracheal route. The dose is 1 to 2 mEq/kg of a 4.2 percent (0.5 mEq/mL) solution or 2 to 4 mL/kg. Blood gases should be obtained, and further treatment should be reassessed.

NALOXONE HYDROCHLORIDE Naloxone hydrochloride is used to reverse narcotic respiratory depression and should not be given until adequate ventilation has been established. The dose is 0.1 mg/kg of

TABLE 13-4 Umbilical Artery Catheterization**Equipment:**

 iodine solution 3.5-French catheter for
 infant <1200 g 5.0-French catheter for
 infant >1200 g **Method:**

1. Immobilize the patient. Measure the distance between the umbilicus and the right shoulder.
2. Clean the umbilical stump and surrounding area with povidone-iodine solution. Drape the umbilical area, but leave the infant's head and feet uncovered.
3. Tie the base of the cord with the umbilical tape, using a single throw, and apply traction to minimize blood loss.
4. Cut the cord cleanly across its length to 1 cm with the scalpel. The arteries are small and have pinpoint openings. The vein is larger and has thinner walls and a larger opening.
5. Grasp the edge of the cord with the forceps. Using the iris forceps, enlarge the opening of the umbilical artery first with the tip of one arm of the forceps.
6. Insert both arms of the forceps to dilate the artery so that it will accept the catheter.
7. The length of the catheter inserted for the low position is two thirds the distance from the umbilicus to the right shoulder, and the length for the high position is the full measurement from the right shoulder to the umbilicus.
8. Attach the three-way stopcock and aspirate blood with a syringe. Clear the catheter with normal saline.
9. Anchor the catheter with silk suture to the umbilical stump. The umbilical tape also can be used to secure the catheter.
10. Check the position of the catheter tip with an x-ray. It should be at the level of L4 for the low position or between T6 and T9, which is above the diaphragm, for the high position.

0.4 mg/mL solution. It may be administered intravenously or through the endotracheal tube. Intramuscular or subcutaneous administration is associated with a delayed onset of action. Naloxone hydrochloride may precipitate withdrawal in infants whose mothers are addicted to opiates.

DISCONTINUATION OF RESUSCITATION

If no heart rate is established after 15 min, it is appropriate to discontinue resuscitative efforts. Current data indicate that resuscitation after 10 min of asystole is very unlikely to result in survival without severe disability.

TRANSFERS

Once an infant has been successfully resuscitated, it should be transferred as soon as possible to an intensive care unit with equipment and trained personnel for the management of newborns.

EMERGENCIES IMMEDIATELY AFTER BIRTH

This section discusses selected emergencies that can develop immediately after birth. Chaps. 117, 118, and 120 discuss other aspects of neonatal problems in detail.

Apnea

Apnea is the absence of respirations for a period of 20 s or for shorter durations when associated with a heart rate slower than 80 beats/min and/or cyanosis or pallor. Apnea is categorized as *central apnea* when it originates from the central nervous system (CNS). There are no respiratory efforts and no gas flow in central apnea. In *obstructive apnea*, there is impaired gas flow in the presence of respiratory effort. In *mixed apnea*, there are components of central and obstructive apnea. *Periodic breathing* is apnea of a few seconds' duration in a 20-s span of otherwise normal breathing. In term infants, apnea is never physiologic and is usually secondary to a serious disorder. Pathologic conditions associated with neonatal apnea are listed in Table 13-6. Detailed discussion of apnea is provided in Chap. 119.

Neonatal Shock

The risk factors for shock and hypotension in newborn infants are low birthweight, perinatal sepsis, prolapsed cord, and acute blood loss. Clinical signs of hypovolemia are pallor, tachycardia, grunting respirations without pulmonary disease, mottling of skin, poor capillary filling, thready pulse and hypotension (systolic <40 mm Hg in a 1000-g premature neonate or <55 mm Hg in a term infant), and persistent metabolic acidosis. A hematocrit should be obtained, and, if anemia (hematocrit <35 vol%) or hypotension is diagnosed, immediate plasma expansion in the form of packed red blood cells, 10 to 15 mL/kg, or whole blood, fresh-frozen plasma, or 5 percent albumin, 10 mL/kg, should be given IV over 10 min.

Neonatal Seizures

Seizures in neonates are common, with an incidence of 1 in 200 live births, and may represent primary CNS disease or a systemic or metabolic disorder. Hypoxic-ischemic encephalopathy is the most common cause of neonatal seizures. The seizures usually occur between 6 and 18 h of life but may be seen as early as age 1 h. In full-term neonates, the hypoxic injury may result in a cerebral hemorrhage, watershed infarct, posterior fossa hematoma, or subarachnoid or subdural hemorrhage. In premature infants, hypoxic injury often results in periventricular-intraventricular hemorrhage. This type of seizure has a poor prognosis. Recent data suggest that seizure activity itself may adversely affect the growing brain. It is important to distinguish seizures from tremors or jitteriness, which may be seen in infants who have hypocalcemia, hypoglycemia, drug withdrawal, or no identifiable disease. Tremors are uniform, fine movements that respond to sensory stimuli, stop with manual stabilization, and do not occur spontaneously. They are not accompanied by eye, oral, or lingual movements. The types of neonatal seizures include subtle seizures, tonic seizures, multifocal clonic seizures, focal clonic seizures, and myoclonic seizures.

Subtle seizures occur in preterm and term neonates. These seizures consist of ocular, facial, oral, or lingual movements and respiratory manifestations, such as apnea or stertorous breathing.

Tonic seizures are characteristic of premature infants. The seizures appear as decerebrate or decorticate posturing. There are sustained deviation of the eyes and asymmetric posturing of the limbs and trunk.

Multifocal clonic seizures are seen in term infants. These are initially noted in one limb and migrate to another part of the body. There are rhythmic and slow movements at one to six times per second.

Focal clonic seizures are well localized and accompanied by specific sharp activity on the electroencephalogram (EEG). These seizures occur more commonly in full-term infants.

Myoclonic seizures are expressed as single or multiple jerks of flexion of the upper or lower extremities. They are rare and occur in premature and full-term infants.

TABLE 13-5 Neonatal Resuscitation Drug Chart

PATIENT DOSE						
Drug, Concentration, and Indication	Syringe Size (mL)	Dose by Weight	Weight (kg)	VOLUME (mL)		Administration
				IV	ET	
Epinephrine 1:10,000(0.1 mg/mL)for bradycardia	1	0.01-0.03 mg/kg	1 2 3 4	0.2 0.4 0.6 0.8	0.5 1 1.5 2	IV push or ET followed by 1 mL NS solution. Repeat q5 min as needed. <i>Do not mix with sodium bicarbonate. Never inject into an artery.</i>
Sodium bicarbonate 4.2% (0.5 mEq/mL) for metabolic acidosis	6, 10, or 12	2 mEq/kg	1 2 3 4	4 8 12 16		IV over at least 2 min. <i>Do not mix with epinephrine.</i> Ensure adequate ventilation.
Whole blood, albumin 5%, NS, or LR for volume expansion	20 or 35	10 mL/kg	1 2 3 4	10 20 30 40		IV over at least 10 min.
Naloxone 0.4 mg/mL for opiate-induced respiratory depression	1	0.1 mg/kg	1 2 3 4	0.25 0.50 0.75 1	0.25 0.50 0.75 1	IV push or ET May repeat 2 to 3 times. <i>Use cautiously if maternal narcotic addiction is suspected.</i>

Abbreviation: ET = endotracheally.

CLINICAL FEATURES The metabolic disturbances associated with neonatal seizures include hypoglycemia, hypocalcemia, hypomagnesemia, hyperammonemia, hypematremia, and hyponatremia. Hypoglycemia, hypocalcemia, and hypomagnesemia are often found in premature infants with perinatal asphyxia. Hypematremia occurs in neonates with volume depletion secondary to excessive fluid losses or treatment with large doses of sodium bicarbonate. Hyponatremia may be seen secondary to inappropriate antidiuretic hormone secretion or acute volume overload. Inborn errors of amino acid metabolism also may present as seizures.

Hyperkalemia
Hypocalcemia
Hypomagnesemia
High serum levels of phenobarbital, diazepam, opiates, and chloral hydrate

Seizures can result from bacterial meningitis, encephalitis associated with the TORCH complex (toxoplasmosis, rubella, cytomegalovirus infection, and herpes simplex infection), or enteroviral encephalitis. Developmental abnormalities, including congenital hydrocephalus, microcephaly, and other congenital brain anomalies, can cause seizures. Drug withdrawal from maternal use of methadone, barbiturates, alcohol, pentazocine (Talwin), and tripeleminamine (Pyribenzamine) rarely presents as seizures. Pyridoxine dependence occurs rarely but should be considered in neonatal seizures unresponsive to standard therapy. A rare cause of neonatal seizures is inadvertent fetal scalp injection of maternal local anesthetic agents. Neonatal stroke diagnosed by computed tomography recently has been described in term infants with focal motor seizures. Neonatal stroke may occur in the setting of diverse cerebrovascular disorders, such as hypoxic-ischemic encephalopathy, polycythemia, acute severe hypertension, and cocaine use.

A careful history, including intrapartum monitoring data and physical examination, is essential when considering drug withdrawal, birth asphyxia, or metabolic disorders as a cause of the seizures. A lumbar puncture with analysis of cell count, culture, Gram stain, and blood specimens for culture and determinations of glucose, calcium, magnesium, and blood urea nitrogen levels should be obtained. The echoencephalogram and EEG can be obtained after the seizures have been controlled. In a full-term infant, computed tomography or magnetic resonance imaging of the head to look for ischemic injury may be necessary, because an echoencephalogram may not provide adequate visualization of the subarachnoid space or posterior fossa. Recently, positron emission tomography of the head has been used to evaluate the effects of asphyxia and seizures on cerebral blood flow.

TREATMENT Repeated seizures in neonates may be accompanied by hypoventilation and apnea, resulting in hypercapnia and hypoxemia. Increases in cerebral blood flow and arterial hypertension occur with neonatal seizures. Treatment of seizures should be initiated while awaiting results of laboratory data. An intravenous access route should be established immediately, and the airway should be maintained; assisted ventilation should be initiated if apnea is present. Hypoglycemia is treated with 2 mL/kg of a D10W solution given IV at 2 mL per min, followed by a maintenance infusion of D10W at 80 mL/kg a day.

Hypocalcemia is total calcium less than 7 mg/dL and should be treated with 10 percent calcium gluconate, 2 mL/kg, given IV at a maximal rate of 3 mL per min. If the heart rate decreases, the infusion should be slowed or stopped. Hypomagnesemia, less than 1.6 mg/dL, is often associated with hypo-calcemia and should be treated IV or IM with 0.1 to 0.2 mL/kg of 50 percent magnesium sulfate solution. Blood glucose, calcium, and magnesium should be determined before treatment of seizures from low levels of these three substances.

The anticonvulsant drugs used most frequently include phenobarbital and phenytoin. The loading dose of phenobarbital is 20 mg/kg IV given slowly over 10 min, and the maintenance dose is 5 mg/kg a day IM or PO in two divided doses. If the initial 20 mg/kg dose of phenobarbital is not effective in controlling the seizures, additional doses of 5 mg/kg may be administered every 5 min until the seizures have ceased or the total dose of 40 mg/kg has been reached. In unresponsive cases, phenytoin may be administered with a similar loading dose followed by a maintenance dose of 3 to 5 mg/kg a day by the IV route in only two divided doses 20 min apart to avoid disturbance of cardiac function. Lorazepam is recommended for status epilepticus as long as ventilation and blood pressure are supported. The dose of lorazepam is 0.05 to 0.1 mg/kg administered IV. Infants with pyridoxine dependence respond immediately to an intravenous injection of pyridoxine, 50 to 100 mg. For further discussion, see Chap. 125.

Diaphragmatic Hernia

A failure of development of the posterolateral parts of the diaphragm at the Bochdalek foramen or retrosternally at the Morgagni foramen allows herniation of the gut into the chest cavity. Associated anomalies with diaphragmatic hernias include congenital heart diseases, genitourinary anomalies, and gastrointestinal anomalies. Frequently the lungs are hypoplastic bilaterally and have abnormal pulmonary vasculature, thus predisposing the infant to pulmonary hypertension.

Fifty percent of fetuses with diaphragmatic hernia have difficulty swallowing, and the condition may be associated with polyhydramnios. The diagnosis often can be made by prenatal ultrasonography.

CLINICAL FEATURES The clinical findings are localized to the respiratory and digestive tracts. The chest is large, and the abdomen is scaphoid. Bowel sounds may be heard in the left chest, and the heart is displaced to the right. Dyspnea, cyanosis, retractions, and vomiting are proportional to the amount of abdominal viscera herniated into the thorax. Radiologic study shows air-filled loops of bowel in the chest cavity and an absent diaphragmatic margin. The lungs are hypoplastic and have abnormal vasculature.

TREATMENT The neonate should be stabilized as much as possible before surgery. The infant should be intubated immediately, and little or no attempt should be made to ventilate with a mask. Rapid ventilatory rates and low peak inspiratory pressures are used to ventilate the infant and prevent reactive respiratory acidosis and hypercarbia, which are potentially conducive to the development of pulmonary hypertension. A large-caliber 10-French tube should be placed in the stomach, with low continuous suction applied. An umbilical artery catheter is useful to monitor blood gases. Any acidemia should be corrected, and the pH should be maintained in the normal range, if possible. Intravenous fluids should be given, and the patient should be kept warm.

The outcome of an infant with diaphragmatic hernia depends on the degree of pulmonary hypoplasia and vascular abnormalities leading to persistent pulmonary hypertension. The morbidity is higher when the symptoms present at birth and when the diaphragmatic hernia is detected prenatally. Common complications include pneumothorax, persistent pulmonary hypertension, and chylothorax. The introduction of extracorporeal membrane oxygenation (ECMO) for in-

fants with persistent pulmonary hypertension has had minimal effect on outcome.

Tracheoesophageal Fistula

A defect in the separation of the trachea from the esophagus results in a persistent channel connecting the trachea and the esophagus. There are five types of tracheoesophageal fistulas: (1) esophageal atresia with a distal fistula between the trachea and the esophagus, the most common presentation (85 percent); (2) isolated esophageal atresia; (3) H-type fistula; (4) esophageal atresia with a proximal fistula; and (5) esophageal atresia with proximal and distal fistulas. The potential exists for respiratory distress in the first hours after birth in neonates with a proximal fistula. A proximal fistula can lead to massive aspiration at the first feed. Other types of esophageal atresia can lead to respiratory distress from inability to handle oral secretions, aspiration, and choking.

Congenital heart malformation, vertebral anomalies, imperforate anus, and radial aplasia are associated anomalies.

The inability to pass a catheter from the nose or mouth to the stomach is the hallmark of esophageal atresia. A radiograph may show the air-filled proximal pouch, and the catheter, if left in place, may coil in the proximal esophagus. Recurrent pneumonias occur in infants with an H-type fistula.

It is important to provide respiratory support by assisted ventilation, if needed, to correct acidosis before any surgical repair can be undertaken. A plastic sump catheter should be left in the pouch and connected to constant, low-pressure suction. The patient should be maintained in the reverse Trendelenburg or semi-Fowler position to prevent further reflux of gastric secretions through the fistula into the trachea. Intravenous fluids and antibiotics are indicated. Consultation with a neonatologist is advised.

Most (80 percent) infants with tracheoesophageal fistula survive. Operative mortality is low.⁴

Pneumothorax

Pulmonary air leaks may present as pneumothorax, pulmonary interstitial emphysema, pneumomediastinum, pneumopericardium, or pneumoperitoneum. Spontaneous pneumothorax can occur in term and post-term infants after intrapartum asphyxia and aspiration syndromes. The incidence of pneumothorax is higher in infants who require positive airway pressure, mechanical ventilation, and cardiopulmonary resuscitation. Uneven ventilation caused by aspirated blood, mucus, meconium, and amniotic fluid debris also can result in an air leak. Atelectasis, poor ventilation, and air trapping are common predisposing factors. Premature, low-birthweight infants with surfactant deficiency have a high incidence of air leaks (30 percent), as do newborns with meconium aspiration syndrome (10 percent).

CLINICAL FEATURES The signs and symptoms of an air leak (pneumothorax) are those of respiratory distress and often present as an acute clinical deterioration. Grunting respirations and intercostal, sternal, and subcostal retractions may be seen. Cyanosis, elevated respiratory rate, and elevated heart rate are common. Auscultation of the chest reveals decreased breath sounds on the affected side of a pneumothorax, distant heart sounds, and a shift of the mediastinum. Transillumination of the chest with a high-intensity lamp may aid in the diagnosis. A chest radiograph is diagnostic. The accuracy can be improved with a cross-table lateral film of the chest, in addition to anteroposterior and lateral views.

TREATMENT An asymptomatic pneumothorax that is less than 20 percent of the volume of the affected side may be followed clinically with no therapy and with serial radiographic studies every 4 h. Any

pneumothorax with severe respiratory distress and clinical deterioration needs emergency treatment. When there are mediastinal shift and cardiovascular collapse, rapid decompression at the fourth intercostal space with a 21-gauge needle alone or attached to a three-way stopcock and a large syringe can be lifesaving.

Indications for thoracostomy tube placement are post-decompression of a tension pneumothorax or relief of respiratory compromise for simple pneumothorax, hemopneumothorax, or pleural fluid. The same equipment used for adults is required. A 10-French chest tube is used for infants weighing less than 1500 g, whereas a 12-French chest tube is appropriate for infants weighing more than 1500 g. The procedure is similar to that in adults and is described in Chap. 259. Placement of the tube can be at the second or third intercostal space in the midclavicular line or at the fifth or sixth intercostal space in the anterior axillary line. The same precaution regarding avoidance of injury to the intercostal nerve, artery, and vein, which run on the lower edge of the rib, is required. The skin wound is similarly closed, and the chest tube is severed. The position of the chest tube is verified with a chest x-ray. The lung should re-expand promptly after evacuation of the air in the pleural space.

Gastroschisis and Omphalocele

An omphalocele is a defect in the umbilical ring that allows the intestines to protrude out of the abdominal cavity in a sac. A gastroschisis is a defect in the abdominal wall that allows the antenatal evisceration of abdominal structures without a sac being present.

The emergency management of the two conditions is not different, especially when the sac in an omphalocele is ruptured. The eviscerated bowel should be wrapped in saline-soaked gauze and placed in a plastic bag to protect it from hypothermia and evaporative losses. A nasogastric tube should be inserted to decompress the intestines. Rapid infusion of LR 20 mL/kg, may be necessary to restore vital signs, after which the infusion should be adjusted to maintain a urine output of at least 2 mL/kg per h. Intravenous antibiotics should be administered.

Primary fascial closure is the treatment of choice and often is accomplished within hours after birth. The mortality of omphalocele is 25 to 30 percent, largely as a result of concomitant congenital heart disease and sepsis, whereas death in patients with gastroschisis is associated with intestinal atresia.

Cyanotic Newborns

Cyanosis in neonates may be central or peripheral. Central cyanosis is defined as cyanosis of the tongue, mucous membranes, and peripheral skin and indicates the presence of reduced hemoglobin. Peripheral cyanosis is defined as blue discoloration confined to the skin of the extremities; the arterial saturation is greater than 94 percent. Peripheral cyanosis is common in neonates and may persist for 2 to 3 days. It is usually due to vasomotor instability secondary to a cold environment.

Normal newborn infants have a partial pressure of oxygen above 50 mm Hg by 5 to 10 min of age; hence, it is pathologic for central cyanosis to persist beyond 20 min after birth. Diagnostic considerations in central cyanosis are presented in Table 13-7.

DIAGNOSTIC APPROACH TO CENTRAL CYANOSIS Neonates with cyanosis secondary to congenital heart disease rarely have respiratory symptoms other than tachypnea. A murmur may be present. Neonates with lung disease producing cyanosis have respiratory distress, grunting, tachypnea, and retractions. Cyanotic infants with CNS disturbances or sepsis have apnea, bradycardia, lethargy, and seizures. Neonates with methemoglobinemia have minimal distress despite their cyanotic appearance.

TABLE 13-7 Differential Diagnosis of Central Cyanosis in the Neonate

Congenital heart disease with intracardiac right-to-left shunt
Transposition of the great vessels

Pneumonia
Meconium aspiration syndrome
Persistent pulmonary hypertension
Pneumothorax
Diaphragmatic hernia
Lobar emphysema
Mucous plugs
Other causes
Central nervous system disorders (e.g., intracranial hemorrhage)
Polycythemia
Shock
Sepsis

The "hyperoxia test" (arterial partial pressure of oxygen [P_{aO_2}] in response to breathing 100 percent oxygen) may be of use in distinguishing heart disease from other causes of cyanosis. Neonates with cyanotic heart disease do not demonstrate an increase in P_{aO_2} over 20 mm Hg, because of the right-to-left shunting of the circulation. Most neonates with lung disease, however, demonstrate an increase in P_{aO_2} after breathing 100 percent oxygen for 20 min. The neonate with CNS disorders, polycythemia, sepsis, and shock also demonstrates an increase in P_{aO_2} . Infants with persistent pulmonary hypertension may or may not demonstrate a significant rise in partial pressure of oxygen. There is no response elicited in the neonate with methemoglobinemia. When a blood specimen is exposed to air, it turns pink in all the conditions described above except in methemoglobinemia, where the blood remains chocolate colored.

The chest radiograph may demonstrate pulmonary oligemia with normal heart size in the tetralogy of Fallot and pulmonary or tricuspid atresia, and pulmonary vascularity is increased in transposition of great vessels, truncus arteriosus, anomalous pulmonary venous return, and hypoplastic left heart. Neonates with lung disease have radiographs characteristic of the underlying disease. The electrocardiogram and echocardiogram are useful in diagnosing congenital heart disease. Right ventricular hypertrophy may be seen in lung disease, with associated pulmonary hypertension.

TREATMENT Infants with cardiac causes of cyanosis that have decreased pulmonary blood flow or left heart obstruction are dependent on the postnatal patency of the ductus arteriosus for maintenance of adequate pulmonary blood flow and systemic oxygenation. Prostaglandin E1 infusion at 0.05 to 0.1 μ L/kg per min in these infants has allowed stabilization before surgery. Oxygen and ventilation are indicated for other causes.

Congestive Cardiac Failure

Causes of congestive heart failure in newborn infants are listed in Table 13-8. For detailed discussion see Chap. 120.

Neonates with severe heart failure from left-to-right shunts with cardiogenic shock and bradycardia may require inotropic support. Dobutamine and/or dopamine at 5 to 15 μ g/kg per min can be used. Isoproterenol infused at 0.01 to 0.04 μ g/kg per min may be helpful if

TABLE 13-8 Etiologies of Newborn Congestive Heart Failure

Structural heart disease
Heart disease without structural abnormalities (myocarditis, cardiac dysrhythmias, glycogen storage disease, and endocardial fibroelastosis)
Respiratory disease with patent ductus arteriosus with left-to-right shunt
Anemia (hemoglobin <3.5 g/dL) Polycythemia
Cerebral or other arteriovenous malformation
Sepsis Systemic hypertension

the heart rate is slower than 140 beats/min. Careful monitoring of blood pressure and heart rate is required.

Neonatal Transfers

Many facilities will not be able to care for neonates after emergency department resuscitation. Providers should be aware of the nearest hospital able to accommodate transfers. A specially trained team is likely to do the transportation, whether by ground or by air (see Chap. 4).

Children have very poor survival rates from cardiac arrest, because it is often associated with prolonged hypoxia or shock.^{1,2} After a cardiac arrest, the survival rate without devastating neurologic sequelae in children is only 2 percent.³ The best chance for a good outcome is to recognize impending respiratory failure or shock and intervene to prevent the development of cardiopulmonary arrest.

Age-related differences are important within the pediatric population.⁴ An appropriate drug dose for a 6 month old may be excessive for a 1 month old but inadequate for a 5 year old. Other aspects of resuscitation, such as endotracheal tube size, tidal volumes, cardiac compression rates, and respiratory rates, vary with a child's age.

The priorities of resuscitation are airway, oxygenation, ventilation, and shock management. Cardiopulmonary arrest may be prevented with prompt recognition of and intervention for compromised physiology.⁴ International consensus guidelines for basic life support procedures⁵ are listed in Table 14-1.

AIRWAY

Anatomy

A child's airway is much smaller than an adult's, and the size varies by age. The anatomic and functional differences are more pronounced in infants and young children. The airway is higher and more anterior in a child's than in an adult's neck. The tongue and epiglottis are relatively larger and thus more likely to be an obstructing element in a child's airway. Infants younger than 6 months are primarily nasal breathers. Thus, keeping the nasal passages clear is vital in a young, spontaneously breathing infant. When a child is supine, the prominent occiput causes flexion of the neck on the chest, thereby occluding the airway. The occlusion can be corrected by mild extension of the neck to the sniffing position. Overextension or hyperextension, acceptable for adults, causes obstruction and may kink the trachea, because the cartilaginous support is poor.

Positioning

The sniffing position can be maintained by placing a towel or other object beneath the shoulders. Despite good head position, a child's hypotonic mandibular tissues may still allow the relatively large tongue to occlude the airway posteriorly. This condition can be relieved by a chin lift or jaw thrust that elevates the mandible anteriorly and separates the tongue from the posterior pharyngeal wall. The jaw-thrust technique is preferred in a child with a possible cervical spine injury, because it minimizes the movement of the neck and allows maintenance of a neutral position of the cervical spine. If these maneuvers are unsuccessful, an oral airway or endotracheal tube should be considered.

PEDIATRIC CARDIOPULMONARY RESUSCITATION

William E. Hauda II

This chapter reviews CPR in children and pertinent differences from adults. One major difference between adult and pediatric cardiopulmonary arrest is etiology. The most common cause of primary cardiac arrest in adults is coronary artery disease. Children usually develop cardiac arrest secondary to respiratory arrest and shock syndromes.

TABLE 14-1 Guidelines for Pediatric Basic Life Support

Maneuver	Newborn	Infant <1 Year	Child 1-8 Years	Adult >8 Years
irway If trauma If foreign body	Head tilt/chin lift Jaw thrust Suction	Head tilt/chin lift Jaw thrust Back blows and chest thrusts	Head tilt/chin lift Jaw thrust Abdominal thrusts	Head tilt/chin lift Jaw thrust Abdominal thrusts

NASOPHARYNGEAL AIRWAY Nasopharyngeal airways tend to be less useful in children, because of the small nasal passages and the presence of hypertrophic adenoid tissue in the posterior nasopharynx, which is easily traumatized when inserting a nasopharyngeal airway.

ORAL AIRWAY Oral airways, which should be used only in unconscious children, are most useful in patients who require a continuous jaw thrust or chin lift to maintain airway patency. Oral airways are inserted with a tongue depressor to push the tongue down into the mandible so that the airway can be inserted under direct vision.

Intubation

Endotracheal intubation of infants and children is felt by many to be easier than the same procedure in adults. There are, however, some differences related to a child's anatomy and proper sizing of equipment. Pediatric airway management is discussed in detail in Chap. 15. A brief overview is provided here for perspective.

POSITIONING Hyperextension of the neck must be avoided by placing the child in the sniffing position before intubation. Also, the stretcher should be raised so that the child's head is at least at the level of the intubator's waist. All equipment should be located within easy reach of the team, including the bag-valve mask, oxygen source, monitoring equipment, and, perhaps most importantly, the suction device.

LARYNGOSCOPE BLADES For two reasons, the curved (Macintosh) blade is rarely used in children younger than 4 years. First, the relatively large and flaccid epiglottis is not effectively displaced by pulling on it indirectly from the vallecular space. Second, an exact-size blade must be used to fit the curvature of the tongue. For these reasons, a straight (Miller) blade is preferred. The straight blade is inserted in the midline with the tip underneath the epiglottis, such that the epiglottis is directly lifted up to allow tracheal visualization.

ENDOTRACHEAL TUBE Tracheal tube sizes vary with a patient's age. An often quoted rule is that the correct internal diameter tube size is approximately the same size as the end of the patient's little finger. However, this tenet has been disproved.^{6,7} The age-based formula, $(\text{age} + 16)/4$, remains a better predictor of correct endotracheal tube size for children. **Uncuffed tubes are used for children up to 7 or 8 years old** (tube size, 2.5 to 5.5 mm), because in children (unlike adults) the subglottic trachea is the narrowest spot of the trachea and forms an adequate seal around the endotracheal tube in this age group. In patients older than 8 years, the vocal cords become the narrowest part to the airway, and a cuff is needed to provide an adequate seal for positive pressure ventilation. One can almost always intubate with a laryngoscope blade that is too large and with a tube that is too small, but not vice-versa.

SECURING THE AIRWAY Once a child has been intubated, one person should be assigned to hold the endotracheal tube in place until it is securely fastened. Confirmation of endotracheal intubation is similar to that in adults: adequate chest rise, symmetric breath sounds, capnographic or capnometric readings,⁸ improved oxygenation, and clinical improvement.⁴ Because a young child has a small chest, listening to breath sounds in each axilla and over the stomach will minimize the chance of hearing sounds transmitted from the other lung.⁴ The tube should be taped to the upper lip and jaw, ideally from both sides of the face. Especially in small infants, small movements can easily displace the tube from the trachea into the esophagus. Tape or ties should not be wrapped around the head of a young child, because these can slide off the occiput and easily allow displacement of the tube. Mechanical ventilation is discussed in the section on Breathing, which follows.

Foreign-Body Management

There is controversy concerning the safest and most effective emergency maneuvers to use with a choking child. The American Heart Association specifically discourages two common maneuvers used with adult patients: (1) the Heimlich maneuver for patients younger than 1 year, because of the potential for injury to abdominal organs, and (2) blind finger sweeps, because of the possibility of pushing the foreign body farther into the airway.⁴ Serious differences of opinion exist, but current recommendations rely on the back blow and chest thrust to clear an infant's airway.

CONSCIOUS CHILDREN A child who is choking but is able to maintain some ventilation or vocalization should be allowed to clear the airway by coughing. Once a child cannot cough, vocalize, or breathe, a sequence of steps must be instituted immediately. Choking infants are treated with an alternating sequence of five back blows and five chest thrusts. With the infant's torso positioned prone and head down along the rescuer's arm, or the older child draped prone and head down across the rescuer's knees, five blows are delivered to the interscapular area. The infant is then repositioned supinely along the rescuer's arm, or the larger infant can be placed on the floor, as for external cardiac compression, and five chest thrusts (cardiac compressions) are delivered. This sequence is continued until the child's airway obstruction is relieved or the child becomes unconscious. In older children, the Heimlich maneuver is used, with the rescuer kneeling or standing behind the child. The clenched fist is placed at the level of the umbilicus, and firm upward thrusts are continued until the obstruction is cleared or the child becomes unconscious.

UNCONSCIOUS CHILDREN In all cases in which a child becomes unconscious with the rescuer present, the rescuer should first attempt ventilation, because the object may have become dislodged. If an obstruction is still present, then airway clearance maneuvers must be continued. For infants, the same sequence is used, but between each cycle of back blows and chest thrusts (the same technique as for CPR), an attempt at ventilation should be made. Before attempting a ventilation, the airway should be inspected to see whether an object is present. Only a visible object is removed; blind finger sweeps should be avoided. If the obstruction persists, the sequence is repeated. For children older than 1 year, chest compressions are performed with the child lying on its back. Future investigation may well lead to revised recommendations.

The foregoing recommendations are directed primarily at a first responder who has neither access to nor the skills to use airway management equipment. For unconscious children in emergency departments, direct laryngoscopy, visualization, and removal of the foreign body with McGill forceps should be attempted rapidly. Until this equipment is ready, basic life support techniques should be used.

BREATHING

Mouth to Mouth

Whether to use mouth-to-mouth or mouth-to-mouth-and-nose ventilation depends on the size of the patient. The rate of ventilation is shown in Table 14-1. Ventilations are done slowly to avoid the generation of high airway pressures, which can overcome esophageal resistance and result in gastric distention.

Bag-Valve Mask

The self-inflating bag-valve mask system is most commonly used for ventilation. Ventilation bags used for infants and children should have a minimum volume of 450 mL. There is a common misconception that

children are more susceptible to pneumothoraces at high inspiratory pressures. In fact, pediatric lung compliance is very good, and children can tolerate relatively high pressures. Pneumothoraces more commonly result from the administration of excessive tidal volume. The tidal volume necessary to ventilate children is the same as that for adults: 10 to 15 mL/kg. Because it is impractical to calculate the tidal volume in emergency situations, ventilation is started with the smallest volume that causes adequate chest rise. Careful monitoring of the rate of ventilation is crucial to avoid excessive hyperventilation, a very common mistake.

Mechanical Ventilation

If an endotracheal tube is placed, then mechanical ventilation should be instituted promptly. Determining appropriate initial settings for the mechanical ventilation of children can be difficult. For children weighing less than 10 kg, time-flow or pressure preset ventilators should be used. For time-flow ventilators, inspiratory and expiratory times are needed. Typical inspiratory times are 0.5 to 1 s, depending on ventilation frequency. For pressure ventilators, inflating pressures are determined by using pressures necessary to inflate the lungs and cause the chest to rise. Pressures usually range from 15 to 40 mm Hg. Excess pressures can cause barotrauma. For older children, volume ventilators can be used, starting with a tidal volume of 10 mL/kg, as for adults. If the lungs have normal compliance and the child does not require hyperventilation, then the respiratory rate should be started at half the normal rate for age (20 breaths/min for infants, 15 breaths/min for young children, and 10 breaths/min for older children and adolescents). Children should be adequately sedated and paralyzed during mechanical ventilation, until definitive care is started in a pediatric intensive care unit.

CIRCULATION

External Cardiac Compression

The brachial pulse is recommended for monitoring purposes for infants younger than 1 year. For older children, the femoral pulse is most easily accessible, but most guidelines recommend assessment of the carotid pulse by laypersons. Absence of pulse or poor perfusion, With a heart rate of 60 beats/min or slower, mandates external cardiac compression. Current standards advocate compressions over the lower sternum as opposed to the midsternum.⁵ The depth of compressions should be approximately one third the anteroposterior diameter of the chest to be effective. Patients should be placed on a hard surface to improve the effectiveness of compressions. To assess the adequacy of the compression depth and rate, the femoral or carotid artery should be palpated during compressions.

INFANTS The two-thumb technique is the recommended technique when two health care providers are present. Compressions should be at a rate of at least 100 per min. There should be a brief pause after five compressions to administer one ventilation. This ratio of 5:1 should be used whether there are one or two health care providers. If the patient is intubated, then compressions and ventilations may be performed without synchronization, but the rate of compressions should be maintained at 100 per min.

CHILDREN 1 TO 8 YEARS OLD The heel of one hand should be used to compress the lower half of the sternum. If unable to adequately depress the sternum with one hand, then the two-hand technique should be used. At least 100 compressions per min must be achieved. Compressions should be performed in a series of 5:1 with interposed ventilation, whether there are one or two health care providers. If the patient is intubated, then compressions and ventilations may be per-

formed without synchronization, but the rate of compressions should be maintained at 100 per min.

CHILDREN OLDER THAN 8 YEARS A significant change in the recent emergency care guidelines was the recommendation that children older than 8 years be treated similarly to adults with respect to basic life support. The two-hand technique of chest compressions should be performed. Compressions should be performed in sets of 15, with two interposed ventilations. If the patient is intubated, then compressions and ventilations may be performed without synchronization, but the rate of compressions should be maintained at 100 per min.

VASCULAR ACCESS

Difficulty in obtaining rapid IV access is certainly one of the major differences between adult and pediatric resuscitation (see Chap. 21). Two important facts should be kept in mind. First, a significant portion of children respond to airway management alone, because most cardiac arrests in children are secondary to hypoxia from respiratory arrest. Time spent securing vascular access at the expense of adequate airway management is a common mistake in dealing with children. Second, once a patient has been intubated, the tracheal route may be used to administer drugs, such as lidocaine, epinephrine, atropine, and naloxone (mnemonic: LEAN). The dose of endotracheal epinephrine for symptomatic bradycardia or pulseless cardiac arrest is 0.1 mg/kg, 1:1000 concentration, every 3 to 5 min. Although the ideal endotracheal doses for drugs other than epinephrine have never been studied in children, current recommendations support the use of two to three times the respective IV dose.⁴

Although central access would be ideal for administration of drugs during CPR, many emergency medicine practitioners are not highly skilled in placing central lines in children. Therefore, the most frequently used sites are peripheral: scalp, arm, hand, or antecubital veins; the external jugular vein; femoral vein; or distal saphenous vein via cutdown. Intraosseous infusion and fluid administration are quick, safe routes for resuscitation drugs (see Chap. 21). The general order of attempts during a resuscitation should be antecubital, hand or foot, and then intraosseous.

FLUIDS

In the face of hypotension due to volume depletion, isotonic fluid boluses of 20 mL/kg should be given as rapidly as possible and repeated, depending on response.⁴ A syringe attached to a three-way stopcock and extension tubing can be used to deliver aliquots of fluid rapidly, until the entire bolus is administered. Gravity or pressure bags should not be relied upon. The bolus should be delivered in a maximum of 20 min, and then the child's condition should be reassessed. If volume depletion has been corrected (at most, three to four boluses) and hypotension persists, a pressor agent should be strongly considered, preferably with the aid of a central venous catheter. In normotensive patients or when the IV line is being used for drug administration only, it should be maintained at the minimum rate that will keep the vein open. Fine fluid and electrolyte calculations and adjustments can be made af-

TABLE 14-2 Body Weight Estimation Guidelines

Age	Weight (kg)	
Terra infant	3.5	Birthweight
6 Months	7	2 X birthweight
1 Year	10	3 X birthweight
4 Years	16	i, Adult weight of 70 kg
10 Years	35	» Adult weight

ter the emergency treatment has been completed. Overhydration, even when IV lines are set to keep the vein open, is common when adult equipment is used in pediatric resuscitations. To enable easy monitoring of the total volume given and prevent accidental overhydration, a pediatric microdrip should always be used when resuscitating children.

PHARMACOLOGIC AGENTS

The indications for the use of specific drugs are essentially the same for children as for adults. Particular to pediatrics, however, is the problem of drug dosage. Proper dosage in children requires knowledge of the patient's weight (Table 14-2), knowledge of the dose (usually given in milligrams per kilogram), and error-free calculation and delivery. Problems may arise in remembering the correct dose, performing calculations in the crisis situation (a common error involves the misplacement of a decimal point and results in 10 times or one tenth the

correct dosage), and delivery of the correct dosage (because of an error in drawing up the correctly calculated amount). Use of a chart with precalculated drug doses can help reduce dosage errors (Tables 14-3 and 14-4). However, estimating a child's weight accurately so that the proper dosage can be determined from the table is not easy, especially in a crisis situation. Choosing the proper-size equipment for pediatric patients is similarly difficult. Valuable time can be lost in weight estimation, dosage calculations, and equipment selection.

Systems based on a direct measurement of a patient's length recently have been developed for estimating dosages and selecting equipment in pediatric emergencies (Table 14-5).⁹ In children, length has a direct correlation with weight. Length also has been shown to be one of the most accurate predictors of correct equipment sizes for pediatric patients, especially endotracheal tube sizes. The use of a length-based system is currently included in the American Heart Association's Pediatric Advanced Life Support Course. These systems use a

TABLE 14-3 Drugs Commonly Used in Pediatric Resuscitation

Drug	Pediatric Dosage	Remarks
Adenosine	IV: 0.1-0.2 mg/kg, followed by 2-5 mL NS bolus Double dose and repeat X 1 if needed	Maximum single dose: 12 mg
Amiodarone	IV: 5 mg/kg over 20-60 min; then 5-15 µg/kg per min infusion	Maximum bolus repetition to 15 mg/kg per d. Use lowest effective dose. Bolus may be given more rapidly in shock states.
Atropine	IV: 0.02 mg/kg of 1:10,000 (0.1 mg/mL), repeat in 5 min (minimum single dose is 0.1 mg) ET: double IV dose and dilute with NS to 3-5 mL	Maximum single dose: 0.5 mg (child) and 1.0 mg (adolescent)
Bretylium	IV: 5 mg/kg, may be increased to 10 mg/kg	Maximum cumulative dose: 1.0 mg (child) and 2.0 mg (adolescent) Rapid IV Dosage in pediatric patients not well defined
Calcium chloride (10%)	20 mg/kg	6 x weight in kg = mg of drug to add to a diluent to make a final volume of 100 mL. 1 mL/h = 1 µg/kg per min Slow push
Dopamine infusion	IV: 2.0-20 µg/kg per min titrate to desired effect Renal dose (dopaminergic effects): IV: 2-5 µg/kg per min infusion Cardiac dose (Pi effects) IV: 5-10 (xg/kg per min infusion Vasopressor dose (a effects): IV: 10-20 (Jig/kg per min infusion	
Dobutamine infusion	IV: 2.0-20 n.g/kg per min, titrate to desired effect	6 X weight in kg = mg of drug to add to a diluent to make a final volume of 100 mL. 1 mL/h = 1 j.g/kg per min
Epinephrine	Brady cardia: IV/IO: 0.01 mg/kg (0.1 mL/kg of 1:10,000) ET: 0.1 mg/kg (0.1 mL/kg of 1:1000) Pulseless arrest: First dose: IV/IO: 0.01 mg/kg (0.1 mL/kg of 1:10,000) ET: 0.1 mg/kg (0.1 mL/kg of 1:1000) Second dose: IV/IO/ET: 0.1 mg/kg (0.1 mL/kg of 1:1000) q3 min IV: 0.1-1.0 µg/kg per min	Unlike other agents, epinephrine per ET tube is 10 times the IV dose. Follow ET dose with several positive pressure ventilations.
Epinephrine infusion		0.6 X weight in kg = mg of drug to add to a diluent to make a final volume of 100 mL. 1.0 mL/h = 0.1 (J-g/kg per min
Lidocaine	IV: 1.0 mg/kg bolus ET: double IV dose and dilute with NS to 3-5 mL	
Lidocaine infusion	IV: 20-50 fjug/kg per min	60 X weight in kg = mg of drug to add to a diluent to make a final volume of 100 mL. 1 mL/h = 10 µg/kg per min
Naloxone	If <5 y or £20 kg: 0.1 mg/kg If >5 y and >20 kg: 2.0 mg	Titrate to desired effect
Nitroprusside infusion	IV/IO: 1-8 jxg/kg per min	6 X weight in kg = mg of drug to add to a diluent to make a final volume of 100 mL. 1 mL/h = 1 n.g/kg per min
Norepinephrine infusion	IV/IO: 0.1-2 µg/kg per min	0.6 X weight in kg = mg of drug to add to a diluent to make a final volume of 100 mL. 1 mL/h = 0.1 (j-g/kg per min
Sodium bicarbonate	IV/IO: 1 mEq/kg(1 mEq/mL)	Infuse slowly and use only if ventilation is adequate.

Abbreviations: ET = endotracheally; IO = intraosseously; NS = normal saline.

TABLE 14-4 Calculation Dosage of Medications Delivered by Constant Infusion Using the Rule of 6 for

Drug	Continuous Infusion Dose	Conversion Factor	Delivery
Epinephrine dose	0.1-1.0 (JLg/kg per min	0.6 mg X wt (kg)	1 mL/h = 0.1 M-g/kg per min
Dobutamine dose	5-20 xg/kg per min	6 mg X wt (kg)	1 mL/h = 1.0 p-g/kg per min
Dopamine	5-20 p-g/kg per min	6 mg X wt (kg)	1 mL/h = 1.0 ig/kg per min
Lidocaine	20-50 xg/kg per min	60 mg X wt (kg)	1 mL/h = 0.1 fig/kg per min
Isoproterenol	0.1-1.0 (JLg/kg per min	0.6 mg X wt (kg)	1 mL/h = 10 j.g/kg per min

Dosage of medications delivered by constant infusions is calculated in terms of micrograms per kilogram per minute. Actual calculation can be confusing and a source of lethal decimal errors. The *rule of 6* can be used for *dopamine* and *dobutamine* to simplify dosage calculation:

$$6 \text{ mg X wt (kg), fill to 100 mL with D5W}$$

The medication is mixed in an intravenous set with a measured chamber and a microdrip (1 drop/min = 1 mL/h). Rate of administration is best set by an electric pump.

Example: For a 10-kg infant requiring dopamine:

$$6 \text{ mg X } 10 = 60 \text{ mg dopamine}$$

In a measured chamber/; to 100 mL with D5W. Weight is now factored in so that

$$\begin{aligned} 1 \text{ mL/h} &= 1 \text{ jJig/kg per min} \\ 5 \text{ mL/h} &= 5 \text{ |J.g/kg per min} \\ 10 \text{ mL/h} &= 10 \text{ (Ag/kg per min} \end{aligned}$$

For *epinephrine* and *isoproterenol*, the rule of 6 is:

$$\begin{aligned} 0.6 \text{ mg x wt (kg), fill to 100 mL with D5W} \\ 1 \text{ mL/h} &= 0.1 \text{ (j-g/kg per min} \\ &= 0.5 \text{ (xg/kg per min} \end{aligned}$$

Abbreviation: D5W = 5% dextrose in water.

tape to assist in making appropriate selections. Most tapes are two sided and display emergency resuscitation drug dosage and equipment selection based on length (Figures 14-1 to 14-3). Fluid volumes for resuscitation and appropriate basic life support techniques are often also displayed. To make optimal use of these systems, emergency personnel must be able to find the proper equipment rapidly. Equipment can

be stored on shelves or in drawers labeled by age and weight, or a system of color codes can be used in which color-coded shelves, carts, or equipment organizers correspond to specific length categories.

The pharmacology of resuscitation drugs has been well described in other chapters (see Chap. 29), but a few peculiarities pertain to pediatric resuscitation drug use.

FIG. 14-1. The Broselow resuscitation tape.

Epinephrine

Epinephrine is the one drug proven beneficial in cases of cardiac arrest. It is specifically indicated for hypoxia- or ischemia-induced slow rates that fail to respond to adequate oxygenation and ventilation and for pulseless arrest situations (i.e., asystole, pulseless electrical activity, and ventricular fibrillation). If the initial dose of epinephrine is not effective, subsequent doses should be given at the same dose, although larger doses can be considered. The use of high-dose epinephrine 0.1 mg/kg of the 1:1000 concentration for resuscitation in infants and children has not been associated with increased survival rate in any controlled prospective studies. The American Heart Association currently recommends that subsequent doses of epinephrine be at the standard dose.⁴ High-dose epinephrine may be useful in catecholamine-resistant states, such as anaphylaxis, α - or β -blocker overdose, or severe sepsis. Adverse effects associated with the use of high-dose epinephrine in the clinical setting include intracranial hypertension, myocardial hemorrhage, and myocardial necrosis.⁵

Epinephrine, rather than dopamine, is the vasopressor infusion of choice in children (see Table 14-4), because dopamine requires release of endogenous norepinephrine. In children with cardiac arrest, norepinephrine stores may be low.

Amiodarone

Amiodarone has been added to the most recent guidelines for pediatric cardiopulmonary resuscitation to treat atrial and ventricular arrhythmias. The pharmacology of amiodarone is complex; the inhibition of a variety of receptor and ion channels explains the utility of amiodarone in a range of arrhythmias. Dosage for pediatric patients is 5 mg/kg over 20 to 60 min and may be repeated to a maximum of 15 mg/kg per d. Amiodarone is a potent vasodilator and a potential pro-arrhythmic agent. However, in shock-resistant ventricular tachycardia or ventricular fibrillation, the dose should be given rapidly.

Atropine

Although primary cardiac causes of slow rates are rare in the pediatric population, atropine is recommended for pharmacologic treatment of slow rates after adequate oxygenation and ventilation. The recommended dose of atropine is 0.02 mg/kg IV. The minimum dose is 0.1 mg, with maximum single doses of 0.5 mg for children and 1.0 mg for adolescents. The dose may be repeated once, with maximum total doses of 1.0 mg for children and 2.0 mg for adolescents. There is no particular proscription against additional doses, but the maximum dose is considered fully vagolytic. If no response to atropine is seen, then dosing beyond the vagolytic amount is unlikely to be effective. If an effect is seen but not maintained, additional doses should be considered.

Sodium Bicarbonate

Sodium bicarbonate is a recommended drug in only limited situations, because it worsens acidosis when administered in the presence of inadequate ventilation and perfusion. Because other resuscitation drugs are less effective in the face of severe acidosis, sodium bicarbonate may be a useful agent in prolonged resuscitations. An initial dose of 1 mEq/kg IV is given only after the airway has been secured, the patient is adequately ventilated, and CPR is initiated. In neonates or premature infants, sodium bicarbonate should be diluted 1:1 with sterile water, not with saline. Indications for bicarbonate include hyperkalemia, sodium channel blocker toxicity, and severe metabolic acidosis with adequate ventilation.

Calcium

Because of lack of proven efficacy and because of possible deleterious effects, routine calcium administration is not recommended during resuscitation. Calcium should be used for documented and symptomatic hyperkalemia, hypocalcemia, and calcium channel blocker overdose. Calcium may be given as calcium chloride 20 mg/kg (0.2 mL/kg of a 10 percent solution), or calcium gluconate 60 to 100 mg/kg (0.6 to 1.0 mL/kg of a 10 percent solution) via the IV or intraosseous route.

The Rule of 6

Often there is great confusion when attempting to calculate the dose of a medication to be delivered by constant infusion. The *rule of 6* can be used to avoid mistakes (see Table 14-4), although there are limitations to using this technique in the older child. Length-based resuscitation aids or other resuscitation references should be used to assist with calculating infusion rates.

DYSRHYTHMIAS

Dysrhythmia management plays only a small role in the resuscitation of children. Because rhythm disturbances are usually secondary to hypoxia and not primary cardiac events, careful attention must be given to the correction of hypoxia, acidosis, and fluid balance. Ventilation and oxygenation must be accomplished first. Pulse oximetry, or arterial blood gas analysis, should be performed to assess oxygen and blood gas status. An IV of NS or LR solution should be established, and the child should be placed on a cardiac monitor.

A patient with an abnormal cardiac rhythm or rate, coupled with evidence of poor end-organ perfusion (cyanosis, mottled skin, lethargy, etc.), has an unstable cardiac rhythm and requires immediate intervention. The parameters of clinical assessment and expression of instability vary with a child's age. In neonates, blood pressure measurement is difficult, and a heart rate of 80 beats/min or slower, coupled with evidence of poor end-organ perfusion, requires immediate intervention. In infants and children, variations in heart rate may be well tolerated clinically, and a blood pressure of 70 plus (age in years) divided by 2 mm Hg or less, coupled with evidence of poor end-organ perfusion, is used to define instability. Figures 14-4, 14-5, and 14-6 summarize electrical and drug therapies of unstable cardiac rhythms in children.

The most common rhythms seen in pediatric arrest are the bradycardias, which lead to asystole if untreated. Treatment consists of maximizing oxygenation and ventilation. Chest compression should be started in children with a heart rate slower than 60 beats/min and signs of poor perfusion.

Paroxysmal atrial tachycardia (supraventricular tachycardia, or SVT) is seen most commonly in infants and most often presents as a narrow complex tachycardia with rates usually between 250 and 350 beats/min. Treatment of unstable patients consists of rapid synchronized cardioversion. Treatment of stable patients varies. Adenosine, vagal maneuvers, or cardioversion are used to treat stable SVT. Adenosine (0.1 mg/kg) is the current recommended drug for SVT in children. This dose can be doubled if the first dose is unsuccessful.

Differentiating a rapid secondary sinus tachycardia from a rapid primary cardiac tachycardia can be difficult. Although heart rates of 150 to

200 beats/min in adults are usually cardiac in origin, young children not uncommonly have compensatory sinus tachycardias as fast as 200 to 220 beats/min, especially small infants. Children can tolerate rapid primary cardiac heart rates for long periods before congestive heart failure or lethal dysrhythmias develop. Differentiating primary from secondary tachycardia is critical to patient management. However, an electrocardiogram may not be very helpful, because, at very fast rates, in sinus tachycardia or SVT, identifiable P waves may not be readily apparent. Historical features pointing to volume loss likely suggest sinus tachycardia. Evidence of congestive heart failure more likely is associated with a pathologic rhythm than a compensatory sinus tachycardia.

CARDIOVERSION, DEFIBRILLATION, AND PACING

Electric conversion is used on an emergency basis to treat ventricular fibrillation (defibrillation) and symptomatic tachydysrhythmia (cardioversion). Ventricular fibrillation as a cause of cardiac arrest is rare in children and even more rare in infants.

Paddle Size

Paddle size is usually 4.5 cm for infants (who weigh less than 10 kg) and 8 cm for children. The paddle should be in contact with the chest wall over its entire surface area. The larger 8-cm paddles can be used for infants in the anteroposterior position.

Interface

Electrode cream, electrode paste, and saline-soaked gauze pads are acceptable. Alcohol pads are to be discouraged, because serious burns may be produced. Care must be taken so that the interface substance from one paddle does not come in contact with the substance from the other paddle. This creates a short circuit, and insufficient energy may be delivered to the heart.

Electrode Position

One paddle is placed on the right of the sternum at the second intercostal space. The other is placed on the left midclavicular line at the level of the xiphoid. The anteroposterior approach also can be used.⁴

Defibrillation

Initially, 2 J/kg should be used. If that is unsuccessful, the amount should be doubled and performed twice at the higher energy level, if necessary. If the three attempts are unsuccessful, epinephrine should be given at the standard dose. The oxygenation and ventilation of the child should be maximized for 1 to 2 min before repeating a defibrillation attempt at the higher setting.

Cardioversion

Tachydysrhythmias are generally very sensitive to electric conversion. The initial dose is 0.5 J/kg. The energy level is doubled if the first attempt is unsuccessful. If the device has only a few energy settings available, the one closest to the desired energy setting is chosen. All tachydysrhythmias should be treated with synchronized cardioversion. If synchronization is not possible (i.e., if the device cannot identify the QRS), then the defibrillator is used in the unsynchronized mode.

Transcutaneous Pacing

Children with a severe bradycardia or asystole may respond to pacing. Because transvenous pacing requires central venous access with large tubing and proficient skill in placing the pacing electrodes, most emergency practitioners and prehospital providers should attempt only transcutaneous pacing. Adult patches should be used in children who

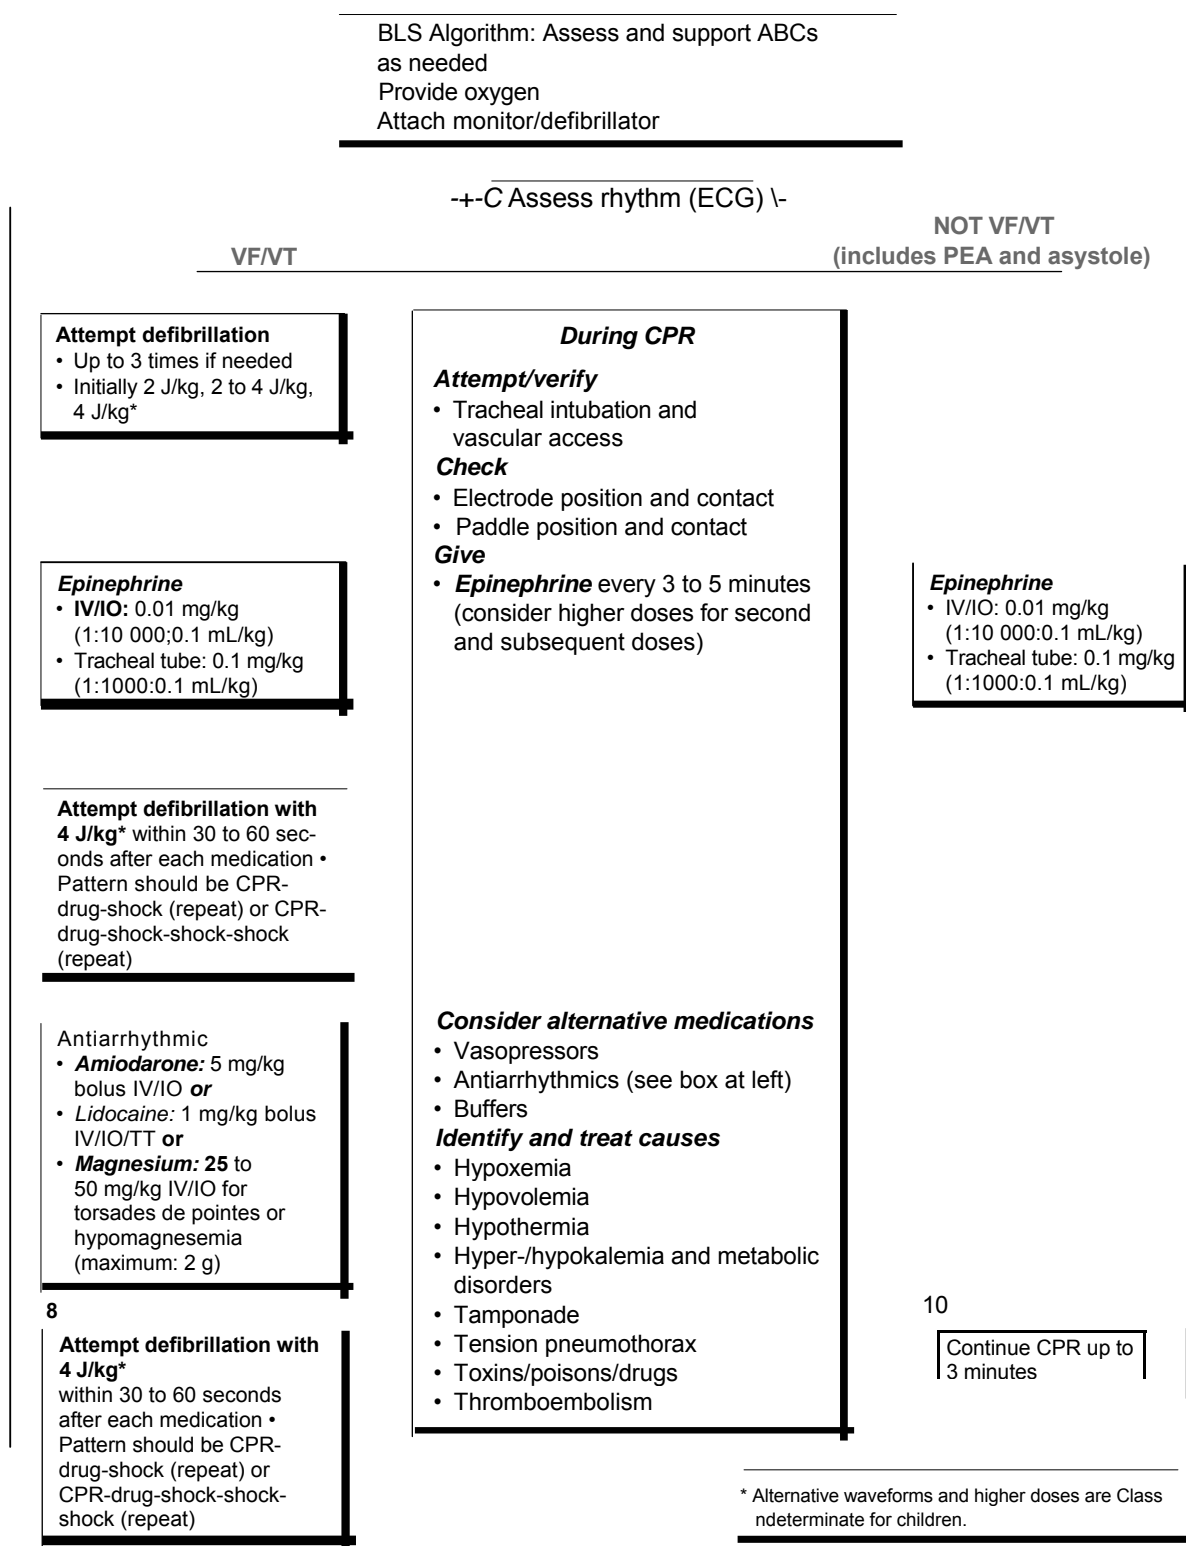

FIG. 14-4. Pediatric pulseless arrest decision tree. ET = endotracheal; IO = intraosseous; IV = intravenous. (Reproduced with permission from *Pediatric Advanced Life Support Instructors Manual*. American Heart Association, 2001.)

weigh more than 15 kg.¹⁰ The negative electrode patch should be placed on the anterior chest at V3, and the positive electrode patch is placed on the posterior chest between the shoulder blades at the T4 vertebral level. Ventricular capture is determined by the palpation of a pulse or the appearance of an arterial waveform, if an arterial pressure

catheter is present. Maximal energy output is used first. If ventricular capture occurs, then the energy setting is decreased progressively until the lowest setting is found that allows ventricular capture. The pacing rate should be set at a rate slightly higher than the normal rate for age. Transcutaneous pacing has not been associated with greatly

improved survival rates, but it can be lifesaving if applied quickly in a child with sudden asystole or bradycardia.

Automated External Defibrillators

A recent change to the American Heart Association guidelines includes the use of an automated external defibrillator (AED) in pedi-

atric patients. Because children 8 years and older may have life-threatening arrhythmias similar to adults and because their body weights approach those of adults, an AED may be used successfully in a pediatric resuscitation. Few AEDs allow changing the cardioversion energy levels, so infants and young children may receive a dose that is too high. A child older than 8 years and weighing more than 25 kg who suffers a sudden collapse should have an AED applied as soon as pos-

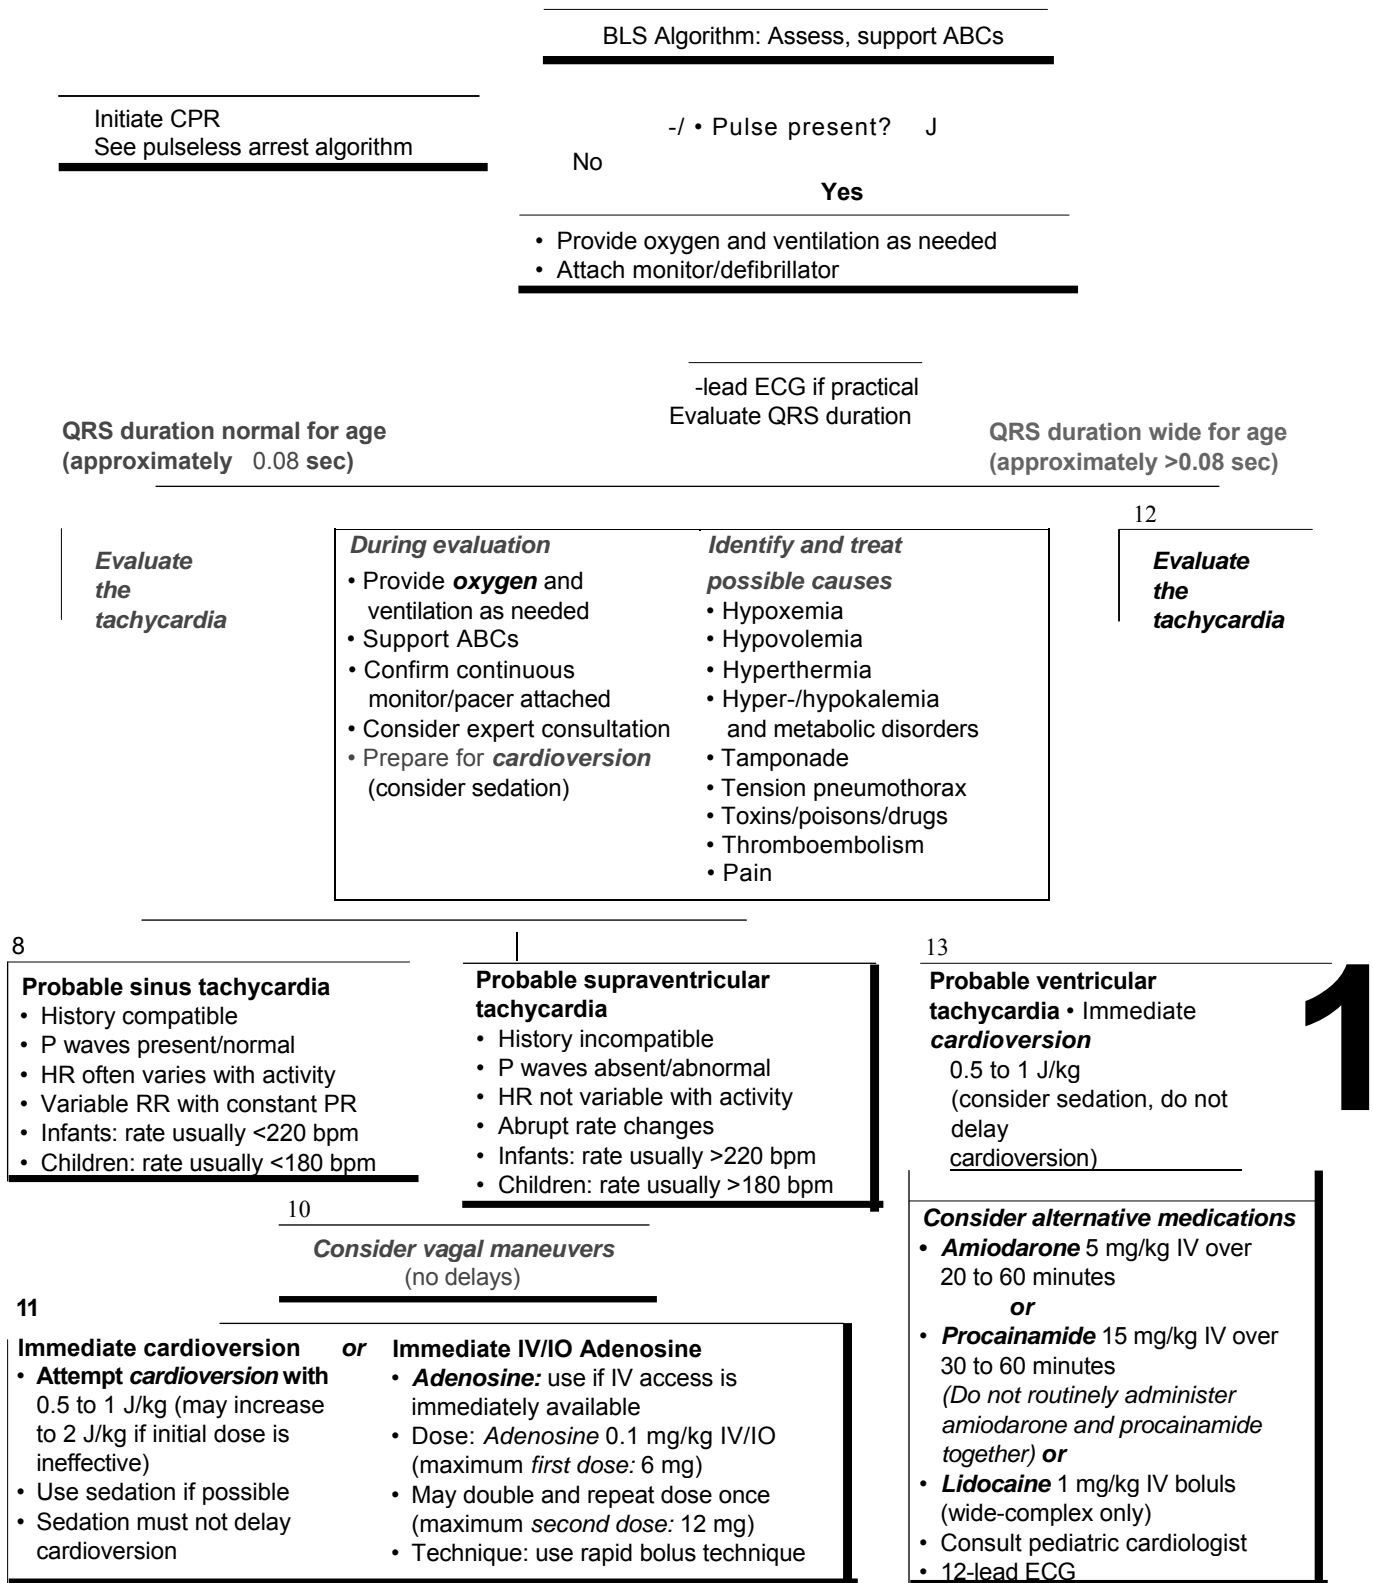

FIG. 14-6. Pediatric tachycardia decision tree for infants and children with rapid rhythm and poor perfusion. ET = endotracheal; IO = intraosseous; IV = intravenous. (Reproduced with permission from *Pediatric Advanced Life Support Instructors Manual*. American Heart Association, 2001.)

sible (class lib recommendation). Should the AED not recommend defibrillation, then CPR should be initiated. The AED should remain applied until other means of cardiac monitoring become available to the health care provider.

TERMINATION OF EFFORTS

Pediatric cardiopulmonary arrest longer than 20 min or with no response to two doses of epinephrine has been associated with a dismal outcome.¹ **Resuscitation should be continued until a core temperature of 30°C is reached, if cardiac electrical activity is present in a child with hypothermia.**

COPING WITH THE DEATH OF A CHILD

Family members and member of the resuscitation team will mourn the death of a child. Little attention has been focused on this issue for the family or the ED staff. Several *tasks of mourning* have been described that must occur for successful resolution of grieving (Table 14-6).¹¹ Whether a child dies in the emergency department or after several days of hospitalization does not seem to affect the grieving process.¹² Pathologic grief reactions are often the result of fear that the child will be forgotten. Excessive focus of time, energy, and effort is spent on remembering the child without resolving the grief. Sharing feelings and memories about the child is crucial; persons who do not allow parents to express their feelings may mar the grieving process.¹²

Physicians and other health care providers can shape the way families remember the death of a child. Guidelines for communicating with parents are listed in Table 14-7.¹² Parents remember how compassionately the bad news is given, but most families still want the "bottom line" when they are first told of their child's death. They are waiting for it. Saying "I am very sorry, we did everything we could, but Sally died" is compassionate and direct. Most families do not want all the technical details about the resuscitation efforts. After delivering the bad news, have a chaplain or social worker stay with the family to allow the family time to deal initially with the shocking news. The physician should remain quietly in the room or return after a few minutes (or later, if other duties require) to answer questions. This is also the time to ask whether the family would like to see the child and to prepare them for what they will see. This is also the time to inquire about organ or tissue donation, if a regional transplant consortium does not provide this service already. Although parents do not regret organ donation, donation is not associated with a higher likelihood of successful grieving.¹²

Many hospitals have policies requiring that family wait outside the area where resuscitation efforts are being conducted, but family presence during resuscitation efforts is increasing in popularity. Positive and negative family responses can occur during resuscitation.¹³ Family presence during the resuscitative effort may enable family members to begin appropriate grieving earlier. No studies have shown beneficial long-term effects on family grieving by allowing family presence during the resuscitation, however. Some family members may become distressed or exceedingly emotional while care is being given to a loved one. Worries by emergency department staff members about the family's critiques of the resuscitation or the family's unwillingness to terminate efforts contribute to the desire not to have the family present during resuscitation. However, the desire to have family members present during a resuscitation is a holistic approach to patient care, with the family's and the patient's needs addressed simultaneously. In general, the resistance of emergency department staff members to the

PEDIATRIC AIRWAY MANAGEMENT
Marcie Rubin Nicholas Sadovnikoff
NORMAL PEDIATRIC AIRWAY ANATOMY

The normal airway of a pediatric patient has important anatomic differences from that of the adult. These differences are most apparent in infants and become relatively insignificant by age 8 years. Differences include the size of the occiput and the tongue in the infant, the high position of the larynx, the configuration of the larynx, and the position of the vocal cords.

The infant has a large occiput. Positioning of the head to obtain the optimum orientation for laryngoscopy, or the "sniffing position," is accomplished simply by rotating the head so that it rests on the occiput. Elevating the head with padding can lead to excessive flexion of the neck and may contribute to upper airway obstruction and difficulty during intubation. The infant's tongue is also relatively large, and this can impair laryngoscopy and contribute to upper airway obstruction. An infant's larynx is higher in the neck, located at the C3 level, than

that of an adult, which is found at the C4 to C5 level. The larynx also has a funnel shape in infants, with the narrowest portion at the subglottic area, rather than at the level of the vocal cords, as in an adult. Hence, in infants and small children, an endotracheal tube that passes easily through the vocal cords may encounter resistance more distally. In addition, infants' vocal cords are slanted anteriorly rather than being perpendicular to the trachea, as in an adult, and this characteristic, too, can result in more difficult visualization and intubation in the pediatric population.¹

ABNORMAL PEDIATRIC AIRWAYS

Congenital

Numerous airway anomalies may be present at birth or develop over the first several months of life. Although they rarely lead to the need for emergent airway control, their presence will complicate management of other emergencies requiring intubation.

Choanal atresia is the most common congenital anomaly of the nose. It may be unilateral or bilateral. Infants with this condition may not have difficulty breathing at birth if they can breathe PO, but they often present several months after birth when there is a concurrent problem, such as an upper respiratory infection. Maintaining an oral or tracheal airway overcomes the obstruction. ED treatment is placement of oral airway, tube feedings, and admission for surgical repair.

Cystic hygroma is a benign congenital tumor of lymphatic origin. About 60 percent appear within the first year of life, and 80 to 90 percent occur before the second year. Cystic hygroma usually occurs in the neck or tongue but may also be found in the mediastinum. Progressive growth can lead to compromise of the structures of the pharynx and trachea, leading to airway obstruction and impairing or preventing laryngoscopy. The treatment is surgical resection.²

There are five types of tracheoesophageal fistulas, the most common defect consisting of a blind upper esophageal pouch and a fistula between the lower esophagus and the trachea. The diagnosis is usually made soon after birth, when an infant becomes cyanotic and starts coughing after feeding or when a catheter cannot be passed into the stomach. Although most patients present soon after birth, a few with tracheoesophageal fistula with esophageal atresia present some time after discharge with pneumonia and cyanosis with feeding. Placement of the endotracheal tube in patients with tracheoesophageal fistula is crucial to avoid gastric insufflation and resultant aspiration. The tube should be above the carina but below the fistula. This is often achieved by intubation of the right mainstem bronchus and then pulling back until breath sounds are heard bilaterally.

The common congenital syndrome of trisomy 21 (Down syndrome) may present significant difficulties in airway management. Characteristic of these patients is a short neck, small mouth, narrow nasopharynx, and large tongue; moreover, approximately 20 percent have asymptomatic dislocation of the atlas on the axis.³ All potential difficulties must be considered before initiating intubation. Many congenital syndromes include airway abnormalities (Table 15-1). In controlled settings, management is preceded by careful evaluation and planning. Unfortunately, in the ED, this is rarely possible, and thus the approach to airway management must be mastered in all facets by those whose practice, even infrequently, involves pediatrics.

Acquired

Acquired abnormalities in pediatric airways can be subdivided into acute and chronic. Acute obstruction can result from foreign-body aspiration, infection such as laryngotracheobronchitis or epiglottitis, subglottic edema secondary to previous intubation or allergy, or internal or external airway trauma. Chronic obstruction can result from subglottic stenosis (posttraumatic or postsurgical), tumor, or abscess formation.

Note: If patient has history of significant airway obstruction or apnea, premedication is best avoided or used with extreme caution.

The management of an infant or child with airway obstruction depends on the use of a safe, calculated approach to securing the airway. Such an approach requires a systematic evaluation of the pediatric airway, familiarity with pediatric airway equipment and pharmacologic agents, and recognition of a difficult airway and its appropriate management.

EVALUATION OF A PEDIATRIC AIRWAY

The first step in evaluating a pediatric airway is a directed history and physical examination. The time course of the present episode should be determined, as should a history of any recent fever, cough, or sore throat. Any history of previous airway problems should be elicited. If time permits, the history should include a review of the antenatal and perinatal periods, with an emphasis on feeding or sleeping difficulties. Any history of snoring or noisy breathing, recurrent croup or upper respiratory infections, or cyanosis or coughing during feedings should alert the clinician to the possibility of an abnormal airway.

The physical examination of a pediatric patient may be hindered by lack of cooperation, and care should be taken not to frighten the child. Visual signs of possible airway compromise include tachypnea, cyanosis, drooling, nasal flaring, and intercostal retractions. The child may assume a "tripod" position to enhance the use of accessory respiratory muscles. Auscultation may reveal stridor, wheezing, or grunting. Any change in the child's mental status, including agitation or somnolence, may further indicate airway difficulties. As in adults, features suggesting potentially difficult intubation include a small or recessed mandible, a prominent tongue, prominent upper incisors, and impairment of neck mobility.

Pediatric patients often have a period of compensated respiratory compromise before an arrest.⁴ Pulse oximetric measurements should be monitored continuously, but adequate oxygen saturation should not be considered assurance of respiratory stability, because this measurement may not reflect declining ventilatory performance. All patients with potential airway compromise require attentive observation and frequent examination.

PEDIATRIC AIRWAY EQUIPMENT

Oropharyngeal and Nasopharyngeal Airways

Oropharyngeal airways are easy to use and available for pediatric patients of all ages. An oral airway should extend from the corner of the mouth to just cephalad to the angle of the mandible. To estimate the

correct size, the airway can be placed next to the face. The oral airway should not be used in a conscious child, because it may induce vomiting. The nasopharyngeal airway can be used in awake or semicomatose patients. The proper length is estimated by measuring the distance from the tip of the nose to the tragus of the ear. Complications include damage to adenoid tissue, epistaxis, and laryngospasm. Because the diameters of the nasal airways are so small in the pediatric population, they easily may become obstructed with blood, mucus, or vomitus and thus require frequent suctioning.

Bag-Valve-Mask Devices

The ideal pediatric mask should provide an airtight seal between the mask and the patient's face. A poor mask fit results in gas leaks, inability to maintain positive pressure, and potential compromise to ventilation and oxygenation. Child-size and adult-size self-inflating bags (Ambu, Inc., Linthicum, MD) may be used for the entire range of infants and children. Maximum oxygen delivery occurs at an oxygen flow of 15 L/min.¹

Laryngoscope Blades

Two types of blades are most commonly available in emergency departments for pediatric intubation: curved (Macintosh) and straight (Miller). The tip of the Macintosh blade is inserted into the vallecula anterior to the epiglottis, and, as the blade is lifted, the epiglottis is elevated passively beneath the blade tip to expose the glottic opening. The tip of the Miller blade is placed beneath the epiglottis, which is directly elevated as the blade is lifted. A straight blade is superior to a curved blade in children younger than 2 years. Table 15-2 presents a guide for laryngoscope selection in pediatric patients.

Endotracheal Tubes

There are numerous methods for selecting the correct endotracheal tube size for a given pediatric patient, including age, height, weight, and diameter of the fifth digit. Endotracheal tube size for premature and full-term infants usually is selected by weight, because, given the rapid growth during this period, age formulas become invalid. The rule usually employed is a 2.5-mm tube below 1.5 kg of body weight, a 3.0-mm tube between 1.5 and 2.5 kg, and a 3.5-mm tube above 2.5 kg. The most commonly used formula for age determination of endotracheal tube size in children older than 1 year is: tube size (in millimeters) = 4 + age (in years)/4.⁵ However, single-formula methods based on age have been shown to lead frequently to inappropriate tube selection.⁶ Resuscitation measuring tapes have been found to be more accurate than age-based formulas, which in turn are superior to the diameter of the fifth digit.^{7,8}

The tube should fit sufficiently snugly to prevent any leakage at pressures up to 10 cm H₂O but should leak at a pressure lower than

30 cm H₂O. An insufficiently snug fit will result in difficulty ventilating, compromised airway protection, and leakage of inhalational agents if the patient undergoes anesthesia. An overly tight-fitting tube risks endotracheal injury, with the potential for development of subglottic stenosis due to the anatomic reasons noted above. For the same reason, **cuffed tubes are generally avoided in patients 8 years and younger**. Clearly, in the care of an unstable patient in the emergency department, a suboptimal tube that provides adequate ventilation is preferable to no airway at all, and exchange for a more appropriate tube can be deferred until the patient has been stabilized.

The ideal depth of placement is midway between the glottis and the carina. Because of substantial variability in tracheal length, especially before the age of 1 year, formulas predicting the distance to the lips are unreliable. Because most pediatric tubes have a series of marks at the distal end, one technique is to simply advance the tube so that the second mark is just past the vocal cords. This results in a conservatively high tube that will not risk bronchial intubation. However, inadvertent dislodgement of the tube with head and neck manipulation may occur. A second technique is to initially and deliberately perform a bronchial intubation by advancing the tube until breath sounds are heard only unilaterally and then to back the tube up to a point 1 cm above where the breath sounds are again heard bilaterally. This method results in a conservatively low tube, but with little risk of inadvertent displacement out of the airway.

Laryngeal Mask Airway

The laryngeal mask airway (LMA) has been used widely in the pediatric population.⁹ It has been found to be extremely useful in the management of difficult airways. It consists of a large-bore tube terminating in an ovoid, fenestrated cup with an inflatable rim that, when properly placed, forms a seal over the laryngeal orifice (see Figure 18-6). The result is an airway that is superior to a face mask in that it prevents supraglottic obstruction and greatly reduces the likelihood of gastric insufflation, but it is less reliable at preventing aspiration than an endotracheal tube. Because it is placed blindly, it avoids the complications of endotracheal intubation that arise from the need to visualize and penetrate the glottic opening. It provides a useful rescue device in the event of a failed endotracheal intubation. Once in place, it can be used as a conduit for fiberoptically guided endotracheal intubation. Its applications and experience with its use continue to expand, and emergency physicians should be familiar with its insertion. Laryngeal mask airways can be sized from neonates to adults. Table 15-3 presents a guideline of sizes according to weight.

RAPID SEQUENCE INTUBATION OF THE PEDIATRIC PATIENT

Rapid sequence intubation (RSI) is the nearly simultaneous administration of a potent intravenous anesthetic agent and a neuromuscular blocking agent to facilitate endotracheal intubation. The process involves

TABLE 15-2 Laryngoscope Blade Selection for Pediatric Patients

preparation, preoxygenation, application of cricoid pressure (Sellick maneuver), induction of anesthesia, neuromuscular blockade, and intubation without attempting mask ventilation. Although some remain advocates of other airway management methods, this technique provides unsurpassed airway access and minimizes complications. Its use in critically ill children is well described, and it is regarded as the first choice in the absence of contraindications (see below).^{10,11}

Preparation

Before undertaking an RSI, all necessary tools and materials should be prepared. A well-functioning intravenous line must be in place, and all drugs to be used for the RSI should be predrawn in syringes and labeled. Laryngoscopes with blades of the appropriate sizes, with lights checked and working, should be within reach, as should suction equipment and a bag-mask-ventilation apparatus connected to oxygen. Any materials for rescue maneuvers after failed intubation, such as LMAs, jet ventilation devices, and cricothyrotomy trays, should be immediately available. An endotracheal tube of the estimated size should be styletted, with tubes a size larger and a size smaller present. At least one additional experienced provider should be present to apply cricoid pressure and provide assistance as needed. **Continuous pulse oximetric monitoring and an exhaled CO₂ detection device are strongly recommended.**

Preoxygenation

Due to their relatively high oxygen consumption, smaller children, and especially infants, undergo rapid desaturation with cessation of ventilation, even with normal lungs. Once drugs have been administered in RSI, patients rapidly become apneic. Positive pressure mask ventilation is not performed at this point due to the risk of gastric insufflation and resultant regurgitation. Therefore, it is important to maximize the length of time that adequate saturation is maintained by maximizing the reservoir of oxygen in the lungs. The lung volume remaining at end-expiration, or functional residual capacity, contains less than 20 percent oxygen in a patient breathing room air, with nearly 80 percent occupied by nitrogen. Preoxygenation is effectively denitrogenation of functional residual capacity, and it increases by roughly fivefold the oxygen reservoir in the lungs once apnea occurs. Effective denitrogenation is ideally accomplished by having a patient breathe 100 percent oxygen from a tight-fitting mask for 2 min or for four vital capacity breaths. Often this is not possible with a critically ill pediatric patient, but as long a period of preoxygenation as circumstances permit should be provided before RSI.

Premedication

Atropine should be available and given preemptively when succinylcholine is being considered. Some authorities suggest the use of atropine (0.015 to 0.20 mg/kg IV push) for all RSI to prevent bradycardia associated with posterior pharynx stimulation. In patients in whom increased intracranial pressure is a consideration, premedication with lidocaine (1.5 mg/kg IV) 1 to 5 min prior to intubation is recommended. Lidocaine is believed to decrease the adrenergic response to laryngoscopy, sedatives, and neuromuscular blocking agents,¹² although of 25 studies reviewed by Lev and Rosen, only 60 percent claimed some cardiovascular benefit.¹³ Lidocaine has also been shown to attenuate cough¹⁴ and increases in intracranial¹⁵ and intraocular pressure. The review by Lev and Rosen showed no adverse effects of premedication with lidocaine,¹³ thus it appears appropriate to consider its use routinely in pediatric RSI.

Cricoid Pressure

Application of cricoid pressure entails the manual application of firm pressure at the level of the cricoid cartilage anteroposteriorly to oc-

clude the esophagus and minimize the risk of aspiration. It should not be applied over the thyroid cartilage or over the entire larynx. It should be initiated immediately before the administration of the RSI drugs and not released until correct endotracheal tube position is confirmed. The amount of pressure should be graded according to the size of the patient. In smaller patients, the person applying cricoid pressure may wish to use the other hand under the neck to avoid altering the neck position.

Induction of Anesthesia

Laryngoscopy and endotracheal intubations are extremely stimulating events that are powerfully resisted by the unanesthetized patient. The goal of RSI is to overcome this resistance while preserving hemodynamic stability. The term *induction of anesthesia* is used rather than *sedation*, because, although the distinction between the two is somewhat indistinct, performance of laryngoscopy and intubation without causing major hemodynamic perturbations requires a deep state of anesthesia, for which the term *sedation* is inappropriate. The drugs commonly used for induction of anesthesia and their pediatric doses are listed in Table 15-4. **Note the absence of opioid agents for induction, because they do not reliably induce rapid hypnosis.** These doses are appropriate for healthy, well-hydrated patients. The dose for critically ill patients and for those who have received other agents, such as opioid analgesics, should be adjusted downward accordingly. All of these drugs are appropriate for this indication; however, the profiles and side effects of each differ somewhat, as discussed below.

SODIUM THIOPENTAL Sodium thiopental is the most commonly employed drug for induction of anesthesia and has been in use for some five decades. It is very inexpensive and provides reliable induction of anesthesia within 1 min. It causes significant venodilation and moderate direct myocardial suppression, which result in decreases in blood pressure and cardiac output despite an increase in heart rate mediated by a minimally suppressed baroreceptor reflex. It lowers intracranial and intraocular pressures and has long been the drug of choice when elevations of these pressures are a concern. Only barbiturates, of all the pharmacologic interventions studied, have been shown to provide cerebroprotection in acute brain injury, leading to the preference for this drug in the setting of intracranial mass lesions or head trauma. Its side effects include histamine release, which may manifest as flushing, exaggerated hypotension, and wheezing in patients with reactive airways. Neuroexcitatory effects during induction, such as twitching, cough, and hiccups, are relatively common. It can cause extensive tissue necrosis if extravasated.

PROPOFOL Since its release in the United States in 1989, this drug has enjoyed increasing popularity, particularly in elective settings. Its onset of action is similar to that of thiopental, and it produces comparable decreases in blood pressure and cardiac output. Unlike thiopental, there is no reflex increase in heart rate. Propofol appears to be superior to thiopental at suppressing pharyngeal and laryngeal reflexes and for this reason is usually chosen for insertion of an LMA without paralysis. Like thiopental, it lowers intracranial and intraocular pressures, and although experience with propofol is less extensive, it is probably as good a choice as thiopental in similar settings. It does not cause histamine release or stimulate bronchospasm, and extravasation has not been reported to cause significant tissue injury. It is notorious for causing pain on injection, which may be markedly attenuated by preadministration of a small dose of lidocaine. It is significantly more expensive than thiopental, and, given the overall similarity of their profiles, propofol has not been widely adopted for use in RSI due to this factor. Because it is prepared as an emulsion that readily supports bacterial growth, propofol must be administered or discarded within 6 h of opening its container.

TABLE 15-4 Drugs for Pediatric Intubation

Drug	Dose	Duration	Comments
Neuromuscular blockade			
Vecuronium	0.15-0.20 mg/kg	to 60 min	Atropine 0.02 mg/kg
Rocuronium	0.9-1.2 mg/kg	60 min	Atropine 0.02 mg/kg
Succinylcholine	1-2 mg/kg	3-5 min	Atropine 0.02 mg/kg
Anesthetic agents			
Etomidate	0.3 mg/kg	5-10 min	Cardiostable; not an analgesic
Midazolam	0.1-0.2 mg/kg	30^5 min	Cardiostable; reversible
Ketamine	2 mg/kg	4	Cardiostable; use atropine
Thiopental	4	20-60 min	Hypotension, histamine release
Propofol	2.5-3.5 mg/kg	5-10 min	Hypotension
		4-8 min	

KETAMINE Unlike any of the other induction agents, ketamine tends to increase heart rate, blood pressure, and cardiac output. These effects appear to be mediated through central sympathetic stimulation, because ketamine appears to be a weak myocardial depressant in isolated heart preparations. Such effects enhance its attractiveness in settings such as trauma with hypovolemia. It is also a bronchodilator with no suppression of ventilatory drive, making it an excellent choice for patients with known reactive airway disease. In addition, it has significant analgesic and amnestic properties. It can be given intramuscularly in a dose of 4 to 6 mg/kg, with onset of anesthesia within 5 min. This may be desirable in the combative patient in whom intravenous access has not been secured. Unfortunately, it also carries a number of undesirable side effects. Despite the bronchodilation, there are marked increases in upper airway secretions, which can occur briskly and complicate airway management. It increases cerebral blood flow, intracranial pressure, and intraocular pressure and should not be used in patients in whom these effects are a concern. Moreover, it is associated with a significant incidence of emergence hallucinations, particularly in patients with a known history of psychosis, although this reaction is less common in children than in adults. This response can be attenuated by coadministration of benzodiazepines.

MIDAZOLAM Of the benzodiazepines, midazolam is the most popular for induction of anesthesia due to its rapid onset time and lack of venous irritation. The doses required for induction are much larger than those used for sedation. The onset of action is still somewhat slower than with the other induction agents discussed in this section. As a consequence of the large dose, the time to recovery is prolonged compared with that for the other induction agents. Unlike the other induction agents, midazolam can be reversed by the benzodiazepine antagonist flumazenil, although this should be avoided due to the risk of seizures. Remarkably little hemodynamic perturbation occurs with an induction dose, although significant hypotension may occur in a hypovolemic or critically ill patient. Apnea is common, and coadministration of opioids markedly potentiates respiratory suppression. Amnesia is accomplished most reliably with this induction agent. Although expensive when compared with thiopental, it is commonly used in the emergency department due to its stable hemodynamic profile.

ETOMIDATE Etomidate has a stable hemodynamic profile. An induction dose results in almost no change in heart rate, blood pressure, or cardiac output, because it appears to affect neither vascular tone nor baroreceptor reflex. It has little effect on ventilatory drive and none on airway smooth muscle. It lowers cerebral blood flow, intracranial pressure, and intraocular pressure much to the same degree as do thiopental and propofol. It completely lacks any analgesic properties and may require a low (2 to 4 (ig/kg) dose of fentanyl to fully suppress the re-

sponse to intubation. Side effects include pain on injection, myoclonic movements on induction, and a high incidence of subsequent nausea and vomiting. Reports suggesting adrenal suppression occurring with only an induction dose of the drug decreased its popularity, but evidence of the clinical significance of this observation has not been reported.

CHOICE OF AGENTS The choice of agent should be dictated by the specifics of the patient's physiologic status and by the experience of the emergency physician. Factors such as cost and convenience of storage and administration affect a department's choice of options. Specific scenarios for which pharmacologic management may be tailored are discussed below.

Neuromuscular Blockade

The goal of neuromuscular blockade in RSI is to obtain the optimal conditions for laryngoscopy as quickly as possible. The neuromuscular-blocking drug (NMB) is thus injected immediately after the injection of the induction agent. Complete neuromuscular blockade enables maximal laryngoscopic displacement of the tongue and mandible to optimize the view of the glottic aperture. In most children without anatomic deformities, glottic visualization is relatively simple once neuromuscular blockade is accomplished. Neuromuscular blockade also ensures that the vocal cords will be open, thus facilitating atraumatic passage of the endotracheal tube. There are many NMBs available, but only those with the most rapid times of onset can be recommended for RSI. These include the depolarizing NMB, succinylcholine, and two nondepolarizing NMBs, vecuronium and rocuronium.

Although many practitioners may be more familiar with pancuronium, which is inexpensive and has a long history of use in the emergency department, its long time of onset and very long duration of action make it a suboptimal choice for RSI.

SUCCINYLCHOLINE Succinylcholine, the only depolarizing NMB available in the United States, remains the drug of choice for RSI. Although the U.S. Food and Drug Administration has issued an advisory against its elective use in children, it continues to be approved for emergency airway management. The reason for the limitation of its use is that it has been associated with hyperkalemic arrest in children subsequently found to have underlying but undiagnosed myopathies (see below).

The advantages of succinylcholine include its extremely reliable and rapid time to onset of action; intubating conditions are obtained generally within 45 s. As noted, children become hypoxemic with apnea more rapidly than do adults, and even a 15-s advantage can be meaningful. Unlike nondepolarizing NMBs, duration of action is

short. Spontaneous ventilation usually returns within 3 to 5 min. This is particularly important when ongoing neurologic assessment is desired, or when a difficult airway is anticipated or encountered, as options are preserved in the case of a failed intubation.

Unfortunately, the potential disadvantages of the drug are relatively numerous and include hyperkalemia; malignant hyperthermia; elevations in intracranial, intraocular, and intragastric pressures; prolonged blockade; and fasciculations. These are described in detail in Chapter 19. Fasciculations are not inherently dangerous as long as the patient is protected from involuntary physical injury. As in adults, they can be prevented by preadministration of a small "defasciculating" dose (10 percent of an intubating dose) of a nondepolarizing NMB 2 min before succinylcholine is given.

Bradycardia occurs unpredictably in some patients receiving succinylcholine and is more common after a second dose. When it does occur, hypoxia, rather than drug effect, should be the first consideration. This is of particular concern in small children and neonates, whose cardiac output is directly dependent on heart rate. **Premedication with atropine 0.015 to 0.20 mg/kg is advisable in children younger than 5 years or in any child with a heart rate slower than 120 beats/min.**

Prolonged blockade is not inherently dangerous in and of itself. The implication is that occasionally a patient has a prolonged apparent absence of neurologic function that could be mistaken for central nervous system injury. Train-of-four monitoring, the elicitation of muscular response after a standardized series of four electrical pulses stimulating a particular nerve, is used primarily in the operating room and intensive care unit settings. Absence of any twitch response to train-of-four muscular stimulation 10 min after a dose of succinylcholine reflects prolonged neuromuscular blockade.

A small subset of patients develops masseter spasm on receiving succinylcholine, making intubation more difficult. These patients are at increased risk of developing myoglobinuria and have a greater propensity for developing malignant hyperthermia. Fewer than 1 percent of patients manifest this complication.

In the event that succinylcholine is contraindicated, a fast-acting nondepolarizing NMB may be chosen with the knowledge that the onset will be slightly slower and the duration of action substantially longer.

VECURONIUM Vecuronium was the first nondepolarizing NMB to be recommended for use in RSI. To obtain intubating conditions in 60 to 90 s, a dose of 0.3 to 0.4 mg/kg is given. This results in a duration of action of 90 to 150 min. Alternatively, if time permits, a "priming" dose of 0.01 mg/kg should be given 2 to 3 min before an intubating dose of 0.15 to 0.2 mg/kg. The priming technique entails no clinically significant issues, but it speeds the onset of intubating conditions after the intubating dose and shortens the duration of action to 60 to 75 min. Vecuronium is essentially devoid of hemodynamic effects and does not cause histamine release. It is stored as a powder that is easily diluted for use.

ROCURONIUM Rocuronium is similar to vecuronium in its lack of hemodynamic effects. It is somewhat less potent, giving it a more rapid time to onset of intubating conditions, sufficiently so that priming is not considered necessary. Doses of 0.9 and 1.2 mg/kg have been shown in adults to result in times to intubating conditions of 75 and 55 s, respectively, approaching the 45 s typical of succinylcholine.¹⁶ The duration of action is comparable to that of vecuronium 0.1 mg/kg, at the 0.9-mg/kg dose and somewhat longer at the 1.2-mg/kg dose. Rocuronium is supplied as a solution that requires refrigeration, making it slightly less convenient to stock and store than vecuronium.

Contraindications to RSI

There are few contraindications to RSI. A known difficult airway requires an alternative approach. A variety of other approaches may be considered in a patient known to have experienced failed laryngoscopic intubation in the past or whose anatomy or injuries preclude direct laryngoscopy. These approaches include blind techniques, fiberoptically assisted techniques, and techniques employing an LMA. (These are detailed in Chap. 19.) Invasive emergency airway management approaches are discussed below. Patients who are judged to be too ill to receive anesthetic drugs, such as those who are comatose, profoundly hypotensive, or without circulation, may be intubated without pharmacologic assistance. Cricoid pressure nonetheless should be applied, because regurgitation and aspiration may still occur in these patients.

INVASIVE AIRWAY TECHNIQUES

Needle Cricothyroidotomy

Emergency surgical airways are often difficult to establish in children and have high complication rates. Hence, needle cricothyroidotomy has been advocated as the preferred airway access technique in the pediatric population. Needle cricothyroidotomy is performed by first identifying the cricothyroid membrane. A large-bore (14-gauge) intra-venous catheter is passed through the membrane into the airway at a 45-degree caudad angle. The needle is removed, and an adapter is placed on the catheter so a standard bag-valve-mask can be connected for oxygenation. This system has been shown to provide adequate oxygenation for prolonged periods. It cannot, however, provide adequate ventilation.¹⁷

Transtacheal jet ventilation (TTJV) allows ventilation and oxygenation through a catheter. Ventilation is provided with short, intermittent bursts of oxygen. This requires high-pressure (50 psi) oxygen-delivery systems. The system of choice is a jet injector regulated by a flow meter attached to a wall or tank unit. The less optimal choice is an unregulated wall or tank system. A 1-s jet of oxygen followed by a 4-s expiratory phase achieves satisfactory ventilation.¹⁸

Complications of needle cricothyroidotomy include bleeding, infection, esophageal perforation, breakage or bending of the needle, subcutaneous emphysema, pneumothorax, pneumomediastinum, and pneumopericardium.

Surgical Cricothyroidotomy and Tracheostomy

Emergency surgical cricothyroidotomy and tracheostomy in pediatric patients is much more difficult than in adults due to the smaller dimensions of the structures and the relatively higher position of the larynx in the neck. Cricothyroidotomy should be avoided in children under 10 years due to technical difficulties and TTJV is preferred. Few emergency physicians are experienced in emergency tracheostomy, and again TTJV or LMA should be considered. Sufficient literature documenting the true complication rates of these procedures in the pediatric population is not available.

SPECIAL CONSIDERATIONS

Head Trauma or Intracranial Mass Lesion

Securing the airway in a pediatric patient with head trauma or an intracranial mass lesion plays an important role by correcting or preventing hypercarbia and hypoxemia, factors that can increase intracranial pressure. Because endotracheal intubation itself is inherently

stimulating to intracranial pressure, all possible precautions should be taken to suppress this response. In addition, in the setting of head trauma, RSI should be undertaken with strict head and neck immobilization due to the potential for concomitant cervical spine injuries.

Rapid sequence intubation is the preferred method of intubation in pediatric patients with suspected or known intracranial hypertension. In addition to the agents previously discussed, lidocaine at a dose of 1.5 mg/kg IV should be given before laryngoscopy.¹⁹ This intervention blocks the rise in intracranial pressure that commonly accompanies endotracheal intubation. It is important to remember that in pediatric patients, as in adults, head injuries can also be associated with intra-oral and intratracheal injuries. When managing the airway of a head-injured patient, one must always be prepared for invasive airway management.

Epiglottitis and Croup

For a detailed discussion of pediatric upper airway obstruction, see Chap. 133. Optimal airway management for pediatric patients with epiglottitis is in the operating room. If the patient is stable, he or she should be transported to the operating room accompanied by a skilled airway manager and the proper equipment. A patient with complete airway obstruction often can be ventilated until an airway can be established. If this is unsuccessful, emergent orotracheal intubation should be attempted. If this fails, invasive airway techniques should be used.

Uncommonly, a child with croup may be unresponsive to medical management and may require an artificial airway. An endotracheal tube is optimally placed in the operating room, allowing for inhalation induction of anesthesia. Intubation, however, may have to be performed in the emergency department if the patient is in extremis.

Airway Foreign Bodies

Management of an unstable patient with acute airway obstruction requires immediate attention to the airway. In the prehospital setting, the American Heart Association recommends a series of five back blows and five chest thrusts in a child younger than 1 year (see Chap. 14). The child should have the oropharynx examined between each series. In a child older than 1 year, the recommendation is a series of abdominal thrusts in the upright or the supine position.

In the emergency department, the child with a partially obstructed airway should be rapidly assessed. If the child will tolerate it, a visual inspection of the hypopharyngeal and laryngeal areas should be attempted. Commonly, a child will tolerate this procedure poorly and thus should be taken to the operating room for general anesthesia and removal of the foreign body. In an unstable or completely obstructed patient, orotracheal intubation may dislodge the foreign body, and this should be attempted before needle cricothyroidotomy.

RESUSCITATION ISSUES IN PREGNANCY

Elizabeth M. Datner Susan
B. Promes

ETIOLOGY OF MATERNAL DEATH

Although cardiac arrest in pregnant patients is rare (it is estimated to occur once in every 30,000 deliveries), the incidence of maternal death has been increasing recently. In 1999, there were 11.8 deaths per 100,000 live births. However, the National Health Promotion and Disease Prevention Objectives of Healthy People 2010 identified a rate of no more than 3.3 maternal deaths per 100,000 live births as a national goal. Some of the factors associated with a higher risk of pregnancy-related death include advancing maternal age, race, increasing live birth order, lack of prenatal care, and unwed mothers.¹

The leading causes of maternal death are pulmonary embolism, hemorrhage, pregnancy-induced hypertension, and infection¹ (Table 16-1). Although pulmonary embolism is considered the most common medical cause of death in pregnant women, several studies have indicated that maternal death from homicide is the most common form of fatal injury.^{2,3} Domestic violence and its relation to pregnancy and homicide is poorly understood, but domestic violence indicators should be examined in all pregnant patients as a preventive measure.

MATERNAL AND FETAL PHYSIOLOGIC CHANGES THAT AFFECT CARDIAC ARREST

Uteroplacental blood flow is directly related to maternal blood volume and arterial pressure. Support of maternal blood volume and oxygenation is the best way to prevent fetal hypoxia. With this principle in mind, a detailed understanding of cardiac arrest physiology is important. A full discussion of fetomaternal physiology can be found in Chap. 104, but several points are discussed and put in perspective here.

The maternal cardiovascular system undergoes dramatic changes. Cardiac output increases to 30 to 45 percent above baseline levels by the twentieth week of gestation and remains at that level until delivery. In addition, the mean arterial blood pressure gradually falls throughout the first two trimesters of pregnancy and returns to baseline levels by term. This change is a result of decreased resistance in the pulmonary and uteroplacental circulations. The uteroplacental mass increases and requires 10 percent of systemic blood volume by term, compared with a baseline of 2 percent. By the second half of pregnancy, the uteroplacental vascular bed functions as a passive low-resistance system, with flow determined by maternal perfusion pressure. Thus, in a state of cardiac compromise, uterine blood flow is greatly diminished. The addition of vasopressors with α - and π -adrenergic effects can cause significant vasoconstriction, thereby decreasing uterine blood flow even further.

By the twentieth week of pregnancy, the enlarged uterus mechanically compresses the great vessels in the pelvis, particularly when the patient is in the supine position. As a result of decreased venous return from compression of the inferior vena cava, cardiac output is reduced 10 to 30 percent during spontaneous circulation (Figure 16-1). Administration of medications through intravenous sites in the infradiaphragmatic vessels, such as the femoral or saphenous vein, is also compromised because of poor venous flow. These vascular sites therefore are not recommended for intravenous access in the resuscitation of a pregnant patient with greater than 20 weeks gestation. Aortic compression also occurs, causing diminished distal blood flow. The untoward effects of great vessel compression are worsened in the setting of maternal hypotension and uterine contractions, leading to an even more pronounced decrease in uteroplacental blood flow.

Pregnancy also alters the respiratory system. A state of chronic respiratory alkalosis develops during the first trimester of pregnancy due

to increased minute ventilation secondary to increased tidal volume and mild progesterone-stimulated hyperventilation. The resulting compensatory decrease in serum bicarbonate levels due to decreased partial pressure of carbon dioxide (P_{CO_2}) makes the woman less able to buffer a state of acidosis from hypotension or cardiac arrest. In addition, the decreased functional residual capacity (FRC) and increased maternal oxygen consumption and basal metabolic rate during pregnancy results in more rapid onset of anoxia with respiratory arrest. Arterial oxygen content drops more quickly in pregnant than in nonpregnant patients. Rapid resumption of respiration, whether mechanical or spontaneous, is essential to minimize hypoxic damage. Progesterone also increases gastric emptying time and decreases lower esophageal sphincter tone, making the gravid patient prone to aspiration. This is another reason to initiate endotracheal intubation early.

Fetal physiology appears to be protective of severe hypoxia. There are several reports of fetal survival when delivery occurred more than 20 min after maternal cardiac arrest in patients receiving CPR. However, the trauma literature indicates that absence of maternal vital signs for longer than 20 min renders emergency cesarean section futile. It is unclear whether CPR plays a role in potential fetal survival beyond 20 min. The fetal oxyhemoglobin dissociation curve is shifted to the left relative to the maternal oxyhemoglobin dissociation curve, because of the greater affinity of hemoglobin F for oxygen. Thus, at any partial pressure of oxygen (P_{O_2}), fetal hemoglobin will bind oxygen more strongly, resulting in greater saturation. Fetal P_{O_2} does not fall significantly unless maternal P_{O_2} falls below 60 mm Hg.⁴ Below this level, only slight decreases in maternal P_{O_2} will result in significant decreases in fetal P_{O_2} . In addition, there is a higher concentration of fetal hemoglobin in fetal erythrocytes than maternal hemoglobin in maternal erythrocytes, and the fetus exists in a physiologically

acidemic state relative to the mother, which allows preferential oxygen transfer at the fetal tissue level. Acidemia favors a rightward shift of the oxyhemoglobin dissociation curve. Thus, a greater amount of oxygen is supplied to fetal tissues.

Fetal cardiac output protects against hypoxia with increases in umbilical blood flow and placental gas exchange. Fetal blood flow is then preferentially redistributed to vital tissues. As a result, fetuses exposed to short periods of maternal hypoxia may not suffer neurologic damage.

Resuscitation of a pregnant patient can become a chaotic event. Particularly in major centers, there may be other specialists involved, including pediatricians, neonatologists, anesthesiologists, obstetricians, and possibly others. These specialists have unique skills and experience that will help in the resuscitation. However, many of the specialists are poorly versed in emergency medicine and advanced cardiac life support (ACLS) protocols. It is particularly important that the team leader of the resuscitation take strict control of the events and the order in which they occur. The other specialists involved should not be allowed to deviate from the proper process. The team leader for such resuscitations may be decided by hospital policy. If such a policy does not exist, then typically the emergency physician should be the director of the resuscitation and take firm control.

AIRWAY ISSUES

The airway presents special concerns in obstetric patients. Attention to a few details, particularly in the setting of maternal cardiac arrest, may reduce morbidity and mortality. Airway management and its associated problems, most commonly failed intubation and aspiration of gastric contents, represent the greatest risk factors for anesthetic-related maternal deaths, most of which occur in the setting of an emergent cesarean section. Maternal death related to anesthesia most commonly results from aspiration of gastric contents or failure to intubate the trachea, resulting in hypoxia, which ultimately can result in cardiac arrest. Mask ventilation can be difficult and ineffectual in obstetric patients, because of low FRC, elevated diaphragms, and raised intra-abdominal pressure. Due to the risk of aspiration, mask ventilation should be avoided unless hypoxia is present. According to Hawthorne and colleagues, the incidence of failed intubation in the obstetric population is 0.4 percent.⁵ Complicating the fact that pregnant patients develop hypoxia more quickly and are less tolerant of apneic periods, the airway poses more difficulties than in the general population. The potential factors accounting for these difficulties should be assessed before attempting an intubation.

Parturients in general are in an edematous state, which affects the tongue and supraglottic soft tissues.⁶ The edema may compromise the airway lumen, making mask ventilation, laryngoscopy, and endotracheal intubation more challenging. The incidence of Mallampati class III airway increases as pregnancy progresses.⁷ Smaller endotracheal tubes may be needed to achieve a successful intubation and should be readily available. Mucosal engorgement and increased friability make the airway more likely to bleed and swell. This in itself can cause rapid deterioration. Increased gastric emptying time and diminished lower esophageal sphincter tone allow for increased gastric insufflation and result in a greater risk of aspiration during intubation. The most experienced physician should undertake the intubation. Blind nasotracheal intubation is relatively contraindicated, and nasogastric tubes generally should be avoided, given the engorgement and friability of the mucosa in pregnant patients. Orogastric tubes may be used with caution in pregnant patients in cardiac arrest.

Several other physical conditions should be considered before intubating a parturient. Pregnant patients are likely to have full and intact dentition, and there may be little interdental distance in which to maneuver a laryngoscope. Obesity is relatively common in pregnant patients, causing relative neck extension when patients are supine, which results in greater anterior placement of the larynx. The neck is shortened, and there are often redundant pharyngeal and palatal folds in

the airways of obese gravid women. In addition, enlarged and engorged breasts may obstruct placement of the laryngoscope in the mouth and the hand of an assistant attempting to maintain cricoid pressure.

The technique for intubating pregnant patients may require several modifications. As in any intubation, adjunctive equipment, including small endotracheal tubes, short laryngoscope handles, and stylets, should be readily available and familiar to the physician managing the airway. In addition, special airway devices, including the fiberoptic bronchoscope and the laryngeal mask airway, may be helpful in managing a difficult airway. The patient should be placed in the supine position, with the right hip elevated 10 to 12 cm to minimize aortocaval compression. The head and shoulders can be elevated with a pillow or folded sheets to achieve the sniffing position. This maneuver is particularly important in obese patients.

Use of rapid sequence induction with cricoid pressure has become the standard of care for intubating pregnant women, in particular unstable patients with airway compromise. Administration of an induction agent, such as thiopental or etomidate, is followed by administration of succinylcholine, the muscle relaxant of choice, unless there is a contraindication to its use. Standard doses are used (see Chap. 19). It is helpful to allow a sufficient period for muscle relaxants to take effect and for adequate preoxygenation before attempting laryngoscopy, given its potential hazards in pregnant patients. Preoxygenation, rather than mask ventilation with its associated risk of aspiration, before intubation is important because of the parturient's decreased FRC. However, hyperventilation may lead to respiratory alkalosis, which, in addition to shifting the oxyhemoglobin dissociation curve to the left, causes decreased uterine blood flow. Cricoid pressure must be applied carefully throughout the intubation procedure. In the case of failed intubation and inability to maintain oxygenation and ventilation with alternative airway devices (i.e., laryngeal mask airway, Combitube), more invasive maneuvers, such as percutaneous transtracheal jet ventilation or cricothyrotomy, may need to be performed to maintain oxygenation and prevent hypercarbia. Ventilator settings for pregnant patients are similar to those for nonpregnant patients, with minor modifications. Minute ventilation should aim to maintain a P_{CO_2} of approximately 30 mm Hg. Normal antepartum arterial blood gas values should be sought at term: pH, 7.43 ± 0.027 ; P_{CO_2} (mm Hg), 30.4 ± 2.7 ; and P_{O_2} (mm Hg), 102 ± 5 , indicating a chronic respiratory alkalosis.⁸ Significant respiratory alkalosis must be avoided to prevent decreased uterine blood flow.

MODIFICATIONS OF CARDIOPULMONARY RESUSCITATION

All common underlying conditions can be influential, and the etiology of cardiac arrest in pregnant patients is different from that in nonpregnant patients (see Table 16-1) and includes pulmonary embolism, amniotic fluid embolism, eclampsia, drug toxicity (e.g., magnesium sulfate or epidural anesthetics), cardiomyopathy, aortic dissection, trauma, and hemorrhage. As always, one should address the potential underlying etiology and the cardiovascular collapse.

Cardiopulmonary arrest in a pregnant patient must be considered under two scenarios: before fetal viability and after fetal viability. The accepted age of fetal viability may vary among institutions, but 24 to 26 weeks is generally considered the age of viability. The uterine fundus is palpable at the umbilicus at 20 weeks. After 20 weeks, the gestational age of the fetus can be estimated by measuring the fundus from the pubic symphysis to the top of the fundus. The fundal height in centimeters corresponds roughly to the gestational age in weeks. **Before 24 weeks' gestation, all efforts should focus on the mother, with no modifications to CPR.** However, early intubation and resumption of respirations and circulation are essential in all gravid arrests for the reasons mentioned earlier. Beyond 20 weeks or if the gravid uterus can be palpated above the umbilicus, several modifica-

TABLE 16-2 Algorithm for Cardiopulmonary Resuscitation in Pregnant Patients

Early intubation, protect vulnerable airway, supply oxygen
Tilt the patient, limit aortocaval compression
Obtain rapid intravenous access, avoid the femoral and saphenous veins
Follow current ACLS recommendations
Perimortem cesarean section within 5 min of maternal arrest if fetus >20 wks
Consider open chest CPR within 15 min of maternal arrest
Explore differential diagnosis, include iatrogenic causes, e.g., spinal analgesia
Consider cardiopulmonary bypass, if indicated

Abbreviation: ACLS = advanced cardiac life support.

tions of CPR should be instituted: (1) the patient should be positioned to minimize aortocaval compression, and (2) an emergency cesarean section should be considered and appropriate preparations made for its potential performance and for care of a viable fetus.

Aortocaval compression must be limited in all patients beyond the twentieth week of gestation. This can be achieved by (1) having someone manually displace the uterus to the left, (2) tilting the patient 15 to 30 degrees on a tiltable table, or (3) placement of a roll or a Cardiff wedge, if available, under the patient's right hip and flank. The Cardiff wedge provides a tilt of 27 percent, allowing 80 percent of the compressive force, compared with CPR in the supine position.⁹ Even this is minimal blood flow, considering that correctly performed CPR maintains 30 percent or less of normal cardiac output in nonpregnant adults.^{10,11} The "human wedge" has been advocated for bystander CPR. In this technique, the patient lies across the thighs of the rescuer, who is in a kneeling position. Despite relatively clear current recommendations regarding resuscitation in pregnancy, summarized in Table 16-2, there remains a paucity of research in this area.

Five factors have been suggested as important to improving the chance of fetal survival when the mother suffers cardiac arrest: gestational age older than 28 weeks or fetal weight greater than 1 kg, short interval between maternal death and delivery, a cause of maternal death not related to chronic hypoxia, fetal status before maternal death, availability of neonatal intensive care facilities, and quality of maternal resuscitation.¹²

The role of open chest CPR remains unclear. There is some evidence that early thoracotomy and open chest cardiac massage may improve maternal and fetal outcomes. If, after several minutes of external CPR (15 min has been suggested), a pregnant woman has failed to achieve return of spontaneous circulation, open chest CPR should be considered.

DEFIBRILLATION AND MEDICATIONS

Pregnant patients in cardiac arrest should be treated according to current ACLS guidelines. Defibrillation has never been found to have adverse effects on the fetus and thus is not contraindicated. The patient should be placed in the left lateral tilt position, if possible, before defibrillation or cardioversion. Large-bore intravenous lines should be placed, preferably above the diaphragm, and LR or NS solution infused. Supplemental oxygen should be given. Apgar scores and fetal outcome are positively affected by greater fetal oxygen reserves. In limited published reports, the standard medications used in ACLS have not been demonstrated to have adverse effects on the fetus and thus are recommended in the setting of cardiac arrest.¹³ Table 16-3 presents details regarding ACLS medications. Vasopressors, such as epinephrine and dopamine, may be detrimental in the setting of maternal hypotension because they cause uteroplacental vasoconstriction, but should be used as needed during cardiac arrest. In the setting of hypotension alone without cardiac arrest, ephedrine, in standard doses (5 mg IV every 5 min until a response is seen), is the preferred pressor

TABLE 16-3 Medications Used During Cardiopulmonary Resuscitation—Considerations in Pregnancy

Drug	Indications	Considerations in Pregnancy
Epinephrine	Potentially beneficial in all forms of cardiac arrest	category C. Has been shown to be teratogenic in animals in large doses; may induce uteroplacental vasoconstriction.
Lidocaine	Ventricular ectopy, tachycardia, and fibrillation	category C. Use during pregnancy is not well studied; crosses the placenta but in therapeutic doses has no teratogenic effect on the fetus; may cause fetal bradycardia.
Bretylium	Ventricular fibrillation and tachycardia unresponsive to other therapy	category C. No longer recommended as a first-line drug for resuscitation, because of potential risk of reduced uterine blood flow and fetal hypoxia (bradycardia); appropriate when benefits outweigh risks.
Atropine	Symptomatic bradycardia, asystole	category B. Crosses placenta but results in no fetal abnormalities; can cause fetal tachycardia.
Sodium bicarbonate	Cardiac arrest unresponsive to other measures; documented preexisting metabolic acidosis	category C. Studies to define risk of hypertonic sodium bicarbonate therapy in pregnancy have not been done.
Dopamine	Hemodynamically significant hypotension in the absence of hypovolemia	category C. No teratogenic effects have been observed in laboratory animals, but sufficient studies in humans are lacking; use only when clearly indicated.
Dobutamine	Short-term inotropic support of patients with depressed myocardial contractility	category C. Not found to be teratogenic in animal studies, but its effects in pregnant humans are unknown; use only if clearly indicated
Amiodarone	Ventricular fibrillation, tachycardia, and supraventricular tachycardia	category D. Should not be used in pregnancy; serious fetal adverse effects have been observed.
Adenosine	Supraventricular tachycardia	class C. Multiple case reports have described the safe use of adenosine to treat maternal and fetal supraventricular tachycardia.
Magnesium sulfate	Acute myocardial infarction and torsades de pointes	lass B. This drug is commonly used in pregnancy for toxemia and tocolysis with no reports of congenital defects; neonatal neurologic depression may occur with respiratory depression, muscle weakness, and loss of reflexes.

when fluids fail to restore adequate blood pressure. The use of sodium bicarbonate is not well studied. Sodium bicarbonate crosses the placenta slowly and can be problematic for the fetus for the following reason. Rapid correction of maternal acidosis may decrease maternal respiratory drive and lead to a further rise in, or pseudonormalization of, maternal P_{CO_2} . As maternal P_{CO_2} increases, the concomitant rise in fetal P_{CO_2} occurs at a faster rate than does the rise in HCO_3^- , causing the fetus to become more acidemic.

COMPLICATIONS FROM CARDIOPULMONARY RESUSCITATION

Complications may occur from standard resuscitation. Maternal problems secondary to CPR include liver lacerations, uterine rupture, hemothorax, and hemopericardium. Potential fetal complications include cardiac dysrhythmias from maternal defibrillation and ACLS drugs, central nervous system toxicity from ACLS drugs, and altered uteroplacental blood flow from maternal hypoxia, acidosis, and vasoconstriction. Despite all of the aforementioned problems, standard ACLS protocols, with the addition of a pelvic tilt, are still the standard of care in resuscitating pregnant patients. The ultimate goal is to oxygenate the mother, and in turn the fetus, and achieve return of spontaneous circulation as soon as possible.

PERIMORTEM CESAREAN SECTION

Perimortem cesarean section must be considered as part of any resuscitation in the case of maternal cardiac arrest and a viable fetus. Prognosis for intact survival of the infant is excellent if delivery occurs within 5 min of maternal arrest and initiation of CPR. If the 5-min time frame has been exceeded, it is still recommended to perform a perimortem cesarean section. One case has been reported of a perimortem cesarean section performed 22 min after maternal cardiac arrest that resulted in a normal living infant.¹⁴ No cases have been reported of live births by perimortem cesarean section beyond 25 min after maternal arrest. Ideally, an obstetrician and a pediatrician or neonatologist are present at the time of a perimortem cesarean section. In the absence of these specialists, the emergency physician must be prepared to perform the procedure. **It is not necessary and only delays a potentially lifesaving procedure to evaluate fetal viability before initiation of the cesarean section.** For the same reasons, the patient should not be moved to an operating suite, because this only wastes time. The decision to perform a perimortem cesarean section should be made by 4 min after cardiac arrest, with delivery of the fetus by 5 min post-arrest.

Maternal CPR should be continued throughout the procedure and for a brief time afterward, because a few cases of successful resuscitation after such a procedure have been reported. Necessary equipment is listed in Table 16-4. The goal of this procedure is to remove and resuscitate the fetus.

Abdominal preparation and insertion of a Foley catheter to decompress the bladder may be performed before initial incision, if time al-

lows, but should not delay the procedure. No anesthesia is required, because the mother is in cardiac arrest. A vertical midline (classic) incision is made from 4 to 5 cm below the xiphoid process to the pubic symphysis through the abdominal wall. The rectus muscles may be separated with blunt dissection, and the peritoneum is entered with a midline incision that is continued superiorly and inferiorly to allow visualization of the uterus. A vertical uterine incision is made from the fundus to the point at which the opaque bladder is adherent to the uterus. An initial small inferior incision may be made until amniotic fluid is obtained and then extended with scissors by using the free hand to elevate the uterus, thereby avoiding injury to the fetus. An anterior placenta should be incised to reach the fetus. The fetus is then delivered and resuscitated. The placenta is then manually removed from the uterus, and the uterus is wiped clean of membranes with a sponge or towel. The uterus is closed with one or two layers with a locked running stitch using number 0 or number 1 semipermanent (e.g., chromic) suture and a large needle. The fascia and peritoneum may be closed with a permanent or semipermanent number 0 or number 1 suture with a running stitch. Finally, the skin is closed. Closure of the abdomen may be delayed until maternal pulse and blood pressure are restored, to allow direct observation of the uterus for ongoing bleeding. Uterine atony after perimortem cesarean section is common and may lead to significant blood loss when the uterus fails to contract after delivery. Because maternal blood circulation may not be sufficient to deliver intravenously administered medication, dilute oxytocin (10 U in 9 mL of NS solution) may be injected directly into the myometrium in divided doses until contraction occurs. Other possible therapeutic medications include ergometrine (intravenous or intramuscular) or prostaglandin $F_{2\alpha}$ injected into the uterus.

Informed consent for perimortem cesarean section is not necessary. The procedure needs to be performed expediently and should be considered part of the resuscitation. Perimortem cesarean section during cardiac arrest fulfills criteria for absence of maleficance and beneficence for the mother and the fetus. Maternal and/or fetal death, and deciding to perform a perimortem cesarean section, impose a highly emotional impact on all parties involved in the resuscitation. Debriefing and counseling services should be provided to all participants in such cases.¹⁵ The question of when emergent cesarean section should be performed in critically ill, prearrest patients has not been adequately addressed in the literature. In addition, the recommendations for perimortem cesarean section are based on multiple case reports. No experimental studies have evaluated this procedure.

CARDIAC ISCHEMIA

Pregnant women with acute cardiac ischemia are treated the same as nonpregnant patients, with the exception of thrombolytic therapy. Pregnancy is considered a relative contraindication to thrombolytic therapy by the American College of Cardiology and the American Heart Association.¹⁶ No controlled trials using thrombolytic agents, such as streptokinase, urokinase, or tissue plasminogen activator, have been performed on pregnant women or are currently feasible. Patients with suspected myocardial infarction should be evaluated for emergent percutaneous interventional therapy or medical management.

PULMONARY EMBOLISM

Thromboembolic disease is increased in pregnancy. Anticoagulation with heparin is currently the treatment of choice for a pulmonary embolism, in addition to ensuring adequate oxygenation and treating hypotension. Either unfractionated or low-molecular-weight heparin are acceptable treatment regimens. When pulmonary embolism is suspected, empiric treatment with heparin should be started immediately, especially if the patient is hypoxic or hemodynamically unstable. Once treatment has begun, a CT scan or ventilation-perfusion scan should be obtained to confirm the diagnosis. Traditionally, thrombolytic ther-

10-mL syringe with intramuscular needle

apy for pulmonary embolism has been considered relatively contraindicated in pregnant patients. However, there are multiple case reports of pregnant women who have been treated successfully with thrombolytics for thromboembolic disease, with no untoward complications.¹⁷ The use of thrombolytics should be reserved for patients in extremis for whom the potential benefit outweighs the potential risks.

AMNIOTIC FLUID EMBOLISM

The classic presentation of amniotic fluid embolism is the development of dyspnea and hypotension in association with labor or an abortion. Milder forms can present with sudden onset of shortness of breath and air hunger and a decreased oxygen saturation that resolves spontaneously. Amniotic fluid embolism can be difficult to distinguish from pulmonary embolism. Patients can develop cardiac arrest within minutes, and, if they survive, they will go on to develop disseminated intravascular coagulation and potentially multiorgan failure.¹⁸ Treatment is primarily supportive care in addition to invasive cardiac monitoring and correction of the coagulopathy. The use of cardiopulmonary bypass and open pulmonary artery thromboembolism has been used with success in a moribund patient with amniotic fluid embolism.¹⁹

DISPOSITION

The presence of experienced obstetricians, anesthesiologists, and pediatricians or neonatologists will facilitate the care of pregnant patients with cardiac arrest. However, none of the required care and procedures should be delayed if these specialists are not available; further, many of these specialists are not well versed in orchestrating resuscitation or resuscitative techniques. When trained staff are available to perform external fetal tococardiography without diverting care from the mother, it should be provided for pregnancies beyond 20 weeks' gestation. If this technology is not available or personnel are limited, the often-quoted maxim, "maternal resuscitation is the best fetal resuscitation," should be kept in mind. The closest center providing neonatal services should be contacted as soon as possible to facilitate rapid transport of the newly delivered infant.

ETHICAL ISSUES OF RESUSCITATION

Catherine A. Marco

GENERAL PRINCIPLES OF MEDICAL ETHICS

The study of ethics has been defined as the way of understanding and examining the moral life¹ and as the discipline dealing with moral duty and obligation.² The Hippocratic Oath has been revered as one of the oldest codes of medical ethics. More recently, the American Medical Association (AMA) Code of Ethics (earliest version in 1847) and the American College of Emergency Physicians (ACEP) Code of Ethics (1997) have provided guidance to emergency physicians in application of ethical principles to clinical practice. Most ethical codes address common features, such as *beneficence* (doing good), *nonmaleficence* (*primum non nocere*, or "do no harm"), respect for patient *autonomy*, *confidentiality*, *honesty*, *distributive justice*, and *respect for the law*. Ethical dilemmas may arise when there is a potential conflict between two principles or values. Ethical dilemmas may be resolved by various means, including individual physician judgment, additional information gathering, and meetings with health care professionals, patients, and families. In some circumstances, the involvement of the institutional ethics committee or the judicial system may be sought.

CARDIAC RESUSCITATION AND OUTCOMES

There are 460,000 sudden deaths in the United States annually.³ The outcome of resuscitative efforts for victims of cardiac arrest is uniformly poor but varies depending on a variety of factors. The most important factor determining outcome is the time elapsed since arrest (*down time*). Studies over several decades have demonstrated improved survival rates for patients who received early advanced cardiac arrests to hospital discharge has been estimated in many studies to be between 0 and 10 percent.

life support (ACLS).^{4,5} Another important prognostic factor is the presenting rhythm. Previous studies have demonstrated improved survival rates for patients with presenting rhythms of ventricular fibrillation or ventricular tachycardia and reduced survival rates for patients with asystole or pulseless electrical activity. The underlying medical condition of the patient is another important factor affecting outcome.

A potentially poor response to resuscitation can be expected for patients with metastatic disease, acute cerebrovascular accident, sepsis, renal failure, or pneumonia. Failure to respond to prehospital advanced life support (ALS) protocols leads to a survival rate of less than 2 percent. The age of the patient also affects predicted survival rate, with a nearly 0 percent survival rate for unwitnessed arrests of elderly patients⁶ and for long-term care patients.⁷ Overall, survival of victims of

cardiac arrests to hospital discharge has been estimated in many studies to be between 0 and 10 percent. Based on such data, several authors have suggested proposed criteria for withholding resuscitative efforts for patients in certain clinical settings with a low likelihood of successful resuscitation [e.g., apneic, pulseless for longer than 10 min prior to emergency medical service (EMS) arrival, no response to ACLS, and preexisting terminal disease].^{8,9} Knowledge of data regarding resuscitation outcomes in various clinical settings is crucial when making evidence-based decisions regarding the risks and benefits of attempting CPR and the duration of the resuscitation attempt.

RISKS AND BENEFITS OF RESUSCITATIVE EFFORTS

When considering offering or withholding resuscitative efforts, risks and benefits of resuscitative efforts should be considered carefully. The goal of resuscitative efforts is to restore circulation and life to the patient. Other less tangible benefits may include such entities as resolution of guilt of the survivors and the additional time for acceptance of bad news for survivors.

However, often resuscitative measures are undertaken in clinical situations in which physiologic survival is very unlikely, if not all but impossible. In some situations, there is a substantial risk that if circulation is restored, significant anoxic brain injury will result, resulting in significant impairment of quality of life (dementia, persistent vegetative state, or other cognitive impairments).

Additionally, substantial resources (supply costs as well as personnel) are often invested in this clinical setting of low likelihood of benefit, while the care of many other patients is delayed (distributive justice). Another consideration for limiting resuscitative efforts is the potentially large investment of human resources that otherwise might be used for family counseling and communication.

FUTILITY AND NONBENEFICIAL INTERVENTIONS

The term *futility* is fraught with difficulties in definition and interpretation. Health care professionals may interpret futile interventions as those which carry an absolute impossibility of successful outcome, a low likelihood of success, a low likelihood of survival to discharge from the hospital, or a low likelihood of restoration of meaningful quality of life. Schneiderman and colleagues defined *futility* as "any effort to achieve a result that is possible but that reasoning or experience suggests is highly improbable and that cannot be systematically produced."¹⁰ Several authors have demonstrated that there is no consensus among physicians about the meaning of futility. Because of these difficulties, it is probably more accurate to use the appropriate terminology, such as *nonbeneficial*, *ineffectual*, or *low likelihood of success*.

The withholding or limitation of medical interventions that have a predicted low likelihood of producing a successful outcome can be a difficult and far-reaching decision. Many emergency physicians continue to attempt resuscitation on patients in cardiac arrest in situations considered nonbeneficial, often because of fears of litigation or criticism."

Many ethicists agree that physicians are under no obligation to render treatments that they deem of little or no benefit to the patient. There have been numerous ethical opinions supportive of the position of offering only those treatments judged to be of likely medical benefit. The AMA Council on Ethical and Judicial Affairs wrote that CPR may be withheld, even if requested by the patient, "when efforts to resuscitate a patient are judged by the treating physician to be futile."¹² Numerous other ethicists and authors support withholding of interventions deemed unlikely to benefit patients.¹³

Dilemmas regarding nonbeneficial interventions often arise due to inadequate or ineffective communication between physician, patient,

and family. This is of particular concern in emergency medicine, where previous relationships with patients and family rarely exist and time is often inadequate to establish effective relationships. In fact, verification of family status is often impossible. Thus, when a difference of opinion exists, initial efforts should be made to improve communication, education, and joint decision making.

There exist several policies that may be of guidance in decision making regarding nonbeneficial interventions. The ACEP approved a policy statement on futile treatment in 1998. This policy asserts ACEP's belief that "physicians are under no ethical obligation to render treatments that they judge have no realistic likelihood of medical benefit to the patient." The policy goes on to state that emergency physicians' judgments should be unbiased, based on available scientific evidence and societal and professional standards, and sensitive to differences of opinion regarding the value of medical intervention in various situations.¹⁴

The AMA Council on Ethical and Judicial Affairs recommends a process-based approach to the determination of futility¹⁵ to include such actions as

1. deliberation and resolution;
2. joint decision making with physician and patient or proxy;
3. assistance of a consultant or patient representative; and
4. use of an institutional committee (i.e., ethics committee).

Ultimately, the decision regarding CPR and its likelihood of benefit to the patient and decisions to provide, limit, or withhold resuscitative efforts are to be made by the emergency physician in the context of well-accepted research results, patient and family wishes, and professional judgment. Individual bias regarding quality of life or other related issues should be avoided. There are many cases where dying should be accepted as a natural process, even in an emergency setting.

ADVANCE DIRECTIVES

An *advance directive* refers to any proactive document stating the patient's wishes in various situations, should he or she be unable to state his or her wishes. The *living will*, which was adopted by many states in 1990, is a document suitable for terminally ill individuals, and the treating physician accepts the provisions in advance. Many state that no life support be used in cases where meaningful recovery will not occur. *Durable power of attorney* specifies a surrogate decision maker in the event that the patient no longer has the capacity to make medical decisions. In 1991, the Federal Patient Self-Determination Act mandated the opportunity to sign an advance directive for all patients admitted to a hospital. In many cases, the existence of an advance directive can facilitate the implementation of the patient's specific wishes.

Despite widespread advocacy and legal mandates (such as the 1991 Federal Patient Self-Determination Act) for the increased use of advance directives, only a minority of patients have completed an advance directive, and an even smaller minority presents to the emergency department with the necessary documentation.¹⁶ Although some health care providers are reluctant to discuss issues such as end-of-life care and advance directives, many patients welcome the opportunity to discuss their wishes. Most patients have definite opinions regarding resuscitation preferences, despite the lack of completion of legal advance directives.¹⁷ Without advance directives, surrogate decision makers and physicians often make erroneous assumptions regarding the preferences of patients.

Although studies conducted in other settings have demonstrated variable compliance with advance directives by medical personnel, recent studies have indicated that emergency medical personnel may comply with advance directives more often than previously believed. Most emergency physicians (78 percent) withhold resuscitation attempts for patients with a legal advance directive, indicating a willingness to honor patients' wishes regarding their own medical care.¹¹

Additionally, most prehospital providers (89 percent) withhold resuscitation attempts for patients with a legal advance directive.¹⁸ These results suggest that advance directives may be especially significant in medical decision making to emergency health care providers.

PUBLIC EDUCATION ABOUT RESUSCITATION AND ALTERNATIVES

Numerous studies have demonstrated that accurate knowledge regarding probability of survival influences patient preferences.¹⁹ Improved knowledge base regarding resuscitation may be achieved through a variety of venues, including television, radio, online education, physicians' offices, and many others, and may contribute to improved knowledge and, in turn, action regarding communication of personal preferences regarding CPR, including advance directives.

FAMILY PRESENCE DURING RESUSCITATION

Although, traditionally, family members have not been allowed to witness resuscitation attempts, several recent reports have demonstrated positive results of this practice.^{20,21} Although most research to date has addressed medical arrests, the practice also should be considered for traumatic procedures and arrests. Family presence may serve to relieve guilt or disappointment and may be a helpful part of the grieving process. Many families simply wish to have the option of being present. If family members are allowed to be present, a chaperone is recommended to assist with communication and education about procedures and other medical issues.

PROCEDURES ON RECENTLY DECEASED PATIENTS

The practices of teaching and performing procedures on recently deceased patients are controversial. The most important benefit of these practices is the fulfillment of the recognized need for hands-on practice for students and house staff, as well as experienced physicians.²² The setting of the recently deceased patient provides a unique clinical setting with literally *no* tangible risk to the patient. Following this rationale, physicians so inclined forward the unsubstantiated assertion that such practice allows the performance of these procedures competently on future, living patients, resulting in overall benefit to society. However, this assertion has not been demonstrated. Further, informed consent is rarely obtained or available in these settings. Some consider performing procedures without informed consent to be disrespectful, deceptive, or unethical.²³

In the absence of formal policy set by the local institution, and until formal policies are developed by governing organizations in emergency medicine, emergency physicians must make the choice most appropriate in the specific clinical situation encountered. Factors to be considered when making such decisions include availability of the family and feasibility of informed consent, teaching benefit to the student and his or her future patients, the overall benefit to society, invasiveness and disfigurement produced by the procedure(s), interference with forensic assessment, potential distress to the family, other potential avenues for teaching procedures, and any institutional policies on this issue.

RESUSCITATION RESEARCH

Research on resuscitation techniques and Pharmaceuticals has been problematic due to the frequent inability to obtain informed consent and the constraints of the decision-making process. Ordinarily, the process of obtaining informed consent for human subject research is designed to ensure protection and autonomy of the subject. However, the process of obtaining informed consent is time-consuming and requires competence of the subject. Because of these difficulties, the Food and Drug Administration (FDA) recently issued guidelines under

which resuscitation research may be performed with a waiver of informed consent under certain conditions.²⁴ When designing such research protocols, factors to be considered include the patient's wishes (if known), expected safety of the study protocol, expected benefit of the therapeutic intervention, overall expected benefit to society by improved knowledge regarding resuscitation, related animal data, feasibility of surrogate consent, local institutional review board (IRB) opinion, and local general public opinion, if available. Waiver of consent is obtained by application with the FDA with local IRB approval.

COMMUNICATION AND COUNSELING FOR SURVIVORS

In many cases, the communication, care, and counseling provided for survivors (family, friends, and the like) of victims of cardiac arrest will have more impact than the actual resuscitative efforts. Optimal care should be provided for families and friends of victims of cardiac arrest, regardless of the level of treatment rendered and outcome. See Chap. 294 for detailed discussion on communication.

protects the glottis (the narrowest portion of the airway); past the false and true vocal cords; and into the larynx. Surrounding the larynx is the thyroid cartilage, cricoid cartilage, and thyroid gland. The upper airway ends here. The lower airway then continues to the trachea and into the lungs. Potential obstruction may develop anywhere along this route. In infants and small children, the anatomy is somewhat different than in the adult. The tongue is relatively larger in relation to the mandible. The glottis is higher and more anterior and the vocal cords are angled more anteriorly and inferiorly. The epiglottis is large and floppy and may lie against the posterior wall of the pharynx.

AIRWAY OBSTRUCTION

Table 18-1 lists potential causes of upper airway obstruction. Basic management of the obstructed airway is discussed in Chap. 12. Most of these entities cause soft tissue swelling or themselves are soft tissue masses that compromise the upper airway, but a few need mentioning. Certain medical diseases, such as respiratory syncytial virus (RSV) and cystic fibrosis, produce copious secretions in the upper airway that can lead to partial or complete occlusion. Angioedema may present with soft tissue swelling sufficient to preclude an oral airway, requiring a nasal pharyngeal airway, nasotracheal intubation, or surgical intervention to reestablish patency. Laryngospasm, the feared complication of any invasive airway technique, needs to be considered in any patient with a compromised airway, especially in children. It is defined as closure of the glottis by the constriction of intrinsic/extrinsic laryngeal muscles, which can completely restrict ventilation. This pathophysiologic state often persists long after the stimulus has ceased. Laryngospasm may occur secondary to contact with the upper airway receptors on the tongue, palate, and oropharynx. Light touch to the upper airway, traction on the pelvic/abdominal viscera, chemical irritation, secretions, blood, water, and vomitus may all cause laryngospasm. Hypoxia and hypercapnia depress the activity of laryngeal adductor neurons, so laryngospasm is somewhat self-limited. Laryngospasm and bronchospasm occur more frequently in children and particularly following a recent respiratory tract infection.

NONINVASIVE AIRWAY MANAGEMENT

A. Michael Roman

ANATOMY AND PATHOPHYSIOLOGY

Prior to airway management procedures, when there is sufficient time, the physician should:

1. Inspect the patient's mouth for size of teeth and for size and mobility of the jaw.
2. Open the patient's mouth and observe the palate, tongue, and oropharynx.
3. Flex the stable neck (in the absence of trauma), assess mobility, and place in the sniffing position.
4. Examine the size and alignment of the neck.
5. Inspect the nasal openings for patency.
6. Listen for abnormal airway sounds such as stridor, hoarseness, or gurgling.
7. Ask the patient's history, if possible.
8. Be sure to have suction available at all times, especially during any procedures.

The anatomic airway (Figure 18-1) begins at the oral/nasal cavities and continues posteriorly to the tongue/turbinate, the tonsils/adenoids; past the palate; through the oropharynx; across the epiglottis, which

FIG. 18-1. The anatomic airway.

TABLE 18-1 Causes of Upper Airway Obstruction

Congenital/ Genetic	Infectious	Medical	Trauma/Tumor
Large tonsils	Tonsillitis	Cystic fibrosis	Laryngeal trauma
Macroglossia	Peritonsillar abscess	Angioedema	Hematoma/masses
Micrognathia	Retropharyngeal abscess	Laryngospasm	Smoke inhalation
Neck masses	Pretracheal abscess	Airway muscle relaxation	Thermal injuries
Large adenoids	Epiglottitis	Inflammatory	Foreign body
	Laryngitis/RSV*	Asthma	
	Ludwig angina		

*Respiratory syncytial virus.

Altered mental status, somnolence, or even sleep can depress the intrinsic and extrinsic muscle tone of the airway and produce obstruction. Some authors question the long-standing belief that the tongue falling back and occluding the lower pharynx is the major cause of airway obstruction in the somnolent or comatose patient. Recently, it was shown that during anesthesia in the supine patient, the tongue does, in fact, displace posteriorly, but it does not appear to occlude the pharynx. Upper airway obstruction in the unconscious patient occurs primarily because the epiglottis occludes the laryngeal inlet because of intrinsic muscle relaxation, which can be relieved simply by extending the neck. Extension of the neck and anterior displacement of the mandible moves the hyoid bone anteriorly and, in turn, lifts the epiglottis away from the laryngeal inlet. In a supine individual, the degree of extension of the head required to open the airway depends on elevation of the occiput above the horizontal plane. Relative to the neck, the more the occiput is elevated (to a degree), the less extension is required to open the airway, which explains why patients with airway compromise need to have their heads in the "sniffing" position. One can place a folded towel (not rolled) or foam rubber device underneath the patient's occiput (not neck) to create this position. Flexion of the neck has a marked effect of closing the airway, specifically the oropharynx. Recent magnetic resonance imaging (MRI) studies show that the soft palate also relaxes significantly during sedation, partially occluding the nasopharynx and causing complete obstruction when the patient is fully anesthetized. Moreover, extension of the anterior tongue does not appear to relieve this obstruction.¹

Esophageal foreign bodies can also obstruct the airway. They can impinge upon the larynx or trachea, causing either acute or subacute obstruction. Some foreign bodies, such as large fruit pits, may have been present for some time; thus, there may not be a history of swallowing or choking on an object.

ORAL/NASAL AIRWAYS

The oral airway (Figure 18-2) is an "S"-shaped, rigid instrument that is used to prevent the base of the tongue from occluding the hypopharynx. It should be used to maintain the airway only in a patient with an absent gag reflex. The operator places the oral airway over the tongue, being careful not to push it further into the hypopharynx. A tongue blade can be used to aid insertion. The concave portion is placed cephalad, rotated 180 degrees, or aimed toward the ear and rotated 90 degrees inferiorly to hold the tongue away from the pharyngeal wall. It can also be used as a bite block during orotracheal intubation.

A nasal airway (nasopharyngeal tube) (Figure 18-3) is made of a pliable material that allows it to be placed into the nostril of a somnolent patient with an intact gag reflex. The nasal airway is a wonderful

FIG. 18-2. An oral airway.

tool that can be quickly placed in a somnolent patient who may have decreased pharyngeal muscle tone and an obstructing soft palate and tongue. It allows air to bypass such obstructions, and if topical anesthesia is used as a lubricant, may ease subsequent passage of a nasogastric tube. The nasopharyngeal tube should be inserted into the most patent nostril (with the tip lubricated, ideally with a topical anesthetic such as lidocaine jelly) horizontal to the palate, and advanced until

FIG. 18-3. Nasal airways.

maximal airflow is heard. It is important to use the correct size tube and to avoid inserting it far enough to stimulate the gag reflex.

THE BAG-VALVE-MASK UNIT

The bag-valve-mask (BVM) unit (Figure 18-4) is a self-inflating bag with a nonbreathing valve that can be attached to a face mask. This design allows room air or oxygenated air to be manually delivered into the victim's lungs after any obstruction has been eliminated. This apparatus can be used initially while preparing for definitive airway maintenance. After the mask is placed, the handler clamps it snugly to the face. The thumb and index finger grasp the mask while the other fingers grasp the chin and pull it forward to hyperextend the stable neck. The other hand compresses the bag, expelling air into the patient's respiratory tree. This procedure can be used to manage respiratory failure temporarily, to assist poor inspiratory effort, or to temporize respiratory fatigue. The most common problem with a one-person operation is air leaks around the mask. A two-person operation employs two hands to hold the mask flush and has been shown to result in more effective ventilation.² Placement of an oral or nasal airway further facilitates airflow. The BVM unit may also be used prior to rapid-sequence intubation (RSI) to quickly assess the ease of BVM ventilation in cases where oral intubation fails. After an intubation, the BVM unit can be attached to the proximal end of the endotracheal tube.

To deliver 100 percent oxygen, there must be a reservoir with the same volume as the bag and an oxygen flow rate equal to the respiratory minute volume of the patient. By using a 2.5-L reservoir bag with an oxygen flow of 15 L per min, 100 percent oxygen can theoretically be delivered, although most nonbreathers deliver about 75 percent oxygen. Similarly, a demand valve attached to the reservoir port of the ventilation bag will deliver a high concentration of oxygen.

ESOPHAGEAL AIRWAYS

Esophageal obturator airways (EOAs) (Figure 18-5)—the pharyngotracheal lumen airway and the esophageal tracheal Combitube—are all devices used in the prehospital setting when oral endotracheal intubation is not a viable option. These devices are designed to be placed in apneic, unconscious adults only.

Esophageal Obturator Airway/ Esophageal Gastric Tube Airway

EOAs/esophageal gastric tube airways (EGTAs) are mentioned here only for historic reasons. They are rarely used now. The original primary benefit, placement without direct laryngeal visualization, has been supplanted by other more efficacious devices. The EGTA is a modification of the EOA and has an open distal tube containing a valve that allows passage of a nasogastric tube. Compared with the endotracheal tube (ETT), ventilation and oxygenation studies reveal varying results but suggest that the EOAs are adequate during cardiac

FIG. 18-4. Bag-valve-mask unit.

arrest. One study showed that some physicians had never seen an EOA, and unfamiliarity is reason enough to avoid using this tool.

Pharyngotracheal Lumen Airway

The pharyngotracheal lumen airway (PTLA) (Figure 18-5A) is another two-tubed, cuffed airway that seals the oropharynx proximally and occludes the esophagus distally, allowing for ventilation through the short tube. There is no need for a face-to-mask seal. If the trachea is intubated by the long tube, ventilation can occur through the lumen, similar to an ETT.

Esophageal Tracheal Combitube

The esophageal tracheal Combitube (ETC) (Sheridan Catheter Corp.) (Figure 18-5B) is a plastic twin-lumen tube with a proximal low-pressure cuff that seals the pharyngeal area and a distal cuff that seals the esophagus, allowing ventilation between the cuffs. The proximal seal also removes the need for a facemask and, as compared with the PTLA, minimizes dental damage to the cuff. The distal cuff is similar to an ETT and serves to seal either the esophagus or the trachea when inflated. If the distal tube enters the esophagus, perforations in the esophageal lumen serve to ventilate the patient. If the trachea is intubated, the patient is ventilated directly, as with the cuffed ETT.

Tracheoesophageal Airway

The tracheoesophageal airway (TEA) (Figure 18-5C) is a standard ETT attached to a ventilation mask with two ports, one for the ETT and the other for oropharyngeal mask ventilation. It is designed to function equally well if inserted into the trachea or the esophagus. Tracheal intubation is facilitated by using cricoid pressure and extending the neck. While the tube is in the trachea, the cuff is inflated and the patient is ventilated normally. While the tube is in the esophagus, the patient is ventilated through the mask and the ETT allows for gastric venting or decompression.

Laryngeal Mask Airway

The laryngeal mask airway (LMA) (Intavent, Ltd.) (Figure 18-6) was developed by Brain, in 1983, as another artificial airway that can be placed blindly yet can provide a positive-pressure airway. The LMA consists of a tubular oropharyngeal airway similar to the ETT, but it is shorter and has a distal silicone laryngeal mask (balloon-type bulb) that inflates and provides a seal around the larynx. The LMA, when placed, is similar to other esophageal airways in that it can be inserted without manipulation of the patient's head. Because of its large diameter and short length, intubation of the bronchi or esophagus is circumvented. The hypopharynx, which is adapted to the passage of food, is less sensitive to a foreign body than the larynx and vocal cords, which have sensitive, protective reflexes.

Many published cases show the LMA to be an effective alternative when the ETT fails because of nonvisualization of the cords secondary to ETT difficulty, airway masses, or cervical pathology. One study of LMA use by nonphysician emergency personnel in fasting patients found it easier to place than the ETT. In this study, there was no failure in LMA placement, whereas 21 percent of ETT placement attempts failed. Furthermore, the LMA required only half as many attempts and one-fifth the time to perform, and was rated equal to the ETT as an airway by anesthesiologists.⁴ Complications of the LMA include partial or complete respiratory obstruction (approximately 3 percent) and general failure to protect against aspiration of gastric contents. The LMA is also inadequate in severe chronic obstructive pulmonary disease (COPD) because of the high pressure requirement.⁵ Applying cricoid pressure in the acute setting almost always impedes insertion of the LMA and therefore reduces the chance of

FIG. 18-5. A. Pharyngotracheal lumen airway. Inflation line to proximal cuff. B. Esophageal tracheal Combitube. C. Tracheo-esophageal airway (used with permission).

successful ventilation of the patient.⁶ Therefore the LMA seems an effective alternative to the ETT when endotracheal intubation fails or when cervical pathology exists.

NONINVASIVE POSITIVE-PRESSURE VENTILATION

The widespread use of noninvasive positive-pressure ventilation (NIPPV) for chronic sleep apnea in the 1980s has prompted investigators to look at NIPPV in the acute setting today. NIPPV can be described as an application of a preset volume/pressure of inspiratory air through a face or nasal mask.

Inspiratory muscle fatigue is the final phase of ventilatory failure in patients with severe reactive airway disease, COPD, and end-state pulmonary edema/pneumonia. The airway resistance overcomes the patient's muscular ability to ventilate. An effective alternative to the traditional ETT, with its potential complications, is noninvasive, mechanically assisted ventilation with continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP).

Continuous Positive Airway Pressure

CPAP is one method of NIPPV where positive pressure is held constant throughout the respiratory cycle and applied through a face or nasal mask. It recently received renewed application in the treatment of patients with acute hypoxemic respiratory failure.⁷ CPAP improves

pulmonary function by reducing the work of breathing, maintaining inflation of atelectatic alveoli, and improving pulmonary compliance. CPAP also improves hemodynamics by reducing preload and afterload, therefore improving patient's cardiac output in left ventricular failure.

NIPPV has been used to support patients with acute respiratory failure but has been primarily studied in the intensive care setting. Only in the last decade have patient diagnostic categories individually been studied in the emergency department (ED) using CPAP. Those diseases include COPD, status asthmaticus, adult respiratory distress syndrome (ARDS), acute cardiogenic pulmonary edema (ACPE), pneumonia, or traumatic respiratory insufficiency. CPAP can be adjusted according to the patient's clinical response. Pressures of 5 to 10 cm of H₂O are most commonly used, and pressures above 15 are rare.

In early published and unpublished studies, CPAP at 10 cm of H₂O used in the hospital and prehospital settings showed more rapid improvement of vital signs (heart rate, respiratory rate, blood pressure) and oxygen saturation versus standard medical therapy alone in ACPE patients.⁸ In other studies, using CPAP up to 10 to 12.5 cm H₂O, there was a significant improvement in Pao₂, stroke volume index, lower rate-pressure product, intrapulmonary shunt fraction, alveolar-arterial oxygen gradient, and, more importantly, lower rate of tracheal intubation.⁹ After meta-analysis on the above studies, there was found a statistically significant reduction in the need for tracheal intubation and possibly a decrease in mortality.¹⁰

FIG. 18-6. A. Laryngeal mask airway (LMA). B. LMA diagram showing placement at the larynx (used with permission).

Bilevel Positive Airway Pressure

BiPAP is a method of NIPPV where positive airway pressure is used to assist the patient's spontaneous ventilation at a "bilevel." The positive airway pressure increases during inspiration and a positive expiratory pressure provides the physiological positive end-expiratory pressure known as PEEP. BiPAP machines respond to the patient's respiratory cycle by alternating between a higher flow rate during the inhalation phase of respiration and a lower flow rate during the exhalation phase. The use of face-mask positive-pressure ventilation with acute exacerbation of COPD avoids intubation up to 76 percent of the time.¹¹ The benefits of BiPAP have been proven most effectively in the setting of severe COPD and is now being evaluated for ACPE. With the positive inspiratory pressure decreasing the work of breathing, and the positive expiratory pressure providing the physiologic CPAP, BiPAP has a theoretical advantage over CPAP alone. BiPAP has shown to reduce respiratory rate, dyspnea, and allow a more rapid improvement in both oxygenation and ventilation versus CPAP. Most recent studies us-

ing BiPAP with ACPE has shown to be an effective treatment in acute respiratory failure when compared to conventional oxygen therapy alone.^{12,14}

NIPPV has been shown to decrease need for endotracheal intubation (ETI), thus decreasing the risks of ETI in the immunocompromised patient.¹⁵ A major goal in the management of respiratory failure in the immunocompromised patient is avoiding ETI. These patients are at high risk of pneumonia, bronchitis, sinusitis, and ETI increases the risk of acquiring these diseases. In patients with pulmonary infiltrates, fever, and acute respiratory failure, early NIPPV has shown to decrease rates of ETI and the serious associated complications. Early NIPPV improves the likelihood of survival to hospital discharge.¹⁵ One intensive care unit study showed that irrespective of the severity of the patient's illness, the use of NIPPV reduced the risk of ventilation-associated pneumonia and nosocomial infections.¹⁶

NIPPV decreases the requirement for mechanical support and lowers the average stay in the intensive care unit, among hemodynamically stable patients with impending respiratory failure.¹⁷ Studies also demonstrate arterial blood gas improvement, intubation avoidance, and decreased respiratory rates with low complication risk.^{7,18}

In the elderly, where the decision to intubate is more complex (because of age, illness, or cancer), nasal-mask ventilation yielded improvements in P_{aO_2} similar to those of other studies (60 percent), but hypercarbia improved more slowly.¹⁹ NIPPV should be considered for any patient where invasive respiratory support presents significant risk of sequelae.

In the pediatric patient population, BiPAP appears to improve respiratory rate, heart rate, P_{aCO_2} , and O_2 saturation. It also decreases the need for intubation in obstructive apnea.

Trauma patients frequently have a significant loss of functional residual capacity (FRC) that often leads to mild to moderate respiratory insufficiency. In such instances, CPAP has been used to improve respiratory function and reduce hypoxemia.²⁰ CPAP is helpful in decreasing the work of breathing and improving FRC, thus preventing hypoxemia, hypocarbia, and tachypnea. Criteria for NIPPV have included spontaneous respirations, absence of respiratory acidemia/hypercarbia, intact mental status, a P_{aO_2} above 65 mm Hg, presence of a functioning nasogastric tube, and absence of severe maxillofacial injury. Improvement may be seen starting at 5 cm H_2O . Studies show that a mean CPAP of 8.6 cm H_2O meets therapeutic goals. Duration of therapy may range from a few hours to 2 days. Trauma conditions that have been studied include pulmonary contusion, flail chest, pneumothorax, hemothorax, and multiple chest and abdominal gunshot/stab wounds. In this setting, a functioning nasogastric tube and respective chest tube placement, when indicated, are extremely important. Patients suffering high esophageal or tracheal injuries should not be supported with a NIPPV. Maxillofacial and basilar skull fractures are also contraindications to NIPPV by face mask. Because many traumatized patients exhibit a remarkable capacity to breathe spontaneously and improvements in hemodynamics are one of the benefits of using spontaneous ventilation versus mechanical ventilation, CPAP/BiPAP is an appropriate adjunct for managing the airway in the trauma patient assuming non-airway related indications for ETI do not exist.

Technique

Nasal-mask or facial-mask ventilation employs a tight-fitting mask that allows for a CPAP or BiPAP support system. The patient with impending respiratory failure receives either continuous pressure or inspiratory/expiratory (bilevel) support, thus allowing a decrease in inspiratory effort, rest for respiratory and accessory muscles, improvement of gas exchange, avoidance of intubation, and improved comfort.^{11,21} A nasal-mask protocol with BiPAP appears to be the most advanced protocol and appears to allow more sensitive changes during the course of treatment (Figure 18-7). The nasal mask allows the pa-

FIG. 18-7. A patient with severe COPD on nasal BiPAP (used with permission).

tient to eat, drink, and converse with the emergency staff. However, the nasal positive-pressure ventilation (NPPV) (distinct from NIPPV) does allow for air leaks through the mouth.

The ideal BiPAP ventilator is small, relatively inexpensive, very mobile, and tolerates some leaks. It is possible to set the inspiratory positive airway pressure (IPAP) and the expiratory positive airway pressure (EPAP/PEEP) independently. Three modes of ventilatory triggering are available: spontaneous, combined spontaneous/timed, and timed. The proper-size mask should be chosen (allowing no mouth coverage) and tight enough to allow a good, comfortable seal. Settings should include spontaneous mode, IPAP set at 10, EPAP set at 3 cm H₂O initially and increasing IPAP in 3-cm increments and EPAP slowly. Continuing hypercarbic failure is treated by increasing IPAP alone in 3-cm increments.²² Caution must be applied when using NIPPV at pressures approaching 15 cm H₂O. There is evidence of increased risk of acute myocardial infarction with higher NIPPV pressures. BiPAP, CPAP, and NIPPV at high pressures (15 cm H₂O), may produce a greater fall in blood pressure because of a higher intrathoracic pressure reducing myocardial perfusion.^{13,14}

Complications

Known complications include difficulty with mask seal requiring multiple readjustments, gastric distention, aspiration (rare), intolerance of the positive pressure, and facial skin breakdown (with long-term use). These complications appear to occur infrequently, but the most common intolerance is excessive respiratory secretions, which, in fact, may be a relative contraindication to NPPV along with life-threatening epistaxis, or pre-existing bullous lung disease. Other contraindications to NPPV are severe maxillofacial trauma and potential basilar skull fracture where pneumocephalus may occur, pneumothorax, pneumomediastinum, or hypotension due to or associated with intravascular volume depletion. Another problem with mask ventilation is that using a conventional ventilator can be difficult or even counterproductive because of the inadvertent triggering of alarms in systems in masks not designed for this use. The BiPAP ventilatory system, which is designed for NIPPV use, has been used with success, but may not be readily available in the ED, and respiratory services may have to be contacted for this setup.

Application of NPPV provides ventilatory support for impending respiratory failure and has been shown to decrease the workload of the respiratory muscles. Oxygen saturation, Pao₂, and pH remain stable

or improve as compared with unassisted ventilation. Therefore this technique may prove useful in respiratory failure when complication of intubation is high.

This modality may decrease long-term hospital admissions, prevent unwanted intubations in the elderly or severely ill, and circumvent borderline respiratory failure intubations. Each patient must be closely monitored for tolerance of upper airway positive pressure and for instability.

Patients who receive NIPPV need to be cooperative and should not have life-threatening cardiac ischemia, dysrhythmias, or hypotension. NIPPV is inappropriate in patients who have absent or agonal respiratory effort, or who produce excessive airway secretions. Airway management and apparatus associated with NIPPV can be distracting. However, medical treatment, such as in-line nebulized updrafts, anticholinergics, steroids, and respiratory hygiene should proceed as appropriate.

TRACHEAL INTUBATION AND MECHANICAL VENTILATION

Daniel F. Danzl
Robert J. Vissers

Airway integrity, assurance of oxygenation, ventilation, and prevention of aspiration are the mainstays of emergency airway management. The indications for tracheal intubation in the emergency setting most commonly include correction of hypoxia or hypercarbia, prevention of impending hypoventilation, and ensuring maintenance of a patent airway. Secondary indications include provision of a route for resuscitative medication administration and to permit temporizing paralysis during diagnostic testing.

OROTRACHEAL INTUBATION

The most reliable way to ensure a patent airway, provide oxygenation and ventilation, and prevent aspiration is endotracheal intubation. Many unconscious and even conscious patients may be unable to spontaneously clear the airway of secretions, may require mechanical ventilation, may have aspirated, or lack protective airway reflexes.¹

Preparation

The clinical assessment of oxygenation and ventilation may be unreliable in a chaotic emergency department (ED). Continuous, noninvasive bedside monitoring of arterial oxygen saturation is helpful. Isolated oximetry does not assess the status of alveolar ventilation, whereas *capnography* does allow estimation of the partial pressure of carbon dioxide (Paco₂) based on the waveform display of the end-tidal

partial pressure of carbon dioxide. *Capnometry* refers to the numerical display. In combination, these noninvasive modalities affect decisions regarding tracheal intubation.

Checking the necessary equipment should be standard procedure for ED clinicians at the beginning of their clinical duties. The following items should be available: oral and nasal airways, different-size orotracheal tubes, an O₂ setup that is appropriately connected, a self-inflating ventilation bag, different-size masks, and various sizes of Miller and Macintosh blades with the light checked and the suction attached and tested. When intubation is required, the appropriate-size tube and an additional tube (0.5 to 1 mm in diameter smaller) should be selected, and the cuffs should be checked for air leaks with a 10-mL syringe. Selecting a tube of the proper diameter is essential. The approximate sizes for endotracheal tubes are 8.0 to 8.5 mm inner diameter for an adult male and 7.5 to 8.0 mm inner diameter for an adult female. The second hole at the end of the tube above the bevel is called *Murphy eye*. This hole permits some uninterrupted airflow if the tip is occluded.

Endotracheal tubes (ETTs) with high-volume, low-pressure cuffs are the best design for adults. When properly inflated, thin-walled cuffs prevent aspiration better than medium-walled cuffs. The operator should test the light on the laryngoscope and then pick an appropriate-size blade. The straight Miller blade is used to physically lift the epiglottis. The curved Macintosh blade is placed in the vallecula above the epiglottis and is used to indirectly lift the epiglottis off the larynx owing to the traction on the frenulum.

The development of expertise with both blade types is desirable, because they offer different advantages. The curved blade may cause less trauma and be less likely to stimulate an airway reflex, because, when used properly, it does not directly touch the larynx. It also allows more room for adequate visualization during tube placement and is helpful in the obese patient. The straight blade is mechanically easier to insert in many patients who do not have large central incisors. Selecting the proper-size blade greatly facilitates intubation. In adults, the curved Macintosh no. 3 is the most popular, and no. 4 is more useful in large patients. The straight Miller no. 2 or 3 is popular for the same purposes.

The patient should be thoroughly preoxygenated before intubation, ideally for several minutes. Hypoxia develops more quickly in children, pregnant women, and patients in other hyperdynamic states. Flexion of the lower neck with extension at the atlantooccipital joint (sniffing position) aligns the oropharyngeal-laryngeal axis, allowing a direct view of the larynx (Figure 19-1). The inexperienced laryngoscopist's most common reasons for failure, inadequate equipment preparation and poor patient positioning, arise before using the laryngoscope.

Technique

The laryngoscope is held in the left hand, and an ETT or suction apparatus is held in the right. After dentures and any obscuring blood, secretions, or vomitus have been removed, the suction is exchanged for the ETT and inserted during the same laryngoscopy.

The blade is inserted into the right corner of the patient's mouth. If a curved Macintosh blade is used, the flange will push the tongue toward the left side of the oropharynx. If the blade is inserted directly down the middle, the tongue can force the line of sight posteriorly, which is a common reason for the putative "anterior larynx." After visualization of the arytenoids, the epiglottis is lifted directly with the straight blade or indirectly with the curved blade. The larynx is exposed by pulling the handle in the direction that it points, i.e., 90 degrees to the blade. Cocking the handle back, especially with the straight blade, risks fracturing central incisors and is ineffective at revealing the cords.

There are a variety of other straight and curved blades available. For example, the Guedel blade is a straight blade with an acute, 72-degree angle to the handle. The Schapira straight blade has a side concavity that helps cradle the large tongue and push it toward the left

FIG. 19-1. A. Oral, pharyngeal, and laryngeal axes. B. Sniffing position.

side of the mouth. The CLM curved laryngoscope blade has a hinged tip, which permits elevation of the epiglottis with minimal force, as the fulcrum is repositioned down within the pharynx.

One technique that avoids the most common error, i.e., overly deep insertion of the blade, is to look for the arytenoid cartilages. If only the posterior commissure is visible, an assistant should apply more pressure on the cricoid (Sellick maneuver) or perform the laryngeal lift. Another option is the "burp" technique. The larynx is manually displaced posteriorly (backward) against the cervical vertebrae, superiorly (upward), and laterally to the right (rightward pressure). To avoid error, the cuff must be seen passing completely through the cords. "Last ditch" attempts at blind passage invite anoxia. The intubator should never be reluctant to abort the attempt if visualization of the larynx is not successful. Whenever feasible, an assistant should apply steady cricoid pressure with the thumb and index finger during the intubation to help prevent aspiration.

With proper technique and practice, semirigid, malleable, blunt-tipped metal, or plastic stylets are not usually necessary for most patients. Nevertheless, a selection of proper-size stylets should be available. The tip of the stylet should not extend beyond the end of the ETT or exit Murphy eye.

One aid to intubation with direct vision is the use of a thin, flexible intubation stylet. This type of stylet can be inserted blindly around the epiglottis into the trachea. The ETT is then threaded over it into the trachea, and the stylet is removed. The Eschmann tracheal tube introducer or stylet, also known as the "gum elastic bougie," is a valuable aid for difficult oral intubations. Another option is to use the tip on the laryngeal tracheal anesthesia kit. With either stylet, orient the tube so that Murphy eye is at the 12-o'clock position.

The tube should never be forced through the vocal cords, which can result in avulsion of the arytenoid cartilages or laceration of the vocal cords. Usually, any difficulty in passing the tube is a result of the tube being too large or too soft and flexible. Directed transoral or translaryngeal anesthesia with lidocaine can help relax the cords. If anesthesia fails, aligning the bevel with the glottic opening may be successful.

The tube should be advanced until the cuff disappears below the cords. Because head motion may move the tip of the tube 1 to 2 cm,

correct tube placement is a minimum of about 2 cm above the carina. From the corner of the mouth, this location is approximately 23 cm in men and 21 cm in women. The base of the pilot tube (a tube with the adapter to inflate the cuff) is usually at the level of the teeth. To avoid ischemia of the tracheal mucosa, cuff pressure should be kept below 40 cm H₂O. The minimal intracuff pressure to prevent aspiration is 25 cm H₂O.² The operator should secure the tube, being careful not to impede cervical venous return with the umbilical tape or fixator. The use of a modified clove-hitch knot or a commercial fixator is ideal and helps to avoid **kinking** the pilot tube.

CONFIRMATION OF INTUBATION Endobronchial or esophageal intubation will result in hypoxia or hypercarbia. There is no clinically reliable substitute for direct visualization of the tube passing through the vocal cords. Hence the adage, "when in doubt, take it out." Nevertheless, there are a number of options to help confirm intratracheal tube positioning. Clinical assessments, including chest and epigastric auscultation, tube condensation, and symmetrical chest wall expansion, are not infallible in the ED. "Breath sounds" from the stomach can be transmitted through the chest after gastric insufflation.

The two basic categories of confirmatory adjuncts are end-tidal CO₂ (ETCO₂) detectors or monitors and esophageal detection devices. Both have advantages provided that the operator remains cognizant of the sources of interpretation error. Capnometers measure CO₂ in the expired air. The most commonly used capnometric devices in the ED are colorimetric, with a pH-sensitive purple filter paper. When in contact with CO₂, hydrogen ions are formed, resulting in color changes according to the concentration of CO₂. For example, with the Nellcor Easy Cap II, the paper turns yellow after exposure to 2 to 5 percent ETCO₂, which is equivalent to 15 to 38 mm Hg Pco₂. There is no color change, the filter paper remains purple, with an ETCO₂ of less than 0.5 percent, equivalent to less than 4 mm Hg Pco₂. Colorimetric capnometers are useful for general readings, as in assessing proper ETT placement, but are not accurate enough when precise determinations are necessary. Capnography displays real-time characteristic CO₂ waveforms.

The use of ETCO₂ pressure (PETCO₂) monitoring can help confirm endotracheal intubation.² Colorimetric or infrared detection of PETCO₂, however, may not occur even with proper ETT placement, during states of low pulmonary perfusion such as cardiac arrest, inadequate chest compressions during cardiopulmonary resuscitation, or massive pulmonary embolism. Another cause of false-negative interpretations is massive obesity. Severe pulmonary edema may obstruct the ETCO₂ or PETCO₂ monitor with secretions. Alternatively, there may be an initial false-positive detection of CO₂ after esophageal intubation if carbonated beverages have been ingested by the patient or for a few minutes after bolus sodium bicarbonate administration. Another cause is gastric distention resulting from bag-valve-mask (BVM) ventilation. A heated humidifier or nebulizer or epinephrine instilled through the ETT also can cause false-positive interpretations.

After intubation and cuff inflation, the capnometer is attached to the ETT. Then a BVM unit is attached to the detector, and the patient is given about six ventilations to wash out residual CO₂. The PETCO₂ monitor is then checked for color changes. If capnography is available, a persistent positive capnograph formation after clear and direct visualization of tube placement approaches certainty. On rare occasion, misplacement of the hypopharyngeal glottic tube tip may result in misleadingly normal oximetry and capnography. This error can be recognized by the inadequate depth of tube insertion or inadequate ventilatory volumes or on chest x-ray.

Esophageal detection devices also offer the potential to accurately determine tube location. The various designs depend on their proper function as inline aspirators of the ETT. The device adaptors fit over the 15-mm ETT connector. One advantage of the esophageal detection devices is that accuracy does not depend on adequate cardiac output and pulmonary perfusion. Rather, proper functioning is predicated on

the anatomic differences between the esophagus and the trachea. When the ETT is in the esophagus, the soft, non-cartilaginous walls will collapse, and air cannot be aspirated easily.

To perform the syringe aspiration technique, the device should be attached after intubation but before ventilation. The syringe plunger should then be retracted. Resistance to aspiration reflects occlusion from esophageal collapse. If there is no resistance during aspiration, then the tube is assumed to be in the trachea. If a self-inflating bulb is used, the bulb should be compressed and then attached to the ETT. One advantage of the bulb is that it requires one hand.

COMPLICATIONS The emergency physician should never assume that continued airway patency is assured after ETT insertion.³ Repeated suctioning is necessary to prevent thrombotic or inspissated secretions from obstructing the tube. Endobronchial ball-valve obstruction also can be caused by a clot. The clot can impair ventilation and produce hyperinflation of individual lobes. Cuff displacement or overinflation can result in ball-valve obstruction of the airway. Cuffs inflated in the field during frigid conditions will expand with warming. If tracheal ball-valve obstruction is suspected, the cuff should be deflated. If the tube is blocked, deflation will allow exhalation.

There are many other correctable intubation complications that should be kept in mind. If the ETT cuff leaks after the intubation, the inflation valve should be checked, because it may be defective. One simple remedy is to attach a three-way stopcock to the valve, re-inflate the cuff, and turn off the stopcock. A cuff that seems to be leaking slowly might be sealable. One type of sealant involves instilling an aspirable mixture of normal saline and 2 percent lidocaine jelly, at a 3:1 ratio, into the cuff.

If the ETT needs to be replaced, a tube changer might be considered. There are many commercially available, semirigid catheters that include 15-mm adaptors or connectors to permit ventilation during the tube exchange. These devices have quick-connect adapters that incorporate through-lumen designs to ensure adequate airflow during the procedure.

Although uncommon, morbidity related to emergent endotracheal intubation does occur and may be quite debilitating. Arytenoid cartilage avulsion or displacement, usually on the right, prevents the patient from phonating properly. Intubation of the pyriform sinus and pharyngeal-esophageal perforation has been reported. Chordal synechiae may develop anteriorly, or commissural stenosis can develop posteriorly.

Subglottic stenosis is the most disastrous sequela. The physician should avoid cuff overinflation and attempt to minimize tube motion in the larynx and trachea. Subglottic stenosis usually occurs in patients with poorly secured tubes who are combative or on ventilators.

ALTERNATIVE AIRWAY MANAGEMENT TECHNIQUES

Nasotracheal Intubation

Nasotracheal intubation (NTI) is an essential psychomotor skill that may be useful in many difficult situations. Operators adept at rapid sequence intubation (RSI) and NTI are in the best position to assess and act on the following prime considerations: What are the potential risks and benefits to having spontaneous respirations preserved rather than ablated? Is there a safe alternative in this patient that may avoid precipitating the need for a potentially unnecessary surgical airway?

Nasal intubation is helpful in situations where laryngoscopy or cricothyrotomy may be difficult and neuromuscular blockade hazardous.⁴ Severely dyspneic patients with congestive heart failure, chronic obstructive pulmonary disease, or asthma and who are awake often cannot remain supine but can tolerate NTI in the sitting position. It may be impossible to align the oropharyngeal-laryngeal axis in patients with arthritis, masseter spasm, temporomandibular dislocation,

or recent oral surgical procedures. Patients with a peculiar body habitus may be difficult to intubate orally. Other considerations for NTI include persistent trismus from seizures, facial trauma, infection, tetanus, or decorticate-decerebrate rigidity. Patients with certain neuromuscular disorders or dystrophies or significant electrolyte abnormalities are not ideal candidates for oral intubation.

To minimize epistaxis, both nares should be sprayed with a topical vasoconstrictor anesthetic. During the brief period for the anesthetic to take effect, a cuffed ETT 0.5 to 1 mm smaller than optimal for oral intubation should be selected. The integrity of the cuff should be verified, and the tube adapter should be checked to ensure a snug fit. Because secretions and blood may be expelled into the air and onto the intubator's face, universal precautions should be observed. An option in addition to a face shield is the use of a protective filtering adapter, such as the Humid-Vent 1, which can be attached to the proximal end of the ETT (Gibeck Respiration, Stockholm, Sweden).

The tube, lubricated with a water-soluble (2 percent lidocaine or K-Y) jelly, is advanced along the nasal floor on the more patent side. Abrasions of the Kiesselbach plexus can be minimized by having the bevel face the septum. Steady, gentle pressure or slow rotation of the tube usually bypasses small obstructions. Passage of the tube is straight back toward the occiput (not upward). If the right side is not passable, the tube should be advanced along the other side before resorting to a smaller tube.

In patients with intact protective airway reflexes, directed transoral or translaryngeal anesthesia often facilitates intubation. Translaryngeal anesthesia, although not widely used in the ED, should be considered when the initial intubation attempt is unsuccessful. After palpating the superior border of the cricoid cartilage in the midline, the cricothyroid membrane is punctured with a 22- to 25-gauge 0.5- to 1-in. needle (Figure 19-2). The needle should be perpendicular to the membrane in the midline, with the point of injection just cephalad to the cricoid cartilage. Aspirate air, swiftly inject 1.5 to 2.0 mL of 4 percent lidocaine (sterile for injection), and press the site firmly with one finger for a few seconds. This technique prevents small degrees of subcutaneous emphysema that would erroneously suggest a laryngeal injury. Translaryngeal anesthesia is contraindicated if the landmarks are obscured by thyroid or tumor impingement on the cricothyroid membrane and in obese or combative patients.

An assistant should immobilize the patient's head and initially maintain it in a neutral or slightly extended position ("sniffing position"). The physician should stand beside the patient, with one hand on the tube and with the thumb and index finger of the other hand straddling the larynx. The tube is then advanced while rotating it medially 15 to 30 degrees until maximal airflow is heard through the tube. Then the tube is gently but somewhat swiftly advanced. The best time for advancement is at the initiation of inspiration. Entrance into the larynx may initiate a cough, and most expired air should exit through the tube even though the cuff is uninflated. **The presence of any vocal sounds indicates a failed attempt.**

The advancement of the tube toward the carina can be observed externally. The normal distance from the external nares to the carina is 32 cm in the adult male and 27 to 28 cm in the adult female. Therefore, before obtaining a chest x-ray, the optimal initial depth of tube placement for NTI in adults, measured at the nares, is 28 cm in men and 26 cm in women. Standard tube confirmation techniques should be performed. Secretions or blood in the tube should be removed before initiating positive-pressure ventilation.

If intubation is unsuccessful, the neck is carefully inspected to determine malposition of the tube. Most commonly, the tube is in the pyriform fossa on the same side as the nostril used. A bulge will be seen and can be palpated laterally. The tube is withdrawn into the retropharynx until breath sounds are heard. The tube is then redirected while the larynx is manually displaced toward the bulge. If there is no contraindication, flexion and rotation of the neck to the ipsilateral side while the tube is rotated medially often is effective.

B

FIG. 19-2. Translaryngeal anesthesia via cricothyroid puncture. A. Anatomy, anterior view. B. Anatomy, cross-sectional view. Same landmarks as those for translaryngeal ventilation.

The other most common tube misplacement is posteriorly in the esophagus. There are no breath sounds through the tube, and the trachea is slightly elevated. The intubator should attempt redirection after extending the patient's head and performing Sellick maneuver. When cervical spine pathology is suspected, a directional tip-control tube (Endotrol) or a fiberoptic laryngoscope should be considered. Endotrol tubes smaller than 7.5 mm (inner diameter) tend to soften and obstruct and can be difficult to suction. However, the use of these directional-tip tubes often improves the success rate of the first attempt at NTI.

When the tube hangs up on the vocal cords, shrill, turbulent air noises will be heard. The tube can be rotated slightly to realign the bevel with the cords. Alternatively, 2 mL of 4 percent lidocaine (80 mg) can be administered down through the tube onto the cords if transoral or translaryngeal anesthesia was omitted.

Nasal intubation with a fiberoptic laryngoscope may be required when neoplastic lesions, lymphoid tissue, Ludwig angina, peritonsillar abscess, or epiglottitis obstructs the pharynx. The presence of facial trauma does not appear to be a contraindication to NTI.⁵ Complex nasal and massive midfacial fractures and bleeding disorders are relative contraindications to NTI.

Conversely, oral intubation can impede prompt reduction and stabilization of some maxillary fractures. Because a LeFort I fracture does not extend to the cribriform plate, it is not a contraindication. Fiberoptic guidance or RSI is preferable for LeFort II and III fractures.

The risk of inadvertent intracranial passage of a nasotracheal tube is extremely low, unlike that with nasogastric tube insertion. Very poor

technique in the setting of obvious massive head trauma would be required for such an outcome. Severe traumatic nasal or pharyngeal hemorrhage may necessitate orotracheal intubation or cricothyrotomy. Contamination of the spinal fluid is a hazard with some basilar skull fractures.

Serious complications of NTI are rare. In a number of large series, there was no permanent laryngeal damage. Epistaxis will occur with inadequate topical vasoconstriction, excessive tube size, poor technique, or anatomic defects. Excessive force can damage the nasal septum or turbinates.

Frequent suctioning, especially if epistaxis or other upper airway hemorrhage is present, will help to prevent thrombotic occlusion of the tube or a mainstem bronchus. Retropharyngeal lacerations, abscesses, and nasal necrosis have been reported.

Paranasal sinusitis, especially occurring with prolonged NTI or severe cranial trauma, can be an unrecognized source of sepsis. The risk of postintubation sinusitis correlates with the duration of intubation, which often reflects the neurologic insult. In the setting of craniofacial trauma, any subsequent computed tomographic scans should include views of the paranasal sinuses. Other factors causing sinusitis include the presence of a nasogastric tube, sinus hemorrhage or fracture, and administration of glucocorticoids.

Digital Intubation

Digital intubation is an underused, noninvasive technique for ETT insertion. The performance of this maneuver requires tactile recognition of the epiglottis. Visual landmarks may be impossible to identify with a laryngoscope, because of patient positioning, anatomic disruption, or significant hemorrhage. Tactile digital intubation can avert cricothyrotomy when direct laryngoscopy after neuromuscular blockade has failed. Patients with micrognathia or temporomandibular immobility are poor candidates for this technique.

The patient must be deeply comatose, in cardiac arrest, or in a state of adequate neuromuscular blockade. Before insertion, the well-lubricated ETT should be shaped with a stylet into a J configuration. Then, unless the operator is quite confident, a bite block should be inserted in the opposite side of the mouth. The tongue should be lifted and the mandible pulled forward with the gloved dominant hand. The lubricated middle and index fingers of the gloved nondominant hand are inserted down the middle of the tongue and the cartilaginous epiglottis is palpated with the middle finger.

While the epiglottis is being palpated, the well-lubricated, J-shaped ETT and stylet are inserted and slid along the middle finger. The path from the corner of the mouth opposite the bite block to the epiglottis is the shortest distance. The index finger can help guide the tube from behind. As the larynx is entered, resistance will be encountered. At this point, it is essential to partly withdraw the stylet. Otherwise, the tube will lodge against the anterior wall of the trachea and become difficult to advance.

Transillumination

Transillumination with a lighted stylet can facilitate oral or nasal intubation and help to confirm ETT placement and positioning. This technique is particularly useful when direct laryngoscopy is anatomically impossible. Oral intubation is easiest with a semirigid stylet. Before insertion, the patient's cheek is transilluminated. This serves as a check of the ambient light and will predict the laryngeal light intensity. It may be necessary to dim or shield bright ambient light from the neck. Obese patients who do not transilluminate buccally may not do so laryngeally.

For oral insertion, the lubricated ETT and lighted stylet are inserted after pulling the tongue forward with a 4 X 4 in. gauze pad. The tube initially should be directed into the ipsilateral pyriform fossa to establish the depth of the epiglottis. Then the tube is slightly withdrawn, and

the tip is directed toward the midline. The intubator must discriminate between the light emanating from the larynx and the much dimmer light transmitted from the esophagus. Usually the "jack-o-lantern" glow arising from the larynx or trachea is not appreciated when the light source is misplaced in the esophagus. For nasal intubation, the flexible stylet or wand instrument is inserted into a directional-tip ETT (e.g., Endotrol). After positioning the tube in the retropharynx, very gentle traction is applied to the ring to achieve slight flexion of the tip of the ETT.

Intubating Laryngeal Mask Airway

The laryngeal mask airway (LMA) is a ventilatory device that looks like an ETT with an inflatable silicone mask on the distal end. The LMA is placed blindly, and the mask is inflated over the larynx to provide a supraglottic seal. The technique is quickly mastered, and in most cases the LMA is placed rapidly. LMA's inability to protect against aspiration has limited its role in the ED to a temporizing rescue device.

The intubating LMA (ILMA) addresses this deficiency by providing a conduit to facilitate endotracheal intubation.⁶ This device also is inserted blindly and uses a rigid handle for insertion, making it an excellent rescue device. Ventilation is achieved in almost all patients, even those with difficult airways or distorted anatomy. Blind intubation through the ILMA with an ETT is over 90 percent successful and improves to almost 100 percent when a lighted stylet or fiberoptic bronchoscope is used to assist.⁷

The ILMA can be used successfully in cervical spine injuries. Its primary role is as a rescue device, although it has been used as an intubation technique in awake patients with known difficult airways. Aspiration of gastric contents is the most common complication with ILMA and continues to be a risk until successful placement of the ETT.

Fiberoptic Assistance

The flexible fiberoptic laryngoscope can be a valuable adjunct when there are anatomic or traumatic limitations that prevent visualization of the vocal cords. Clinical examples include conditions that prevent opening or movement of the mandible, massive tongue swelling (hemorrhage or angioedema), congenital anatomic abnormalities, and cervical spine immobility. These instruments allow visualization of la-

ryngeal structures and can enable difficult intubations, including those around expanding hematomas (Figure 19-3). Patients in need of an immediate airway or those with ongoing hemorrhage or copious secretions are poor candidates.

Directed transoral or transnasal and translaryngeal topical anesthesia is essential. The nasal mucosa should be sprayed with a vasoconstrictor. Dual suctioning capability is needed; a suction port should be attached to a suction apparatus for oral blood and secretions. Tongue extrusion and anterior mandibular displacement are helpful if the oral route is chosen. Fragile equipment is more frequently damaged transorally. The nasal route is also preferred, because the optic tip can enter the glottis at a less acute angle.

For this procedure, the eyepiece is focused, and the flexible shaft is lubricated. The lens at the tip of the laryngoscope is then immersed in warm water to prevent fogging. The intubator should continuously monitor pulse oximetry and ensure that the gag reflex is not present. After attachment of oxygen tubing to the suction port, intermittent insufflation of oxygen at 10 to 15 L per min to keep the optic tip clear should be considered. Insufflation is usually superior to suction for clearing secretions.

The adapter initially is removed from an ETT that is at least 7.0 mm in inner diameter. To prevent barotrauma when high-flow oxygen is insufflated, an ETT of at least 7.5 mm in inner diameter is used. Then the lubricated ETT is slipped over the shaft up to the handle. The distal end of the fiberoptic laryngoscope must extend beyond the end of the ETT. The laryngoscope is held with the left hand, and tip deflection is controlled while advancing it through the cords. The laryngoscope will function as a stylet for the tube. After the laryngoscope is in the trachea, the ETT is advanced and the laryngoscope is removed.

Another option is to insert a nasotracheal tube blindly into the posterior pharynx and stop about 1 to 2 cm proximal to the epiglottis. The scope is then inserted through this hollow conduit, and the fiberoptic tip can be directed into the glottis. The lubricated scope should not pass through Murphy eye. If this occurs, it will be impossible to advance the ETT.

The fiberoptic scope cannot be used as a stylet to guide the ETT into the trachea. The stiffer ETT often will deflect the thin scope tip posteriorly into the esophagus. In addition, the concavity of the ETT is kept anterior toward the 12 o'clock position and places the tube tip and Murphy eye at 3 o'clock (90 degrees to the right). The tip then often hits the right arytenoid cartilage. Rotating the tube 90 degrees

FIG. 19-3. A fiberoptic laryngoscope and a Shikani endoscope.

counterclockwise aligns the tip with the upper triangular entrance into the trachea.

Indirect Fiberoptic Laryngoscopes

There are many devices that incorporate fiberoptics into a laryngoscope, allowing for indirect visualization of the cords in potentially difficult airways. They are particularly useful when direct visualization of the larynx is impossible due to neck immobility, reduced oral opening, or an anterior larynx. They do not replace the diagnostic capabilities of a flexible fiberoptic scope and have the same visualization restrictions when blood and excessive secretions are present. The Bullard laryngoscope (Circon, ACMI, Stamford, CT), the Upsher-Scope (Mercury Medical, Clearwater, FL), and the WuScope (Pentax, Fremont, CA) are available. These devices are best used for the anticipated difficult airway as opposed to an emergent rescue device. Only the Bullard model has pediatric sizes.

The Shikani scope (Claras Medical, Minneapolis, MN) is a device that incorporates the fiberoptics into a malleable stylet.⁸ Similar to the other devices, the light source is in a portable handle. Setup only requires mounting the ETT. Pediatric sizes are available. The ability to manipulate the angle of the stylet and its brightness allows the use of a blind technique similar to that with the lighted stylet.

Fiberoptic ETTs also are commercially available. Direct line of sight can improve visualization in many difficult intubations. The advantages of direct vision include verification of tube positioning, identification of the right- or left-sided source of pulmonary hemorrhage, and inspection of tracheal injury.

Retrograde Tracheal Intubation

Retrograde tracheal intubation is another option when conventional airway approaches fail. The landmarks are the same as those for cricothyroid puncture (see Figure 19-2). Cervical or mandibular ankylosis and upper airway masses are some of the potential conditions in which retrograde tracheal intubation may help.

The insertion of a retrograde translaryngeal catheter is a less invasive option than cricothyrotomy. **This technique can be time consuming and will not be quick enough for apneic patients.** The initial angle of the needle should be 30 to 45 degrees cephalad, and a 70- to 75-cm flexible-tip guidewire is advanced through the needle. The wire is then grasped in the oropharynx or nares with Magill forceps. A J wire, which can be slowly twisted once it arrives at the oropharynx, can be easier to locate than a straight guidewire.

The next step is to clasp the guidewire securely with a hemostat at the neck. Then the proximal end of the guidewire is threaded through the Murphy eye on the ETT. This allows more of the ETT to enter the trachea before the guidewire is removed. With both hands, the wire is tightened, like a tightrope, and the tube is advanced. When the ETT will pass no farther, guidewire or catheter is cut flush with the cricothyroid membrane to minimize soft tissue contamination.

Rapid Sequence Intubation

The term *induction* refers to the production of a deep level of unconsciousness. *Rapid sequence induction* is the classic anesthesia term pertaining to the induction of anesthesia. In emergency medicine parlance, RSI most commonly involves the combined administration of a sedative and a neuromuscular blocking agent to facilitate tracheal intubation after preoxygenation (Table 19-1).⁹⁻¹⁰ Tracheal intubation follows laryngoscopy, and cricoid pressure is maintained to prevent aspiration. Sellick maneuver is performed, beginning with the administration of the first RSI agent, and maintained until the cuff is passed through the cords and inflated. The principal contraindication to RSI is any condition preventing mask ventilation or intubation, because this may be the only way to ventilate a patient once the patient is paralyzed."

TABLE 19-1 Rapid Sequence Intubation

1. Set up intravenous X2; cardiac monitor, oximetry, and capnography
2. Prepare equipment, suction, difficult-airway cart
3. Explain procedure; document neurologic status
4. Preoxygenate (100%, fraction of inspired oxygen), ideally, for several minutes; no positive pressure ventilation
5. Consider sedation, analgesia, adjunctive lidocaine, and/or atropine
6. Defasciculation agent, if necessary
7. Induce with sedative agent
8. Perform Sellick maneuver
9. Give neuromuscular blocking agent
10. Intubate trachea and release Sellick maneuver
11. Confirm placement

Patient care is optimized if emergency physicians are adept with all methods for managing standard and difficult airways in nonfasting patients. Otherwise, the incidence of cricothyrotomy will exceed the current 1 to 2 percent of patients when RSI is selected and fails.¹² The prime goal is to avoid placing the breathing patient in the "can't ventilate, can't intubate" predicament.

PRETREATMENT AGENTS Pretreatment agents attenuate the pathophysiologic responses to laryngoscopy and intubation that may be harmful in certain clinical circumstances (Table 19-2).¹³ The reflex sympathetic response causes increases in heart rate and blood pressure, which may be harmful in patients with intracranial hemorrhage, myocardial ischemia, and aortic dissection. In children, the vagal response predominates and can result in significant bradycardia, even in the absence of succinylcholine. Patients without cerebral autoregulation can experience a centrally mediated rise in intracranial pressure (ICP). Laryngeal stimulation also can have respiratory effects, including laryngospasm, cough, and bronchospasm.

To be effective, pretreatment agents are usually given 3 to 5 min before initiation of RSI. Although there is evidence that the adverse effects listed above may be mitigated by use of these agents, it is unclear whether their use improves outcome. Constraints on time or resources may preclude their use in some circumstances, although every effort should be made to use atropine before intubation of children.

INDUCTION AGENTS There is no single initial agent of choice for achieving hypnosis and sedation during RSI in the ED. All the commonly used agents offer distinct advantages in specific clinical conditions. Each agent also has significant potential side effects and specific contraindications (Table 19-3).

Barbiturates Thiopental is a short-acting barbiturate sedative. An intravenous dose of 3.0 to 5.0 mg/kg will induce unconsciousness in 30 to 60 s and last 10 to 30 min. Hypotension is commonly observed because of myocardial depression and venous dilatation. An ultra-short-acting barbiturate option is methohexital. It is twice as potent as thiopental, with onset of action in 60 s and a duration of action of 5 to 7 min. These cerebroprotective agents should be avoided if systemic hypotension is a problem, as may be the case in the multiple trauma patient. Thiopental and methohexital should be avoided in the setting of left ventricular dysfunction, asthma, or porphyria. Methohexital also can cause laryngospasm. A very rare complication is trismus, or masseter muscle spasm, which also has been reported with fentanyl and propofol, often with rapid bolus administration. Methohexital can reduce the seizure threshold.

Ketamine Ketamine, a phencyclidine derivative, is a potent bronchodilator to be considered particularly in difficult hypotensive or bronchospastic patients. This agent is indicated for refractory status asthmaticus. Because ketamine increases blood pressure, it is an appropriate choice in hypovolemic patients. It also can increase ICP and

TABLE 19-2 Pretreatment Agents Used in Rapid Sequence Intubation

Agent	Dose	Indications	Precautions
Lidocaine	1.5 mg/kg IV/topically	Elevated ICP Bronchospasm	May be ineffective Does not attenuate sympathetic response
114 Fentanyl	SECTION 3 • RESUSCITATIVE PROBLEMS AND TECHNIQUES 3 xg/kg IV	Cardiac ischemia Aortic dissection Children <5 y Children <10 y receiving succinylcholine	Hypotension Chest wall rigidity Minimal dose 0.10 mg

Defasciculating agents	10% of normal paralyzing dose	Elevated ICP	Weakness Occasional apnea
Haloperidol	5 mg aliquots	Combative Extreme agitation	Dystonia Rare hypotension
Midazolam	0.1 mg/kg IV	Sedation Reversible Amnesia	Wide therapeutic index No analgesia Apnea

Abbreviation: ICP = intracranial pressure.

thus should be avoided in patients with head injuries. Due to its inotropic and chronotropic cardiac effects, caution is indicated in the elderly. As consciousness returns, the patient may experience "emergence phenomenon" in the form of nightmares, visual hallucinations, and dissociative sensations, although benzodiazepines may attenuate this phenomenon. The dose of ketamine for induction is 1 to 2 mg/kg IV

Etomidate Etomidate is a non-barbiturate, non-receptor hypnotic. The advantages of etomidate include protection from myocardial and cerebral ischemia, minimal histamine release, a stable hemodynamic profile, and short duration of action.¹⁴ This agent should be considered if patients are hypovolemic or have closed head injury. Myoclonus, nausea, and vomiting do occur, and seizure foci may be stimulated. The incidence of severe etomidate-induced myoclonus can be decreased by pretreatment with diazepam or fentanyl (see Table 19-2). Etomidate lacks analgesic efficacy and does not blunt the sympathetic response to intubation. With one administration as an induction agent, inhibition of adrenocortical function is not a major concern. The dose of etomidate is 0.3 mg/kg IV

Propofol Another option is propofol, a highly lipophilic, rapid-acting sedative. During RSI, this agent provides effective hypnosis. Propofol has a more rapid onset of action than does etomidate and a shorter duration of action. Some of the pharmacologic advantages include its anticonvulsant and antiemetic properties and its ability to lower intracranial pressure. A fluid challenge before propofol administration may minimize hypotension. The dose is .5 to 1.5 mg/kg IV

Opioids Although not first-line selections, opioids are potent reversible induction agents. Fentanyl has an onset of action of shorter than 2 min. The ideal dose is highly variable (3 to 8 |xg/kg IV). Fentanyl is popular because of its sedative and analgesic properties. This agent provides a very neutral hemodynamic profile during RSI. Rapid injection of high doses may cause chest wall rigidity. Related compounds, alfentanil (3 to 8 |JLg/kg IV) and remifentanyl (1 |JLg/kg IV over 30 to 60 s), are more potent and have a more immediate onset of action.

PARALYTIC AGENTS Depolarizing and nondepolarizing neuromuscular blocking agents facilitate airway management of selected pa-

TABLE 19-3 Sedative Induction Agents

Agent	Dose	Induction	Duration	Benefits	Caveats
Thiopental	3-5 mg/kg IV	30-60 s	10-30min	ICP	IBP

tients in the ED. Depolarizing neuromuscular blocking agents have high affinity for cholinergic receptors of the motor end plate and are resistant to acetylcholinesterase. Initially they produce transient muscle fasciculations, followed by paralysis. This type of blockade is not antagonized, and may be enhanced, by anticholinesterase agents. Succinylcholine, a depolarizing agent, inhibits neuromuscular transmission as long as an adequate concentration remains at one receptor site. However, succinylcholine is rapidly hydrolyzed by plasma cholinesterase. Potential adverse effects are listed in Table 19-4. In contrast, nondepolarizing neuromuscular blocking agents compete with acetylcholine for the cholinergic receptors and usually can be antagonized by anticholinesterase agents. Vecuronium, doxacurium, atracurium, and rocuronium are commonly used nondepolarizing agents (Table 19-5).

In the ED, neuromuscular blockade can facilitate tracheal intubation, improve mechanical ventilation, and help control intracranial hypertension. Paralysis improves oxygenation and decreases peak airway pressures in a variety of disorders, including refractory pulmonary edema and the respiratory distress syndrome. Patients with refractory status asthmaticus, status epilepticus, or tetanic spasms resulting from clostridial infections or a variety of toxins, including strychnine, may improve with blockade. In addition, extremely violent, agitated patients who jeopardize air medical personnel or their own airway security, spinal cord integrity, or fracture stability may require the ultimate pharmacologic restraint (i.e., paralysis).

After documentation of the neurologic examination, including pupil size, pre-sedation with an induction agent is advised unless there are other mitigating circumstances, such as significant head injury or overdose. Neuromuscular blockers (NMBs) are neither anxiolytics nor analgesics. **Omission of sedation is a common error in patients who remain aware of their paralysis.** The resultant increased sympathetic tone can exacerbate dysrhythmias.

Succinylcholine When the indication for neuromuscular blockade is tracheal intubation, succinylcholine is the most commonly used agent. It has a more rapid onset (45 to 60 s) and shorter duration of action (average, 5 to 9 min) than do the nondepolarizing agents. After a brief fasciculation, complete relaxation occurs at 60 s, with maximal paralysis at 2 to 3 min. Effective respirations resume in 9 to 12 min.

The dosage of succinylcholine is 1.0 to 1.5 mg/kg IV for adults. Succinylcholine can result in excellent intubation conditions. Succinylcholine is generally preferable to nondepolarizing agents for RSI in the ED. In the event of a failed airway, the duration of B VM ventilation is generally only 10 to 12 min. Giving an induction agent before succinylcholine should be considered to avoid the cognition scenario of the "sentient being in an unresponsive body."

Before injection of succinylcholine, atropine, 0.01 mg/kg IV, may attenuate muscarinic vagal effects, especially in vagotonic adults and adolescents. In infants and small children, atropine pretreatment is essential to avoid bradyarrhythmias and asystole. An additional pretreatment to consider is a subparalytic dose of vecuronium, 0.01 mg/kg, or another nondepolarizing agent of similar duration to prevent the initial muscle fasciculations, which may cause long bone fractures to become displaced. Such fasciculations are most pronounced in muscular adolescents.

Succinylcholine increases intraocular pressure. In addition, the increased intraocular pressure predisposes to aspiration, thus emphasizing the importance of cricoid pressure. Another concern with succinylcholine is its potential to increase ICP. There are no data establishing the clinical relevance of the transient intracranial pressure response to intubation, so it is not contraindicated in patients with head trauma.

Serum potassium will transiently rise an average of 0.5 mEq/L with succinylcholine. Hyperkalemia may be pronounced hours to days after muscle trauma or burns. A clinically significant hyperkalemic response should not be a factor in the immediate aftermath of such injury. Nevertheless, it may be advisable to avoid depolarizing agents in patients with burns, muscle trauma, crush injuries, myopathies, rhabdomyolysis, narrow-angle glaucoma, renal failure, or neurologic disorders. Any patient with "denervated musculature" (e.g., Guillain-Barre syndrome or spinal cord injury) is particularly at risk.

Genetically susceptible individuals may develop acute malignant hyperthermia. Dantrolene sodium should always be available. Patients with an atypical pseudocholinesterase will require prolonged ventilatory support, as will those with burns, cirrhosis, or carcinomas who have low plasma pseudocholinesterase levels. Also, patients recently abusing amphetamines or cocaine may have a prolonged duration of neuromuscular blockade, because cocaine is metabolized by plasma cholinesterase, which reduces the amount of enzyme available for succinylcholine metabolism.¹⁵

For the conditions described above, nondepolarizing agents are preferable to succinylcholine. Although the onset of action is delayed, nondepolarizing agents produce fewer adverse cardiovascular and histaminic effects and a longer duration of paralysis.

TABLE 19-5 Nondepolarizing Neuromuscular Relaxants

Agent	Adult Intubating iV Dose	Onset	Duration	Complications
Vecuronium (intermediate/long)	0.08-0.15 mg/kg 0.15-0.28 mg/kg (high-dose protocol)	2-4 min	25-40 min 60-120 min	Prolonged recovery time in obese or elderly, or if there is hepatorenal dysfunction
Rocuronium (intermediate/long)	0.6 mg/kg	1-3 min	30-45 min	Tachycardia
Doxacurium	0.05-0.08 mg/kg	3.5 min	80-100 min	Prolonged block
Atracurium (intermediate)	0.4-0.5 mg/kg	2-3 min	25-45 min	Hypotension Histamine release Bronchospasm

Nondepolarizing Agents Pancuronium and d-tubo curare have been largely supplanted by agents with more rapid onset, shorter durations of action, and more favorable hemodynamic profiles. *Vecuronium bromide* is an intermediate- to long-acting nondepolarizing agent. The usual dose of vecuronium is 0.08 to 0.15 mg/kg IV. Maximal paralysis occurs within 2 to 4 min, with full blockade lasting for 25 to 40 min. One advantage of vecuronium is the lack of hemodynamic alterations. Hypersensitivity reactions are rare, doses are only minimally cumulative, and excretion is biliary. Despite the lack of histamine release, hypotension may occur through two other mechanisms. Blockage of sympathetic ganglia occurs, and venous return is decreased from absent muscle tone and the positive-pressure ventilation.

Rocuronium is an intermediate-duration nondepolarizing agent that is an option for RSI when successful visualization of the trachea is a certainty. The onset of action is more rapid than that with vecuronium. By increasing the dose of rocuronium to 0.9 to 1.2 mg/kg, the onset approximates that of succinylcholine, but also prolongs its duration of action. There are fewer side effects and contraindications with rocuronium than with vecuronium.

Doxacurium chloride is a long-acting nondepolarizing NMB used to facilitate prolonged mechanical ventilation after tracheal intubation. It provides skeletal muscle relaxation, with no dose-related cardiovascular effects.

Atracurium is an agent well suited for patients with hepatic or renal failure. Elimination occurs by ester hydrolysis and Hoffman degradation, a non-enzymatic process. This nondepolarizing agent's elimination half-life is approximately 20 min, as opposed to 65 to 75 min for vecuronium. Recovery time is consistent and unaffected by anticonvulsants. This agent is suitable for intubated patients requiring brief diagnostic or therapeutic procedures. Atracurium also offers advantages when continuous infusion is essential to maintain a precise, required level of neuromuscular blockade. A disadvantage is that histamine release can cause bronchospasm and hypotension. The risk with prolonged infusion is accumulation of laudanosine, a neuroexcitatory metabolic byproduct.

Other nondepolarizing options include *cisatracurium* and *mivacurium*. Cisatracurium is an intermediate-duration NMB agent. None of the metabolites have NMB activity, and excretion is independent of hepatorenal function. Mivacurium is the nondepolarizing agent with the shortest duration of action. Histamine release can be minimized by slow infusion.

The reversal of nondepolarizing muscle relaxants is rarely necessary in the ED. Reversal should not be attempted before some sign of motion or spontaneous recovery, because these enzyme inhibitors will have no effect until at least 40 percent of spontaneous recovery has occurred. Reversal is not innocuous and requires atropine 0.01 mg/kg IV, to prevent muscarinic side effects, followed by edrophonium 0.5 to 1.0 mg/kg IV. Edrophonium is an acetylcholinesterase inhibitor with a faster onset of cholinergic and fewer muscarinic side effects than the longer-acting neostigmine. The onset of action is 30 to 60 s, with a duration of 10 to 30 min. This reversal may be shorter than the duration of the muscle relaxant.

The normal sequence in RSI is to induce sedation before administration of the depolarizing NMB agent. If a nondepolarizing agent has been selected, some physicians reverse the sequence of administration by giving the nondepolarizing agent first because of its longer onset of action. Giving a rapid-acting hypnotic agent seconds later results in both medications having a synchronized peak effect.

DIFFICULT AIRWAY

The management of the difficult airway in the ED is, in many ways, more challenging than in the controlled setting of the operating room. The patient generally has not been fasting and is not premedicated. There is rarely time for a leisurely evaluation of the "airway history" and "airway physical examination." The difficult airway constitutes

the clinical scenario in which mask ventilation or tracheal intubation is challenging. Approximately 2 to 3 percent of tracheal intubations prove impossible with standard techniques. *Difficult mask ventilation* is defined as the inability to maintain O₂ saturation above 90 percent. Intubation is considered as difficult if more than three attempts are necessary or if conventional laryngoscopy requires more than 10 min. Many emergency physicians prefer to ensure the availability of the appropriate airway equipment by customizing the contents of a portable airway kit (Table 19-6).

The identification of a potentially difficult airway is perhaps more important than the subsequent management and may obviate a rescue airway in the "cannot-intubate, cannot-ventilate" scenario. Before any attempt at airway management, an assessment of potential difficulties with B VM ventilation and intubation must be performed. Once the potential for difficulty is identified, the management will vary with not only the type of airway difficulty but also the operator's experience and availability of alternative devices.¹⁶

Potential impediments of BVM ventilation should be considered before proceeding with RSI. The presence of two of the following five factors is predictive of difficult BVM: facial hair, obesity, edentulous patient, advanced age, and snoring. An inability to adequately ventilate with a BVM is usually solved by better positioning, jaw thrust, a tighter seal with two-person bagging, and the use of oral and nasal airways to improve patency. A poor seal due to a beard may be improved with a lubricant. Dentures facilitate BVM ventilation.

Multiple external features are also associated with difficult intubation. These features include facial hair, obesity, a short neck, small or large chin, buckteeth, high arched palate, and any airway deformity due to trauma, tumor, or inflammation. Most studies of airway difficulty use the grade of laryngoscopic view, which is impractical in the ED setting. A simple, systematic, and rapid evaluation of the airway is needed to predict a potentially poor laryngoscopic view before the initiation of neuromuscular blockade.

Clinical examination of the airway anatomy can identify more subtle predictors. The mandibular opening in an adult should be at least 4 cm, or two to three fingerbreadths. The ability of the mandible to accommodate the tongue can be estimated by the distance between the mentum and the hyoid bone, which should be three to four fingerbreadths. A small mandible is more likely to have a tongue that obstructs visualization during laryngoscopy. An unusually large mandible also may impair visualization by elongating the oral axis, referred to above. A high, anterior larynx is possible if the space between the mandible and top of the thyroid cartilage is narrower than two fingerbreadths. The degree to which the tongue obstructs the visualization of the posterior pharynx on mouth opening has some correlation with the visualization of the glottis. This correlation can be assessed with Mallampati's criteria, with classes III and IV being associated with poor visualization and higher failure rates (up to 5 and 20 percent, respectively) (Figure 19-4).¹⁷ Neck immobility also interferes

with the ability to align the visual axes by preventing the desired "sniffing position." Neck immobility may be imposed by the presence of a cervical collar. If there is no suspicion of cervical injury, atlanto-occipital extension should be assessed, even in the uncooperative patient.

Airway obstruction presents a particular difficulty in airway management. If evidence of obstruction is present, three aspects must be considered: the location of the obstruction, whether it is fixed (e.g., tumor) or mobile (e.g., epiglottitis), and how rapidly it is progressing. The location may determine which approach or rescue device can be used. Oral airway obstruction from angioedema of the tongue may limit the physician to nasal techniques or surgical airways that use the cricothyroid membrane. The BVM method is more likely to be successful in mobile as opposed to fixed obstruction. The speed of progression determines whether the management can await transport to another facility, management in the operating room, or immediate management in the ED.

STRATEGIES FOR SPECIFIC CLINICAL SCENARIOS

Cerebral Perfusion Issues

Patients with suspected acute intracranial hypertension require aggressive airway management. Direct laryngoscopy can elevate the

ICP. Before oral or nasal intubation, pretreatment with intravenous lidocaine may help blunt this deleterious cardiovascular response. Fentanyl also will blunt the hemodynamic changes.

In certain situations, succinylcholine may increase ICP, so the intubator should consider prior use of a defasciculating dose of a nondepolarizing NMB agent. If one is selected, the use of a priming dose will shorten the onset of action. However, a significantly prolonged duration of action may be the result, thereby extending the risks if a difficult airway is encountered. Another consideration is the use of a short-acting sedative induction agent. Several of these drugs, including thiopental, fentanyl, and etomidate, directly decrease ICP.

Effective oxygenation and ventilation during cerebral resuscitation often require prolonged neuromuscular blockade. Autoregulation of cerebral blood flow (CBF) over a range of perfusion pressures may be impaired. As a result, CBF becomes pressure dependent: $CBF = CPP/CVR$, where CPP is cerebral perfusion pressure and CVR is cerebral vascular resistance. Autoregulation is usually intact when the CPP ranges between 50 and 150 mm Hg. The CPP equals the mean arterial pressure minus the ICP.

In traumatic brain injury, the goal therefore is to maintain the mean arterial pressure above 90 mm Hg throughout the patient's course; doing so usually will maintain the CPP above 70 mm Hg. Other treatment modalities, such as mannitol administration and hyperventilation, can exacerbate intracranial ischemia. Of note, when cerebral autoregulation is lost, the ability to vasoconstrict with hyperventilation may be maintained. Therefore, prophylactic hyperventilation therapy ($Paco_2 < 35$ mm Hg) should be avoided during the first 24 h after injury.

Conversely, brief hyperventilation therapy should be initiated rapidly in the ED in patients with definite acute signs of intracranial hypertension. If the intracranial hypertension does not respond to adjunctive osmotic diuretics, sedation, neuromuscular blockade, and neurosurgical drainage of CSF, protracted hyperventilation may be necessary.

After blockade, the fraction of inspired oxygen (Fio_2) sufficient to maintain a PaO_2 of 100 mm Hg is selected. Significant hypoxia can increase reactive oxygen species and contribute to oxidative brain injury. Positive end-expiratory pressure (PEEP) of up to 5 cm H_2O may help prevent atelectasis. Higher levels will impair cerebral venous drainage, because of the elevated intrathoracic pressure. Excessively tight ETT straps, tight cervical collars, or Trendelenburg positioning potentiate increased ICP and should be avoided.

Cardiopulmonary Disease

Tracheal intubation and mechanical ventilation can have other significant physiologic consequences. Any conditions that result in the cardiovascular system's reliance on preload to maintain perfusion will predispose to hypotension and cardiac decompensation. Particular caution is needed when intubating previously hypotensive patients who require vasopressor support. In addition, patients with hypercarbia and chronic obstructive pulmonary disease require special consideration. Mechanical ventilation increases the positive intrathoracic pressure, which decreases the preload by decreasing venous return. Hypotension may be anticipated. Additional physiologic considerations include the decreased left ventricular compliance and the fact that most medications useful in RSI decrease the sympathetic tone.

Trauma Airway Management

Airway management of patients with the potential to have an unstable injury of the cervical spine challenges clinical judgment. There is no single best algorithm. Cervical spine radiography without a thorough and reliable neurologic examination does not "clear the neck." From 20 to 30 percent of cervical spine injuries are not appreciated on one cross-table lateral view. In addition, patients with blunt major trauma requiring tracheal intubation have associated unstable cervical spine

injuries that range from 1 to 12 percent. Spinal cord injury without radiographic abnormality (SCIWORA) is an important consideration, especially in adolescents and children.

The initial decision is to determine whether immediate airway intervention is really needed. Patients not in urgent need of an airway should be neurologically and radiographically evaluated as thoroughly as is practical given their condition. The need for inline cervical stabilization should not be considered a license for axial inline traction. For example, attempting to visualize C7 radiographically by countertraction of the head and shoulders of the near-hanging patient can cause further distraction injury.

There is a large selection of airway options to consider while attempting to maintain cervical spine immobilization. The selection is far less critical than the timing. Rapid sequence intubation, NTI, transillumination, and fiberoptic laryngoscopy are commonly selected options. Oral intubation appears safe when achieved without hyperdistraction, flexion, or extension of the neck. Maintenance of cervical spine immobilization is the paramount objective, not the approach to secure the airway. Careful endotracheal intubation causes less cervical spine motion than does BVM ventilation.

Visualization of the larynx before cervical spine clearance is difficult, because alignment of the oropharyngeal-laryngeal axis is not possible. One method to move the tip of the tube anteriorly is to use a slightly flexed directional-tip tube (Endotrol) coupled with Sellick maneuver. Another is to use a flexible stylet, such as the Flexiguide, which passes through the tube and has a trigger similar to that of the Endotrol. Another option is to aim the tip of the tube anteriorly with Magill forceps while an assistant advances the tube.

There are several commercially available laryngoscope blade designs that allow vocal cord visualization without manipulation of the neck. Most designs have fiberoptic attachments to the blade, which allow elevation of the tongue to avoid the blood or secretions. Technically, these blades may prove simpler to use than conventional fiberoptic laryngoscopes.

Victims of trauma may be hypotensive due to hemorrhagic shock or maintain a "normal" blood pressure in compensated shock. Many agents used in RSI may cause myocardial depression and vasodilation, potentially worsening hypotension or precipitating decompensation. Barbiturates and benzodiazepines should be avoided in this scenario. Etomidate has a better hemodynamic profile and is the preferred induction agent. Although ketamine will maintain blood pressure, it should be avoided in patients with intracranial injury. If hypotension is due to a clinically suspected tension pneumothorax, a chest tube thoracostomy should be performed before, or simultaneously with airway management.

SUCTIONING

Many conditions render patients unable to clear their own secretions. Aspiration usually occurs when the tone of the lower esophageal sphincter is insufficient to deal with the increased intragastric pressure and the protective laryngeal airway reflexes are depressed. The common iatrogenic causes include BVM ventilation, the presence of nasogastric tubes, and pharmacologic neuromuscular paralysis. Some common predisposing conditions include trauma, bowel obstruction, obesity, overdose, pregnancy, hiatus hernia, and seizures.

Aspiration after urgent ETT intubation occurs infrequently in ED patients if there is attention to technique. The intubator should consider using large-diameter suction systems or tubing for the removal of particulate matter or clots that are larger than the standard Yankauer tip can handle. The rigid-tip plastic tonsil suction catheter can remove large quantities of oropharyngeal secretions.

When necessary, the patient is placed in a left lateral Trendelenburg position. This position helps get the tongue out of the laryngoscopist's way and facilitates immediate endotracheal suctioning. To suction the nasopharynx and tracheobronchial tree, a well-lubricated, soft, curved-

tip catheter is used. Straight catheters usually will pass into the right mainstem bronchus. If a curved-tip catheter is available, turning the head to the right and rotating the catheter often will facilitate passage into the left bronchus. A suction catheter no larger than half the diameter of the tube to be suctioned should be selected to prevent pulmonic collapse from insufficient ventilation during suctioning. The patient should be oxygenated before and after suctioning to avoid transient desaturation. The catheter should be inserted without suctioning and then slowly removed while suctioning with rotation over 10 to 15 s.

Some complications of suctioning include hypoxia, cardiac dysrhythmias, hypotension, pulmonic collapse, and direct mucosal injury. The magnitude of the ICP increase during endotracheal suctioning may be related to the increase in intrathoracic pressure with coughing if lidocaine has been omitted.

MECHANICAL VENTILATORY SUPPORT

The knowledge of the pathophysiology of acute respiratory failure and the changes in lung physiology during positive-pressure ventilation will aid in the selection of an appropriate ventilatory modality and of the initial settings. Ventilators are pressure or volume cycled. Volume-cycled ventilators are used routinely in EDs. Other decisions with regard to mechanical ventilatory support in the ED include the rate, mode, Fio_2 , minute ventilation, use of PEEP, continuous positive airway pressure (CPAP), or bilevel pressure ventilation (BiPAP).

There are three common ventilator methods for providing the tidal volume: controlled mechanical ventilation, assist-control (A/C), and intermittent mandatory ventilation (IMV). The control mode is used for apneic patients. The A/C mode allows the patient to trigger a cycle by inhaling and lowering the air pressure, which can be adjusted by the ventilator's trigger "sensitivity" (1 to 3 cm H_2O). The ventilator will provide an untriggered "controlled" breath unless one is triggered during the selected time cycle. A predetermined number of ventilator-generated tidal volumes can be ensured either unsynchronized (IMV) or, more commonly, synchronized to patient effort (SIMV). In the ED, A/C or SIMV is the preferred initial mode, except as noted with an apneic patient.

The initial Fio_2 should be guided by the oximetry. Initially, the tidal volume is set at 10 mL/kg ideal body weight, and the rate is adjusted accordingly. Sufficient time should be allowed for expiration. The peak airway pressure is maintained below 35 to 45 cm H_2O to prevent barotrauma. The peak airway pressure appears to be related to barotrauma more than to the level of CPAP.

To reclaim lung volumes, PEEP or CPAP should be considered if the decreased pulmonary compliance prevents delivery of an adequate tidal volume or if hypoxemia persists despite 100 percent Fio_2 . Even low levels (3 to 5 cm H_2O) of PEEP/CPAP usually render ventilator "sighs" (1.5 X tidal volume) unnecessary. If hypotension develops, the respiratory rate and PEEP should be adjusted to lower the *mean* airway pressure.

Selected patients with acute respiratory failure will benefit from noninvasive BiPAP (see Chap. 19).¹⁸ Nasal mask or full-face mask BiPAP can decrease length of stay and improve survival. Although pretrial arterial blood gas (ABG) levels do not predict success, a BiPAP trial for stable patients with acute respiratory failure can be followed by intubation and mechanical ventilation if there is inadequate improvement within 30 min.

EXTUBATION

Inherently more relaxing than intubation, extubation nevertheless can be hazardous. This maneuver is rarely indicated in the ED but may be required in some systems that have an observation center. Patients recovering their protective airway reflexes may "fight" the tube yet need to remain intubated. Instillation of 1 to 2 mL of 4 percent lidocaine (sterile for injection) down the ETT will decrease "bucking." The ab-

sorption of lidocaine through the airway yields a maximum serum level that is only slightly lower than that from an equivalent intravenous dose.

Before extubation, the physician should consider the impact of metabolic or circulatory abnormalities. The patient should be checked for respiratory insufficiency, and nasogastric decompression is advised. On command, the patient should have an inspiratory capacity of at least 15 mL/kg. Ideally, there should be no intercostal or suprasternal reactions, and the patient's grip should be firm.

After suctioning secretions, the physician should ensure adequate oxygenation and explain the procedure to the patient. Positive-pressure ventilation with a mask will help to exsufflate secretions while the cuff is deflated. At the end of a deep inspiration, the tube should be removed and oxygenation continued by mask to prevent secretory reaccumulation.¹

The patient should be observed closely for stridor. Postextubation laryngospasm is treated initially with oxygen by positive pressure. If necessary, nebulized racemic epinephrine (0.5 mL of 2.25 percent epinephrine in 4 mL saline) is often helpful.

SURGICAL AIRWAY MANAGEMENT

David R. Gens

The rate of failed ED intubations and subsequent surgical airway placement is below 0.6 percent.¹ About 3 percent of intubation attempts are in difficult airways where a surgical airway should be anticipated.¹

The term *cricothyroidotomy* technically means "vertically incising (splitting) the cricoid and thyroid cartilages," and *coniotomy* means "incising the cricothyroid (conic) ligament," which runs from the cricoid to the thyroid cartilage. Although *coniotomy* is the correct term for incising between these two cartilages, the term *cricothyroidotomy* is now commonly used to denote this procedure.

CLINICAL FEATURES

The indications for an emergency surgical airway are several; however, most are due to an inability to establish an orotracheal or nasotracheal airway. This may be due to anatomy (short, obese neck), a disease state (epiglottitis, laryngeal edema, paralyzed vocal cords, or retropharyngeal abscess), trauma from distortion of the neck by hematoma (cervical fracture or major vessel injury), aspiration of blood (facial trauma), or loss of supporting structures (mandibular fractures). Clinical manifestations of acute airway obstruction are stridor (in a patient who is still able to breathe) or cyanosis. Clinical signs and symptoms are listed in Table 20-1.

SPECIFIC ISSUES THAT AFFECT EVALUATION AND TREATMENT

Age

Needle cricothyroidotomy is the preferred emergency surgical airway in children younger than approximately 10-12 years who cannot be intubated orotracheally or nasotracheally. A 12- or 14-gauge catheter over a needle will support ventilation and oxygenation in a child until a tracheostomy can be performed in the operating room by a surgeon familiar with the anatomy of a child's neck. The larynx is easily damaged by surgical cricothyroidotomy, and younger individuals have a higher incidence of late airway complications.²

Associated Injuries

The standard indications for an airway in emergency patients are mentioned below; however, some specific types of trauma usually have a

TABLE 20-1 Clinical Manifestations Associated with Acute Airway Obstruction

Etiology	Manifestation
Vascular	Hematoma External hemorrhage Hypotension Hemoptysis
Laryngotracheal	Stridor Subcutaneous air (massive) Hoarseness Dysphonia Hemoptysis
Pharyngeal and/or hypopharyngeal	Subcutaneous air Hematemesis Dysphagia Sucking wound

greater need for a surgical airway. Penetrating trauma to the neck (gun-shot or stab wound) that injures a major artery (carotid, vertebral, or thyroid) and demonstrates an expanding hematoma around the injured artery may cause obstruction of the airway by pressure. The need for a surgical airway should be anticipated. Infrequently, free blood from concomitant vascular and pharyngeal or tracheal injuries spills into the oro- or hypopharynx and causes severe aspiration of blood; in such cases, a cuffed tube (surgical cricothyroidotomy, not needle cricothyroidotomy) is needed. Difficulty in establishing an airway occurs in approximately 10 percent of penetrating cervical trauma cases.³

Blunt trauma to the neck or face may cause hemorrhage of the soft tissues or injury to the trachea or larynx itself. The trachea may become detached from the larynx at the level of the first tracheal ring, and the larynx or the trachea may become ruptured. In either of these rare circumstances, an emergency tracheostomy is required. This procedure should be performed by someone with experience in surgery of the neck. It is difficult to perform an emergency tracheostomy, especially with an awake patient who is becoming hypoxic and combative. Severe edema of the larynx or, rarely, fracture of the cartilages of the larynx may obstruct the airway.

In blunt facial trauma, the principal cause of death is obstruction of the airway. This occurs for several reasons. In patients with mandibular fractures, the loss of supporting structure for the tongue allows the base of the tongue to fall back into the hypopharynx and obstruct the airway. Also, these patients, placed supine and with major facial bleeding, will often continuously aspirate blood.

Type of Emergency Airway and Tube Selection

Surgical cricothyroidotomy is always preferred over needle cricothyroidotomy (except for children younger than 10-12 years, as noted above), simply because of the larger diameter of the 6-mm (internal diameter) endotracheal or tracheostomy tube compared with the needle cricothyroidotomy catheter. Adequate ventilation is crucial in the early prevention of cerebral edema after brain injury. Ventilation is practically impossible through a 14- or 12-gauge catheter. Emergency tracheostomy is rarely indicated and extremely difficult to perform. This procedure should be performed only by physicians who are familiar with surgical anatomy and skilled in the procedure.

A tracheostomy tube is preferred to an endotracheal tube for several reasons. A tracheostomy tube has an obturator, which makes entry through the narrow cricothyroid membrane easier. The tracheostomy tube is shorter and therefore easier to suction. Most important, it has flanges on each side that allow it to be sutured to the neck and secured with a cloth ribbon around the neck (Figure 20-1). The endotracheal tube (when used for cricothyroidotomy) is very difficult to affix to the neck and moves easily no matter how well it has been secured with adhesive tape. Unfortunately, many EDs are not stocked with tracheostomy tubes, because of their infrequent need, or, when they are stocked, they may not be readily available. Therefore, an endotracheal tube is most commonly used and is readily available. When a tracheostomy tube becomes available, a tube change can be made by using Seldinger technique; a suction catheter with the suction vent cut off at one end is readily available and easy to use.

The diameter of the tube inserted is crucial. **A 6-mm tracheostomy or 6-mm endotracheal tube is preferred (never larger than 7 mm in either case).** Tubes with internal diameters larger than 7 mm are difficult to insert in the narrow space between the cricoid and thyroid cartilages. If airway pressures are high with the small-diameter tube, the cricothyroidotomy tube may be changed to a tracheostomy or endotracheal tube with a larger diameter at a later, convenient time.

Availability of Equipment and Staff Education

The success rates with either type of surgical airway depend largely on the preparedness of the ED and the training of the staff. Two recent

FIG. 20-1. Tracheostomy tube with obturator.

European studies have shown that EDs are rarely prepared for performing an emergency surgical airway. A recent study in Great Britain found that only 47 percent of EDs had made provisions for the immediate use of a needle cricothyroidotomy and only 45 percent of the physicians were conversant in its use.⁴ In an Austrian study of intensive care staff, only 70 and 60 percent of the staff were able to successfully perform a surgical cricothyroidotomy and a needle cricothyroidotomy, respectively.⁵ All ED staff should be trained in the performance of an emergency surgical airway (through advanced trauma life support), and all EDs should be properly equipped.

Conversion from Cricothyroidotomy to Tracheostomy

The question frequently arises as to how long to leave a cricothyroidotomy tube in place in the larynx. A tube left in the narrow space between the cricoid and thyroid cartilages can erode both cartilages, and a bacterial chondritis may occur. The cartilages will be destroyed and eventually scar, leading to stenosis and loss of the function of the larynx. Because cricothyroidotomy has a higher incidence of airway stenosis, a cricothyroidotomy should be converted to a tracheostomy.⁶ As a rule of thumb, **if the airway will be needed for more than 2 to 3 days, the cricothyroidotomy should be changed to a tracheostomy.** Otherwise, the cricothyroid tube may stay in place.

PROCEDURE

Surgical Cricothyroidotomy

ANATOMY The cricothyroid membrane is located between the thyroid and cricoid cartilages (Figure 20-2A). Both structures are easily palpated. The cricothyroid membrane can be found approximately one third the distance from the manubrium to the chin in the midline in patients with normal habitus (see Figure 20-2B). In a patient with a short, obese neck, the membrane may be hidden at the level of the manubrium; in a patient with a thin, long neck, it may be midway between the chin and the manubrium. The thyroid gland overlies the trachea; both structures are difficult to palpate.

The only vascular structure that may be injured during the course of a properly performed cricothyroidotomy is the thyroid ima artery, a branch of the aorta that runs up to the thyroid gland in the midline and infrequently reaches the level of the cricothyroid membrane. When injured, it needs to be surgically ligated to control the hemorrhage.

FIG. 20-2. A. Anatomy of the neck. B. Location of the cricothyroid membrane.

INDICATIONS AND CONTRAINDICATIONS Inability to orotracheally intubate an emergency patient is the prime indication for surgical or needle cricothyroidotomy. Orotracheal (or nasotracheal) intubation should be attempted first. Inline cervical stabilization must be maintained in trauma patients. If orotracheal intubation is unsuccessful, then cricothyroidotomy should be considered.

Surgical cricothyroidotomy is reserved for patients older than 12 years and is contraindicated in patients younger than 12 years. Needle cricothyroidotomy is the procedure of choice in those younger than 12 years.

COMPLICATIONS Acute complications after emergency cricothyroidotomy occur in up to approximately 10 percent of cases.⁷

Bleeding from the Insertion Site Venous bleeding almost always occurs from small veins and usually stops spontaneously (using a vertical neck incision decreases the chance of bleeding). Arterial bleeding can be from the thyroid ima artery or from a small artery at the base of the cricothyroid membrane. Gentle pressure is applied to stop the bleeding. If bleeding persists, surgical control may be necessary in the operating room.

Misplacement of the Tube In an obese neck, it is possible to place the tube anterior to the larynx and trachea into the mediastinum. Ventilation is not possible. Manifestations of an incorrectly positioned tube are high airway pressures, absent breath sounds, and massive subcutaneous emphysema. The tube should be removed and a second attempt should be made.

Laceration of the Structures of the Neck Laceration of the trachea, esophagus, or recurrent laryngeal nerves is extremely rare and is due to inadequate knowledge of the anatomy of the neck.

Pneumothorax This complication is probably secondary to barotrauma caused by ventilation initiated immediately after tube placement. Late airway complications may occur in up to 52 percent of cases. These complications include voice changes and laryngeal and/or tracheal stenosis.^{8,10}

EQUIPMENT NEEDED

1. Personal protective equipment
2. Scalpel with a no. 10 (preferable because of its greater width) or no. 11 blade
3. A 6-mm endotracheal tube or tracheostomy tube (preferred); tubes larger than 6 mm are difficult to place through the cricothyroid membrane.
4. Tape to secure the endotracheal tube in place; cloth ribbon and sutures to secure tracheostomy tube in place
5. Bag-valve-mask device and oxygen source

PATIENT PREPARATION AND POSITIONING The patient should be placed supine, with the neck positioned in the midline. Povidone iodine solution should be quickly applied to the skin, if time permits. If the patient still has a patent airway (albeit minimal), oxygen should be administered by mask.

STEPS OF PROCEDURE

1. Stand to one side of the patient at the level of the neck. A right-handed practitioner should stand on the right side, and a left-handed practitioner should stand on the left side.
2. Locate the cricoid ring. Place the index finger at the sternal notch and palpate cephalad until the first rigid structure is felt (cricoid ring). Roll the index finger one finger breadth above to locate the "hollow" between the cricoid and thyroid cartilages. This is the cricothyroid membrane.
3. Using the thumb and middle finger of the nondominant hand, stabilize the two cartilages (Figure 20-3).
4. Use the scalpel to make a vertical incision in the midline between the two cartilages. The incision should go through the skin and subcutaneous tissues. The structures are superficial, and care should be taken not to incise deeper, because this may result in damage to the cricoid or thyroid cartilage or vascular structures (Figure 20-4).
5. With the scalpel blade positioned horizontally, perforate the cricothyroid membrane so that the blade goes in approximately half its length (Figure 20-5).

FIG. 20-3. Surgical cricothyroidotomy. Palpating the cricothyroid membrane and stabilizing the laryngeal cartilages.

FIG. 20-4. Surgical cricothyroidotomy. Incision between the cricoid and thyroid cartilages.

6. Place the back end of the scalpel handle into the incision in the cricothyroid membrane to widen the opening (Figure 20-6).
7. Place the endotracheal tube (or tracheostomy tube) in the opening (Figure 20-7).
8. Secure the tube carefully with a ribbon and/or adhesive tape. If using an endotracheal tube, take special care that the tube is inserted no more than 2 to 3 cm; otherwise, the tube will slip down the right main-stem bronchus with even minimal movement.
9. Connect to a bag-valve-mask device for ventilation. Check for breath sounds with ventilation. If no ventilation is heard bilaterally, then pull the tube out and reinsert it. Constantly recheck for breath sounds to ensure that the endotracheal tube is correctly positioned. If breath sounds are absent only on the left side, then the tube has been inserted down the right main-stem bronchus and needs to be pulled back a few centimeters. This usually occurs with the use of an endotracheal tube.

DRESSING AND STABILIZATION If a tracheostomy tube has been used, a simple dressing may be fashioned by cutting a slit halfway down the middle of a 4 X 4 cm dressing and placing it under the tracheostomy tube. This tube may be secured with a ribbon placed through the flanges of the tracheostomy tube. For added security, 2-0 nylon sutures may be used to fix the tube to the skin. Endotracheal tubes are extremely difficult to secure properly to the neck and should be changed to tracheostomy tubes whenever possible.

FIG. 20-5. Surgical cricothyroidotomy. Puncturing the cricothyroid membrane with a scalpel blade.

FIG. 20-6. Surgical cricothyroidotomy. Placing the scalpel handle to widen the hole in the cricothyroid membrane.

DEVICE REMOVAL The cricothyroidotomy tube may be removed once the patient has a patent airway or has been changed to a tracheostomy tube, as mentioned above. Patency may be evaluated by deflating the cuff of the tube and assessing airflow by breathing or by speech.

Needle Cricothyroidotomy

Needle cricothyroidotomy entails insertion of a catheter (generally an intravenous catheter) through the cricothyroid membrane. Although this procedure is easier to perform than surgical cricothyroidotomy, it is greatly inferior in providing adequate ventilation. The diameter of the catheter used is the limiting factor for airflow.

ANATOMY See the discussion under "Surgical Cricothyroidotomy."

INDICATIONS AND CONTRAINDICATIONS The general indications are listed under "Surgical Cricothyroidotomy." However, needle cricothyroidotomy is usually deemed the only type of emergency surgical airway that is indicated in children younger than 10-12 years. Although, in general, there are no contraindications to needle cricothyroidotomy, adult patients can be ventilated for only approximately 15 to 20 min and should have an alternative airway secured immediately (by surgical cricothyroidotomy, endotracheal intubation, or tracheostomy).

FIG. 20-7. Surgical cricothyroidotomy. Placement of tracheostomy tube with obturator.

FIG. 20-8. Needle cricothyroidotomy. Puncturing the skin with needle and catheter.

COMPLICATIONS Complications after needle cricothyroidotomy are less frequent than after surgical cricothyroidotomy. Bleeding at the puncture site and infection may occur. Inadvertent perforation of the esophagus or back wall of the trachea or larynx is infrequent. Massive subcutaneous emphysema will develop during ventilation. The catheter also may be misplaced in the soft tissues of the neck.

EQUIPMENT NEEDED

1. Personal protective equipment
2. A 14- or 12-gauge sheathed needle catheter
3. A 3-mL syringe
4. Adapter from the end of a 7-mm endotracheal tube
5. Wall oxygen source at 15 L/min (40 to 50 psi) connected by tubing with a Y connector or fashioned with a side hole (a bag-valve-mask device can be substituted but is not optimal)

PATIENT PREPARATION AND POSITIONING See the discussion under "Surgical Cricothyroidotomy."

STEPS OF PROCEDURE

1. The operator should be positioned above the head of the patient.
2. Locate the cricoid ring. Place the index finger at the sternal notch and palpate cephalad until the first rigid structure is felt (cricoid ring). Roll the finger one finger breadth above to locate the "hoi-

FIG. 20-9. Needle cricothyroidotomy. Catheter in place with adapter and syringe.

FIG. 20-10. Needle cricothyroidotomy. Endotracheal setup with tube, syringe, and catheter.

low" between the cricoid and thyroid cartilages. This is the cricothyroid membrane (see Figure 20-3).

3. Attach a 3-mL syringe to the catheter (12 or 14 gauge).
4. Introduce the catheter into the subcutaneous tissue at a 90-degree angle to the skin. Aspirate gently while advancing the catheter over the needle. When air suddenly returns (indicating entry into the airway), change the angle to 45 degrees and advance the catheter over the needle into the larynx. Withdraw the needle and syringe (Figure 20-8).
5. Disconnect the 3-mL syringe from the bare needle.
6. Withdraw the plunger from the syringe and attach the plungerless 3-mL syringe barrel to the catheter in the neck.
7. Attach the adapter (from the end of a 7-mm endotracheal tube) to the open end of the 3-mL syringe (Figure 20-9), or place a 7-mm endotracheal tube into the empty syringe barrel and inflate the balloon (Figure 20-10).
8. Attach the oxygen source to the adapter and start ventilation with 100 percent oxygen. Intermittent jet insufflation (50 psi) can be achieved by occluding the Y connector or side hole in the connecting tubing. Insufflate for 1 s and then release the occlusion for 4 s. To achieve the required high pressures, it is best to use a jet injector regulated by a flowmeter attached to a wall unit on a tank. An unregulated wall unit or tank is a less optimal choice.
9. The operator must hold the catheter securely as it can become displaced with minimal movement. The inspiration-to-expiration ratio may need to be 1:10 to 1:15 to allow for expiration. Needle cricothyroidotomy does not provide for adequate ventilation and this technique is only a temporizing measure until definitive airway establishment.

DRESSING AND STABILIZATION Stabilization is maintained by the operator until another choice of airway is established, either tracheostomy or oro- or nasotracheal intubation (if possible). Dressings are not necessary.

DEVICE REMOVAL A needle cricothyroidotomy catheter should be removed as expediently as possible. The catheter almost always becomes inadvertently dislodged from the airway, and the ability to ventilate is poor.

VASCULAR ACCESS

William A. Berk Bharat Sutariya

Obtaining access to the venous and arterial circulation enables the administration of drug, crystalloid, and blood products and measurement of central venous and arterial pressures. About one-third—or more than 33 million ED patients each year—require vascular access.

During resuscitation, venous access should be obtained at the site of the largest vein that is accessible without disrupting resuscitation. When peripheral sites are not available, central veins should be accessed for monitoring of central venous pressure or the administration of drugs directly into the central circulation.

ENDOTRACHEAL TUBE SUBSTITUTION FOR VASCULAR ACCESS

A number of medications may be administered by endotracheal tube in the critical minutes of resuscitation before intravenous access is obtained. These include atropine, diazepam, epinephrine, isoproterenol, lidocaine, and naloxone but *not* sodium bicarbonate or calcium chloride. Epinephrine as a preparation of 1 mg/mL (1:1000) should be given in a dosage of 0.1 mg/kg (standard dosage). The American Heart Association Advanced Cardiac Life Support (ACLS) and Pediatric Advanced Life Support (PALS) guidelines recommend increasing the intravenous dosages of other resuscitation medications by a factor of 2 to 3 and diluting with 3 to 5 mL of NS before administration via endotracheal tube. Drug administration is followed by several positive-pressure ventilations using a bag-to-tube device.

ISSUES OF FLOW DYNAMICS

Infusion rate is crucial in resuscitation for severe hypovolemia or hemorrhage. Fluid in a medical catheter behaves for practical purposes according to the Poiseuille law:

$$\text{Rate of flow} = \frac{n}{8} \times \frac{m}{\text{dynamic fluid viscosity}} \times \frac{r^4 \times (\text{catheter radius})^4 \times \text{pressure gradient}}{B}$$

The fact that flow is a function of the fourth power of the radius of the tube lumen means that the internal catheter diameter is a major limiting factor.¹ A fluid delivery system is only as effective as its slowest component, whether this is intravenous tubing, in-line filters, or the catheter itself. Flow rates may also be affected by temperature, pres-

sure, and viscosity, the latter being an especially important consideration in relation to red blood cell transfusion.¹ Rate of infusion is also directly proportional to catheter length, which is why a long central catheter will have a slower infusion rate than a shorter catheter of the same caliber in a peripheral vein.²

Placement of two large-bore 16-gauge or greater catheters is indicated in stable adult trauma patients whose injuries could cause potentially life-threatening hemorrhage or for initial therapy of medical patients with hypovolemic shock. In the management of exsanguination, an 8.5-F catheter with a manually operated pressure bag or a wall-mounted external pneumatic device delivers crystalloid at the rate of almost 0.5 L per min. A second catheter may be needed for drug infusion. Rapid infusion of larger volumes of fluid should be accompanied by careful monitoring for volume overload, especially in older patients or those with cardiovascular disease.

Volume repletion and measurement of central venous pressure can be accomplished by a Y-arm catheter sheath passed percutaneously into the femoral vein. An 8.5-F catheter can then be used for volume repletion, while a smaller catheter can simultaneously be inserted through the other arm of the Y and directed into the right atrium for the measurement of central venous pressure. Femoral catheters should generally be left in place no longer than 48 h, since iliofemoral thrombophlebitis can result. However, with sterile technique and the use of Silastic catheters, the deep femoral system may safely be employed for a longer duration.

Pressure infusion increases crystalloid flow two to three times above that achieved by gravity alone and is superior to the use of on-line hand-pumped bulbs. Pressure devices are also available for the administration of packed red blood cells. Use of a standard Y irrigation set augments flow rates by reducing resistance in the tubing leading to the catheter site. For maximum infusion rates of either blood or crystalloid, use of blood administration tubing eliminates on-line micro-pore filters, stopcocks, and one-way valves, all of which increase resistance. Addition of NS to packed red blood cell infusions decreases viscosity, increasing the speed of transfusion.¹

Warming of crystalloid and blood before infusion is essential when volume resuscitation is massive. Crystalloid may be stored in a heating bath or oven, safely microwaved, or warmed with a heating coil or heat packs. Blood warming coils that allow transfusion rates of up to 500 mL per min are now available. Alternatively, cold-packed red blood cells may be warmed by diluting them with an equal amount of warmed saline (up to 60°C); this will also decrease viscosity and thus enhance flow.¹ An in-line microwave blood warmer may be used to heat blood safely to 49°C without any significant increase in hemolysis.^{1,3}

VENOUS ACCESS SITES

Peripheral venous catheterization is a routine component of emergency medical practice. The normal human anatomy offers many potential sites for catheterization (Figures 21-1 and 21-2). The cephalic vein, in both the forearm and the upper arm, is large, constant, and straight; easily catheterized, it is the time-honored choice for peripheral access in both adults and children. The superficial radial vein at the wrist is well developed in adults, though it is difficult to locate in a small child. Veins of the hand are usually accessible even in obese persons but are short, tortuous, and difficult to stabilize. Veins in the antecubital fossa are excellent in emergency situations, but an arm-board is necessary to prevent catheter kinking or dislodgement with movement, and the resulting elbow extension is a relatively uncomfortable position for patients if required for more than a few hours. The large basilic vein in the upper arm is usually not visible, but with practice it can be catheterized by palpating the brachial artery and searching blindly for the medially placed vein. Puncture of the brachial artery is common but rarely of clinical significance if care is taken to prevent hemorrhage or hematoma formation. Transitory paresthesias may also occur.

FIG. 21-1. Veins of the upper extremity.

Veins in the legs often require cutdown for catheter placement. The superficial saphenous vein at the ankle is large, constant, and easy to isolate and cannulate. The proximal great saphenous vein in the thigh may be found reliably 5 cm below the inguinal ligament at the junction of the medial and middle third of the thigh (between the pubis symphysis and superior iliac spine) in the supine patient. The deep femoral vein is accessible percutaneously, just medial to the femoral artery which is found approximately midway between the superior iliac spine and the pubic symphysis below the inguinal ligament (see Figure 21-2). In the pulseless patient, the landmark is the junction of the medial and middle third of the inguinal ligament. From the great saphenous and deep femoral veins, advancement of catheters into the right atrium for the measurement of central venous pressure is possible.

Peripheral venous catheterization should not be attempted in an extremity distal to cellulitis, burns, or serious injury, or when potential for vascular disruption due to injury is anatomically proximate.

Catheterization of arms in the presence of an indwelling fistula or serious ipsilateral neck trauma should also be avoided. Hyperosmolar fluids and agents known to cause chemical phlebitis or sclerosis of peripheral veins should not be infused through such veins.

FIG. 21-2. Veins of the torso and lower extremities.

Internal jugular, subclavian, or femoral vein catheterization is performed when peripheral access is impossible or when the measurement of central venous pressure is desired. The relative risk for a catheter-related bloodstream infection is significantly higher with central than peripheral venous catheters.⁴ The external jugular vein can provide reliable access in both adults and children. Although this vein is readily distended by the Valsalva or Trendelenburg maneuvers, scant subcutaneous support can make it difficult to catheterize. However, access to central veins without the risk that attends direct internal jugular and subclavian puncture is a major advantage. In young children, intraosseous infusion provides rapid and reliable access in emergencies (see Chap. 14).

TECHNIQUE FOR PERIPHERAL VENOUS ACCESS

Insertion of peripheral venous catheters should be preceded by wiping with an antiseptic solution and followed routinely by placement of a sterile transparent or gauze dressing. Although a 2 percent chlorhexidine-based preparation is preferred, tincture of iodine, an iodophor, or 70 percent alcohol may be used.⁵ If peripheral veins are small, size and visibility can be enhanced by application of hot, moist compresses for 5 min, by tapping gently on the vein before attempting puncture, or by application of nitroglycerin ointment (0.4 percent for children less than 1 year old; 2 percent for others) over an area 1 in. in diameter for 2 min and then wiping it off. Once access has been obtained, gentle circumferential occlusive taping may be necessary if stability of the site is tenuous, with the intravenous line looped and secondarily secured to prevent traction at the point at which the line penetrates the skin. The size of the catheter can usually be determined by the color of the hub; otherwise, it should be written on the tape dressing. When venous access is required primarily for drug administration, consideration should be given to placing a saline or heparin lock.

Obtaining intravenous access in young children can be a challenge. Children tend to be more anxious and thus uncooperative. Generous

SECTION 3 e RESUSCITATIVE PROBLEMS AND TECHNIQUES

subcutaneous fat may prevent vessel palpation and direct visualization. Finally, a child's vessels are smaller, and children readily lose body heat, which promotes vasoconstriction. It is helpful to have an experienced assistant who can help in holding and distracting the child. When possible prior application of a topical anesthetic can reduce the pain of needle puncture (see Chap. 37).

Complications

Complications from placement of peripheral intravenous lines include hematoma formation, phlebitis, and cellulitis. Phlebitis may occur in up to 75 percent of hospitalized patients. There is general agreement that peripheral venous catheters should not be left in place for longer than 3 days before replacement. Nerve and tendon damage, deep venous thrombosis, suppurative thrombophlebitis, and septicemia are rare. The unusual event of extravasation of irritative, vasoconstricting, or tissue-toxic substances such as 50 percent dextrose, epinephrine, phenytoin, and some drugs used for chemotherapy of malignancies may cause problems ranging from minor pain and inflammation to full-thickness sloughing of skin, necessitating skin grafting. In rare situations, reactive arterial vasospasm has led to ischemia and ultimately tissue necrosis in extremities with very distally placed intravenous lines that have infiltrated. Catheter-over-needle assemblies are now in common use and provide more stable, reliable access than the steel needles they replaced. Microparticulate matter in intravenous solutions is removed by in-line micropore filters.

CENTRAL VENOUS PRESSURE CATHETERIZATION AND MONITORING

Central venous catheterization should be performed:

1. When access to the central circulation is necessary for procedures such as pulmonary artery catheter or pacemaker placement;
2. For access when peripheral veins cannot be cannulated; or
3. When measurement of central venous pressure is desired.

Hypovolemic shock by itself is not, however, an indication for central venous catheterization. Many patients who require large-volume infusions or transfusion with multiple units of blood can be managed with large-bore peripheral intravenous lines. Determination of central venous pressure is indicated when:

1. Massive volume repletion is administered to elderly patients or those with heart disease,
2. Fluid administration is being monitored in patients with visceral trauma and severe head injuries; or
3. Pericardial tamponade is suspected.

A variety of sites and techniques are available to access the central circulation. Most commonly, a catheter is placed in the superior vena cava via the internal jugular or subclavian vein; the external jugular vein is less commonly employed. The femoral vein may also be used, but it requires subsequent immobilization of the leg, and the procedure is accompanied by a higher risk of infection and thrombosis. Emergency physicians should become skilled in at least two approaches for central venous catheterization, using one as the primary while reserving the other as a backup.

Use of peripheral veins to access the central circulation and measure central venous pressure has the advantage of avoiding the risk associated with direct puncture of the subclavian and internal jugular veins. However, low flow is inevitable due to the long course of the catheter from the extremity to the superior vena cava. Peripheral sites also fail frequently due to catheter malposition and kinking. In the arm the brachial-basilic system must be used, since catheters in the cephalic system often become kinked in the plexus of veins at the shoulder. Smooth passage and correct tip positioning are more likely if the patient is sitting with his or her head angulated sharply toward

the catheterized arm, the arm is held abducted, and the catheter is wire-guided. In emergency situations, however, this time-consuming approach to the central circulation is often impractical.

Anatomy

A brief review of anatomy is warranted (Figures 21-1 and 21-3). The major veins of the upper thorax are deeply and centrally placed and well protected by the clavicles, sternum, and strap muscles. The internal jugular veins join the subclavian veins to form the brachiocephalics (innominate), which in turn join to become the superior vena cava. The sternocleidomastoid muscle attaches separately by two heads to the sternum and clavicle; the triangle formed by these two heads and the clavicle is just above the internal jugular vein. The right internal jugular has a straight path into the superior vena cava, whereas all the other major tributaries curve. Both external jugular veins enter the subclavian veins at close to right angles. The subclavian veins lie immediately posterior to the junction of the medial and middle thirds of the clavicle and are anterior and inferior to the artery; the pleura are immediately posterior and inferior to the subclavian vessels (Figure 21-4). The internal jugular vein usually lies anterolateral to the carotid. The basilic and brachial veins join to form the axillary vein. The cephalic vein joins the axillary vein more superiorly, just before it becomes the subclavian vein. The axillary vein continues the distal subclavian vein and runs medial to the axillary artery from the distal arm. The femoral vein is medial to the femoral artery. The relative locations of components of the neurovascular-lymphatic bundle in the groin from lateral to medial can be recalled by the mnemonic NAVEL (*nerve, artery, vein, empty space, /ymphatic*).

Equipment and General Technique for Central Venous Catheterization

All equipment should be at the bedside, including a central venous (CV) pressure manometer if CV pressure monitoring is desired. Catheter-through-needle devices, whose large 14-gauge insertion needles are prone to complications and whose 16-gauge catheters allow maximum gravity-assisted flow of 100 to 150 mL per min, have been largely supplanted by wire-guided (Seldinger) catheters.⁶ Their use allows use of a small needle to place any size catheter into a vessel.

FIG. 21-4. Coronal section through the midclavicle.

The patient should be placed in a neutral to maximum of 30 degrees head rotation and 15 degrees Trendelenburg position, and the entire route of the neck should be prepped so that all three approaches are possible in case the primary approach fails. The right side is preferred over the left, since (1) the lung apex is slightly lower, (2) there is a straight relationship between the right internal jugular vein and the superior vena cava, and (3) the left-sided thoracic duct cannot be injured. With unilateral chest trauma in the absence of suspected vessel injury, the attempt should be on the injured side in order to protect the uninjured hemithorax in the event of complications from the procedure.

When the procedure is performed electively, preceding the approach for catheter placement with a 22-gauge needle attached to a 5- or 10-mL syringe filled with lidocaine facilitates local anesthesia and allows the operator to locate the vein. After landmarks are identified, an 18-gauge needle is then inserted into the vein (Figure 21-5A). Gentle, continuous negative pressure on the syringe should be maintained until free flow of blood is obtained. The syringe is removed and a fingertip is used to occlude the hub before wire insertion (Figure 21-5B). This often forgotten or ignored maneuver is important to prevent aspiration of air, particularly in internal jugular or subclavian vein catheterizations. The needle is then removed (Figure 21-5C), leaving just the wire in the vein. A small skin incision (1 to 2 mm) is often made over the wire (Figure 21-5D) to facilitate smooth entry of the catheter, which is threaded over the wire and into the vein with a twisting motion (Figure 21-5E). The wire is then removed, leaving only the catheter in place (Figure 21-5F). If a large-bore catheter is necessary, the apparatus is used with a venodilator. In this situation, the veno-dilator is removed with the wire, leaving the large-bore 8.5-F catheter sheath in place.

The principal advantages of wire-guided catheters are:

1. Use of a small (and thus safer) needle for insertion
2. The step-up capability with a venodilator, allowing for the higher flow rates often required in trauma resuscitation
3. The flexibility of exchanging standard intravenous catheters, central venous catheters, and pulmonary artery catheters without repeated stab, and
4. The use of J wires to access the central circulation from the external jugular vein

Ultrasound visualization of the central vein while puncture is attempted reduces the number of punctures necessary for cannulation to

FIG. 21-5. Seldinger technique of catheter insertion (wire-guided). (Reproduced with permission from Conahan TJ III, Schwartz AJ, Geer RT: Percutaneous catheter introduction: The Seldinger technique. *JAMA* 237:446, 1977.)

establish central access, while also reducing the incidence of complications. The technique is particularly helpful when the traditional landmark-based techniques fail or are impractical due to vascular anomalies or body habitus, or when patients with a coagulopathy require central venous access.^{7,8}

Complications

The three most common serious complications of central venous catheterization are mechanical problems (pneumothorax, arterial puncture, and malpositioning), catheter-related infection, and thrombosis (Table 21-1). A large body of reported experience suggests that for internal jugular access there are more arterial punctures but fewer catheter malpositions than with subclavian access. There is, however, no evidence of a difference in the incidence of hemo- or pneumothorax or vessel occlusion. Femoral venous catheterization is associated with greater risk of infection and thrombotic complications than subclavian catheterization.⁹ In children, the success rate for subclavian catheterization is higher and the complication rate is lower (3.2 percent) than for internal jugular venous access. Other, less common complications include hydrothorax, chylothorax (left side), hydromediastinum, air or catheter embolism, vessel thrombosis, dysrhythmia, nerve injuries, osteomyelitis of the clavicle, catheter tip perforation of

TABLE 21-1 Central Venous Access Complication Rate

	Subclavian	Internal jugular	Femoral
Infection	4-5%	8-9%	15-19%
Thrombosis	1-2%	1%	12-21%
Pneumothorax	1.5%	1.3%	0%
Arterial puncture	<1%	3%	8%
Malposition	9%	5%	<1%

Note: Data is compiled from a number of studies.

SECTION 3 . RESUSCITATIVE PROBLEMS AND TECHNIQUES

the superior vena cava (causing hydromediastinum or hydrothorax) or right atrium (causing hydropericardium), knotting with other catheters, and puncture of endotracheal tube cuffs.¹⁰ Care in executing the procedure and in the selection of patients who will benefit from central venous catheterization will minimize the occurrence of complications.

Technique of Commonly Used Approaches

EXTERNAL JUGULAR VEIN The external jugular vein is a superficial, readily accessible vessel that lies in the subcutaneous tissue over the sternocleidomastoid muscle. The vein courses inferior and joins the subclavian vein under the clavicle (see Figure 21-3). Central venous access via this route has an increased success rate if a J-wire-guided catheter assembly is used. Success is enhanced by introducing the wire through a 16-gauge catheter rather than through a needle, using a J tip with no more than a 3-mm radius, exaggerating head tilt with marked traction on the skin of the neck. The latter technique in particular should be tried before making a second attempt. Wire-through-needle techniques may be met with resistance at the level of the clavicle that can be overcome by twisting the tip of the J wire 180 degrees. It is also recommended that a small syringe (insulin or TB syringe) be attached to the introducing needle-catheter assembly for both stabilization and to maintain negative pressure. The external jugular vein is very pliable and collapses easily during initial skin puncture. Gently withdrawing the needle back while maintaining suction improves chances of successful catheterization.

The main disadvantage of external jugular catheterization is difficulty in securing the catheter in the neck. Other potential problems are:

1. The venous valves within its course may impede catheter placement
2. Patient movement makes most external jugular lines short-lived, and
3. Neck rotation impedes flow of the infusion, making the line unreliable for fluid or medications unless it is constantly watched

INTERNAL JUGULAR VEIN There are three traditional approaches to catheterization of the internal jugular vein. In the central approach (Figure 21-6B), after the patient is placed in Trendelenburg position, the needle should puncture the skin 1 cm below the apex of a triangle at the midpoint formed by the tendinous and muscular heads of the stern-

ocleidomastoid muscle. The palpation and definition of the margin of the carotid artery is not as important as in the anterior approach, but is helpful in locating the vein and to avoid puncture of the artery. Held at a 60 degree angle with the plane of the skin, the needle is directed slightly lateral to the axis of the body (lateral to the pulsation of the carotid artery). Common helpful landmarks for needle direction include the ipsilateral nipple and a plane parallel to the medial border of the lateral head of the sternocleidomastoid muscle. Blood return should be obtained within 3 cm, since the vein is very superficial here. If the attempt appears to fail, the needle should be withdrawn slowly, as success is often evident only on slight withdrawal. If the attempt has clearly failed, the needle should be withdrawn completely before the next attempt.

In the lateral or posterior approach, the head is turned slightly away from the selected side; after the patient is placed in Trendelenburg position, the needle is inserted at the posterior margin and deep to the sternocleidomastoid muscle two to three fingerbreadths above the clavicle and directed toward the suprasternal notch (Figure 21-6A). Frequently, the external jugular vein crosses the lateral wall of the sternocleidomastoid muscle at this point. If it does, the needle should be inserted at the junction of the crossing at a 90 degree angle to the external jugular vein. Blood should be aspirated within 4 to 5 cm. The carotid artery is just behind this path, albeit slightly posterior, and may be at increased risk for puncture.

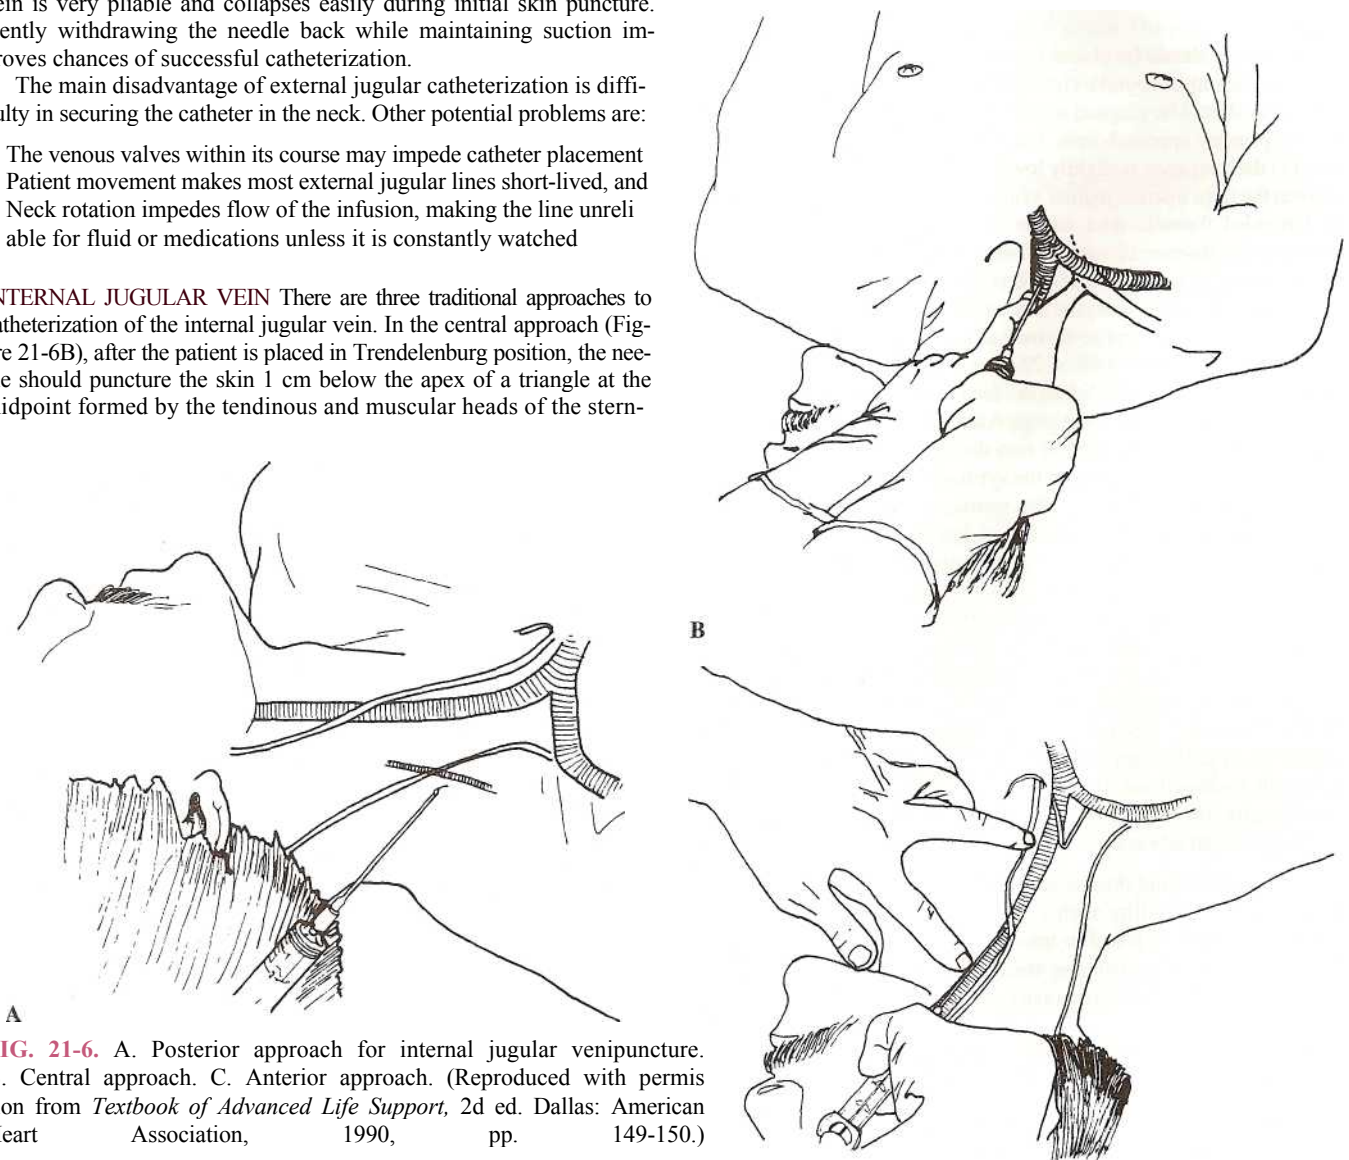

FIG. 21-6. A. Posterior approach for internal jugular venipuncture. B. Central approach. C. Anterior approach. (Reproduced with permission from *Textbook of Advanced Life Support*, 2d ed. Dallas: American Heart Association, 1990, pp. 149-150.)

The anterior approach (Figure 21-6C) and its variants may well be the most technically difficult. After the carotid is identified, the needle is entered at the midpart of the medial border of the sternocleidomastoid. With the fingers over the carotid, the needle is directed 30 to 45 degrees from the midline plane toward the ipsilateral nipple. This approach has the greatest likelihood of carotid puncture and appears to be the least favored of the intravenous cannulation approaches.

SUBCLAVIAN VEIN The subclavian vein is still the most commonly used site for central venous access. The right side is preferred because the pleural dome is lower on that side. The fact that the point of insertion is in a broad, flat area of the chest makes it ideal for use when central venous access will be required for a prolonged period. The patient is placed in the Trendelenburg position. If the patient is a child, a towel is placed under the thoracic spine. This may also be helpful in some adults.

The *infraclavicular* subclavian approach is the most commonly taught technique. There is no universal agreement on exactly where the needle should enter. The bisection of the middle and medial thirds of the clavicle is an appropriate landmark. Another is a point just lateral and inferior to the junction of the clavicle and first rib. Using the former landmark (Figure 21-7), the skin is penetrated about 1 cm inferior to the clavicle and directed inferomedially. With the index or middle finger of the other hand in the suprasternal notch, the needle is aimed at the superior and most posterior portion of the ipsilateral clavicular head. Inferomedial orientation of the needle bevel facilitates entry of the wire or catheter into the vein. Vessel entry occurs at a depth of 3 to 4 cm.

For the *supraclavicular* subclavian approach, the patient's head is turned slightly away from the selected side. The needle enters just above the clavicle, 1 cm lateral to the insertion of the clavicular head of the sternocleidomastoid muscle and 1 cm posterior to the clavicle. It is then directed to bisect the angle formed between the sternocleidomastoid and the clavicle, at an angle of 10 degrees above the horizontal, with the tip pointing just caudad to the contralateral nipple. Keeping the bevel up prevents trapping of the wire or catheter against the inferior wall of the vessel. Vessel puncture occurs at a depth of 2 to 3 cm.

FEMORAL VEIN Femoral vein catheterization is used when the vessels of the upper body are not suitable, and when access is required

above and below an injury. Although femoral vein catheterization is somewhat easier than subclavian or internal jugular catheterization, the insertion site is difficult to sterilize and keep clean, and patient movement may make it difficult to keep the line secured.

The patient should be supine with the ipsilateral hip in a neutral to slightly externally rotated position. The approximate position of the femoral vein can be determined by dividing the distance between the anterior superior iliac spine and the pubic tubercle into three equal segments (see Figure 21-2). In most patients, the femoral artery usually lies at the midpoint. If the femoral pulse is palpable, the needle puncture site should be 1.5 cm medial and 1.5 cm inferior to the inguinal ligament. Once venous blood is obtained, the guidewire is inserted though the needle, the needle is removed, and the catheter is inserted over the wire.

This access can be used for the measurement of central venous pressure, for intravenous pacing, for pulmonary artery catheterization, and to administer large volumes of fluids rapidly. The increased risk of infection and thrombosis make it less than ideal as a route for hyperalimentation. It is not an ideal central access site for administration of ACLS medications.

AXILLARY VEIN The axillary vein (see Figure 21-2) is used for central venous access when the femoral, subclavian, and jugular veins are unavailable. This useful technique is unfortunately rarely used by emergency physicians. With practice, the success rate for central access via the axillary vein is similar to that for puncture of the internal jugular or subclavian vein. There is no risk of pneumothorax and the method has the advantage that if arterial puncture should occur, direct pressure can be applied.

Patients are placed supine with head-down tilt and the arm abducted to 45 degrees. In this position the axillary vein follows a straight course from the arm to the subclavian vein. An insertion point is chosen approximately 2.5 cm inferior to the axillary pulse and lateral to the midclavicular line. The introducer needle is then inserted along a line formed by the insertion point and suprasternal notch, at an angle of 30 degrees to the skin, and directed parallel to the course of the artery toward the chest wall. In children and thin adults, the artery is easily palpable.

VENOUS CUTDOWN

The basilic vein in the antecubital fossa and the saphenous vein in the leg are the most commonly utilized vessels for cutdowns. The basilic vein is located two fingerbreadths above and two fingerbreadths medial to the olecranon. The saphenous vein is just anterior to the medial malleolus at the ankle (Figure 21-8A) and is also accessible in the proximal thigh three fingerbreadths below the midpoint of the inguinal ligament (see Figure 21-2). Although experienced operators may be able to complete the procedure in less than a minute, for most operators 5 or 6 min will be required. In many situations, this implies that cutdown should be resorted to only when percutaneous access has failed or is deemed likely to be unsuccessful.

The operator begins by disinfecting and anesthetizing the skin (Figure 21-8). A transverse skin incision is made, and by blunt dissection the subcutaneous tissue is separated until the vein is exposed. Any accompanying artery is identified by slipping a forceps or hemostat under the vessels and applying pressure; pulsatile flow will be evident in the artery. (However, with patients who are in shock, this maneuver may be unsuccessful.) After freeing the vein from the surrounding tissues, two separate sutures are passed beneath the vein, one proximally and one distally. The proximal sutures are left untied, while the distal suture is tied to occlude the vein. The ends of the sutures are kept long so that they can be used for applying traction to the vein. A small incision is made in the vein between the proximal and the distal sutures (it should not be cut through and through). While applying traction on the vein, the operator inserts the catheter into the vein. Some cutdown

FIG. 21-7. Infraclavicular subclavian venipuncture.

FIG. 21-8. Venous cutdown. A. A skin incision is made perpendicular to the course of the vein. B. Skin retracted and vein exposed. C. Proximal and distal ties are passed under the vein. If the vein is to be sacrificed, the distal suture is tied to prevent bleeding, and the ends are left long to help stabilize the vein during cannulation. The proximal tie is not tied at this point, but traction on it will control back bleeding. D. The vein is stretched flat and incised at a 45 degree angle. Approximately one-third of the lumen must be exposed. (Reproduced with permission from Roberts JR, Hedges JR: *Clinical Procedures in Emergency Medicine*, 2d ed. Philadelphia: Saunders, 1991, p. 321. Parts B and C first appeared in Vander Salm TJ, et al: *Atlas of Bedside Procedures*. Boston: Little, Brown, 1979.)

kits contain a vein "holder," which may help to prepare the vein to accept a catheter. The proximal suture is tied to secure the catheter in the vein and the skin is closed. Care must be exercised throughout the procedure, since poor technique can result in injury to a tendon or nerve or extensive hemorrhage from soft tissue.

An alternate method of cannulating the vessel is to perform a "mini-cutdown" (Figure 21-9). In this technique, the vein is fully exposed and an over-the-needle catheter is inserted into the vein under direct visualization. Great care must be taken to avoid through-and-through puncture. The advantage of this technique is that it is easier to perform, especially in young children, and the vessel does not have to be sacrificed. Extensive tissue dissection and complete isolation of the vein are avoided, there is no need to place proximal and distal suture ties, and the catheter can be discontinued with simple pressure at the site.

The potential complications of venous cutdown include infection, phlebitis, and laceration of a nerve or artery.

INTRAOSSEOUS VASCULAR ACCESS

When vascular access cannot be obtained through other sites, intraosseous infusion may be life- or limb-saving. This method of vascular access, usually considered for children, may be used in adults as well. After 5 years of age, however, red marrow is steadily replaced by yellow marrow in the limbs, making infusion more difficult, and decreasing the potential infusion rate.

Arterial supply to bones is by a nutrient artery that pierces the cortex and bifurcates into ascending and descending branches; these further divide into arterioles that pierce the endosteal surface to become capillaries. The capillaries drain into medullary venous sinusoids within the medullary space; these then drain into a central venous channel. Catheter placement in the sinusoids provides ready access to the venous circulation.

For pediatric patients up to 5 years of age, the tibia is the preferred site (Figure 21-10). In adults, the most commonly used site is the medial malleolus. Although the sternum offers higher infusion rates for adults, this approach is attended by the potentially disastrous complication of puncture into the thoracic cavity. The tibial approach is technically more difficult in adults than in children because the adult bone is thicker and the needle tends to slip off the bone. Other potential insertion sites include the distal femur, clavicle, humerus, and ileum.

FIG. 21-9. A "mini-cutdown." The vessel is elevated with a hemostat and occluded with gentle traction from a distal tie. The needle is inserted and the sheath is advanced into the vessel. The vessel should not be tied off with this technique.

FIG. 21-10. The needle is inserted 2 cm distal to the tibial tuberosity on the medial aspect of the tibia. It is inserted in a caudal direction, away from the joint space.

Technique

Either standard bone marrow aspiration needles or specialized intraosseous infusion needles must be used because standard intravenous stylets and spinal needles are likely to bend during the procedure. For the proximal tibia, the puncture site is 1 to 2 cm distal to the midpoint between the tibial tuberosity and the medial aspect of the tibia; for the distal tibia, it is the medial surface of the ankle just proximal to the medial malleolus; and for the distal femur, it is the dorsal surface at the point where the condyles join the shaft of the bone. After disinfecting skin and anesthetizing skin and periosteum, the operator inserts the needle with the point directed away from the joint space (distally if the site is the proximal tibia, proximally at the other two sites). The needle is grasped in the palm of the hand and directed into the bone using a twisting motion to break through the cortex. Once this has occurred, resistance decreases and crepitus is encountered as the needle enters the marrow cavity. The stylet is then removed and aspiration with a syringe is performed to obtain blood and marrow for confirmation of positioning. If shock is present, aspiration may be unsuccessful; if this is the case, cautious infusion of several milliliters of NS should be attempted with careful observation for extravasation. If there is none, then the needle may be assumed to be positioned in the marrow cavity. A postprocedure x-ray should be performed to rule out the complication of iatrogenic fracture.

Complications

The incidence of infection, including both cellulitis and osteomyelitis, is less than 1 percent, similar to that for other techniques. The potential for infection can be minimized by limiting the duration of intraosseous infusion and avoiding hypertonic solutions. Fractures of the tibia have been reported. Fat embolism is rare and has been reported only in adult patients. Injury to the growth plate has also been mentioned as a potential complication, but there are no reports of serious morbidity arising from an injury to developing bone.

VASCULAR ACCESS IN CHILDREN

Scalp Vein Access

Scalp veins are easily accessible in children less than 1 year of age and provide a good route for maintenance fluid and drug administration (Figure 21-11). The superficial temporal, posterior auricular, and supratrochlear veins are the most easily catheterized scalp veins. In all cases, the vein must be differentiated from its respective artery. Arteries are generally more tortuous; they pulsate, and they fill from below, whereas veins fill from above.

FIG. 21-11. A tourniquet is placed around the infant's head and the needle inserted 0.5 cm from the intended puncture site in the direction of blood flow.

The operator begins by shaving and disinfecting an area large enough to secure butterfly needle wings. A rubber-band tourniquet is placed around the head proximal to the venipuncture site and a butterfly needle—usually 23 to 27 gauge—is advanced into the vein. The needle is then taped at the skin entry point and at the butterfly is taped with cotton support under the wings. A cover (medicine cup) may be used to protect the area. Complications from this procedure include infection, bleeding, extravasation of fluid or medications, and inadvertent arterial puncture.

Umbilical Vein Access

In the first 1 to 2 weeks after birth, the umbilical vessels offer easy central venous access. Even a severely dehydrated umbilical stump may yield good vessels with adequate preparation. In a normal infant, there are two small umbilical arteries and a single larger vein. The arteries arise from the internal iliac artery while the vein is continuous with the portal vein.

The operator begins by cleansing the cord with an antiseptic. Avoid tincture of iodine because of the potential effect on the neonatal thyroid.⁵ A transverse cut is made 1 cm above the junction of skin and cord, at which point a purse-string suture is placed. The single large vein and two smaller arteries are identified. A 3.5- to 5.0-F catheter is inserted into the vein and advanced to 4 to 5 cm in a term infant; further advancement may cause liver damage. The catheter should be filled with NS solution and flushed properly prior to placement to ensure an air-free system.

The most common complications relate to vascular insufficiency induced by the catheter. Evidence of ischemia—such as necrotizing enterocolitis, liver necrosis, poor peripheral circulation, or abdominal distention—is an indication for immediate removal of the catheter. The potential for infectious complications is equivalent to that for other indwelling catheters.

ARTERIAL ACCESS

Arterial access is predominantly concerned with arterial pressure monitoring or repeated arterial blood sampling. This is described in detail in Chap. 22, on invasive monitoring techniques.

SPECIAL PROBLEMS RELATED TO VENOUS ACCESS

Complications of Total Parenteral Nutrition

Central venous catheter placement for total parenteral nutrition (TPN) may be done short-term as a part of hospital care or long-term at home or in extended-care facilities. TPN is usually administered through a catheter placed into either the subclavian or jugular vein. The incidence of mechanical and septic complications depends on the skill, experience, and commitment of both the patient and the nutrition support team.¹¹ Suspicion of line sepsis demands immediate consultation. Most patients should be admitted, although the catheter may not need to be removed in selected cases.

Catheter occlusions occur in approximately 5 percent of patients receiving long-term TPN. If the first-line remedy of flushing the catheter with NS or heparin solution fails, thrombolytic agents, such as alteplase and reteplase may be used to lyse clots that obstruct the lumen of the catheter without obstructing the vessel. These agents are as effective as urokinase,^{12,13} which was commonly used prior to its removal from the market in 1998. The recommended dose of alteplase is 1 to 2 mg, depending on the type of intravascular device and its filling volume. Alteplase is available in a small-dose 2 mg/2 mL vial (Cathflo). An appropriate volume of alteplase is instilled into the catheter, which is then clamped for 30 min. If no blood return is achieved, then one should wait another 120 min. If there is still no return, then a second attempt may be made with the same dosage and dwell times. Failure to clear the catheter after two dosages suggests either organized thrombus or anatomic abnormality; further diagnostic study such as angiography and ultrasound-Doppler duplex scanning may be indicated. Some authors have reported high success rates infusing ethanol (up to 3 mL of 70 percent solution) for presumed lipid occlusions, or hydrochloric acid (HCl 0.1N, up to 3 mL) to clear presumed mineral oil or other precipitates.

Catheter-related sepsis in patients receiving TPN is usually a result of catheter contamination by organisms colonizing the skin. Gram-negative bacteremia, sepsis syndrome, and fungemia are treated by removal of the catheter in association with appropriate antimicrobial therapy. Gram-positive infections can often be managed with the catheter left in place while antibiotic therapy is administered. The delivery of TPN through peripherally inserted central catheters (PICCs) is associated with slightly lower infection rates but a higher rate of mechanical failure. Because there is a considerably increased risk of both infection and thrombosis when femoral lines are used for TPN, this mode of access is less than optimal for patients requiring parenteral nutrition. Other reported complications include pulmonary embolism, line fracture, embolized catheter fragment, mediastinitis, superior vena cava syndrome, pneumothorax, air embolism, and lymphatic duct injury.

Accessing Indwelling Catheters

It is increasingly common for patients to present to EDs with specialized devices, such as Hickman catheters, which have been placed to provide long-term intravenous access. Such devices facilitate outpatient treatment in an era of increasing cost-consciousness. Emergency physicians can access these devices to obtain specimens for laboratory study as well as to administer intravenous fluids and medications.

When indwelling catheters are accessed, meticulous care should be taken to maintain sterility at the site. Depending on the type of device (implanted versus externalized), specialized equipment may be required to obtain access. Five milliliters of either NS or heparin flush (100 U/tmL) is injected and then withdrawn gently to ensure catheter patency. Blood for laboratory study is collected only after a dead-space volume (5 to 10 mL) has been collected and discarded. Since these devices are heparinized, coagulation studies performed on such

samples are unreliable; blood for these studies should be obtained from other sites. After access has been terminated, implanted devices should be flushed with heparin solution of 1000 U/mL strength. Other externalized devices should be flushed using a solution of 100 U/mL strength.

Arteriovenous fistulas and shunts should be used only for access in the most extreme of emergency situations, since complications, including loss of the access site, are common. The smallest needle appropriate to the task at hand should be inserted. Afterward, local pressure should be applied for 5 min or more, and these arterialized sites should be carefully monitored for hemorrhage for 12 h.

INVASIVE MONITORING, PACING TECHNIQUES, AND AUTOMATIC AND IMPLANTABLE DEFIBRILLATORS

Edward S. Bessman

INVASIVE MONITORING TECHNIQUES

General Considerations

Invasive pressure monitoring should never be the initial step in resuscitation. When clinically indicated, arterial line or pulmonary artery catheter (PAC) placement may be considered after initial stabilization is completed. If possible, these procedures should be deferred until the patient reaches the more controlled environment of the intensive care unit, unless there will be a significant delay.

The two essential components of any pressure monitoring system are a properly placed and secured catheter and a functioning pressure

transducer-monitor. Ideally, the transducer and line for pressure monitoring should be set up and ready for use prior to the patient's arrival in the ED.

Arterial Cannulation

Arterial lines offer several advantages over monitoring blood pressure with an arm cuff. The arterial line provides continuous measurement of blood pressure and can be used for easy sequential sampling of blood gases. In the setting of marked vasoconstriction or hypotension, the arterial line usually gives more accurate pressure readings than a blood pressure cuff. The American College of Cardiology/American Heart Association practice guidelines for patients with acute myocardial infarction recommend intraarterial pressure monitoring for patients with severe hypotension or cardiogenic shock or who are receiving potent vasoactive infusions.¹ Other appropriate scenarios include hypertensive crisis, hypothermic cardiac arrest, and prolonged ED resuscitation.

Although the radial artery is the most frequently employed site, extensive experience using the brachial, femoral, and dorsalis pedis arteries has shown them to be equally satisfactory. In infants and neonates, the temporal or umbilical and dorsalis pedis arteries are most often accessed, although radial artery cannulation is also acceptable. While many operators are most familiar with the radial artery site, use of the femoral artery leaves the arm clear for other procedures and, in the presence of shock, the femoral artery is less difficult to cannulate percutaneously. Cutdown on the radial artery is an alternative in such patients.

Assessment

Although catheterization of the radial artery is associated with up to a 20 percent incidence of temporary flow obstruction by Doppler study, permanent ischemic complications requiring surgical reanastomosis or amputation are quite rare. Confirmation of collateral flow through a patent ulnar artery can be obtained by performing the Allen test: while the patient clenches the wrist for 1 min, the examiner compresses the radial and ulnar vessels with thumb and forefinger.² On release of ulnar compression, the patient partially extends the fingers, which are observed for accentuated rubor in comparison to the untested side. Patent ulnar circulation is indicated by return of rubor within 7 s; an equivocal result is 7 to 14 s. Greater than 14 s is considered definitely abnormal. If ulnar cannulation is contemplated, patency of the radial artery can be tested by the same test, with release of that vessel fol-

lowing compression. If the test result is positive, another site should be considered, but if that is not practical, then the clinician may have to proceed with radial artery cannulation in any case.³

Technique

Landmarks for radial and femoral artery cannulation are shown in Figure 22-1. The catheter (usually 20-gauge, 2 in. long for radial cannulation, and 18-gauge, 4 in. long for femoral cannulation) can be introduced by direct puncture threaded over the needle or by Seldinger technique threaded over a guidewire. Freely flowing, pulsatile, bright-red blood indicates proper placement. With marked hypotension or hypoxia, arterial blood flow may be mistaken for venous (nonpulsatile, dark blood returned). In all cases, connection to the transducer should reveal an arterial waveform if the catheter is in the proper position. Failure to visualize a waveform can be due to venous placement, air in the line, a closed stopcock, or a malfunction in the transducer or monitor.

Percutaneous cannulation of the brachial or femoral arteries may be possible when the radial pulse is absent in a hypotensive patient. The technique is similar to radial artery cannulation, although a careful groin preparation, preceded by removal of hair at that site to minimize the risk of infection, is necessary.

With profound hypotension, cutdown to the radial artery may be required to cannulate the artery. This is performed through a transverse incision similar to a venous cutdown (see Chap. 21). When 1 cm of artery is visible, the vessel is isolated by passing two lengths of silk suture beneath it using a hemostat. A catheter-through-needle device is passed through the skin distal to the area of exposure and advanced into the site. The artery may then be punctured and the catheter advanced. The suture, which is used only to control the artery, may then be removed and the skin incision closed.

Complications

Serious complications, such as infection and occlusion, are most closely related to duration of cannulation and are much more common among critically ill patients than among those undergoing adjunct monitoring. In the past, incidence of local infection in an ICU setting could approach 20 percent. Recent data indicates infection rates of less than 1 percent with no site differentiation (radial, brachial, femoral). Other complications that may be apparent in an ED include hematoma formation and hemorrhage. Both can usually be controlled with a pressure

FIG. 22-1. Anatomic landmarks for arterial line placement. A. Femoral triangle. Note that the femoral artery lies lateral to the vein and midway between the pubis and the iliac crest. B. New York: Macmillan, 1982.]

dressings. Arterial occlusion, thrombosis, or embolization with distal ischemia may occur. They are associated with placement in smaller vessels or in atherosclerotic vessels, with prolonged catheterization, and with use of end arteries that supply areas with poor collateral circulation. Permanent ischemic injury is very rare. Sepsis may result from local infection at the insertion site. Using the femoral or radial site can minimize these complications, along with proper attention to sterile technique and removal of the line as soon as feasible after the patient is stabilized.¹

Pulmonary Artery Cannulation

A PAC is helpful in the measurement of critically ill patients with hemodynamic instability, particularly in the setting of acute myocardial infarction. Most important, the PAC can help to differentiate between shock due to intravascular volume depletion and that due to extensive left ventricular (LV) dysfunction. When the balloon tip of a PAC is properly inflated in a branch of the pulmonary artery, the pressure sensed by the catheter corresponds approximately to that in the left atrium. Left atrial pressure (which equals LV filling pressure) is an excellent indication of the adequacy of fluid resuscitation. If this pressure is low (<12 mm Hg), additional fluid resuscitation is indicated. If this pressure is high (>20 mm Hg), additional fluids are unlikely to improve cardiac performance; instead diuresis, afterload reduction, inotropic support, or vasopressors should be considered. Although the PAC can yield useful diagnostic information (Table 22-1), the distinction between the need for more fluids and the need for more LV support is its most useful application during resuscitation.¹ Volume assessment by central venous pressure monitoring is less reliable than PAC, especially in the presence of valvular or pulmonary disease.

A standard PAC is shown in Figure 22-2. The catheter has two fluid paths, one that terminates at the tip (the distal port) and a second that opens 10 to 15 cm from the tip (the proximal port). A third lumen connects to a 1.5-mL balloon located at the tip of the catheter. The balloon is ordinarily deflated except during insertion and when taking occlusion pressure measurements. When inflated during insertion, the balloon surrounds the tip of the PAC to prevent it from causing injury to the heart or great vessels as well as to help float the catheter through the heart as it is advanced. A temperature sensor is located about 5 cm proximal to the catheter tip and can be used to measure cardiac output via the thermodilution technique.

The procedure for insertion is described in detail elsewhere⁴ but briefly is as follows. After central venous access is secured (see Chap. 21), the PAC, which has already been attached to a monitor and a pressure transducer, is slowly advanced through the introducer sheath. Once the tip of the catheter enters the vein, the balloon is inflated. By observing the pressure waveform transmitted via the distal port, the operator can follow the progress of the catheter through the heart, and ultimately into a branch of the pulmonary artery (Figure 22-3). Fluoroscopy is helpful to ensure quick and proper placement, but rarely is available in the ED.

With the PAC in position, the clinician can occlude the branch pulmonary artery by inflating the balloon. This gives the pulmonary ar-

tery occlusion pressure, or as it is more commonly known, the pulmonary capillary wedge pressure, which best reflects the pressure in the pulmonary capillary bed and the left atrium. The clinician can also rapidly measure pulmonary artery pressure, cardiac output, and central venous pressure. These measurements, when combined with arterial pressure measurement, enable the clinician to calculate systemic vascular resistance (see Chap. 30). These parameters are useful in the diagnosis and treatment of various shock states and in guiding therapy in acute myocardial infarction (see Table 50-8).

As with arterial cannulation, therapeutic procedures or definitive care should not be delayed solely to allow PAC placement. Complications include all the complications of central venous line placement (see Chap. 21). In addition, cardiac dysrhythmias and right bundle-branch block may occur as the catheter traverses the heart. Other potential complications include pulmonary embolism or infarction, knotting of the catheter, infection, and rupture of a small branch of the pulmonary artery.

The safety of PACs in the critical care environment has been questioned because of an association between its use and increased mortality rates.⁵ Current consensus favors the continued use of PACs,¹ but underscores the need for definitive investigation. Benefits of PAC insertion in the ED have not been investigated. The advent of newer techniques, such as transesophageal echocardiography,⁶ transthoracic impedance cardiography,⁷ and magnetic resonance velocimetry⁸ may further reduce the role of PACs in the ED. Recent studies have demonstrated the utility of these noninvasive hemodynamic monitoring techniques in the ED for both trauma and nontrauma patients.⁹

EMERGENCY PACING TECHNIQUES

General Considerations

Cardiac pacing serves to maintain or restore myocardial depolarization and thus ensure adequate cardiac output. In the ED, pacing may be performed therapeutically to correct an ongoing rhythm disturbance, or prophylactically in anticipation of possible conduction problems. Common situations that may respond to emergency pacing include bradyarrhythmias, asystole, and overdrive pacing of tachyarrhythmias. Detailed guidelines regarding the indications for emergency cardiac pacing may be found in Chap. 28. The techniques are described below.

Transcutaneous Pacing

Transcutaneous pacing has become the emergency technique of choice because of its easy application. It uses externally applied electrodes to deliver an electric impulse directly across the intact chest wall to stimulate the myocardium. Transcutaneous pacers differ from standard pulse generators in several important ways. The pulse duration of the stimulating impulse is longer and the current output higher than for internal pacing. Muscle contraction (usually the chest wall or diaphragm) is notable during pacing, especially at higher outputs. This results in a twitching or bucking activity that can make assessment of cardiac output by palpation of the radial, carotid, or femoral pulse unreliable during transcutaneous pacing. The higher current outputs used make cardiac monitoring with standard electrocardiogram (ECG) monitors problematic due to interference from the large-amplitude pacing spike. Most transcutaneous pacing units come equipped with a monitor that automatically filters the pacing spike so that simultaneous monitoring is possible.

The external pacing electrodes are quickly and easily applied to the chest and back. If separate defibrillator pads or paddles are used, they should be placed at least 2 to 3 cm away from the pacing pads. There is little risk of electrical injury to health care providers during transcutaneous pacing. **The electrodes are insulated, and chest compressions CPR can be administered directly over them while pacing,**

TABLE 22-1 Hemodynamic Diagnosis of Shock States

Type of Shock	CO	PCWP	SVR
Cardiogenic	↓	↑	↑
Hypovolemic	↓	↓	↑
Septic	↓ or ↑	↓	↓
Neurogenic	↑	↓	↓
Anaphylactic	↓	↓	↓

Abbreviations: CO = cardiac output; PCWP = pulmonary capillary wedge pressure; SVR = systemic vascular resistance; ↑ = increased; ↓ = decreased.

FIG. 22-2. Pulmonary artery thermodilution catheter. [Reproduced with permission from Beal JM (ed): *Critical Care for Surgical Patients*. New York: Macmillan, 1982.]

although it is recommended that pacing be discontinued during CPR to minimize inappropriate stimulation of the patient due to electrical artifacts. Inadvertent contact with the active pacing surface results only in a mild shock. In the setting of bradyasystolic arrest, it is reasonable to turn the stimulating current to maximum output and then decrease the output if capture is achieved. In a patient with a hemodynamically compromising bradycardia (but not in cardiac arrest), the operator should slowly increase the output from the minimum setting until capture is achieved; usually between 50-100 mA. Capture is assessed by following the ECG on the filtered monitor of the pacing unit and palpation of peripheral pulses. Bedside ultrasound may also be useful for determining external pacer capture.¹⁰ The hemodynamic response to pacing must also be assessed, either by blood pressure cuff or arterial catheter. Ideally, pacing should be continued at 1.25 times the threshold of initial electrical capture.

As with other pacing systems, transcutaneous pacing may be fixed rate (asynchronous) or demand (synchronous). Asynchronous pacing delivers an electrical impulse at a regular interval without regard to intrinsic cardiac pacemaker activity. This creates the risk of precipitating

dysrhythmias if a pacing stimulus is given during the vulnerable period of ventricular repolarization. Synchronous pacing is therefore safer, since the pacing impulse is delivered only if an intrinsic electrical complex is not sensed within a preset interval. An increasing number of defibrillators include a built-in transcutaneous pacemaker. These units are equipped with multifunctional electrodes that allow defibrillation, pacing, and ECG monitoring through one set of pads. This development ensures that pacing will be available as soon as the defibrillator reaches the patient in cardiac arrest.

Failure to capture with transcutaneous pacing may be related to electrode placement or the patient's size. Patients who are conscious or who regain consciousness during transcutaneous pacing may experience discomfort due to muscle contraction. Analgesia with incremental doses of morphine or sedation with a benzodiazepine makes this discomfort tolerable. There is no evidence of clinically significant myocardial damage from properly performed transcutaneous pacing." Nonetheless, transcutaneous pacing should be used for temporary stabilization only and should always be followed as soon as feasible by an internal pacing technique if there is a prolonged need for pacing.

Transvenous Pacing

Transvenous pacing consists of endocardial stimulation of the right ventricle by an electrode introduced into a central vein. The most commonly encountered difficulties with transvenous pacing are securing venous access and obtaining proper placement of the stimulating electrode, both of which can be time-consuming. Venous access can be by any route. Transvenous pacing catheters can be inserted through a variety of venous introducers. A soft, flexible, semifloating bipolar catheter is preferred. This type of pacer is safest to use and takes advantage of any forward blood flow that may be present.

Placement of the catheter tip into the apex of the right ventricle is the key to successful transvenous pacing. Several techniques can aid successful placement. Fluoroscopic guidance is the surest method of right ventricular placement but is rarely available in the ED. Electrocardiographic guidance is useful in patients with narrow complexes and/or P waves when fluoroscopy is unavailable. There are some promising reports on the use of bedside ultrasound to guide transvenous pacemaker placement in the ED.^{12,13} The safety and availability of ultrasound make this technique potentially very attractive. Balloon-tipped floating catheters may aid placement when used in conjunction with ECG and fluoroscopic guidance or when used alone. The balloon is inflated after catheter insertion into a central vein. Forward blood flow then directs the catheter tip toward the ventricle as the operator slowly advances the catheter. As with all balloon-tipped catheters, the balloon should always be deflated prior to withdrawal.

When patients have decreased or no forward blood flow (including many circumstances in which transvenous pacing would be used in the ED), positioning of the pacer tip within the right ventricle is difficult.

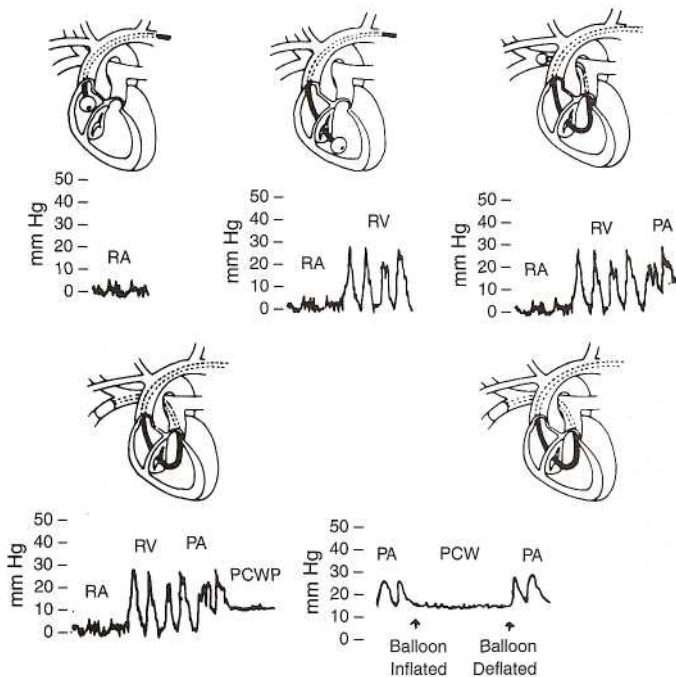

FIG. 22-3. Hemodynamic aspects of balloon catheter insertion into the pulmonary artery. [Reproduced with permission from Gottlieb AJ (ed): *The Whole Internist Catalog*. Philadelphia: Saunders, 1980.]

Balloon-tipped catheters are not much of an aid in placement during low- or no-flow states. In a true emergency, the pacemaker electrodes are connected to the power source and the catheter advanced blindly in hopes that the tip will encounter the endocardium of the right ventricle and that capture will result. In this setting a right internal jugular venous access route should be used. From this approach, the catheter traverses a straight line into the right ventricle and rarely curls in the atrium or deflects into the inferior vena cava.

Pacer settings vary with the clinical situation. An initial rate of 80 to 100 impulses/min is appropriate for most patients. Asynchronous mode (sensitivity off) is used initially in patients requiring emergency pacing for hemodynamically unstable bradycardias. The ECG should be followed to determine the presence or absence of capture (Figure 22-4). Output should initially be set at maximum (usually 20 mA) and then decreased after capture is achieved. With optimal tip position, capture should occur at less than 2 mA. Pacing should be continued at 1.5 to 2 times the threshold output required for capture. Subsequent rate and sensitivity settings should be adjusted as clinically indicated by the patient's hemodynamic status and underlying rhythm disturbance.

Chest radiographs should be obtained after the patient is stabilized to ensure proper tip placement and to evaluate the possibility of pneumothorax from the preceding central venous line placement. Finally, care should be taken to firmly affix the pacing catheter to the insertion site prior to transferring the patient. Transvenous pacing is best used in urgent rather than emergent situations, particularly when there is adequate time to utilize fluoroscopy. In the setting of cardiac arrest, transcutaneous pacing is preferred.

Transthoracic pacing is mentioned here largely for historic reasons, since external pacing techniques have largely replaced its use. However, whenever transvenous pacing is tried but unsuccessful, transthoracic pacing may still be attempted. When the latter technique is performed blindly, the likelihood of successful placement is low, with risk of liver, pulmonary artery, diaphragm, lung, or coronary artery puncture.¹⁴ Although it has not been studied, use of ultrasound-guided placement may improve results.

AUTOMATIC AND IMPLANTABLE DEFIBRILLATORS

In 1933, William Kouwenhoven observed in dogs that closed-chest electrical shocks delivered within 30 s of inducing ventricular fibrillation (VF) were 98 percent effective in terminating the dysrhythmia. After 2 min of VF, the rate of resuscitation fell to 27 percent. He reported similar results in human subjects.¹⁵ Modern research indicates that the likelihood for successful resuscitation decreases roughly 10 percent/min after the onset of VF. Thus the goal of emergency cardiac care is to deliver defibrillation as quickly as possible.

Two recent technologic developments have led to the more rapid application of defibrillation. Automatic external defibrillators allow first responders to rapidly institute defibrillation. Even laypersons, such as family members or bystanders, can learn to use these devices.

In addition, implanted defibrillators allow patients with frequent malignant ventricular dysrhythmias to carry their own defibrillators with them at all times. Emergency physicians need to be familiar with these devices and the special considerations associated with their use.

Automatic External Defibrillators

Automatic external defibrillators (AEDs) have relatively simple controls and can be used by minimally trained providers to initiate defibrillation. The operator places electrode pads at the patient's right sternal border and cardiac apex. Pads are used both for monitoring and defibrillating. Once applied, the AED must be turned on. The AED analyzes the cardiac rhythm and initiates its treatment algorithm. A fully automatic device will deliver a countershock once ventricular tachycardia or VF has been sensed. The AED gives an audible announcement that defibrillation will commence, and the only way the operator can prevent discharge is to turn off the device. A semiautomatic AED analyzes the rhythm and then advises whether a shock is indicated. The operator must press the control button in order to initiate defibrillation.

AEDs shock patients in VF several times sequentially until an organized cardiac rhythm results or until the maximum number of shocks allowed by the programmed algorithm is reached. Many devices also provide a record of rhythms and events during their use, which allows the emergency physician to subsequently reconstruct the sequence of events during resuscitation.

An AED may be placed on an unstable patient in anticipation of subsequent deterioration, but the device should not be activated until or unless the patient is pulseless. Since motion artifacts may confuse the rhythm-analysis circuitry, the **AED should not be in the sensing mode during CPR, during transport, or if the patient has a seizure.** Unlike transcutaneous pacemakers, AEDs can deliver a debilitating shock to the operator or other personnel, and the same precautions regarding contact with the patient during defibrillation should be followed with AEDs as with standard defibrillators. The failure of an AED to restore a perfusing rhythm is a poor prognostic sign often associated with long arrest times or arrest rhythms other than VF. When an AED fails to resuscitate a patient in arrest, advanced cardiac life support (ACLS) guidelines should be followed.

AEDs are most effective in tiered emergency medical services systems where AED-equipped first responders reach the patient rapidly and are backed up by the later arrival of paramedics with full advanced life-support capabilities. There is ongoing interest in making AEDs available for widespread use by nonmedical personnel and the lay public,^{16,18} although this initiative is controversial.¹⁹

Implantable Cardioverter-Defibrillators

The first human placement of an implantable cardioverter-defibrillator (ICD) took place in 1980 at the Johns Hopkins Hospital. Since that

FIG. 22-4. Pacing with intermittent capture. "P" indicates paced beats and "A," pacer artifact without capture.

time it has become the treatment of choice for sudden cardiac death, reducing mortality from about 30 to 45 percent/year to less than 2 percent/year. This remarkable efficacy, coupled with the failure (and potentially proarrhythmic effects) of pharmacologic therapy and the increasing sophistication and miniaturization of the devices, has led to an explosion in ICD use. Through 1994 there had been roughly 50,000 ICDs implanted worldwide; in 1995 there were more than 20,000 implantations in the United States alone. Expanding indications for ICD implantation make it likely that emergency physicians will regularly see patients with these devices.²⁰

An ICD consists of a pulse generator, a lead system with both sensing and shocking electrodes, circuitry to analyze the cardiac rhythm and trigger defibrillation, and a power supply. There are currently three generations of ICDs. In each successive generation, the devices have become smaller, more sophisticated, more reliable, and easier to implant. Second-generation ICDs are still quite common. These devices generally were placed by thoracotomy or sternotomy, and defibrillation occurred through electrodes positioned inside or outside the pericardium. Rate-sensing electrodes were placed epicardially or transvenously. The sensing algorithms for second-generation ICDs were relatively unsophisticated; they reliably detected ventricular tachycardia and VF, but would cause the devices to inappropriately shock supraventricular rhythms as well. Roughly one-third of patients with second-generation ICDs receive at least one shock triggered by a supraventricular tachycardia during the working life of the device.

Third-generation ICDs have a volume of about 60 mL, or roughly one-quarter that of second-generation devices. The sensing-pacing-defibrillation electrodes are placed transvenously, and the device itself is generally implanted subcutaneously in the subpectoral region or in an abdominal pocket. A subcutaneous patch electrode may be used to help lower the defibrillation threshold. On a chest radiograph, at first glance these devices can easily be mistaken for conventional pacemakers. Careful examination of the electrodes will reveal their true nature (Figure 22-5). Newer ICDs are better at discriminating supraventricular tachycardia and are capable of a variety of responses to ventricular tachycardia and VF. Most are programmed to follow a tiered approach to ventricular dysrhythmias: antitachycardia pacing, low-energy cardioversion, and finally defibrillation. Depending on the frequency of discharge and whether the pacemaker function is used, the latest ICDs have a projected life span of about 8 years.

FIG. 22-5. Chest radiograph of a patient with a nonthoracotomy implanted third-generation defibrillator. The ICD is in the left subpectoral area. The electrodes (arrows) have been placed transvenously. The proximal spring electrode is positioned at the junction of the superior vena cava and the right atrium. The distal electrode is in the right ventricle.

EMERGENCY DEPARTMENT EVALUATION AND THERAPY

ICDs are remarkably effective in preventing sudden cardiac death. The most common cause of death in patients with ICDs is congestive heart failure, which should be managed in standard fashion in the ED. However, the most common reason an ICD patient comes to the ED is to be evaluated for the appropriateness of a previously delivered shock. Causes of inappropriate shock delivery are summarized in Table 22-2. It is important to determine the number of shocks delivered, the activity of the patient at the time, and any prodromal symptoms or postshock trauma. Recent changes in antiarrhythmic drug dosage should be noted. The physical examination should focus on the vital signs, the cardiovascular status, the generator pocket, and evidence of incidental trauma. The patient should be monitored during the evaluation. An ECG should be obtained and interpreted with the knowledge that ST-segment elevations or depressions due exclusively to the shock will resolve within 15 min. A chest radiograph may reveal electrode migration, displacement, or fracture. Drug levels of antiarrhythmics should be determined and electrolyte disturbances explored.

Admission criteria depends on the reason for shock delivery. The patient's cardiologist should be consulted and the ICD can be interrogated by external telemetry devices that are manufacturer and model specific. General admission recommendations include unstable patients, two or more shocks in a 1-week period, correctable causes of dysrhythmia, and any sign of infection or mechanical disruption of the ICD or lead system. The ICD can be interrogated by external telemetry devices that are specific to the individual ICD manufacturers and models.

For an ICD patient in cardiac arrest, normal basic and advanced resuscitation measures are followed. **If defibrillation is necessary, the operator should avoid placing either paddle directly over the ICD.** The presence of epicardial patch electrodes may shield the myocardium from the countershock and may therefore necessitate repositioning of the paddles. CPR may be performed in the usual fashion. If the ICD should discharge during CPR, the provider may perceive a small electrical shock, but it is neither uncomfortable nor dangerous.

Occasionally it may become necessary to temporarily deactivate the ICD, as in the case of inappropriate shock for a stable rhythm. Second-generation devices may be deactivated by placing a donut-shaped magnet over the right upper quadrant (Figure 22-6) of the pulse generator for 30 s until the intermittent beeping ceases and a solid tone is heard. The magnet is then removed. If this does not succeed, then deactivation is attempted by placing the magnet over the opposite corner of the pulse generator (some are surgically positioned upside down). The response of third-generation devices to a magnet can be complex, but generally defibrillation is deactivated only when the magnet is present. This requires taping the magnet to the skin overlying the ICD. Defibrillation can be reenabled by removing the magnet. Some third-generation devices are programmed so that they cannot be deactivated by a magnetic field. All ICDs should be evaluated by a cardiologist after exposure to a magnet.²¹

TABLE 22-2 Potential Causes of Inappropriate ICD Shock Delivery

False sensing
Supraventricular tachycardia with rapid ventricular response
Muscular activity (shivering, diaphragmatic contraction)
Extraneous source (tapping of chest wall, vibrations, pacer spikes)
Sensing T waves as QRS complex (double counting)
Sensing lead fracture or migration
Unsustained tachyarrhythmia ICD-pacemaker interactions Component failure

CEREBRAL RESUSCITATION

Gary S. Krause Blaine
C. White

Cerebral ischemia continues to affect a substantial portion of the population of the United States. Data from the ARIC (Atherosclerotic Risk in Communities), CHS (Cardiovascular Health Study), and the NHLBI (National Heart, Lung, and Blood Institute) show that about 600,000 people suffer a new or recurrent stroke each year. Furthermore, stroke is the leading cause of serious, long-term disability in the United States. Three million Americans are currently permanently disabled because of stroke, and 31 percent of stroke survivors need help caring for themselves, 20 percent need help walking, 71 percent have an impaired vocational capacity when examined an average of 7 years later, and 16 percent have to be institutionalized. The direct and indirect cost of stroke in 1998 was estimated at over \$40 billion. In addition, cardiopulmonary resuscitation for victims of cardiac arrest, both within and outside of the hospital, succeeds in restoring spontaneous circulation in about 70,000 patients a year in the United States. At least 60 percent of these patients subsequently die in the hospital as a result of extensive brain damage; only 3 to 10 percent of resuscitated patients are finally able to resume their former lifestyles. Clearly, the development of effective interventions to prevent these sequelae of brain ischemia and reperfusion would enormously enhance the value of the investment already made and would return thousands of these impaired patients to renewed vigorous and productive time with their families and in our society.

There are two important issues involved in the ongoing effort to reduce this neurologic morbidity. One is discovery of the mechanisms involved in tissue injury and repair, and the other is the identification of clinically effective therapy. Clinical trials conducted more than a decade ago utilizing postresuscitation treatment with barbiturates or calcium antagonists were disappointing. More recently, clinical treatment of stroke with a radical scavenger (tirilazad), intercellular adhesion molecule-1 antagonist (enlimomab), glutamate receptor antagonist (aptiganel, gavestinel), glutamate release inhibitor (lubluzole), ganglioside administration (GM1), calcium channel blockade, or up-regulation of the GABA receptor (clomethiazole) were all found ineffective. This suggests that our understanding of the mechanisms involved in damage and repair of neurons remains incomplete.

Four major observations have provided the foundation for investigation of brain injury by ischemia and reperfusion:¹ (1) rapid loss of

high-energy phosphate compounds during ischemia followed by their recovery within the first 15 min of reperfusion, (2) morphologic evidence that most structural damage occurs during reperfusion, especially in selectively vulnerable zones, (3) progressive brain hypoperfusion during postischemic reperfusion, and (4) prolonged suppression of protein synthesis in selectively vulnerable neurons. Cardiac arrest resulting in ischemic-anoxic brain injury is characterized by three phases: ischemia, early reperfusion, and late reperfusion. We have published extensive reviews of our theoretical model of the causal interactions of neuronal injury and repair mechanisms during ischemia and reperfusion.^{1,2} Briefly, primary injury mechanisms include, at a minimum, activation of phospholipases and proteolytic enzymes (calpain) during ischemia and generation of radicals accompanied by lipid peroxidation and caspase activation during reperfusion. This chapter outlines the crucial role of calcium and iron in these injury mechanisms and suggests possible therapies to ameliorate brain injury following an ischemic insult.

ISCHEMIC PHASE

Morphologic studies have shown that the extent of tissue injury observed following ischemia largely reflects damage incurred during reperfusion and have identified specific populations of brain neurons that are exceptionally susceptible to damage and death. These selectively vulnerable neurons include the pyramidal neurons in layers 3 and 5 of the cortex and those found in the CA1 and hilum of the hippocampus. Minimal ultrastructural injury is seen in the brain during complete ischemia. Some margination and clumping of nuclear chromatin is seen by 10 to 15 min of complete ischemia. Mitochondria may be slightly swollen, but their structure does not show major degenerative alterations for up to 30 min of complete ischemia. Similarly, some swelling of the endoplasmic reticulum (ER) may be seen during ischemia, but the polyribosomes remain appropriately associated with the ER, and disaggregation of polyribosomes does not occur during complete ischemia. Nuclear and plasma membranes show a normal, well-defined bilaminar structure without evidence of holes or general structural disintegration.

In contrast to the paucity of morphologic findings, there are severe biochemical alterations. With the onset of cardiac arrest there is precipitous decline in brain oxygen content, which approaches zero within 6 to 12 s. Neurons have very limited reserves of glucose, glycogen, or phosphocreatine; therefore oxygen depletion leads to a sharp decline in tissue adenosine triphosphate (ATP) levels, which approach zero within 4 min. Anaerobic glycolysis and ATP depletion lead to lactic acidosis and hypoxanthine accumulation, respectively, during the ischemic phase. Since about 80 percent of the brain's ATP is used to maintain transmembrane ionic gradients for potassium, sodium, and calcium, these ionic gradients also decay rapidly. During complete ischemic anoxia, these ions equilibrate between the extra- and intracellular fluid within 5 to 10 min of the insult.

The high cytosolic calcium level, thought to be a major initiating event leading to cell death,³ causes several key events: the activation of membrane phospholipase A₂, proteolytic cleavage of xanthine dehydrogenase, activation of the proteolytic enzyme calpain, activation of nitric oxide synthase (NOS), and release of excitatory neurotransmitters such as glutamate. Phospholipase A₂ cleaves a fatty acid, primarily arachidonate, from the cell membrane lipids, yielding a free fatty acid and in the process damaging the membrane's structure. The proteolysis of xanthine dehydrogenase in brain endothelial cells produces xanthine oxidase, which will react with hypoxanthine to produce the superoxide radical (O₂'⁻) upon reperfusion. Proteins that are degraded by calpain during either ischemia or reperfusion include microtubule-associated protein kinase-2, tubulin, neurofilament protein, spectrin, protein kinase C, calcium/calmodulin kinase II, and the translation initiation factors eIF4E and eIF4G (see below).

EARLY REPERFUSION

During early reperfusion, ATP levels and total adenylate charge recover rapidly. If the ischemic insult has been less than 20 min, the membrane ionic gradients also recover quickly. After much longer insults of 1 to 3 h, total tissue calcium loads actually increase during reperfusion. It is felt that this reflects extensive and irreversible cell membrane injury during these very prolonged periods of ischemia.

Arachidonate is rapidly oxidized by both cyclooxygenase and lipoxygenase, and returns to preischemic levels within 30 min of reperfusion. Several vasoactive substances are produced by the metabolism of arachidonate. The prostaglandins are the products of cyclooxygenase, and the leukotrienes are the products of lipoxygenase. The production of the vasodilatory prostaglandin prostacyclin is severely inhibited during early reperfusion. Thus vasospastic compounds predominate in the leukotriene and prostaglandin products. While the free arachidonic acid levels rapidly return to baseline during reperfusion, leukotrienes remain markedly elevated for at least 24 h. The time course of leukotriene elevation may explain the alterations in blood flow seen in the postischemic brain (the "no-reflow" phenomenon). Restoration of normal or mildly hypertensive systemic arterial pressure produces an initial brain hyperperfusion. However, within 1 h, global brain perfusion has dropped to levels of 20 to 40 percent of normal, where it remains for up to 1 to 2 days. This phenomenon occurs without a change in intracranial pressure and was originally thought to lead to failure of high-energy metabolism and neuronal death during reperfusion. However, therapy that inhibited postischemic brain hypoperfusion had little effect on neurologic outcome.

Membrane lipids are extensively peroxidized by iron-dependent radical reactions during reperfusion. Within the first 30 s of reperfusion, there is a brief burst of oxygen-based free radical production, although the precise identity of the radical species remains unknown. Xanthine oxidase and cyclooxygenase, whose substrates are hypoxanthine and arachidonate respectively, produce O₂'⁻ as a side product. In addition, O₂'⁻ reacts with nitric oxide produced by NOS to form peroxynitrite which may also initiate lipid peroxidation. Availability of a transition metal, such as iron, is required for reaction of oxygen radicals with tissue macromolecules, including lipids (lipid peroxidation). The brain glia have abundant stores of oxidized (ferric) iron, mostly in ferritin and transferrin, forms in which the iron is unable to act as a catalyst for oxygen radical reactions. However, O₂'⁻, which is present in excessive amounts during early reperfusion, promotes reduction of ferric iron and release of ferrous iron from ferritin, and lipid peroxidation in the reperfused brain has been demonstrated by many laboratories and maps to selectively vulnerable neurons. These reactions also appear to be involved in the genesis of the postischemic hypoperfusion phenomenon, which is inhibited by superoxide dismutase and deferoxamine or U74006F, a lipid peroxidation chain terminator.

Excitatory amino acid neurotransmitters appear to play a role in the injury produced by focal brain ischemia such as stroke; it is unclear whether the same holds true in global brain ischemia. However, excitatory neurotransmitter uptake is inhibited by arachidonate and products of lipid peroxidation, and thus continued stimulation of receptors may contribute to neuronal damage by as yet unidentified mechanisms.

Suppression of protein production has long been known to occur in the brain following ischemia and reperfusion and is likely to be an important contributing factor in neuronal death. The brain has a substantial requirement for protein synthesis just to maintain cerebral function. It expresses the largest percentage of its DNA of any organ, and its protein turnover is approximately equal to 100 percent of its protein content every 48 h. Additionally, as a result of ischemia and reperfusion, there is a significant need for replacement of proteins damaged by calpain-mediated proteolysis and membrane lipid peroxidation (neuronal membranes are ~50 percent protein). Because proteins have such fundamental roles in the cell, including enzymatic reactions

governing intermediary metabolism, transport, and storage, as well as intracellular signaling and cellular structure, significant changes in the neurons' ability to produce and maintain proteins would be expected to have considerable effect on the cells' capacity to survive. Indeed, inhibition of protein synthesis may itself trigger apoptosis.

Protein synthesis is suppressed during ischemia by lack of ATP.⁴ However, even with the rapid restoration of ATP levels that accompanies reperfusion, there is a severe suppression of protein synthesis that varies with duration of ischemia, brain region, and individual proteins. Whereas most regions of the brain recover their ability to synthesize protein following a short ischemic period, protein synthesis in the selectively vulnerable regions is depressed by about 90 percent early in reperfusion and does not recover significantly. Failure of protein synthesis is due to a disruption in the formation of new ribosomal translation complexes. Initiation, the rate-limiting step in translation, requires the coordinated assembly of the ribosomal subunits, the mRNA to be translated, and the amino-acyl tRNA for the first amino acid (always methionine in eukaryotes). This process is orchestrated by a family of proteins named *eukaryotic initiation factors* (eIFs). The eIF4 and eIF2 complexes are the major regulatory points for translation initiation. Cellular mRNAs vary greatly in their binding efficiency to eIF4E, and under normal physiologic situations, message selection for translation initiation is modulated by altering the phosphorylation of Ser²⁰⁹ on eIF4E. However, under conditions of cellular stress (e.g., heat shock, viral infection, or starvation), rates of global protein synthesis are downregulated by phosphorylating Ser⁵¹ on the α -subunit of eIF2 [eIF2a(P)].

Studies have now identified important changes in eIFs that occur during brain ischemia and reperfusion: (1) there is a modest degree of proteolytic degradation of eIF4E during ischemia, but without change in its phosphorylation state during either ischemia or reperfusion;^{5,6} (2) there is substantial proteolytic degradation of eIF4G mediated by calpain during both ischemia and reperfusion;^{7,8} and (3) probably most important, there is an approximately twentyfold increase in eIF2a(P) during early reperfusion. In nonischemic tissue, phosphorylated eIF2a is found exclusively in astrocytes.⁹ After only 10 min postischemic reperfusion, there is prominent eIF2a(P) immunostaining in the cytoplasm of neurons in both the hippocampus and cortex. After 1 h of reperfusion, eIF2 α (P) is prominent in both the nuclei and cytoplasm of selectively vulnerable neurons in both the hippocampus and cortex; nuclear eIF2a(P) is never seen in ischemia-resistant neurons. By 4 h reperfusion, the pattern of nuclear eIF2a(P) immunostaining in vulnerable neurons suggests nuclear condensation consistent with the early stages of apoptosis. These results provide a mechanism for the inhibition of protein synthesis in vulnerable neurons during reperfusion and, together with other evidence suggesting a role for eIF2a(P) in causing apoptosis, may represent a fundamental phenomenon in the causal pathway leading to the death of vulnerable neurons. It is interesting to note that animals treated with 20 units/kg insulin at resuscitation are able to dephosphorylate eIF2a(P) and recover protein synthesis in vulnerable hippocampal neurons by 90 min reperfusion. The activation of the eIF2a kinase PERK, which phosphorylates eIF2a during reperfusion, and the salutary effects of high-dose insulin imply that cell signaling pathways, in particular the unfolded protein response (UPR) and the PI-3 kinase/Akt pathway respectively, play a role in neuronal injury/survival mechanisms. Thus, growth factors, including fibroblast growth factor, nerve growth factor, insulin-like growth factor 1, and insulin, all of which have been shown to improve neuronal survival in the laboratory, may have a role in limiting and repairing neuronal damage.¹⁰

LATE EVENTS DURING REPERFUSION

After 15-min transient global ischemia, caspases have been proteolytically activated in the hippocampal CA1 neurons at 8 to 72 h of reperfusion, resulting in deoxyribonuclease activity, PKR activation and

eIF2a phosphorylation, cleavage of eIF4E-binding protein 1, which inhibits cap-dependent translation, and cleavage of eIF2a, eIF4B, and eIF4G. Studies will be needed to examine alterations in message translation and in intracellular signaling that occur following an ischemic insult.^{11,12} Brain tissue ionic concentrations are indistinguishable from normal after 4 h of reperfusion following a 15-min cardiac arrest. The tissue iron has been recovered into high-molecular-weight species by 8 h of reperfusion. However, after 8 h large shifts of the concentrations of calcium, potassium, and sodium are observed. These shifts most likely reflect equilibration between the cytosol and the interstitial fluid for these ions. Electron microscopic examination of brains fixed in situ after 8 h reperfusion reveals an obvious general degradation of membrane structure with large holes in the plasmalemma in the vulnerable neurons. Nuclear chromatin is densely clumped, with grossly abnormal nuclear architecture. Mitochondrial architecture is well preserved. The ER is dilated and ragged, and normally arranged polyribosomes are virtually nonexistent. Histochemical evidence of lipid peroxidation can be seen by as early as 90 min following a 10-min arrest and involves approximately 30 percent of the neurons in the cortex and most neurons in CA1 and the hilum. Membrane injury by lipid peroxidation produces degradation of membrane structure to the point that the membrane becomes freely permeable to ions and the cell is irreversibly injured.

THERAPY

Clearly, the first priority in the treatment of cerebral ischemia is the reestablishment of blood flow. Methods of restoring spontaneous circulation in cardiac arrest are described in Chaps. 12, 14, and 24. Trials of thrombolytics have shown tissue plasminogen activator to be of some benefit in select subgroups of stroke patients, but it must be administered within a 3-h window.¹³ Although neurons at the core of the ischemic area die within a few minutes of the onset of ischemia, animal studies indicate that there is an approximately 3- to 4-h therapeutic window when neuroprotective drugs may be beneficial before infarction occurs in the ischemic penumbra.

Because the ultimate extent of injury observed following ischemia largely reflects damage incurred during reperfusion (reperfusion injury), effective therapy must not only limit ongoing mechanisms of damage, but also facilitate repair of the damage that has already occurred. The optimal therapy for preventing continuing injury and salvaging viable brain tissue is unknown.¹⁴ In addition to those agents mentioned above, several other therapies including pentobarbital coma, calcium antagonists, and glucocorticoids have been advocated, but human studies have failed to show efficacy.^{15,16} However, a few general principles can be stated. Perfusion should be maintained at normal levels. It does not appear that intracranial pressure is increased in the postresuscitation period, and therefore therapies directed at increased intracranial pressure (hyperventilation and osmotic agents¹⁷) are unnecessary. Hypotension should be avoided for obvious reasons. Oxygenation should be maintained at or near normal levels. Hyperoxia should be avoided, because it is toxic to the lungs and may increase brain damage.¹⁸ Pre- and post-arrest hyperglycemia is associated with poor neurologic outcome and must be avoided.^{19,20}

Ischemic injury of the brain is complex, and this complexity indicates that single-drug therapeutic approaches will continue to fail. The pattern of ATP and ionic recovery and DNA transcription during reperfusion shows that several cellular systems are intact following prolonged ischemia and reperfusion. Future investigation of therapeutic approaches may combine calpain/caspase antagonists, iron chelators, lipid peroxidation chain reaction terminators, and growth factors to forestall further lipid peroxidation and to stimulate repair mechanisms. Phase I trials are underway in which clonal neuronal grafts are implanted into stroke victims. Effective therapeutic protocols will be identified only by continued studies.

NEWER RESUSCITATIVE TECHNIQUES James E. Manning Christopher W. Barton Laurence M. Katz

Despite advances in the science of cardiopulmonary and cerebral resuscitation, the prospects for long-term survival with good neurologic recovery remain exceedingly poor. A major limitation of present therapy is the marginal blood flow generated by closed chest CPR. Cardiac output has been reported to be 25 to 33 percent of normal at best and decreases with time delays to initiation of CPR. With increasing duration of arrest and progressive loss of peripheral arterial resistance,

Phased chest and abdominal compression and decompression (Lifestick)

even optimally performed closed chest CPR is unlikely to result in return of spontaneous circulation (ROSC).

Successful resuscitation of the patient in cardiac arrest requires at least some minimal amount of blood flow to the heart. Myocardial perfusion during closed chest CPR is directly related to the pressure gradient across the coronary vasculature. This gradient is equal to the aortic pressure minus the right atrial pressure and is termed the *coronary perfusion pressure* (CPP). Aortic pressure largely determines the CPP gradient and depends on the level of residual peripheral arterial vasomotor tone. Research has shown that the CPP gradient is greatest during the relaxation phase of CPR chest compressions (CPR diastole). Laboratory and clinical data have indicated that a CPP of at least 15 mm Hg is almost always required to achieve ROSC. In contrast, human studies have indicated that CPP gradients attained with standard CPR are usually in the ineffective range of 1 to 8 mm Hg.

Much of the research into CPR has focused on methods to improve artificial perfusion during cardiac arrest. In addition to the originally described "conventional" CPR technique, several alternative methods of performing closed chest CPR have been investigated (Table 24-1). Vasoconstrictor agents have long been used as the pharmacologic adjunct to improve vital organ perfusion by increasing aortic pressure and CPP. Although epinephrine has been the principal drug, vasopressin has been added to the 2000 American Heart Association guidelines for advanced cardiac life support as an acceptable alternative to epinephrine for treating ventricular fibrillation (VF) and pulseless ventricular tachycardia.¹ A recent conference on the "Post-Resuscitative and Initial Utility in Life Saving Efforts," focused on strategies and priorities for future resuscitation research, with an emphasis on interventions that promote functional neurologic recovery.²

Noninvasive and invasive monitoring techniques have been examined to identify clinically useful and reliable parameters to guide resuscitative efforts (Table 24-2). Invasive perfusion techniques capable of providing near-normal artificial vital organ perfusion also have been described (Table 24-3). Direct mechanical ventricular assistance (or actuation) and cardiopulmonary bypass have been reported in laboratory models and a few clinical reports. Methods of artificial perfusion using aortic balloon catheters recently have been described in laboratory investigations. These newer invasive techniques have attempted to address the issue of clinical feasibility during sudden cardiac death.

Reperfusion-induced injury is a major focus of research in many fields of medicine and for numerous ischemic diseases states, including cardiac arrest, and is discussed in detail elsewhere (see Chap. 23). Cerebral resuscitation with favorable neurologic outcome after prolonged global ischemia will be the ultimate obstacle to overcome in cardiac arrest therapy. Brain-oriented therapies, such as hypothermia, may substantially improve post-resuscitation neuronal survival and functional neurologic recovery. Pharmacologic agents capable of limiting ischemia-induced cellular damage and reperfusion-induced injury from reactive oxygen species likely will be an important form of therapy for cardiac arrest patients in the resuscitation and post-resuscitation phases.

ALTERNATIVE METHODS OF CLOSED CHEST CPR

The rationale for most alternative methods of closed chest CPR that have been described are based on one of two proposed mechanisms of blood flow during CPR chest compression. The *cardiac pump theory* proposes that compression of the heart between the sternum and the spine squeezes blood out of the ventricles in a forward flow direction in a manner generally similar to normal myocardial contraction. The *thoracic pump theory* proposes that pressurization of the entire thorax, not just the heart, is responsible for blood flow and that the heart serves only as a passive or partially compressed conduit for blood flow. Net forward blood flow occurs due to competent closure of venous valves during diastole at the thoracic inlet during chest compression. The evidence for and against each theory is beyond the scope of this chapter, but it is accurate to state that the precise mechanism of blood flow during closed chest CPR remains controversial and may vary based on individual anatomic features. Alternative methods of performing closed chest CPR have been based largely on efforts to exploit one or both of the proposed mechanisms.

High-Impulse CPR

In 1984, Maier and colleagues reported a laboratory study comparing compression rates of 100 and 150 per min with the conventional rate of 60 per min advocated before 1986.³ They observed increases in cardiac output that were roughly linear to the increase in compression rate, whereas stroke volume remained relatively constant. The compression force and velocity of impact used with these rapid CPR compression rates led to the term *high-impulse* CPR. This work was partly responsible for the increase in the recommended CPR compression rate from 60 per min to 80 to 100 per min.

Interposed Abdominal Compression CPR (IAC CPR)

Compression of the abdomen during cardiac arrest generates aortic pressures similar to those of chest compressions. The hypothesis that CPR diastolic aortic pressure and venous return from the abdomen might be augmented by abdominal compressions led to the idea of IAC CPR. One person performs the chest compressions of standard CPR, and another person applies a similar compression over the cen-

tral abdomen during the relaxation phase of chest compression. The hemodynamic effects of IAC CPR in laboratory investigations have not been consistent, but most have shown increases in CPR diastolic aortic pressure, CPP, and cardiac output. Results of clinical studies of IAC CPR have been highly variable. Some studies have shown no evidence of improved resuscitation outcome, whereas others have demonstrated significant improvements in ROSC and survival to hospital discharge.⁴ Differences in study populations and the technical performance of IAC CPR may be the reasons for the variable results obtained. At present, the data supporting the use of IAC CPR are not sufficient to recommend its routine application. It could also be argued that IAC CPR is physiologically very similar to high-impulse CPR with the compressions performed by two persons rather than one. However, if perfusion with standard CPR is judged to be inadequate, attempting IAC CPR is a reasonable alternative intervention.

Active Compression and Decompression CPR (ACD CPR)

Standard CPR involves a forceful, or "active," chest compression phase with elastic recoil of the chest wall during the relaxation phase ("passive" decompression). The ACD CPR device consists of a circular suction cup connected to a handle with a force gauge (Figure 24-1). With the suction cup securely attached at the midsternal chest, CPR is performed with force applied downward (active compression) and upward (active decompression) during CPR.⁵ One advantage of the ACD CPR device is that it tends to decrease the venous system pressure to a greater extent than the arterial pressures during the active decompression phase. This may increase venous return and increase the CPP gradient during CPR diastole. Although initial clinical reports have indicated some improvement in ROSC and survival, a large randomized clinical trial in in-hospital cardiac arrest (773 patients) and out-of-hospital cardiac arrest (1011 patients) showed no improvement in survival for the ACD CPR device as compared with

FIG. 24-1. The Ambu CardioPump (Ambu International Inc., Copenhagen, Denmark) is used for active compression and decompression cardiopulmonary resuscitation (CPR). The silicone rubber suction cup is positioned midchest at the level of the nipples. Using the circular plastic handle, the device is pushed downward during the compression phase, followed by active withdrawal during the decompression phase. Force of compression and decompression is measured by the gauge located within the handle and is easily viewed by the operator during CPR. (Reproduced with permission from Lurie KG, Shultz JJ, Callahan ML, et al: Evaluation of active compression-decompression CPR in victims of out-of-hospital cardiac arrest. *JAMA* 271:1405, 1994.)

standard CPR.⁵ There is presently insufficient evidence to support the routine use of ACD CPR. However, as noted for other alternative CPR techniques, if standard CPR is judged to be ineffective, ACD CPR is another option. Unlike some of the other alternative techniques, ACD CPR requires a special device, and this limits its applicability.

Phased Chest and Abdominal Compression and Decompression

Tang and associates described the use of a device that combines the concepts of IAC CPR and ACD.⁶ This technique involves the use of a device called the Lifestick resuscitator. This device has chest and abdominal pads connected to an adjustable rigid frame with a handle at each end (Figure 24-2). The pads are attached to the sternum and the upper abdomen by an adhesive. Using a seesaw motion, the chest and abdomen are compressed in an alternating pattern. The preliminary report of this technique by Tang and colleagues in a survival model of swine cardiac arrest showed improved CPP, ROSC, and 48-h survival. At present, there have been no reports of the use of this device in human cardiac arrests.

FIG. 24-2. Sequencing compression and decompression with the Lifestick resuscitator. The subject's head is on the right. Chest compression (A) is coincident with abdominal decompression (B). This is followed by chest decompression (C) and abdominal compression (D). (Reproduced with permission from Tang W, Weil MH, Schock RB, et al: Phased chest and abdominal compression-decompression: A new option for cardiopulmonary resuscitation. *Circulation* 95:1335, 1997.)

Circumferential Thoracic Vest CPR

The thoracic pump theory proposes that cyclic fluctuations in intrathoracic pressure created by CPR chest compressions are responsible for blood flow. Thus, efforts to maximize the intrathoracic pressure generated and limit trauma to the chest would be advantageous. This led to the conception of the circumferential thoracic vest CPR device. This method involves the placement of a vest around the thorax and pressurizing the thorax from all directions as opposed to localized pressure over the lower sternum (Figure 24-3). Halperin and colleagues reported their preliminary experience in humans with a refined circumferential vest CPR device and found significant improvements in CPP and initial ROSC.⁷ In patients failing prolonged resuscitative efforts, peak CPR systolic aortic pressure increased from an average of 78 mm Hg with manual CPR to an average of 138 mm Hg with vest CPR. In 34 patients randomized to receive manual versus vest CPR, after an average of 11 min of unsuccessful manual CPR, 8 of 17 vest CPR patients had ROSC compared with only 3 of 17 manual CPR patients. Although this appears to be a promising alternative method of CPR, a substantial amount of clinical investigation is still needed to clarify its potential benefit.

Inspiratory Impedance Threshold Valve During CPR

Improving venous return to the thorax and heart during the relaxation phase of CPR should have a beneficial effect on the blood flow generated during the compression phase. To enhance this venous return, an inspiratory impedance threshold valve for the ventilation circuit was developed to augment the negative intrathoracic pressure that occurs during the relaxation phase of CPR. Laboratory study has demonstrated substantial increases in CPP and vital organ perfusion during standard CPR. The magnitude of effect has been shown to be even greater when combined with ACD CPR. Clinical experience with the inspiratory impedance threshold valve has been limited, but early reports have shown increased early survival.⁸

PHARMACOLOGIC INTERVENTIONS

Adrenergic Therapy

Adrenergic drugs have been the primary agents studied and used in all types of cardiac arrest. Epinephrine is the predominant adrenergic drug and remains the recommended agent. The mechanism of action of adrenergic therapy in cardiac resuscitation has been convincingly shown to be primarily α -adrenergic receptor-mediated vasoconstriction in the peripheral arterial system, resulting in increased aortic pressure and thus increased CPP. In addition to epinephrine, several other pure α -adrenergic or mixed α - and (J)-adrenergic agents have been studied. However, none of these agents has been shown to increase ROSC or long-term survival as compared with epinephrine.

The appropriate dosage of adrenergic drugs during cardiac arrest is the subject of ongoing controversy. Although based on early animal studies and on very limited anecdotal clinical evidence, an epinephrine dose of 1 mg was the standard recommendation for many years. Laboratory investigations and clinical reports in the 1980s suggested that substantially higher doses are required for optimal beneficial effect. These studies led to large, randomized, controlled clinical trials in the early 1990s that showed variable effects on the rate of ROSC but failed to show improvement in survival to hospital discharge or neurologic outcome.¹ Although no benefit was demonstrated, no adverse results were identified with the use of higher doses of epinephrine. Nonetheless, there have been anecdotal complaints from intensivists that the temporary ROSC achieved unnecessarily diverts intensive care resources for futile situations. The 2000 AHA ACLS guidelines largely discourage the use of higher doses of epinephrine but leave this open to the clinician's discretion if standard doses of epinephrine have been unsuccessful.¹

FIG. 24-3. A comparison of the thoracic vest system for cardiopulmonary resuscitation (vest CPR) with the standard manual CPR. The vest contains a bladder that is inflated and deflated by the pneumatic system. Defibrillation can be accomplished during chest compression through the flat defibrillator electrodes (dashed circles) under the vest. The electrocardiogram can be recorded through the same electrodes. The lower panels show schematic representations of transverse sections of the midthorax during vest CPR and manual CPR. The thoracic size during chest relaxation is shown by the solid lines. The arrows indicate force applied to the thorax during chest compression. With vest inflation, there is a relatively uniform decrease in the dimensions of the thorax. With manual CPR, the sternum is displaced during compression (arrow), and the lateral thorax can bulge, thereby increasing thoracic volume and reducing the intrathoracic pressure generated during compression. (Reproduced with permission from Halperin HR, Tsitlik JE, Gefand M, et al: A preliminary study of cardiopulmonary resuscitation by circumferential compression of the chest with use of a pneumatic vest. *New Engl J Med* 329:762, 1993.)

Nonadrenergic Vasoconstriction (Vasopressin)

The 40-year reign of epinephrine as the sole recommended vasoconstrictor during cardiac arrest has come to an end. Vasopressin, a nonadrenergic vasoconstrictor, now shares the podium with epinephrine in the 2000 AHA ACLS guidelines. Although vasopressin has undergone extensive laboratory investigation, the clinical evidence supporting the use of vasopressin over epinephrine remains limited. However, vasopressin appears to be at least as effective as epinephrine. The principal advantage of vasopressin may be its greater duration of action, which allows for more sustained increases in CPP during CPR than that seen with epinephrine due to its shorter duration of action. Linder and associates reported a small randomized clinical study comparing intravenous vasopressin (40 units) with intravenous epinephrine (1 mg) and showed a significant increase in initial ROSC, hospital admission, and 24-h survival.⁹ There was also a trend toward improved survival to hospital discharge. Another nonadrenergic agent that has undergone only limited laboratory investigation is angiotensin II. **The use of vasopressin is now accepted for routine management of VF cardiac arrest.** The use of vasopressin or other nonadrenergic vasoconstrictor in conjunction with adrenergic vasoconstrictor agents may prove to be more effective than either alone.

Thrombolytic Therapy

Coronary thrombosis and pulmonary thromboembolism are known pathologic entities that can cause cardiac arrest, and both disorders are treatable with thrombolytic therapy. The estimated incidence of these disorders in cardiac arrest is variable, but estimates as high as 50 to 70 percent have been reported. Concern about bleeding complications in the setting of thoracic trauma associated with CPR chest compressions

has discouraged its use in cardiac resuscitation. However, there has been growing interest in thrombolysis during cardiac arrest when initial standard resuscitative measures have failed. In addition to the obvious benefit of restoring blood flow to through an occluded vessel, thrombolytic therapy might improve microcirculatory reperfusion, most importantly cerebral perfusion, by reversing microcirculatory sludging. Several clinical anecdotes and case series have suggested that thrombolysis improves resuscitation success rates and early survival.¹⁰ However, long-term survival benefit has not been clearly demonstrated. Prospective, randomized, controlled clinical studies are needed to determine whether these expensive agents are justified in the routine treatment of cardiac arrest. It seems reasonable to consider the use of thrombolytic agents in cardiac arrest victims with high suspicion for coronary thrombosis or massive pulmonary embolism.

Adenosine Antagonism

Release and accumulation of adenosine in ischemic tissues and adenosine's role as a depressant of cardiac pacemaker automaticity have been defined more clearly in recent years. There is limited clinical evidence to suggest that aminophylline can reverse these effects (by acting as an adenosine antagonist) and may be useful in the treatment of bradydysrhythmia associated with myocardial ischemia. Clinical studies have shown favorable initial response to aminophylline bolus, but long-term survival does not appear to be affected." Laboratory studies have shown no apparent benefit of aminophylline in cardiac arrest. Thus, adenosine antagonism remains an unproven therapy. However, given the dismal prospects for survival associated with bradyasystolic arrest, use of aminophylline is not unreasonable and is unlikely to be harmful.

Amiodarone is an antiarrhythmic agent with a complex electropharmacologic profile that has been used for long-term control of a variety of atrial and ventricular dysrhythmias. Despite its reportedly limited effect on ventricular effective refractory period after acute intravenous administration, it has been shown to be effective in the treatment of acute unstable ventricular dysrhythmias refractory to lidocaine and procainamide. In a recent randomized, double-blind, clinical trial, amiodarone was compared with lidocaine in victims of out-of-hospital cardiac arrest, with the primary end point being survival to hospital admission. Patients receiving amiodarone had a significantly greater survival to admission rate than patients receiving lidocaine (22.8 vs. 12 percent, respectively).¹² However, long-term survival benefit has not been clearly demonstrated. Nonetheless, based on the early benefit observed, **the 2000 AHA ACLS guidelines recommend amiodarone as an acceptable alternative to lidocaine in the treatment of VF and pulseless ventricular tachycardia.**

Magnesium

Clinical studies have shown improved survival with magnesium supplementation in the setting of acute myocardial infarction. The cardioprotective effects of magnesium are thought to be related to suppression of automaticity, coronary vasodilation, platelet inhibition, and inhibition of calcium influx. Although an association between hypomagnesemia and cardiac dysrhythmias has been recognized, the value of magnesium in the treatment of acute, life-threatening ventricular dysrhythmias has not been established. Thel and associates reported a randomized, double-blind, placebo-controlled clinical trial of magnesium administration in 156 in-hospital cardiac arrest patients (MAGIC trial).¹³ Administration of magnesium (initial 2 g bolus during cardiac arrest followed by an infusion of 8 g over 24 h) showed no difference from placebo in ROSC, survival to 24 h, survival to hospital discharge, or Glasgow Coma Scale score on discharge. However, among survivors to hospital discharge (21 percent in each group), quality of life assessed by Karnofsky's performance status was better in the magnesium group, and no adverse effects of magnesium administration were noted. **Thus, the use of magnesium in cardiac arrest remains incompletely defined.** Magnesium administration during cardiac arrest seems acceptable based on clinical judgment, especially in cases of suspected hypomagnesemia or refractory cardiac arrest.

Sodium-Hydrogen Exchanger Inhibition

Studies in models of ischemic myocardium have shown that sodium-hydrogen exchanger inhibitors have a protective effect on the myocardium by limiting intracellular accumulation of calcium. One inhibitor, cariporide, has recently been studied in laboratory rat models of VF to determine its effect on subsequent defibrillation success. The remarkable finding in the early reports of administering cariporide during VF has been the predominant occurrence of spontaneous defibrillation without the need for electrical shock.¹⁴ This finding of "pharmacologic defibrillation" has exciting prospects for the treatment of VF cardiac arrest. However, this has been demonstrated only in rat models at present, and further testing in larger animal models of VF will be necessary. Even if spontaneous defibrillation does not occur in larger animal models or, ultimately, in humans, sodium-hydrogen exchanger inhibitors may be a useful therapy if they enhance the VF energy profile and promote successful electrical defibrillation.

Routes for Medication Delivery

Recommended routes for the administration of resuscitation drugs include intravenous, endotracheal, and intraosseous. Intravenous administration is considered optimal, **with central venous delivery preferred over peripheral venous delivery**, provided there is no delay in

gaining central venous access. Intracardiac drug injection has largely been discouraged. Central arterial administration of medications has received little attention but may be a useful alternative, especially for delivery of vasoconstrictor agents, which have their effector sites in the peripheral arterial system.

Catheterization to measure arterial pressure during cardiac arrest is becoming a more accepted intervention to help guide resuscitative efforts. Thoracic aortic catheterization via a femoral artery approach allows for pressure monitoring and homogeneous arterial drug administration. When aortic arch and central venous routes of epinephrine administration were compared in a laboratory model, aortic arch delivery resulted in a more rapid increase in CPR diastolic aortic pressure, a greater magnitude of aortic pressure increase, and a maximal response consistently seen within 30 to 50 s of injection.¹⁵ The rapidity of initial and maximal aortic pressure responses suggests that adrenergic therapy could be rapidly adjusted based on a parameter reflecting vital organ perfusion. Thus, thoracic aortic catheterization allows for rapid delivery of vasoconstrictor agents to effector sites and rapid assessment of therapeutic effect, such that therapy can be rapidly titrated on an individual basis. The major limitation of this route is the need to establish central arterial access.

TECHNIQUES FOR ASSESSMENT OF RESUSCITATIVE EFFORTS

The lack of an accurate and readily measurable parameter to guide resuscitative efforts has long frustrated clinicians and clinical investigators. Pulse quality, pupillary reactivity, serial blood gases, and the coarseness of VF were the only parameters available until relatively recently. None of these was sufficiently accurate to allow for therapeutic adjustments on an individual basis. Fortunately, recent technologic advances have led to monitoring techniques that allow for much more accurate assessment and guidance of therapy.

Capnometry or End-Tidal Carbon Dioxide

Capnometry (the measurement of exhaled end-tidal carbon dioxide levels) has become a valuable and standard monitoring tool in the ED. Although used primarily to assess endotracheal tube placement and monitor ventilation, end-tidal carbon dioxide (ETCO₂) can be used to assess blood flow. End-tidal carbon dioxide is proportional to pulmonary perfusion, which in turn reflects systemic perfusion. It is this principle that makes ETCO₂ monitoring of value in the assessment of perfusion during CPR.

The use of quantitative or semiquantitative ETCO₂ as an indicator of the effectiveness of artificial perfusion has received considerable attention over the past decade or so. Laboratory models or cardiac arrest have demonstrated a statistically significant correlation between ETCO₂ and CPP. In one clinical study, the initial ETCO₂ served to predict which patients would regain a pulse during the resuscitation. Those patients with an ETCO₂ of at least 15 mm Hg on arrival in the ED had a greater than 90 percent probability of regaining a pulse, whereas those patients with an ETCO₂ of less than 15 mm Hg almost never regained a pulse.¹⁶ In many of these patients, a sudden, dramatic increase in the ETCO₂ was noticed well before a pulse could be detected. Unfortunately, ETCO₂ does not always correlate precisely with CPP, and the relation between the two can be affected by therapeutic interventions such as adrenergic therapy. Although these studies cannot be used as an endorsement for deciding when to quit or continue CPR, they do lend support to the validity of ETCO₂ as a reflection of cardiac output.

End-tidal carbon dioxide is the most accurate noninvasive method of monitoring CPR effectiveness currently available, and its use is encouraged. The most appropriate way to use ETCO₂ is to maintain minute ventilation relatively constant while adjusting the mechanics of CPR chest compression and titrating adrenergic therapy in an effort to maximize the ETCO₂.

Ventricular Fibrillation Waveform Analysis

It has long been recognized that the coarseness of the VF waveform has a rough correlation with the duration of cardiac arrest and the prospects for successful defibrillation with ROSC. With the onset of VF, there is a gradually progressive decrease in the peak-to-peak amplitude of the VF waveform in the absence of resuscitative interventions. The recorded amplitude of the VF waveform, however, is subject to such factors as body habitus, electrode location and contact, and instrumentation. By using mathematical formulas (the fast Fourier transform) and high-speed computers, a digital characterization of the VF waveform can be derived. This method provides a discrete digital number with which to describe the distribution of frequencies present in the waveform. One measure, the median or centroid frequency, has been found to correlate with defibrillation success and to predict the duration of VF. As VF continues without resuscitation, the median frequency gradually deteriorates over time. When effective resuscitation measures are instituted, the median frequency promptly increases.¹⁷ Such interventions as invasive perfusion support or pharmacologic therapy with epinephrine or vasopressin have successfully raised the median frequency of VF and have been associated with enhanced resuscitation success in animal models. The median frequency (or other measures derived from the fast Fourier transform) may eventually find their way to the bedside in the form of a monitor used by the clinician to guide therapy during resuscitation attempts.

Invasive Hemodynamic Pressure Monitoring

Laboratory and clinical studies have demonstrated that aortic pressure and CPP correlate strongly with coronary blood flow and ROSC. Although placement of arterial pressure catheters is a common occurrence in critical care medicine, arterial catheterization is not routinely performed in cardiac arrest patients, in part because of the technical difficulties associated with performing this during CPR. However, arterial pressure monitoring provides a very useful parameter to guide resuscitative efforts. The CPR diastolic arterial pressure is the major predictor of the actual CPP. Thus, adjusting therapeutic interventions to maximize CPR diastolic arterial pressure will result in greater CPP and improved chances of survival.

Central venous catheterization in addition to arterial and aortic catheterization allows for the accurate measurement of the aortic-to-right atrial pressure gradient or CPP. Although clearly one of the most useful measurable parameters in human resuscitation, it has been studied by only a few investigators and only as an in-hospital procedure. Thus, out-of-hospital cardiac arrest patients undergoing CPP monitoring have generally been in arrest for an extended period. Paradis and colleagues reported that ROSC in the ED correlates with achieving a CPP greater than 15 mm Hg among patients with prolonged cardiac arrest.¹⁸ None of the patients with ROSC survived, suggesting that CPP monitoring after prolonged cardiac arrest is likely to be of limited benefit. Thus, efforts to perform invasive monitoring more rapidly upon hospital arrival or even in the prehospital setting should be pursued. The feasibility of performing prehospital invasive hemodynamic monitoring has been demonstrated with the use of a commercially available, lightweight, and portable monitoring system that can be easily transported to the scene of out-of-hospital cardiac arrest.

Central Venous Oxygen Saturation Monitoring

Rivers and associates reported the use of central venous oximetry in the evaluation of cardiac arrest patients.¹⁹ Central venous oxygen saturation provided important information about tissue oxygen delivery and consumption balance and was predictive of ROSC. A central venous oxygen saturation of less than 30 percent resulted in a 0 percent ROSC rate, whereas a value greater than 72 percent resulted in a 100 percent ROSC rate. Impending ROSC was foreshadowed by an abrupt

or gradual increase in central venous oxygen saturation. Interestingly, a supranormal central venous oxygen saturation, termed *venous hyperoxia*, was seen frequently during the early phase of ROSC, followed by a return to normal levels.

INVASIVE PERFUSION TECHNIQUES

Direct Mechanical Ventricular Assistance

Direct mechanical ventricular assistance (DMVA) was first described by Anstadt and colleagues in 1965, and several laboratory studies have investigated this technique in cardiac arrest models. Direct mechanical ventricular assistance uses a cup-shaped device that fits around the ventricles and is held in place by a vacuum at the apex of the heart (Figure 24-4). Cyclic positive and negative pressures are transmitted to a flexible diaphragm on the inner surface of the cup, resulting in compression and re-expansion of the ventricles, respectively. The clinical utility of this technique in the treatment of cardiac arrest has not been established. The major advantage of DMVA is that it can be sustained for an extended period. The major limitation of DMVA is the requirement of a thoracotomy, which largely precludes its use within an effective time frame for most victims of out-of-hospital cardiac arrest.

Cardiopulmonary Bypass

Cardiopulmonary bypass (CPB; Figure 24-5) is an effective means of providing sustained global perfusion and has been advocated in the treatment of cardiac arrest. Several laboratory studies have demonstrated improved ROSC and neurologic recovery with CPB compared with standard ACLS interventions. There are also several case series describing the successful use of femorofemoral CPB in the treatment of cardiac arrest. The major advantages of CPB are that it can be performed with only a femoral vessel cutdown, artificial perfusion can be sustained for an extended period, and perfusion support can be gradually withdrawn. The major disadvantages are the equipment, skill, and time required to perform CPB. A recent report of 10 cardiac arrest victims in whom CPB was initiated in the ED showed that ROSC was achieved in all 10, but there were no long-term survivors.²⁰ The average time from onset of arrest to onset of CPB support was 32 min. To achieve long-term survival, the time interval to CPB support must be much shorter. Unless the technique can be extended to the prehospital setting, it will be of very limited value in the treatment of victims of out-of-hospital cardiac arrest. However, technologic advances offer the

FIG. 24-5. Schematic diagram of a cardiopulmonary bypass system.

prospect of developing CPB devices that can be used in the prehospital setting.

Hemopump

The Hemopump is a catheter-based, temporary ventricular assist device consisting of an axial flow pump component at the distal end of the catheter powered by an external motor via a flexible drive cable that runs the length of the catheter. The distal tip of the axial flow pump component is advanced from a femoral artery into the left ventricle (Figure 24-6). When it is in operation, forward blood flow is generated by blood entering the axial flow pump component in the left ventricle and exiting in the aortic arch. Laboratory investigation in a cardiac arrest model has demonstrated sustained mean arterial pressures of approximately 60 mm Hg and cardiac output averaging 2.3 L per min.²¹ The major drawback with the use of this device in the setting of cardiac arrest is that one must be able to insert the catheter from a femoral artery into the left ventricle.

FIG. 24-6. Schematic diagram of the Hemopump positioned in the left

ventricle.

Aortic Catheter Perfusion Techniques

During the past decade, there has been interest in the use of aortic balloon occlusion catheters to enhance vital organ perfusion during cardiac arrest. The use of standard intra-aortic balloon pumping has been shown to increase CPP during closed chest CPR, but the effect is not dramatic. However, the use of aortic balloon catheters for the infusion of resuscitation solutions during cardiac arrest holds greater promise for improving resuscitation outcome.

Selective aortic arch perfusion (SAAP), as described by Manning and associates,²² or selective aortic perfusion and oxygenation, as described by Paradis and colleagues,²³ uses a large-lumen balloon occlusion catheter positioned in the descending aortic arch to provide selective perfusion of the heart and brain during cardiac arrest (Figure 24-7). The catheter is inserted into a femoral artery (percutaneously or via a cutdown) and blindly advanced into the thoracic aorta. With the balloon inflated and pressure cuffs applied to the upper arms, the coronary and cerebral circulations are relatively isolated for brief perfusion. The resuscitation solution infused consists of an oxygenated blood substitute, such as a perfluorocarbon emulsion or polymerized hemoglobin solution, that might contain various agents to enhance restoration of spontaneous cardiac contraction, maintain neuronal viability, and limit myocardial and neuronal reperfusion injuries. One major advantage of SAAP is the ability to administer agents to combat reperfusion injury at the moment of or just before reperfusion. In addition, the temperature of the infused resuscitation solution can be adjusted to rapidly induce protective hypothermia. Once ROSC is achieved, SAAP can be used to provide partial perfusion support dur-

FIG. 24-7. Selective aortic arch perfusion (SAAP). Positioning of the

SAAP balloon occlusion catheter at the end of the descending aortic arch through a femoral artery. Placement of the balloon at this level restricts flow to aortic arch vessels including coronary arteries. (Reproduced with permission from Manning JE, Murphy CA, Hertz CM, et al: Selective aortic arch perfusion during cardiac arrest: A new resuscitation technique. *Ann Emerg Med* 21:1058, 1992.)

ing the early post-resuscitation phase. The concept of SAAP was created primarily with a focus on the prehospital environment, but it also can be used in-hospital. The intravascular volume loading associated with SAAP therapy makes it particularly attractive for the treatment of hemorrhage-induced hypovolemic cardiac arrest. Although laboratory results in VF and exsanguination cardiac arrest models have been very favorable, the efficacy of this invasive perfusion technique in human cardiac arrest has not been studied.

Safar and colleagues recently described using a descending aortic arch balloon occlusion catheter for the purpose of infusing very cold fluid (4°C) to rapidly induce protective brain and heart hypothermia while in a persistent cardiac arrest.²⁴ The rationale for this "suspended animation" state is to protect the vital organs from further ischemic damage or reperfusion injury until the patient can be transported to a facility with CPB capability. Thereafter, CPB would be used for controlled reperfusion, leading to stable restoration of spontaneous circulation. This approach might minimize ischemic and reperfusion cellular injuries sufficiently to promote normal functional neurologic recovery. This approach has been shown to be effective in laboratory models of primary cardiac arrest and hemorrhage-induced cardiac arrest.

Tang and colleagues described the use of a balloon occlusion catheter positioned in the ascending aortic arch.²⁵ Laboratory investigations of this technique have shown marked increases in coronary perfusion with intermittent balloon occlusion. Infusion of fluid through the catheter results in isolated coronary artery perfusion. The technical feasibility of rapidly and reliably positioning the tip of this catheter in the ascending aortic arch may prove to be a significant challenge in the clinical setting.

Minimally Invasive Direct Cardiac Massage

In 1995, Buckman and colleagues reported the use of a relatively simple device for the rapid initiation of internal cardiac compression through a small thoracic incision.²⁶ The technique, called *minimally invasive direct cardiac massage*, uses a rectangular, curved, padded plate connected to a handle to compress the heart through an intercostal incision at the anterolateral left chest at the level of the lower sternum (Figure 24-8). In a swine cardiac arrest model, the device generated CPP and cardiac output similar to that produced by manual open chest cardiac massage. It has been suggested that a modified device could be inserted via a smaller (2 to 3 cm) intercostal incision.

FIG. 24-8. The heart-contacting baseplate and a portion of the stem of the cardiac compressive device are inserted into the thorax through a small, parasternal

incision. The manually operated handle remains outside the chest. The base plate is positioned directly on the cardiac ventricles, lying within an intact pericardium. Manual depression of the device compresses the heart and produces an artificial systole.

ACID-BASE DISORDERS

David D. Nicolaou Gabor D. Kelen

Many diseases, including those presenting an imminent life threat, produce acid and base (acid-base) disturbances that provide important clues concerning the nature of the underlying illness and suggest immediate therapeutic interventions. This chapter describes a practical approach to the clinical evaluation of acid-base disorders.

MEASUREMENT OF PLASMA ACIDITY

Plasma hydrogen ion concentration ($[H^+]$) is normally 40 nmol/L, corresponding to a pH of 7.4. Because pH is a logarithmic transformation of $[H^+]$, the relation of $[H^+]$ to pH is not linear for all pH values (Table 25-1). However, for pH values from 7.20 to 7.50, the relation between $[H^+]$ and pH is nearly linear; pH changes of 0.01 correspond to approximately 1 nmol/L change in $[H^+]$. This linear relation allows very rapid bedside interpretation of blood gas and electrolyte results.

Plasma Acid Homeostasis

Plasma $[H^+]$ is influenced by the rate of endogenous production, the rate of excretion, and buffering capacity of the body. Buffers mitigate the impact of large changes in available hydrogen ion on plasma pH.

Buffer systems that are effective at physiologic pH include hemoglobin, phosphate, proteins, and bicarbonate (Figure 25-1).¹ One can consider the $[H^+]$ to be the result of all physiologic buffers acting on the common pool of hydrogen ions.

The familiar Henderson-Hasselbalch equation, shown in Eq. (1),

demonstrates the interrelationship between carbonic acid, bicarbonate, and pH; any two of these determine the third.

However, the clinical utility of the Henderson-Hasselbalch equation is limited.

Nevertheless, if all constants are inserted into the Henderson-Hasselbalch equation and the anti-log of all its terms is taken, the resulting simplified Kaissirer-Bleich equation, shown in Eq. (2), is of great clinical utility.²

$$[H^+] = 24 \times \frac{P_{CO_2}}{[HCO_3^-]} \quad (2)$$

The Kassirer-Bleich equation may be used to calculate the concentration of any component of the bicarbonate buffer system provided the concentrations of the other two components are known. It therefore allows clinicians to determine, for example, what the pH *must be* when the partial pressure of carbon dioxide (P_{CO_2}) and $[HCO_3^-]$ are known.* Performing such a calculation with values reported by the laboratory permits the clinician to check the internal consistency of the reported data. (In fact, in most hospital laboratories, the $[HCO_3^-]$

*The "bicarbonate concentration" measured by the clinical laboratory is actually the total CO_2 , a figure that is the sum of bicarbonate and dissolved CO_2 plus H_2CO_3 . The latter term is the P_{CO_2} multiplied by the solubility coefficient of CO_2 in blood (a), 0.03. Thus, total $CO_2 = [HCO_3^-] + (0.03) (P_{CO_2})$. Most clinicians simply neglect the second term when the P_{CO_2} is normal; when hypercapnia is present, however, the second term contributes significantly to total CO_2 .

TABLE 25-1 pH and Hydrogen Ion Concentrations

PH	$[H^+]$ nmol/L
6.8	158
6.9	126
7.0	100
7.1	79
7.2	63
7.3	50

PHYSIOLOGY OF ACID PRODUCTION AND EXCRETION

The quantity of $[HCO_3^-]$ in relation to carbonic acid buffer in the system is not fixed but varies according to physiologic need. This flexibility is largely provided by pulmonary excretion of P_{CO_2} , which can vary significantly and rapidly according to the exigencies of the acid-base milieu. The kidney regulates $[HCO_3^-]$ excretion and the formation of new $[HCO_3^-]$ and can change the rate of these processes when demanded by the acid-base milieu. However, renal response to pulmonary acid-base disturbances requires hours to days to reach equilibrium.

Hepatic Influence on Acid-Base Balance

Increasing attention is being given to the role of the liver in acid-base homeostasis. Approximately 1 mol each of $[HCO_3^-]$ and ammonium is generated every day by protein catabolism. The irreversible synthesis of urea by the liver results in consumption of virtually all of this $[HCO_3^-]$. The rate of this reaction is closely tied to extracellular pH and $[HCO_3^-]$. This control, mediated by glutaminase and carbonic anhydrase, can result in significant retention and neutralization of bicarbonate during acidosis. The fixation of ammonium ions into urea

FIG. 25-1. Schematic representation of hydrogen ion homeostasis.

slows, but the kidney increases ammonia synthesis and excretion. This process not only prevents ammonia accumulation but also allows hydrogen ion trapping in the distal tubule. Further, hepatic cells without the cellular apparatus to fix ammonia into urea avidly use excess ammonia to synthesize glutamine.³ Thus, the liver is the "third organ" of acid-base balance.

Renal Influence on Acid-Base Balance

Bicarbonate homeostasis requires the reclamation of filtered HCO_3^- , 85 percent of which occurs in the proximal convoluted tubule. Sodium is extruded from the tubular cell into the plasma in exchange for K^+ (via the Na^+/K^+ -ATPase pump). To maintain equilibrium, cellular Na^+ is absorbed from the filtrate into the cell as H^+ is secreted into the lumen. This H^+ combines with the filtered HCO_3^- to produce carbonic acid (H_2CO_3), which carbonic anhydrase in turn converts to CO_2 and H_2O . To maintain equilibrium, CO_2 diffuses back into the cell, where cytoplasmic carbonic anhydrase regenerates H_2CO_3 , which in turn completes the cycle by dissociating into $[\text{HCO}_3^-]$ and H^+ (thereby providing a supply of H^+ for extrusion). If tubular disease (such as occurs in renal tubular acidosis) inhibits H^+ extrusion, serum $[\text{HCO}_3^-]$ decreases to a steady-state level where reclaimed HCO_3^- effectively equals H^+ extrusion.

The balance (15 percent) of HCO_3^- reclamation occurs in the distal tubule. Via a *sodium-independent* process, cytoplasmic carbonic anhydrase generates H_2CO_3 , which dissociates. HCO_3^- diffuses into plasma, and H^+ is secreted into the lumen by an H^+ -ATPase pump, thereby maintaining cellular electrical neutrality. H^+ is trapped in the lumen by inorganic phosphate or ammonia $[\text{NH}_4^+]$. Failure of $[\text{H}^+]$ secretion is the underlying mechanism of distal renal tubular acidosis (RTA). A *sodium-dependent* process allows the generation of HCO_3^- in the distal tubule. Intracellular glutamine generates HCO_3^- and ammonia $[\text{NH}_4^+]$. The Na^+/K^+ pump moves $[\text{Na}^+]$ into the lumen, but $[\text{Na}^+]$ diffuses back across the cell membrane, and $[\text{NH}_4^+]$ is secreted into the lumen in exchange. Thus, the $[\text{HCO}_3^-]$ generated simply stays in the cell. Formation of $[\text{HCO}_3^-]$ by this process may require 4 to 5 days to reach equilibrium when acidosis so demands. Drugs that alter uptake or delivery of $[\text{Na}^+]$ to the distal tubule can significantly interfere. The process of acid secretion allows the regeneration of $[\text{HCO}_3^-]$ in proportion to the daily production of acid. Urine, especially under conditions of acidosis, can be made almost entirely free of $[\text{HCO}_3^-]$.

FUNDAMENTAL ACID-BASE DISORDERS

Any condition that disturbs acid-base balance by increasing $[\text{H}^+]$ —whether through endogenous production, decreased buffering capacity, decreased excretion, or exogenous addition—is termed *acidosis*. Similarly, any condition that decreases $[\text{H}^+]$ is termed *alkalosis*. The terms *acidemia* and *alkalemia* refer to the net imbalance of $[\text{H}^+]$ in the blood. The difference between acidosis and acidemia is not merely semantic but of great clinical importance. For example, a patient with acidosis and alkalosis of equal magnitude will have a normal pH. Thus a patient with these disturbances has neither acidemia nor alkalemia but has two simultaneously occurring primary disturbances, acidosis and alkalosis. It is therefore important to appreciate that, although acidemia is diagnostic of acidosis and alkalemia of alkalosis, a normal or high pH does not exclude acidosis and a normal or low pH does not exclude alkalosis. Acid-base disturbances are further classified as respiratory or metabolic. Respiratory acid-base disorders are due to primary changes in Pco_2 , and metabolic disorders reflect primary changes in $[\text{HCO}_3^-]$. If there were no compensatory mechanism, the Kassirer-Bleich equation states that the magnitude of change in Pco_2 or $[\text{HCO}_3^-]$ would directly determine the magnitude of change in the pH. However, physiologic mechanisms tend to mitigate pH changes by effecting offsetting changes in bicarbonate and CO_2 levels. For example, the Pco_2 is elevated in respiratory acidosis, but the corresponding decrease in pH is attenuated over time by renal retention of bicarbonate.

Compensatory mechanisms are, by definition, not "disorders," but rather constitute normal physiologic responses to acid-base derangements. Terms such as *compensatory respiratory alkalosis* therefore are not only confusing but also misleading. The clinician is concerned with the adequacy of compensation, however, because failure of adequate compensation implies the presence of another primary acid-base disturbance. For example, a patient with metabolic acidosis who does not exhibit adequate respiratory compensation has a superimposed respiratory acidosis. Normal compensatory responses to each primary acid-base disturbance have been established through careful study and are presented later in this chapter.

It is important to note that compensatory mechanisms return the pH toward, but not completely to, normal.* The fact that compensatory mechanisms cannot become complete is evident when one considers that complete compensation would necessarily remove the (physiologic) stimulus driving the compensation.¹

The "normal" values of pH, Pco_2 , and $[\text{HCO}_3^-]$ for a given laboratory are ranges, intended to include 95 percent of patients without an acid-base disorder. The normal pH range is 7.35 to 7.45, the "normal" Pco_2 range is 35 to 45 mm Hg, and the "normal" $[\text{HCO}_3^-]$ is usually 21 to 28 mEq/L. However, a patient may have no value outside the "normal range" and still have significant acid-base disturbances. As detailed further below, a patient with a wide anion gap (AG) acidosis and a concomitant metabolic alkalosis of nearly equal magnitude will have a perfectly "normal" pH, Pco_2 , and $[\text{HCO}_3^-]$. In contrast, abnormal-appearing values may, in fact, be appropriate for a given simple acid-base disturbance. For example, in the presence of a metabolic acidosis ($[\text{HCO}_3^-] = 15$; pH = 7.3), an appropriate respiratory compensation should result in a Pco_2 of about 30 mm Hg. The Pco_2 is below the "normal" range but at the expected level for the degree of (metabolic) acidosis. In this example, the finding of Pco_2 in the normal (35 to 45) range actually implies the presence of a respiratory acidosis, because the expected physiologic respiratory response is inadequate.

The Anion Gap

The principle of electrical neutrality requires that plasma have no net charge. The charge of the predominant plasma cation, sodium, therefore must be "balanced" by the charge of plasma anions. Although $[\text{HCO}_3^-]$ and $[\text{CP}]$ constitute a significant fraction of plasma anions, the sum of their concentrations does not equal that of sodium. Therefore, there must be other anions present in the serum that preserve electrical neutrality. These anions are mostly serum proteins, phosphate, sulfate, and organic anions, such as lactate, and the conjugate bases of ketoacids. Because these substances are not commonly measured, they are termed *unmeasured anions* (UA). Unmeasured cations (UC) also exist, largely in the form of $[\text{Ca}^{2+}]$ and $[\text{Mg}^{2+}]$. Because all cations, measured and unmeasured, must equal all anions (measured and unmeasured),

$$\text{MC} + \text{UC} = \text{MA} + \text{UA} \quad (3)$$

it follows that

$$\text{MC} - \text{MA} = \text{UA} - \text{UC} = \text{AG} \quad \text{Thus,} \quad (4)$$

substituting measured ions produces

$$[\text{Na}^+] - ([\text{HCO}_3^-] + [\text{CT}]) = \text{AG} \quad (5)$$

The difference between the serum $[\text{Na}^+]$ (the contribution of $[\text{K}^+]$, largely an intracellular ion, is usually neglected) and the sum of serum $[\text{CP}]$ and $[\text{HCO}_3^-]$ equals the concentration of the unmeasured anions. For the purposes of AG determination, correction of serum $[\text{Na}^+]$ in the face of hyperglycemia is unnecessary, because this condition similarly dilutes $[\text{CP}]$.⁴

The sole exception is in chronic respiratory alkalosis, where bicarbonate levels may decline to a level that nearly normalizes the pH such that differentiating the actual pH from normal falls within the range of laboratory error.

The unmeasured anion concentration is commonly called the *anion gap*, and its normal value had been considered to be 12 ± 4 mEq/L. Recent reports have suggested that a normal AG value of 7 ± 4 mEq/L may be more appropriate to electrolyte measurements made with ion-specific electrodes.⁵ However, the value used by the clinician should reflect institutional practice.⁶ As with other acid-base concepts, the accepted "normal" range for the AG is less important than whether it has changed in relation to the patient's steady-state (baseline) value. Thus, a relative change in AG is more important than the actual value. However, virtually all values above 15 mEq/L can be considered abnormal, even when there are no previous comparison values available.

The AG may change even in the absence of acid-base disturbances. It may rise when (unmeasured) cations are decreased, as in severe states of hypomagnesemia, hypokalemia, and hypocalcemia. A reduced (narrow) or even negative anion gap may result from an increase in unmeasured *cations*, such as lithium, and unmeasured positively charged proteins resulting from myeloma and polyclonal gammopathies or from a decrease in unmeasured anions, such as albumin and 7 globulin. A narrow or negative AG also may be the result of confounders of chloride measurement. Bromide is measured as chloride on an equimolar basis by chloride-specific electrodes. Other techniques of chloride measurement may produce even more inaccurate results in the presence of bromide.⁷ Triglyceride levels greater than 600 mg/dL produce overestimation of chloride levels measured by colorimetric techniques and may result in underestimation of serum sodium, resulting in an apparently narrow or even negative AG.⁴

Although increases in the AG are traditionally considered in the context of metabolic acidosis, elevation of the AG may be seen with many acid-base disturbance. Metabolic and respiratory alkalosis, for example, may elevate the AG by 2 to 3 mEq/L, because of elevations in lactate produced by enhancement of glycolysis. Penicillin and carbenicillin, as anions, produce elevations in the AG. Their charges must be balanced by sodium, which is retained by renal tubules at the cost of enhancing secretion of potassium and hydrogen ions. This effect is enhanced by the presence of the poorly reabsorbed penicillin and carbenicillin ions in the tubule lumen, the negative charges of which serve as an electrical gradient for hydrogen and potassium ion secretions. The result is an elevated AG with a hypokalemic alkalosis, illustrating the principle that anions principally cleared by the kidney may elevate the AG, particularly when aldosterone activity is high.

However, elevation of the AG is most commonly associated with metabolic acidosis (Table 25-2). Traditional mnemonics for the differential diagnosis of an elevated AG acidosis unfortunately suggest that iron, theophylline, cyanide, biguanides, and other compounds *are* unmeasured anions. These substances actually elevate the AG by producing lactic acidosis, discussed later in this chapter. The result of using traditional mnemonics in evaluating elevated AG acidosis may result in a satisfaction-of-search error, where the discovery of lactic acidosis provides a ready explanation for the elevated AG and thereby inhibits con-

sideration of the full differential diagnosis of lactic acidosis. We suggest that the differential diagnosis of metabolic acidosis with an elevated AG should emphasize distinctions between endogenous and exogenous unmeasured anion sources and avoid mixing the etiology of lactic acidosis with that of other increased unmeasured anions.

Clinical use of the AG requires an appreciation of its limitations. Although an AG greater than 30 mEq/L is usually caused by lactic acidosis or ketoacidosis, these conditions may exist even when the AG is normal. An AG value less than 25 mEq/L has been found to be an insensitive indicator of elevated lactate levels in critically ill patients⁸; in trauma patients, the post-resuscitation AG does not predict lactate levels.⁹ Thus, a "normal" AG does not exclude the presence of increased concentrations of unmeasured anions. An AG increased from baseline but still within the "normal" range may be a clue. Direct measurements of lactate, formate, ketoacids, methanol (parent of formic acid), ethylene glycol (parent of oxalic acid and numerous other organic acids), and salicylate should be ordered when the presence of any of these substances is suspected but the AG is "normal" (particularly when the value is in the upper range of normal).

A common clinical problem is the diagnosis of mixed acid-base disturbances in the presence of an elevated AG. Simple acid-base disturbances that produce elevated AGs are referred to as *wide-AG metabolic acidoses*. If a wide-AG metabolic acidosis is the only disturbance, then the change (elevation from baseline) in value of the AG (sometimes referred to as the *delta gap*)¹⁰ should exactly equal the change (decrease) in the $[\text{HCO}_3^-]$. This is a one-to-one relationship. This concept is represented mathematically in Eq. (6).

$$\Delta \text{TAG} = \Delta [\text{HCO}_3^-] \quad (6)$$

This simple relationship can be used to great advantage in determining the presence of other metabolic acid-base disturbances. If the $[\text{HCO}_3^-]$ is even lower than predicted by the delta AG, then there must be a concomitant hyperchloremic (i.e., non-AG type) metabolic acidosis (Figure 25-2A). Similarly, if the decrease in $[\text{HCO}_3^-]$ is less than expected based on the delta AG, there must be a concomitant metabolic alkalosis present. Note that acute respiratory conditions (respiratory acidosis or alkalosis) do not affect these determinations. Potential acid-base disturbances related to respiratory status must be further determined, as discussed below (Figure 25-2A to 25-2C).

Parameters Required for Clinical Acid-Base Evaluation

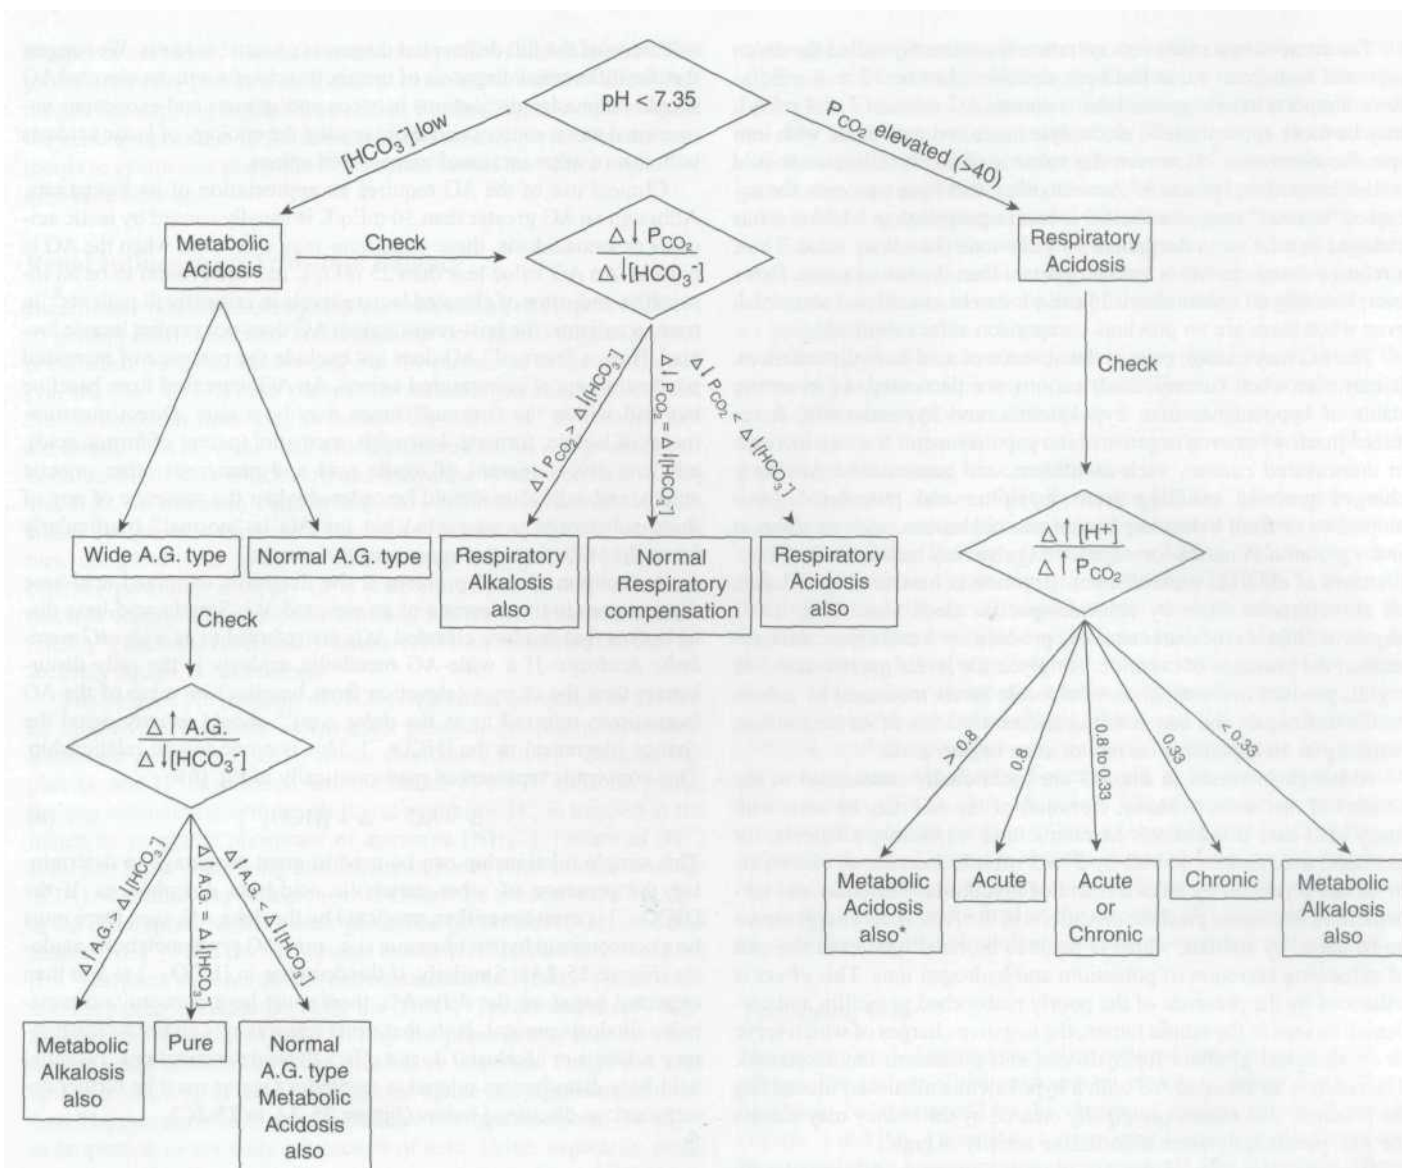

When taking a medical history, one should emphasize events that may result in the gain or loss of acid or base, such as vomiting, diarrhea, medications, or ingestions, and seek evidence of dysfunction of the organs of acid-base homeostasis: the liver, kidneys, and lungs.

Laboratory evaluation requires blood samples for determination of electrolyte concentrations ($[\text{Na}^+]$, $[\text{K}^+]$, $[\text{Cl}^-]$, $[\text{HCO}_3^-]$) and blood gases (pH, Pco_2 , and $[\text{HCO}_3^-]$). Most clinical laboratories measure

TABLE 25-2 Unmeasured Anions Associated with an Elevated Anion Gap and Metabolic Acidosis

Diagnostic Category	Species	Origin	Diagnostic Adjuncts
Renal failure (uremia)	$[\text{PO}_4^{2-}]$, $[\text{SO}_4^{2-}]$	Protein metabolism	BUN/Creatinine
Ketoacidosis Diabetic Alcoholic Starvation	Ketoacids β -hydroxybutyrate Acetoacetate	Fatty acid metabolism	Serum/urine ketones
Lactic acidosis	Lactate	Metabolism	Lactate level
Exogenous poisoning Methanol Ethylene glycol (EG) Salicylate	Formate Oxylate and organic anions Salicylate	Methanol metabolism EG metabolism, also results in high NAD/NADH ratio, favoring pyruvate conversion to lactate Salicylate, lactate, ketoacids	Osmolal gap Osmolal gap Oxylate crystals (urine) Concomitant respiratory alkalosis and metabolic alkalosis

Abbreviations: BUN = serum urea nitrogen; NAD = nicotinamide adenine dinucleotide.

Key : *It is likely that $[\text{HCO}_3^-]$ is < 25 in this scenario and the tree could have been started on the left. A.G., anion gap.

FIG. 25-2. A. Algorithm for determination of type of acidosis and mixed acid-base disturbances when pH indicates acidemia.

two of the parameters reported in blood gas results (most commonly the pH and Pco_2) and use the Henderson-Hasselbalch equation to calculate the third ($[\text{HCO}_3^-]$).

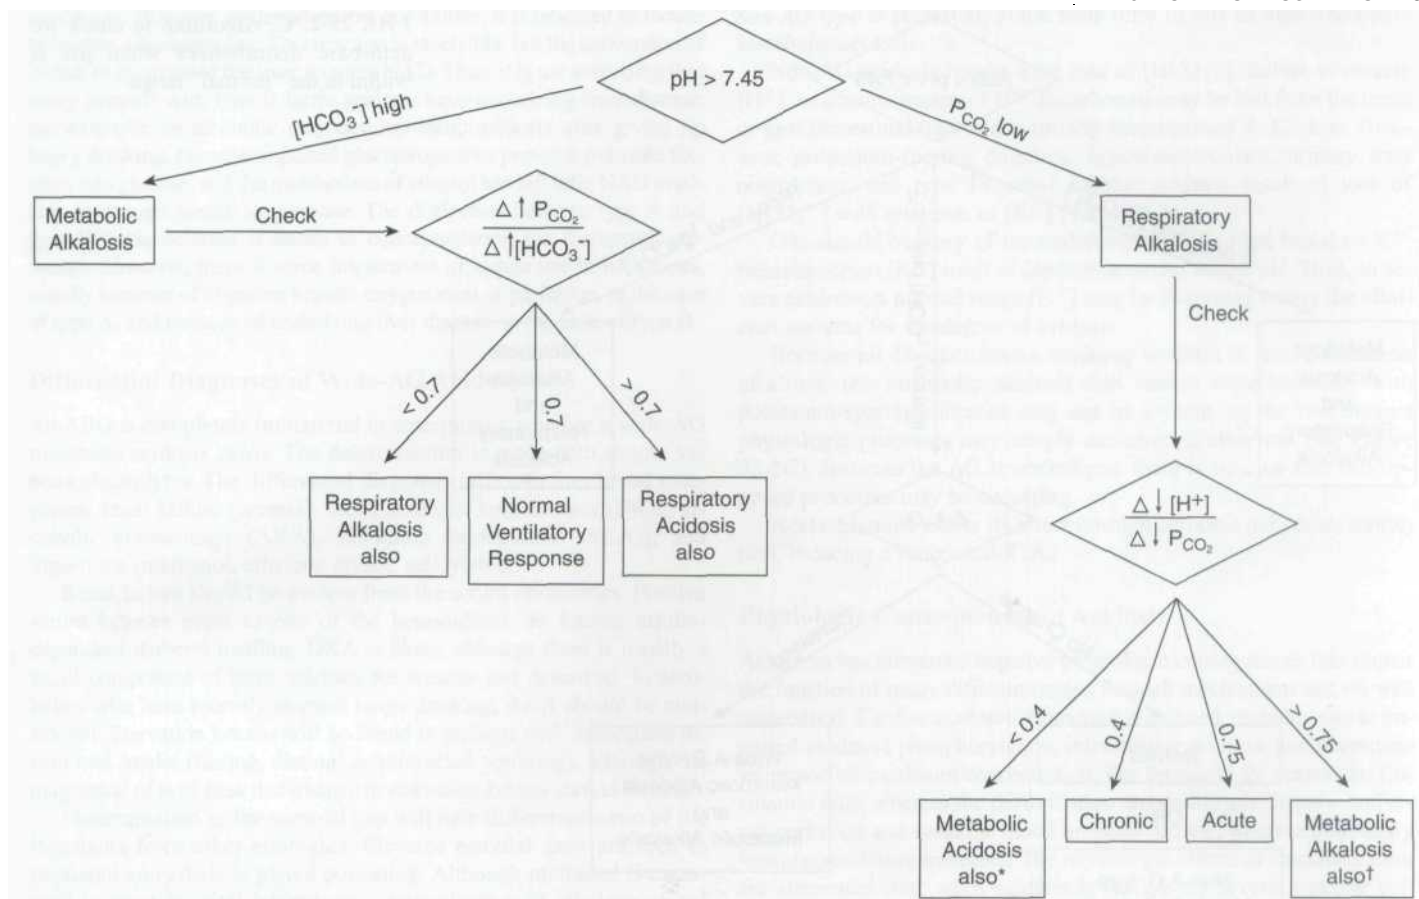

Blood samples for acid-base evaluation are traditionally obtained by arterial puncture, but there is some evidence that venous blood may be used instead. Arterial and capillary values of pH and CO_2 content in normal patients and those with diabetic ketoacidosis correlate well (correlation coefficients of 0.9 and 0.98, respectively). Recent work has demonstrated high correlations between arterial and venous pH ($r = 0.9689$) and between arterial and venous bicarbonate concentrations ($r = 0.9543$) in ED patients with diabetic ketoacidosis.¹⁰ The correlation between venous and arterial blood gas values in patients with severe shock remains uncertain, but in other circumstances the use of venous values seems reasonable. Inexperienced clinicians frequently resort to arterial blood gas (ABG) determination as a means to "know" the pH. However, the pH per se is often the least important value for diagnosis and management. When respiratory status is not compromised, the pH can be calculated with the aid of the Kassirer-

Bleich equation [see Eq. (2)] from knowing the venous $[\text{HCO}_3^-]$ alone, as described below.

METABOLIC ACIDOSIS

Metabolic acidosis may result from $[\text{HCO}_3^-]$ loss per se, administration of acid, or endogenous production and accumulation of acid. Loss of $[\text{HCO}_3^-]$ occurs in externalization of intestinal contents (e.g., vomiting, enterocutaneous fistulae) and renal wasting of bicarbonate (e.g., renal tubular acidosis, carbonic anhydrase inhibitor therapy). Administration of acid (unlikely to be seen in the ED) occurs primarily in total parenteral nutrition, where patients receive hydrochloric salts of basic amino acids. Endogenous acids accumulate in renal tubular acidosis, ketoacidosis, and lactic acidosis.

Unopposed metabolic acidosis results in a decreased serum $[\text{HCO}_3^-]$ and an increase in serum $[\text{H}^+]$. The increased $[\text{H}^+]$ stimulates the respiratory center, resulting in increased alveolar ventilation. The physiologically based "respiratory compensation" is an attempt to lower the $[\text{H}^+]$

Key: "Implies that the A in $[H^+]$ is not low, but elevated, and thus the pH would be < 7.40 . Therefore, this algorithm would not be selected but rather Fig. 21-2A. †It is likely that the HCO_3^- will be > 25 in this scenario and then the tree could have started on the left. A.G., anion gap.

FIG. 25-2. B. Algorithm for determination of type of alkalosis and mixed acid-base disturbances when pH indicates alkalemia.

by a reduction in P_{CO_2} . The steady-state relationship between the P_{CO_2} and the $[HCO_3^-]$, determined from a study of 60 patients who had only metabolic acidosis of more than 24-h duration, is shown in Eq. (7).^{12*}

$$P_{CO_2} = (1.5 \times [HCO_3^-] + 8) \pm 2 \quad (7)$$

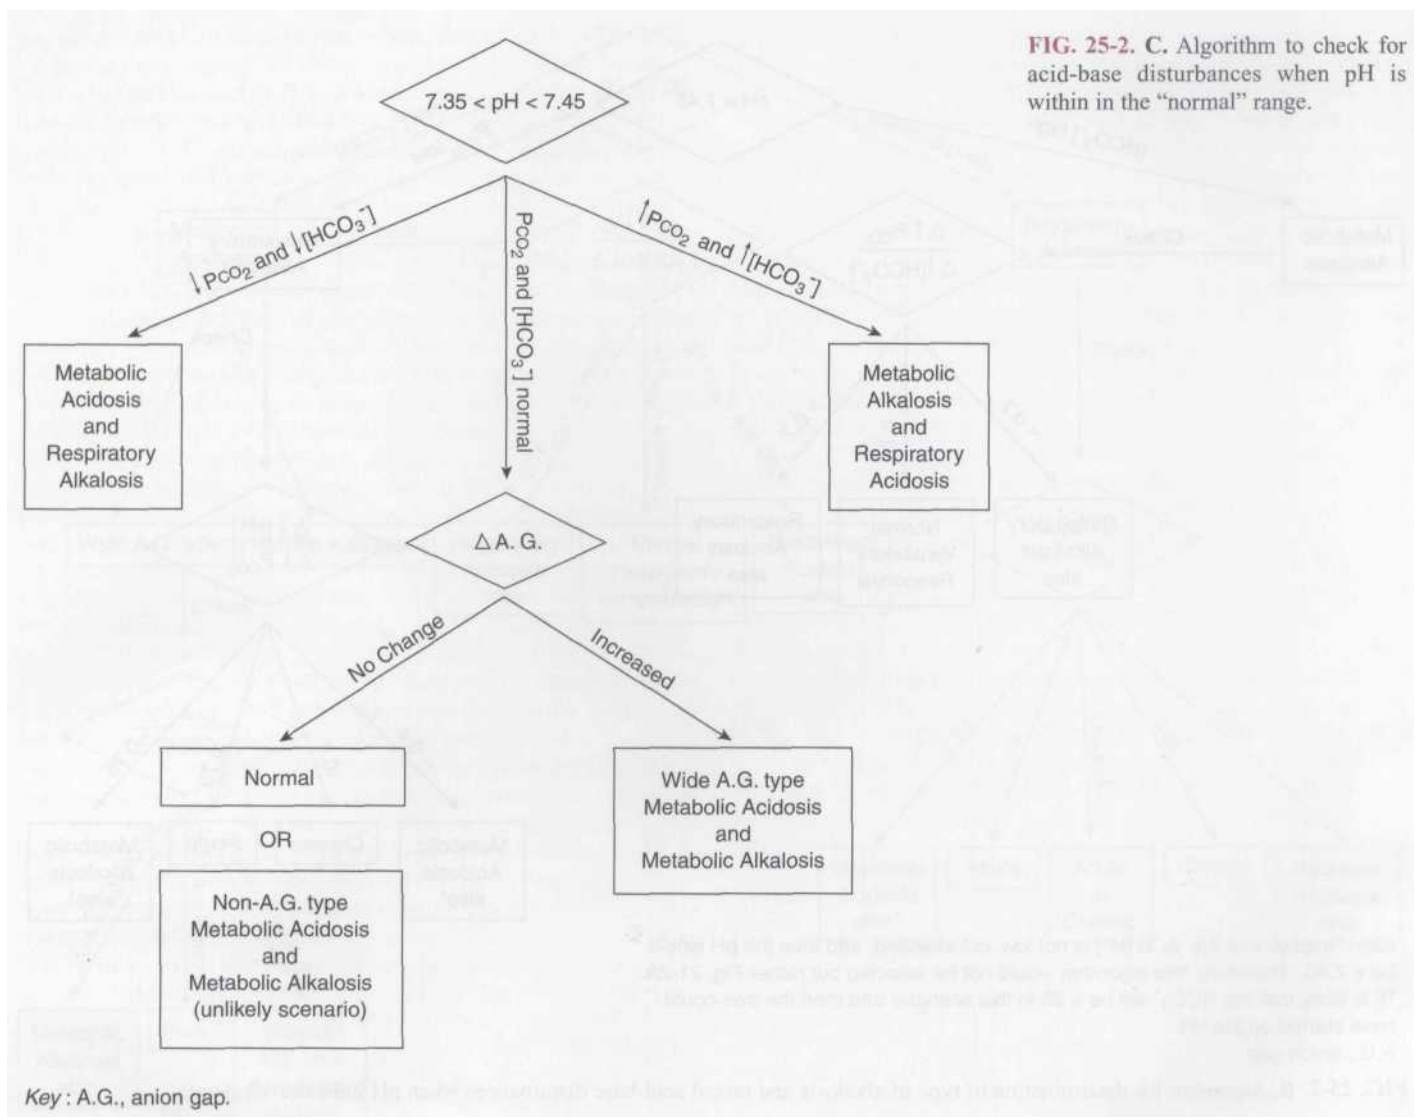

Equation (7) was derived from patients with more than 24 h of metabolic acidosis, although the respiratory response is almost immediate. When $[HCO_3^-]$ is greater than about 8 mEq/L, the relation between P_{CO_2} and $[HCO_3^-]$ is simpler: With normal respiratory compensation, P_{CO_2} falls by 1 mm Hg for every 1 mEq/L fall in $[HCO_3^-]$. Use of these relationships allows the clinician to calculate the expected P_{CO_2} (when respiratory compensation is normal) from the measured $[HCO_3^-]$. If the expected P_{CO_2} value differs from the measured value in uncomplicated steady-state metabolic acidosis, a primary respiratory disorder also exists. For example, if the $[HCO_3^-]$ is 15 mEq/L, the expected P_{CO_2} is about 30 mm Hg. If it is higher than this value (say 35 mm Hg), then by definition there is also a concomitant respiratory acidosis (see Figure 25-2A). If the value is lower than expected (say 25 mm Hg), then there is a concomitant respiratory alkalosis. This latter case is not an "overcompensation" but rather a second primary disturbance occurring simultaneously. These are important concepts. The body cannot tolerate metabolic and respiratory mechanisms for acidosis simultaneously, because one cannot buffer or compensate for the other.

*The constants in this equation ($P_{CO_2} = 1.54 \times [HCO_3^-] + 8.36 \pm 2$) have been rounded for ease of use.

Unfortunately, the ED patient's illness can rarely be assumed to be in steady state. Pierce and colleagues, in physiologic studies of otherwise healthy persons with acute metabolic acidosis caused by diarrhea, found that the completeness of the respiratory response to metabolic acidosis depends on the duration of the acidosis, the time course of its development, and its severity.¹³ If acidosis develops quickly, the P_{CO_2} is often higher than that observed in steady state; the more rapid and severe the acidosis, the larger the difference between the observed P_{CO_2} and the predicted steady-state P_{CO_2} . When $[HCO_3^-]$ is then held constant, steady-state P_{CO_2} is reached in 11 to 24 h. When acidosis develops or is corrected more slowly, there is no lag in respiratory compensation.

There are limits to the adequacy of respiratory compensation during metabolic acidosis. In a study of diabetic ketoacidosis, Kety and colleagues found that respiratory minute volume actually declines when pH decreases below 7.10.¹⁴ This finding led Albert and associates² and Pierce and colleagues¹³ to initiate bicarbonate therapy when their subjects' pH fell below 7.10. These studies appear to have established 7.10 as the definition of "severe" metabolic acidosis. It is particularly important to appreciate any contribution to the acidosis from inadequate respiratory response. Simply initiating bicarbonate therapy when a pH of less than 7.1 is encountered may miss the respiratory insufficiency, which, if addressed, may obviate the use of solutions containing $[HCO_3^-]$. Further, administration of $[HCO_3^-]$ in the face of inadequate ventilatory response may actually exacerbate the respiratory acidosis, because the $[HCO_3^-]$ is converted to CO_2 and H_2O . The development of metabolic acidosis in which the pH is below 7.10 probably is associated with a very high risk of

FIG. 25-2. C. Algorithm to check for acid-base disturbances when pH is within the "normal" range.

ventilatory insufficiency, because there is a limit to respiratory compensation. The lowest Pco_2 level achievable is about 12 mm Hg. The restriction of air movement and the CO_2 generated by the exertion required for rapid ventilation limits the attainable nadir for Pco_2 . The superimposition of respiratory acidosis on a patient in such straits will result in a rapid decline of pH to levels at which organ function and pharmacotherapy will fail. Mechanical ventilation usually should be instituted in such situations. The serum $[\text{K}^+]$ level is affected by metabolic acidosis. The movement of H^+ into cells is associated with extrusion of K^+ . Changes in $[\text{K}^+]$ are more substantial in inorganic acidosis, although elevated serum $[\text{K}^+]$ are typically seen in diabetic ketoacidosis (DKA). In general, for each 0.10 change in the pH, serum $[\text{K}^+]$ will increase by approximately 0.5 mEq/L. Whatever the mechanism of the acidosis, it is important to remember that normal in addition to low serum $[\text{K}^+]$ likely reflects severe intracellular K^+ depletion. The reversal of the acidosis in such circumstances may result in severe hypokalemia, with attendant cardiovascular effects.

Causes of Metabolic Acidosis

The causes of elevated-AG metabolic acidosis are listed in Table 25-2. We re-emphasize that the AG may be within the normal range, even when a metabolic acidosis associated with increased concentrations of unmeasured anions is present. A comparison with the patient's steady-state AG should occur whenever possible. Measurement or detection of specific anions may be indicated. However, caution is necessary when serum ketone testing is performed, because the chemical reac-

tion used to measure serum ketones has an important limitation: the nitroprusside reaction for ketones is positive only for species whose carbonyl moiety has an α -methyl group. The major ketone present in the sera of patients with untreated diabetic or alcoholic ketoacidosis may be 3-hydroxybutyrate, which has no α -methyl group and is not detected by the nitroprusside reaction. The result may be a paradox: initial serum ketone assays in a patient with clinically severe diabetic ketoacidosis are only weakly positive yet rise despite clear clinical improvement. This occurs because appropriate treatment alters the hepatic ratio of nicotinamide adenine dinucleotide (NAD) to NADH_2 , and the restoration of NAD concentrations allows oxidation of (3-hydroxybutyrate to acetoacetate. The addition of several drops of hydrogen peroxide to serum also will oxidize P-hydroxybutyrate to acetoacetate in cases in which this distinction is clinically important. See Chap. 211 for a detailed discussion.

Lactic acidosis occurs whenever lactate production exceeds lactate use or metabolism and is classically of two types. The first, in which tissue hypoxia is present and lactate production is elevated, is referred to as *type A*. Normal tissue oxygenation and impairment of lactate use define the second, called *type B*. Type B lactic acidosis is further subdivided. Type B₁ lactic acidosis is associated with systemic disorders, such as diabetes, renal insufficiency, sepsis, and leukemia; type B₂ is associated with various substances, especially biguanides (phenformin, metformin), salicylates, methanol, iron, and isoniazid; and type B₃ is associated with hereditary metabolic diseases.

The pyruvate produced by glycolysis may be transported across mitochondria! membranes and metabolized in the Krebs cycle under aerobic

conditions. However, under anaerobic conditions, it is oxidized to lactate by lactate dehydrogenase. This reaction is reversible, but the conversion of lactate to pyruvate in the liver requires NAD. Thus, it is not surprising that many patients with type B lactic acidosis have underlying liver disease. For example, an alcoholic may develop lactic acidosis after giving up heavy drinking, because impaired gluconeogenesis prevents pyruvate fixation into glucose, and the metabolism of ethanol has left little NAD available to convert lactate to pyruvate. The distinction between type A and type B lactic acidosis is useful in conceptualizing the therapeutic approach. However, there is some impairment of lactate use in both types, usually because of impaired hepatic oxygenation or perfusion, in the case of type A, and because of underlying liver disease, in the case of type B.

Differential Diagnoses of Wide-AG Acidosis

An ABG is completely immaterial in determining whether a wide-AG metabolic acidosis exists. The determination is made with simple venous electrolytes. The differential diagnosis falls into four broad categories: renal failure (uremia), lactic acidosis, ketoacidosis [DKA, alcoholic ketoacidosis (AKA), starvation ketoacidosis (SKA)], and ingestions (methanol, ethylene glycol, salicylates).

Renal failure should be evident from the serum chemistries. Positive serum ketones point to one of the ketoacidoses. In known insulin-dependent diabetes mellitus, DKA is likely, although there is usually a small component of lactic acidosis for reasons just described. In alcoholics who have recently stopped binge drinking, AKA should be considered. Starvation ketosis will be found in patients with inadequate recent oral intake (fasting, dieting, or protracted vomiting), although the magnitude of acid-base disturbance in starvation ketosis should be small.

Determination of the osmolal gap will help differentiate two of the ingestants from other etiologies. Elevated osmolal gaps are seen in methanol and ethylene glycol poisoning. Although methanol is measured in most hospital laboratories, determination of ethylene glycol levels is performed off-site in many institutions. A widened osmolal gap without evidence of methanol ingestion may determine the diagnosis long before confirmatory laboratory evidence is available. Calculation adjustments to the osmolal gap may need to be made if ethanol is a coingestant (see Chap. 27 for detailed discussion).

When the diagnosis remains in doubt or poor tissue perfusion is a diagnostic possibility, lactate levels should be specifically sent. It should be noted that several poisonings may result in lactic acidosis, including isoniazid, iron, carbon monoxide, methemoglobin, and cyanide. This is but one reason investigators shun the overtaught mnemonic of *MUD-PILES*. For example, this mnemonic does not clearly reflect the fact that isoniazid and iron exert their effects on the AG through lactic acidosis. Also, ethanol is frequently cited as a cause of wide-AG acidosis. However, **ethanol should never be considered the etiologic source of any significant metabolic acidosis**. Although ethyl alcohol metabolism may lead indirectly to very mild lactic acidosis, usually due to AKA, neither the alcohol nor its metabolites directly contribute to the acidosis.

Severe acidosis that is resistant to treatment is seen in various type B lactic acidoses and ingestions. AKA and SKA tend to be mild. Acidosis seen in initial stages of renal failure may be severe but tends to be stable ($[\text{HCO}_3^-]$ about 15 mEq/L) in chronic renal failure. Concomitant acid-base disturbance may further assist in determining the etiology. The triple acid-base disturbance of wide-AG metabolic acidosis, metabolic alkalosis, and respiratory alkalosis is seen with sepsis (lactic acidosis) and salicylate poisoning. The latter also may be associated with a mild temperature elevation.

The relation of $[\text{HCO}_3^-]$ to the AG and the $[\text{HCO}_3^-]$ to the expected Pco_2 compensation must be examined in every patient with wide-AG acidosis to determine whether other (respiratory) acid-base disturbances exist (see Figure 25-2A).

Differential Diagnosis of Unchanged (Normal) AG Acidosis

The non-AG type of acidosis is often referred to as "normal" AG acidosis. Issues related to the AG are relative, so the term *unchanged* or

non-AG type is preferred. Some texts refer to this as *hyperchloremic metabolic acidosis*.

Non-AG acidosis results from loss of $[\text{HCO}_3^-]$, failure to excrete $[\text{H}^+]$, or administration of H^+ . Bicarbonate may be lost from the urine or gastrointestinal tract and is usually accompanied by K^+ loss. However, potassium-sparing diuretics, hypoaldosteronism, urinary tract obstruction, and type IV renal tubular acidosis result in loss of $[\text{HCO}_3^-]$ with retention of $[\text{K}^+]$ (Table 25-3).

One should be wary of the traditional classification based on K^+ , because serum $[\text{K}^+]$ itself is dependent on the actual pH. Thus, in severe acidosis, a normal range $[\text{K}^+]$ may be deceiving unless the clinician corrects for the degree of acidosis.

Because all diuretics have a tendency to result in mild contraction alkalosis, the metabolic acidosis that occurs simultaneously with potassium-sparing diuretics may not be evident, as the two distinct physiologic processes may simply cancel each other out (see Figure 25-2C). Because the AG is unchanged, there is no clue that two opposed processes may be occurring.

Acetazolamide exerts its effect through carbonic anhydrase inhibition, inducing a functional RTA.

Physiologic Consequences of Acidosis

Acidemia has numerous negative physiologic consequences that impair the function of many different organs through mechanisms not yet well understood. Cardiac contractile function is reduced, probably due to impaired oxidative phosphorylation, intracellular acidosis, and alterations in intracellular calcium concentration. The threshold for ventricular fibrillation falls, whereas the defibrillation threshold rises. Hepatic and renal perfusion and systemic blood pressure decline, whereas pulmonary vascular resistance increases. The physiologic effects of catecholamines are attenuated, and, when acidosis is sufficiently severe, vascular collapse may result. A catabolic state develops, including a generalized increase in metabolism, resistance to insulin, and inhibition of anaerobic glycolysis. The effect of hypoxia on all organs is aggravated.¹⁵

Treatment

The treatment of acidosis reflects that of the underlying disorder but particularly emphasizes restoration of normal tissue perfusion and oxygenation. The most important step is to determine whether there is a respiratory component to the acidosis (i.e., a primary respiratory acidosis), because the treatment approach differs. If there is inadequate respiratory compensation, the most appropriate treatment will be to first correct the respiratory problem.

Buffer Therapy in Acidosis

The adverse effects of acidemia make the concept of buffer therapy teleologically appealing, but the role of buffer therapy in cardiac arrest

TABLE 25-3 Causes of Normal Anion Gap Metabolic Acidosis

With a tendency to hyperkalemia	With a tendency to hypokalemia
Subsiding diabetic ketoacidosis	Renal tubular acidosis, type I (classical distal acidosis)
Early uremic acidosis	Renal tubular acidosis, type II (proximal acidosis)
Early obstructive uropathy	Acetazolamide
Renal tubular acidosis, type IV	Acute diarrhea with losses of $[\text{HCO}_3^-]$ and $[\text{K}^+]$
Hypoaldosteronism (Addison disease)	Ureterosigmoidostomy with increased resorption of $[\text{H}^+]$ and $[\text{Cl}^-]$ and losses of $[\text{HCO}_3^-]$ and $[\text{K}^+]$
Infusion or ingestion of HCl , NH_4Cl , lysine-HCl, or arginine-HCl	Obstruction of artificial ileal bladder
Potassium-sparing diuretics	Dilution acidosis

and severe metabolic acidosis is uncertain. The traditional therapeutic buffer, sodium bicarbonate, may have negative effects in the treatment of acidosis. Bicarbonate therapy results in the generation of significant quantities of CO_2 , which diffuses readily into cells, in particular those of the central nervous system, and therefore may cause paradoxical worsening of intracellular acidosis. An abrupt CO_2 load also may exceed the ventilatory capacity of a maximally ventilating patient, thereby producing abrupt or worsening respiratory failure. After successful treatment with bicarbonate, "overshoot" alkalosis may result. Bicarbonate therapy imposes an osmotic and sodium load (1000 mEq/L of typical IN solution). These concerns suggest that bicarbonate therapy should not be used in the ED treatment of mild to moderate metabolic acidosis.

Kraut and Kurtz recently reviewed the literature concerning buffer therapy in cardiac arrest, diabetic ketoacidosis, and lactic acidosis.¹⁶ Several studies of HCO_3^- use (adult and pediatric, including patients with severe acidosis) failed to show any improvement in speed of recovery or complication rates with buffer therapy. However, it remains unclear whether certain subgroups of patients, for example, those with cardiac or other disease, may benefit from bicarbonate therapy in DKA.

Similarly, a review of studies of HCO_3^- use suggested that patients with mild lactic acidosis derive no mortality benefit from bicarbonate therapy, and such patients who also have severe cardiac disease may actually suffer deleterious effects. However, patients with severe acidosis demonstrated a mortality benefit when treated with "large" doses of bicarbonate and concomitant dialysis. The goal of high-dose bicarbonate and dialysis therapy in lactic acidosis may be to "bridge" the patient physiologically to definitive treatment of the etiology of the acidosis. Bicarbonate therapy seems reasonable, therefore, in situations in which the effects of lactic acidosis are so severe that they preclude or jeopardize therapy for the underlying disease (Table 25-4).

When $[\text{HCO}_3^-]$ is used, Adroque and Madias¹⁵ recommended administering $[\text{HCO}_3^-]$, 0.5 mEq/kg, for each milliequivalent per liter desired rise in $[\text{HCO}_3^-]$. The goal is to restore adequate buffer capacity ($[\text{HCO}_3^-] > 8$ mEq/L) or achieve clinical improvement in shock or dysrhythmias. Bicarbonate should be given as slowly as the clinical situation permits; 75 mL of 8.4 percent sodium bicarbonate in 500 mL of D5W produces a nearly isotonic solution for infusion. Adequate time should be allowed for the desired effect to be achieved, and close monitoring of acid-base balance, especially in patients with organic acidosis, is critical.

Newer buffers appear to show promise in the treatment of metabolic acidosis. Carbicarb, an equimolar solution of sodium bicarbonate and sodium carbonate $[\text{CO}_3^{2-}]$, produces significantly less CO_2 than an equimolar dose of bicarbonate. The carbonate ion, a strong base, combines avidly with protons to form bicarbonate, resulting in increased pH, an increased $[\text{HCO}_3^-]$, and limited CO_2 production. Clinical stud-

ies of Carbicarb use in lactic acidosis models have shown improvements in pH with little or no change in Pco_2 .^{17,18} Trials of Carbicarb therapy in cardiac arrest have yielded equivocal results. Thus, Carbicarb, although a promising agent for buffer therapy, remains experimental. Tris-hydroxymethyl amino-methane (THAM), an inert amino acid, has been studied as a buffer; its promise resides in its pK_a (at 7.8, THAM should be a more effective buffer than HCO_3^-) and its ability to penetrate cells (in reducing intracellular Pco_2). Limited studies, generally not in humans, have suggested that THAM provides salutary pH and Pco_2 changes when given in metabolic acidosis. However, information about its effects in humans and its role in treatment is still developing, and THAM is at present an experimental agent.

METABOLIC ALKALOSIS

Metabolic alkalosis is typically classified as chloride-sensitive and chloride-insensitive, thus indicating the treatment approach. Metabolic alkalosis results from gain of bicarbonate or loss of acid. The relation of metabolic alkalosis to chloride balance defines pathophysiologic features of the disease and its therapy. Bicarbonate and chloride represent the major serum anions whose concentrations may be readily altered, and their homeostasis is therefore closely intertwined.

Conditions that produce chloride loss, such as vomiting (which also produces acid loss), diarrhea, diuretic therapy, and chloride-wasting diseases (e.g., cystic fibrosis and chloride-wasting enteropathy) tend to reduce serum chloride concentration and extracellular volume. The reduction in extracellular volume increases mineralocorticoid activity, which enhances sodium reabsorption and potassium and hydrogen ion secretion in the distal tubule, which in turn enhance bicarbonate generation. The resulting increase in serum $[\text{HCO}_3^-]$ eventually exceeds the tubule's maximum ability to reabsorb filtered bicarbonate. The resulting alkaline urine, because its anionic content is mostly bicarbonate, is largely free of chloride (<10 mEq/L), although the urine chloride may be normal after diuretics have been administered. The result is hypokalemic, hypochloremic alkalosis that responds to normal saline (chloride-responsive alkalosis).

Other diseases that cause metabolic alkalosis are usually associated with normovolemia or hypervolemia and often hypertension. These diseases usually cause excess mineralocorticoid activity, resulting in the same pathophysiologic cascade described above. However, the excess mineralocorticoid activity is not associated with hypovolemia, so the urine chloride is generally normal or elevated (>10 mEq/L) and the alkalosis cannot be reversed with normal saline. Diseases producing "chloride-unresponsive alkalosis" and hypertension include renal artery stenosis, renin-secreting tumors, adrenal hyperplasia, hyperaldosteronism, Cushing syndrome, Liddle syndrome, and exogenous mineralocorticoids (e.g., licorice, fludrocortisone). Chloride-unresponsive alkalosis caused by Bartter and Gitelman syndromes usually is associated with normotension.

The compensation for metabolic alkalosis involves reduction in alveolar ventilation, but the exact relation between Pco_2 and $[\text{H}^+]$ is not well established. Most studies to date have been conducted in dialysis patients or patients with conditions that predispose to alveolar hypoventilation (e.g., sepsis, pneumonia). As a guideline, Pco_2 in patients with significant metabolic alkalosis should rise 0.7 mm Hg for each milliequivalent increase in $[\text{HCO}_3^-]$. The Pco_2 also rarely rises above 55 mm Hg in compensation for metabolic alkalosis.

Consequences of Alkalosis

The physiologic effects of alkalemia are substantial. Neurologic abnormalities, especially tetany, neuromuscular instability, and seizures, are common. Reduction in $[\text{H}^+]$ results in reductions in ionized calcium, potassium, magnesium, and phosphate levels. Constriction of arterioles occurs, resulting in reduced coronary and cerebral blood flow. Refractory dysrhythmias may develop.¹⁵ Alkalemia may be of

TABLE 25-4 Indications for Bicarbonate Therapy in Metabolic Acidosis

Indication	Rationale
Severe hypobicarbonatemia (<4 mEq/L)	Insufficient buffer concentrations may lead to extreme increases in acidemia with small increases in acidosis
Severe acidemia (pH <7.20) with signs of shock or myocardial irritability that is not rapidly responsive to supportive measures	Therapy for the underlying cause of acidosis depends upon adequate organ perfusion
Severe hyperchloremic acidemia*	Lost bicarbonate must be regenerated by kidneys and liver, which may require days

*No specific threshold indication by pH exists. The presence of serious hemo-dynamic insufficiency despite supportive care should guide the use of bicarbonate therapy for this indication.

particular concern in patients with chronic obstructive pulmonary disease (COPD), because of the shift of the oxygen hemoglobin to the left, making O₂ less available to the tissues. Many such patients are taking diuretics, which lead to a contraction alkalosis. Also, the alkalemic environment tends to depress ventilatory drive further.

Treatment

Therapy of alkalemia, as with all acid-base disorders, emphasizes treatment of the underlying cause and careful supportive care. Acetazolamide produces significant bicarbonaturia and is effective in the treatment of metabolic alkalosis, but its use requires very careful monitoring of potassium, magnesium, and phosphate concentrations. If alkalosis is severe ($[\text{HCO}_3^-] > 45 \text{ mmol/L}$) and associated with serious signs or symptoms not responsive to supportive care, the use of intravenous hydrochloric acid should be considered. A 0.1 normal solution (100 mmol/L), infused at no more than 0.2 mmol/kg per h through a central venous catheter is used; higher concentrations may degrade the catheter material.¹⁹ The dose is calculated as shown in Eq. (8), with the result in millimoles of bicarbonate.

$$\text{Dose} = (A[\text{HCO}_3^-])(\text{weight, in kg})(0.5) \quad (8)$$

RESPIRATORY ACIDOSIS

Respiratory acidosis is defined by alveolar hypoventilation and is diagnosed when the Pco₂ is greater than the expected value. Acute respiratory acidosis may have origins in other conditions, such as increased CO₂ production (high-glucose diet) and abnormal gas exchange (e.g., pneumonia). However, the final common path is inadequate ventilation.

Inadequate minute ventilation is most frequently due to head trauma, chest trauma, lung disease or excess sedation. The chronic hypoventilation seen in extremely obese patients is often referred to as the *pickwickian syndrome*, after an obese character in Charles Dickens' *Pickwick Papers*. Patients with severe COPD have increased dead space and frequently also have a decreased minute ventilation.

In general, a rise in the Pco₂ stimulates the respiratory center to increase respiratory rate and minute ventilation. However, if the arterial Pco₂ chronically exceeds 60 to 70 mm Hg, as may occur in 5 to 10 percent of patients with severe emphysema, the respiratory acidosis may depress the respiratory center. Under such circumstances, the stimulus for ventilation is provided primarily by hypoxemia acting on chemoreceptors in the carotid and aortic bodies. Giving oxygen could remove the main stimulus to breathe, causing the Pco₂ to rise abruptly to extremely dangerous levels. Consequently, one should not administer oxygen to patients with COPD without carefully watching for the development of apnea or hypoventilation.

Evaluation of ventilation requires attention to several important clinical issues. First, the ventilation that would be expected based on assessment of the respiratory rate and depth should be compared with

the actual ventilation of the patient (i.e., Pco₂). A "normal" Pco₂ of 40 mm Hg in a tachypneic, dyspneic patient likely reflects significant ventilatory insufficiency. Second, the impact of respiratory acidosis on partial pressure of oxygen in the alveoli (PAO₂) in such a patient may be considerable. The alveolar gas equation suggests that, if inspired oxygen concentration and respiratory quotient do not change, increases in Pco₂ will result in reductions in PAO₂.

The relation of Pco₂ to hydrogen ion concentration in acute respiratory acidosis is suggested by the Kassirer-Bleich equation shown in Eq. (9):

$$A[\text{H}^+] = 0.8(\text{APco}_2) \quad (9)$$

Each 1-mm Hg increase in Pco₂ results in a 1-mmol increase in $[\text{H}^+]$. Across the linear portion of the pH-hydrogen ion concentration relationship, each 1-mmHg increase in Pco₂ should theoretically produce a 0.01 decrease in pH. The actual relation between changes in Pco₂ (up to values of 90 mm Hg) and changes in $[\text{H}^+]$ determined in normal humans is about 8 to 10, as shown in Eq. (9). Thus, a 10-mm Hg increment in Pco₂ produces an 8-mmol increase in $[\text{H}^+]$, with little change in bicarbonate concentration (usually 1 mEq/L) or urinary acid excretion.²⁰ If the $[\text{H}^+]$ is higher or lower than that suggested by the change in the Pco₂, a mixed disorder is present.

The adaptation to chronic respiratory acidosis is complex. Over time, chronic elevation of Pco₂ reduces carotid sinus sensitivity to hypercapnia; ventilatory drive is then controlled by PAO₂. The acidosis results in significant increases in renal HCO₃⁻ generation and avid reclamation of filtered HCO₃⁻. The relation between $[\text{H}^+]$ and $[\text{HCO}_3^-]$ in chronic respiratory acidosis at steady state, derived from studies in humans, is shown in Eq. (10).

$$A[\text{H}^+] = 0.3(\text{APco}_2) \quad (10)$$

It is rarely certain during a given clinical encounter whether a patient has an acute respiratory acidosis, a chronic respiratory acidosis, or a mixed disorder. Evaluation of the acid-base status in such circumstances does not require "baseline" ABG values. Instead, the change in $[\text{H}^+]$ is compared with the change in Pco₂. If this ratio is 0.3, the patient has a chronic respiratory acidosis; if it is 0.8, the patient has an acute respiratory acidosis. States resulting in other ratios suggest a mixed acid-base disturbance, as shown in Table 25-5.

Treatment of respiratory acidosis is designed primarily to improve alveolar ventilation. In general, if the minute ventilation is doubled, the Pco₂ will be reduced by 50 percent. In patients with COPD, bronchodilators such as (3-agonists, anticholinergics, or systemic sympathomimetic agents, with careful administration of small amounts of oxygen, may substantially improve ventilation. However, ventilatory assistance (intubation or noninvasive ventilatory support) may be required in some patients who do not respond adequately to lesser measures, particularly if the pH falls below 7.25.

In patients with a chronic respiratory acidosis, reduction of the Pco₂ should generally proceed slowly. The minute ventilation for a 70-kg person is normally about 6 L/min; in COPD patients, it may be

TABL 25-5 Evaluation of Acid-Base Status in Respiratory Acidosis

RATIO = $A[\text{H}^+]/\text{APco}_2$				
Ratio < 0.3	Ratio = 0.3	0.3 < Ratio < 0.8	Ratio = 0.8	Ratio > 0.8
Change in hydrogen ion concentration is less than accounted for by chronic change in Pco ₂ . Metabolic alkalosis is also present.	Change in hydrogen ion concentration matches chronic change in Pco ₂ . Chronic respiratory acidosis is present.	Change in hydrogen ion concentration is larger than accounted for by chronic change in Pco ₂ . Chronic respiratory acidosis plus either acute respiratory alkalosis or metabolic acidosis is present; examine pH.	Change in hydrogen ion concentration matches acute change in Pco ₂ . Acute respiratory acidosis is present.	Change in hydrogen ion concentration is larger than accounted for by acute or chronic change in Pco ₂ . Metabolic acidosis is also present.

Abbreviation: Pco₂ = partial pressure of carbon dioxide.

less than 4 L/min. It is beyond the scope of this chapter to discuss in detail the approach to management of a patient with COPD and severe hypercarbia. If treatment is indicated in the ED, it may be wise to start with a minute ventilation of about 5 L/min and then gradually increase it according to the clinical response and changes in P_{CO_2} .

In patients with a chronic respiratory acidosis, the arterial P_{CO_2} should not be reduced by more than 5.0 mm Hg/h. Rapid correction of a chronic respiratory acidosis can cause sudden development of a severe combined metabolic and respiratory alkalosis with resulting dysrhythmias. A rapid rise in pH can cause an abrupt fall in ionized calcium and in hypokalemia. Both may cause dangerous dysrhythmias or seizures.

RESPIRATORY ALKALOSIS

Respiratory alkalosis is defined by alveolar hyperventilation and exists when P_{CO_2} is less than expected. It is caused by conditions that stimulate respiratory centers, including central nervous system tumors or stroke, infections, pregnancy, hypoxia, and toxins (e.g., salicylates). Anxiety, pain, and iatrogenic overventilation of patients on mechanical ventilators also cause respiratory alkalosis.

Whatever the etiology, the clinical symptoms of acute respiratory alkalosis are predictable from its physiologic effects. Acute reduction in P_{CO_2} produces a reduction in $[\text{H}^+]$, resulting in an increase in negative charge on anionic buffers. The now relatively negatively charged proteins instead bind calcium, and, if sufficient, the reduction in ionized calcium produces carpopedal spasm and paresthesias.¹⁵ Hypocapnia also produces substantial reductions in cerebral blood flow and results in reduced tissue oxygen delivery due to a leftward shift in the oxygen-hemoglobin dissociation curve (i.e., increased hemoglobin oxygen binding).

The theoretical relationship of $[\text{H}^+]$ and P_{CO_2} predicted by the Kassirer-Bleich equation is that a 1-mmol decrease in $[\text{H}^+]$ results from each 1-mm Hg reduction in P_{CO_2} . The actual observed relationship is very close to that predicted by the Kassirer-Bleich equation.²¹ Each millimeter of mercury reduction in P_{CO_2} results in a 0.75-mmol reduction in $[\text{H}^+]$ (Eq. II).²¹

$$A[\text{H}^+] = 0.75(\Delta P_{\text{CO}_2}) \quad (11)$$

Chronic respiratory alkalosis is unique among the acid-base disorders in that its compensation may be complete. Compensatory events include bicarbonaturia and a reduction in acid excretion, requiring 6 to 72 h to develop fully and at least 1 week to normalize pH. The steady-state relationship between $[\text{H}^+]$ and P_{CO_2} in chronic respiratory alkalosis observed in normal human subjects at high altitude is shown in Eq. (12).²²

$$A[\text{H}^+] = 0.4(\Delta P_{\text{CO}_2}) \quad (12)$$

Therapy for acute respiratory alkalosis emphasizes identification and treatment of the underlying cause. The use of paper-bag rebreathing in the treatment of respiratory alkalosis should be avoided. Callahan evaluated paper-bag rebreathing in voluntarily hyperventilating volunteers and found that, although the inspired P_{CO_2} increased by 20 mm Hg in 30 s, it never increased above 40 mm Hg. However, inspired oxygen concentration decreased by an average of 27 mm Hg in 180 s, and in 5 percent of subjects the decrease was greater than or equal to 42 mm Hg.²³ If the cause of hyperventilation is actually cellular hypoxia, such a decrease could be catastrophic.²⁴ Further, there is evidence that expectation of efficacy and suggestion, rather than elevations, of inspired CO_2 tension are responsible for relief of symptoms in hyperventilation.²⁵ An oxygen mask might provide benefits similar to those of paper-bag rebreathing with less risk of hypoxia.

Chronic respiratory alkalosis is seen at high altitudes, in particular among mountaineers climbing over 3700 m (12,000 ft) (where the partial pressure of O_2 is significantly diminished). Acetazolamide is frequently prescribed to counter the physiologic respiratory effects of such ascents.

CLINICAL APPROACH TO ACID-BASE PROBLEMS AND MIXED ACID-BASE DISTURBANCES

The evaluation of an acid-base problem begins with a history and physical examination, with particular attention to sources of acid or alkali gain or loss and to diseases that affect renal, hepatic, or pulmonary function. Blood should be obtained for gas analysis and electrolyte determination, and the AG should be calculated. Blood gas results should be checked for internal consistency with the Henderson-Hasselbalch or Kassirer-Bleich equation [Eq. (1) or (2)].

In metabolic acidosis, where the respiratory response appears clinically appropriate, the P_{CO_2} and pH can be predicted. Thus, one ABG to prove there is no abnormal respiratory component may be sufficient, and further evaluation can be determined from serum (venous) $[\text{HCO}_3^-]$ alone. For example, when the $[\text{HCO}_3^-]$ is 15, the expected physiologic respiratory compensatory response is expected to be a decline in P_{CO_2} equal to the decline in $[\text{HCO}_3^-]$, i.e., in this scenario, 30 mm Hg. The values for known $[\text{HCO}_3^-]$ and predicted P_{CO_2} can then be inserted in the Kassirer-Bleich equation shown in Eq. (2) to determine the $[\text{H}^+]$, which in this case is calculated to be about 48. The $[\text{H}^+]$ can then be related to the corresponding pH, which is close to linear for values from 22 to 55 nmol/L, in this case, about 7.32.

Methodical interpretation of laboratory results followed by correlation with the clinical scenario are necessary to prevent erroneous acid-base evaluation. Although we suggest one method that has worked well for us, the particular method used matters less than the consistency of its application. However, **reliance on "acid-base disturbance maps" is discouraged.** First, they may be misleading, particularly when there is more than one primary disturbance. Second, they offer no understanding of the processes. Without an understanding of the complex but not difficult to master concepts of interrelationships in acid-base balance, the clinician misses diagnoses and has little understanding of the appropriate approach to therapy. As long as the method selected reflects the acid-base relationships presented in this chapter, the result should be the same. One suggested method follows:

1. Look at the pH. If it is decreased, the primary or predominant disturbance is acidosis. If the pH is increased, the predominant disturbance is alkalosis.
2. If the pH indicates acidosis, the primary (or predominant) mechanism can be ascertained by examining the $[\text{HCO}_3^-]$ and P_{CO_2} (see Figure 25-2A).
 - a. If the $[\text{HCO}_3^-]$ is low (implying a primary metabolic acidosis), then the AG should be examined and, if possible, compared with a known steady-state value.
 - i. If the AG is increased compared with the known previous value or is greater than 15, then by definition a wide-AG metabolic acidosis is present, and the absolute change in the AG should be compared with the absolute change in the $[\text{HCO}_3^-]$ from normal, ii. If the AG is unchanged, then the disturbance is (non-widened) *unchanged AG* or *hyperchloremic* metabolic acidosis. iii. If the change in the AG is equal to the change in the $[\text{HCO}_3^-]$, then the wide AG-acidosis is termed *pure*. If the AG has risen more than the $[\text{HCO}_3^-]$ has decreased, then there is also likely to be a concomitant metabolic alkalosis. If the change in the AG is less than the change in the $[\text{HCO}_3^-]$, then a non-AG acidosis is also present. (This is a difficult concept, but two separate physiologic mechanisms resulting in increased $[\text{H}^+]$ can occur simultaneously.) Next examine whether the ventilatory response is appropriate.
 - (1) If the decrease in the P_{CO_2} equals the decrease in the $[\text{HCO}_3^-]$, there is appropriate respiratory compensation. Note that the pH will not return to normal.
 - (2) If the decrease in the P_{CO_2} is greater than the decrease in the $[\text{HCO}_3^-]$, there is a concomitant respiratory alkalosis. (Although there are other formulas for this comparison, this is the simplest, as explained earlier in the text.)

- (3) If the decrease in the P_{CO_2} is less than the decrease in $[HCO_3^-]$, there is also a concomitant respiratory acidosis. b. If the P_{CO_2} is elevated (rather than the $[HCO_3^-]$ being decreased), the primary disturbance is respiratory acidosis (see Figure 25-2A). The next step is to determine which type it is by examining the ratio of (i.e., the change in) $[H^+]$ to (the upward change in) the P_{CO_2} .
- If the ratio is 0.8, it is considered acute.
 - If the ratio is 0.33, it is considered chronic.
 - If the ratio is between 0.8 and 0.33, it is probably an acute exacerbation of the chronic condition.
 - If the ratio is greater than 0.8, there must be a metabolic explanation for the excess $[H^+]$.
 - If the ratio is less than 0.33, a metabolic alkalosis must also be present.
3. If the pH is greater than 7.45, the primary or predominant disturbance is alkalosis (see Figure 25-2B).
- It is best to look at the $[HCO_3^-]$ first. If it is elevated, there is a primary metabolic alkalosis. There is an expected ventilatory response, although it is quite varied. The ratio of the change upward in P_{CO_2} to the change upward in $[HCO_3^-]$ can be examined. If the ratio is much less than 0.7, there is also a respiratory alkalosis (in addition to the metabolic alkalosis). If the ratio is more or less 0.7, this is likely to be a compensatory ventilatory response. If the ratio is well above 0.7, respiratory acidosis is concomitantly present.
 - If the P_{CO_2} is low, there is a primary respiratory alkalosis, and the ratio of the change in $[H^+]$ to the change in P_{CO_2} should be examined. Acute respiratory alkalosis has a ratio of about 0.75. If the ratio is well above 0.75, there is probably also a concomitant metabolic alkalosis to explain the greater than expected decline in $[H^+]$. If the ratio is smaller, the condition is chronic or there may also be a metabolic acidosis component.
4. Every ABG that shows no or minimal pH derangement should still call for examination of the P_{CO_2} , $[HCO_3^-]$, and the AG, because there may well be a mixed acid-base disturbance (see Figure 25-2C). It is quite possible for the pH, $[HCO_3^-]$, and P_{CO_2} to be normal and yet have significant acid-base disturbances. The only evident abnormality may be the AG. Take the example of an $[Na^+]$ of 145, $[Cl^-]$ of 97, $[K^+]$ of 4.5, and $[HCO_3^-]$ of 25 and a normal ABG. All the numbers look reasonably normal. However, the AG is 23, so by definition there must be a wide-AG metabolic acidosis. The only explanation for the normal numbers is a concomitant metabolic alkalosis.

Human lungs serve two distinct functions: ventilation and oxygenation. Ventilation, which determines the clearance of carbon dioxide from the body, is a function of the rate and depth of breathing. Oxygenation is the diffusion of oxygen from the lungs to the bloodstream for subsequent delivery to the tissues. The separation between oxygenation and ventilation is dramatically demonstrated by the apnea test for determining brain death. During this test, 100 percent oxygen is insufflated via a thin catheter placed near the carina in an apneic, unventilated patient. The peripheral oxygen saturation is 90 to 100 percent despite no clearance of carbon dioxide with severe respiratory acidosis. This distinction should be considered when managing patients who are receiving mechanical ventilation.

VENTILATION

Minute Ventilation

Minute ventilation (VM), the total amount of new air moved in and out of the airways and lungs each minute, is equal to the tidal volume (VT) multiplied by the respiratory rate (f).

$$VM = VT \times f \quad (1)$$

SECTION 3 • RESUSCITATIVE PROBLEMS AND TECHNIQUES

The normal V_T is about 7 mL/kg, or 500 mL in an adult, and the normal f is 12 breaths per minute. Therefore, the normal minute ventilatory volume required to maintain a partial pressure of carbon dioxide (P_{CO_2}) of 40 mm Hg averages about 6 L/min. However, the V_M required to maintain a normal P_{CO_2} depends on the amount of CO_2 being produced and the amount of dead space in the lung. People who are exercising or patients who are febrile or hypermetabolic have increased CO_2 production and thus an increased V_M that can be greater than 20 L/min, while patients who are severely hypothermic may have decreased CO_2 production and thus a decreased V_M . A V_M less than 2 L/min, even in a hypothermic patient, leads to respiratory acidosis. The f occasionally rises to as high as 40 to 50 breaths per minute, and the V_T can become almost as great as the forced vital capacity, which is about 4500 to 5000 mL, or 65 to 70 mL/kg in a young adult male. However, a person usually cannot sustain a V_T greater than 40 percent of the vital capacity for more than a few hours.

Dead Space

Approximately 30 percent of the air that a person breathes does not participate in alveolar gas exchange and is thus called dead space ventilation (V_{DS}). Dead space ventilation is made up of anatomic dead space and alveolar dead space. Anatomic dead space is the volume of air that fills the conducting airways (trachea, bronchi, and bronchioles). Alveolar dead space, or high ventilation-perfusion (V/Q) mismatch, occurs when ventilation of an alveolar-capillary unit is normal but perfusion of the alveolar capillary is absent. The combination of alveolar and anatomic dead space is called the physiologic dead space, which is about 30 percent of the V_T or 150 mL (about 2 mL/kg) in a young male adult with a V_T of 500 mL. The normal ratio between dead (V_{DS}) space ventilation and tidal volume (V_T), V_{DS}/V_T , is 0.3.

When the physiologic dead space is increased, some of the work of ventilation is wasted because a greater fraction of ventilated air never reaches the functional alveolar-capillary units to exchange gas. Certain disease states, such as acute respiratory distress syndrome (ARDS) and chronic obstructive pulmonary disease (COPD), may have an increase in the physiologic dead space that can exceed 60 percent of the V_T . The increased dead space requires a tremendous increase in the V_M (usually by an increase in f) to prevent the development of respiratory acidosis. A patient with a dead space ratio greater than 0.6 generally requires mechanical ventilation to maintain a normal P_{aCO_2} .

Alveolar Ventilation

The main function of the pulmonary ventilatory system is to continually renew the air in the alveoli, where it is brought into close proximity to the pulmonary capillary blood. The rate at which new air reaches these areas is called alveolar ventilation (V_A):

$$(V_A) = V_M - V_{DS} \quad (2)$$

Consider a patient with myasthenia gravis who is developing progressive respiratory failure. The patient's baseline V_A is V_M ($500 \times 12 = 6$ L/min) - V_{DS} ($150 \times 12 = 1.8$ L/min) = V_A (4.2 L/min). If the patient's V_T is decreased to 250 due to weakness, the patient cannot simply double f , but must increase it almost four times, to 42 breaths per minute [$(250 \times 42 = 10.5$ L/min) - $(150 \times 42 = 6.3$ L/min) = 4.2 L/min], to maintain the same alveolar ventilation. An increased f increases the patient's work of breathing, which in and of itself generates increased CO_2 and may lead to respiratory failure.

DIFFUSION OF GASES

Factors Affecting the Rate of Gas Diffusion

Rate of gas diffusion in a fluid is directly related to (1) the partial pressure of the gas, (2) the solubility of the gas in the fluid, (3) the surface

area available for diffusion, and inversely related to (4) the distance through which the gas must diffuse, and (5) the molecular weight of the gas. All these factors can be expressed in a single formula:

$$D = \quad (3)$$

Where D = diffusion rate

P = pressure difference between the two ends of the diffusion pathway

A = cross-section area of the pathway S

= solubility of the gas d = distance of

diffusion MW = molecular weight of the gas

The solubility coefficient at body temperature for oxygen is 0.024; for carbon dioxide, 0.57; for carbon monoxide, 0.018; and for nitrogen, 0.012. Thus carbon dioxide is more than 20 times as soluble as oxygen, and oxygen is twice as soluble as nitrogen. The solubility helps to determine the quantity of gas dissolved in the fluids of the body, which is a major factor in determining the rate at which the gas can diffuse through tissues.

The characteristics of a gas determine its solubility and molecular weight, which determine the diffusion coefficient of the gas. The diffusion coefficient, which equals S/MW , determines the relative rates at which different gases at the same pressure will diffuse. If the diffusion coefficient of oxygen is 1.0, the relative diffusion coefficients of other gases of respiratory importance are carbon dioxide, 20.3; carbon monoxide, 0.81; nitrogen, 0.53; and helium, 0.95.

Oxygen, carbon dioxide, and nitrogen are all highly soluble in lipids and consequently are also highly soluble in cell membranes. The major limitation to the movement of these gases in tissues is the rate at which the gases can diffuse through the tissue water, an important consideration in pulmonary edema.

For oxygen (or any other gas) to move from the alveolus into the pulmonary capillary bed, it must pass through four separate layers, referred to collectively as the alveolar-capillary, or respiratory, membrane. These layers include (1) a layer of fluid, called alveolar fluid, lining the alveolus and containing surfactant that reduces its surface tension; (2) the alveolar epithelium, composed of very thin epithelial cells and a basement membrane; (3) a very thin interstitial space between the alveolar epithelium and the capillary membrane; and (4) the capillary endothelial membrane and its basement membrane, which fuses with the alveolar basement membrane in many places.

The average diameter of the pulmonary capillaries is less than 0.8 microns, which means that red blood cells must actually squeeze through them. Therefore at least part of the red blood cell membrane touches the capillary wall. Where this occurs, oxygen does not have to pass through significant amounts of plasma as it diffuses from the alveolus to the red blood cell. This reduces the diffusion distance and thus increases the rapidity of diffusion of gases between the alveolus and the hemoglobin molecules.

Diffusion Through the Respiratory Membrane

The total diffusing surface area of the lung is enormous (160 m²) and very thin (averaging 0.63 mm). These characteristics, combined with the solubility of CO_2 and O_2 , make the lungs very efficient for maximizing gas exchange. The factors that determine how rapidly a gas passes through the respiratory membrane are (1) the thickness of the membrane, (2) the surface area of the membrane, (3) the diffusion coefficient of the gas in the water of the membrane, and (4) the pressure difference between the two sides of the membrane.

Thickness of the membrane is rarely a significant impediment to the transfer of CO_2 , but O_2 , being 20 times less soluble than CO_2 , can be affected by processes that increase the diffusion distance. Two common clinical entities that increase the diffusion distance are pulmonary

edema and pulmonary fibrosis, which explains the common finding of hypoxemia (but not always hypercarbia) in patients with congestive heart failure. Another example of how the factors that determine gas diffusion can be applied clinically is the treatment of carbon monoxide poisoning with 100 percent oxygen, or hyperbaric oxygen. These therapies increase the pressure difference between the two sides of the alveolar capillary membrane and thus facilitate oxygen loading.

The surface area of the respiratory membrane may be greatly decreased by a variety of conditions, such as atelectasis, resection of lung tissue, or emphysema. When the total surface area of the lung is decreased to approximately one-third to one-fourth normal as may be seen with emphysema, exchange of gases through the membrane is impeded significantly. During strenuous exercise, even the slightest increase in dead space in patients with severe emphysema can seriously interfere with gas exchange.

The pressure difference across the respiratory membrane is the difference between the partial pressure of the gas in the alveoli and the partial pressure of the gas in the blood. In room air, the normal difference between the partial pressure of alveolar oxygen (PAO₂) and the partial pressure of arterial oxygen (PaO₂), (PAO₂ — PaO₂), or [P(A — a)O₂], is 2 to 10 mm Hg. The normal difference between the partial pressure of alveolar carbon dioxide (PACO₂) and the partial pressure of arterial carbon dioxide (Paco₂), (PACO₂ - Paco₂), or [P(A - a)CO₂], is zero. An increase in the P(A — a)CO₂ is due to an increase in dead space. The dead space air does not participate in gas exchange and thus dilutes the alveolar CO₂.

ALVEOLAR GASES

Inspired Gases

Air at sea level has an average barometric pressure of 760 mm Hg and contains approximately 21 percent oxygen and 0.04 percent carbon dioxide, with nitrogen making up most of the remainder. Thus the partial pressures of oxygen and carbon dioxide in the air at sea level are 159 and 0.3 mm Hg, respectively (Table 26-1).

Alveolar air does not have the same concentration of gases as atmospheric air. The reasons for the difference include the following: (1) dry atmospheric air that enters the respiratory passages is humidified before it reaches the alveoli; (2) alveolar air is only partially replaced by atmospheric air with each breath; (3) oxygen is constantly being absorbed from the alveolar air; and (4) carbon dioxide is constantly diffusing from the pulmonary blood into the alveoli.

Humidification of Inspired Air

When air enters the respiratory passageways, water immediately evaporates from the surfaces of these passages and humidifies the inhaled air. At 37°C (98.6°F), water has a vapor pressure of 47 mm Hg (regardless of barometric pressure). This partial pressure is designated PH₂O and must be subtracted from atmospheric pressure (760 mm Hg) prior to calculation of the partial pressures of the dry gases in the alveoli

olus (760 — 47 = 713). The remaining gases are predominantly nitrogen (79 percent, or 563 mm Hg), oxygen (21 percent, or 149 mm Hg), and CO₂ (0.04 percent, or 0.3 mm Hg) (Table 26-1). If the patient is breathing 60 percent oxygen, the inspired oxygen pressure (Pio₂) in the trachea or bronchi is determined by the fraction of inspired oxygen (Fio₂) as follows:

$$P_{iO_2} = (P_B - P_{H_2O}) F_{iO_2} = 427.8 \text{ mm Hg} \quad (4)$$

where PB is barometric pressure (assumed to be 760 mm Hg at sea level).

Rate at Which Alveolar Air Is Renewed by Atmospheric Air

The functional residual capacity of the lungs, which is the amount of air remaining in the lungs at the end of normal expiration, is approximately 2500 to 3000 mL (35 to 45 mL/kg). Only 350 mL of new air is brought into the alveoli with each new VT and the same amount of old alveolar air is expired.

The slow replacement of alveolar air helps prevent sudden changes in gas concentrations in the blood. This helps to prevent excessive changes in tissue oxygenation, tissue carbon dioxide concentration, and tissue pH when ventilation is temporarily interrupted. This is also the basis for preoxygenation of patients prior to elective intubation, which could be more accurately described as denitrogenation, or replacing the alveolar nitrogen with oxygen.

Oxygen Concentration and Partial Pressure in the Alveoli

Oxygen is continually being absorbed into the blood in the alveolar capillaries, and new oxygen is continually entering the alveoli from the atmosphere. The more rapidly oxygen is absorbed, the lower its concentration in the alveoli. The more rapidly new oxygen is brought into the alveoli from the atmosphere, the higher its concentration becomes. Therefore, oxygen concentration in the alveoli is controlled by the rate of absorption of oxygen into the blood and the rate of entry of new oxygen into the lung.

Carbon Dioxide Concentration in the Alveoli

Carbon dioxide is continually formed and discharged into the alveoli and continually removed from the alveoli by ventilation. Therefore, the two factors that determine the PACO₂ are (1) the rate of diffusion of carbon dioxide from the blood into the alveoli and (2) the rate at which carbon dioxide is removed from the alveoli by VA.

At a normal rate of VA of 4.2 L/min, the PACO₂ is usually 40 mm Hg. If VA is doubled, the PACO₂ is reduced to 20 mm Hg. If VA is decreased by half to 2.1 L/min, the PACO₂ rises to 80 mm Hg. These estimations change with metabolic activity, nutritional state, temperature, and so on.

Alveolar Gas Equation

Inspired gas in the trachea has a partial pressure of oxygen (Po₂) of about 149 mm Hg and a Pco₂ of about 0.3 mm Hg. As the warm, water-saturated air enters the alveoli, oxygen diffuses through the alveolar capillary membranes into the plasma and carbon dioxide diffuses from the blood into the alveoli. The mixed venous blood brought to the pulmonary capillaries normally has a Po₂ of about 40 mm Hg and a Pco₂ of 46 mm Hg. On the average, for each milliliter of oxygen that leaves the alveolus, 0.8 to 1.0 mL of carbon dioxide enters it. This relationship is defined as the respiratory quotient (RQ), which can be expressed as

$$\frac{\text{rate of CO}_2 \text{ production}}{\text{consumption}} \text{ rate of O}_2 \quad (5)$$

TABLE 26-1 Partial Pressure of Gases while Breathing Room Air, mm Hg

Value	Air	Inspired Air in Trachea	Average Alveolar Gas	Average Expired Gas
PO ₂	159.0	149.3	104.0	120.0
Pco ₂	0.3	0.3	40.0	28.0
PN ₂	597.0	563.4	569.0	565.0
PH ₂ O	3.7	47.0	47.0	47.0
Total	760.0	760.0	760.0	760.0

SECTION 3 • RESUSCITATIVE PROBLEMS AND TECHNIQUES

To determine how well the lungs are functioning at oxygenation, the difference between PAO_2 and Pao_2 is often estimated. To estimate PAO_2 from the P_{iO_2} and $Paco_2$, one needs a correction factor to determine how much oxygen is consumed for each 1.0 mm Hg of $Paco_2$ resulting from carbon dioxide that enters the alveoli. Thus for the usual circumstances, in which the RQ is 0.8, the alveolar gas equation is

$$PAO_2 = (PB - PH_2O)(F_{iO_2}) - (Paco_2/RQ) \quad (6)$$

In room air ($F_{iO_2} = 0.21$) at sea level with a $Paco_2$ of 40 mm Hg, the PAO_2 is expected to be

$$PAO_2 = (760 - 47 \times 0.21) - (40/0.8) = 150 - 50 = 100$$

The normal difference between PAO_2 and Pao_2 is 2 to 10 mm Hg.

Expired Gases

Expired air is a combination of dead space air and alveolar air, and its overall composition is determined by the proportion of each in expired air. At the end of normal exhalation nothing but alveolar air is expired. Therefore, to collect alveolar air for study, one simply collects end-tidal gas. Determination of end-tidal carbon dioxide ($ETCO_2$) levels is a useful measure of the adequacy of ventilation. In patients with normal lungs, $ETCO_2$ is approximately 3 mm Hg lower than $PACO_2$, but in patients with obstructive airways disease, typically asthma, there can be a large difference between $ETCO_2$ and $PACO_2$, since dead space air is never fully exhaled and thus neither is pure alveolar air. In the ED, the use of $ETCO_2$ monitors helped to reduce undetected esophageal intubations.

ARTERIAL BLOOD GASES

Partial Pressure of Arterial Carbon Dioxide

ALVEOLAR VENTILATION Carbon dioxide diffuses so rapidly that the $Paco_2$ usually provides an excellent index of the adequacy of ventilation. If the $Paco_2$ is greater than expected based on the HCO_3^- , one can assume that V_A is inadequate since by definition a respiratory acidosis exists. The patient may have a low respiratory rate or tidal volume or may also have increased dead space due to emphysema, pulmonary emboli, or increased carbon dioxide production as in thyroid storm or sepsis. An elevated $Paco_2$ in the presence of metabolic alkalosis usually reflects compensatory physiologic effects to restore arterial pH toward (but never all the way to) normal. An increased $Paco_2$ in a patient with metabolic acidosis is ominous and generally indicates impending respiratory failure.

TRANSPORT OF CARBON DIOXIDE IN THE BLOOD Under resting conditions, each 100 mL of blood transports an average of 4 mL of carbon dioxide from the tissues to the lungs. Transport of carbon dioxide is not as great a problem as is transport of oxygen because, even under the most abnormal conditions, carbon dioxide can usually be transported in far greater quantities than can oxygen. However, carbon dioxide in the blood does affect acid-base balance.

The carbon dioxide formed in cells diffuses out in the form of carbon dioxide rather than bicarbonate because the cell membrane is almost impermeable to bicarbonate ions. As the carbon dioxide enters the capillary, it initiates a number of almost instantaneous reactions essential for carbon dioxide transport. Carbon dioxide is transported in the blood in three forms: as dissolved carbon dioxide, as bicarbonate, and in combination with proteins as carbamino compounds.

Dissolved A small portion of the carbon dioxide is transported to the lungs dissolved in plasma. The dissolved portion is approximately 0.36 mL of carbon dioxide in each 100 mL of blood. This is about 9 percent of all carbon dioxide transported.

Bicarbonate Much of the carbon dioxide in the blood reacts with water to form carbonic acid and subsequently to bicarbonate. The first reaction is very slow in plasma, but carbonic anhydrase inside the red blood cells speeds up the reaction about 500-fold. The reaction occurs so rapidly that it reaches almost complete equilibrium within a fraction of a second. This allows tremendous amounts of carbon dioxide to react with red blood cell water even before the blood leaves the tissue capillaries.

In another fraction of a second, the carbonic acid formed in the red blood cells dissociates into hydrogen and bicarbonate ions.

Some of the hydrogen ions liberated are bound to hemoglobin (Hb). Reduced Hb is less acidic than the oxygenated form, and is therefore a better proton acceptor. The presence of reduced Hb in the peripheral blood helps with the loading of CO_2 , while the oxygenation that occurs in the pulmonary capillary assists in the unloading. Deoxygenation of the blood that increases its ability to carry CO_2 is known as the *Haldane effect*, and is quantitatively far more important in promoting CO_2 transport than the Bohr effect is in promoting O_2 transport (see "Oxyhemoglobin Saturation").

The reversible combination of carbon dioxide with water in the red blood cells, under the influence of carbonic anhydrase, accounts for at least 60 to 70 percent of all the carbon dioxide transported from the tissues. Indeed, when a carbonic anhydrase inhibitor (acetazolamide) is administered to block the action of carbonic anhydrase in the red blood cells, carbon dioxide transport from the tissues becomes very poor and the tissue Pco_2 rises abruptly.

Carbaminohemoglobin and Carbaminoproteins Carbamino compounds are formed by the combination of CO_2 with terminal amine groups in blood proteins. The most important protein is the globin of hemoglobin to form carbaminohemoglobin ($HbCO_2$). Since this reversible reaction occurs with a very loose bond, the carbon dioxide is easily released into the alveoli, where the Pco_2 is lower than that in the tissue capillaries. Thus, again the unloading of O_2 in peripheral capillaries facilitates the loading of CO_2 , while oxygenation has the opposite effect. A small amount of carbon dioxide (usually equivalent to about 0.5 to 1.0 mEq/L of bicarbonate) also reacts in this way with the plasma proteins, forming carbaminoproteins. This reaction is much less significant because the quantity of these proteins is only about one-fourth to one-half the quantity of hemoglobin.

The theoretical quantity of carbon dioxide that can be carried to the lungs in combination with hemoglobin and plasma proteins is approximately 20 to 30 percent of the total quantity transported—that is, about 1.5 mL of carbon dioxide in each 100 mL of blood. However, this reaction is much slower than the reaction of carbon dioxide with water, and it is doubtful that more than 15 to 25 percent of the total quantity of carbon dioxide is transported via hemoglobin and plasma proteins.

CHANGE IN BLOOD ACIDITY DURING CARBON DIOXIDE TRANSPORT The transport of CO_2 has a profound effect on the acid-base status of the blood. The lung excretes over 10,000 mEq of carbonic anhydrase per day compared with less than 100 mEq of fixed acids by the kidney. Therefore, by altering alveolar ventilation and the elimination of CO_2 , the body has great control over the acid-base balance.

The carbonic acid formed when carbon dioxide enters the blood in the tissue capillaries decreases the pH. However, the buffers of the blood prevent the hydrogen ion concentration from rising greatly. Ordinarily, arterial blood has a pH of approximately 7.40, and as the blood acquires carbon dioxide in the tissue capillaries, the pH falls to approximately 7.35. The reverse occurs when carbon dioxide is released from the blood in the lungs. Under conditions of high metabolic activity or when blood flow through the tissues is extremely sluggish, the decrease in pH in the blood as it leaves the tissues can be 0.50 or more.

Partial Pressure of Arterial Oxygen

The P_{aO_2} in normal, healthy young adults breathing room air at sea level is considered to be 90 to 100 mm Hg. The P_{aO_2} is extremely important because it not only reflects the functional capabilities of the lungs but also determines the rate at which oxygen enters the tissue cells.

FACTORS AFFECTING P_{aO_2} Factors that affect the P_{aO_2} include the V_A , the F_{iO_2} , altitude, age, and the oxyhemoglobin dissociation curve (discussed later).

Alveolar Ventilation If the patient hyperventilates, the P_{aCO_2} tends to fall and the P_{aO_2} tends to rise. In accordance with the law of additive properties, if the P_{aCO_2} falls by 1 mm Hg, the P_{aO_2} rises by about 1.0 to 1.2 mm Hg. The lungs can make up for some pulmonary dysfunction by hyperventilating. This is seen in pregnant patients who have normal arterial blood gas values at term showing normal pH, a P_{aCO_2} of 30 to 32, a P_{aO_2} of 110 to 115, and a serum bicarbonate level of 20 to 22 mEq/L. This is due to an increase in V_M (predominantly due to increased V_T), with resultant respiratory alkalosis with increased urinary excretion of bicarbonate to compensate.

Fraction of Inspired Oxygen Unfortunately, the F_{iO_2} is often not considered adequately in evaluating the P_{aO_2} . If a patient is receiving oxygen by nasal cannula, the actual delivered F_{iO_2} is usually only 25 to 30 percent. With a properly fitting face mask, the inhaled F_{iO_2} is usually less than half that delivered to the mask. The approximate P_{aO_2} values that might be expected in normal persons who are inhaling various concentrations of oxygen are listed in Table 26-2.

The expected P_{aO_2} when the patient is given oxygen can be estimated by multiplying the actual delivered percentage of oxygen by 6. Thus a patient getting 60 percent oxygen would be expected to have a P_{aO_2} of about 60×6 , or 360 mm Hg.

Altitude The P_{aO_2} expected when a patient is breathing room air varies with height above sea level. The greater the altitude, the lower the P_{O_2} in the air and the greater the tendency for the patient to hyperventilate (Table 26-3).

The PAO_2 drops about 3 to 4 mm Hg for each 1000-foot rise above sea level. When a person breathes air at 30,000 ft, where the barometric pressure is about 226 mm Hg, the PAO_2 is only 21 mm Hg. At this height above sea level, almost three-fourths of the alveolar air is nitrogen. However, if the person breathes pure oxygen instead of air, most of the space in the alveoli formerly occupied by nitrogen becomes occupied by oxygen. Nevertheless, even if the person is breathing 100 percent oxygen at 30,000 ft, the PAO_2 is only 139 mm Hg (Table 26-4).

Age Even in healthy individuals, pulmonary changes that cause a fall in the P_{aO_2} occur with advancing age. On the average, the P_{aO_2} falls about 3 to 4 mm Hg per decade after the patient reaches 20 to 30 years of age. Thus an otherwise normal 20-year-old patient with a P_{aO_2} of about 90 to 100 mm Hg (breathing room air at sea level) might be expected to have a P_{aO_2} of only about 75 to 80 mm Hg at 80 years of age.

TABLE 26-2 Expected P_{aO_2} in Patients Inhaling Various Concentrations of Oxygen, mm Hg

F_{iO_2}	0.21 (room air)	0.4	0.6	0.8	1.0
P_{aO_2} *	100	227	370	512	655

*Assuming a $PAO_2 - P_{aO_2}$ of 10 mm Hg and a P_{CO_2} of 40 mm Hg.

Note: Concentrations of inspired O_2 greater than 60% are not achievable by face mask regardless of flow rate.

TABLE 26-3 Changes in P_{O_2} at Various Altitudes

Altitude Above Sea Level, ft	Barometric Pressure, mm Hg	P_{O_2} in Air, mm Hg	PAO_2 , mm Hg	P_{aO_2} , mm Hg*
0	760	159	105	100

30,000	226	47	21	19

* Assuming ideal circumstances with a $PAO_2 - P_{aO_2}$ of 5 mm Hg or less.

Alveolar-Arterial Oxygen Differences

One method of determining the degree to which lung function is impaired is to determine the alveolar-arterial oxygen gradient [$P(A - a)O_2$]. The P_{aO_2} can be determined from arterial blood samples and the PAO_2 can be determined using the alveolar air equation previously discussed (Equation 6). The $P(A - a)O_2$ is essentially:

$$PAO_2 - P_{aO_2} \quad (7)$$

Generally speaking the $P(A - a)O_2$ should be about 10 plus one tenth the patient's age. A $P(A - a)O_2$ of 20 to 30 mm Hg on room air usually indicates mild pulmonary dysfunction, and a $P(A - a)O_2$ greater than 50 mm Hg on room air usually indicates severe pulmonary dysfunction. The causes of an increased A-a gradient include intrapulmonary shunt (relatively less ventilation than perfusion, or a low V/Q ratio), intracardiac shunt, and diffusion abnormalities.

Physiologic Shunting in the Lung (Venous-Arterial Admixture)

Although abnormal gas diffusion or distribution in the lungs can cause abnormal blood gas values, the most important cause is usually V/Q mismatching. When considering ventilation and perfusion, there can be four types of alveolar capillary units: (1) if ventilation and perfusion are normal, the unit is normal; (2) if there is ventilation without perfusion, the unit is considered to be dead space (or high V/Q); (3) if there is perfusion without ventilation, the unit is considered to be a (right-to-left) shunt (or low V/Q); and (4) if there is neither ventilation nor perfusion, the unit is silent.

TABLE 26-4 Effects of Acute Exposure to Low Atmospheric Pressure on Alveolar Gas Concentrations and on SaO_2

Altitude Above Sea Level, ft	Barometric Pressure, mm Hg	WHILE BREATHING 100% O_2			
		WHILE BREATHING AIR		WHILE BREATHING 100% O_2	
		PAO_2 , mm Hg	P_{aO_2} , mm Hg	PAO_2 , mm Hg	Oxygen Saturation, mm %
0	760	159	40	673	100
10,000	523	110	40	436	100
20,000	349	73	40	262	100
30,000	226	47	40	139	99
40,000	141	29	36	58	87
50,000	87	18	24	16	22

The amount of physiologic shunting in the lung, or venous-arterial admixture (QS/QT), is probably the most sensitive guide to the onset and progression of acute respiratory failure. The shunt is that fraction of blood passing through the lungs without being oxygenated. Normally, the amount for venous-arterial admixture is about 3 to 5 percent of the cardiac output. This small amount of shunting is largely due to the drainage of deoxygenated blood in bronchial veins into oxygenated blood in pulmonary veins.

Physiologic shunting is harder to determine than alveolar-arterial oxygen differences because it requires drawing both arterial and mixed venous (pulmonary artery) blood samples and determining their oxygen contents. Mixed venous samples from the pulmonary artery are preferable to those obtained from central venous pressure catheters. However, central venous blood does give a reasonable estimate of the amount of shunting present if cardiac output is relatively normal.

Although a F_{iO_2} of 1.0 was generally used in the past to determine the amount of physiologic shunting in the lung, the high F_{iO_2} in itself may cause increased shunting. The shunt with a F_{iO_2} of 0.4 is considered to be a better indicator of lung function.

Oxygen Availability

Oxygen availability is determined by the amount of oxygen brought to the capillaries, or oxygen delivery (Do_2), and the dissociation of oxygen from hemoglobin at the tissues. Oxygen delivery is dependent upon oxygen content and cardiac output. Generally, a healthy heart that can increase cardiac output appropriately can make up for diseased lungs and a low hemoglobin level. The reverse is also true. However, a combination of poor oxygenation, low hemoglobin level, and low cardiac output may be rapidly fatal.

OXYGEN DELIVERY

Oxygen Content Oxygen is carried in the blood either dissolved or in combination with hemoglobin. Primarily the hemoglobin level and the oxyhemoglobin saturation determine the oxygen content of blood. When fully saturated, each gram of hemoglobin measured clinically can carry 1.34 mL of oxygen. Thus a patient with a hemoglobin concentration of 15.0 g/dL can carry about 20.1 mL of oxygen per 100 mL in the red blood cells when the hemoglobin is fully saturated. Although the P_{aO_2} determines the rate at which oxygen enters the tissues, it contributes very little to the total oxygen content of blood. Each millimeter of mercury of P_{aO_2} represents only 0.003 mL of oxygen in 100 mL of blood. Thus a patient with a normal P_{aO_2} of 100 mm Hg has only 0.3 mL of oxygen dissolved in the plasma.

The oxygen content of arterial blood (CaO_2) can be calculated from the following formula:

$$CaO_2 = [Hb](1.34)(SaO_2/100) + (PaO_2)(0.003)$$

Thus in a patient with a hemoglobin concentration of 15.0 g/dL, an SaO_2 (arterial saturation of oxygen) of 98 percent, and a P_{aO_2} of 100 mm Hg,

$$CaO_2 = (15)(1.34)(98/100) + (100)(0.003) = 20.0 \text{ mL } O_2 \text{ per deciliter of blood}$$

If the hemoglobin concentration falls to 10.0 g/dL, even if SaO_2 and P_{aO_2} remain the same, CaO_2 falls by about a third. For example,

$$CaO_2 = (10)(1.34)(98/100) + (100)(0.003) = 13.132 + 0.30 = 13.4 \text{ mL } O_2 \text{ per deciliter of blood}$$

Even with only 10 g of hemoglobin, the red blood cells are carrying over 40 times as much oxygen as is the plasma. While the formula for CaO_2 is complex, the only variables that can be affected through intervention are Hb (with transfusions of red blood cells) and oxygen saturation (with oxygen administration).

Cardiac Output Oxygen content (in milliliters per liter of blood) multiplied by cardiac output (in liters per minute) is equal to Do_2 . Thus, the Do_2 in a patient with 15.0 g of 98 percent saturated hemoglobin, a P_{aO_2} of 100 mm Hg, and a cardiac output (CO) of 5 L/min is

$$\begin{aligned} Do_2 &= (CaO_2)(10)(CO) \\ &= [\text{hemoglobin}](1.34)(SaO_2/100) + (PaO_2)(0.003)(10)(CO) = \\ &= (15 \times 1.34 \times 98/100) + (100)(0.003)(10)(5) = 1000 \text{ mL/min} \end{aligned}$$

The factor 10 is used to convert oxygen content from milliliters per 100 mL of blood to milliliters per liter of blood.

Since the normal oxygen consumption of an average resting adult male is about 250 to 300 mL/min or approximately 3 mL/kg per min, the tissue on average takes up about 25 percent of the oxygen brought to it, although the percent of oxygen extracted varies by organ. Thus, the SaO_2 falls from about 98 percent in arterial blood to about 73 percent in mixed venous blood. If there is no change in oxygen consumption but cardiac output doubles to 10 L/min, the amount of oxygen removed from each liter of blood is halved, and the venous oxyhemoglobin saturation will be about 85 percent. On the other hand, if cardiac output falls to 2.5 L/min, venous oxyhemoglobin saturation will fall to about 48 percent.

OXYHEMOGLOBIN SATURATION

Normal Relationships When arterial blood gas study results are obtained, P_{aO_2} levels in the 60- to 90-mm Hg range often concern clinicians. A P_{aO_2} of 60 mm Hg correlates to an SaO_2 of 90 percent. Furthermore, if the hemoglobin level is 15.0 g/dL and the tissue removes 5.0 mL of oxygen from each 100 mL of blood, the P_{o_2} of the venous blood falls to about 36 mm Hg, which is only 4 mm Hg below the arterial value. Thus, the tissue P_{o_2} often changes minimally despite a marked fall in P_{aO_2} .

On the other hand, if the P_{aO_2} rises far above the upper limit of normal (90 to 100 mm Hg), the oxygen saturation of hemoglobin cannot rise above 100 percent. Therefore, even if the P_{aO_2} rose to 600 mm Hg or more, the saturation of hemoglobin would increase only 1 to 2 percent because at P_{aO_2} of 100 mm Hg the SaO_2 is only 98 to 99 percent. This, combined with some evidence (predominantly in animals) that an F_{iO_2} greater than 50 can be associated with pulmonary toxicity, should guide the clinician to supply only the amount of oxygen required to produce a P_{aO_2} between 70 and 100 mm Hg.

Under circumstances of normal body temperature [37°C (98.6°F)] and blood pH 7.40, certain standard relationships exist between the oxyhemoglobin saturation and the plasma P_{O_2} (Table 26-5 and Figure 26-1). The curved shape of the O_2 dissociation curve has several physiologic advantages. The flat portion means that even if the P_{o_2} in alveolar gas falls somewhat, loading of O_2 will be affected little. The steep lower part of the dissociation curve means that the peripheral tissue can withdraw large amounts of O_2 for only a small drop in capillary P_{O_2} . This maintenance of blood P_{O_2} assists the diffusion of O_2 in the tissue cells. Thus, the relationship between SaO_2 and plasma P_{O_2} is almost linear when the SaO_2 is 60 to 90 percent. However, as the SaO_2 rises above 90 percent, the P_{O_2} begins to rise much faster than the saturation. A simplification to remember for clinical practice is that a P_{aO_2} of 30, 40, 50, and 60 correspond approximately to an SaO_2 of 60, 70, 80, and 90 percent, respectively.

Factors Affecting Oxyhemoglobin Dissociation The best known of the factors affecting the oxyhemoglobin dissociation curve are pH,

TABLE 26-5 Relation Between Oxyhemoglobin Saturation and Plasma P_{O_2}

Oxygen														
saturation, %	100.0	98.4	95	90	80	73	60	50	40	35	30			
P_{O_2} , mm Hg	677	100	80	59	48	40	30	26	23	21	18			

FIG. 26-1. The hemoglobin dissociation curve. This curve demonstrates the relationship of plasma oxygen partial pressure to the degree to which potential oxygen-carrying hemoglobin sites have oxygen attached. The P_{50} is the P_{O_2} at which hemoglobin is 50 percent saturated and correlates with P_{O_2} of 27 mm Hg normally. Normal mixed venous blood has an oxygen partial pressure (P_{vO_2}) of 40 mm Hg and an oxyhemoglobin saturation of 75 percent. A P_{O_2} of 60 percent normally results in approximately 90 percent saturation of hemoglobin. (Reprinted with permission from Civetti JM, Taylor RW, Kirby RR (eds): *Critical Care*, 3d ed. Baltimore, Lippincott Williams, & Wilkins, 1997.)

temperature, and the amount of 2,3-diphosphoglycerate (2,3-DPG) in the red blood cells. Other related factors include P_{CO_2} and exercise (Table 26-6).

pH The more acidic the blood, the more readily hemoglobin gives up its oxygen and the higher the P_{aO_2} (the partial pressure of oxygen dissolved in blood) for a particular oxyhemoglobin saturation. In contrast, alkalosis makes hemoglobin hold on to its oxygen more tightly, lowering the P_{aO_2} present at a particular oxyhemoglobin saturation. In general, a rise or fall in pH of 0.10 causes a fall or rise (i.e., an opposite change) in the P_{aO_2} of about 10 percent (Table 26-7).

PARTIAL PRESSURE OF CARBON DIOXIDE A shift of the oxyhemoglobin dissociation curve, as a result of changes in the blood levels of carbon dioxide (Haldane effect) and hydrogen ions (Bohr effect), enhances oxygenation of the blood in the lungs and promotes release of oxygen from the blood in the tissues. As the blood passes through the lungs, carbon dioxide diffuses from the blood into the alveoli. This reduces the blood P_{CO_2} and decreases the hydrogen ion concentration be-

TABLE 26-7 Changes in P_{aO_2} Related to pH

pH	7.60	7.50	7.40	7.30	7.20	7.10	7.00

*Assuming a temperature of 37°C (98.6°F) and a hemoglobin saturation of 98.4%.

cause of the resulting decrease in the blood carbonic acid level. Both changes shift the oxyhemoglobin dissociation curve to the left. With a shift to the left, the quantity of oxygen binding to hemoglobin at any given P_{aO_2} is increased, allowing greater oxygen transport to the tissues. Then, when the blood reaches the tissue capillaries, the opposite effect occurs. Carbon dioxide entering the blood from the tissues shifts the curve to the right. This displaces oxygen from the hemoglobin and delivers oxygen to the tissues at a higher P_{O_2} than would otherwise occur.

TEMPERATURE As blood temperature increases, hemoglobin gives up oxygen more readily, raising the P_{O_2} in the plasma. The opposite occurs during cooling. For each 1°C rise in temperature, the P_{aO_2} rises about 5 percent (Table 26-8). With hypothermia, the P_{CO_2} falls by about the same amount.

EXERCISE During strenuous exercise, several factors can shift the oxyhemoglobin dissociation curve to the right. Exercising muscles release large quantities of carbon dioxide and other acids, increasing the hydrogen ion concentration in muscle capillary blood. In addition, the temperature of the muscle often rises as much as 3 to 4°C, and phosphate compounds are also released. All these factors acting together shift the oxyhemoglobin dissociation curve of the blood in the muscle capillaries considerably to the right. This allows oxygen to be released to the muscle at a P_{O_2} as high as 40 mm Hg even though as much as 75 percent of the oxygen has been removed from the hemoglobin. In the lungs, the shift occurs in the opposite direction, allowing pickup of extra amounts of oxygen from the alveoli.

2,3-DIPHOSPHOGLYCERATE Except for hemoglobin, the compound present in greatest quantity in red blood cells is 2,3-DPG. A normal concentration of 2,3-DPG in a red blood cell keeps the oxyhemoglobin dissociation curve shifted slightly to the right all the time. In addition, under hypoxic conditions lasting longer than a few hours, the quantity of 2,3-DPG increases considerably, shifting the oxyhemoglobin dissociation curve even farther to the right. This can cause the P_{O_2} in the plasma to be as much as 10 mm Hg higher than it would have been otherwise. However, the presence of increased 2,3-DPG makes it more difficult for the hemoglobin to combine with oxygen in the lungs.

If the concentration of 2,3-DPG falls, as it does in stored blood or during sepsis, the hemoglobin holds on to its oxygen more tightly and the P_{aO_2} tends to fall. This is an important consideration during large-volume resuscitations with banked blood.

CARBON MONOXIDE Carbon monoxide combines with hemoglobin at the same point on the hemoglobin molecule that oxygen does. Its presence shifts the oxyhemoglobin dissociation curve to the left. Its physiology is discussed in detail in Chap. 203.

Oxygen Reserve The ability of blood to give up more oxygen (increasing the arteriovenous oxygen difference) as cardiac output falls and thus maintain oxygen delivery is an important defense mechanism sometimes referred to as oxygen reserve. Unfortunately, there is a

TABLE 26-8 Changes in P_{aO_2} Related to Temperature

Temperature, °F	104.0	102.2	100.4	98.6	95.0	89.6
Temperature, °C	40	39	38	37	35	32
P_{aO_2} , mm Hg*	117	111	105	100	90	76

*Assuming a pH of 7.40 and a hemoglobin saturation of 98.4%.

limit to this "reserve" because the P_{O_2} in most tissues seldom falls below 26 mm Hg, which is the P_{50} for hemoglobin (P_{O_2} at which hemoglobin is 50 percent saturated).

The lowest value to which the P_{O_2} in capillaries can fall is about 18 to 20 mm Hg because this is the usual capillary-mitochondrial gradient for oxygen. The saturation at a P_{O_2} of 20 mm Hg is referred to as the S_{20} , and this is normally about 33 percent. The only places where the P_{O_2} in venous blood is normally as low as 20 mm Hg are the coronary sinus, renal medulla, and perhaps the jugular venous bulb at the base of the brain. A relatively mild degree of alkalosis can raise the S_{20} by 4 to 5 percent, thereby greatly reducing oxygen availability to the myocardium. Thus alkalosis (e.g., when metabolic acidosis is treated with bicarbonate) in low-flow states can be deleterious.

OTHER METHODS OF EVALUATING BLOOD GASES

PCIO₂/FIO₂ RATIO A quick way to estimate the impairment of oxygenation is to calculate the P_{aO_2}/F_{IO_2} ratio. Normally, the ratio is about 500 to 600, which usually correlates to a pulmonary shunt (QS/QT) of about 3 to 5 percent. However, if a patient has a P_{aO_2} of 80 mm Hg on 40 percent oxygen, the P_{aO_2}/F_{IO_2} ratio is 80/0.4, or 200. A P_{aO_2}/F_{IO_2} ratio of less than 200 corresponds with a QS/QT of about 20 percent. The usual relationship between P_{aO_2}/F_{IO_2} ratios and the QS/QT in patients with a normal cardiac output is shown in Table 26-9. P_{aO_2}/F_{IO_2} ratios are also used as criteria for the diagnosis of ARDS/acute lung injury (ALI). In a patient with alveolar infiltrates in at least 3 of 4 quadrants on chest x-ray, a normal pulmonary capillary wedge pressure, and a mechanism known to cause ARDS/ALI, a P_{aO_2}/F_{IO_2} of less than 300 indicates at least ALI, while a ratio less than 200 indicates ARDS. However, some researchers no longer distinguish between ARDS and ALI and classify all patients with a P_{aO_2}/F_{IO_2} ratio less than 300 as having ARDS.

PULMONARY ARTERY CATHETERS A number of pulmonary artery catheters have been developed to continuously monitor mixed venous oxygen saturation ($SmvO_2$). The normal $SmvO_2$ is about 70 to 75 percent. A change in Do_2 could serve as an early warning of inadequacy of perfusion and oxygenation. A rise in $SmvO_2$ can signal an increase in cardiac output and Do_2 beyond that required for metabolism, shunting of blood from tissues (sepsis), or an inability of the peripheral tissues to extract and utilize O_2 (cyanide poisoning). It can also be simply a reflection of the location of the catheter tip in a persistently wedged position so that pulmonary capillary (oxygenated) blood is being analyzed. A fall in $SmvO_2$ below 50 to 60 percent is usually due to a significant decrease in cardiac output or lung function and requires urgent investigation. It is important to remember that, while a change in $SmvO_2$ may indicate important physiologic change, there can be major changes in the patient's condition without corresponding changes in the $SmvO_2$. A major criticism of the use of $SmvO_2$ to guide therapy is that it is a measure of all of the blood returning to the lungs and

gives little information about the adequacy of perfusion of individual organ systems, such as the kidneys, brain, heart, or liver.

CLINICAL EXAMINATION A patient who is awake, alert, comfortable, and cooperative and has normal vital signs is generally oxygenating and ventilating adequately. However, if a patient is tachypneic and/or tachycardic and appears to be anxious and/or confused, hypercarbia or hypoxemia should be considered early. In comatose patients, it is sometimes very difficult to judge how well the patient is oxygenating or ventilating without serial blood gas determinations.

Because reduced Hb is purple, a low arterial O_2 saturation causes cyanosis. Since it is the amount of reduced Hb that is important, cyanosis as a sign of inadequate oxygenation is almost worthless when the hemoglobin is less than 10 g/dL. Under such circumstances, the arterial oxygen saturation (S_{aO_2}) must be less than 65 percent, corresponding to a P_{aO_2} of about 30 to 35 mm Hg, before the patient looks cyanotic. It must be remembered that oxygenation and ventilation are two separate systems. **A common clinical misconception is that a patient with an adequate S_{aO_2} must be ventilating adequately. This assumption is incorrect and dangerous,** particularly with patients who are receiving supplemental oxygen. This is discussed further below.

PULSE OXIMETRY The use of pulse oximetry for monitoring S_{aO_2} and pulse amplitude in the fingers, nose, or toes can provide early warning of pulmonary or cardiovascular deterioration before it is clinically apparent. This technique employs a microprocessor that continuously measures pulse rate and oxyhemoglobin saturation. The photosensor is not heated and does not require calibration. Oxyhemoglobin is red and reduced hemoglobin is blue, and each has a different absorption of light at their given wavelengths. Because the ratio of transmittance at each of the two wavelengths (660 nm for red and 940 nm for infrared) varies according to the percentage of oxyhemoglobin, pulse oximeters can be programmed to calculate and display the percentage of oxyhemoglobin saturation at each pulse.

There is a predictable correlation between noninvasive S_{aO_2} monitoring and measured arterial oxygen saturation from arterial blood gas over a wide range of values. Pulse oximetry has only a minimal error, of 1 to 2 percent, above 60 percent saturation. However, a number of factors can limit the effectiveness and accuracy of pulse oximetry, including impaired local perfusion (e.g., in patients who are hypothermic or on vasopressors); ambient light, particularly fluorescent (easily eliminated by placing a towel over the pulse oximeter); nail polish (particularly blue, which absorbs near 660 nm); abnormal hemoglobin; and very high P_{O_2} .

Carboxyhemoglobin falsely raises oxyhemoglobin saturation readings because bedside pulse oximeters read carboxyhemoglobin as oxyhemoglobin, in contrast to methemoglobin, which lowers them (at high levels of methemoglobin the pulse oximeter will read 85 percent regardless of the actual blood oxygenation, as may be seen after the treatment of cyanide poisoning). Fetal hemoglobin has nearly the same absorption spectrum as hemoglobin A and thus has little effect on the readings.

It is important to remember that a pulse oximeter does not provide a good measure of the adequacy of ventilation of patients on supplemental oxygen. A quick calculation using the alveolar gas equation (see Equation 6) shows that a person on 50 percent oxygen would be able to increase the P_{aO_2} to greater than 230 mm Hg before the saturation would drop below 90 [$P_{aO_2} = (713)(0.5) - 230/0.8 = 356 - 287 = 69$].

CAPNOGRAPHY By providing a real-time estimate of P_{aCO_2} , capnography is a useful and accurate means of assessing ventilation, respiratory gas exchange, and carbon dioxide production, and it can give some indication of cardiovascular status (primarily cardiac output).¹ The capnogram during expiration is normally divided into three phases (Figure 26-2): phase I represents the low CO_2 tension in gas expelled from the anatomic dead space; phase II represents the increasing CO_2 tension as the exhaled gas becomes composed of increasingly more alveolar gas; and phase III represents the CO_2 plateau

TABLE 26-9 Interpretation of P_{aO_2}/F_{IO_2} Ratio

P_{aO_2} , mm Hg	F_{IO_2} , mm Hg	Ratio	QS/QT, %	Impairment of Oxygenation
240	0.4	600	5	None
120	0.4	300	10	Minimal
100	0.4	250	15	Mild
80	0.4	200	20	Moderate
60	0.4	150	30	Severe*
40	0.4	100	40	Very severe*

*In trauma or septic patients, ventilatory assistance and PEEP to reduce the QS/QT (pulmonary shunt) to 15 percent should be considered. The higher the QS/QT, the greater the need for ventilatory assistance and PEEP.

FIG. 26-2. A normal exhaled CO₂ curve. Phase I represents dead space. Phase II represents the increasing CO₂ tension as the exhaled gas becomes composed of increasingly more alveolar gas. Phase III represents the CO₂ plateau, where the exhaled gas is composed primarily of gas from the alveoli. The inset shows the normal disparity between PaCO₂ and the carbon dioxide tension of end-exhalation (end-tidal) gas, which is less than 3 mm Hg. An increase in this disparity probably reflects increases in alveolar dead space ventilation. (Reprinted with permission from Civetti JM, Taylor RW, Kirby RR (eds): *Critical Care*, 3d ed. Baltimore, Lippincott Williams, & Wilkins, 1997.)

reached when the exhaled gas is composed primarily of gas from the alveoli. When inspiration starts, the CO₂ level drops sharply and there is a rapid downstroke of the curve to zero. The point at which the plateau ends just before inspiration is the pulmonary end-tidal CO₂ concentration (PETCO₂). PETCO₂ is commonly used to estimate PaCO₂ quantitatively; however, even in healthy people the PETCO₂ is usually 3 mm Hg less than PaCO₂. This gradient is higher in situations that increase the physiologic dead space, cause V/Q mismatch, or increase shunting. PETCO₂ can be used reliably to estimate the PaCO₂ as long as airway resistance and the VDS/VT ratio are unchanging. Table 26-10 describes the different clinical conditions that may affect PETCO₂.

Mainstream and sidestream infrared capnometers are commercially available. A mainstream capnometer connects directly to the endotracheal tube, thus providing real-time breath-by-breath analysis. The major disadvantages of this system are its size and bulk and that it cannot be used in nonintubated patients. Sidestream capnometers aspirate gas at the sample site. The principal advantages of this system are that it reduces mechanical dead space and can be used in nonintubated patients; however, many mechanical factors related to gas sampling require much expert attention and time, and can affect the results.

There are several clinical applications for capnography and ETCO₂. A frequent use of ETCO₂ is to evaluate the adequacy of alveolar ventilation in relatively healthy patients undergoing general anesthesia. Capnography has been shown to be useful during intubations to ensure tracheal, rather than esophageal, intubation. CO₂ may initially be detected with esophageal intubation from exhaled gas in the stomach; however, this is usually very low (3 to 5 mm Hg) and decreases to zero rapidly, within 3 to 5 breaths. Accidental tracheal extubation, endotracheal tube obstruction, or disconnect from a ventilation system can also be readily detected. These monitors can reduce the number of ar-

terial blood gas determinations obtained and can be very useful in weaning patients from mechanical ventilatory support.

Finally, they can also be useful in determining the adequacy of circulation during cardiopulmonary resuscitation.^{3,4} The decrease in cardiac output and pulmonary blood flow during cardiac arrest results in decreased elimination of CO₂ by the lungs and therefore a low PETCO₂. Successful resuscitation results in an increase in cardiac output that will in turn lead to an increase in PETCO₂. Capnographic monitoring is a useful guide to the adequacy of closed cardiac compressions during CPR.

Pulse oximetry, and to some extent capnography, have become standard monitors in most locations that provide for the acute care of unstable patients. While understanding that they have limitations, the clinician can use them for second-to-second indications of the adequacy of ventilation and oxygenation.

FLUIDS

Compartments

The total body water (TBW) can be divided into intracellular and extracellular fluids (ICF and ECF, respectively). In addition, the ECF can be divided into interstitial and intravascular. Body fluid compartment sizes for an adult are diagrammed in Figure 27-1. The concentrations

As a function of	TBW	ICF	ECF	IF	IVF
Total Weight	60%	40%	20%	15%	5%
TBW		67%	33%	25%	8%
ECF compartment				75%	25%

FIG. 27-1. Relation of fluid compartment to body weight and each other. ECF = extracellular fluid; ICF = intracellular fluid; IF = interstitial fluid; IVF = intravascular fluid; TBW = total body water.

of the most abundant anions and cations of the fluid compartments and the constituents of commonly used intravenous fluids are listed in Table 27-1.

Solutes

Concentrations are often expressed in moles, equivalents, or osmoles per liter. A *mole* (abbreviation: mol) of any compound contains 6.02×10^{23} molecules of that compound. The *molecular weight* of a substance is the weight, in grams, of a mole of that substance.

An *equivalent* of a substance is the mass (in grams) of a mole of that substance (molecular weight) divided by its charge. Therefore, 1 eq of Na^+ is equal to 23 g/1, or 23 g, whereas 1 eq of Ca^{2+} is equal to 40 g/2, or 20 g.

An *osmole* is the amount of a substance (in moles) that dissociates to form 1 mol of osmotically active particles. For example, 1 mol of NaCl dissolves to produce 1 mol of Na^+ and 1 mol of Cl^- , for a total of 2 mol of osmotically active particles. Therefore, 1 osmol of NaCl is 0.5 mol of NaCl.

Osmolarity is the number of osmoles per liter of solution, whereas *osmolality* is the number of osmoles per kilogram of solvent.

The serum osmolality can be measured directly by determining the freezing point of the serum, because 1 mol of solute will lower the freezing point of 1 kg of water by 1.86°C . Osmolarity can be estimated by adding the measured $[\text{Na}^+]$, $[\text{Cl}^-]$, and bicarbonate to the glucose and blood nitrogen blood (BUN) divided by their respective molecular weights divided by 10 (to convert from dL to L):

$$\text{osmolality (mosmol/L)} = 2 \times [\text{Na}^+] + \frac{\text{glucose}}{18} + \frac{\text{blood urea nitrogen}}{2.8}$$

Because the sum of the measured $[\text{Cl}^-]$ and bicarbonate approximates the measured $[\text{Na}^+]$, twice the measured $[\text{Na}^+]$ is generally used in this calculation. Because the density of water is 1 kg/L, the osmolality (in osmol/L) is roughly equivalent to the osmolality (in osmol/kg) in water-based systems with limited temperature variation, such as the human body; thus, the terms are frequently interchanged in medical texts.

The normal serum osmolality ranges from 275 to 295 mosmol/L. The presence of additional osmotically active agents should be suspected when the measured osmolality (measure via freezing point) differs from the calculated osmolality by more than 10. This is termed an *osmolar gap*. If an osmolar gap is encountered, the following possibilities should be considered:

1. Laboratory analytic error
2. Decreased serum water content: hyperlipidemia and hyperproteinemia
3. Additional low-molecular-weight substances in the serum, such as ethanol, methanol, isopropyl alcohol, ethylene glycol, acetone, ethyl ether, paraldehyde, lactate, or mannitol

If the substance ingested is known to be ethanol, the osmolar gap can be used to estimate the blood alcohol level, because osmolality increases 22 mg/dL for every 100 mg/dL of ethanol. Other substances can be similarly estimated (see Table 166-1 in Chap. 166).

$$\text{blood alcohol level in mg/dL (estimated)} = \text{osmolar gap} \times (100/22) = \text{osmolar gap} \times 4.6$$

Homeostasis

To maintain fluid balance, an average normal adult requires approximately 2000 to 3000 mL of water per day. This accounts for the volume of water lost in a day due to insensible and urinary losses. The insensible losses include the respiratory tract (500 to 700 mL per d), the

TABLE 27-1 Electrolyte Concentration of Body Fluids (mEq/L)

Abbreviations: LR = lactated Ringer; NS = normal saline.

skin (250 to 350 mL per d), and the feces (100 mL per d). This insensible loss can accelerate dramatically in the setting of fever (500 mL/d per 1°C fever), sweating (up to 1500 mL), and gastrointestinal losses.

ELECTROLYTES

Each electrolyte disorder can be assessed with the same general approach. In general, increased concentration of an electrolyte (hyper-) is a result of (1) excess total body amount, (2) shift between compartments, and (3) a relative fluid loss. Similarly, decreased concentrations (hypo-) are a result of (1) depleted total body amount, (2) shift among compartments, and (3) relative fluid gain. It is usually the rate of change of an electrolyte rather than the absolute value that determines the severity of symptoms. Correction of electrolyte disturbance should follow a time frame similar to the development of the abnormality.

SODIUM (Na^+)

The total body Na^+ content is between 40 and 50 mEq/kg, which is approximately 2800 mEq in a normal 70-kg man. It is found predominantly in the ECF space (98 percent), with a concentration of approximately 140 mEq/L. The intracellular concentration is usually less than 10 to 12 mEq/L. Sodium passively moves into cells along its concentration gradient and is actively extruded via an adenosine triphosphatase (ATPase) dependant system.

Hyponatremia

Hyponatremia is strictly defined as a measured serum $[\text{Na}^+]$ less than 135 mEq/L. This can result from primary water gain and/or Na^+ loss greater than that of water, alteration in the distribution of body water, or aberrant laboratory measurement. The development of symptoms is related more to the rate of change of the serum $[\text{Na}^+]$ than to the absolute value. Values less than 120 mEq/L are more likely to lead to symptoms, even when slowly developing. Common presenting symptoms include, but are not limited to, confusion, lethargy, nausea, vomiting, anorexia, muscle cramps, and hypothermia and culminate ultimately in seizures and coma. Seizures are quite likely at $[\text{Na}^+]$ of 113 mEq/L or less.

PATHOPHYSIOLOGY

Central Nervous System As serum $[\text{Na}^+]$ decreases, the osmotic gradient that develops across the blood-brain barrier causes water to move into the brain, causing apathy, agitation, headache, altered consciousness, seizures, and even coma. The severity of symptoms is dependent on not only the rapidity but also the magnitude of the decrease in the serum $[\text{Na}^+]$. Acute hyponatremia occurring in 24 h or less and resulting in a serum $[\text{Na}^+]$ of less than 120 mEq/L, or declining at a rate of 0.5 mEq/L or more per hour, can cause muscular twitching, seizures, and coma. The mortality rate with acute severe hyponatremia and central nervous system (CNS) changes has been reported to be as high as 50 percent in adults. Patients are usually less symptomatic when $[\text{Na}^+]$ decreases gradually, but even patients with chronic hyponatremia may experience focal weakness, hemiparesis, ataxia, and a positive Babinski sign.

The brain has two mechanisms to protect against fluid shifts secondary to hyponatremia: (1) The increase in the hydrostatic pressure causes movement of interstitial fluid into the cerebrospinal fluid and via the arachnoid villi; and (2) The loss of cellular K^+/Na^+ and organic osmolytes decreases the osmotic gradients.

The adaptive changes that protect the brain from excessive swelling also render it susceptible to volume depletion during correction of the fluid and electrolyte problem. There is often more risk of brain damage during treatment than from the hyponatremia itself. The rate of rise of brain intracellular potassium and organic osmolytes during correction of the hyponatremia is much slower than the rate of loss of these

substances during the development of the problem. If correction of hyponatremia occurs more rapidly than the brain can recover solute, the higher plasma osmolality may result in a fluid shift out of cells and injury to the brain. This is referred to as the *osmotic demyelination syndrome*, or *central pontine myelinolysis* (CPM). (See Complications of Therapy.)

Cardiovascular System In volume-depleted patients, hyponatremia can cause a further decrease in the intravascular volume by allowing movement of water out of the ECF compartment into the ICF space. Accordingly, shock occurs at lesser degrees of TBW depletion in hyponatremia than similar fluid deficits when the plasma is hypertonic or isotonic.

Antidiuretic hormone (ADH) release occurs in almost all hyponatremic conditions. The function of ADH in this setting initially may seem paradoxical, because it potentiates the hyponatremic state by increasing water reabsorption by the renal tubules. Antidiuretic hormone is also a potent vasoconstrictor, and, even at the low ADH concentrations that are characteristic of clinical hyponatremia, it increases peripheral vascular resistance, thereby increasing blood flow to the liver and kidneys at the expense of the skin and muscle.

Musculoskeletal System Most patients with hyponatremia have normal muscle tone and function. However, muscle cramps and weakness can occur during strenuous exercise, especially if excess sweating is replaced with water. These symptoms usually resolve rapidly when the serum $[\text{Na}^+]$ is corrected back toward normal.

Renal System The usual renal response to hyponatremia is the production of dilute urine; however, this process is abrogated to some extent by the presence of increased concentrations of ADH. The amount of ADH present depends on the primary disease process and the effective arterial blood volume.

A urine $[\text{Na}^+]$ less than 10 mEq/L usually indicates that the renal handling of Na^+ is intact and that the effective arterial blood volume is contracted. In contrast, a urine $[\text{Na}^+]$ greater than 20 mEq/L often indicates intrinsic renal tubular damage or a natriuretic response to hypervolemia. The urine $[\text{Na}^+]$ also will vary somewhat according to the ongoing gains and losses of salt and water. Urine $[\text{Na}^+]$ will tend to increase if the underlying disease significantly impairs renal function.

DIAGNOSIS The actual $[\text{Na}^+]$ does not confer information regarding volume status. Therefore, the first step in the evaluation of a patient with a low measured $[\text{Na}^+]$ should include a clinical evaluation of ECF volume status and measured and calculated plasma osmolalities. This provides a means for the first tier in categorizing hyponatremic disorders. In *true* hyponatremia, the plasma osmolality is reduced; in *factitious* hyponatremic states, the plasma osmolality is normal or increased.

HYPERTONIC HYPONATREMIA ($P_{\text{OSM}} > 295$) Hyponatremia with an increase in osmotically active solutes occurs when there is an accumulation of large quantities of solutes restricted primarily to the ECF space. In this setting, there is a net movement of water from the ICF to the ECF, thereby effectively diluting the ECF $[\text{Na}^+]$. The most common cause of this is hyperglycemia. Each 100 mg/dL increase in plasma glucose decreases the serum $[\text{Na}^+]$ by 1.6 to 1.8 mEq/L. The differential diagnosis of hypertonic hyponatremia is shown in Table 27-2. Treatment of hyponatremia in this class includes reduction of the ECF hypertonicity by correction of the underlying disorder with close observation. Unless detected during the very acute phase or in the face of renal failure, an osmotic diuresis is likely, resulting in total body Na^+ deficit. Volume depletion is often associated, so volume repletion with Na^+ -containing fluids is required.

ISOTONIC HYPONATREMIA ($P_{\text{OSM}} 275$ TO 295) Hyponatremia associated with normal plasma osmolality is often termed *pseudohy-*

TABLE 27-2 Etiology of Hyponatremia

Hypertonic hyponatremia ($P_{\text{osm}} > 295$)
Hyperglycemia Mannitol excess
Glyceroltherapy
Isotonic (pseudo)hyponatremia ($P_{\text{osm}} 275\text{--}295$)
Hyperlipidemia Hyperproteinemia (e.g., multiple myeloma, Waldenstrom macroglobulinemia)
Hypovolemic (usually associated with volume replacement with hypotonic fluids)
Renal
Diuretic use Salt-wasting nephropathy (renal tubular acidosis, chronic renal failure, interstitial nephritis)
Osmotic diuresis (glucose, urea, mannitol, hyperproteinemia)
Mineralocorticoid (aldosterone) deficiency Extrarenal
Volume replacement with hypotonic fluids Gastrointestinal loss (vomiting, diarrhea, fistula, tube suction) Third-space loss (e.g., burns, hemorrhagic pancreatitis, peritonitis) Sweating (e.g., cystic fibrosis) Hypervolemic
Urinary $[\text{Na}^+] > 20$ mEq/L
Renal failure (inability to excrete free water)
Urinary $[\text{Na}^+] < 20$ mEq/L
Congestive heart failure (perceived as low-flow state by kidneys, stimulates ADH)
Nephrotic syndrome (low serum protein secondary to urinary loss)
Cirrhosis (low intravascular oncotic pressure secondary to decreased protein production)
Euvoletic (urine $[\text{Na}^+]$ usually > 20 mEq/L)
SIADH (see Table 27-3)
Hypothyroidism (possible increased ADH or decreased GFR) Pain, stress, nausea, psychosis (stimulates ADH) Drugs: ADH, nicotine, sulfonylureas, morphine, barbiturates, NSAIDs, acetaminophen, carbamazepine, phenothiazines, TCAs, colchicine, clofibrate, cyclophosphamide, isoproterenol, tolbutamide, vincristine, MAOI
Water intoxication (psychogenic polydipsia, lesion in thirst center)
Glucocorticoid deficiency (glucocorticoids required to suppress ADH)
Positive-pressure ventilation Porphyria Essential (reset osmostat or sick cell syndrome—usually in the elderly)

Abbreviations: ADH = antidiuretic hormone; GFR = glomerular filtration rate; MAOI = monoamine oxidase inhibitor; NSAIDs = nonsteroidal anti-inflammatory drugs; SIADH = syndrome of inappropriate secretion of antidiuretic hormone; TCAs = tricyclic antidepressants.

ponatremia. High levels of plasma proteins and lipids increase the non-aqueous, non- Na^+ -containing fraction of plasma. Because traditional methods of Na^+ measurement use a "mass per volume" of serum method (such as flame emission spectrophotometry), the laboratory analysis reports a factitious lower value of $[\text{Na}^+]$ than the serum truly contains. The true $[\text{Na}^+]$ and osmolality of plasma water are normal. The differential diagnosis of isotonic hyponatremia is shown in Table 27-2. Treatment of hyponatremia in this class is not required.

HYPOTONIC HYPONATREMIA ($P_{\text{osm}} < 275$) This category of hyponatremia results in intracellular volume expansion with consequent derangement of cellular functions. This category can be further subdivided into classifications based on functional ECF volume and urinary $[\text{Na}^+]$ (accounting for possible recent use of diuretics). The assessment of ECF should focus on predisposing factors once volume status is ascertained. In addition to the electrolytes and plasma osmolality, urine electrolytes and osmolality should be obtained. This will help facilitate classification into hypovolemic, hypervolemic, and euvoletic categories.

Hypovolemic hyponatremia is associated with a loss of Na^+ and water, often with disproportionate water replacement through oral intake or the administration of hypotonic fluids. Losses of Na^+ may be renal or extrarenal.

Patients with extrarenal losses of Na^+ and water will demonstrate a urinary $[\text{Na}^+]$ of less than 20 mEq/L. The unequal balance of electrolyte and water loss produces a contracted ECF and hyponatremia. This is maintained by the physiologic effect of volume depletion on the kidneys inhibiting the excretion of free water. The impairment of water excretion to defend ECF volume at the expense of tonicity is accomplished by four mechanisms:

1. Decreased glomerular filtration
2. Increased proximal tubular reabsorption of solute and water
3. Decreased delivery of fluid to the diluting segment of the nephron
4. Antidiuretic hormone released by nonosmotic stimuli

The differential diagnosis of hypovolemic hyponatremia from extrarenal losses is shown in Table 27-2.

The decreased ECF volume also may be due to renal losses. In this setting, the urinary $[\text{Na}^+]$ will be greater than 20 mEq/L. The clinical manifestations are usually due to the volume deficit rather than to the hyponatremia. Treatment of hypovolemic hyponatremia includes re-expansion of the ECF volume with isotonic saline and appropriate correction of any underlying disorder.

Euvoletic hyponatremia is described as having a combination of normal volume status and hyponatremia. Although ECF volume may be slightly increased, patients are not clinically edematous and have nearly normal total body Na^+ content despite the presence of hyponatremia. When symptoms are present, they usually relate to CNS hypotonicity. Urinary $[\text{Na}^+]$ is usually greater than 20 mEq/L and may be much higher in instances of ADH excess. The most notable cause of euvoletic hyponatremia is the syndrome of inappropriate ADH secretion. This is characterized by six criteria:

1. Hypotonic hyponatremia
2. Inappropriately elevated urinary osmolality (usually > 200 mosmol/kg)
3. Elevated urinary $[\text{Na}^+]$ (typically > 20 mEq/L)
4. Clinical euvoletic
5. Normal adrenal, renal, cardiac, hepatic, and thyroid functions
6. Correctable with water restriction

The diagnosis of syndrome of inappropriate ADH is made primarily by exclusion (Table 27-3). The other causes of euvoletic hyponatremia are listed in Table 27-2. Some of these may stimulate ADH secretion. Treatment for patients with euvoletic hyponatremia requires fluid restriction and appropriate diagnosis and management of the underlying disorder. Admission is usually warranted.

Hypervolemic hyponatremia is described as TBW in great excess. Patients have manifestations of volume overload, such as peripheral and/or pulmonary edema. They usually have impaired ability to excrete a water load. This allows for water retention in excess of Na^+ re-

TABLE 27-3 Etiology of Syndrome of Inappropriate Antidiuretic Hormone

tention. These patients can be further categorized into two groups (see Table 27-2). The first of these is generalized edematous states without advanced renal insufficiency. These patients have urinary $[\text{Na}^+]$ of less than 20 mEq/L. They include patients with cirrhosis and/or ascites, congestive heart failure, and nephrotic syndrome. The second category is advanced acute or chronic renal insufficiency. These patients have urinary $[\text{Na}^+]$ in excess of 20 mEq/L.

Management of patients with hypervolemic hyponatremia includes optimizing treatment for the underlying disorder coupled with judicious salt and water restriction. Often diuretics are required to aid in management. Dialysis may be necessary.

EMERGENCY TREATMENT OF SEVERE HYPONATREMIA Although specific or general treatment of hyponatremia for the condition discussed may be initiated in the ED, there is little urgency to address the hyponatremia immediately when $[\text{Na}^+]$ is above 120 mEq/L. In cases in which hyponatremia is severe (less than 115 mEq/L or when the patient is symptomatic), treatment should be initiated.

EVALUATION AND TREATMENT Urine electrolytes are useful only before beginning treatment and therefore should be collected in the ED. Situations that warrant consideration of emergent treatment are hypovolemic patients and patients in extremis, e.g., mental status changes or coma. In hypovolemic patients, the Na^+ deficit should be calculated and replaced with normal saline solution. The formula is:

$$\text{total body Na}^+ \text{ deficit (mEq/L)} = (\text{desired plasma } [\text{Na}^+] - \text{actual plasma } [\text{Na}^+]) \times \text{TBW}$$

In cases in which hyponatremia is severe (<120 mEq/L), develops rapidly (>0.5 -mEq/L decrease in serum $[\text{Na}^+]$ per h), and is associated with a patient in extremis (i.e., coma or seizures), administration of 3 percent saline solution (513 mEq/L) should be considered. This can be administered at 25 to 100 mL/h, with careful observation for fluid overload and the rise in serum $[\text{Na}^+]$ levels. **The rise in $[\text{Na}^+]$ should be no greater than 0.5 to 1.0 mEq/L per h. In the face of seizures, this can be increased to 1 to 2 mEq/L per h.** It is sometimes necessary to administer concomitant furosemide to reduce the amount of water present in the body, thereby allowing more rapid correction of plasma $[\text{Na}^+]$.

COMPLICATIONS OF THERAPY Complications with the treatment of acute hyponatremia, especially when there is no underlying CNS, hepatic, or renal disorder, are uncommon and occur in fewer than 2 percent of patients. Patients with chronic hyponatremia appear to be at greater risk for CPM brain injury during the correction process. The injury reportedly occurs after hyponatremia has been corrected, and progresses in a predictable manner. These neurologic changes are believed to be due to correction of the serum $[\text{Na}^+]$ at a rate faster than the brain can adapt to the higher osmolality. In patients with chronic hyponatremia, other factors contributing to CPM may include alcoholism, malnutrition, toxins, and metabolic imbalance. In patients with chronic severe hyponatremia, the threshold for the production of CPM is a rate of correction of $[\text{Na}^+]$ levels faster than 0.5 mEq/L per h (12 mEq/L per d).

In typical cases, the neurologic findings include fluctuating levels of consciousness, behavioral disturbances, dysarthria, dysphagia, or convulsions progressing to pseudobulbar palsy and quadriparesis. Improvement may occur after several weeks of severe debilitation, but some patients are permanently impaired.

Hypernatremia

PATHOPHYSIOLOGY Hypernatremia is defined as serum $[\text{Na}^+]$ greater than 150 mEq/L and can be classified as a decrease in TBW (the most common cause) or, less likely, from increased sodium (from increased intake or decreased excretion; Table 27-4).

TABLE 27-4 Etiologic Classification of **Hypernatremia**

Inadequate water intake*
Inability to obtain or swallow water
Impaired thirst drive; examples include
hypothalamic lesion
Increased insensible loss
Excessive sodium
Iatrogenic sodium administration Sodium bicarbonate
Hypertonic saline Accidental/deliberate ingestion of large
quantities of sodium
Substitution of salt for sugar in infant formula or tube feedings
Seawater ingestion or drowning Mineralocorticoid or glucocorticoid
excess* Primary aldosteronism Cushing syndrome
Ectopic adrenocorticotrophic hormone production
Peritoneal dialysis
Loss of water in excess of sodium (without simultaneous water intake)
Gastrointestinal*
Vomiting, diarrhea, intestinal fistula
Renal loss
Central diabetes insipidus Impaired renal
concentrating ability Osmotic diuresis
(multiple causes)* Hypercalcemia
Decreased protein intake Prolonged,
excessive water intake Sickle cell disease
Multiple myeloma Amyloidosis
Sarcoidosis Sjogren syndrome
Nephrogenic diabetes insipidus Congenital
Drugs, including
Alcohol, lithium, phenytoin, propoxyphene, sulfonyleurea
hypoglycemic agents, amphotericin B, colchicine
Skin loss
Burns, sweating
Essential hypernatremia

*Likely or important emergency department diagnostic consideration.

The main defense against hypernatremia is thirst. A 2 percent increase in plasma osmolality should stimulate thirst to increase free water intake. The problem arises when patients, such as those in a coma or those who are bedridden, are unable to obtain adequate fluid.

Virtually all hypernatremia encountered in the ED is related to volume loss, usually severe. In otherwise healthy hypovolemic patients, conservation of free water by the kidneys results in low urine output (<20 mL per h) that has a high osmolality (usually >1000 mosmol/kg water). Although the urine is concentrated, it is of such low volume as to limit the excretion of sodium.

Diabetes Insipidus

In diabetes insipidus (DI), there is failure of central or peripheral ADH response. Urine osmolality is low (200 to 300 mosmol/kg, with urinary $[\text{Na}^+]$ of 60 to 100 mEq/kg), resulting in excessive loss of hypotonic urine. Diabetes insipidus may be central (due to a failure of secretion of ADH) or nephrogenic (due to renal unresponsiveness to ADH) in origin. Specific causes are listed in Table 27-5. Diagnosis of central and nephrogenic DI is best achieved by noting the response of serum and urine osmolality to water deprivation (trying to reach a serum osmolality >295 mosmol/L) and the response to 5 units of subcutaneous aqueous vasopressin. A lack of response to fluid loss is diagnostic of DI. Patients with central DI respond well to vasopressin (urine osmolality >800 mosmol/L), whereas patients with nephrogenic DI show little or no response to vasopressin.

	Hematologic disorders
	Malnutrition

SYMPTOMS Acute symptomatology is seen in many patients once serum $[\text{Na}^+]$ exceeds 158 mEq/L, although the rate of change of $[\text{Na}^+]$ is an important factor. Neurologic symptoms predominate. Patients tend to become irritable. One may see increased muscle tone or even coma with eventual seizures. Fever can be a contributing cause and a result of hypernatremic dehydration.

The serum osmolality at which signs and symptoms occur can be found in Table 27-6. If the plasma osmolality exceeds 350 mosmol/kg, the incidence of severe morbidity or mortality may exceed 50 percent.

Hypocalcemia, which is frequently seen in patients with hypernatremia, may contribute to the CNS symptomatology. However, the mechanism of the hypocalcemia is unclear.

Massive brain hemorrhage or multiple small hemorrhages and thromboses may occur when hypernatremia causes enough cellular fluid loss and resultant brain shrinkage to cause tearing of cerebral blood vessels.

If the hypernatremia persists for more than a few days, brain water content may return to normal or near-normal levels due to accumulation in the brain cells of amino acids known as *idiogenic osmoles*, in particular taurine. The formation of these idiogenic osmoles increases intracellular osmolality, attracts water back into the brain cells, and restores their cellular volume. If the hypertonicity develops gradually, this protective mechanism tends to prevent severe brain cell shrinkage.

TREATMENT The cornerstone of treatment is volume repletion. Volume should be replaced first with NS or LR. Either will have, by definition, a lower $[\text{Na}^+]$ than the patient's serum. Some practitioners inappropriately fear using NS solution from concern that an $[\text{Na}^+]$ of 154 mEq/L is higher than normal serum $[\text{Na}^+]$. However, in most hypernatremic states, there is a total body Na^+ deficit, and the use of NS allows a more gradual decrease in serum $[\text{Na}^+]$. Plasma-expanding fluids should continue until tissue perfusion is restored. Once perfusion has been established, the solution should be converted to 0.45 percent saline or other hypotonic solution. This should continue until the urine output is at least 0.5 mL/kg per h. The reduction in $[\text{Na}^+]$ should not exceed 10 to 15 mEq/L per d. A calculation to estimate free water deficit is:

$$\text{water deficit (L)} = \text{TBW} \times \left(\frac{\text{measured } [\text{Na}^+]}{\text{normal } [\text{Na}^+]} - 1 \right)$$

As a general rule, each liter of water deficit results in serum $[\text{Na}^+]$ rise of 3 to 5 mEq/L.

TABLE 27-6 Clinical Manifestations of Hypernatremic States Related to Serum Osmolality

Osmolality (mosmol/kg)	Manifestations
350-375	Restlessness, irritability
375-400	Tremulousness, ataxia
400-430	Hyperreflexia, twitching, spasticity
>430	Seizures and death

Unless the hypernatremia is of short duration, idiogenic osmoles are presumably present in brain cells. Consequently, too rapid rehydration and lowering of serum $[\text{Na}^+]$ can cause brain cells to swell, resulting in cerebral edema and an increased likelihood of seizures, permanent neurologic sequelae, or even death. **In acute hypernatremia, serum $[\text{Na}^+]$ levels can be corrected rather rapidly** with little fear of cerebral edema, because idiogenic osmoles will not yet be present in brain cells.

POTASSIUM (K^+)

Elemental K^+ is the major intracellular cation of the body. The normal intracellular concentration is 100 to 150 mEq/L, and the normal extracellular concentration is 3.5 to 5.0 mEq/L. The total body K^+ store ranges from 35 to 55 mEq/kg or 3500 mEq in a healthy 70-kg man. Approximately 70 to 75 percent of total body K^+ is found in muscle tissue; therefore, in patients with severe muscle wasting, total body stores may be as low as 20 to 30 mEq/kg. Daily intake of K^+ ranges from 50 to 150 mEq. Foods high in K^+ include oranges, grapefruit, tomatoes, bananas, avocados, and raisins. K^+ is excreted predominantly by the kidneys (90 percent), with some loss in the stool and by sweating. K^+ is filtered freely through the glomerulus and then reabsorbed in the proximal and ascending tubules. It is secreted in the distal tubule in exchange for Na^+ . In healthy individuals, the kidneys are able to excrete up to 6 mEq/kg per d.

In the absence of an acid-base disturbance, measuring extracellular $[\text{K}^+]$ is a reasonably accurate way to assess total body K^+ in relatively healthy patients. A decrease in measured serum $[\text{K}^+]$ from 4 to 3 mEq/L (with pH remaining steady) represents a total body deficit of approximately 200 to 400 mEq. An increase in measured serum $[\text{K}^+]$ from 4 to 5 mEq/L represents a total body K^+ increase of approximately 100 to 200 mEq/L. Extracellular K^+ represents about 2 percent of total body K^+ , or 70 mEq, and is influenced by two important variables: total body K^+ stores and distribution between the ICF and ECF spaces. Significant and rapid intracellular to extracellular shifting occurs in response to severe injury (i.e., surgical stress, trauma, or burns), acid-base imbalance, catabolic states, increased extracellular osmolality, or insulin deficiency. These shifts are important when viewed in light of the role of K^+ in maintaining the resting membrane potential. The normally balanced intracellular to extracellular gradient facilitates propagation of electrical impulses. This is particularly important in the functioning of the heart.

Hypokalemia

PATHOPHYSIOLOGY Hypokalemia is defined as a serum $[\text{K}^+]$ of less than 3.5 mEq/L. The most frequent causes of hypokalemia are intracellular shifts and increased losses (Table 27-7). K^+ will shift into cells as the pH of the ECF rises in exchange for hydrogen ions. A rise in the pH of 0.10 generally causes a 0.5 mEq/L decrease in serum $[\text{K}^+]$ levels. This relation applies to metabolic acid-base derangements. Although the reasons are unclear, respiratory alkalosis and acidosis have minimum effect on K^+ shift.

The clinical manifestations of hypokalemia usually start when serum concentrations reach 2.5 mEq/L, although they may appear sooner with rapid decreases in concentration (Table 27-8). The symptoms result from abnormalities in membrane polarization and affect almost every system.

TREATMENT The treatment of hypokalemia is replacement of K^+ . This can be done orally in stable patients who are able to tolerate oral intake. Foods rich in K^+ , salt substitutes, or K^+ supplements will work. **The oral dose is 20 mEq K^+ every 60 min until the anticipated result is achieved.** Intravenous replacement is appropriate for patients with severe hypokalemia. To prevent sudden or excessive

elevations in $[K^+]$, intravenous KCl should be administered in 10 mEq increments over 30 to 60 min, via a well running peripheral IV line. A cumulative dose of 20 mEq will raise serum $[K^+]$ by about 0.25 mEq/L. **No more than 40 mEq should be added to each L of IV fluid and infusion rates should be no greater than 40 mEq per h. Cardiac monitoring is recommended for infusion rates greater than 20 mEq per h.**

Hyperkalemia

PATHOPHYSIOLOGY Hyperkalemia is defined as measured serum $[K^+]$ of greater than 5.5 mEq/L. The most common cause is hemolysis during phlebotomy. Other causes are listed in Table 27-9.

TABLE 27-8 Symptoms and Signs of Hypokalemia

Cardiovascular
Hypertension

Renal
Increased ammonia production
Urinary concentrating defects
Metabolic alkalemia, paradoxical aciduria
Nephrogenic diabetes insipidus
Endocrine
Glucose intolerance

Clinical manifestations of hyperkalemia usually result from derangement in membrane polarization. Cardiac manifestations are the most serious. The following ECG changes are associated with hyperkalemia:

$[K^+]$ 6.5 to 7.5 mEq/L: tall peaked T waves, short QT interval, and prolonged PR interval

$[K^+]$ 7.5 to 8.0 mEq/L: QRS widening and flattening of the P wave

$[K^+]$ 10 to 12 mEq/L: the QRS complex may degrade into a "sine wave" pattern

In chronic or slowly developing hyperkalemia, ECG changes will occur at higher $[K^+]$ levels.

Ventricular fibrillation, complete heart block, and asystole may occur. Death from hyperkalemia is usually the result of diastolic arrest or ventricular fibrillation. Other symptoms include neuromuscular dysfunction weakness, paresthesias, areflexia, ascending paralysis, and gastrointestinal (nausea, vomiting, and diarrhea).

TREATMENT If there are no cardiac derangements, the initial step in the treatment of hyperkalemia is to confirm the presence of "true" hyperkalemia by a repeat sample. Immediate cessation of further K^+ administration and clinical determination of severity will drive management. Asymptomatic patients with relatively small elevation of K^+ (5.0 to 6.0 mEq/L) require determination and treatment of the underlying cause. Emergent treatment for symptomatic patients is divided into three phases:

1. Membrane stabilization (especially cardiac tissue)
2. Shift of K^+ into cells
3. Removal of K^+ from the body

Therapies used to treat hyperkalemia are outlined in Table 27-10. **If calcium is to be given to a patient on digitalis, great caution must be exercised, because hypercalcemia potentiates the toxic cardiac effects of digitalis.** In severe hyperkalemia, however, the risk-to-benefit ratio may be such that giving Ca^{2+} is warranted.

CALCIUM (Ca^{2+})

Ca^{2+} is the most abundant mineral in the body. The total body Ca^{2+} is 15 g/kg of body weight, or about 1 kg in an average-sized adult. Ca^{2+} is 99 percent bound in bone as phosphate and carbonate (mineral apatite), with the remainder in the ECF compartment. The normal daily intake of Ca^{2+} is 800 to 3000 mg, one third of which is absorbed primarily in the small bowel by active (vitamin D dependent) and passive (concentration dependent) absorption. Excretion of Ca^{2+} is primarily via the stool.

The measured serum $[Ca^{2+}]$ ranges from 8.5 to 10.5 mg/dL and is maintained by the function of parathyroid hormone, vitamin D metabolites (1,25-dihydroxyvitamin D₃, or calcitriol), and calcitonin.

Parathormone (parathyroid hormone, or PTH) is secreted by the parathyroid gland in response to low ionized Ca^{2+} levels. It raises $[Ca^{2+}]$ primarily by stimulating osteoclasts to increase bone resorption. It secondarily increases $[Ca^{2+}]$ by indirect action in the kidney (increases Ca^{2+} resorption and phosphorus excretion) and in conjunction with calcitriol to increase intestinal absorption. Calcitonin is influenced by elevations in $[Ca^{2+}]$, epinephrine, glucagon, and gastrin. Its primary effect is to inhibit the activity of osteoclasts, with a limited secondary effect to potentiate Ca^{2+} loss through the kidney.

The intravascular Ca^{2+} exists as 50 percent bound to plasma proteins, i.e., albumin, 45 percent free active ions, and 5 percent non-ionized (bound to other substances in plasma and interstitial fluids). A laboratory value reported in milliequivalents per liter is equal to half the amount in milligrams per deciliter; e.g., a value of 4.2 mg/dL is equal to 2.1 mEq/L (or 1.05 mosmol/L).

Changes in $[H^+]$ result in changes of the ionized $[Ca^{2+}]$, because Ca^{2+} and protons competitively bind to proteins. For example, hyperventilation leads to respiratory alkalosis and an attendant decrease in $[H^+]$. The decreased $[H^+]$ causes an increase in protein-bound Ca^{2+}

TABLE 27-9 Etiology of Hyperkalemia

Pseudohyperkalemia	Intra- to Extracellular Potassium Shift	Potassium Load	Decreased Potassium Excretion

and a decrease in serum ionized Ca^{2+} . It is the ionized fraction that is physiologically activity.

Various factors affect $[\text{Ca}^{2+}]$ protein binding;

1. Serum protein, of which albumin is the major component. On average, 0.8 mg of Ca^{2+} binds to 1 g of protein. Therefore, total serum $[\text{Ca}^{2+}]$ is equal to ionized $[\text{Ca}^{2+}]$ plus the product of 0.8 and total protein. A 1 g decrease in albumin results in a 0.8 mg/dL decrease in total calcium, with no change in ionized fraction.
2. Alkalosis produces a decrease in ionized fraction with no change in the total serum $[\text{Ca}^{2+}]$. Each 0.1 rise in pH lowers ionized $[\text{Ca}^{2+}]$ by about 3 to 8 percent.
3. Acidosis produces an increase in ionized fraction with no change in the total serum $[\text{Ca}^{2+}]$.

Hypocalcemia

PATHOPHYSIOLOGY Hypocalcemia is defined by an ionized $[\text{Ca}^{2+}]$ level of below 2.0 mEq/L. Normal ionized $[\text{Ca}^{2+}]$ is 2.1 to 2.6 mEq/L (1.05 to 1.3 mmol/L). Some common causes of hypocalcemia are shock, sepsis, renal failure, and pancreatitis. It is quite uncommon in ambulatory patients, except those with hypoparathyroidism (secondary to surgery) or chronic renal disease (Table 27-11).

Cellular Dysfunction Any process that interferes with cell metabolism, such as shock or sepsis, will tend to reduce ionized $[\text{Ca}^{2+}]$ by al-

lowing increased net movement of Ca^{2+} across the cell membrane into the cytoplasm of the poorly functioning cells. After trauma, serum $[\text{Ca}^{2+}]$ may be low, especially with the fat embolism syndrome, not only because of cell dysfunction and binding of calcium to free fatty acids but also because of fatty inhibition of cell membrane calcium pumps.

Pancreatitis Acute pancreatitis is an important cause of hypocalcemia. Pancreatic lipase breaks down fat into fatty acids and glycerol. The fatty acids combine with Ca^{2+} to form insoluble Ca^{2+} soaps and reduce serum $[\text{Ca}^{2+}]$. The combination of necrotic fat cells plus Ca^{2+} soaps makes up much of what is recognized as the fat necrosis of pancreatitis.

Drugs Many drugs can cause hypocalcemia (Table 27-12).

Postoperative Hypocalcemia Currently, more than 10 percent of post-parathyroidectomy patients may have hypoparathyroidism as defined by a fasting $[\text{Ca}^{2+}]$ of less than 8.5 mg/dL and a simultaneous inorganic phosphorus level of greater than 4.5 mg/dL. Postoperative hypocalcemia can be due to hypoparathyroidism from the permanent surgical removal of parathyroid tissue, from transient ischemia of the parathyroid glands in patients who have extensive bilateral neck surgery, or because of long-term hypercalcemic suppression of the non-adenomatous parathyroid glands.

TABLE 27-10 Emergency Therapy of Hyperkalemia

Therapy	Mechanism	Dose and Route	Onset of Action	Duration of Effect
Albuterol (nebulized)	Upregulates cAMP, shifts K^+ into cell	2.5 mg in 4 mL NS nebulized over 20 min	15-30 min	2 ^h
CaCl_2 (10%)*	Membrane stabilization	5-10 mL IV	1-3 min	30-50 min
Ca gluconate (10%)*	Membrane stabilization	10-20 mL IV	1-3 min	30-50 min
NaHCO_3	Shifts K^+ into cell	50-100 mEq IV	5-10 min	1-2 h
Insulin and glucose	Shifts K^+ into cell	10 units regular insulin 50 g glucose	30 min	4-6 h

Rhabdomyolysis

Renal Failure Hypocalcemia is a frequent finding in renal failure. This may be due in part to the resulting hyperphosphatemia, but there is also decreased production of 1,25-(OH)₂-vitamin D in the kidney, which in turn decreases intestinal absorption of calcium.

Phosphate Overload Phosphate overload from nonrenal causes also may lead to hypocalcemia. This is the presumed mechanism in the acute rhabdomyolysis of hyperpyrexia and major trauma. Hypomagnesemia in association with hypocalcemia may be seen in alcoholism, diuretic use, epilepsy, and renal failure.

Etiologies less likely to be encountered are listed in Table 27-11.

SYMPTOMS Serious physiologic changes do not usually occur until ionized levels in serum are less than 1.4 to 1.6 mEq/L (0.7 to 0.8 mmol/L; Table 27-13).

The severity of signs and symptoms depends greatly on the rapidity of the decrease in Ca²⁺. As serum [Ca²⁺] falls, neuronal membranes become increasingly more permeable to sodium, thereby enhancing excitation.

Decreased ionized [Ca²⁺] reduces the strength of myocardial contraction primarily by inhibiting relaxation. Hypocalcemia decreases the sensitivity of the heart to digitalis.

The most characteristic initial symptom of hypocalcemia after thyroid or parathyroid surgery is paresthesias around the mouth or in the fingertips. Hypocalcemia should be suspected in any patient who is irritable and has hyperactive deep tendon reflexes after neck surgery. It also should be suspected in patients who have seizures, particularly if they have ever had thyroid surgery, even if many years previously.

A positive Chvostek or Trousseau sign is generally considered to be good clinical evidence of hypocalcemia. A positive Chvostek sign is a twitch at the corner of the mouth when the examiner taps over the

TABLE 27-13 Symptoms and Signs of Hypocalcemia

Heart failure	
Vasoconstriction	

facial nerve just in front of the ear. However, it is present in about 10 to 30 percent of normal individuals. Nevertheless, eyelid muscle contraction with the Chvostek maneuver is said to be almost diagnostic of hypocalcemia.

The Trousseau sign, which is generally a more reliable indicator of hypocalcemia, is positive if carpal spasm is produced when the examiner applies a blood pressure cuff to the upper arm and maintains a pressure above systolic for 3 min. The fingers are spastically extended at the interphalangeal joints and flexed at the metacarpophalangeal joints. The wrist is flexed and the forearm is pronated.

Decreased plasma levels of ionized Ca²⁺ are diagnostic, but one also should suspect hypocalcemia if a patient has decreased levels of total Ca²⁺ in the presence of normal plasma proteins.

Electrocardiography The most characteristic ECG finding in hypocalcemia is a prolonged QT interval. However, the T wave is of normal width, and it is the ST segment that is really prolonged. This finding is usually seen with total serum calcium levels below 6.0 mg/dL.

TREATMENT Treatment of hypocalcemia is tailored to the individual and directed toward the underlying cause. If a patient is asymptomatic, oral Ca²⁺ therapy with or without vitamin D may be sufficient. Ca²⁺ lactate, gluconate, ascorbate, carbonate, and gluconate are available in oral preparations. Milk, because of the large amount of phosphate present, is not really a very good source of Ca²⁺, except in normal growing children who also need the phosphate.

If the patient is not symptomatic or if the hypocalcemia is not severe and prolonged for more than 10 to 14 days, treatment with Ca²⁺ may not be required. Symptomatic patients after thyroid or parathyroid surgery are often treated with parenteral Ca²⁺. With severe acute hypocalcemia, 10 mL of 10 percent CaCl₂ (or 10 to 30 mL of 10 percent Ca²⁺ gluconate) may be given IV over 10 to 20 min followed by a continuous IV infusion of 10 percent CaCl₂ at 0.02 to 0.08 mL/kg per h (1.4 to 5.6 mL/h in a 70-kg patient). The serum [Ca²⁺] should be rechecked at that point before continuing parenteral Ca²⁺. Intravenous calcium is recommended only in cases of symptomatic or severe hypocalcemia (ionized [Ca²⁺] <1.3 mEq/L or <0.65 mmol/L), because intravenous Ca²⁺ administration causes vasoconstriction and possible ischemia, especially in patients with low cardiac output who already have significant peripheral vasoconstriction. In addition, intravenous Ca²⁺ should be used with extreme caution in patients taking digitalis, because hypercalcemia can potentiate digitalis toxicity.

During massive transfusions, if the blood is being given faster than 1 unit every 5 min, 10 mL of 10 percent CaCl₂ can be given after every 4 to 6 units of blood if a patient is in shock or has heart failure despite adequate volume replacement therapy.

TABLE 27-12 Drugs That Can Cause Hypocalcemia

Phosphates (e.g., enemas, laxatives)
Phenytoin, phenobarbital
Gentamicin, tobramycin, actinomycin
Cisplatin
Heparin
Theophylline
Protamine
Glucagon
Norepinephrine
Citrate
Loop diuretics
Glucocorticoids
Magnesium sulfate
Sodium nitroprusside

Similar to hypokalemia, hypocalcemia is difficult to correct in the setting of hypomagnesemia. Hypomagnesemic states reduce parathormone and Ca^{2+} releases from bone. Therefore, magnesium should be replaced before, or in conjunction with, Ca^{2+} replacement.

Hypercalcemia

PATHOPHYSIOLOGY Hypercalcemia is a relatively common entity. It is defined as a total $[\text{Ca}^{2+}]$ exceeding 10.5 mg/dL or an ionized calcium level exceeding 2.7 mEq/L. More than 90 percent of occurrences are associated with hyperparathyroidism or malignancy, the latter being the most likely underlying presentation in the ED. A list of potential etiologies for hypercalcemia can be found in Table 27-14.

The effects of hypercalcemia can be neuromuscular, cardiovascular, gastrointestinal, renal, and skeletal. Neuromuscular changes include decreased sensitivity, responsiveness, and strength of muscular contraction and nerve conduction.

In mild hypercalcemic states, the heart's conduction is slowed and automaticity is decreased with a shortening of the refractory period. There is also increased sensitivity to digitalis preparations.

Loss of renal concentrating ability is the most frequent renal effect of hypercalcemia. This is a reversible tubular defect, which results in polyuria and volume depletion despite polydipsia. Potassium wasting results in hypokalemia in up to one third of patients. Nephrocalcinosis and nephrolithiasis are caused by the hypercalcemia and aggravated by volume depletion. As the hypercalcemia persists, increasing microscopic Ca^{2+} deposits in the kidney may result in progressive renal insufficiency.

SYMPTOMS Hypercalcemic patients with plasma total $[\text{Ca}^{2+}]$ below 12.0 mg/dL are usually asymptomatic, but higher levels can cause a wide variety of symptoms and signs (Table 27-15).

Patients with total $[\text{Ca}^{2+}]$ above 14 to 16 mg/dL are usually very weak, lethargic, and confused. Polyuria and polydipsia are due to impaired renal tubular reabsorption of water and result in volume depletion. Total $[\text{Ca}^{2+}]$ above 15.0 mg/dL may cause somnolence, stupor, and even coma.

A mnemonic sometimes used for the signs and symptoms of hypercalcemia is *stones* (renal calculi), *bones* (osteolysis), *moans* (psychiatric disorders), and *groans* (peptic ulcer disease, pancreatitis, and constipation).

Hypercalcemia should be suspected in patients with extensive metastatic bone disease, particularly if the primary site involves the breast, lungs, or kidneys, and in individuals with combinations of clinical problems, such as renal calculi, pancreatitis, or ulcer disease.

TABLE 27-14 Causes of Hypercalcemia

Malignancy*	Granulomatous disease*

TABLE 27-15 Symptoms and Signs of Hypercalcemia

General	Cardiovascular
Malaise, weakness	Hypertension
Polydipsia, dehydration	Dysrhythmias
Neurologic	Vascular calcifications
Confusion	ECG abnormalities
Apathy, depression, stupor	QT shortening
Decreased memory	Coving of ST-T wave
Irritability	Widening of T wave
Hallucinations	Digitalis sensitivity
Headache	Gastrointestinal
Ataxia	Anorexia, weight loss
Hyporeflexia, hypotonia	Nausea, vomiting
Mental retardation (infants)	Constipation
Metastatic	Abdominal pain
calcification	Peptic ulcer disease
Band keratopathy	Pancreatitis
Conjunctivitis	Urologic
Pruritus	Polyuria, nocturia
Skeletal	Renal insufficiency
Fractures	Nephrolithiasis
Bone pain	
Deformities	

Abbreviation: ECG = electrocardiogram.

On ECG, hypercalcemia may be associated with depressed ST segments, widened T waves, and shortened ST segments and QT intervals. Bradyarrhythmias may occur, and bundle branch patterns may progress to second-degree block and then to complete heart block. Levels above 20 mg/dL may cause cardiac arrest.

TREATMENT Treatment for hypercalcemia should be initiated in any symptomatic patient, or if $[\text{Ca}^{2+}]$ is above 14 mg/dL. Treatment consists of volume repletion (with NS), increasing renal Ca^{2+} elimination, decreasing Ca^{2+} mobilization from bone, and correction of the underlying disorder. Up to one third of patients with hypercalcemia have hypokalemia. Hypomagnesemia also is common.

Renal elimination of Ca^{2+} can be increased with furosemide (40 to 100 mg IV every 2 to 4 h) or other loop diuretic. Care must be taken, because diuresis can worsen the volume depleted state, hypokalemia, and hypomagnesemia.

Decreased mobilization of Ca^{2+} from bone through reduction of osteoclast activity can be accomplished with several medications. Recommendations for initiating the following medications in the ED are generally lacking, but consideration should be given to using them if the patient is symptomatic or the $[\text{Ca}^{2+}]$ is greater than 14 mg/dL. Mithramycin (25 $\mu\text{g/kg}$ IV) is particularly useful in patients with metastatic bone disease, but calcitonin (4 IU/kg SC or IM every 12 h) is less toxic. Glucocorticoids (hydrocortisone, 3 mg/kg per d in divided doses) are useful in patients with sarcoidosis, vitamin A or D intoxication, multiple myeloma, leukemia, or breast cancer. They work by inhibiting bone resorption and gastrointestinal absorption of Ca^{2+} . It is also postulated that they cause Ca^{2+} to shift inside cells, where it may become bound to mitochondria. Gallium nitrate has been approved for use in the United States. It acts by decreasing the solubility of base crystals. It potentiates nephropathy, and its use should be avoided in renal disease. Intravenous phosphates are no longer used.

MAGNESIUM (Mg^{2+})

The total body content of Mg^{2+} is 24 g, or 2000 mEq, 50 to 70 percent of which is fixed in bone and only slowly exchangeable. Most of the remaining Mg^{2+} is found in the ICF space, with a concentration of approximately 40 mEq/L. The distribution of Mg^{2+} is similar to that of K^{+} , with the major portion being intracellular. It is the second most abundant intracellular cation. Normal serum $[\text{Mg}^{2+}]$ ranges between 1.5 and 2.5 mEq/L. Mg^{2+} present in blood is 25 to 35 percent protein

bound, 10 to 15 percent complexed, and 50 to 60 percent ionized. The normal dietary intake of Mg^{2+} is approximately 20 to 28 mEq per d, or 240 to 336 mg per d, and is found in vegetables such as dry beans and leafy greens, meat, and cereals. Sixty percent of excreted Mg^{2+} is via the stool, with the remainder via the urine. Mg^{2+} promotes enzyme reactions within the cell during metabolism, helps in the production of ATP, participates in protein synthesis, and plays a role in coagulation, platelet aggregation, and neuromuscular activity.

Hypomagnesemia

PATHOPHYSIOLOGY A wide variety of problems can cause hypomagnesemia (Table 27-16). In adults, magnesium deficiencies are seen most frequently in alcoholics, in malnourished patients, and in patients with cirrhosis, pancreatitis, or excessive gastrointestinal fluid losses. Diarrhea produces greater Mg^{2+} losses ($[Mg^{2+}]$ of 10 to 14 mEq/L) than does upper gastrointestinal loss (1 to 2 mEq/L).

Intravenous hyperalimentation or treatment of diabetic ketoacidosis without providing adequate Mg^{2+} , especially in a previously malnourished patient, can cause an abrupt fall in plasma magnesium levels. Renal wasting of Mg^{2+} can be seen with loop diuretics, hypophosphatemia, ketoacidosis, aminoglycosides, and nephrotoxic chemotherapeutic agents.

Magnesium is essential to a large number of vital enzymes, including membrane-bound ATPase. Consequently, hypomagnesemia may result in a wide variety of neuromuscular, gastrointestinal, and cardiovascular changes (Table 27-17).

SYMPTOMS The diagnosis of hypomagnesemia in the presence of normal serum calcium levels is suggested by increased neuromuscular irritability (hyperreflexia, positive Chvostek or Trousseau sign, tremor, tetany, or even convulsions). Hypomagnesemia should be suspected in alcoholics, cirrhotics, and patients on intravenous fluids for prolonged periods. Hypomagnesemia also may develop rapidly during intravenous hyperalimentation, especially when anabolism begins.

The ECG changes seen with magnesium deficiencies include prolonged PR and QT intervals, widened QRS complexes, depression of ST segments, and inversion of T waves, especially in the precordial leads. The changes may be somewhat similar to those caused by hypokalemia and/or hypocalcemia, and many of these changes may be related to Mg^{2+} deficiency altering cardiac intracellular potassium content.

TREATMENT Hypokalemia, hypocalcemia, and hypophosphatemia are often present with severe hypomagnesemia and must be monitored carefully. Hypocalcemia does not develop until $[Mg^{2+}]$ falls below 1.2 mg/dL.

Patients with Mg^{2+} deficiency may require more than 50 mEq of oral Mg^{2+} (6 g of $MgSO_4$) per day. In chronic alcoholics with delirium tremens and in patients with severe proven hypomagnesemia, up to 8 to 12 g of $MgSO_4$ may be given IM or IV the first day. The first 10 to 15 mEq (1.5 to 2.0 g) of intravenous $MgSO_4$ can be given over 1 to 2 h. This may be followed by up to 4 to 6 g per d thereafter. Approximately half of the administered Mg^{2+} will be lost in the urine.

Hypermagnesemia

PATHOPHYSIOLOGY Hypermagnesemia is rarely encountered in emergency practice. A small elevation in serum concentration has little clinical significance. The most common etiology for hypermagnesemia can be found in patients with renal insufficiency or renal failure who ingest Mg^{2+} -containing drugs. Hypermagnesemia may be seen in the perinatal setting in a mother and her neonate secondary to the treatment of preeclampsia or eclampsia. Other etiologies of hypermagnesemia include lithium ingestion, volume depletion, or familial hypocalciuric hypercalcemia (Table 27-18).

SYMPTOMS Hypermagnesemia only rarely produces symptoms. Mg^{2+} decreases the transmission of neuromuscular messages and thus acts as a CNS depressant and decreases neuromuscular activity. Approximate $[Mg^{2+}]$ causing signs and symptoms can be found in Table 27-19.

EVALUATION AND TREATMENT Serum $[Mg^{2+}]$ are usually diagnostic. The possibility of hypermagnesemia should be considered in patients with hyperkalemia or hypercalcemia. Hypermagnesemia also should be suspected in patients with renal failure, particularly in those who are taking magnesium-containing antacids (see Table 27-18).

The primary treatment available is the immediate cessation of Mg^{2+} administration. If renal failure is not evident, dilution by intravenous fluids followed by furosemide (40 to 80 mg IV) may be helpful. Calcium directly antagonizes the effects of magnesium; severe

	Anemia

symptomatic hypermagnesemia can be treated with 5 mL 10 percent CaCl_2 IV over 5 min. Patients with renal failure may benefit from dialysis using a decreased Mg^{2+} bath that lowers serum $[\text{Mg}^{2+}]$.

CHLORIDE (CF)

Alteration in serum chloride is seldom a primary disturbance. Chloride is a major extracellular anion that has the power of increasing or decreasing in concentration whenever changes occur in the concentration of other anions. For example, in non-anion gap metabolic acidosis, the decrease in serum $[\text{HCO}_3^-]$ is replaced by Cl^- . CF plays a major role in the maintenance of urinary output, ECF, acid and base, and potassium balance. $[\text{CF}]$ should be between 95 and 105 mEq/L. CF is easily absorbed in the intestine by active and passive transport. Ninety percent of CF is excreted through the kidney, with the remainder secreted in sweat and stool.

Hypochloremia

PATHOPHYSIOLOGY Hypochloremia usually manifests when levels are below 95 mEq/L. It is usually caused by excessive diuresis, vomiting, or nasogastric tube drainage. Volume loss results in alkalosis. When CF is lost via the urine or gastrointestinal fluids, there is an increase in Na^+ and HCO_3^- resorption secondary to the volume contraction. Na^+ may be resorbed in the kidney with CF or HCO_3^- .

SYMPTOMS There are no signs or symptoms specific for hypochloremia. The clinical approach is based on the findings of the secondary effects. It is important to determine the urinary $[\text{CF}]$, because low urinary $[\text{CF}]$ (<10 mEq/L) in the setting of metabolic alkalosis implies chloride-responsive alkalosis (see Chap. 25). If the urinary CF levels are higher (>40 mEq/L), the hypochloremia may be secondary to volume overload or dilution. Increased urinary CF also may result from increased mineralocorticoid activity, which leads to the retention of HCO_3^- and Na^+ at the expense of H^+ , K^+ , and CF .

TABLE 27-18 Causes of Hypermagnesemia

TABLE 27-19 Symptoms and Signs of Hypermagnesemia

Level (mEq/L)	Symptom
2.0-3.0	Nausea
3.0-4.0	Somnolence
4.0-8.0	Loss of DTRs
8.0-12.0	Respiratory depression
12.0-15.0	Hypotension, heart block, cardiac arrest

Abbreviation: DTRs = deep tendon reflexes.

TREATMENT Generally speaking, emergency practice concerns itself with addressing the acute issues associated with the underlying condition. The treatment of chloride-responsive metabolic alkalosis (urinary $[\text{CF}] = 10$ mEq/L) is intravenous NS administration.

Hyperchloremia

PATHOPHYSIOLOGY Excessive concentration of CF is usually the result of administration of NaCl , volume depletion, or entities causing metabolic acidosis without a widened anion gap (see Chap. 25).

TREATMENT Treatment is aimed at the underlying issues (see Chap. 25).

PHOSPHORUS

Phosphorus is an essential mineral that exists mainly as hydroxyapatite (85 percent) or as an intracellular constituent (10 to 15 percent). Only about 1 percent is in the ECF, so serum measurements may not accurately reflect total body stores. Serum phosphate levels decrease with age from a high of 4.0 to 7.0 mg/dL in newborns to 2.5 to 5.0 mg/dL in adults. The total body phosphorus in a normal man is approximately 700 g (10 to 15 g/kg). This amount is predominantly in bone (80 percent), where phosphorus plays a major role in structural integrity. Serum Ca^{2+} and phosphate are inversely proportional, and the product of their concentrations is maintained at approximately 30 to 40 mg/dL. Intracellular phosphorus is bound to protein or exists as organic esters.

Serum phosphorus, unlike the other elements, is 85 percent free and only 15 percent bound to proteins. Phosphate (PO_4^{3-}) may be present in different forms such as H_2PO_4^- or HPO_4^{2-} . Plasma phosphorus levels, unlike Ca^{2+} or Mg^{2+} , demonstrate diurnal variation with a morning nadir and are affected by age, hormones (insulin and growth hormone), and the amount of carbohydrate ingestion. Therefore, fasting levels are the most useful, because glucose infusion and carbohydrate and phosphorus ingestion lower serum levels.

Normal daily intake is between 10 and 12 mmol. Phosphorus absorption is proportional to dietary intake. Approximately 70 percent is absorbed via passive transport, with the remainder via active transport, which is dependent on $1,25-(\text{OH})_2\text{-vitamin D}$. Excretion is predominantly in the urine by the glomerulus, with the majority resorbed in the proximal tubules. This is regulated by PTH, which acts to lower serum phosphate by increasing renal excretion. Proximal tubule absorption increases when serum PO_4^{3-} levels drop, and with hypoparathyroidism, volume depletion, hypocalcemia, or the presence of growth hormone. Excretion increases in the presence of volume expansion, hypercalcemia, acidosis, hypomagnesemia, hypokalemia, glucocorticoids, diuretics, calcitonin, or PTH. Phosphate is essential to a wide variety of biochemical reactions, especially energy metabolism in the form of high-energy phosphate and phosphocreatine.

Hypophosphatemia

PATHOPHYSIOLOGY Because phosphorus is abundant in many foods and readily absorbed, hypophosphatemia is relatively unusual. Mechanisms leading to hypophosphatemia include movement of phosphate into cells, increased renal excretion, and decreased gastrointestinal absorption. Significant hypophosphatemia is unlikely to be encountered in the ED, because it is associated most often with hyperalimentation. There may be a shift into cells seen with alkalosis (respiratory or metabolic). Other conditions that may on occasion present to the ED with complications related to phosphate depletion include hyperparathyroidism, malignancy with hypercalcemia (phosphaturia), renal tubular defects, and use of phosphate-binding antacids. Conditions unlikely to be seen in ED practice but associated with hypophosphatemia include rapid healing, prolonged anabolic states, recovery from starvation or severe burns, and partial hepatectomy.

Redistribution phenomena also can occur with glucose infusion. Phosphorus is consumed during phosphorylation as glucose moves into cells. This is one of the theoretical reasons potassium phosphate is advocated as part of K^+ replacement regimens in the treatment for diabetic ketoacidosis. **However, it should not be the initial form of K^+ replacement in the ED, because significant hypophosphatemia is unlikely to occur for 12 to 24 h, and parenteral administration may cause precipitous falls in serum (Ca^{2+}).** (Also see Chap. 211).

SYMPTOMS Symptoms of hypophosphatemia are unlikely to appear until levels are quite low, usually below 1 mg/dL. Hypophosphatemia should be particularly sought as a potential complication 12 to 24 h after initiating treatment for diabetic ketoacidosis and 24 to 96 h after treatment for alcoholic ketoacidosis. Detecting total body depletion cannot reliably be ascertained from blood phosphorus levels, because the ratio of intracellular to extracellular phosphorus is approximately 100:1. Specific findings of hypophosphatemia are presented in Table 27-20.

TREATMENT Fortunately, PO_4^{3-} deficiency is easily reversible by correcting the underlying disorder and replacing phosphorus. Milk is an excellent source of phosphorus and contains 1000 mg/L. Tablets come in the form of sodium or potassium phosphate. If symptoms are severe enough, intravenous PO_4^{3-} may be necessary.

The oral replacement dosage for uncomplicated, mild hypophosphatemia (>2 mg/dL) is 1200 to 1500 mg daily, given in divided doses. Intravenous replacement for severe (<1 mg/dL) hypophosphatemia, concomitant cardiac, or respiratory compromise is 2.5 to 5 mg/kg (0.08 to 0.16 mmol/kg) over 6h. Electrolytes should be

rechecked after 6 h before further replacement. Slower rates are required in patients with renal insufficiency, and less total replacement is given in patients with hypercalcemia to avoid metastatic calcifications.

Hyperphosphatemia

PATHOPHYSIOLOGY Hyperphosphatemia may be due to reduced renal excretion, increased PO_4^{3-} movement out of cells into the ECF, or increased phosphorus or vitamin D intake. Hyperphosphatemia is most apt to be seen with renal dysfunction. It also may be seen with hypoparathyroidism or any problem associated with hypocalcemia or hypomagnesemia.

SYMPTOMS Problems due to hyperphosphatemia are usually those due to associated renal failure, hypocalcemia, or the hypomagnesemia that is usually present.

TREATMENT Therapy is aimed at treating the underlying cause and restricting calcium phosphate intake to less than 200 mg per d. With normal renal function, PO_4^{3-} excretion can be increased with saline (1 to 2 L every 4 to 6 h) and acetazolamide (500 mg every 6 h). Phosphorus absorption from the gastrointestinal tract can be decreased with oral phosphate binders (i.e., aluminum carbonate or hydroxide 30 to 45 mL daily). These binders also absorb PO_4^{3-} secreted into the gut lumen and are of benefit even if no oral phosphorus is given. In severe cases, hemodialysis may be required.

THE NORMAL CARDIAC CONDUCTING SYSTEM

The heart consists of variations of three types of specialized tissue: (1) pacemaker cells that undergo spontaneous depolarization and can initiate an electric impulse (this property is called *automaticity*); (2) cells that conduct electrical waves more rapidly than other cardiac cells, causing a very rapid propagation of the electric impulse through out the heart; and (3) contractile cells, which contract when electrically depolarized.

The sinus [sinoatrial (SA)] node is normally the dominant cardiac pacemaker unless disease or drugs depress its activity. The SA node is near the junction of the superior vena cava and right atrium. Blood supply is from the sinus node artery, which arises from the proximal few centimeters of the right coronary artery (in about 55 percent of individuals) or from the proximal few millimeters of the left circumflex artery (in the other 45 percent). Sympathetic and parasympathetic nerves, which are the primary controls of the heart rate, innervate the SA node. The normal sinus discharge rate is 60 to 100 beats/min.

The electric impulse generated by the SA node spreads in waves through the cardiac muscles of the atria, thus activating atrial contraction. In addition, specialized atrial conduction tracts (anterior, middle, and posterior internodal tracts) serve to propagate the electric impulse through the atria and between the sinus node and the atrioventricular (AV) node.

The atria and ventricles are insulated electrically from each other by the fibrous connective tissue of the AV ring (annulus fibrosus).

SECTION 3 • RESUSCITATIVE PROBLEMS AND TECHNIQUES

Normally, electrical impulses from the atria can reach the ventricles only by passing through the AV node and infranodal conducting system.

The AV node is under the surface of the right atrial endocardium and directly above the insertion of the septal leaflet of the tricuspid valve. The AV node receives its blood supply from the right coronary artery as it turns to form the posterior descending artery in 90 percent of individuals or as it comes off the left circumflex artery in the other 10 percent. This accounts for the common occurrence of AV conduction disturbances with acute inferior myocardial infarctions (MIs). The AV node is innervated by sympathetic and parasympathetic fibers. It has two important electrophysiologic characteristics: a slow conduction velocity and a long refractory period. The slow conduction velocity through the AV node allows time for atrial contraction to give an extra 10 percent ventricular filling, which increases stroke volume according to the Frank-Starling principle. This "atrial kick" is most important for patients with ventricular failure. The long refractory period of the AV node protects the ventricles from excessively rapid stimulation; very rapid heart rates decrease the diastolic filling period and thereby reduce cardiac output, which may cause deterioration into ventricular fibrillation or cardiac failure. Cells near the AV node have automaticity and will escape from the control of the SA node if its rate becomes too slow, normally slower than 60 beats/min.

Electrical impulses leave the inferior pole of the AV node along the bundle of His, which travels downward along the posterior margin of the membranous portion of the intraventricular septum to reach the top of the muscular portion. The bundle of His consists of Purkinje cells, which are the most rapidly conducting cells of the heart. The common bundle is only 1 to 2 cm in length before it divides at the crest of the muscular intraventricular septum into the right and left bundle branches (RBB and LBB, respectively). The RBB is a compact group of fibers that travels down to the apex of the right ventricle before separating into smaller branches. The LBB travels 2 to 3 cm before fanning out into a virtual sheet of fibers to cover the left ventricle. There are two relatively distinct pathways to the base of the papillary muscles, the left anterior superior fascicle (LASF) and the left posterior inferior fascicle (LPIF). These fascicles are distinguished more readily by electrical means than by anatomy in humans, but they can be seen clearly in animals.

The blood supply to the RBB and LASF is from the same sources: about half the time from the AV nodal artery and branches from the left anterior descending coronary artery and the other half from the left anterior descending artery alone. The LPIF is supplied about half the time from the AV nodal artery and the other half by the AV nodal artery and left anterior descending artery. Infarction in the region supplied by the left anterior descending artery can affect the RBB and LASF but very rarely the LPIF.

Accessory tracts are embryologic remnants of myocardium found in the AV annulus that can transmit electrical impulses between the atria and the ventricles and thus bypass all or part of the AV node and infranodal system. These bypass tracts conduct at different rates and are the anatomic basis for the preexcitation syndrome.

THE NORMAL ELECTROCARDIOGRAM

The clinical surface electrocardiogram (ECG) records the potential (voltage) differences between "neutral" ground and recording electrodes. The ECG is generated by the electrical activity of the heart and depicts the net sum of this activity recorded over time. By convention, a potential difference that points toward a recording electrode is assigned a positive deflection on the ECG, and a potential that points away from the recording electrode is assigned a negative deflection. Also by convention, routine ECG recordings are obtained with paper speed of 25 mm/s (2.5 cm/s) and signal calibration of 1.0 mV/10 mm (1.0 cm).

In Figure 28-1, depolarization starts on the left side of the ventricular septum and initially proceeds to the right; this action is recorded as a small negative deflection in the recording electrode. Subsequent

FIG. 28-1. Ventricular depolarization recorded in lead V₆.

depolarization involves the free walls of both ventricles; further, because the left side has a much larger mass, the net sum of electrical activity is directed toward the recording electrode, and a tall, positive deflection is recorded.

The P-QRS-T complex of the normal ECG represents electrical activity over one cardiac cycle (Figure 28-2). The P wave is caused by atrial depolarization. The QRS complex usually obscures atrial repolarization. The normal P-wave duration is shorter than 0.10 s (2.5 mm), and normal amplitude is less than 0.3 mV (3 mm). A P wave originating from the SA node is directed inferiorly and to the left on the frontal plane. The P-R interval is the time between the onset of depolarization in the atria and the onset of depolarization in the ventricles. It is commonly used as an estimation of AV nodal conduction time, because the AV node is the most likely site for delay in conduction. For adults in sinus rhythm, the P-R interval is 0.12 to 0.20 s (3 to 5 mm at 25 mm/s).

The QRS complex indicates ventricular depolarization. In general, depolarization starts on the endocardium and spreads outward to the epicardium. Despite the large amount of myocardium that must be depolarized, the specialized conducting system makes this a rapid process, and the normal QRS duration is 0.06 to 0.10 s (1.5 to 2.5 mm). Any delay in intraventricular conduction results in a wide QRS. Ectopic impulses that originate below the bundle of His or that arrive before repolarization of the bundle branches also result in a widened QRS, because they do not use the Purkinje network.

Although small negative initial deflections (Q waves) are normal, large Q waves can be due to an electrically nonexcitable area just under the recording electrode. **An abnormal Q wave has a width of 0.04 s or greater and a height one third that of the QRS complex.**

The ST segment represents the plateau phase of ventricular depolarization. Although the ST segment is usually isoelectric, a small deviation, less than 0.1 mV (1 mm), may be normal.

The T wave is caused by ventricular repolarization. Depolarization is a rapid, nearly simultaneous release of stored energy (like the re-

FIG. 28-2. Normal P-QRS-T electrocardiographic pattern.

lease of a compressed spring); repolarization is a slow, asynchronous event in which the metabolic machinery of each cell restores the transmembrane potential. Therefore, the T-wave duration is much longer and the amplitude much lower than those of the QRS complex. In general, repolarization starts on the epicardium and spreads to the endocardium. Many factors can influence this normal repolarization sequence: (1) metabolic factors (hypoxia, fever, drugs), (2) autonomic stimuli (abdominal pain, hyperventilation), (3) myocardial hypertrophy, (4) myocardial ischemia or inflammation, and (5) abnormal depolarization (bundle-branch block).

The QT interval represents ventricular depolarization and repolarization. QT duration is commonly between 0.33 and 0.42 s, but it does vary inversely with heart rate. The corrected interval is obtained by dividing the measured QT interval (in seconds) by the square root of the R-R interval (in seconds; i.e., $QT_c = QT/\sqrt{RR}$). The normal corrected QT interval is shorter than 0.47 s. This corrected QT should be checked before giving drugs such as ibutilide, and other drugs that can prolong the QT interval and may cause torsade de pointes (TdP). The potential association of droperidol to prolongation of the QT interval has been recently questioned.¹

The U wave may be seen as a normal component of the surface ECG. It is best seen in leads V_1 and V_2 . There is still some dispute as to the origin of the U wave. The classic explanation is that the U wave represents the delayed repolarization of the Purkinje network. More recent research has shown that the U wave can be seen at the same time as early afterdepolarizations in patients with a prolonged QT interval and TdP.^{1,2}

CARDIAC DYSRHYTHMIAS

There are many protocols for the classification of dysrhythmias and conduction disturbances. Dysrhythmias are basically classified in relation to the rate and site of abnormality. Conduction disturbances are usually classified as to the site and degree of block.

Cardiac dysrhythmias may decrease cardiac output if the ventricular rate is too fast or slow. In an adult without cardiac disease, heart rates between 40 and 160 beats/min are usually well tolerated, because physiologic adaptations can maintain adequate cardiac output and blood pressure. In adults with significant heart disease, rates slower than 50 or faster than 120 beats/min may decrease cardiac output based on a poorly functioning ventricle, because of basic myocardial cell damage, ischemic cells, valvular disease, or a combination of these.

Mechanisms of Tachydysrhythmia

There are three accepted mechanisms for tachydysrhythmias: (1) increased automaticity in a normal or ectopic site, (2) reentry in a normal or accessory pathway, and (3) afterdepolarizations causing triggered rhythms. Although treatment is best directed by an understanding of the underlying process, uncertainty still exists over the precise mechanism of many dysrhythmias, and therapy is often empiric.

An ectopic focus is an area of the heart, away from the normal sinus node pacemaker, that acquires independent pacemaker activity and usurps the pacemaking role. The result can be one extrasystole or multiple extra depolarizations. These ectopic pacemakers can be the result of (1) enhanced automaticity of subsidiary pacemaker cells (i.e., in the AV node or infranodal conducting system) or (2) abnormal automaticity of myocardial cells, which seldom possess pacemaking activity (i.e., Purkinje cells). Dysrhythmias due to an ectopic focus usually have a gradual onset ("warmup period"). The termination is also gradual, as opposed to the abrupt onset and termination seen with reentry or triggered mechanisms.

Reentry requires a temporary or permanent unidirectional block in one limb of a circuit and slower-than-normal conduction around the entire circuit. These conditions are secondary to disease, drugs, accessory pathways, or when tissue is stimulated during the partial refractory period (before full repolarization), as with premature depolarizations.

As indicated in Figure 28-3, the inciting impulse traveling in the normal downward direction encounters the two limbs, finds limb *a* blocked, and travels down limb *b*. Upon reaching the bottom portion of the circuit where the two limbs rejoin, the impulse can then travel retrograde up limb *a* and reach the upper connection of the circuit. Normally, conduction is so rapid that the impulse would encounter limb *b* still refractory to stimulation, and no further propagation would occur. However, if conduction around the circuit were slow enough, limb *b* would be able to conduct the impulse again in the antegrade direction. With the right size circuit and conduction velocity, an electrical impulse can continue traveling around the circuit in a cyclic manner. Each time the impulse passes the upper and lower limb connections, a depolarization occurs.

Reentry can occur around anatomically defined circuits, resulting in a regular rapid rhythm, such as paroxysmal supraventricular tachycardia (SVT). Conversely, reentry can occur in a disorganized and chaotic fashion through a syncytium of myocardial tissue as seen, for example, in atrial or ventricular fibrillation.

Triggered dysrhythmias are due to the oscillations of the transmembrane potential during or after repolarization (afterpotentials). Under ideal conditions of rate, afterpotentials reach threshold and trigger a complete depolarization (afterdepolarization). Once triggered, this process may be self-sustaining. Triggered dysrhythmias associated

FIG. 28-3. Reentry circuit.

with early afterpotentials are enhanced by slow heart rates and usually treated by accelerating the ventricular rate with positive chronotropic drugs or electrical pacing. Triggered dysrhythmias associated with delayed afterpotentials are enhanced by fast heart rates. Treatment with agents that have a negative chronotropic action is usually effective.

The urgency with which tachydysrhythmias require treatment is guided by two considerations: (1) evidence of hypoperfusion (shock, altered mental status, anginal chest pain, or pulmonary edema) and (2) the potential to degenerate into a more serious dysrhythmia or cardiac arrest. The two treatment methods most commonly used are intravenous drugs for the clinically stable patient and synchronized cardioversion or defibrillation for the unstable patient. Some tachydysrhythmias are amenable to overdrive electrical pacing but frequently require rates faster than 200 beats/min to capture the ventricle.

Mechanisms of Bradydysrhythmia

Bradycardias can be caused by two mechanisms: depression of sinus nodal activity or conduction system blocks. In both situations, subsidiary pacemakers take over and pace the heart; provided the pacemaker is above the bifurcation of the bundle of His, the rate is generally adequate to maintain cardiac output.

The need for emergent treatment of bradycardias is guided by two considerations: (1) evidence of hypoperfusion and (2) the potential to degenerate into a more profound bradycardia or ventricular asystole. In general, emergent treatment is not required, unless (1) the heart rate is slower than 50 beats/min and there is clinical evidence of hypoperfusion or (2) the bradycardia is due to structural disease of the infra-nodal conducting system (transient or permanent) that has a risk of progressing to complete AV block. The first group of patients requires immediate treatment during assessment of the etiology of the bradycardia and consideration of whether internal pacing will be required. The second group of patients does not always require immediate treatment but should be monitored closely, with therapy readily available, while arrangements are made for further evaluation and possible internal cardiac pacing.

Three methods are currently available for emergent treatment of bradycardias: atropine, isoproterenol, and transcutaneous cardiac pacing.

Atropine should be the initial agent, at doses of 0.5 mg intravenously every 5 min until the desired response is achieved or a total vagolytic dose (about 0.05 mg/kg in humans) is given. Usually, if no response is seen after a cumulative dose of 2.0 mg, further doses are not effective. The vast majority of bradycardias due to problems of the sinus or AV node respond to atropine. Even some patients with infra-nodal blocks may respond, so atropine deserves consideration in most bradycardias when emergent treatment is desired. Atropine can increase rate and myocardial oxygen consumption; therefore, it has no place in an otherwise stable patient with bradycardia.

Isoproterenol can be used for refractory symptomatic bradycardia (when atropine is ineffective), generally as a result of disease of the infra-nodal conducting system. Isoproterenol is given as a constant infusion, starting at a rate of 0.5 to 2.0 μ g/min and increasing to 10 μ g/min, as required, to maintain a heart rate of 60 beats/min. Isoproterenol increases myocardial oxygen demand, stimulates ventricular ectopy, and produces peripheral vasodilation, making it a significantly less attractive agent than atropine. The reported response to isoproterenol is weaker than that observed with atropine, although isoproterenol is usually used only in patients who fail while receiving atropine. It is difficult to say how effective isoproterenol would be if used initially, but there is no recommendation for its use as a front-line agent.

External cardiac pacing represents a reemergence of an old concept with new electronics that make the technique more sensitive and likely to capture rhythm. This device should be available in every emergency facility. The emergency physician must become familiar with the technique of applying the transcutaneous pacemaker so that it will sense and pace appropriately.

Internal pacing is the definitive treatment for progressive or persistent bradycardias. Emergent internal pacing is possible with the use of balloon-tipped or semi-flexible flotation catheters, although, without fluoroscopic guidance, it is often technically difficult to achieve stable placement in a patient with low cardiac output.

Supraventricular Dysrhythmias

SINUS DYSRHYTHMIA Some variation in the sinus node discharge rate is common, but **if the variation exceeds 0.12 s between the longest and shortest intervals, sinus dysrhythmia is present.** The ECG characteristics of sinus dysrhythmia are (1) normal sinus P waves and P-R intervals, (2) 1:1 AV conduction, and (3) variation of at least 0.12 s between the shortest and longest P-P interval (Figure 28-4).

Clinical Significance Sinus dysrhythmia is frequently a normal finding in children and young adults; it tends to disappear with advancing age. Sinus dysrhythmia is most commonly a phasic (respiratory variation) variety and less commonly a nonphasic variety. In the phasic variety, the sinus node rate accelerates during inspiration and decelerates during expiration, because of changes in vagal tone occurring with respiration (Bainbridge reflex). The irregularity in the phasic or nonphasic varieties can be exaggerated by conditions that increase vagal tone. During long intervals of sinus dysrhythmia, junctional escape beats may occur.

Treatment None is required.

SINUS BRADYCARDIA Sinus bradycardia occurs when the sinus node rate falls below 60 beats/min. The ECG characteristics of sinus bradycardia are (1) normal sinus P waves and P-R intervals, (2) 1:1 AV conduction, and (3) atrial rate below 60 beats/min.

Clinical Significance Sinus bradycardia represents a suppression of the sinus node discharge rate. Sinus bradycardia can be (1) physiologic (in well-conditioned athletes, during sleep, or with vagal stimulation), (2) pharmacologic (digoxin, opioids, reserpine, (3-adrenergic antagonists, calcium channel blockers, quinidine), or (3) pathologic (acute inferior MI, increased intracranial pressure, carotid sinus hypersensitivity, hypothyroidism).

Treatment

1. Sinus bradycardia usually does not require specific treatment unless the heart rate is slower than 50 beats/min and there is evidence of hypoperfusion.
2. Therapy should begin with atropine as previously described. Most patients will respond to one or two doses.
3. Isoproterenol can be used if atropine is ineffective.
4. External cardiac pacing can be used in the patient refractory to atropine or isoproterenol.
5. Internal pacing is required in the patient with symptomatic recurrent or persistent sinus bradycardia.

SINUS TACHYCARDIA Sinus tachycardia originates from acceleration of the sinus node discharge rate. The ECG characteristics of sinus tachycardia are (1) normal sinus P waves and P-R intervals, (2) 1:1 AV conduction, and (3) an atrial rate usually between 100 and 160 beats/min.

FIG. 28-4. Sinus dysrhythmia.

Clinical Significance Sinus tachycardia represents an acceleration of the sinus node discharge rate, usually in response to three categories of stimuli: (1) physiologic (infants and children, exertion, anxiety, emotions), (2) pharmacologic (atropine, epinephrine and other sympathomimetics, alcohol, nicotine, caffeine), or (3) pathologic (fever, hypoxia, anemia, hypovolemia, pulmonary embolism). In many of these conditions, the increased heart rate is due to an effort to increase cardiac output to match increased circulatory needs.

Treatment

1. No specific treatment is usually required, but any underlying conditions should be investigated and treated.
2. Some patients with acute MI have an "inappropriate" tachycardia and benefit from slowing heart rate with p-adrenergic antagonists.

PREMATURE ATRIAL CONTRACTIONS Premature atrial contractions (PACs) originate from ectopic pacemakers anywhere in the atrium other than the sinus node. The ECG characteristics of PACs are (1) an ectopic P' wave that appears sooner (prematurely) than the next expected sinus beat, (2) an ectopic P' wave that has a different shape and axis, and (3) the ectopic P' wave may or may not be conducted through the AV node (Figure 28-5). A PAC is not conducted through the AV node if it reaches the AV node during the absolute refractory period and is conducted with a delay (longer P'R interval) during the relative refractory period. Most PACs are conducted with typical QRS complexes, but some may be conducted aberrantly through the infra-nodal system, if they reach a bundle branch during the refractory period. The sinus node is often depolarized and "reset," so that, although the interval after the PAC is often slightly longer than the previous cycle length, the pause is less than fully compensatory.

Clinical Significance Premature atrial contractions are common at all ages and often without heart disease. It is generally assumed, although it remains unproven, that stress, fatigue, alcohol, tobacco, and coffee may precipitate PACs. Frequent PACs may also be seen in chronic lung disease, ischemic heart disease, or digitalis toxicity. Premature atrial contractions may precipitate sustained atrial tachycardia, flutter, or fibrillation under certain circumstances.

Treatment

1. Any precipitating drugs or toxins should be discontinued.
2. Underlying disorders should be treated.

3. Premature atrial contractions that produce symptoms or initiate sustained tachycardias can be suppressed with calcium channel blockers, p-adrenergic antagonists, quinidine, or procainamide.

MULTIFOCAL ATRIAL TACHYCARDIA Multifocal atrial tachycardia (MFAT; also known as "chaotic atrial rhythm" or "wandering atrial pacemaker") is an irregular rhythm caused by at least three different sites of atrial ectopy. The ECG characteristics of MFAT are (1) three or more differently shaped P waves; (2) changing P-P, P-R, and R-R intervals; and (3) atrial rhythm usually between 100 and 180 beats/min (Figure 28-6). Multifocal atrial tachycardia is frequently confused with atrial flutter (AF) or fibrillation.

Clinical Significance Multifocal atrial tachycardia is found most often in elderly patients with decompensated chronic lung disease, but it may also complicate congestive heart failure (CHF) or sepsis or be caused by methylxanthine toxicity. Digoxin toxicity is an unlikely cause of MFAT.

Treatment

1. Treatment is directed toward the underlying disorder. With decompensated lung disease, oxygen and bronchodilators improve pulmonary function and arterial oxygenation and decrease atrial ectopy. Theophylline agents have been associated with the production or exacerbation of this dysrhythmia.
2. Specific antiarrhythmic treatment is rarely indicated. Standard antiarrhythmics appear to be ineffective in suppressing these multiple sites of atrial ectopy, and toxic side effects from these agents have been reported. Likewise, attempts to slow the ventricular rate by depressing AV nodal conduction with digoxin is difficult without producing toxic side effects. Recently, three modes of therapy have been described that may be helpful in some patients. Magnesium sulfate 2 g intravenously over 60 s, followed by a constant infusion of 1 to 2 g/h, has been shown to reduce atrial ectopy in these patients and is sometimes associated with conversion to sinus rhythm. The full antiarrhythmic effect of magnesium requires supplemental potassium to maintain serum potassium levels above 4 mEq/L. Intravenous verapamil (5 to 10 mg) slows the ventricular response in most patients, decreases atrial ectopy in some patients, and is associated with conversion to sinus rhythm in many patients. The p-adrenergic antagonists esmolol, acebutolol, and metoprolol decrease the ventricular rate in MFAT. However, theoretically, p-blocker therapy may worsen bronchospasm. The value of such specific antiarrhythmic treatment in MFAT is unproven.
3. Cardioversion has no effect on these multiple sites of atrial ectopy.

FIG. 28-5. Premature atrial contractions. (Top) Ectopic P' waves (arrows). (Bottom) Atrial bigeminy.

FIG. 28-6. Multifocal atrial tachycardia.

ATRIAL FLUTTER Atrial flutter usually originates from a localized area within the atria. The exact mechanism (reentry, automatic focus, or triggered dysrhythmia) is not known. Intracardiac studies have demonstrated electrical activity usually originating in the inferior right atrium and propagating upward and to the left. The ECG characteristics of AF are (1) regular atrial rate between 250 and 350 beats/min (most commonly 280 and 320 beats/min); (2) sawtooth flutter waves directed superiorly and most visible in leads II, III, and aVF; and (3) AV block, usually at 2:1, but occasionally greater, causing a ventricular rate between 125-175 beats/min (Figure 28-7). One-to-one AV conduction may occur in the presence of bypass tracts or if drugs are used to slow the atrial rate to the level that the AV node can conduct one-to-one. A ventricular rate faster than 300 beats/min definitely should be investigated with electrophysiology (EP) studies. Carotid sinus massage is a useful technique to slow the ventricular response, increase the AV block, and unmask flutter waves.

Clinical Significance Atrial flutter is usually associated with heart disease. It is found most commonly in patients with ischemic heart disease or acute MI. Less common causes include congestive cardiomyopathy, pulmonary embolus, myocarditis, blunt chest trauma, and, rarely, digoxin toxicity. Atrial flutter may be a transitional dysrhythmia between sinus rhythm and atrial fibrillation.

Treatment

1. Low-energy cardioversion (25 to 50 J) is very successful in converting more than 90 percent of cases of AF into sinus rhythm. Energies weaker than 10 J should be avoided, because they are more likely to convert AF into atrial fibrillation than into sinus rhythm.
2. If cardioversion is contraindicated, control of ventricular rate can be achieved with digoxin, verapamil, diltiazem, esmolol, or propranolol (see Chap. 29 for dosage). If there is 1:1 conduction and the rate is 300 beats/min and faster, preexcitation should be considered, and procainamide may be the drug of first choice.
3. Quinidine or procainamide can be used after ventricular rate control is achieved to chemically slow or convert AF or prevent recurrence of the dysrhythmia.
4. Intravenous esmolol will convert up to 60 percent of patients with new-onset AF to sinus rhythm.
5. Intravenous verapamil or diltiazem occasionally will convert AF into sinus rhythm.³
6. Some of the newer antiarrhythmics may have a role in the chemical conversion of AF. Ibutilide (0.01 mg/kg IV over 10 min) can convert AF and fibrillation to normal sinus rhythm. This drug should be

used in new-onset AF, because of the chance of emboli if used in long-term AF. Ibutilide is very effective in the conversion of AF or atrial fibrillation; however, there is a significant possibility of initiating TdP. To reduce the chance of TdP, it is suggested that the [K⁺] and the corrected QT interval be checked before administration of the agent. This agent should not be given in the presence of hypokalemia, prolonged corrected QT interval, or history of CHF. The chance of TdP can extend 4 to 6 h after the drug is given.

ATRIAL FIBRILLATION Atrial fibrillation occurs when there are multiple, small areas of atrial myocardium continuously discharging and contracting. There is no uniform atrial depolarization and contraction, but rather, only a quivering of the atrial wall. Although the atrial rate is usually faster than 400 beats/min, the ventricular rate is limited by the refractory period of the AV node or an accessory pathway. The ECG characteristics of atrial fibrillation are (1) fibrillatory waves of atrial activity, best seen in leads V₁, V₂, V₃, and aV_F; and (2) irregular ventricular response, usually around 170 to 180 beats/min in patients with a healthy AV node (Figure 28-8). Disease or drugs (especially digoxin) may reduce AV node conduction and markedly slow ventricular response. A more rapid ventricular response may be seen in patients with bypass tracts, and the rate in these patients has been suggested as a way of estimating the refractory period of the accessory path. Ventricular rates faster than 300 beats/min are possible and dangerous. In this case, because ventricular activation occurs by way of the bypass tract, the QRS complex is usually wide. The configuration of the aberrancy may differ with the site of the accessory pathway.

Clinical Significance Atrial fibrillation can occur in a paroxysmal or a sustained manner. Predisposing factors for atrial fibrillation are increased atrial size and mass, increased vagal tone, and variation in refractory periods between different parts of the atrial myocardium. Atrial fibrillation is usually found in association with four disorders: rheumatic heart disease, hypertension, ischemic heart disease, and thyrotoxicosis. Less common causes are chronic lung disease, pericarditis, acute alcoholic intoxication, pulmonary embolus, and atrial septal defect.

In patients with left ventricular failure, left atrial contraction contributes significantly to cardiac output. The loss of effective atrial contraction, as in atrial fibrillation, may produce heart failure in these patients. Atrial fibrillation also predisposes to peripheral venous and atrial emboli, with the risk of pulmonary and systemic arterial embolism. Up to 15 percent of patients in chronic atrial fibrillation have at least one embolic episode each year. Conversion from chronic atrial fibrillation to sinus rhythm also carries a 1 to 2 percent risk of arte-

FIG. 28-7. Atrial flutter.

FIG. 28-8. Atrial fibrillation.

rial embolism. Patients with chronic atrial fibrillation are frequently anticoagulated.

Treatment

1. Atrial fibrillation with a rapid ventricular response and acute hemodynamic deterioration should be treated with synchronized cardioversion. More than 60 percent of patients can be converted with 100 J, and more than 80 percent can be converted with 200 J. Conversion to and retention in sinus rhythm are more likely when atrial fibrillation is of short duration and the atria are not greatly dilated. If initial cardioversion is unsuccessful, procainamide should be given intravenously to facilitate further cardioversion attempts. Oral quinidine or low-dose amiodarone can enhance maintenance of sinus rhythm. Meta-analysis and decision analysis of postconversion antiarrhythmic treatment have found that the benefits of maintaining sinus rhythm with antiarrhythmics are partly offset by an increase in sudden death, presumably due to the proarrhythmic properties of these drugs. In the ED setting, all other causes of hypotension, such as acute blood loss, should be ruled out before concluding that the rate is causing the hemodynamic deterioration.
2. In the more stable patient, the first priority is to achieve ventricular rate control. Diltiazem, 20 mg (0.25 mg/kg) given IV over 2 min, is extremely effective in achieving ventricular rate control, with the peak response seen in 2 to 7 min. An infusion of 5 mg/h is usually started after the initial dose to maintain control, and a second dose of 25 mg (0.35 mg/kg) can be given after 15 min if rate control is not achieved. Verapamil 5 to 10 mg IV is effective in slowing the ventricular response in 60 to 70 percent of patients with atrial fibrillation and converts 10 to 15 percent into sinus rhythm. Intravenous β -adrenergic blockers (e.g., esmolol and propranolol) are effective, especially in patients with thyrotoxicosis or rheumatic mitral stenosis, but the depressive effects on myocardial contractility make them poor agents to use in patients with ventricular failure. Intravenous digoxin is an effective agent for this purpose, although the onset of action is slow, with a mean time longer than 11 h to achieve ventricular rate control. With a rapid digitalization protocol, an effect may be seen within 3 to 6 h.
3. Once ventricular rate control has been achieved, chemical conversion can be considered with procainamide, quinidine, or verapamil. Intravenous procainamide has been used as a single agent to chemically convert atrial fibrillation of short duration into sinus rhythm; however, ibutilide is being touted as a better agent. Amiodarone (300 mg IV 1h; 20 mg/kg over the next 24 h) has recently been shown to be a safe and highly effective first-choice drug for restoring sinus rhythm in patients with atrial fibrillation who present to an ED.⁴ Because of the risk of intraatrial thrombi and arterial embolization, patients with atrial fibrillation of more than 2 days' duration should be anticoagulated systemically for 1 to 3 weeks before attempts at chemical or electrical conversion. More recent work has indicated that there may be some increased risk of embolism even with AF of less than 2 days' duration. An alternative to prolonged preanticoagulation is to exclude atrial thrombi by transesophageal echocardiography. **Those without visible thrombi can be safely cardioverted following a loading dose of heparin and oral warfarin for one month.**⁵

4. Patients with a slow ventricular response not due to digitalis have AV node disease and probably a more generalized disorder of cardiac conduction (second- or third-degree AV block is seen in these patients when in sinus rhythm). These patients are at increased risk for profound bradycardias or asystole after cardioversion or antiarrhythmic drug therapy.
5. In some patients with a rapid ventricular response, conversion will reveal a very slow rate (tachybrady syndrome) because of underlying disease of the pacemaker tissue (sick sinus syndrome).

SUPRAVENTRICULAR TACHYCARDIA Supraventricular tachycardia is a regular, rapid rhythm that arises from reentry or an ectopic pacemaker in areas above the bifurcation of the bundle of His. The reentrant variety is clinically the most common. These patients often present with acute, symptomatic episodes termed *paroxysmal supraventricular tachycardia*.

Ectopic SVT usually originates in the atria, with an atrial rate of 100 to 250 beats/min (most commonly 140 to 200 beats/min; Figure 28-9). The regular P waves can be mistaken for AF or, if there is a 2:1 AV block, sinus rhythm.

Reentrant SVT is seen in most patients with SVT: about 60 percent of these patients have reentry within the AV node, and 20 percent have reentry involving a bypass tract. The remainder have reentry in other sites. In the normal heart, reentrant SVT at the typical rates of 160 to 200 beats/min is often tolerated for hours or days. However, cardiac output is usually depressed, regardless of the blood pressure, and rapid rates may produce heart failure depending on the health of the myocardium.

Reentrant SVT within the AV node usually is initiated when an ectopic atrial impulse encounters the AV node during the partial refractory period (Figure 28-10). There are two functionally different parallel conducting limbs within the AV node that are connected above, at the atrial end, and below, at the ventricular end of the node. This circuit is capable of sustained reentry when properly stimulated. In AV nodal reentry, the P wave is usually buried in the QRS complex and not visible, there is 1:1 conduction, and the QRS complex is normal.

Patients with bypass tracts have two parallel limbs of the reentry circuit, the AV node and the bypass tract, with connections at the atrial and ventricular ends by myocardial cells. Although reentry can occur in either direction, it usually occurs in a direction that is antegrade through the AV node and retrograde through the bypass tract, thus producing a narrow QRS complex (orthodromic conduction). In the Wolff-Parkinson-White (WPW) syndrome, about 85 percent of the reentrant SVTs have narrow QRS complexes. If the conduction is antegrade through the accessory bundle and retrograde through the AV node (antidromic conduction), the complexes are wide and difficult to differentiate from ventricular tachycardia.

Clinical Significance Ectopic SVT may be seen in patients with acute MI, chronic lung disease, pneumonia, alcohol intoxication, and digoxin toxicity (where it is often associated with AV block and termed *paroxysmal atrial tachycardia with block*). It is commonly held that a high percentage of SVT with block, as much as 75 percent, is due to digoxin toxicity. However, not all studies have found this to be the case.

FIG. 28-9. Ectopic supraventricular tachycardia with 2:1 atrioventricular conduction.

FIG. 28-10. Reentrant supraventricular tachycardia (SVT). (*Top*) initiates run of paroxysmal atrial tachycardia. (*Bottom*) SVT, rate of 286 beats/min.

Reentrant SVT can occur in a normal heart or in association with rheumatic heart disease, acute pericarditis, MI, mitral valve prolapse, or one of the preexcitation syndromes.

Supraventricular tachycardia often causes a sensation of palpitations and lightheadedness. In patients with coronary artery disease, anginal chest pain and dyspnea may occur from the rapid heart rate. Frank heart failure and pulmonary edema may occur in patients with poor left ventricular function. The decrease in diastolic filling period and subsequent decrease in cardiac output cannot be tolerated in the patient with left ventricular failure.

Treatment Reentrant SVT can be converted by impeding conduction through one limb of the reentry circuit; sustained reentry is then impossible and extinguishes, allowing sinus rhythm to resume ventricular pacing. Because it is usually clinically impossible to differentiate ectopic from reentrant SVT, treatment is initially the same.

1. Maneuvers that increase vagal tone have been shown to slow conduction and prolong the refractory period in the AV node. These maneuvers can be done by themselves or after administration of drugs.
 - a. Carotid sinus massage exerts pressure on the carotid sinus and baroreceptors against the transverse process of C6. Bruits should be discovered before the procedure. Massage should be done for 10 s at a time, first on the side of the nondominant cerebral hemisphere, and should never be done simultaneously on both sides. Prolonged AV block during carotid massage may occur in patients with AV node disease or who are taking digoxin. Patients with carotid artery stenosis may develop cerebral ischemia or infarction from overly vigorous carotid massage.
 - b. Facial immersion in cold water is done for 6 to 7 s with the nostrils held closed ("diving reflex"). This maneuver is particularly effective in infants. The patient's parents may develop greater vagal tone than the infant, so this must be approached carefully.
 - c. The Valsalva maneuver performed in the supine position appears to be the most effective vagal maneuver for the conversion of reentrant SVT. For maximal effectiveness, the strain phase must be adequate (usually at least 10 s), with slowing or conversion seen during the release phase.
2. Adenosine, an ultra-short-acting (20 s) agent, produces AV block and has been observed to convert over 90 percent of reentrant SVT.⁶ The initial dose is a 6-mg rapid intravenous bolus. This **must be** given in a large vein, preferably in the antecubital space. If no effect is seen within 2 min, a second dose of 12 mg can be given. There is no proven benefit to repeated doses or administration of more than 20 mg. At least 50 percent of patients experience

distressing, albeit transient, side effects of facial flushing or chest pain. Obviously this should be discussed with the patient, when possible. Because adenosine possesses no sustained antiarrhythmic effect, subsequent ectopic beats can reinitiate the dysrhythmia, and early recurrences of SVT are seen in up to 25 percent of patients. The major advantage of adenosine is its ultrashort effect⁷ and its lack of hypotensive or myocardial depressive activity. Adenosine is also safe and effective in unstable patients (chest pain and/or hypotension) with reentrant SVT. It is safe in pregnancy. In addition, it is not contraindicated in the presence of WPW syndrome.

3. Verapamil 0.075 to 0.15 mg/kg (3 to 10 mg) IV over 15 to 60 s, with a repeat dose in 30 min, can be used, if necessary. Studies have found that more than 90 percent of adults with reentrant SVT will respond within 1 to 2 min to verapamil. In patients with a normal blood pressure, intravenous verapamil is almost always associated with a decrease in blood pressure, even after successful conversion of SVT. The falls in systolic and mean arterial pressures are approximately 20 and 10 mm Hg, respectively. The drop in blood pressure due to verapamil can be prevented and/or treated with intravenous calcium without reducing the antiarrhythmic action of verapamil. Although the use of different calcium doses and salts has been reported, elemental calcium, 90 mg given IV over 3 to 6 min, appears safe and effective (90 mg elemental calcium = 10 mL calcium gluconate 10% solution = 3.3 mL calcium chloride 10% solution). Whenever verapamil is used IV calcium should be readily available. Intravenous verapamil is generally considered to be contraindicated in the hypotensive patient. Many would consider cardioversion a better approach to the hypotensive patient with SVT.
4. Diltiazem 20 mg (0.25 mg/kg) IV over 2 min is reported to be 75 to 100 percent effective in converting reentrant SVT.
5. Vagal tone can be enhanced by pharmacologically **elevating** blood pressure with a pure peripheral vasoconstrictor: agents without P-adrenergic activity should be used. This method should be combined with carotid sinus massage. Blood pressure should be monitored frequently, and diastolic pressure should not be allowed to exceed 130 mm Hg. This method should not be used if hypertension is already present.
 - a. Metaraminol 200 mg/500 mL D5W or norepinephrine 4 mg/500 mL D5W can be infused at rates of 1 to 2 mL/min and titrated until the rhythm converts.
 - b. Methoxamine or phenylephrine, 0.5 to 1.0 mg IV **over** 2 to 3 min, can be administered, with repeat doses, as required.
6. Esmolol is an intravenous p-adrenergic blocker **with** an ultrashort duration of activity that can be titrated to effect. This agent can be used to control the ventricular rate in most tachycardias of supraventricular origin and is capable of converting about half of reentrant SVT. Esmolol is given as a bolus dose of 300 (J-g/kg over 60 s, followed by an infusion starting at 50 μ g/kg per min. If there is an inadequate response after 2 to 5 min, a repeat bolus of 300 μ g/kg should be given, and increases in the infusion rate in increments of 50 μ g/kg per min should be made. The maximal recommended infusion rate is 300 μ g/kg per min, although most patients respond to rates of 200 μ g/kg or less per min. With aggressive dosing regimens, hypotension occurs in approximately 50 percent of patients but can be quickly reversed by halting the infusion.
7. Propranolol 0.5 to 1.0 mg IV, slowly over 60 s, can be repeated every 5 min, until the rhythm converts or the total dose reaches 0.1 mg/kg. Overall, propranolol has a nearly 50 percent success rate in converting reentrant SVT: about 80 percent with AV nodal reentry and 15 to 20 percent with accessory tract retrograde reentry.
8. Digoxin 0.5 mg IV, with repeat doses of 0.25 mg in 30 to 60 min, can be used until a response occurs or the total dose reaches 0.02 mg/kg. The chief drawback of digoxin has been its long onset of action and potential hazard in patients with accessory (bypass) tracts who develop atrial fibrillation or AF.

9. External noninvasive pacing has been used in a limited number of patients to terminate reentrant SVT. Asynchronous pacing with 2 to 10 external pulses at a rate 240 to 280 beats/min (typically 40 beats/min faster than the SVT rate) with an impulse amplitude of 120 mA is effective in young, hemodynamically stable adults. Most pacing units in the ED do not pace at 240 to 280 beats/min. Some automatic internal cardiac defibrillators have overdrive-pacing capability.
10. Synchronized cardioversion should be done in any unstable patient with hypotension, pulmonary edema, or severe chest pain. The dose required is usually small, less than 50 J.

Ectopic SVT due to digoxin toxicity is treated as follows:

1. Discontinuation of the digoxin.
2. As long as there is not a high-grade AV block, correction of any existing hypokalemia to bring serum potassium into the high-normal range in an effort to reduce atrial ectopy is indicated.
3. Digoxin-specific antibody fragments should be considered for patients with hemodynamic deterioration or serious ventricular dysrhythmias due to digoxin toxicity.
4. Phenytoin, lidocaine, or magnesium given intravenously can reduce atrial ectopy. Published reports are not methodologically adequate for determination of the response rate, risks, and benefits of each agent, so the choice is guided by personal preference. Historically, phenytoin has been the most commonly used drug, but its response rate has not been impressive and toxic side effects are common with full loading doses (15 to 18 mg/kg IV). Lidocaine has not been considered a useful agent for this dysrhythmia, but case reports have indicated some benefit. Recent studies have indicated that magnesium sulfate 1 g IV impressively reduces atrial ectopy due to digoxin toxicity, and perhaps this agent has a greater effect than phenytoin or lidocaine.
5. **Cardioversion is not effective and is potentially hazardous in digoxin-induced dysrhythmias.**

Junctional Dysrhythmias

Traditionally, a junctional impulse is considered to arise from the AV node or bundle of His above the bifurcation. Pacemaker tissue cannot be found in the AV node of experimental animals. The question is not settled in humans. From its source, probably in the junction, the impulse spreads retrogradely toward the atria and antegradely toward the ventricles. Depending on the site of origin, conduction velocity, and refractory periods, the atria may be activated before, during, or after ventricular depolarization. Atrial depolarization may not be visible if retrograde conduction is blocked or atrial activation occurs simultaneously with ventricular activation and the QRS complex obscures the P waves. Atrioventricular dissociation may occur if the rate of discharge from the junctional pacemaker is faster than the sinus node rate and the junctional impulse is blocked from retrograde conduction toward the atria.

JUNCTIONAL PREMATURE CONTRACTIONS Junctional premature contractions (JPCs) are due to an ectopic pacemaker within the AV node or common AV bundle. The ECG characteristics of JPCs are as follows:

1. The ectopic QRS complex is premature.
2. The ectopic P' wave has a different shape and direction (usually inverted in leads II, III, and aVF).
3. The ectopic P' wave may occur before or after the QRS complex.
4. The P-R interval of the ectopic beat is shorter than normal.
5. The QRS complex is usually of normal shape unless there is aberrant conduction.
6. The sinus node is usually affected, and the postectopic pause is not fully compensatory (Figure 28-11). Some JPCs do not conduct retrogradely; therefore, a compensatory pause may be seen.

FIG. 28-11. Junctional premature contractions.

Junctional premature contractions may be isolated, multiple (as in bigeminy or trigeminy), or multifocal.

Clinical Significance Junctional premature contractions are uncommon in healthy hearts. They occur in CHF, digoxin toxicity, ischemic heart disease, and acute MI (especially of the inferior wall).

Treatment

1. No specific treatment is usually required.
2. Treat the underlying disorder.
3. Antiarrhythmic therapy with quinidine or procainamide may be useful if JPCs are frequent, symptomatic, or initiate more serious dysrhythmias.

JUNCTIONAL RHYTHMS Under normal circumstances, the sinus node discharges at a faster rate than the AV junction, so the pacemaker function of the AV junction and all other slower pacemakers is suppressed (overdrive suppression). If sinus node discharges slow or fail to reach the AV junction, then junctional escape beats may occur, usually at a rate between 40 and 60 beats/min, depending on the level of the pacemaker. In general, junctional escape beats do not conduct retrograde into the atria, so a QRS complex without a P' wave is usually seen (Figure 28-12).

Under other circumstances, enhanced junctional automaticity may override the sinus node and produce an accelerated junctional rhythm (rate 60 to 100 beats/min) or junctional tachycardia (rate \geq 100 beats/min). Usually, the enhanced junctional pacemaker (Figure 28-13) captures the atria and ventricles.

Clinical Significance Junctional escape beats may occur whenever there is a long enough pause in the impulses reaching the AV junction: sinus bradycardia, slow phase of sinus dysrhythmia, AV block, or during the pause after premature beats. Sustained junctional escape rhythms may be seen with CHF, myocarditis, hypokalemia, or digoxin toxicity. If the ventricular rate is too slow, myocardial or cerebral ischemia may develop.

Accelerated junctional rhythm and junctional tachycardia may occur from digoxin toxicity, acute rheumatic fever, or inferior MI. With digoxin toxicity, the rate is usually between 70 and 130 beats/min. If this rhythm develops in a patient being treated with digoxin for atrial fibrillation, the ECG is characterized by regular QRS complexes superimposed on atrial fibrillatory waves. Regulation of ventricular response during digoxin therapy in a patient with atrial fibrillation should raise the suspicion of digoxin toxicity.

FIG. 28-12. Junctional escape rhythm, with a rate of 42 beats/min.

FIG. 28-13. Accelerated junctional rhythm, with a rate of 61 beats/min.

Treatment

1. Isolated, infrequent junctional escape beats usually do not require specific treatment.
2. If sustained junctional escape rhythms are producing symptoms, the underlying cause should be treated. Atropine can be used to accelerate the sinus node discharge rate temporarily and enhance AV nodal conduction.
3. Accelerated junctional rhythm and junctional tachycardia usually do not produce significant symptoms. If the cause is digoxin toxicity, the drug should be discontinued. If the rate is fast and producing symptoms, giving supplemental potassium to increase the serum level into the high-normal range may decrease it.

Ventricular Dysrhythmias

PREMATURE VENTRICULAR CONTRACTIONS Premature ventricular contractions (PVCs) are due to impulses originating from single or multiple areas in the ventricles. The ECG characteristics of PVCs are as follows:

1. There is a premature and wide QRS complex (Figure 28-14).
2. There is no preceding P wave.
3. The ST segment and T wave of the PVC are directed opposite the major QRS deflection.
4. Most PVCs do not affect the sinus node, so there is usually a fully compensatory postectopic pause or the PVC may be interpolated between two sinus beats (Figure 28-14).
5. Many PVCs have a fixed coupling interval (within 0.04 s) from the preceding sinus beat.
6. Some PVCs are conducted into the atria, producing a retrograde P wave.

A

B

C

FIG. 28-14. Premature ventricular contractions: unifocal (top), interpolated (center), and multifocal (bottom).

Occasionally, a *ventricular fusion beat* occurs when supraventricular and ventricular impulses depolarize the ventricles almost simultaneously. The QRS configuration of a fusion beat contains features of the individual components.

A PVC may be confused with an aberrantly conducted supraventricular beat. Several clinical and ECG criteria can be used to help distinguish aberrantly conducted supraventricular beats from PVCs; this is discussed later in this section.

Clinical Significance Premature ventricular contractions are very common, even in patients without evidence of heart disease. They occur in most patients with ischemic heart disease and are universally found in patients with acute MI. Other common causes of PVCs include digoxin toxicity, CHF, hypokalemia, alkalosis, hypoxia, and sympathomimetic drugs.

Although there is a correlation between the severity of underlying coronary artery disease and the degree of ventricular ectopy, there is disagreement as to whether ventricular ectopy itself is an independent risk factor for future morbidity or mortality. Most studies have indicated that repetitive PVCs (two or more in a row) do have some associated independent risk in patients with coronary artery disease, but the evidence for other forms of ventricular ectopy is less convincing. Lown has made an attempt with his classification to quantitate the risks associated with chronic ventricular ectopy, but his classification is not universally accepted (Table 28-1). It must be remembered that his classification was developed from patients with recent acute MI.

In the setting of an acute MI, PVCs indicate the underlying electrical instability of the heart. The patients are at increased risk for the development of primary ventricular fibrillation. Current work indicates that various degrees of PVCs ("warning dysrhythmias") are not reliable predictors of subsequent ventricular fibrillation.

Although it is experimentally established that electrical impulses, such as PVCs, that occur during or soon after repolarization (the so-called vulnerable period) can initiate ventricular tachycardia or fibrillation, clinical studies have found that late-coupled PVCs initiate more paroxysms of ventricular tachycardia than early-coupled PVCs (R-on-T phenomenon).

Treatment

1. Most patients with acute myocardial disease and PVCs will respond to intravenous lidocaine, although some patients may require procainamide. In the setting of acute myocardial ischemia (unstable angina or acute MI), many physicians would treat frequent or multiform PVCs with the goal of reducing deaths due to sudden ventricular tachycardia or fibrillation. Although single studies have suggested benefit, **pooled data and meta-analyses have found no reduction in mortality from suppressive or prophylactic treatment of PVCs.**⁸ The use of (3-blockers may be a better choice, and at least metoprolol has been associated with better mortality reduction in post-MI patients.
2. In patients with chronic PVCs, there is no evidence that oral antiarrhythmics enhance survival. To the contrary, large, randomized studies of postinfarction patients found that treatment with en-

TABLE 28-1 Lown Grading System for Ventricular Ectopy

Grade	ECG Characteristics
1	Uniform PVCs < 30/h
2	Uniform PVCs > 30/h
3	Multiform PVCs

4B	Triplets (3 or more consecutive PVCs)
5	R-on-T PVCs

Abbreviations: ECG = electrocardiogram; PVC = premature ventricular contraction.

cainide, flecainide, or moricizine increased the incidence of cardiac arrest or arrhythmic death, probably related to their pro-arrhythmic effects.⁹ Before treating chronic PVCs, the physician should consider several factors:

- Underlying heart disease
- The nature of the ectopy
- The presence or absence of symptoms
- The potential side effects of oral antiarrhythmic therapy
- Which technique will be used to judge efficacy of therapy (continuous monitoring vs. EP studies)? Oral antiarrhythmic therapy requires careful monitoring. In some patients at risk of sudden cardiac death, automatic internal cardiac defibrillators are used in conjunction with antiarrhythmics.

VENTRICULAR PARASYSTOLE Parasytyle occurs when an independent ectopic pacemaker is protected from the influence of outside impulses (entrance block) and competes with the dominant pacemaker to produce myocardial depolarizations. A parasystolic pacemaker can arise anywhere in the heart but is most often in the ventricles, where it produces a rhythm that operates in competition with the sinus node. This ectopic pacemaker has an innate rate; however, not all beats depolarize the ventricle (exit block).

The ECG characteristics of ventricular parasystole are (1) variation in the coupling interval between the preceding sinus beat and the ectopic beat, (2) common relation between the interectopic beat intervals, and (3) occurrence of fusion beats (Figure 28-15). Usually, long rhythm strips are necessary to establish that the interectopic intervals are multiples of a common parasystolic pacemaker. Because of the difference in response to antiarrhythmics, it is important to recognize and differentiate parasystolic beats from PVCs.

Clinical Significance Ventricular parasystole most often is associated with severe ischemic heart disease, acute MI, hypertensive heart disease, or electrolyte imbalance. Parasytyle is often self-limited and benign but infrequently may lead to ventricular tachycardia or fibrillation.

Treatment

- The underlying disease should be treated.
- Antiarrhythmics are indicated in patients with symptomatic episodes or beats that initiate ventricular tachycardia.

ACCELERATED IDIOVENTRICULAR RHYTHM Accelerated idioventricular rhythm (AIVR) is an ectopic rhythm of ventricular origin occurring at a rate of 40 to 100 beats/min. Even though AIVR is not a tachycardia, terms such as *idioventricular tachycardia*, *nonparoxysmal ventricular tachycardia*, or *slow ventricular tachycardia* are sometimes used to describe this rhythm.

The ECG characteristics of AIVR are (1) wide and regular QRS complexes, (2) a rate between 40 and 100 beats/min that is often close to the preceding sinus rate, (3) usually runs of short duration (3 to 30 beats/min), and (4) often beginning with a fusion beat (Figure 28-16).

FIG. 28-15. The fifth and eighth ventricular complexes are premature and of similar morphology but have different coupling intervals. The second complex (*F*) represents a fusion beat. The interectopic interval is 2.36 s. (Reproduced with permission from Heger JW, Niemann JT, Boman KG, et al: *Cardiology for the House Officer*. Baltimore, Williams & Wilkins, 1982.)

FIG. 28-16. Accelerated idioventricular rhythms.

Clinical Significance This condition is found most commonly in the setting of an acute MI. Reports have indicated that AIVR sometimes appears during successful thrombolysis of an occluded coronary artery. Accelerated idioventricular rhythm and other ventricular dysrhythmias seen during this time are termed *reperfusion dysrhythmias*. Accelerated idioventricular rhythm may be seen infrequently in patients without organic heart disease. Although there is some variable association with ventricular tachycardia, there is no apparent association with ventricular fibrillation. Accelerated idioventricular rhythm usually produces no symptoms itself. Sometimes the loss of atrial contraction and subsequent fall in cardiac output may produce hemodynamic deterioration.

Treatment

- Treatment is not necessary. On occasion, AIVR may be the only functioning pacemaker, and suppression with lidocaine can lead to cardiac asystole.
- If sustained AIVR produces symptoms secondary to a decrease in cardiac output, treatment with atrial pacing may be required.

VENTRICULAR TACHYCARDIA Ventricular tachycardia is the occurrence of three or more depolarizations from a ventricular ectopic pacemaker at a rate faster than 100 beats/min. The ECG characteristics of ventricular tachycardia are (1) wide QRS complexes; (2) rate faster than 100 beats/min (most commonly 150 to 200 beats/min); (3) rhythm usually regular, although there may be some beat-to-beat variation; and (4) QRS axis usually constant (Figure 28-17). Uncommonly (about 5 percent of episodes), ventricular tachycardia may have a narrow (<120 ms) QRS complex. In these cases, ECG criteria usually suggest a ventricular origin (see "Aberrant versus Ventricular Tachyarrhythmias," below). Ventricular tachycardia can occur in a nonsustained manner—usually short episodes, lasting seconds, with spontaneous termination—or in a sustained fashion—longer episodes that typically require treatment.

There are several variants of ventricular tachycardia. *Ventricular flutter* is the phrase used for a regular zigzag pattern without distinguishable QRS complexes or T waves. In *bidirectional ventricular tachycardia*, the QRS complexes alternate polarity as recorded in a single lead. In *alternating ventricular tachycardia*, the QRS complexes alternate in height (but not polarity) in a single lead. (Bidirectional and alternating ventricular tachycardias indicate serious myocardial disease and often are due to digitalis toxicity.)

In *polymorphic ventricular tachycardia*, the QRS complexes have many different shapes in one lead. This pattern has been recently described in Brugada syndrome, which consists of syncope, sudden death, unusual J-point elevation in V_1 and V_3 , and RBB block.¹⁰ It was initially described in 1991 and was not well known until late 1990s (Figure 28-18). **Brugada syndrome should be considered a potential cause of syncope**

FIG. 28-17. Ventricular tachycardia.

FIG. 28-18. Brugada syndrome.

in ED patients and a family history of sudden death. Further referral should be considered for provocative tests even with a normal ECG. The disease is genetically determined, with a very high incidence of sudden death. The only treatment available is an automatic implanted cardiac cardioverter-defibrillator. The ECG can be normal but frequently may be unmasked by procainamide, flecainide, or ajmaline. The abnormality is in the gene *SCN5A* on chromosome 3, and the electrophysiologic mechanism is theorized to concern the transient currents (Ito) at a myocardial cellular level.

Atypical ventricular tachycardia (TdP, or "twisting of the points") is where the QRS axis swings from a positive to a negative direction in a single lead (Figure 28-19). This rhythm results from a triggered arrhythmic mechanism. Torsade de pointes usually occurs in short runs of 5 to 15 s at a rate of 200 to 240 beats/min. This form of ventricular tachycardia generally occurs in patients with serious myocardial disease who have a prolonged and uneven ventricular repolarization (prolonged QT interval; Table 28-2).

Drugs that further prolong repolarization, such as quinidine, disopyramide, procainamide, phenothiazine, and tricyclic antidepressants, exacerbate this dysrhythmia. Conventional treatment with lidocaine often is ineffective. To date, treatment for TdP consisted of accelerating the heart rate (thereby shortening ventricular repolarization) with isoproterenol (2 to 8 μ g/min) while making arrangements for a ventricular pacemaker to overdrive the heart at rates of 90 to 120 beats/

FIG. 28-19. Two examples of short runs of atypical ventricular tachycardia showing sinusoidal variation in amplitude and direction of the QRS complexes, i.e., torsade de pointes (twisting of the points). The top run was initiated by a late-occurring premature ventricular contraction (lead II).

min. Temporary pacing is the most effective and safest method to treat TdP and prevent its recurrence in the emergency setting. Recent reports have found that magnesium sulfate 1 to 2 g IV over 60 to 90 s, followed by an infusion of 1 to 2 g/h, is effective in abolishing these runs of TdP, although recurrences are seen despite continued infusion. A wide variety of other agents and antiarrhythmics have been reported anecdotal successes, but overall efficacy has been inconsistent.

Clinical Significance Ventricular tachycardia is very rare in patients without underlying heart disease. The most common causes of ventricular tachycardia are ischemic heart disease and acute MI. Less common causes include hypertrophic cardiomyopathy, mitral valve prolapse, and toxicity from many drugs (digoxin, quinidine, procainamide, and sympathomimetics). Hypoxia, alkalosis, and electrolyte abnormalities exacerbate the tendency toward ventricular ectopy and tachycardia.

It is a common misconception that patients with ventricular tachycardia appear clinically unstable; this is the basis for the mistaken assumption that patients who appear stable with a wide complex tachy-

TABLE 28-2 Etiologies and Associated Conditions in Torsade de Pointes

Familial
Jervell and Lange-Nielsen syndrome (congenital deafness)
Romano-Ward syndrome (without deafness)
Toxins and drugs

Postoperative complication

cardia (WCT) have SVT with aberrancy rather than ventricular tachycardia. **Ventricular tachycardia cannot be differentiated from SVT with aberrancy on the basis of clinical symptoms, blood pressure, or heart rate.** Patients who are unstable should be cardioverted; this is effective for both dysrhythmias. In patients who are stable, a 12-lead ECG should be obtained first and examined for evidence favoring one dysrhythmia over another; but even then, it is often difficult to decide. Therefore, in general, it is best to treat all WCTs as ventricular tachycardia with lidocaine or procainamide. These drugs are obviously effective in ventricular tachycardia and often surprisingly effective in SVT with aberrancy, and they carry little risk of harming the patient. Conversely, verapamil is harmful in most patients with ventricular tachycardia, because it accelerates the heart rate and decreases blood pressure without converting the rhythm. Adenosine appears to do little harm in patients with ventricular tachycardia and has potential merit for the treatment for wide QRS complex tachycardias.

Treatment

1. Unstable patients or those in cardiac arrest should be treated with synchronized cardioversion. Symptomatic ventricular tachycardia with a pulse should be treated with synchronized cardioversion, beginning at 100 J. For pulseless ventricular tachycardia, unsynchronized cardioversion should begin with 200 J.
2. Clinically stable patients may be treated with intravenous antiarrhythmics.
 - a. Lidocaine 75 mg (1.0 to 1.5 mg/kg) IV over 60 to 90 s can be used, followed by a constant infusion at 1 to 4 mg/min (10 to 40 μ g/kg per min). A repeat bolus dose of 50 mg may be required during the first 20 min to avoid a subtherapeutic dip in serum level due to the early distribution phase.
 - b. Amiodarone, 150 mg over the first 10 min, may be repeated every 10 min up to a total dose of 2 g. Or a maintenance dose of 0.5 mg/min over 18 h can be administered.
 - c. Procainamide can be given at a rate slower than 50 mg/min IV until the dysrhythmia converts, the total dose reaches 15 to 17 mg/kg in normal patients (12 mg/kg in patients with CHF), or early signs of toxicity develop with hypotension or QRS prolongation. The loading dose should be followed by a maintenance infusion of 2.8 mg/kg per h in normal subjects (1.4 mg/kg per h in patients with renal insufficiency).
 - d. A variety of other antiarrhythmics have been studied for the treatment of ventricular tachycardia. Most class I and III agents are effective for the acute termination of ventricular tachycardia when given IV. Recommendations concerning their routine use will have to await further studies.

VENTRICULAR FIBRILLATION Ventricular fibrillation is the totally disorganized depolarization and contraction of small areas of ventricular myocardium: there is no effective ventricular pumping activity. The ECG of ventricular fibrillation shows a fine to coarse zigzag pattern without discernible P waves or QRS complexes (Figure 28-20).

A pulse or blood pressure never accompanies ventricular fibrillation. In patients who are awake and responsive, the ECG pattern of ventricular fibrillation is caused by a loose lead artifact or electrical interference.

Clinical Significance Ventricular fibrillation is seen most commonly in patients with severe ischemic heart disease, with or without

an acute MI. Primary ventricular fibrillation occurs suddenly, without preceding hemodynamic deterioration, whereas secondary ventricular fibrillation occurs after a prolonged period of left ventricular failure and/or circulatory shock. Ventricular fibrillation also may occur from digoxin toxicity, quinidine toxicity, hypothermia, blunt chest trauma, severe electrolyte abnormality, or myocardial irritation caused by an intracardiac catheter or pacemaker electrode.

Treatment

1. Current Advanced Cardiac Life Support (ACLS) guidelines recommend immediate electrical defibrillation with 200 J. If ventricular fibrillation persists, defibrillation should be repeated immediately with 200 to 300 J for the second attempt and increased to 360 J for the third attempt.¹¹
2. If the initial three attempts at defibrillation are unsuccessful, cardiopulmonary resuscitation should be initiated, and according to ACLS guidelines, further electrical defibrillations should be done after the administration of various intravenous drugs.

ABERRANT VERSUS VENTRICULAR TACHYDYSRHYTHMIAS Differentiation between ectopic beats of ventricular origin and those of supraventricular origin but conducted aberrantly can be difficult, especially in sustained tachycardias with wide QRS complexes (WCT). In general, most **patients with WCT have ventricular tachycardia and should be approached as having ventricular tachycardia until proven otherwise.** Several guidelines might help in the distinction.

1. A preceding ectopic P' wave is good evidence favoring aberrancy, although coincidental atrial and ventricular ectopic beats or retrograde conduction can occur. During a sustained run of tachycardia, AV dissociation greatly favors a ventricular origin of the dysrhythmia.
2. A postectopic, i.e., fully compensatory, pause is more likely after a ventricular beat, but exceptions do occur.
3. Fusion beats are good evidence for ventricular origin, but exceptions do occur.
4. A varying bundle branch block pattern suggests aberrancy.
5. Coupling intervals are usually constant with ventricular ectopic beats unless parasystole is present. Varying coupling intervals suggest aberrancy.
6. Response to carotid sinus massage or other vagal maneuvers will slow conduction through the AV node and may abolish reentrant SVT and slow the ventricular response in other SVTs. These maneuvers have essentially no effect on ventricular dysrhythmias.
7. A QRS duration longer than 0.14 s usually is found only in ventricular ectopy or tachycardia.
8. With regard to QRS morphology, Wellens and colleagues studied patients with ventricular tachycardia and SVT with aberrancy using His bundle electrocardiography.¹² Several morphologic ECG criteria were found useful in differentiating between the two (Table 28-3). In the ED, these morphologic criteria are less useful.
9. Historical criteria have been found to be useful: age older than 35 years and/or history of MI, CHF, or coronary artery bypass graft strongly suggest ventricular tachycardia in patients with WCT.

3TUBANCES

Sinoatrial Block

The sinus node discharge must be conducted into the atria to pace the heart during sinus rhythm. If sinus node discharges are delayed or blocked in their outward propagation (exit block), then SA block is present. Sinoatrial block is divided into first-, second-, and third-degree varieties.

In first-degree SA block, the impulse is delayed in its conduction out of the sinus node into the atria, a condition that cannot be recognized on the clinical ECG.

FIG. 28-20. Ventricular fibrillation.

TABLE 28-3 Aberrancy versus Ventricular Ectopy

QRS Pattern in V ₁	Favors	QRS Pattern in V ₆	Favors

Abbreviation: RBBB = right bundle branch block.

Source: Wellens HJ, Bar FW, Lie KI: The value of the electrocardiogram in the differential diagnosis of tachycardia with a widened QRS complex. *AmJMed* 64:27, 1978.

In *second-degree SA block*, some impulses get through and some are blocked. Second-degree SA block can be suspected whenever an expected P wave and the corresponding QRS complex are absent. In the variable (Wenckebach) type of second-degree SA block, the missing P wave appears after a period of progressive prolongation of the conduction time from the sinus node to the atrium, something undetectable on the clinical ECG. However, another ECG finding common to the Wenckebach phenomenon can be seen: progressive shortening of the P-P intervals before the missing P wave (Figure 28-21). In the constant type of second-degree SA block, the SA conduction time remains constant before and after the blocked impulses. In this situation, the interval encompassing the missing beat is an exact or nearly exact multiple of the cycle length (Figure 28-22).

Third-degree SA block occurs when the sinus node discharge is completely blocked, and no P wave originating from the sinus is seen. There are three other causes of absent sinus P waves in addition to third-degree SA block: (1) sinus node failure, (2) a sinus node stimulus inadequate to activate the atria, and (3) atrial unresponsiveness.

Clinical Significance Sinoatrial block usually arises from myocardial disease (acute rheumatic fever, acute inferior MI, or other causes of myocarditis) or drug toxicity (digoxin, quinidine, salicylates, 3-adrenergic blockers, or calcium channel blockers). In rare individuals, vagal stimulation can produce SA block.

Treatment

1. Treatment depends on the underlying cause, associated dysrhythmias, and whether symptoms of hypoperfusion are present.
2. Sinus node discharge rate and SA conduction can be facilitated by atropine or isoproterenol, when clinically required; however, ischemia may result from a rhythm that is accelerated.
3. Cardiac pacing is indicated for recurrent or persistent symptomatic bradycardia.

FIG. 28-21. Second-degree sinoatrial block type I (Wenckebach). (Reproduced with permission from Braunwald E: *Heart Disease. A Textbook of Cardiovascular Medicine*. Philadelphia, WB Saunders, 1980.)

FIG. 28-22. Second-degree constant sinoatrial block type II (lead V₄).

Sinus Arrest (Pause)

Sinus pause is a failure of impulse formation within the sinus node. In sinus arrest, the P-P interval has no mathematical relation to the basic sinus node discharge rate (Figure 28-23).

Clinical Significance The same conditions that produce SA block can produce sinus arrest, especially digoxin toxicity and aging disease of the SA node, as in sick sinus syndrome, discussed below. **The combination of digoxin and carotid sinus massage is well known to be able to produce prolonged sinus arrest.** Brief periods of sinus arrest may occur in healthy individuals due to increased vagal tone. If sinus arrest is prolonged, AV junctional escape beats often occur.

Treatment

1. Treatment depends on the underlying cause, associated dysrhythmias, and whether symptoms of hypoperfusion are present.
2. If sinus arrest is symptomatic, atropine usually will increase the sinus node discharge rate.
3. Cardiac pacing is indicated for recurrent or persistent symptomatic bradycardia.

Atrioventricular Dissociation

Atrioventricular dissociation is a condition in which separate and independent pacemakers drive the atria and ventricles. It is not a primary rhythm disturbance but is secondary to another conduction or rhythm abnormality. There are two varieties of AV dissociation: passive (default or "escape") and active (usurpation).

Passive AV dissociation occurs when an impulse fails to reach the AV node because of sinus node failure or block. Usually an escape rhythm takes over and paces the ventricles. When the sinus node recovers, atrial activity resumes, but there may be a period during which the ventricles are still driven by the escape pacemaker and the P waves and QRS complexes occur independently of each other (Figure 28-24).

Active AV dissociation occurs when a slower pacemaker accelerates to usurp the sinus node and captures the ventricles but the atria are still paced as before (Figure 28-25).

In both varieties of AV dissociation, fusion beats are common. It is also common for the two pacemakers to operate with nearly identical rates, possibly as a result of mechanical or electrical influences that tend to keep them in phase with each other, a condition termed *isorhythmic dissociation*.

Clinical Significance Passive AV dissociation occurs when the sinus node discharge rate is slowed by sinus bradycardia, sinus dysrhythmia, SA block, or sinus pause. Common causes include (1) ischemic heart disease (especially acute inferior MI), (2) myocarditis (especially acute rheumatic fever), (3) drug toxicity (especially digoxin), and (4) vagal reflexes. It also may be seen in well-conditioned athletes.

FIG. 28-23. Sinus pause.

FIG. 28-24. Passive atrioventricular (AV) dissociation, secondary to third-degree AV block.

Active AV dissociation occurs when the automaticity of lower pacemakers is enhanced. Common causes include myocardial ischemia and drug toxicity (especially digoxin). This form of AV dissociation is seen only when the lower tachycardiac rhythm is not conducted to the sinus node with capture of the SA node. Ventricular tachycardia is the classic example of an active AV dissociation.

Treatment

1. Most occurrences of AV dissociation have an acceptable heart rate and are well tolerated.
2. Therapy, if any, is directed toward the underlying cause.

Atrioventricular Block

Clinical classification of AV block occurred before the sites and mechanisms involved in impairing conduction between the atria and ventricles were understood. As a matter of fact, Wenckebach described his block before the development of ECGs by looking at the A and V waves in the jugular veins. Mobitz described his classification after the invention of the ECG but before His bundle recordings. This classification is too simple to categorize all the problems that may occur with AV conduction. However, this system is used almost universally in respect to their observations.

First-degree AV block is characterized by a delay in AV conduction manifest by a prolonged P-R interval. Second-degree AV block is characterized by intermittent AV conduction: some atrial impulses reach the ventricles and others are blocked. Third-degree AV block is characterized by the complete interruption of AV conduction.

Precise localization of AV conduction blocks can be made with His bundle electrocardiography. Although this method is not available for use in the ED, correlations can be made between the clinical ECG, approximate location of the block, and risk of future progression.

Atrioventricular blocks also can be divided into nodal and infra-nodal blocks. This is an important distinction, because the clinical significance and prognosis differ with the site. Atrioventricular nodal blocks (block at the AH area) are usually due to reversible depression of conduction, are often self-limited, and generally have a stable infra-nodal escape pacemaker pacing the ventricles. Therefore, AV nodal

FIG. 28-25. Active atrioventricular dissociation (arrows = P waves).

blocks usually do not have a serious prognosis. Infranodal blocks (block at the HV area) usually are due to organic disease of the His bundle or bundle branches; often the damage is irreversible. They generally have a slow and unstable ventricular escape rhythm pacing the ventricles, and they may have a serious prognosis, depending on the clinical circumstance.

FIRST-DEGREE AV BLOCK In first-degree AV block, each atrial impulse is conducted into the ventricles, but more slowly than normal. This is recognized by a P-R interval longer than 0.20 s (Figure 28-26). The AV node is usually the site of conduction delay, although this block may occur at any infranodal level.

Clinical Significance First-degree AV block occasionally is found in normal hearts. Other common causes include increased vagal tone (any cause), digoxin toxicity, acute inferior MI, and myocarditis. Patients with first-degree AV block without evidence of organic heart disease appear to have no significant difference in mortality compared with matched controls.

Treatment

1. None is usually required.
2. Prophylactic pacing in acute MI is not indicated unless more serious infranodal conduction disturbances are present.

Second-Degree Mobitz I (Wenckebach) AV Block

In this block there is progressive prolongation of AV conduction (and the P-R interval) until an atrial impulse is completely blocked (Figure 28-27). This property of a gradually increasing block until it is complete is a normal property of cardiac tissue. In the face of disease, this property occurs at a much slower rate. In the EP laboratory, a Wenckebach type of block is frequently seen when atrial pacing occurs at fast rates to uncover an accessory pathway. Conduction ratios are used to indicate the ratio of atrial to ventricular depolarizations: 3:2 indicates that two of three atrial impulses are conducted into the ventricles. Usually, one atrial impulse is blocked. After the dropped beat, the AV conduction returns to normal, and the cycle usually repeats itself with the same conduction ratio (fixed ratio) or a different conduction ratio (variable ratio). This type of block almost always occurs at the level of the AV node and is often due to reversible depression of AV nodal conduction.

The Wenckebach phenomenon involves a seeming paradox. Even though the P-R intervals progressively lengthen before the dropped beat, the increments by which they lengthen decrease with successive beats; this produces a progressive shortening of the R-R interval before the dropped beat (see Figure 28-27). This sign can be used to indicate that a Wenckebach phenomenon is occurring even when the conduction delay cannot be seen, as in Wenckebach SA block.

Wenckebach block is believed to occur because each successive depolarization produces prolongation of the refractory period of the AV node. When the next atrial impulse comes upon the node, it is earlier in the relative refractory period, and conduction occurs more slowly relative to the previous stimulus. This process is progressive until an atrial impulse reaches the AV node during the absolute refractory

FIG. 28-26. First-degree atrioventricular block (P-R interval = 0.3 s).

FIG. 28-27. Second-degree Mobitz I (Wenckebach) atrioventricular (AV) block with 4:3 AV conduction.

period, and conduction is blocked altogether. The pause allows the AV node to recover, and the process can resume.

Clinical Significance This block is often transient and usually associated with an acute inferior MI, digoxin toxicity, or myocarditis, or it is seen after cardiac surgery. Wenckebach block may occur when a normal AV node is exposed to very rapid atrial rates.

Treatment

1. Specific treatment is not necessary unless slow ventricular rates produce signs of hypoperfusion.
2. Atropine 0.5 mg IV is the initial treatment of choice, repeated every 5 min as necessary, titrated to the desired effect, or until the total dose reaches 2.0 mg. Almost all patients will respond to atropine. The need for an increased rate and, one hopes, increased perfusion must be consistently balanced with the increased myocardial O₂ consumption in the ischemic patient.
3. Isoproterenol is hazardous in the setting of acute MI or digoxin toxicity, and its use should be avoided.
4. Transcutaneous or transvenous ventricular demand pacing should be initiated if atropine is unsuccessful. It must be confirmed that the hypoperfusion is due to the rate and not to decreased preload, as in some patients with inferior MI.

Second-Degree Mobitz II AV Block

In this block, the P-R interval remains constant before and after the nonconducted atrial beats (Figure 28-28). One or more beats may be nonconducted at one time.

Mobitz II blocks usually occur in the infranodal conducting system, often with coexistent fascicular or bundle branch blocks, and the QRS complexes therefore are usually wide. Even if the QRS complexes are narrow, the block is generally in the infranodal system.

When second-degree AV block occurs with a fixed conduction ratio of 2:1, it is not possible to differentiate between a Mobitz type I (Wenckebach) or Mobitz type II block (see Figure 28-28). If the QRS complex is narrow, then the block is in the AV node or infranodal system with about equal incidence. If the QRS complex is wide, the block is more likely to be in the infranodal system.

A

FIG. 28-28. Top: Second-degree Mobitz II atrioventricular (AV) block. Bottom: Second-degree AV block with 2:1 AV conduction.

Clinical Significance Type II blocks imply structural damage to the infranodal conducting system, are usually permanent, and may progress suddenly to complete heart block, especially in the setting of an acute MI.

Treatment

1. Emergent treatment is required when slow ventricular rates produce symptoms of hypoperfusion. Atropine should be the first drug used, and up to 60 percent of patients will respond. Isoproterenol is effective in up to 50 percent of cases but is potentially hazardous in the setting of acute MI or digoxin toxicity, and its use should be avoided. Transcutaneous cardiac pacing is a useful modality in patients unresponsive to atropine.
2. Most patients, especially in the setting of acute MI, will require transvenous cardiac pacing.

Third-Degree (Complete) AV Block

In third-degree AV block, there is no AV conduction. An escape pacemaker at a rate slower than the atrial rate (Figure 28-29) paces the ventricles. Third-degree AV block can occur at nodal or infranodal levels.

When third-degree AV block occurs at the AV node, a junctional escape pacemaker takes over with a ventricular rate of 40 to 60 beats/min, and because the rhythm originates above the bifurcation of the bundle of His, the QRS complexes are narrow.

When third-degree AV block occurs at the infranodal level, the ventricles are driven by a ventricular escape rhythm at a rate slower than 40 beats/min. In third-degree AV block at the His bundle level, the escape rhythm has narrow QRS complexes about half of the time. Presumably in these cases, the escape pacemaker resides above the bifurcation of the conducting system into the separate bundle branches. Third-degree AV blocks in the bundle branch or elsewhere in the Purkinje system invariably have escape rhythms with wide QRS complexes.

Clinical Significance Nodal third-degree AV block may develop in up to 8 percent of acute inferior MIs, where it is usually transient, although it may last for several days.

Infranodal third-degree AV blocks indicate structural damage to the infranodal conducting system, as seen with an extensive acute anterior MI. The ventricular escape pacemaker is usually inadequate to maintain cardiac output and is unstable, with periods of ventricular asystole. When third-degree block is seen in acute MI, mortality is increased even when rhythm is controlled with pacing.

Treatment

1. Nodal third-degree AV blocks should be treated like second-degree Mobitz I AV blocks with atropine or ventricular demand pacemaker, as required.
2. Infranodal third-degree AV blocks require a ventricular demand pacemaker. When other measures fail, isoproterenol can be used temporarily to accelerate the ventricular escape rhythm, or external cardiac pacing can be performed before transvenous pacemaker placement.

FASCICULAR BLOCKS

Unifascicular Block

Unifascicular block is a conduction block that affects one of the three major infranodal conduction pathways: RBB, LASF, or LPIF. A wide

FIG. 28-29. Third-degree atrioventricular block.

FIG. 28-30. Left anterior superior fascicular block.

variety of disease processes can produce conduction block in the fascicles: ischemia, cardiomyopathies, valvular (especially aortic), myocarditis, cardiac surgery, congenital conditions, and degenerative processes affecting the conduction tissue (Lenegre or Lev diseases). The RBB and the LASF are relatively small and easily affected parts of the conduction system. The LPIF is very broad and is caused by disease affecting a large area of myocardium.

In LASF block, left ventricular activation is by way of the LPIF and proceeds in an inferior-to-superior and right-to-left direction. The ECG characteristics of LASF block are (1) normal QRS duration, (2) frontal plane mean QRS axis between -30 and -90 degrees, (3) R wave in lead I greater than the R waves in lead II or III, (4) a qR complex in lead aV_L , and (5) deep S wave in leads II, III, and aV_F (Figure 28-30). The LASF is small and easily affected by focal lesions. Other causes of left axis deviation should be excluded: inferior MI, hyperkalemia, preexcitation syndromes, or body habitus. Left ventricular hypertrophy can cause left axis deviation as seen with LASF block; however, the axis is infrequently less than -30 degrees.

In the LPIF block, left ventricular activation is by way of the LASF and proceeds in a superior-to-inferior and left-to-right direction. The ECG characteristics of LPIF block are (1) normal QRS duration, (2) frontal plane mean QRS axis between 110 and 180 degrees, (3) small r and deep S waves in lead I, (4) an R wave in lead III larger than the

R wave in lead II, and (5) a qR complex in lead III (Figure 28-31). The LPIF is broad and not affected by focal lesions; its presence indicates widespread organic heart disease. Other causes of right axis deviation are chronic cor pulmonale, right ventricular hypertrophy, and lateral ML. In RBB block (RBBB), ventricular activation is by way of the LBB, proceeding from the left to the right ventricle. The ECG characteristics of RBB block are (1) prolonged QRS duration (≥ 0.12 s); (2) triphasic QRS complexes (RSR') in lead V_1 ; (3) wide S waves in the lateral leads I, V_5 , and V_6 ; and (4) normal onset of ventricular activation in lead V_6 (Figure 28-32). The frontal plane mean QRS axis is usually not deviated to the right, unless there is associated right ventricular hypertrophy or LPIF block.

Bifascicular Block

The term *bifascicular block* refers to conduction blocks over two fascicles: (1) RBB and LASF, (2) RBB and LPIF, or (3) LBB block (LBBB). In LBBB, ventricular activation is by way of the RBB and proceeds from right to left and inferior to superior. The ECG characteristics of LBBB are (1) prolonged QRS duration (≥ 0.12 s); (2) large and wide R waves in leads I, aV_L , V_5 , and V_6 ; (3) small r wave followed by deep S wave in leads II, III, aV_F , and V_1 to V_3 ; and (4) no q waves in leads I, V_5 , and V_6 (Figure 28-33).

FIG. 28-31. Left posterior inferior fascicular block.

FIG. 28-32. Right bundle branch block.

Trifascicular Block

The term *trifascicular block* refers to a combination of conduction blocks in all three fascicles, either permanent or transient: (1) RBB and LAFB with first-degree AV block, (2) RBB and LPIF with first-degree AV block, (3) LBB with first-degree AV block, or (4) alternating RBBB and LBBB.

Although bi- and trifascicular conduction blocks indicate advanced organic heart disease, long-term follow-up studies of ambulatory patients have indicated that the risk of sudden progression to complete heart block and sudden death due to ventricular asystole is not great. Placement of a ventricular demand pacemaker is indicated only for symptoms due to documented bradyarrhythmias.

In the face of an acute MI, the risks of complete heart block are much greater when new or preexisting bi- or trifascicular conduction blocks are present. In this setting, prophylactic placement of a ventricular demand pacemaker is indicated.

PRETERMINAL RHYTHMS

Several dysrhythmias may be seen during cardiac resuscitation. Ventricular tachycardia and fibrillation potentially are treatable, and re-

suscitation may result in a functional survivor. The four other dysrhythmias included here have a low rate of successful resuscitation and are much less likely to result in a functional survivor.

Pulseless Electrical Activity

Pulseless electrical activity (PEA) is the presence of electrical complexes without accompanying mechanical contraction of the heart. In the setting of a cardiac arrest, PEA is due to a profound metabolic abnormality of the myocardium that renders it noncontractile. At this time, there is no clearly beneficial therapy; the best that can be recommended currently is continued cardiopulmonary resuscitation and α -adrenergic agents. Although calcium has been advocated traditionally, most studies have found no consistent benefit, and there are serious biophysiologic reasons to question the use of calcium in the setting of cardiac arrest. Electrical pacing is not effective.

Other conditions associated with PEA are (1) severe hypovolemia, (2) cardiac tamponade, (3) tension pneumothorax, (4) massive pulmonary embolus, and (5) rupture of the ventricular wall. The first three conditions are potentially treatable if recognized early.

FIG. 28-33. Left bundle branch block

Idioventricular Rhythm

An idioventricular rhythm is an escape rhythm of ventricular origin with very wide QRS complexes (>0.16 s) and a rate slower than 40 beats/min (Figure 28-34). Effective cardiac contractions and pulses may or may not be present. Idioventricular rhythm may occur as the result of complete infranodal AV block, acute MI, cardiac tamponade, or exsanguinating hemorrhage. Treatment consists of accelerating the heart rate and enhancing mechanical contractility by using cardiopulmonary resuscitation and α -adrenergic agents. There is no proven benefit to the use of atropine or isoproterenol to treat idioventricular rhythm during cardiac resuscitation.

Agonal Ventricular Rhythm

Agonal rhythm is the occurrence of very broad and irregular ventricular complexes at a slow rate, usually without associated ventricular contractions (Figure 28-35).

Cardiac Asystole (Cardiac Standstill)

Asystole is the complete absence of cardiac electrical activity. Treatment consists of stimulating electrical activity and mechanical contractions with continued cardiopulmonary resuscitation and α -adrenergic agents. Transthoracic or transvenous ventricular pacing occasionally may produce electrical capture but rarely yields effective pumping action if prior agents were unsuccessful.

TACHYCARDIA-BRADYCARDIA SYNDROME (SICK SINUS SYNDROME)

Sick sinus syndrome (SSS) is a heterogeneous disorder consisting of abnormalities of supraventricular impulse generation and conduction that produce a wide variety of intermittent supraventricular tachy- and bradydysrhythmias. The tachydysrhythmias are usually atrial fibrillation, junctional tachycardia, reentrant SVT, and AF. The bradydysrhythmias are marked sinus bradycardia, prolonged sinus arrest, and SA block, usually associated with AV nodal conduction abnormalities and inadequate AV junctional escape rhythms.

Clinical Significance Symptoms of SSS are due to the effects of fast or slow heart rate. Common symptoms include syncope or near syncope, palpitations, dyspnea, chest pain, and cerebrovascular accidents.

A wide variety of cardiac diseases can affect the sinus and AV nodes and produce the dysrhythmias of SSS: ischemic and rheumatic disorders, myocarditis and pericarditis, rheumatologic disease, metastatic tumors, surgical damage, or cardiomyopathies.

Conditions such as abdominal pain, increased intracranial pressure, thyrotoxicosis, and hyperkalemia, which increase vagal tone, may exacerbate the abnormalities of SSS and increase symptoms. Drugs such as digoxin, quinidine, procainamide, disopyramide, nicotine, β -adrenergic antagonists, or calcium channel blockers also can increase symptoms.

Ambulatory ECG monitoring or EP studies are usually necessary for the diagnosis of SSS, because a routine ECG will not normally

FIG. 28-34. Idioventricular rhythm.

FIG. 28-35. Agonal ventricular rhythms: regular (top) and irregular (bottom).

demonstrate the intermittent dysrhythmias common in this syndrome. The demonstration of increased sensitivity of the sinus node to carotid sinus massage, the Valsalva maneuver, or atropine suggests sinus node dysfunction but is not conclusive proof for the diagnosis of SSS.

Treatment

1. Sick sinus syndrome is the most common indication for a permanent pacemaker. This disease of the SA and AV nodes accounts for 48 percent of primary pacemaker implants. Retrospective analysis indicates that a reduction in mortality and in the incidence of CHF, AF, and thromboembolism occurs in patients with atrial pacing (AAI or DDD) as opposed to ventricular pacing (VVI) (see Pacing, below).
2. Treatment of atrial tachyarrhythmias with digoxin, quinidine, disopyramide, procainamide, propranolol, or verapamil carries the risk of aggravating preexisting AV block or sinus arrest. Therefore, most patients should have pacemaker implantation before drug therapy is begun.

PREEXCITATION SYNDROMES

Preexcitation occurs when the ventricles are activated by an impulse from the atria sooner than would be expected if the impulse were transmitted down the normal conducting pathway (the AV node). Several different forms of preexcitation have been described, based on anatomic, clinical, ECG, and EP abnormalities. All forms of preexcitation are felt to be due to accessory tracts that bypass all or part of the normal conducting system. These bypass tracts have specific names (Figure 28-36). *James fibers* (atriohisian connection) are a continuation of the posterior internodal tract and connect the atrium and proximal His bundles.

FIG. 28-36. Anatomic sites of bypass tracts.

Atrial impulses can therefore completely bypass the AV node to activate the ventricles. On ECG, this appears as (1) a short P-R interval because the usual delay in the AV node is bypassed and (2) a normal QRS because James fibers insert directly into the infranodal conducting system and the ventricles are activated normally. When this is associated with reentrant SVT, the clinical condition is termed *Lown-Ganong-Levine syndrome*.

Mahaim bundles are composed of myogenic tissue; they originate from the AV node, His bundle, or bundle branches and insert into the ventricles in the septal region. Atrial impulses pass through the AV node but then bypass all or part of the infranodal conducting system to activate the ventricles. Ventricular activation then occurs from two sources, the bypass tract and the normal conducting system, and the QRS complex represents a fusion of the two. The initial depolarization starts at the ventricular insertion of the bypass tract and is spread slowly by cell-to-cell transmission of the impulse. Subsequent depolarization by way of the faster normal conducting system then overtakes the initial depolarization and activates the bulk of ventricular myocardium. The QRS complex is basically normal, with a slurred and distorted initial portion termed a *delta wave*. On ECG, this wave appears as a normal P-R interval and an initial distortion of ventricular depolarization (delta wave).

Kent bundles are composed of myogenic tissue and directly link the atria to the ventricles, completely bypassing the AV node and infranodal system. This is the most common form of preexcitation and is the anatomic basis for the WPW syndrome. On ECG, this appears as a shortened P-R interval with an initial distortion of ventricular activation (delta wave). Sometimes the bypass tract does not conduct an atrial impulse in the antegrade direction and the QRS complex is entirely normal. However, these concealed bypass tracts may conduct retrogradely and be able to sustain reentrant SVT.

The WPW syndrome has been divided into types, depending on the direction of the initial delta wave on the surface ECG. This in turn is determined by where the bypass tract (bundle of Kent) inserts into the ventricles and which portion of the ventricles is activated first. In reality, accessory tracts can insert anywhere around the AV annulus; the three types are just the most common locations.

In type A WPW syndrome, ventricular activation first occurs in the inferior-posterior region of the left ventricle and the delta wave is directed anteriorly. A positive initial deflection with a dominant R wave is seen in lead V₁. Q waves in leads II, III, and aV_F are common (Figure 28-37).

In type B WPW syndrome, ventricular activation first occurs in the inferior-posterior region of the right ventricle and the delta wave is di-

rected posteriorly and to the left. A negative initial deflection and RS or QS pattern are seen in lead V₁ (Figure 28-38).

In type C WPW syndrome, ventricular activation first occurs in the posterior-lateral region of the left ventricle and the delta wave is directed to the right, superiorly, and anteriorly. A positive delta wave is seen in lead V₁, with a negative or isoelectric delta wave in leads V₅ and V₆.

Because there is altered depolarization, repolarization is often abnormal, with changes in the ST segments and T waves. The ECG changes of WPW syndrome may mimic changes seen with myocardial ischemia, infarction, or ventricular hypertrophy. Type A WPW syndrome may imitate as a posterior MI, and type B WPW syndrome may imitate an inferior MI.

Clinical Significance There is a high incidence of tachyarrhythmias in patients with WPW syndrome. Atrial flutter occurs in about 5 percent, atrial fibrillation in 10 to 20 percent, and paroxysmal reentrant SVT in 40 to 80 percent.

Reentrant SVT occurs when an impulse is sustained around a loop composed of the bypass tract and the AV conducting system, with the impulse traveling down one and up the other. Whether the QRS complex is wide or narrow depends on which limb of the circuit is used as the downward pathway to activate the ventricles. About 80 to 95 percent of the time, reentrant SVT occurs with the impulse being conducted down the normal AV conducting system and up the bypass tract (*orthodromic* AV reciprocating tachycardia). In this situation, ventricular activation occurs entirely over the normal system, the QRS complex is normal, and no delta wave is seen. Because the entire heart is used as the reentrant pathway, these arrhythmias are easily converted. Conversely, 5 to 10 percent of the time, the impulse is conducted down the bypass tract and retrogradely up the AV node (*antidromic* AV reciprocating tachycardia). In this case, the QRS complex is wide, and in the ED setting, this arrhythmia is treated as ventricular tachycardia. Reentry usually is initiated by a premature atrial contraction that encounters a bypass tract that is still refractory from the previous sinus beat, but the AV node has partly recovered and conducts the impulse more slowly than normal (Figure 28-39). In some patients, the bypass tract does not conduct antegradely during sinus rhythm, so no delta wave is seen, but it does conduct retrogradely, so reentrant SVT occurs. Patients with concealed bypass tracts account for about 20 percent of all patients with reentrant SVT.

If patients with WPW syndrome develop AF or atrial fibrillation, impulses can reach the ventricles via the accessory tract, the normal

FIG. 28-37. Type A Wolff-Parkinson-White syndrome.

FIG. 28-38. Type B Wolff-Parkinson-White syndrome.

conducting system, or both. Which pathway is used depends on the refractory period of each. Most patients with WPW syndrome have longer refractory periods in their accessory tracts than in the AV node, but a minority has the opposite. In patients with short refractory periods in their accessory tracts, more atrial impulses can be conducted through the accessory tract than through the AV node, so most of the QRS complexes will be wide. In AF, 1:1 AV conduction is possible with ventricular rates of 300 beats/min (Figure 28-40). In atrial fibrillation, very rapid and irregular ventricular rates are possible. These rapid rhythms may resemble ventricular tachycardia, and excessive stimulation of the ventricles may precipitate ventricular fibrillation.

Any patient with a ventricular rate faster than 300 beats/min should raise the suspicion of preexcitation syndrome.

Treatment

1. Reentrant SVT (orthodromic AV reciprocating tachycardia, narrow QRS complex) in the WPW syndrome can be treated like other cases of reentrant SVT. Because the AV node is involved in the reentry circuit, any maneuver or drug that slows conduction through the AV node is usually effective. Verapamil in the patient who is not hypotensive or in CHF is by some accounts the optimal drug. Adenosine is very successful at terminating this dysrhythmia in patients with WPW; however, there is some proclivity to increase atrial vulnerability to AF and to ectopic atrial activity, which may reinitiate the dysrhythmia.
2. Antidromic tachycardia (antidromic AV reciprocating tachycardia, wide QRS complex) is usually associated with a short refractory period in the bypass tract, and such patients are at risk for rapid ventricular rates and degeneration into ventricular fibrillation. Stable patients should be treated with intravenous procainamide, and unstable patients should be cardioverted. **(B-Blocking agents, adenosine, and calcium channel blockers should be avoided.)**
3. Atrial flutter or fibrillation with a rapid ventricular response is best treated with cardioversion. As an alternative, agents that prolong the refractory period of the accessory tract, such as intravenous procainamide, can be used. Experimental studies with intravenous flecainide have shown promise. In general, phenytoin, esmolol, propranolol, or verapamil should not be used, because of their variable effects on accessory conduction. Digoxin is contraindicated, because it may shorten the refractory period and enhance conduction over the bypass tract.

DEFIBRILLATION AND SYNCHRONIZED CARDIOVERSION

Defibrillation and cardioversion is the technique of passing a short burst (about 5 ms) of direct electric current across the thorax to terminate tachyarrhythmias. The electric current simultaneously depolarizes all excitable cardiac tissue and terminates any areas of reentry by halting further propagation of the impulse around the reentry loop. This places all cardiac cells in the same depolarized state, and a dominant pacemaker (usually the sinus node) paces the heart in a regular manner.

Defibrillation or cardioversion uses the same type of equipment. A device stores a known quantity of electrical energy in a storage capacitor

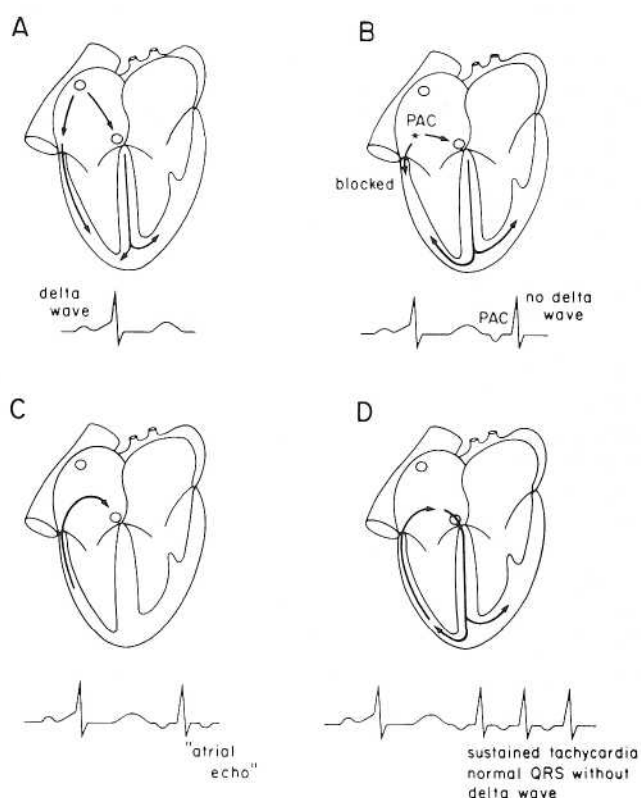

FIG. 28-39. Onset of reentrant supraventricular tachycardia in Wolff-Parkinson-White syndrome.

FIG. 28-40. Atrial fibrillation in Wolff-Parkinson-White syndrome.

and, on command, discharges it through two electrodes placed on the chest wall. Usually, a rhythm monitor and a synchronizer circuit are built into the device. Electrode placement can be anterior and posterior or apex and right parasternal. Whereas some investigators have used a lower energy requirement for conversion using anterior and posterior electrodes, others have not. For emergencies, electrode placement probably does not matter.

To reduce transthorax electrical impedance and increase the amount of current passing through the heart, certain techniques are important at the electrode-chest wall interface. Electrode paste, gel, or saline pads are applied to the surface of the electrodes. Firm pressure of 10 to 12.5 kg/cm² (20 to 25 lb/in.²) is used to achieve good electrical contact. Larger electrodes or defibrillator pads, within reason, have a reduced impedance, but this does not appear to significantly influence the energy required for conversion.

Older devices had significant internal energy losses and delivered as little as 40 percent of the stored energy to the patient. This is not a problem with modern defibrillators, because they deliver very close to the stored amount.

Defibrillation should be done as soon as ventricular fibrillation is diagnosed. The longer ventricular fibrillation persists, the less likely it is that resuscitation will be successful. Current ACLS guidelines recommend 200 J for the first attempt, 200 to 300 J for the second attempt, and 360 J for subsequent defibrillations.¹¹ Several studies have found that most patients can be defibrillated with 160 to 200 J. Recommendations for children are 2 J/kg (1 J/lb) in the initial attempt and 4 J/kg in subsequent attempts.

Synchronized cardioversion applies the electric current at a time during the cardiac cycle well away from the vulnerable period when there is little chance of inducing ventricular fibrillation, usually about 10 ms after the peak of the R wave. On most machines, the synchronizer circuit must be turned on each time an impulse is desired. Many devices also display on the monitor screen or by a flashing light that the synchronizer circuit is properly detecting the QRS complex. Cable leads, rather than the paddles, should be used to monitor the cardiac rhythm to avoid any movement artifact that could be misinterpreted by the synchronizer circuit as the QRS complex.

Complications of defibrillation or cardioversion include the following:

1. Direct myocardial damage is unusual unless there are repeated shocks at high energy (S325 J).
2. Incidence of ventricular fibrillation is less than 5 percent with a synchronized discharge but probably greater in the presence of digoxin or quinidine toxicity, hypokalemia, or acute MI. However,

patients on maintenance digoxin therapy can be safely cardioverted using low energies (≤50 J).

3. Systemic emboli occur in about 1.2 to 1.5 percent in patients with chronic atrial fibrillation.
4. ST-segment changes (transient elevations or depressions) usually resolving within 5 min.
5. Bradycardias are more common in patients with inferior MI and those requiring multiple defibrillations and cardioversions. Brady cardias are usually evident during the first 5 s after shock and occasionally may persist for longer than 20 s and require external or internal pacing.
6. Tachycardias (usually sinus tachycardia, occasionally AF or fibrillation) usually resolving spontaneously within 5 min.
7. Atrial, junctional, or ventricular ectopy is usually transient and benign.
8. Pulmonary edema is uncommon but may occur in patients with mitral or aortic valvular disease or left ventricular failure.
9. Hypotension is rare, inexplicable, and may last for several hours before spontaneously resolving.
10. Muscle damage: elevated levels of creatine phosphokinase and lactate dehydrogenase are common, but other more specific indicators (CK-MB and troponin) are rarely abnormal.

Automated internal defibrillators are discussed in Chap. 22.

CARDIAC PACEMAKERS

Artificial cardiac pacemakers have two components: a power source (battery with pulse generator) and an electrode that delivers current to the heart (transvenous, epicardial, transthoracic, and transcutaneous). In permanent pacemaker placement, the power source is implanted subcutaneously, and the electrodes are run through the veins to inside the heart or through the subcutaneous tissue to the epicardial surface. In temporary pacemaker placement, the power source is external to the body, and electrodes are placed in one of two ways: transvenously to an intracardiac location or transcutaneously with electrodes placed on the thoracic skin. The pulse generator can be designated to operate in a fixed-rate mode (asynchronous or competitive) or a demand mode (synchronous or noncompetitive). In the fixed-rate mode, the pulse generator produces an electrical signal at the preset rate regardless of the patient's own intrinsic cardiac rhythm. Serious dysrhythmias or ventricular fibrillation may occur if the pacemaker discharges during the vulnerable period (T wave); for this reason, fixed-rate pacing is rarely done.

In the demand mode, the pulse generator has a sensing circuit that detects spontaneous cardiac activity and will discharge only if no cardiac depolarization is detected for a preset interval. Demand pacemakers may have two response modes, inhibited and triggered. Pacemakers set to be inhibited have a pulse generator that is inhibited by the sensed cardiac activity and do not generate an impulse. In the triggered-response mode, the pacemaker detects the patient's intrinsic cardiac activity and then discharges during the absolute refractory period. On ECG, this discharge appears as pacing spikes after each intrinsic QRS complex.

The most recent five-letter code system is shown in Table 28-4. This coding system has added antitachyarrhythmic and shocking capabilities of the latest pacemakers. Many patients carry cards indicating the type of pacemaker they have. The simplest type of pacemaker used, the ventricular-demand inhibited-response pacemaker, would be designated as VVI.

The modern permanent pacemaker is powered by a lithium battery that has an approximate lifetime of 8 to 12 years. Most units are preset for rates near 70 beats/min, with a pacing interval of 0.84 s. The demand pacemaker has a built-in refractory period (0.2 to 0.4 s) during which it will not sense. This prevents it from being inhibited by its own stimulus. Most demand pacemakers have a magnetic switch, which temporarily converts the pulse generator from the demand mode to the fixed-rate mode when a magnet is held over the unit. In this way, the pacing rate can be quickly determined, but the magnet should be applied for only short periods to avoid initiating tachyarrhythmias. The rate and stimulus strength can be reset by noninvasive means in programmable pacemakers. Some of the more sophisticated pacemakers can be interrogated to indicate events such as tachyarrhythmias and conversions. Because pacemaker complexity varies, the manufacturer supplies an identification card with each unit that patients should carry.

Temporary pacemakers are powered by 9-V radio-type batteries. On these pacemakers, there are settings for the mode (fixed or demand), rate (40 to 140 beats/min), and stimulus strength (0.2 to 20 mA). During emergency pacing, initial settings should be in the demand mode with a rate near 70 beats/min and stimulus strength near 3.0 mA. The negative terminal should be connected to the distal electrode.

The transvenous intracardiac electrode may be unipolar or bipolar. The unipolar setup has the negative electrode within the heart and the positive electrode in the chest wall. Permanent pacemakers using the unipolar setup have the positive electrode in the surface covering. Temporary pacemakers using the unipolar setup have their positive electrode connected to a needle implanted in the skin of the anterior thorax. With the bipolar setup, both electrodes are within a few millimeters of each other and both lie within the heart. Transvenous electrodes are placed most commonly into the apex of the right ventricle.

This causes an LBBB pattern when pacing. Different catheters are used depending on the clinical situation. Semirigid catheters (6 or 7 French) are inserted through a venous puncture or cutdown. They usually require fluoroscopy for correct placement. Semifloating (3 or 4 French) or flexible balloon-tipped catheters (3 or 5 French) can be introduced and directed into the right ventricle without fluoroscopy by using blood flow. Flexible catheters can become dislodged by patient or cardiac movement and are usually replaced with semirigid catheters within 24 h.

Transthoracic cardiac pacing has been largely replaced by transcutaneous pacing. Transthoracic pacing is fraught with many complications, including coronary artery laceration and cardiac tamponade in addition to pneumothorax.

Transcutaneous electrodes are self-adhesive pads that are usually placed with the negative electrode over the left anterior precordium and the positive electrode over the left infrascapular area. Transcutaneous pacing is then initiated by using the lowest current setting, which is increased until electrical capture is achieved. Most patients can be paced with 100 mA, but some may require up to 200 mA. The newer pacemakers cause much less discomfort, can be applied faster, and combine defibrillator and pacing functions from the same pads.

Indications for Emergency Pacing

Emergency cardiac pacing is indicated therapeutically (for symptomatic bradyarrhythmias) or prophylactically (for conduction defects that pose a high risk of sudden complete heart block or asystole).

Symptomatic bradyarrhythmias should be treated with atropine and/or isoproterenol as a temporary measure to support cardiac rhythm before pacemaker placement. Some patients may respond adequately to atropine alone and do not require pacemaker insertion.

Most investigators recommend prophylactic placement of a pacemaker in any patient with acute MI who has a new or age-indeterminate bi- or trifascicular block. In addition, second-degree Mobitz II and third-degree AV blocks are indications for pacemaker insertion or transcutaneous pacer pad placement. Despite successful pacing, many patients with acute MI and these serious conduction blocks have extensive left ventricular damage and a high mortality from pump failure.

Pacemaker Malfunction

Malfunction of a permanent pacemaker can be categorized as (1) failure to sense, (2) failure to pace, (3) oversensing, or (4) combinations of the first three. With current lithium batteries and reliable circuitry, most pacemaker malfunctions are due to problems with the electrodes and not the result of battery exhaustion or pulse-generator failure.

TABLE 28-4 NASPE/BPEG Generic Pacemaker Code

Letter Position	II	III	IV	V	
Category	Chamber(s) Paced	Chamber(s) Sensed	Response to Sensing	Programmability, Rate	Antitachyarrhythmic Function(s)
	0, none	0, none	0, none	0, none	0, none

f Dual (atrial and ventricular) and inhibited.

{Pacing and shock.

Failure to sense may occur when the voltages of the patient's own intrinsic QRS complex is too low to be detected by the sensing circuit of the pacemaker. Changing from a bipolar to a unipolar setup (if possible) may help the pacemaker sense the intrinsic cardiac activity. Failure to sense may cause the pacemaker to become a fixed-rate pacemaker, discharge during the T wave, and trigger serious dysrhythmias.

Failure to pace may occur when tissue reaction around the electrode makes the myocardium insensitive to the electric discharge that is generated by the pacemaker. It is common for the pacing threshold to increase during the first few weeks after insertion, but further rises are infrequent.

Failure to sense and pace may be due to battery exhaustion, fracture of the wires in the catheter, or displacement of the electrodes. Battery exhaustion is indicated when the pacing rate slowly decreases. With lithium batteries, such decreases usually occur years before actual battery exhaustion. Greater than a 10 percent change from the initial rate is an urgent indication for replacement. Catheter wire fracture may cause sustained or intermittent interruption in electrical conductivity. Sudden onset of symptoms and/or bradyarrhythmias suggest catheter fracture. Catheter fractures are rarely seen on routine chest radiographs. The transvenous electrode is usually positioned in the right ventricular apex, with a characteristic appearance on the chest radiograph and ECG. Displacement can be suggested when changes on radiographs or ECG occur.

Oversensing is used to describe the situation in which the pacemaker senses electrical activity not associated with atrial or ventricular depolarizations; it is thus inhibited, and generation of the pacemaker impulse is suppressed. Causes of oversensing include physiologic electrical activity (T waves, muscle potentials), external electromagnetic interference, and signals generated by the interaction of different portions of the pacing system. Unipolar electrodes are more sensitive to physiologic electrical activity and electromagnetic interference than to bipolar electrodes.

Under certain conditions, pacemakers may initiate tachyarrhythmias despite functioning as designed; this usually results from an intrinsic depolarization occurring during the pacemaker refractory period, the depolarization not being sensed, and the pacemaker firing soon thereafter and initiating a reentrant tachycardia. In this setting, maintenance of the dysrhythmia does not require further participation of the pacemaker. Dual-chamber pacemakers also can induce and sustain dysrhythmias. In this situation, emergent treatment requires reprogramming the pacemaker, if possible, or converting to asynchronous mode by placing a magnet over the pulse generator.

EVALUATION OF PALPITATIONS

Palpitations are common symptoms that may be due to a dysrhythmia.¹³ Frequently, palpitations are no longer present when the patient presents to the ED. The term is nonspecific, but certain descriptions may be helpful in pointing toward certain types of rhythm disturbances. Premature atrial or ventricular contractions followed by a compensatory pause are often described as a flip-flopping in the chest. Atrial or ventricular dysrhythmias can cause a fluttering feeling. Pounding in the neck can be felt when atrial and ventricular contractions are dissociated, as in supraventricular or junctional tachycardias. Inappropriate sinus tachycardia is also in the differential diagnosis.

History taking should include questions regarding prescribed medications, including herbals; recreational drugs; and use of caffeine-containing beverages. History suggestive of endocrine disorders such as hyperthyroidism should be sought. If the clinical presentation suggests potassium abnormality, electrolytes can be checked.

Palpitations associated with dizziness, syncope, or presyncope should be assumed to be associated with ventricular tachycardia until proven otherwise. Although panic attack is often assumed to be associated with palpitations, this diagnosis cannot be established in the ED.

The ECG should be examined for evidence of dysrhythmia, bypass tracts, and QT-interval prolongation. Patients with a family history of sudden death, syncope, or dysrhythmia; those with any evidence of or-

ganic heart disease; and those with presyncope, syncope, or dizziness can be admitted or placed in an observation unit for monitoring and EP testing. Patients felt to be at lower risk can be discharged, and ambulatory monitoring can be arranged by the continuing-care physician.

PHARMACOLOGY OF ANTIDYSRHYTHMIC AND VASOACTIVE MEDICATIONS

Elizabeth A. Clements

Bryan R. Kuhn

This chapter discusses the actions, indications, pharmacokinetics, dosing, and adverse effect profiles of antidysrhythmic and vasoactive drugs that are pertinent to emergency medicine practice. Specific antidysrhythmics and vasoactive medications also are discussed. Vasodilating agents, such as phentolamine, hydralazine, and clonidine, and other drugs used in hypertension management are discussed in Chap. 57.

ANTIDYSRHYTHMIC AGENTS

Optimal therapy of dysrhythmias requires knowledge of the mechanism of action, pharmacokinetics, indications, appropriate dosing and administration, and types of adverse effects that may occur with each medication. Antidysrhythmic drugs are divided into four classes based on their electrophysiologic properties (Table 29-1). Class I drugs are further subdivided into three subgroups.

TABLE 29-1 Electrophysiologic Actions of Antidysrhythmic Agents

Class	Subclass	Generic Name	Trade Name	Electrophysiologic Actions
I Fast sodium channel blockers	Ia	Quinidine Disopyramide Procainamide	— Norpace Pronestyl	↓↓ conduction velocity ↑ action potential duration 0/↓ automaticity (↓↓ automaticity in higher doses) ↑↑ effective refractory period 0/↑ PR, QRS, and QT intervals (drug- and dose-related)
	Ib	Lidocaine Phenytoin Mexiletine Tocainide	Xylocaine Dilantin Mexitil Tonocard	↓↓ phase 0 of action potential ↓ automaticity ↓↓ effective refractory period (in ischemic tissue) ↑ fibrillatory threshold ↓ repolarization period 0/↓ PR and QT intervals 0/↑ in AV nodal conduction
	Ic	Encainide Flecainide Propafenone Indecainide Morcizine*	Enkaid Tambacor Rhythmol Decabid Ethmozine	↓↓ phase 0 of action potential ↓ automaticity ↓↓ conduction velocity ↑ action potential duration ↑ effective refractory period ↑ PR and QRS intervals (drug- and dose-related) 0/↑ QT intervals
II β-blockers		Propranolol	Inderal	↓ conduction velocity ↑ automaticity ↑ effective refractory period ↓↓ AV nodal conduction 0/↑ PR interval 0/↓ QT interval
III		Bretylium	Bretylol	↑↑ effective refractory period 0/↑ in automaticity 0/↑ in AV conduction
		Amiodarone	Cordarone	↑ fibrillatory threshold ↑ action potential duration
		Sotalol	Betapace	0/↑ PR, QRS, and QT intervals (amiodarone)
IV Calcium channel blockers		Verapamil	Isoptin Calan	0/↓ automaticity ↓/↓↓ AV nodal conduction
		Diltiazem (also see text)	Cardizem	↑ AV node effective refractory period ↑ PR interval
Unclassified		Digoxin Adenosine Magnesium sulfate	Lanoxin Adenocard —	0/↓ automaticity; ↑ automaticity in high levels ↓ AV nodal ↑ AV nodal refractory period ↓ refractory period in ventricle ↑ PR interval ↓ QT interval

*Very minimal negative inotropic effects.

Class I Antidysrhythmics

LIDOCAINE

Actions Lidocaine (Xylocaine), a class Ib antidysrhythmic drug, controls ventricular dysrhythmias by binding to fast sodium channels in their inactive state, thereby inhibiting recovery after repolarization in a time- and voltage-dependent manner. Lidocaine suppresses automaticity in the His-Purkinje system and spontaneous depolarization of the ventricles during diastole. Lidocaine appears to act preferentially on ischemic myocardial tissue, causing little or no effect on atrioventricular (AV) nodal or His-Purkinje conduction velocity in normal heart tissue. Lidocaine has local anesthetic effects that stabilize membranes, elevate ventricular fibrillation threshold, and suppress ventricular ectopy in tissues during myocardial ischemia. Unlike quinidine

and procainamide, lidocaine has little effect on peripheral vascular tone, myocardial contractility, or cardiac output in normal doses. It does, however, possess central nervous system (CNS) depression activity and can produce sedative, analgesic, and anticonvulsant effects.¹

Pharmacokinetics The onset of action after IV administration is 45 to 90 s, with a duration of action of 10 to 20 min. Subsequent bolus doses are generally required to maintain therapeutic plasma levels early in treatment; maintenance infusions started without an initial bolus will not attain therapeutic levels for up to 30 min to several hours. Lidocaine has apparent volumes of distribution (V_d) of 1.3 L/kg in normal patients and 0.9 L/kg in patients with liver disease, congestive heart failure (CHF), or hypotension. Lidocaine is only available for parenteral administration, because of poor gastrointestinal (GI) absorption and extensive first-pass metabolism.

Lidocaine has an initial distribution half-life of 7 to 30 min. The elimination half-life in healthy patients ranges from 80 to 108 min but may be up to 7 h in patients with CHF or liver disease, and is greatly prolonged in cardiac arrest. In healthy patients, the elimination half-lives of lidocaine's two active metabolites (MEGX and GX) are 2 and 10 h, respectively. Therapeutic serum levels range from 1.5 to 6 $\mu\text{g/mL}$; CNS effects can be seen with serum levels above 5 $\mu\text{g/mL}$.

Indications Lidocaine is used in the treatment of ventricular dysrhythmias and ectopy. In the most recent advanced cardiac life support (ACLS) guidelines, the use of lidocaine as the first-line agent in the treatment of pulseless ventricular tachycardia (VT) and ventricular fibrillation (VF) has been challenged.² Lidocaine may be used to maintain normal sinus rhythm after successful conversion of pulseless VT/VF by defibrillation and is a second-line agent (after procainamide and amiodarone) for hemodynamically stable VT.^{3,4}

Dosing and Administration The loading dose is 1 to 1.5 mg/kg, with an additional bolus of 1 to 1.5 mg/kg to a maximum of 3 mg/kg, or 1 to 4 mg/min by continuous infusion. **The dose should be reduced by 50 percent in patients with CHF or liver disease and in those older than 70 years.** Toxicity is likely with infusions longer than 24 h, and in patients with hepatic or renal insufficiency.

The loading dose must be followed immediately by a maintenance infusion, usually starting at 2 mg/min, provided there is spontaneous circulation. With prolonged administration, serum levels should be obtained, and infusions should be adjusted accordingly. Lidocaine toxicity can result from prolonged infusions (>24 h) and in patients with renal dysfunction due to accumulation of active metabolites. Those patients who are successfully converted to normal sinus rhythm (NSR) with lidocaine and require long-term therapy should be converted to an oral antidysrhythmic within the first 24 h.

Adverse Effect Profile Adverse effects from lidocaine usually occur when excessive doses are administered or when a drug interaction potentiates toxicity. Symptoms of lidocaine toxicity that correlate with levels above 5 $\mu\text{g/mL}$ include slurred speech, drowsiness, confusion, nausea, vertigo, ataxia, tinnitus, paresthesias, and muscle twitching. An abrupt change in mental status is indicative of lidocaine toxicity and may indicate that an excessive dose was administered. Serious symptoms occurring at plasma levels above 9 $\mu\text{g/mL}$ may include psychosis, seizures, and respiratory depression. Lidocaine is contraindicated in patients with known sensitivities to amide-type anesthetics and those with high degrees of sinoatrial (SA) or AV block.

PROCAINAMIDE

Actions Procainamide (Pronestyl), a class Ia antidysrhythmic agent, shares the same mechanism of action as the other class Ia agents, disopyramide (Norpace) and quinidine (various). Class Ia antiarrhythmic agents suppress automaticity by binding with fast sodium channels in their inactive state and thereby inhibit recovery after repolarization in a time- and voltage-dependent manner. Procainamide prolongs the action potential duration and reduces the speed of impulse conduction, which directly depresses myocardial conduction, suppresses fibrillatory activity in the atria and ventricles, and prevents ectopic or reentrant dysrhythmias. In therapeutic plasma concentrations, procainamide causes prolongation of the PR and QT intervals, and the QRS complex.

Procainamide also has anticholinergic properties. Large doses can exaggerate the anticholinergic activity and may even increase automaticity (i.e., a pro-dysrhythmic effect). Class Ia antidysrhythmic agents may decrease the force of myocardial contraction by inhibition of calcium transport across the cell membrane. The negative inotropic effect is more pronounced in ischemic myocardial tissue. At high plasma concentrations, procainamide may result in hypotension

caused by vasodilation of the peripheral vasculature. This hypotension can produce a sinus tachycardia as a result of a reflexive sympathetic response to hypotension.

Pharmacokinetics The onset of action of procainamide is 5 to 10 min after IV administration and 10 to 30 min after IM injection. Procainamide has an initial half-life of 4 to 5 min and a terminal half-life of 2.5 to 4.7 h in patients with normal renal function. The apparent Vd is 2 L/kg. However, in patients with CHF and renal dysfunction, the elimination half-life may increase and the Vd decreases, thus requiring a smaller dose. Procainamide is metabolized via acetylation in the liver to an active metabolite, JV-acetyl procainamide (NAPA). This metabolite has antidysrhythmic activity and may represent more than 50 percent of the total drug in plasma. JV-acetyl procainamide has an average half-life of 7 h in patients with normal renal function. Acetylation is related to genetic phenotype, with rapid acetylators converting greater amounts of procainamide to NAPA than slow acetylators. Plasma procainamide levels of 4 to 8 $\mu\text{g/mL}$ are usually required to suppress ventricular dysrhythmias. Refractory dysrhythmias may require levels up to 20 $\mu\text{g/mL}$ (usually 10 to 15 $\mu\text{g/mL}$). However, adverse events are associated with plasma levels above 12 $\mu\text{g/mL}$.

Indications Procainamide is used to treat and prevent recurrence of ventricular dysrhythmias, specifically stable VT and wide complex tachycardia of unknown type in patients with preserved left ventricular (LV) function and unresponsive pulseless VT/VF. Procainamide also may be used for converting supraventricular tachycardias (SVT), including atrial flutter and fibrillation, even if associated with Wolff-Parkinson-White (WPW) syndrome and paroxysmal supraventricular tachycardia (PSVT). It is infrequently used in VF or pulseless VT, because the dosing requires prolonged administration times. Contraindications include complete AV heart block, second- or third-degree heart block (without an electrical pacemaker present), bundle-branch block or severe cardiac glycoside intoxication, prolonged QT interval, and torsades de pointes. Procainamide should be used with caution in patients with systemic lupus erythematosus (SLE), CHF, bone marrow suppression or cytopenia of any type, and hepatic or renal disease and those with allergies to procaine or ester-type local anesthetics.

Dosing and Administration Previous recommendations for IV loading of procainamide called for a bolus injection. However, a continuous infusion rate has been shown to be safer (fewer adverse effects). Typically, a loading dose starts at 20 mg/min (in urgent situations, 30 mg/min) and is instituted until any of the following occur: a maximum dose of 17 mg/kg is reached, termination of the dysrhythmia, prolongation of the QRS interval by greater than 50 percent of baseline, or hypotension. If procainamide loading suppresses the dysrhythmia, a continuous infusion of 1 to 4 mg/min is used to maintain the suppression. Alternatively, oral therapy may be started after IV loading with an immediate-release preparation (50 mg/kg daily given in divided doses every 3 h) or a sustained-release preparation (500 to 1000 mg PO every 6 to 8 h). Normal procainamide and NAPA levels are 4 to 12 $\mu\text{g/mL}$ and 10 to 30 $\mu\text{g/mL}$, respectively. Lower doses may be required for patients with hypotension, CHF, and renal or hepatic dysfunction. Daily procainamide or NAPA levels should be followed in patients with risk factors for impaired clearance.

Adverse Effect Profile The most serious adverse effects of procainamide are from myocardial depression. Electrocardiographic changes may include QRS and QT interval prolongations, VT, VF, frequent premature ventricular contractions (PVCs), complete AV block, and torsades de pointes. Procainamide should be discontinued if any of these ECG changes appear. High doses or rapid infusion rates are associated with significant hypotension. The pro-dysrhythmic effects may be more pronounced in patients with extensive myocardial injury. Procainamide and NAPA levels should be monitored in the following

patients: those receiving procainamide longer than 24 h, those on a maintenance infusion of 3 mg/min or higher, and those with acute CHF or renal failure.

Antinuclear antibodies are found in at least 50 percent of individuals receiving long-term therapy with procainamide (usually within 2 to 18 months) that can increase the risk of developing SLE. Hypersensitivity reactions may occur as a result of sensitization by the parent compound (an ester-type structure). Serious hematologic effect also can occur, including agranulocytosis, leukopenia, bone marrow suppression, hypoplastic anemia, and thrombocytopenia. **Procainamide is contraindicated in patients with myasthenia gravis**, because it may increase weakness.

OTHER CLASS I AGENTS Propafenone and flecainide are class Ic antiarrhythmics that are available. Encainide is also a class Ic antiarrhythmic but was voluntarily withdrawn by the manufacturer in 1991. Flecainide use has been limited by significant adverse effects, although it can be used in the treatment of atrial fibrillation/flutter of recent-onset (<48 h) to convert rhythm to sinus in patients with preserved LV function. The dose of flecainide is 2 mg/kg at 10 mg/min IV (the IV preparation is not available in the United States). Propafenone, interestingly, has recently been used in the treatment of recent-onset atrial fibrillation in the ED in Europe (namely Italy and Spain), in each of the two studies, patients with recent onset atrial fibrillation (<72 h) were randomized to propafenone, 450 to 750 mg PO as a single dose (Azpitarte) or 2 mg/kg IV for 10 min (Ganau), or placebo. Although both studies found significantly more patients receiving propafenone who converted to sinus rhythm early, the oral load study found no difference at 24 h when compared with placebo. Hypotension was the most common adverse effect in the propafenone-treated patients. This is known to occur especially in patients with LV dysfunction. In the acute setting, there is more evidence supporting the use of agents, such as ibutilide, amiodarone, or procainamide, all of which are available in intravenous form in the United States.^{5,6}

Class II Antidysrhythmics: Beta Blockers

GENERAL INFORMATION

Actions and Pharmacokinetics There are many p-blockers from which a clinician can choose to treat various disease states. Although these drugs share the principal characteristic of blocking catecholamine effects on p-receptors, they differ with respect to cardioselectivity, intrinsic sympathomimetic activity (ISA), α -adrenergic blocking activity, membrane-stabilizing effect, and pharmacokinetic properties.

Cardioselective P-blocking (specific for β_1 -receptors) drugs include acebutolol, atenolol, esmolol, and metoprolol. They may be better choices for use in patients with a history of asthma, chronic obstructive pulmonary disease, or diabetes, because the blockade of β_2 receptors may result in adverse effects. At high doses, these drugs lose their cardioselectivity. Unfortunately, the dose at which this occurs has not been clearly established.

P-Blockers with ISA, such as acebutolol, carteolol, penbutolol, and pindolol, occupy the p receptor and produce a low level of stimulation. Despite this stimulation, the receptor is functionally blocked to high sympathetic tone. Theoretically, these drugs would be safer because of their intrinsic ability to stimulate the heart. This ability may prevent acute drug-induced heart failure, but this has not been proven in clinical trials.

P-Blockers with α -blocking activity are covered later in this chapter (see Labetalol).

Membrane-stabilizing effect is a characteristic of propranolol, acebutolol, pindolol, and alprenolol, which results in a reduction of membrane permeability to the fast inward current of sodium ions. This is otherwise known as a quinidine-like effect. Although the clinical relevance of this effect is unknown, the membrane-stabilizing effect is

usually seen at supra-therapeutic doses and may precipitate a prolongation of the QRS complex.

Indications With the exception of esmolol and sotalol, all P-blockers are indicated for the treatment of hypertension. Cardio-selective beta blockers are used in patients with asthma or insulin-dependent diabetes, but drugs with ISA may be better tolerated by some patients (e.g., CHF patients, although there are no clinical data to support this). Some p-blockers have been shown to decrease morbidity and mortality in patients with acute myocardial infarction (e.g., metoprolol and atenolol) and CHF (metoprolol and carvedilol). Beta-blockers should be administered within 12 h of an acute myocardial infarction⁷ if no contraindications exist. P-Blockers in the acutely decompensated CHF patient may further aggravate the heart failure. P-Blockers, if desirable, are typically instituted in the stable CHF patient at doses lower than those used to treat hypertension.

Adverse Effect Profile Adverse effects are remarkably similar across this class of agents and include nausea, vomiting, lightheadedness, mental depression, bradycardia, hypotension, bronchospasm, hyperglycemia, and pulmonary edema. Cardioselective drugs cause less bronchospasm and hyperglycemia than do nonselective drugs, but they can mask the symptoms of hypoglycemia (e.g., blocking tachycardia and blood pressure changes, but not sweating). These drugs are generally contraindicated in patients with heart block other than first-degree or cardiogenic shock.

ESMOLOL

Actions Esmolol (Brevibloc) is a short-acting drug selectively blocking β_1 -receptors in the myocardium, with minimal effect on β_2 -receptors of bronchial and vascular smooth muscle. As with other P-blocking drugs, esmolol exhibits negative inotropic and chronotropic effects. Esmolol prevents excessive adrenergic stimulation of the myocardium by blocking the β_1 -receptors, thus producing an increase in sinus cycle length, prolongation of SA nodal recovery time, and a decrease in conduction through the AV node. At higher doses (e.g., >300 n-g/kg per min), the β_1 selectivity usually diminishes, and the drug will competitively inhibit β_1 and β_2 -receptors. Esmolol is effective in treating SVT and elevated blood pressure. Anti-hypertensive effects may be due to its ability to decrease cardiac output, sympathetic outflow, and renin release from the kidneys.

Pharmacokinetics Esmolol is available only in a parenteral formulation with an onset of action of 1 to 4 min. Compared with other P-blockers, esmolol has the shortest duration of action. The elimination half-life is approximately 9 min, and complete reversal of drug effects are seen within 30 min after discontinuation of IV administration. This short duration of action makes esmolol an attractive drug for the management of acute unstable SVT. Although 90 percent of esmolol is eliminated in urine as metabolites, the metabolites possess minimal, if any, p-blocking activity. Therefore, dosing adjustments are not required in renal or hepatic insufficiency.

Indications Esmolol is an ultra-short-acting, cardioselective (β_1 -blocker) that is effective in the treatment of supraventricular dysrhythmias, including atrial fibrillation/flutter and sinus tachycardia in acute myocardial ischemia.

Dosing and Administration The loading dose is a 500 μ g/kg bolus over 1 min, followed by an infusion at 50 (μ g/kg per min for 4 min. If there is no response, another 500 μ g/kg bolus should be given and the infusion increased to 100 μ g/kg per min. Thereafter, the bolus should be repeated and the infusion increased to 200 (μ g/kg per min. Hypotension is the most common adverse effect and depends on dose.

Infusion rates greater than 200 $\mu\text{g/kg}$ per min have not been studied for safety.

Adverse Effect Profile The most common adverse effect is hypotension. Other cardiovascular adverse effects include bradycardia, syncope, and heart block. Abrupt discontinuation may cause rebound hypertension or angina. Other adverse effects may include bronchospasm or pulmonary edema producing wheezing, dyspnea, rhonchi, and rales.

LABETALOL

Actions Labetalol (Normodyne, Trandate) is a non-cardioselective P-adrenergic blocking agent and a selective α_1 -adrenergic blocking agent. The (3-blocking effects of labetalol are greater than the α_1 -blocking effects, in ratios of 3:1 in the oral formulation and 7:1 in the parenteral formulation. The mechanisms by which labetalol elicits its antihypertensive effects may include any or all of the following: (1) synergistic effects resulting in hypotension when α_1 and β_1 -receptors are blocked, (2) β_2 -receptor stimulation, and (3) direct vasodilatory action. Labetalol decreases heart rate, contractility, cardiac output, cardiac work, and total peripheral resistance.

Pharmacokinetics The onsets of action of labetalol are 2 to 5 min after IV administration and 20 min to 2 h after oral administration. The durations of action are 2 to 4 h after IV administration and 8 to 24 h after oral administration. Labetalol is eliminated primarily by the liver and undergoes extensive first-pass metabolism, with approximately 25 percent of an oral dose reaching the circulation. First-pass metabolism may be reduced in the elderly and those with hepatic dysfunction. Labetalol has an apparent Vd of 3.2 to 15.7 L/kg. The elimination half-life is approximately 2.5 to 8 h.

Indications Labetalol is used principally for its antihypertensive effects. Intravenous labetalol rapidly and effectively reduces elevated blood pressures, causing only minimal alterations in heart rate and cardiac output. It is a good choice for treating hypertension in patients with myocardial ischemia. It has little effect on cerebral perfusion pressure or intracranial pressure and can be used in patients with acute neurologic emergencies. Oral labetalol may be substituted once control of blood pressure has been established. It has also been used safely during pregnancy.

Dosing and Administration Labetalol can be administered intravenously by multiple boluses or as a continuous infusion. The initial dose for an IV bolus is 20 mg followed by repeat doses of 40 to 80 mg every 10 min until the desired effect is reached or a maximum cumulative dose of 300 mg is attained. It is best to double the previous dose when using multiple boluses to provide a gradual increase in dose. A smaller alternative dose would be 10 to 15 mg every 15 min. Alternatively, labetalol can be administered as a continuous IV infusion at a rate of 0.5 to 2 mg/min until the desired effect is reached. There are reports of labetalol being used as a continuous infusion for longer than 24 h in severe and refractory cases. **Patients receiving labetalol as a continuous infusion should be placed in a supine position** and remain so approximately 3 h after receiving any IV doses, because symptomatic orthostatic hypotension may occur. Acute dosing of IV labetalol can lead to a "cumulative effect," because each dose will persist for 2 to 4 h. These patients must be diligently observed to avoid hypotensive episodes. After stabilization, a patient can be converted to oral labetalol (up to 2400 mg per d in two to four divided doses).

Adverse Effect Profile Labetalol has the same adverse effect profile as other β_1 - and α_1 -blocking agents. The most frequent adverse effect is symptomatic orthostatic hypotension, which can occur in up to 5 and

60 percent of patients after oral and IV administration, respectively. Symptomatic heart failure also may occur. Adverse CNS effects may include lightheadedness, drowsiness, dizziness, fatigue, lethargy, and vivid nightmares. However, these effects may be obviated by the slow, upward titration of the dosage over 4 to 12 weeks. Labetalol also may cause reversible increases in the hepatic enzymes or, rarely, jaundice and hepatitis.

PROPRANOLOL

Actions In therapeutic doses, the major effect of propranolol (Inderal) is its (3-adrenergic blocking activity. The drug competitively blocks the effects of P-adrenergic stimuli on receptors within the myocardium and bronchial and vascular smooth muscles. Propranolol is a non-cardioselective P-blocker without ISA. Inhibition of myocardial P-receptors decreases chronotropic, inotropic, and vasodilator responses to p-adrenergic stimuli. Propranolol slows the sinus rate, depresses AV conduction, decreases cardiac output, prevents exercise-induced increases in blood pressure, and reduces supine and standing blood pressures. Propranolol also decreases myocardial oxygen consumption.

Pharmacokinetics The onset of action of propranolol is 1 to 2 h after an oral dose and within 1 min after IV administration. The half-life shows great variability. Short-term treatment has an elimination half-life of 2 to 3 h, whereas long-term treatment has an elimination half-life of 3.4 to 6 h. Propranolol is widely distributed throughout body tissue, undergoes extensive first-pass metabolism after oral administration, and is significantly bound to sites within the liver. For these reasons, propranolol has a low bioavailability when taken PO as opposed to IV administration, making the IV dose approximately one tenth of the oral dose. The Vd of propranolol is 6 L/kg, but varies widely in proportion to the fraction of unbound drug in whole blood. At least eight metabolites have been identified and are principally excreted in the urine. No dose adjustments are required for patients with renal insufficiency.

Indications Propranolol is indicated for a wide variety of supraventricular dysrhythmias. These include multifocal atrial tachycardia (MFAT), in particular those dysrhythmias induced by digoxin or catecholamines; rate control of atrial flutter or fibrillation with preserved LV function excluding those associated with WPW; persistent atrial extrasystoles that do not respond to conventional therapy; and tachydysrhythmia associated with thyrotoxicosis. Propranolol is less effective for ventricular than for supraventricular dysrhythmias, but it can be used for ventricular tachycardias or ectopy due to digoxin or catecholamine toxicity and polymorphic ventricular tachycardia.

Other indications for propranolol include the management of angina, because it decreases myocardial oxygen demand; management of all chronic types of hypertension alone or in combination with other antihypertensive agents (propranolol is not indicated for hypertensive emergencies); the treatment of hypertrophic cardiomyopathy; prophylaxis for common migraine headaches; management of familial or hereditary essential tremor; and as an adjunctive drug after administration of an α -adrenergic blocker in controlling tachycardia due to pheochromocytoma. Propranolol has been used to reduce the autonomic symptoms associated with anxiety disorders (mild tremor, tachycardia, and sweating).

Dosing and Administration The loading dose is 0.5 to 1 mg IV at a rate not to exceed 1 mg per min. The dose may be repeated after 2 min. Esmolol is as effective as propranolol in decreasing heart rate and is titrated more easily.

Because significant myocardial depression can occur with doses larger than 3 mg, caution should be used if additional doses are required.

Adverse Effect Profile The adverse effect profile for propranolol is similar to that for the non-cardioselective β -blockers. The drug is generally not given to patients with asthma or allergic rhinitis and is contraindicated in those with sinus bradycardia or advanced SA or AV block and intermittent claudication. Propranolol also should not be used in CHF or cardiogenic shock, unless these conditions are due to tachydysrhythmia.

SOTALOL

Actions Sotalol (Betapace) is a unique non-cardioselective β -blocker without ISA or membrane-stabilizing activity. The mechanism of action is similar to that of other non-cardioselective β -blockers by inhibiting the response of adrenergic stimuli in the myocardium and bronchial and vascular smooth muscles. Sotalol also exhibits electrophysiologic characteristics of class III antiarrhythmics (i.e., prolongs repolarization and refractoriness without affecting conduction). Sotalol is available only in an oral formulation in the United States, which contains a racemic mixture of the two optical isomers, although only the *-*-isomer exhibits (3-blocking activity).

Pharmacokinetics The onset of action after oral administration is 2 to 3 h, with duration of action of approximately 24 h after one dose. The elimination half-life is 7 to 18 h in the normal patient and depends on renal function. Patients with a creatinine clearance (CrCl) of 10 to 30 mL/min have an elimination half-life of 22 to 24 h and up to 97 h in patients with a CrCl of less than 10 mL/min. No metabolites are formed, and the drug is principally eliminated unchanged in the urine.

Indications Sotalol has been shown to be an effective agent for the suppression of life-threatening ventricular dysrhythmias refractory to other antidysrhythmic drugs. Clinical trials have shown sotalol to be effective in patients who have been refractory to other conventional antidysrhythmic drugs. Although not approved for this indication by the U.S. Food and Drug Administration, double-blind trials have shown that sotalol can suppress SVT and atrial fibrillation.²

Dosing and Administration The usual initial oral dose is 80 mg twice daily, which can be titrated every 3 days between dosing increments to allow for attainment of steady-state plasma concentrations and to monitor for changes in the QT interval. The usual maintenance dose is 160 to 320 mg per d. The dosing intervals should be increased to every 24 h when CrCl is 30 to 59 mL/min and to 36 to 48 h when CrCl is 10 to 29 mL/min. The dosing interval should be individualized when CrCl is less than 10 mL/min. The maximum dose is 480 to 640 mg per d and should be used only when the potential benefits outweigh the increased risk of adverse effects (e.g., pro-dysrhythmic activity).

Adverse Effect Profile Sotalol is generally well tolerated, and the adverse effects are dose related; the most common are related to that of non-cardioselective (3-blockade (e.g., bradycardia, hypotension, and hypo- or hyperglycemia). Sotalol also can have pro-dysrhythmic effects, particularly in patients with torsade de pointes, prolonged QTc intervals, hypokalemia, or those taking high doses of the drug.

Class III Antidysrhythmic Drugs

AMIODARONE

Actions Although the exact mechanism of action has not been conclusively determined, amiodarone (Cordarone) is classified as a class III antidysrhythmic. The primary effect of the drug on cardiac tissue is to delay repolarization by prolonging the action potential duration and effective refractory period, especially when administered for a long period. Amiodarone slows the heart by impairing SA nodal function, de-

pressing AV nodal conduction, modifying the automaticity of spontaneously firing fibers in the Purkinje system, and prolonging the refractory period in an accessory pathway (e.g., WPW syndrome). The drug also produces an inhibition of sodium channels and (3-adrenergic activity, further contributing to the antidysrhythmic effects.

Pharmacokinetics Most of the pharmacokinetic information in the literature is for the oral formulation. Due to a rapid redistribution phase, the concentration of amiodarone declines to 10 percent of peak values within 30 to 45 min after the end of IV infusion. Amiodarone is approximately 96 percent bound to plasma proteins. The apparent Vd of the major metabolite averages to 65.8 L/kg (range, 18.3 to 147.7 L/kg) after IV administration. Amiodarone is metabolized in the liver and eliminated by biliary excretion. The terminal half-life is 25 days after IV therapy. However, after chronic oral therapy, the terminal half-life increases to 40 to 55 days, with maximal antidysrhythmic effects usually seen within 1 to 5 months.

Indications Oral amiodarone appears to be effective in the management of a wide variety of ventricular and supraventricular dysrhythmias. However, due to its potentially life-threatening adverse effect profile, chronic amiodarone therapy is used only to suppress and prevent the recurrence of life-threatening ventricular dysrhythmias that do not respond to documented adequate dosages of other currently available antidysrhythmic drugs or when these drugs cannot be tolerated. Amiodarone has been used effectively in the suppression and prevention of recurrent ventricular fibrillation and tachycardia, atrial fibrillation and flutter, and junctional and wide-complex tachycardias. It has recently been added to the ACLS pathway to treat patients with pulseless VT/VF and atrial dysrhythmias with a significant decrease in ejection fraction (i.e., <40 percent).

Dosing and Administration For VF/pulseless VT, the loading dose is a 300-mg IV bolus that may be repeated with a 150-mg bolus. For other dysrhythmias, the dose is 150 mg IV in 100 mL D5W over 10 min. The loading dose is followed by an infusion at 1 mg/min for 6 h, and then 0.5 mg/min thereafter. Oral maintenance doses typically are 200 to 600 mg per d.

Amiodarone is available in oral and IV formulations. Either formulation is as effective as loading and maintenance doses in stable patients.

Alternatively, oral daily loading doses of 800 to 1600 mg per d are generally required for 1 to 3 weeks until an initial therapeutic response occurs. When adequate control of the dysrhythmia is achieved or adverse effects become apparent, the dosage should be reduced to 200 to 600 mg as a single oral dose. Short-term IV therapy is associated with bradycardia and hypotension. Long-term oral therapy is associated with thyroid disorders, pulmonary fibrosis, skin discoloration, hepatic dysfunction, and other conditions. Before long-term treatment, patients should undergo baseline ophthalmologic and pulmonary function tests.

Adverse Effect Profile After IV administration, adverse effects are typically limited to hypotension and bradycardia, although asystole, cardiac arrest, and shock have been reported. However, after chronic oral therapy, amiodarone exhibits several serious and potentially fatal toxicities, including pulmonary fibrosis, pro-dysrhythmic activity, and hepatotoxicity. In patients receiving more than 400 mg per d, some adverse effects are present in up to 75 percent of those patients and will be responsible for discontinuance in up to 20 percent of patients. The most common adverse reactions requiring discontinuance of the drug are pulmonary infiltrates or fibrosis, paroxysmal ventricular tachycardia, CHF, and elevations in the serum hepatic enzyme concentrations. The likelihood of most adverse effects appears to increase after the first 6 months of therapy and remains relatively constant beyond 1 year of therapy. Corneal microdeposits are reported in all patients after chronic administration. Additional adverse effects include rash,

skin discoloration, constipation and other GI symptoms, and falsely elevating or decreasing thyroid function tests. Amiodarone contains iodine, 37.3 percent by weight and, as such, is contraindicated in patients with an iodine or shellfish allergy.

Amiodarone is also responsible for several clinically significant drug interactions. Initiation of amiodarone therapy after warfarin therapy is stabilized can result in a 50 percent decrease in warfarin metabolism and subsequent increase risk of bleeding. Amiodarone increases serum concentrations of many drugs, including digoxin, procainamide, quinidine, theophylline, and others. Concurrent use of amiodarone with calcium channel or (3-blockers may potentiate sinus bradycardia, sinus arrest, and AV block.

DOFETILIDE

Actions Dofetilide (Tikosyn) is a class III antidysrhythmic agent that prolongs repolarization without affecting the conduction velocity. Dofetilide is a pure class III antidysrhythmic, because it selectively blocks the cardiac delayed rectifier potassium current. Other class III antiarrhythmics, such as amiodarone or sotalol, possess class I or II antiarrhythmic properties in addition to class III properties. The cardiac delayed rectifier potassium current is responsible for termination of the action potential plateau. Dofetilide prolongs the action potential duration, atrial and ventricular effective refractory periods, and the effective refractory period of the accessory pathway. This results in prolongation of the QT and QTc intervals without change in the QRS interval. This result allows dofetilide to suppress dysrhythmias dependent on a reentry mechanism. Dofetilide produces a dose-dependent negative chronotropic effect but lacks negative inotropic effects. Given IV, it is effective for the conversion of atrial fibrillation to NSR.⁸ However, only the oral formulation is available in the United States.

Pharmacokinetics The onset of action of dofetilide is 2 h, and the duration of action is 4 h after oral administration. The time to peak response occurs in 1 to 3 h after oral administration. Dofetilide is well absorbed from the GI tract, with a bioavailability of 96 to 100 percent and is not affected by food or antacids. The apparent Vd is 3 to 4 L/kg. Approximately 50 percent of a dose is metabolized by the liver (cytochrome 3A₄) to inactive metabolites, with about 80 percent of the drug and metabolites eliminated in the urine. The elimination half-life is 7.5 to 10 h after oral administration and is increased in patients with renal insufficiency.

Indications Dofetilide is indicated for the conversion to, and maintenance of, NSR in patients with atrial fibrillation or flutter. However, because dofetilide has a significant pro-dysrhythmic effect, it should be reserved for patients in whom atrial fibrillation or flutter is highly symptomatic.

Dosing and Administration The loading dose is based on QTc interval and CrCl. If the baseline QTc interval is longer than 440 ms, dofetilide is contraindicated. The doses are 500 µg PO twice a day when the CrCl is greater than 60 mL/min, 250 µg PO twice a day when the CrCl is 40 to 60 mL/min, and 125 µg PO twice a day when the CrCl is 20 to 39 mL/min. Dofetilide is contraindicated if the CrCl is less than 20 mL/min, the baseline QTc interval is longer than 440 ms, or the QTc interval exceeds 500 ms while on therapy. The ECG is repeated 2 to 3 h after the dose. If the QTc interval is less than 15 percent from baseline, the current dose is continued; if it is greater than 15 percent from baseline, the dose is decreased.

Patients should be admitted for a minimum of 3 days to a facility that can provide CrCl calculations, continuous ECG monitoring, and cardiac resuscitation. Prescribing is restricted to physicians with evidence of having received educational information of dofetilide dosing and administration.

Adverse Effect Profile The most serious adverse effect of dofetilide is QTc interval prolongation, which can result in torsade de pointes. The risk of developing torsade de pointes is associated with larger dofetilide doses, occurring during the first few days of therapy, and in patients with electrolyte imbalances. Ventricular tachycardia is another adverse effect associated with dofetilide. The most common adverse effects reported in clinical trials are headache, dizziness, and chest pain. Dofetilide is contraindicated in patients with a CrCl of less than 20 mL/min or a QTc interval longer than 440 ms before initiating therapy or 500 ms at any time after initiating therapy.

IBUTILIDE

Actions Ibutilide (Corvert) is a class III antidysrhythmic agent that prolongs the action potential duration and effective refractory period in atrial and ventricular cardiac tissues. This action is caused by activation of a slow inward sodium current, as opposed to inhibition of outward potassium currents. However, data suggest that blockade of the delayed rectifier potassium current, which slows repolarization, may contribute, in a minor way, to its clinical effects.

Pharmacokinetics The onset of action of ibutilide is 20 to 30 min, with a duration of action of 24 h after one IV dose. The apparent Vd is 9 to 13 L/kg. Ibutilide is metabolized in the liver via oxidation to several metabolites, of which at least one has significant activity. Approximately 80 percent of an IV dose is eliminated in urine within 24 h, with the remaining 20 percent being excreted in feces over a period of 1 week. The elimination half-life of the parent compound is 2 to 12 h (average, 6 h) after IV administration.

Indications Ibutilide is indicated for the rapid conversion of recent-onset (<30 days) atrial fibrillation or flutter to NSR. Atrial dysrhythmias that are not of recent onset may be less likely to respond to ibutilide. Ibutilide may be used as an alternative to electrical cardioversion, which is one of the most rapid and frequently used methods of converting atrial fibrillation and atrial flutter of less than 48 h duration.

Dosing and Administration Ibutilide is administered only as an IV infusion. The loading dose is 1 mg IV in 50 mL D5W over 10 min (patient weight >60 kg) or 0.01 mg/kg IV in 50 mL D5W over 10 min (patient weight <60 kg). The dose may be repeated 10 min after completion of the first dose. Electrocardiographic monitoring is continued for at least 4 h or until the QTc interval returns to baseline, or longer if dysrhythmias are observed.

Adverse Effect Profile Cardiovascular adverse effects include hypotension, hypertension, bradycardia, sinus arrest, syncope, prolongation of the QTc interval, and CHE. Ibutilide is capable of inducing or exacerbating dysrhythmias, such as sustained polymorphic ventricular tachycardia including torsade de pointes, supraventricular and ventricular extrasystoles, and monomorphic ventricular tachycardia. Patients should be observed with continuous ECG monitoring for at least 4 h after infusion or until the QTc interval has returned to baseline. Longer monitoring is required if any dysrhythmic activity is noted.

Class IV Antidysrhythmic Drugs: Calcium Channel Antagonists

DILTIAZEM

Actions Diltiazem (Cardizem) is a non-dihydropyridine calcium channel antagonist that interferes with the influx of extracellular calcium through "slow" channels in the cardiac smooth muscle. At doses slightly higher than those used clinically, diltiazem also inhibits the influx of sodium through "fast" channels. The net result is a slowing of AV nodal conduction (although less than with equivalent doses of ve-

rapamil) and a prolongation of AV nodal refractoriness. Diltiazem produces minimal systemic vasodilation and preferentially dilates the coronary vasculature, allowing for a decrease in oxygen consumption, improved oxygen delivery, and an overall improvement in oxygen balance in those with chronic stable angina. Although diltiazem has no effect on sinus node recovery or the SA conduction time in patients without SA nodal dysfunction, patients with sick sinus syndrome experience a decrease in SA node automaticity.

Pharmacokinetics The onset of action of diltiazem is 2 to 3 min after IV administration and 15 to 60 min after oral administration, with peak responses in 2 to 7 min and 1.5 to 4 h after IV and oral administrations, respectively. The duration of action is 1 to 3 h after single IV administration but can be prolonged up to 10 h after multiple IV doses. The bioavailability of oral diltiazem is 35 to 40 percent due to first-pass metabolism. The elimination half-life is 3.1 to 6.6 h. However, the extended- and controlled-release formulations have a longer time-to-peak response and longer elimination half-life: 3 to 6 h and 4.5 to 10 h, respectively. This results in once-daily dosing of the controlled-release formulations and twice-daily dosing of the extended-release formulations. The apparent Vd is 5.3 L/kg. Diltiazem undergoes extensive hepatic metabolism to active and inactive metabolites.

Indications Intravenous diltiazem is effective for rapid conversion of PS VT to NSR and to slow ventricular response in atrial fibrillation or atrial flutter. It should not be used in patients with a wide-complex tachydysrhythmia suggesting an accessory bypass tract (e.g., WPW syndrome). Oral diltiazem is indicated for the treatment of vasospastic and chronic stable angina and is considered one of the drugs of choice for vasospastic angina. The extended-release formulations are indicated for the treatment of hypertension alone or in combination with other antihypertensives.

Dosing and Administration The loading dose is 0.25 mg/kg (maximum, 20 mg) IV push over 2 min. The dose is repeated in 15 min with 0.35 mg/kg (maximum, 25 mg) IV push over 2 min, if the patient is not responsive.

The recommended initial infusion rate is 5 mg per h, (which can be increased to 15 mg per h if required). Once the heart rate is controlled, the patient can be converted from IV to oral diltiazem. The IV infusion should be continued for 1 h after the first oral dose to allow for adequate peak oral response.

The approximate oral dosage (in mg per d) can be calculated as follows: (infusion rate [mg/hr] X 3 + 3) X 10. This daily dose can be given as the short-acting formulation (in four divided doses) for the first 24 h and then converted to a long-acting formulation thereafter.

The maximal antihypertensive effect is usually observed within 14 days. Dose adjustments should be made accordingly. Dosages may need to be decreased in patients with hepatic or renal insufficiency.

Adverse Effect Profile The cardiovascular side effects associated with diltiazem may include angina, bradycardia, asystole, CHF, AV block, bundle branch block, flushing, hypotension, palpitations, and peripheral edema. Noncardiac adverse effects may include headache, dizziness, nausea, constipation, rash, vomiting, diarrhea, dry mouth, pruritus, nervousness, somnolence, insomnia, tinnitus, depression, sexual dysfunction, hyperglycemia, and photosensitivity. Diltiazem also may cause transient increases in liver function test enzymes, which may resolve despite continued therapy with diltiazem. Cimetidine increases serum diltiazem through inhibition of its metabolism.

VERAPAMIL

Actions Verapamil (Verelan, Isoptin, Calan, and Tarka), a non-dihydropyridine calcium channel antagonist, is a class IV antidysrhythmic agent.

Like other calcium channel antagonists, the principal action is to inhibit the transmembrane influx of extracellular calcium ions across the membrane of myocardial cells and vascular smooth muscle. However, unlike dihydropyridine calcium channel antagonists, verapamil has substantial inhibitory effects on the cardiac conduction system. It slows conduction and prolongs refractoriness in the AV node and, rarely, may reduce the resting heart rate and produce sinus arrest or SA block in patients with SA node dysfunction (e.g., sick sinus syndrome). In patients with PSVT, verapamil's effects at the AV node result in an interruption of the reentrant pathway and restoration of NSR. Verapamil also decreases the ventricular response in patients with atrial fibrillation/flutter. It has minimal or no effects on antegrade or retrograde conduction of the accessory pathways.

Pharmacokinetics The onset of action of verapamil is within 5 min, a peak response of 10 to 20 min, and a duration of action of 30 to 60 min after IV administration. The onset, peak response, and duration after oral administration are 1 to 2 h, 4 to 11 h (depending on oral formulation), and 6 to 12 h, respectively. The apparent Vd is 12 L/kg. Verapamil is metabolized extensively in the liver to at least 12 metabolites, at least one of which is active (approximately 20 percent activity of the parent compound). Approximately 70 and 16 percent of oral and IV doses, respectively, are eliminated in the urine and feces as metabolites within 5 days. The elimination half-life after one oral dose or IV infusion is 2 to 8 h. After 1 to 2 days of therapy, the half-life increases to 4.5 to 12 h, presumably due to saturation of hepatic enzymes. Plasma half-life can be prolonged to 14 to 16 h in patients with hepatic insufficiency.

Indications Verapamil is as effective as adenosine and diltiazem in terminating narrow-complex PSVT and for controlling the ventricular response in atrial fibrillation/flutter. Oral verapamil can be used for the management of vasospastic, chronic stable, and unstable angina and may be used for the prophylaxis of PSVT. It is also used for essential hypertension. Verapamil should not be used for the management of atrial fibrillation/flutter in patients with an accessory bypass tract (e.g., WPW or Lown-Ganong-Levine syndrome), because life-threatening adverse effects (e.g., ventricular fibrillation and/or cardiac arrest) may occur due to accelerated accessory bypass tract conduction.

Dosing and Administration For the treatment of PSVT, the initial dose is 5 to 10 mg IV push over 2 min, although some experts recommend an initial dose of 2.5 to 5 mg IV push over 2 min to minimize adverse effects, particularly in elderly patients and those with hepatic dysfunction. Blood pressure should be checked immediately before and after verapamil administration. Pretreatment with calcium chloride or gluconate (500 to 1000 mg) can be given before or after verapamil administration to prevent or manage verapamil-induced hypotension, although calcium use is largely anecdotal. For the prevention of recurrent PSVT, oral administration of 240 to 480 mg per d should be given. Maximum antidysrhythmic effects are generally seen within 48 h after initiating verapamil therapy. For the treatment of vasospastic, unstable, or chronic stable angina, oral doses of 240 to 480 mg per d in three to four divided doses can be given, although efficacy with doses larger than 360 mg per d have not been proven. Conversion to an extended-release formulation should be done as soon as dose titration is completed with a satisfactory clinical response. The dose of the extended-release formulation is the total daily dose of the immediate-release formulation. The initial dose for the treatment of hypertension is 240 mg every morning, with titration upward by 120-mg increments in the evening. Antihypertensive effects are evident within the first week of therapy.

Adverse Effect Profile Most adverse effects are related to its pharmacologic properties. The incidence of adverse effects is increased in

patients with severe heart failure, cardiomyopathy, or conduction disturbances. Hypotension, bradycardia, AV block, bundle branch block, and pulmonary edema are possible cardiac adverse effects. Noncardiac adverse effects include constipation, dizziness, headache, and nausea. Verapamil should be given with caution to patients who are concurrently receiving β -blockers, other antihypertensives, and other antidysrhythmics, because their effects may be additive. Concurrent administration of digoxin and verapamil may result in increased digoxin serum concentrations.

Other Antidysrhythmic Drugs

ADENOSINE

Actions Adenosine (Adenocard) is an endogenous nucleoside produced by the degradation of adenosine triphosphate (ATP). Adenosine and ATP have been shown to exert transient negative inotropic, dromotropic, and chronotropic effects on SA and AV nodal tissues. Adenosine produces a transient AV nodal block, which breaks the re-entrant circuit of atrial tachydysrhythmia involving the AV node. Re-entrant SVTs not involving the AV node are not terminated by adenosine. It has no effect on anterograde conduction over accessory pathways in patients with WPW syndrome. When administered as a rapid IV bolus, adenosine slows cardiac conduction and restores sinus rhythm. However, when administered as a continuous infusion, it is a potent vasodilator. Adenosine is rapidly metabolized by circulating adenosine deaminase to an inert compound, giving the drug a very short half-life (<10 s).

Pharmacokinetics The onset of action of adenosine is 20 to 30 s, with a duration of action lasting approximately 60 to 90 s. The drug is rapidly metabolized by circulating adenosine deaminase to inosine, an inactive metabolite. Adenosine is also rapidly taken up by most types of cells, where deamination to the inactive metabolite occurs. This contributes to the less than 10-s half-life of adenosine. Other pharmacokinetic parameters such as V_d , therapeutic plasma concentrations, and clearance are difficult to assess due to the very short half-life of the drug.

Indications Adenosine is used for the emergency treatment of SVT. Although adenosine is effective in the initial conversion of re-entrant PSVT, recurrence of the dysrhythmia may occur within minutes after conversion. Although repeat doses of adenosine may be used, consideration of a longer-acting antidysrhythmic agent often may be necessary. Adenosine may be a preferable agent for the treatment of PSVT in infants, children, and pregnant women. Adenosine shortens the action potential duration and slows the heart rate; it is contraindicated in second- or third-degree AV heart block or sick sinus syndrome if no pacemaker (implanted or external) is present. Adenosine is not effective in converting atrial fibrillation or flutter to NSR; rather, it can be used to distinguish these rhythms from other tachydysrhythmias.

Dosing and Administration The initial dose for the treatment of PSVT is 6 mg given as a rapid IV bolus over 1 to 2 s directly into the vein or in the most proximal port of the IV tubing. The dose may be repeated with 12 mg IV push two times if dysrhythmia persists every 1 to 2 min. The bolus dose should be followed immediately by a 10- to 20-mL fluid flush, and the arm should be elevated to maximize distribution of the drug before its metabolism and inactivation. It is important to administer adenosine as fast as possible; if infused too slowly, it can cause systemic vasodilation and a reflexive tachycardia.

Adverse Effect Profile The adverse effects of adenosine are typically minor and well tolerated, because they last less than 1 min due to the short half-life. The most common adverse effects include dyspnea,

cough, syncope, vertigo, paresthesias, numbness, nausea, and metallic taste. Cardiovascular adverse effects include facial flushing, headache, palpitations, retrosternal chest pain, sinus bradydysrhythmia (i.e., bradycardia, sinus arrest, AV block), PVCs, and hypotension. These adverse effects rarely require specific management. Occasionally, patients will have feelings of impending doom and should be reassured. Dipyridamole and carbamazepine have been shown to enhance the negative chronotropic and dromotropic effects of adenosine and may increase the degree of adverse effects. In contrast, methylxanthines and caffeine compete for adenosine receptors. Therefore, patients receiving these drugs may require a higher dose of adenosine to achieve a therapeutic effect. Adenosine should be used with caution in asthmatics, because it may induce bronchoconstriction.

DIGOXIN

Actions Digoxin has three basic actions: it increases the force, strength, and velocity of cardiac contractions (positive inotropic effect); it slows the heart rate (negative chronotropic effect); and it slows conduction velocity through the AV node (negative dromotropic effect). Digoxin inhibits Na^+K^+ ATPase enzyme pump system, which is responsible for maintaining a high intracellular potassium concentration and high extracellular sodium concentration in the normal resting myocyte. Inhibition of Na^+K^+ ATPase leads to a net loss of potassium and a net gain of sodium in the intracellular fluid, which activates a $\text{Na}^+\text{-Ca}^{2+}$ channel that pumps sodium out and calcium into the cell. The increase in intracellular calcium improves the efficiency of excitation and contraction coupling of myocytes, resulting in increased myocardial contractility. There is an inverse relation between the extent of the positive inotropic effect and the initial condition of the myocardium. Thus greater improvements in contractility will be greater in a myocardium with decreased contractility.

Digoxin increases the refractory period and decreases the conduction velocity of the SA and AV nodes but shortens the refractory period and increases conduction velocity in atrial tissue, including atrial bypass tracts as present in WPW syndrome. Therefore, digoxin generally should *not* be used in the management of WPW syndrome, because it may enhance conduction via the accessory pathway and, in the presence of atrial fibrillation/flutter, result in extremely rapid ventricular rates and even VF. The primary effect on SA and AV nodal conduction is secondary to indirect vagal stimulation.

Slowing of the heart results in a prolonged diastolic period, allowing improved coronary blood flow and myocardial perfusion. A decrease in oxygen demand also may occur secondary to the decrease in heart rate.

Pharmacokinetics The onsets of action of digoxin are approximately 5 to 30 min after IV administration and 30 to 120 min after oral administration, and peak effects are 1.5 to 4 h and 2 to 6 h for IV and oral administrations, respectively. The apparent V_d is 5.6 L/kg and is proportional to lean body mass, with muscular individuals having larger V_d s than obese individuals based on body weight. As a result of a large V_d , hemo- and peritoneal dialyses are ineffective in removing significant amounts of digoxin.

The bioavailability varies with the tablet, elixir, and capsule formulations, being 70, 80, and 90 percent, respectively. Digoxin is eliminated primarily through the kidneys unchanged, with approximately 20 to 40 percent of the dose metabolized in the liver to two active metabolites and excreted in bile and feces. The half-life of digoxin in patients with normal renal function is 1.5 to 1.8 days and can be extended up to 4 to 6 days in patients with renal insufficiency.

Indications Digoxin is indicated to improve cardiac output in CHF and to control the ventricular response in atrial fibrillation, atrial flutter, and PSVT. Digoxin can be used in CHF in conjunction with β -blockers, diuretics, and angiotensin-converting enzyme inhibitors to

control symptoms of CHF. Unlike these medications, which have a demonstrated benefit on mortality, digoxin has been shown to reduce hospitalizations, not mortality. It is not recommended in patients with New York Heart Association class I failure. Digoxin is generally most effective in low-output failure secondary to hypertensive, atherosclerotic heart disease, primary myocardial disease, nonobstructive cardiomyopathies, and valvular heart disease. It is less effective in high-output heart failure caused by bronchopulmonary insufficiency, infection, hyperthyroidism, anemia, fever, or arteriovenous fistulas.

Dosing and Administration Digoxin can be administered by the oral or IV route. The IV route is preferred when a more rapid onset of action and peak effect is desired. Due to increased bioavailability, the IV dose is 20 to 30 percent less than the oral dose. The IV dose is 10 to 15 $\mu\text{g/kg}$, or 0.75 to 1.5 mg given as a series of three injections: the first is half the total dose, and the second and third are one fourth the total dose each. The three doses should be separated by 4 to 8 h to allow for distribution and minimize toxicity. Administering digoxin by the IM route is not recommended, because it offers no advantages over oral or IV administration and can cause severe pain at the injection site. Therapy with oral digoxin should replace IV administration as soon as is feasible. The oral dose is 0.125 to 0.5 mg per d. The therapeutic serum digoxin level is 0.8 to 2 ng/mL. Oral and IV doses should be decreased in elderly patients and those with renal insufficiency. The dose to provide symptomatic relief in patients with CHF is lower (8 to 12 $\mu\text{g/kg}$) than that for treating SVT but is administered in the same manner. The loading dose should be calculated by using the patient's lean body weight, because this method generally provides therapeutic effects with minimal risk of toxicity. Intravenous digoxin should be administered slowly over 5 min or longer. Serum levels should not be obtained any sooner than 6 to 8 h after loading to allow for distribution of the drug. Reductions in maintenance doses are required in patients with renal insufficiency, dehydration, hypokalemia, hypocalcemia, hypomagnesemia, and hypothyroidism. Several drug interactions can increase serum digoxin levels, including amiodarone, verapamil, nifedipine, diltiazem, flecainide, quinidine, erythromycin, and tetracycline. In contrast, cholestyramine, metoclopramide, kaolin-pectin, penicillamine, and dietary fiber may result in decreased serum digoxin levels.

Adverse Effect Profile Adverse effects of digoxin are generally GI in nature, including abdominal pain, diarrhea, nausea, and vomiting. Other adverse effects may include gynecomastia, skin rash, eosinophilia, and thrombocytopenia. Digoxin also can result in cardiac dysrhythmias, such as sinus bradycardia, AV or SA nodal block, and ventricular dysrhythmias. The clinician must be vigilant in recognizing the signs and symptoms associated with digoxin toxicity, which can be fatal if not properly treated. If digoxin toxicity is suspected, the drug should be discontinued and a serum level obtained.

Symptoms of digoxin toxicity include mental status changes, confusion, headache, drowsiness, anorexia, nausea, vomiting, weakness, visual disturbances, delirium, and seizures. Almost any type of dysrhythmia can manifest as a result of digoxin toxicity. The most common dysrhythmias include an increased number of unifocal or multifocal PVCs, VT, junctional tachycardia, high-degree AV block, SVT with block, and sinus arrest. Atrial fibrillation, bradycardia, bidirectional VT, and VF also may occur.

Although hypokalemia increases the risk of digoxin toxicity, significant digoxin toxicity itself may produce hyperkalemia. When digoxin toxicity is associated with hyperkalemia, a corresponding intracellular deficiency of potassium exists, which may be the causative factor of subsequent dysrhythmias. Lidocaine and phenytoin are antidysrhythmic drugs that have classically been used in digoxin toxicity, but their efficacy has not been proven. Atropine and transcutaneous pacing also have been used. Hemo- and peritoneal dialyses are ineffective in significantly reducing serum digoxin levels due to the large

Vd of digoxin. Charcoal hemoperfusion has been used with limited success for the same reasons. Digoxin antibody fragments (Digibind) is an antidote for digoxin toxicity and is indicated for life-threatening tachydysrhythmia, sinus bradycardia, severe AV blocks, and/or serum potassium greater than 5 mEq/L resulting from overdose or accidental ingestion of digoxin or other cardiac glycosides. Once digoxin antibody fragments has been administered, subsequent serum digoxin levels are of no use.

MAGNESIUM

Actions Magnesium increases skeletal and smooth muscle contractility, vasomotor tone, and neuronal transmission by directly activating the $\text{Na}^+\text{K}^+\text{ATPase}$ pump and indirectly by calcium channel blockade. It increases membrane potential, prolongs AV conduction, and increases the absolute refractory period. Hypomagnesemia can precipitate life-threatening dysrhythmias, symptoms of cardiac insufficiency, and sudden cardiac death after myocardial infarction. Supplementation with magnesium helps to replenish intracellular potassium in hypomagnesemic, hypokalemic patients; blocks calcium to cause vasodilation; and reduces platelet aggregation.

Pharmacokinetics The onset of action of magnesium sulfate is immediate, with a duration of action of approximately 30 min after IV administration. The onset after IM administration increases to 1 h and a duration of 3 to 4 h. Magnesium is minimally eliminated via the urine at a rate that is directly proportional to the plasma concentration and glomerular filtration rate. A high percentage of magnesium is reabsorbed in the proximal tubule.

Indications Magnesium is indicated for torsade de pointes and refractory VT/VF, regardless of pre-arrest serum magnesium levels. It has shown efficacy in treating MFAT, SVT, and ventricular dysrhythmias associated with cardiac arrest and/or digoxin toxicity in patients who are, or are likely to be, hypomagnesemic. Other uses for magnesium include seizures associated with toxemia/eclampsia/nephritis, hypomagnesemia (mild to severe), acute asthma exacerbations, and hyperalimination.

Dosing and Administration The loading dose is 1 to 4 g in 50 to 100 mL D5W over 20 to 60 min in patients with spontaneous circulation or 1 to 2 g in 10 mL D5W over 1 to 2 min in patients in cardiac arrest. The rate should be reduced or the infusion stopped temporarily if hypotension develops.

Adverse Effect Profile Hypotension is the predominant adverse effect but is surprisingly uncommon, even when a 1- to 2-g IV push dose is given over 1 to 2 min. Other signs of hypermagnesemia, which may begin at serum concentrations of 4 mEq/L, include flushing, sweating, nausea, vomiting, CNS depression, depression of deep tendon reflexes, flaccid paralysis, depression of cardiac function, circulatory collapse, and respiratory depression.

VASOACTIVE DRUGS

ATROPINE

Actions Atropine sulfate, a naturally occurring antimuscarinic drug, competitively antagonizes the effects of acetylcholine and other muscarinic agents. Its effect on the heart is to increase sinus node automaticity and AV conduction by blocking vagal activity. It thus has been termed a *parasympatholytic* drug.

Pharmacokinetics The onset of action of atropine after IM, IV, and endotracheal (ET) administration is rapid, with peak increases in heart rate occurring within 2 to 4 min and a duration of action of up to 5 h.

The half-lives of atropine are 4 h in adults and 6.5 h in children but can be longer. Atropine elimination occurs at two rates: an initial fast rate of about 2 h and a slow rate ranging from 12.5 to 38 h. It is well absorbed and distributed throughout the body, metabolized in the liver, and excreted in the urine.

Indications Atropine sulfate reverses cholinergic-mediated decreases in heart rate. Atropine is useful in treating symptomatic sinus bradycardia (e.g., decreased heart rate with hypotension, altered mental status, "escape beats," or chest pain). Atropine is generally effective for AV block at the nodal level and ineffective when the block is infra-nodal. Atropine is rarely effective for pulseless electrical activity (PEA) with bradycardia and asystole.

Dosing and Administration For bradycardia, the loading dose is 0.5 mg rapid IV push every 3 to 5 min (maximum, 0.04 mg/kg). For PEA or asystole, the dose is 1 mg rapid IV push every 3 to 5 min (maximum, 0.04 mg/kg).

Atropine can be administered by several routes, including IV, IM, ET, SC, and intraosseous. When atropine is administered by ET tube, the dose should be increased 2 to 2.5 times the IV dose (the ET dose is diluted to 10 mL of the compatible solution). No dilution is required when administering the preloaded syringe (1 mg/10 mL), but dilution with 10 mL of NS is recommended when the 1 mg/mL ampules are used for ET administration. A total dose of 0.04 mg/kg produces complete vagal blockade.

Adverse Effect Profile Atropine is not indicated to correct bradycardia in the hemodynamically stable patient. If administered, marked increases in heart rate can increase myocardial oxygen consumption, possibly inducing ischemia and precipitating ventricular tachyarrhythmia. Doses smaller than 0.4 mg and therapeutic doses administered slowly can cause a paradoxical bradycardia that may be due in part to a central reflex stimulation of the vagus nerve. Other adverse effects may include other anticholinergic symptoms (e.g., blurred vision, dry mouth, CNS stimulation, hallucinations, mydriasis, and tachycardia).

DOBUTAMINE

Actions Dobutamine (Dobutrex) is a synthetic sympathomimetic drug that exerts potent inotropic and mild chronotropic activities. Dobutamine is formulated as a racemic mixture with p_1 and p_2 -adrenergic and α -adrenergic agonist activities that are offset by α -adrenergic antagonist activity (Table 29-2). The net result is an increase in myocardial contractility and systemic vasodilation, with minimal changes in heart rate. Doses of up to 20 μ g/kg per min will increase cardiac output, decrease peripheral vascular resistance, and decrease pulmonary occlusive pressures. Conversely, doses larger than 20 μ g/kg per min will increase the heart rate and induce dysrhythmias.

TABLE 29-2 Ability of Commonly Used Sympathomimetic Agents to Stimulate Adrenergic Receptors

	Receptor Type			Dopamine
	α	β_1	β_2	
Phenylephrine	++++	—	—	
Norepinephrine	++++	++++	—	
Epinephrine	+++	++++	+++	
Dopamine	++/+++	++++	++	++++
Dobutamine	+	++++	++	
Isoproterenol	—	++++	++++	

Pharmacokinetics The onset of action of dobutamine is 1 to 2 min, and the peak response occurs within 10 min after IV administration. The apparent Vd is 0.2 L/kg, and the drug is metabolized primarily in tissue and the liver to inactive metabolites. The elimination half-life is 1 to 2 min, with the majority of the drug being eliminated within 48 h in the urine as inactive metabolites.

Indications Dobutamine is indicated for short-term positive inotropic support for the treatment of cardiovascular decompensation secondary to ventricular dysfunction or low-output heart failure. It is also usually the preferred agent in the management of cardiogenic shock.⁹ Dobutamine increases cardiac output and renal and mesenteric blood flow without direct stimulation of the heart rate and decreases systemic vascular resistance.

Dosing and Administration Dobutamine is administered only as a continuous IV infusion. The dosage range is 2 to 20 μ g/kg per min; however, most patients can be maintained on 10 μ g/kg per min. Doses larger than 20 μ g/kg per min are associated with increased risk of tachyarrhythmia. To assess effectiveness of the dose administered, patients should be monitored with a central venous pressure or pulmonary artery catheter.

Adverse Effects Profile The primary adverse effects of dobutamine are modest increases in heart rate (increases greater than 5 to 15 beats/min are uncommon), blood pressure (increases greater than 10 to 20 mm Hg are uncommon), and ectopic dysrhythmias (escape beats, unifocal and multifocal ventricular ectopic beats, and ventricular bigeminy). Less common adverse effects include headache, paresthesias, tremors, nausea, angina, and dyspnea. Heart rate increases greater than 10 percent may induce or exacerbate myocardial ischemia.

DOPAMINE

Actions Dopamine (Intropin) is an endogenous catecholamine and a precursor of norepinephrine and other endogenous catecholamines. It acts on dopaminergic, (3_r and α -adrenergic receptors. In low doses, dopamine causes vasodilation in the renal, mesenteric, coronary, and intracerebral vasculatures via stimulation of the dopaminergic receptors. This stimulation results in an increase in renal blood flow, glomerular filtration rate, sodium excretion, and urine output. Recently, however, the ability of dopamine to significantly increase urine output has been questioned.¹⁰ At intermediate doses, dopamine stimulates α_1 -adrenergic receptors, thereby improving myocardial contractility and cardiac output and increasing SA nodal conduction. At high doses, dopamine stimulates α -adrenergic receptors, causing peripheral vasoconstriction and increasing blood pressure. At very high doses, the α -adrenergic effects dominate, causing peripheral vasoconstriction and vasoconstriction of the mesenteric and renal vascular beds.

Pharmacokinetics The onset of action of dopamine is 5 min, with a duration of action of 10 min after IV administration. Dopamine is used only as a continuous IV infusion. The apparent Vd is 1.8 to 2.5 L/kg. Dopamine is 75 percent metabolized by monoamine oxidase and catechol-O-methyltransferase (COMT) in the liver, kidneys, and plasma to an inactive metabolite. The remaining 25 percent is metabolized to norepinephrine in the adrenergic nerve terminals. The elimination half-life is 2 min and is 80 percent eliminated by the kidneys as the inactive metabolite and norepinephrine. The elimination half-life may be prolonged in patients with hepatic or renal insufficiency and in pediatric patients.

Indications Dopamine is indicated for reversing hemodynamically significant hypotension caused by myocardial infarction, trauma, sepsis, heart failure, and renal failure when fluid resuscitation is unsuccessful or not appropriate. Dopamine is used to increase cardiac output, blood pressure, urine output, and peripheral perfusion.

Dosing and Administration The lowest dose of dopamine should be used to maintain a desired blood pressure based on the clinical presentation. Most patients can be maintained on doses between 0.5 and 20 $\mu\text{g}/\text{kg}$ per min (continuous infusion). It is important to note that tachyphylaxis may occur with larger doses because the actions of dopamine are dependent on endogenous stores of norepinephrine and other catecholamines. As with all vasoactive drugs, dopamine should be discontinued by tapering the dose.

Adverse Effect Profile Dopamine produces dose-dependent adverse effects, including hypotension at low doses, hypertension at higher doses, ectopic beats, headache, nausea, vomiting, angina, palpitations, and tachycardia. Necrosis can develop if extravasation occurs. Gangrene of the extremities has been reported in patients with occlusive vascular disease or diabetes and in those who have received prolonged high-dose infusions. Monoamine oxidase inhibitors, halogenated anesthetics, sympathomimetics, and phosphodiesterase inhibitors will prolong and intensify the effects of dopamine. It is contraindicated in patients with pheochromocytoma or tachydysrhythmia. As with epinephrine, dopamine should not be infused in the same IV line with alkaline infusions.

EPINEPHRINE

Actions Epinephrine is an endogenous catecholamine and a nonselective α - and β -adrenergic agonist that is used in anaphylactic shock, a bronchodilator in acute asthma, and a myocardial stimulant in cardiac arrest. It increases heart rate, ventricular contractility, and peripheral vascular resistance. This effect causes vasoconstriction of arterioles in the skin mucosa and mesenteric vasculature by redistributing blood to the heart and brain. This leads to improved cardiac and cerebral perfusion during resuscitation. Epinephrine also causes bronchodilation and antagonizes the effects of histamine.

Pharmacokinetics The onset of action is 1 to 2 min, with a duration of action of 2 to 10 min after IV administration. The drug quickly becomes fixed in the tissues and is rapidly inactivated via oxidation by monoamine oxidase and methylation by COMT. The drug is eliminated via the kidneys predominantly as inactive metabolites.

Indications Epinephrine is indicated for the treatment of anaphylactic reactions and acute asthma exacerbations. It is considered a first-line agent in the treatment of cardiac arrest (i.e., pulseless VT/VF, asystole, and PEA). Epinephrine is also used as a vasopressor to increase blood pressure and to reverse bronchospasm due to anaphylactic and hypersensitivity reactions. Epinephrine infusions are used to increase heart rate in refractory symptomatic bradycardia.

Dosing and Administration For bradycardia, the dose is 2 to 10 $\mu\text{g}/\text{min}$ IV. For asthma, the dose is 0.3 to 0.5 mL of a 1:1000 concentration SC every 20 to 30 min, for a maximum of three doses.

Epinephrine remains the adrenergic drug of choice in the ACLS guidelines. Although there have been various administration methods of epinephrine described in the past (e.g., escalating and high dose), the current guidelines recommend the administration of 1 mg IV every 3 to 5 min. In fact, the guidelines stress that doses larger than 1 mg are not recommended and may be harmful. However, if IV access is unavailable during a cardiac arrest situation, 2 to 2.5 mL of a 1:1000 solution, diluted with 10 to 20 mL of saline, can be administered via the ET tube, followed by several rapid mechanical ventilations to disperse the drug throughout the airways for maximal absorption.

Adverse Effect Profile Adverse effects are of minimal importance in the setting of cardiac arrest. Epinephrine significantly increases myocardial oxygen consumption and thus can exacerbate ventricular irritability in the setting of myocardial ischemia. Adverse effects are ex-

tensions of the drug's action and include hypertension, tachycardia, palpitations, and dysrhythmias. Epinephrine is not compatible in the same IV line with alkaline solutions.

INAMRINONE

Actions Inamrinone (Inocor) contains the same chemical formula as the previously available product, amrinone. The name was changed to prevent potential confusion with similarly sounding drugs. Inamrinone produces inotropic effects by inhibition of the phosphodiesterase enzyme, which is responsible for the degradation of intracellular cyclic adenosine monophosphate (cAMP). The increased intracellular concentration of cAMP results in an increase in intracellular calcium and thus increases myocardial contractility and the force of contractions. In addition to positive inotropic effects, inamrinone has vasodilatory properties. It appears to have a direct action on vascular smooth muscle but may also cause vasodilation secondary to a decrease in sympathetic tone resulting from improved myocardial contractility. The net effect is an increase in myocardial contractility and stroke volume, with a reduction in preload and afterload.

Pharmacokinetics The onset of action of inamrinone is 2 to 5 min, with peak effects seen within 10 min and a duration of action of 0.5 to 2 h after IV administration. The duration of action is dose dependent. The apparent V_d is 1.2 L/kg, and the terminal half-life is 3.6 h. The terminal half-life may be prolonged up to 8.3 h in patients with CHF. Inamrinone is metabolized by the liver to several metabolites, which are eliminated principally in the urine.

Indications Inamrinone is indicated for the short-term management of decompensated CHF. Because of the potential for serious adverse effects, inamrinone should be reserved for CHF refractory to or intolerant of conventional therapy (e.g., cardiac glycosides, diuretics, and/or vasodilators). Inamrinone has been used in clinical studies for up to 48 h, and prolonged use has not been found to be safe and effective.

Dosing and Administration The loading dose is a bolus of 0.75 mg/kg IV over 2 to 3 min, followed by a maintenance infusion of 5 to 15 $\mu\text{g}/\text{kg}$ per min. A second bolus of 0.75 mg/kg may be given 30 min after the initial bolus dose.

Inamrinone is available only for IV administration. The total daily dose should not exceed 10 mg/kg. Inamrinone should be diluted in 0.45 or 0.9 percent saline solutions. Dextrose-containing solutions may eliminate the drug's activity. Adjustments in the maintenance dose should be titrated to clinical response.

Adverse Effect Profile The most common adverse effects are thrombocytopenia, ventricular and supraventricular dysrhythmias, hypotension, and nausea. Other adverse effects, which occur in fewer than 1 percent of patients, include vomiting, anorexia, fever, chest pain, and burning at the injection site. Hepatotoxicity has been reported, although rarely.

ISOPROTERENOL

Actions Isoproterenol (Isuprel) is a synthetic sympathomimetic agonist with β_1 - and β_2 -adrenergic receptor affinity only. The β_1 -receptor interaction results in increased chronotropic and inotropic activities in the myocardium and vasodilation by β_2 -receptor-mediated relaxation of smooth muscle.

Pharmacokinetics The onset of action of isoproterenol is 1 to 5 min and the duration of action is 1 to 2 h. Fifty percent of the dose is eliminated unchanged in the urine, and COMT is responsible for metabolizing 25 to 35 percent in the liver, lung, and other body tissues. The elimination half-life is 3 to 7 h.

Indications Isoproterenol use is limited to refractory torsade de pointes and temporary control of refractory symptomatic bradycardia. Due to significant increases in myocardial oxygen demand with the use of isoproterenol, its use has been restricted to refractory arrhythmias.

Dosing and Administration The dose is 2 to 10 $\mu\text{g}/\text{min}$ IV by continuous infusion. Larger doses are considered harmful.

Adverse Effect Profile The significant increases in heart rate seen with isoproterenol therapy causes dramatic increases in myocardial oxygen demand that can result in ischemic complications and tachydysrhythmia. The lowest possible effective dose should be used to prevent VT.

NESIRITIDE

Actions Nesiritide (Natrecor) is a recombinant B-type natriuretic peptide that is endogenously produced in the human heart under conditions of increased pressure load or ventricular stretch, usually in association with increased intravascular volume. When B-type natriuretic peptide is produced and released from ventricular myocytes in response to increased pressure, it binds to and stimulates guanylate cyclase-linked GC-A receptors. This causes an increase in intracellular cyclic guanosine monophosphate, which results in its natriuretic, diuretic, vasodilatory, and smooth muscle relaxant activity. GC-A receptors are located primarily in the adrenal gland, lungs, kidneys, and endothelial and smooth muscle vasculatures. Nesiritide also inhibits renin-aldosterone release.

Pharmacokinetics The onset of action of nesiritide is 15 to 30 min, with a peak response seen in approximately 60 min and a duration of action of 30 to 120 min after continuous IV administration. The apparent V_d is 0.19 L/kg. Metabolism occurs in the kidneys via proteolysis of nesiritide, although no dosage reduction is recommended in patients with renal insufficiency. The elimination half-life is 18 to 23 min.

Indications Nesiritide is indicated for the treatment of acutely decompensated heart failure. It reduces pulmonary capillary wedge pressure and improves dyspnea. Nesiritide also can result in symptomatic hypotension comparable to nitroglycerin. However, when compared with dobutamine, ventricular dysrhythmias and cardiac arrest occur less frequently with nesiritide. Nesiritide is contraindicated in patients with a systolic blood pressure of less than 90 mm Hg.

Dosing and Administration The loading dose is a 2 mg/kg IV bolus over 1 min followed by continuous infusion of 0.01 $\mu\text{g}/\text{kg}$ per min. The infusion is titrated by 0.005 $\mu\text{g}/\text{kg}$ per min every 3 h as needed, up to a maximal rate of 0.03 $\mu\text{g}/\text{kg}$ per min.

Nesiritide is available only for continuous IV infusion. Hypotension is a dose-limiting effect and may necessitate a decrease in the infusion rate or discontinuation of the drug.

Adverse Effects Profile Hypotension (11 percent) is the most common adverse effect of nesiritide and may require a reduction in dosage or discontinuation of the drug. Headache is also a common adverse effect. In at least 1 percent of patients who received nesiritide during clinical trials, bradycardia, ventricular dysrhythmias, and atrial fibrillation were reported. Less common adverse effects include confusion, paresthesias, somnolence, tremor, and lightheadedness.

NICARDIPINE

Actions Nicardipine (Cardene) is a dihydropyridine calcium channel antagonist that is structurally similar to nifedipine. It inhibits the slow

inward current of calcium into normal cardiac cells, resulting in coronary and peripheral vasodilation. Nicardipine will significantly increase cardiac index and output in a dose-related fashion, with reduction of systemic vascular resistance. Similar to other dihydropyridine calcium channel antagonists, nicardipine has little to no effect on SA and AV nodal conduction and, hence, is not associated with any negative inotropic or antidysrhythmic effects.

Pharmacokinetics The onset of action of nicardipine is 1 min, with a duration of action of 3 h after IV administration. The apparent V_d is 0.64 L/kg. Metabolism occurs almost exclusively in the liver to an inactive metabolite, 65 percent of which is eliminated in the urine and 35 percent is excreted in feces. The elimination half-life is 44 to 107 min.

Indications Nicardipine is available in oral and IV formulations. The IV formulation is indicated for the short-term management of hypertensive crises or essential hypertension when oral therapy is not feasible or desired.

Dosing and Administration The loading dose is 5 mg/h by continuous infusion. The dose is titrated in increments of 2.5 mg per h every 15 min, to a maximum of 15 mg per h.

Adverse Effects Profile Adverse effects associated with the IV formulation are usually dose dependent. Most common cardiovascular adverse effects include hypotension and tachycardia. Other adverse effects include headache, flushing, nausea, vomiting, and dizziness.

NIFEDIPINE

Actions Nifedipine (Procardia and Adalat) is a dihydropyridine calcium channel antagonist with actions similar to other drugs in this class. Calcium channel inhibition in smooth muscle and cardiac cells results in a decrease in total peripheral resistance, a decrease in systemic blood pressure, a decrease in the afterload of the heart, a small reflex increase in the heart rate, and an increase in the cardiac index. Coronary artery vasodilation results in improved oxygen delivery, benefiting patients with vasospastic angina. Systemic artery vasodilation results in decreased afterload, leading to decreased oxygen consumption in patients with chronic stable angina. A reflexive increase in heart rate and cardiac output is seen with nifedipine use. Unlike verapamil or diltiazem, nifedipine has little effect on SA and AV nodal conduction. Nifedipine may, however, result in a decrease in left ventricular end diastolic pressure or left ventricular end diastolic volume in patients with moderately to severely impaired LV function, thereby worsening their condition.

Pharmacokinetics The onset of action of nifedipine is 20 min, a peak response of 20 to 30 min and a duration of 6 h after oral immediate-release administration. The onset and duration of action after oral extended-release administration are 30 min and 12 h, respectively. Regardless of formulation, nifedipine has 45 to 70 percent bioavailability due to first-pass hepatic metabolism. Liver metabolism results in inactive metabolites, which are 90 percent eliminated in urine. The elimination half-life is 2 to 5 h and may be increased up to 7 h in patients with hepatic dysfunction. Nifedipine is 90 to 96 percent protein bound and should be taken on an empty stomach. Concurrent administration with grapefruit juice may increase serum concentration through inhibition of intestinal metabolism.

Indications Previous recommendations for the sublingual use of the oral immediate-release formulation called for its use in the treatment of hypertensive emergencies. However, recent data have shown that a precipitous drop in blood pressure may worsen outcomes in these patients by the development of ischemic complications. Grossman and

associates called for the abandonment of nifedipine in the routine treatment of hypertensive crisis based on reports of serious adverse effects, despite its effectiveness in reducing blood pressure.¹¹ Both oral formulations are indicated for the treatment of vasospastic and chronic stable angina. Nifedipine sustained-release, alone or in combination with other anti-hypertensive drugs, is indicated in the management of essential hypertension.

Dosing and Administration For hypertension or angina, the dose is 30 to 60 mg per d of an extended-release formulation (maximum, 120 mg per d). For angina, the dose is 10 mg of immediate-release formulation (swallowed whole) three times daily (maximum, 180 mg per d). Sublingual or chewing the immediate-release formulation can cause a precipitous drop in blood pressure and has been implicated in ischemic events.

Adverse Effect Profile Most adverse effects of nifedipine are related to its vasodilatory activity on the smooth muscle and include lightheadedness, flushing, headache, and hypotension. The most serious adverse effects reported with the sublingual use of the immediate-release formulation include cerebrovascular ischemia, stroke, severe hypotension, and acute myocardial infarction. Other, less severe, cardiovascular adverse effects include a peripheral edema, CHF, reflex tachycardia, and pulmonary edema. Noncardiac adverse effects include nervousness, sleep disturbances, blurred vision, nausea, somnolence, insomnia, and diarrhea. Concomitant administration with other antihypertensive drugs may enhance the hypotensive effects. Nifedipine should be used with caution in patients with CHF, aortic stenosis, and concomitant (3-blocker therapy).

NIMODIPINE

Actions Nimodipine (Nimotop) is a dihydropyridine calcium channel antagonist with actions similar to those of other calcium channel antagonists. Nimodipine has a relative selectivity for vascular smooth muscle when compared with the myocardium and therefore has minimal effects on conduction and inotropism of the myocardium. Because it dilates cerebral vessels to a greater extent than peripheral or coronary vessels, nimodipine's primary indication is in the treatment of subarachnoid hemorrhage (SAH). Nimodipine use results in an increase in cerebral blood flow and may shunt blood to ischemic areas. Although it is believed that prevention of vasospasm after a SAH may lead to improved outcomes, improved collateral blood flow and prevention of large calcium influxes in to neurons (causing cell destruction) may be of greater benefit.

Pharmacokinetics The peak response seen after oral administration is 60 min. It is 95 percent protein bound and readily crosses the blood-brain barrier. Metabolism occurs extensively in the liver to numerous inactive metabolites that are eliminated almost entirely in the urine or feces. The elimination half-life is 8 to 9 h.

Indications Nimodipine is indicated for the treatment of recent (within 96 h) SAH from ruptured congenital intracranial aneurysm.

Dosing and Administration The loading dose is 60 mg PO every 4 h for 21 days. The dose may be changed to 30 mg PO every 2 h if hypotension develops. If oral administration is not feasible, the capsule can be punctured, with the contents administered through a nasogastric tube and flushed with 30 mL of saline.

Adverse Effect Profile The most common adverse effect is hypotension, which is often dose related. In addition, edema and headache have been reported in patients with SAH. Other, less frequent, dose-related adverse effects include tachycardia, bradycardia, palpitations, flushing, hypertension, rebound vasospasm, CHF, and pulmonary edema.

NITROGLYCERIN

Action Nitroglycerin (various trade names) is an organic nitrate that readily enters vascular smooth muscle, where it undergoes conversion to nitric oxide. Nitric oxide is a direct vasodilator that primarily produces systemic venodilatation by reducing preload as measured by pulmonary capillary wedge pressure and left ventricular end-diastolic volume and pressure. Venodilatation is typically seen at doses smaller than 100 µg per min, whereas arteriolar vasodilation is seen at doses larger than 200 µg per min.

Pharmacokinetics Table 29-3 lists the onset and duration of action of various nitroglycerin formulations. Nitroglycerin has a half-life of 2 to 33 min and is metabolized by the liver to inactive metabolites. The apparent Vd is 3 L/kg. Oral nitroglycerin formulations undergo extensive first-pass metabolism.

Indications Nitroglycerin, in its various formulations, is indicated for the prophylaxis and management of angina pectoris. Intravenous nitroglycerin may be preferable to sodium nitroprusside for decreasing preload in acute decompensated heart failure, due to its more favorable effects on regional ischemia and pulmonary artery pressure. Intravenous nitroglycerin is also used in the treatment of hypertensive crisis and for the management of perioperative hypertension, especially hypertension associated with cardiovascular procedures.

Dosing and Administration Nitroglycerin can be administered sublingually, lingually, intrabuccally, PO, topically, or by IV infusion. See Table 29-3 for specific dosing regimens. The sublingual and intrabuccal formulations should not be swallowed, and the extended-release formulations should not be chewed. Patients should be in a sitting or supine position immediately after sublingual, lingual, or intrabuccal

TABLE 29-3 Nitroglycerin Chart

Sublingual: 0.3, 0.4, and 0.6 tablets
Dissolve 1 tablet under tongue q5 min until pain relief or hypotension occurs
Onset: 1-3 min
DOA: 30-60 min Translingual
spray: 0.4 mg/spray
1—2 metered-dose sprays into oral mucosa q3-5 min
Onset: 2 min
DOA: 30-60 min Topical ointment: 2%
nitroglycerin ointment
Apply 1 to 2 in. to chest wall q4-8 h
Onset: 20-60 min
DOA: 2-12 h
Intravenous infusion
Give 5—10 µg per min, titrate in increments of 5-10 (µg per min q3—5 min until desired results (standard dose, 50-200 µg per min)
Onset: 1-2 min
DOA: 5-10 min
Sustained-release pill
Starting dose is 2.5 mg PO TID
Onset: 20~5 min
DOA: 4-8 h
Transmucosal tablets
Place 1-mg pill between lip and gum above incisors or between cheek and gum q3-5h while awake
Onset: 1-2 min
DOA: 3-5 h
Transdermal patch
Apply to hair-free area and rotate sites. 2.5—15-mg patches are available; start with low dose and titrate upward
Onset: 30-60 min
DOA: up to 24 h

Abbreviation: DOA = duration of action.

administration. Intravenous nitroglycerin should be administered by an infusion pump. Patients may exhibit tolerance to nitroglycerin infusions of 24 h or longer and thus may need increasing infusion rates over time although tolerance may be seen with any formulation when dosed continuously for longer than 24 h. To minimize tolerance to nitroglycerin, IV infusion should be maintained at the lowest effective dose for the shortest duration possible. A "drug-free period" of 6 to 12 h is recommended for the oral, topical, and transdermal formulations. Intravenous nitroglycerin should not be discontinued abruptly. Rather, it should be titrated down slowly to minimize any rebound effects (e.g., angina or myocardial infarction).

Adverse Effect Profile Most adverse effects are related to the cardiovascular actions caused by nitroglycerin. These effects include headache, dizziness, weakness, syncope, flushing, hypotension, reflex tachycardia, and, occasionally, bradycardia. Caution is advised when using nitroglycerin in patients who are hemodynamically unstable (including those who are volume depleted) or who have increased intracranial pressure or severe anemia. Nitroglycerin also should be used with caution in cases of constrictive pericarditis, pericardial tamponade, and hypertrophic cardiomyopathy. Extended-release formulations should be avoided in patients with GI hypermotility or malabsorption syndromes. Transdermal patches and topical ointment should be removed before defibrillation or synchronized cardioversion. Topical nitroglycerin formulations alter electrical conductivity and enhance the potential for electrical arcing to occur. Concurrent use with sildenafil (Viagra) has been reported to cause excessive hypotension and should be avoided.

NOREPINEPHRINE

Actions Norepinephrine bitartrate (Levophed) is identical to the endogenous catecholamine synthesized in the adrenal medulla and sympathetic nervous tissue. Norepinephrine stimulates α and β_1 receptors. The net results are increases in arterial and venous vascular tone and increases in inotropic and chronotropic activity of the heart. Paradoxical decreases in heart rate may result from reflex increase in parasympathetic tone. Norepinephrine differs from epinephrine in that it has no effect on β_2 -receptors.

Pharmacokinetics The onset of action of norepinephrine is 1 to 2 min and the duration of action is 5 to 10 min after IV administration. Metabolism of norepinephrine occurs in the liver and other tissues, mainly by COMT. Elimination occurs via uptake by adrenergic neurons, with a small percentage being eliminated via the kidneys.

Indications Norepinephrine is a direct-acting sympathomimetic and is used to produce vasoconstriction and cardiac stimulation as an adjunct to correct hemodynamic imbalances in the treatment of shock that persists after adequate fluid volume replacement. Norepinephrine may be particularly useful when endogenous stores of norepinephrine are low. This scenario may arise in patients who have been on prolonged infusions of dopamine. Other specific uses for norepinephrine include controlling hypotensive states during poliomyelitis, drug overdoses (various phenothiazines, and tricyclic antidepressants), spinal anesthesia, pheochromocytoma, and sympathectomy.

Dosing and Administration The initial dose is 2 μ g per min by constant infusion. The rate should be adjusted in increments of 1–2 μ g per min every 3 to 5 min as needed. The maximal recommended dose is 12 μ g per min.

Norepinephrine is available for continuous IV infusion only. As with any vasopressor, adequate fluid or blood replacement should be corrected before starting norepinephrine. Norepinephrine infusions should not be discontinued abruptly. Rather, a slow titration down should be instituted to avoid rebound hypotension.

Adverse Effect Profile High doses of norepinephrine may result in ventricular irritability, cardiac depression, decreased renal blood flow, and a reflex bradycardia. Acute hypertension may occur in patients on monoamine oxidase inhibitors or tricyclic antidepressants. Care should be taken to avoid extravasation. To prevent necrosis and sloughing if extravasation occurs, the area should be infiltrated as soon as possible with 5 to 10 mg of phentolamine (Regitine). Norepinephrine is contraindicated in patients with hypotension resulting from cyclosporine or halogenated hydrocarbon anesthesia, uncorrected blood deficits, or in mesenteric or peripheral vascular thrombosis.

VASOPRESSIN

Actions Vasopressin (Pitressin) is identical to endogenous vasopressin (antidiuretic hormone). The primary physiologic role of vasopressin is to maintain serum osmolality. It produces relatively concentrated urine by increasing reabsorption of water by the renal tubules. Maintenance of osmolality is mediated by renal vasopressin V_2 receptors, which are coupled to adenyl cyclase activity and cAMP formation. In doses larger than those required for antidiuretic effects, vasopressin directly stimulates contraction of smooth muscle V_1 receptors. Vascular V_1 receptors are coupled to phospholipase C, resulting in release of calcium from sarcoplasmic reticulum in smooth muscle cells, leading to vasoconstriction. Vasoconstriction, which occurs particularly in the capillaries and small arterioles, results in decreased blood flow to the splanchnic, coronary, GI, pancreatic, skin, and muscular systems. Endogenous vasopressin concentrations in patients undergoing cardiopulmonary resuscitation are higher in those who have a return of spontaneous circulation (ROSC) than in those who do not. This finding suggested that exogenous vasopressin might be beneficial during cardiac arrest.

Pharmacokinetics The onset of action on vasopressin is immediate, with a duration of action of 10 to 30 min. Vasopressin has a half-life of approximately 10 to 20 min and is rapidly metabolized in the liver and kidneys.

Indications Vasopressin is indicated for the prevention and treatment of diabetes insipidus, treatment of GI hemorrhage, and, more recently, as an alternative to epinephrine for its vasopressor effects as a nonadrenergic peripheral vasoconstrictor during cardiopulmonary resuscitation. Vasopressin is indicated only in the treatment of pulseless VT/VF. Preliminary clinical evidence shows that vasopressin may be effective in enhancing the probability of ROSC in patients with out-of-hospital VF. Low-dose vasopressin infusions have been shown to be an effective alternative to traditional high-dose catecholamine therapy in septic patients with refractory hypotension.

Dosing and Administration The initial dose in cardiac arrest is 40 units IV push. If there is no ROSC in 10 min, epinephrine 1 mg every 3 to 5 min can be used. Vasopressin can be used in place of, but not concurrent with, the initial dose of epinephrine. There are no data to support the use of a second dose of vasopressin during cardiac arrest.

Adverse Effect Profile In the dose recommended in cardiac arrest, vasopressin may produce increased blood pressure, bradycardia, dysrhythmias, premature atrial contractions, heart block, peripheral vascular constriction or collapse, coronary insufficiency, decreased cardiac output, myocardial ischemia, and mesenteric thrombosis.

APPROACH TO THE PATIENT IN SHOCK Emanuel P. Rivers Ronny M. Otero H. Bryant Nguyen

EPIDEMIOLOGY

More than 1 million cases of shock are estimated to present to U.S. hospital EDs each year.¹ The presentation may be cryptic, as in the patient with compensated heart failure, or obvious as in the ultimate shock state of cardiac arrest. Despite aggressive treatment, mortality from shock remains high. Approximately 30 to 45 percent of patients in septic shock, and 60 to 90 percent for those with cardiogenic shock, die within 1 month of presentation.^{2,3} The definition and treatment of shock continues to evolve. With a contemporary understanding of the disease and new evolving technology, the emergency physician can recognize shock at an earlier stage and initiate expert, timely intervention. The general approach to a patient in the initial stages of shock follows similar principles regardless of the inciting factors or etiology.

PATHOPHYSIOLOGY

Shock is defined as circulatory insufficiency that creates an imbalance between tissue oxygen supply and oxygen demand. The result of shock is global tissue hypoperfusion and is associated with a decreased venous oxygen content and metabolic acidosis (lactic acidosis). Shock is classified into four categories by etiology: (1) hypovolemic (caused by inadequate circulating volume), (2) cardiogenic (caused by inadequate cardiac pump function), (3) distributive (caused by peripheral vasodilatation and maldistribution of blood flow), and (4) obstructive (caused by extra cardiac obstruction to blood flow). Clinically, shock may have a predominant cause, but as the shock state persists or progresses to irreversible end organ damage, other pathophysiologic mechanisms become operative.

Knowledge of the principles of oxygen delivery and consumption is important to the understanding of shock. A maximum of four molecules of oxygen is loaded onto each molecule of hemoglobin as it passes through the lungs. If all available oxygen sites are occupied (four per molecule of hemoglobin), arterial oxygen saturation (SaO_2) is 100 percent (Table 30-1). Arterial oxygen content (CaO_2) is the amount of oxygen bound to hemoglobin plus the amount dissolved in plasma (Table 30-2). Oxygen is delivered to the tissues by the pumping function (cardiac output) of the heart.

Systemic oxygen delivery (DO_2) is the product of the CaO_2 and cardiac output (CO). Systemic oxygen consumption (VO_2) comprises a sensitive balance between supply and demand. Normally, the tissues consume approximately 25 percent of the oxygen carried on hemoglobin, and venous blood returning to the right heart is approximately 75 percent saturated [mixed venous oxygen saturation (pulmonary artery) ($SmvO_2$)]. When oxygen supply is insufficient to meet demand, the first compensatory mechanism is an increase in CO. If the increase in CO is inadequate, the amount of oxygen extracted from hemoglobin by the tissues increases, which decreases $SmvO_2$.

When compensatory mechanisms fail to correct the imbalance between tissue supply and demand, anaerobic metabolism occurs, resulting in the formation of lactic acid. Lactic acid is rapidly buffered, resulting in the formation of measured lactate; normally between 0.5 and

1.5 mM/L. An elevated lactate level is associated with an $SmvO_2$ <50 percent. Most cases of lactic acidosis are a result of inadequate oxygen delivery, but lactic acidosis occasionally can develop from an excessively high oxygen demand, for example, in status epilepticus. In other cases, lactic acidosis occurs because of an impairment in tissue oxygen utilization, as in septic shock and postresuscitation from cardiac arrest; a normal $SmvO_2$ with an elevated lactate indicates such an impairment. Elevated lactate is a marker of impaired oxygen delivery and/or utilization and correlates with short-term prognosis of critically ill patients in the ED.

$SmvO_2$ can also be used as a measure of the balance between tissue oxygen supply and demand. $SmvO_2$ is obtained from the pulmonary artery catheter, but similar information can be obtained by central venous blood cannulation ($ScvO_2$). $ScvO_2$ correlates well with $SmvO_2$ and can be more easily obtained in the ED setting.⁴

Shock is usually, but not always, associated with systemic arterial hypotension; i.e., systolic blood pressure less than 90 mm Hg. Pressure is the product of flow and resistance [mean arterial pressure (MAP) = CO X systemic vascular resistance (SVR)]. Blood pressure may not fall if there is increase in peripheral vascular resistance in the presence of decreased cardiac output, resulting in inadequate flow to the tissue or global tissue hypoperfusion. The insensitivity of blood pressure to detect global tissue hypoperfusion has been repeatedly confirmed. Thus, shock may occur with a normal blood pressure, and hypotension may occur without shock.

The onset of shock provokes a myriad of autonomic responses, many of which serve to maintain perfusion pressure to vital organs. Stimulation of the carotid baroreceptor stretch reflex activates the sympathetic nervous system leading to (1) arteriolar vasoconstriction, resulting in redistribution of blood flow from the skin, skeletal muscle, kidneys, and splanchnic viscera; (2) an increase in heart rate and contractility that increases cardiac output; (3) constriction of venous capacitance vessels, which augments venous return; (4) release of the vasoactive hormones epinephrine, norepinephrine, dopamine, and cortisol to increase arteriolar and venous tone; and (5) release of antidiuretic hormone and activation of the renin-angiotensin axis to enhance water and sodium conservation to maintain intravascular volume. These compensatory mechanisms attempt to maintain DO_2 to the most critical organs—the coronary and cerebral circulation. During this process, blood flow to other organs such as the kidneys and gastrointestinal tract may be compromised.

The cellular response to decreased DO_2 is adenosine triphosphate depletion leading to ion-pump dysfunction, influx of sodium, efflux of potassium, and reduction in membrane resting potential. Cellular edema occurs secondary to increased intracellular sodium, while cellular membrane receptors become poorly responsive to the stress hormones insulin, glucagon, cortisol, and catecholamines. As shock progresses, lysosomal enzymes are released into the cells with subsequent hydrolysis of membranes, deoxyribonucleic acid, ribonucleic acid, and phosphate esters. As the cascade of shock continues, the loss of cellular integrity and the breakdown in cellular homeostasis result in cellular death. These pathologic events give rise to the metabolic features of hemoconcentration, hyperkalemia, hyponatremia, prerenal azotemia, hyper- or hypoglycemia, and lactic acidosis.

In the early phases of septic shock, these physiologic changes produce a clinical syndrome called the systemic inflammatory response syndrome or SIRS, defined as the presence of two or more of the following features: (1) temperature greater than 38°C (100.4°F) or less than 36°C (96.8°F); (2) heart rate faster than 90 beats/min; (3) respiratory rate faster than 20 breaths/min; and (4) white blood cell count

CO	Cardiac output
CPP	Coronary perfusion pressure
CVP	Central venous pressure
Do ₂	Systemic oxygen delivery
DBP	Diastolic blood pressure
Hb	Hemoglobin
MAP	Mean arterial pressure
MODS	Multiorgan dysfunction syndrome
OER	Oxygen extraction ratio
Paco ₂	Arterial carbon dioxide pressure
Pao ₂	Arterial oxygen pressure
PAOP	Pulmonary artery occlusion (wedge) pressure
Sao ₂	Arterial oxygen saturation
Scvo ₂	Central venous oxygen saturation
Smvo ₂	Mixed venous oxygen saturation (pulmonary artery)
Srvo ₂	Retinal venous oxygen saturation
SIRS	Systemic inflammatory response syndrome
SVR	Systemic vascular resistance
Vo ₂	Systemic oxygen consumption

greater than $12.0 \times 10^9/L$, less than $4.0 \times 10^9/L$, or with greater than 10 percent immature forms or bands.⁵ As SIRS progresses, shock ensues, followed by multiorgan dysfunction syndrome (MODS) manifested by myocardial depression, adult respiratory distress syndrome, disseminated intravascular coagulation, hepatic failure, or renal failure. The fulminate progression from SIRS to MODS is determined by the balance of anti-inflammatory and proinflammatory mediators or cytokines that are released from endothelial cell disruption (Figure 30-1).

Global tissue hypoperfusion alone can independently activate the inflammatory response and serve as a comorbid variable in the pathogenesis of all forms of shock.⁶ The failure to diagnose and treat global tissue hypoperfusion in a timely manner leads to an accumulation of an oxygen debt, the magnitude of which correlates with increased mortality.

TABLE 30-2 Oxygen Transport and Utilization Components

Arterial oxygen content	$Cao_2 = 0.0031 \times Pao_2 + 1.38 \times Hb \times Sao_2$
Cao ₂ is the amount of O ₂ within 100 mL blood. Oxygen is contained within blood in two forms: dissolved in plasma and chemically combined with hemoglobin. Assuming 15 g hemoglobin per 100 mL blood and an oxygen saturation of 97%, the representative normal value of Cao ₂ is 20.1 mL/100 mL blood (vol%).	
Central venous/mixed venous oxygen saturation	Scvo ₂ or Smvo ₂
Smvo ₂ reflects physiologic efforts to meet tissue O ₂ demands. Normal Smvo ₂ is 65 to 75%. When the Smvo ₂ falls below 50%, the body's limits to compensate have been reached and O ₂ availability for tissue metabolism will be compromised, leading to lactic acidosis.	
Central venous/mixed venous oxygen content	$Cmvo_2 = 0.0031 \times Pmvo_2 + 1.38 \times Hb \times Smvo_2$
Cmvo ₂ is the amount of oxygen content returning to the heart. Normal Cmvo ₂ is 15 mL/100 mL blood (vol%).	
Systemic oxygen extraction ratio (OER)	$OER = C(a-v)O_2 / Cao_2$
The amount of O ₂ taken out of the blood by the tissues is the systemic OER. It is described as a percentage. Normal OER is about 25%. Lactic acid production, an indicator of anaerobic metabolism, usually accompanies an OER of greater than 50%.	
Oxygen delivery	$Do_2 = CO \times Cao_2 \times 10$
Do ₂ is the amount of O ₂ delivered to the tissues per minute. Assuming a normal cardiac output of 5 L per min and a Cao ₂ of 20.1 vol%; a normal value for O ₂ delivery would be 1000 mL O ₂ per min.	
Oxygen consumption	$Vo_2 = CO \times Hb \times 1.38 \times (Sao_2 - Smvo_2) \times 10$
The amount of O ₂ consumed by tissues each minute and is equal to the difference in O ₂ delivered to tissues and the O ₂ returning from tissues. The normal value is about 250 mL O ₂ per min. Note that this formula ignores the small contribution from dissolved oxygen.	
Oxygen affinity	
Shifts in the oxyhemoglobin dissociation curve affect the release of O ₂ in the peripheral circulation. Increased pH, decreased temperature, decreased carbon dioxide concentration (Pco ₂) and decreases in 2,3-DPG levels all result in a shift of the oxyhemoglobin curve to the left. Thus, for any particular value of Pao ₂ , the O ₂ saturation will be higher. This increased affinity of hemoglobin for O ₂ makes O ₂ loading easier, but release of O ₂ in the peripheral tissues is impaired. The reverse is true with a decreased pH, increased temperature, increased Pco ₂ , and increased 2,3-DPG: there is a shift of the oxyhemoglobin dissociation curve to the right resulting in a decreased affinity of hemoglobin for O ₂ .	

Note: See Table 30-1 for abbreviation definitions.

CLINICAL FEATURES

History

Often, the presence of shock will be instantly apparent along with the underlying cause, such as acute myocardial infarction, anaphylaxis, or hemorrhage. Some patients may be in shock with few symptoms other than generalized weakness, lethargy, or altered mental status. Symptoms that suggest volume depletion include bleeding, vomiting, diarrhea, excessive urination, insensible losses because of fever, or orthostatic light-headedness. A history of cardiovascular disease is important, particularly episodes of chest pain or symptoms of congestive heart failure. Prior neurologic diseases can render patients more susceptible to complications from hypovolemia. Medication use, both prescribed and nonprescribed, is important. Some medication will cause volume depletion (e.g., diuretics) whereas others depress myocardial contractility (e.g., fJ-blockers and calcium channel blockers). The possibility of an anaphylactic reaction to a new medication, or cardiovascular depression as a consequence of drug toxicity should be considered.

Physical Examination

The clinical presentation of shock can be dramatic, as in profound hypotension caused by hemorrhage from a gunshot wound. On the other hand, shock can be subtle, as in heart failure, or, paradoxically, with hypertension. No single vital sign or value is diagnostic of shock as vital signs are insensitive in detecting and assessing the severity of tissue hypoperfusion. Measurement of blood pressure can be particularly difficult because of peripheral vascular disease, tachycardia with a small pulse pressure, and arrhythmias such as atrial fibrillation. Although not specific, physical findings taken as a composite may be useful in the assessment of patients in shock (Table 30-3).

DIAGNOSIS

Ancillary Studies

The clinical presentation and the presumptive etiology of shock will dictate the use of ancillary studies. A battery of standard hematologic,

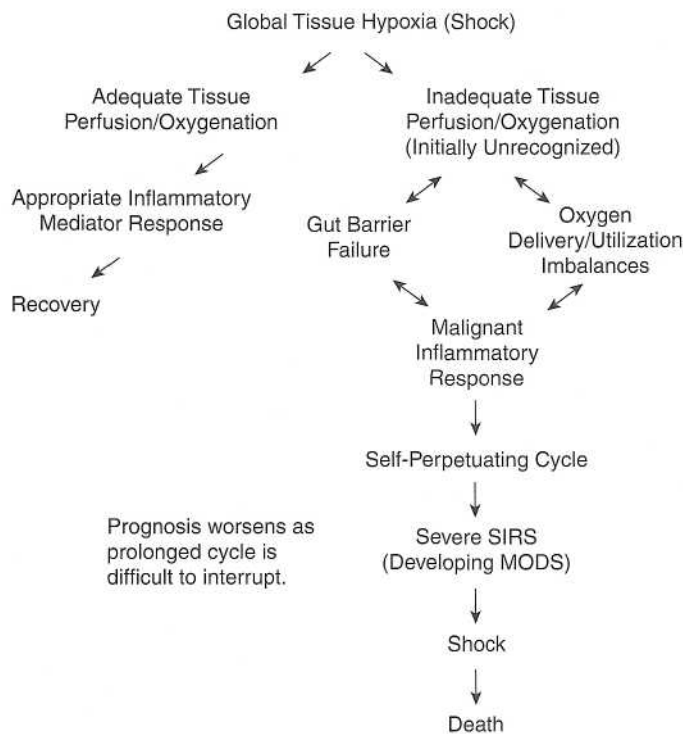

FIG. 30-1. The pathophysiology of shock, SIRS, and MODS.

coagulation, and biochemical tests usually provides an assessment of the patient's general physiologic condition and occasionally detects an abnormality that requires specific treatment (Table 30-4). A wide range of laboratory abnormalities may be encountered in shock, but most abnormal values merely point to the particular organ system that is either contributing to or being affected by the shock state. No single laboratory value is sensitive or specific for shock.

TABLE 30-3 Physical Examination

Temperature	Hyperthermia or hypothermia may be present. It is important to distinguish endogenous hypothermia (hypometabolic shock) from exogenous hypothermia secondary to environmental exposure. The treatment is obviously aggressive resuscitation in the former and exogenous heat application in the latter. Usually elevated. However, paradoxical bradycardia can be
Heart rate	seen in shock states such as hemorrhagic shock (up to 30%), hypoglycemia, (3-blocker use, and preexisting cardiac disease.
Systolic blood pressure	May actually increase slightly when cardiac contractility increases in early shock and then fall as shock advances. Correlates
Diastolic blood pressure	with arteriolar vasoconstriction and may rise early in shock and then fall when cardiovascular compensation fails. Systolic
Pulse pressure	minus diastolic pressure and related to stroke volume and rigidity of the aorta. Increases early in shock and decreases
Pulsus paradoxus	before systolic pressure. The change in systolic blood pressure with respiration. The rise and fall in intrathoracic pressure affects cardiac output. This
Mean arterial blood pressure	can be seen in asthma, cardiac tamponade, and severe cardiac decompensation. Diastolic blood pressure + [pulse pressure/3]. The relationship between cardiac output and vascular resistance determines
Shock index	can be seen in asthma, cardiac tamponade, and severe cardiac decompensation. Shock index = heart rate/systolic blood pressure. Normal = 0.5 to 0.7. The shock index is related to left ventricular stroke
Central nervous system	work in acute circulatory failure. A persistent elevation of the shock index (>1.0) indicates an impaired left ventricular function (as a result of blood loss and/or cardiac depression) and carries a high mortality rate. ¹⁵ Acute delirium or brain
Skin	failure; restlessness, disorientation, confusion, and coma secondary to decrease in cerebral perfusion pressure (mean arterial pressure — intracranial pressure). Patients with chronic hypertension may be symptomatic at normal
Cardiovascular	blood pressures.
Respiratory	Pallor, pale, dusky, clammy, cyanosis, sweating, altered temperature, and decreased capillary refill. Neck vein distention or flattening, tachycardia, and arrhythmias. An S3 may result from high-output states. Decreased
Splanchnic organs	coronary perfusion pressures can lead to ischemia, decreased ventricular compliance, increased left ventricular diastolic
Renal	pressure, and pulmonary edema. Tachypnea, increased minute ventilation, increased dead space, bronchospasm, hypocapnia
Metabolic	with progression to respiratory failure, and adult respiratory distress syndrome.
	Ileus, gastrointestinal bleeding, pancreatitis, acalculous cholecystitis, and mesenteric ischemia can occur from low flow states.
	Reduced glomerular filtration rate, renal blood flow redistributes from the renal cortex toward the renal medulla leading to
	oliguria. Paradoxical polyuria can occur in sepsis, which may be confused with adequate hydration status. Respiratory
	alkalosis is the first acid-base abnormality, as shock progresses metabolic acidosis occurs. Hyperglycemia,
	hypoglycemia, and hyperkalemia.

Hemodynamic monitoring is important in the assessment of patients in shock and evaluation of response to treatment. Monitoring capabilities will vary from institution to institution, but should include pulse oximetry, electrocardiographic monitoring, continuous noninvasive but preferably intraarterial blood pressure monitoring, end-tidal CO₂ monitoring, and central venous pressure (CVP) monitoring.⁷ Because hemodynamic measurements are physiologic values, they should be used to answer specific physiologic questions rather than to serve as therapeutic end points.

TREATMENT

The Rationale for Early Intervention

The tenet of trauma resuscitation is to initiate care within the "golden hour" of disease presentation. A similar principle applies to patients with nonsurgical causes of shock. Current national increases in ED patient acuity and overcrowding have resulted in extending the golden hour into *hours* and even *days*, consequently requiring the provision of critical care in the ED. The benefit of timely ED intervention in non-traumatic critical illness is significant; standard ED care can significantly decrease the predicted mortality of critically ill patients in as little as 6 h of treatment.⁸ Application of an algorithmic approach to optimize hemodynamic endpoints with early goal-directed therapy in the ED reduces mortality by 16 percent in patients with severe sepsis or septic shock.⁹ The *ABCDE* tenets of shock resuscitation are establishing Airway, controlling the work of Breathing, optimizing the Circulation, assuring adequate oxygen Delivery, and achieving *End* points of resuscitation.

Establishing Airway

Airway control is best obtained through endotracheal intubation for airway protection, positive pressure ventilation (oxygenation), and pulmonary toilet. Sedatives, which are frequently used to facilitate intubation, can exacerbate hypotension through arterial vasodilatation,

venodilation, and myocardial suppression. Furthermore, positive pressure ventilation reduces preload and cardiac output. The combination of these interventions can lead to hemodynamic collapse. Volume resuscitation or application of vasoactive agents may be required prior to intubation and positive pressure ventilation.

Controlling the Work of Breathing

Control of breathing is required when tachypnea accompanies shock. Respiratory muscles are significant consumers of oxygen during shock and contribute to lactate production. Mechanical ventilation and sedation decrease the work of breathing and have been shown to improve survival. Sao₂ should be restored to greater than 93 percent and ventilation controlled to maintain a Paco₂ 35 to 40 mm Hg. Attempts to normalize pH above 7.3 by hyperventilation are not beneficial. Mechanical ventilation not only provides oxygenation and corrects hypercapnia but assists, controls, and synchronizes ventilation, which ultimately decreases the work of breathing. Neuromuscular blocking agents are used as adjuncts to further decrease respiratory muscle, oxygen consumption and preserve Do₂ to vital organs.

Optimizing the Circulation

Circulatory or hemodynamic stabilization begins with intravascular access through large-bore peripheral venous lines. Trendelenburg positioning, historically considered necessary for maintaining perfusion in the hypotensive patient, does not improve cardiopulmonary performance compared with the supine position. It may worsen pulmonary gas exchange and predispose to aspiration. If a volume challenge is urgently required, rather than using the Trendelenburg position, an alternative is to raise the patient's legs above the level of

the heart with the patient supine. Central venous access will aid in assessing volume status (preload) and monitoring Scvo₂. It is the preferred route for the long-term administration of vasopressor therapy, and provides rapid access to the heart if pacemaker placement is required.

Fluid resuscitation begins with isotonic crystalloid; the amount and rate are determined by an estimate of the hemodynamic abnormality. Most patients in shock have either an absolute or relative volume deficit, except the patient in cardiogenic shock with pulmonary edema. Fluid is given rapidly, in set quantities (e.g., 500 or 1000 mL), with reassessment of the patient after each amount. Patients with modest degree of hypovolemia usually require an initial 20 mL/kg of isotonic crystalloid. More fluids may be necessary with profound volume deficits.

The colloid-versus-crystalloid resuscitation controversy remains despite evidence that there is a slight increase in mortality when colloids are used for volume replacement in critically ill patients.¹⁰ Some studies have found a lower incidence of pulmonary edema, and possibly greater benefit, in elderly patients with colloid resuscitation, although survival is not statistically improved. In the acute situation with severe shock, colloids may be considered to achieve rapid plasma expansion using less volume compared to crystalloids.

Without invasive hemodynamic monitoring, noncardiogenic pulmonary edema may be difficult to differentiate from cardiogenic pulmonary edema in the ED. Even though the former may respond to fluids, fluids should be minimized in a patient with clinical or radiographic evidence of pulmonary edema until appropriate monitoring is established.

Vasopressor agents are used when there has been an inadequate response to volume resuscitation or when a patient has contraindications to volume infusion.¹¹ They are most effective when the vascular space is "full" and least effective when the vascular space is depleted. However, vasopressors may be necessary early in the treatment of shock, before volume resuscitation is complete, in order to prevent potentially lethal consequences of prolonged systemic arterial hypotension. This is especially important in elderly patients with significant coronary and cerebrovascular disease. Rapidly restoring the MAP to 60 mm Hg or systolic pressure to 90 mm Hg may avoid the coronary and cerebral complications of decreased blood flow. Vasopressor agents are based on the catecholamine molecule and have variable effects on the α -adrenergic, β -adrenergic, and dopaminergic receptors (Table 30-5).¹²

The use of vasopressors is accompanied with potential pitfalls. While improving perfusion pressure in the large vessels, they may decrease capillary blood flow in certain tissue beds, especially the bowel. Vasopressors also may alter the relationship between volume and pressure measurements through their effect on the pulmonary and peripheral vascular beds. In other words, vasopressors will falsely elevate intracardiac filling pressures (i.e., CVP). They should be used judiciously, generally only after volume resuscitation. When multiple vasopressors are used, they should be simplified as soon as the best therapeutic agent is identified.

Assuring Adequate Oxygen Delivery

Once blood pressure is stabilized through optimization of preload and afterload, Do₂ can be assessed and further manipulated. Arterial oxygen saturation should be returned to physiologic levels (93 to 95 percent) and hemoglobin maintained above 10 g/dL.¹³ If cardiac output can be assessed, it should be increased by using volume infusion and inotropic agents in incremental amounts until venous oxygen saturation (SmvO₂ or Scvo₂) and lactate are normalized.

The control of Vo₂ is important in restoring the balance of oxygen supply and demand to tissues. A hyperadrenergic state results from the compensatory response to shock, physiologic stress, pain, and anxiety. Shivering frequently results when a patient is unclothed for examination and then left inadequately covered in a cold resuscitation room.

TABLE 30-5 Commonly Used Vasoactive Agents

Drug	Dose/Mixture*	Action	Cardiac Stimulation	Vasoconstriction	Vasodilation	Cardiac Output	Side Effects and Comments
Dopamine	0.5–25 µg/kg per min 400 mg/250 mL	α, β, and dopaminergic	++ at 2–10 µg/kg per min	++ at 7 µg/kg per min	+ at 0.5–5.0 µg/kg per min	Usually increases	Tachydysrhythmias, increases myocardial O ₂ consumption, a cerebral, mesenteric, coronary and renal vasodilator at low doses
Norepinephrine	0.01–0.5 µg/kg per min 4 mg/250 mL	Primarily α ₁ , some β ₁	++	++++	0	Slight decrease	Dose related, reflex bradycardia; useful when loss of venous tone predominates, spares the coronary circulation
Phenylephrine	0.15–0.75 µg/kg per min 10 mg/250 mL	Pure α	0	++++	0	Decrease	Reflex bradycardia, headache, restlessness, excitability, rarely arrhythmias; ideal for patients in shock with tachycardia or supraventricular arrhythmias
Ephedrine	5–25 mg	α and β	+++	++	+	Increases	Causes palpitations, hypertension, cardiac arrhythmias, an indirect-acting CNS stimulant; limited long-term value as therapy for shock.
Vasopressin	0.01–0.04 units per min 200 units/250 mL	α		++++			Primarily vasoconstriction, outcome data from its use is lacking; infusions of >0.04 units per min may lead to adverse, vasoconstriction-mediated events
Epinephrine	0.01–0.75 µg/kg per min 1 mg/250 mL	α and β	++++ at 0.03–0.15 µg/kg per min	++++ at 0.15–0.30 µg/kg per min	+++	Increases	Causes tachydysrhythmia, leukocytosis, increases myocardial oxygen consumption
Dobutamine	2.0–20 µg/kg per min 250 mg/250 mL	β ₁ , some β ₂ and α ₁ in large dosages	++++	+	++	Increase	Causes tachydysrhythmia, occasional GI distress, increases myocardial oxygen consumption, hypotension in volume depleted patient; has less peripheral vasoconstriction than dopamine, can cause fewer arrhythmias than isoproterenol
Isoproterenol	0.01–0.05 µg/kg per min 1 mg/250 mL	β ₁ and some β ₂	++++	0	++++	Increases	Causes tachydysrhythmia, facial flushing, hypotension in hypovolemic patients; increases myocardial oxygen consumption; never use alone in shock.

Note: 0 = no effect, + = mild effect, ++ = moderate effect, +++ = marked effect, ++++ = very marked effect.

Abbreviations: CNS = central nervous system; GI = gastrointestinal.

*Individual drugs may be diluted in D5W or NS, and may be diluted in larger volumes or concentrated into smaller volumes according to the fluid needs of the individual patient.

SECTION 4 • SHOCK

The combination of these variables increases systemic oxygen consumption. Pain further suppresses myocardial function, thus impairing DO_2 and VO_2 . Providing analgesia, muscle relaxation, warm covering, anxiolytics, and even paralytic agents, when appropriate, decreases this inappropriate VO_2 .

Tissue oxygen extraction assesses adequacy of the resuscitation in meeting the oxygen needs of the tissues. Sequential examination of lactate and Smvo_2 or Scvo_2 is a method to assess adequacy of tissue oxygen extraction. Continuous measurement of Smvo_2 or Scvo_2 through fiberoptic technology can be used in the ED.⁴ A variety of other technologies have potential to assess tissue perfusion during resuscitation (Table 30-6).¹⁴⁻¹⁷

Achieving End Points of Resuscitation

Traditional end points have been normalization of blood pressure, heart rate, and urine output. Because these underestimate the degree of remaining hypoperfusion and oxygen debt, more physiologic end points have been investigated (Tables 30-7 and 30-8).¹⁸ No therapeutic end point is universally effective, and only a few have been tested in prospective trials, with mixed results.¹⁸ The goal of resuscitation is to maximize survival and minimize morbidity using objective hemodynamic and physiologic values to guide therapy. A goal-directed approach at achieving urine output >0.5 mL/kg per h, CVP 8 to 12 mm Hg, MAP 65 to 90 mm Hg, and $\text{Scvo}_2 >70$ percent during ED resuscitation of septic shock significantly decreases mortality.⁹

Troubleshooting a Persistently Hypotensive Patient

Treatment of a persistently hypotensive patient after maximal therapy can be a harrowing experience. Similar principles apply to both the trauma patient with ongoing hemorrhage and the persistently hypotensive medical patient. Issues to keep in mind include the following: (1) Is the patient appropriately monitored?⁷ (2) Is there malfunction-

ing arterial blood pressure monitoring, such as dampening of the arterial line or disconnection from the transducer? (3) Is the patient adequately volume resuscitated? (4) Does the early use of vasopressor falsely elevate CVP and disguise hypovolemia? (5) Is the intravenous tubing into which the vasopressors are running connected appropriately? (6) Are the vasopressor infusion pumps working? (7) Are the vasopressors mixed adequately? (8) Does the patient have a pneumothorax after placement of central venous access? (9) Has the patient been adequately assessed for an occult penetrating injury (a bullet hole or stab wound)? (10) Is there hidden bleeding from a ruptured spleen or ectopic pregnancy? (11) Does the patient have adrenal insufficiency? The incidence of adrenal dysfunction can be as high as 30 percent in this subset of patients.¹⁹ (12) Is the patient allergic to the medication just given (e.g., penicillin) or taken before arrival? (13) Is there cardiac tamponade in the chronic renal failure patient on dialysis or cancer patient?

Bicarbonate Use in Shock

The primary treatment of acidosis in shock is to reverse the underlying cause. Because this goal is not rapidly attainable, intravenous bicarbonate is often administered. The rationale for giving bicarbonate is that it will diminish myocardial depression and counteract the insensitivity to endogenous catecholamines attributed to acidosis, but experimental data indicate that exogenous bicarbonate can actually worsen intracellular acidosis, and prospective studies have not shown benefit. Bicarbonate also shifts the oxygen-hemoglobin dissociation curve to the left and impairs tissue unloading of hemoglobin-bound oxygen. However, many clinicians remain uncomfortable withholding bicarbonate, which has created disparate opinions in the medical literature. A compromise is to partially correct the metabolic acidosis over time. The bicarbonate deficit is determined, which is equal to (normal HCO_3^- minus the patient's HCO_3^-) $\times 0.5 \times$ body weight (kilograms). One-half of this amount is infused slowly and the remainder over 6 to

TABLE 30-6 Adjuncts in Assessing Tissue Perfusion

Base deficit	Base deficit is an indicator of metabolic acidosis and is an index of hemodynamic and tissue perfusion changes in shock. Predicts illness severity in intra-abdominal hemorrhage and blunt trauma.
Invasive blood pressure monitoring	Intensive vasoconstriction caused by sympathetic activity or vasopressors given will cause the cuff pressure to underestimate true blood pressure. A Doppler may be used in conjunction with a sphygmomanometer may enable more accurate measure of systolic blood pressure once Korotkoff sound are no longer audible. Intra-arterial pressure measurement is preferable because vasoactive drugs may cause rapid swings in blood pressure and multiple blood samplings will typically be required.
Central venous pressure (CVP)	Aids in assessing volume status. Preferred for the long-term administration of vasopressor therapy and provides rapid access to the heart if pacemaker placement is required. May not reliably reflect the left ventricular filling pressure in clinical states such as pulmonary embolus, obstructive airway disease, right ventricular infarction, and pericardial effusion. Common iliac venous pressure can approximate CVP.
Central venous oximetry (Scvo_2)	Scvo_2 closely approximates mixed venous O_2 saturation (Smvo_2) and can be monitored continuously using infrared oximetry. This technology enables the clinician to detect clinically unrecognized tissue global tissue hypoperfusion in the treatment of myocardial infarction, general medical shock, trauma, hemorrhage, septic, hypovolemic, end-stage heart failure, and cardiogenic shock during and after cardiopulmonary arrest.
Arterial-central venous CO_2 difference	Increased arterial-mixed venous carbon dioxide gradients or (a-v) CO_2 are seen in acute circulatory failure, and inversely correlate with the cardiac index (CI).
Pulmonary artery catheterization	The standard of care for assessing cardiac status. Valuable in determining left-sided heart filling, pulmonary artery pressure, and assessing the cause of pulmonary edema. Can obtain cardiac output and mixed venous oxygen saturation. Will be able to calculate hemodynamic (i.e., SVR) and oxygen transport variables (VO_2 and DO_2). The effectiveness of this monitoring technique on improving outcome is challenged.
Noninvasive cardiac output Gastric tonometry and sublingual capnography	Cardiac output can be measured by transesophageal Doppler, cutaneous bioimpedance, and lithium dilution. Serial measurements of gastric and sublingual mucosal blood flow are based on hydrogen ion diffusion and carbon dioxide elimination. Inadequate visceral perfusion as evidenced by persistently low intramucosal pH or increased sublingual carbon dioxide concentration after resuscitation is associated with subsequent organ dysfunction and death.
Retinal venous O_2 saturation	Retinal venous O_2 saturation (Srvo_2) correlates with blood volume, central venous O_2 saturation and arterial O_2 saturation.
Metabolic cart	Directly measured VO_2 without a pulmonary artery catheter. A reduction in VO_2 (after acute myocardial infarction) predicts cardiogenic shock and mortality after human cardiac arrest.

TABLE 30-7 End Points of Resuscitation

Traditional: normalization of blood pressure, pulse, and urine output

 Restoration of aerobic metabolism, elimination of tissue acidosis, and
 repayment of oxygen debt

8 h. Additional bicarbonate should be withheld once arterial pH is 7.25 or greater.

DISPOSITION AND TRANSITION TO THE INTENSIVE CARE UNIT

Documentation and communication are important. Resuscitation in the ED is commonly performed in "ordered chaos." Even though resuscitation is systematic and thoughtful, miscommunication with the intensivist or subspecialist accepting the patient can undo the benefits of initial treatment. A system-oriented problem list with an assessment and plan, including all procedures and complications, should be verbally communicated and written or dictated prior to transfer. For prolonged ED stays, notations regarding patient status, diagnostic and therapeutic intervention, and sentinel events should be provided frequently.

PROGNOSIS

Outcome prediction at ED disposition has not been fully studied; however, some clinical variables are associated with poor outcome, such as severity of shock, temporal duration, underlying cause, preexisting vital organ dysfunction and reversibility. Direct noninvasive measurement of Vo_2 is predictive of outcome in patients who developed cardiogenic shock secondary to myocardial infarction and after cardiac arrest.⁸ Persistent elevated lactate levels are prognostic in trauma, septic shock, and after cardiac arrest.⁸ Base deficit is also correlated with the development of multisystem organ failure in trauma.²⁰ Elevated sublingual partial pressure of carbon dioxide (Pco_2) is associated with increased mortality.¹⁴ Outcome predictions using physiologic scoring systems in the ED are also being studied.⁸

TABLE 30-8 Hemodynamic Resuscitation End Points

	Modality	Goals
Preload	CVP	10-12 mm Hg
	PAOP	12-18 mm Hg
Afterload	MAP SVR = (MAP - CVP/CO)(80)	90-100 mm Hg 800-1400 dyne • s/cm ⁵
Contractility	CO	5.0 L/min
	CI	2.5–4.5 L per min • m ²
	SV = CO/heart rate	50-60 mL per min
Heart rate	60-100 bpm	Avoid >100 bpm; this will decrease SV and increase myocardial oxygen consumption
Coronary perfusion pressure	CPP = DBP - CVP (or PAOP)	>60 mm Hg
Tissue oxygenation	Scvo ₂ or Smvo ₂	>70%
	Serum lactate	<2mM/L

Note: See Table 30-1 for abbreviation definitions.
 Abbreviation: bpm = beats per min.

FLUID AND BLOOD RESUSCITATION

James E. Manning

Fluid resuscitation is the initial therapy for disorders causing intravascular volume depletion with resulting tissue hypoperfusion and organ dysfunction. In addition, other causes of shock may have a relative hypovolemia and benefit from fluid administration. Fluid and blood resuscitation serve as the bridge to maintain survival and limit morbidity until the underlying cause can be corrected. Acute hemorrhage is the predominant cause of acute intravascular volume loss requiring aggressive fluid resuscitation (Table 31-1). Other processes that cause loss of plasma fluid and electrolytes (e.g., dehydration, burns) may require aggressive fluid therapy, but blood replacement is usually not an

TABLE 31-1 Causes of Intravascular Volume Loss**Hemorrhagic hypovolemia**

Thorax

- Pulmonary parenchymal trauma
- Pulmonary vascular injury
- Intercostal vascular injury
- Aortic disruption
- Massive hemothysis

- Large soft tissue injuries

Nonhemorrhagic hypovolemia

- Gastrointestinal disorders: vomiting, diarrhea, ascites
- Burns
- Environmental exposure or neglect
- Renal salt wasting

issue. This chapter focuses on the issues related to fluid resuscitation in acute hemorrhagic shock.

Until recently, the widely accepted goal of fluid resuscitation was to restore a state of normovolemia (i.e., "to fill the tank"). However, laboratory studies and limited clinical reports have raised controversy about the presumed benefit of restoring normal intravascular volume in the setting of ongoing hemorrhage. Limited-volume "hypotensive" resuscitation and even "no fluid" resuscitation approaches have been proposed. Questions about the optimal initial resuscitation fluid to use and the extent of volume to administer remain.

The principal objective of fluid resuscitation is to restore sufficient intravascular volume and oxygen-carrying capacity to maintain cellular delivery of metabolic substrates (principally oxygen) in order to sustain cellular viability. Achieving this goal requires attentive responses by the clinician to the dynamic changes that occur during hemorrhage and the ability to accurately monitor, as best as possible, the physiological state of the patient.

PATHOPHYSIOLOGY

Injuries to major vascular structures, solid organs, and large bones are the major causes of severe traumatic hemorrhage. Common nontraumatic causes of hemorrhage include gastrointestinal bleeding, vascular aneurysm rupture, and ruptured ectopic pregnancy. The acute loss of intravascular volume triggers a wide range of physiological regulatory responses aimed at compensating for the blood loss and maintaining perfusion to the most important vascular beds. These compensatory mechanisms include cardiovascular, autonomic nervous system, endocrine, renal, coagulation system, and respiratory responses. Depending upon the severity of the hemorrhage and the ability of the body to compensate, variable regional or global hypoperfusion may result. Although transient, moderate hypoperfusion may be well tolerated, prolonged or severe hypoperfusion leads to shock physiology with progressive cellular and organ dysfunction.

At the cellular level, hemorrhagic shock can be defined as a state of impaired oxidative metabolism and homeostasis due to inadequate oxygen delivery and inadequate cellular waste removal resulting from hypoperfusion. The compensatory physiologic responses to acute hemorrhage seek to maintain adequate tissue oxygen delivery and sus-

tain cellular homeostasis. Loss of circulating blood volume leads to decreases in arterial blood pressure, venous return, and ventricular stroke volume. Cardiac stretch receptors and aortic baroreceptors are stimulated along with the sympathetic nervous system resulting in increased heart rate, arterial and venous vasoconstriction, increased ventricular contractility, and extravascular to intravascular fluid shift. Conversely, vagal tone is decreased. The kidneys, through stimulation of the renin-angiotensin-aldosterone system and antidiuretic hormone release, retain sodium and water to further support intravascular volume. Angiotensin II and vasopressin promote vasoconstriction. Activation of the coagulation system leads to platelet deposition and release of local mediators (thromboxane, platelet aggregating factor), local vasoconstriction at bleeding sites, platelet plug formation and fibrin deposition to seal vascular injury sites. Together these responses serve to increase intravascular volume, limit further blood loss, optimize cardiac output, and preserve vital organ perfusion.

Despite the activation of these physiologic responses, severe hemorrhage causes decreased cardiac output, and vital organ perfusion can only be maintained at the expense of nonvital organs. Progressive vasoconstriction in the splanchnic, musculoskeletal, and cutaneous vascular beds allows for sustained critical perfusion to the heart, brain, and kidneys. Renal perfusion is also sacrificed in severe states. This redistribution of blood flow is not without potential adverse effects since prolonged or severe splanchnic hypoperfusion could potentially trigger responses leading to subsequent multiple organ failure.¹ Renal hypoperfusion can lead to acute renal failure.

Progressive failure of oxidative metabolism with lactate production in hypoperfused areas leads to worsening systemic metabolic acidosis that will eventually overcome compensatory mechanisms. If hypoperfusion is not reversed or progresses beyond the capacity of the cardiovascular system, hemodynamic decompensation will occur as depression of myocardial contractility develops and local tissue acidosis and hypoxia result in loss of peripheral vasoconstriction. Death rapidly ensues. Even if the patient is resuscitated, release of inflammatory mediators and activation of cellular apoptotic pathways may be so advanced that survival is jeopardized. The goal of fluid resuscitation is to assist the body in its efforts to compensate and, above all, to avoid reaching the critical point of hemodynamic decompensation.

CLINICAL FEATURES

The clinical presentation of the patient with acute hemorrhage depends upon the cause, rate, volume, and duration of bleeding, the presence of other acute pathological processes, and the patient's baseline physiologic status. Nontraumatic causes will often have signs that indicate the source of bleeding and have symptoms specific to the disease process in addition to signs of hypovolemia. However, many causes of nontraumatic hemorrhage can have initially occult presentations. Traumatic injuries usually show some evidence of the source of bleeding, but the search must not end with the obvious since victims of major trauma can have multiple sites of significant bleeding. The presence of associated central nervous system trauma, alcohol and drug abuse, airway compromise, pulmonary injury, and other acute processes can significantly affect response to hemorrhage. Chronic underlying disease processes and medications that affect cardiovascular responsiveness can also affect response to hemorrhage.

The hemodynamic profile in response to significant acute hemorrhage-induced hypovolemia commonly includes tachycardia, hypotension, and signs of poor peripheral perfusion (cool, pale, clammy extremities with weak peripheral pulses and prolonged capillary refill). Arterial and venous vasoconstriction leads to a narrowing of the pulse pressure. Cerebral hypoperfusion causes alterations in mental status that range from subtle hypo-alertness (e.g., unusually quiet for the situation) to confusion and, ultimately, severe lethargy. Associated head injury or recreational substance intoxication can make it impossible to distinguish cerebral hypoperfusion, but this pos-

sibility should be kept in mind and evidence of systemic hypoperfusion should be sought.

With increasing blood loss, signs and symptoms of acute hemorrhage become more pronounced. The normal total circulating volume of an adult is approximately 7 percent of ideal body weight or about 5 L for an average 70-kg adult patient divided into about 3 L of plasma and 2 L of red blood cell (RBC) volume (Table 31-2). The American College of Surgeons classification of hemorrhage from their Advanced Trauma Life Support course is a useful guide for estimating blood loss and judging fluid resuscitation needs.² In general, loss of up to 15 percent (about 750 mL) of circulating blood volume (class I hemorrhage) is tolerated well in healthy patients. There is minimal or no tachycardic response, and changes in blood pressure usually do not occur. Without further bleeding, fluid replacement therapy is usually not needed. Blood loss of 15 to 30 percent (about 750 to 1500 mL) of total blood volume (class II hemorrhage) generally results in tachycardia and narrowed pulse pressure. The blood pressure response ranges from minimal to moderate hypotension as blood loss progresses. Compensatory peripheral vasoconstriction results in skin and pulse changes of decreased perfusion. There may be mild mental status changes. Provided the patient had a normal RBC volume before hemorrhage, this degree of blood loss is tolerated without RBC replacement provided circulating volume is restored. As blood loss increases beyond 30 percent (> 1500 mL) (class III hemorrhage) there is worsening hypotension, tachycardia, peripheral hypoperfusion, and decline in mental status. At greater than 40 percent (>2 L) blood loss (class IV hemorrhage) the ability of the body to compensate has reached its limits and hemodynamic decompensation is imminent without effective resuscitation. Although this classification is helpful in estimating severity of hemorrhage, it must be remembered that there can be substantial individual variation related to baseline health status, intoxicants, and other factors.

Patients with excellent baseline physiologic status (e.g., young athletes) may have such a robust compensatory response to hemorrhage that they do not manifest tachycardia or hypotension in response to even significant hemorrhage. Such patients can appear deceptively stable for the severity of hemorrhage. Signs of peripheral hypoperfusion and subtle mental status alterations may be the only clues that the severity of hemorrhage is greater than predicted based on hemodynamic parameters. Elderly patients may not develop a tachycardic response to blood loss because of underlying heart disease or medications (e.g., 3-adrenergic blocking agents). Bradycardia or lack of tachycardia may occur in approximately 30 percent of patients with intra-abdominal hemorrhage from increased vagal tone because of the hemoperitoneum. In a pregnant trauma patient, compression of the inferior vena cava by the gravid uterus can decrease central venous re-

turn, thereby worsening hypotension and tachycardia in the setting of less-severe hemorrhage.

Systemic hypoperfusion usually results in decreased urine output because of renal hypoperfusion and compensatory fluid reabsorption. Urine output is not helpful in the initial assessment of the patient with acute hemorrhage but is valuable over time in assessing response to therapy.

It must be remembered that hypotension in the setting of trauma does not always indicate hemorrhage. Other etiologies, such as primary myocardial dysfunction, airway compromise, hypoxemia as a result of lung injury, pericardial tamponade, tension pneumothorax, spinal cord injury, and toxicologic syndromes should be kept in mind. However, hypotension always warrants a careful search for occult hemorrhage.

MANAGEMENT

Initial therapy in the setting of acute hemorrhage should involve securing the airway, assuring adequate ventilation and oxygenation, controlling external bleeding (if present), and protecting the spinal cord (if potentially vulnerable). Fluid resuscitation should be determined with the following objectives in mind: (1) restoring intravascular volume sufficiently to reverse systemic hypoperfusion and limit regional hypoperfusion; (2) maintaining adequate oxygen-carrying capacity so that tissue oxygen delivery meets critical tissue oxygen demand; and (3) limiting ongoing loss of circulating RBCs. Unfortunately, there are no readily available precise parameters that allow the clinician to optimally balance these three objectives in the midst of the dynamic physiologic changes seen in acute hemorrhage and resuscitation. Nonetheless, the patient will most likely benefit from the clinician's best efforts to maintain this balance until surgical control of ongoing hemorrhage can be achieved.

Airway Control, Ventilation, and Oxygenation

The first step, as always, in patient care is assuring that the airway is patent, or securing the airway as necessary. Assuring adequate spontaneous ventilation or providing ventilation (partially or completely) logically follows. Providing oxygen is the third crucial step. Supplemental oxygen therapy aimed at achieving a fraction of inspired oxygen (F_{iO_2}) as close to 100 percent as possible is an appropriate objective in the initial management of the patient in hemorrhagic shock. Trauma patients may have associated pulmonary injuries or underlying lung disease that may limit oxygenation of blood as it passes through the lungs. The principal objective in the treatment of hemorrhagic shock is to maintain adequate tissue oxygen delivery, so every effort should be made in the respiratory management of hemorrhagic shock patients to maximize tissue oxygen delivery by optimizing arterial hemoglobin oxygen saturation. Positive pressure ventilation in the setting of hypovolemia may significantly diminish venous return and, thereby, have the adverse effect of decreasing cardiac output. Therefore, adequate ventilation and optimal oxygenation should be sought while avoiding overzealous positive pressure ventilation. Evaluation for potentially immediately treatable injuries that can compromise ventilation and oxygenation, including pneumothorax, tension pneumothorax, hemothorax, and airway foreign body is important.

Vascular Access and Monitoring

Establishing adequate intravenous access should be underway concurrent with airway management. Large-bore peripheral lines may be adequate if two or more can be secured. The rate at which crystalloid can be infused is dependent on the catheter diameter and the driving pressure (Table 31-3). If peripheral lines are not easily achieved or the patient shows evidence of severe hemorrhagic shock, the insertion of a large catheter introducer (8 to 9 Fr) in a femoral vein is appropriate.

TABLE 31-2 Spaces

Fluid Compartment	% Body Weight* (BW)	% Total Body Water* (TBW)	Volume* (70 kg)
Total body water	60%	100%	42 L
Intracellular	40%	67%	28 L
Extracellular	20%	33%	14 L
Interstitial	15%	25%	10 L
Intravascular	-7-8%	-11-13%	-5-5.5 L
Plasma	~4-4.5%	-7%	-3-3.5 L
Red blood cellst	-3-3.5%	-5%	-2-2.5 L

*Approximate percentage and amount.

t Percentages do not add to 100% because fluid contained within intravascular red blood cells is included within the intracellular fluid compartment.

TABLE 31-3 Isotonic Crystalloid Intravenous Infusion Rates

IV Access	Gravity (80-cm Height)	Pressure (300 mm Hg)
18 g peripheral IV	50-60 mL/min	120-180 mL/min
16 g peripheral IV	90-125 mL/min	200-250 mL/min
14 g peripheral IV	125-160 mL/min	250-300 mL/min
8.5 Fr central venous introducer	200 mL/min	400-500 mL/min

The subclavian and jugular veins can also be used but with the understanding that in the setting of significant hypovolemia they may be partially collapsed. An iatrogenic pneumothorax during attempted cannulation could lead to hemodynamic decompensation. In profound hemorrhagic shock with impending cardiovascular collapse, saphenous vein cutdown at the ankle or the proximal anteromedial thigh is also a reasonable option. Vascular access above the diaphragm is prudent if there is concern of major vascular injury in the area of the abdomen or pelvis. With initial vascular access, a full set of blood tubes should be drawn for appropriate laboratory studies and blood bank procedures (Table 31-4).

The patient should have continuous electrocardiographic heart rate monitoring, continuous pulse oximetry, and, if possible, continuous end-tidal carbon dioxide monitoring. Frequent checks of arterial blood pressure are also warranted. In severe hemorrhage, insertion of an arterial line is reasonable to allow for continuous arterial blood pressure monitoring and ease of arterial blood sampling. Serial arterial blood gas (ABG) and arterial lactate analyses yield important information about respiratory and metabolic status. For example, assessing the severity and trend in base deficit and lactate are helpful in determining the presence of ongoing systemic hypoperfusion that needs further intervention. A urinary catheter should be inserted to initiate urine output monitoring. The urine should be checked for blood and a urine pregnancy test should be performed on female patients of potential childbearing age. Insertion of a central venous line allows for central venous pressure (CVP) monitoring and assessment of central venous oxygen saturation. CVP measurements can be used to assess response to fluid administration; low central venous oxygen saturation is an indication of systemic hypoperfusion. In addition to frequent assessment of vital signs, mental status, and peripheral perfusion signs should be regularly assessed. Various newer monitoring technologies may prove to be very useful in the assessment of patients in hemorrhagic shock. These include pulse contour analysis continuous cardiac output, transcutaneous oximetry, tissue capnometry, and thoracic impedance monitors.

Fluid Resuscitation

Intravascular volume replacement to treat hemorrhage has been the accepted dogma for decades. The goal of restoring normal intravascular volume and normal arterial blood pressure was generally accepted for most of this time. The major area of controversy was the optimal resuscitation fluid. However, over the past decade the accepted practice of resuscitating patients to a normal blood pressure has been questioned. The early studies that supported aggressive volume replacement were performed in laboratory models of controlled hemorrhage. In such a circumstance, rapidly restoring normovolemia optimized outcome and had no appreciable adverse effects. However, this laboratory model does not accurately reflect the clinical situation. Most hemorrhagic shock patients have not had control of their bleeding achieved prior to initiation of fluid resuscitation. This fact raised concern that fluid resuscitation to a normal blood pressure might actually be deleterious by exacerbating ongoing hemorrhage and ultimately worsening outcome. Formation of clots at areas of vascular injury is facilitated by the lower blood pressure that results during hemorrhage. Increased blood pressure may dislodge these fragile developing clots. Because crystalloid solutions have essentially no oxygen-carrying capacity, any exacerbation of hemorrhage resulting from their infusion will lower the oxygen-carrying capacity of the circulating blood. Laboratory models of acute vascular injury with uncontrolled hemorrhage verified that raising the arterial blood pressure to the normal range increased the rate of ongoing bleeding. This led to the concept of limited volume or "hypotensive" resuscitation.³

The goal of this limited approach is to provide sufficient fluid resuscitation to maintain vital organ perfusion and avoid cardiovascular collapse while keeping the arterial blood pressure relatively low (e.g., mean arterial pressure of 60 mm Hg) in the hope of limiting further loss of red blood cells until surgical control of bleeding can be achieved. The potential adverse effect of this approach is that it accepts the presence of regional hypoperfusion, the effects of which are dependent on both the severity and duration of the hypoperfusion. Splanchnic hypoperfusion is especially of concern because this may be a major contributor to the development of subsequent multiple organ dysfunction.¹ Unfortunately, accurate clinical assessment of regional hypoperfusion is not presently possible. Thus, the optimal resuscitation end point is not clear and likely varies with the individual patient. A randomized clinical study that aimed to evaluate hypotensive resuscitation to a systolic blood pressure of 70 mm Hg did not show any mortality benefit for this approach.⁴ However, the target pressure of 70 mm Hg was difficult to maintain, with the systolic blood pressure in the hypotensive group reaching an average of 100 mm Hg. This demonstrates the difficulty of achieving and maintaining a specific hypotensive blood pressure target in the dynamic setting of hemorrhagic shock resuscitation. At present, this is still a concept that has not been clearly shown to improve survival. However, it seems reasonable to keep this concept in mind and to avoid excessive fluid resuscitation.

Even more radical than the concept of low volume or hypotensive resuscitation is the suggestion that no fluid should be administered in some cases of acute hemorrhage until surgical repair is ready to begin. A randomized study of hypotensive patients with penetrating torso injuries found that delaying fluid resuscitation until surgical hemostasis improved survival.⁵ The full consequences of this bold approach to acute hemorrhage have not been adequately evaluated. It seems that for some patients that are able to adequately compensate for their blood loss, this may be an acceptable approach. However, in the setting of ongoing hemorrhage with impending cardiovascular collapse, it is difficult to justify this approach.

Despite numerous laboratory and clinical investigations, the choice of resuscitation fluid remains controversial (Table 31-5). Crystalloid solutions and various colloids have both been widely used, but studies comparing these two fluid types have yielded varying results. An extensive meta-analysis of available clinical trials found no difference in survival

TABLE 31-5 Resuscitation Fluids

Isotonic crystalloid
Normal saline (NS)
Lactated Ringer's (LR) solution
Ringer's acetate
Colloids
Albumin: 5% and 25% concentrations
Fresh-frozen plasma
Hetastarch: 6% hydroxyethyl starch concentration
Dextran -40 (molecular weight 40 kDa) 10% solution
Dextran -70 (molecular weight 70 kDa) 6% solution
Gelatin Hypertonic solutions
Saline: 7.0 to 7.5% NaCl
Saline and dextran: 7.5% NaCl and 6% Dextran-70
Oxygen carrying resuscitation fluids
Hemoglobin-based oxygen carriers
Fluorocarbon-based oxygen carriers

Packed red blood cells

comparing crystalloid with colloid resuscitation.⁶ The cost of colloid agents tips the recommendation for fluid choice to crystalloid solutions.

Isotonic Crystalloid Solution

Isotonic crystalloid solutions, normal saline (NS) or lactated Ringer's (LR) solution, have been the preferred resuscitation fluid in the United States for many years. Crystalloid solutions are hypo-oncotic because they lack the large protein molecules present in the plasma. This causes a substantial amount of the crystalloid solution administered to shift in to the extravascular space corresponding to the relative size of the intravascular and interstitial fluid compartments (Table 31-6). This is the physiologic basis for the 3:1 ratio for isotonic crystalloid volume replacement: for every amount of blood lost, three times that amount of isotonic crystalloid is required to store intravascular volume because, at best, about 30 percent of the infused fluid stays intravascular. Based on this rule, a loss of 1 L of blood (approximately 15 to 20 percent of total circulating blood volume) would require about 3 L of isotonic crystalloid to restore normovolemia. Bearing this in mind, the recommendations for initial fluid resuscitation have been to administer 2 to 3 L of crystalloid solution in acute hemorrhage and then assess the response. If this amount of crystalloid solution has not stabilized the patient's hemodynamic status, it suggests that blood loss either exceeds 15 to 20 percent of total blood volume, or that there is significant ongoing blood loss, or both.

The choice of NS versus LR solution has been the focus of controversy over time. However, there is no clear evidence that either of these crystalloid solutions is superior to the other. Concerns have been raised about each fluid: (1) infusion of large volumes of either causes increased neutrophil activation; (2) LR solution also increases cytokine release and may increase lactic acidosis when given in large

volumes; and (3) NS exacerbates intracellular potassium depletion and causes hyperchloremic acidosis.

Blood Transfusion

There are no clearly defined parameters that trigger the switch from crystalloid to blood resuscitation. However, it is generally accepted that a patient in shock that demonstrates minimal or only modest hemodynamic improvement after rapid infusion of 2 to 3 L of crystalloid is in need of blood transfusion. However, it would be acceptable to start blood immediately if it is clear that the patient has suffered profound blood loss and is on the verge of cardiovascular collapse. Some patients may have an adequate hemodynamic response to initial crystalloid therapy that is transient. In such cases, continued crystalloid infusion beyond the first 2 to 3 L might be used for hemodynamic support so long as attention is paid to progressive hemodilution and its effect on tissue oxygen delivery. This hemodilution also lowers the concentration of clotting factors and platelets needed for intrinsic hemostasis at bleeding sites. Serial assessment of blood hemoglobin concentration is useful in such a situation. An American Society of Anesthesiologists task force review found that a blood hemoglobin concentration >10 g/dL (hematocrit >30 percent) very seldom requires blood transfusion, whereas a level <6 g/dL (hematocrit <18 percent) almost always requires blood transfusion.⁷ This leaves a rather wide intermediate range of hemoglobin—between 6 and 10 g/dL—where the decision to administer blood is significantly influenced by other factors, such as the presence of underlying disease processes that are sensitive to decreased tissue oxygen delivery and the rate of continued blood loss, if present. Understandably, as the hemoglobin concentration decreases, especially to 8 g/dL or less, the likelihood of needing blood markedly increases.

When possible, typed and cross-matched blood is preferable. However, in the acute setting where time does not permit full cross-matching, type-specific blood is the next best option followed by low-titer O-negative blood. Blood can be administered as whole blood or packed RBC preparations. In U.S. blood banks, whole blood is not stocked, and only packed RBCs are available. In the setting of massive hemorrhage with large volumes of crystalloid and blood resuscitation, fresh-frozen plasma and platelet transfusions may be needed to reverse the associated dilutional coagulopathy.

Red blood cell transfusion obviously restores lost hemoglobin, but stored blood components may also not be fully functional and can have adverse effects, which appear to be exacerbated with longer storage time.⁸ Using current preservatives, RBCs can be stored for up to 42 days and it has been reported that the average age of a unit of blood administered in the United States is approximately 21 days old. Stored RBCs can lose deformability, which can limit their ability to pass normally through capillary beds, or can cause capillary plugging. The oxygen dissociation curve is altered by loss of 2,3-diphosphoglycerate in the erythrocyte, which adversely affects the off-loading of oxygen at the tissue level. Clinical studies report worsening of splanchnic ischemia and an increased incidence of multiple-organ dysfunction associated with transfusion of RBCs that have been stored for longer than 2 weeks.^{9,10} Therefore, RBC transfusion, although a critical intervention in severe hemorrhagic shock, has limitations and potential adverse effects that should be kept in mind.

Colloid Resuscitation

Several colloid agents have been studied experimentally and used clinically for the treatment of hemorrhagic shock (see Table 31-5). Colloids have larger molecular weight particles with plasma oncotic pressures similar to normal plasma proteins. Therefore, colloids would be expected to remain in the intravascular space, replacing plasma proteins lost as a consequence of hemorrhage, and more effectively restore circulating blood volume than crystalloid solutions. An argument

TABLE 31-6 Theoretical Volemic Effect of 1 L of Fluid Administration on Fluid Compartments

	Intracellular	Interstitial	Plasma
D5W	660 mL	255 mL	85 mL
NS or LR	-100 mL	825 mL	275 mL
7.5% Saline	-2950 mL	2960 mL	990 mL
5% Albumin	0	500 mL	500 mL
Whole blood	0	0	1000 mL

Abbreviations: D5W = 5% dextrose in water; LR = lactated Ringer's solution; NS = normal saline.

favoring the use of colloids has been the concern that extravascular shift of infused crystalloid solutions has potential adverse effects, including pulmonary interstitial edema with impaired oxygen diffusion and intraabdominal edema with diminished bowel perfusion. However, pathologic conditions, such as hemorrhagic shock and sepsis, lead to increased vascular permeability that can allow for extravascular leakage of these larger colloid molecules.

The colloids that have been used as resuscitation fluids are a heterogeneous group of agents with widely varying characteristics and effects. These agents have been compared to each other as well as to crystalloids. A systematic review of the use of albumin in critically ill patients found an increased relative risk of death, as compared to use of crystalloids or no albumin.¹¹ The value of other colloid agents such as hetastarch, modified gelatin, and dextran, has not been clearly demonstrated. An extensive review and meta-analysis of clinical studies comparing crystalloids and colloids for fluid resuscitation failed to show any evidence of improved outcome with the use of colloids.⁶ Furthermore, a review of different colloids did not demonstrate that any particular colloid product is superior to the others, although confidence intervals were wide, making this conclusion less certain.¹² Given the much greater cost of colloid products, there is no clear basis for the choice of these agents over crystalloid solutions for fluid resuscitation.

Hypertonic Resuscitation Fluids

Hypertonic saline has been proposed as a potential crystalloid solution alternative that would limit the tissue edema effects that are of concern with isotonic crystalloid solutions. Hypertonic saline has been shown to rapidly expand intravascular volume and enhance tissue perfusion with hemodynamic effects beyond the degree of intravascular volume expansion. The intravascular shift of fluid from the extravascular space may be potentially beneficial in head trauma patients by limiting cerebral edema, lowering intracranial pressure, and improving cerebral perfusion. This effect may also limit pulmonary interstitial fluid shift that could potentially adversely affect oxygen diffusion. In early studies, it was noted that the effect of hypertonic saline alone was often transient. The addition of dextran to hypertonic saline was aimed at sustaining the hemodynamic effect of the hypertonic saline. The volume of hypertonic saline solution that can be given during resuscitation is limited due to the potential for hypernatremia.

Laboratory studies show beneficial hemodynamic effects and decreases in intracranial pressure. However, clinical studies comparing hypertonic saline and hypertonic saline/dextran do not show clear evidence of improved outcome, although a trend toward benefit has been suggested for seriously injured trauma patients.¹³ The military has a particularly strong interest in hypertonic resuscitation solutions because of the logistics of battlefield care. Recent recommendations have advocated the use of hypertonic saline for battlefield resuscitation.¹⁴

Oxygen-Carrying Resuscitation Fluid

A major limitation of all crystalloid and colloid resuscitation fluids is that none of these products restores the oxygen-carrying capacity of the lost red blood cells. Tissue oxygen delivery may be improved as a result of improved tissue perfusion but with severe and ongoing hemorrhage loss of hemoglobin becomes critical requiring blood transfusion. The problems of blood availability, transfusion reaction, viral infection, and loss of normal oxygen delivery properties with packed RBCs has led to a search for products that can serve as a substitute for blood transfusion, at least on a temporary basis.

Two classes of agents, hemoglobin-based oxygen carriers and fluorocarbon-based oxygen carriers, have been under development in recent decades to try to meet this demand.¹⁵ Ideally, such an oxygen-carrying resuscitation fluid would have tissue-oxygen-delivery properties comparable to native red blood cell hemoglobin, temperature sta-

bility, long shelf-life, no preparation requirements, and no adverse side effects. None of the oxygen therapeutic agents presently approaching clinical availability meets all these ideal characteristics but some of the hemoglobin-based oxygen carriers have proven sufficiently effective and safe to be close to approval for clinical use. However, the use of large volumes of such products in the setting of severe hemorrhage has not been adequately studied. Furthermore, despite repletion of oxygen-carrying capacity, these products do not restore coagulation components and the lowered viscosity because of loss of cellular elements can further diminish hemostasis at sites of ongoing bleeding. Therefore, the value of oxygen therapeutic agents may be primarily as an "oxygen bridge" until surgical hemostasis can be achieved and normal blood components can be, at least partially, restored.

Hemoglobin-based oxygen carriers have been developed from human hemoglobin (outdated blood units), bovine blood, and recombinant DNA technology. The hemoglobin is free of cellular stroma and must be polymerized or cross-linked to maintain the hemoglobin tetramer intact (two α chains and two β chains) that will adequately carry oxygen and stay within the circulation for a reasonable time. Lack of 2,3-diphosphoglycerate in acellular hemoglobin solution shifts the oxygen dissociation curve toward increased oxygen affinity, which decreases off-loading of oxygen at the tissues. This requires chemical alteration of the oxygen-binding sites to promote effective tissue oxygen delivery. Hemoglobin-based oxygen carriers have been shown to result in significant vasoconstriction. This is a characteristic that must be considered if these products are to be used in the treatment of hemorrhagic shock because blood pressure may be increased disproportionately for the level of intravascular volume replacement. To date, no hemoglobin-based fluid has proven both effective and safe; a multicenter trial of diaspirin cross-linked hemoglobin (DCLHB) for traumatic hemorrhagic shock was prematurely halted when interim analysis found a higher mortality in patients receiving DCLHB. Despite the theoretical attractiveness of such a product, even if a hemoglobin-based solution is proven both effective and safe for human use, the cost of the product may be prohibitively expensive.

Fluorocarbon-based oxygen carriers are emulsions that dissolve respiratory gases in direct proportion to the partial pressure of the respiratory gas (i.e., oxygen). Unlike the S-shaped oxygen dissociation curve of hemoglobin, the relationship for fluorocarbons is linear. Unfortunately, an Fio_2 of greater than 70 percent is required before these fluorocarbons carry physiologically useful concentrations of oxygen. Fluorocarbon emulsions have been studied in laboratory models of hemorrhage, but the toxicity to the reticuloendothelial system from these agents at higher doses and the requirement for sustained levels of Fio_2 limits their potential for use in the setting of severe hemorrhage. Limited replacement of surgical blood loss may be possible with these products, but large volume resuscitation presently appears doubtful.

Assessing Response to Resuscitation

One of the greatest limitations in the early management of hemorrhagic shock is the lack of adequate, easily measurable parameters that accurately reflect the physiologic status of the patient both prior to and during the course of fluid resuscitation. It is widely recognized that arterial blood pressure does not adequately reflect cardiac output or regional hypoperfusion. Clinical evidence of peripheral hypoperfusion is useful in alerting the clinician to ongoing hypoperfusion but is not quantitative. Monitoring modalities noted previously but not commonly used in the emergency department may be useful in the management of acute hemorrhagic shock patients.

Central venous pressure response to fluid administration is useful in assessing volume status. The principle is that if the CVP does not rise after infusion of a quantity of fluid—typically isotonic crystalloid 250 to 500 mL—then the vascular system is still very compliant (on the flat portion of the pressure-volume compliance curve) and is not

"full." If the CVP rises appreciably (>5 to 7 mm Hg) after fluid infusion, then the vascular system has reached the limits of easily distensibility (on the steep portion of the pressure-volume compliance curve) and is therefore "full."

Central venous oxygen saturation (ScvO₂) has been shown to correlate with pulmonary artery mixed venous oxygen saturation (SmvO₂) and central venous catheterization is much more feasible than pulmonary artery catheterization in the ED.¹⁶ Thus, central venous oximetry is an available and useful parameter for assessing global oxygen supply-demand balance. Low ScvO₂ (<50 percent) indicates global hypoperfusion leading to high tissue oxygen extraction in response to inadequate tissue oxygen delivery. However, ScvO₂ may not be sensitive enough to identify regional hypoperfusion (e.g., splanchnic hypoperfusion) unless it is severe or fairly widespread, recognizing that regional and global hypoperfusion are on a continuum.

Simultaneous arterial and central venous blood gases allow for the calculation of systemic oxygen extraction ratio (OER, normally about 25 percent). An elevated OER, especially greater than 50 percent, indicates oxygen supply-demand imbalance consistent with global or significant regional hypoperfusion. The relatively recent availability of arterial pulse contour analysis catheters allows for continuous cardiac output measurement via an arterial line. This, in addition to central venous oximetry, could prove very helpful in assessing the dynamic changes and adjusting therapy during resuscitation. End-tidal CO₂ is predictive of eventual outcome in severely hypoperfused trauma patients, but it is not yet clear how effective this parameter is in assessing patients with lesser degrees of hypoperfusion.¹⁷ Serial assessment of metabolic parameters, especially lactate and base deficit, can be useful in assessing the correction of systemic metabolic acidosis because of hypoperfusion.^{18,19}

All of the monitoring parameters noted above are indicators of global or systemic perfusion status. It would be advantageous to have a means of assessing regional perfusion, especially in the splanchnic circulation, which is particularly vulnerable during hemorrhagic shock caused by compensatory redistribution of blood flow and its potential major role in the subsequent development of multiple organ dysfunction. Gastric intramucosal pH has been suggested as a parameter that reflects splanchnic perfusion. Recently, gastric tissue oxygen saturation, measured using near-infrared spectroscopy, has been reported to rapidly and accurately reflect splanchnic perfusion in a laboratory model of hemorrhagic shock.²⁰ These are promising parameters that might significantly influence clinical decisions in fluid resuscitation.

SEPTIC SHOCK

Jonathan Jui

Sepsis is a heterogeneous clinical syndrome that can be caused by any class of microorganism. Although gram-negative and gram-positive bacteria account for most sepsis cases, fungi, mycobacteria, rickettsia, viruses, or protozoans can cause similar presentations. Microbial blood invasion is not essential to the development of sepsis.

EPIDEMIOLOGY

An extrapolation from hospital discharge data from 1995 in seven U.S. states yielded a national estimate of 751,000 cases of severe sepsis per year, or about 3.0 cases per 1000 population and 2.26 cases per 100 hospital discharges.¹ The rate per hospital discharge agrees with a study from eight academic medical centers that reported an incidence of 2 cases of sepsis per 100 hospital admissions.² Of these cases, 55 percent occurred in the intensive care unit (ICU), 12 percent in the emergency department, and 33 percent in a non-intensive patient care unit. Up to half of sepsis patients develop shock, with an overall mortality rate of about 45 percent, but with a wide range of 20 to 80 percent depending on host age and comorbidities. Clinical studies in patients with bacteremia indicated that gram-positive and gram-negative bacteria are the etiology of the sepsis in 35 to 40 percent and 55 to 60 percent of the episodes, respectively. The most frequent sites of infection are the lungs, abdomen, and the urinary tract. Factors that predispose to gram-negative bacteremia include diabetes mellitus, lymphoproliferative diseases, cirrhosis of the liver, burns, invasive procedures or devices, and chemotherapy. Major gram-positive bacteremia risk factors include vascular catheters, indwelling mechanical devices, burns, and injection drug use. Fungemia most often occurs in immunocompromised patients.

Although there is no reason to suspect that the occurrence of septic shock would differ according to the patient's gender, studies have found a slightly higher incidence of sepsis in men.¹ This slight difference may

SECTION 4 • SHOCK

reflect a higher rate of preceding surgical procedures in men as opposed to women. Sepsis is more common in older adults; the mean age reported is 55 to 60 years. Older patients are more likely to have conditions that predispose to bacterial infection, such as diabetes, surgical procedures, and cancer.

DEFINITIONS AND RISK CATEGORIZATION

In 1991, the American College of Chest Physicians and the Society of Critical Care proposed a set of definitions that could be applied to patients with sepsis and its sequelae (Table 32-1).³ The primary goals of this classification were to provide a conceptual and practical framework of the systemic inflammatory response to infection; to improve the ability of clinicians to make early bedside detection of sepsis, thus allowing early therapeutic intervention; and to standardize the definition which would allow better comparison and analysis of research protocols.

The identification of systemic inflammatory response syndrome (SIRS) does not confirm a diagnosis of infection or sepsis, because the features of SIRS can be seen in many other conditions, such as trauma, pancreatitis, burns, or infection (Figure 32-1). Systemic inflammatory response syndrome is not a diagnosis, nor is it a good indicator of outcome. The SIRS criteria may be considered a crude stratification for patients with systemic inflammation. In a prospective study of the epidemiology of SIRS in medical and surgical patients, mortality rates were 3 percent in patients without SIRS, 6 percent in those with two criteria, 10 percent in those with three positive criteria, and 17 percent in those meeting all four criteria.⁴ Death rates were similar for patients with culture-negative SIRS and those with culture-positive SIRS. A complementary method of classification of sepsis based primarily on physiologic abnormalities such as the Third Acute Physiology and Chronic Health Evaluation acuity system has been developed. Multivariate analysis using initial Acute Physiology and Chronic Health

FIG. 32-1. The interrelationship between systemic inflammatory response syndrome (SIRS), sepsis, and infection. (Reproduced with permission from American College of Chest Physicians/Society of Critical Care Medicine: American College of Chest Physicians/Society of Critical Care Medicine consensus conference: Definitions for sepsis and organ failure and guidelines for the use of innovative therapies in sepsis. *Chest* 101:1644, 1992.)

Evaluation score, etiology of sepsis (urosepsis or other), and treatment location before ICU admission enables the risk of hospital death from sepsis to be predicted.

PATHOPHYSIOLOGY

Sepsis starts as a focus of infection (urinary tract infection, pneumonia, cellulitis, abscess, or indwelling prosthetic device) resulting in blood stream invasion or a proliferation of organisms at the infected site (Figure 32-2). These growing organisms release a large amount of exogenous toxins consisting of endotoxins, exotoxins, and other components of the organism's structural components. The host's reaction to these toxins results in the release of endogenous mediators and activation of other humoral defense mechanisms including complement, kinins, and coagulation factors. Among the most prominent of the endogenous mediators are the cytokines [e.g., tumor necrosis factor (TNF- α) and interleukins (ILs)], platelet-activating factor (PAF), arachidonic acid metabolites, and myocardial depressant substances. Release of myocardial depressant substances results in the depression of myocardial function, dilation of the ventricles, and vasodilation.

Molecular Mediators in the Pathophysiology of Sepsis

Until recently, septic shock and its morbid consequences were attributed to the direct result of endogenous proteins and phospholipid mediators secreted by the infected individual.⁵ However, the evidence of overstimulated immune response to microbial infection in sepsis is not as convincing as originally thought. Although some sepsis conditions, such as meningococemia, have high levels of circulating cytokines that correlate with mortality, generally fewer than 25 percent of patients with sepsis from other organisms have elevated cytokines. Conversely, the presence of elevated cytokines in sepsis correlates with an increased rate of circulatory shock and overall mortality. Cytokine pathophysiology of sepsis can be divided into three phases: induction, cytokine synthesis and secretion, and cascade.

The induction of cytokines involves the interaction of certain microbial molecules that, when recognized by the host, results in the production of mediators that amplify and transmit the microbial signal to

TABLE 32-1 Definitions

Infection = microbial phenomenon characterized by an inflammatory response to the presence of microorganisms or the invasion of normally sterile host tissue by those organisms.

Bacteremia = the presence of viable bacteria in the blood.

Systemic inflammatory response syndrome = the systemic inflammatory response to a variety of severe clinical insults. The response is manifested by two or more of the following conditions: (1) temperature $>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$; (2) heart rate >90 beats/min; (3) respiratory rate >20 breaths/min or $\text{Paco}_2 <32$ mm Hg; and (4) white blood cell count $>12,000/\text{JL}$, $<4000/\text{JL}$, or $>10\%$ immature (band) forms.

Sepsis = the systemic response to infection, manifested by two or more of the following conditions as a result of infection: (1) temperature $>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$; (2) heart rate >90 beats/min; (3) respiratory rate >20 breaths/min or $\text{Paco}_2 <32$ mm Hg; and (4) white blood cell count $>12,000/\text{xL}$, $<4000/\text{xL}$, or $>10\%$ immature (band) forms.

Severe sepsis = sepsis associated with organ dysfunction, hypoperfusion, or hypotension. Hypoperfusion and perfusion abnormalities may include, but are not limited to lactic acidosis, oliguria, or an acute alteration in mental status.

Septic shock = sepsis-induced hypotension despite adequate fluid resuscitation along with the presence of perfusion abnormalities that may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status. Patients who are receiving inotropic or vasopressor agents may not be hypotensive at the time that perfusion abnormalities are measured.

Sepsis-induced hypotension = a systolic blood pressure <90 mm Hg or a reduction of >40 mm Hg from baseline in the absence of other causes for hypotension.

Multiple organ dysfunction syndrome = presence of altered organ function in an acutely ill patient such that homeostasis cannot be maintained without intervention.

Abbreviation: Paco_2 = arterial partial pressure of carbon dioxide.

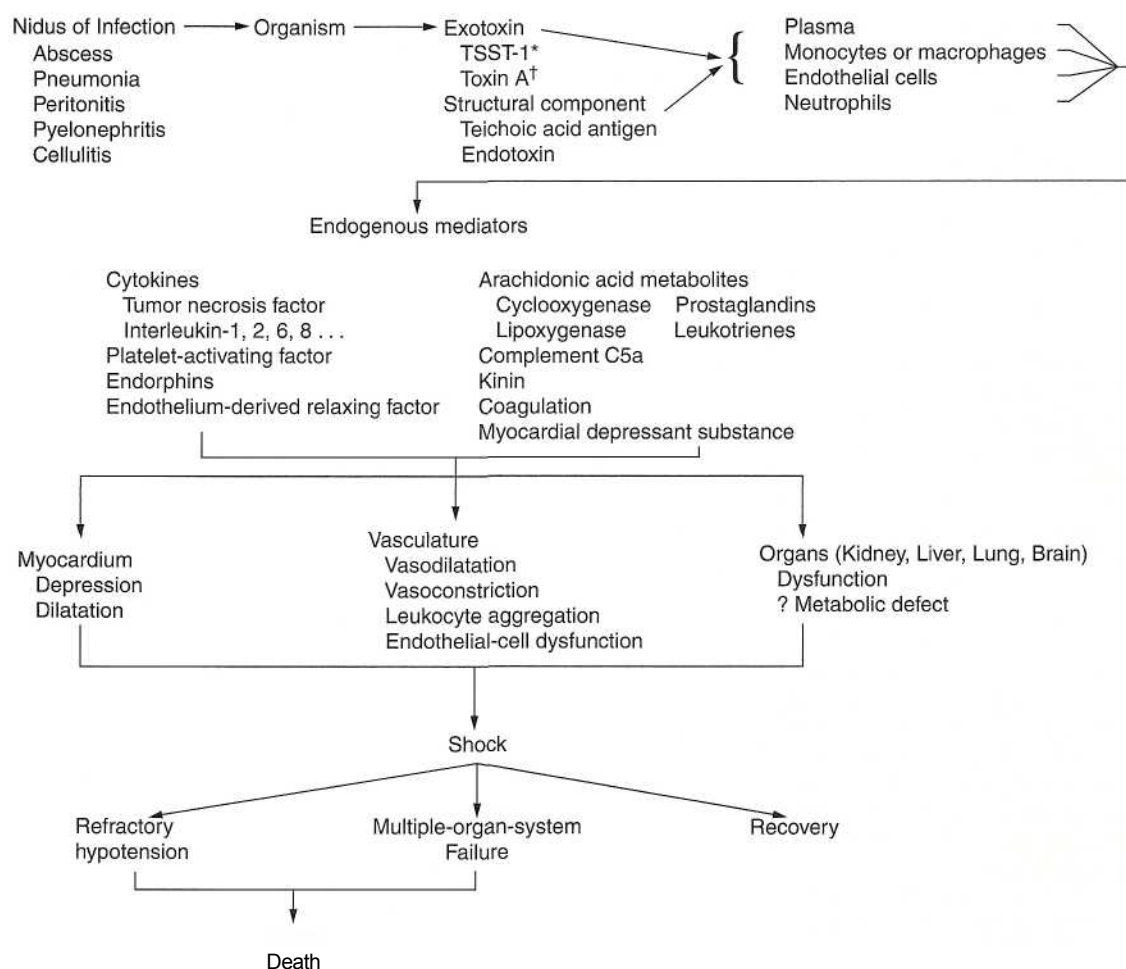

FIG. 32-2. Pathogenic sequence of the events in septic shock. *TSST-1 = toxic shock syndrome toxin 1; †(Toxin A = *Pseudomonas aeruginosa* toxin A).

other cells and tissues. For example, in a gram-negative infection, the host is not only exposed to membrane bound lipopolysaccharides (LPSs) at the site of infection but also is systemically exposed to the free endotoxin on fragments of bacterial outer membrane commonly shed during bacterial growth and replication. Lipopolysaccharide binds to LPS-binding protein, forming an LPS-LPS-binding protein complex. This complex is 1000-fold more potent than LPS alone in inducing TNF- α production by macrophages. The receptor for this complex is the CD 14 molecule that is found on monocytes, macrophages, and neutrophils. The peptidoglycan and lipoteichoic acids of gram-positive bacteria, certain polysaccharides, extracellular enzymes, and toxins induce cytokine synthesis in manner similar to LPS.

Cytokine synthesis and secretion involves several regulated steps: (1) transcription (synthesis of messenger RNA from the DNA template), (2) translation of mRNA into protein, (3) post-translational processing, and (4) secretion of protein. For example, when the LPS-LPS-binding protein complex interacts with the CD 14 receptor in vitro, transcription of the TNF gene increases threefold, with levels of TNF mRNA increasing 100-fold. Biosynthesis and secretion of TNF- α , however, increase over 10,000-fold, primarily due to increased translational efficiency of preformed TNF mRNA and efficient translation of newly transcribed TNF mRNA.

The cytokine cascade in sepsis results from the activation and release of a central mediator (TNF- α , IL-1), which results in the secretion of various secondary mediators (IL-6, IL-8, PAF, prostaglandins, and leukotrienes); the activation of neutrophils, the complement system, and vascular endothelial cells; and synthesis of acute phase reactants. Lipopolysaccharide and TNF- α probably pro-

mote intravascular coagulation initially by inducing blood monocytes to express tissue factor, by initiating the release of plasminogen activator inhibitor type 1, and inhibiting the expression of thrombomodulin and plasminogen activator by vascular endothelial cells. The physiologic outcome of this complex cascade produces the physiologic changes recognized as the SIRS.

Parallel to SIRS is the body's intrinsic anti-inflammatory response. This response, termed the *compensatory anti-inflammatory response syndrome* (CARS), attempts to down-regulate the SIRS response. Agents identified as participating in CARS include interleukins (IL-4, IL-10), transforming growth factor (3, colony-stimulating factor, soluble receptors to tumor necrosis factor, and antagonists to TNF- α and IL-1 receptors. These mediators inhibit T- and B-lymphocyte activities and decrease antigen-presenting activity on the monocyte. The body normally maintains a delicate balance between SIRS and CARS. Uncontrolled SIRS leads to profound hypotension, inadequate perfusion, and death. If the CARS reaction is severe, it will manifest clinically as anergy and increase susceptibility to infection.

Vasoactive Mediators in the Pathophysiology of Sepsis

One of the most important of the vasoactive mediators is nitric oxide. Nitric oxide is a low-molecular-weight membrane-permeable gas with harmful and beneficial effects in shock. Under normal conditions, this gas is produced in the endothelium by a calcium- and calmodulin-dependent nitric oxide synthase (NOS), which converts L-arginine and O₂ to L-citrulline and nitric oxide. This pathway is normally well regulated by signal transduction pathways linked to cell-surface receptors

SECTION 4 • SHOCK

for vasodilators such as acetylcholine and histamine. However, inflammatory mediators induce a calcium-independent form of NOS that is not controlled by this mechanism. This form may rise to abnormal amounts of nitric oxide in septic patients and patients given IL-2 for cancer treatment.

Three distinct NOS enzyme complexes have been described. The first, neuronal NOS, is found in central nervous system cells and is thought to support a neurotransmitter function. The second, constitutive NOS, is found in endothelial cells and is thought to play a role in the maintenance of normal vascular tone. The third, a high-output inducible NOS (iNOS), is found in many cell types, including endothelial cells, vascular smooth muscle cells, and macrophages.

Nitric oxide actions include functioning as a neurotransmitter, regulating vascular tone, and inhibiting platelet aggregation and leukocyte adhesion. At higher doses, nitric oxide has antitumor and antimicrobial activities thought to have a beneficial role in sepsis. Nitric oxide is important in maintaining visceral and microvascular blood flow by acting as a counter-regulatory mechanism to the vasoconstriction mediators (thromboxane and endothelin 1) released in inflammation. Nitric oxide is thought to be an important free radical scavenger that prevents microvascular stasis and thrombosis by blocking platelet aggregation and leukocyte adhesion.

However, excess or sustained levels of nitric oxide may have several harmful effects in sepsis. Nitric oxide has been implicated as a major mediator for vasodilation and hypotension in septic shock. Inflammatory mediators, including TNF- α and IL-1, stimulate iNOS. Once induced, iNOS is likely to persist for many hours to days. Peroxynitrite, which is formed from the reaction between superoxide radicals and nitric oxide, may cause direct cellular injury. Nitric oxide also may contribute to the myocardial depression and increased permeability seen in septic shock.

CLINICAL FEATURES

Constitutional

Hyperthermia or hypothermia, tachycardia, wide pulse pressure, tachypnea, and mental status changes are early systemic signs of infection and septic shock. Endotoxin, TNF- α , IL-1, and interferon- α have been shown to elicit febrile responses in humans. Acute hyperventilation with respiratory alkalosis (arterial partial pressure of carbon dioxide <30 mm Hg) is common in sepsis. The etiological mechanism of this tachypnea is thought to be due to the direct effects of endotoxins or secondary to kallikreins, bradykinin, prostaglandins, or complement activation.

The most frequent mental status change in sepsis is mental obtundation. The neurologic findings are nonfocal and range from mild disorientation to confusion, lethargy, agitation, and coma. The pathophysiology is still unknown; an altered state of amino acid metabolism producing a state similar to portosystemic encephalopathy or decreased cerebral blood flow with secondary disruption of the blood-brain barrier are proposed mechanisms.

Cardiovascular

In the early stages of septic shock, the vasodilatory mediators predominate, and patients present with warm extremities. Cardiac output and stroke volume are usually well maintained. Frequently, cardiac output is increased concomitantly with tachycardia. Hemodynamic measurements during the first 24 h show that the characteristic pattern of septic shock consists of an initial decrease in left and right ventricular ejection fractions, with an increase in end-diastolic and end-systolic volume indices, normal stroke volume, and decreased peripheral vascular resistance. In survivors, the changes are reversible, and the ventricular function and size return to normal by 7 to 10 days

after septic shock onset. Patients with septic shock have been shown to have markedly diminished cardiac response to volume administration, with only minor increments in end-diastolic volume index and left ventricular stroke work index.

Myocardial depression is present in early septic shock. The hypothesis that coronary hypoperfusion with secondary ischemic myocardial dysfunction is the cause of the myocardial depression is not supported by studies showing that the perfusion of the coronary arteries in patients with septic shock are equal to or greater than that in controls. Significant evidence points toward the existence of several active circulating myocardial depressant substances.

Substances that have demonstrated myocardial depressant activity include TNF- α (when IL-1 p is present), nitric oxide, PAF, oxygen free radicals, interferon-7, and arachidonic acid metabolites. The compounds that have received the most scrutiny are the combination of TNF- α , IL-1p, and nitric oxide. Tumor necrosis factor α , in the presence of IL-1 (3), has been shown to produce significant myocardial depression in vitro. Another major contributor to the prolonged myocardial depression is the stimulation of constitutive NOS and the induction of iNOS in myocytes by TNF- α , IL-1, possibly IL-2, and activated macrophages. Constitutive NOS appears to be involved in the physiologic regulation of myocardial contractility through the interaction between endothelial cells and cardiac myocytes. The inflammatory stimulus of sepsis is sustained at higher capacity through iNOS, which is responsible for a large portion of the prolonged myocardial depression in sepsis.

Pulmonary

Sepsis remains the most common condition associated with adult respiratory distress syndrome (ARDS). Adult respiratory distress syndrome is a physiologic syndrome characterized acutely by lung edema resulting from increased alveolar and capillary permeability resulting from global microcirculatory injury. In trauma and sepsis, this microvascular injury affects capillary beds throughout the body concurrently. The lung is a conspicuous organ, because, when increased microvascular permeability develops in the lung, alveolar flooding occurs, causing dyspnea, hypoxemia, and abnormal opacities on chest radiographs. The appearance of ARDS varies from minutes to hours after the onset of sepsis. Although there are no specific and sensitive markers for ARDS, diagnostic criteria for ARDS include bilateral pulmonary infiltrates, pulmonary artery occlusion pressure (PAOP or "wedge" pressure) below 18 mm Hg, a ratio of arterial to alveolar partial pressure of oxygen less than 0.2, and static airway compliance of less than 40 mL/cm H₂O. Clinically, severe refractory hypoxemia, noncompliant "heavy" lungs, and a chest radiograph showing bilateral pulmonary alveolar infiltrates should suggest the presence of ARDS. The hypoxemia is due to perfusion of the underventilated alveoli; right-to-left shunting has been reported as high as 30 to 50 percent in this syndrome. Pathogenic factors implicated in the global microcirculatory injury are endotoxin, TNF- α , IL-1, IL-6, IL-8, and bacteriocidal/permeability-increasing (BPI) protein.

Renal

Renal manifestations of septic shock include acute renal failure (ARF) with azotemia, oliguria, and active urinary sediment. Factors associated with the development of ARF in septic shock include hypotension, dehydration, aminoglycoside administration, and pigmenturia. Within the kidney, vasoconstrictive and vasodilator mediators are generated, and their balance dictates renal hemodynamics. Renal ischemic injury from hypoperfusion is considered to be a major factor in the pathogenesis of ARF in sepsis. Toxic products resulting from neutrophil-endothelial interactions, endothelial damage by various mediators, reperfusion injury, and microvascular thrombosis in the kidney also contribute to renal dysfunction. In patients without shock, infection may produce renal insufficiency as a consequence of

glomerulonephritis or interstitial nephritis. Glomerular disease in the setting of sepsis has been reported in subacute bacterial endocarditis, pyogenic visceral abscesses, and other non-renal distant infections. Urine sediment in glomerular disease contains red blood cells, casts (red, white, or pigmented), and protein. Renal biopsy usually shows proliferative changes. Immune complex deposition with glomerular deposits of immunoglobulin G (IgG), IgM, C3, bacterial antigens, and antibodies to these antigens has been reported. Tubulointerstitial disease has been associated with *Streptococcus pneumoniae*, *Staphylococcus pyogenes*, *Legionella pneumophila*, salmonellosis, brucellosis, and diphtheria infections. Acute interstitial nephritis secondary to allergic reaction from antibiotics (most commonly methicillin) usually produces eosinophilia and eosinophiluria.

Hepatic

Liver dysfunction is frequently seen in patients with sepsis; the most frequent abnormality is cholestatic jaundice. Increases in transaminase, alkaline phosphatase (one to three times normal), and bilirubin concentrations (usually not > 10 mg/dL) are frequently noted. The proposed mechanism for bilirubin elevation involves hemolysis of red blood cells and hepatocellular dysfunction due to endotoxin, cytokines, or immune complex disease. Prolonged or severe hypotension may induce acute hepatic injury or ischemic bowel necrosis.

Hematologic

Major blood loss secondary to upper gastrointestinal bleeding occurs in only a small percentage of patients with sepsis. However, minor blood loss within 24 h of developing a severe infection is common as patients develop painless 1- to 2-mm erosions in the mucosal layer of the stomach and/or duodenum. Proposed mechanisms for these ulcerations include decrease in the blood flow, hypoxia of the mucosal cells, interruption of the gastric mucosal barrier, and release of mucosal lysozyme.

The most frequent hematologic changes in the septic patient are neutropenia or neutrophilia, thrombocytopenia, and disseminated intravascular coagulation (DIC). Sepsis most frequently produces a neutrophilic leukocytosis with a "left shift." These early changes result from demargination and release of less mature granulocytes from the marrow storage pools. One proposed mechanism for demargination and bone marrow release is the presence of endotoxin or other similar substances and activation by complement (C3a) causing the release of a neutrophil-releasing substance. The sustained neutrophilia that accompanies chronic infection is thought to be secondary to colony-stimulating factors. These glycoproteins increase granulocyte production by activating committed stem cells. Infection increases the colony-stimulating factor elaboration by macrophages, lymphocytes, and other tissues. In certain cases of sepsis, leukemoid reactions with leukocyte counts of 50,000 to 100,000/ μ L have been reported.

Neutropenia, occurring rarely, is associated with an increase in mortality. The etiology of this neutropenia includes increased peripheral use of neutrophils, damage to neutrophils by bacterial byproducts, or depression of marrow granulocyte production by inflammatory mediators. Morphologic and functional changes to neutrophils have been reported in sepsis. The most commonly reported morphologic changes include the presence of toxic granulations, Dohle bodies, and vacuolization. Functional changes reported in sepsis include increased phagocytic and cytotoxic activities. Eosinophilia occurring in the presence of sepsis has been attributed to the effect of margination or migration of these cells from the vascular space.

Red cell number and morphologic characteristics are not usually affected by sepsis. However, red cell production and survival are decreased during sepsis. Decreased production and survival usually do not cause anemia unless the infection is prolonged. Septic patients generally possess low serum iron concentrations. Sepsis and its intermediaries cause a rapid iron flux into the liver and other parts of the

reticuloendothelial cells, with the serum iron concentration decreasing by 50 percent or more within a period of hours, and this effect may last days. An attractive hypothesis is that this represents a host defense mechanism, because the addition of iron to normal human serum enhances the growth of organisms, and iron in the reticuloendothelial system may be beneficial to the host cells in detoxifying bacterial activity.

Thrombocytopenia frequently arises as a consequence of DIC, although isolated thrombocytopenia is present in more than 30 percent of cases of sepsis. Thrombocytopenia may be an early clue to bacteremia and may be useful in observing patient's response to therapy. The proposed mechanisms for the thrombocytopenia include inhibition of thrombopoiesis, increased platelet turnover, increased endothelial adherence, and increased destruction secondary to immunologic mechanisms.

Disseminated intravascular coagulation is a condition in which the clotting and fibrinolytic systems are systemically activated, leading to the consumption of many coagulation factors and platelets. Disseminated intravascular coagulation, with disseminated fibrin deposition in the microcirculation of various organ systems, is a frequent finding in patients with septic shock. The activation of the hemostatic (clotting) system is due primarily to the activation of the extrinsic pathway of clotting. This cascade is triggered by multiple sources, including bacteria (gram-negative and gram-positive), viruses, fungi, endotoxins, and exotoxins (see Figure 32-2). Gram-negative infections precipitate DIC more readily than does gram-positive infections. The fibrinolytic system is also activated in sepsis and plays an important role in limiting fibrin deposition in the microcirculation. Studies of septic patients have demonstrated the release of tissue type plasminogen activator, which activates the fibrinolytic system, at least initially in sepsis. As sepsis progresses, there is an increased release of plasminogen activator inhibitor type 1, which blocks plasmin generation and thus contributes to fibrin deposition in the microcirculation and subsequent multiple-organ failure.

Disseminated intravascular coagulation can be categorized into two forms. The compensated form of DIC is characterized by a "slower" generalized activation of the hemostatic system. Although platelets and coagulation factors are consumed more rapidly than normal, bleeding is prevented by increasing coagulation factor production in the liver, by the release of the platelets from reserve storage sites, and by the synthesis of inhibitors at an accelerated rate. Patients with decompensated DIC will have clinical bleeding and/or thrombosis. Laboratory studies suggesting the presence of DIC include thrombocytopenia, prolonged prothrombin and activated partial thromboplastin values, decreased fibrinogen and antithrombin (AT) III levels, and increased fibrin monomer, fibrin split products, and D-dimer levels.

Endocrine

Hyperglycemia may be seen in septic patients, even without a history of diabetes. Proposed pathogeneses include increased amounts of catecholamines, increased cortisol and glucagon in the circulation, peripheral insulin resistance, impaired glucose use, and decreased insulin secretion. Uncontrolled hyperglycemia is a significant risk for adverse outcome.⁶ Hypoglycemia with glucose levels as low as 10 to 20 mg/dL has been reported but is a relatively uncommon manifestation of sepsis. Bacterial infections associated with hypoglycemia include *S. aureus*, *S. pyogenes*, *S. pneumoniae*, *Listeria monocytogenes*, *Haemophilus influenzae*, *Neisseria meningitidis*, and *Enterobacteriaceae*. The proposed pathogenesis of hypoglycemia includes the depletion of hepatic glycogen and inhibition of gluconeogenesis.

Acid-Base

Blood gas analysis performed early in the course of septic shock usually finds respiratory alkalosis. Relative or absolute hypoxemia is often

SECTION 4 • SHOCK

present due to ventilation perfusion mismatches. The development of metabolic acidosis reflects inadequate tissue perfusion, increased glycolysis in peripheral tissues, and impaired hepatic clearance of lactate and pyruvate. As perfusion worsens and continues, tissue hypoxia generates more lactic acid and metabolic acidosis worsens.

Cutaneous

Cutaneous lesions that occur as a result of sepsis can be divided into three categories: direct bacterial involvement of the skin and underlying soft tissues (cellulitis, erysipelas, and fasciitis); lesions that occur as a consequence of sepsis, hypotension, and/or DIC (acrocyanosis and necrosis of peripheral tissues); and lesions secondary to intravascular infections (microemboli and/or immune complex vasculitis).

DIAGNOSIS

Septic shock should be suspected in any individual with a temperature above 38°C or below 36°C and a systolic blood pressure below 90 mm Hg with evidence of inadequate organ perfusion. The hypotension should not reverse with rapid volume replacement of at least 1 L of isotonic crystalloid. Frequently, the diagnosis is straightforward, with the patient presenting with hypotension, inadequate perfusion, and complaints attributable to a serious infection such as pneumonia, acute pyelonephritis, or an acute peritonitis. Other early clinical features of sepsis include mental obtundation; hyperventilation; hot, flushed skin; and a widened pulse pressure. In the elderly, very young, or immunocompromised patient, the clinical presentation may be atypical, with no fever or localized source of infection.

The differential diagnosis of septic shock includes the other non-septic causes of shock such as cardiogenic, hypovolemic, anaphylactic, neurogenic, obstructive (pulmonary embolism, tamponade), and endocrine (adrenal insufficiency, thyroid storm) causes.

History and physical examination with some basic laboratory or radiologic investigations are usually successful in the initial assessment and identification of a presumptive source of sepsis. Particular attention should be focused on infections in these organ systems: central nervous system, pulmonary, intra-abdominal, urinary tract, skin, and soft tissue.

Acute bacterial meningitis is the central nervous system infection most commonly associated with shock. Community-acquired meningitis with shock is usually due to *S. pneumoniae* or *N. meningitidis*. Most patients present with nuchal rigidity and a depressed level of consciousness. Chest radiographs may show pneumonia with secondary bacteremia due to *S. pneumoniae*. Disseminated meningococcemia may present only with shock without meningismus. Frequently, these patients possess a "new petechial rash," which is the major clue to the etiology of shock. Brain abscesses, subdural or epidural empyemas, and viral central nervous system infections are seldom associated with shock on the initial presentation. Shock is also unusual in neurosurgical patients with *S. aureus* or enteric gram-negative meningitis secondary to neurosurgical procedure or skull fracture.

The major pulmonary entity commonly leading to septic shock is acute bacterial pneumonia. The most frequent organisms are *S. pneumoniae*, *S. aureus*, gram-negative bacilli, and *L. pneumophila*. The physical examination and chest radiograph almost always indicates the presence of pneumonia.

Intra-abdominal processes are the source of infection leading to septic shock in the largest proportion of patients. Acute pancreatitis with or without infection can result in a presentation identical to septic shock. Suppurative cholangitis and empyema of the gallbladder are the primary considerations for the biliary tree. In women of childbearing age, septic abortion and postpartum endometritis or myometritis are the dominating presenting infections leading to septic shock. Acute pyelonephritis secondary to gram-negative enteric bacteria or enterococci occasionally can present with shock. Ureteric obstruction is often present in these syndromes.

The most common skin and soft tissue infection associated with septic shock is cellulitis due to *S. aureus* or *S. pyogenes*. Soft tissue infections secondary to gram-negative organisms are indistinguishable from those due to primary infection by staphylococci or streptococci. Shock associated with soft tissue infections is frequently associated with bacteremia. Shock associated with a generalized erythematous macular rash may represent toxic shock syndrome. Necrotizing soft tissue infections are usually seen in immunocompromised patients, diabetics, or in patients with history of poor vascular circulation.

Individuals without obvious source of septic shock may have a primary bacteremia, or endocarditis. The most prevalent etiologies of primary bacteremias in outpatients are *S. aureus*, *S. pneumoniae*, and *N. meningitidis*. Encapsulated species such as *Salmonella* or *H. influenzae* are important pathogens in individuals who are asplenic. *Pseudomonas aeruginosa* and other gram-negative bacteria are occasional etiologies of bacteremia and endocarditis in injection drug users.

Ancillary Studies

Although there is no specific laboratory test for the diagnosis of septic shock, tests are useful because they (1) assess the general hematologic and metabolic state of the patient, (2) provide results that suggest the potential for occult bacterial infection, and (3) detect a specific microbial etiology for infection. Basic laboratory studies should include a complete blood count including platelet count; DIC panel (prothrombin time, activated partial thromboplastin time, fibrinogen, D-dimer, ATIII concentration); serum electrolytes (including magnesium, calcium, phosphate, and glucose); liver function panel (bilirubin, alkaline phosphate, and alanine aminotransferase); renal function panel (blood urea nitrogen and creatinine); arterial blood gas analysis; and urinalysis. Blood should be typed and crossed if low hematocrit is suspected. A chest radiograph should be part of the basic evaluation. Flat and upright abdominal films are helpful in patients in whom there is a potential abdominal source of infection and should be considered in every patient except individuals with a completely benign abdomen or an obvious alternate source. Any patient with a clinical presentation compatible with meningitis should undergo a lumbar puncture with cerebrospinal fluid collected for analysis without delay in the emergency department. In individuals with papilledema, focal neurologic deficits, or the potential for brain abscess or epidural or subdural empyema, the lumbar puncture should be deferred until an imaging study is performed. However, if meningitis is an important consideration, empiric antimicrobial therapy should be initiated prior to the imaging study.

Bacterial cultures of blood and urine should be obtained from all septic patients. At least two separate sets of blood cultures from different venipuncture sites should be obtained. Gram stain and culture of secretions from any potential site of infection should be performed. Gram stain and other means of rapid identification of microbial etiologies are generally the only immediately available tests useful in selection of antimicrobial therapy.

Laboratory markers of sepsis are subjects of intense interest. Only a few candidates with clinical utility are currently available: C-reactive protein, lactate, pro-calcitonin, and semiquantitative IL-6 levels.^{7,8} Comparisons of C-reactive protein and pro-calcitonin in the same patients have shown that pro-calcitonin has greater sensitivity, specificity, overall accuracy, and better predictive power in sepsis and septic shock than does C-reactive protein.^{9,10}

STANDARD TREATMENT

Airway and Respiratory Management

Immediate assessment of oxygenation and ventilation status is the first priority in the management. Oxygen by mask and consideration of endotracheal intubation should be done immediately if the patient's air-

way is not secure or if respirations are inadequate. In addition, patients with hypotension not responding acutely to rapid fluid resuscitation should be intubated to avoid respiratory arrest from fatigue of the respiratory muscles due to inadequate perfusion of these muscles. There is no consensus concerning acceptable levels of oxygen saturation or tensions; however, most experts recommend maintaining oxygen saturations above 90 percent in a septic patient.

Hemodynamic Stabilization

FLUID ADMINISTRATION Correction or stabilization of hypotension and inadequate perfusion is the second goal of resuscitation." Rapid fluid administration at a rate of 0.5 L (10 mL/kg in children) of normal saline or similar isotonic crystalloid should be administered every 5 to 10 min, as needed; it is not unusual for the patient to require 4 to 6 L (60 mL/kg in children) or more of crystalloid in the initial phase of resuscitation. Stabilization of the patient's mentation, blood pressure, respiration, pulse rate, skin perfusion, and central venous pressure, with urine output greater than 30 mL per h (1 mL/kg per h in pediatric patients) are useful clinical parameters in monitoring the response to fluid administration.

INOTROPIC SUPPORT If no response to the fluid infusion is noted after 3 to 4 L of fluid, or if there are signs of fluid overload (elevated central venous pressure or pulmonary edema), an infusion of dopamine can be started.¹¹ If the patient has a pulmonary artery catheter in place during this resuscitation, dopamine should be added in the setting of a PAOP of 15 to 18 mm Hg or if there are marked increases of the PAOP with additional fluids. Doses of dopamine often required are 5 to 20 μ g/kg per min, resulting in β_1 -adrenergic inotropic and α -adrenergic vasopressor activities. If the patient does not adequately respond to a rate of 20 μ g/kg per min, norepinephrine should be started with the goal of keeping the mean blood pressure at least at 60 mm Hg. Once the blood pressure and perfusion have been stabilized by norepinephrine, the lowest dosage that maintains blood pressure should be used to minimize the complications of vasoconstriction. In addition, data from the canine model have suggested that the use of low-dose dopamine or dobutamine (1 to 4 μ g/kg per min) in patients on norepinephrine results in significantly higher renal blood flow and reduced renal vascular resistance. The effect of norepinephrine on survival from septic shock is debatable, but survival rates of up to 40 percent have been reported.

Vasodilators are rarely used in the emergency department, but they have been used in the ICUs in situations of severe myocardial depression, increased system vascular resistance, and adequate blood pressure. Several investigators have published the results of short-term vasopressin infusion (0.04 units/min for 4 to 16 h) in patients with vasodilatory septic shock. Although the numbers of patients were small, all studies to date have suggested a beneficial response of vasopressin with a decreased catecholamine requirement and increase in urine output.^{12,14}

HEMODYNAMIC END POINTS There is good evidence for hemodynamic goal-directed therapy in sepsis and septic shock.¹⁵ Rivers and associates used a standardized protocol for fluid resuscitation, vasopressors, inotropes, mechanical ventilation, maintenance of central venous pressure between 8 and 12 mm Hg, hematocrit of 30 percent, and central venous oxygen saturation of at least 70 percent in 130 patients with severe sepsis and septic shock. They found a reduction in hospital mortality from 44% in the control group to 29% in the intervention group [absolute reduction 15%; 95% CI 3.6 to 26.6%].¹⁵ They concluded that early goal-directed therapy initiated in the emergency department provides significant benefit and improves outcome in patients with severe sepsis and septic shock.

Empiric Antimicrobial Therapy

All patients with septic shock should receive empiric antimicrobial therapy as soon as possible. Whenever possible, samples of blood or fluids from potential sites of infection should be obtained before the initiation of antimicrobial therapy. Selection of antibiotics should be based on the adequate coverage of potential pathogens from the potential infection sites and the anticipated antimicrobial susceptibility patterns of the bacterial isolate(s). Survival in septic shock correlates with the initial administration of antibiotics effective against the infecting organism (Table 32-2). In general, empiric therapy should be effective against gram-positive organisms (*Streptococcus* spp. and *Staphylococcus* spp.) and gram-negative bacteria. The route of administration should be intravenous in the maximum doses allowed.

Removal of Source of Infection

If a focal source of sepsis is identified, removal of the nidus of infection is absolutely mandatory for successful treatment. Indwelling intravenous catheters should be removed, and the tips should be sent for quantitative culture. Urinary drainage catheters should be replaced if obstructed. Intra-abdominal or soft tissue sites of pus require urgent drainage.

Initial Baseline Assessment

Hemodynamic and laboratory monitoring is critical to the resuscitation of a patient in septic shock. Some clinicians advocate following the serum lactate as a monitor of response to therapy. Arterial blood gas should be obtained to monitor adequacy of ventilation and perfusion. Septic shock patients should have at least two large-bore intravenous catheters for administration of fluids and vasoactive drugs. Early placement of a central venous catheter (ideally with a 8.5-French catheter introducer) may help in the monitoring of fluid resuscitation. Placement of a flow-directed thermal-dilution pulmonary artery catheter should be considered in patients requiring vasoactive therapy, in whom there is difficulty in assessing volume status, or ongoing hemodynamic instability is present. In general, the placement of this catheter can wait until the patient is in the ICU.

There are several noninvasive methods of patient monitoring for use in severe sepsis and septic shock: sublingual capnography, gastric pH tonometry, muscle oximetry, and bioimpedance determination of cardiac output. Other techniques, such as near-infrared spectroscopy and transcranial Doppler measurement to assess intracerebral oxygenation and evaluation of blood flow velocities in some cerebral arteries, are the current research tools.

NEW INNOVATIVE THERAPIES

Advances in molecular biology and immunology suggest that the host's inflammatory response to infection contributes to the development of severe sepsis and septic shock. Despite aggressive hemodynamic support, broad-spectrum potent antibiotics, and surgical treatment, the mortality rate of septic shock remains high. The development of new interventions is based on the premise that neutralizing bacterial toxins, cytokines, and other mediators could stop or slow this syndrome (Table 32-3).⁵

Currently, only a few randomized controlled trials have shown efficacy of these innovative therapies in the treatment of septic shock in humans. In the cases of interventions directed at endogenous cytokines, none of the studies has produced unequivocal benefit in the treatment of sepsis. Great potential danger exists in altering the natural balance of inflammatory mediators. These mediators perform important functions, such as clearing bacterial toxins and the mobilization of the host defenses that control the infection. Attempting to block the harmful effect of inflammatory mediators may compromise host

TABLE 32-2 Empiric Antibiotic Selection in Severe Sepsis and Septic Shock

Host	Potential Pathogens	Initial Antibiotic Selection
Neonates <1 wk	Group B streptococci <i>Escherichia coli</i> , <i>Klebsiella</i> , <i>Enterobacter</i>	Ampicillin plus cefotaxime
Neonates 1–4 wk	Group B streptococci <i>E. coli</i> , <i>Klebsiella</i> , <i>Enterobacter</i> , <i>Haemophilus influenzae</i> , <i>S. epidermidis</i>	Ampicillin plus cefotaxime Ampicillin plus ceftriaxone
Infants 1–3 mo	<i>E. coli</i> , <i>Klebsiella</i> , <i>Enterobacter</i> , <i>H. influenzae</i> , <i>Streptococcus pneumoniae</i> , <i>Neisseria meningitidis</i>	Cefotaxime Ceftriaxone
Children (non-neutropenic) >3 mo	<i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>H. influenzae</i> , <i>Staphylococcus aureus</i>	Cefotaxime Ceftriaxone Cefuroxime
Adults (non-neutropenic) without an obvious source of infection	Gram-negative bacilli, as shown Gram-positive cocci	Antipseudomonal penicillin/β-lactamase inhibitor (e.g., piperacillin/tazobactam) plus Third-generation cephalosporin (e.g., cefotaxime) Some experts advise the addition of an aminoglycoside (tobramycin, gentamicin, or amikacin) Alternatively, imipenem or meropenem alone is acceptable
Neutropenic children and adults	Gram-negative bacilli, especially <i>Pseudomonas aeruginosa</i> <i>S. aureus</i>	Cefepime, imipenem, or meropenem alone Antipseudomonal aminoglycoside (e.g., gentamicin) plus ceftazidime Antipseudomonal aminoglycoside (e.g., gentamicin) plus antipseudomonal penicillin/β-lactamase inhibitor (e.g., piperacillin/tazobactam)
Patients with history of injection drug use	<i>S. aureus</i>	Nafcillin or vancomycin (if MRSA is suspected) should be added to the regimen
Anaerobic source is suspected: intra-abdominal, biliary, female genital tract, necrotizing cellulitis, odontogenic infection, or an anaerobic soft tissue infection	Anaerobic bacteria plus gram-negative bacilli	Metronidazole or clindamycin should be added to the regimen
Patients with indwelling vascular devices	Coagulase-negative staphylococcus	Vancomycin should be added to the regimen
Potential for <i>Legionella</i> species infection		Azithromycin or erythromycin should be added to the regimen
Asplenic patients	<i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>H. influenzae</i> , <i>Capnocytophaga</i>	Cefotaxime Ceftriaxone

Abbreviation: MRSA = Methicil I in-resistant *S. aureus*.

defenses and ultimately worsen the outcome.⁵ Successful therapeutic approaches may depend on determining which inflammatory mediators should be inhibited or augmented and when to do so. In almost all the animal models, anti-endotoxin therapy is effective only if given before or simultaneously with endotoxin challenge. Thus, it is very unlikely that anti-endotoxin treatment alone will change outcome in patients in shock and with organ failure. The situations in which these agents may be the most effective are those in which the patients are in early gram-negative sepsis or as a prophylaxis for high-risk patients.

Coagulation Modulation Therapy

The management of DIC has three basic approaches: elimination of the underlying disorder or source of infection, replacement of coagulation constituents lost in the clotting process, and arrest of the intravascular clotting process. If the patient is actively bleeding and decompensated DIC is present, urgent replacement of coagulation factors and platelets is indicated with the rapid infusion of fresh frozen plasma and/or platelets. Reasonable guidelines in the actively bleeding patient with DIC include the transfusion of platelets to maintain a concentration of 50,000/ μ L and cryoprecipitate and fresh frozen plasma to keep the coagulation parameters (fibrinogen, prothrombin time, and activated thromboplastin time) close to normal.

Interruption of the activated hemostatic system has been attempted by the use of heparin, primarily outside the United States, with mixed results. Currently, no conclusive evidence is available to suggest that heparin therapy reduces morbidity or mortality in septic patients with DIC. Inhibitors of systemic fibrinolysis, such as ε-aminocaproic acid, have been advocated in DIC without clear evidence of benefit.

Several procoagulation mechanisms have been associated with decreased survival in patients with sepsis, including elevated levels of plasminogen activator inhibitor type 1 and decreased levels of anti-thrombin III and protein C.

Activated protein C inhibits factors Va and Vila, activates fibrinolysis, inhibits thrombin production, and has additional anti-inflammatory effects. In one study, recombinant human activated protein C [drotrecogin-a (activated)] reduced 28-day mortality from 31% in the control group to 25% in the intervention group (absolute reduction 6.1%; 95% CI 1.9 to 10.4%) in patients with severe sepsis.¹⁶ Treatment was effective regardless of age, severity of illness, the number of dysfunctional organs or systems, the site of infection, and the type of infecting organisms. Notably, 70 percent of the patients were in shock, with 75 percent receiving mechanical ventilation. The investigators noted a 1.5 percent increase in the risk of serious bleeding (3.5% in treated patients and 2% in control patients). Patients were eligible if they met these criteria within a 24-h period: three or more

Intensive insulin therapy*

signs of systemic inflammation and sepsis induced dysfunction of at least one organ or system that lasted no longer than 24 h. Excluded subjects included patients with chronic liver disease, those with chronic renal failure on dialysis, those with recent surgery, those with organ transplant, those with thrombocytopenia (platelet count <30,000/ μ L), and those taking acetylsalicylic acid at a dose larger than 650 mg per d within 3 days before the study. Most experts now recommend that administration of activated protein C should be seriously considered in patients who meet these inclusion criteria.⁵

Administration of a natural anticoagulant, such as ATIII, may arrest clotting without concomitant risk of bleeding. Antithrombin III is a single-chain glycopeptide that is produced by the liver and is an important regulator of hemostasis by inhibiting several serine proteases of the coagulation system, predominately thrombin and factor Xa. Plasma ATIII levels decrease in septic patients with DIC; in healthy in-

dividuals, the half-life of ATIII is approximately 60 h; but in patients with sepsis and septic shock, this half-life may be shortened to 4 to 6 h. The possibility that replacement of ATIII neutralizes excess thrombin and dampens the intravascular coagulation process has prompted several experimental and clinical studies. In several animal models of DIC, infusion of ATIII concentrates shortened the duration of DIC and reduced multiple organ failure and mortality. However, results of human clinical studies have been mixed. A large multicenter trial of high-dose ATIII (30,000 IU in total over 4 days) administered within 6 h in severe sepsis found no difference in overall 28-day mortality: 38.7 percent in the placebo group and 38.9 percent in the ATIII-treated group.¹⁷ High-dose ATIII was associated with increased risk of hemorrhage (from 13.5 to 23.8 percent) when administered with heparin. There was a trend toward improved survival with ATIII in a subgroup of patients not receiving heparin. At this point, some experts have recommended that patients with DIC secondary to a septic process receive replacement of ATIII to a level of 70 to 80 percent of normal. Other investigators have suggested that a much higher level of ATIII (140 to 150 percent) is required for efficacy.

Anti-Endotoxin Therapies

The most studied exogenous mediator is endotoxin. This macromolecule is found in gram-negative bacteria as one of the integral components of the outer bacterial LPS cell wall. The molecule can be functionally divided into three parts: a highly variable O-polysaccharide side chain that provides the heat-stable serologic specificity of gram-negative bacteria and is the basis for the O (somatic) antigen-type scheme; an oligosaccharide or R-core region composed of approximately 10 monosaccharides; and a lipid backbone referred to as *HpidA*. The lipid A portion of endotoxin is responsible for the majority of the molecule's toxicity; this portion is also highly conserved and is essentially invariable and ubiquitous.

Experimental studies of the administration of endotoxin have produced physiologic changes paralleling those of sepsis and septic shock. The cellular basis for the pathophysiologic response to endotoxin is that endotoxin, an LPS-binding protein (LBP), and CD 14 (a protein found on the surface of monocytes and macrophages) form a complex that activates the cell and triggers the cascade of events leading to septic shock. Many strategies have been developed to manipulate this complex, including enhanced endotoxin clearance (anti-endotoxin antibodies, direct removal of endotoxin via hemadsorption, hemofiltration, or hemodialysis), direct neutralization of circulating endotoxin (anti-endotoxin antibodies and endotoxin neutralizing proteins), and inhibition of the endotoxin-LBP complex.

Use of dialysis, adsorption, or filtration therapy to remove circulating endotoxin or cytokines has been proposed. In general, the benefits are controversial, and there is no randomized trial data to support the routine use of plasma filtration or hemodialysis in sepsis.¹⁸

ANTI-ENDOTOXIN ANTIBODIES At least four anti-endotoxin antibodies have been developed and studied in human trials of severe sepsis and septic shock: J5 (a polyclonal antibody), E5 (a murine-murine hybridoma-derived monoclonal antibody), MAB-T88 (a human-derived monoclonal antibody), and HA-1A (a human-murine hybridoma-derived monoclonal antibody). Despite initial promise, trials using J5 found no improved survival in sepsis or septic shock. Trials of E5 found no overall improvement in mortality, but there appeared to be a more rapid resolution of organ failure in patients with gram-negative sepsis without hypotension or shock. Overall, the benefits of E5 are too limited to justify the expense of routine use. After limited phase I trials, MAB-T88 has not been studied further for its outcome effect in sepsis and septic shock in humans. Human trials with HA-1A have not found improved survival and suggested that mortality is worsened in patients without gram-negative bacteremia. The multicenter European Pediatric Meningococcal Septic Shock Trial found no benefit with HA-1 A (6 mg/kg of body weight intravenously;

SECTION 4. SHOCK

maximum, 100 mg) in children presenting with meningococcal septic shock; the 28-day mortality rates were 27% in the control group and 18.5% in the treatment group (absolute reduction 8.6%; 95% CI -1.4 to 18.5%).¹⁹

ENDOTOXIN-NEUTRALIZING PROTEIN A number of endotoxin-neutralizing proteins has been described, of which BPI, a 55-kD neutrophil-derived polypeptide, has been studied most extensively. A recombinant 21-kD modified fragment of human BPI (rBPI21) was studied as an adjunctive treatment for children with severe meningococcal sepsis.²⁰ Overall survival was not improved (9.9% in the control group and 7.4% in the treated group), but treatment reduced the incidence of amputations and improved functional outcome.

LIPID A ANALOGUES Inhibition of the endotoxin-LBP interaction is an attractive and potential method of intervention. Analogues can be developed based on the structure of lipid A that will bind to LBP but result in reduced or absent cellular toxicity. These compounds can block endotoxin binding to cells and inhibit LPS-induced TNF- α release. A lipid A analogue, E5531, inhibited physiologic response to experimental endotoxin infusion.²¹ No human trials of a lipid A analogue in the treatment of sepsis and septic shock have been reported.

SUMMARY OF ANTI-ENDOTOXIN THERAPY Anti-endotoxin antibodies have not shown an overall survival benefit for patients with sepsis. The anti-endotoxin antibody HA-1A and the modified human BPI (rBPI21) have shown some benefit as adjunctive treatment for children with severe meningococcal sepsis.

Anti-Cytokine Therapy

Cytokines are peptides that function as cellular signals to regulate the amplitude and duration of the host's inflammatory response and play protective roles in the host's immune response to infection. The host's response to these cytokines consists of recruited and activated neutrophils, macrophages and lymphocytes, increased gene expression, and release of granulocyte colony-stimulating factors. Two cytokines, TNF- α and IL-1, have been studied extensively in patients with sepsis.

TUMOR NECROSIS FACTOR AND TNF- α RECEPTOR Tumor necrosis factor α is a polypeptide hormone that can stimulate the release of other mediators, including IL-1, IL-6, and PAF. It also promotes the metabolism of arachidonic acid, leading to eicosanoid formation. Tumor necrosis factor α is directly toxic to endothelial cells, increases the adhesion of polymorphonuclear leukocytes to the endothelial cells, and enhances the phagocytic activity of these cells. It also reduces the transmembrane potential of muscle cells, depresses myocardial function, and activates coagulation.

Administration of TNF- α to experimental animals and healthy human subjects duplicates many of the signs and symptoms of sepsis. Injection of TNF- α into animals results in hemodynamic collapse, multiple-organ injury, and a life-threatening vascular leak syndrome. In humans, injection of TNF- α produces hypotension, chills, fever, headache, and malaise synchronously with the time of the peak serum TNF- α level. In addition, rapid and sustained activation of the common pathway of the coagulation system occurs.

Numerous studies have reported a positive correlation between level of serum concentrations of TNF- α and clinical outcome in patients with sepsis. Significantly higher levels of TNF- α were found in non-survivors of meningococcemia, sepsis, children with infectious purpura, and ARDS. Absolute TNF- α levels were a significant predictive factor for morbidity and mortality in patients with septic shock. Perhaps the most compelling evidence that TNF- α is a causal rather than an associative factor are animal studies demonstrating that antibodies to TNF- α enhance survival and reduce physiologic derangements after challenge with endotoxin or live bacteria.

However, human studies with anti-TNF- α therapy have been disappointing.²² A variety of anti-TNF- α antibodies have been developed, such as TNF- α monoclonal antibody, MAK195F or afelimomab, and BAY 1351. Even though individual trials have found different results, the greatest benefit was a slight 3 to 4 percent non-statistical improvement in survival with anti-TNF- α antibody treatment.²² Attempts to determine subgroups of septic patients who would be more likely to benefit from anti-TNF- α antibody therapy have not been successful. Investigations using infusion of a TNF- α receptor-IgG fusion protein (TNFR55-IgG1) to "trap and eliminate" circulating TNF- α have not improved survival.²³

INTERLEUKIN 1 Interleukin-1 β is also present in the blood of patients with septic shock. Both TNF and IL-1 (3 induce hypotension, and a combination of these cytokines is a more potent inducer of shock than either cytokine alone. Both cytokines induce IL-6, a nonlethal cytokine that serves as an excellent marker of cytokine activity in patients with sepsis. An IL-1 receptor antagonist has been shown to block the hemodynamic consequences of *Escherichia coli* endotoxin and heat-killed *Staphylococcus epidermidis* in experimental animals. However, human studies on the efficacy of recombinant human IL-1 receptor antagonist in patients with sepsis syndrome found no consistent reduction in 28-day mortality.²⁴

SUMMARY OF ANTI-CYTOKINE THERAPY Most investigators believe that TNF- α is a key and perhaps central mediator in sepsis. To date, anti-TNF- α and anti-IL-1 agents have not been shown to consistently improve outcome in the treatment of septic patients.

Neutrophil-Directed Therapy

Evidence suggests that the neutrophil has beneficial and harmful effects in sepsis and septic shock. The neutrophil is a key component of the host defense. Data from neutropenic animals and humans have suggested that augmented neutrophil count and function reduce the risk of infection. Conversely, studies have shown that the neutrophil and its toxic byproducts produce tissue injury and organ dysfunction in sepsis and septic shock.

One area of intense interest is the leukocyte-endothelium interaction that appears to be a crucial step in activated neutrophil migration into an area of inflammation. A neutrophil membrane glycoprotein complex, termed CD11/CD18, and an endothelial cell-expressed intercellular adhesion molecule 1 are involved in transendothelial neutrophil migration. Monoclonal antibodies against the CD11/CD18 complex, in vitro and in vivo, prevent endotoxin, TNF- α , and complement-induced neutrophil adhesion; neutrophil-mediated injury to endothelial cells; and neutrophil extravascular migration. Monoclonal anti-CD 11/CD 18 antibody therapy in animal models of sepsis have produced conflicting results and suggest that efforts to inhibit neutrophil function by blocking the CD 11/CD 18 complex may lead to more tissue injury and more adverse outcomes.

Pentoxifylline, a methylxanthine derivative, inhibits cytokine activation of neutrophils and the production of TNF- α by endotoxin-exposed monocytes. This prevents the adherence of neutrophils to endothelium and the release of toxic degranulation products. The mechanism of this action is believed to be via increasing cyclic adenosine monophosphate concentrations. Animal experiments have suggested that treatment with pentoxifylline decreases mortality rate and prevents lung injury by inhibiting migration of neutrophils through the pulmonary capillary endothelium. In small studies, improved survival using pentoxifylline infusion has been seen in adults with severe sepsis and premature neonates with blood culture positive sepsis.^{25,26}

Intravenous Immunoglobulin

The role and efficacy of intravenous polyclonal or monoclonal immunoglobulin (WIG) in the treatment of septic shock remains unde-

fined and is not routinely recommended, but two studies have suggested a role in some circumstances. The Canadian Streptococcal Study Group performed an open-label study on the use of IVIG in patients with streptococcal toxic shock syndrome. The 30-day survival was 34.4% in the control group and 66.7% in the treated group (absolute increase 32.3%; 95% CI 6.3 to 58.3%).²⁷ Postulated beneficial mechanisms for IVIG therapy are the enhanced ability of the patient's plasma to neutralize bacterial mitogenicity, reduced T-cell production of IL-6 and TNF- α , Fc γ receptor blockade, accelerated clearance of endogenous pathogenic auto-antibodies, inhibition of components of the complement cascade, neutralization of super-antigens and bacterial toxins, and anti-cytokine and anti-idiotypic effects. A systemic review of IVIG for sepsis and septic shock found a significant trend toward reduction in mortality (relative risk, 0.91; CI, 0.86 to 0.96).²⁸ The investigators concluded that "polyclonal IVIG significantly reduced mortality and is a promising adjuvant in the treatment of sepsis and septic shock." They also noted that "the trials were small and the totality of evidence is insufficient to support a robust conclusion of benefit. Adjunctive therapy with monoclonal IVIG remains experimental."

Corticosteroids

Although some animal models have shown that high-dose corticosteroid therapy is effective, large clinical trials have shown (1) no differences in mortality between patients treated with high-dose corticosteroid and control patients, and (2) an increased rate of superinfection in corticosteroid treated patients.^{29,30} Conversely, recent studies have associated septic shock with relative adrenal insufficiency and glucocorticoid peripheral resistance. A multicenter trial with low-dose corticosteroid (hydrocortisone 50 mg IV every 6 h, and fludrocortisone 50 μ g PO once per day for 7 days) in patients in septic shock significantly reduced the risk of death in patients with septic shock who were relatively adrenal insufficient from 63.5% in the control group to 52.6% in the treated group (absolute reduction 10.9%; 95% CI -1.9 to 23.6%).³¹ No significant increase in adverse effects was noted. Thus the primary role of steroids in sepsis and septic shock is in patients with suspected or documented adrenal insufficiency. Adrenal insufficiency should be considered in septic patients with fulminant *N. meningitidis* bacteremia, disseminated tuberculosis, acquired immunodeficiency syndrome, prior glucocorticoid use, or refractory hypotension.

Nitric Oxide Synthase Inhibitors

There is good evidence from a large number of studies that humans with sepsis syndrome also have increased systemic nitric oxide production. The higher the nitric oxide level, the more pronounced the septic hypotension.

Animal studies using NOS inhibitors have shown mixed results. A handful of studies using an NOS antagonist, such as the arginine analogue monomethyl-L-arginine, in septic patients has shown transient improvements in blood pressure but no effect on overall mortality. A small study in 20 patients on the effects of a continuous infusion of methylene blue, an inhibitor of the nitric oxide pathway, on the hemodynamics and organ function in human septic shock found improved cardiac function and a reduced need for inotropic support.³² Survival rates were 30% in the control group and 50% in the methylene blue-treated group (absolute reduction 20%; 95% CI -22 to 62%). In summary, the role of nitric oxide in septic shock warrants further investigation. To date, only nonselective nitric oxide synthetase inhibitors that block both forms of NOS inhibitors have been studied extensively. Future research most likely will be performed with selective inhibitors.

Cyclooxygenase Inhibitors

There are two principal pathways of arachidonic acid metabolism: the lipoxygenase pathway leads to the production of leukotrienes, which

are potent leukocyte chemoattractants, and the cyclooxygenase pathway results in the release of thromboxanes and prostaglandins, which are important regulators of vascular tone.

Ibuprofen is a cyclooxygenase inhibitor. In animal models of endotoxin shock and shock from peritoneal implantation or intravenous infusion of bacteria, ibuprofen administered before or after the septic insult decreased mortality, reversed hemodynamic, metabolic, and blood coagulation abnormalities, improved pulmonary gas exchange, and attenuated the development of increase in microvascular permeability. The Ibuprofen in Sepsis Study Group found that intravenous ibuprofen (10 mg/kg of body weight given every 6 h for a total of eight doses) produced significant declines in temperature, heart rate, oxygen consumption, lactic acidosis, and urinary levels of prostacyclin and thromboxane.³³ However, ibuprofen did not reduce the incidence or duration of shock or ARDS and did not significantly reduce 30-day mortality rate. Subgroup analysis of the 10 percent of study patients who were hypothermic found a significant reduction in 30-day mortality, from 90% in the control group to 54% in the treated group (absolute reduction 36%; 95% CI 12 to 60%).³⁴ No increase in adverse events (renal dysfunction or gastrointestinal bleeding) was noted in the ibuprofen group. Human and animal studies to date have suggested that ibuprofen decreases the metabolic demand on patients with sepsis.

Miscellaneous

Hyperglycemia is a significant risk factor for developing an infection, and persistent hyperglycemia results in increased morbidity and reduced survival. Tight glucose control (between 80 and 100 mg/dL) with intensive insulin therapy reduced mortality from multiorgan failure in patients with sepsis, regardless of a history of prior diabetes.⁶ Studies investigating PAF, bradykinin antagonists, anti-oxidant therapy using 7V-acetylcysteine, interferon- γ , and granulocyte colony-stimulating factor have not shown conclusive evidence of efficacy with reduced mortality or morbidity.

Summary of Potential New Therapies

To date, the only potential new therapies that produce significant benefit as adjuncts to standard treatment have been (1) early goal-directed hemodynamic resuscitation, (2) tight control of blood glucose with insulin, and (3) treatment with activated protein C.^{5-6,16}

CARDIOGENIC SHOCK

W. Franklin Peacock IV Jim
Edward Weber

Cardiogenic shock is defined as a state of decreased cardiac output (CO) producing inadequate tissue perfusion despite adequate or excessive circulating volume.¹ Clinical signs of cardiogenic shock include evidence of poor CO with tissue hypoperfusion (hypotension, mental status changes, cool mottled skin) and evidence of volume overload (dyspnea, rales). Hemodynamic criteria for cardiogenic shock include (1) sustained hypotension [systolic blood pressure (BP) <90 mm Hg], (2) reduced cardiac index (<2.2 L/min per m²), and (3) an elevated (>18 mm Hg) pulmonary artery occlusion pressure. Cardiogenic shock is a true emergency that needs aggressive intervention to avert an extremely high mortality rate.^{2,3} Although usually caused by contractile failure of the myocardium, other processes may impair CO to produce shock (Table 33-1).

ETIOLOGY

Cardiogenic shock usually results from an acute myocardial infarction (AMI) that affects over 40 percent of the left ventricular myocardium. Cardiogenic shock is the most common cause of AMI-related in-hospital death, with an overall mortality of 50 to 90 percent and accounting for 50,000 to 70,000 deaths each year in the United States. The overall incidence of cardiogenic shock in AMI is 6 to 8 percent, a rate that remained constant from 1975 to 1997.^{3,4} Although some patients have cardiogenic shock on initial presentation, the median time from the onset of infarction to the development of shock is 8 h.⁵

Risk factors for post-AMI cardiogenic shock have been identified (Table 33-2). The more risk factors that present, the greater the amount of vulnerable myocardium and the greater the likelihood of cardiogenic shock. Early identification of increased risk may suggest more aggressive reperfusion strategies to prevent cardiogenic shock.

PATHOPHYSIOLOGY

Cardiogenic shock most often is the end result of acute myocardial ischemia and infarction affecting the left ventricle (LV). Acute heart failure may occur with loss of systolic contraction of at least 25 percent of the LV. If over 40 percent of the LV loses contractile function, clinical cardiogenic shock ensues. Most cases of AMI-related cardiogenic shock have ST-segment elevation on the initial electrocardiogram (ST-segment elevation myocardial infarction, or STEMI) that in

time will evolve Q waves in the same leads. Prior LV dysfunction can affect these percentages; a relatively small AMI may cause cardiogenic shock in a patient with pre-existing heart failure. Cardiogenic shock can develop from mechanical complications of an AMI: myocardial free-wall rupture, acute ventricular septal defect (VSD), or mitral regurgitation from valvular dysfunction or papillary muscle rupture. Less common causes of cardiogenic shock include myocardial depression from conditions such as sepsis or myocarditis, LV outflow obstruction (e.g., aortic stenosis), and severe regurgitation of LV output (acute aortic regurgitation or mitral valve chordae rupture).

Some patients presenting with decompensated congestive heart failure (CHF) may have occult cardiogenic shock and may be clinically indistinguishable from those with mildly decompensated CHF and stable CHF.⁶ Central venous oximetry and serum lactate measurements are required to detect those with occult cardiogenic shock.

In post-AMI cardiogenic shock, myocytes in the ischemic border zone demonstrate various stages of cell death, probably from inadequate collateral blood flow. Cellular dysfunction at the edge of the ischemic myocardium is further exacerbated by hypotension. Apoptosis (programmed cell death) may activate inflammatory pathways, increase oxidative stress, and further worsen the dysfunction.⁷ With progression, areas of focal necrosis develop throughout the heart, producing further loss of contractile function and hypotension. With arterial hypotension, coronary perfusion pressure declines and worsens already impaired myocardial oxygen delivery. If pulmonary edema develops, hypoxia and acidosis further diminish myocardial contractility. These processes contribute to a rapidly progressive cycle of deterioration leading to irreversible shock.

The severe reduction in CO and subsequent compensatory mechanisms have systemic consequences: oliguria, hepatic failure, gastrointestinal ischemia, anaerobic metabolism, lactic acidosis, and hypoxia. Although LV mass loss is the major predictor for developing cardio-

genic shock, disease in non-infarct-related coronary arteries, diastolic dysfunction, or arrhythmia can amplify the negative impact and result in cardiogenic shock with lesser insult.

To compensate for decreased stroke volume, tachycardia develops. The combination of hypotension and tachycardia drastically reduces coronary artery flow by decreasing perfusion pressure and diastolic filling time (when the majority of coronary flow takes place). This results in further ischemia and myocardial dysfunction.

With AMI, neurohormonal mechanisms are triggered to maintain CO and tissue perfusion. Sympathetic nervous system activation leads to increased heart rate, systemic vasoconstriction, and enhanced myocardial contractility. Increased contractility is seen as hyperkinesis in the uninvolved myocardium. Absence of hyperkinesis, from fibrosis or diffuse coronary artery disease, results in end-systolic LV volume increases and is associated with increased cardiogenic shock risk. Another neurohormonal reflex that occurs is activation of the renin-angiotensin aldosterone system as a result of inadequate renal perfusion pressure. Increased angiotensin II leads to peripheral vasoconstriction and aldosterone synthesis. Aldosterone causes retention of sodium and water, which increases blood volume. The net effect of sympathetic nervous system and renin-angiotensin activation may preserve CO and maintain end-organ perfusion, but at the cost of increased systemic vascular resistance (SVR) and higher myocardial oxygen consumption.

Right ventricular (RV) infarction complicates up to 30 percent of inferior wall AMI.⁸ Although hypotension is not rare with an RV infarct, shock is much less common and accounts for only 3 to 4 percent of cardiogenic shock cases. The major determinate of cardiogenic shock with RV infarction is the presence of LV dysfunction. With decreased LV contractility, systolic septal function is impaired and RV stroke volume is reduced. With a smaller volume coursing through the RV, LV preload is reduced and LV stroke volume is decreased, producing more arterial hypotension and further reducing coronary perfusion pressure.

Hemodynamic assessment by pulmonary artery catheterization in AMI patients has identified four profiles based on CO and LV preload that are strong predictors of mortality independent of reperfusion therapy (Table 33-3).⁹ Patients in cardiogenic shock typically have low cardiac index (<2.2 L/min per m²) and elevated LV end-diastolic pressure (pulmonary artery occlusion pressure > 18 mm Hg).

CLINICAL FEATURES

History

History can be difficult to obtain due to the severity of the clinical presentation; mental obtundation or confusion may preclude patient cooperation. Emergency medical service personnel, family, or the

TABLE 33-3 Mean Hemodynamic Values in Subsets of Acute Myocardial Infarction⁹

Class	Description	Cardiac Index, L/min per m ²	Pulmonary Artery Occlusion Pressure, mm Hg	Approximate Mortality, %	Comments
I	No congestion or peripheral hypoperfusion	2.7 (normal)	12 (normal)	2	Good prognosis
II	Isolated congestion	2.3 (low to normal)	23 (elevated)	10	Vasodilation and diuresis result in clinical improvement

medical record may offer historical information. Patients commonly complain of breathlessness. When AMI is the cause of cardiogenic shock, patients may report chest pain or an ischemic equivalent. The history should attempt to exclude other causes of shock, such as sepsis, gastrointestinal hemorrhage, or massive pulmonary embolism; ask about a history of pre-existing valvular disease or injection drug use.

Physical Examination

Shock is characterized by hypoperfusion and is often, but not always, accompanied by hypotension. Systolic BP is usually below 90 mm Hg, although it can be higher with pre-existing hypertension. A higher BP may reflect compensatory increases in SVR. A pulse pressure less than 20 mm Hg may be evident, due to extreme vasoconstriction. Compensatory sinus tachycardia is common. Unless the patient has advanced to the stage of respiratory fatigue or agonal respirations, tachypnea is common. The lung examination demonstrates rales due to the presence of pulmonary edema. Jugular venous distention and a positive abdominal jugular reflex are usually present. However, with RV infarction, the lung fields may be clear despite hypotension and jugular venous distention. Cool, pale extremities with skin mottling indicates poor perfusion. Peripheral edema suggests pre-existing heart failure. Diaphoresis indicates activation of the sympathetic nervous system.

If the cardiac point of maximal impulse is normally located, shock is likely due to an acute event. If the point of maximal impulse is laterally shifted and diffuse from cardiac remodeling and enlargement, long-standing cardiac disease can be presumed. Loud or new systolic murmurs suggest mechanical dysfunction. Acute mitral regurgitation can occur from chordae tendineae rupture or papillary muscle dysfunction. Chordae tendineae rupture is characterized by a soft holosystolic murmur at the apex radiating to the axilla but is often obscured by rales. With papillary muscle dysfunction, the murmur starts with the first heart sound but terminates before the second. An acute VSD is associated with a new loud holosystolic left parasternal murmur, often with a palpable thrill, that decreases in intensity as the intraventricular pressures equalize.

ANCILLARY STUDIES

Electrocardiogram (ECG)

The ECG is necessary to detect ischemia or infarction, evaluate for arrhythmia, and provide evidence of electrolytic abnormality (e.g., hypokalemia) or drug toxicity (e.g., digoxin). Left ventricular hypertrophy suggests chronic heart failure or hypertension. ST-segment elevation in two or more contiguous ECG leads supports the diagnosis of AMI. Right ventricular infarction complicating inferior MI is detected by ST-segment elevation in the right precordial ECG leads (usually V₄R). Right ventricular infarction complicating inferior MI increases mortality from about 6 percent (without RV involvement) to 31 percent (with RV involvement).⁸

Chest Radiography

A chest radiograph is indicated in all unstable patients. It typically shows pulmonary congestion or edema, Kerley lines, increased pulmonary vascularity, alveolar infiltrates, and pleural effusion. However, these findings may lag the clinical appearance by hours, so their absence does not exclude cardiogenic shock. Another confounder to interpreting the chest radiograph is underlying disease; pulmonary edema is difficult to detect on chest radiography in patients with severe chronic obstructive lung disease. Cardiomegaly is the end result of long-standing myocardial remodeling, and its presence may not explain the acute symptoms. Obtaining prior radiographs may help. The chest radiograph can suggest alternative or confounding diagnoses,

such as pneumonia, pneumothorax, aortic dissection, or pericardial effusion (globular cardiac shape).

Laboratory

The level of serum B-type natriuretic peptide (BNP) correlates with LV end-diastolic pressure and ventricular stretch. BNP has good direct correlation with pulmonary artery occlusion pressures as measured by a pulmonary artery catheter. BNP also is an excellent predictor of the clinical development of heart failure after AMI.¹⁰ Normal serum BNP levels are less than 100 pg/mL.

In cardiogenic shock, cardiac markers of acute injury are needed. Acute MI can be diagnosed, but not excluded, by a single measurement. Arterial blood gas measurements help identify those at risk of CO₂ retention, quantify the presence and severity of acidosis, and determine the contribution of metabolic or respiratory components. An elevated serum lactate may detect unsuspected hypoperfusion. Electrolytes, which change rapidly with acidosis, pulmonary and perfusion changes, and renal dysfunction, should be evaluated. Serum magnesium should be measured with arrhythmia or severe hypokalemia. A complete blood cell count excludes anemia, which can contribute to cardiac ischemia. Obtaining specific drug levels (i.e. digoxin, ethanol, or illicit drugs) is guided by the clinical presentation.

Echocardiography

Transthoracic echocardiography (TTE) is a useful technique for documenting impaired LV contractility and supporting the diagnosis of cardiogenic shock.⁴ Echocardiography provides information on ventricular dysfunction (e.g., regional hypokinesis, akinesis, or dyskinesis) and can identify early myocardial dysfunction by visualizing a lack of compensatory hyperkinesis in uninvolved cardiac segments. With the addition of color flow Doppler, TTE can define the mechanical causes of cardiogenic shock, such as acute mitral regurgitation or VSD.

Transthoracic echocardiography is useful for determining other causes of decreased CO. Acute RV dilatation, tricuspid insufficiency, paradoxical systolic septal motion, and high estimated pulmonary artery and RV pressures suggest pulmonary hypertension, as occurs with pulmonary embolus. Loss of RV contractility, RV dilatation, and normal estimated pulmonary pressures occur more commonly with RV infarction. Pericardial effusion, with diastolic collapse of the right atrium or right ventricle, indicates hemodynamically significant cardiac tamponade. Further, TTE may allow for visualization of aortic root dissection, although transesophageal echocardiography is better for sonographic detection of aortic dissection.

Mechanical Catastrophe Diagnosis

With mechanical catastrophe, patients are usually in extremis, and emergent echocardiography may be the best tool for the diagnosis. In the case of myocardial free-wall rupture, death is probable, unless a pseudoaneurysm forms, which may be detected as an acute pericardial effusion on echocardiography. An acute VSD is confirmed by echocardiography or right heart catheterization demonstrating an O₂ saturation step-up from the right atrium to the RV. Acute mitral regurgitation, from papillary muscle rupture or dysfunction, can complicate AMI. Because the murmur may be undetectable by auscultation, echocardiography is a very useful test to detect this treatable cause of cardiogenic shock.

Hemodynamic Monitoring

In patients at risk for cardiogenic shock, there is fair correlation between clinical and hemodynamic assessments of CO and LV preload during AMI. Patients with cardiogenic shock have decreased CO and increased LV pressures (see Table 33-3). However, imprecision in clin-

ical assessment between the different classes limits therapy based solely on clinical criteria. Invasive hemodynamic monitoring with a pulmonary artery catheter can provide confirmatory data and guide treatment, but it is typically unavailable to most emergency physicians.⁹ Noninvasive hemodynamic monitoring shows promise. One technique uses bioimpedance to measure systolic stroke volume and multiplies this value by heart rate to calculate cardiac output. Approved by the U.S. Food and Drug Administration, bioimpedance monitoring is reasonably accurate, is useful for diagnosis, and may be used to exclude other causes of shock, such as volume depletion or septic shock.¹¹ Bioimpedance collects data by the application of two ECG-type electrodes to the neck and thorax. The signal is then analyzed and coupled with BP and ECG data to provide real-time CO, SVR, and thoracic fluid content values.^{11,12}

DIFFERENTIAL DIAGNOSIS

In suspected cardiogenic shock, AMI is always a possibility. Dyspnea in cardiogenic shock is common, so pulmonary embolus, emphysema exacerbation, and pneumonia are considered. Hypertension, peripheral vasoconstriction, and dyspnea suggest acute pulmonary edema. Although diffuse ST-T changes can be seen with acute pericarditis or myocarditis, a nondiagnostic ECG should prompt the consideration of other causes of hypotension. These include aortic dissection, pulmonary embolus, pericardial tamponade, acute valvular insufficiency, hemorrhage, or sepsis. Overdose by a toxin with negative inotropic or chronotropic effects (e.g. (3-blocker, calcium channel blocker, or digoxin overdose) should be considered.

TREATMENT

Medical therapy should be considered a temporizing measure while arranging for definitive treatment to re-establish coronary patency.⁴ In the prehospital setting, EMS should consider directing the suspected cardiogenic shock patient to a facility that has intraaortic balloon pump (IABP) and 24-h emergency cardiac revascularization capability (i.e., cardiac bypass team). Initial management focuses on airway stability and improving myocardial pump function. Diagnostic and therapeutic interventions should proceed simultaneously in unstable patients.

Airway

Therapy begins with supplemental oxygen to reduce dyspnea and hypoxic anxiety. Because hypoxia is a greater risk than hypercarbia, supplemental oxygen is not withheld due to concerns about CO₂ retention. Impending or acute respiratory failure requires immediate mechanical ventilation. Failure to anticipate airway and ventilatory requirements may result in rapid cardiovascular collapse. Noninvasive ventilation techniques (e.g., continuous positive airway pressure or bilevel positive airway pressure) can serve as temporary airway support for patients with respiratory distress. However, these methods require a hemodynamically stable, cooperative patient, which excludes most with cardiogenic shock.

Endotracheal intubation is often necessary to maintain oxygenation and ventilation. However, the change to positive pressure ventilation may further decrease preload and CO and worsen hypotension. The physician should anticipate this occurrence and be prepared to administer a fluid bolus, in the absence of pulmonary congestion, or initiate the appropriate vasopressor or inotrope.

Stabilization

Cardiac monitoring and intravenous access are necessary. Hypoxia, hypovolemia, rhythm disturbances, electrolyte abnormalities, and acid-base alterations should be corrected as soon as possible. An arte-

rial line, although not mandatory, helps for frequent arterial blood gases and BP monitoring. A urinary drainage catheter may be used to monitor urine output in response to therapy. Pulmonary artery catheter and hemodynamic monitoring should be considered in all unstable patients.

In AMI, aspirin and full-dose heparin should be given unless there is an absolute contraindication.⁴ If there is adequate BP, chest pain may be relieved by careful use of intravenous nitroglycerin or morphine. (3-blockers and angiotensin-converting enzyme inhibitors should be withheld until the patient's condition is stable. Similarly, other vasodilators cannot be used in most cases when hypotension is present.

Hypotension

Initial therapy must be guided by clinical findings. Because some patients with cardiogenic shock develop hypotension without pulmonary congestion, a small fluid challenge (NS 100 to 250 mL) may be appropriate. If there is pulmonary congestion, this volume infusion should be omitted. If there is no improvement in perfusion with the fluid bolus, or there is hypotension with pulmonary congestion, inotropes are considered.

Inotropes do not change outcome but can temporize while ED personnel arrange interventions to restore coronary artery perfusion and LV function.^{13,14} Inotrope selection depends on the suspected etiology of hypotension. If hemodynamics stabilize after inotropes are started, therapy for pulmonary congestion may be started (i.e., diuretics) while arranging admission to the intensive care unit.

Pure vasoconstrictors, such as phenylephrine, are generally contraindicated, because they increase cardiac afterload without augmenting cardiac contractility. Dopamine is used if there is hypotension but may increase cardiac work by increasing heart rate. It may also increase LV end-diastolic pressure by its α -agonist effect. Dobutamine may be effective in increasing cardiac contractility, but it generally should be avoided when systolic BP is below 90 mm Hg, because of its vasodilator potential. Phosphodiesterase inhibitors (e.g., milrinone) augment contractility, but have significant vasodilatory properties, and can decrease BP even greater than dobutamine. Combination therapy with a vasopressor (i.e., dopamine) and an inotrope (i.e., dobutamine) may be more effective than use of either agent alone, although hemodynamic data from a pulmonary artery catheter may best guide these decisions.

In RV infarct with hypotension, fluid infusion should be the first action. In the absence of profound hypotension, dobutamine is a mainstay of initial pharmacologic treatment.¹³ With systolic BP below 70 mm Hg, dopamine is preferred as a single agent or in combination with dobutamine. When shock persists despite use of these agents, mechanical inotropic support with an IABP is required.^{4,15,16}

In acute mitral regurgitation, hemodynamic support can be initiated with dobutamine and nitroprusside. This treatment supports contractility and provides afterload reduction, respectively, and promotes forward systemic blood flow. The IABP is also beneficial for temporary support.⁴ Acute VSD is treated with dobutamine, nitroprusside, and an IABP.⁴ Confirmatory evidence for these emergent conditions with two-dimensional echocardiography should be sought, concomitant with emergency consultation from the cardiac surgical team.

REPERFUSION FOR CARDIOGENIC SHOCK

Thrombolytic Therapy

Recent data suggest that patients in cardiogenic shock treated with thrombolytics have better outcomes than those not treated with thrombolytics.¹⁶ The lowest mortality rate was observed with treatment using thrombolytics followed by revascularization.¹⁷ Incomplete lysis in

SECTION 4 . SHOCK

the infarct-related artery and the high frequency of multivessel disease in patients with cardiogenic shock may limit the efficacy of thrombolytic therapy.¹⁸

Intraaortic Balloon Counterpulsation

The IABP provides hemodynamic support by decreasing afterload (which lowers myocardial oxygen consumption) and increasing diastolic BP (which augments coronary perfusion) and should be considered in patients presenting with cardiogenic shock.^{4,15,16} Recent data suggest that IABP improves survival after thrombolytic therapy by augmenting diastolic perfusion pressure and unloading the LV.^{17,19} The IABP does not improve survival without successful revascularization or surgical correction of an acute mechanical catastrophe.¹⁸

Early Revascularization

In cardiogenic shock, early revascularization with percutaneous coronary intervention or coronary artery bypass graft is the most important life-saving intervention.^{4,17,18,20} The greatest short-term benefit is reported in patients younger than 75 years, those with previous MI, and those treated within 6 h of symptom onset. Patients older than 75 years have better survival with medical management.^{4,17} Coronary artery bypass graft requires extensive surgical and medical resources and poses significant operative risk for these seriously ill patients, thereby limiting its use. However, outcome studies support that early revascularization should be performed in most patients younger than 75 years with cardiogenic shock.^{17,18} Mechanical complications (e.g., acute VSD or mitral regurgitation) producing cardiogenic shock require temporary inotropic support with IABP, followed by early surgical repair.⁴

INOTROPIC MEDICATIONS

Dopamine

Dopamine, a first-line agent for cardiogenic shock, has dose-dependent effects. At infusion rates slower than 2.5 $\mu\text{g/kg}$ per min, dopaminergic stimulation dilates renal, cardiac, and splanchnic vessels. At rates between 2.5 and 5 $\mu\text{g/kg}$ per min, β_1 -adrenergic effects predominate, with increased heart rate and cardiac contractility. At rates between 5 and 10 $\mu\text{g/kg}$ per min, α_1 - and β_2 -adrenergic effects occur. At rates faster than 10 $\mu\text{g/kg}$ per min, α_1 -adrenergic tone progressively increases with increased BP and systemic vascular resistance. Dosing usually begins at 3 to 5 $\mu\text{g/kg}$ per min and is titrated up to 20 to 50 $\mu\text{g/kg}$ per min to maintain BP (Table 33-4). Complications include arrhythmias, extremity gangrene, and tachycardia at high doses (which increases myocardial oxygen demand and may extend ischemia). Consequently, the lowest possible dose of dopamine should be used.

TABLE 33-4 Inotropic Medications for Cardiogenic Shock*

Drug	Dose	Comments
Dopamine	3–5 $\mu\text{g/kg}$ per min, titrated up to 20–50 $\mu\text{g/kg}$ per min as needed	Use lowest effective dose
Dobutamine	2–5 $\mu\text{g/kg}$ per min, titrated up to 20 $\mu\text{g/kg}$ per min	May need dopamine also
Norepinephrine	2 $\mu\text{g/min}$, titrate to response	
Milrinone	50 $\mu\text{g/kg}$ IV over 10 min Maintenance infusion of 0.5 $\mu\text{g/kg}$ per min	

*Best with hemodynamic monitoring.

Dobutamine usually is used for signs of poor perfusion when systolic BP is higher than 90 mm Hg. Primarily a selective β_1 -adrenergic agonist, it also has mild α_1 and β_2 -adrenergic effects. This sympathomimetic agent improves myocardial contractility and augments diastolic coronary blood flow without inducing excessive tachycardia. The net effect is increased CO, lowered SVR, and reduced LV filling pressure, with little BP change. Dobutamine is started at 2 to 5 $\mu\text{g/kg}$ per min, and it is titrated up to 20 $\mu\text{g/kg}$ per min according to clinical and hemodynamic responses. Complications include arrhythmias, nausea, and headache. If there is an inadequate response to this agent alone, dopamine may be added to support blood pressure.

Norepinephrine

Norepinephrine is used when there is inadequate response to other pressors. Primarily an α_1 -agonist, norepinephrine infusion is started at 2 μg per min and titrated according to response. Complications are similar to those with high-dose dopamine.

Milrinone

Milrinone is a phosphodiesterase inhibitor that increases cyclic adenosine monophosphate, increases contractility and CO, and causes peripheral vasodilation. The drop in SVR may require additional therapy with vasopressors to maintain BP, so milrinone use in cardiogenic shock is best guided by hemodynamic measurements from a pulmonary artery catheter. Milrinone is administered with a loading dose of 50 $\mu\text{g/kg}$ IV over 10 min, followed by a maintenance infusion of 0.5 $\mu\text{g/kg}$ per min.

DISPOSITION

Patients in cardiogenic shock are best treated in an institution with invasive revascularization capability. Transfer should be accomplished as quickly as possible. In a large cardiogenic shock registry, mortality rates were 77 percent without thrombolytic therapy or IABP, 63 percent with thrombolytic therapy alone, 57 percent with IABP alone, and 47 percent with thrombolytic therapy and IABP.¹⁸ Although those with IABP were more likely to receive invasive revascularization, there was no outcome difference as long as IABP was begun within 6 h. Although further study is needed, these observations suggest that the best results may be obtained by thrombolytic therapy and IABP, if possible, and early transfer.⁴

All patients with cardiogenic shock requiring hemodynamic monitoring, thrombolytic or inotropic therapy, or an IABP require admission to the intensive care unit. The rare stable patient without multiple comorbidities or a history of heart failure and who does not require hemodynamic monitoring or inotropic support is appropriate for admission to a monitored setting. Not all patients will benefit from aggressive care, particularly elderly patients with multiple comorbid conditions. The decision to perform or withhold therapies should be made in conjunction with the patient's wishes. Factors that may influence the decision to pursue aggressive therapy include advanced age and diminished functional status.

ANAPHYLAXIS AND ACUTE ALLERGIC REACTIONS **Brian H. Rowe Stuart Carr**

DEFINITIONS

Anaphylaxis is a severe systemic hypersensitivity reaction characterized by multisystem involvement, which may include hypotension or airway compromise. Anaphylaxis is a potentially life-threatening cascade caused by the release of mediators from mast cells and basophils in an IgE-dependent fashion. *Anaphylactoid* describes responses that are clinically indistinguishable from anaphylaxis, which are not IgE mediated, and which do not require a sensitizing exposure.¹ Research shows that the final pathway in "classic" anaphylactic and anaphylactoid reactions is identical, and *anaphylaxis* is now used to refer to both IgE and non-IgE reactions.² Hypersensitivity describes an inappropriate immune response to generally harmless antigens, while anaphylaxis represents the most dramatic and severe form of immediate hy-

persensitivity. That being said, it is critical to remember that even apparently mild acute allergic reactions may progress to this severe systemic response, anaphylaxis, and death.

EPIDEMIOLOGY

Neither age, occupation, race, gender, nor geographic factors increase the risk of anaphylaxis. Most studies indicate that atopic individuals are at no greater risk for anaphylaxis from insect stings or drug reactions than are non-atopic individuals.¹ Poorly controlled asthma and previous anaphylaxis is a risk factor for fatal or near-fatal anaphylaxis.¹ The only other factors known to increase the risk of anaphylaxis are a previous exposure to a sensitizing antigen and previous anaphylaxis. Notably, anaphylaxis recurrence risks are not 100 percent for reexposure. The reoccurrence rate is 40 to 60 percent for insect stings, 20 to 40 percent for radiocontrast agents, and 10 to 20 percent for penicillin. Limited data are available on the epidemiology of allergic reactions in the ED. The prevalence of anaphylaxis ranges from as high as 5 per 1000 to as low as 2 per 10,000 ED visits.^{13,14} The prevalence of less-severe allergic reactions in the emergency department is much higher, but data are infrequently reported. Currently, the most common causes of serious anaphylaxis are antibiotics, such as penicillin, insects, and food.^{1,15} (J-Lactam antibiotics are estimated to cause 400 to 800 deaths in the United States annually, with a systemic allergic reaction occurring in 1 per 10,000 exposures.¹ Hymenoptera stings constitute the next most common cause of anaphylaxis, with fewer than 100 deaths in the United States annually.¹ Table 34-1 contains a partial list of the more common causative agents; however, the causes vary with age.⁶ Pediatric surveillance studies have shown food allergy to be a very common cause of anaphylaxis in children.^{6,7} Latex hypersensitivity is also increasing in prevalence in the general population, with a resultant risk for anaphylaxis.

PATHOPHYSIOLOGY

The basic mechanism underlying allergic reactions is mast cell and basophil degranulation and mediator release.⁸ The causes of cell degranulation include IgE cross-linking, complement activation, nonimmunologic or direct activation, modulation of arachidonic acid

metabolism, exercise or temperature-dependent effects, and idiopathic causes.⁸

Consensus on classification of hypersensitivity has been elusive, significant overlap may exist in some cases, and some clinical reactions do not fit classification. The four classic mechanisms of hypersensitivity are (1) cross-linking of two adjacent IgE molecules on a mast cell or basophil by a multivalent antigen; (2) reaction of IgG and IgM to cell-surface antigens, resulting in complement activation and cytotoxicity; (3) soluble antigen-antibody complexes that activate the complement system; and (4) activation of T lymphocytes. The first three mechanisms have been mentioned in the literature in relation to anaphylaxis.¹

The "classic" anaphylaxis (IgE-mediated hypersensitivity) pathway requires two separate exposures to either an antigen or a hapten-protein antigenic complex. An antigen is a molecule, usually a protein, that can stimulate an immune response on its own. Haptens are small molecules, such as penicillin, that are incapable of stimulating an immune response, unless they are bound to endogenous proteins (e.g., albumin), resulting in an antigenic complex large enough to be recognized.

On first exposure, the antigen or hapten-protein complex is processed by macrophages and dendritic cells, and then presented externally on the cell surface bound to the major histocompatibility complex (MHC)-2. T helper cells recognize the antigen-MHC-2 complex and subsequently induce proliferation and differentiation of antibody-producing plasma cells. In the presence of interleukin (IL)-4, secreted from proallergic T-2 cells, these plasma cells produce and release IgE antibody into the bloodstream. The IgE antibody (like all antibodies) has a variable and a constant region. The variable region is specific for the antigen that induced the immune response, and the constant region binds to high-affinity IgE receptors present in vast quantities on mast cells and basophils, resulting in cells covered with antigen-specific IgE molecules. This sensitizing process takes days to weeks, resulting in a latent period during which no clinical response to antigen occurs. After the latent period, on antigen reexposure the variable regions on the IgE bind the antigen, resulting in bridging of adjacent IgE molecules on the mast cell surface. This IgE-antigen-IgE bridging results in activation of cell degranulation with release of chemical mediators.¹ Examples of IgE-mediated reaction triggers include antibiotics, foods, and Hymenoptera stings.

Complement-mediated anaphylactic reactions occur after the administration of blood products secondary to the formation of immune complexes. Immune complex formation results in activation of the complement pathway and formation of the anaphylatoxins C3a and C5a, which directly cause cell degranulation.⁸ Immune complexes include IgG aggregates and IgA-IgG from human immunoglobulin therapy, and IgE-IgA complexes formed in selective IgA-deficient patients (1 in 700 people) who have been given blood products repeatedly. Administration of mismatched blood also causes complement activation secondary to the production of IgG and IgM antibodies against transfused red blood cells, resulting in cell lysis, agglutination, anaphylatoxin generation, and subsequent anaphylaxis.

Nonimmunologic anaphylaxis occurs when an exogenous substance results in mast cell degranulation either by direct stimulation of the mast cell or by unknown mechanisms. These reactions are often referred to as anaphylactoid.¹ Substances that cause anaphylactoid reactions include radiocontrast dyes, muscular depolarizing drugs, opiates, and dextrans. The mechanism of radiocontrast reactions is uncertain but is believed to be caused by the activation of the complement and coagulation systems, related in part to the high osmolarity of these dyes. Since the advent of nonionic contrast dyes, the incidence of reactions has dramatically decreased. Opiates and neuromuscular depolarizing drugs cause direct release of mediators from cells.

Aspirin and other nonsteroidal drugs cause anaphylactic symptoms by a non-mast cell process. The mechanism is not precisely known; however, it is thought to involve modulation of the cyclooxygenase-

arachidonic acid metabolism pathway, specifically an alteration in prostaglandin and leukotriene synthesis. Five to ten percent of asthmatics have these reactions, which include bronchospasm, bronchorrhea, rhinorrhea, and, rarely, hypotension. Nonasthmatics may experience urticaria, angioedema, and hypotension. New, highly selective COX-2 inhibitors appear to be safe for aspirin-sensitive asthmatics in challenge studies.⁹

Idiopathic anaphylaxis is a diagnosis of exclusion, occurring when no causative agent can be identified for anaphylaxis. Patients suffer recurrent attacks, with no trigger identified after extensive allergy evaluation. They often need prolonged treatment with alternate-day prednisone to maintain remission from attacks.¹⁰

CLINICAL FEATURES

Anaphylaxis is the most severe life-threatening form of a systemic allergic reaction, often involving respiratory or cardiovascular compromise. The clinical signs of systemic allergic reactions include diffuse urticaria and angioedema. At times, these major symptoms are accompanied by any of the following: abdominal pain or cramping, nausea, vomiting, diarrhea, bronchospasm, rhinorrhea, conjunctivitis, dysrhythmias, and/or hypotension.¹ The clinician should be aware that even mild, localized urticaria can progress to full anaphylaxis, and even to death.

The "classic" presentation of anaphylaxis begins with pruritus, cutaneous flushing, and urticaria. These symptoms are followed by a sense of fullness in the throat, anxiety, a sensation of chest tightness, shortness of breath, and lightheadedness. As the cascade progresses, decreased level of consciousness, respiratory distress, and circulatory collapse may ensue. In its severest form, loss of consciousness and cardiorespiratory arrest may result. A complaint of a "lump in the throat" and hoarseness heralds life-threatening laryngeal edema in a patient with symptoms of anaphylaxis.

In the vast majority of patients, signs and symptoms begin within 60 min of exposure. In general, the faster the onset of symptoms, the more severe the reaction, as evidenced by the fact that one-half of anaphylactic fatalities occur within the first hour. After the initial signs and symptoms have abated, patients are at risk for a recurrence of symptoms. This biphasic phenomenon occurs in 3 to 20 percent of patients.³ The effect is caused by a second phase of mediator release, peaking 4 to 8 h after the initial exposure and exhibiting itself clinically 3 to 4 h after the initial clinical manifestations have cleared. The late-phase allergic reaction is primarily mediated by the release of newly generated cysteinyl leukotrienes, the former "slow-reacting substance of anaphylaxis."³

DIAGNOSIS

The diagnosis of anaphylaxis is made by history and physical examination. Anaphylaxis should be considered clinically when involvement of any two or more body systems is observed, with or without hypotension or airway compromise (e.g., some combination of cutaneous, respiratory, gastrointestinal or cardiovascular systems). The diagnosis is easily made with a clear history of exposure, such as a bee sting, shortly followed by the multisystemic signs and symptoms described above. Unfortunately, diagnosis is not always easy or clear, because symptom onset is delayed more than 1 h in a small percentage of cases. Often, such as in food allergy, the inciting substance may not be known. The differential diagnosis of anaphylactic reactions is extensive, including vasovagal reactions; myocardial ischemia; arrhythmias; status asthmaticus; seizure; epiglottitis; hereditary angioedema; foreign-body airway obstruction; carcinoid; mastocytosis; vocal cord dysfunction; and non-IgE-mediated drug reactions.¹ The most common anaphylaxis imitator is a vasovagal reaction, which is characterized by hypotension, pallor, bradycardia, diaphoresis, and weakness, and sometimes by syncope.

Because the diagnosis of anaphylaxis is made clinically, laboratory investigations have no role to play. Histamine levels, elevated for 5 to 30 min postreaction, are unhelpful because they decline by presentation to the ED. Tryptase is a neutral protease of unknown function in anaphylaxis that is found only in mast cell granules and is released with degranulation. Serum tryptase levels are elevated for several hours and are useful for later confirmation of a suspected anaphylactic episode.¹

TREATMENT

Emergency Treatment

Given the possible development of life-threatening complications, all acute allergic reactions should be triaged expeditiously. Anaphylaxis, as defined by airway compromise or hypotension, is obviously a true medical emergency and must be rapidly assessed and treated. With *suspected* anaphylaxis, the single most important step in treatment is the rapid administration of epinephrine. Moreover, with this rapid administration, many of the secondary measures discussed below may not be necessary.

First-Line Therapy

Emergency management starts with the ABC (airway, breathing, circulation) of resuscitation. The first-line therapies for anaphylaxis (e.g., epinephrine, intravenous fluids, and oxygen) have immediate effect during the acute stage of anaphylaxis. Vital signs, intravenous access, oxygen, cardiac monitoring, and pulse oximetry measurements should be obtained immediately.

AIRWAY AND OXYGENATION Securing the airway is the first priority. The airway should be examined for signs and symptoms of angioedema (e.g., uvula edema, stridor, respiratory distress, hypoxia). If angioedema is producing respiratory distress, intubation should be completed early, because delay may result in complete airway obstruction secondary to progression of angioedema. The patient should be given sufficient oxygen to maintain arterial oxygen saturation greater than 90 percent.

DECONTAMINATION Exposure to the causative agent, if identified, should be terminated; however, gastric lavage is not recommended for food-borne allergens.

EPINEPHRINE Epinephrine is the cornerstone of treatment for anaphylactic reactions; however, research suggests that epinephrine in anaphylaxis is underused.^{4,7} If the patient has signs of cardiovascular compromise or collapse, epinephrine may be delivered intravenously. Initially, epinephrine 100 μ g (0.1 mg) IV should be given as a 1:100,000 dilution. This can be done by placing epinephrine 0.1 mg (0.1 mL of the 1:1000 dilution) in 10 mL of NS solution and infusing it over 5 to 10 min (a rate of 1 to 2 mL/min).² If the patient is refractory to the initial bolus, then an epinephrine infusion can be started, by placing epinephrine 1 mg (1.0 mL of the 1:1000 dilution) in 500 mL of D5W or NS and running at a rate of 1 to 4 μ g/min (0.5 to 2 mL/min), titrating to effect. Physicians are often hesitant to give intravenous epinephrine because of its side effects (e.g., tachycardia, arrhythmia, tremor). It should be stressed that the initial adult dose is very dilute, is given over 5 to 10 min, and can be stopped immediately if arrhythmias or chest pain occur.

For less-severe symptoms, intramuscular epinephrine can be given.¹¹ The dose is epinephrine 0.3 to 0.5 mg (0.3 to 0.5 mL of the 1:1000 dilution) repeated every 5 to 10 min according to response or relapse. Most patients do not need more than a single dose. Intramuscular dosing provides higher, more consistent, and more rapid peak blood epinephrine levels than subcutaneous administration, and

should now be the treatment of choice for adults and children.^{12,13} Moreover, injections into the thigh are more effective at achieving peak blood levels than are injections into the deltoid area.¹² If the patient is refractory to treatment despite repeated intramuscular epinephrine, then an epinephrine infusion should be instituted. Caution is warranted in patients taking (3-blockers, because epinephrine use may result in severe hypertension secondary to unopposed α -adrenergic stimulation.

CRYSTALLOIDS If hypotension is present, it is generally the result of distributive shock and responds to fluid resuscitation. Patients should receive a NS bolus of 1 to 2 L (10 to 20 mL/kg in children) concurrently with the epinephrine infusion.

Second-Line Therapy

The second-line anaphylaxis treatments include corticosteroids, antihistamines, asthma medications, and glucagon.¹ These drugs are used to treat anaphylaxis refractory to the first-line treatments or associated with complications, and also to prevent recurrences.

CORTICOSTEROIDS All patients with anaphylaxis should receive corticosteroids. Methylprednisolone 125 mg IV (2 mg/kg in children; up to 125 mg) or hydrocortisone 250 to 500 mg IV (5 to 10 mg/kg in children; up to 500 mg) are appropriate. Methylprednisolone produces less fluid retention than does hydrocortisone and is preferred for elderly patients and for those patients in whom fluid retention would be problematic (e.g., renal and cardiac impairment).

ANTIHISTAMINES All patients with anaphylaxis should receive histamine-1 (H₁) blockers, such as diphenhydramine 25 to 50 mg IV.^{2,14} Because the histamine-2 (H₂) blockers are effective in shock refractory to epinephrine, fluids, steroids, and H₁ blockers, it is recommended that H₂ antihistamines be considered as well.^{2,14} Use of H₂ antihistamines is common in refractory urticaria; however, clear evidence of benefit from controlled trials is lacking. If considered, H₂ blockers such as ranitidine and cimetidine may be used in anaphylaxis. Cimetidine should not be used for patients who are elderly (side effects), with multiple comorbidities (interference with metabolism of many drugs) have renal or hepatic impairment, or whose anaphylaxis is complicated by p-blocker use (prolongs metabolism of p-blockers and may prolong anaphylactic state). After the initial intravenous dose of steroids and antihistamines, the patient may be switched to oral medication (Table 34-2).

AGENTS FOR ALLERGIC BRONCHOSPASM If wheezing is present, a selective bronchodilator, such as intermittent or continuous nebulized albuterol, should be instituted. As might be expected, asthmatics are often more refractory to the treatment of allergic bronchospasm. For severe bronchospasm refractory to the above-mentioned treatments, other treatments such as anticholinergics and magnesium sulfate can be added.¹⁵ Anticholinergic agents should be added to the nebulized albuterol (ipratropium bromide 250 to 500 μ g/dose) in severe acute bronchospasm. Magnesium sulfate improves pulmonary functions and reduces admissions when administered in severe acute asthma.¹⁵ It is inexpensive and free of major side effects when used in single doses of magnesium sulfate 2 g IV over 20 to 30 min in adults and 25 to 50 mg/kg in children. Bronchodilator and stimulant agents should be used with caution (lower dose and slower rate) in elderly patients. Intravenous aminophylline and (3-agonists have no role to play in the early management of acute bronchospasm because their benefit is marginal, as compared to other agents, and their side-effect profile is impressive. There are no data yet on the role of leukotriene receptor antagonists in the treatment of anaphylaxis, although this area warrants further study, given the proven role of the cysteinyl leukotrienes in late-phase allergic responses.

TABLE 34-2 Anaphylaxis and Allergic Reactions Drug Dosing

Drug	Adult Dose	Pediatric Dose
Epinephrine	IV single dose: 100 μ g over 5–10 min; 1:100,000 dilution given as 0.1 mg in 10 mL at 1 mL per min IV infusion: 1–4 μ g per min IM: 0.3–0.5 mg (0.3–0.5 mL of 1:1000 dilution)	IV infusion: 0.1–0.3 μ g/kg per min; maximum 1.5 μ g/kg per min IM: 0.01 mg/kg (0.01 mL/kg of 1:1000 dilution)
IV fluids: NS or LR	1–2 L bolus	10–15 mL/kg bolus
Diphenhydramine	25–50 mg q6h IV, IM, or PO	1 mg/kg q6h IV, IM, or PO
Ranitidine	50 mg IV over 5 min	0.5 mg/kg IV over 5 min
Cimetidine	300 mg IV	4–8 mg/kg IV
Hydrocortisone	250–500 mg IV	5–10 mg/kg IV (max: 500 mg)
Methylprednisolone	125 mg IV	1–2 mg/kg IV (max: 125 mg)
Albuterol	Single treatment: 2.5–5.0 mg nebulized (0.5–1.0 mL of 0.5% solution) Continuous nebulization: 5–10 mg per h	Single treatment: 1.25–2.5 mg nebulized (0.25–0.5 mL of 0.5% solution) Continuous nebulization: 3–5 mg per h
Ipratropium bromide	Single treatment: 250–500 ng nebulized	Single treatment: 125–250 (xg nebulized
Magnesium sulfate	2 g IV over 20 min	25–50 mg/kg IV over 20 min
Glucagon	1 mg IV q5min until hypotension resolves, followed by 5–15 μ g per min infusion	50 μ g/kg IV q5min
Prednisone	40–60 mg per d PO divided bid or qd (for outpatients: 3–5 days; tapering not required)	1–2 mg per d PO divided bid or qd (for outpatients: 3– 5 days; tapering not required)

GLUCAGON Concurrent use of (3-blocking drugs by the patient is a risk factor for severe prolonged anaphylaxis. In one study, 3 of 5 patients who had severe protracted reactions were being treated with (3-blocking drugs.³ For patients taking (3-blockers with hypotension refractory to fluids and epinephrine, glucagon should be used in a dose of 1 mg IV every 5 min until hypotension resolves, followed by an infusion of 5 to 15 μ g/min.¹ The side effects of glucagon include nausea, vomiting, hypokalemia, dizziness, and hyperglycemia.

DISPOSITION

Admission

An unstable patient with anaphylaxis refractory to treatment should be admitted to the intensive care unit. All patients who receive epinephrine should be observed; however, the timing of observation is based on experience rather than clear evidence. If the patient remains symptom free after appropriate treatment following 4 h of observation, the patient can be discharged home.³ Late recurrence is rare, but should be considered in patients with a past history of severe reaction and those using β -blockers. Other factors to consider in discharge planning include distance from medical care, whether the patient lives alone, significant comorbidity (including but not limited to asthma), and age.³

Outpatient Care and Prevention

Emergency physicians should provide discharge plans for patients that reduce the chance of recurrence and reduce the frequency and severity of future episodes. For all allergic reactions, the patient should be instructed on how to avoid future exposure to the causative agent, if possible. A prescription and clear instructions on the use of an epinephrine autoinjector should be provided to patients with serious allergic reactions or anaphylaxis when the risk of another reaction is judged to be substantial. All patients with severe or frequent allergic reactions warrant referral to an allergist for in-depth preventive management and at-

tempts at allergen identification.⁸ Patients with anaphylactic reactions should be encouraged to wear personal identification of this condition (e.g., Medic-Alert™ bracelets). Any anaphylactic patient on a (3-blocker should be switched to another antihypertensive drug.

Treatment in the outpatient setting should include antihistamines and a short course of corticosteroids, although the evidence for this is weak. Prolonged corticosteroid treatment should not be required for most cases; however, an aggressive longer-term approach does reduce the frequency of relapses in patients with idiopathic anaphylaxis.¹⁰ The evidence to treat less-severe allergic reactions with corticosteroids awaits further research. All patients should be provided with a patient information sheet detailing signs and symptoms to watch for and clear instructions for follow-up and immediate return if there is any recurrence of symptoms. Finally, a written action plan on steps to take in the event of future allergen exposure or symptom development may reduce the severity of future attacks.

URTICARIA AND ANGIOEDEMA

Urticaria, or hives, is a cutaneous reaction marked by the development of pruritic, erythemic wheals of varying size that generally are described as "fleeting." Erythema multiforme is a more pronounced variation of urticaria, characterized by typical target skin lesions. Angioedema is believed to be a similar but deeper reaction characterized by edema formation in the dermis, most generally involving the face and neck, and distal extremities. These manifestations may accompany many allergic reactions, but also may be nonallergic in nature. As with all allergic manifestations, a detailed history should be obtained. If an etiologic agent can be identified, future reactions may be avoided, although the majority of acute urticarial reactions are viral in nature. This is especially true in children, or with any hives persisting or recurring for more than 24 h. Treatment of these reactions is generally supportive and symptomatic, with attempts to identify and remove the offending agent. Antihistamines, with or without steroids, are usually sufficient, although epinephrine can be considered in severe or re-

fractory cases. The addition of an H₂ receptor blocker, such as ranitidine, may also be useful in more severe, chronic, or unresponsive cases. Cold compresses may be soothing to affected areas. Referral to an allergy specialist is again indicated in severe, recurrent, or refractory cases.

Angioedema of the tongue, lips, and face is another cause of presentation to the ED with the potential for airway obstruction. Angioedema is caused by a variety of agents; however, use of angiotensin-converting enzyme (ACE) inhibitor is a common trigger with angioedema occurring in 0.1 to 0.7 percent of patients taking ACE inhibitors. Fortunately, most cases are mild and transient. Management is supportive, with special attention to the airway, which can become occluded rapidly and unpredictably.¹⁶ Typical allergic-reaction drugs, such as antihistamines and steroids, are not proven to be beneficial because ACE-inhibitor angioedema is not associated with an increase in IgE. Epinephrine, antihistamines, and steroids are often still used; however, their benefits have not been clearly demonstrated in the literature.

Immediate withdrawal from the ACE inhibitor is indicated, and another antihypertensive should be prescribed with the important exception that angiotensin II receptor-blocking agents should not be used. Patients with mild swelling and no evidence of airway obstruction can be observed in the ED and discharged if swelling diminishes. Rebound or recurrent swelling will not occur unless the patient takes an ACE inhibitor again. Patients with moderate-to-severe swelling, dysphagia, or respiratory distress are best admitted for close observation.

Hereditary angioedema is an autosomal dominant disorder with a characteristic complement pathway defect: low levels of C1 esterase inhibitor or elevated levels of dysfunctional C1 esterase inhibitor with low levels of C4 between acute attacks.¹⁷ Reactions often involve the upper respiratory tract and gastrointestinal tract. Attacks can last from a few hours to 1 to 2 days. Minor trauma often precipitates a reaction. Many of the typical treatments of allergic reactions, such as epinephrine, steroids, and antihistamines, have been ineffective. Prophylaxis of acute attacks may be possible with attenuated androgens, such as stanozolol 2 mg/d or danazol 200 mg/d. Acute attacks can be shortened by C1 esterase inhibitor (C1INH inhibitor) replacement by a concentrate. Treatment of patients is complex and best done in coordination with the appropriate specialist.

OTHER COMMON ALLERGIC PROBLEMS

Food Allergy

Hypersensitivity reactions to ingested foods are generally caused by IgE-mediated reactions to food proteins, and, rarely, by additives; their frequency is rising for unknown reasons.¹⁸ IgE-coated mast cells lining the gastrointestinal tract react to presented allergens in ingested foods and produce clinical findings associated with the release of biologic mediators, as previously described. Non-IgE-mediated food allergy reactions have also been described. Dairy products, eggs, nuts, and shellfish are some of the most commonly implicated foods.

A detailed dietary history within the 24 h of allergic symptoms may provide the best clues to food allergy, with particular attention to other allergic history and prior reactions. Diagnosis is often difficult, however, and it may require multiple episodes before an offending agent is identified. Symptoms of food allergy include swelling and itching of the lips, mouth, and pharynx; nausea; abdominal cramps; vomiting; and diarrhea. Cutaneous manifestations, such as angioedema and urticaria, as well as anaphylaxis, can occur. Treatment for mild reactions is supportive, with the administration of antihistamines to lessen symptoms. More severe reactions or anaphylaxis are managed as previously described.

Insect Sting Allergy

Insect stings can produce significant, and sometimes fatal, reactions, particularly in sensitized patients. True stinging insects belong to the order Hymenoptera, which includes three families: Apidae (honeybees), Formicidae (fire ants), and Vespidae (wasps, yellow jackets, and hornets) (see Chap. 194). The venoms of each family are unique, although all have similar types of components, mostly proteins. This difference accounts for the limited cross-reactivity seen between the insect families, although cross-reactivity among the vespids is common. The normal, toxin-mediated reaction to these stings includes localized pain, pruritus, swelling, and redness. Often this is confused with cellulitis; and antibiotic treatment, alone or in combination with allergy medications, may be inappropriately initiated. Sensitized individuals may have exaggerated local reactions with or without systemic manifestations. Systemic reactions run from mild to angioedema, or anaphylaxis.

Diagnosis depends on clinical history, with particular attention to past reactions, and an examination to locate the site of the sting. Treatment is symptomatic and supportive. Mild local reactions can be managed with application of ice and oral antihistamines. More generalized reactions or local reactions of the head and neck may benefit from a short course of corticosteroids. Severe reactions are managed as previously described. Patients with severe reactions should be advised to carry self-administered epinephrine and antihistamines.

Drug Allergy

Although adverse reactions to drugs are a common clinical problem, true hypersensitivity reactions probably account for less than 10 percent of these problems.¹⁹ Because most drugs are small organic molecules, they are generally unable to stimulate an immune response alone. However, when a drug or metabolite becomes protein-bound, either in serum or on cell surfaces, the drug-protein complex can become an allergen and stimulate immune system responses. Thus, the ability of a drug or its metabolites to sensitize the immune system depends on the ability to bind to tissue proteins. Penicillin is the drug most commonly implicated in eliciting true allergic reactions and accounts for approximately 90 percent of all allergic drug reactions. Of those patients with fatal anaphylactic drug reactions, more than 95 percent reacted to penicillin. Overall, less than 25 percent of patients who die of penicillin anaphylaxis exhibited allergic reactions during previous treatment with the drug. Parenteral penicillin administration is more than twice as likely to produce fatal allergic reactions than is oral administration. The cross reactivity of penicillin allergy with cephalosporins is about 7 percent. Patients with a previous life-threatening or anaphylactic reaction to penicillin should not be given cephalosporins.²⁰

The clinical manifestations of drug allergy vary widely. A generalized reaction similar to immune-complex or serum sickness reactions is very common, especially with common agents like trimethoprim-sulfamethoxazole and certain cephalosporins (cefactor being the most frequent). Although data are conflicting on the crossreactivity of sulfonamide antibiotics with other sulfa-containing compounds, it is best to avoid the latter in patients with allergy to sulfonamide antibiotics (Table 34-3).²¹ Beginning usually in the first or second week after the

TABLE 34-3 Some Products Containing Sulfonamides

Furosemide
Glipizide
Thiazides
Diazoxide
Silver sulfadiazine
Mafenide acetate
Bumetanide
Celecoxib

administration of the drug, this reaction may take many weeks to subside after drug withdrawal. Generalized malaise, arthralgias, arthritis, pruritus, urticarial eruptions, and fever are common symptoms; adenopathy and hepatosplenomegaly may be identified on examination. Drug fever may occur without other associated clinical findings and may also occur without an immunologic basis. Circulating immune complexes are probably responsible for the lupus-like reactions caused by some drugs. Cytotoxic reactions, such as penicillin-induced hemolytic anemia, can occur. Skin eruptions may include erythema, pruritus, urticaria, angioedema, erythema multiforme, and photosensitivity, and severe reactions, such as those seen in Stevens-Johnson syndrome and toxic epidermal necrolysis may also occur. Pulmonary complications, including bronchospasm and airway obstruction, can occur.

Delayed hypersensitivity reactions may be manifested as a contact dermatitis from drugs applied topically. Diagnosis is best determined by a careful and thorough history. Treatment is supportive, with oral or parenteral antihistamines, glucocorticoids, and (3-adrenergic agents, as discussed above. Immediate drug withdrawal is important; however, reactions can continue or recur after a period of abstinence. Referral to an allergy specialist is indicated in these cases.

NEUROGENIC SHOCK

Brian Euerle Thomas M.
Scalea

Neurogenic shock, characterized by hypotension and bradycardia, occurs after an acute spinal cord injury that disrupts sympathetic outflow, leaving unopposed vagal tone.¹ The term neurogenic shock must be carefully differentiated from another that has a very different meaning—namely, *spinal shock*. Spinal shock refers to the temporary loss of spinal reflex activity that occurs below a total or near total spinal cord injury.² These terms are not interchangeable.

The vast majority of patients who sustain a spinal cord injury are initially evaluated in an ED.³ Although the definitive care of these patients is provided by a variety of specialists, the emergency physician usually performs the initial evaluation, resuscitation, stabilization, and transfer. The patient's prognosis and eventual outcome often depend on initial ED care. Early recognition of the potential injury, along with early spinal immobilization, will help prevent any possible worsening of an injury. For high-dose methylprednisolone therapy to be effective, it should be given within 8 h of injury.⁴ The search for associated injuries must be done early, often by the emergency physician.

EPIDEMIOLOGY

Acute spinal cord injury is usually caused by blunt trauma; penetrating trauma causes only 10 to 15 percent of cases.^{1,3} The majority of penetrating wounds that produce acute spinal cord injury are caused by gunshot wounds, with a small minority caused by stab wounds.¹ Of the blunt trauma causes, automobile accidents are the most frequent, followed by falls and sports.^{5,6} The cervical region is the most commonly injured, followed by the thoracolumbar junction, the thoracic region, and the lumbar segments.⁶ Each year, in the United States, approximately 10,000 people sustain spinal cord injury.⁵

PATHOPHYSIOLOGY

The spinal column is composed of 33 bony vertebrae with interspersed cartilaginous intervertebral disks. The typical vertebra consists of an anterior vertebral body and a posterior vertebral arch. These elements form the borders of the vertebral foramen, which contains and protects the spinal cord. The superior and inferior articular processes arising from most vertebrae allow the spine to be a strong yet flexible structure. The pedicles and laminae form the sides of the vertebral arch and are notched to allow for the passage of nerves and blood vessels.

The spinal cord is a cylindrical structure arising at the base of the brain and passing through the skull at the foramen magnum. It is surrounded and protected by three layers of meninges as well as cerebrospinal fluid. Thirty-one pairs of spinal nerves exit the spinal column via the intervertebral foramen. The spinal nerves are formed by the junction of the anterior and posterior nerve roots as they exit from the spinal cord.

The spinal cord consists of both white and gray matter. In general, the white matter is the outer covering of the cord. It contains the nerve fibers running up and down the spinal cord in tracts. The gray matter is made up of nerve cells and is formed in the shape of an H when viewed on cross section (Figure 35-1).

The autonomic nervous system, which maintains the internal balance of the body's many systems, has two main divisions: the sympathetic and parasympathetic. The sympathetic nervous system activates the "fight or flight" response, increasing the heart rate and blood pressure and constricting arterioles of the skin and intestines in order to redistribute blood flow, preferentially to the brain, heart, and skeletal muscle. The parasympathetic nervous system has the opposite effect, slowing the heart rate, decreasing blood pressure, and increasing the peristaltic activity of the gastrointestinal tract.

FIG. 35-1. Section of the spinal cord, showing the white and gray matter, spinal roots, and spinal nerve (adapted with permission from Snell RS: *Clinical Anatomy for Medical Students*. Philadelphia, Lippincott-Raven, 1973, p. 828), as well as the efferent portion of the autonomic nervous system (used with permission from Snell RS: *Clinical Neuroanatomy for Medical Students*. 4th ed. Philadelphia, Lippincott-Raven, 1997, p. 463).

The anatomy of the autonomic nervous system is quite complex (see Figure 35-1). The outflow portion of the sympathetic system starts with neuron cell bodies located in the lateral gray horns of the first thoracic to the second lumbar segments. In some cases, they may extend to the third lumbar segment. These cells are controlled by the hypothalamus via descending tracts of the reticular formation. The axons from the sympathetic nerve cells in the lateral gray horns leave the spinal cord in the anterior nerve roots and connect to the ganglia of the paraspinal sympathetic trunk. The sympathetic trunk is located along each side of the spinal column and extends along the entire length of the vertebral column. Axons arising from neurons in the sympathetic ganglia then travel throughout the body. The sympathetic fibers that innervate the heart arise primarily from the second to fourth thoracic segments.

The anatomy of the parasympathetic system is very different. The majority of the parasympathetic system is carried along the cranial nerves, although there is a portion that involves the second to fourth sacral segments of the spinal cord. The parasympathetic axons synapse with the cranial nerves in peripheral ganglia close to or within the target organ. The parasympathetic axons from the sacral segments form the pelvic splanchnic nerves. The portion of the parasympathetic system that innervates the heart originates in the dorsal nucleus of the vagus nerve and travels to the heart via the vagus nerves.

In evaluating patients with spinal cord injuries, the concepts of primary and secondary cord injury are important. When the spinal cord is initially injured, the pathologic picture may be relatively benign, showing some scattered hemorrhages and edema.⁷ Several weeks later, the appearance is much worse, with large cavities surrounded by gliosis and fibrosis.⁷

These primary or initial changes are caused by the traumatic event, which can cause compression, laceration, or stretching of the cord.⁵ Over several days to weeks, the initial injury evolves to what is termed *secondary cord injury*. Spinal cord ischemia has been suggested as the principal etiology of secondary changes, although other mechanisms may exist.^{5,7} Ischemia of the spinal cord can be caused by a variety of events. The blood supply to the spinal cord is, in general, not very substantial, and can be easily disrupted by either local trauma to the small anterior and posterior spinal arteries or injury and thrombosis to a large regional vessel, such as the great radicular artery of Adamkiewicz. General systemic hypotension and shock, if severe enough, can cause a low-flow state such that blood flow to the cord is compromised, even with an intact arterial supply.

The clinical relevance of secondary injury is that a patient's presentation can change in the period following the traumatic event. An incomplete lesion can evolve to a complete injury, or the level of injury can become higher because of the cord changes that occur during secondary cord injury.

CLINICAL FEATURES

The initial cardiovascular response after spinal cord injury may include hypertension, widened pulse pressure, and tachycardia.¹ In animal experiments, the hypotension that is characteristic of neurogenic shock generally begins within 5 min of the acute spinal cord injury and lasts 2 to 3 min.⁸

Patients with neurogenic shock are hypotensive and usually have warm, dry skin.⁸ Bradycardia is characteristic but not universal. The patient may lose the ability to redirect blood from the periphery to the core because of the loss of sympathetic tone resulting in excessive loss of heat from the skin, with subsequent hypothermia.⁸

These symptoms of neurogenic shock can be expected to last from 1 to 3 weeks.⁹ In some cases, significant rehabilitation using elastic stockings, an abdominal binder, and a tilt table may be required to prevent an orthostatic drop in blood pressure when the patient is placed upright.¹⁰

The anatomic level of the spinal cord injury influences the likelihood and severity of neurogenic shock. Any injury above T1 should be capable of disrupting the spinal tracts that control the entire sympathetic system. Any injury from T1 to L3 has the potential to partially disrupt the sympathetic outflow; intuitively, the higher the injury in this zone, the more likely or more severe the resulting neurogenic shock.¹

Incomplete spinal cord injury may also cause neurogenic shock. In a large study of 408 patients with cervical cord/column injuries, Soderstrom and Ducker reported a near equal incidence of neurogenic shock in patients with incomplete versus complete lesions; 31.6 percent versus 20.7 percent, respectively.¹¹ The explanation for this is not entirely clear. Guha and Tator, working with an acute spinal cord injury model in rats, suggest that the decline in cardiac output following acute cord injury is not a result of decreased sympathetic tone alone, but may also be caused by direct myocardial injury, similar to that seen after head injury or subarachnoid hemorrhage.¹²

An interesting difference was found with regard to incidence of neurogenic shock between patients with blunt versus penetrating spinal cord injuries. In a study of patients with blunt cervical spine/cord injury, neurogenic shock alone was believed to be responsible in 69 percent of all patients in shock.¹³ In Zipnick's study of patients with penetrating spinal injury at various anatomic levels, neurogenic shock was thought to be responsible in only 22 percent of patients in shock.¹ The reason for the difference is unclear, but is probably related to the fact that the two groups were not equivalent: blunt trauma patients had only cervical injuries, while the penetrating injury patients had injuries at all levels of the spinal cord. Also, part of the difference may stem from the fact that patients with penetrating trauma are more likely to have associated injuries.

TREATMENT

Evaluation and treatment of patients with spinal injury and neurogenic shock starts with the "ABCDEs" of trauma assessment: the "A" is not only for airway but also includes cervical spine protection, and the "D" represents disability, or neurologic evaluation (Table 35-1).^{5,9} Cervical spine protection and neurologic evaluation are not discussed further here except to say that they form the cornerstone of all further management of patients with neurogenic shock.

It is impossible to separate the initial evaluation and management of the patient with neurogenic shock from that of the general trauma patient. In essence, the diagnosis of neurogenic shock should be one of exclusion. Certain clues—such as bradycardia and warm, dry skin—may be evident, but hypotension in the trauma patient can never be presumed to be caused by neurogenic shock until all other possible sources of hypotension have been eliminated.¹ Again, a difference has been noted between blunt and penetrating spinal injuries, but a large percentage of these patients will have significant concomitant injuries, causing blood loss, which will explain their hypotension.^{1,13} It is only

Disability (neurologic evaluation)
Exposure Fluid resuscitation with crystalloid—consider pulmonary artery catheter to
avoid over hydration. Carefully search for and treat any possible causes of hypotension and blood
loss.
Maintain mean arterial pressure at 85–90 mm Hg. Transfer patient, after resuscitation, to regional spine or trauma center.

after these other injuries have been excluded that neurogenic shock can be said to be present.

Once the ABCDEs have been attended to and all other possible sources of hypotension have been investigated and treated, treatment focuses on the hypotension and bradycardia of neurogenic shock.

Hypotension is treated by rapid infusion of crystalloid; this is usually effective in treating neurogenic shock.^{6,9} During neurogenic shock, blood pools in the distal circulation because of the loss of sympathetic innervation. Infusion of intravenous crystalloid will correct this relative hypovolemia. Adequate fluid resuscitation should be undertaken with the aim of keeping the mean arterial blood pressure at 85–90 mm Hg for the first 7 days after acute spine injury.¹⁴ This level of blood pressure is a bit arbitrary and has been arrived at by clinical experience. It is thought that this level of pressure provides adequate perfusion and minimizes the effects of secondary cord injury.

The use of fluids in neurogenic shock must, however, be judicious. There is a danger of excessive fluid replacement, with resultant heart failure and pulmonary edema.¹⁵ The placement of a pulmonary artery catheter and its resultant pressure measurements can be of tremendous benefit and help prevent excess fluid administration. If intravenous fluids are not adequate to maintain organ perfusion, the use of positive inotropic pressor agents such as dopamine or dobutamine may be beneficial.⁹ These agents will improve cardiac output and raise perfusion pressure. The doses required are variable and should be titrated to the patient's hemodynamic response.

Bradycardia, when present, usually occurs within the first few hours or days of spinal cord injury because of a predominance of vagal tone to the heart.¹² In severe cases, and when the patient's hemodynamics warrant, atropine can be used for treatment. In some patients who may present with heart block or asystole, a pacemaker may be required.¹²

The use of steroids in spinal cord injury is discussed in Chap. 256. Steroids are not indicated for the treatment of neurogenic shock per se.

DISPOSITION

Any patient with neurogenic shock has suffered a severe traumatic injury will obviously be admitted to the hospital. In general, the patient with a spinal cord injury is best cared for at a trauma or spine center. Most areas have a regional spine care center, centralizing the extensive resources needed for the care of these patients and standardizing patient care.

While in the ED, the patient with a spinal cord injury and neurogenic shock can benefit from early consultation and involvement of the appropriate specialty services, namely neurosurgery, trauma surgery, and orthopedics.¹⁶ Early consultation and the consideration of transfer is most important for the patient with continuing or worsening hypotension, an evolving deficit, or a progressing level of injury.

ANALGESIA, ANESTHESIA, AND SEDATION

ACUTE PAIN MANAGEMENT IN THE ADULT PATIENT Gary D. Zimmer

Acute pain accompanies 50 to 60 percent of ED patient visits in the United States and Great Britain. Longstanding tradition and common practice have limited the assessment and treatment of pain in ED patients. Fortunately, resistance to treating acute pain in the ED is diminishing as physicians have become educated and comfortable with the benefits of treating pain in this patient population. "Oligo-analgesia" first appeared in the medical literature in 1973 and in the emergency medicine literature in 1989. Variation in analgesic use among ED patients has been correlated with ethnicity, age, and gender^{1,3} (Table 36-1). Although the source of pain varies greatly based on disease process, specific measures should be taken to address *the pain and suffering* in addition to its underlying cause.

The route of administration of analgesics is less important than the need for adequate dosing and rapid onset. In selected patients, oral or intramuscular injection of analgesics is adequate, but most patients with severe pain are best served by titrated doses of intravenous analgesics, anxiolytics, and comfort measures.

Guidelines and standards for acute pain management have been published by the Agency for Health Care Policy and Research and the Joint Commission on Accreditation of Healthcare Organizations.^{4,5} These documents are a useful guide but should be supplemented with more detailed and current information as appropriate.

PATHOPHYSIOLOGY

Pain is the physiologic response to a noxious stimulus, whereas suffering reflects the perception of pain. Acute pain management is best accomplished with analgesia and anxiolysis. The experience of pain is determined by many factors, including medical condition, physical and emotional maturity, cognitive state, meaning of pain, family attitudes, culture, and environment. Fear and anxiety accentuate physical pain.

Pain involves the release of potent mediators of inflammation and is modulated by neurocognitive factors resulting in an unpleasant sensory and emotional experience. The peripheral nervous system (e.g., nociceptors, C fibers, A-8 fibers, and free nerve endings) is responsible for somatic pain. It registers the original noxious stimulus and conducts it to the central nervous system. The primary afferent peripheral nociceptors have poorly differentiated nerve fiber terminals with slow conduction velocities (ranging from 2.5 ms⁻¹ for C fibers to 2.5 to 20.0 ms⁻¹ for A-8 fibers) and are normally activated by stimuli of strong to noxious intensity. Stimulation of these peripheral nociceptors releases several neurotransmitters. Glutamate, an excitatory amino acid released from these nociceptors, elicits fast synaptic responses in second-order neurons that are mediated by at least two excitatory amino acid receptor subtypes. Some primary afferent nerve fibers also express and synthesize neuropeptides (substance P, neurokinin A, and calcitonin gene-related peptide) that are coreleased with glutamate within the spinal cord.⁶

The dorsal horn of the spinal cord (e.g., dorsal root ganglion, inhibitory interneurons, and ascending pain tracts) integrates and modulates pain and other sensory stimuli. Supraspinal centers (e.g., hypothalamic centers, thalamic nuclei, the limbic system and reticular activating system) integrate and process pain information, allowing detection and perception of pain. Cognitive interpretation, localization,

identification of pain, and triggering of emotional and physiologic reactions also occur at this site. Unlike somatic pain, which is easily localized, visceral pain pathways are more complex and differ in structure from somatic pain pathways, which may explain the poor localization of visceral pain.

Opioid analgesics work by binding to the pain receptors in the spinal cord and brain. There are three main opioid receptors and different agents bind to and stimulate them to different degrees. Stimulation of the μ 1 receptor produces supraspinal analgesia, euphoria, miosis, and urinary retention. Stimulation of the μ 2 receptor is responsible for respiratory depression, gastrointestinal slowing, and cardiovascular depression and is the likely source of addiction. The κ receptor produces dysphoria and spinal-level analgesia. Unfortunately, there are no pure μ 1 agonists. If such an agent were developed, many of the concerns about analgesic abuse and adverse reactions would be mitigated.

EVALUATION

Pain assessment in the ED involves determining its duration, location, quality, severity, exacerbation, and mitigation. Because pain is dynamic and changes with time, its severity requires frequent reassessment, ideally involving the use of validated objective and subjective pain assessment instruments. Documentation of initial pain assessment and progress over time is important for clear communication of successful pain management strategies. There are several assessment scales useful for standard documentation.

Non-Self-Report Measurement

Variation in respiratory and cardiovascular signs and changes in patient expression and movement can occur due to pain. However, factors other than pain can cause or inhibit the same changes, making interpretation difficult. Physiologic parameters may be more useful to confirm a clinical impression than as a primary assessment tool. Non-self-report tools are more commonly used in the pediatric setting (see Chap. 134).

Self-Report Measurement

Self-report tools are the mainstay of pain assessment. Several instruments have been derived and validated in patients with acute pain and usually require only a verbal response (Table 36-2). It is important to understand the limitations of the tool used, so that the response to intervention can be adequately measured. The ideal pain assessment tool would be easy to administer, reliable, valid, and applicable to all patients, irrespective of education, culture, or psychological or developmental level. Naturally, there is no perfect tool. However, several visual scales exist that can be used to monitor pain. The most important element to these tools is that they need to be applied at the onset of intervention and then re-evaluated frequently after an intervention.

The end point for pain management is clinically significant pain relief. The interpretation of pain is variable, and the only relevant goal is to satisfy the needs of the patient. It is not acceptable to look for signs of pain relief without clearly eliciting whether the patient's symptoms have been relieved. All visual scales allow for thresholds for statistically significant decrease in pain, but *clinical significance* is the relevant end point.⁷ Therefore, each of these tools should be used in conjunction with an ongoing dialog with the patient regarding satisfaction with the attempted pain relief.

TABLE 36-1 Barriers to Adequate Emergency Department Pain Control

Patient related
Ethnicity: African-American, Hispanic
Age: elderly
Gender: male
Cognitive level: inability to verbalize pain
Terminal illness: acceptance of continued pain
Provider related
Education: inadequate understanding of pain
Fear of adverse events

ADJECTIVE RATING SCALE This is a simple, descriptive pain-intensity scale presented graphically or verbally as a linear list of pain descriptors. The labels range from *no pain* to *worst possible pain*, and the instrument allows for marks between discrete labels (Figure 36-1).

VISUAL ANALOG SCALE The Visual Analog Scale (VAS) is a 10-cm linear scale marked at one end with a term such as *no pain* and at the other end with *worst imaginable pain* (Figure 36-2). The patient places a mark on the line at the point that best represents the pain. The VAS is scored by measuring the distance of the patient's mark from either end. The VAS has been validated in trauma patients and general ED patients with acute pain.^{8,9} A change of 13 mm along this scale has been shown to be clinically and statistically significant in groups of patients, although results with individual patients will certainly vary. A disadvantage of the VAS is that it requires visual, manual, and some conceptual skill.

NUMERICAL RATING SCALE The Numerical Rating Scale (NRS) can be presented as a verbal or graphic scale to describe pain intensity. The patient is asked to self-report pain on a scale from 0 (no pain) to 10 (worst possible pain) and mark it off graphically; self-report verbally; or, when language or speech is difficult, indicate the numerical value with upheld fingers (Figure 36-3). Although not as precise as the VAS, the NRS requires no visual or manual skill and is easy to use.

FIVE-POINT GLOBAL SCALE This scale is simple to administer and does not require any significant patient interpretation. By limiting the results to five gradations of pain, however, it fails to detect small changes in perceived pain.

VERBAL QUANTITATIVE SCALE This is one of the most commonly used verbal pain scales. Patients are asked to rate their pain on a scale

from 1 to 10 without descriptors, as opposed to the NRS. Patients are familiar with the concept and usually comfortable assigning a number. It is important to remember that the value assigned by a patient is not an absolute value but rather a reference point on which to base pain control. For example, some patients with chest pain during acute myocardial infarction only report the pain as 2 to 3, whereas those with less life-threatening pain may rate it as 10.

GLOBAL SATISFACTION QUESTION The global satisfaction question is an important part of the management of all forms of pain. It does not adequately follow the improvement in pain over the course of therapy. Rather, it allows the user to know when pain relief is adequate for an individual patient.

UNIQUE PATIENT POPULATIONS

The awake, cooperative, competent patient can describe and locate pain and be assessed easily and reliably. Patients who have difficulty communicating are at risk of inadequate pain management. Patients who are cognitively impaired, psychotic, extremely young or old, or who are unable to communicate with their caregivers are at particular risk. In addition, language barriers or extreme cultural or educational disparity between the patient and the caregiver increases the risk of inadequate pain management. These scenarios require a rigorous approach to pain and the use of translators, family members, and validated, objective measurements of pain.

Extremes of Age

For comprehensive assessment of pain in the pediatric patient, age-appropriate, developmentally specific techniques are essential, and assessment is enhanced by the involvement of the parents or caregiver (see Chap. 134).

The elderly often report pain very differently from younger patients, because of physiologic, psychological, and cultural changes associated with aging. The high prevalence of visual, hearing, motor, and cognitive impairments among the elderly can be barriers to effective pain assessment, thus affecting the reliability of traditional pain assessment instruments.

Gender and Culture

Women are more likely to express pain and to actively seek treatment. However, gender-related differences in reporting of pain intensity are equivocal. Yet, physicians have a tendency to underestimate and un-

TABLE 36-2 Pain Scales

Scale	Method	Comments
Adjective Rating Scale	Patient rates pain by choosing from a linear list of pain descriptors (Figure 36-1)	
Visual Analog Scale	Patient places a mark that best describes pain intensity along a 10-cm linear scale marked at one end with a term such as <i>no pain</i> and at the other end with <i>worst imaginable pain</i> (Figure 36-2)	Pain intensity measured in millimeters from one end. Change of greater than 13 mm significant
Numerical Rating Scale	The patient is asked to self-report pain on a scale of 0 to 10 with descriptors (Figure 36-3)	Can be used in patients with visual, speech, or manual dexterity difficulties
5-Point Global Scale	Patient rates pain as: 0 = none 1 = a little 2 = some 3 = a lot 4 = worst possible	A decrease of one point is a large change; other scales allow monitoring of small changes in pain and may be more sensitive
Verbal Quantitative Scale	The patient is asked to self-report pain on a scale of 0 to 10 without descriptors	Most commonly used scale, easy to administer
Global Satisfaction Question	"Are you satisfied with the pain relief?"	May be clouded by non-pain concerns

FIG. 36-3. Numeric Rating Scale.

der treat pain in female patients. Ethnicity has a bearing on different cultural concepts of pain and on the characteristics of culturally appropriate pain-related behaviors. There is also an interplay between the ethnicity of the patient and that of the physician. Most pain instruments are, to some extent, language dependent. In practical consideration of language difficulties and cross-cultural measurement, the VAS is the preferred modality for assessment of pain.

MODALITIES OF PAIN MANAGEMENT

Effective management of acute pain includes pharmacologic agents in addition to nonpharmacologic, cognitive-behavioral, and physical techniques. The key to effective pain management in the ED is prompt onset of analgesic activity, ease of administration, safety, and efficacy (Table 36-3).

Pharmacologic Modalities

The primary agents for the control of pain are the opioids, nonsteroidal anti-inflammatory drugs (NSAIDs), and acetaminophen. Adjuncts, such as anxiolytics and antiemetics, have significant synergy but should not be used without one of the primary analgesics. Adequate control of pain with an analgesic has a mild anxiolytic effect. Using an anxiolytic alone for the control of pain has a less than expected result, because the ongoing pain serves as a nidus for additional anxiety.

A tiered approach should be used. Agents such as NSAIDs should be considered for mild pain, and systemic opioids and/or NSAIDs should be considered for moderate to severe pain. Local or regional neural blockade is a useful technique to minimize the use of narcotic agents (Table 36-4).

Although opioid analgesics are occasionally associated with adverse drug events, the biggest problem is their improper use. Several small case series have found that the incidence of overmedication is comparable to that of undermedication. This finding suggests that undermedication is actually more common, because overmedication is more likely to be recognized and documented.¹⁰

Opioid Agonists

Opioid analgesics are the cornerstone of pharmacologic management of moderate to severe acute pain (Table 36-5). Proper use of opioids requires careful and deliberate planning:

1. Route of administration
2. Suitable initial dose
3. Frequency of administration titrated against analgesic response
4. Optimal use of nonopioid analgesics and adjunctive agents
5. Incidence and severity of side effects
6. Whether the analgesic will be continued in an inpatient or ambulatory setting

FIG. 36-2. Visual Analog Scale.

Patients differ greatly in their responses to opioid analgesics; these variations are related to age, body mass, and previous or chronic exposure to opioids. Relative potency estimates provide a rational basis for selecting the appropriate starting dose to initiate analgesic therapy, changing the route of administration (e.g., from parenteral to oral), or switching to another opioid (Table 36-6). The classes of opioids include the phenanthrene derivatives, the phenylpiperidine derivatives, and the diphenylheptane derivatives (Table 36-7). Opiate hypersensitivity is uncommon and true allergic reactions are extremely rare. There is too little data to determine if there is clinical cross-sensitivity within opioid classes. Possible cross-sensitivity has been suggested among the phenylpiperidine class (fentanyl, alfentanil, sufentanil, and meperidine). Until more is known, it would be prudent to switch to a drug from a different opioid class if a patient develops a hypersensitivity reaction to an opiate. When they are used in equianalgesic doses, there is no compelling evidence to recommend one opioid over another. As much as possible, avoid using multiple agents. Become comfortable with a few agents and, whenever possible, titrate a single drug to effect in each individual. Caution is advised with the use of meperidine and codeine; although both agents are capable of producing adequate analgesia at high doses, adverse effects are more common with these two drugs compared with other opioids.

Meperidine was once the mainstay of pain management in EDs. Meperidine should no longer be routinely used for acute pain management, for several reasons: (1) it is the lowest potency opioid and, as a result, often is underdosed; (2) normeperidine, the metabolite of meperidine, has been shown to cause central nervous system toxicity in patients with compromised renal function or those taking monoamine oxidase inhibitors; (3) normeperidine can produce prolonged states of sedation (up to 48 h in rare cases); and (4) meperidine is reported to produce more euphoria and may have an increased risk for addiction when compared with other opioids.

Codeine produces more nausea, vomiting, and dysphoria than other opioids. The standard oral dose of 30 to 60 mg produces little analgesic effect above that of acetaminophen or NSAIDs.

Adverse effects of opioids include nausea, vomiting, constipation, pruritus, urinary retention, confusion, and respiratory depression. Pruritus, urinary retention, confusion, and respiratory depression are more common with intravenous, transmucosal, and epidural administrations as opposed to oral administration. As a practical matter, opioids should be withheld with respiratory depression (fewer than 10 breaths/min in an adult).

Opioids are frequently combined with adjunctive drugs (hydroxyzine or benzodiazepines), which may provide pain relief at a lower opiate dose than using an opiate alone (Table 36-8), yet the data supporting such action are scarce, and polypharmacy may produce unexpected results. Prophylactic dosing of adjuncts before treatment with analgesics is not appropriate as the incidence of adverse side effects is small.¹¹ However, symptom-targeted therapy with anxiolytics and antiemetics is sometimes necessary.

TABLE 36-3 Goals of Pain Management

Efficacy
No significant interference with evaluation of the underlying disease process
Rapidity of onset
Ease of administration

TABLE 36-4 Comparison of Pharmacologic

Class	Route	Advantages	Disadvantages
NSAIDs	Oral Parenteral	Mild/moderate somatic pain plus severe colicky pain Does not require GI absorption	Use caution in the elderly and in those with renal, GI, and hematologic disorders No more effective than oral (well-known placebo effect); costly
Opioids	Oral Intramuscular Intravenous	Can be effective if adequately dosed No IV access required Ideal for titrated dosing	Variable absorption Painful injections; unreliable absorption May require monitoring; potential for overdose
Local anesthetics	Infiltration Peripheral nerve block Regional anesthesia	Technical ease Opioid sparing Opioid and general anesthetic sparing	Limited duration of action Technical difficulty Risk of autonomic instability, hemodynamic collapse

Abbreviations: GI = gastrointestinal; NSAIDs = nonsteroidal anti-inflammatory drugs.

Concerns have been raised about delayed-release transdermal formulations, because of delayed onset and prolonged duration of action. Transdermal fentanyl preparations are used in the chronic pain and oncology setting. In general, transdermal fentanyl should be avoided for acute pain management.

Opioid Agonist-Antagonists

Opioid agonist-antagonists comprise a group of synthetic analgesics that was developed to minimize some of the adverse effects of pure opioid agonists. The major benefit has been a ceiling on respiratory depression: no further reduction in respiration with increasing doses past a set amount. Concern has been expressed about the possible ceiling effect for analgesia, but the significance of this potential problem is not clear. The variability in efficacy relates to each particular agent's affinity for the various central pain receptors. These agents should be used with extreme caution in patients with opioid addiction because they may precipitate withdrawal symptoms.

Nonopioid Agents

Acetaminophen is an effective analgesic that is adequate for mild to moderate pain. Acetaminophen does not affect platelet aggregation, and it is not an anti-inflammatory (Table 36-9). Dosing is constant throughout life, and no change is required for renal or mild hepatic impairment. The recommended maximal adult daily dose for repetitive use is 4 g per day.

The *NSAIDs*, including aspirin, naproxen, indomethacin, ibuprofen, and ketorolac, are excellent analgesics and anti-inflammatory agents. In therapeutic doses, these agents decrease inflammatory mediators generated at the site of tissue injury. They do not cause sedation, respiratory depression or interfere with bowel or bladder function. Even when insufficient alone, NSAIDs have significant opioid dose-sparing effects. There are oral, rectal, intravenous, and topical preparations. Ketorolac is the only parenteral agent available in the United States. Topical NSAIDs, effective in acute musculoskeletal injuries and chronic pain, are associated with the lowest side effect pro-

TABLE 36-5 Initial Dosing of Common Opioid Analgesics for Acute, Severe Pain

Drug	Adult Dose	Pharmacokinetics	Toxicity
Morphine	0.1 mg/kg IV 10 mg IM 0.3 mg/kg PO	Onset: 5 min IV and 10–15 min IM/SC Peak effect: 15–30 min Duration: 1–2 h IV and 3–4 h IM/SC	Histamine release may result in anaphylactoid reaction
Hydromorphone	0.015 mg/kg IV 1–2 mg IM	Same as morphine	
Fentanyl	0.5–3 µg/kg IV	Onset: almost immediately Peak effect: 1–5 min Duration: 30–40 min	High doses can cause chest wall rigidity (>5 µg/kg IV)
Meperidine	1–1.5 mg/kg IV/IM	Duration: 2–3 h	Not recommended; see text
Oxycodone	5–10 mg PO 30 mg PR	Duration: 3–6 h	Lower incidence of nausea Possible inadvertent acetaminophen overdose with combination agents
Hydrocodone	5–10 mg PO	Duration: 3–6 h	Lower incidence of nausea Possible inadvertent acetaminophen overdose with combination agents
Codeine	30–60 mg PO 30–100 mg IM	Duration: 4 h	High incidence of nausea Small portion is metabolized to morphine Low potency results in underdosing Possible inadvertent acetaminophen overdose with combination agents

TABLE 36-6 Equipotent Opioid Doses

Drug	Equipotent IV dose	Equipotent PO Dose
Morphine	1.0	3
Fentanyl	0.01	0.02 (transmucosal)
Hydromorphon	0.2	0.6
Meperidine	5	15
Oxycodone		1.5
Hydrocodone		2.0
Codeine	13	20

file, but are not widely available in the United States.¹¹ Adverse effects of NSAIDs include platelet dysfunction, impaired coagulation, and gastrointestinal irritation and bleeding. Therefore, they should be used with caution in patients with thrombocytopenia or coagulopathies and in those at risk for bleeding or gastric ulceration. Acute renal failure has been reported and may be precipitated in elderly patients, those who are volume depleted or have lost more than 10 percent of their blood volume, have preexisting renal or cardiac disease, or are taking loop diuretics.

Corticosteroids are potent inhibitors of inflammation and are excellent analgesics for visceral, orthopedic, and neuropathic pain. They are well absorbed from oral and parenteral routes. There are numerous long-term side effects of systemic corticosteroids, thus limiting their efficacy. For short-term pain management, corticosteroids are effective and safe. Dexamethasone is a good agent, because of its minimal mineralocorticoid effects.

Other Agents

Ketamine and nitrous oxide are two agents that have been used widely for brief analgesic therapy; these agents also have sedative properties. Tricyclic antidepressants and anticonvulsants are useful in treating neuropathic pain.

KETAMINE A phencyclidine derivative, ketamine produces analgesia and dissociative anesthesia with the advantage of causing minimal respiratory depression. The ability of ketamine to produce amnesia makes it a good agent for brief, minor procedures such as wound repair. Adverse effects include increased intracranial pressure, increased intraocular pressure, hypersalivation, and reemergence phenomena (disagreeable dreams or hallucinations upon awakening). It should be avoided in patients with closed head injuries or other conditions associated with increased intracranial pressure. It is a useful agent in the pediatric ED (see Chap. 134).

NITROUS OXIDE Nitrous oxide is a fast-onset, short-acting analgesic and sedative inhalational agent useful for wound dressing and brief, minor procedures. The primary adverse effects are nausea and vomiting. Barriers to ED use of nitrous oxide include the need for patient cooperation and an effective scavenging system. In addition, it cannot be used in patients with altered mental status, head injury, suspected pneumothorax, or perforated abdominal viscus. Severe pulmonary disease also may alter the respiratory elimination of nitrous oxide.

TABLE 36-7 Classification of Opioid Analgesics

Phenanthrene	Morphine, hydromorphone, nalbuphine, oxycodone, codeine, butorphanol, levorphanol, nalbuphine
Phenylpiperidine	Fentanyl, alfentanil, meperidine, sufentanil
Diphenylheptane	Methadone, propoxyphene

TRICYCLIC ANTIDEPRESSANTS AND ANTICONVULSANTS Patients with neuropathic pain are difficult to treat with standard analgesics and are often quite resistant to opioids. Amitriptyline and gabapentin have been effective in treating this type of pain.^{13,14}

Route of Administration

Systemic pain medications can be given orally, rectally, intravenously, intramuscularly, transmucosally, transdermally, by inhalation, or by epidural administration (Table 36-10). Intravenous opioids are suitable for bolus administration or continuous infusion and are preferred to intermittent intramuscular injections. Repeated intramuscular injections themselves can cause pain and trauma and may deter patients from requesting pain medication. Patient-controlled intravenous analgesic systems do have a role in the ED for the stabilized patient who is to be admitted. Oral administration is convenient and inexpensive and is appropriate once the patient can tolerate oral intake; it is a mainstay of pain management in the ambulatory ED population.

Nonsystemic agents can be delivered transdermally, transmucosally, by infiltrative local and regional injection, or IV for specific regional blocks. Alternative delivery techniques such as iontophoresis and single-dose jet injectors have been available for several years but have not yet emerged as practical, cost-effective products for routine use.

Dosage and Precautions

BASIC DOSING GUIDELINES The key principle for safe and effective use of opioids is to titrate the dose toward the desired effect while minimizing unwanted effects. In excessive or inappropriate doses, opioids can result in respiratory depression and hypotension. Relative potency estimates provide a rational basis for selecting the appropriate dose. In the setting of comorbidity, such as altered mental status, hemodynamic instability, respiratory dysfunction, or multisystem trauma, initial dosing should be decreased. However, these patients may still require large doses of analgesics, so titration becomes even more important.

EXTREMES OF AGE Patients at the extremes of age are at risk for inadequate analgesia and pharmacotherapy complications. For the comprehensive management of pediatric pain, age-appropriate assessment techniques and medication dosages and developmentally specific nonpharmacologic adjuncts are essential (see Chap. 134). Elderly patients may have more than one source of pain and comorbidity and are at increased risk for interactions between drugs and between the drug and the disease. The elderly, especially opioid-naïve patients, are more sensitive to the analgesic effects of opioid drugs, because they experience a higher peak and longer duration of pain relief. Moreover, they are more sensitive to sedation, respiratory depression, and cognitive and neuropsychiatric dysfunction.

ADDICTION The appropriate use of opioid analgesics has not been shown to produce dependence after a short duration of therapy for acute pain.¹⁵ Care must be used in the patient with concern for addiction, but reassurance and appropriate dosing guidelines should be used rather than withholding appropriate agents.

Dosing Adjustments

RENAL AND HEPATIC DYSFUNCTION Because most analgesics are metabolized by the liver or kidney, caution is required when using opioids in patients with altered hepatic or renal function. Renal excretion is a major route of elimination for such pharmacologically active opioid metabolites as norpropoxyphene, normeperidine, morphine-6-glucuronide, and dihydrocodeine. Mild renal failure can impede

TABLE 36-8 Analgesic Adjuncts

Drug	Initial Dosing	Pharmacokinetics	Comments
Anxiolytics			
Lorazepam	0.5–2 mg IV/IM	Duration: 2–6 h	Respiratory depression Synergy with opiates Idiosyncratic agitation
Midazolam	0.5–2 mg IV/IM	Duration: 0.5–2 h	Same
Diazepam	5–10 mg IV/IM	Duration: 4–6 h	Repeated doses can prolong sedation
Oxazepam	15–30 mg PO	Duration: 4–8 h	Not recommended in this setting
Antiemetics			
Prochlorperazine	5–10 mg IV/IM	Duration: 4–6 h	Can cause extrapyramidal reaction
Promethazine	25–50 mg IV/IM	Duration: 4–6 h	Same
Metoclopramide	5–10 mg IV/IM	Duration: 4–6 h	Somewhat less effective Primary action is gastric emptying
Hydroxyzine	25–50 mg IM	Duration: 4–6 h	Reported to potentiate narcotics Limited to IM use Benefit not proven

excretion of the metabolites of many opioids, resulting in clinically significant narcosis and respiratory depression. Mild hepatic dysfunction has little effect on analgesic metabolism. In patients with severe hepatic dysfunction, titration of low doses of analgesics will minimize the risk of overdose.

RESPIRATORY INSUFFICIENCY Patients with respiratory insufficiency and those with chronic obstructive pulmonary disease, cystic fibrosis, and neuromuscular disorders affecting respiratory effort (e.g., muscular dystrophy and myasthenia gravis) are particularly vulnerable to the respiratory depressant effects of opioids and nitrous oxide. Appropriate monitoring of respiratory function and adequacy of gas exchange is necessary.

DRUG INTERACTIONS Opioids may have adverse synergistic sedative effects in patients with psychiatric illnesses taking anxiolytics or other psychoactive drugs. The use of monoamine oxidase inhibitors with meperidine has been associated with severe adverse reactions, including death through mechanisms that mimic malignant hyperthermia. The tricyclic antidepressants clomipramine and amitriptyline may increase morphine levels.

Nonpharmacologic Modalities

Traditionally, nonpharmacologic techniques of pain management in the ED are limited to application of heat or cold and immobilization and elevation of injured extremities. Other techniques may prove to have a role in the ED and post-ED setting. Examples include cognitive-behavioral techniques, which are effective in reducing pain and anxi-

ety, may control mild pain when used alone, and enhance patient satisfaction. These techniques include reassurance, explanation, relaxation, music, psychoprophylaxis, biofeedback, guided imagery, hypnosis, and distraction. They are a useful adjunct to pharmacologic management of moderate to severe pain. Successful application of these therapies requires a cognitively intact patient and skilled personnel, but many of the techniques require only a few minutes to teach the patient.

Physical nonpharmacologic agents are becoming increasingly relevant to ED pain management. In addition to the traditional techniques noted above, the less commonly used physical modalities such as transcutaneous electrical nerve stimulation and acupuncture may have some potential role in the ED in the future. Although specific technical skills and equipment are required, there is no need for intravenous access, and there is no systemic effect such as respiratory depression or altered mental status.

Specific Situations

There are a number of situations in which the ideal ED analgesic management approach is complex or controversial. Acute abdominal pain, migraine, and trauma are such situations.

ABDOMINAL PAIN The 20th edition of *Cope's Early Diagnosis of the Acute Abdomen* marks a historic change in the traditional view of pain management in patients with abdominal pain: "The realization, likely erroneous, that narcotics can obscure the clinical picture has given rise to the unfortunate dictum that these drugs should never be given until a diagnosis has been firmly established. With the numer-

TABLE 36-9 Nonopioid Analgesics

Drug	Adult Dose	Toxicity
Acetaminophen	650–1000 mg PO q4h 1–2 g PR q4h	Toxic dose: 140 mg/kg in 24 h
Aspirin	650–1000 mg PO q4h	Reye syndrome in children, tinnitus
Ibuprofen	400–800 mg PO q4–6h	GI upset, platelet dysfunction, renal dysfunction, bronchospasm
Naproxen	250 mg PO q6–8h 500–1000 mg PR q 6–8h	Same as ibuprofen plus interacts with protein-bound drugs
Indomethacin	25–50 mg PO q12h 100 mg PR q24h	Same as ibuprofen
Ketorolac	30–60 mg IV q6h 60 mg IM	Same as ibuprofen

Abbreviation: GI = gastrointestinal.

TABLE 36-10 Delivery Routes of Systemic Analgesia

Method	Advantages	Disadvantages
Oral	Ease Painless Minimal cost No technical skill required Patient acceptability	Unreliable gastrointestinal absorption Requires gastric motility Slow onset Titration less reliable
Intravenous	Rapid onset Titratable Usually easier to reverse Can use medications with short half-life	Venous access required Potential for overdose
Intramuscular or subcutaneous	Convenient More rapid onset than oral route	Painful Titration difficult and requires repeated injections Absorption variable More expensive than oral route
Rectal (transmucosal)	No first-pass hepatic metabolism No reliance on gastric motility	Requires patient acceptance and cooperation Variable absorption
Buccal/nasal (transmucosal)	Ease Painless	Difficult to control dose Can irritate nasal mucosa
Transdermal	Ease Painless	Variable dose and duration Difficult to titrate Slow onset Prolonged duration after removal
Inhalational	Rapid onset and offset	Requires patient cooperation Scavenger equipment required

ous layers of triage nurses, medical students, residents, and attending physicians in modern emergency units, and with the addition of time-consuming tests often done before an adequate history *and* physical examination, the suffering patient is sometimes forced to wait for many hours before any relief is offered. This cruel practice is to be condemned, but I suspect that it will take many generations to eliminate it because the rule has become so firmly ingrained in the minds of physicians."¹⁶

Cope's book, originally published nearly a century ago, continued to advise until the 1990s against the administration of analgesics during the evaluation of acute abdominal pain. This dogma has been challenged and is without scientific basis. Early administration of intravenous opioids has been shown to be a safe and effective analgesic in patients with acute abdominal pain in the ED and does not have adverse effects on the accuracy of the evaluation, diagnosis, and management.¹⁷ The one valid concern regarding analgesia and abdominal pain concerns the patient who will not be imaged or held for serial abdominal examinations. In the absence of a diagnostic plan, the indiscriminate use of opioids is potentially dangerous.

MIGRAINE There is no obvious, best analgesic agent for the management of a patient with migraine headache in the ED. Success rates as high as 95 percent have been reported using promethazine, chlorpromazine, and prochlorperazine.¹⁸ 5-Hydroxytryptamine agonists are very effective in aborting early migraine but have limited effect after the initial prodrome. Migraine recurrence is 20 to 50 percent within 48 h with all of these agents. Headache rate at 24 h was significantly higher for patients who left the ED with persisting headache than in those who left with no pain.¹⁹ More aggressive ED treatment may result in higher successful treatment rates but also may be associated with more adverse effects from the therapy.

Dopamine antagonists, antiemetics, metoclopramide, phenothiazine, haloperidol, sumatriptan, dihydroergotamine, NSAIDs, acetaminophen, and opioids have been studied in acute migraine. The relative benefit of these agents or combinations of therapies remains unclear. Opioid use has lost favor due to poor performance in clinical trials and the potential association with drug-seeking behavior.

TRAUMA Patients in shock and those with trauma, burns, and hemodynamic or respiratory instability mandate judicious use of narcotics. Titration of short-acting, intravenous opioid analgesics, such as fentanyl, and maximal use of regional analgesia are recommended. The intramuscular route has poor and variable absorption and bioavailability in this setting and should be avoided. If patients require parenteral analgesia, they warrant close observation for occult injuries. Use of analgesic therapy also must allow for continuous monitoring of neurologic status after a head injury and neurovascular status after limb injury. In the setting of closed head injury or multiple injuries, maximal use of regional and nonpharmacologic modalities is desirable. Although of value in the patient with minor trauma, the use of NSAIDs in the major trauma patient remains controversial. Risks include (1) excessive bleeding from platelet dysfunction and gastric stress ulcers, and (2) the potential for acute renal failure in the volume-depleted patient, minimizing their usefulness for this patient group.

DISPOSITION

Although pain control alone occasionally is an adequate indication for admission, such severe pain often is associated with an underlying condition that is the primary reason for the admission. Most patients may be safely discharged with a plan for the management of their pain. Communication with a primary care provider is important to allow for the continued monitoring of pain control. Patients at risk for serious pathology should not be discharged to an unmonitored setting with opioids. This is the scenario where patients could be harmed by their analgesics, because they self-medicate and may fail to seek appropriate follow-up. Disposition is affected by knowledge of the underlying pathologic diagnosis and an awareness of the home environment and support system.

Awareness of the duration of action of analgesic medications and the time of offset with respect to discharge planning and disposition is essential. In general, shorter-acting agents are preferable, because they allow for more frequent reassessments of ongoing pain. Patients should be counseled to take subsequent doses on a regular basis or when their pain begins to return, rather than when it approaches its

peak. In addition, recent recommendations from the Food and Drug Administration have strongly discouraged the use of long-acting agents (such as sustained release oxycodone; OxyContin) for acute pain, because of the serious risk of abuse.

Written discharge instructions detailing specific medication procedures will help patients to take their medications correctly and enhance patients' awareness of side effects. This information should include names of medications, dosages and frequencies, and adverse effects.

LOCAL AND REGIONAL ANESTHESIA

Eric Higginbotham Robert J. Vissers

Local anesthesia, as it is known today, is the result of the discovery of suitable drugs and delivery methods. Cocaine was first isolated in Europe between 1859 and 1860 and introduced into clinical practice about 25 years later. Simultaneously, the advent of a precise syringe that allowed the delivery of an exact amount of a pharmaceutical agent

was being developed concomitantly in Scotland and Lyon, France.¹ Together these discoveries led to the invention of local anesthesia.

Impure cocaine's toxic and addictive effects were rapidly noticed as its use spread throughout Europe, resulting in many deaths among patients and addicted medical staff. Newer, safer agents were developed in the late 19th and 20th centuries, the ester local anesthetics (e.g., tropocaine, eucaine, benzocaine, and tetracaine) and the amide local anesthetics (e.g., procaine, lidocaine, mepivacaine, prilocaine, and bupivacaine). Overall, these drugs are less toxic than cocaine but still possess central nervous system (CNS) and cardiovascular (CV) system toxicity.

Local and regional anesthetics are essential tools in the ED for procedure- and trauma-related pain management. Local anesthetic (LA) techniques provide short-term pain relief by (1) infiltration or application of LA directly into the area to be anesthetized, (2) infiltration of LA into the region of peripheral nerves supplying the area, or (3) infusion of LA into the venous system of an extremity. Specific skills and anatomic knowledge for regional anesthesia techniques are necessary for the effectiveness of LA procedures, and knowledge of the dosages, actions, and toxicity of the LA medications are required for safe use of these agents.

LOCAL ANESTHETICS

Local Anesthetic Agents

Almost all LA agents are synthetic drugs derived from cocaine (except diphenhydramine and benzyl alcohol, which are discussed separately). The chemical structure includes hydrophilic and hydrophobic regions and a linkage (amide or ester) region. Local anesthetics are weak bases supplied as a salt (usually HCl) in an acidic pH solution to increase stability, solubility, and shelf life. The most commonly used pharmacologic agents for local infiltrative and regional anesthesia are the amide agents, with lidocaine and bupivacaine being most often used. Lidocaine has a shorter duration of action than does bupivacaine, but it possesses a lower toxicity profile. Mepivacaine, with an onset of action close to that of lidocaine, with a longer duration of action and devoid of bupivacaine toxicity, is becoming an increasingly recognized alternative.² Tetracaine, an ester LA, is frequently used in topical anesthetic preparations. Ester LAs are hydrolyzed by cholinesterase enzymes in plasma. Amide LAs are metabolized by hepatic microsomal enzymes. The metabolism rates of the amide LA (prilocaine > lidocaine > mepivacaine > bupivacaine) are slower overall than those of ester LA, creating the potential for sustained plasma levels and cumulative effects of amide LA. Maximum doses and duration of action of various anesthetics are shown in Table 37-1.

The anesthetic action of LA is produced when the drug molecules occupy enough sodium channels within the axon to interrupt activity and temporarily stop conduction. Local anesthetics bind to receptor sites on the voltage-gated sodium channels (a four-subunit transmembrane protein) in the neuronal membrane and impair or block sodium influx. As LAs increasingly occupy sodium channels, there is a decrease in the rate and degree of depolarization and repolarization, a decrease in conduction velocity, and a prolongation of the refractory period of the neural action potential.³

The pharmacologic activity of the LA agents is based on several of their biochemical properties; lipid solubility, pAT₅₀, and protein binding are the key characteristics. Potency is related to lipid solubility; LAs that are more lipid-soluble easily penetrate the nerve cell wall and result in higher intracellular concentrations and thus more blockade. The P-K_a, the pH at which 50 percent of the drug exists in the basic or non-ionized state, determines the speed of onset of conduction block. The base form is more lipid-soluble than the ionized form. Therefore, the lower the pK_a for a specific LA, the more uncharged form of the drug is present at tissue pH, and the faster it traverses lipid layers to the

TABLE 37-1 Local Anesthetic Doses for Infiltration

Drug	Concentration for Infiltration (%)†	Onset (min)	Duration (min)	Maximum Dose*			
				Without Epinephrine		With Epinephrine	
				mg/kg	Total mg	mg/kg	Total mg
Esters

Others							
Diphenhydramine	0.5–1	<2	20–30	1.25–1.7	90	§	
Benzyl alcohol	0.9	2–5	Unknown	**	**	**	

*Maximum dose based on a 70-kg patient.

†Percentage of solution defined as the number of grams per deciliter: 0.25% = 2.5 mg/mL, 0.5% = 5 mg/mL, and 1.0% = 10 mg/mL.

‡Lidocaine dose can be repeated in 2 to 4 h.

#Bupivacaine can be repeated every 4 to 6 h (maximum daily dose, 400 mg per d).

§Not given with epinephrine.

**See text.

axoplasm. Protein binding is the affinity an LA has for the sodium channel, and duration of action is related to this affinity; the longer the LA binds to the sodium channel and effects conduction block, the longer the duration of the anesthesia.

Addition of epinephrine (usually in a concentration of 1:100,000, or 10 (jbg/mL) provides a longer duration of anesthesia, promotes wound hemostasis, and slows systemic absorption, thereby decreasing the potential for toxicity and allowing a greater volume of agent to be used for extensive laceration repair.⁴ Epinephrine can increase the pain of infiltration, because it lowers the overall pH of the solution. Epinephrine acts through vasoconstriction to achieve these actions ("chemical tourniquet"). Because of this vasoconstriction, epinephrine has traditionally been avoided in an end-arterial field (e.g., digits, pinna, nose, and penis), although a recent comprehensive review found no cases of digital ischemia since the advent of commercial lidocaine with epinephrine (introduced in 1948).⁵ If epinephrine is inadvertently injected into an end-arteriole field, 1 in. of topical nitroglycerin paste applied to the affected area will quickly restore perfusion. Blood pressure should be checked to make sure hypotension does not occur, thought it is unlikely. Vasospasm and ischemia from end-arteriole or arterial injection can also be reversed with local or intravascular injection of phentolamine 1.5 to 5 mg. The main side effect of phentolamine, hypotension, is unlikely in this setting.

Toxicity

Toxicity of LA is related to the potency (i.e., lipid solubility) and duration of action (i.e., protein binding) as expressed in the target organ. Toxicity correlates with the amount of nonionized and unbound LA present. It is also related to the total dose of LA and the rate of plasma increase of the LA, with more rapid accumulation being more toxic. The relative absorption of LA is dependent on the vascularity of the site. The absorption therefore, from most rapid to slowest, is: intercostal/intratracheal > epidural/caudal > brachial plexus > mucosal > distal peripheral nerve > subcutaneous. Caution should be exercised with intercostal blocks: the recommended LA dose for intercostal blocks is one-tenth maximum for peripheral blocks. Serious adverse reactions, including systemic toxic reactions, are more frequently encountered with the use of amide rather than with the use of ester LA agents, due in part to the slower amide metabolism. However, patients with atypical plasma cholinesterase may be prone to systemic toxicity

from ester LA. The systemic toxicity of LA is enhanced by hypercarbia, hypoxemia, and acidosis. Systemic toxicity is usually the result of rapid inadvertent intravenous injection or delivery of an excessive total dose of LA. Serious systemic toxicity primarily involves the CNS and CV system (Table 37-2).

CENTRAL NERVOUS SYSTEM TOXICITY Central nervous system toxicity is due to conduction block that occurs within CNS structures. The CNS toxic effects are directly related to lipid solubility; therefore, the agents that are the most effective LAs also carry the greatest CNS toxicity. The more protein bound the agent is, the narrower the gap is between the initial milder symptoms of CNS toxicity and the more catastrophic cardiovascular reactions to LA. Toxicity is due to a combination of central excitatory and depressant activities of the LA, ranging from perioral tingling and numbness to confusion, seizure, and coma. Vigilance for the subtle symptoms of CNS toxicity is important, because the therapeutic-to-toxic ratios are often narrow with these agents. Seizure, although ominous, should be viewed as a warning for impending ventricular arrhythmias and cardiovascular collapse. Because toxicity of the LA agents is potentiated by hypoxia, hypercarbia,

TABLE 37-2 Toxicity of Local Anesthetics

	Toxic Effects
Central nervous system	Mild: visual disturbance, tongue numbness, lightheadedness, apprehension, restlessness Moderate: perioral paresthesia, muscle twitching, slurred speech, excitability, drowsiness Severe: seizures, cardiorespiratory depression, coma
Cardiovascular system	Palpitations, vasodilation, hypertension, ventricular dysrhythmias (particularly bupivacaine), myocardial depression, hypotension, bradycardia, cardiovascular collapse
Respiratory system	Hypoventilation, respiratory arrest
Allergy Amides (rare)	Esters (more common) associated with para-aminobenzoic acid metabolite
Methemoglobinemia	Cyanosis, dyspnea, dizziness, lethargy; children more susceptible

and acidosis, seizures with resultant compromise or loss of the airway can hasten life-threatening CV toxicity.³

CARDIOVASCULAR TOXICITY All LAs have a dose-dependent CV toxic effect that is mediated through sodium channel blockade within the heart. This blockade results in two main types of CV toxicity: myocardial depression and dysrhythmias. All LAs have CV toxicity, although the drugs with the highest lipid solubility have the highest incidence of significant CV toxicity (e.g., bupivacaine). In addition, bupivacaine has a "fast-in, slow-out" kinetic pattern that results in accumulation of the drug within the conduction system that increases as heart rate increases. These pharmacologic properties make bupivacaine particularly cardiotoxic and, for this reason, is contraindicated for intravenous regional anesthesia. When the primary cardiac conduction system is blocked, there is increased activity in re-entrant pathways that predisposes the heart to ventricular arrhythmias. Ventricular fibrillation or tachycardia from LA toxicity can be refractory to treatment due to the degree of sodium channel blockade. Pregnancy has been noted to worsen the toxicity of LA, bupivacaine in particular, which is probably mediated through progesterone and the adverse effects of pregnancy on venous return.

METHEMOGLOBINEMIA Prilocaine and benzocaine can cause the oxidation of the ferric form of hemoglobin to the ferrous form, creating methemoglobin. When the methemoglobin concentration exceeds 1.5 g/dL, visible cyanosis results. This cyanosis is usually benign, but when oxygen transport needs to be preserved or signs of hypoxia occur, specific treatment may be necessary (see Chap. 189).

ALLERGIC REACTIONS True allergic reactions to local anesthetics are rare and usually due to the metabolite para-aminobenzoic acid, in the case of ester anesthetics, or the preservative methylparaben, which is structurally similar to para-aminobenzoic acid, in the case of amide anesthetics. Esters are more commonly associated with allergic reactions than are amides. If a true allergy is suspected based on history or documentation, the optimal approach is to use a preservative-free agent from the other class. Diphenhydramine (0.5 to 1.0%) and benzyl alcohol are alternative anesthetic choices in patients allergic to either amide and/or ester-type anesthetics.

MANAGEMENT Management of systemic LA toxicity follows standard advanced life-support protocols (ensure a patent airway, oxygen, and ventilatory and circulatory support), immediate discontinuation of the administration of LA and prompt treatment of the CNS and CV complications. Correcting hypoxia, hypercarbia, and metabolic acidosis is paramount, because these conditions enhance the toxicity of LA. Incremental doses of intravenous benzodiazepines are usually effective to control seizures, and standard protocols should be followed for the management of ventricular arrhythmias. Arrhythmias refractory to standard advanced cardiac life-support protocols have met with anecdotal success with the use of bretylium and cardiopulmonary bypass.

Specific Agents

AMIDE LOCAL ANESTHETICS

Lidocaine Lidocaine is an amide anesthetic available in 0.5, 1.0, and 2% concentrations for injection. It is the most commonly used anesthetic in the ED, because of its excellent efficacy and low toxicity profile. Lidocaine has a rapid onset of action and intermediate duration. It has a pZ_a of 7.9, with a pH in commercial preparations of 5.0 to 7.0. Lidocaine with epinephrine has a pH within 3.3 to 5.5 (necessitating bicarbonate buffering to decrease pain during infiltration). The elimination half-life is 45 to 60 min. Metabolism is predominantly hepatic,

with high plasma levels occurring due to hepatic failure and decreased hepatic blood flow (e.g., congestive cardiac failure). Caution should be exercised if these conditions exist.

Bupivacaine Bupivacaine is an amide anesthetic that is highly protein bound. The concentration appropriate for local anesthetic use is 0.25%. It has a pAT_a of 8.1 and in commercial preparations has a pH of 3.3 to 5.5. Alkalinization with bicarbonate can cause precipitation at a pH of 6.8 or higher. Some studies suggest that its injection is more painful, possibly owing to the lower pH. It has a slow onset, long duration, and a higher CV toxicity potential. The duration of action is 4 to 6 h. Bupivacaine is preferred for prolonged procedures (such as ingrown toenail removal), when longer postprocedural analgesia is desired, and for peripheral nerve regional blocks. Bupivacaine is contraindicated for intravenous regional blocks due to its cardiac toxicity, from which fatalities have been reported. Bupivacaine also should be used very cautiously in any condition affecting hepatic metabolism.

Mepivacaine Mepivacaine is an amide anesthetic, with a pif_a of 7.6 and a pH of 4.5 to 6.8 in commercial preparations. It has a rapid onset, intermediate duration, and intermediate toxicity. Toxicity, which was once thought to approximate the level of bupivacaine, has been for the most part repudiated.² Local infiltration with a 1% concentration has been associated with anesthesia of 1.5 to 3 h in duration. Redosing for longer procedures does not cause tachyphylaxis, and cumulative toxicity is low.³

Prilocaine Prilocaine, an amide LA with pZ_a of 7.9, has a lower cardiac toxicity profile than does lidocaine or bupivacaine, with similar anesthetic potency. It has rapid onset and intermediate duration. After intravenous injection, its CNS toxicity is less than that of lidocaine due to a lower blood level, because of differences in its distribution and peripheral uptake. It is also broken down by amidases in the liver more rapidly than is lidocaine, resulting in a shorter duration of toxic effects. Prilocaine may lead to methemoglobinemia after a large intravenous bolus (or total dose >600 mg) due to the oxidative properties of one of its metabolites, o-toluidine. Clinical uses include infiltration with up to a 1% solution with an anesthetic duration of 60 to 120 min. Due to its lower toxicity, a 0.25 to 0.5% concentration is commonly used in Australia for intravenous regional arm blocks. Prilocaine and lidocaine are the active agents in a cream consisting of an eutectic mixture of LAs (EMLA) for topical use on intact skin.

ESTER LOCAL ANESTHETICS

Procaine Procaine is a short-acting ester LA, with a pK_a of 8.9. Commercially prepared solutions have a pH of 5.5 to 6.0. Procaine has a slow onset and very short blood half-life (approximately 20 s) owing to the rapid hydrolysis by plasma cholinesterase; hence, little toxicity is associated with this agent. Procaine can be used for patients who are allergic to the amide anesthetics (e.g., lidocaine).

Tetracaine Tetracaine is an ester local anesthetic, with a pK_a of 8.6. In liquid form, the pH can vary from 4.5 to 6.5. It has a slow onset, short plasma half-life (2.5 to 4 min), and long duration of action. Injectable tetracaine 0.2% is used most commonly in spinal anesthesia. In addition, it is used for topical anesthesia of the eye (0.5%) mucous membranes (2%), and skin (4% gel or cream). When applied to the larynx, anesthesia of the airway will persist for a very long duration, with absent airway reflexes. The potential for rapid uptake from mucous membranes does exist with the risk for systemic toxicity. The toxic dose is believed to be approximately 2 mg/kg.

ALTERNATIVE AGENTS Diphenhydramine 0.5 to 1.0% and benzyl alcohol 0.9% are alternative anesthetic choices in patients with true allergies to the amides and/or ester-type anesthetics.^{6,7} Although

diphenhydramine is an effective local anesthetic, its injection is more painful than lidocaine and can cause tissue irritation and even skin necrosis.⁶ Thus, its role for local anesthesia is extremely specific and limited to those patients who have true allergies to ester or amide anesthetics, which are quite rare. Benzyl alcohol 0.9% with epinephrine (1:100,000) is as effective as lidocaine and superior to diphenhydramine as an LA.^{6,7} However, the duration of action is short, and about 30 percent of patients need additional anesthetic injection during the procedure.⁷

LOCAL ANESTHETIC INFILTRATION

The most common usage of LA in the ED is local infiltration for wound repair and invasive procedures. Local infiltration has a rapid onset and low risk of systemic toxicity. Infiltration can be into the wound margins or as a field block in a "diamond-shaped wheal" of LA surrounding the wound or procedure site. Lidocaine is the drug of choice for LA infiltration for brief procedures. Bupivacaine or mepivacaine is preferable for longer procedures due to their longer duration of action, but with due caution regarding the increased toxicity. Epinephrine can be added to enhance safety and efficacy, and bicarbonate can be added to minimize pain of infiltration. The maximal dosages commonly cited apply to infiltration of LA, in contrast to the lower maximal dosages for most regional procedures (Tables 37-1 and 37-3).

Additives and Adjuncts to Minimize Pain of Infiltration

Many variables influence the degree of pain experienced with LA infiltration. The depth and rate of injection and the temperature and buffering of the agent are considerations in the attempt to make infiltration painless. Slow infiltration of the anesthetic (30 s/mL) with a 27- or 30-gauge needle will decrease the pain as compared with rapid injection with a larger needle, probably due to less rapid distention of local tissue. Numerous clinical studies have demonstrated attenuation of pain on infiltration with buffered lidocaine.⁸ Buffered lidocaine is prepared

by mixing a solution of 9 mL of lidocaine 1% (with or without epinephrine) with 1 mL of sodium bicarbonate 8.4% (1 mEq/mL). The resultant mixture can be prepared ahead of time and stored for future use. Bicarbonate can cause precipitation of bupivacaine and should not be added to this anesthetic unless it can be used immediately. It is prepared by mixing a solution of 29 mL of bupivacaine 0.25% with 1 mL of sodium bicarbonate 8.4% (1 mEq/mL). The exact mechanisms by which buffering of lidocaine reduces pain is not clear. Buffering increases the pH of these acidically packaged anesthetics, bringing the mixture's pH closer to the drug's p*i*_Q, resulting in a higher percentage of the uncharged species. The higher percentage of uncharged molecules allows faster diffusion into the nerve fiber, resulting in more rapid sensory nerve blockade. Buffering to a higher pH also may reduce direct tissue irritation by reducing the acidity of the agent. Because buffered lidocaine undergoes biodegradation at room temperature, its shelf life is limited; studies suggest that efficacy is maintained from 7 to 30 days.

Studies evaluating the efficacy of warm lidocaine (anywhere from 37°C to 42°C) to decrease injection pain have yielded equivocal results.⁸ It is postulated that warming the anesthetic causes faster diffusion into tissues and reduces or avoids stimulation of cold receptors, thereby increasing the rate of onset of neuronal block. Lidocaine can be warmed in dry heat (blanket warmers) or in temperature-regulated water baths at 37°C. From a practical standpoint, anesthetics should be administered at least at room temperature. Unlike buffered lidocaine, heated lidocaine undergoes no chemical denaturation, so there are no limitations on shelf life.

Injection through the margins of a wound rather than through intact skin surrounding it greatly reduces the pain associated with infiltration.⁹ Use of long needles reduces the number of puncture sites. To prevent breakage, no more than two thirds of the needle should be inserted. The smallest appropriate syringe allows for greater control over the volume and rate of injection.

The nuances of local wound infiltration should be mentioned and in most ways is more important than the agent selected in obtaining a desirable outcome. If the caregiver attempts to establish rapport and allay fears early in the encounter, anxious and uncooperative patients can be calmed and much of their evaluation completed before anesthetic infiltration has occurred. The neurologic examination should be demonstrated on an uninvolved, uninjured area first, to reassure the patient that the examiner will not inflict pain. Distraction techniques are beneficial, including the use of music, skin pressure, or pinching. The needle should be hidden from view of the patient, if possible. The analogy of a bee sting or insect bite should be avoided; most patients are terrified of insect bites, and for most children that has been the most painful experience in their memory. Although unstudied, a topical anesthetic application followed by infiltration may be less painful and better tolerated in selected patients.

To summarize, the least painful method of infiltration is deep, slow injection through the wound margins using a warm, buffered solution with the use of a 27- or 30-gauge needle and a concerted effort to minimize the anxiety surrounding the process.

TOPICAL ANESTHETICS

Topical anesthetics can be used to reduce the discomfort of local procedures and may eliminate or decrease the need for local infiltrative injection.¹⁰ When compared with local infiltration, topical anesthetics can be applied painlessly, do not distort wound edges, and may provide good hemostasis if the formulation includes a vasoconstrictive agent. In general, topical anesthetics work better on the head and neck than on the extremities, have a slower onset, and are less efficacious than injectable LAs. There are a number of available formulations in common use: TAC (tetracaine, adrenaline, and cocaine), LET (lidocaine, epinephrine, and tetracaine), and EMLA (lidocaine and prilocaine).

TABLE 37-3 Suggested Volumes for Regional Nerve Blocks in Adults (Weight >40 kg)

Location	Total Volume Lidocaine 1% or Bupivacaine 0.25%
Median nerve	3-5 mL
Ulnar nerve	5-7 mL
Radial nerve	5-10 mL
Digital	3-4 mL
Metacarpal	2-3 mL
Posterior tibial	3-7 mL
Sural nerve	3-5 mL
Saphenous nerve	3-5 mL
Superficial peroneal nerve	3-5 mL
Deep peroneal nerve	3-5 mL
Great toe	4-6 mL
Lesser toes	2-3 mL
Forehead	3-6 mL
Inferior alveolar nerve	1-2 mL
Mental nerve	1—2 mL (intraoral), 2—4 mL (extraoral)
Infraorbital	2-3 mL
Femoral nerve	10-20 mL
Intercostal nerve (per segment)	3-5 mL

Tetracaine, Adrenaline, and Cocaine

The TAC (original formulation: tetracaine 0.5%, adrenaline 0.05%, and cocaine 11.8%) solution has been largely replaced by other mixtures that are less likely to cause toxicity, cost less, and do not have the regulatory issues associated with a controlled substance. The TAC solution has been associated with seizures, respiratory arrest, and, rarely, death in children due to inadvertent systemic absorption of cocaine. Systemic absorption was most common when used on mucosal surfaces or in large amounts. Other agents such as LET have been found to be equally efficacious and have a more desirable safety profile.¹¹

Lidocaine, Epinephrine, and Tetracaine

The LET (lidocaine 4%, epinephrine 0.1%, and tetracaine 0.5%) solution should be prepared in single-use 5-mL vials.¹⁰ It may be applied to the wound directly as drops from a syringe, and then the remainder of the solution is soaked into a cotton ball or gauze, which is then held against the wound. The individual applying the LET should use gloves in order to prevent topical absorption to the caregiver. The LET solution should be applied for at least 20 to 30 min to achieve adequate anesthesia.¹¹ Contact with mucous membranes, fingers and toes, the ear pinna, the penis, and the tip of the nose should be avoided. It also can be used in a gel form by adding 150 mg of methylcellulose to 3 mL of LET solution. The gel may be applied directly to the wound with a cotton applicator and irrigated off after 20 min. The gel form is more likely to remain in the wound and may be associated with a higher rate of complete anesthesia.

Eutectic Mixture of Local Anesthetics (EMLA)

The EMLA cream contains lidocaine 2.5% and prilocaine 2.5%.^{10,12} The EMLA cream has been shown to be effective in relieving the pain associated with venipuncture, port access, arterial puncture, lumbar puncture, and superficial skin procedures. It has been investigated as an anesthetic for open wounds; however, the available preparation is not sterile, and its use is presently recommended only for application on intact skin. Systemic reactions are rare; however, the prilocaine may cause methemoglobinemia, particularly in children younger than 3 months. The EMLA cream should be used sparingly and with caution in infants younger than 3 months (1 g maximum dose for 1 h) and avoided in patients predisposed to methemoglobinemia. EMLA cream in adults is applied by squeezing a dollop of about 2g directly onto the skin and covering the area with an occlusive dressing; the cream layer should be left thick and not massaged or rubbed into the skin. The depth of anesthesia is related to the duration of contact, with satisfactory analgesia achieved at 1 h, peak effect at 2 h, and duration for 1 h after removal.

Lidocaine

Lidocaine is available in solution, ointment, cream, and jelly preparations in concentrations from 1 to 30%. It is commonly used to facilitate the placement of urinary catheters, nasogastric tubes, and the passage of oral and nasal fiberoptic scopes. Two percent viscous lidocaine in an oral solution has been used to provide temporary relief of stomatitis, but the patient must be cautioned to use the solution sparingly (not to exceed 1 teaspoon every 3 h) and expectorate the excess anesthetic. Lidocaine 4% solution applied intranasally with a disposable atomizer has been shown to reduce the discomfort of nasogastric tube placement, even in addition to lidocaine jelly.¹³ Plasma levels after topical mucosal applications are similar to those associated with intravenous use, and doses should not exceed 4.5 mg/kg.

The anesthetic ELA-Max is a 4% liposomal lidocaine cream.¹² The lidocaine is encapsulated in liposomes, which enhances the rate and amount of absorption in intact skin and resists rapid metabolism,

thereby prolonging its effects. Compared with EMLA, the onset is approximately twice as fast and does not require occlusion.¹² Similar to EMAL, ELA-Max should be applied in a thick layer (like cake frosting) and should not be rubbed into the skin. It is not recommended for mucosal application.

Other Topical Anesthetic Agents

A number of topical anesthetic combinations have been studied, mainly in comparison with TAC, and have demonstrated different degrees of efficacy. These preparations include prilocaine, tetracaine, or bupivacaine in combination with a vasoconstrictor, such as phenylephrine. It is unclear whether any of these have significant advantages over LET.

Benzocaine is available as a 20% liquid, gel, or spray formulation for mucosal anesthesia. It is used to relieve the pain from oral ulcers, wounds, and inflammation and to facilitate the passage of oral nasogastric tubes and endoscopy. Benzocaine rarely may precipitate methemoglobinemia. A topical combination of antipyrine and benzocaine is used to temporarily relieve the pain of otitis media or externa.

Iontophoresis is a method of delivering a topical anesthetic with a mild electric current. The device is bulky and may cause an uncomfortable electrical sensation. Presently, it has limited use in the emergency setting.

Ethyl Chloride

Ethyl chloride is not an LA but rather a skin refrigerant or vaporocoolant delivered by a spray. Upon contact with the skin, it vaporizes, causing a transient drop in temperature to — 20°C, temporarily freezing it, and causing anesthesia through nerve desensitization. It is useful for venipuncture, injections, and incisions of small abscesses.

Ethyl chloride is applied by inverting the bottle at a distance of 10 to 30 cm from the skin and spraying for 3 to 7 s. The affected area will turn white. Anesthesia is present for only 30 to 60 s. Prolonged spraying could cause chemical frostbite and skin ulceration, and it should not be used on mucosal surfaces. Ethyl chloride should not be inhaled, because it may cause general anesthetic and opioid effects. It is also flammable.

REGIONAL ANESTHETIC PROCEDURES

Regional anesthetic procedures performed in the ED include peripheral nerve blocks, hematoma blocks, and intravenous (Bier's) blocks. In addition to their utility during invasive procedures, these techniques can minimize opiate use and decrease the need for procedural sedation or general anesthesia. The safety and effectiveness of LA for regional anesthetic procedures depends on proper dosage, correct technique, adequate precautions, and preparations to deal with emergencies, if they arise. Regional procedures with LA should be employed only by clinicians who are well-versed in diagnosis and management of LA dose-related toxicity and other acute emergencies that might result from inadvertent systemic absorption of the LA or intra-arterial injection of an epinephrine-containing LA solution. The setting should have resuscitative measures immediately available, if necessary. LA should be administered in the lowest dosage that results in an effective block. Epinephrine can be added to some blocks to enhance the duration, quality, efficacy, reliability, and safety of a block. However, epinephrine is contraindicated in nerve blocks in end-arterial areas except, perhaps, digital nerve blocks.

Peripheral Nerve Blocks

Peripheral nerve blocks are advantageous in the ED environment, particularly for procedures on the digits, hand, or foot. They require less total LA medication, and the site of drug delivery often is less painful

than that for local infiltration.¹⁴ It is imperative to document neurovascular status before application of the block, to prevent masking a primary traumatic neurovascular injury. During needle insertion, if the patient reports paresthesia in the nerve distribution, that sensation can be taken as a sign of proper localization for LA injection. The onset of anesthesia with peripheral nerve blocks is more delayed than by direct infiltration and may be up to 15 min. Lidocaine 1% or bupivacaine 0.25% can be used to achieve peripheral nerve blockade (see Table 37-3). The duration depends on the agent used and the amount of drug injected. Complications of nerve blocks include nerve injury and systemic LA toxicity. During injection, severe pain suggests that contact has been made with the nerve. In this circumstance, the needle must be withdrawn and repositioned before anesthetic is injected. Intravascular injection can result in limb and systemic toxicity. Local anesthetic dose exceeding the maximum may result in systemic toxicity, primarily cardiac and CNS. To minimize the likelihood of intravascular injection, the plunger on the needle syringe apparatus should be drawn back in all nerve block procedures before infiltration; if blood is withdrawn, the needle should be repositioned. Total doses of the agent should be calculated in all cases and doubled-checked against the concentration to prevent inadvertent overdosing of a specific LA available in more than one concentration (see Table 37-1).

Wrist Blocks

MEDIAN NERVE The median nerve provides sensation to the lateral two thirds of the palm of the hand, palmar surfaces of the lateral three and one half digits, and their fingertips. The palmar branches of the median digital nerves extend dorsally over the digit to supply the dorsum of the thumb, the index finger, the middle finger, and lateral half of the ring finger distal to the proximal interphalangeal joint and including the nail and the nail bed (Figure 37-1). The median nerve enters the hand through the carpal tunnel, deep to the flexor retinaculum, between the tendons of the flexor digitorum superficialis and the flexor carpi radialis.

For lacerations of the hand, regional blocks at the wrist are performed at the level of proximal volar skin crease (Figure 37-2). The median nerve is anesthetized by inserting a 27-gauge needle perpendicular to the skin between the tendons of the palmaris longus and flexor carpi radialis muscles at the midpoint of the distal volar crease and injecting 3 to 5 mL of the LA solution with epinephrine (1:100,000).¹⁴

ULNAR NERVE The ulnar nerve can be blocked at the elbow or the wrist to provide anesthesia to the medial aspect of the hand and the small finger, including its nail and nail bed (see Figure 37-1). Just

Ulnar N Radial N | Median N FIG. 37-1. Sensory distribution of

FIG. 37-2. Palmar view of the left hand demonstrating sites for median and ulnar nerve blocks at the wrist.

proximal to the wrist, the ulnar nerve gives off a palmar cutaneous branch, which passes superficially to the flexor retinaculum and palmar aponeurosis to supply the skin of the ulnar side of the palm. It also gives off a dorsal cutaneous branch that supplies the ulnar half of the dorsum of the hand, the small finger, and the ulnar half of the ring finger. The ulnar nerve ends by dividing into a superficial and a deep branch. The superficial branch supplies cutaneous fibers to the anterior surfaces of the small finger and the ulnar half of the ring finger. In the small finger, the dorsal digital nerve extends to the tip of the digit.

A regional block of the ulnar nerve at the wrist is accomplished by passing a 27-gauge needle between the ulnar artery and the flexor carpi ulnaris at the level of the proximal volar skin crease (see Figure 37-2). Alternatively, the needle can be inserted underneath the flexor carpi ulnaris on the ulnar side of the wrist and directed toward the radial side. Once the needle is positioned and especially if the patient reports paresthesia, 5 to 7 mL of LA solution with epinephrine (1:100,000) is injected slowly.¹⁴

RADIAL NERVE The radial nerve provides sensation to the lateral two thirds of the dorsum of the hand; the proximal aspect of the dorsum of the thumb, index, and long finger; and the lateral aspect of the dorsum of the ring finger, excluding the nails and nail beds of these digits (see Figure 37-1). The superficial branch of the radial nerve is the direct continuation of the radial nerve along the anterolateral side of the forearm and is entirely sensory.

The superficial rami of the radial nerve can be blocked by raising a subcutaneous wheal with 5 to 10 mL of LA solution with epinephrine (1:100,000), beginning at the level of the tendon of the extensor carpi radialis and extending around the dorsum of the wrist to the styloid process, a distance of about 6 to 8 cm (Figure 37-3).¹⁴

FIG. 37-3. Radial view of the left hand demonstrating location for radial nerve block at the wrist.

Digital Blocks

DIGITAL NERVE BLOCK The digital nerve block provides excellent anesthesia for fingers and has a more rapid onset than the metacarpal block. It is commonly used for laceration repair, incision and drainage of paronychia, and finger or toenail removal or repair. Preparation with EMLA or ethyl chloride can minimize the pain of injection for these blocks. Epinephrine traditionally has been avoided for digital blocks, although there is no evidence to support this practice.⁵ Contraindications to performing this block are any compromise to the digits' blood supply. Complications are few, but large volumes of anesthetic can result in a compartment syndrome. Each digit is supplied by a palmar (volar) and a dorsal digital nerve on each side of the digit, superficial to the digital arteries (Figure 37-4A).

A 27- or 30-gauge needle is inserted through the skin into one side of the extensor tendon of the affected finger just proximal to the web (see Figure 37-4B, 1). After aspirating, approximately 1 mL of LA solution is injected superficially into the subcutaneous tissue lying on the dorsal surface of the extensor tendon to block the dorsal digital nerve. The needle is then advanced toward the palm until its tip is palpable beneath the volar skin at the base of the finger, just distal to the

web (see Figure 37-4B, 2). After aspirating, another 1 mL of the anesthetic solution is injected to block the palmar digital nerve. Before removing the needle, it is redirected across the extensor tendon to the opposite side of the finger, and approximately 1 mL of the anesthetic solution is injected into the tissue overlying the other dorsal digital nerve (see Figure 37-4B, 3). Five minutes later, the needle is reintroduced in the anesthetized skin on the opposite side of the finger and advanced to block the palmar digital nerve on that side of the digit (see Figure 37-4B, 4). The total volume of the anesthetic agent should not exceed 4 mL.

METACARPAL BLOCK Metacarpal blocks can be used to anesthetize the index, long, ring, or small finger, although digital blocks are preferred. The block is performed on each side of the affected finger by inserting a 27-gauge needle at a 90-degree angle to the dorsum of the hand approximately 1 cm proximal to the metacarpophalangeal joint midway between each metacarpal bone. The needle is then advanced at a 90-degree angle to the skin until its tip is at the level of the lateral volar surface of the metacarpal head or until resistance of the palmar aponeurosis is detected. After aspirating, 3 mL of LA solution is injected slowly.¹⁴

Toe Blocks

Digital nerve blocks of the toe are used for laceration repair and minor surgical procedures of the toes. Epinephrine is avoided as an adjunct to lidocaine, because of the largely theoretical risk of irreversible ischemic injury. For the lesser toes, a 27- or 30-gauge needle should be introduced through the skin on the dorsal aspect of the base of the mid-point of the involved toe (Figure 37-5B). The needle should be angled around the bone until it induces blanching of the skin on the plantar surface. As the needle is withdrawn, approximately 1.5 mL of LA solution is injected. Before the needle is withdrawn completely from the skin, it should be redirected to the opposite side of the injured toe to inject the LA agent in a similar manner. The total volume of the injected LA agent should not exceed 3 mL.

For the hallux (great toe), a modified collar (ring) block is used (see Figure 37-5A) because of the frequency of occurrence of accessory nerves over the dorsum of the great toe. The 27-gauge needle is inserted through the skin on the dorsolateral aspect of the base of the toe until it blanches the plantar skin. As the needle is withdrawn, 1.5 mL of LA solution is injected into the tissues. Before the needle is removed completely from the skin, the needle is passed under the skin on the dorsal aspect of the toe, and 1.5 mL of LA solution is injected as the needle is withdrawn from the skin. The needle is then introduced through the anesthetized skin on the dorsomedial aspect of the toe and advanced until it produces blanching of the plantar skin, at which time the needle is withdrawn and 1.5 mL of LA solution is injected. To complete the collar block, the needle is inserted at the plantar and medial aspect and advanced to the lateral side until it blanches the skin, and then withdrawn as an additional 1.5 mL of LA solution is injected. Approximately 6 mL of LA solution is needed to anesthetize the hallux.¹⁵

Foot Blocks

These regional nerve blocks are used for anesthesia of surgical procedures of the foot. There are five nerves that supply sensation to the foot. Most foot blocks involve a block of at least two nerves; it is unusual in the ED setting to need to block the whole foot. The sole of the foot is a commonly injured area, and local infiltration directly into the sole is extremely painful, difficult to perform effectively, and is not recommended. Regional nerve blocks are the preferred LA technique. Buffered lidocaine 1% and bupivacaine 0.25% are the LA agents of choice. Epinephrine is contraindicated, and these blocks should not be used in patients with peripheral vascular disease or traumatic circulatory compromise. All peripheral nerves involved in blocks of the foot

FIG. 37-4. A. Digit cross-section showing location of digital nerves. B. Needle positions for digital nerve block. 1. Initial injection to block dorsal digital nerve. 2. Needle is advanced to block palmar digital nerve on same side. 3. Needle is directed across dorsum of digit to block dorsal digital nerve on opposite side. 4. Needle is inserted to complete block of palmar digital nerve on opposite side of initial injection.

FIG. 37-5. A. Regional block of the great toe using collar infiltration technique. B. Digital nerve block of the lesser toes.

are branches of the sciatic nerve, except for the saphenous nerve (a branch of the femoral nerve; Figure 37-6).

The sensory innervations of the plantar surface of the foot are primarily the two main branches of the tibial nerve (posterior tibial and sural nerves) and a small contribution from the saphenous nerve medially. The sensory innervations of the dorsum of the foot are predominantly from the two main branches of the common peroneal nerve (the superficial and deep peroneal nerves), with contribution from the sural nerve laterally and the saphenous nerve medially. The saphenous nerve is the only branch of the femoral nerve below the knee. It becomes subcutaneous at the medial side of the knee joint and then follows the saphenous vein to a site anterior to the medial malleolus. It provides sensory innervation to the skin over the medial malleolus and extends to the skin over the medial side of the foot to the base of the great toe. The superficial peroneal nerve becomes the dorsal digital nerves. It descends toward the ankle in the lateral compartment, entering the ankle just lateral to the extensor digitorum longus, and pro-

Sural

FIG. 37-6. Sensory innervation of the foot and ankle.

vides the cutaneous supply to the dorsum of the foot and all five toes, except for the adjacent sides of the first and second toes (deep peroneal nerve) and lateral side of the fifth toe (sural nerve; see Figure 37-6). It also supplies the peroneus longus and brevis muscles. The sensory supply of the deep peroneal nerve is limited to the 1-cm area of web space between the first and second toes. Thus, blocks of the deep peroneal nerve are not reasonable or practical to perform.¹⁵

The three nerves that supply the sole of the foot are the posterior tibial nerve (most of the sole and heel), the sural nerve (posterolateral sole), and the saphenous nerve (small area, medially over the arch; see Figure 37-6). The posterior tibial nerve is located along the medial aspect of the ankle, lying between the medial malleolus and the Achilles tendon, just posterior and slightly deeper than the posterior tibial artery (Figure 37-7A) and gives off the three terminal branches, the medial calcaneal branch and the medial and lateral plantar nerves. The sural nerve travels with the short saphenous vein, posterior and inferior to the lateral malleolus; it terminates as the dorsal lateral cutaneous nerve. The saphenous nerve follows the great saphenous vein to the medial malleolus.

POSTERIOR TIBIAL NERVE BLOCK A posterior tibial nerve block is best performed with the patient in the prone position. The posterior tibial nerve is blocked by injecting the LA solution between the posterior tibial artery and Achilles tendon, at the level of the upper border of the medial malleolus (see Figure 37-7B).¹⁵ Careful aspiration is necessary to ensure no inadvertent intravascular access. Paresthesia upon needle insertion is a sign of correct placement, and adequate block is achieved with 3 to 5 mL of LA solution. If no paresthesia is encountered, then 5 to 7 mL of LA solution should be injected as the needle is withdrawn. Onset of anesthesia should occur within about 5 to 10 min if paresthesia has been elicited and in about 30 min if it has not.

SURAL NERVE BLOCK The sural nerve is blocked between the lateral malleolus and the Achilles tendon (see Figure 37-7). It is superficial, lying just anterior to the short saphenous vein, and is blocked by superficially injecting 3 to 5 mL of LA solution in a fanlike distribution just lateral to the Achilles tendon 1 cm above the lateral malleolus.¹⁵

SAPHENOUS NERVE BLOCK The saphenous nerve lies superficially between the medial malleolus and the anterior tibial tendon (Figure 37-8) and is blocked anteriorly by infiltration of 3 to 5 mL of LA between these landmarks as the needle is withdrawn.

FIG. 37-7. Posterior view of the left foot demonstrating sites for posterior tibial and sural nerve blocks.

FIG. 37-8. Anterior view of the left foot demonstrating sites for superficial peroneal, saphenous, and deep peroneal nerve blocks.

PERONEAL NERVE BLOCKS Regional block of the dorsum of the foot has fewer ED applications than do blocks for the sole of the foot, because direct infiltration of the dorsum is more easily performed. The superficial peroneal nerve primarily supplies the sensory innervation of the dorsum of the foot, with contributions from the deep peroneal nerve over the first web space, the sural nerve laterally extending to the lateral malleolus, and the saphenous nerve extending medially over the arch and the medial malleolus (see Figure 37-8).

Peroneal nerve block is best performed with the patient in the supine position. With a 30-gauge needle, a small wheal of LA is raised just above the level of the talocrural joint in the midline anteriorly, between the extensor digitorum longus and the extensor hallucis longus. The superficial peroneal nerve is then blocked by infiltration of 3 to 5 mL of buffered LA solution in a large wheal extending from this point just superior to the talocrural joint at the anterior border of the tibia to the lateral malleolus (see Figure 37-8).¹⁵ The deep peroneal nerve can be blocked by infiltrating 5 mL of buffered LA solution between the tendons of the tibialis anterior and the extensor hallucis longus just above the talocrural joint.¹⁵ However, the area supplied by the deep peroneal nerve is so small that a digital block or local infiltration would achieve the same effect.

Facial and Oral Blocks

Facial blocks are ideal anesthesia techniques for commonly injured areas such as the forehead, chin, lips, nose, tongue, and ear, where local infiltration is often not possible, extremely painful, or results in tissue distortion or potential tissue necrosis. These blocks, similar to foot blocks, often require blockade of more than one nerve to provide for adequate regional anesthesia. For all intraoral routes of infiltration, a small amount of 2% viscous lidocaine should be applied to the mucosa before injection. The needle should not be inserted to its full length during an intraoral procedure nor should the direction of the needle be changed while it is deep in tissue; if inadvertent breakage occurs, retrieval may be difficult. Injection should be slow to minimize pain, and careful aspiration should occur before any injection.^{16,17} For percutaneous routes of infiltration, topical EMLA cream, topical ELA-Max cream, or refrigerant sprays should be applied before injection.

FOREHEAD The sensory innervation of the forehead (anterior aspect from eyebrows extending posteriorly to the lambdoid suture) is supplied by the lateral and medial branches of the frontal (or supraorbital) nerve, the supratrochlear nerve, and fibers from the ophthalmic branch of the trigeminal nerve (Figure 37-9). Regional nerve block of

FIG. 37-9. Regional block of the frontal nerve above the eyebrow.

the forehead can be achieved by infiltration of 3 to 6 mL of LA solution with a 27-gauge needle into the skin immediately above the full length of the eyebrow.^{16,17}

LOWER LIP/AND CHIN Direct infiltration to the lip is very painful and causes tissue distortion, which can interfere with the quality of the repair of lacerations. The skin of the chin and lower lip is supplied by the mental nerve (branch of the inferior alveolar nerve). A block of the inferior alveolar nerve as it enters the mandibular foramen, medial and just behind the anterior border of the ramus of the mandible, is performed by the intraoral route (Figure 37-10). Block of the mental nerve can be performed by an intraoral or extraoral percutaneous route (Figure 37-11). The mental foramen is located at the mucosal reflection of the lower lip and gum, inferior to the second premolar (tooth number 20 or 29; see Chap. 242).

The landmark for the inferior alveolar nerve block is the medial surface of the mandibular ramus posterior to and 1 cm above the occlusal surface of the third molar. The physician first identifies the anterior border of the ramus and the oblique alveolar ridge by palpation with the tip of the thumb. The buccal tissues then can be pulled laterally away from the mandible by the pad of the thumb, with the index finger placed externally behind the ramus to stabilize the mandible. The mucosal injection site, 1 cm above the occlusal surface of the third molar, should be anesthetized with a topical agent. A 27-gauge needle is directed from the other side of the mouth, typically between the opposite first and second premolars, and inserted slowly until the needle point touches the bony surface of the medial surface of the ramus (see Figure 37-10). The needle is withdrawn slightly, and 1 to 2 mL of LA solution (with or without epinephrine) is infiltrated.¹⁶

For the intraoral approach to the mental nerve, the lip is retracted with the thumb and index finger, and topical anesthetic is applied to the mucosa (see Figure 37-11). A 27-gauge needle is inserted at the mucosal junction of the lower lip and gum beneath the second premolar, and 1 to 2 mL of LA solution (with or without epinephrine) is infiltrated while taking care that the needle is not introduced into the mental foramen to avoid neural injury. For the extraoral percutaneous

FIG. 37-10. Intraoral approach for inferior alveolar and lingual nerve blocks.

FIG. 37-11. Intraoral approach for mental nerve block.

approach, the mental foramen is located, and percutaneous infiltration of 2 to 4 mL of LA solution close to that location is done.^{16,17} The intraoral approach is less painful than the percutaneous approach.

TONGUE Direct infiltration into the sensate tongue is painful and poorly effective, and a regional block is preferred. The lingual nerve provides sensory innervation to the anterior two thirds of the tongue, the floor of the mouth, and gums. It lies in close proximity to the inferior alveolar nerve at the entrance to the mandibular foramen. The lingual nerve can be blocked by the intraoral route similarly to that for the inferior alveolar nerve (see Figure 37-10).

From an intraoral approach, the vertical ridge of the anterior border of the ramus of the mandible is identified by palpation with the index finger. After the mucosal injection site is anesthetized topically, the procedure for an inferior alveolar nerve block (same as above) is followed. Infiltration of the LA solution as the needle is withdrawn will anesthetize the lingual nerve. Alternatively, the lingual nerve can be anesthetized by injecting 2 to 3 mL of LA solution into the lateral floor of the mouth adjacent to the premolar teeth.¹⁶

CHEEK, LOWER EYELID, UPPER LIP, AND LATERAL ASPECT OF THE NOSE The infraorbital nerve supplies sensory innervation to the cheek, lower eyelid, upper lip, and lateral aspect of the side of the nose. A regional block of the infraorbital nerve can be performed by an intraoral approach (Figure 37-12) or extraoral percutaneous approach. The duration of action is more prolonged with the intraoral approach. To identify the infraorbital foramen, the midpoint of the lower margin of the orbit is palpated; approximately 1 cm inferior to this point, the infraorbital nerve exits the infraorbital foramen. For the in-

FIG. 37-12. Intraoral approach for infraorbital nerve block.

traoral approach, a palpating finger is positioned over the infraorbital foramen (see Figure 37-12). The cheek is retracted cephalad with the thumb and index finger, and a 27-gauge needle with syringe, held in the other hand, is directed through the mucosa at the reflection of the upper gum opposite and parallel to the long axis of the upper premolar tooth. The needle is then advanced until it is palpated near the infraorbital foramen, approximately a depth of 2.5 cm.^{16,17} Caution should be used so as not to introduce the needle directly into the infraorbital foramen, to avoid neural injury. Also, caution should be used so as not to direct the needle too far superiorly or posteriorly, to avoid inadvertently entering the orbit. The syringe should be aspirated to ensure that the facial artery and vein are avoided. Then 2 to 3 mL of LA solution is instilled adjacent to the foramen. The extraoral (percutaneous) approach uses the same landmarks for identification of the infraorbital foramen. Epinephrine is best avoided due to the proximity of the facial artery.¹⁶

NOSE The ophthalmic and maxillary branches of the trigeminal nerve also supply the sensory supply of the nose; block of the infraorbital nerve alone will not provide adequate anesthesia of the nose. The mucosal surface of the nose can be anesthetized by topical application of LA spray or gel. The ophthalmic branch of the trigeminal nerve (infratrochlear and external nasal nerves) provides sensation to the majority of the external nose in the midline. These nerves can be blocked by percutaneous infiltration of LA at the sites of their emergence from bony foramina. The remaining aspects of the nose are supplied by the maxillary branch of the trigeminal nerve, the infraorbital nerve for the lateral aspect (see above for intraoral and extraoral block technique), and the posterior nasal and nasopalatine nerves for the septum and inferior midline. The posterior nasal and nasopalatine nerves are best approached intraorally in the midline from the mucosal surface of the reflection of the upper lip.

EAR The sensory innervation to the external ear is supplied anteriorly by the auriculotemporal nerve (mandibular branch of the trigeminal nerve) and posteriorly by the greater auricular nerve and the mastoid branch of the lesser occipital nerve (branches of the cervical plexus; Figure 37-13A). Direct infiltration of the pinna should be avoided due to the risk of tissue necrosis. Regional block of the ear is

FIG. 37-13. A. Sensory nerve supply to the auricle. B. Technique for regional anesthesia of the auricle.

achieved by infiltration of LA solution via a 27- or 30-gauge needle at the base of the ear from an inferior and superior direction, anteriorly and posteriorly (see Figure 37-13B).

Femoral Nerve Block

Femoral nerve block is an effective technique for relieving pain of a femoral shaft fracture and is useful in the multiple trauma patient when minimizing opiates is important. The femoral nerve is lateral to the femoral artery at the inguinal ligament and innervates the anterior thigh, the periosteum of the femur, and the knee joint (Figure 37-14). Bupivacaine 0.25 to 0.5% is suggested as the preferred LA agent, because of its longer duration of action. A sterile field is prepared over and surrounding the femoral triangle. The femoral artery is located midway between the anterior superior iliac crest and the pubic tubercle. The femoral artery is compressed 1 to 2 cm below the inguinal ligament with the nondominant hand. A wheal of LA is raised in the skin and subcutaneous tissues lateral to the artery; the needle is then introduced at an angle 45 to 60 degrees to the skin lateral and parallel to the femoral artery and directed cephalad. A double loss of resistance, or "pop," is felt as the needle traverses the fascia overlying the femoral nerve. Ten to 20 mL of LA without epinephrine is slowly injected. Onset of anesthesia is 10 to 20 min, and the duration is 3 to 8 h.

FIG. 37-14. A. Location for femoral nerve block. B. Sensory innervation for the femoral nerve (shaded area).

Intercostal Block

Intercostal block is valuable for the management of pain after chest trauma (typically rib fracture) or discomfort from a chest tube. It is a simple block; however, caution should be exercised due to the rapid and high systemic absorption of LA at this site. Contraindications are local soft tissue disease and contralateral pneumothorax. Complications include pneumothorax and systemic toxicity. The intercostal nerves run anteriorly within the neurovascular bundle along the inferior portion of the rib. Addition of epinephrine enhances the safety of this block. The LA dosage range for an adult is 3 to 5 mL per segment (pediatric dosage, 1 to 3 mL). To perform this procedure, the landmarks are the palpable intercostal spaces and the midaxillary line. The intercostal space is identified by palpation. On the upper margin of this space, the inferior border of the upper rib is palpated. At the mid or posterior axillary line, the needle is inserted and advanced at a 90-degree angle until the rib is reached. The needle is withdrawn slightly and redirected caudally to the inferior aspect of this upper rib (Figure 37-15).

HEMATOMA BLOCKS

Hematoma blocks are a simple, quick, and effective mode of regional anesthesia for isolated closed fracture reduction. Although hematoma blocks are safe, the anesthesia that they provide is not as efficacious as the intravenous regional (Bier's) block.¹⁸ The hematoma block is a useful alternative when the intravenous block is contraindicated.

Superficial anesthesia is obtained with local infiltration or other technique such as EMLA applied to the skin over the fracture site. An analgesic dose of opiate also can be given, if deemed appropriate. The fracture site is identified and, using sterile technique, the hematoma is aspirated with a 10-mL syringe and a 20- to 22-gauge needle. Lidocaine 1% without epinephrine is infiltrated to a dose of 3 to 10 mL into the fracture cavity and around the periosteum. The block is effective within 5 to 10 min, with several hours' duration.

INTRAVENOUS REGIONAL BLOCK (BIER'S BLOCK)

The intravenous regional block is an anesthetic procedure involving intravenous infusion of LA distal to an inflated pneumatic tourniquet.¹⁹ It is useful for fracture reductions, large laceration repairs, and foreign body removal. Duration of regional anesthesia is 30 to 60 min. In addition to routine monitoring and resuscitation equipment, the procedure requires a double-cuff tourniquet with a constant pressure gas source. A standard blood pressure cuff is not acceptable and can result in catastrophic systemic leakage of LA. Contraindications include peripheral vascular disease, Raynaud syndrome, sickle cell disease, cardiac conduction abnormalities, hypertension, cellulitis, and children

FIG. 37-15. Intercostal nerve block.

younger than 5 years. The need for patients to have nothing by mouth for 4 h before the procedure also may limit the usefulness of the technique. Intravenous regional blocks are used most commonly for upper extremity procedures. Less frequently, this technique has been applied to the lower limb in children.

Lidocaine (3 mg/kg or 0.6 mL/kg of 0.5% solution) without epinephrine is used. In Australia and the United Kingdom, prilocaine (3 mg/kg or 0.6 mL/kg of 0.5% solution) is used. Increased efficacy has been shown with the addition of intravenous ketorolac (60 mg) or fentanyl (1 fLg/kg) to the lidocaine.²⁰ Bupivacaine is absolutely contraindicated due to cardiac toxicity. A "minidose" block with lidocaine (1 to 1.5 mg/kg) has been used effectively in children.

Vital signs and limb neurologic status and perfusion should be monitored and recorded. Intravenous access should be established in both upper limbs, distal to the fracture site on the affected limb. Standard resuscitation equipment and medications should be available. A small dose of intravenous opiate may allay apprehension and the pain of the cuff, which usually occurs after 15 to 30 min. The injured extremity is elevated, and an Esmarch bandage may be applied (distal to proximal) to exsanguinate the limb. Protective padding is then applied to the upper arm to minimize cuff discomfort. Pneumatic double cuffs are then positioned over the padding on the upper arm. The proximal cuff is inflated to 50 to 100 mm Hg above systolic pressure. A venous tourniquet may be positioned just proximal to the fracture site to contain the intravenous local anesthetic to this site. The lidocaine (or prilocaine) 0.5% solution is injected slowly over 2 min into the intravenous cannula in the affected limb. Mottling of the affected limb should occur within 2 to 5 min, followed by anesthesia and paresis of the limb, usually within 10 to 20 min. After 10 min, the distal cuff should be inflated (the area under this cuff should now be anesthetized); once the distal cuff is securely inflated, the proximal cuff can be deflated to minimize cuff pain. The distal cuff should not be deflated until at least 30 min has elapsed from the time of LA injection for tissue binding of the LA agent to occur and thus to minimize the potential for toxicity. Loss of tourniquet pressure before this time will result in a systemic bolus of LA and potential systemic cardiac and CNS toxicity. After completion of the procedure, deflation of the distal cuff should be cycled to prevent the bolus infusion of the LA into the systemic circulation. The cuff is deflated for 5 s, followed by inflation for 1 to 2 min. This cycling action should be repeated three to four times.

PROCEDURAL SEDATION AND ANALGESIA

David D. Nicolaou

Pain is the chief complaint in approximately 50 percent of patients who seek care in the ED.¹ In addition, physical examination, diagnostic tests, and therapeutic procedures in the ED are often painful. Sedation and analgesia for these painful circumstances is useful to reduce patient pain and anxiety and enhance the success of ED evaluation and treatment.

DEFINITIONS

Pain is a noxious sensation transmitted by specialized nervous structures to the brain, where its perception is modified by cognition and emotion.² Analgesic and anesthetic techniques may modulate pain at the level of the peripheral nerves, spinal cord, thalamus, or cortex.

Analgesia is "relief of perception of pain without intentional production of a sedated state. Altered mental status may be a secondary effect of medications administered for this purpose."³ Agents for pain relief interrupt axonal action potential propagation (e.g., local anesthetics), modulate the inflammatory cascade (e.g., ibuprofen), or modulate central nervous system (CNS) responses to pain (e.g., enkephalins and opioids).

Anxiolysis is the reduction of apprehension without alterations in the level of consciousness.³ A kind approach to the patient, a realistic and unhurried explanation of what may be expected, distracting conversation, and music have anxiolytic properties.⁴

Neuroleptosis is quiescence, indifference to surroundings, and reduced motor activity. Agents used for this purpose include haloperidol and droperidol.

Dissociation is characterized by amnesia, analgesia, sedation, and maintenance of muscle tone. Ketamine is the only commonly used dissociative agent.

Sedation is controlled reduction of environmental awareness.³ It is not so much a specific level of consciousness as a continuum incorporating anxiolysis or light sedation at one extreme and general anesthesia at the other. The agent or agents chosen, the rate of delivery, the pharmacokinetics of CNS uptake and redistribution, the kinetics of metabolic and elimination pathways, and the degree of patient stimulation may result in different degrees of sedation over time. The level

of sedation is dynamic within a given patient and must be continually assessed to detect changes in its depth.

The term *conscious sedation* has been abandoned in favor of *procedural sedation and analgesia* (PSA).⁵ The levels of sedation and analgesia defined by the Joint Commission on Accreditation of Health Care Organizations (JCAHO) are:⁶

1. Minimal sedation (anxiolysis): A drug-induced state during which individuals respond normally to verbal commands. Although cognitive function and coordination may be impaired, ventilatory and cardiovascular functions are unaffected.
2. Moderate sedation and analgesia (previously termed "conscious sedation"): A drug-induced depression of consciousness during which individuals respond purposefully to verbal commands alone or accompanied by light tactile stimulation. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained.
3. Deep sedation and analgesia: A drug-induced depression of consciousness during which individuals cannot be easily aroused but respond purposefully after repeated or painful stimulation. The ability to independently maintain ventilatory function may be impaired. Individuals may require assistance in maintaining a patent airway and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.
4. Anesthesia: Consists of general anesthesia and spinal or major regional anesthesia. It does *not* include local anesthesia. General anesthesia is a drug-induced loss of consciousness during which individuals cannot be aroused, even by painful stimulation. The ability to independently maintain ventilatory function is often impaired. Individuals often require assistance in maintaining a patent airway, and positive pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.

PRINCIPLES OF PSA

The indications for PSA include the treatment of severe pain, attenuation of the pain and anxiety associated with procedures, rapid tranquilization, and the need to perform a diagnostic procedure. No single regimen fits all patients and their clinical problems, so agents and amounts used should be individualized. The physician must integrate the nature of the planned procedure with an assessment of the patient's wishes and physical status, the physician's skills, the patient's intended disposition, the available resources, and a sound knowledge of the pharmacology of the available drugs to formulate a management plan.

The agents used for PSA often have a relatively narrow therapeutic index. *They should therefore be given in small incremental intravenous doses, allowing adequate time for the development and assessment of peak effect.* If the desired effect seems unusually difficult or easy to achieve, no additional medication should be administered and the patient should be carefully monitored until the cause is determined (Table 38-1). Monitoring of patients and medication administration should be performed by another provider who understands the pharmacology of the agents used, possesses sound advanced airway-management skills, and will not be distracted by other tasks during the period when the patient's ability to independently maintain their airway is in doubt.

Ideally, a dedicated area for PSA should be established, with well-labeled supplies and equipment always in a consistent location (Table 38-2). A supply cart or cabinet can easily be stocked with drugs and labels, resuscitation and monitoring equipment, and equipment for common procedures. Drug dosages and documentation tools may be kept in one location, thereby improving risk management and quality-improvement efforts.

The use of pulse oximetry during PSA is important. By 1990, more than 80 deaths had been reported after the use of midazolam, commonly in conjunction with an opioid, for sedation.⁷ Co-administration of midazolam (0.05 mg/kg) and fentanyl (2.0 mg/kg) to 12 healthy

TABLE 38-1 Differential Diagnosis of Unexpected Drug Effects by Phase of Drug Disposition

Phase of Disposition	Clinical Effect	
	Less Than Expected	More Than Expected
Delivery	Blood pressure cuff/tourniquet up IV catheter dislodged IV line clamped/kinked IV bag empty Syringe dose less than intended	Syringe dose more than intended
Uptake and distribution	Hypovolemia Acidosis (opioids) Elevated acute-phase reactants (fentanyl)	Alkalosis (opioids) Hypoproteinemia (protein-bound drugs) Pregnancy (fentanyl)
Redistribution	Obesity (fentanyl)	Reperfusion of muscle (after large doses of fentanyl)
Metabolism	Alcohol use P450 enzyme underexpression (codeine)	P-450 enzyme inhibitors (e.g., cimetidine) P450 enzyme substrates which compete for metabolism (e.g., erythromycin, lidocaine, midazolam, opioids) Liver disease (morphine)
Elimination		Renal disease Hypovolemia (especially fentanyl) Advanced age (especially fentanyl)
Other	Tolerance	Use of other drugs Delirium Metabolic encephalopathy

volunteers produced hypoxemia (oxygen saturation <90 percent for longer than 10 s) in 11 and apnea in six.⁷ A study of pulse oximetry and nasal end-tidal CO₂ values in 27 ED patients who were sedated with benzodiazepines and/or opiates for a painful procedure noted that one patient developed clinically significant apnea and eight developed clinically silent hypoxemia.⁸ The American Medical Association's Council on Scientific Affairs subsequently called for the development of standards by specialty societies for the use of pulse oximetry during PSA.⁹ Several investigators have noted that, when oxygen supplementation is given, extreme ventilatory insufficiency may develop in the absence of hypoxemia. The clinical significance of hypoxemia during sedation is still uncertain, but abnormal pulse oximetry certainly counsels providers to evaluate the patient carefully.

ASSESSMENT OF PATIENTS

A patient's general physical status can be described conveniently by using the American Society of Anesthesiologists' classification (Table 38-3). Any medications or intoxicants should be solicited and their effects considered when selecting medications. The patient's airway should be systematically evaluated by the provider who will be responsible for its management during PSA (Chap. 19).

It is important to recognize that not every patient can or should undergo PSA in the ED. Depending on clinical circumstances, a patient with an anticipated difficult airway or an American Society of Anesthesiologists classification of III or IV may require consultation with an anesthesiologist. Patients with underlying neurologic diseases such as cerebral palsy, myasthenia gravis, or mental retardation may be much more sensitive to sedatives, and consultation is suggested in such cases.

Procedural sedation and analgesia requires careful assessment of its risks and benefits based on the clinical scenario and the agents to be used. Patients should be fully informed of the risks of the procedure and the alternatives available. The patient's expectations should be carefully explored and should be corrected when these are not reasonable. Clarify to the patient that PSA is not general anesthesia and that no surety of complete amnesia and analgesia can be offered. Written informed consent for PSA, separately or as part of the procedural consent, is important, as is the physician's documentation of the discussion with the patient.

PHARMACOLOGY

Analgesics

Opioids are the most common analgesics used in PSA. Classes of opioid analgesics include natural (e.g., morphine) and semisynthetic (e.g., codeine, hydromorphone, oxycodone) 5-ring opium derivatives (phenanthrene) and synthetic 3-ring compounds. Of the semisynthetic opioids, phenylpiperidines (e.g., meperidine, fentanyl, sufentanil, and alfentanil) are the only compounds commonly used for PSA (Table 38-4). The analgesic activity of a drug is traditionally referenced to morphine (Table 38-4). After systemic administration, morphine analgesia is mediated through supraspinal μ receptors (possibly by activating descending inhibitory pathways to the dorsal horn cells, and possibly by activating more rostral mechanisms in the brainstem). Spinal cord analgesia is mediated by κ_2 receptors. All opioids have analgesic, sedative, and antitussive effects; they do not reliably produce amnesia when given in doses commonly used for PSA. Opioids also may pro-

duce muscle rigidity, pruritus, nausea, vomiting, and constipation and impair ventilation. Respiratory depression is potentiated in the presence of other CNS depressants. The two opioids in common use for ED PSA are morphine and fentanyl.

Morphine is a naturally occurring opioid that is approximately 35 percent protein bound, 77 percent ionized at pH 7.4, and is poorly lipid soluble. It therefore is slow to penetrate the blood-brain barrier and, after small bolus injections, 10 to 30 min is required before its peak effects are seen. Doses of 0.2 mg/kg result in peak effects in less than 1 h that may last for 4 to 6 h. Morphine releases histamine and therefore may produce hypotension, especially in preload-dependent patients. Its analgesic effects and its respiratory depression have been shown to be potentiated by coadministration of hydroxyzine in post-operative patients¹⁰; the significance of this finding for ED PSA is uncertain, especially because hydroxyzine is not recommended for intravenous use. Morphine undergoes hepatic glucuronidation to morphine-3-glucuronide and morphine-6-glucuronide; the latter is four times as potent as morphine and has a duration of action approximately double that of its parent. The daughter compounds are renally excreted and accumulate in renal insufficiency.

Fentanyl is a synthetic phenylpiperidine derivative that is approximately 80 to 85 percent protein bound and 92 percent ionized at pH 7.4. However, it is highly lipid soluble, resulting in rapid CNS uptake with an effect onset half-time of 6.4 min. Fentanyl is also distributed into adipose tissue, creating a "reservoir" of fentanyl. The size of this reservoir is dose dependent, with higher doses resulting in a progressively increasing duration of effect as the drug is released from tissue stores and then eliminated. Further, distribution from plasma may not result in drug levels below those associated with clinical effects and respiratory depression. Thus, the use of relatively high doses of fentanyl (i.e., in the range of 10 μ g/kg) results in greatly prolonged clinical effects and elimination half-times. Fentanyl is metabolized in the liver to inactive compounds.

Fentanyl has been shown to have a low complication rate when used for PSA in the ED. Chudnofsky and colleagues noted six cases of respiratory depression (largely in patients who were intoxicated or had received other drugs) and three cases of hypotension among 841 ED patients receiving fentanyl.¹¹ Respiratory depression occurs at significantly lower fentanyl doses when another respiratory depressant, such as alcohol or midazolam, is present. Chest wall rigidity may occur in a dose-dependent fashion after fentanyl administration; approximately half of healthy volunteers develop chest wall rigidity in response to 15 μ g/kg, a dose not usually used in PSA in the ED. Rigidity and apnea, however, may occur with even small doses of fentanyl, resulting in respiratory insufficiency. The rigidity is not reliably antagonized by naloxone and may require neuromuscular blockade and intubation to enable adequate ventilation. Fentanyl does not release histamine, which mediates most of the peripheral vascular effects of opioids, so it rarely produces hypotension.¹²

Meperidine is a poor choice for ED analgesia in general. It causes more histamine release than morphine or fentanyl.¹² Its primary metabolite, normeperidine, is bioactive and toxic. Normeperidine causes CNS excitation, including tremors, myoclonus, and seizures, effects that are not antagonized by naloxone. Normeperidine is excreted by the kidneys and therefore accumulates in renal insufficiency and with repeated doses. Meperidine also may cause a fatal reaction when coadministered with monoamine oxidase inhibitors. This reaction may be excitatory (agitation, rigidity, hyperpyrexia, seizures, and coma) or depressive (respiratory depression, hypotension, and coma). For these reasons, there are better choices than meperidine for treatment of pain with opioid analgesics.

Anxiolytics

The prototypical anxiolytics in common use for PSA in the ED are the benzodiazepines, which potentiate the inhibitory activity of

TABLE 38-3 American Society of Anesthesiologists Physical Status Classification

Class	Description	Examples
I	Normal, healthy patient	—
II	Mild systemic disease	Asthma, controlled diabetes
III	Moderate systemic disease	Stable angina, diabetes with hyperglycemia, moderate chronic obstructive pulmonary disease
IV	Severe systemic disease	Unstable angina, diabetic ketoacidosis
V	Moribund	—
+E	Modifier added to any classification indicating "emergency" status	All emergency department patients

TABLE 38-4 Drugs Used for Procedural Sedation and Analgesia

Drug	Dose*	Peak Effect	Duration of Effect	Notes
Morphine	0.05-0.1 mg/kg IV	10-30 min	%4 h	Releases histamine
Fentanyl	1-2 μ g/kg IV	2.5-10 min	30-90 min	Does not release histamine
Midazolam	0.01 mg/kg IV	1-2 min	60 min	Respiratory depression
Propofol	0.2 mg/kg per min infusion	6-7 min	5-10 min	Respiratory depression, deep sedation
Etomidate	0.1 mg/kg IV	20-30 s	2-3 min	Respiratory depression, deep sedation
Ketamine	1-2 mg/kg IV	5 min	30-60 min	Avoid with elevated intracranial pressure
Methohexital	1 mg/kg IV	30-60 s	10 min	Avoid in patients with seizure disorders

incremental doses, given in small intravenous amounts, allow adequate time for the development and assessment of peak effect.

7-aminobutyric acid (GABA) in the CNS by binding to benzodiazepine-specific receptors on the GABA_A-benzodiazepine receptor complex. This binding induces a conformational change that potentiates GABA-mediated chloride influx, resulting in sedation, amnesia, anxiolysis, and anticonvulsant effects and respiratory depression. The benzodiazepine most commonly used for PSA in the ED is midazolam, which produces earlier sedation, more frequent amnesia, less pain on injection, and improved 90 min alertness and readiness for discharge when compared with diazepam.¹³

Midazolam has a number of characteristics favorable for use in ED PSA. Its diazepine ring opens at pH values below 4, in which form it is quite water soluble. At physiologic pH, the ring closes, rendering midazolam highly lipid soluble, with associated rapid CNS uptake producing peak effects within a few minutes of intravenous administration. Midazolam's relatively high volume of distribution compared with other benzodiazepines derives from its lipophilicity. This characteristic is greatly amplified in obese patients, resulting in an increase in plasma half-life from 2.7 to 8.4 h. Midazolam is cleared by hepatic hydroxylation to 1-hydroxymidazolam (which is pharmacologically active) and to 4-hydroxymidazolam and 1,4-dihydroxymidazolam, which are conjugated and excreted in the urine.

The combination of midazolam with alcohol or opioids greatly increases sedative and respiratory-depressant effects and increases the risk of cardiovascular depression. Midazolam should be used cautiously in such cases, with careful monitoring of respiratory and hemodynamic status. The dose of midazolam should be individualized. Midazolam should be given in small incremental doses until the desired effect is achieved. Aliquots of 0.25 to 0.5 mg given every 3 to 5 min in healthy adults, or 0.1 to 0.25 mg every 5 to 10 min in the intoxicated or elderly patient, is a reasonable starting point. Chronic alcohol users who do not have cirrhosis may require relatively high doses of midazolam to achieve the clinical effects desired.

Anesthetic Agents

Some agents traditionally used for induction of general anesthesia are also used for PSA: propofol, etomidate, ketamine and methohexital.

Propofol (2,6-diisopropylphenol) is a lipid-soluble anesthetic agent that is supplied in an emulsion of soybean oil and purified egg phosphatide, which most egg-allergic patients should tolerate, because it contains no protein. The emulsion is responsible for frequent burning on injection and contains no preservatives, resulting in the risk of bacterial growth in improperly handled solutions. When given by infusion, the onset of sedation is rapid (6 to 7 min), and it resolves rapidly (5 to 10 min) upon discontinuation of the infusion.¹⁴ Amnesia, however, is not reliably produced in doses used for sedation. The drug possesses antiemetic properties. Propofol produces significant cardiovascular depression, with dose-related declines in systolic blood pressure of up to 25 to 40 percent when given in induction doses. This effect is more pronounced in those with impaired hemodynamic status and in the elderly.

The use of propofol for ED PSA is controversial, and its use outside the operating room by nonanesthesia personnel may be restricted by hospital policy. Limited studies using propofol for ED PSA in children and adults have found a rapid onset of sedation, rapid recovery, and high patient and physician satisfaction scores.¹⁴ Propofol is an attractive agent for ED PSA, because it rapidly produces sedation that quickly abates when the infusion is discontinued. In doses usually used for PSA, however, analgesic and amnestic agents may be required, which may result in hypoventilation and potentiate the already significant hemodynamic effects of propofol. The research agenda and issues surrounding propofol use by the emergency physician have been delineated.¹⁵

Etomidate is an imidazole derivative that has sedative and hypnotic properties but no analgesic activity; its effects, although not fully understood, may be mediated through the GABA complex. Etomidate reliably produces hypnosis of about 100 s in duration for each 0.1 mg/kg administered by bolus injection. It is rapidly metabolized in the liver to largely inactive compounds, with a short elimination half-life, but redistribution (also rapid) is responsible for the resolution of hypnosis. Etomidate itself is highly (75 percent) protein bound, producing exaggerated effects in hypoproteinemic patients. It produces little alteration in hemodynamics, cerebral blood flow, respiratory function, or coronary oxygenation. Reported adverse effects include nausea and vomiting, myoclonus, and suppression of adrenal steroid synthesis after long-term infusion.¹⁶ The dose used for induction of anesthesia is 0.2 to 0.6 mg/kg as a bolus; doses used for PSA include titrated boluses of 0.1 mg/kg or an infusion of 5 to 8 μ g/kg per min, with or without opioid analgesic supplementation. The use of opioids increases the frequency of respiratory depression.

Experience with etomidate for PSA in the ED is limited. Small prospective trials in adults and children and retrospective reviews of the use of etomidate for PSA have suggested that the agent is promising.¹⁶ These studies found a low risk of apnea, intubation, and hemodynamic compromise with good patient acceptance; however, deep sedation frequently occurred.¹⁶

Ketamine is a phencyclidine derivative that has analgesic and anesthetic properties. Ketamine anesthesia is often called "dissociative," reflecting electroencephalographically demonstrable discontinuity of the corticothalamic and limbic systems. The patient's eyes often remain open, with spontaneous horizontal and vertical nystagmus. Muscle tone may be increased, and corneal reflexes and spontaneous swallowing are preserved; occasional purposeful movements unrelated to the environment occur. Emergence reactions, characterized by disturbing dreams and vivid, sometimes frightening hallucinations, occur in 5 to 30 percent of patients. Patients at greatest risk for emergence reactions are older than 16 years, female, normally dream, have personality disorders, or receive droperidol or atropine. These phenomena may be attenuated with benzodiazepines given before or at the completion of the procedure.

Ketamine is highly lipid soluble and has a pKa of 7.5, accounting for the rapid (within 1 min) onset of hypnosis after intravenous injection.

tion. Peak brain and plasma concentrations develop within 1 min; rapid redistribution to peripheral tissues results in a mean hypnosis time of 6 min (1.0 mg/kg) to 10 min (2.0 mg/kg). Ketamine is metabolized by the hepatic P-450 system to several active metabolites, the chief among which is norketamine. Norketamine appears within 2 min of a bolus injection and is one-tenth to one-third less potent than the parent drug, but does not appear to penetrate the CNS in quantities sufficient to produce hypnosis. Subsequent metabolites are conjugated and renally excreted, but, because they are much less active, the dose appears not to require adjustment in patients with renal insufficiency. Drugs that induce the P-450 system increase the metabolism of ketamine, whereas inhibitors prolong the duration of effect.

The hemodynamic response to ketamine is complex. It is a direct myocardial depressant and vasodilator, but these effects are typically overshadowed by stimulation of significant CNS sympathetic outflow, resulting in tachycardia and vasoconstriction. (My experience is that fentanyl 1 to 2 (xg/kg given 3 to 5 min before the procedure, attenuates this effect but increases the frequency of hypoxemia, especially when ketamine is given rapidly and/or midazolam is also used.) However, profoundly hypovolemic patients or those with little sympathetic reserve (e.g., cocaine users) may develop hypotension, particularly at rapid rates of injection.

The pulmonary effects of ketamine make it an appealing agent. Although it produces bronchodilation and bronchorrhea, it rarely causes significant respiratory depression unless given by rapid injection (over less than 60 s) or coadministered with other agents. Patients nearly always retain protective airway reflexes, but this is not a certainty.¹⁷ Careful monitoring is therefore necessary when ketamine is used, especially with other agents or for deep sedation.

Before giving ketamine, it is important to consider the drug's likely nontherapeutic effects. If a hyperdynamic state or bronchorrhea may not be well tolerated, then appropriate premedication (opioids or glycopyrrolate) should be given or another agent chosen. A specific discussion of the emergence phenomenon with the patient, family, and friends will reduce the impact of this occasionally dramatic event.

The dose of ketamine commonly used for analgesia is 0.5 to 1.0 mg/kg IV over 60 s. Anesthesia is produced by doses of 1 to 2 mg/kg. When relatively larger doses are administered, midazolam should be given during the emergence phase to attenuate emergence phenomena.

Methohexital is a highly lipophilic short-acting barbiturate with a rapid onset of sedative action, typically 30 to 60 s. Intravenous doses of 1 mg/kg produce sedation for about 10 min. Cumulative doses of 4 to 5 mg/kg are commonly used for procedures with a relative low incidence of complications. In contrast to other barbiturates, methohexital may worsen or precipitate seizures, and it is prudent to avoid methohexital in patients with known seizure disorders.

Adjunctive Agents

Antiemetic agents are useful in the treatment of nausea and vomiting accompanying opioid therapy. Their value as "potentiators" of opioids is not clear, and they should not be used routinely for this purpose.

Antidotal Agents

Agents to reverse the effects of opioids and benzodiazepine should be available, but with careful titration of the drugs used for PSA, reversal agents should infrequently be needed.

Naloxone, a competitive antagonist of opioids at (x receptors, is indicated for reversal of unwanted respiratory depression after opioid administration. Naloxone may not reverse chest wall rigidity caused by fentanyl. Patients who are opioid dependent may develop withdrawal or pain after the administration of naloxone, and when circumstances permit they should be given titrated doses (0.1 to 0.2 mg IV every 1 to 2 min) rather than large bolus doses until the desired effect is achieved. Because patients who receive long-acting opioids or who

metabolize opioids slowly may redevelop respiratory depression after clearing all or part of an effective dose of naloxone, continual patient reassessment is required after naloxone administration.

Flumazenil, which is a competitive antagonist of benzodiazepines, is given in intravenous aliquots of 0.1 to 0.2 mg every 1 to 2 min until the desired effect is achieved. It has a half-life of 45 to 104 min, rendering relapse of sedation a possibility if the effects of a long-acting benzodiazepine are reversed with flumazenil. Flumazenil should be used with caution in benzodiazepine-dependent patients. In one study of 133 ED patients,¹⁸ flumazenil was found to reverse midazolam-induced sedation safely and effectively. However, the time from completion of the procedure to discharge from the ED was no shorter in the group treated with flumazenil than in the control group.¹⁸ Flumazenil is indicated for reversal of respiratory depression caused by benzodiazepine during PSA, but its routine use to "awaken" patients cannot be recommended.

DISCHARGE

Patients receiving PSA require a period of observation to allow the sedative and analgesic effects to resolve sufficiently before discharge (Table 38-5). Guidelines for safe discharge may require modification based on the patient's age, clinical circumstances, the agents used, and the patient's social situation. Patients must not be permitted to drive or operate heavy machinery for at least 24 h after PSA. The agents used for PSA often produce anterograde amnesia, which may be present even when consciousness appears otherwise normal. It is therefore vital to evaluate the patient's ability to retain information before discharge.

Discharge planning is an important component of PSA and should be part of the pre-procedure evaluation process. A patient who is likely to require prolonged post-procedure monitoring or treatment should be considered for hospital admission. If a companion is required for discharge, he or she should be identified before beginning PSA.

POLICY ISSUES

Clinical Standards and Documentation

The increasingly widespread use of PSA outside the operating room has garnered the attention of various organizations. The clinician's decisions regarding PSA are increasingly subject to regulations and standards, and these in turn are evolving in parallel with local and national PSA experience. The development of guidelines concerning ED PSA has been hampered by the lack of high-quality clinical evidence, such as clinical trials, supporting particular practices. As a result, few evidence-based standards exist.

The JCAHO standard specifies that a uniform standard of care must be provided throughout an accredited institution. This means that situations in which protective airway reflexes are typically expected to be lost might be held to the standard of care provided in the operating room. The American College of Emergency Physicians¹⁹ and the American Society of Anesthesiologists²⁰ have begun to promulgate guidelines. Each ED should develop standards for PSA that are carefully reconciled with JCAHO, hospital, evidence-based, and peer

TABLE 38-5 Discharge Criteria for Patients Receiving Procedural Sedation and Analgesia

Vital signs stable for at least 30 min	No evidence of respiratory distress	Minimal or no nausea, vomiting, or dizziness	Alert, oriented, and able to retain information	Able to take fluids and medications by mouth	Ambulation consistent with preprocedure status	Receives, comprehends, and retains discharge instructions	Responsible person present to accompany patient
--	-------------------------------------	--	---	--	--	---	---

requirements and practices and then strive to provide and document care consistent with that standard.

Chronic pain serves no obvious biologic function. Chronic pain patients presenting to the ED have not been well studied, despite their apparent numbers.

Complete eradication of pain is not a reasonable end point in most cases. Rather, the goal of therapy is pain reduction and return to functional status. Chronic pain syndromes discussed in this chapter include myofascial headaches, "transformed" migraine headaches, fibromyalgia, myofascial chest pain, back pain, complex regional pain types I and II, postherpetic neuralgia, and phantom limb pain. Drug-seeking patients are also covered.

EPIDEMIOLOGY

Chronic pain affects about one-third of the U.S. population at least once during an individual's lifetime, with an estimated annual cost of 80 to 90 billion dollars in health care payments and lawsuit settlements. Chronic pain may be associated with a chronic pathologic process in the musculoskeletal or vascular system, a chronic pathologic process in one of the organ systems, a prolonged dysfunction in the peripheral or central nervous system, or a psychological or environmental disorder. Discussion of the numerous epidemiologic factors that have been associated with various chronic pain syndromes is beyond the scope of this chapter. In general, patients who attribute their chronic pain to a specific traumatic event experience more emotional distress, more life interference, and more severe pain than those with other causes.¹

PATHOPHYSIOLOGY

The pathophysiology of chronic pain can be divided into three basic types: nociceptive pain is associated with ongoing tissue damage, neuropathic pain is associated with nervous system dysfunction in the absence of ongoing tissue damage, and psychogenic pain has no identifiable cause.² Many chronic pain states begin with an episode of nociceptive pain and then continue with neuropathic or psychogenic pain. For example, an acute injury with fracture involves nociceptive pain, but an associated nerve injury may lead to neuropathic pain, and chronic disability may lead to psychogenic pain. Nociceptive pain results from the stimulation of nociceptors in tissues or organs by noxious mechanical, thermal, or chemical stimuli. Chemical mediators of inflammation, such as bradykinins and prostaglandins, are essential elements in the pathophysiology of nociceptive pain. Examples of chronic nociceptive pain are cancer pain and pain due to chronic pancreatitis. Patients with nociceptive pain usually respond well to centrally acting analgesics. Neuropathic pain is caused by disease of the central or peripheral nervous system. Examples of neuropathic pain include complex regional pain type II (causalgia), postherpetic neuralgia, and phantom limb pain. Neuropathic pain responds poorly to common analgesics, including opioids. Psychogenic pain is a diagnosis of exclusion and can be difficult to establish in the ED. Patients with psychogenic pain believe their pain is physical and tend to strongly reject the concept that it is psychological.

CLINICAL FEATURES

To better define the psychology of chronic pain, psychiatrists have divided patients' characteristics into two groups. The first group has normal psychological function at baseline. However, continued pain and its effects, such as inability to work or altered body image, result in psychological dysfunction. The second group has primary psychopathology that predates the onset of chronic pain. Hypochondriacal, hysterical, pain-prone, and depressive personalities are included in this group. The "seven Ds" (Table 39-1) summarize the clinical features of this second group.

The following set of historical inquiries may prove helpful in the ED. The patients should be asked to describe the nature of the current

MANAGEMENT OF PATIENTS WITH CHRONIC PAIN David M. Cline

Chronic pain is defined as a painful condition that lasts longer than 3 months, a pain that persists beyond the reasonable time for an injury to heal, or a pain that persists 1 month beyond the usual course of an acute disease. There are four basic types of chronic pain: pain persisting beyond the normal healing time for a disease or injury, pain related to a chronic degenerative disease or persistent neurologic condition, cancer-related pain, and pain that emerges or persists without an identifiable cause. Chronic pain differs from acute pain in its function. Acute pain is an essential biologic signal to warn the individual to stop a potentially injurious activity or to prompt one to seek medical care.

TABLE 39-1 Psychological Characteristics of Chronic Pain Patients

Characteristic	Features
Drugs	Misuse of opioids or other medications
Doctors	Tendency to "doctor shop" and play one physician against another
Dysfunction	Bodily impairment related to the physical and emotional factors
Disability	Inability to work or hold a job
Dependence	Loss of self-reliance and helplessness
Dramatization	Exaggeration, acting out by verbalization or by body language
Depression	Despair and negative attitudes

Source: Brena SF, Chapman SL: The "learned pain syndrome": Decoding a patient's pain signals. *Postgrad Med* 69:53, 1981.

pain and the initiating and exacerbating or relieving factors. Other useful information includes determination of the chronic nature of the pain, quantification of similar episodes, and sources and modes of treatment, including medications and dosages for physician-prescribed, over-the-counter, or alternative medications. Outcomes of previous therapeutic efforts and the effect of the condition on the patient's functional status are also important. Addiction to drugs or alcohol or experience with detoxification programs should be noted. A review of systems should be done to rule out other conditions. Substance abuse is a frequent problem in chronic pain patients. Drug detoxification is often the first step of the therapeutic plan for new patients referred to a pain clinic.

Objective findings of acute pain include tachycardia, hypertension, diaphoresis, and muscle spasms on stimulation. Objective evidence of chronic pain includes muscle atrophy in the distribution of pain due to disuse, skin temperature changes due to the effects of the sympathetic nervous system after disuse or secondary to nerve injury, and trigger points, which are focal points of muscle tenderness and tension. How-

ever, these findings do not have to be present for the pain to be factual (Table 39-2).

Myofascial Headaches and Transformed Migraine

Myofascial headache is a variant of tension headache characterized by the presence of trigger points on the scalp; constant, squeezing pain; and occasionally shooting pain. Nausea, vomiting, neck pain, and neck tenderness may be present. It is important to differentiate this disorder from common tension headache, because myofascial headache may benefit from referral for injection of trigger points. *Transformed migraine* is a syndrome in which classic migraine headaches change over time and develop into a chronic pain syndrome. One cause of this change is frequent treatment with opioids. In this regard, patients who initially have "vascular symptoms" eventually have predominantly muscular symptoms: non-throbbing, squeezing, bandlike pain associated with muscle tenderness and tension. Nausea and vomiting or failure of oral antimigraine medications often prompts an ED visit.

Fibromyalgia and Chronic Myofascial Chest Pain

Fibromyalgia is classified by the American College of Rheumatology as the presence of 11 of 18 specific tender points, non-restorative sleep, muscle stiffness, and generalized aching pain, with symptoms persisting for longer than 3 months (www.rheumatology.org). *Chronic myofascial chest pain* classically is a dull, constant pain associated with trigger points on the chest wall. Symptoms may mimic ischemic myocardial-type chest pain but usually is not provoked by exercise (unless the movement involves the use of chest or arm muscles) and is not completely relieved by rest.

Back Pain

Risk factors for chronic back pain after an acute episode include male sex, advanced age, evidence of nonorganic disease, leg pain, prolonged initial episode, and significant disability at onset.³ Chronic back pain symptoms and causes can be divided into myofascial or muscular, articular, and neurogenic types. Myofascial back pain is

TABLE 39-2 Signs and Symptoms of Chronic Pain Syndromes

Disorder	Pain Symptoms	Signs
Myofascial headache	Constant dull pain, occasional shooting pain	Trigger points on scalp, muscle tenderness, and tension
Transformed migraine	Initially migraine-like, becomes constant, dull; nausea, vomiting	Muscle tenderness and tension, normal neurologic examination
Fibromyalgia	Diffuse muscle pain, stiffness, fatigue, sleep disturbance	Diffuse muscle tenderness, > 11 trigger points
Myofascial chest pain	Constant dull pain, occasional shooting pain	Trigger points in area of pain
Myofascial back pain syndrome	Constant dull pain, occasional shooting pain, does not follow nerve distribution	Trigger points in area of pain, usually no muscle atrophy, poor ROM in involved muscle
Articular back pain	Constant or sharp pain exacerbated by movement	Local muscle spasm
Neurogenic back pain	Constant or intermittent, burning or aching, shooting or electric shock-like; may follow dermatome; leg pain > back pain	Possible muscle atrophy in area of pain, possible reflex changes
Complex regional pain type I (RSD)	Burning persistent pain, allodynia, associated with immobilization or disuse	Early: edema, warmth, local sweating Late: above alternates with cold; pale, cyanosis, eventually atrophic changes
Complex regional pain type II (causalgia)	Burning persistent pain, allodynia, associated with peripheral nerve injury	Early: edema, warmth, local sweating Late: above alternates with cold; pale, cyanosis, eventually atrophic changes
Postherpetic neuralgia	Allodynia; shooting, lancinating pain	Sensory changes in the involved dermatome
Phantom limb pain	Variable: aching, cramping, burning, squeezing or tearing sensation	None

Abbreviations: ROM = range of motion; RSD = reflex sympathetic dystrophy.

characterized by constant dull and occasional shooting pain that does not follow a classic nerve distribution. Pain may or may not be exacerbated by movement. Usually trigger points can be found at the site of greatest pain, and muscle atrophy is not found. Range of motion of the involved muscle is reduced, but there is no actual muscle weakness. Previous recommendations for bedrest in the treatment of back pain have proven counterproductive.⁴ Exercise programs have been found to be more helpful in chronic low back pain.⁵ Articular back pain is characterized by constant or sharp pain that is exacerbated by movement and associated with local muscle spasm. Myofascial and articular back pain may be indistinguishable from each other except by advanced imaging techniques beyond the usual scope of practice in the ED. Neurogenic back pain is classically characterized by constant or intermittent pain that is burning, shooting, or aching. The pain is usually more severe in the leg than in the back and follows a dermatome. Muscle atrophy and reflex changes can be seen over time.

Complex Regional Pain

Patients with complex regional pain type I, also known as reflex sympathetic dystrophy, and complex regional pain type II, also known as causalgia, may be seen in the ED as early as the second week after treatment of an acute injury.⁶ These disorders cannot be differentiated from one another on the basis of signs and symptoms. Type I occurs because of prolonged immobilization or disuse, and type II occurs because of a peripheral nerve injury. These disorders should be suspected when a patient presents with classic symptoms: allodynia (pain provoked with a gentle touch of the skin) and a persistent burning or shooting pain. Associated signs early in the course of the disease include edema, warmth, and localized sweating. Therefore, it may be difficult to distinguish this disorder from an underlying wound infection or osteomyelitis. Later signs include periods of edema and warmth that alternate with cold, pale, cyanotic skin and eventually atrophic changes. Complex regional pain is an important diagnosis to make, because early steroid treatment may reduce ongoing symptoms. Further, when complex regional pain is associated with a cast, pin, or external fixation apparatus, the device may need to be removed.⁶

Postherpetic Neuralgia

The classic pain of postherpetic neuralgia may follow the course of an acute episode of herpes zoster in 8 to 70 percent of cases; increased incidence is seen with advancing age. Pain is characterized by allodynia and shooting, lancinating (tearing or sharply cutting) pain. Often patients have hyperesthesia in the involved dermatome. Occasionally there are pigmentation changes in the distribution of the involved dermatome, but this is not unique to postherpetic neuralgia.

Phantom Limb Pain

Phantom limb pain is quite variable in presentation but is more frequent in patients who had pain in the extremity before amputation. Pain may be aching, cramping, burning, tearing, or squeezing. Failure to respond to any treatment, including opioids, is common.

DIAGNOSIS

The most important task of the emergency physician is to distinguish an exacerbation of chronic pain from a presentation that heralds a life- or limb-threatening condition. The history and physical examination should confirm the chronic condition or point to the need for further evaluation when unexpected signs or symptoms are elicited. Because chronic pain patients may be frequent visitors to the ED, the entire staff may prejudge the complaint as chronic or factitious. Physicians should insist that routine procedures be followed, including a full triage assessment and a complete set of vital signs.

Rarely is a provisional diagnosis of a chronic pain condition made for the first time in the ED. The exception is a form of post-nerve injury pain, complex regional pain. The sharp pain from acute injuries, including fractures, rarely continues beyond 2 weeks' duration. Pain in an injured body part beyond this period should alert the clinician to the possibility of nerve injury, and proper treatment (Table 39-3) should be instituted.

Definitive diagnostic testing of chronic pain conditions is difficult and requires expert opinion and often expensive procedures such as

TABLE 39-3 Management of Selected Chronic Pain Syndromes

Disorder	Primary ED Treatment	Secondary Treatment*	Possible Referral Outcome
Cancer pain	NSAIDs, opiates	Long-acting opiates	Optimization of medical therapy
Myofascial, headache	NSAIDs, cyclobenzaprine	Antidepressants, phenothiazines	Trigger point injections, optimization of medical therapy
Transformed migraine	NSAIDs, cyclobenzaprine	Antidepressants	Optimization of medical therapy, opioid withdrawal
Fibromyalgia	NSAIDs	Antidepressants, exercise program	Optimization of medical therapy, dedicated exercise program
Myofascial, chest pain	NSAIDs	Antidepressants	Trigger point injections, optimization of medical therapy
Myofascial, back pain syndrome	NSAIDs, stay active	Antidepressants	Trigger point injections, optimization of medical therapy
Articular back pain	NSAIDs		Surgery, physical therapy
Neurogenic back pain	Acute: tapered prednisolone or prednisone	NSAIDs, muscle relaxants	Epidural steroids, surgery, exercise program
Complex regional pain types I and II (RSD and causalgia)	Prednisone 60 mg/d X 4 d and then taper to include 3 wk of therapy	Calcitonin, antidepressants, anticonvulsants	Spinal cord stimulation, intrathecal baclofen, sympathetic nerve blocks, spinal analgesia
Postherpetic neuralgia	Simple analgesics	Gabapentin, antidepressants	Regional nerve blockade
Phantom limb pain	Simple analgesics	Antidepressants, anticonvulsants	TENS, sympathectomy

*If started in the ED, consultation and/or follow-up with a pain specialist or personal physician is recommended.

Abbreviations: NSAIDs = nonsteroidal anti-inflammatory drugs; RSD = reflex sympathetic dystrophy; TENS = transcutaneous electrical nerve stimulation.

magnetic resonance imaging, computed tomography, and thermography. Therefore, referral back to the primary source of care and eventual specialist referral are warranted to confirm the diagnosis.

TREATMENT

The management of chronic pain conditions uses a multitude of modalities; some are listed in Table 39-3. Emergency physicians must avoid both labeling patients with pain as drug seekers or legitimate patients deserving opioids for pain relief. With these labels, emergency physicians may exacerbate the problem and promote the learned pain response, in which patients believe that they must come to the ED for pain relief. Chronic pain patients often request opioids, although the lure of going to the ED can be just as strong without receiving opioids. Any drug that alters sensorium can exacerbate the learned pain response. The external rewards of visiting the ED for medication or evaluation are many: attention and comforting from family and nursing staff, status as a special patient who must go the ED for pain control, avoiding responsibilities at work and at home, potential money if litigation is involved, and potential income if a disability claim is pending.

Opioids

Before approximately 1990, the use of opioids for chronic pain was discouraged by pain specialists. Since that time, pain specialists have recommended opioids as an important option in a well-integrated treatment program.⁷ In a general medical population, 44 percent of those with chronic pain were being managed in part with opioid analgesics.⁸ Data from the Drug Abuse Warning Network showed the national trend of increased medical use of opioid analgesics without a concomitant increase in opioid addiction.⁹ However, treatment with opiates frequently contributes to the psychopathologic aspects of chronic pain. Further, many types of chronic pain are poorly controlled by opiates, and yet the side effects remain. There are two essential points that affect the use of opioids in the ED: opioids should be used for chronic pain only if they enhance function at home and at work, and one practitioner should be the sole prescriber of opioids or should be aware of their administration by others. A previous opioid addiction is a relative contraindication to the use of opioids in chronic pain; when such patients are treated with opioids, addiction relapse rates approach 50 percent.¹⁰

Long-acting opioids, such as methadone or transdermal fentanyl, may be more effective than the short-acting agents. Controlled release oxycodone (OxyContin, Purdue Pharma, Stamford, CT) has received considerable attention as a drug frequently abused and diverted for illegal sale. The drug can be easily altered to compromise its controlled release properties. The U.S. Drug Enforcement Administration initiated a comprehensive effort in February 2001 to prevent the diversion of OxyContin. Pain specialists defend its continued use for chronic pain provided potential patients are appropriately screened and monitored.¹¹

Nonsteroidal Anti-Inflammatory Drugs

Although nonsteroidal anti-inflammatory drugs (NSAIDs) are most helpful in conditions in which there is ongoing tissue injury, such as chronic inflammatory arthritis or cancer-related nerve or bone damage, they are also helpful in many cases of chronic pain in which no evidence of tissue damage or inflammation is evident. Nonsteroidal anti-inflammatory drugs have been shown to be more helpful in acute than in chronic pain¹²; however, NSAIDs have been found to be the most frequently used analgesic for the treatment of chronic pain in a general population.⁸ Standard dosing procedures may be followed except in the elderly patients with a history of GI bleeding, those with renal insufficiency, or salicylate hypersensitivity.

Antidepressants

Antidepressants and, most commonly, the tricyclic antidepressant drugs are the most frequently used drugs for the management of chronic pain. Often effective pain control can be achieved at doses lower than those typically required for relief of depression.² An evidence-based review found antidepressants effective in chronic low back pain, fibromyalgia, osteoarthritis, and neuropathic pain.¹³ A separate meta-analysis found tricyclic antidepressants more effective in states in which symptoms were unexplained, such as fibromyalgia.¹⁴ A meta-analysis looking at the efficacy of selective serotonin reuptake inhibitors in chronic pain found them effective for mixed chronic pain but less effective for migraine headache, fibromyalgia, tension headaches, and diabetic neuropathy.¹⁵ When antidepressants are prescribed in the ED, a follow-up plan should be in place and discussion with a pain specialist is often beneficial. The most common drug and initial dose is amitriptyline, 10 to 25 mg, 2 h before bedtime.

Anticonvulsants

Anticonvulsants are used for several pain disorders, especially neuropathic pain. Anticonvulsants prevent bursts of action potentials, which may prevent the severe lancinating pain of certain neuropathic syndromes. Carbamazepine (starting at 100 to 200 mg twice daily), valproic acid (starting at 15 mg/kg daily divided into two doses), and clonazepam (starting at 0.5 mg thrice daily) are frequently used. Gabapentin, a structural analog of 7-aminobutyric acid, has been shown to be effective in postherpetic neuralgia¹⁶ and painful diabetic neuropathy¹⁷ and may have some benefit in complex regional pain syndromes. Gabapentin is started with an initial dose of 300 mg per d and is increased up to 1200 mg thrice daily according to the patient's response.

Other Agents

A meta-analysis has found calcitonin to be effective in the treatment of complex regional pain, type I (reflex sympathetic dystrophy).¹⁸ Calcitonin can be given at a dose of 100 IU/d as an intranasal spray. Prednisone at 60 mg per d also has been recommended for complex regional pain, types I and II, when first recognized after an injury. Muscle relaxants, such as cyclobenzaprine 10 mg every 8 h, have been useful for chronic pain patients, but sedating effects may limit their success. Tramadol is an atypical centrally active analgesic. It produces less respiratory depression, less tolerance, and less potential abuse than do opiates. Tramadol has been used with success in patients with fibromyalgia, migraine headaches, low back pain, and neuropathic pain. The dose of tramadol is 50 to 100 mg every 4 to 6 h by mouth.

Chronic Pain in the Elderly

Elderly patients frequently complain of chronic pain. Unfortunately, many of the commonly used medications for pain have higher complication rates in the elderly. In particular, the NSAIDs are associated with higher rates of gastrointestinal bleeding and renal disease in the elderly. Opioids also may cause debilitating sedation and/or constipation in the elderly; however, opioids may produce fewer serious side effects than NSAIDs. Doses of many agents should be reduced when treating the elderly to avoid side effects, and it is essential that a follow-up plan be in place at the time of discharge. There is a perception that the elderly are undermedicated for pain control. This may be true, but the elderly do not seem to be undermedicated more than any other age group.

DISPOSITION

Referral to an appropriate specialist is one of the most productive means of aiding in the care of chronic pain patients who present to the ED. Chronic pain crises have been successful in changing the lives of

characterized by constant dull and occasional shooting pain that does not follow a classic nerve distribution. Pain may or may not be exacerbated by movement. Usually trigger points can be found at the site of greatest pain, and muscle atrophy is not found. Range of motion of the involved muscle is reduced, but there is no actual muscle weakness. Previous recommendations for bedrest in the treatment of back pain have proven counterproductive.⁴ Exercise programs have been found to be more helpful in chronic low back pain.⁵ Articular back pain is characterized by constant or sharp pain that is exacerbated by movement and associated with local muscle spasm. Myofascial and articular back pain may be indistinguishable from each other except by advanced imaging techniques beyond the usual scope of practice in the ED. Neurogenic back pain is classically characterized by constant or intermittent pain that is burning, shooting, or aching. The pain is usually more severe in the leg than in the back and follows a dermatome. Muscle atrophy and reflex changes can be seen over time.

Complex Regional Pain

Patients with complex regional pain type I, also known as reflex sympathetic dystrophy, and complex regional pain type II, also known as causalgia, may be seen in the ED as early as the second week after treatment of an acute injury.⁶ These disorders cannot be differentiated from one another on the basis of signs and symptoms. Type I occurs because of prolonged immobilization or disuse, and type II occurs because of a peripheral nerve injury. These disorders should be suspected when a patient presents with classic symptoms: allodynia (pain provoked with a gentle touch of the skin) and a persistent burning or shooting pain. Associated signs early in the course of the disease include edema, warmth, and localized sweating. Therefore, it may be difficult to distinguish this disorder from an underlying wound infection or osteomyelitis. Later signs include periods of edema and warmth that alternate with cold, pale, cyanotic skin and eventually atrophic changes. Complex regional pain is an important diagnosis to make, because early steroid treatment may reduce ongoing symptoms. Further, when complex regional pain is associated with a cast, pin, or external fixation apparatus, the device may need to be removed.⁶

Postherpetic Neuralgia

The classic pain of postherpetic neuralgia may follow the course of an acute episode of herpes zoster in 8 to 70 percent of cases; increased incidence is seen with advancing age. Pain is characterized by allodynia and shooting, lancinating (tearing or sharply cutting) pain. Often patients have hyperesthesia in the involved dermatome. Occasionally there are pigmentation changes in the distribution of the involved dermatome, but this is not unique to postherpetic neuralgia.

Phantom Limb Pain

Phantom limb pain is quite variable in presentation but is more frequent in patients who had pain in the extremity before amputation. Pain may be aching, cramping, burning, tearing, or squeezing. Failure to respond to any treatment, including opioids, is common.

DIAGNOSIS

The most important task of the emergency physician is to distinguish an exacerbation of chronic pain from a presentation that heralds a life- or limb-threatening condition. The history and physical examination should confirm the chronic condition or point to the need for further evaluation when unexpected signs or symptoms are elicited. Because chronic pain patients may be frequent visitors to the ED, the entire staff may prejudge the complaint as chronic or factitious. Physicians should insist that routine procedures be followed, including a full triage assessment and a complete set of vital signs.

Rarely is a provisional diagnosis of a chronic pain condition made for the first time in the ED. The exception is a form of post-nerve injury pain, complex regional pain. The sharp pain from acute injuries, including fractures, rarely continues beyond 2 weeks' duration. Pain in an injured body part beyond this period should alert the clinician to the possibility of nerve injury, and proper treatment (Table 39-3) should be instituted.

Definitive diagnostic testing of chronic pain conditions is difficult and requires expert opinion and often expensive procedures such as

TABLE 39-3 Management of Selected Chronic Pain Syndromes

Disorder	Primary ED Treatment	Secondary Treatment*	Possible Referral Outcome
Cancer pain	NSAIDs, opiates	Long-acting opiates	Optimization of medical therapy
Myofascial, headache	NSAIDs, cyclobenzaprine	Antidepressants, phenothiazines	Trigger point injections, optimization of medical therapy
Transformed migraine	NSAIDs, cyclobenzaprine	Antidepressants	Optimization of medical therapy, opioid withdrawal
Fibromyalgia	NSAIDs	Antidepressants, exercise program	Optimization of medical therapy, dedicated exercise program
Myofascial, chest pain	NSAIDs	Antidepressants	Trigger point injections, optimization of medical therapy
Myofascial, back pain syndrome	NSAIDs, stay active	Antidepressants	Trigger point injections, optimization of medical therapy
Articular back pain	NSAIDs		Surgery, physical therapy
Neurogenic back pain	Acute: tapered prednisolone or prednisone	NSAIDs, muscle relaxants	Epidural steroids, surgery, exercise program
Complex regional pain types I and II (RSD and causalgia)	Prednisone 60 mg/d X 4 d and then taper to include 3 wk of therapy	Calcitonin, antidepressants, anticonvulsants	Spinal cord stimulation, intrathecal baclofen, sympathetic nerve blocks, spinal analgesia
Postherpetic neuralgia	Simple analgesics	Gabapentin, antidepressants	Regional nerve blockade
Phantom limb pain	Simple analgesics	Antidepressants, anticonvulsants	TENS, sympathectomy

*If started in the ED, consultation and/or follow-up with a pain specialist or personal physician is recommended.

Abbreviations: NSAIDs = nonsteroidal anti-inflammatory drug; RSD = reflex sympathetic dystrophy; TENS = transcutaneous electrical nerve stimulation.

Diagnosis

The diagnosis of drug-seeking behavior may not be possible in the ED. The medical record can provide a wealth of information about the patient, including documentation proving that the patient is supplying false information. Often the diagnosis is suspected in the ED but cannot be confirmed. In such cases, a notation should be made in the chart listing the physician's concerns, but physicians should be careful when using diagnoses such as "drug-seeking behavior" without solid evidence. A listing or card file at the nurses' desk of "drug seekers" violates confidentiality between patient and physician unless it is part of the patient's permanent medical record and subject to the same controls restricting access. Drug-seeking behaviors can be divided into two groups: predictive and less predictive (Table 39-5). The predictive behaviors are illegal in many states and form a solid basis to refuse opioids to the patient. Even so, the patient may have pain and should be evaluated for a medical or surgical illness and possibly treated with a non-opioid drug.

Schedule drug registries and other computerized tracking systems may help emergency physicians identify patients who are abusing or overusing prescription drugs. For example, Kentucky has initiated the Kentucky All Scheduled Prescription Electronic Registry that tracks the dispensing of all scheduled drugs in that state. Turn-around time is not immediate, and information lags 2 to 3 weeks after prescriptions are filled, but the information is valuable to track repeat patients. Pharmacy chains maintain computerized records, and occasionally pharmacists can help physicians make assessments of patients' controlled substance use.

Specific Issues: Legal Implications

The Drug Enforcement Agency (in addition to state agencies) licenses physicians to administer or dispense controlled substances. However, state law determines most prescribing regulations. Physicians should be aware of state laws regulating controlled substances prescribed in their practice setting. Prescribing opioids to a known drug addict could result in restriction of the physician's medical license in some states. However, if a patient refuses to acknowledge an addiction, the physician cannot be held accountable unless medical records at the facility where the patient presents document the addiction. In all states, it is illegal for patients to forge or alter prescriptions. In some states, it is illegal for patients to use aliases or factitious illness to obtain opioids. Further, in some states, concealing previous or recent prescriptions for opioids when requesting opioids from a new practitioner is illegal.

Treatment and Disposition

The treatment of drug-seeking behavior is to refuse the controlled substance, consider the need for alternative medication or treatment, and

consider referral for drug counseling. The patient who complains of multiple drug allergies can be difficult. Occasionally the medical record will show previous administration of the drug in question (usually an opioid substitute) with no adverse reaction other than no pain relief. When confronted with a physician's discovery of their fraudulent behavior, many drug-seeking patients become verbally abusive, and hospital security may be required to escort the patient out of the ED. Alternatives to opioids can be offered, and patients should be told that refusal to prescribe opioids is not a refusal of care.

When drug-seeking behavior is confirmed or suspected in the ED, it should be documented in the chart, with careful attention to the facts. When physicians are notified by a pharmacist of forged or altered prescriptions, law enforcement authorities should be called, and physicians should cooperate with the legal investigation. The prosecution of many fraudulent behaviors, such as using aliases to obtain opioids, requires the involvement of the state bureau of investigation or a similar state agency. Physicians may inquire about the legal proceedings with the hospital attorney or the police.

TABLE 39-5 Characteristics of Drug-Seeking Behavior

Behaviors predictive of drug-seeking behavior*
Sells prescription drugs
Forges/alters prescriptions
Factitious illness, requests opioids
Uses aliases to receive opioids
Admits to illicit drug addiction
Conceals multiple physicians prescribing opioids
Conceals multiple emergency department visits receiving opioids
Less predictive of drug-seeking behavior
Admits to multiple doctors prescribing opioids
Admits to multiple prescriptions for opioids
Abusive when refused
Multiple drug allergies
Uses excessive flattery
From out of town
Asks for drugs by name

*Behaviors in this category are unlawful in many states.

EMERGENCY WOUND MANAGEMENT

EVALUATION OF WOUNDS Judd

E. Hollander Adam J. Singer

EPIDEMIOLOGY

In 2000, over 8 million traumatic wounds were evaluated in emergency departments across the United States, accounting for about 7 percent of all ED visits.¹ The face, scalp, fingers, and hands are the most commonly involved areas of injury.² Approximately 40 percent of traumatic lacerations seen in the ED are caused by blunt objects.² Wounds on children differ from wounds on adults; lacerations in children are more likely to be located on the head, linear, shorter, less contaminated, and more often caused by blunt trauma.^{3,4}

INITIAL EVALUATION

Evaluation of the patient with a traumatic wound should begin with an overall assessment of the patient. Practitioners should exclude less obvious but more serious life-threatening injuries before directing attention to wound management. Initial wound management should be conducted in concert with ascertainment of the patient's past medical history and circumstances surrounding the injury.⁵

External bleeding can usually be controlled by application of pressure over the bleeding site. Tourniquet application is not recommended for routine wound care. When possible, skin flaps should be returned to their original position prior to application of pressure in order to prevent worsening vascular compromise. When amputated fingers or extremities are recovered, they should be covered with a moist, sterile, protective dressing, placed in a waterproof bag, and then placed in a container of ice water for preservation and consideration of future reattachment. Constricting rings or other jewelry that encircle the injured body part should be removed as soon as possible to prevent circumferential objects from acting as constricting bands when swelling progresses. Clothing over the injured area should be removed to reduce the potential for contamination.

Patient comfort should be considered a priority. Pain can initially be minimized by compassionate and professional evaluation of the patient. Before wound exploration, cleansing, and repair, most patients will need some form of anesthesia.⁶ Preparing the local anesthetic out of the sight of the patient will help reduce anxiety caused by seeing the needle. Systemic analgesia or procedural sedation may be required (see Chap. 38).

Medical History

Proper wound management begins with a thorough patient history (Table 40-1). The practitioner should ascertain the presence or absence of various factors that can have adverse effects on wound healing. Host factors such as patient age, diabetes mellitus, chronic renal failure, obesity, malnutrition, and the use of immunosuppressive medications may increase the risk of wound infection and impair wound healing.⁷ The presence of connective tissue disorders such as Ehlers-Danlos syndrome, Marfan syndrome, osteogenesis imperfecta, and protein and vitamin C deficiencies can also impact wound healing.⁸ The tendency of patients to form keloids should be ascertained by both history and examination, since past keloid formation may predict poor scar formation. Both Black and Asian patients are prone to keloid formation. Keloids grow beyond the original wound boundaries compared

to hypertrophic scars, which stay within the original wound boundaries and are usually due to tissue tension during healing.

A detailed history of any allergies to anesthetic agents or antibiotics is essential. With the increased incidence of severe reactions to latex products, one must also review any prior allergies to latex.⁹ The history of prior tetanus immunization and the need for further tetanus vaccination should be determined (see Chap. 48).

Identification of the mechanism of injury will help identify the presence of any potential wound contaminants and foreign bodies. Bite wounds are at high risk for infection and must be managed differently than other lacerations (see Chap. 47). Patients should be questioned about the presence of a foreign body. Patients with a foreign body sensation are more likely to have a retained foreign body than those without (sensitivity = 43%, specificity = 83%, LR(+) = 2.49, and LR(−) = 0.69).¹⁰ Both foreign body retention and visible contamination increase the risk of infection. Organic and inorganic components of soil can cause infection; wounds contaminated by soil can become infected by very small doses of bacterial inoculum. The major inorganic soil components that cause infection are the clay fractions; sand grains and black dirt from roadways are relatively inert.

The type of forces applied at the time of injury also helps predict the likelihood of infection.¹¹ The most common mechanism of injury is application of a blunt force such as bumping the head against a stationary object. The skin is crushed against an underlying bone, and it splits. Sharp objects that cut through the skin produce shear forces. Crush injuries are more susceptible to infection than wounds resulting from shearing forces, because they tend to cause greater tissue devitalization.¹²

Low-energy impact injuries may not result in lacerations; instead they may disrupt vessels, leading to ecchymosis or hematoma formation. Some hematomas spontaneously resorb. Those that become encapsulated usually require treatment by aspiration or incision and drainage.

The practitioner should determine the time that the injury occurred. The time interval from injury to closure of a laceration is directly related to the growth of the bacterial inoculum that presumably leads to an increased incidence of wound infection. However, the length of time from injury to closure that results in an clinically relevant increase in the incidence of infection is less clear^{8,13} (Table 40-2). A widely quoted study from Jamaica used healing, defined as epithelialization without infection, as the main outcome.¹⁴ This study of 204 lacerations found that head lacerations healed well regardless of the time to closure, even up to 100 h. In contrast, lacerations of the trunk or extremities had lower rates of healing, particularly if they were closed more than 19 h after injury. Other studies have not found a correlation between time from injury to closure and postrepair wound infection.^{4,15} Therefore time from injury until presentation is only one element to be considered, in addition to the wound etiology, location, degree of contamination, host risk factors, and the importance of cosmetic appearance, before determining whether or not to perform primary wound closure. Wounds that are not closed primarily because of a high risk of infection should be considered for delayed primary closure after 4 days. After 4 days of open wound management, the risk of infection after closure substantially decreases.

The patient should be asked whether the wound was sustained from an intentional act (e.g., assault or self-inflicted) or unintentional event. Most states have regulations that require the reporting of intentional injuries, and patients with self-inflicted injuries should be considered for psychiatric evaluation. Occupational injuries may require alternative follow-up arrangements, so their presence should be ascertained.

Medications
Chronic medical conditions that increase risk of infection Chronic medical conditions that increase likelihood of poor wound healing Previous scar formation (hypertrophic scars or keloids)

Many patients may have already attempted to cleanse or care for their wound. The clinician should inquire about any treatments or home remedies that the patient has used to self-manage the laceration, including solutions or cleansing agents that may have been applied.

The anatomic location of the injury helps predict the clinical outcome, both in terms of infection risk and cosmetic result^{4,11,15} (Table 40-3). The risk of infection is determined largely by the interplay between baseline bacterial colonization and vascular blood supply. With respect to bacterial colonization, the density of the bacterial population is low on the upper arms, legs, and torso. Conversely, moist areas of the body, such as the axilla, perineum, toe webs, and intertriginous areas harbor millions of bacteria per square centimeter, including anaerobes. Obviously, any wounds with human or animal fecal contaminants run a high risk of infection, even with therapeutic intervention.

In addition to bacterial flora, anatomical variation in regional blood flow also plays a role in determining the likelihood of infection. Wounds located on highly vascular areas, such as the face or scalp, are less likely to be infected than wounds located in less vascular areas.^{4,11,14} The in-

creased vascularity of the area more than offsets the high bacterial inoculum found in the scalp. Lacerations of the scalp and face have a very low infection rate regardless of the intensity of cleansing.¹⁶

Wound Examination

Wound examination should be conducted when the patient is calm and cooperative and positioned appropriately, with optimal lighting conditions, and with little or no residual bleeding. cursory examination under poor lighting or when the depths of the wound are obscured by blood will occasionally result in poor detection of foreign bodies and possibly damage to important structures. If bleeding is a problem, epinephrine-containing anesthetic solutions may be helpful, when not contraindicated. Finger tourniquets may be used to obtain a bloodless field, but they should not be used for more than 30 to 60 min. Missed tendon and nerve injuries and retained foreign bodies are common wound-related causes of litigation. The likelihood of these complications can be minimized by performing a compulsory complete physical examination. Lacerations over joints may have penetrated the joint capsule and often the joint should be injected to ensure that there is no communication between the joint space and the laceration. Lacerations over the metacarpophalangeal joints are suspicious for having occurred during a fight (clenched fist injury) and should be treated as though they are human bites.

Adjunctive Testing

Although most lacerations will not require any diagnostic testing, on occasion, wound imaging for detection of foreign bodies may be necessary. Most foreign bodies commonly found in wounds are much denser than the surrounding tissue and are readily apparent on plain radiographs. Metal, bone, teeth, pencil graphite, certain plastics, glass, gravel, sand, some fish bones, some painted wood, and most aluminum are visible on plain radiographs (see Chap. 46). Almost all (>95 percent) glass fragments are visible on radiographs if they are 2 mm or larger in size.¹⁷ If the wound was caused by metal or glass and no foreign body is found on wound exploration or on plain films, it is unlikely that a foreign body exists.¹⁰ Radiopaque skin markers such as paper clips can be placed around the wound entrance so the position of the object can be determined relative to these markers. Some objects will not be identifiable with plain radiography. Computed tomography (CT) and magnetic resonance (MR) imaging are useful for identifying and locating objects that have densities similar to soft tissue. Sonography may also be useful, particularly for wooden foreign bodies, although the sensitivity of sonography is inadequate to reliably exclude small (<2.5 mm) wood fragments.

TABLE 40-2 Risk of Wound Infection as Function of Time from Injury to Closure

	Comments	Distinction Between Early and Late Closure	Infection Rate/Inadequate Healing with Early Closure	Infection Rate/Inadequate Healing with Late Closure	Percent Difference (95% CI)
Morgan 1980 ¹³	Hand and forearm, all patients received IM penicillin and half received PO clindamycin	4h	10/148 (7%)	14/69 (21%)	13.5% (3.2 to 23.9%)
Baker 1990 ⁴	Children, 59% head and neck location	6h	32/2665 (1.2%)	2/147 (1.3%)	-0.16% (-1.76 to 2.08%)
Berk 1988 ¹⁴	All locations	19 h	8/97 (8.2%)	25/107 (23.4%)	15.1% (5.4 to 24.8%)
	Head	19 h	2/44 (5%)	1/36 (3%)	-1.8% (-9.9 to 6.4%)
	Trunk and extremities	19 h	6/53 (11.3%)	24/71 (33.8%)	22.5% (8.6 to 36.4%)

TABLE 40-3 Risk of Wound Infection as a Function of Anatomic Location

Location	Risk of Infection
Head and neck	1-2%
Upper extremity	4%
Lower extremity	7%

Patient Education

Patients should be carefully educated regarding the expected cosmetic outcome; they should be informed that there will be some scarring, and if predisposed, possible keloid formation.¹⁵ Some indication of the maximal width of the scar can be predicted based upon wound location, whether the laceration is aligned parallel or perpendicular with lines of minimal tension, and how gaping the wound is while at rest (static tension) or when put through a range of motion (dynamic tension).^{15,18} Lacerations over joints (which have more dynamic tension) will have wider scars than similar lacerations subject to less tension. Wounds that deviate from the lines of skin tension will also be prone to greater scar formation after suturing than wounds which are more closely aligned with skin tension.¹⁸ The most important determinant of cosmetic outcome under control of the treating physician is meticulous wound repair with approximation of viable wound edges under little tension. If this is not possible, patients should clearly understand that all lacerations result in some scarring.

WOUND PREPARATION

Susan Stone Wallace

A. Carter

Wound preparation is the single most important step in treating a traumatic wound. Proper preparation helps set the stage for restoring both the integrity and function of the injured tissue and minimizes the risk of infection and assures the best possible cosmetic result. The majority (80 to 90 percent) of wounds treated in EDs heal with a good outcome. However, careful preparation is particularly important when underlying medical conditions affecting wound healing are present; patients with these conditions have a higher risk of infection (Table 41-1). Many traditional methods of wound preparation have surprisingly little scientific validation.^{1,2} This chapter reviews the basic principles of wound preparation, using available experimental models and prospective clinical studies, where available, to justify these techniques.

STERILE TECHNIQUE

While adoption of aseptic technique represented a major advance in medical care, the extent required for ED wound repair remains unclear. Most physicians use sterile gloves alone for ED laceration closure. The use of full sterile technique—with the physician wearing a face mask and hair-covering cap in addition to sterile gloves—does not reduce the incidence of wound infection compared to the use of sterile gloves alone.³ Conversely, the use of clean, nonsterile examination gloves for suturing does not appreciably increase the incidence of wound infection compared to the use of sterile gloves.⁴ Nevertheless, adherence to sterile technique remains the standard of care.

ANESTHESIA

In general, pain control should be provided before extensive wound preparation. Not only is this more humane, the administration of anesthesia and analgesia will enable better preparation and treatment if patients are relaxed and able to cooperate without undue anxiety and pain. Prior to the administration of local or regional anesthetic, the sensory, motor, and vascular examination should be performed.

HEMOSTASIS

Control of bleeding is necessary for proper evaluation of a wound. Diffuse bleeding most often occurs from the subdermal plexus and superficial veins. Direct pressure with saline-soaked sponges or gauze is usually effective in stopping this type of bleeding.

Bleeding from an exposed lacerated vessel is best controlled by direct pressure applied with a gloved fingertip directly on the vessel. Once bleeding is halted, more permanent control can be achieved by clamping the involved vessel, isolating a short length, and ligating it with absorbable synthetic suture (typically 5-0). This approach is most useful for bleeding minor vessels in the extremities, but major arteries of an extremity should not be ligated. Extreme caution must be exercised in the face because of the proximity of important facial structures. Scalp lacerations can bleed extensively from the wound edges due to the highly vascular subcutaneous layer. This bleeding can be

TABLE 41-1 Risk Factors for Poor Wound Repair Outcome

Location

controlled by the use of specially designed clips applied along the wound edges. For bleeding wounds where the involved vessel is not visible, a figure-of-eight or horizontal mattress suture applied adjacent to the wound edge near the site of bleeding will sometimes achieve control. However, this technique may impair blood flow and leave nonviable tissue in the wound.

Chemical means of hemostasis include injected epinephrine, Gelfoam, Oxygel, and Actifoam. Most commonly, epinephrine is mixed with local anesthetics in concentrations of 1:100,000 or 1:200,000 and injected into the wound area. This will induce local vasoconstriction that will allow a longer duration of anesthesia and a larger total local anesthetic dose due to the depot effect of the vasoconstriction. Current practice avoids the use of epinephrine in end organs such as fingers, toes, and tip of nose, ears, and penis, although that practice has been challenged regarding the use of epinephrine mixed with local anesthetics for digital nerve blocks.⁵ If epinephrine with lidocaine is inadvertently injected into a digit, nitropaste 1" can be applied topically to the digit until the effect of epinephrine has dissipated. Blood pressure should be checked to ensure that hypotension does not result. No increase in wound infection has been observed with the addition of epinephrine to local anesthetics used in the ED. Gelfoam, made from denatured gelatin, has no intrinsic hemostatic properties and works by the pressure it exerts as it becomes a fluid-filled sponge. Oxygel, a cellulose derivative, and Actifoam, a collagen sponge, react with blood, forming an artificial clot. These products are not particularly effective for actively bleeding wounds, as the blood can wash them out.

Bipolar electrocautery can achieve hemostasis in blood vessels smaller than 2 mm in diameter, but if improperly or too extensively applied, results in tissue necrosis. Electrocautery units are not routinely available in many EDs. Battery-powered hand-held cautery units are more readily available but do not generate sufficient heat to produce coagulation in vessels larger than capillaries.

Extremity wounds that are refractory to direct pressure, ligation, or cautery may require a tourniquet. Although helpful in stopping exsanguination, tourniquets may compress and damage underlying blood vessels and nerves, reducing tissue viability. The simplest tourniquet to use in an ED is a blood pressure cuff placed proximal to the wound and inflated above the patient's systolic pressure. Elevating the extremity to reduce venous blood volume prior to cuff inflation is useful. If an extremity tourniquet is needed to control bleeding, the patient is best explored and repaired in the operating room.

FOREIGN-BODY REMOVAL

Obvious foreign debris should be carefully removed from the wound, using forceps to avoid injury to the physician from sharp edges or points. Probing wounds with a gloved fingertip to detect foreign bodies by palpation is discouraged. Clinical clues to the presence of a foreign body include foreign body sensation, point tenderness, or increased pain on range of motion. Visual wound inspection, down to the full depth and along the full course of the wound, is the most important method for detecting foreign bodies. Imaging modalities—plain radiology, ultrasound, computed tomography (CT), and magnetic resonance (MR) imaging—have a role in selected patients (see Chap. 46).

SKIN DISINFECTION

A common practice is to disinfect intact skin around the wound with either a povidone-iodine based or chlorhexidine-containing agent. While these agents suppress bacterial growth on intact skin, they impair host defenses and promote bacterial growth in the wound itself. When used, skin disinfectants should be applied from the wound edges outward and care taken to avoid spillage into the wound.

HAIR REMOVAL

Hair can interfere with wound closure, become entangled in sutures or staples, and act as a foreign body, potentially increasing the risk of wound infection. Conversely, in well perfused tissues (e.g., scalp) wounds closed without prior hair removal heal with no apparent increase in infection.⁶ If necessary, hair should be removed by clipping 1 to 2 mm above the skin with scissors.¹² Shaving the area with a razor damages the hair follicle, allowing bacterial invasion, and is associated with a tenfold increase in infection rates when compared with clipping. An alternative method to clipping is to use ointment or saline to allow hair to be parted away from wound edges. Hair should never be removed from the eyebrows, because of the potential for that hair to not regenerate or to grow back abnormally. Likewise, hair may provide good landmarks for alignment of wound edges during suturing, and removal at the skin-hair interface (eyebrows or scalp) should be avoided when possible.

IRRIGATION

Effective irrigation decreases bacterial count and helps to remove foreign bodies, thereby reducing the risk of wound infection.¹² Because of the discomfort involved, local anesthetic is usually necessary prior to irrigation. Irrigation pressures of 5 to 8 psi are recommended, which are easily achieved using a 19-gauge needle with either a 35-mL or 65-mL syringe.⁷ Sufficient pressures will not be generated using a bulb syringe or fluid directly from the intravenous fluid bags. Although the exact volume of irrigant required is not known, a common recommendation is to use 60 mL per cm of wound length, although a large observational study found no correlation between the incidence of infection and the volume of irrigation, provided at least 200 mL was used.⁸

Wound soaking is not effective in cleansing contaminated wounds and may actually increase wound bacterial counts.⁹ Routine scrubbing of traumatic wounds with a sponge is ineffective, inflicting trauma and impairing resistance to infection.

Sterile normal saline, the most commonly used irrigant, also has the lowest toxicity. There is no added benefit to the addition of an antiseptic (such as povidone-iodine or hydrogen peroxide) to the irrigant.¹⁰ Recent studies have found that tap water irrigation of simple cutaneous lacerations is as safe and efficacious as sterile normal saline.¹¹ In addition, tap water is easily obtained in large quantities at almost no cost.

Universal Precautions should be observed while participating in wound care. Contaminated fluid can easily be splashed onto health

care workers during irrigation, so barrier protection should be used. Irrigation shields attached to the irrigation system may prevent some of the splashing associated with irrigation, but are no substitute for Universal Precautions.

Recently, the need for routine irrigation of traumatic wounds has been questioned, particularly for simple non-bite, non-contaminated wounds in highly vascular areas, such as the scalp and face, and in wounds closed with skin tapes instead of sutures.^{12,13}

DEBRIDEMENT

The next step in wound preparation is debridement of nonviable tissue.¹² Devitalized tissue may increase the risk of infection and delay healing by acting as a culture medium and inhibiting leukocyte phagocytosis. Debridement not only removes foreign matter, bacteria, and devitalized tissue, but it also creates a clean wound edge that is easier to repair. After debridement is completed, wounds should be re-irrigated.

The most effective type of debridement is excision, because it converts a contaminated wound into a clean surgical wound. A standard surgical blade is recommended. Tissue that has a narrow base or lacks capillary refill will require excision. The goal of debridement is to reestablish a margin of normal tissue at wound edges. The easiest technique for excisional debridement is to mark an elliptical area around the sides of the wound, and then use a surgical blade to cut only through the epidermis. Skin lines should be respected, and extensive excision should be avoided.

Wounds with an extensive amount of nonviable tissue or heavy contamination are more problematic. They may require a large amount of tissue removal and will need more delayed wound closure or grafting. In general, a surgeon should be consulted to manage these wounds.

Debridement has become such a standard in wound care, it is difficult to conceive of a situation in which it should not be applied. However, in cases of wounds that were not sutured (e.g., low-velocity civilian gunshot wounds to the extremities), conservative wound care (irrigation and cleaning) had the same incidence of wound infection as routine wound debridement.¹⁴

PROPHYLACTIC ANTIBIOTICS

Infections occur in approximately 3 to 5 percent of traumatic wounds repaired in EDs, although this rate varies widely according to mechanism, location, and patient factors.³ Wound location, extremes of age, crush injuries, puncture or avulsion wounds, retained foreign bodies, and contamination are all risk factors for infection. Less vascular areas, moist areas (axilla and perineum), and exposed areas (feet and hands) also tend to be at higher risk for infection. Crush or puncture wounds are more prone to infection due to the tensile and compressive forces generated that increase the potential for devitalized tissue. The most important step in prevention of a wound infection is adequate irrigation and debridement.

To reduce the incidence of wound infections, antibiotics have been commonly used for years, although there is no clear evidence that antibiotic prophylaxis prevents wound infections in most patients whose wounds are closed in the ED^{3,15} (see Chap. 48). Antibiotic prophylaxis has been studied and well accepted in some surgical procedures.¹⁶ The 15 principles learned from these studies are that effectiveness requires the achievement of antimicrobial blood levels prior to or rapidly after wound contamination, and there is no benefit for continuing antibiotics past 24 h in most cases. If used, antibiotic prophylaxis for traumatic wounds in an ED should be (1) initiated before significant tissue manipulation is done; (2) performed with agents that are effective against predicted pathogens; and (3) administered by routes that rapidly achieve desired blood levels. There are no studies that compare the common practice of intravenous administration of the initial dose of prophylactic antibiotics with oral administration. Based on the

above principles, the oral route may be as effective if administered before manipulation using an agent with appropriate spectrum and rapid oral absorption.

For wounds contaminated by debris or feces or caused by punctures or bites, wounds with tissue destruction or in avascular areas, and neglected wounds, sufficient bacteria may be present to cause infection, and prophylactic antibiotics are often administered. Since most non-bite wound infections are due to staphylococci or streptococci, amoxicillin-clavulanate or a first-generation cephalosporin provides reasonable coverage. For human bites in all locations and for mammalian bites on the hands, amoxicillin-clavulanate should be used to cover both *Pasteurella* and *Eikenella*. Prophylactic antibiotics do not reduce the incidence of wound infection following dog or cat bites on areas other than the hands.^{17,18} Full-thickness oral lacerations should receive penicillin.¹⁹ Wounds contaminated by fresh water and plantar puncture wounds through athletic shoes, should include *Pseudomonas* coverage.

The duration for antibiotic prophylaxis is unknown; most physicians use 3 to 5 days for non-bite wounds and 5 to 7 days for bite wounds. Patients with established wound infections usually require longer treatment. A wound warranting antibiotics should be reevaluated at 24 to 48 h, or patients should be given clear instructions to return at the earliest sign of infection. Contaminated wounds, or those with undetected foreign bodies, may still develop infection despite antibiotic prophylaxis.

METHODS FOR WOUND CLOSURE

Adam J. Singer Judd E.
Hollander

The skin is the largest organ in the human body; its primary function is to serve as a barrier between the organism and the external environment. The major goal of wound closure is to restore the skin's integrity in order to reduce the risk of infection, scarring, and impaired function.¹ This may be achieved by one of three methods. With primary closure, the wound is immediately closed by approximating its edges. The main advantage of primary closure is a reduction in healing time in comparison with other closure methods. Rapid wound closure also may reduce bleeding and discomfort often associated with open wounds. Secondary wound closure, in which the wound is left open and allowed to close on its own, is particularly well suited for highly contaminated or infected wounds as well as in patients at high risk of infection. While this method may reduce the risk of infection, it is relatively slow and uncomfortable and leaves a larger scar than primary closure. Delayed primary (or tertiary) closure combines the advantages of both primary and secondary closure. With this method the wound is left open for a period of 4 to 5 days after which it may be closed if no infection supervenes. A recent small study of simple hand and finger lacerations challenges the principle of primary closure.² Wounds randomized to secondary closure healed as fast as those closed primarily with no notable differences in appearance and function.² However, since this study was limited to short, superficial hand lacerations it cannot be widely recommended for all wounds and lacerations at this time.

OVERVIEW OF WOUND CLOSURE METHODS

Lacerations may be closed by one of four commonly available methods or devices: sutures, staples, adhesive tapes, or tissue adhesives. Each method has advantages and disadvantages (Table 42-1). Choice of the wound closure method and timing should take into account both patient and wound characteristics (Table 42-2). Cosmetic outcome is more

Technique	Advantages	Disadvantages
Suture	Time-honored Meticulous closure Greatest tensile strength Lowest dehiscence rate	Requires removal Requires anesthesia Greatest tissue reactivity Highest cost Slowest application
Staples	Rapid application Low tissue reactivity Low cost Low risk of needle-stick	Less meticulous closure May interfere with some imaging techniques (CT, MRI)
Tissue adhesives	Rapid application Patient comfort Resistant to bacterial growth No need for removal Low cost No risk of needle-stick	Lower tensile strength than 5-0 or larger sutures Dehiscence over high tension areas (joints) Not useful on hands Cannot bathe or swim (can shower)
Adhesive tapes	Least reactive Lowest infection rates Rapid application Patient comfort Low cost No risk of needle-stick	Frequently fall off Lower tensile strength than sutures Highest rate of dehiscence Require use of toxic adjuncts Cannot be used in areas with hair Cannot get wet

TABLE 42-1 Advantages and Disadvantages of Wound Closure Devices

TABLE 42-2 Patient and Wound Considerations that Affect Wound Healing

Patient Characteristics	Clinical Implications
Age	Increased infection rates at the extremes Impaired healing in elderly or with peripheral vascular disease
Immunocompromising conditions: Diabetes mellitus, renal failure, AIDS, splenectomy, etc.	Increased infection rates
Medications	Increased infection rates with systemic steroids and other immunocompromising agents
Wound Characteristics	Clinical Implications
Time from injury	Increased bacterial counts with time; "golden period" (time during which it is safe to close wounds) is highly variable
Location	Increased infection rates with extremity lacerations Very low infection rates with scalp and facial lacerations
Etiology	Increased infection rates with bites, presence of foreign bodies or debris
Mechanism of injury	Increased infection rates and poorer scarring with crush injuries
Laceration width	Increased infection rates and poorer scarring with wider lacerations

closely related to practitioner technique and the patient's own healing characteristics than to any specific closure method or device.

One of the most important considerations when choosing a wound closure method is the amount of tension on the wound, both static (at rest) and dynamic (with motion). *Linear lacerations subject to little tension* can usually be closed by any one of the four closure methods. In this case, the practitioner should take into consideration patient characteristics and preferences such as compliance, the availability to return for follow-up and device removal, and overall level of anxiety. *With low-tension irregular lacerations*, sutures may be the best alternative, allowing the greatest degree of precision with accurate wound approximation. *With lacerations subject to high tension* (static and/or dynamic) it is vital to relieve the amount of tension on the wound in order to avoid early dehiscence or gradual widening of the scar.³ Relief of tension is best achieved by careful undermining, placement of deep dermal sutures, and wound immobilization (when appropriate). After placement of deep, tension-relieving sutures, the superficial epidermal layer may be closed by any of the aforementioned closure methods.

With patients at risk of keloid formation, it is best to relieve tension and minimize the amount of foreign material introduced into the wound.

SUTURES

Sutures are the most commonly used method to close lacerations.⁴ Sutures are the strongest of all closure devices and allow the most accurate approximation of wound edges, regardless of its shape. However, sutures are the most time consuming and operator dependent of all wound closure methods. In general, sutures may be divided into absorbable and nonabsorbable. By definition, *nonabsorbable sutures* retain their tensile strength for at least 60 days. They are most often used to close the outermost layer of the skin or for repair of tendons. Non-absorbable sutures are classified based on their origin and configuration (Table 42-3). Monofilament synthetic sutures (such as nylon or

TABLE 42-3 Nonabsorbable Suture Characteristics

Suture	Structure	Raw Material	Tensile Strength Retention In Vivo	Tissue Reactivity	Common ED Uses
Silk	Braided	Organic protein called fibroin	Degradation of fiber results in loss of strength over many months	Significant inflammatory reaction	Intraoral mucosal surfaces for comfort
Nylon (Ethilon, Dermalon)	Monofilament	Polyamide polymer	Hydrolysis results in loss of strength over years	Minimal	Soft tissue and skin reapproximation
Polypropylene (Prolene, Surgipro)	Monofilament	Polypropylene polymer	No degradation or weakening	Least	Soft tissue and skin reapproximation
Polyester (Mersilene, Ticon)	Braided and monofilament	Polyethylene terephthalate	No degradation or weakening	Minimal	Tendon repair using undyed (white) color
Polybutester (Novafil)	Monofilament	Poly (butylene) and poly (tetramethylene ether) glycol terephthalate	No degradation or weakening	Minimal	Soft tissue approximation, easy handling, and knot security

Source: Reproduced with permission from Hollander JE, Singer AJ, in AJ Singer, JE Hollander (eds): *Lacerations and Acute Wounds. An Evidence-Based Guide*. Philadelphia, FA Davis, 2003.

polypropylene) have the lowest rates of infection and are the most commonly used nonabsorbable sutures in the ED. Specific choice of the suture type should be left to individual preferences. *Absorbable sutures* lose most of their tensile strength in less than 60 days. As a result, they are best suited for closure of deep structures such as the dermis and fascia. Due to their strength, handling, and relatively low tissue reactivity, synthetic monofilament sutures are preferred (Table 42-4). Rapidly absorbing sutures (e.g., Vicryl Rapide) can also be used to close the superficial skin layers, especially when avoidance of suture removal is desirable.⁵ Lacerations in the hand and fingers should be closed with 5-0 sutures while facial lacerations should be closed with 5-0 or 6-0 sutures. For lacerations in most other locations a 4-0 suture is most appropriate.

Improper tissue handling further traumatizes the tissues and results in an increased risk of infection and poor scarring.⁶ Gentle tissue handling using either skin hooks or the open limb of fine forceps is encouraged (Figure 42-1). Hemostasis is best achieved by direct pressure with or without a topical vasoconstrictor (such as epinephrine 1:1000). With injury to vessels larger than 2 mm in diameter, careful and selective placement of a ligature tie is often necessary. Bipolar electrocautery should only rarely be used since this increases the risk of infection and scarring.⁶

The best cosmetic outcome is achieved by carefully matching each layer of the wound with its corresponding counterpart on the opposite side, ensuring eversion of the wound edges, and minimizing the amount of tension on the wound. As the wound heals and the swelling subsides, the wound will eventually flatten, becoming flush with the surrounding skin surface. Inadvertent inversion of the wound edges may result in an unsightly depressed scar. Suggested indications for the most commonly used suturing methods are presented in Table 42-5.

Simple Interrupted Percutaneous Sutures These are the most basic and most commonly used sutures in the ED. With this method individual sutures are placed, sequentially bisecting the original wound into smaller segments until adequate coaptation of the edges is achieved. The needle is introduced through the outer layer of the skin and exits at the level of the dermis on one side of the wound. The needle is then inserted through the opposite wound edge starting at the level of the dermis and exiting superficially (Figure 42-2). In order to ensure proper wound edge eversion, the needle should enter and exit the skin at equal distances and at an angle of 90 degrees. Taking a larger bite at the depth of the wound than through the more superficial layers helps achieve wound eversion. Generally, the number of ties

should correspond to the suture size (i.e., 4 ties for a 4-0 suture, 5 ties for a 5-0 suture, etc.).

Continuous (Running) Percutaneous Sutures The major advantage of this method is its rapidity, since the entire wound is closed before dividing the suture material. It is most appropriate for long linear wounds. Because it does not allow perfect wound edge apposition it should be avoided in irregular lacerations. With this method the first suture is placed similarly to an interrupted percutaneous suture. However, the suture is not cut and the needle is reintroduced into the skin on the opposite side so the suture crosses the wound superficially at a 65 degree angle (Figure 42-3). The needle then crosses the depth of the wound in a circular motion perpendicular to the wound, exiting on the opposite side approximately 3 to 5 mm from the wound edge. This process is repeated as needed until the entire wound is approximated.

Deep Dermal Sutures The major role of these sutures is to reduce tension. They are also used to close dead spaces. However, their presence increases the risk of infection in contaminated wounds.⁷ Sutures through adipose tissue do not hold tension, increase infection rates, and should be avoided.⁸ With deep dermal sutures, the needle is first inserted at the level of the mid dermis on one side of the wound and then exits more superficially below the dermal-epidermal junction (Figure 42-4). The needle is then introduced below the dermal epidermal junction on the opposite wound side and exits at the level of the mid dermis. Thus the knot becomes buried in the depth of the tissue when tying of the suture is completed. The first suture is placed at the center of the laceration, while additional sutures then sequentially bisect the wound. The number of deep sutures should be minimized.

Continuous Subcuticular Sutures Rarely used in the ED setting, this is one of the most complex methods of wound closure. The major advantage of this method is that it results in fairly good wound approximation without requiring any more superficial wound closure devices. One may use either absorbable or nonabsorbable sutures with this method. However, nonabsorbable sutures require removal. With this method, after anchoring the suture in the deep dermis, sequential horizontally oriented "bites" are taken immediately below the dermal-epidermal junction until the wound is adequately approximated (Figure 42-5).

Horizontal Half-Buried Mattress Sutures These sutures are particularly well suited for closing the tip of skin flaps since they minimize

TABLE 42-4 Absorbable Sutures

Suture	Types	Material	Tensile Strength Retention In Vivo	Absorption Rate	Tissue Reactivity	Common ED Uses
Surgical gut	Plain	Collagen derived from bovine intestine	Retains 50% tensile strength for 5–7 days	Absorbed by proteolytic processes in weeks	Moderate reactivity	Rarely, for intraoral wounds
Chromic gut	Chromium coating	Collagen derived from bovine intestine	Retains 50% tensile strength for 10–14 days	Absorbed by proteolytic processes in weeks	Moderate reactivity	Rarely, for subcutaneous closures and intraoral wounds
Polyglycolic acid (Dexon)	Braided	Polymer of glycolic acid	Retains 65% tensile strength at 2 weeks, 35% at 3 weeks	Completely absorbed by slow hydrolysis by 60–90 days	Minimal	Approximation of deep soft tissue structures (i.e., dermis), for ligation
Polyglactin 910 (Vicryl)	Braided	Copolymer of lactide and glycolide coated with polyglactin 370 and calcium stearate	Retains 65% tensile strength at 2 weeks, 40% at 3 weeks	Completely absorbed by slow hydrolysis by 56–70 days	Minimal	Approximation of deep soft tissue structures, (i.e., dermis), for ligation
Polyglactin 910 (Vicryl Rapide)	Braided	Copolymer of glycolide and lactide coated with polyglactin 370 and calcium stearate	Retains 50% tensile strength for 5 days; all lost by 2 weeks	Absorbed by hydrolysis; usually complete by 42 days	Minimal to moderate	Skin approximation when absorbable sutures used
Polyglactin 910 (Lactomer)	Braided	Copolymer of glycolide and lactide coated with caprolactone and glycolide	Retains 40% tensile strength for 3 weeks	Absorbed by hydrolysis; usually complete by 56–70 days	Minimal	Subcutaneous soft tissue approximation
Polydioxanone (PDS II)	Monofilament	Polyester polymer	Retain 50% tensile strength for 4 weeks; 25% for 6 weeks	Minimal until 90 days, complete by 6 months	Slight	Subcutaneous soft tissue approximation where more prolonged strength is needed
Poliglecaprone 25 (Monocryl)	Monofilament	Copolymer of glycolide and epsilon-caprolactone	Retains 60% tensile strength for 1 week; 30% at 2 weeks	Absorbed by hydrolysis within 3–4 months	Minimal	Subcutaneous soft tissue approximation where more prolonged strength is needed
Glycomer 631	Monofilament	Terpolymer of glycolide, trimethylene carbonate and dioxanone	Retains 70% tensile strength 28 days; 13% at 56 days	Complete by 90–110 days	Slight	Subcutaneous soft tissue approximation where more prolonged strength is needed
Lactide glycolide (Panacryl)	Braided	Copolymer of lactide and glycolide	Retains 80% tensile strength at 3 months, 60% at 6 months, 20% at 1 year	Complete within 1.5–2.5 years	Minimal	Subcutaneous soft tissue approximation (e.g., fascia) where more prolonged strength is needed, excellent handling
Polyglyconate (Maxon)	Monofilament	Polyglyconate polymer	Retains 70% tensile strength 28 days; 13% at 56 days	Complete by 90–110 days	Slight	Subcutaneous soft tissue approximation where more prolonged strength is needed

FIG. 42-1. Handling of the skin with skin hook (*left*) and open limb of fine forceps (*right*). [Reproduced with permission from Singer AJ, Hollander JE (eds): *Lacerations and Acute Wounds. An Evidence-Based Guide*. Philadelphia, PA: FA Davis, 2003, p. 109.]

strangulation of the tip. The needle is introduced percutaneously through one side of the wound, then horizontally through the flap tip at the level of the dermis. The suture is completed by exiting through the remaining wound side from dermis to epidermis (Figure 42-6).

Vertical Mattress Sutures These sutures combine some of the advantages of deep and percutaneous sutures. They also result in excellent wound edge eversion. Vertical mattress sutures are particularly useful in very thin or lax skin, and in areas where the deep subcutaneous tissues are too fragile to be used for anchoring tension-reducing sutures (e.g., over the shin). After taking a large deep bite from both sides of the wound, the direction of the needle is reversed and a smaller superficial bite is taken from both sides of the laceration (Figure 42-7). Care should be taken since vertical mattress sutures may result in too much tension on the more superficial skin edges, which reduces blood supply to the skin.

STAPLES

The major advantages of staples are their speed and relative ease of use.^{9,11} They are also cost effective, especially when devices containing fewer staples are used in the ED, where most lacerations are relatively short. However, of all closure devices, staples allow the least precision in wound approximation. As a result their use should be limited to linear, nonfacial lacerations. They are particularly useful for scalp lacerations.¹⁰ However, deep sutures may be required to close lacerations of the galea aponeurotica, while percutaneous sutures are always desirable when hemostasis is problematic. In experimental animal models, staples result in less tissue reactivity than sutures;¹² however, infection rates and cosmetic outcome are similar to sutures in the clinical setting.^{9,11} Staple removal is more painful than removal of sutures.¹¹ While a variety of stapling devices are commercially available, there are few practical differences between them from the standpoint of the emergency practitioner.

TABLE 42-5 Selecting Closure Method Based on Wound Type

Suture Type	Advantages	Disadvantages	Frequent Uses
Interrupted percutaneous	Excellent approximation	Time-consuming May strangulate tissues	Low-tension wounds May be used with deep sutures for high-tension wounds
Continuous percutaneous	Rapid closure Accommodates edema	Less meticulous closure than interrupted sutures If a single knot unravels the wound may dehisce (if no deep sutures are placed)	Percutaneous closure in conjunction with deep sutures
Interrupted dermal	Reduces tension on wound surface Allows early removal of percutaneous sutures, avoiding hatch marking May reduce scar width	May increase infection in contaminated wounds	High-tension wounds Closure of dead space
Continuous dermal	Rapid Reduces tension on wound surface Allows early removal of percutaneous sutures, avoiding hatch marking May reduce scar width	Technically difficult Less accurate approximation than interrupted sutures If a single knot unravels, the wound may dehisce	High-tension wounds require interrupted dermal sutures Closure of dead space
Vertical mattress	Excellent wound edge eversion Combines advantages of deep and superficial sutures	May cause tissue strangulation	Thin or lax skin with little dermal or fascial tissue High-tension areas (e.g., extremities)
Horizontal mattress	More rapid than simple interrupted sutures Excellent wound edge eversion	May cause tissue strangulation	Bleeding scalp wounds Initial approximation of high-tension wounds
Half-buried, horizontal mattress	Less compromising to flap perfusion	Time-consuming Technically difficult	Corner stitches and flaps

FIG. 42-2. Placement of simple interrupted percutaneous sutures. The distance of the suture from the wound edge is greater at the depth of the wound than at the surface, promoting wound edge eversion when tightened. [Reproduced with permission from Singer AJ, Hollander JE (eds): *Lacerations and Acute Wounds. An Evidence-Based Guide*. Philadelphia, PA: FA Davis, 2003, p. 115.]

ADHESIVE TAPES

Adhesive tapes are the least reactive of all wound closure devices.¹² Their application is simple, painless, and rapid. They are also inexpensive and do not require formal removal. However, they tend to slough off when exposed to any tension or moisture. As a result their

FIG. 42-3. Placement of continuous percutaneous sutures. The suture crosses the wound superficially at a 65° angle and traverses the depth of the wound at a 90° angle, perpendicular to the wound. [Reproduced with permission from Singer AJ, Hollander JE (eds): *Lacerations and*

use is limited to very low-tension simple wounds or for closure of fragile skin subject to low tension. They are also of little use in non-compliant patients since they are so easy to remove. In order to increase their adhesiveness skin tapes should be used in conjunction with an adhesive adjunct such as mastisol or tincture of benzoin that is gently painted on either side of the wound edges. Since these adhesive adjuncts are toxic to wounds, care must be taken to avoid their introduction into the wound itself. The tapes should be placed perpendicular to the wound edges approximately 2 to 3 mm apart. With long lac-

FIG. 42-5. Placement of continuous subcuticular sutures. Small horizontal bites are taken beneath the dermal-epidermal junction. Slight backtracking of the needle path should be performed to ensure wound coaptation. [Reproduced with permission from Singer AJ, Hollander JE (eds): *Lacerations and Acute Wounds. An Evidence-Based Guide*. Philadelphia, PA: FA Davis, 2003, p. 125.]

FIG. 42-6. Placement of horizontal half-buried mattress sutures. The needle enters the skin on one side of the laceration, passes across the gap, traverses the tip of the flap underneath the epidermis, crosses the gap at the other side, and then exits the skin from the other side. [Reproduced with permission from Singer AJ, Hollander JE (eds): *Lacerations and Acute Wounds. An Evidence-Based Guide*. Philadelphia, PA: FA Davis, 2003, p. 130.]

erations, the first strip of tape should be placed across the center of the wound followed by additional strips on either side of the wound center. To reduce the possibility of skin blistering or premature dislodgement, additional strips should be placed over the ends of the other strips, parallel to the laceration. With the introduction of more durable skin tissue adhesives, tapes are mostly used to reinforce lacerations after suture or staple removal. The cosmetic results and dehiscence rates after closure of small and superficial facial lacerations with tapes is similar to cyanoacrylate tissue adhesives.¹³

FIG. 42-7. Placement of vertical mattress sutures. The first bite is taken far from the wound, the needle is reversed, and the second bite is taken close to the wound edge. The wound edges evert as the knot is tied. [Reproduced with permission from Singer AJ, Hollander JE (eds): *Lacerations and Acute Wounds. An Evidence-Based Guide*. Philadelphia, PA: FA Davis, 2003, p. 127.]

CYANOACRYLATE TISSUE ADHESIVES

The cyanoacrylate tissue adhesives have been used to close lacerations and surgical incisions for several decades, but have only recently become available in the United States. The cyanoacrylate tissue adhesives are liquid monomers that polymerize into a stable bond when they come into contact with moisture. They are applied topically to the apposed wound edges and should not be introduced into the wound. The tissue adhesives offer many advantages over standard wound closure devices. They may be applied rapidly and painlessly to any easily approximated laceration. Because they slough off spontaneously within 5 to 10 days, they do not require removal. They are equivalent in strength to 5-0 sutures, and thus should not be used alone for high-tension wounds. They can be used in conjunction with deep sutures and/or immobilization aimed at reducing wound tension. The cyanoacrylates form an occlusive dressing that serves as a barrier to microbial penetration and have been shown to reduce infection rates in experimental animal models.^{14,15}

Currently, the only FDA-approved tissue adhesives are Dermabond (Ethicon Inc., Somerville, NJ), an octyl-cyanoacrylate (OCA)-based adhesive, and Indermil (Dimensional Analysis Systems, Inc., Leonia, NJ), a butyl-cyanoacrylate-based adhesive. The tensile strength of octyl-cyanoacrylate is three times greater than that of butyl-cyanoacrylates. Furthermore, it is more flexible than the butyls, allowing its use on irregular surfaces and for long lacerations.

The first randomized clinical trial comparing octyl-cyanoacrylate to sutures for closing 136 facial (as well as selected extremity and torso) lacerations in adults was reported by Quinn et al in 1997.¹⁶ At 3 months there were no differences between the groups in the visual analogue cosmesis scores or the percentage of wounds receiving optimal wound evaluation scores. Wound closure with the adhesive was found to be faster and less painful than with sutures. The cosmetic results were also comparable after 1 year of follow-up.

The largest prospective randomized clinical trial to date evaluating octyl-cyanoacrylate for wound closure has recently been published.¹⁷ This study included data from ten clinical sites that included urgent care centers, ED, and a variety of operating room settings (general, orthopedic, dermatologic, and gynecologic surgery). Enrolled patients had a variety of traumatic lacerations, surgical incisions as well as surgical excisional wounds. Wounds ranged in size from 0.1 to 14 cm with over 100 wounds greater than 4 cm in length. These wounds were located on a wide range of body areas including the head and neck, trunk, and extremities. This study concluded that wound closure with OCA was faster than with standard wound closure devices, and had comparable rates of infection, dehiscence, and optimal cosmetic appearance.¹⁷

FIG. 42-8. Application of tissue adhesive. The wound edges are held in apposition with the fingers of the nondominant hand as the tissue adhesive is applied. TABLE 42-6 Avoiding Potential Pitfalls of Tissue Adhesives

Problem	Ways To Avoid the Problem
Runoff	Position patient with wound parallel to floor Circumscribe wound with ointment
Spillage into eyes	Cover eyes with gauze barrier Position patient so wound is not above eye Apply petrolatum jelly barrier before applying adhesive
Wound dehiscence	Avoid adhesive use for high-tension wounds Avoid frequent exposure to friction or moisture Use deep sutures or immobilization for high-tension wounds
