Wound infection	Use adhesives only for properly selected wounds Use proper wound preparation, including irrigation, exploration, and when necessary, debridement Use proper application technique
Getting stuck to the wound	Practice expressing small amounts of adhesive and controlling runoff Alternate the hand used to appose wound edges prior to complete polymerization of the adhesive

Source: Reproduced with permission from Singer AJ, Quinn JV, in AJ Singer, JE Hollander (eds): *Lacerations and Acute Wounds. An Evidence-Based Guide*. Philadelphia: FA Davis, 2003.

The Cochrane Library published a systematic review on the use of tissue adhesives in 2002. The authors concluded that (1) there is no significant difference in cosmetic result between tissue adhesives and standard wound closure, (2) patient-reported pain scores and physician-reported procedure time were significantly lower with tissue adhesives, and (3) there is a small increase (absolute difference = 4 percent, 95% CI 1 to 7 percent) in wound dehiscence using tissue adhesives.¹⁸

While there are many studies evaluating different cyanoacrylates individually and in comparison with sutures, few studies have directly compared the various cyanoacrylate tissue adhesives against each other. A recent comparison of OCA and a butyl-cyanoacrylate (Histoacryl Blue) demonstrated comparable cosmetic results after closure of selected, short, simple facial lacerations in children.¹⁹ In contrast, a study comparing OCA and the same butyl-cyanoacrylate for closure of pediatric operative wounds found that OCA was superior in terms of dehiscence rates.²⁰

In order to ensure optimal results, tissue adhesives should only be used when laceration edges are easily approximated with the practitioner's hands or forceps. Occasionally an assistant can be valuable in helping to ensure constant and meticulous wound edge apposition while the adhesive is applied. The adhesive is carefully expressed through the tip of the applicator and gently brushed over the wound surface in a continuous steady motion (Figure 42-8). The adhesive should cover the entire wound as well as an area extending 5 to 10 mm on either side of the wound edges. After allowing the first layer of the adhesive to polymerize for 30 to 45 s, 2 to 3 additional layers of the adhesive are similarly brushed onto the surface of the wound, waiting 5 to 10 s between successive layers. Care in application will reduce some of the commonly reported pitfalls associated with tissue adhesives (Table 42-6). A new high viscosity octyl-cyanoacrylate that is six times thicker than the current octyl-cyanoacrylate formulation is now available that reduces runoff and spillage.

LACERATIONS TO THE FACE AND SCALP

EPIDEMIOLOGY

Lacerations to the face and scalp account for approximately 50 percent of the wounds treated in EDs in the United States.¹ The most cosmetically apparent wounds are those that appear on the face; therefore careful evaluation and meticulous repair technique are important for excellent results. The emergency physician can repair the majority of facial lacerations; however, because of the cosmetic impact of these wounds, consultation with specialists is encouraged when the technical aspects of closure exceed the physician's ability.² Wounds to the face that involve areas of tissue avulsion may best be repaired primarily in the operating room so flaps or grafts can be applied. When the emergency physician initially evaluates the wound, it should be cleaned and properly irrigated even if a delayed repair by a specialist is anticipated.

In today's society, a growing number of victims of domestic violence are identified in the ED. Anyone with facial trauma should be questioned about the possibility of domestic violence and appropriate authorities should be notified (Table 43-1).^{3,4}

TABLE 43-1 Maxillofacial Injuries and Domestic Violence in the ED

Most victims of domestic violence have maxillofacial injuries
Women more commonly affected than men
Fist is most common weapon
Left side of face is most common site of injury
Nasal bone commonly fractured

PATHOPHYSIOLOGY

Facial and scalp wounds are most often caused by a combination of sharp and blunt mechanisms. For example, a victim of a motor vehicle accident may bluntly strike the windshield and be cut by the glass as it shatters. People involved in interpersonal trauma or falls may have a similar pattern of injury. Lacerations caused by sharp objects are likely to have more discrete edges, but may be deeper and involve underlying structures such as the muscles of facial expression, nerves, and arteries. Wounds caused by blunt forces burst the skin open, damage cells, and produce tissue edema, which slows the wound-healing process. As a result, it takes an average often times fewer bacteria to cause an infection in a blunt wound compared to a sharp wound. Blunt forces are more likely to cause diffuse underlying damage, such as fractures of the facial bones or skull. The presence of foreign bodies such as soil, glass, or wood fragments further complicates the potential for good healing.⁵

SCALP AND FOREHEAD

Anatomy

The scalp and forehead have a similar structure (Figure 43-1). The skin is thick, and on the scalp it has abundant hair follicles and sebaceous glands. There is a rich network of blood vessels: the arterial supply to each side of the scalp includes three branches off the external carotid artery (occipital, superficial temporal, and posterior auricular arteries) and two branches from the internal carotid artery (supraorbital and supratrochlear arteries).⁶ Since the dermal tissue is so fibrous, vessel retraction is limited following injury, and significant hemorrhage can result. The potential space between the periosteum and the galea aponeurosis allows for easy movement of the scalp over the cranium. However, hematoma and infection can collect and spread within this space to involve the entire forehead and scalp. This high degree of mobility sometimes leads to a scalping injury, in which a large segment of the scalp is torn off in one piece.

FIG. 43-1. The layers of the A. scalp, B. temporal region, and C. eyebrow. TM = temporalis muscle.

Evaluation

For many patients with scalp and forehead lacerations, the wound may be only a minor part of the overall injury; prior to definitive wound care, airway, breathing, circulation, hemorrhage control, and spinal and neurologic injury should be addressed. In some cases it may be necessary to control scalp hemorrhage urgently by applying direct pressure or clamping the involved vessel(s) at the wound edges (e.g., using Raney clips).

Routine lacerations should be inspected and gently palpated to determine their depth, noting whether the galea is lacerated or if there is an underlying depressed skull fracture. Palpable depressions in the outer table of the skull should be evaluated further with computed tomography. Orientation of forehead lacerations has important cosmetic implications; in general, wounds that fall along the lines of skin tension have better cosmetic results. Skin tension lines are perpendicular to the underlying muscles. As an obvious example, the horizontal lines seen on the forehead when the brow is raised are perpendicular to the frontalis muscle underneath (Figure 43-2). Forehead lacerations that extend to other structures, such as the eyebrow, nose, or ear must be evaluated and managed with the cosmetic result of these structures in mind.

Wound Preparation

For wound preparation and closure in pediatric patients, sedation may be required during the procedure (see Chap. 134). Anesthesia can be provided by topical, local, or regional infiltration. A supraorbital block can be used to anesthetize one side of the forehead and anterior third of the scalp. The advantage of a regional block in the face is that the volume of locally instilled anesthetic does not distort the wound (see Chap. 37). Local anesthetics containing epinephrine are often used in highly vascular wounds to help control hemorrhage from small vessels.⁷ Topical agents such as LET (lidocaine-epinephrine-tetracaine) or EMLA (eutectic mixture of local anesthetics) may provide adequate anesthesia alone in about 50 percent of patients and reduce the pain of local anesthetic injection in those who require it.^{8,9} TAC (tetracaine-adrenaline-cocaine) is not recommended because of the potential for systemic absorption and cocaine toxicity.

All traumatic wounds are irrigated to reduce contamination and lessen the risk of wound infection. However, in nonbite, noncontaminated facial and scalp wounds presenting within 6 h, routine irrigation does not alter the rate of infection or subsequent cosmetic appearance after suture repair.¹⁰

Repair of Scalp Lacerations

It is not necessary to shave or cut scalp hair prior to wound closure; shaving increases the likelihood of a wound infection.¹¹ In most cases,

FIG. 43-2. Skin tension lines are perpendicular to underlying muscles.

the hair can be brushed aside or an ointment such as bacitracin zinc or petrolatum can be applied to mat down the hair adjacent to the laceration.

Large galeal defects should be sutured if possible to prevent a wide, depressed appearance of the final scar and to minimize the development of a subgaleal hematoma. Buried 4-0 nonabsorbable monofilament nylon or polypropylene interrupted or horizontal mattress sutures may be used (Table 43-2). In large wounds, the muscle layer may be approximated with 4-0 absorbable monofilament or multifilament in a simple interrupted fashion. This reduces the apparent width and depth of the final scar. Conversely, the skin and muscle layers can be closed with a single suture layer through both structures. The skin can be closed with surgical staples or by simple interrupted nylon or rapidly absorbable braided sutures. It is helpful to leave the tails long and use sutures of a color different than the hair to facilitate removal. Superficial scalp lacerations without galeal injury can be closed with staples alone.^{12,13}

Hair braiding has been described as an alternate closure technique for scalp lacerations.¹⁴ While tissue adhesive alone is not recommended for the scalp, recently a technique combining hair apposition and tissue adhesive has been described for closure of scalp lacerations.¹⁵ In this technique, 4 to 5 strands of hair from opposite sides of the wound are brought together, twisted once, and secured with tissue adhesive.

A pressure dressing should be considered for the first 24 h on a deep scalp laceration to prevent the formation of a hematoma. Patients who have sustained a significant scalping injury should be sent to the operating room for definitive repair.

Repair of Forehead Lacerations

The deep layers of the forehead may be approximated in a similar fashion to the scalp. In this area, unrepaired muscle layers are more likely to produce noticeable scars, especially when the facial muscles of expression are involved. The skin may be closed with 6-0 nonabsorbable interrupted suture or tissue adhesive. For deep wounds under tension, a buried 5-0 intradermal, absorbable monofilament or multifilament suture can be used. The epidermal layer can be closed with 6-0 nonabsorbable sutures in a simple, interrupted fashion; with skin closure

strips over adhesive adjuncts; or with tissue adhesive¹⁶ (Table 43-3). Alternate methods of closure are especially attractive if the patient is at risk to develop keloids or hypertrophic scars. Care should be taken in the forehead to approximate the skin tension lines and hairline precisely (Figure 43-3).

Repair of Eyebrow Lacerations

The eyebrow marks the lowest portion of the forehead. The eyebrows should never be clipped or shaved because their delicate contour and form are valuable landmarks for the meticulous reapproximation of the wound edges. If shaved it is also unlikely that they will grow back in exactly the same fashion as they had been prior to the injury. If debridement in any hairy area must take place, the scalpel should cut at an angle parallel to the hair follicles to minimize the area of subsequent alopecia. When repairing a laceration that involves the eyebrow, the hair margins must be lined up exactly. It is helpful to use sutures that are a different color from the hair and to leave long tails to facilitate removal.

Disposition

Patients whose overall medical condition does not warrant surgery or admission to the hospital can be discharged with routine wound-care instructions and, if the injury resulted from a major blunt impact, closed head injury precautions. Removal of scalp sutures or staples should take place in 7 to 10 days, while nonabsorbable sutures in the face should be removed in 3 to 5 days.

EYELIDS

Anatomy

The eyelid is a thin tissue that covers the globe and is composed of five layers: skin, subcutaneous tissue, orbicularis oculi muscle, tarsal plate, and conjunctiva. The muscular layer controls lid closure and forms both the medial and lateral canthus; fibers of the orbicularis oculi wrap

TABLE 43-2 Suturing Guidelines for the Face and Scalp

Area	Suture	Size	Anesthetic	Removal
Scalp and face				
Galea	Nylon	4-0	Local or supraorbital	Not removed
Muscle	Monofilament or braided absorbable	4-0	Local or supraorbital	Not removed
Skin	Staples	Standard	Local or supraorbital	7-10 days
	Nylon	4-0		
	Rapidly absorbing	4-0		
Forehead	Coated or plain nylon	6-0	Local or supraorbital	5 days
	Tissue adhesive	May need deep layer		
Face	Coated or plain nylon	6-0	Local, infraorbital, or mandibular	5 days
	Tissue adhesive	May need deep layer		
Eyelids	Coated or plain nylon	6-0 or 7-0	Supra- or infraorbital	3 days
Nose				
Cartilage	Braided absorbable	5-0	Intranasal pack (no epinephrine)	Not removed
Skin	Coated or plain nylon	6-0	Intranasal pack (no epinephrine)	3-5 days
Ears				
Cartilage	Coated nylon	6-0	Auricular block (no epinephrine)	Not removed
Skin	Coated nylon	6-0	Auricular block (no epinephrine)	5 days
Lips				
Mucosa	Rapidly absorbing	5-0	Local, infraorbital, or mandibular	Not removed
Muscle	Monofilament or braided absorbable	4-0 or 5-0	Local, infraorbital, or mandibular	Not removed
Skin	Plain or coated nylon	6-0	Local, infraorbital, or mandibular	3-5 days

Minimal tension
Avoid hairy areas
Epidermal closure only (no mucosa)
Do not use on human or animal bites

around the lacrimal system. Nerve supply to the eyelid arises from the temporal and zygomatic branches of the facial nerve. The tarsal plate forms the main body of the lower half of the lid and consists of elastic tissue in a dense matrix of connective tissue. Embedded in the tarsal plate are the Meibomian glands, which open into the white line just in front of the conjunctival edge of the lid margin. In the lid margin, the eyelashes are arranged in three irregular rows with their follicles extending obliquely into the tarsal plate.

The lacrimal system begins at the upper and lower puncta as they form the canaliculi. The nasolacrimal duct extends 3 to 5 mm above the level of the medial canthus. It is responsible for tear drainage.

Evaluation

The structures surrounding the eye and eyelids are very delicate and are cosmetically and functionally important. A high degree of suspicion for injury to these structures from periorbital trauma is required and the emergency physician should have a low threshold for referring these lacerations to an ophthalmologist or oculoplastic specialist for definitive treatment.

The eyelids are very thin and do not offer any protection from penetrating injuries to the globe. A complete examination of the eye's structure and function and a search for foreign bodies must be completed before wound care is carried out. Once the integrity of the globe and muscular structures is verified, the lid should be examined for involvement of the canthi, the lacrimal system, or penetration through the tarsal plate or lid margin. The following injuries should be referred to an ophthalmologist or oculoplastic specialist: (1) involving the inner surface of the lid, (2) involving the lid margins, (3) involving the lacrimal duct, (4) associated with ptosis, or (5) extending into the tarsal plate. Poor approximation of the lid margins leads to a notched appearance. Failure to recognize and properly repair the lacrimal system can result in chronic tearing (epiphora). In general, wounds that

are superficial and especially those parallel to the lid margins may be carefully repaired by the emergency physician (Figure 43-4).

Treatment and Disposition

Gentle irrigation with normal saline should be performed after anesthesia. Closure with 6-0 or 7-0 nonabsorbable simple interrupted nylon suture or polypropylene is preferred. Extreme care should be taken to avoid deep penetration of the needle through the lid and into the underlying globe; small bites only through the skin layer should be taken. Tissue adhesive is contraindicated near the eye. In the event of inadvertent tissue adhesive contact with the eye, copious irrigation and/or application of a petrolatum ointment is indicated. Routine evaluation and treatment of the subsequent corneal abrasion should follow. Sutures should be removed in 3 to 5 days. A thin layer of antibiotic ointment may be applied in place of a dressing.

NOSE

Anatomy

As a protuberant structure, the nose is especially vulnerable to blunt trauma. It is the most common fracture in victims of domestic violence and assault.⁴ The nose is composed of cartilaginous and osseous structures that support the overlying skin and musculature and the underlying mucosa. It is separated into halves by the septum. Two C-shaped alar cartilages that are covered directly by skin form the tip of the nose. The interior of the nose is covered by specialized skin with mucus-producing cells and thick, long hairs near the end, while the proximal portion of the nasal lining is made up of ciliated pseudostratified columnar epithelial cells.⁶

Evaluation

The most important assessment of nasal lacerations is to determine their depth and the involvement of the deeper tissue layers.¹⁷ Exposed

Supraorbital nerve

FIG. 43-3. Key stitches in the forehead.

FIG. 43-4. Eyelid anatomy. A. External landmarks. B. Simple closure of a superficial laceration of the upper lid.

SECTION 6 • EMERGENCY WOUND MANAGEMENT

cartilage or penetration through all tissue layers increases the risk of infection. When there is septal trauma, the presence of a hematoma underneath the cartilage and its protective mucoperichondrial layer may eventually lead to permanent thickening of the septum, causing partial airway obstruction of the nasal passage. Alternatively, the pressure exerted by a large, untreated septal hematoma may cause necrosis and subsequent erosion of the septum, enabling communication between the nasal passageways. Besides the annoyance to the patient, it may lead to a cosmetic saddle-nose deformity. If the mechanism of injury includes blunt force delivered to the nose, the possibility of a cribriform plate fracture with cerebrospinal fluid rhinorrhea should be considered.

Treatment and Disposition

Local anesthesia of the nose may be attempted but is difficult because of the tightly adhering skin. Injection of epinephrine-containing anesthetics should be avoided on the tip of the nose. Regional anesthetic injection is difficult, but topical application of lidocaine into the nasal cavity may provide sufficient anesthesia. Insertion of multiple cotton-tipped swabs or plain nasal packing gauze soaked in the 4% lidocaine solution is usually sufficient (Figure 43-5). After several minutes and prior to repair, the swabs or gauze should be removed.

Superficial lacerations to the skin layer may be closed with 6-0 nonabsorbable monofilament simple interrupted sutures, which may be removed in 3 to 5 days. Lacerations over exposed cartilage should be closed promptly. Small pieces of cartilage that may be present should be preserved under the skin to provide the optimal cosmetic result. Future revision by a plastic surgeon will be easier if there is abundant tissue available for reconstruction.

If the laceration extends through all tissue layers, closure should begin with a 5-0 monofilament synthetic suture that aligns the skin surrounding the entrance to the nasal canals at the alar rim (Figure 43-5). Initially, the ends can be left untied and long to facilitate the closure of the deeper structures. *Gentle* traction on this suture provides alignment of the mucosa and cartilage layers. The mucosal layer is closed with 5-0 rapidly absorbable interrupted sutures and the area is reirrigated gently from the outside. The cartilage may rarely need to be approximated with a minimal number of 5-0 absorbable sutures. In sharply demarcated linear lacerations, closure of the overlying skin is usually sufficient. Finally, the initial stitch at the alar margin should be reevaluated for precise alignment and tied; then the remainder of the skin should be sutured with 6-0 monofilament nonabsorbable material. Removal of the external sutures may take place in 3 to 5 days.

Septal hematomas should be drained. For a small, unilateral hematoma, the clot can often be aspirated through an 18-gauge needle. Larger hematomas require a horizontal incision at the base (Figure 43-5). Following the procedure, nasal packing prevents the reaccumulation of blood. A brief course of prophylactic antibiotics is recommended to prevent infection of the cartilage. The packing may be removed in 2 to 3 days. Bilateral hematomas are often drained in the operating room.

LIPS

Anatomy

The external surfaces of the lips have three distinct regions: the skin, the vermillion, and the oral mucosa. The cosmetically important junction of the skin and the red portion of the lip is called the *vermillion border*. The orbicularis oris muscle surrounds the mouth. Its integrity is responsible for retaining the saliva inside the mouth, producing the bilabial sounds of speech, and providing important facial expressions.

FIG. 43-5. The nose. A. Nasal anesthetic technique using cotton-tipped applicators. B. Septal hematoma and lateral anatomy. C. Frontal view showing closure of skin edges.

The infraorbital nerve supplies the upper lip and the mental nerve supplies the lower lip. Both are branches of the trigeminal nerve and can easily be blocked by regional anesthetic techniques. The lips are richly supplied by the labial arteries.⁶

Evaluation

External as well as intraoral examination is required to appreciate the complete injury. Lacerations should be fully explored. Missing, impacted, or fractured teeth; involvement of the parotid (Stensen) duct; or exposed bone of the maxilla or mandible should be noted. Lacerations that cross the vermillion border are of the utmost cosmetic importance.

Treatment and Disposition

Isolated intraoral mucosal lacerations may not need to be sutured, or if closed, a rapidly absorbable suture is recommended. Through-and-through lacerations that do not include the vermillion border can be closed in layers. The mucosal layer is closed with a 5-0 rapidly absorbable suture followed by gentle reirrigation from the outside. Next, the orbicularis oris muscle is approximated with 5-0 absorbable suture material with a simple interrupted or horizontal mattress technique. Finally, the skin is sutured with 6-0 nonabsorbable monofilament sutures in a simple interrupted fashion. The sutures should be removed in 5 days. Alternatively, the skin can be approximated with tissue adhesive.

Wounds that cross the vermillion border should be repaired by placing the first stitch to precisely approximate the edges of the vermillion border (Figure 43-6). Even 1 mm of step-off will be cosmetically unappealing. Following this first stitch, the repair can proceed as previously described. In some cases, it is helpful to place this crucial suture and leave it untied until the remainder of the skin is sutured. Gentle traction on the ends can help approximate underlying tissue to provide optimal cosmesis. Care should be taken to avoid pulling the suture through the skin in this delicate area. Patients with sutured intraoral lacerations should receive prophylactic antibiotics, usually penicillin.

FIG. 43-6. Irregular-edged vertical laceration of the upper lip. A. Traction is applied to the lips and closure of the wound is begun first at the vermillion-skin junction. B. The orbicularis oris muscle is then repaired with interrupted, absorbable 4-0 synthetic sutures. C. The irregular edges of the skin are then approximated.

Orbicularis Oris Muscle

EARS

Anatomy

The external ear begins with the external auditory canal and extends to the fibrocartilaginous framework of the auricle and the soft fatty tissue of the earlobe. The blood supply to the ear arises from the superficial temporal and posterior auricular arteries. The majority of the sensory innervation is from the anterior and posterior branches of the greater auricular nerve. The auricular branches of the vagus nerve supply the posterior wall of the external auditory canal, so lacerations that involve this area cannot be anesthetized with auricular nerve blocks.⁶

Evaluation

Lacerations caused by blunt forces to the ear can rupture the tympanic membrane or produce a subchondral hematoma. Hematomas can form even in the absence of a laceration. Lacerations caused by blunt or shear forces may involve the cartilage.¹⁷ The presence of cerebrospinal fluid otorrhea signals a basilar skull fracture.

Treatment and Disposition

During routine wound preparation, a cotton plug can be inserted into the ear canal during irrigation. If a wound extends deep into the canal, the integrity of the tympanic membrane should be verified. Regional anesthesia by auricular nerve block is ideal. Epinephrine should be avoided in lacerations involving the auricle. Impeccable hemostasis prior to repair of an auricular laceration is required to prevent the formation of a hematoma.

Superficial lacerations to the skin can be closed with 6-0 monofilament interrupted sutures (Figure 43-7). Any exposed cartilage should be covered to prevent subsequent infection. If an injury produces several crushed pieces of cartilage under the skin, they should not be removed; remaining cartilage will be beneficial if reconstructive surgery is necessary. Debridement of skin is not advisable, since there is very little excess skin available to cover the existing cartilage. In most through-and-through lacerations of the auricle, the skin can be approximated and the underlying cartilage will be supported adequately. In a large, gaping wound, one or two 6-0 nonabsorbable coated nylon stitches can be used to approximate the edges of cartilage. The knots should be tied so they will not cause an obvious deformity through the skin. If the overlying skin is avulsed, referral to a plastic surgeon for repair using a flap is recommended.¹⁸

Following repair of the simple ear laceration, a small piece of non-adherent gauze may be applied over the laceration only and a pressure dressing applied. Gauze squares are placed behind the ear to apply pressure and the head is wrapped circumferentially with gauze. The dressing may be tied into place by cutting the last portion of the gauze longitudinally (Figure 43-8). Sutures should be removed in 5 days. Complete avulsion of the ear must be urgently referred to a plastic surgeon.

If an auricular hematoma is suspected, consultation with a plastic surgeon or otolaryngologist is recommended. Proper treatment requires the complete and permanent evacuation of the hematoma and definitive control of the bleeding that caused it. Neglecting to treat an auricular hematoma may produce a cauliflower-ear type cosmetic defect of the cartilage.

THE CHEEKS AND FACE

Lacerations that involve the surface of the face may be repaired carefully using standard wound-care techniques. In general, facial lacerations are closed with 6-0 monofilament nylon simple interrupted sutures that are removed in 5 days. Tissue adhesive may be used in superficial wounds after proper irrigation. If there is significant ten-

FIG. 43-7. A. Laceration through auricle. B. One or two interrupted, 6-0 coated nylon sutures will approximate divided edges of cartilage. C. Interrupted nonabsorbable 6-0 synthetic sutures approximate the skin edges.

FIG. 43-8. Pressure dressing for ear lacerations. A. Gauze placed behind auricle. B. Bandage wrapped around head with two ends cut for tying. C. Ends tied.

sion, an underlying layer of 4-0 absorbable suture closure is indicated. Attention to underlying anatomic structures including the facial nerve and parotid gland is important (Figure 43-9).⁶ If these structures are involved, operative repair is indicated.

INJURIES TO THE ARM, HAND, FINGERTIP, AND NAIL Fiona E. Gallahue Wallace A. Carter

Soft tissue upper extremity injuries account for about 35 percent of the wounds and lacerations evaluated in the ED.¹ Specific issues relative to wounds and lacerations of the arm and hand include: (1) the potential of injury to the arteries, nerves, and tendons that lie close to the skin, and (2) the importance of hand function in daily and occupational life. Injuries may be classified as closed crush, simple lacerations, open crush with partial amputation, and complete amputation.^{2,3} The approach to treatment depends on multiple factors: the mechanism of injury; location of the injury; injury to adjacent arteries, nerves, and tendons; patient's age, sex, handedness, occupation and concurrent medical problems; presence of exposed bone; and anticipated future use of the hand.

GENERAL MANAGEMENT PRINCIPLES

History and Examination

The majority of hand and arm injuries are isolated injuries and can be managed in the ED. Complex or extensive injuries calling for skin grafting or technically advanced skills require consultation with a specialist. Specific considerations in the history include age (potential for underlying bony injury and likelihood for healing and functional recovery), occupation (necessity for arm and hand function), and hand dominance.

Examination of arm and hand injuries includes inspection, evaluation of motor nerve and tendon function, evaluation of sensory nerve function, and evaluation of perfusion.

During inspection, note the position and stance of the arm, hand, and digits. Note if the wound is adjacent to major arteries, nerves, and tendons. Is there exposed tendon or bone? Does the wound contain foreign bodies, debris, or visible contamination? Has there been avulsion of soft tissue or loss of length?

Examining active motion and resistance to passive movement assesses motor function. Patients with a painful injury may be unwilling to move the hand; providing appropriate anesthesia after checking sen-

sory nerve function may provide enough comfort to obtain an adequate motor exam. Despite some overlap, there are pure motor functions of each nerve that should be tested against resistance (Table 44-1). Each tendon in or adjacent to the injured area should be individually assessed. For injuries to the hand and fingers, the extensor digitorum (ED), flexor digitorum profundus (FDP), and the flexor digitorum superficialis (FDS) to each digit is examined individually. The FDS, which splits and inserts at the proximal interphalangeal (PIP) joint, can be examined by holding all other digits in extension and flexing the PIP joint against resistance. The FDP, which runs below the FDS past the split to attach at the distal interphalangeal (DIP) joint, can be examined by holding the PIP joint in extension and flexing the DIP joint against resistance. Limited or painful movement suggests partial involvement of a tendon.³ Abnormality in motor nerve or tendon function testing warrants a more in-depth examination including visual inspection and appropriate consultation.

Sensation should be assessed in the median, ulnar, and radial nerve distribution (Table 44-2 and Figure 44-1). For injuries distal to the mid-palm, the digital nerves should be assessed by static two-point discrimination longitudinally along the ulnar and radial aspect of the volar pad of the potentially involved digits. Static two-point discrimination is evaluated by using ECG calipers or a paper clip bent into a "V" shape with the two ends separated by approximately 5 to 6 mm. During testing, the two points should not cross the midline and each stimulus should be 3 to 4 s apart. Normal two-point discrimination is defined as <6 mm; good is 6 to 10 mm; fair is 11 to 15 mm, and poor is >15 mm. Two-point spatial acuity of touch diminishes with age; young (18 to 33 years) patients have a mean two-point acuity of 2 mm while elderly (>66 years) patients have a mean acuity of 5 mm.⁴ The two most important areas to maintain sensation are the ulnar side of the thumb and the radial side of the index volar pads in order to preserve pinch sensation.

Intact radial and ulnar pulses and capillary refill are usually adequate to exclude significant vascular injury. However, an arterial injury proximal to the wrist may not be obvious due to good collateral circulation. For forearm wounds proximal to the wrist, an Allen test should be performed. A Doppler probe is useful to detect a diminished pulse, detect flow in digital arteries, and to calculate an arterial pressure index (API = the ratio of the systolic blood pressure between the injured and the uninjured side). In the absence of a diminished pulse or a ratio less than 1.0, the likelihood of a clinically significant occult arterial injury is exceedingly small. Lack of obvious arterial bleeding does not rule out arterial injury since cleanly transected arteries may contract and prevent obvious bleeding.²

Imaging Studies

Radiographic evaluation with anteroposterior (AP) and lateral films is indicated if bony injuries, retained radiopaque foreign bodies, or joint penetration are suspected. Oblique views of the hands and digits are useful to visualize small areas with overlapping bones. For finger injuries, isolated radiographs of the involved digit(s) are better because the detail on hand films alone is often not adequate for complete evaluation.

Where there is suspicion for a radiolucent retained foreign body, especially wood, another imaging study (ultrasound, computed

TABLE 44-1 Motor Testing of the Peripheral Nerves of the Upper Extremity

Nerve	Motor Exam

tomography [CT], or magnetic resonance [MR]) may be necessary (see Chap. 46). Ultrasound may detect radiolucent objects such as vegetative matter as small as 1 X 2 mm, but requires operator skill and experience. CT can also identify radiolucent objects and localizes a foreign body in relationship to the surrounding anatomy. MR has similar capabilities as CT but cannot be used for metal objects.

Adequate Visualization

Since wounds and the adjacent structures are often small, patient positioning, adequate lighting, and a bloodless field are necessary for wound evaluation.

For some injuries, a bloodless field may require a proximal tourniquet to temporarily halt arterial inflow. The two most commonly used tourniquets are the rubber (Penrose) drain for finger injuries and the pneumatic tourniquet placed around the upper arm for forearm and hand injuries.

For a rubber tourniquet for digital injuries, a 1-inch Penrose drain is placed around the base of the finger, stretched away from the hand, and secured with a clamp or hemostat. If time allows, the digit can be exsanguinated prior to tourniquet placement by wrapping the digit with the Penrose drain from distal to proximal, then carefully removing the drain from distal to proximal before securing it around the base of the digit. Excessively high pressures and duration, which can cause neurovascular damage, may be avoided by limiting the stretch of the drain to no more than 50 percent of the original length for 15- to 20-min periods.^{3,5}

For more proximal injuries, especially those with brisk arterial bleeding, a pneumatic tourniquet using the manual blood pressure cuff is useful. Esmarch's technique is to elevate the injured extremity and apply an elastic bandage starting distally and proceeding proximally to the area where the cuff is to be applied. This will help to exsanguinate the limb and prevent backflow bleeding. The cuff is applied around the upper arm and inflated to pressures above the systolic blood pressure of the patient, but not to exceed 250 mm Hg.³ The cuff tubing is clamped with a hemostat instead of closing the air release valve in order to prevent slow air leakage. The maximum cuff inflation time is

1 h, although a limit of 30 min is recommended to ensure patient safety.

Once adequate visualization is obtained, the injury can be examined for foreign bodies and tendon and joint capsule injuries. It is important to examine the arm and hand in the position of injury in order to avoid missing injuries that may have moved out of the field of view when examined in a neutral position.

Lacerations in proximity to joints should be carefully examined for potential violation of the joint capsule. If the depth of the injury raises the question of extension into the joint capsule, joint injection is warranted. After antiseptic preparation of the area, the joint is injected with normal saline from an area away from the laceration site. Fluid dripping from the joint indicates an open joint capsule and requires specialty consultation.⁶ For small joints or questionable exams, a few drops of fluorescein may be added to the injected saline and the joint examined with a Wood's lamp for evidence of fluorescent effluent. Methylene blue, once used to aid in this diagnosis, is discouraged due to the staining of the intra-articular surfaces.

Wound Dressing and Postrepair Care

Once the injury is repaired, antibiotic ointment should be applied to the repaired incision and sutures and the wound covered with a nonadherent dressing (see Chap. 48). The area should always be wrapped loosely in a soft dressing to allow for adequate circulation. Where possible, the fingernail or volar pad should remain visible so capillary refill can be followed. Depending on the size or nature of the injury, especially injuries in close proximity to a joint or with tendon involvement, splinting may be advisable for protection and avoidance of painful stimulation (see Chap. 267). Isolated digital lacerations may be better served with a padded aluminum splint. The extremity should be kept elevated above the level of the heart to reduce edema and adequate analgesia should be provided. A follow-up wound check is recommended within 48 to 72 h. Sutures are usually removed 8 to 10 days after the injury.

Prophylactic antibiotics are not routinely indicated, but may be considered in wounds that are contaminated, due to mammalian bites, for injuries that are more than 12 h old, in the presence of exposed bone, or in patients with concurrent medical problems that may affect wound healing (i.e., those with diabetes or renal or peripheral vascular disease) (see Chap. 48). Antibiotics should be chosen to cover suspected contaminants and pathogens and given early by a route that quickly achieves high blood and tissue levels.

Indications for admission to the hospital include injuries that require repair in the operating room, those that require a course of intravenous antibiotics, or the presence of social issues such as homelessness or the patient's inability to follow basic aftercare instructions.

SPECIAL CONSIDERATIONS

High Pressure Injection Injuries

Injuries to the hand from high-pressure injectors have potentially devastating consequences. Substances such as grease and oil-based compounds do not produce an inflammatory response until much later due to their high viscosity. These injuries often go unsuspected since they usually present with an initially benign appearance, most commonly an isolated puncture wound to the index finger of the nondominant hand.⁷ The patient and physician may not be aware that they have an injected substance subcutaneously until radiographs are obtained. The severity of these injuries is based on several factors: properties of the injected material, amount of injected material, velocity of the injectant, anatomy of the injection site, spread of the injectant, and time to diagnosis and treatment. Injection injuries should be referred immediately to a hand specialist or plastic surgeon for operative debridement. The amputation rate for these injuries ranges from 16 to 55 percent.⁷

FIG. 44-1. Sensory innervation to the hand.

Injuries in Children

In a child, identifying a fracture with plain radiographs may be difficult owing to an open epiphysis. It is often necessary to obtain radiographs of the opposite side for comparison. If a surgical procedure is indicated and the child is unable to tolerate the procedure after local anesthesia alone, procedural sedation may be required.

Keeping dressings intact on children poses a problem because of their continuous activity, rendering a routine hand dressing and protective finger splint ineffective. If the dressing is essential to wound healing, the child should be placed in a long arm cast.⁸

SPECIFIC TREATMENT STRATEGIES

Forearm and Wrist Lacerations

Patients with wrist lacerations should be questioned about suicidal gestures or attempts. Patients with suicidal intent require psychiatric evaluation after wound repair.

Tendons and nerves distal to the wound should be individually examined. The forearm has six extensor compartments located dorsally, innervated by the radial nerve (Table 44-3). Located on the volar surface of the forearm and crossing the wrist are the 12 flexor tendons innervated by the median and ulnar nerves (Table 44-4).

Injuries about the elbow may affect the radial and ulnar nerves, which are in close proximity to the lateral and medial epicondyles, respectively. The radial nerve emanates from the spiral groove in the humerus approximately 10 cm proximal to the lateral epicondyle. The ulnar nerve travels behind the medial epicondyle as it runs between the two heads of the flexor carpi ulnaris into the forearm. The median nerve is more protected in the elbow region as it runs in close proximity with the brachial artery, crossing anteriorly to the ulnar artery at the origin of the anterior interosseous nerve in the forearm. Though injuries to these nerves are more common in fractures and dislocations, these nerves can be compromised by simple soft tissue injuries at the elbow due to their location and lack of overlying protective soft tissue in this area.⁹

For most simple lacerations to the forearm and wrist, 4-0 or 5-0 nonabsorbable monofilament sutures such as nylon or polypropylene should be used. For gaping injuries or injuries under high stress, deep sutures using 4-0 absorbable material may be required. Injuries that involve more than one parallel laceration, classic for suicide attempts,

may require horizontal mattress sutures to cross all lacerations for closure to prevent compromising the vascular supply of the island of skin located between incisions (Figure 44-2). Adhesive tapes or tissue adhesives in conjunction with sutures or alone for closure may also be useful.¹⁰

Palm Lacerations

The palmar skin surface is adapted for contact with objects in the environment; it is thicker with an underlying connective tissue layer of fascia, making it much more adherent to bone than dorsal skin. The thenar, palmar, and digital creases are connections between the skin and underlying fascia without intervening adipose tissue.³ These creases should be carefully approximated during closures. The thickness of palmar skin makes eversion of the edges especially difficult. For this reason, interrupted horizontal mattress sutures with 5-0 nonabsorbable monofilament suture are recommended to ensure that these sutures do not pull through.¹⁰

FIG. 44-2. Horizontal mattress sutures for multiple parallel lacerations.

Dorsal Hand Lacerations

CLENCHED FIST INJURIES Patients with injuries to the dorsum of the hand should be questioned about the possibility of a clenched fist injury (CFI) with a human bite. These wounds generally produce a small laceration (3 to 5 mm) over the dorsal MCP joint.¹¹ After contact is made, the patient is likely to extend the hand, which deeply inoculates oral bacteria into the wound. Human saliva contains as many as 50 species of bacteria with a microbe concentration of 1×10^8 organisms per mL. *Staphylococcus aureus* is the most common bacterial species isolated from human bite wounds followed by *Streptococcus* spp., *Corynebacterium* spp., and *Eikenella corrodens*. Human bites have been documented to transmit herpes, actinomycosis, syphilis, tetanus, and hepatitis B and C.¹² HBIG and Hepatitis B vaccine should be given if indicated. In CFI infections, polymicrobial involvement is the rule.

Radiography should be performed in these injuries to evaluate for embedded teeth, air in the joint or soft tissues, or fractures. For patients who delay evaluation and develop obvious infection, exploration, open irrigation, and debridement in the operating room are required followed by admission for intravenous antibiotics and elevation. If the patient presents soon after the injury and without evident infection, evaluation, exploration, irrigation, and debridement can be done in the ED with appropriate equipment and physician expertise. It is important to visualize the full extent of the wound, evaluate the hand through full range of motion, and exclude injury to the extensor tendon or joint capsule. If no injury to these structures is seen, the wound should be copiously irrigated and dressed with a nonadherent dressing. The hand should be splinted in a position of function. A 3- to 5-day course of prophylactic antibiotics should be prescribed, usually amoxicillin-clavulanate, (see Chap. 48). The patient should be instructed to elevate the extremity and re-evaluation within 24 to 48 h is recommended. If there are any issues of patient compliance, comorbid illness causing immunocompromise, current evidence of infection, or joint or tendon involvement, a hand surgeon should be consulted and the patient admitted for observation and IV antibiotics, usually ampicillin-sulbactam or cefoxitin.

SKIN LACERATIONS The dorsal skin of the hand is thin and freely mobile, allowing for extensive range of motion for all joints. Because of the mobility of the skin and superficial nature of the extensor tendons, a careful examination through a full range of motion at the site of injury as well as in the position of injury is necessary to avoid missing a tendon injury. The thinness and lack of underlying tissue allows skin avulsion to occur easily, making skin approximation difficult.^{3,10} Simple 5-0 nonabsorbable sutures should be adequate for closure. To provide better cosmesis for injuries to the dorsum of the hand, subcuticular stitches with 5-0 absorbable, a pull-through subcuticular closure with nonabsorbable suture for linear lacerations, or a corner stitch for a V-shaped laceration may be considered¹⁰ (Figure 44-3).

Extensor Tendon Lacerations

The proximity of the extensor tendons to the surface makes them vulnerable to any open injury. An emergency physician who is experienced and comfortable with the procedure can repair extensor tendon injuries between the distal wrist and metacarpophalangeal joints. However, it is good practice to discuss these cases with the consulting hand surgeon for treatment preferences and continuity of care. Extensor tendon injuries of the thumb or those with severe contamination should be referred to a hand surgeon. Small partial extensor tendon injuries (<50 percent transected) should be repaired with absorbable synthetic material.^{3,12} Larger partial tendon injuries (>50 percent transected) and complete extensor tendon lacerations should be sutured with 4-0 (5-0 for smaller tendons) colorless nonabsorbable material such as polypropylene or nylon, and the skin closed with 5-0

FIG. 44-3. Pull-through subcuticular suture.

nonabsorbable suture material.^{3,12} A figure-of-eight stitch with the knot placed at the edge of the tendon is recommended to repair lacerated extensors^{3,12} (Figure 44-4). After repair of the tendon and overlying skin, the hand or digit should be splinted in position of function with instructions to maintain elevation of the extremity. Follow-up with a hand surgeon is recommended within 7 days.

Certain complications can be seen with disrupted extensor mechanisms. A swan neck deformity or mallet finger deformity is caused by the complete disruption of the terminal extensor mechanism and subsequent proximal and dorsal displacement of the lateral bands (Figure 44-5A). A boutonniere deformity is usually a delayed complication after injury to the PIP joint. The central slip becomes disrupted and there is unopposed action of the FDS tendon, forcing the lateral bands to move volarly and operate as flexors (Figure 44-5B). If open, these injuries require operative repair. If they are closed injuries, they require splinting in extension for up to 6 weeks or operative repair, and referral to a hand surgeon.³

Flexor Tendon Lacerations

Flexor tendon injuries are usually repaired in the operating room by a hand surgeon because of the complexity required. Early consultation is important because many surgeons will repair complete flexor tendon lacerations no later than 12 to 24 h after injury.³ If operative repair of the flexor tendon is going to be delayed, as a temporizing measure the wound should be appropriately cleaned, the skin closed, and the hand splinted in flexion to prevent contraction of the surrounding muscles. The hand surgeon can follow-up the patient in 2 to 3 days and schedule the flexor tendon repair within 7 days. Postinjury scarring and tendon retraction make flexor tendon repairs more difficult after 10 to 14 days.

Finger Lacerations

In general, isolated finger lacerations are straightforward injuries to examine and repair. Vascular status is checked by capillary refill and sensory nerve status is checked by static two-point discrimination. Motor function of the extensor and two flexor mechanisms should be examined. Simple interrupted sutures with 5-0 nonabsorbable suture provide adequate closure for most digital lacerations.¹⁰

Deep finger lacerations may include partial or complete amputations of the digit. These injuries should involve the consultation of a hand surgeon to discuss the possibility of replantation. Guidelines for digit replantation are only that-general principles and not absolute criteria. Relative indications for replantation are injuries in children, injuries to the thumb, multiple digit amputation, and single digit am-

FIG. 44-4. Extensor tendon laceration repair with a figure-of-eight stitch

FIG. 44-5. A. Mallet finger. B. Boutonniere deformity.

Digital Nerve Injuries

Injuries to the digital nerve can be classified as contusion (neuropraxia), crush (axonotmesis), or transection (neurotmesis). Digital nerve injuries are suspected when static two-point discrimination is distinctly greater on one side of the volar pad than the other, or when it is > 10 mm. Digital nerve injuries can be repaired using microsurgical techniques either acutely or days to weeks after the injury. Concomitant injuries and wound contamination are typical indications for delayed repair. Prognosis depends on the specific injury and age of the patient. Neuropraxias heal in 12 days to 6 months. Transection injuries do slightly better than crush injuries, but even with microsurgical repair, recovery is often incomplete.

Fingertip Injuries

Fingertip injuries are those that occur distal to the insertion of the flexor and extensor tendons about at the level of the lunula. These injuries are among the most frequently injured parts of the hand and such injuries may involve the skin, pulp tissue, distal phalanx, and the perionychium, which is made up of the nail, nail bed, and surrounding structures.^{14,15} (Figure 44-6). The goals of healing are to maintain length and cosmetic appearance, have the fingertip approach normal sensation and function, and have as short and uncomplicated a healing period as possible.

FIG. 44-6. Anatomy of the perionychium. [Reproduced with permission from Zook EG: The perionychium, in DP Green, (ed): *Operative Hand Surgery*, 2d ed. New York, NY: Churchill Livingstone, 1988, p. 1332.]

putation proximal to the insertion of the FDS.^{3,13} The strongest contraindications to replantation are crash injuries and avulsion injuries since the neurovascular damage to the amputated digit is significant and offers a poor prognosis. Other relative contraindications include multiple levels of injury to the amputated part, long ischemia time (>24 h) of the amputated part, patients in poor health, or significant comorbid factors such as diabetes or severe pulmonary or cardiac disease which may lead to significant perioperative mortality.^{3,13} Another relative contraindication is a smoking history since replants in smokers are prone to profound vasospasm leading to loss of the replanted digit. The final relative contraindication for replantation is injuries between the MCP joint and the mid-level of the middle phalanx. Fingers replanted at this level are often stiff due to recurrent tendon adhesions between the FDS and FDP tendons, limiting the function of the adjacent uninjured fingers.⁸

DIGITAL TIP INJURIES WITH SKIN AND PULP TISSUE LOSS ONLY Distal fingertip amputations that are 1 cm² or less in size without exposed bone can usually be treated conservatively with serial dressing changes alone (Figure 44-7A).^{14,15} This is a desirable option, because healing occurs by secondary intention and results in very little scarring. Follow-up is arranged in 2 days for wound check and the patient is made aware that wound care is vital to the success of this technique. The patient is instructed to soak the injured fingertip in warm water to which an antibacterial soap has been added once a day for 10 min, followed by tap-water irrigation and application of a sterile nonadherent dressing. This procedure is performed daily for the first 10 to 15 days and every other day thereafter. On average, complete healing may take 4 to 8 weeks, and both the cosmetic appearance and sensibility of the fingertip are quite satisfactory with this technique. Conservative management is advocated in children less than 12 years of age, since they have greater regenerative potential than do adults.¹¹

In cases in which the severed skin tip is available, an alternative means of treatment is to use the amputated portion as a full-thickness skin graft. The amputated tissue is cleaned and debrided of nonviable tissue, the undersurface of the skin is then defatted with sharp scissors, and the graft is sutured to the defect using nylon sutures. Sutures are left long and tied over a 2 X 2 cm gauze stent dressing to compress the graft firmly against the fingertip. Appropriate follow-up is made and unless obvious purulence ensues, the stented dressing is left undisturbed for 7 to 12 days.

A split- or full-thickness skin graft harvested from a distant site is another means of wound closure. This procedure may be indicated in situations in which the severed skin tip is either not available or nonviable, significant pulp tissue loss is greater than 1 cm², or the patient's desire to have full use of the hand precludes waiting the 4 to 8 weeks necessary for healing by secondary intention. In these cases, consultation with a specialist is appropriate.

Many authors agree that conservative management of fingertip injuries without bone exposure, as opposed to the above techniques, is superior in terms of cosmetic appearance, improved function, and sensibility of the involved digit.^{8,14,15}

DIGITAL TIP INJURIES WITH EXPOSED BONE If a significant loss of tissue to the fingertip causes exposure of the tuft of the distal phalanx, skin grafting will be unsuccessful since bone does not provide adequate vascularity to support the donor tissue.^{14,15} Several treatment options exist, always keeping in mind the important goals of preserving digit

length, especially with regard to the thumb and index finger, as well as sensitivity and functionality of the fingertip. The size and geometry of the injury, the angle of tip amputation, and the availability of the amputated tip will determine the options available for wound closure.

If the bony protuberance is less than 0.5 cm in length and the soft tissue defect is less than 1 cm², the bone may be trimmed back using a rongeur and the wound left to heal by secondary intention as previously described. A dorsal obliquely angulated wound may be treated in the ED with bone shortening followed by primary closure of the wound using the adjacent volar tissue (see Figure 44-7D). An injury of this type has a favorable prognosis because the sensate volar skin is intact. Fat from the local tissue may need to be trimmed to allow wound closure without tension. The nail should be removed and attention paid to associated injuries to the nail bed and surrounding structures. Although results are comparable to those following conservative management, shortcomings include loss of length as well as tenderness of the fingertip and some degree of functional disability.

Amputations that are angled either in a transverse or volar direction have less favorable outcomes because they do not always have adequate soft tissue and skin coverage to allow for primary closure and preservation of length (see Figures 44-7B and C). Consultation with a plastic or hand surgeon is necessary, as these injuries often require techniques beyond the scope of practice of most emergency physicians.

Incomplete digital tip amputations, defined by the retention of the neurovascular bundle as well as portions of the underlying bone, are among the most difficult injuries to reconstruct and require consultation with a specialist. If adequate circulation is retained in the tip, the injury is treated with fracture reduction, internal pin fixation, and repair of the soft tissue injury. This procedure is optimally performed in the operating room.

In all patients with a complete amputation that occurs proximal to the lunula, consultation with a hand or plastic surgeon is recommended for possible replantation in the operating room.¹³ Conversely, in the adult patient, replantation of a complete amputation distal to the lunula is not usually advocated. This is because the procedure is technically demanding owing to the arborization of the neurovascular bundle at this location, and carries a poor prognosis. However, consultation with the surgical specialist is clearly indicated in all patients with specific occupational concerns and when the injured digit is the thumb or index finger.

Although fingertip injuries are quite common in children, most require only conservative management because of the rapid healing process.⁸ Repairs should be done using absorbable sutures. Surgical procedures such as grafts and advancement flaps should be avoided where possible. A completely amputated composite tip may be reattached to serve solely as a biologic dressing, and parents should be informed that the tip might necrose, dry up, and turn black as the underlying wound continues to heal. In children less than 6 years of age, replantation and revascularization of the composite tip may be a viable treatment option when performed by the surgical specialist.

INJURIES INVOLVING THE PERIONYCHIIUM The nail, nail bed, and surrounding soft tissue make up the perionychium (see Figure 44-6). The nail bed is made up of the germinal and sterile matrix. The germinal matrix begins 3 to 5 mm proximal and deep to the eponychium and extends distally to the lunula. From there, the sterile matrix extends distally to the hyponychium. Nail injuries can be described as simple nail bed laceration, stellate laceration, severe crush, and complete avulsion. Injury to the perionychium is most commonly due to closure of the fingertip in a door, and is usually in the distal portion of the nail bed. The mechanism of injury is a force directed to the dorsum of the nail, causing it to bend or break and crushing the nail bed against the unyielding tuft of the distal phalanx. There is an associated distal tuft fracture in approximately 50 percent of nail bed injuries; thus all patients require the standard three radiographic views of the involved digit(s). Nail plate deformity permanently affecting nail growth is the most common complication resulting from lack of treatment.

Dorsal angulation with bone exposure. [Reproduced with permission from Russell RC: Fingertip injuries, in J McCarthy (ed): *Plastic Surgery*. Philadelphia, PA: Saunders, 1990, p. 4479.]

Subungual Hematoma These are injuries due to disruption of the blood vessels of the nail bed. The area of the hematoma is directly proportional to the degree of vascular damage. If the subungual hematoma covers greater than 50 percent, treatment can be accomplished with trephination of the nail plate to allow for adequate decompression and drainage of the hematoma. Various tools have been used effectively for this purpose, including a heated paper clip, electric nail drill, electrocautery, 18-gauge needle, and scalpel. The disadvantages of the heated paper clip include coagulation of the hematoma and introduction of carbon particles called "lampblack" into the nail bed, which may delay healing and cause tattooing. Use of a needle, scalpel, or nail drill can be painful and may necessitate local anesthesia. A hand-held electrocautery device permits rapid and painless trephination and is sterile and disposable. However, not every ED will be equipped with such a tool, and emergency physicians will likely perform nail trephination using tools they are familiar with. Patients are discharged with local wound care instructions to soak the affected finger in warm water containing antibacterial soap two to three times a day for 7 days.

Previously, it was commonly recommended that for a subungual hematoma occupying more than 50 percent of the nail bed area, the nail be removed in order to evaluate the nail bed and repair any underlying laceration. This practice has fallen out of favor with recent prospective studies showing that simple trephination produces a good to excellent outcome in most patients with subungual hematoma regardless of size, injury mechanism, or the presence of fracture.^{16,17} Nail removal is recommended only if there is associated nail avulsion or surrounding nail fold disruption.

Nail removal can be accomplished with adequate anesthesia, digit tourniquet, nail elevation off the nail bed using iris scissors, elevation of the eponychium off the nail, and then removal by gentle longitudinal traction with a hemostat. Lacerations of the nail bed are carefully repaired using 6-0 absorbable sutures. Crush injuries often result in stellate lacerations, which may require extensive meticulous repair using a magnifying loupe for visualization. The nail is gently cleaned with saline, taking care not to damage the germinal matrix; it is then trephinated and secured in its anatomic position. This is accomplished by placing a 5-0 nonabsorbable suture through the proximal end of the nail plate and then passing it underneath and through the center of the eponychial fold. Once the nail plate is returned to its anatomic position, the suture is tied down over the nail. The replaced nail acts as a natural splint to the terminal phalanx, prevents formation of synechiae, and protects the sensitive nail bed. If the nail is not available, nonbiologic stents or a sterile piece of the aluminum foil used to wrap suture materials may be fashioned to resemble the avulsed nail and inserted under the eponychium. The fingertip is then dressed in nonadherent gauze and placed in a volar splint to limit movement at the DIP joint. Patients are given postoperative wound care instructions (e.g., as to hand elevation as well as neurovascular checks) and are given adequate pain relief. Unless obvious purulence is noted, the dressing is left undisturbed for 5 to 7 days, after which the site is examined for new hematoma formation. The suture attached to the nail is removed after 3 weeks and the existing nail will be dislodged by the new ingrowing nail after 1 to 3 months.

If an associated distal phalanx fracture coexists with a nail bed laceration, it usually manifests as an avulsion of the nail out of the proximal eponychial fold. If this happens, the nail is removed, the fracture is stabilized by manual reduction, and the nail bed is repaired as previously described. The nail replaced in its anatomic position serves as a biologic splint to maintain fracture reduction, owing to its proximity to the underlying bone. Unstable reductions require consultation with a plastic or hand surgeon for internal fixation using Kirschner wires to prevent deformity of the nail bed.

Nail Bed Avulsion Injuries An avulsion or crush injury may tear the nail completely away from the digit, with fragments of matrix tissue left on the underside of the avulsed nail. These matrix fragments

should be preserved for use as free grafts, and when possible attached to the nail bed using 6-0 or 7-0 absorbable sutures. When the nail or avulsed nail bed fragments are not available, or in the case of a large defect, a full-thickness nail bed graft can be harvested from the patient's toe and sutured into the nail bed of the affected finger. As these injuries are complex and their repair is technically challenging, consultation with a hand or plastic surgeon is appropriate. In addition, avulsion injuries to the nail bed have the poorest prognosis of any fingertip injury.

Avulsion injuries may also incompletely tear the proximal portion of the nail out from under the eponychium. Management entails replacement of the nail root into its anatomic position using a series of three horizontal mattress sutures (Figure 44-8). One suture is placed through the center and one in each corner of the eponychial fold. The sutures are then passed through the proximal portion of the corresponding segment of avulsed germinal matrix and then back out through the nail fold, pulling the matrix back to its anatomic position.

Ring Tourniquet Syndrome

A tight ring encircling the proximal phalanx may become entrapped because of distal swelling. Such swelling may be the result of trauma, infections, skin disorders, allergic reactions, or the tight ring alone. As the digit expands, venous outflow is restricted by the tight ring, producing more swelling. This vicious cycle may lead to nerve damage, ischemia, and digital gangrene. The presence of impaired sensation (diminished static two-point discrimination) or diminished perfusion (delayed capillary refill) indicates significant constriction; rapid ring removal is then warranted. Rapid removal usually requires cutting the ring. If sensation and perfusion are intact, removal can be attempted with slower techniques that preserve the ring. The exception to ring preservation methods arises when there is an underlying phalangeal fracture; it is then prudent to cut the ring off. After removal, sensation and perfusion should be reassessed.

In all methods, the hand should be elevated to encourage venous and lymphatic drainage, thus reducing swelling. Alternatively, the finger can be circumferentially wrapped with a y- to 1-inch elastic band (e.g., Penrose drain), starting from the distal tip and winding the band tightly around the finger, progressing toward the proximal phalanx to reduce swelling. The wrap is left in place for several minutes before it is unwrapped and the ring is removed by one of the methods described

FIG. 44-8. Technique for repair of an avulsion of the germinal matrix using three horizontal mattress sutures. (Reproduced with permission from Chudnofsky CR, Sebastian S: Special wounds—Nail bed, planar puncture, and cartilage. *Emerg Med Clin North Am* 10:808, 1992.)

below. Regional anesthesia is often required, particularly in patients who cannot tolerate the pain of circumferential compression. The metacarpal block is ideal because it produces less swelling of the finger than a digital block (see Chap. 37).

The simplest technique is lubrication. A variety of water-soluble lubricants can be applied to the digit and the ring removed with circular motion and traction.

The string technique uses a length of string wound circumferentially around the finger. When the string is unwrapped, the ring is advanced toward and off the distal tip of the finger. Either string, umbilical tape, or 0-gauge silk sutures can be used. Synthetic monofilament sutures should not be used because they tend to cut the skin. The required length depends on the diameter of the string and the size of the finger; up to 100 in. of string may be required. The method starts by passing one end of the string under the ring and then wrapping the finger, starting next to the ring and winding clockwise, with each loop snug against the previous one, from proximal to distal. With each loop, the tissue underneath is compressed. When it is completely wrapped, the finger should be entirely covered by the string with no tissue showing between the loops (Figure 44-9A). Wrapping and compression is a painful process and usually requires regional anesthesia. To remove the ring, the proximal end of the string is slowly unwrapped in a counterclockwise manner, advancing the ring toward the distal end as the string unwinds (see Figure 44-9B). The PIP region is the widest portion of the finger and is the most difficult site over which to maneuver the ring. Abrasions are commonly produced with the string method.

A variety of modifications to the string technique have been described. One involves wrapping from distal to proximal so as to reduce distal edema. Elastic band compression to reduce digital edema can be combined with a blood pressure cuff inflated above systolic pressure to prevent reaccumulation of edema once the elastic band is removed.¹⁸ Another method uses a self-adherent compression bandage.¹⁹

The rubber band technique uses a 3- to 4-mm rubber band that is passed between the ring and skin; the two ends of the rubber band are then picked up by a clamp and used to place distal traction on the ring. The finger and ring are then lubricated. Traction is applied to the rubber band as it is moved circumferentially around the ring, slowly pulling it distal.²⁰

Ring cutters are available in both manual and power models. The cutter has a small guard that fits underneath the ring and contains a

channel allowing the circular blade to cut down through the ring without coming in contact with the skin. Sometimes, the swelling is so severe that the guard cannot slip under the ring. In these cases, reducing edema by using an elastic band as noted above may be successful. Alternatively, the circular ring may be deformed into an oval, creating a gap on the long axis of the ring. Rings should be cut in the thinnest and most accessible site. Thick rings cannot easily be bent; such rings may need to be cut in two locations, opposite each other, separating the ring into two halves.

LACERATIONS OF THE LEG AND FOOT Earl J. Reisdorff

EPIDEMIOLOGY

Injuries to the leg and foot account for about 13 percent of traumatic wounds evaluated in the ED, distributed roughly into a third each for the foot, calf, and knee and thigh regions.¹ Any injury to the lower ex-

tremity (especially the foot) jeopardizes the ability to walk. Traumatic wounds to the foot can be sustained in a variety of ways, from simple plantar puncture wounds to catastrophic lawn mower injuries. The leg or foot is commonly injured in sports and recreational activities.² Urban children can sustain foot lacerations while playing in water from fire hydrants, mostly due to stepping on broken glass.³ Bicycle spoke injuries result in complex lacerations with marked surrounding abrasions and even tissue loss, usually occurring over the Achilles tendon area.⁴ Lawn mower injuries are usually sustained from the blades of push mowers, often when being pulled backwards.⁵ Lawn mower-induced lacerations are heavily contaminated with multiple organisms. Lawn mower-induced foot lacerations can also be sustained from debris flying out from the undercarriage. Unfortunately, footwear does not provide protection from such injury. Metal lawn and garden edging is associated with plantar and knee lacerations.⁶ Hockey skates are associated with boot-top injuries; typically these consist of a small cutaneous laceration with injury to the underlying tibialis anterior tendon, extensor hallucis tendon, and dorsalis pedis artery and nerve.⁷ High-pressure water spray cleaning systems cause complex laceration-injection injuries. Blunt-force wounds often have irregular edges and are more likely to be associated with an underlying fracture. These characteristics increase the likelihood of wound infection compared to wounds caused by sharp objects.⁸ Given the proximity of the foot and ankle to the ground, soil contamination of lacerations is common, increasing the risk of infection, worsening scarring, and slowing healing. Due to the biomechanical importance of the foot and the enhanced risk of infection with wounds to the foot, lacerations must be treated properly to avoid complications.

PATHOPHYSIOLOGY

During standing and walking, the soles of the feet are in contact with the ground. This relatively small area of contact surface tells the body about its position, as well as detailed information about the terrain being traversed. The tough plantar epidermis and dermis are thick, except in the arch area. This thick skin is able to withstand the numerous forces that a moving body produces, but is also quite sensitive to two-point discrimination and pressure. The primary "shock absorber" in the sole of the foot is a modified layer of fat. The heel has an 18-mm-thick modified pad of fat separated into chambers by fibrous septa. There is an additional broad internal fibrous arch, called the inner cup ligament, that helps maintain the shape of the heel. The skin of the sole readily hypertrophies and can become quite thickened, especially in people who walk barefoot. The blood and lymphatic vessels of the foot are under high hydrostatic pressure. As a consequence, edema easily results from injury and can retard healing.

The dorsal aspect of the foot and the entire ankle provides little protection for underlying tendons, nerves, and blood vessels. The dorsum of the foot and the ankle is particularly vulnerable to work-related injuries such as when heavy objects are dropped on the foot. The shin is especially vulnerable when struck.

The pattern of pedal tendons roughly approximates that of the hand. One important location is just posterior to the lateral malleolus, where the peroneus longus tendon runs and can easily be lacerated at this location. Lacerations of the shin rarely involve vital nerves or tendons. However, in the infrapatellar area, lacerations can transect the patellar tendon, resulting in inability to extend the leg.

The dense fibrous fatty tissue of the ball of the foot and heel makes wound exploration and visualization difficult in the ED. However, lacerations to the arch, although more uncommon, are more readily explored. Most lacerations about the ankle are easily explored, except for posterior ankle lacerations, an unfortunate limitation when a partial laceration of the Achilles tendon is considered. Lacerations involving the shin, calf, and thigh present few problems regarding wound exploration and visualization.

CLINICAL FEATURES

History

The time interval from injury to evaluation is important to note because of the increased incidence of infection, especially with delayed presentations. The mechanism of the injury determines the likelihood of injury to underlying tissue, the risk of a retained foreign body, and degree of potential contamination. For example, the following circumstances are associated with specific pathogens: (1) farming accidents (*Clostridium perfringens*), (2) wading in a freshwater stream (*Aeromonas hydrophila*), (3) high-pressure water systems used for cleaning surfaces (*Acinetobacter calcoaceticus*), and (4) animal bites (*Pasteurella multocida* and *Capnocytophaga canimorsus*). The complaint of any new paresthesia, anesthesia, weakness, or loss of function suggests a nerve, vascular, or tendon injury, prompting a careful examination of the affected site.

The past medical history should include questions about tetanus immunization status and conditions that increase the risk for infection or delayed wound healing (diabetes mellitus, immunosuppression), and risk of bacteremia (valvular heart disease, asplenia).

Physical Examination

Physical examination should determine the location, length, depth, and shape of the wound. A wound on the weight-bearing surface is important to note because the wound care plan should consider avoiding weight bearing. As with all lacerations, the distal sensory nerve function, motor function, and vascular integrity (as assessed by pallor and capillary refill) should be evaluated prior to the administration of local or regional anesthesia, if possible. Nerves and tendons are easily involved in lacerations of the foot and ankle (Figure 45-1). If a nerve laceration is suspected, both light touch and static two-point discrimination should be tested in the foot and toes, and compared to the uninjured side (Figure 45-2). Motor function may be easier to assess after anesthesia or reduction of an associated fracture or dislocation. The superficial peroneal nerve is responsible for foot eversion, the deep peroneal nerve causes foot inversion and ankle dorsiflexion, and the posterior tibial nerve produces ankle plantarflexion. The wound should be inspected for foreign bodies during the general examination as well as during sterile inspection with a bloodless field just prior to wound closure. The loose thin skin over the dorsum of the foot allows for adequate visual, digital, and instrument exploration for tendon lacerations, as well as for foreign body discovery. Direct visualization of the tendon should be attempted because a partially lacerated tendon can mimic normal function, especially with the Achilles and patellar tendons. The dense tissue of the plantar surface of the foot severely limits wound visualization and the risk of creating new or further injury limits exploration at weight-bearing sites. The exception to this general policy of limited exploration on weight-bearing plantar surfaces is in an infected wound with suspected foreign body.

Ancillary Studies

While the most important parameter to monitor in a wound infection is the clinical appearance, a white blood cell count may assist in determining the degree of inflammation and the effectiveness of antibiotic therapy. Some clinicians also measure an erythrocyte sedimentation rate and C-reactive protein if underlying osteomyelitis is considered. Blood cultures should be obtained if bacteremia is anticipated.

Radiographic imaging is useful when a fracture, radiopaque foreign body, or joint penetration is suspected. Soft tissue radiography is not required for the initial evaluation of every laceration at risk for containing a foreign body. If the clinician feels that adequate wound exploration has reasonably excluded the presence of a foreign body, the wound can be irrigated and closed, forgoing radiographic evaluation.

FIG. 45-1. Anatomy of the ankle and foot.

With radiopaque material, standard plain-film radiographs suffice; glass fragments larger than 2 mm and gravel larger than 1 mm are typically seen (>95 percent sensitivity) (see Chap. 46). For radiolucent material, the wound site can be marked with a radiodense marker and the retained material may be seen from distortion of soft tissue shadows around the foreign body. For some types of highly reactive organic material with a high risk of infection and complications, computed tomography or magnetic resonance imaging is required. Retained for-

eign bodies can be visualized on ultrasound, although experience using this modality on the foot is limited.

Lacerations over the ankle and knee should be examined for joint capsule integrity. The clinical detection of joint penetration by physical examination alone is often incorrect.⁹ Air within the joint space on plain radiographs is a sign of joint penetration. The other method to evaluate joint capsule integrity is to inject sterile saline into the joint space, in an amount sufficient to cause synovial distension using a

FIG. 45-2. Sensory innervation to the foot.

standard arthrocentesis approach at a site separate from the laceration. Fluid leaking from the wound indicates joint penetration.⁹

TREATMENT

Age Considerations

Elderly patients tend to have thin skin and decreased subcutaneous fat, especially over the anterior shin, making wound edges more difficult to appose, resulting in closure under tension. Elderly patients are more likely to have medical conditions that can delay wound healing and are less likely to be adequately immunized against tetanus.

The preverbal child may have difficulty limiting movement of the injured extremity, and is more likely to contaminate the wound. Generous dressings aid in protecting any lower extremity laceration; the general rule to follow is "the smaller the child, the larger the dressing."

Wound Anesthesia

The sensory examination should precede the administration of anesthesia. Lacerations to the dorsum of the foot can be sufficiently anesthetized by infiltration of local anesthetic, usually with epinephrine. Certain areas of the foot, especially the plantar surface, are particularly sensitive to the infiltration of a local anesthetic, so nerve blocks are very useful (see Chap. 37). The toes can be anesthetized using standard digital blocks. Epinephrine-containing local anesthetics are traditionally avoided in toes because of the potential risk of digital ischemia. For extensive plantar lacerations, regional nerve blocks are useful, with supplemental local infiltration as required. The two most commonly used foot nerve blocks are the sural nerve block and the posterior tibial nerve block. The lateral aspect of the sole is anesthetized using a sural nerve block, by depositing a generous band-like deposit of lidocaine 1 cm posterior to the distal aspect of the lateral malleolus. The posterior tibial nerve block numbs most of the sole, and is accomplished by infiltrating the area next to the posterior tibial artery, just posterior to the distal aspect of the medial malleolus. Procedural sedation should be considered for plantar surface lacerations in children (see Chap. 134).

Topical anesthetic preparations, such as lidocaine-epinephrine-tetracaine (LET) or eutectic mixture of local anesthetics (EMLA) are poorly effective on the dense epidermis of the sole, especially at the contact areas. Conversely, adequate anesthesia with topical preparations can usually be achieved on the dorsum of the foot and elsewhere on the leg.¹⁰ If topical preparations are used, the blood coagulum is first removed and the solution-soaked cotton or gauze pledget is placed firmly into the wound.

Wound Preparation and Repair

The repair of lower extremity lacerations, and especially plantar surface foot lacerations, has been poorly studied and only recently have observational outcome studies been published. Too few randomized studies evaluating various methods of wound preparation or closure for foot and leg lacerations have been done to scientifically direct clinical practice. Most recommendations are based on reasonable extrapolations from the existing studies and common sense clinical judgment.

Due to the inherent risk of infection with foot lacerations, wound irrigation with copious amounts of saline at pressures of 5 to 8 psi is important. The ideal time to perform a thorough dry-field exploration evaluating tendon integrity and detecting foreign bodies is when the wound is completely anesthetized and after irrigation.

Lacerations of the lower extremity tend to be under increased wound tension compared to other anatomic sites. Lacerations under significant tension should be repaired with a multiple-layered closure using buried deep 3-0 or 4-0 absorbable sutures followed by simple in-

terrupted 3-0 or 4-0 nonabsorbable monofilament sutures. Simple interrupted sutures of 4-0 nonabsorbable suture material may be used for skin closure in lacerations under minimal tension. Horizontal mattress sutures are ideal for wounds under moderate tension in the lower extremity. Wounds proximal to the knee and in areas that are usually covered (i.e., where cosmesis is not an issue) can be closed with skin staples. In wounds that are prone to infection, deep absorbable material is avoided and skin staples or horizontal mattress sutures are used. For large thigh lacerations (e.g., a chain saw injury), running sutures are avoided so if there is an infection, selected sutures can be removed.

Debridement to remove devitalized tissue is considered an important aspect of wound care to reduce the risk of wound complications. Nonetheless, debridement should be limited on the plantar surface because the thick, dense, fibrous tissue is not pliable, and any defect resulting from debridement is thus closed under tension across the laceration. Likewise, anterior shin lacerations should undergo minimal debridement.

Lacerations associated with nail injuries require close attention. On the dorsum of the phalanx, the skin is attached directly to the periosteum with no intervening layer of subcutaneous tissue. Therefore, a laceration to the nail bed places the underlying bone at risk for bacterial contamination.

The timing of closure should also be considered. The foot is a body area with a high concentration of bacteria. Therefore the risk of foot infection increases significantly with delay in closure. The "golden period" during which a wound may be closed with minimal risk of infection is unknown. The common recommendation of limiting primary closure to lower extremity wounds less than 6 h old is without much support in the limited number of studies that address this issue (see Chap. 40). Each wound should be evaluated on its individual merits and the decision to undertake primary closure made encompassing all the factors. A delayed primary closure should be considered in cases of delayed presentation or contamination. For delayed primary closure, the wound is packed with saline-soaked gauze and the patient is placed on an antistaphylococcal antibiotic. At 4 days after injury, the wound is reevaluated, and if not clinically infected, closed using interrupted nonabsorbable monofilament sutures.

Plantar Lacerations

Repairing a laceration on the plantar surface is best done with the patient placed in a prone position, with the foot overhanging the cart or elevated by placing a pillow beneath the ankle. Heavy, large suture needles and thick thread are required to penetrate the hypertrophied epidermis and dermis of the sole of the foot, typically 3-0 and sometimes 4-0 suture with a large curved cutting needle. Simple interrupted sutures usually suffice. The advantage of interrupted sutures is that if the foot becomes infected, individual sutures can be selectively removed. If there is tissue loss or the site is under tension, a vertical mattress suture may be required. In the arch area, achieving tissue eversion can be difficult. Adhesive tapes, tissue adhesives, and staples are avoided on the plantar surface.

Dorsal Lacerations

Dorsal surface lacerations are repaired almost exclusively with nonabsorbable monofilament suture material, most commonly 4-0 or 5-0 for small lacerations. Running sutures are acceptable on the dorsal surface. Under select circumstances adhesive tapes or tissue adhesives with splints to restrict movement during the first 5 to 7 days can be used.¹¹

Interdigital Lacerations

Lacerations between the toes are difficult to repair; the interdigital space is confined within a deep web space. Having an assistant gently

separate the toes enhances the exploration and repair of interdigital lacerations. The use of simple interrupted sutures often leads to skin inversion and risk of failure of the initial wound repair. The more effective closure technique, albeit somewhat more difficult to perform, is to place horizontal or vertical mattress sutures. This is best accomplished with 5-0 monofilament nonabsorbable suture on a small cutting needle. In young children, monofilament absorbable suture can be used, thus avoiding suture removal. When a web space laceration involves the neurovascular bundle, the skin is usually closed without any subsequent consideration to repairing the neurovascular injury.

Shin Lacerations

Wounds over the anterior tibial surface are under considerable tension. Whenever possible, they should be approximated with a multiple-layered closure, first using buried deep 3-0 or 4-0 absorbable sutures followed by simple interrupted or horizontal mattress 4-0 nonabsorbable sutures. In elderly patients, the skin may be extremely thin, creating difficulty for closure. Deep closure with absorbable material should first be attempted. The skin is closed with wide horizontal mattress sutures using 4-0 nonabsorbable material. Occasionally, the 4-0 suture is too fine and cuts through the skin, requiring 3-0 monofilament suture. Broad adhesive strips (one-half inch) can be placed with adhesive adjunct (e.g., tincture of benzoin) over the suture site to minimize dynamic tension across the wound. An elastic bandage is placed over a generous dressing. Weight-bearing should be limited for the first 5 days of wound healing if there is significant wound tension.

Alternatively, a new technique using deep reinforced sutures placed through adhesive strips laid down parallel to the wound edges has been recently described.¹² This technique is useful for both linear and flap lacerations and limits tearing by the suture material of the often fragile skin over the shin.

Knee Lacerations

For lacerations about the knee, potential joint capsule penetration and laceration of the patellar and quadriceps tendons should be assessed. The common peroneal nerve is prone to injury as it runs over the head of the fibula laterally, and distal function should be assessed (inversion, eversion, and dorsiflexion). Deep popliteal wounds can injure the popliteal artery and tibial nerve. Popliteal artery injuries are serious because the leg has minimal collateral circulation distal to the knee.

Simple lacerations about the knee can be closed with 4-0 nonabsorbable material, using simple interrupted or horizontal mattress sutures because of the marked active skin tension in this area. Skin staples are an alternative in patients subject to poor wound healing. The knee should be splinted or placed in a knee immobilizer to decrease active tension and promote better wound healing. Limited experience suggests that lacerations about the knee in children can be closed with tissue adhesives and splints to restrict movement.¹¹

Tendon Lacerations

The decision to repair tendon lacerations in the foot depends on the functional impairment caused by the injury compared to the benefits of repair.^{13,15} Many extensor tendon lacerations involving the midfoot and forefoot can go unrepaired without sacrificing any necessary foot function; the skin is closed and the foot splinted.¹⁵ However, any laceration of the extensor hallucis longus or tibialis anterior requires discussion with an orthopedist since dorsiflexion of the great toe and foot can be important in walking or running.¹⁵ Flexor tendon lacerations across the toes (excluding the great toe) can be left unrepaired without significant functional sequelae. Occasionally, a hammer toe or claw toe deformity results from the failure to repair a tendon (usually flexor tendon) laceration.¹⁴ Although lacerations of the flexor hallucis longus are frequently repaired, no long-term evaluation has determined that

this is essential.¹⁵ In fact, there are limited data indicating that unrepaired flexor hallucis longus tendon lacerations do not result in a functional deficit, even among athletes.¹⁵

Since the Achilles tendon is not the only tendon responsible for plantarflexion of the foot, its individual function may be difficult to assess. The Achilles tendon is first palpated for defects. A complete laceration produces a conspicuous absence of the tendon at the posterior ankle. The patient then lies prone on the examination cart with the foot hanging over the edge of the bed and the mid calf is squeezed by the examiner (Thompson test). If the Achilles tendon is intact, the foot plantarflexes. Comparison to the unaffected calf can be helpful. If the Achilles tendon injury results from a laceration, the Achilles tendon may easily be seen with simple exploration through the open wound.

Significant tendon lacerations of the lower extremity are usually repaired a few days to weeks after the initial injury. Treatment in the ED consists of skin closure; splinting of the foot, ankle, and leg; initiation of prophylactic antibiotics; instruction for non-weight-bearing crutch use; and arrangement for the patient to follow-up with an orthopedist.

Tissue Loss and Amputation

Certain injuries can lead to major tissue loss as well as toe or foot amputation (e.g., motorcycle, lawn mower, and antipersonnel land mine injuries). Tissue grafts and flap reconstruction by an orthopedist or plastic surgeon may be required. Reimplantation of a severed toe is not typically performed. Reattachment of an amputated great toe, forefoot, or entire foot is occasionally done, although it is extremely complex. Immediate consultation with a reimplantation surgeon is essential in such circumstances. Any severed part should be gently washed (not scrubbed) with sterile saline to remove gross debris, wrapped in saline-soaked gauze, and placed in a plastic bag that is then closed and placed in an ice water bath.

Retained Foreign Bodies

Retained (nonreactive) foreign bodies such as glass can pose a problem. Chronic pain, especially during walking, can occur if the material is not removed. In the absence of chronic discomfort, inert foreign bodies can remain in the foot. The material typically becomes encapsulated, as is sometimes seen with insulin needles retained in the feet of patients with diabetic neuropathy. Conversely, reactive organic material must be aggressively sought and removed. Deep foreign bodies in the foot can be extremely difficult to remove in the ED. Fluoroscopy can be useful to help locate and remove radiopaque foreign bodies.

Hair Tourniquet Syndrome

Hair tourniquet syndrome is an unusual type of toe injury that is seen during infancy.^{16,17} A long strand of hair becomes wrapped around a toe, often producing strangulation and digital ischemia. This can be an occult source of irritability for infants. Removal must be complete to restore perfusion. Moreover, complete removal eliminates any further circumferential laceration of the skin around the toe. The standard approach to salvage the compromised digit is to make a midline longitudinal incision along the extensor surface of the toe.¹⁷ The incision should be deep enough to split the fibers of the extensor ligament without transecting the fibers. The multiple strands of hair are then removed using fine forceps without teeth. Unfortunately, the toe often retains the initial appearance, making one uncertain whether all of the strands have been removed or cut. A novel approach to removal involves the use of hair-dissolving compounds, although this approach has not been studied sufficiently to routinely recommend it.

Despite the unusual nature of this injury, the consensus in the medical literature is that hair tourniquet syndrome is not the result of intentional injury and does not warrant reporting as suspected child abuse.

DISPOSITION

A bulky dressing is applied to the plantar surface to cushion any plantar laceration. For large lacerations on the plantar surface, weight-bearing is avoided for at least 5 days. However, infants will naturally step on the injured site. Since crutches are too difficult to use in children younger than age 7 years, young children may need to be carried. Elevation of the extremity decreases swelling and infection risk. Sutures are typically removed in 10 to 14 days.

Prophylactic Antibiotic Use

While infection occurs in 3 to 8 percent of lower extremity lacerations^{8,18} and up to 34 percent of plantar lacerations,³ there is no evidence that prophylactic antibiotics reduce the frequency of postrepair wound infections¹⁹ (see Chap. 48). Therefore, the decision to use prophylactic antibiotics is made using clinical judgment according to the degree of contamination, the presence of foreign debris, the presence of associated injuries, and host factors that predispose to infection. At one extreme, clean, small lacerations to the dorsum of the foot do not require antibiotic prophylaxis. At the other extreme, patients with grossly contaminated lawn mower-induced wounds should have it.

Animal bites to the leg and foot require coverage against *Staphylococcus*, *Streptococcus*, and *Pasteurella*. Asplenic or immunocompromised patients who sustain a dog bite should receive coverage against *C. canimorsus*. Amoxicillin-clavulanate will cover all four organisms. Lacerations sustained when wading in freshwater streams should receive antibiotic prophylaxis for *Aeromonas hydrophila* (a gram-negative bacillus) with a fluoroquinolone. *Aeromonas* infections occur 8 to 48 h after inoculation and are rapidly progressive. Fascia, tendon, muscle, bone, or joint involvement occurs in 39 percent of cases.²⁰ Compartment syndrome, myonecrosis, and foot amputation can result. Effective antibiotic coverage against *Aeromonas* includes aminoglycosides, trimethoprim-sulfamethoxazole, and fluoroquinolones. Open fractures are most commonly infected by *S. aureus*, so patients should receive antibiotic prophylaxis with a first-generation cephalosporin and an aminoglycoside in the ED.

SOFT TISSUE FOREIGN BODIES

Richard L. Lammers

Soft tissue foreign bodies may be encountered when managing new wounds or evaluating complications of old wounds. When evaluating fresh injuries, the physician is responsible for detecting foreign bodies and for deciding if removal is urgent, can be delayed, or is even necessary. Many foreign bodies should be removed in the ED; for example, all foreign material within the cavities of fresh lacerations should be irrigated away, debrided, or extracted with instruments. The decision to remove foreign bodies embedded below the dermal layer of skin depends on the size, location, composition, accessibility, and anticipated mechanical and inflammatory effects of the object. Occasionally, patients with subcutaneous foreign bodies should be referred to appropriate physicians for delayed removal.

Many foreign bodies are detectable during clinical examination, but some will not be apparent to the sight or touch of the examining physician. Various imaging studies can be used to evaluate wounds when nothing is found during exploration but the probability of a concealed object remains high. Some foreign bodies, however, may be invisible to radiographic or sonographic study. Consequently, liability for missed foreign bodies will continue to plague emergency physicians.

PATHOPHYSIOLOGY

Transient inflammation is an integral part of normal wound healing. A small amount of foreign debris in a wound provokes an inflammatory response in an effort to eliminate or contain the invader. When large quantities of devitalized tissue, foreign debris, bacteria, or other irritants are present within a wound, this protective response intensifies. Excessive or prolonged inflammation may delay wound healing or destroy surrounding soft tissue and bone, producing periosteal reactions, osteolytic lesions, synovitis, and arthritis. If the body fails to dissolve or extrude foreign material, it will become encapsulated within a fibrous capsule. Many granulomas result from chronic inflammation caused by foreign bodies that inflammation could not eliminate. Once a retained foreign body is encapsulated, inflammation subsides.

The type and intensity of an inflammatory reaction is determined primarily by the chemical composition and physical form of the foreign object. Material that is inert—such as glass, metal, or plastic—may not elicit any abnormal tissue response. Objects with smooth, nonporous surfaces produce less inflammation and fibrosis than those with rough surfaces. Most metals are inert, but those that oxidize will cause mild to moderate inflammation. Earrings with studs dipped in gold paint cause earlobe swelling and inflammation when the paint flakes off. Vegetative foreign bodies, such as wood, thorns, and spines, trigger the most severe inflammatory reactions. Sea urchin spines, other marine foreign bodies, and hair may cause chronic inflammation with granuloma formation.

In some cases, inflammation is caused by a local toxic reaction. For example, blackthorns contain an alkaloid that produces intense inflammation. The oils and resins in redwood and cedar splinters also cause considerable inflammation. Sea urchin spines and catfish spines contain venom that causes severe burning pain at the puncture site and a variety of systemic symptoms (see Chap. 196). A sudden, local **inflammatory** reaction from a rose thorn or cactus spine may be an allergic response to fungi on the plant. Some cacti cause a delayed hypersensitivity reaction. Systemic toxic and allergic reactions are unusual but serious complications of foreign bodies. Foreign bodies containing lead have the potential to produce systemic lead poisoning, particularly if they are in contact with pleural, peritoneal, cerebrospinal, or joint fluid.¹

Infections are the most common complication of retained foreign bodies, even when the foreign material itself is not contaminated. Foreign bodies may incite a variety of soft tissue infections, including local wound infection, cellulitis, abscess formation, lymphangitis, tenosynovitis, bursitis, and osteomyelitis. These infections are characteristically resistant to therapy; antibiotics, antiinflammatory drugs, and steroids may produce a partial regression of symptoms but seldom eradicate the infection. Some infections will resolve spontaneously once the foreign bodies are removed. Vegetative foreign bodies may cause fungal infections, particularly in immunosuppressed patients.

Foreign objects can also cause mechanical damage by compressing or lacerating anatomic structures or occluding vessels. Repeated movement of tissue containing a foreign object increases the fibrous reaction.

CLINICAL FEATURES

History

Every wound has the potential for concealing a foreign body, but only a small percentage of lacerations and puncture wounds actually contain them.^{2,3} Certain historical factors are associated with a higher risk for a retained foreign body: the mechanism of injury, composition and shape of the wounding object, and the shape and location of the resulting wound.^{2,3} Objects that shatter, splinter, or break in the process of causing a wound often leave remnants behind. For example, a wound caused by glass that broke on the skin is more likely to contain shards than a wound caused by previously-broken glass. Dental fractures following a blow to the mouth serve as a warning that fragments of teeth may be embedded in the lip or tongue of the patient or in the hand of the assailant. Thorns, spines, and sharp wooden branches are usually brittle and tend to penetrate deeply into puncture wounds before breaking. Wood splinters are notorious for fragmenting when they are pulled out of a puncture wound. Patients impaled by long, thin metallic objects such as hypodermic or sewing needles may remove them without realizing that a portion of the object broke off beneath the skin surface. Both remnants of a needle and impurities in street drugs can cause persistent pain or abscess formation at the site of intravenous drug use. Nails that penetrate socks and shoes may drive leather, rubber, or cloth into the plantar surface of a patient's foot. Blunt objects with a diameter greater than 4.5 mm may push a plug of skin deep into a wound, resulting in an epidermal inclusion cyst, (f any object pulled from a wound does not appear intact, the wound should be explored for further contaminants.

The patient's perception of a foreign body sensation in a fresh wound with an actual foreign body is modestly useful [sensitivity = 43%, specificity = 83%, LR(+) = 2.49, and LR(-) = 0.69].³

Patients with retained foreign bodies may present to the ED after a wound heals, complaining of sharp pain with movement or with pressure over the site. Failure to heal a wound also may be evidence of a retained irritant. Chronic, delayed, and recurrent infections also can be associated with retained foreign bodies. New puncture wounds that become infected and infections that are resistant to antibiotic therapy suggest that a foreign body has been missed. Arthritis in a joint near an old puncture wound may be a thorn-induced synovitis. Delayed nerve, vessel, or tendon injuries also require further investigation.

Physical Examination

Physicians are occasionally surprised by foreign bodies that can be embedded in small or seemingly superficial wounds.² Several physical findings indicate the presence of a foreign body. A discoloration or visible mass under the epidermis makes the diagnosis obvious. Sometimes a mass cannot be seen but can be palpated. Sharp, well-localized pain with palpation over a puncture wound is a useful sign. If passive range of motion of a joint near a wound is limited, a foreign body may be responsible.

Old wounds with retained foreign bodies may have a persistent purulent drainage, a chronic draining sinus, or a chronic granulomatous reaction. A sterile abscess that complicates wound healing may be the result of a foreign body.

Some foreign bodies are discovered in wounds unexpectedly, but most are found during a deliberate and careful exploration of wounds considered to be at risk.^{2,m} Adequate lighting, good hemostasis, complete local anesthesia, and patient cooperation are essential. Every effort should be made to visually inspect all recesses of a wound. Wounds deeper than 5 mm and wounds whose depth cannot be visualized have a higher association with foreign bodies.² If punctures and other narrow wounds make direct visualization difficult and the physician is concerned about the possibility of a foreign body below the surface, the wound margins should be extended with a scalpel (Figure 46-1). However, wounds that penetrate deeply into adipose tissue are difficult to explore and easily hide foreign material. Blind probing with a hemostat is a less effective but sometimes acceptable alternative to wound exploration when the wound is narrow and deep and extending the wound is not desirable. This method is used frequently to evaluate plantar puncture wounds caused by nails and to search for clear glass, which is difficult to see in a wound. A closed hemostat should be introduced into the wound and either used as a probe or spread open and then withdrawn. If an instrument strikes a metallic or glass foreign body, it will produce a grating sensation. The instrument should not be used to grasp blindly in hopes of clamping an unseen object. This technique is especially dangerous in hands, feet, or faces, where direct visualization is the preferred method of exploration.

DIAGNOSIS

Imaging studies should be ordered **in** most cases in which a retained foreign body is suspected but not found during wound exploration or when exploration is technically impossible. They are also useful after initial removal of multiple foreign bodies to determine if all the pieces were found. A number of imaging modalities are available. The ability of any of these modalities to find a foreign body depends on the characteristics of the study as well as the object's size, shape, density, and orientation relative to the imaging beam. Materials that are the same density as surrounding soft tissue are difficult to see with any type of radiographic or sonographic technique.

Plain Radiography

It is fortunate that many foreign bodies are radiopaque; most foreign bodies that can be missed during the initial clinical evaluation can be seen *on* plain films.⁴ Plain films are readily available but must be obtained with appropriate **technique** and inspected carefully to detect small and faint foreign bodies. Metal, mammalian bone, some types of fish bones (cod, haddock, grey mullet, red snapper, and sole), teeth, pencil graphite, certain plastics, glass, gravel, sand, and aluminum are visible on plain radiographs^{4,10} (Table 46-1). Almost all glass is visible on radiographs if it is 2 mm or larger, and contrary to myth, glass does not have to contain lead to be visible on plain films.^{4,5,7,8} A radiopaque fragment is more easily seen if it is positioned parallel to the central ray of the x-ray beam, which increases its apparent density.

Radiographs should be obtained with an underpenetrated soft tissue technique, producing a lighter film that increases the contrast between the foreign body and surrounding tissue. The contrast and brightness of digital radiographs can be adjusted to achieve the same

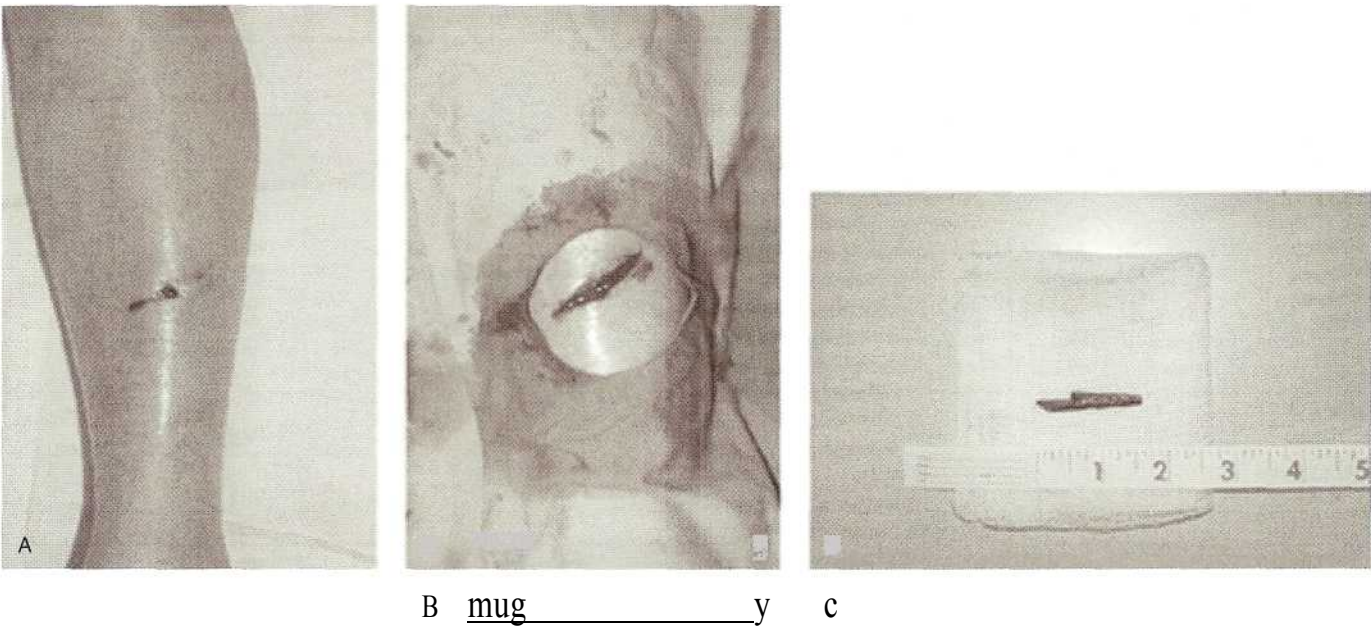

FIG. 46-1. A. This patient's leg was punctured by a wooden stake 2 days prior to presentation. Surrounding cellulitis and point tenderness lateral to the wound indicated the probability of a retained foreign body. B. The entrance to the wound was extended. C. A 1.5-cm piece of wood was removed from a 3.5-cm-deep wound.

effect as an underpenetrated film.⁷ Plain films should be taken in multiple projections to separate the shadow of the foreign body from underlying bone and to help gauge the depth of the object in the tissue. Chronic inflammatory changes may create secondary bony changes such as osteolytic and osteoblastic lesions, pseudotumor formation, and periosteal reaction, revealing the object's location.

Many common or highly reactive materials such as wood, thorns, cactus spines, some fish bones, other organic matter, and most plastics are not visible on plain films.^{4,7,8,10} Sometimes there is indirect evidence of their presence; a radiolucent filling defect may occur when the object is less dense than surrounding tissue. However, even radiopaque foreign bodies may be invisible on plain films if they are obscured by or impacted in bone.

Computed Tomography (CT)

CT is capable of detecting more types of foreign materials than plain-film radiography because it is 100 times more sensitive in differentiating densities.^{4,8} Subtle density differences can be distinguished with a narrow radiographic density window adjustment, particularly if a computer workstation is used to vary the gain and contrast settings.⁸ Thorns, spines, wood toothpicks, fish bones, and plastic foreign bodies have been identified with this method.^{4,8,11} CT may detect objects embedded in bone, and isodense objects may be outlined by surrounding

air within the wound. Digital edge enhancement can further improve the visibility of these objects.⁹ CT images can be created in multiple planes and can demonstrate the relationship of a foreign object to important anatomic structures. The principal disadvantages of CT are its cost, higher radiation dose, and the fact that with time, wood and other organic material absorb water from the surrounding tissue, becoming isodense and difficult to distinguish from surrounding tissue.

Ultrasonography

Sonography has been described in clinical series and studied in experimental models to identify soft tissue foreign bodies such as wood, fish bones, sea urchin spines, other organic material, fiber, and plastic.^{12,19} Most authors have reported greater than 90 percent sensitivity with ultrasound for detection of foreign bodies larger than 4 to 5 mm (Table 46-2). In clinical practice, variation in detection rates may be due to the size and sonographic nature of the foreign body, the presence of confounding factors (e.g., bone, blood, air, purulence, scars, old sutures) associated with the foreign body, and operator skill and experience. A hyperechoic rim around or acoustic shadowing behind the foreign body may help to localize it.¹⁴ Areas with many echogenic structures such as calcifications, sesamoid bones, and tendons may hide foreign bodies within their acoustic shadows, so these areas must be scanned slowly to detect foreign bodies that are small or oriented

TABLE 46-1 Studies Using Plain ;raphy to Detect Radiopaque Objects

Material, Author, Reference	Object Size (Approximate)	N (Number of Observations)	Sensitivity (95% CI)
Aluminum Ellis ⁶	0.5-4 mm	6	100% (54-100%)

Schlager ¹⁶	Agave spine	10	100% (92–100%)

perpendicular to the skin surface. Some areas of the body that are prone to foreign body penetration, such as the web spaces of the hands or toes, may not accommodate an ultrasound probe.

Once a foreign body is confirmed by plain films or CT studies, sonography can be used in place of fluoroscopy to guide an instrument to the object during retrieval.^{20,21} The scanning beam should be oriented parallel to the long axis of a hemostat, which can be directed toward the long axis of the foreign body. Transverse and longitudinal scans provide views in multiple planes. A 7.5-MHz linear-array transducer can be used to find objects that are small and superficial (up to 3 cm deep), and a 5.0-MHz transducer can be used for larger and deeper objects. The linear scan is preferred for localization, and the sector scan for retrieval.²⁰ The primary advantage of ultrasonography is the avoidance of radiation exposure.

Xeroradiography

Xeroradiographs enhance soft tissue images, improving images already visible on plain films. However, this modality fails to detect radiolucent foreign bodies and has been supplanted by other imaging techniques.⁵

Magnetic Resonance Imaging (MRI)

MRI can detect nonmetallic radiolucent foreign bodies and in limited comparison studies is more accurate than any other modality in identifying wood, plastic, spines, and thorns.⁵ MRI should not be used with gravel or metal-containing foreign bodies because ferromagnetic streaks obscure visualization. MRI may prove more effective than CT in visualizing organic foreign bodies, but comparison studies are needed.

Fluoroscopy

Bedside fluoroscopy accurately detects radiopaque (metal, gravel, glass, and pencil graphite) foreign bodies as small as 3 mm.^{22–23} Theoretical advantages of fluoroscopy compared to conventional plain film radiography are convenience, reduced cost, shortened ED time, and less radiation exposure. Fluoroscopy can be used to assist foreign body removal by helping guide the instrument.

Selecting an Imaging Study

If a foreign body is suspected but not found during exploration of a wound, a plain film should be ordered first, since plain radiography will detect as many as 80 to 90 percent of all foreign bodies. It is pru-

dent to order films if a patient believes there is a retained object. If the wound was caused by metal, glass, or gravel and no foreign body was found on plain films or wound exploration, the physician can end the search. For objects not routinely visible on plain radiography, CT scans are the modality of choice. Ultrasound is not as reliable as CT in confirming the presence or absence of nonradiopaque foreign bodies.

TREATMENT

General Principles

Once a soft tissue foreign body is discovered, the physician must weigh the risk of leaving the foreign body in place against the potential harm of attempting to remove it. Not all foreign bodies must be removed, and not all that require removal must be extracted in the ED. \ However, every effort should be made to identify their presence during the initial visit. General indications for foreign body removal include potential for later infection, toxicity, injury, and functional problems (Table 46-3). Usually, objects that are small, inert, deeply embedded, and causing no symptoms can be left in place. A common question concerns bullets that come to rest deep within a muscle belly; they are usually not removed because the procedure can cause more

TABLE 46-3 Indications for Foreign Body Removal

Potential for inflammation or infection
Vegetative or chemically reactive material
Heavy bacterial contamination (e.g., teeth, soil)
Proximity to fractured bone
Established infection
Allergic reaction
Toxicity
Spines with venom
Heavy metals
Functional and cosmetic problems
Impingement on nerves, vessels, or tendons
Restriction of joint mobility
Proximity to tendons
Impairment of gait
Persistent pain
Cosmetic deformity (e.g., tattooing)
Psychological distress
Potential for later injury
Intraarticular location
Intravascular location
Migration toward important structures

FIG. 46-2. A. An incision is made perpendicular to the needle at its midpoint. B. The needle is grasped through the incision with a hemostat and backed out of the puncture wound.

damage than leaving the foreign object in place. Projectiles may drag bits of clothing or skin into the wound, so the entrance wound deserves cleaning and debridement. Bullet migration and embolization are rare but possible complications. Bullets near vessels can enter the systemic circulation. Bullets that cause distal ischemia, thrombus formation, or wall erosion or that lie within the lumen of a blood vessel require immediate removal in the operating room.

Thorns, spines, wood splinters, and other vegetative materials require immediate removal because they cause intense and excessive inflammation. Foreign objects that are heavily contaminated, such as fractured teeth and soil-covered objects, should be removed as soon as possible; antibiotic treatment will not take the place of foreign body removal. Glass, metal, and plastic are relatively inert, and removal can be postponed if necessary. Glass foreign bodies in hands or feet can cause persistent pain with gripping or walking, and they can sever nerves or tendons years after the initial injury. Patients with deep, sharp foreign bodies in these locations should be referred to appropriate specialists for eventual removal.

Sometimes harmless foreign bodies are psychologically distressing to patients, particularly when they are visible under the skin surface or produce a lump. Patient concern may be a justification for elective removal.

Successful removal of foreign bodies requires adequate local or regional anesthesia and good lighting. Depending on location and depth, tourniquet control of bleeding and assistance may be needed. Depth and accessibility of the object and physician time are the limiting factors for removal of foreign bodies by the emergency physician. Foreign bodies buried deeply in adipose tissue or muscle are difficult to locate. Most foreign bodies in hands should be removed because the hand is mobile and sensitive. Deep exploration of hands by the emergency physician is not recommended because magnification and experience are needed to avoid injury to numerous closely spaced vital structures.

The emergency physician may not be able to devote more than 15 to 30 min to the removal procedure, particularly when other seriously ill or injured patients demand attention. This amount of time is sufficient for locating most foreign bodies. The patient should be informed before

FIG. 46-4. To remove a friable foreign body such as a wood splinter that is parallel to the skin surface, an incision is made along its long axis. The object can be lifted out and the entire length of the wound inspected for remnants.

the procedure that the duration of the exploration will be limited. If more time is required, the patient should be referred to a surgeon.

Methods of Localization

Accurate localization of a foreign body prior to removal is important because blind searching is time consuming and can cause further injury. However, it is usually easier to detect the presence of a foreign body than to locate its exact position. If a foreign body is radiopaque, one can estimate its location and depth by taping radiopaque skin markers such as lead circles or paper clips on the skin at the wound entrance or directly over the object. With multiple projections the object can be seen in relation to the markers. Hypodermic needles can be used as skin markers. Two or three needles are inserted into the skin near the object at approximately 90 degrees to each other to provide a frame of reference around the object. Plain films taken in multiple projections allow the physician to gauge the distance of the object from the closest needle or its distance between two needles.

The limitations of this technique are that it does not provide a true three-dimensional image and that images on radiographs are distorted by divergence and parallax. Tendons and other structures may block the most accessible path to the foreign body. Alternatively, the site of injury can be rotated under fluoroscopy to visualize the object between the markers.^{22,23} Radiation exposure should be minimized by brief, intermittent imaging and appropriate shielding. An incision is made between needles or markers, or dissection is carried along the path of the closest needle.

Ultrasound can be useful in directing exploration and foreign body removal.^{21,22}

Specific Foreign Bodies and Removal Procedures

METALLIC NEEDLES Long, thin foreign bodies such as sewing and hypodermic needles may be difficult to locate in soft tissue. Two techniques are available for removing needles that are parallel to the surface of the skin. If the needle is superficial enough to be palpable, an

FIG. 46-3. A. The entrance site is enlarged with a skin incision. B. If the incision passes to the side of the object, the skin is undermined. C. Pressure on the skin edges displaces the foreign body into the center of the wound.

FIG. 46-5. Block excision is effective for foreign bodies that are friable, difficult to find, buried in fatty tissue, or stain surrounding tissue. A. A small, elliptical incision is made around the original wound. B. The incision is undercut until contact is made with the foreign body. C. The block of tissue is grasped with a forceps, the foreign body is clamped with a hemostat, and both are removed.

incision is made at one end to expose and grasp it with a hemostat. If the needle is deep, an incision is made perpendicular to the needle at its midpoint, where it can be clamped with a hemostat and pushed out of the entrance of the original wound (Figure 46-2).

Long, thin foreign bodies that are oriented perpendicular to the skin surface can be elusive. If a needle can be reached with an alligator forceps or hemostat, it can be pulled straight out. If a needle lies beyond the reach of a hemostat, the entrance wound must be enlarged with a skin incision (Figure 46-3). However, the incision can easily pass to the side of the object, so the skin edges should be undermined, and pressure applied on the skin edges may displace the foreign body into the center of the wound, where it can be seen and grasped. Once removed, the needle and the wound should be inspected to ensure that the object was removed in its entirety.

WOOD SPLINTERS AND ORGANIC SPINES Solid foreign bodies can be pulled out of puncture wounds with forceps, but wood splinters and organic spines (e.g., cactus, sea urchin, and fish) may disintegrate with this technique. Only superficial splinters that are a few millimeters long can be grasped and removed with a fine-point splinter forceps. A splinter parallel to the skin surface should be lifted out of the wound after incising the skin along the long axis of the object (Figure 46-4). If the splinter is lodged in the subcutaneous tissue, the entrance wound must be enlarged with a skin incision so the foreign body can be grasped under direct visualization. Wood fragments may be impossible to locate precisely. One solution is to create an elliptical incision around the puncture wound and extract the fragment in a block of tissue (Figure 46-5). The physician should avoid incorporating nerves, vessels, or tendons within the excised block. Either technique creates a larger wound but allows a better inspection and more thorough cleaning after removal.

FIG. 46-6. Subungual foreign bodies that are beyond the reach of a splinter forceps can be exposed by excising a wedge of the overlying nail.

Subungual splinters must be removed because subsequent infection is almost inevitable, and the distal phalanx is at risk for osteomyelitis. If the splinter is underneath the distal end of the nail, it can be grasped by a splinter forceps or hooked by a hypodermic needle bent at its tip. More proximal splinters can be reached by anesthetizing the finger and removing a wedge of the nail overlying part of the foreign body (Figure 46-6). If pieces of the splinter remain, the entire nail can be removed.

Numerous, tiny cactus spines in the dermis can be plucked out individually with forceps or extracted together with depilatory wax, professional-quality facial gel, rubber cement, or household glue. Larger spines and thorns should be removed with incision or excision techniques.

FISHHOOKS Fishhooks have a variety of sizes and shapes based on a common pattern (Figure 46-7). The barb, which is a projection extending backward from the point of the hook, keeps the point embedded in the fish's mouth and makes removal from skin a challenging task. Most injuries with fishhooks involve the hand, head, or face.

Several methods for removing fishhooks in skin have been reported. The best strategy depends primarily on the depth of the hook. If the hook has multiple barbs, precautions should be taken to avoid impaling the treating physician, bystanders, or the patient (a second time) during removal by taping or cutting off the exposed barbs. With any technique, the skin should be prepared and anesthetized at the entry site. If the hook is superficial, gentle downward pressure is placed on the shank while the hook is simply pulled in a retrograde direction along the path of entry (Figure 46-8).

The *string-pull method* is a variation on the retrograde technique. String is wrapped around the bend of the hook where it enters the skin.

FIG. 46-7. Anatomy of a fishhook.

FIG. 46-8. Simple retrograde technique. While pressing the skin over the tip of the hook to disengage the barb and applying gentle downward pressure on the shank, the physician backs the hook out of the skin. If the barb catches on skin fibers, other techniques must be used.

FIG. 46-9. String-pull technique. String or suture material is tied to the curve of the hook. The hook is positioned as described in the simple retrograde technique, and a quick pull on the string will dislodge the hook.

FIG. 46-10. Needle-cover technique. The area is anesthetized, and an 18-gauge needle is inserted into the entrance wound along the hook. The lumen of the needle is placed over the barb to cover it, and both the hook and needle are backed out of the wound.

FIG. 46-12. Incision technique. The area is anesthetized, and a small incision is made along the shaft of the hook to the barb. The hook is withdrawn through the incision.

The end of the shank is depressed with one hand to disengage the barb from deeper tissue. The other hand then gives a quick pull on the string, extracting the hook (Figure 46-9). The disadvantages of this technique are that failure can cause further pain to the patient and success can result in ripped tissue or a sharp, blood-contaminated object flying uncontrollably across the room.

The *needle-cover technique* requires physician dexterity. An 18-gauge needle is inserted into the entrance wound alongside the shank of the hook. The needle follows the bend of the hook until the lumen of the needle can be placed over the barb to sheathe it. The hook and needle are then withdrawn from the wound as a unit (Figure 46-10).

The *advance-and-cut technique* is useful for deeply penetrated and larger fishhooks (Figure 46-11). The tip of the hook is advanced through the skin surface. Once exposed, the point and barb are cut with wire cutters, and the remaining part of the hook is rotated back out of the original wound. If barbs along the shank are embedded beneath the dermis, the shank can be clipped near the hook's eye. The remaining part of the hook is then passed antegrade through the skin. Since the advance-and-cut method further traumatizes and contaminates tissue, it probably should be reserved for wilderness situations. However, this may be an effective method in the ED if the barb has nearly or already penetrated the surface of the skin or is embedded within a joint, cartilage, or tendon.

A fifth technique is a modification of the needle cover technique for fishhooks embedded in the dermis. The entrance wound is enlarged to 2 to 3 mm with a no. 11 scalpel blade. The incision is carried along the bend of the hook to the barb until the barb is disengaged from the soft tissue. The hook can then be withdrawn easily through the larger entrance (Figure 46-12). If necessary, the barb can be grasped with a hemostat to prevent it from snagging tissue on the way out. There are two major benefits to enlarging puncture wounds containing foreign bodies. First, the wound is more easily inspected for additional foreign bodies. In the case of fishhook impalement, the wound may be harboring the bait that was on the hook. Second, the wound tract is more easily irrigated through a larger opening. However, the physician must avoid injuring tendons, nerves, or vessels with the scalpel.

FIG. 46-11. Advance-and-cut technique. The area is anesthetized, and the tip of the hook is advanced through the skin surface (A), the barb is cut (B), and the hook is rotated back out of the original wound (C).

TRAUMATIC DERMAL TATTOOING Foreign particulates may be embedded in the epidermal and dermal layers of skin by an abrasion, which permanently stains or "tattoos" the surrounding tissue. If vigorous scrubbing does not remove the particulates, the patient can be referred to specialists for dermabrasion or block excision. The graphite from pencil lead can produce a pigmentation that will never dissolve, and graphite tattoos should be excised in cosmetic areas.

DISPOSITION

Postremoval Treatment

After removal of a foreign body, the wound should be irrigated thoroughly. A puncture wound is difficult to clean adequately because either the small wound diameter prevents the irrigation fluid from reaching the wounded tissue or the fluid enters the wound but does not completely drain. If the puncture is contaminated, the entrance wound can be enlarged to allow more effective cleaning. If foreign debris is impregnated in tissue, the contaminated area can be debrided or excised. If multiple radiopaque objects were removed, a postprocedure plain film should be obtained. The decision to close lacerations, incisions, and block excisions depends on the potential for infection; wounds in which all foreign contaminants can be removed and those in locations with good blood supply can be closed primarily. Otherwise, delayed primary closure is preferred to immediate closure. Necessary tetanus immunization should be provided. If a foreign body is deliberately left in place, the patient should be informed. If foreign material was removed, the patient should be warned that there is always a possibility that not all pieces were found.

Delayed Removal

Many patients must be referred to surgical specialists for delayed removal of foreign bodies. It is important to inform the patient that the object is present but unlikely to cause harm before it is removed. The benefit of prophylactic antibiotics for uninfected wounds containing foreign bodies has not been studied. Antibiotics are justified for infected wounds, particularly when removal must be postponed, even though removal allows infections to clear rapidly. If a foreign body is near a joint or highly mobile region, the affected area should be splinted prior to removal to prevent further injury or migration of the object.

PUNCTURE WOUNDS AND MAMMALIAN BITES

Robert A. Schwab Robert D. Powers

PUNCTURE WOUNDS

Puncture wounds can be loosely defined as wounds whose depth exceeds the diameter of the visible surface injury. They usually involve the plantar surface of the foot; punctures to the leg and upper extremity occur less often.¹ The relatively innocuous-appearing skin wound belies the potential for injury to underlying structures and infection. Punctures caused by high-pressure injection equipment, mammalian bites, and those involving exposure to body fluids each have the potential for unique complications that affects evaluation and management.

Pathophysiology

In puncture wounds, shear forces between the missile and tissue result in tissue disruption, producing hemorrhage and devitalization of skin and underlying tissues. Inoculation of organisms from the missile (with or without a foreign body) or from the skin surface into the deeper tissues is followed by relatively rapid closure of the small skin wound, creating an environment favorable for the development of infection, which is reported to occur in 6 to 11 percent of puncture wounds.²

Most soft-tissue infections from puncture wounds are caused by gram-positive organisms; *Staphylococcus aureus* predominates, followed by other staphylococcal and streptococcal species.² Puncture wounds over joints can penetrate the joint capsule and produce septic arthritis, while penetration of cartilage, periosteum, and bone can lead to osteomyelitis. *Pseudomonas aeruginosa* is the most frequent

pathogen isolated from plantar puncture wound-related osteomyelitis, particularly when the injury occurs through the rubber sole of an athletic shoe.³

The incidence of puncture wound infection is increased in the presence of host factors that inhibit wound healing; diabetes mellitus, peripheral vascular disease, or immunosuppression by disease or chronic immunosuppressive therapy (see Table 42-2).⁴

Clinical characteristics associated with higher complication rates include patients seen more than 6 h after injury, wounds obviously contaminated with debris, wounds occurring outdoors, puncture wounds through footwear, wounds from longer objects with deeper penetration, and host factors inhibiting wound healing.

Most literature related to plantar puncture wounds identifies forefoot injuries as inherently high-risk. Theoretically, since most of the body weight is transmitted to the metatarsal heads during walking, a puncture in this area might penetrate deeply. A published case series of patients hospitalized with infected plantar puncture wounds seemed to confirm this theory.⁵ However, although a majority of these patients had sustained forefoot injuries, neither this study nor any other has prospectively followed enough forefoot injuries to definitively determine the incidence of complications from this injury and the assertion that forefoot injuries are higher risk for infection has not been proven.

Clinical Features

Important historical features related to puncture wounds include the time of injury as well as circumstances leading up to the injury. A history of jumping or falling onto an object suggests deeper penetration than other mechanisms. The footwear (for plantar wounds) or clothing through which the missile passed will help assess the potential for foreign body and infection. The patient's estimate of depth as well as foreign body sensation should be elicited, as should the postinjury care rendered prior to presentation. The medical history will disclose host factors predisposing to infection.

The characteristics of the missile are important in predicting risk of foreign body and infection. Materials such as wood, glass, and plastic are prone to break or splinter, leaving retained fragments in the wound. Thin objects such as needles or pins can break off beneath the skin surface.

Physical examination of puncture wounds should assess wound characteristics as well as function of underlying structures. In punctures of the hand, distal function of tendons and nerves and integrity of distal perfusion should be assessed. Puncture wounds should be carefully inspected for their proximity to underlying structures, the condition of the surrounding skin, and the presence of foreign matter or devitalized tissue. Wound infection is suggested by severe pain, swelling, erythema, warmth, fluctuance, drainage, or pain with motion of tendons or joints.

Because the entire depth of a puncture wound cannot be reliably explored, assessment for the presence of a foreign body is problematic. Patient perception of a foreign body is modestly useful in predicting the presence of one [sensitivity = 43%, specificity = 83%, LR(+) = 2.49 and LR(-) = 0.69].⁶ Probing of the wound with a blunt instrument has been recommended as a means of blindly assessing for depth and for the presence of a foreign body, but the benefit of this practice is unproven.

Diagnostic Studies

Plain-film radiographs utilizing soft-tissue visualization techniques are indicated in all infected puncture wounds, in wounds caused by materials prone to fragment, and whenever the patient reports a foreign body sensation. Plain radiographs will detect more than 90 percent of radiopaque foreign bodies larger than 1.0 mm in diameter (see

Chap. 46). Most organic substances such as wood, thorns, and other plant matter have radiodensities close to that of soft tissue and cannot be identified with plain radiographs.

Ultrasonography can identify soft-tissue foreign bodies, but the ability to detect small objects that would be anticipated to be introduced through a puncture wound is limited (see Chap. 46). Computed tomography (CT) can accurately detect radiolucent foreign bodies, and is the method of choice for patients with suspected occult foreign body following a puncture wound. Magnetic resonance imaging (MRI) provides excellent visualization of foreign bodies, but cannot be used to image metallic objects or objects containing certain minerals due to the production of ferromagnetic artifact. CT or MRI should be done on patients with deep-space infection, persistent pain after a puncture wound, or with superficial infections that fail to respond to therapy.

Treatment

Treatment recommendations for puncture wounds are largely based on anecdotal evidence and reviews of uncontrolled case series. The small entrance wound, often closed at the time of presentation, makes traditional wound cleansing techniques ineffective. Therefore aggressive debridement and irrigation are sometimes recommended. However, these recommendations for aggressive wound debridement ignore the benign course of the overwhelming majority of these injuries in an attempt to avoid rare but potentially catastrophic complications.¹

Uncomplicated clean punctures presenting less than 6 h after injury require superficial wound cleansing and tetanus prophylaxis as indicated. Soaking of the wound has no proven benefit. Low-pressure (e.g., 0.5 psi) irrigation of wounds will assist in surface cleansing and allow visualization of the entrance site, whereas high-pressure (e.g., 7 psi) injection of irrigation fluid into the wound has no proven benefit and theoretically could force foreign matter and bacteria deeper into the surrounding tissue.

Debridement or coring of the wound tract in clean wounds has been recommended, but has not been proven to reduce infection or to facilitate accurate diagnosis of deeper structural injury. Without clear evidence of benefit, it is difficult to endorse a procedure that is painful and time consuming, particularly when it leaves the patient with a wound larger than the initial puncture.

Perhaps the greatest controversy in the management of puncture wounds concerns the role of prophylactic antibiotics. There is no proven benefit of prophylactic antibiotics in any type of puncture, although many authorities recommend their use in high-risk patients with plantar puncture wounds. "High-risk" includes patients with impaired host defenses, and may also include forefoot injuries and patients sustaining punctures through athletic shoes. The only published study on prophylactic antibiotics for plantar puncture wounds that compared treated with untreated patients during the same study period was an observational nonrandomized trial using a variety of oral antibiotics.⁷ This study found that none of the 18 patients treated with prophylactic antibiotics within 24 h of injury developed an infection compared to 18 patients who developed infections out of 62 individuals who did not receive prophylactic antibiotics within 24 h (absolute reduction in infection 29%; 95% CI 18 to 40%). A recent review of available evidence concluded that because there were no randomized clinical studies, no evidence-based recommendations can be made regarding the use of prophylactic antibiotics for plantar puncture wounds, and physicians are counseled to "follow local advice" in deciding when or if to treat.⁸

If prophylactic antibiotics are used, an oral fluoroquinolone (ciprofloxacin or levofloxacin) seems sensible although expensive. These broad-spectrum antibiotics achieve high blood levels rapidly after ingestion and possess antipseudomonal activity. Alternative agents, such as dicloxacillin, cephalexin, or erythromycin may be effective despite the theoretical disadvantage of no antipseudomonal coverage.⁷ If antipseudomonal coverage is desired and oral fluoroquinolones are contraindicated, a combination of oral antistaphylococcal and

parenteral antipseudomonal antibiotics (e.g., ticarcillin, ceftazidime, or gentamicin) would be an acceptable albeit inconvenient choice.

Complications

Skin tattooing from foreign material can lead to undesirable cosmetic outcomes, but meticulous wound cleansing can prevent this problem. Two more serious complications are retained foreign body and infection. The hallmark of both of these complications is pain. Any patient with significant pain more than 48 h after the initial injury should undergo a thorough evaluation for missed foreign body or infection; if no definitive infection is found, the use of prophylactic antibiotics in this subgroup of patients is a reasonable if unproven strategy.² Infections that develop after puncture wounds include cellulitis, local abscess, deeper spreading soft tissue infection, and infections of bone or cartilage.

CELLULITIS This localized infection of the dermis surrounding the puncture wound usually becomes clinically detectable within the first 4 days after the injury. The patient typically presents due to persistent pain causing inability to bear weight. The patient may also note swelling. Physical examination usually reveals erythema, warmth, and tenderness surrounding the area of injury. Swelling may be present, but swelling or erythema in areas not contiguous with the injury is absent. Radiographs, if not done at the time of injury, are indicated to exclude a radiopaque foreign body. These infections are generally caused by streptococcal and staphylococcal skin flora, and usually respond to a 7- to 10-day course of a first-generation cephalosporin.

LOCALIZED ABSCESS This complication is usually associated with a retained foreign body. The patient presents due to pain, and may also complain of a foreign body sensation or drainage from the wound site. On examination, a tender, warm, fluctuant mass is palpable at the site of injury, but again no abnormalities are noted in areas not initially affected by the injury. Radiographs are indicated if not done at the time of injury. Incision and drainage will often disclose a foreign body, and is curative. A short course of antibiotics is indicated if there is significant cellulitis in conjunction with the abscess.

Outpatient management of cellulitis and localized abscesses is the rule. Patients should be instructed to apply warm compresses or use warm soaks, avoid weight-bearing on plantar puncture wounds, and to elevate the affected extremity. Appropriate analgesia should be prescribed as well as antibiotics. Routine follow-up within 48 h is recommended.

DEEP SOFT TISSUE INFECTION Patients present with pain that is generally more severe than with cellulitis or localized abscess. Redness, swelling, and drainage at the wound site may be seen. The key physical examination finding is pain, redness, or swelling at a site remote from the puncture site. With plantar puncture wounds, signs of infection on the dorsum of the foot should alert the clinician to the presence of a more serious complication. Radiographs should be performed to identify foreign bodies and to look for gas in the soft tissue planes. These infections may involve gram-negative and anaerobic bacteria, and always require parenteral antibiotics and immediate referral to a specialist for surgical management.

OSTEOMYELITIS Bone and joint infections are the most disastrous sequelae of puncture wounds. The overall incidence following plantar puncture wounds is between 0.1 and 2%, and may be somewhat higher in patients sustaining forefoot punctures through athletic shoes.² These patients present somewhat later than those with other complications, often after a period of symptomatic improvement. Pain, swelling, redness, and drainage may all occur, but pain is the presenting complaint in nearly every case. Examination may reveal erythema, swelling, and drainage, or may be deceptively normal. Radiographs may also be normal in the early stages of osteomyelitis. An elevated white blood cell

count or an elevated erythrocyte sedimentation rate supports the diagnosis of osteomyelitis, but neither test is sensitive enough to absolutely exclude bony infection.⁹ The definitive diagnostic study is a bone scan, which will demonstrate osteomyelitis within 72 h of the onset of symptoms. Once the diagnosis is made, immediate surgical referral should be made; antibiotic administration should be withheld pending discussion with the consultant, since pathogen identification is best done from cultures obtained during operative debridement. If antibiotics are administered before surgery, coverage against staphylococcal and pseudomonal species is recommended.

NEEDLE-STICK INJURIES

Needle-stick injuries are common among health care professionals; a recent survey of emergency medicine residents found that over 50% reported at least one occupational exposure to blood during their training.¹⁰ Most of these exposures involved a puncture with a hollow needle or other sharp object.

Like other punctures, these injuries carry the risk of infection with hepatitis and human immunodeficiency virus (HIV). The risk of clinical infection after an inadvertent needle stick from an infectious source has been estimated to be negligible for hepatitis A, 6 percent for hepatitis B, 2 percent for hepatitis C, and 0.3 percent for HIV.¹¹

Preexposure prophylaxis is available for hepatitis B. Postexposure prophylaxis is available for hepatitis B and HIV. Postexposure prophylaxis of hepatitis C is no longer recommended.¹¹ The specific recommendations for postexposure prophylaxis of HIV are updated regularly by the Centers for Disease Control and Prevention: (<http://www.cdc.gov/health/needlesticks.htm>); PEpline: 1.888.HIV.4911). The latest update, in June 2001 (*Morb Mortal Wkly Rep* 50:RR-11, 2001), emphasized the use of rapid HIV testing on source patients, and 48- to 72-h follow-up when rapid testing is not available, so overuse of antiretroviral therapy can be avoided. Recommendations for management are complex and change frequently; each hospital should have a predetermined needle-stick protocol endorsed by local infectious disease specialists. See Chap. 154 for detailed discussion.

HIGH-PRESSURE INJECTION INJURIES

High-pressure injection injuries are caused by industrial equipment designed to force paint, grease, or other liquids through a small-diameter nozzle at pressures several times higher than that required to penetrate intact skin. Although a significant amount of energy is dissipated in overcoming skin resistance, the material still spreads widely along fascial planes. The type, amount, and viscosity of material injected will determine the degree of tissue inflammatory response, and in less distensible tissue compartments sudden pressure elevations produce vascular injuries, ischemic necrosis, and gangrene.¹²

Most injuries occur in the nondominant hand of an operator using a high-pressure gun. The injury may initially cause little pain, leading to delays in presentation or misdiagnosis of the extent of injury. Within hours, pain typically becomes severe and evidence of ischemia or widespread inflammation is manifest. Unfortunately, delays in initial management increase the risk of amputation or disability.¹²

The apparent lack of significant external injury can be misleading when the patient is first evaluated; the small entrance wound with some surrounding edema suggests only a minor injury. However, the history alone should prompt aggressive treatment and immediate surgical consultation.

ED evaluation should include assessment of neurovascular integrity and tendon function, aggressive pain management utilizing intravenous opioids, prophylactic antibiotic coverage against skin flora, and tetanus prophylaxis as indicated. Radiographs will often demonstrate wide dissemination of radiopaque material as well as injected air along fascial planes. Digital nerve blocks should be avoided, as they may further increase pressure in finger compartments.

Early surgical debridement is necessary to avoid amputation and minimize disability.¹² A hand specialist should be consulted without delay.

MAMMALIAN BITES

Most patients presenting for ED care of bite injuries have been bitten by domestic dogs or cats. The United States has more than 50 million dogs and 100 million cats; in a typical year they inflict more than 12,000 bites each day. Of the nearly 4 million Americans who are bitten each year, just under 500,000 seek medical attention in EDs and 10 to 20 will die of their injuries.^{13,14} The economic cost in homeowners insurance payouts and medical care expenditures exceeds \$100 million. Children seek care for bites more often than adults. Dogs that are specifically trained for guard duty (pit bulls, rottweilers, German shepherds) cause a disproportionate number of serious injuries and deaths.^{13,14}

General Principles of Bite Wound Management

Considerations in caring for patients with bite wounds include the injury inflicted by the bite, prevention or treatment of local bacterial infection, and prevention, recognition, and management of subsequent systemic illness.

In the initial assessment of the injured patient, attention should be paid to the potential for a life-threatening injury. A large animal, or multiple animals attacking a child or small adult can inflict severe injuries, including vascular damage and blunt or penetrating trauma. Standard assessment and resuscitation protocols for trauma victims should be employed in the rare circumstance in which the patient is seriously injured. In the more typical case of an isolated soft tissue injury, wound management and prevention of infectious complications become paramount.

Meticulous examination and wound cleansing measures including aggressive irrigation and debridement of devitalized tissue are important. Care should be taken to determine the extent of underlying tissue damage, with special attention to the potential for penetration into joint spaces and tendon sheaths. Management of wounds involving the face, hands, or perineum will be problematic due to the close proximity of delicate structures. If there is suspicion of foreign material in the wound, imaging may be indicated.

Some bite lacerations can be safely and cosmetically sutured primarily. If closure is desirable for cosmetic or functional reasons, a skilled practitioner should perform this procedure under optimum conditions.^{15,16} Delayed primary closure is a technique that has been used successfully in contaminated wounds, and should be considered in the management of bite injuries. Wounds that are already infected should be managed without closure, as should wounds occurring in immunocompromised hosts. Puncture-type bite wounds, wounds greater than 6 h old, and most wounds on the hand and foot should be left open.

Microbiology and Therapy of Infections from Cat and Dog Bites

Mammalian saliva contains large concentrations of microorganisms, and all bite wounds should be considered to be contaminated with pathogenic bacteria. Their proliferation in tissue can lead to serious cellulitis, tenosynovitis, and pyarthrosis. Despite the presumably large inoculum of bacteria, only about 5 to 6 percent of untreated dog bites will become infected; this infection rate approximates that found with lacerations from nonbite mechanisms.^{17,18} Cats have narrower, sharper teeth than dogs, and the ability to deliver infectious agents deep into a small-bore puncture wound. It is not surprising that as many as 60 to 80 percent of cat bites will become infected.^{17,18}

Infection following a cat bite is likely due to *Pasteurella multocida*, particularly if the infection has a rapid onset. Infected dog bites are also likely to contain *Pasteurella*, as well as anaerobes, streptococcal, and staphylococcal species.

The use of antibiotics in postexposure prophylaxis of bite wounds is controversial. A structured review of eight randomized clinical trials has found evidence lacking for efficacy in dog and cat wounds overall, but the power of the analysis was limited by the small number of patients and the suboptimal spectrum of agents utilized.¹⁸ The only significant benefit was for dog or cat bites of the hands, where the infection rate was reduced by prophylactic antibiotics from 28 percent in the control group to 2 percent in the treated group (absolute reduction 26%, 95% CI 2 to 50%). Only one small, randomized clinical trial of 11 patients total analyzed the effect of prophylactic antibiotics after cat bite; 67 percent (4/6) of control patients developed an infection compared to 0 percent (0/5) of treated patients. However, because of the small number of patients studied, the difference is not statistically significant.

A prudent approach is to treat all infected wounds and to prescribe prophylactic antibiotics for high-risk uninfected wounds. These would include all cat bites, all bites in immunocompromised hosts, deep dog bite puncture wounds, hand wounds, and any laceration that is being sutured. An initial 5- to 7-day course of an appropriate antimicrobial should be sufficient. The patient should receive a follow-up wound check in all but the most trivial cases. In lower-risk situations, counsel and advice regarding relative risk of treatment in addition to wound precautions are warranted.

Amoxicillin-clavulanate is the medication most commonly recommended for therapy and prophylaxis.^{15,17} However, penicillin or ampicillin should be adequate for *Pasteurella multocida* infections, and represent logical lower-cost alternatives for prophylaxis of cat bites. Penicillin-allergic patients require therapy with doxycycline or cefuroxime for cat bites, and clindamycin plus a fluoroquinolone for dog bites. Cephalexin, dicloxacillin, erythromycin, or clindamycin should not be used alone, as their spectrum does not include *Pasteurella* species.

Systemic Bacterial Infections Following Dog and Cat Bites

There are a few serious systemic sequelae of dog and cat bite infections. These febrile illnesses can develop days after the bite, and are not necessarily accompanied by local bite wound infection. *Capnocytophaga canimorsus* causes a rare but fulminant bacteremic illness following a dog bite. Fatal multiorgan failure can occur, particularly in splenectomized patients, or those with alcoholism or other immunosuppressive disorders. Diagnosis is confirmed with positive blood cultures; broad-spectrum therapy with penicillin and other agents is indicated in concert with aggressive support.¹⁹ The virulence of this infection provides some justification for the prophylactic use of penicillins in all immunocompromised patients bitten by dogs.

Cat-scratch disease is a clinical syndrome of regional lymphadenopathy developing 7 to 12 days after a cat bite or scratch. This chronic indolent infection caused by *Bartonella henselae* can result in painful, matted masses of lymph nodes lasting up to 4 months. Diagnosis is made by serology or biopsy; therapy consisting of pain relief, reassurance, and aspiration of symptomatic buboes is usually successful. Azithromycin may speed resolution of adenopathy.²⁰

Human Bites

Human bites deserve special consideration, as they tend to be more serious than those from domestic animals. The low incidence of these injuries has hampered prospective study, but experience suggests that they have a high rate of complication. All should be treated as contaminated puncture wounds; many will present late due to the circumstances leading to the injury. Of particular concern is the closed-fist injury (CFI), incurred when a flexed knuckle strikes a human tooth in the course of an altercation. The subsequent tenosynovitis and pyarthrosis generally require operative management and intravenous antibiotics.

Human bite wound infections are polymicrobial; staphylococcal and streptococcal species are common; other pathogens include the

species-specific gram-negative rod *Eikenella corrodens*. Amoxicillin-clavulanate is recommended for treatment and prophylaxis following all but the most trivial human bites.¹⁸ Parenteral agents of choice include ampicillin-sulbactam, cefoxitin, or piperacillin-tazobactam. Herpes simplex virus can cause local infection following a human bite or contact with infected saliva. The resultant herpetic whitlow is a painful coalescence of pustules, typically on the distal phalanx. Incision and drainage are contraindicated; therapy with acyclovir or other appropriate antiviral is recommended.

Rodents, Livestock, Exotic and Wild Animals

Patients often seek care or consultation after being bitten by a rodent. The injury is usually trivial, the risk of infection is low, and rodents are not known to carry or transmit rabies, so standard wound care and reassurance should suffice. Rat-bite fever consists of two similar febrile illnesses following a small percentage of bites from rats or other rodents. Diagnosis is confirmed by blood cultures positive for *Streptobacillus moniliformis* or *Spirillum minus*; penicillin or streptomycin is appropriate therapy.

Livestock and large game animals can inflict serious tissue injury with their powerful jaws and grinding teeth. In addition, the risk of wound infection and systemic illnesses such as brucellosis, leptospirosis, and tularemia is significant. Aggressive wound care and prophylactic broad-spectrum antibiotics are recommended in these situations; a febrile illness following such a bite usually requires inpatient antibiotic therapy guided by blood culture results.

Systemic Infections: Spirochetes; Rabies and Other Viruses

Disseminated spirochetal and viral illnesses that can result from mammalian bites include syphilis, rabies, hepatitis, and infection with herpes B or human immunodeficiency virus. Spirochetes are present in infectious quantities in the saliva of patients with early syphilis; transmission of the disease can occur via biting or kissing.

Rabies is a rare disease in developed countries; most of the 35,000 cases per year worldwide are concentrated in lesser-developed countries (see Chap. 147). In the United States, there were approximately two cases each year in the latter half of the twentieth century. Many of these were acquired from contact with domestic bats, or from dog bites sustained while traveling abroad. Postexposure prophylaxis with immunoglobulin and vaccine is necessary for patients at risk. Significant North American reservoirs of animal rabies exist in bats, skunks, raccoons, and foxes. All carnivores and omnivores can transmit rabies, whereas rodents, hares, and rabbits are extremely unlikely to harbor the disease. Local public health agencies are a good source of information regarding the rabies risk from contact with specific indigenous animals. In certain parts of the world, notably South Asia, monkeys are presumed to be at high risk for carriage and transmission of rabies.

Herpes B virus, also called *Herpesvirus simiae*, can be transmitted by bites from monkeys and other nonhuman primates. Myelitis and hemorrhagic encephalitis can occur in humans and death occurs in 68 percent of infected individuals. Wound care of the bite location should include scrubbing with povidone-iodine for 15 min followed by copious irrigation. Early therapy with acyclovir 800 mg PO five times per day beginning immediately after injury can prevent or ameliorate these manifestations.

Viral hepatitis and HIV can both be transmitted by a human bite, although HIV concentration in nonbloody saliva is thought to be relatively low. Use of a protocol similar to that for an occupational needle-stick injury should be used when a patient sustains a bite from a high-risk source.

POSTREPAIR WOUND CARE

Adam J. Singer Judd E. Hollander

Postoperative care begins immediately following laceration repair in the ED. Continued care and instructions should be provided so that the outcome of wound repair is optimized and complications are minimized. Immediately following repair, the injured area should be gently cleansed with normal saline to remove any residual blood products or contamination. Postoperative considerations that should be individually considered for each patient in the ED include the use of dressings, topical antibiotics, systemic antibiotics, need for splinting, and evaluation of tetanus status. Prior to ED release, the patient should be counseled regarding wound cleansing, pain control, signs of infection, and short-term and long-term cosmetic expectations.

USE OF DRESSINGS

Postoperative wound care should optimize healing. It must be tailored to both the type of wound and method of wound closure. Many sutured or stapled lacerations should be covered with a protective, nonadher-

ent dressing for 24 to 48 h. Maintaining a warm, moist environment increases the rate of reepithelialization and occluded wounds heal faster than those exposed to air.¹ Although leaving lacerations exposed to air may result in slightly lower healing rate, it does not result in an increased rate of infection.² Therefore, although dressings are one strategy that can be used to maintain a moist wound environment, they have never been shown to decrease the infection rate.

Semipermeable films are manufactured from transparent polyurethane or similar synthetic films, coated on one surface with a water-resistant hypoallergenic adhesive. They are highly elastic, conform easily to body parts, and are generally resistant to shear and tear. They are permeable to moisture vapor and oxygen but impermeable to water and bacteria. Common types of dressings are OpSite, Bioclusive, and Tegaderm. The disadvantages of these materials are that they cannot absorb large amounts of fluid and exudate and they do not adhere well in very moist states.

An alternative to the use of commercial dressings to maintain a moist environment is the use of topical antibiotics for this purpose. Topical antibiotics can be used to maintain a moist environment in sutured or stapled lacerations, but not lacerations repaired with tissue adhesives. As an added benefit, topical antibiotics may help reduce infection rates and may also prevent scab formation.³ However, patients whose lacerations are closed with tissue adhesives should not use topical ointments because they will loosen the adhesive and may result in dehiscence. Tissue adhesives serve as their own antimicrobial barrier and do not require supplementary dressings.

PATIENT POSITIONING AFTER WOUND REPAIR

When possible, the site of injury should be elevated above the patient's heart to limit the accumulation of fluid in the wound interstitial spaces. Wounds with little edema heal more rapidly than those with marked edema. Splints can be used for extremity injuries since they will decrease movement of the injured part, are associated with reductions in edema, and increase the attention paid to the injured body part. Although few wounds actually require splinting, splints are quite useful for extremity injuries, especially over joints. They can also be used to decrease the pain associated with soft-tissue injury.

Pressure dressings can be used to minimize the accumulation of intercellular fluid in the dead space. Pressure dressings are most useful for ear and scalp lacerations. For scalp lacerations that have a tendency to bleed, short-term use of a pressure dressing will help resolve the bleeding. For ear lacerations that might be prone to auricular hematoma formation, pressure dressings help reduce the likelihood of developing a cauliflower deformity. However, excessive pressure should be avoided, especially in the extremities where it may compromise circulation.

PROPHYLACTIC ANTIBIOTICS

Topical antibiotic ointments are commonly used by emergency physicians: one survey found that 71 percent of emergency physicians use topical antibiotics on recently repaired wounds.⁴ Despite the frequent use of topical antibiotics, there are surprisingly few studies that assess the efficacy of topical antibiotics on the suture line after closure. As noted, one randomized study found a reduced infection rate with antibiotic ointment compared to petrolatum control.³ Topical antibiotics provide a warm, moist environment that is beneficial for wound healing; therefore it is reasonable to use them for many lacerations.

On the other hand, the use of prophylactic oral antibiotics is not indicated except for select clinical circumstances. Several studies and a meta-analysis have all found no benefit to prophylactic antibiotics for routine laceration repair.⁵ The use of antibiotics should be individualized based on the degree of bacterial contamination, the presence of infection-potentiating factors (e.g., soil), the mechanism of injury, and the presence or absence of host predisposition to infection.^{6,7} In general, compulsive wound cleansing is far more important than antibi-

otics. Inappropriate use of prophylactic antibiotics will not reduce the overall risk of infection. Rather, it will skew the microbiology toward more unusual or resistant pathogens.

Prophylactic antibiotics should be used for human bites, dog or cat bites on the extremities, intraoral lacerations, open fractures, and wounds with exposed joints or tendons.^{6,7} Additionally, patients with grossly contaminated lacerations who are prone to the development of infective endocarditis, have prosthetic joints or other permanent "hardware," and patients with lymphedema should receive prophylactic antimicrobial therapy. It is recommended that patients at high risk for systemic complications such as endocarditis be given intravenous antibiotics before care of contaminated wounds.

The specific antibiotics used for prophylaxis are similar to those used for treatment of established infections (Table 48-1). For most patients, a first-generation cephalosporin or antistaphylococcal penicillin (e.g., dicloxacillin) is reasonable. Penicillin, which is active against most oral pathogens, should be used for intraoral wounds. Amoxicillin-clavulanate is the preferred prophylactic treatment for high-risk mammalian bite wounds. For open fractures or joints, a parenteral antistaphylococcal agent and an aminoglycoside should be used. There is no clear evidence that patients who receive oral antibiotic prophylaxis benefit from an intravenous dose in the ED, despite this common practice. For antibiotic prophylaxis, a 3 to 5 day course of oral antibiotics for nonbite injuries and 5 to 7 day course for bite wounds is adequate.

TETANUS PROPHYLAXIS

Two-thirds of the recent tetanus cases in the United States have followed lacerations, puncture wounds, and crush injuries. For every wounded patient, information about the mechanism of injury, the characteristics of the wound and its age, previous active immunization status, history of a neurologic or severe hypersensitivity reaction after a previous immunization treatment, and plans for follow-up if primary series should be obtained. Recommendations on tetanus prophylaxis are based on the condition of the wound and the patient's immunization history (Table 48-2). Passive immunization with tetanus immune globulin (TIG) should be considered for each patient, especially those without a history of a primary series of three tetanus immunizations. The only contraindication to tetanus toxoid is a history of neurologic or severe systemic reaction after a previous dose. Local self-limited reactions such as erythema, induration, and pain at the injection site are common and self-limited after tetanus vaccination. These local side effects do not preclude future tetanus immunization. Exaggerated local reactions occur occasionally following tetanus toxoid and involve extensive pain and swelling of the entire extremity. Exaggerated local reactions occur most often in adults with high serum tetanus antitoxin levels who have received frequent doses of tetanus toxoid. These patients should not receive tetanus toxoid more frequently than every 10 years. Severe systemic reactions to tetanus immunization include generalized urticaria, anaphylaxis, or neurologic complications including peripheral neuropathy and Guillain-Barre syndrome. A severe allergic reaction including acute respiratory distress or cardiovascular collapse following a dose of tetanus toxoid is a contraindication to further immunization. A moderate or severe acute illness is also a reason to defer routine immunization, although a minor illness is not. If the use of a tetanus toxoid is contraindicated, passive immunization with TIG against tetanus should be considered in a tetanus-prone wound.

WOUND CLEANSING

Sutured or stapled wounds should be gently washed and cleansed as early as 8 h after closure.⁸ The use of soap and tap water to cleanse lacerations is not associated with an increased infection rate. Gentle blotting should be used to dry the area; aggressive wiping could result in wound dehiscence. Patients with dressings should remove their dressing

SECTION 6 • EMERGENCY WOUND MANAGEMENT

TABLE 48-1 Empiric Antibiotics for Wound Infections

Clinical Situation	First-Line Agent	Alternative Therapy	Comment
Uncomplicated cellulitis	First-generation cephalosporin or antistaphylococcal penicillin	Macrolide	
Patient with underlying immunodeficiency	Amoxicillin-clavulanate or second-generation cephalosporin	Clindamycin plus a fluoroquinolone	
Patient with prosthetic heart valve or orthopedic implant	Consider adding vancomycin to standard regimen		Give prophylaxis before manipulating abscesses
Barnyard injuries, fecal contamination	Amoxicillin-clavulanate or second-generation cephalosporin	Fluoroquinolone plus either clindamycin or metronidazole	
Saltwater exposure	Third-generation cephalosporin ± doxycycline	Fluoroquinolone	<i>Vibrio</i> may cause hemorrhagic, bullous lesions
Freshwater exposure	Antipseudomonal aminoglycoside or antipseudomonal penicillin	Fluoroquinolone	<i>Aeromonas</i> or <i>Pseudomonas</i> may be involved
Abscesses, infections due to intravenous drug use	Amoxicillin-clavulanate or second-generation cephalosporin	Clindamycin	Antibiotics usually not necessary, incision and drainage essential
Necrotizing fasciitis	Imipenem or meropenem	Oxacillin plus gentamicin plus clindamycin	
Bite wounds	Amoxicillin-clavulanate or cefoxitin/cefotetan	Clindamycin plus either a fluoroquinolone or trimethoprim-sulfamethoxazole	
Open fracture	First-generation cephalosporin or antistaphylococcal penicillin	Vancomycin	
Plantar puncture wound osteomyelitis	Ceftazidime	Ciprofloxacin

after 24 to 48 h, cleanse the wound, and examine it for signs of infection.

Daily cleansing ensures that the patient examines the laceration for early signs of infection. Patients should be instructed to observe the wound for redness, warmth, swelling, and drainage, as these findings may indicate infection. Patients who notice signs of infection should initiate contact with the health care system. Standardized wound care instructions improves patient compliance and understanding.⁷

TABLE 48-2 Recommendations for Tetanus Prophylaxis

History of Tetanus Immunization	CLEAN MINOR WOUNDS		ALL OTHER WOUNDS*	
	Administer Tetanus Toxoid†	Administer TIG‡	Administer Tetanus Toxoid	Administer TIG
<3 or uncertain doses	Yes	No	Yes	Yes
≥3 doses				
Last dose within 5 years	No	No	No	No
Last dose within 5–10 years	No	No	Yes	No
Last dose >10 years	Yes	No	Yes	No

*Especially if older than 6 h, deep (> 1 cm), grossly contaminated, exposed to saliva or feces, stellate, ischemic or infected, avulsions, punctures, or crush injuries.

■(■)Tetanus toxoid: Td if older than 7 years and DT if younger than 7 years, preferably administered into the deltoid.

†Tetanus immune globulin: adult dose 250–500 IU administered into deltoid opposite the Td immunization site.

Abbreviations: DT = diphtheria-tetanus toxoid; Td = tetanus-diphtheria toxoid.

Reapplication of topical antibiotics for 3 to 5 days will decrease scab formation, thereby preventing wound-edge separation. Patients with tissue adhesives may shower, but they should avoid bathing and swimming because prolonged moisture will loosen the adhesive bond.

WOUND DRAINS

Drains are placed in wounds and surgical incisions under three circumstances: (1) to drain interstitial fluid or blood and prevent their accumulation into a seroma or hematoma, respectively; (2) maintain a tract so pus can drain from an infected area; or (3) allow for drainage from a contaminated location and prevent an abscess from forming. Drains allow for near complete wound closure in many circumstances in which closure would otherwise be impeded by fluid, pus, or blood accumulation. Drains can be categorized as (1) gauze packing to maintain open drainage and collect the exudate, (2) open systems using soft rubber (e.g., Penrose drain) or silicone tubing to direct drainage onto external gauze dressings, or (3) closed systems using silicone tubing and attached fluid collection reservoirs. Drains can be placed either through the suture line of the initial wound or incision, or through an adjacent incision made specifically for drain access.

The most common type of wound drain placed in the ED is *j*- to 1-inch ribbon gauze used to pack an abscess cavity after incision and drainage. Dressings over draining abscesses may initially require frequent changes. The internal packing should be replaced daily as long as the wound continues to produce exudate. Once the pumulence stops, internal packing is no longer required, and daily cleaning with external dressing changes should continue until enough granulation tissue forms and the wound becomes dry. Maintaining a moist, clean environment promotes wound healing.

Open drainage using soft rubber tubing (e.g., Penrose drains) has been used for years to drain infected or contaminated wounds that have been partially or completely closed. A safety pin placed through the tubing can prevent the drain from inappropriately advancing into the wound. As the exudate diminishes and the wound heals, the Penrose

drain can be pulled out a portion each day to allow the wound to heal from the "bottom up." The disadvantage of open drains such as the Penrose is the access they provide for bacteria into the wound.

For most purposes, especially postsurgery, closed drainage systems are preferred to open wound drains because closed systems prevent access of bacteria into the wound. The collection reservoir for closed drainage systems often has self-inflating ability so it can be squeezed before attachment to the tubing in order to place vacuum suction in the wound to enhance drainage (e.g., Jackson-Pratt, Hemovac, VacuDrain, and Constavac). Assessment of the tubing and emptying of the reservoir should be done with sterile technique (similar to dressing changes for indwelling lines). If a drainage tube is accidentally pulled out, it should not be reinserted. The reservoir may require emptying several times per day, depending on the drainage volume. It is common practice to remove closed drains when the amount of fluid drained each day reaches low levels (typically 30 to 40 mL per d).

PAIN CONTROL

Abrasions and some lacerations can be quite painful. Patients should be educated regarding the expected degree of pain and measures that may help reduce pain. Splints can be used to reduce swelling and pain for extremity lacerations. Appropriate analgesic medications and anti-inflammatory agents will help control pain. The pain from lacerations generally decreases after the initial 48 h and opiate analgesics are rarely necessary after that time. On the other hand, some patients with lacerations have concurrent contusions (such as victims of motor vehicle crashes), and they will often report worsening pain 24 to 48 h after the initial injury.

HEALTH CARE PROVIDER FOLLOW-UP

Patients should be instructed when and with whom to follow-up for suture removal or wound examination.⁹ Sutures or staples in most locations should be removed after approximately 7 to 10 days (Table 48-3). Facial sutures should be removed within 3 to 5 days to avoid formation of unsightly sinus tracts and hatch marks.¹⁰ Sutures over the joints or in the hands should be left in place for 10 to 14 days, since they may be subject to high tension during movement. When removing sutures, care should be taken to avoid applying tension in a direction that would tend to cause dehiscence. Any scab or crusting over the

sutures may be debrided prior to suture removal by gently applying hydrogen peroxide with gauze.

Tissue adhesives will slough off, typically within 5 to 10 days of application. They do not usually require removal by a health care practitioner. When 2-octylcyanoacrylate is used, the patient should be careful to avoid picking at or scrubbing the area or exposing it to water for more than brief periods. When tissue adhesives remain on the skin for prolonged periods, antibiotic ointment, petroleum jelly, or bathing can accelerate removal.

Most patients do not require mandatory "wound checks." This practice might be useful in high-risk patients, high-risk wounds, or patients unable to identify signs of infection. Since many healing wounds may develop erythema and patients are not able to correctly identify wound infections, prescription of antibiotics without a reevaluation is inappropriate and often unnecessary.¹¹ Patients with wound infections should be treated with antibiotics as outlined earlier (see Table 48-1). Patients who require further tetanus immunization to complete their primary series should have the second dose 1 to 2 months later and the third dose 6 to 12 months after the second dose.

PATIENT EDUCATION ABOUT LONG-TERM COSMETIC OUTCOME

Although patients should be educated about the expected outcome before wound closure, the time of suture or staple removal or wound follow-up is another excellent time for patient education. Patients should understand that all traumatic lacerations result in some scarring. They should also understand that the short-term cosmetic appearance is not highly predictive of the ultimate cosmetic outcome.¹² Healing lacerations and abrasions should not be exposed to the sun, since sun exposure can result in permanent hyperpigmentation.¹³ Injured skin should be protected with a sun-blocking agent for at least 6 to 12 months after injury.

CARDIOVASCULAR DISEASE

APPROACH TO CHEST PAIN

Gary B. Green Peter M. Hill

OVERVIEW

Approximately 5 percent of all U.S. ED visits, or about 5 million visits a year, are for chest pain, but accurate diagnosis remains a challenge.^{1,2} This chapter covers the approach to acute chest pain, with attention to identifying patients with potentially serious disorders.

Pathophysiology of Chest Pain

Stimulation of visceral or somatic afferent pain fibers results in two distinct pain syndromes. The dermis and parietal pleura are innervated by somatic pain fibers, which enter the spinal cord at specific levels and are arranged in dermatomal patterns. Visceral pain fibers are found in internal organs, such as the heart and blood vessels, the esophagus, and the visceral pleura. These visceral pain fibers enter the spinal cord at multiple levels and map to areas on the parietal cortex corresponding to the cord levels shared with the somatic fibers. Pain from somatic fibers is usually easily described, precisely located, and experienced as a sharp sensation, whereas pain from visceral fibers is more difficult to describe and is imprecisely localized. Accordingly, those experiencing visceral pain are more likely to use terms such as *discomfort*, *heaviness*, or *aching*. Patients frequently misinterpret the origin of visceral pain, because it is often referred to a different area of the body corresponding to an adjacent somatic nerve. For example, diaphragmatic irritation can present as shoulder pain, and arm pain may actually represent myocardial ischemia.

Gender, age, comorbidities, medications, drugs, and alcohol may interact with psychological and cultural influences to affect the patient's perception and communication of pain.

Definitions

The phrase *acute chest pain*, commonly used in emergency medicine, deserves definition. The term *acute* means of sudden or recent onset. While there is no precise time period defined, in common practice acute means that the patient stops his or her usual activity to seek medical attention, typically within minutes to hours. Some studies of acute chest pain patients in the ED limit entry to those with chest pain of less than 24-h duration. The term *chest* in this context means a location described by the patient on the anterior thorax, from xiphoid to suprasternal notch and between the right and left midaxillary lines. This is because the major serious thoracic disorders typically manifest symptoms localized to the anterior thorax. While it is true that pain localized to the back, between the base of the neck and the lumbar region, is on the thorax cage, in isolation, pain localized to this region is approached differently (see Chap. 282). That said, there are occasional patients with serious and life-threatening intrathoracic disorders who will manifest a location of their most intense pain outside the boundaries noted above. In addition, some patients may have migratory pain that has moved out of the anterior chest by the time the patient reaches medical attention. Therefore, clinicians are encouraged to include within their differential diagnosis important and significant intrathoracic disorders when patients describe pain in adjacent regions; e.g., epigastric, neck and jaw, and arm. The term *pain* describes a noxious uncomfortable sensation. However, pain perception and description

vary widely, and patients may use terms such as *ache* or *discomfort*. Alternative descriptions are common in the elderly. Similar to alternative locations, clinicians should be attuned to variation in the patient's description of the noxious sensation. In summary, acute chest pain refers to (1) recent onset, typically less than 24 h, that causes the patient to seek prompt medical attention, (2) location described on the anterior thorax, and (3) a noxious uncomfortable sensation distressing to the patient.

INITIAL APPROACH

The initial approach to acute chest pain recognizes that some causes are serious and life-threatening, and prompt medical attention may prevent death and limit morbidity. Therefore, patients should be triaged promptly. Patients with visceral-type chest pain (defined below), significantly abnormal pulse or blood pressure measurements, or with dyspnea should be placed directly into a treatment bed, a cardiac monitor initiated, an intravenous line established, oxygen administered, and an ECG ordered. Other less well-defined patients also deserve expeditious evaluation, and experienced triage officers and nurses often have a "gut" feeling about certain patients; that insight should be respected.

The initial evaluation should focus on immediate life threats: ensuring adequate airway, breathing, and circulation. The vital signs should be assessed and repeated at regular intervals as determined by the patient's condition. The initial history should focus on specific questions concerning the character of the chest pain, the presence of associated symptoms, and a history of cardiopulmonary conditions. The patient is asked to grade pain intensity in order to follow response to therapy. A 0 to 10 scale is commonly used, with 10 being the worst pain the patient can imagine and 0 being no pain at all. Focused cardiac, pulmonary, and vascular examinations should follow.

If immediate life threats are not detected or have already been addressed, a more extensive evaluation can be preformed. This "secondary survey" consists of a history that defines symptoms more precisely. Chest pain should be assessed like other pain syndromes, with specific questions concerning quality, location, radiation or migration, severity, time and character of onset, progression, provoking factors, relieving factors, and associated symptoms. If the pain has been episodic, the frequency of pain episodes should be assessed over the past weeks to better determine progression. Risk factors for cardiopulmonary disease should be assessed. The physical examination during this phase should complete those body systems not evaluated initially as well as rechecking abnormalities noted before. Many organizations have developed structured history and physician examination forms for acute chest pain to direct the information-gathering process and organize the diagnostic approach. Such structured records are particularly helpful to less experienced physicians. Further diagnostic testing is directed by the history and physical examination.

Categorization

A useful initial approach is to classify patients into three categories: (1) chest wall pain, (2) pleuritic or respiratory chest pain, and (3) visceral chest pain. Chest wall pain is a somatic pain, usually described as sharp in quality, that can be precisely localized (often with one fingertip) and is reproducible by direct palpation and/or chest wall movement during stretching or twisting. Pleuritic chest pain is also a somatic pain, usually described as sharp in quality that is distinctly worsened by breathing or coughing. The term *pleuritic* is potentially

confusing; more than the pleura moves during respiration, and disorders other than "pleurisy" may be worse with respiration. Visceral chest pain is poorly localized and usually described as aching or heaviness. Important causes of chest pain within each category are noted in Table 49-1.

A very useful principle in the clinical assessment of acute chest pain is that, with rare exception, chest pain diagnosis is a composite picture, no one fact or observation make the diagnosis. The challenge to the clinician is to take the often-confusing history and nondiagnostic physician examination and select the useful features that guide further assessment, management, and disposition.

Assessment of risk factors for cardiovascular disease can play a role in patient assessment. Specifically, the presence of risk factors for coronary artery disease (cigarette smoking, diabetes, hypertension, hypercholesterolemia, family history), aortic dissection (middle aged, male gender, hypertension, Marfan syndrome), and pulmonary embolism (hypercoagulable diathesis, malignancy, recent immobilization or surgery) are useful in judging the probability of these diagnoses. Likewise, age can be used to assess the probability of atherosclerotic disease; clinically significant coronary artery disease is rare in patients under the age of 30. Acute cocaine use has been associated with acute myocardial infarction, and chronic cocaine use is associated with accelerated atherosclerosis and severe coronary artery disease (see Chap. 168). However, youth or absence of risk factors does not completely eliminate any potentially serious cause of acute chest pain.

The patient's medical record should be reviewed. The current ECG should be compared with previous tracings. Results of prior cardiac studies (echocardiograms, stress testing, or catheterizations), esophageal studies (endoscopy, oral contrast swallowing studies), gastrointestinal studies (ultrasound, computed tomography), or pulmonary studies (spirometry) should be reviewed and present symptoms interpreted in comparison with these results. In general, cardiac stress studies within the previous 6 months and coronary angiography within the prior 2 years are considered to likely reflect the current state of the coronary circulation.

A practice to be decried is the use of therapeutic trials in acute chest pain; usually in the form of (1) a "gastrointestinal (GI) cocktail" containing an antacid, antispasmodic, and local anesthetic for gastroesophageal reflux, (2) nitroglycerin for myocardial ischemia, and (3) nonsteroidal anti-inflammatories for chest wall pain. The placebo effect makes it difficult to interpret a positive response; patients with definite myocardial ischemia have been reported as experiencing complete pain relief with a GI cocktail. In addition, nitroglycerin is a smooth muscle dilator and may produce relief in esophageal spasm and biliary colic as well as myocardial ischemia. The analgesic properties of nonsteroidal anti-inflammatories are not specific for any location.

TABLE 49-1 Important Causes of Acute Chest Pain

Chest Wall Pain	Pleuritic Pain	Visceral Pain
Costosternal syndrome	Pulmonary embolism	Typical exertional
Costochondritis	Pneumonia	angina
(Tietze syndrome)	Spontaneous	Atypical
Precordial catch syndrome	pneumothorax	(nonexertional)
Slipping rib syndrome	Pericarditis	angina
Xiphodynia	Pleurisy	Unstable angina
Radicul		Acute myocardial
syndromes		infarction
Intercostal nerve syndromes		Aortic
Fibromyalgia		dissection
		Pericarditis
		Esophageal reflux
		or spasm
		Esophageal rupture
		Mitral valve prolapse

Ischemic Equivalents

A confounding observation is that many patients with acute coronary syndrome (ACS, defined below), perhaps as high as 40 percent, do not describe chest pain as their predominant symptom.³ The absence of chest pain leads to delayed or inadequate anti-ischemic therapy and increased in-hospital mortality.⁴

Truly silent myocardial ischemia does occur, but these patients are not likely to come to the ED. For those that do, ischemic equivalents or atypical presentations are important to note: dyspnea at rest or with less exertion compared to the patient's previous baseline; shoulder, arm, or jaw discomfort; nausea; lightheadedness; generalized weakness; acute change in mental status; or diaphoresis. Epigastric or upper abdominal discomfort can be the presenting symptom of myocardial ischemia. Patients with sensory impairment due to diabetes, advanced age, psychiatric disease, or altered mental status are more likely to present with atypical symptoms with ACS. Atypical presentations of ACS also occur more frequently in women and non-white populations compared to white males.

Differential Diagnosis

When patients present with acute chest pain due to myocardial ischemia, the term *acute coronary syndrome*, or ACS, is used because, on initial assessment, it is not possible to determine if the patient has an acute myocardial infarction (AMI) or unstable angina (UA). ACS is a common cause of acute chest pain: in a typical ED population of adults over the age of 30 presenting with visceral-type chest pain, about 15 percent will have AMI and 25 to 30 percent will have UA.¹

The pain of myocardial ischemia is almost always retrosternal and diffuse, usually described as a heaviness or pressure, and commonly radiates, usually to the neck or left arm (see Chap. 50). In exertional angina, the pain is episodic, lasting minutes (usually <10 min and not seconds or hours), provoked by exertion, and relieved by rest or sublingual nitroglycerin. Exertional angina is most often due to atherosclerotic disease of the epicardial coronary arteries that restricts blood flow. In atypical angina, the pain is the same as that with exertional angina, but pain occurs at rest. Atypical angina appears to be caused by coronary artery spasm. In about two-thirds of patients with atypical angina, coronary artery lesions are seen, and patients may have exertional as well as rest pain. In both exertional angina and atypical angina, the pattern is stable in terms of frequency of episodes, severity, ease of provocation, and response to rest or nitroglycerin. In UA, the episodic anginal pain has changed its pattern; it is either (1) of new onset (less than 1 to 2 months), (2) more frequent, easily provoked, more severe, or difficult to relieve, or (3) occurring at rest for prolonged spells (>20 min). UA is a potentially serious condition and patients are at high risk for early AMI or death. In AMI, the pain is usually persistent (>20 min), severe, and associated with symptoms of dyspnea, diaphoresis, or nausea.

In ACS, the most useful test is an ECG for both detecting myocardial ischemia and risk stratification. Using the initial ECG, the incidence of AMI is approximately 80 percent for patients with new ST-segment elevation greater than 1 mm in two contiguous leads, about 20 percent in patients with new ST-segment depression or T-wave inversion, but less than 4 percent in patients without either of these two patterns.

Pulmonary embolism is common and life-threatening and is a diagnosis that can be missed in the ED due to the frequently atypical nature of its presentation. Pulmonary embolism can manifest with any combination of chest pain, dyspnea, syncope, shock, and/or hypoxia (see Chap. 56). The pain associated with a PE occurs when inflammation of the parietal pleura overlying the infarction causes chest pain that is generally sharp and related to respiration. Dyspnea, fever, cough, and/or hemoptysis also may be present, and the chest wall may be tender to pal-

pation. Patients with massive PEs often present with unstable vital signs and the classic presentation of sharp, pleuritic chest pain and dyspnea associated with tachypnea, tachycardia, and hypoxemia. A clinical scoring system maybe useful in categorizing patients into low (about 10 percent), intermediate (about 40 percent), and high (about 80 percent) prevalence for PE.⁶

Risk factors for *aortic dissection* include atherosclerosis, uncontrolled hypertension, coarctation of the aorta, bicuspid aortic valves, aortic stenosis, Marfan syndrome, Ehlers-Danlos syndrome, and pregnancy (see Chap. 58). The pain of aortic dissection, i.e., midline substernal chest pain, is classically described as tearing, ripping, or searing and radiating to the interscapular area of the back. Typically, the pain is at its worst at symptom onset and is often felt above and below the diaphragm. Symptoms of "secondary" pathologies resulting from arterial branch occlusions, such as stroke, AMI, or limb ischemia, may overshadow the clinical presentation of the dissection and make an accurate diagnosis difficult. No combination of clinical factors or chest radiography findings are adequate to exclude the diagnosis of aortic dissection, and specific imaging studies are usually required.⁷

Spontaneous pneumothorax may occur due to sudden changes in barometric pressure, in smokers or patients with chronic obstructive pulmonary disease or idiopathic pleural bleb disease, or in those with another pulmonary pathology (see Chap. 66). Patients usually complain of a sudden, sharp, lancinating, pleuritic chest pain and dyspnea. Auscultation of the lungs may reveal absence of breath sounds on the ipsilateral side and hyperresonance to percussion, but clinical impression alone is unreliable. Diagnosis of a simple pneumothorax is made by chest radiography.

Esophageal rupture (Boerhaave syndrome) is a rare but potentially life-threatening cause of chest pain. Patients classically present with a history of substernal, sharp chest pain of sudden onset that occurs immediately after an episode of forceful vomiting (see Chap. 75). The patient is usually ill-appearing, dyspneic, and diaphoretic. The physical examination is often normal but may reveal evidence of pneumothorax or subcutaneous air. Chest radiography may be normal or may demonstrate pleural effusion (left more common than right), pneumothorax, pneumomediastinum, pneumoperitoneum, and/or subcutaneous air. The diagnosis can be confirmed by a study with water-soluble contrast.

The pain of *acute pericarditis* is typically acute, sharp, severe, and constant (see Chap. 55). It is usually described as substernal, with radiation to the back, neck, or shoulders, and is exacerbated by lying down and by inspiration. It is classically described as being relieved by leaning forward. A pericardial friction rub is the most important diagnostic finding. The ECG may show diffuse ST-segment elevation and T-wave inversion. In addition, depression of the PR segment is a highly specific ECG finding for pericarditis.

Pneumonia can produce chest pain or discomfort that is usually sharp and pleuritic (see Chap. 63). It is usually associated with fever, cough, and possibly hypoxia. Physical examination may reveal rales over the affected lobes, decreased breath sounds, and signs of consolidation (i.e., bronchial breath sounds). A chest radiograph confirms the diagnosis.

Mitral valve prolapse (MVP) is the most frequently diagnosed cardiac valvular abnormality and is more commonly diagnosed in women than in men. The discomfort of MVP often occurs at rest, is atypical for myocardial ischemia, and can be associated with dizziness, hyperventilation, anxiety, depression, palpitations, and fatigue (see Chap. 54). The discomfort may be related to papillary muscle tension, and many patients benefit from the administration of (3-adrenergic blocking agents. Two-dimensional echocardiography is the diagnostic tool of choice and, with physical examination findings, helps to stratify patients into high- and low-risk categories for developing serious complications. Palpitations and every type of supraventricular or ventricular dysrhythmia have been associated with MVP.

Musculoskeletal or chest wall pain syndromes are characterized by highly localized, sharp, positional chest pain. Pain that is completely

reproducible by light to moderate palpation of a discrete area of the chest wall often represents pain of musculoskeletal origin, although chest wall tenderness occurs in some patients with PE and myocardial ischemia. Costochondritis is an inflammation of the costal cartilages and/or their sternal articulations and causes chest pain that is variably sharp, dull, and/or increased with respirations. *Tietze syndrome* is a particular cause of costochondral pain related to fusiform swelling in one or more upper costal cartilages and has a pain pattern similar to that of other costochondral syndromes. Xiphodynia is another inflammatory process that causes sharp, pleuritic chest pain reproduced by light palpation over the xiphoid process. Texidor twinge or precordial catch syndrome is described as a short, lancinating chest discomfort that occurs in episodic bunches lasting 1 to 2 min near the cardiac apex associated with inspiration and poor posture and inactivity.

Gastrointestinal disorders cannot be reliably discriminated from myocardial ischemia by history and examination alone. Dyspepsia syndromes, including gastroesophageal reflux, often produce pain described as burning or gnawing, usually in the lower half of the chest, and often accompanied by a brackish or acidic taste in the back of the mouth (see Chap. 75). The recumbent position usually exacerbates the symptoms, and although the pain is typically relieved with antacids, this therapeutic response also can be observed in myocardial ischemia. *Esophageal spasm* is often associated with reflux disease and is characterized by a sudden onset of dull, tight, or gripping substernal chest pain, frequently precipitated by the consumption of hot or cold liquids or a large food bolus and often lasting for hours (see Chap. 75). The pain also responds to sublingual nitroglycerin (although supposedly with a slight delay).

Peptic ulcer disease is classically characterized as a postprandial, dull, boring pain in the midepigastriac region (see Chap. 77). Patients often describe being awakened from sleep by discomfort. Duodenal ulcer pain is usually relieved after eating food, in contrast to gastric ulcer symptoms, which are often exacerbated by eating. Symptomatic relief is usually achieved by antacid medications. Acute pancreatitis and biliary tract disease present with right upper quadrant or epigastric pain and tenderness but also can present with chest pain.

Panic disorder (PD) is defined as a syndrome characterized by recurrent unexpected panic attacks (discrete periods of intense fear or discomfort) with at least four of the following symptoms: palpitations, diaphoresis, tremor, dyspnea, choking, chest pain or discomfort, nausea, dizziness, derealization or depersonalization, fear of losing control or dying, paresthesias, chills or hot flushes (see Chap. 292). The diagnosis can be made only in the absence of direct physiologic effects of a substance disorder, a general medical condition, or symptoms better accounted for by another mental disorder. Several studies have used standardized screening tools to evaluate ED chest pain patients for PD and have reported an incidence of 17 to 32 percent. In a small trial, investigators found that ED physicians can successfully diagnose PD by using a brief screening procedure, and they suggested that PD patients could benefit from the initiation of specific pharmacologic therapy (serotonin reuptake inhibitors) in the ED.⁸ Many patients with PD and other anxiety disorders have elevated baseline sympathetic tone, that may be an independent risk factor for coronary artery disease (CAD). In fact, when all ED chest pain patients were screened for PD, 25 percent of those screening positive had a discharge diagnosis of ACS (9.3 percent) or stable angina pectoris (15.7 percent).⁹ Thus, PD always must be considered a diagnosis of exclusion.

ANCILLARY TESTING

Ancillary testing in acute chest pain generally utilizes electrocardiography, measurement of serum markers of myocardial injury, and/or imaging studies to detect intrathoracic pathology. The specific studies are chosen according to the clinical circumstances. That said, because ACS is the most common potentially serious cause of acute chest pain,

clinical studies and common practice focus on the use of the ECG and serum marker measurement to detect or exclude acute myocardial injury. The remainder of this chapter will focus on this topic. The use of ancillary tests in other conditions are discussed in their respective chapters.

Electrocardiography

Due to the importance of early diagnosis of AMI (and, hence, reduced delay of thrombolytic treatment), the American College of Cardiology/American Heart Association (ACC/AHA) guidelines for management of patients with AMI recommend standing orders that all patients with "ischemic-type pain" have a 12-lead ECG performed within 10 min of arrival and that the ECG be handed directly to the treating physician for immediate interpretation.¹⁰ Considering the difficulty of defining "ischemic-type" pain and the frequency of atypical presentations, it may be prudent to extend this protocol to *all* adult patients with chest pain or other symptoms of possible ischemia.

The normal myocardium depolarizes from endocardium to epicardium and repolarizes in the opposite direction. Ischemic myocardium remains electrically less positive than nonischemic myocardium at the end of depolarization. This creates an electrical potential between normal and ischemic myocardium during depolarization and results in ST-segment elevation in an overlying electrode. Conversely, if the electrode is located over normal myocardium opposite an ischemic region, ST-segment depression will be seen. If ischemia is limited to the subendocardial area, an overlying electrode will be separated from the ischemic tissue by a layer of normal myocardium, resulting in an electrical potential pointed inward from the normal to ischemic tissue, resulting in ST-segment depression.

Myocardial ischemia can also delay the repolarization process. In extensive or transmural ischemia, the direction of repolarization is reversed so that recovery occurs from endocardium to epicardium, resulting in T-wave inversions in an overlying electrode. In subendocardial ischemia, the delay does not alter the normal recovery process (epicardium to endocardium), so T waves are not inverted. However, because normal epicardium repolarization is unopposed due to delayed subendocardial repolarization, the T wave in an overlying electrode may be larger than normal (called *hyperacute T waves*).

After infarction, the area of necrosis is electrically silent, not able to depolarize. During ventricular depolarization, initial electrical activity will be generated in normal myocardium, away from the infarcted area. This results in an electrical potential directed from the infarcted area toward normal myocardium, causing an abnormal initial negative deflection (pathologic Q waves) in the QRS complex of overlying electrodes. Occasionally, small Q waves (called septal Q waves) are seen in the limb or lateral precordial ECG leads. Pathologic Q-waves are distinguished by their duration (greater than 40 ms) and depth (greater than 25 percent of the corresponding R wave).

The ECG is an important tool in the detection of acute infarction and conduction blocks.¹¹ Also, the ECG can help identify the infarct-related artery and help predict reperfusion. The sensitivity of the initial ECG for the diagnosis of AMI has been extensively studied. Approximately half of patients with AMI have diagnostic changes on their initial ECG with new ST-segment elevation greater than 1 mm in two contiguous leads. Another 20 to 30 percent will have new ST-segment or T-wave inversion suggestive of myocardial ischemia. About 10 to 20 percent will have ST-segment depressions and T-wave inversions similar to that seen on previous tracings. About 10 percent have nonspecific ST-segment and T-wave abnormalities. Only about 1 to 5 percent of AMI patients will have a truly normal initial ECG.

The sensitivity of the initial ECG in unstable angina is less well defined, probably because the diagnosis is clinical as there is no "gold standard" against which to evaluate a diagnostic test. In addition, the initial ECG would not be expected to be abnormal if a patient with UA presents during a pain-free period.

The positive predictive value of the different ECG patterns has also been studied. For new ST-segment elevation, the positive predictive value for AMI is about 80 percent. For new ST-segment depression and T-wave inversions, the positive predictive value is about 20 percent for AMI and between 14 and 43 percent for UA. With acute chest pain and an initial ECG showing preexisting ST-segment depressions and T-wave inversions, the positive predictive value is about 4 percent for AMI and 21 to 48 percent for UA. Thus, the standard 12-lead ECG is useful in conjunction with the clinical history for detection of ACS.

Variations on the standard 12-lead ECG have been proposed. One approach uses a continuous 12-lead ECG monitor that records (but does not print) a new 12-lead ECG every 20 s. When the ST-segment baseline is altered from the previous tracing, an alarm is raised and a copy of the new ECG is shared or printed. This technology is potentially useful for monitoring patients with ongoing pain and a nondiagnostic initial ECG.¹² Because of the costs, concerns regarding labile ST-segment and T-wave changes from patient movement and respiration, and a lack of ED-based prospective studies, continuous 12-lead ECG monitoring cannot be recommended for routine use.

Electrocardiograms with added leads—for a total of 15, 18, and 22 leads—have been studied. In general, adding more leads increases the sensitivity for AMI detection, but reduces specificity. The only generally agreed upon extension to the standard 12-lead ECG is the use of right-sided precordial leads in the setting of acute inferior myocardial infarction in order to detect right ventricular involvement.¹³

Risk stratification based on the initial ED ECG also has been suggested as a way of improving ED decision making. Although the initial ECG cannot exclude AMI, stable ED patients whose initial ECG is without ischemic changes are at low risk of subsequent life-threatening complications and usually can be managed in a non-intensive-care setting. Conversely, patients whose initial ECG demonstrates ischemic changes (ST-segment depression or T-wave inversion), even in the absence of confirmed AMI, are at significantly greater risk of short- and long-term morbidity and mortality and should be managed accordingly.

Serum Markers of Myocardial Injury

CREATINE KINASE, CREATINE KINASE ISOENZYMES, AND ISOFORMS Creatine kinase (CK; adenosine triphosphate creatine Af-phosphotransferase) is an intracellular enzyme involved in the transfer of high-energy phosphate groups from ATP to creatine. Although found in small quantities in many tissues, CK is present in large concentrations in cardiac and skeletal muscle and the brain. The enzyme is a dimer composed of two subunits, each of which may be the M (muscle) type or the B (brain) type, thus creating three distinct dimers, or isoenzymes: CK-BB, CK-MM, and CK-MB. Type CK-BB predominates in brain tissue, whereas skeletal muscle consists mostly of CK-MM, in addition to CK-MB in small amounts. The "cardiac isoenzyme," CK-MB, accounts for 14 to 42 percent of total cardiac muscle enzyme activity, thus the predominant enzyme in the heart is actually CK-MM.

The quantitative and temporal patterns of appearance and disappearance of CK and its isoenzymes in the blood occur in a reproducible manner but can vary considerably depending on the amount of CK released from cells, the amount of perfusion of damaged tissues, and the rate of clearance by the reticuloendothelial system. The CK levels usually become abnormally high within 4 to 8 h after coronary artery occlusion (onset of symptoms), peak between 12 and 24 h, and return to normal between 3 and 4 days (Figure 49-1). Reports of the sensitivity of total CK vary from 93 to 100 percent, whereas the specificity is lower (57 to 86 percent), owing to the presence of CK in other tissues. Thus, this marker's usefulness is limited. The CK-MB isoenzyme curve parallels the total CK curve, with levels detectable 4 to 8 h after onset of symptoms (see Figure 49-1). Type CK-MB may peak

FIG. 49-1. Typical pattern of serum marker elevation after AMI. *Abbreviations:* CK-MB = creatine kinase-MB isoenzyme; cTnI = cardiac troponin I; cTnT = cardiac troponin T; LD1 = lactate dehydrogenase isoenzyme 1; MLC = myosin light chain.

slightly earlier than total CK, and it is cleared more rapidly, usually within 48 h (vs. 72 to 96 h). Using CK-MB and the ratio of CK-MB to total CK, most studies have reported sensitivity and specificity to be greater than 95 percent. Cutoff values vary between techniques, laboratories, and populations, but CK-MB values in healthy controls may be up to 5 [xg/L and up to 5 percent of total CK. Historically, CK-MB had been universally adopted as the gold standard for diagnosis of AMI. Although specificity is generally improved over total CK, 37 conditions other than AMI have been associated with elevated CK-MB levels (Table 49-2). Fortunately, most of these conditions can be easily differentiated from AMI on clinical grounds. The relatively rapid return of elevated CK-MB levels to normal is another potential disadvantage, because of the possibility of missing the diagnosis in patients presenting later in the course of AMI. However, this rapid clearance may be used to another advantage, because it enables the identification of infarct extension and reinfarction.

The 4- to 8-h delay in CK-MB detection after onset of symptoms has been overcome in part with the development of rapid assays for CK-MB isoforms (subforms). The isoenzymes CK-MM, CK-MB, and CK-BB are dimeric molecules consisting of three different combinations of two monomers, M and B. On its release from damaged cells, the M monomer found in tissue CK (M_1) is acted on by an enzyme present in serum, carboxypeptidase N, which cleaves off the C-

terminal lysine. This action results in its conversion into the M monomer found in serum CK (M_s). Newly released unmodified CK- M_1B (or CK-MB₂) is enzymatically changed into CK- M_sB (or CK-MB₁). Because the rate of this conversion is limited, CK-MB₂ activity reflects new recent release into the serum. By measuring MB₂ activity (>1 U/L) and the MB¹/MB₂ ratio (>1.5), infarction can be detected before the total level of CK-MB exceeds the normal range. Although this method has reported early (<6 h of symptom onset) sensitivity and specificity for AMI of 95.7 percent and 93.9 percent, respectively, technical difficulties with the assay system have thus far limited clinical acceptance.¹⁴

MYOGLOBIN Myoglobin is a small (17,500 Da), heme-containing protein found in striated (skeletal) and cardiac muscle cells. When disrupted, these cells rapidly release myoglobin into the serum. After AMI, serum myoglobin levels begin to rise within 3 h of onset of symptoms and are abnormally elevated in 80 to 100 percent of patients at 6 to 8 h, peak at 4 to 9 h (see Figure 49-1), and with normal kidney function return to baseline within 24 h from symptom onset. A false-negative result may occur if the test is performed after myoglobin has already been cleared from the serum. False positives also abound, because the myoglobin found in myocardium is indistinguishable from that found in skeletal muscle. Fortunately, conditions that also result in myoglobin release usually can be clinically diagnosed. By excluding those patients with known trauma, renal failure, or cocaine use, one study found myoglobin's "clinical specificity" to be equivalent to that of CK-MB and troponin.¹⁵

TROPONINS I AND T The troponin complex is the main regulatory protein of the thin filament of the myofibrils that regulate the Ca^{2+} -dependent ATP hydrolysis of actomyosin. The troponin complex consists of three subunits: an inhibitory subunit (troponin I), a tropomyosin-binding subunit (troponin T), and a calcium-binding subunit (troponin C). Immunoassays based on the significant heterogeneity in amino acid sequences can detect the specific isoforms. The cardiac isoform of troponin I is not found in skeletal muscle during any stage of development and therefore is associated only with myocardial necrosis.

After AMI, cardiac troponin I (cTnI) and troponin T (cTnT) become elevated after approximately 6 h, peak at 12 h, and remain elevated for 7 to 10 days. Both have a higher specificity for myocardial necrosis than CK-MB in selected subsets of patients, such as those presenting late in the course of AMI or those with recent surgery, a cocaine habit, or skeletal muscle disease. Both troponins have been

TABLE 49-2 Conditions Associated with Elevated CK-MB Levels

Common	Uncommon	Rare	Unclear
Unstable angina, acute coronary ischemia	Congestive heart failure	Isolated case in normal person	Acromegaly
Inflammatory heart diseases	Coronary artery disease after stress test		Hypothermia
Cardiomyopathies	Angina pectoris		Rocky Mountain spotted fever
Circulatory failure and shock	Valvular defects		Typhoid fever
Cardiac surgery	Tachycardia		Chronic bronchitis
Cardiac trauma	Cardiac catheterization		Lumbago
Skeletal muscle trauma (severe)	Electrical countershock		Febrile disorder
Dermatomyositis, polymyositis	Noncardiac surgery		
Myopathic disorders	Brain and head trauma		
Muscular dystrophy, especially Duchenne	Peripartum period		
Extreme exercise	Miscellaneous drug overdoses		
Malignant hyperthermia	CO poisoning		
Reye syndrome	Prostatic cancer		
Rhabdomyolysis of any cause			
Delirium tremens			
Ethanol poisoning (chronic)			

Abbreviation: CK-MB = creatine kinase, subunits muscle and brain.

shown to have high sensitivity and specificity for AMI in ED patients with chest pain and among those with possible ischemic equivalents. Elevation of either cardiac troponin also predicts subsequent cardiovascular complications independent of CK-MB and the ECG.¹⁶

Interpretation of troponin results in the presence of renal failure is an area of controversy. Although only troponin T has been found in skeletal muscle biopsies of patients with renal failure, troponins I and T are sometimes elevated in renal patients without other evidence of cardiac disease. Further, there have been conflicting reports as to the prognostic significance of elevated levels of either troponin in patients with renal failure.

OTHER MARKERS Other markers of myocardial ischemia or infarction are currently being evaluated for utility: myoglobin/carbonyl anhydrase III combinations, glycogen phosphorylase BB, and myosin light chains, to name three. In addition, markers of inflammation (e.g., C-reactive protein), platelet activation and adhesion (e.g., P-selectin and other integrins), and cardiac function (B-type natriuretic peptide, or BNP) are theoretically attractive as indicators of ACS. C-reactive protein and BNP have some prognostic value in patients with possible ACS, but their overall role in diagnosis remains to be determined.

Clinical Applications of Myocardial Marker Measurements

The current literature supports the inclusion of myocardial marker measurements in protocols governing the ED evaluation of patients with chest pain for four distinct purposes. The first three applications are discussed below, while the fourth use of an accelerated marker curve is discussed later in Chap. 50.

EARLY DIAGNOSIS OF AMI In those patients whose initial ECG is diagnostic for AMI, no further marker testing is required before initiation of appropriate interventions. In patients with a nondiagnostic ECG, AMI cannot be definitively excluded within the first few hours from symptom onset. However, some AMI patients with nondiagnostic initial ECGs will have positive marker tests upon ED arrival, and many more will develop positive tests during the first few hours after presentation.

In AMI, the initial CK-MB measurement obtained upon ED arrival is elevated in about 30 to 50 percent of patients.¹⁷ By serial measures at 2- to 3-h intervals, diagnostic increases in CK-MB can be obtained in 80 to 96 percent of AMI patients during the initial six hours. The same principle can be applied with serial measurements of cTnI and cTnT. Owing to its earlier release into serum after coronary artery occlusion, myoglobin has a potential advantage over CK-MB and troponin for early diagnosis of AMI. Using a panel of markers (myoglobin, CK-MB, and cTnI) performed upon arrival and after 3 h, it is possible to detect over 90 percent of AMI patients.^{17,18}

IDENTIFYING "MISSED MI" PATIENTS Single-sample myocardial marker measurements cannot be used to exclude the diagnosis of AMI in the ED. However, routine incorporation of marker testing into patient-care algorithms for those patients deemed sufficiently low risk so that they are slated for discharge without definitive AMI rule-out has been shown to identify some patients (admitted and discharged from the ED) with unsuspected MI.¹⁹ Further, a strategy using two CK-MB measurements drawn 3 h apart for patients selected for discharge will identify ACS patients. Although these strategies have not been validated, these and several other studies suggest that ED patients slated for discharge after evaluation for chest pain and ischemic equivalents may benefit from at least one myocardial marker measurement.

EARLY RISK STRATIFICATION Increased use of newer anti-ischemic therapies (angiographic interventions and antiplatelet and antithrombotic drugs), although improving outcomes, carries risks and high

costs. Thus, a selective approach to their use is required. Several investigations have suggested that markers of myocardial injury can be used successfully in the ED to rapidly identify those patients most likely to benefit from a more aggressive approach. Numerous investigations have demonstrated that early ED testing of CK-MB, myoglobin, troponin T, or troponin I yields clinically useful prognostic data for adverse events, and that simultaneous testing of troponin and CK-MB may identify additional high-risk patients as opposed to testing for one marker.

After reviewing this evidence, the Joint European Society of Cardiology/American College of Cardiology Committee for the Re-definition of MI reported in 2000 that there is "no discernible threshold below which an elevated value for cardiac troponin would be deemed harmless. All elevated values are associated with a worsened prognosis."²⁰ Unfortunately, the threshold values historically suggested by the manufacturers of laboratory assays for CK-MB, troponin, and other myocardial markers have been determined based on the traditional definition of MI and are therefore inadequate for risk stratification. Recognizing this, the joint committee went on to recommend that new threshold values for each marker be established at the 99th percentile of the values for an appropriate reference control (normal) group. Because this recommendation has not been uniformly accepted and implemented by hospital laboratories, to optimally use the prognostic information offered by ED myocardial marker testing, emergency physicians should be aware of the appropriate threshold values for risk stratification and for MI diagnosis in their individual institutions.

POINT OF CARE TESTING With current monoclonal antibody technology, qualitative and quantitative cardiac marker panels for CK-MB, troponin I and T, and myoglobin are available for use at the bedside. A quantitative assay for BNP has also been developed for bedside use. Most point of care cardiac marker testing panels provide results within 15 to 20 min, generally faster than most hospital laboratories. Rapid bedside results would be theoretically useful when the results would affect early therapy (e.g., initiation of glycoprotein IIb/IIIa inhibitors) or alter disposition (e.g., primary percutaneous coronary intervention instead of medical therapy). Rapid bedside cardiac marker assessment may also be useful when the initial ECG is rendered difficult to evaluate due to preexisting ventricular conduction blocks or chronic ventricular pacing. The overall value of rapid bedside cardiac marker detection remains to be determined.

COMPUTERIZED DECISION AIDS

To facilitate more accurate disposition decisions and thereby reduce mounting health care costs, several investigators tried to develop computerized decision aids or computer-based triage protocols for ED patients with chest pain. Unfortunately, no simple algorithm has proven both safe and effective for ED-based triage of acute chest pain patients.

Other methods, such as multivariate analysis and artificial neural networks, have been used to develop predictive instruments. Actual clinical use of the most studied of these decision aids, the Acute Cardiac Ischemia Time-Insensitive Predictive Instrument (ACI-TIPI), resulted in a decrease of 26 percent in cardiac care unit admissions and an increase of 47 percent in ED discharges to home without increasing the number of missed AMIs. The ACI-TIPI uses a logistic regression formula that evaluates the probability of acute ischemia by analyzing specific history and ECG characteristics. The instrument has been incorporated into computerized ECG machines in the ED, and the result is printed directly onto the ECG tracing.²¹

An artificial neural network is a nonlinear statistical program that can recognize complex patterns and maintain accuracy even when some of the required data are missing. This theoretically enables users to apply the tool in real time even when they do not have all of the required data elements called for in the stratification model. The accuracy of one such tool was hypothetically tested in 2204 patients. The

network demonstrated a significant improvement over physician decision making, with a sensitivity of 94.5 percent and a specificity of 95.5 percent for the diagnosis of AMI.²² A more recent instrument has been developed to include diagnoses in the overall spectrum of myocardial ischemia.²³

Despite the demonstration of diagnostic superiority and improved cost-effectiveness compared with physician decision making alone, these instruments have not been embraced by clinicians. Among the barriers cited to acceptance of decision aids into clinical practice are medicolegal concerns, slow adoption of new technology, and physicians' fear of losing autonomy. Thus, additional work in this area must now focus on physician behavior and the interface between human and machine.

APPROACH TO LOW PROBABILITY OF ISCHEMIA

Patients identified as having ST-segment elevation MI or recognized as having a high potential for an ACS are addressed as discussed in Chap. 50. Other patients may be classified as having a very low, low, or moderate probability of acute ischemia based on clinical information available within the initial hours of their ED visit. Many investigators now recommend the use of a five-subgroup classification scheme for this initial risk stratification (Table 49-3). However, there is still no consensus regarding optimal risk subgroupings, criteria for such stratification, or agreement as to the most effective evaluation and treatment protocols after initial categorization. There is consensus on two issues regarding lower-risk patients: **history alone is inadequate to exclude the presence of acute ischemia**, and the goal should always be "zero tolerance" for missed AMI. It is also accepted that some form of systematic approach based on objective data is required to accurately and efficiently pursue further diagnostic evaluation to an appropriate end point in each patient (Figure 49-2).¹⁰

TABLE 49-3 Prognosis-Based Classification System for ED Chest Pain Patients*

I. Acute myocardial infarction: immediate revascularization candidate II. Probable acute ischemia: high risk for adverse events	
<i>Any of the following</i>	
Evidence of clinical instability (i.e., pulmonary edema, hypotension, arrhythmia)	
Ongoing pain thought to be ischemic Pain at rest associated with ischemic ECG changes One or more positive myocardial marker measurements Positive perfusion imaging study	
III. Possible acute ischemia: intermediate risk for adverse events	
<i>History suggestive of ischemia with any of the following</i>	
Rest pain, now resolved	
New onset of pain	
Crescendo pattern of pain	
Ischemic pattern on ECG not associated with pain	
IV. A. Probably not ischemia: low risk for adverse events	
<i>Requires all of the following</i>	
History not strongly suggestive of ischemia	
ECG normal, unchanged from previous, or nonspecific changes	
Negative myocardial marker measurement B. Stable angina pectoris: low risk for adverse events	
<i>Requires all of the following</i>	
More than 2 wk of unchanged symptom pattern or longstanding symptoms with only mild change in exertional pain threshold	
ECG normal, unchanged from previous, or nonspecific changes	
Negative initial myocardial marker measurement V. Definitely not ischemia: very low risk for adverse events	
<i>Requires all of the following</i>	
Clear objective evidence of non-ischemic symptom etiology	
ECG normal, unchanged from previous, or nonspecific changes	
Negative initial myocardial marker measurement	

*Authors' analyses from multiple sources.

Abbreviation: ECG = electrocardiogram.

Interpretation of the many diagnostic tests now available to assist in diagnosis and risk stratification of ED patients with possible ACS increasingly has become the responsibility of the emergency physician.

Common Diagnostic Tests Used in Emergency Cardiac Care

ECG-BASED (STANDARD) EXERCISE STRESS TESTING In the ED setting, exercise testing has been recommended for patients applied as the final component of a chest pain observation protocol after the exclusion of AMI or, in selected low-risk patients, soon after presentation as an alternative to an extended observation period.²⁴

Many variations exist in the equipment, procedures, and interpretive algorithms used. Treadmills are used more commonly in the United States, because many patients cannot reach the desired point of maximum oxygen uptake by using cycles or other devices. In appropriate patients, stress testing is safe: dysrhythmia, AMI, and death occur at rates of 4.8, 3.6, and 0.5 per 10,000 tests, respectively.

No consensus exists on the preferred protocol, although the Bruce protocol is the most common and best studied. Depending on the protocol followed, exercise is terminated when the subject reaches a predetermined percentage of predicted maximum heart rate (i.e., 85 percent) or when another defined end point is reached. The most commonly used definition of a positive exercise test result from an ECG standpoint is greater than or equal to 1 mm of horizontal or downsloping ST-segment depression or elevation for at least 60 to 80 ms after the end of the QRS complex.

Exercise stress testing may be contraindicated for various reasons (Table 49-4). If the patient has physical limitations preventing exercise but no other contraindications, a pharmacologic stress test using a chronotropic drug (i.e., dobutamine) may be appropriate. Exercise testing may not be safe for patients at high risk for acute ischemia or those with other uncontrolled cardiovascular or pulmonary pathologies. Further, patients with an abnormal baseline ECG, such as those with left ventricular hypertrophy, bundle-branch block, or digoxin effect, are less likely to benefit from standard exercise testing owing to difficulties in interpretation of exercise-induced ECG changes.

The clinical utility of ED stress testing depends on the test result's ability to modify the pretest probability of the diagnosis and to change treatment and disposition. Emergency department stress testing is particularly difficult to quantify, because test sensitivity and specificity are greatly influenced by the population being tested. As the pretest probability of significant CAD increases, the likelihood of a false-negative test also increases. Conversely, when a population with a very low pretest probability of disease is tested, the likelihood of a false-positive result increases. Therefore, based on current data, **diagnostic stress testing is recommended for patients with a low pretest probability of CAD but is unlikely to be helpful in those at very low risk (<5 percent) or moderate to high risk (>30 percent)**. The pretest probability of disease can be determined semiquantitatively based on demographic, historical, and ECG data with any of the validated decision aids previously described.

Emergency department stress testing may be of further value when applied to a broader range of patients, if the goal of testing is to predict prognosis rather than diagnosis. Many studies have confirmed that ED stress testing of selected patients can reliably predict short-term (< 1 y) prognosis.

Myocardial Imaging

ECHOCARDIOGRAPHY Advantages of *echocardiography* include its noninvasive, dynamic nature, its lack of radioactive materials, and that even sophisticated machines can be used at the bedside in the ED.²⁴ Further, it can assess the potential for other etiologies of chest pain, including aortic dissection, pericardial pathology, valvular disease, and possibly PE (see Chap. 61).

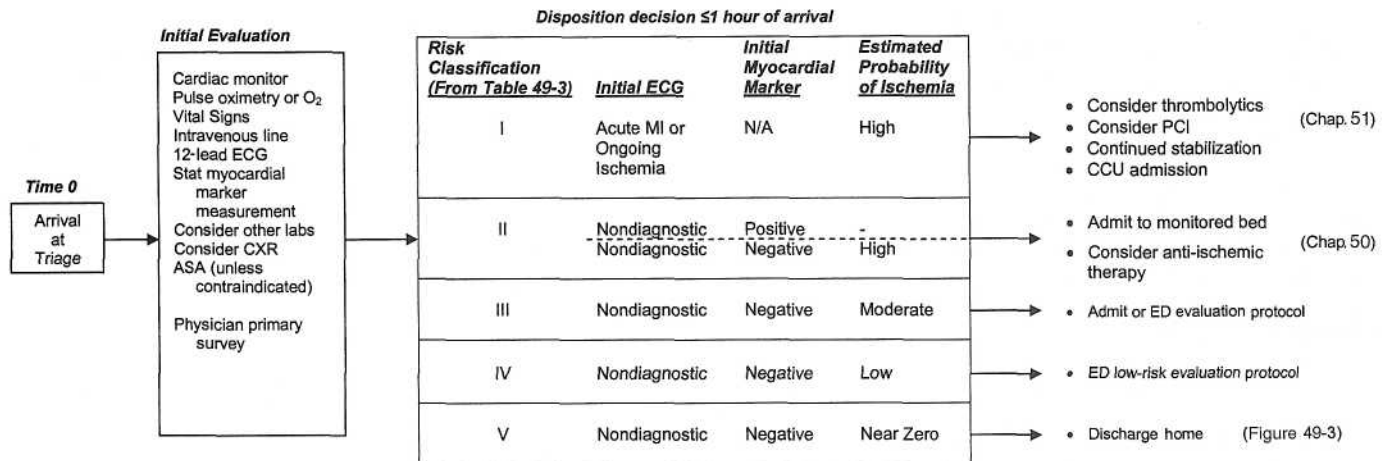

FIG. 49-2. Algorithm for risk-based decision-making. Abbreviation: PCI = percutaneous coronary intervention.

The value of echocardiography in evaluating ischemic heart disease is based largely on the experimental finding in animal and human studies that acute myocardial ischemia reliably and rapidly results in observable wall motion abnormalities. Thus, theoretically, a normal echocardiogram during chest pain should exclude the presence of ischemia. Unfortunately, this finding is limited by several factors. Because the effects of adjacent wall segments commonly lead to false-positive and false-negative interpretations of wall motion abnormalities, systolic wall thickening is used as a more specific indicator of ischemia. However, detection of wall-thickening abnormalities is highly dependent on imaging technique and interpretative skills, with up to 10 percent of tests being technically inadequate. Further, the echocardiogram cannot distinguish between myocardial ischemia and acute infarction, cannot reliably detect subendocardial ischemia, and may be falsely interpreted as positive in the presence of several conditions (conduction disturbances, volume overload, heart surgery, or trauma). Timing of the test relative to the onset of symptoms is critical, because transient wall motion abnormalities may resolve within minutes of an ischemic episode. Indeed, one prospective study of ED

patients found that resting echo within 12 h of ED arrival does not provide additional predictive value for MI over myocardial markers alone. Thus, a normal resting echocardiogram in the ED should not be used to exclude ACS.²⁵

Stress echocardiography combines a standard ECG stress test with cardiac imaging at rest and after exercise (or during pharmacologically induced tachycardia). Thus, it is superior to standard stress testing. When evaluated among low-risk ED patients, three studies have reported negative predictive values for subsequent cardiac events to be 97 to 100 percent, comparable to that of stress testing using nuclear imaging techniques.²⁵

Contrast echocardiography using physiologically safe microbubbles is a newer technique that holds future promise but is not routinely used in clinical practice. Studies have suggested that this technique significantly improves the detection of regional wall motion abnormalities and wall thickening as compared with conventional sonography. In one study, 28 percent of standard stress echoes performed were inconclusive due to difficulties in interpretation but were decisively normal or abnormal with the use of contrast. In the future, contrast echocardiography may be able to directly assess coronary vessel patency, even at the microvascular level, with sensitivity similar to or greater than that of nuclear perfusion imaging.²⁵

TABLE 49-4 Contraindications to Exercise Testing

Absolute

- Acute myocardial infarction (within 2 d)
- Unstable angina not previously stabilized by medical therapy
- Uncontrolled cardiac dysrhythmias causing symptoms or hemodynamic compromise
- Symptomatic severe aortic stenosis
- Uncontrolled symptomatic heart failure
- Acute pulmonary embolus or pulmonary infarction
- Acute myocarditis or pericarditis
- Acute aortic dissection

Relative*

- Left main coronary stenosis
- Moderate stenotic valvular heart disease
- Electrolyte abnormalities
- Severe arterial hypertension
- Tachydysrhythmias or bradydysrhythmias
- Hypertrophic cardiomyopathy and other forms of outflow tract obstruction
- Mental or physical impairment leading to inability to exercise adequately
- High-degree atrioventricular block

*Relative contraindications can be superseded if the benefits of exercise outweigh the risks.

In the absence of definitive evidence, the AHA committee suggests systolic blood pressure of >200 mm Hg and/or diastolic blood pressure of >110 mm Hg. Source: Fletcher GF, Balady G, Froelicher VF, et al: Exercise standards: A statement for healthcare professionals from the American Heart Association Writing Group. Special Report. *Circulation* 91:580, 1995.

PERFUSION IMAGING Myocardial perfusion imaging uses an intravenously injected radioactive tracer that is distributed throughout the coronary circulation (see Chap. 61). Local myocardial uptake and, subsequently, myocardial imaging therefore are dependent on adequate regional coronary flow and myocardial cell integrity. Tracer uptake occurs in direct proportion to regional myocardial blood flow.²⁴

Thallium 201 is the oldest and most studied tracer in common use today. Thallium is rapidly redistributed after initial uptake. The image represents blood flow at the moment of imaging. Areas of positive uptake reflect adequate coronary flow and viable myocardium, whereas areas without uptake represent infarcted or ischemic myocardium. On repeat imaging several hours later, continued lack of perfusion ("irreversible defect") indicates an area of infarction, whereas areas with tracer uptake only on delayed images ("reversible defect") represent previously ischemic myocardium. Combined with conventional ECG-based stress testing, thallium imaging offers improved sensitivity and specificity for detection of significant CAD over ECG-based testing alone. Further, thallium testing (or other perfusion imaging) is likely to be of value in patients who would not otherwise benefit from stress testing due to a confounding or potentially masking abnormal baseline ECG.

There are several limitations of thallium testing. Imaging must be performed soon after injection, making it impractical for use in pa-

tients with ongoing chest pain. Moreover, because of a long half-life, the injected dose of thallium must be kept low to avoid excessive radiation exposure. This and other properties of the tracer result in a relatively poor image quality and the frequent occurrence of artifactual perfusion defects (false positives) due to overlying tissue attenuation. This is particularly common in women and obese patients. Due to these limitations and the lack of ED-based efficacy studies, thallium-201 imaging alone is not an ideal agent for use in the ED.

Myocardial perfusion imaging using *technetium 99m* (^{99m}Tc)-labeled agents such as sestamibi offers advantages over thallium for ED use. Because the half-life of ^{99m}Tc is much shorter than that of thallium (6 vs. 73 h), a larger dosage can be injected without harm to the patient. This results in the superior image quality, decreased tissue attenuation-related artifacts, and higher specificity for sestamibi imaging. Newer ^{99m}Tc agents being introduced continue to improve image quality. In addition, in contrast to thallium, the initial distribution of ^{99m}Tc agents is stable for several hours. Therefore, accurate imaging can occur up to 3 h after injection. The image represents the blood flow at the moment of injection. By using "gated" image acquisition technology, sestamibi scanning can yield an accurate estimation of ejection fraction. As with thallium, resting and stress (exercise or pharmacologic) images can be compared to yield additional data.

Dual isotope stress testing using thallium and sestamibi is an increasingly common component of ED ACS evaluation protocols. In this technique, a resting thallium scan is first performed. Those patients without resting defects can then immediately undergo stress testing with sestamibi imaging, thereby avoiding the delay usually required for isotope "washout" in single isotope techniques. In a recent prospective study, a strategy using this method reliably identified or excluded ACS among 1775 low-risk ED patients.²⁶

The use of *electron-beam computed tomography* for the detection of coronary artery calcification has shown promise as a noninvasive alternative for the diagnosis of CAD. A "calcium score" is generated and is directly related to the likelihood of having CAD (within a given demographic group). Electron-beam computed tomography has a number of limitations. It cannot identify the minority of plaques that do not contain calcium, and it does not demonstrate microvascular or vasospastic disease. Although this technique shows promise as an alternative to the previously discussed imaging techniques, its role in ED evaluation remains undefined.²⁷

Low-Risk Patient Protocols

INPATIENT ADMISSION In settings where extended observation and definitive diagnostic testing are not available in the ED, all patients whose presentations suggest a reasonable plausibility of an acute ischemic event should be admitted to an inpatient bed. Once the need for inpatient admission has been determined, further stratification based on assessment of the patient's short-term risk of morbidity or mortality can be made based on the patient's history and physical examination, initial ECG, and early myocardial marker measurement. Patients with a prior history of CAD, evidence of congestive heart failure on physical examination, recurrent chest pain in the ED, or new or presumed new ischemic ECG changes are at higher short-term risk and may be more appropriately managed in an intermediate-care (step-down) unit. Conversely, patients whose initial ED ECG is normal or unchanged from a previous ECG have a very low risk of adverse events and can safely be evaluated on a monitored floor or telemetry bed. Those with nonspecific changes on the initial ECG represent an intermediate-risk group. A single myocardial marker measurement soon after ED presentation also can identify those patients at greater risk from among those with atypical presentations.

ED OBSERVATION/MONITORING In 1991, the Multicenter Chest Pain Study Group reported that the diagnosis of infarction could have been safely excluded within a 12-h observation period among a

subgroup of patients admitted for chest pain but identified at presentation as having a low probability of AMI.²⁸ The investigators also suggested routine predischARGE stress testing of these patients to reduce the risk of discharging patients with unstable coronary syndromes prematurely. Gibler and colleagues later refined this approach.²⁹ Patients with symptoms consistent but weakly suggestive of acute ischemia were observed for 9 h with continuous 12-lead ST-segment ECG monitoring and serial CK-MB testing at 0, 3, 6, and 9 h after presentation. Those who completed a negative 9-h evaluation subsequently underwent echocardiography followed by graded exercise stress testing in the ED before discharge. With this approach, 82.1 percent of patients were released home from the cardiac evaluation unit.²⁹

Although there is no consensus on the best approach, many studies have documented clinical safety and efficacy and cost savings associated with use of an ED-based Cardiac Evaluation Unit protocol compared with traditional inpatient admission, and their use has continued to expand.

Normal serial ECGs and myocardial marker measurements do not preclude the presence of other ACSs (i.e., unstable angina), which may still put the patient at high risk for a subsequent adverse event. Therefore, further evaluation is generally recommended before discharge (Figure 49-3). The various forms of stress testing (with or without myocardial imaging) currently offer the best noninvasive method to predict the presence of CAD and assess prognosis. Over the past decade, numerous published reports have confirmed the safety, clinical utility, and cost-effectiveness of various versions of this accelerated MI rule-out/early risk stratification concept, and this strategy has been incorporated into the ACC/AHA 2002 guideline update for the management of patients with unstable angina and non-ST-segment elevation MI.¹⁰

DISPOSITION

The assessment of acute chest pain patients is difficult, and the processes and approaches discussed in this chapter are not perfect. This is best illustrated in AMI, where the "miss" rate for AMI in patients evaluated in the emergency department using history, physical examination, ECG, and serum markers is currently about 2 percent; these patients were discharged and upon follow-up were determined to have sustained an AMI. The good news is that the use of serial marker measurements, evaluation or observation units, myocardial imaging studies, and stress testing has the potential to reduce this "missed-MI" rate to close to zero. Unfortunately, UA sometimes remains an elusive and difficult diagnosis. There is little information on the ED "miss rate" for the important diagnoses of aortic dissection and pulmonary embolism. Despite advances in serum marker technology and imaging studies, the physician must still exercise clinical judgment when evaluating acute chest pain patients. To make the best possible decisions, clinicians should collect adequate information first before exercising their judgment. The ability to make good decisions when faced with incomplete or uncertain information is an important skill.

The disposition of patients who have a defined diagnosis as the cause of their chest pain is relatively straightforward. Those patients without a specific diagnosis—so-called atypical chest pain—pose more of a problem. A useful principle in these patients with atypical chest pain is the use of a composite picture to assign patients to a category where the potential for ACS or other serious causes of chest pain is vanishingly small, and such patients can be safely discharged. These patients often have pain described as sharp; well localized; reproducible by position, breathing, or palpation; and have no prior diagnosis of angina or AMI. The pretest probability of ACS or other serious conditions is so low that ancillary testing is usually not indicated and patients can be discharged after the history and physical examination. Conversely, patients with unexplained visceral chest pain should not be discharged unless potentially serious conditions have been excluded using appropriate ancillary testing.

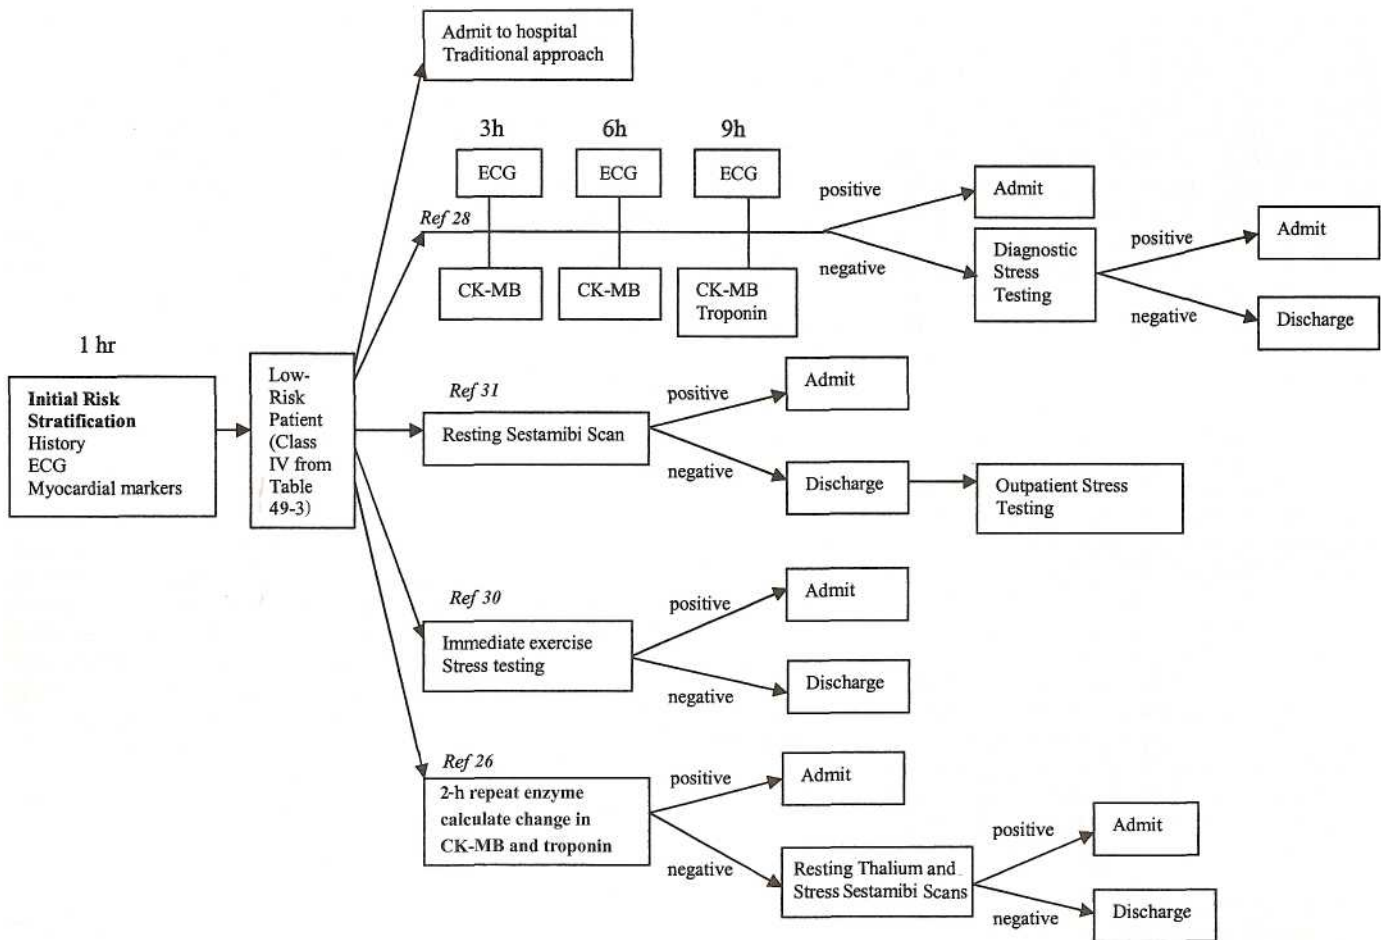

FIG. 49-3. Alternative risk stratification protocols for low-risk patients.

Discharged patients should receive appropriate instructions regarding medications and follow-up directions. They should also be instructed to seek prompt attention or return for recurrent or worsening chest pain or other serious symptoms. Some institutions have instituted chest pain clinics to ensure that patients receive appropriate follow-up after their discharge from the ED.

TABLE 50-1 Canadian Cardiovascular Society Classification of Angina

Class I	Angina occurs only with strenuous, rapid, or prolonged exertion. Ordinary physical activity does not cause angina.
Class II	Slight limitation of ordinary activity. Angina occurs with climbing stairs rapidly, walking uphill, walking after meals, in cold, in wind, or under emotional stress.
Class III	Marked limitations of ordinary physical activity. Angina occurs on walking 1-2 level blocks or climbing one flight of stairs at usual pace.
Class IV	Inability to carry on physical activity without discomfort. Anginal symptoms may be present at rest.

ocardial ischemia, often with diagnostic or suggestive electrocardiographic changes of myocardial ischemia. During the initial assessment, it is often not possible to determine whether the patient has or will sustain permanent damage to the myocardium (necrosis or AMI) or has reversible ischemia (injury or UA). Only in retrospect, after either serial ECG changes and/or serial serum markers of myocardial injury, can this distinction between AMI and UA be made. ACS is a useful concept because the triage, assessment, and initial management of UA and AMI are similar.

ANATOMY

Knowledge of the anatomy of the coronary arteries is essential to understand the effects of myocardial ischemia and why some complications are more common with anterior or inferior wall myocardial infarction (Figure 50-1). The left coronary artery arises from the ascending aorta in the left sinus of the aortic valve. It courses through the atrioventricular sulcus on the left side and divides into the left circumflex and the left anterior descending branch. The left anterior descending branch courses down the anterior aspect of the heart around the inferior margin and anastomoses with the posterior diagonal branch of the right coronary artery. It is the main blood supply to the anterior and septal regions of the heart. The circumflex branch continues around the atrioventricular sulcus, where it anastomoses with the right coronary artery. It supplies blood to some of the anterior wall and a large portion of the lateral wall of the heart. The right coronary artery arises from the right sinus of the aortic valve and runs in the atrioventricular sulcus between the right atrium and right ventricle. It gives off a marginal branch near the lower aspect of the heart and terminates as the right posterior descending artery. The right coronary artery supplies the right side of the heart with blood, and it provides some

TABLE 50-2 Principal Presentations of Unstable Angina

Rest angina	Angina occurring at rest and usually prolonged >20 min occurring within a week of presentation
New-onset angina	Angina of at least CCSC III severity with onset within 2 mo of presentation
Increasing angina	Previously diagnosed angina that is distinctly more frequent, longer in duration, or lower in threshold (increased by at least one CCSC class to at least CCSC III severity).

Abbreviation: CCSC = Canadian Cardiovascular Society Classification. Source: Braunwald E, Mark DB, Jones RH, et al: *Unstable Angina: Diagnosis and Management*. **ACUTE CORONARY SYNDROMES:
ACUTE MYOCARDIAL INFARCTION
AND UNSTABLE ANGINA Judd
E. Hollander**

Ischemic heart disease is the leading cause of death among adults in the United States, accounting for more than 500,000 deaths annually. Atherosclerotic disease of the epicardial coronary arteries—termed *coronary artery disease*, or CAD—accounts for the vast majority of patients with ischemic heart disease. The predominant symptom of CAD is chest pain, and concern over potential CAD and myocardial ischemia contributes to the over 5 million visits each year to U.S. EDs for acute chest pain. In a typical adult ED population with acute chest pain, about 15 percent of patients will have acute myocardial infarction and about 25 to 30 percent will have unstable angina.

Ischemic heart disease represents a spectrum from chronic stable angina to acute myocardial infarction (AMI). Three categorization schemes are commonly used in ischemic heart disease patients. The first is the Canadian Cardiovascular Society categorization of angina into four classes (Table 50-1). The second is the categorization of unstable angina (UA) into three principal presentations by the Agency for Health Care Policy and Research (Table 50-2).¹ Both of these classifications assume a diagnosis of ischemic heart disease and their utility is problematic in the ED when patients present with acute chest pain that may or may not be due to ischemic heart disease. The third categorization scheme assesses the short-term risk for patients with unstable angina (UA) (Table 50-3).

Acute Coronary Syndrome (ACS) is a term used to describe patients who present with acute chest pain and other symptoms of my-

SECTION 7 • CARDIOVASCULAR DISEASE

TABLE 50-3 Short-Term Risk of Death or Nonfatal Myocardial Infarction by Risk Stratification in Patients with Unstable Angina

High Risk	Intermediate Risk	Low Risk
<i>At least one of the following features must be present</i>	<i>No high-risk feature but must have one of the following</i>	<i>No high- or intermediate-risk features but may have any of the following features</i>
Prolonged ongoing (>20 min) rest pain	Prolonged (>20 min) rest angina, now resolved, with moderate or high likelihood of CAD	Increased angina frequency, severity, or duration
Pulmonary edema, most likely related to ischemia	Rest angina (>20 min) not promptly relieved with rest or sublingual nitroglycerin	Angina provoked at a lower threshold
Angina at rest with dynamic ST changes >1 mm	Nocturnal angina	New-onset angina with onset 2 wk to 2 mo before presentation
Angina with new or worsening MR murmur	Angina with dynamic T-wave changes	Normal or unchanged ECG
Angina with S ₃ or new or worsening rales	New-onset CCSC III or IV angina in the past 2 wk with moderate or high likelihood of CAD	
Angina with hypotension	Pathologic Q waves or resting ST depression ≥1 mm in multiple-lead groups (anterior, inferior, and lateral)	
Age >65 y		

Abbreviations: CAD = coronary artery disease; CCSC = Canadian Cardiology Society Classification; ECG = electrocardiogram; MR = mitral regurgitation. **Source:** Braunwald E, Mark DB, Jones RH, et al: *Unstable Angina: Diagnosis and Management*. Clinical Practice Guideline No. 10 (amended). AHCPR Publication No. 94-0602. perfusion to the inferior aspect of the left ventricle through the posterior descending artery.

The atrioventricular (AV) conduction system receives blood supply from the AV branch of the right coronary artery and the septal perforating branch of the left anterior descending coronary artery. Similarly, the right bundle branch and the left posterior division obtain a dual blood flow from the left anterior descending and right coronary arteries. The posteromedial papillary muscle receives blood supply from one coronary artery, usually the right coronary artery.

PATHOPHYSIOLOGY

Hypoxia is a deficiency in oxygen supply or availability to tissues. Ischemia is oxygen deprivation accompanied by inadequate removal of metabolites due to reduced perfusion. Ischemia and hypoxia are relative terms, because conditions that result in ischemia in one patient may not result in ischemia in another. Ischemia occurs when there is an imbalance between oxygen demand and oxygen supply. Oxygen supply is influenced by the oxygen-carrying capacity of the blood and the coronary artery blood flow. The oxygen-carrying capacity of the blood is determined by the amount of hemoglobin present and oxygen

saturation. Coronary artery blood flow is determined by the duration of diastolic relaxation of the heart and peripheral vascular resistance. Humoral, neural, metabolic, and extravascular compressive forces and local autoregulation mechanisms determine the coronary vascular resistance.

Myocardial ischemia and its sequelae usually occur as a result of fixed atherosclerotic lesions. ACS is caused by secondary reduction in myocardial blood flow due to coronary arterial spasm, disruption of atherosclerotic plaques, and platelet aggregation or thrombus formation at the site of an atherosclerotic lesion. Nonatherosclerotic etiologies of ACS are considerably less common.

Atherosclerotic plaque formation occurs through repetitive injury to the vessel wall. Macrophages and smooth muscle cells are the main cellular elements in plaque development, whereas lipids are predominant in the extracellular milieu. Plaque fissuring and rupture are affected by features inherent to the plaque, such as its composition and shape, and local factors, such as shear forces, coronary arterial tone, coronary arterial perfusion pressure, and movements of the artery in response to myocardial contractions. When plaque rupture occurs, potent thrombogenic substances are exposed to circulating platelets.

The platelet response involves adhesion, activation, and aggregation. Platelet adhesion occurs through the weak platelet interactions with subendothelial adhesion molecules, such as collagen, fibronectin, and laminin, and the binding of the glycoprotein Ib receptor to the subendothelial form of von Willebrand factor. Adherent platelets are strongly thrombogenic because subendothelial collagen is a potent inducer of platelet activation. Lipid-laden macrophages in the plaque core and adventitia of the vessel wall release tissue factor, which stimulates the conversion of prothrombin to thrombin. Thrombin and the local shear forces are also potent platelet activators. Platelet secretion of adenosine diphosphate, thromboxane A₂, and serotonin are autostimulatory agonists of platelet activation. Activated platelet glycoprotein IIb/IIIa receptors become cross-linked by fibrinogen or von Willebrand factor in the final common pathway of platelet aggregation.

The extent of oxygen deprivation and thus clinical presentation of ACS depend on the limitation of O₂ delivery imposed by thrombus adhering to fixed, fissured, or eroded atherosclerotic plaque. Myocardial ischemia can be manifest by chest or epigastric discomfort, dyspnea, characteristic or nonspecific electrocardiographic changes, depressed myocardial function, reduced central and peripheral perfusion, or any combination of the above. In stable angina, ischemia occurs only when

FIG. 50-1. diagram of the arteries.

activity induces O₂ demands beyond the supply restrictions imposed by a partially occluded coronary vessel. This occurs at a relatively fixed and predictable point and changes slowly over time. Atherosclerotic plaque has not ruptured, and there is little, if any, superimposed thrombus. In ACS, atherosclerotic plaque rupture and platelet-rich thrombus develop. Coronary blood flow is reduced and myocardial ischemia occurs. The degree and duration of the oxygen supply-demand mismatch determines whether the patient develops reversible myocardial ischemia without necrosis (unstable angina) or myocardial ischemia with necrosis (myocardial infarction). More severe and prolonged obstruction increases the likelihood of infarction.

Acute myocardial ischemia may inhibit myocardial contractility, thereby affecting central and peripheral perfusion. In AMI, the fundamental alteration is loss of functioning myocardium. When an area of the myocardium does not receive adequate O₂, the functional deterioration is progressive through four sequentially abnormal contraction patterns. *Dyssynchrony*, the dissociation in time course of contraction of adjacent segments of myocardium, occurs first. *Hypokinesis*, the reduction in the extent of shortening with contraction, occurs next. *Akinesis*, the cessation of shortening with systolic contraction, follows. *Dyskinesis*, the paradoxical expansion of infarcted tissue, occurs during systole. With increasing size of the infarcted myocardium, left ventricular pump function decreases. Left ventricular end-diastolic pressure and left ventricular end-systolic volume increase. Cardiac output, stroke volume, and blood pressure may decrease. When left atrial and pulmonary capillary pressures increase, congestive heart failure or pulmonary edema may develop. Poor perfusion to the brain and kidneys can result in altered mental status and impaired renal function, respectively.

CLINICAL FEATURES

Clinical History

The main symptom of ischemic heart disease is chest pain, and the history should characterize its severity, location, radiation, duration, and quality. In addition, the presence of associated symptoms, such as nausea, vomiting, diaphoresis, dyspnea, lightheadedness, syncope, and palpitations, may be helpful. A history regarding the onset and duration of symptoms, activities that precipitate symptoms, and prior evaluations for similar symptoms should be ascertained.

Symptoms of acute myocardial ischemia often will be described as discomfort rather than as pain. Anginal symptoms include chest pressure, heaviness, tightness, fullness, or squeezing. Less commonly but not infrequently, patients will describe their symptoms as knifelike, sharp, or stabbing. The classic location is substernal or in the left chest. Radiation to the arm, neck, or jaw may occur. Reproducible chest wall tenderness is not uncommon, possibly because the pericardium may become inflamed and it sits beneath the chest wall.

Exercise, stress, or a cold environment classically precipitates angina pectoris. Angina usually has a duration of symptoms of typically <10 min, occasionally lasting up to 10 to 20 min, and usually improves within 2 to 5 min after rest or nitroglycerin. However, early classic descriptions of angina describe episodes as short as 2 min. In contrast, AMI is usually accompanied by more prolonged and severe chest discomfort, more prominent associated symptoms (nausea, diaphoresis, shortness of breath, etc.), and little, if any, response to initial sublingual nitroglycerin. Easy fatigability may be a prominent symptom of ACS.

It is important to know the frequency of anginal episodes and any change in frequency of episodes over the past months. The patient should be questioned to determine any increase in severity or duration of symptoms or whether less effort is required to precipitate them.

Atypical presentations or silent myocardial ischemia are common. Up to 30 percent of patients with AMI identified in large longitudinal

studies are clinically unrecognized. Some of these patients have had atypical symptoms for which they did not pursue medical advice. Others cannot recall any symptoms. The prognosis for patients who have atypical symptoms at the time of their infarction is worse than that of patients who had more typical symptoms. Women and the elderly are more likely to have atypical presentations.

Cardiac risk factors are modestly predictive of CAD in asymptomatic patients. **In the ED, cardiac risk factors are poor predictors of cardiac risk for myocardial infarction or other ACS.**² Traditional cardiac risk factors for CAD, such as hypertension, diabetes mellitus, tobacco use, family history of CAD at an early age, and hypercholesterolemia, are not predictive of ACS in female ED chest pain patients. In male patients, only diabetes and family history are weakly predictive.³ The distinction between the utility of cardiac risk factors in the asymptomatic patient and the ED chest pain patient is easy to understand. The cardiac risk factors were derived from population-based longitudinal cohort studies of asymptomatic patients to determine risk of CAD. In contrast, cardiac risk factors for CAD have significantly less predictive value for an acute event than the mere presence of symptoms.

Physical Examination

The physical examination is not helpful in distinguishing patients with ACS from those with noncardiac etiologies when an alternate diagnosis is not clear. Patients with ACSs may appear deceptively well without any clinical signs of distress or may be uncomfortable, pale, cyanotic, and in respiratory distress. The pulse rate may be normal or display bradycardia, tachycardia, or irregular pulses. Bradycardic rhythms are more common with inferior wall myocardial ischemia. In the setting of an anterior wall infarction, bradycardic rhythms or heart block is an extremely poor prognostic sign. Blood pressure can be normal, elevated (due to baseline hypertension, sympathetic stimulation, and anxiety), or decreased (due to pump failure or inadequate preload). Extremes of blood pressure are associated with a worse prognosis.

The first and second heart sounds are often diminished due to poor myocardial contractility. An S₃ is present in 15 to 20 percent of patients with AMI. An S₄ is common in patients with long-standing hypertension or myocardial dysfunction. The presence or absence of the noted heart sounds is not usually helpful in the ED, although an S₃, if truly detected, may imply a failing myocardium. However, the presence of a new systolic murmur is an ominous sign, because it may signify papillary muscle dysfunction, a flail leaflet of the mitral valve with resultant mitral regurgitation, or a ventricular septal defect.

The presence of rales, with or without an S₃ gallop, is associated with left ventricular dysfunction and left-sided congestive heart failure. Jugular venous distention, hepatojugular reflex, and peripheral edema suggest right-sided congestive heart failure. It is important to determine the patient's baseline condition from medical records or from the patient's physician to establish the presence of new findings that may help guide management.

Electrocardiography

The standard 12-lead ECG is the single best test to identify patients with AMI upon ED presentation.⁴ **Published consensus guidelines establish a goal that the initial 12-lead ECG be obtained and integrated within 10 min of presentation for patients with acute chest pain or other symptoms suggestive of myocardial ischemia.** Although the ECG is the best immediately available test in the ED, it has relatively low sensitivity for detection of AMI. The ST segment is elevated on the initial ECG in approximately 50 percent of patients; i.e., half of the patients who present to the ED with AMI will not have diagnostic ST-segment changes on the initial ECG. Most other AMI patients without diagnostic ST-segment elevation will have ST-segment depression and/or T-wave inversions, and only 1 to 5 percent of patients with AMI have an entirely normal initial ECG.⁵

Standard diagnostic ECG criteria for AMI are shown in Table 50-4. ST-segment elevations in the distributions shown suggest acute transmural injury. ST-segment depressions in these distributions suggest subendocardial ischemia. **All inferior wall acute myocardial infarctions should have a right-sided lead V₄ (V_{4R}) obtained**, because ST-segment elevation in V_{4R} is highly suggestive of right ventricular infarction.

Reciprocal ST-segment changes (such as ST-segment depressions in the anterior precordial leads in the setting of an inferior wall AMI) predict a larger infarct distribution, an increased severity of underlying CAD, more severe pump failure, a higher likelihood of cardiovascular complications, and increased mortality. In general, the more elevated the ST segments and the more ST segments that are elevated, the more extensive the injury.

The ECG can also be used to predict the infarct-related vessel. Inferior wall myocardial infarctions can result from occlusion of the left circumflex artery or the right coronary artery. In the setting of an inferior wall AMI, ST-segment elevation in at least one lateral lead (V₅, V₆, or aV_L) with an isoelectric or elevated ST segment in lead I is strongly suggestive of a left circumflex lesion. The presence of ST-segment elevation in lead III greater than that in lead II predicts a right coronary artery occlusion. When accompanied by ST-segment elevation in V_I or a V_{4R}, it predicts a proximal right coronary artery lesion with accompanying right ventricular infarction. Reciprocal anterior ST-segment depressions in V_I through V₄ are equally prevalent in right coronary and left circumflex inferior wall AMIs.

The main utility of the ECG is to detect AMI. The standard 12-lead ECG is less helpful in the detection of unstable angina. One classification system divides the ECG into six categories:

1. Normal
2. Nonspecific ST-segment or T-wave changes: less than 1 mm ST-segment depression directed toward the baseline, T waves flattened or diphasic
3. Abnormal, but not diagnostic of ischemia or infarction: less than 1 mm ST-segment depression horizontal to the baseline, T waves inverted
4. Ischemia, strain, or infarction known to be old: Q waves, more than 1 mm ST-segment depression horizontal to or directed away from the baseline, and T-wave inversions noted on prior ECGs.
5. Ischemia, strain, or infarction not known to be old: Q waves, more than 1 mm ST-segment depression horizontal to or directed away from the baseline, and T-wave inversions either not noted on prior ECGs or no prior ECG available.
6. Probable AMI: ST-segment elevation greater than 1 mm in two contiguous ECG leads

This classification and others like it have been used to show that patients with more significant ECG abnormalities are more likely to have

AMI, unstable angina, and serious cardiovascular complications. Nonetheless, even patients with normal or nonspecific ECGs have a 1 to 5 percent incidence of AMI and a 4 to 23 percent incidence of unstable angina. Patients with nondiagnostic ECGs or evidence of ischemia that is age-indeterminate have a 4 to 7 percent incidence of AMI and a 21 to 48 percent incidence of unstable angina. Demonstration of new ischemia in ECG increases the risk of AMI from 25 to 73 percent and the unstable angina risk from 14 to 43 percent.⁴ Thus, the standard 12-lead ECG is useful for cardiovascular risk stratification of patients with ACSs.⁶ It can be used in conjunction with clinical history and cardiac markers to determine admission location for such patients.

The addition of other leads to the standard 12-lead ECG modestly increases sensitivity for detection of AMI, but reduces specificity.⁷ The only recommended addition to the standard 12-lead ECG is the use of right-sided precordial leads in the setting of acute inferior myocardial infarction in order to detect right ventricular involvement.⁴

There are several clinical conditions in which ECG interpretation is difficult (Table 50-5). It is occasionally possible that in the setting of paced rhythms and left bundle-branch blocks, acute myocardial ischemia can be identified. In the setting of a left bundle-branch block, the following three ST-segment patterns are indicative of AMI: (1) ST-segment elevation 1 mm or greater and concordant (in the same direction as the main deflection) with the QRS complex (odds ratio 25.2, 95% CI 11.6 — 54.7), (2) ST-segment depression 1 mm or more in leads V_I, V₂, or V₃ (odds ratio 6.0, 95% CI 1.9 - 19.3), and (3) ST-segment elevation 5 mm or greater and discordant (in the opposite direction) with the QRS complex (odds ratio 4.3, 95% CI 1.8 - 10.6).⁸

Right ventricular pacing causes secondary repolarization changes of opposing polarity to that of the predominant QRS complex. Most leads have predominant negative QRS complexes followed by ST-

TABLE 50-4 Electrocardiographic Criteria for Acute Myocardial Infarction

Location	Electrocardiographic findings
Anteroseptal	QS deflections in V ₁ , V ₂ , V ₃ , and possibly V ₄
Anterior	rS deflection in V _I with Q waves in V ₂ –V ₄ or decrease in amplitude of initial R waves in V _I –V ₄
Anterolateral	Q waves in V ₄ –V ₆ , I, and aV _L
Lateral	Q waves in I and aV _L
Inferior	Q waves in II, III, and aV _F
Inferolateral	Q waves in II, III, aV _F , and V ₅ and V ₆
True posterior	Initial R waves in V ₁ and V ₂ >0.04 s and R/S ratio a 1
Right ventricular	Q waves in II, III, and aV _F and ST elevation in right-side V ₄

segment elevation and positive T waves. ST-segment elevation of at least 5 mm is the finding most indicative of AMI in leads with predominantly negative QRS complexes.⁹ Any ST-segment elevation concordant to the QRS complex in a predominantly positive QRS complex is highly specific for AMI. The QRS complex is predominantly negative in leads V₁ to V₃ with RV pacing. ST-segment depression in these leads has 80 percent specificity for AMI.⁹

Serum Markers of Myocardial Injury

The utility of serum markers depends on their ability to detect and risk-stratify patients with ACS (Table 50-6). For example, patients with diagnostic ST-segment elevation on their initial ECG do not require serum marker measurement to make appropriate treatment and disposition decisions. Conversely, serum markers are useful in patients with nondiagnostic ECGs for both diagnosis and risk stratification.^{10,14} Markers vary in terms of their molecular weight, cellular location, solubility, plasma concentration, clearance, and ability to be detected accurately in serum with rapid immunochemical techniques. In general, serial measurements are more sensitive and accurate than initial single measurements, and serial sampling every 2 to 3 h is a validated practice for the rapid exclusion of AMI in acute chest pain patients.

Serum markers have less utility in the diagnosis of UA, only about half or less of these patients will demonstrate low levels of troponin elevation. Conversely, these low-level troponin elevations are independent risk factors for acute (<30 d) cardiac complications and short-term (<1 y) prognosis in UA.^{12,14}

The creatine kinase MB isoenzyme (CK-MB) is the most commonly used serum marker in ACS. A serial rise in CK-MB to above five times baseline followed by a fall back to baseline is considered diagnostic for AMI. Sensitive mass assays are widely available, and quantitative point-of-care testing technology is available to use at the bedside. The typical time course for CK-MB rise following an AMI is a peak value at 12 to 24 h, with a fall back to baseline in 2 to 3 d. CK-MB is useful for detecting recurrent infarction after the initial 1 to 2 d by noting a repeat elevation in its level.

The troponin complex is the main regulatory protein for the actin-myosin myofibrils. This complex consists of three subunits: an inhibitory subunit (troponin I), tropomyosin-binding subunit (troponin T), and a calcium-binding subunit (troponin C). Isoforms of both troponins I and T specific to cardiac muscle have been identified. In fact, the cardiac isoform of troponin I (cTnI) has not been identified in skeletal muscle during any stage of development, whereas low levels

of the cardiac isoform of troponin T (cTnT) has been found in various skeletal muscle disorders. Assays for both troponins have undergone several generations of development, and currently available tests are highly specific. The typical time course for troponin rise following an AMI is a peak level in 12 h with a prolonged elevation for 7 to 10 d before returning to baseline. This sustained presence makes either troponin useful for diagnosis of AMI when the patient presents days after symptom onset. However, because of the prolonged elevation, troponins are not useful for detecting recurrent infarction during initial hospitalization.

A rise in serum troponin I or T is now accepted as diagnostic for AMI.¹⁵ Low-level elevations in either troponin correlate with risk for cardiovascular complications in UA, CAD, and renal failure.^{12,14}

Cardiac Imaging

Echocardiography and nuclear scintigraphy have a complimentary role in the diagnosis and assessment of ACS patients. Echocardiography, using the criterion of regional wall motion abnormalities, has been reported to have a high sensitivity (above 90 percent) for AMI.¹⁶ However, this imaging study is operator-dependent, many patients have technically inadequate studies, and specificity for AMI is only 50 to 60 percent. Echocardiography is more useful in assessing the extent of myocardial impairment for risk-stratification and detecting complications of acute infarction.¹⁷

Nuclear scintigraphy using technetium-99m sestamibi is a radionuclide that is taken up by the myocardium in proportion to myocardial blood flow at the time of injection. This allows administration of the isotope during symptomatic episodes but enables imaging after patient stabilization. Technetium sestamibi scanning is highly sensitive and specific for CAD and has short-term (< 1 y) predictive value in patients with acute chest pain.¹⁶ Sestamibi scanning is useful in the ACS patient who does not have serial ECG or serum marker changes of AMI and is not a candidate for standard stress testing.

COMPLICATIONS OF MYOCARDIAL INFARCTION AND ISCHEMIA

Myocardial perfusion and cardiac function affect blood flow to the entire body. As a result, any end organ can be damaged when cardiac pump function is decreased. In this section, discussion of the complications of ACS is limited to the direct effects on the heart. The systemic effects of cardiac function are discussed in organ-appropriate

TABLE 50-6 Summary of Predictive Properties of Cardiac Markers of Diagnosis of Acute Myocardial Infarction

At time of presentation					
CK	12	3195	37 (31–44)	87 (80–91)	3.9 (2.7–5.7)
CK-MB	19	6425	42 (36–48)	97 (95–98)	25 (18–36)
Myoglobin	18	4172	49 (53–55)	91 (87–94)	11 (8–15)
Troponin I	4	1149	39 (10–78)	93 (88–97)	11 (3.4–34)
Troponin T	6	1348	39 (26–53)	93 (90–96)	9.5 (5.7–16)
CK-MB and myoglobin	3	2283	83 (51–96)	82 (68–90)	17 (7.6–40)
Serial markers					
CK	2	786	69–99	68–84	12–220
CK-MB	14	11,625	79 (71–86)	96 (95–97)	140 (65–310)
Myoglobin	10	1277	89 (80–94)	87 (80–92)	84 (44–160)
Troponin I	2	1393	90–100	83–96	230–460
Troponin T	3	904	93 (85–97)	85 (76–91)	83 (33–210)
CK-MB and myoglobin	2	291	100	75–91	4.3–14

Marker	Studies, n	Subjects, n	Sensitivity (95% CI)	Specificity (95% CI)	Diagnostic Odds Ratio (95% CI)

chapters of this book. The treatment of these complications is discussed in Chap. 51.

Dysrhythmias and Conduction Disturbances

The genesis, diagnosis, and treatment of dysrhythmias are presented in Chap. 28. The effect dysrhythmias have in complicating the course of patients with ACSs is the subject of this section.

Dysrhythmias occur in 72 to 100 percent of AMI patients treated in the coronary care unit.¹⁸ Table 50-7 shows the approximate frequency of the various dysrhythmias observed in patients with AMI. Many of these dysrhythmias occur in the prehospital and ED settings. The main consequence of these dysrhythmias is that they may impair hemodynamic performance, compromise myocardial viability by increasing myocardial oxygen requirements, and predispose to even more serious rhythm disturbances by diminishing the ventricular fibrillation threshold.

Early in the course of AMI, patients frequently exhibit evidence of increased autonomic nervous system activity. Sinus bradycardia, atrioventricular block, and hypotension may occur from increased vagal tone. Activation of atrial and ventricular receptors in the myocardium may result in enhanced efferent sympathetic activity, increased circulating catecholamines, and increased local catecholamine release. These increased catecholamines in the setting of a sensitive myocardium form the substrate for the generation of tachyarrhythmias. Electrical instability during AMI results in ventricular premature beats, ventricular tachycardia, ventricular fibrillation, accelerated idioventricular rhythms, and some AV junctional tachycardias.

The hemodynamic consequences of dysrhythmias are dependent on ventricular function. Patients with left ventricular dysfunction have a relatively fixed stroke volume. They depend on changes in heart rate to alter cardiac output. The range of heart rate that is optimal becomes narrowed with increasing dysfunction. Slower or faster heart rates may further depress cardiac output.

In addition, maintenance of the atrial kick is important for patients with AMI. Patients with normal hearts have a loss of 10 to 20 percent of left ventricular output when the atrial kick is eliminated. Patients with reduced left ventricular compliance, as occurs from AMI, have up to 35 percent reduction in stroke volume when the atrial systole is eliminated.

TABLE 50-7 Frequency of Occurrence of Arrhythmias During Acute Myocardial Infarction

Arrhythmia	Frequency of Occurrence, %
Bradydysrhythmias	
Sinus bradycardia	15-40
First-degree AV block	4-14
Second-degree AV block, type I	4-10
Second-degree AV block, type II	<1
Third-degree AV block	5-8
Asystole	1-14
Tachydysrhythmias	
Sinus tachycardia	33
Atrial premature contractions	50
Supraventricular tachycardia	
Atrial fibrillation	2-11
Atrial flutter	
Ventricular premature beats	10-15
Accelerated idioventricular rhythm	1-3
Ventricular tachycardia	>90
Ventricular fibrillation	8-20

Abbreviation: AV = atrioventricular.

Source: Pasternack RC, Braunwald E, Sobel BE: Acute myocardial infarction, in Braunwald E (ed): *Heart Disease. A Textbook of Cardiovascular Medicine*, 4th ed. Philadelphia, WB Saunders, 1992, pp. 1239-1245.

"Pump" failure with resultant increased sympathetic stimulation results in sinus tachycardia, atrial fibrillation or flutter, and supraventricular tachycardias. Conduction disturbances result in bradydysrhythmias, such as sinus bradycardia, junctional escape rhythms, and atrioventricular and idioventricular blocks.

The significance of cardiac dysrhythmias during AMI is the subject of some debate. On the one hand, sinus bradycardia during the early phases of AMI may predispose to hypotension and repetitive ventricular dysrhythmias. On the other hand, it appears to be protective, because it reduces the myocardial oxygen requirement. The net effect is that the presence of sinus bradycardia does not appear to increase mortality during AMI.

Almost all patients with first-degree AV block have infranodal disturbances above the His bundle and will not progress to higher degrees of AV block. Mobitz I (Wenckebach) accounts for 90 percent of second-degree AV block. It generally occurs within the AV node, is associated with narrow QRS complexes, and results from ischemic injury. It is more common with inferior than with anterior AMI, is intermittent usually during the first 72 h after infarction, and rarely progresses to complete heart block or other pathologic rhythm. Conversely, Mobitz II second-degree heart block originates from conduction lesions below the His bundle, is associated with a wide QRS complex, is usually associated with anterior AMI, and does progress to complete heart block.

Complete heart block can occur in patients with anterior and inferior AMI, because the atrioventricular conduction system receives blood supply from the AV branch of the right coronary artery and the septal perforating branch of the left anterior descending coronary artery. Complete heart block occurs in the setting of inferior myocardial infarction; it usually progresses from lesser forms of AV block.¹⁹ This form of third-degree block is usually stable and should resolve. In the absence of right ventricular involvement, the mortality is approximately 15 percent. It rises to greater than 30 percent when right ventricular involvement is present. In contrast, complete heart block in the setting of an anterior MI is seldom benign and portends a grave prognosis. Junctional rhythms are usually transient and occur within 48 h of infarction. Whether they affect long-term prognosis is not clear.

Sinus tachycardia is quite prominent in patients with anterior wall AMI. Because of increased myocardial oxygen use, persistent sinus tachycardia is associated with a poor prognosis. The etiology of the sinus tachycardia should be determined. It may include anxiety, pain, left ventricular failure, fever, pericarditis, hypovolemia, atrial infarction, pulmonary emboli, or use of medications that accelerate heart rate. Similarly, paroxysmal supraventricular tachycardia, atrial fibrillation, and atrial flutter are associated with an increased mortality. Atrial premature contractions are common. They occur in up to 50 percent of AMI patients and are not associated with an increased mortality related to the acute event.

Ventricular premature contractions are common in patients with AMI. They do not appear to have much prognostic ability. Accelerated idioventricular rhythms in patients with AMI have not been shown to have an effect on prognosis. Ventricular tachycardia shortly after AMI is often transient and does not portend a poor prognosis. When ventricular tachycardia occurs late in the course of AMI, it is usually associated with transmural infarction and left ventricular dysfunction, induces hemodynamic deterioration, and is associated with a mortality rate approaching 50 percent. Primary ventricular fibrillation occurring shortly after symptom onset does not appear to have a large effect on mortality and prognosis. Delayed or secondary ventricular fibrillation during hospitalization is associated with severe ventricular dysfunction and a 75 percent in-hospital mortality.

Intraventricular conduction disturbances occur in 10 to 20 percent of patients with AMI. Approximately half of these disturbances are already present at the time of ED presentation and may not represent a new finding. Blood supply to the anterior division of the left bundle branch comes from septal perforators of the left anterior descending

coronary artery. The right bundle branch and the posterior division of the left bundle branch obtain a dual blood flow from the left anterior descending and right coronary arteries. For this reason, left anterior hemiblock is more common.

New right bundle-branch block occurs in approximately 2 percent of AMI patients, most commonly anteroseptal AMI, and is associated with an increased mortality, because it often leads to complete AV block. New left bundle-branch block occurs in 5 percent of patients with AMI and is associated with a high mortality. The left posterior fascicle is larger than the left anterior fascicle. Thus, left posterior hemiblock is associated with a higher mortality than is isolated left anterior hemiblock, because it represents a larger area of infarction. Bifascicular block (right bundle-branch block and a left hemiblock) is associated with an increased likelihood of progression to complete heart block; it represents a large infarction and is associated with an increased likelihood of pump failure and mortality.¹⁹ Other combinations of heart block and their treatment are discussed in Chap. 28.

Cardiac Failure

Some 15 to 20 percent of patients with AMI present in some degree of congestive heart failure. One third of these patients have circulatory shock. In the setting of AMI, congestive heart failure can occur through diastolic dysfunction alone or a combination of systolic and diastolic dysfunction. Left ventricular diastolic dysfunction leads to pulmonary congestion. Systolic dysfunction is responsible for decreased forward flow, reduced cardiac output, and reduced ejection fraction. In general, the more severe the degree of left ventricular dysfunction, the higher the mortality. The degree of left ventricular dysfunction in any single patient is dependent on the net effect of prior myocardial dysfunction (prior MI or cardiomyopathy), baseline myocardial hypertrophy, acute myocardial necrosis, and acute reversible myocardial dysfunction ("stunned myocardium").

Patients with AMI can be classified into four subsets based on hemodynamic status (Forrester-Diamond-Swan classification) and clinical status (Killip classification), shown in Tables 50-8 and 50-9. These classifications are useful to guide therapy and predict response to treatment. Patients with decreasing cardiac output or increasing pulmonary congestion have an increasingly higher mortality in the setting of AMI. Class I patients have a mortality of 2 to 5 percent. Class IV patients (i.e., those with cardiogenic shock) are at very high risk of mortality (50 to 80 percent). B-type natriuretic peptide, a powerful predictor of outcome in patients with congestive heart failure, is also useful for risk stratification of patients with non-ST-segment elevation

TABLE 50-8 Forrester-Diamond-Swan Hemodynamic Classification

Class	Cardiac Index L/min per m ²	Pulmonary Artery Wedge Pressure, mm Hg	Approximate Mortality, %
I: No pulmonary congestion or hypoperfusion	>2.2	<18	2–3
II: Isolated pulmonary congestion	>2.2	>18	10
III: Isolated peripheral hypoperfusion	<2.2	<18	2–25
IV: Pulmonary congestion and peripheral hypoperfusion	<2.2	>18	50–55

TABLE 50-9 Killip Clinical Classification

Class	Approximate Mortality, %
I: No congestive heart failure	5
II: Mild congestive heart failure (bibasilar rales and an S ₃)	15–20
III: Frank pulmonary edema	40
IV: Cardiogenic shock	80

myocardial infarction and unstable angina. Elevated levels of BNP early in the hospital course portend a worse 30-day outcome.²⁰

The presence of shock in AMI results in a complex spiral relationship. Coronary obstruction leads to myocardial ischemia, which in turn impairs myocardial contractility and ventricular outflow. The resulting reduction in arterial blood pressure leads to further decreases in coronary arterial perfusion, resulting in worsening myocardial ischemia and more severe myocardial necrosis. Interruption of this downward spiral requires careful attention to fluid management and the use of inotropic agents.²¹ Resolution of ischemia and preventing or minimizing the area of stunned myocardium that progresses to infarction is imperative.

Mechanical Complications of AMI

Sudden decompensation of previously stable patients should always raise concern of the "mechanical" complications of AMI. As a group, these complications usually involve the tearing or rupture of infarcted tissue. Therefore, they are unlikely to occur in patients with non-AMI ACSs. The clinical presentation of these entities depends on the site of rupture (papillary muscles, interventricular septum, or ventricular free wall).

Free wall rupture occurs in 10 percent of AMI fatalities, usually 1 to 5 days after infarction. Rupture of the left ventricular free wall usually leads to pericardial tamponade and death (in more than 90 percent of cases). Patients may complain of tearing pain or sudden onset of severe pain. They will be hypotensive and tachycardic and may have onset of confusion and agitation. Increased neck veins, decreased heart sounds, and pulsus paradoxus may be present. Echocardiography is the diagnostic test of choice, although near equalization of right atrial, right ventricular mid-diastolic, and right ventricular systolic pressures on pulmonary artery catheterization may also be useful. Treatment is surgical.

Rupture has been attributed to intense necrosis at the distal end of blood supply, poor collateral blood flow, and a thin apical left ventricular wall in conjunction with the shearing effects of muscle contraction. Anti-inflammatory medications, steroids, and late administration of thrombolytic agents have been linked to an increased likelihood of cardiac rupture. However, studies remain contradictory. The elderly appear to be more prone to cardiac rupture. Left ventricular hypertrophy appears to be protective.

Rupture of the interventricular septum is more often detected clinically than rupture of the ventricular free wall, despite the fact that rupture of the ventricular free wall is more commonly detected in autopsy studies. The size of the defect determines the degree of left-to-right shunt and the ultimate prognosis. Clinically, interventricular septal rupture presents with chest pain, dyspnea, and sudden appearance of a new holosystolic murmur. The murmur is usually accompanied by a palpable thrill and is heard best at the lower left sternal border. Doppler echocardiography is the diagnostic procedure of choice. Demonstration of left-to-right shunt by pulmonary catheter blood sampling may be useful. An oxygen step-up of more than 10 percent from right atrial to right ventricular samples is diagnostic. Rupture of the interventricular septum is more common in patients with anterior wall myocardial infarction and patients with extensive (three-vessel) CAD.

Papillary muscle rupture occurs in approximately 1 percent of patients with AMI, is more common with inferior myocardial infarction, and usually occurs 3 to 5 days after AMI. In contrast to rupture of the interventricular septum, papillary muscle rupture often occurs with a small to modest-sized AMI. Patients may have relatively limited CAD. Patients present with acute onset of dyspnea, increasing degree of congestive heart failure, and a new holosystolic murmur consistent with mitral regurgitation. The posteromedial papillary muscle is most commonly ruptured, because it receives blood supply from one coronary artery, usually the right coronary artery. Echocardiography often can distinguish rupture of a portion of the papillary muscle from other etiologies of mitral regurgitation. Treatment is surgical.

Pericarditis

Post-AMI pericarditis occurs in 10 to 20 percent of patients. It is more common in patients with transmural AMI. It results from inflammation adjacent to the pericardium on the epicardial surface of a transmural infarction. It generally occurs 2 to 4 days after AMI. Pericardial friction rubs are detected more often with inferior wall and right ventricular infarction, because the right ventricle lies immediately beneath the chest wall. The pain of pericarditis can be confused with that of infarct extension or post-AMI angina. Classically, the discomfort of pericarditis becomes worse with a deep inspiration and may be somewhat relieved by sitting forward. Echocardiography may demonstrate a pericardial effusion, but pericardial effusions are much more common than pericarditis and often are present in the absence of pericarditis. Similarly, pericarditis can be present in the absence of a pericardial effusion. The resorption rate of post-AMI pericardial effusions is slow, often taking several months. Dressier syndrome (post-AMI syndrome) occurs 2 to 10 weeks after AMI and presents as chest pain, fever, and pleuropericarditis.

Right Ventricular Infarction

Isolated right ventricular infarction is extremely rare, and it is usually seen as a complication of an inferior infarction. The right ventricle most commonly receives its blood supply from the right coronary artery. In patients with left dominant systems, the blood supply may come from the left circumflex. The anterior portion of the right ventricle is supplied by branches of the left anterior diagonal artery. Approximately 30 percent of inferior wall myocardial infarctions involve the right ventricle. The presence of right ventricular infarction is associated with a significant increase in mortality and cardiovascular complications. Right ventricular infarction can be diagnosed by the presence of ST-segment elevation in the precordial V_{4R} lead in the setting of an inferior wall myocardial infarction. The presence of elevated neck veins or hypotension in response to nitroglycerin is also suggestive. Echocardiography or nuclear imaging can be diagnostic, but they are less readily available in the ED.

The most serious complication of right ventricular infarction is shock. The severity of the hemodynamic derangement in the setting of right ventricular infarction is related to the extent of right ventricular dysfunction, the interaction between the ventricles (the right and left ventricles share the interventricular septum), and the interaction between the pericardium and the right ventricle. Right ventricular infarction results in a reduction in right ventricular end-systolic pressure, left ventricular end-diastolic size, cardiac output, and aortic pressure as the right ventricle becomes more of a passive conduit to blood flow. Left ventricular contraction causes bulging of the interventricular septum into the right ventricle, with resultant ejection of blood into the pulmonary circulation. As a result, right ventricular infarction with concurrent left ventricular infarction has a particularly devastating effect on hemodynamic function. Fluid balance and maintenance of adequate preload are critical in the treatment of right ven-

tricular infarction. Treatment of right ventricular infarction is discussed in Chap. 51.

Other Complications

Other complications of AMI that occur but are not usually seen in the ED include left ventricular thrombus formation, arterial embolization, venous thrombosis, pulmonary embolism, postinfarction angina, and infarct extension. With the more rapid discharge of uncomplicated AMI patients, the emergency physician should keep these possibilities in mind for patients who return to the ED shortly after hospital discharge.

SPECIFIC ISSUES

Age, Gender, and Diabetes Mellitus

The patient's age and gender and the presence or absence of diabetes mellitus play a role in the presentation of patients with ACS. Advanced age, female gender, and a history of diabetes mellitus are associated with more atypical presentations. However, there is no evidence that AMI patients should be evaluated differently in the ED as a result of age or gender.

Postprocedure Chest Pain

Patients who present with symptoms of an ACS shortly after percutaneous coronary interventions such as angioplasty or stent placement should be assumed to have had abrupt vessel closure until proven otherwise. Subacute thrombotic occlusion after stent placement occurs in approximately 4 percent of patients 2 to 14 days postprocedure. Although less common than closure after percutaneous transluminal coronary angioplasty, it is associated with a high likelihood of major ischemic complications. Patients should be treated aggressively for an ACS, and cardiology or interventional cardiology consultation should be obtained. Patients with chest pain syndromes after coronary artery bypass grafting also may have abrupt vessel closure; however, symptoms of recurrent ischemia can be confused with post-AMI pericarditis, as discussed above.

Cocaine Chest Pain

Chest pain associated with cocaine use is discussed in Chap. 168.

DISPOSITION

All patients with acute chest pain need to be evaluated for the possibility of ACS.²² Based on the initial history, physical examination, and ECG, patients can be subclassified into those with and without known CAD. Patients with known CAD should be subclassified further into those who meet criteria for AMI (and may or may not meet criteria for reperfusion therapy), those with a stable anginal pattern who do not require acute intervention, and those with unstable angina. Patients with unstable angina should be treated according to their risk for AMI and death (see Table 50-3).

Patients without known CAD who do not have an obvious myocardial infarction should be evaluated for their likelihood of CAD (Table 50-10) and the possibility of an alternative diagnosis (not ischemic heart disease). Those with a clear alternative diagnosis should be treated accordingly. Those with risks for CAD should be referred for appropriate outpatient evaluation.

Patients at high risk of AMI or death should be admitted to an intensive care unit (ICU). Moderate-risk patients should be admitted to a non-ICU monitored setting. Patients at low risk can be treated in a non-ICU monitored setting or can be observed in an ED observation unit. Emergency department observation units and non-ICU monitored settings are

TABLE 50-10 Likelihood of Significant Coronary Artery Disease in Patients with Symptoms Suggesting Unstable Angina

High Likelihood (85-99%)	Intermediate Likelihood (15-84%)	Low Likelihood (1-14%)
<i>Any of the following features</i>	<i>Absence of high-likelihood features and any of the following</i>	<i>Absence of high- or intermediate-likelihood features but may have</i>
History of prior AMI, sudden death, or other known history of CAD	Definite angina; males <60 or females <70 years of age	Chest pain classified as probably not angina
Definite angina: males \geq 60 or females \geq 70 y of age	Probable angina: males \geq 60 or females \geq 70 y of age	One risk factor other than diabetes
Transient hemodynamic or ECG changes during pain	Chest pain probably not angina in patients with diabetes	T-wave flattening or inversion < 1 mm in leads with dominant R waves
Variant angina (pain with reversible ST-segment elevation)	Chest pain probably not angina and 2 or 3 risk factors other than diabetes	Normal ECG
ST-segment elevation or depression \geq 1 mm	Extracardiac vascular disease	
Marked symmetric T-wave inversion in multiple precordial leads	ST depression 0.05-1 mm	
	T-wave inversion \geq 1 mm in leads with dominant R waves

safe and cost-effective for patients with a normal ECG and other low-risk clinical features. Prior invasive and noninvasive assessments of cardiac function should be taken into account in making disposition decisions. Patients known to have severe CAD or depressed left ventricular function might be triaged to a more intensive setting than patients with a similar presentation without such dysfunction.

Results of prior cardiac catheterization are very useful for risk stratification. Patients who have previously been documented to have minimal (<25 percent) stenosis or normal coronary arteriograms have an excellent long-term prognosis. More than 98 percent of patients with this profile are free from myocardial infarction 10 years later.²³ Repeat cardiac catheterizations an average of 9 years later found that approximately 90 percent of patients did not develop even single-vessel CAD. Thus, a recent (within the past 2 years) cardiac catheterization with normal or minimally diseased vessels almost eliminates the possibility of an ACS due to atherosclerosis. It would not eliminate the possibility of vasospasm or small vessel disease (syndrome X). Without other complicating circumstances, even observation protocols are unnecessary.

Stress tests are less useful because the precise results of such tests may not be available. When patients complete all stages of the stress protocol, have no ECG changes, and have normal imaging studies, exercise testing can rule out acute ischemic syndromes with sensitivities in the range of 80 to 90 percent. When patients do not meet their target heart rates, exercise testing has poor sensitivity (<80 percent), leading to false-negative results. Unless the patient reached the maximal heart rate (220 beats/min minus the patient's age), had no ECG changes, and had normal imaging (when done), one cannot rely heavily on the results of prior exercise testing in making disposition decisions. The emergency practitioner should read the actual stress report before accepting that it was a "negative" test. However, a negative exercise stress test that meets these criteria predicts a favorable 1-year survival free of cardiac events.

INTERVENTION STRATEGIES FOR ACUTE CORONARY SYNDROMES

Judd E. Hollander Deborah
B. Diercks

The treatment of acute coronary syndromes (ACSs) is individualized based on duration and persistence of symptoms, cardiac history, and findings on physical examination and the initial electrocardiogram. Generally speaking, patients with persistent symptoms and ST-segment elevation myocardial infarction (STEMI) should receive fibrinolytic therapy or mechanical reperfusion (angioplasty). Treatment with antiplatelet agents, anticoagulants, β -antagonists, nitrates, and angiotensin-converting enzyme (ACE) inhibitors should be considered, based on symptoms, vital signs, and the presence or absence of heart failure. Patients with unstable angina or non-STEMI (NSTEMI) should be treated with antiplatelet agents and anticoagulants and possibly β -antagonists and nitrates. Patients refractory to these therapies or patients scheduled to undergo percutaneous coronary intervention (PCI) also benefit from the use of glycoprotein (GP) IIb/IIIa antagonists. Diagnosis of ACS is discussed in Chap. 50.

GENERAL MEASURES

Intravenous access and continued electrocardiographic monitoring should be established in all patients with ACSs. Supplemental oxygen may reduce ST-segment elevation in patients with acute myocardial infarction (AMI). It is therefore reasonable to provide 2 to 4 L of oxygen routinely by nasal cannula, even to patients with normal oxygen saturation. In patients with unstable angina or NSTEMI, O_2 should be provided in patients with signs of hypoxia. Treatment strategies aim to achieve immediate reperfusion and limit infarct size (Table 51-1 and Figure 51-1).

REPERFUSION

Reperfusion therapies can be mechanical or pharmacologic. Angioplasty, coronary stent placement, and atherectomy are the major methods of mechanical reperfusion. Pharmacologic interventions include fibrinolytic and antiplatelet therapy.

Fibrinolytics

Fibrinolytic agents act on the acute thrombosis directly or indirectly as plasminogen activators. Plasminogen, an inactive proteolytic enzyme,

TABLE 51-1 Recommended Doses of Drugs Used in the Emergency Treatment of Acute Coronary Syndromes

Antiplatelet agents		
Aspirin	160-325 mg PO	
Clopidogrel	Loading dose of 300 mg PO followed by 75 mg	
Antithrombins		
Heparin	Bolus of 60-70 units/kg (maximum, 5000 units) followed by infusion of 12-15 units/kg per h (maximum, 1000 units/h) titrated to a PTT 1.5-2.5 times control	
	1 mg/kg SC q12h	
Enoxaparin (LMWH)		
Fibrinolytic agents		
Streptokinase	1.5 million units over 60 min	
Alteplase (tPA)	Body weight >67 kg: 15 mg initial IV bolus; 50 mg infused over next 30 min; 35 mg infused over next 60 min	
	Body weight <67 kg: 15 mg initial IV bolus; 0.75 mg/kg infused over next 30 min; 0.5 mg/kg infused over next 60 min	
Reteplase (rPA)	10 mg IV bolus followed by 10 mg IV bolus 30 min later	
Tenecteplase (TNKase)	Weight	Dose*
	<60kg	30 mg
	>60 but <70 kg	35 mg
	>70 but <80 kg	40 mg
	>80 but <90	45 mg
	>90	50 mg
	*Total dose not to exceed 50 mg	
Glycoprotein IIb/IIIa inhibitors		
Abciximab	0.25 mg/kg bolus followed by infusion of 0.125 μ g/kg per min (maximum, 10 μ g/min) for 12-24 h	
Eptifibatide	180 (μ g/kg bolus followed by infusion of 2.0 μ g/kg per min for 72-96 h	
Tirofiban	0.4 μ g/kg per min for 30 min followed by infusion of 0.1 M-g/kg per min for 48-96 h	
Other anti-ischemic therapies		
Nitroglycerin	SL: 0.4 mg q5 min X 3 pm pain	
	IV: start at 10 μ g/min, titrate to 10% reduction in MAP if normotensive, 30% reduction in MAP if hypertensive	
Morphine	2-5 mg IV q5-15 min prn pain	
Metoprolol	5 mg IV over 2 min q5 min up to 15 mg, followed by 50 mg PO q6h 15 min after last IV dose	
Atenolol	5 mg IV over 5 min, repeat once 10 min later, followed with 50 mg PO	

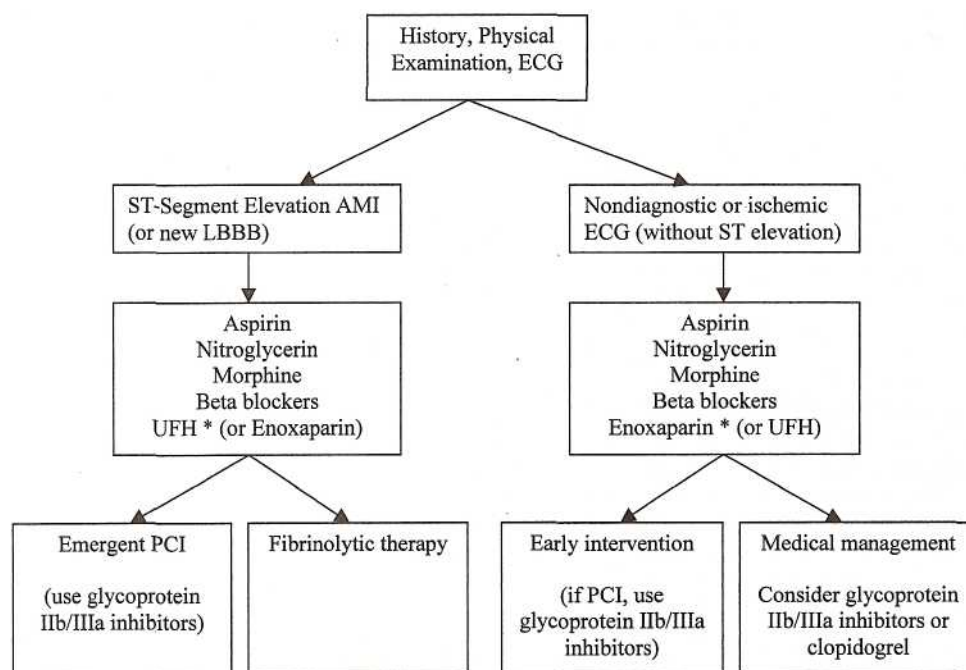

Abbreviation: MAP = mean arterial pressure; PTT = partial thromboplastin time; SL = sublingual.

binds directly to fibrin during thrombus formation to form a plasminogen-fibrin complex. This plasminogen-fibrin complex is more susceptible than plasma plasminogen to activation, and this promotes fibrin proteolysis.

The original randomized controlled clinical trials (RCTs) comparing streptokinase with placebo for treatment of STEMI demonstrated that fibrinolytic therapy improves left ventricular function and short-term and long-term mortalities. A meta-analysis of all nine RCTs found that the net benefit of fibrinolytic treatment in the first 3 h was more than 30 lives saved per thousand patients. The loss of benefit-per-hour delay in fibrinolytic administration was 1.6 lives per 1000 patients per hour.

Fibrinolytic therapy is indicated for patients with symptoms compatible with AMI, if time to treatment is less than 6 to 12 h from symptom onset and the electrocardiogram has at least 1-mm ST-segment elevation in two or more contiguous leads.¹ Therapy is more beneficial if given early and for larger infarctions and anterior infarctions than for smaller or inferior infarctions. In the elderly, the overall risk of

FIG. 51—1. Treatment considerations for patients with acute coronary syndrome. *Preferred antithrombin. AMI = acute myocardial infarction; ECG = electrocardiogram; LBBB = left bundle-branch block; PCI = percutaneous intervention; UFH = unfractionated heparin.

Note: See text for discussion of individual treatment options, indications, and contraindications

mortality from AMI is high. The proportionate reduction in mortality rate appears to be less in patients older than 75 years, but the absolute number of patients who may be saved is still considerable.

Contraindications to fibrinolytic therapy are those that increase the risk of hemorrhage (Table 51-2). The most catastrophic complication is intracranial bleeding. Clinical variables that can be assessed in the ED and predict an increased risk of intracranial hemorrhage are age (>65 years, odds ratio of 2.2), low body weight (<70 kg, odds ratio of 2.1), and hypertension on presentation (odds ratio of 2.0).² Intracranial hemorrhage is also more common with tissue plasminogen activator (tPA) than with streptokinase (odds ratio of 1.6). Patients with relative contraindications may still receive fibrinolytic therapy when the benefits of therapy outweigh the risks of the complications, but institutions with direct PCI availability should consider direct angioplasty over fibrinolytic therapy in the presence of relative contraindications. Although fibrinolytic therapy is the standard of care for patients with STEMI, it does have limitations. First, even the most potent fibrinolytic agents do not achieve early and complete restoration of coronary blood flow in 40 to 50 percent of patients. Fibrinolytics are plasminogen activators. When fibrin is lysed, thrombin is exposed. The exposed thrombin is one of the most potent biologic platelet activators known. As a result, the more fibrin that is lysed, the more thrombin is exposed and the more prothrombotic substrate is engendered. The second limitation of fibrinolytic therapy is that approximately 0.5 to 1 percent of patients have intracranial hemorrhage, which usually results in death or disabling stroke.

STREPTOKINASE Streptokinase is a polypeptide derived from (3-hemolytic *Streptococcus* cultures. It binds 1:1 to plasminogen, causing a conformational change that activates the plasminogen-streptokinase complex. This complex cleaves peptide bonds on other plasminogen molecules to activate them. This activated complex does not have fibrin specificity. Streptokinase compared with placebo reduces mortality rate and improves left ventricular function in patients with STEMI.

Antibodies may develop after treatment, so retreatment is generally avoided. Streptokinase allergy can be seen in approximately 5 percent of patients treated for the first time, especially those with a recent *Streptococcus* infection. Self-limited allergic reactions usually respond to antihistamines. Fewer than 0.2 percent of patients experience a serious anaphylactic reaction. During intravenous administration, approximately 15 percent of patients will experience hypotension, which usually responds to decreasing the rate of infusion and volume

TABLE 51-2 Contraindications to Fibrinolytic Therapy in Acute Myocardial Infarction

Absolute contraindications
Previous hemorrhagic stroke at any time
Bland CVA in past year
Known intracranial neoplasm
Active internal bleeding (excluding menses)
Suspected aortic dissection or pericarditis
Relative contraindications
Severe uncontrolled blood pressure (>180/100 mm Hg)
History of chronic severe hypertension
History of prior CVA of known intracranial pathology not covered in contraindications
Current use of anticoagulants with known INR >2—3
Known bleeding diathesis
Recent trauma (past 2 wk)
Prolonged CPR (>10 min)
Major surgery (<3 wk)
Noncompressible vascular punctures (including subclavian and internal jugular central lines)
Recent internal bleeding (2–4 wk)
Prior streptokinase
Pregnancy
Active peptic ulcer disease
Other medical conditions likely to increase risk of bleeding

Abbreviations: CVA = cerebrovascular accident (stroke); INR = international normalized ratio.

expansion. Streptokinase produces a fibrinolytic state for up to 24 h. Streptokinase is less costly than other fibrinolytic agents.

TISSUE PLASMINOGEN ACTIVATOR Tissue plasminogen activator (tPA) is a naturally occurring enzyme produced by the vascular endothelium and other tissues. It has a binding site for fibrin that allows it to attach to a formed thrombus and trigger fibrinolysis (fibrin specificity). Tissue plasminogen activator achieves higher infarct-related artery patency rates than does streptokinase. Three large RCTs have compared streptokinase with tPA. GISSI-2 (>20,000 patients) found that tPA increases the rate of stroke or death at 5 per 1000 patients in comparison with streptokinase at 30 to 35 days.² ISIS-3 (27,000 patients) found a 1 per 1000 patient benefit in favor of tPA.³ The GUSTO trial found a 5.4 per 1000 patient benefit in favor of tPA, which increased to 9 per 1000 patients when the accelerated tPA regimen was given.⁴ As a result, when tPA is used as the fibrinolytic agent, the accelerated regimen is recommended (see Table 51-1).

Meta-analysis of these three mega-trials found no statistical difference between streptokinase and tPA with respect to the composite end point of stroke and death. Based on this analysis, the choice of which fibrinolytic agent to use is probably less relevant than the speed of fibrinolytic administration (which saves an additional 1.6 per 1000 lives per hour earlier when treatment is provided). In addition, it is reasonable to choose streptokinase over tPA when the risk for intracranial hemorrhage is highest (e.g., in the elderly), because tPA has an increased likelihood of resulting in hemorrhagic stroke.¹ Also, streptokinase is less expensive than other fibrinolysis agents.

The mechanism of improved benefit of tPA is early patency of the infarct-related vessel.⁵ For tPA, streptokinase and subcutaneous heparin, streptokinase and intravenous heparin, and streptokinase and tPA, the patency rates at 90 min were 81, 56, 61, and 73 percent, respectively.⁵ These patency rates were predictive of survival outcomes.

RETEPLASE Reteplase plasminogen activator (rPA) is a genetically engineered modification of tPA, with a prolonged half-life (18 vs 3 min) and reduced fibrin binding. Several smaller studies initially suggested that reteplase has a faster time to reperfusion. However, GUSTO III showed no clinically relevant difference in outcomes (mortality and stroke) between tPA and rPA. Reteplase can be given as a double bolus, 10 mg each, 30 min apart. The easy double-bolus administration is an advantage in the ED.

TENECTEPLASE Tenecteplase (TNK) is another tPA mutant with prolonged half-life, is resistant to endogenous plasminogen activator inhibitor 1 inactivation, and has high fibrin specificity and binding. In animal models, it produces more active and complete fibrinolysis with less risk of intracranial bleeding. In a large RCT study with AMI, there was no difference in 30-day mortality or intracranial hemorrhage rates between TNK and tPA.⁶ Single-bolus administration makes this the easiest fibrinolytic agent to administer, but the requirement of weight-based dosing may not always be practical.

The choice of fibrinolytic agent is generally based on institution. Because tPA, rPA, and TNK have similar efficacy and safety profiles, the decision is usually based on other factors, such as ease of administration, cost, and the personal preference of the cardiologist and emergency physician.

Mechanical Reperfusion

Coronary angioplasty with or without stent placement is the most common PCI. Alternatives include atherectomy and laser angioplasty. Balloon angioplasty increases the size of the arterial lumen through endothelial denudation; cracking, splitting, and disruption of atherosclerotic plaque; dehiscence of intima and plaque from underlying media; and stretching or tearing of underlying media and adventitia. With successful dilatation, small amounts of arterial wall dissection and aneurysmal expansion may be seen. The greater the increase in lumen

size, the lower is the risk of restenosis. However, more aggressive balloon inflation can be associated with excessive dissection, platelet deposition, thrombus formation, and plaque hemorrhage.

Alternative PCI procedures have been developed in an attempt to limit complications. Directional and rotational coronary atherectomy extract atherosclerotic tissue from the coronary artery. Excimer laser atherectomy vaporizes atheromatous tissue. It results in larger luminal diameters but has not reduced rates of restenosis or other complications associated with percutaneous angioplasty procedures.

Coronary stents are fenestrated stainless-steel tubes that are expanded by a balloon to provide scaffolding within the coronary arteries. The addition of antiplatelet therapies (in particular, GP IIb/IIIa inhibitors and clopidogrel) results in lower adverse events at 6 months compared with patients undergoing percutaneous transluminal coronary angioplasty (PTCA) or stent placement without GP IIb/IIIa inhibitors,⁷ and these improved outcomes are apparent up to 3 years after the procedure.

Direct coronary angioplasty has compared favorably with fibrinolytic therapy for the treatment of patients with AMI. In centers with significant expertise in direct angioplasty, primary angioplasty as opposed to fibrinolytic therapy reduces the cardiovascular complication rate in patients with AMI and is considered the optimal treatment by some. In GUSTO IIB, the incidence of death, nonfatal reinfarction, and nonfatal disabling stroke was 33 percent lower in patients who presented within 12 h of AMI onset who received primary angioplasty versus those who received accelerated tPA.⁸ There does not appear to be a large benefit of direct angioplasty over fibrinolysis in the community hospital setting.⁹

Primary angioplasty may offer benefits over fibrinolysis in highly specialized centers, with ready availability of cardiac catheterization and skilled operators, that are not apparent with longer delays or less skilled operators. The decision to use primary interventional procedures rather than fibrinolysis should be individualized based on institutional expertise and availability and risk of complications from fibrinolysis.

There have been multiple trials evaluating the benefit of early angioplasty versus conservative medical treatment for patients with unstable angina (UA) or NSTEMI. In the TACTICS-TIMI 18 trial, 2220 patients with UA or NSTEMI were treated with aspirin, low-molecular-weight heparin, and the GP IIb/IIIa inhibitor tirofiban and were randomized to an early invasive strategy with coronary angiography within 48 h or conservative medical therapy.¹⁰ A reduction in death, myocardial infarction (MI), or rehospitalization was found at 6 months in the invasive group (15.9 vs. 19.4 percent). However, in the absence of high-risk features, [cardiac troponin T (cTnT) >0.1 ng/mL, the presence of ST-deviation, or aTIMI score >3],ⁿ there was no difference in 6-month outcome between the two treatments.

The American Heart Association and American College of Cardiology (AHA/ACC) guidelines for the management of UA/NSTEMI patients recommend early invasive therapy in patients with recurrent angina/ischemia with or without symptoms of congestive heart failure (CHF), elevated cardiac troponins, high-risk findings on noninvasive stress testing, depressed left ventricular function, hemodynamic instability, sustained ventricular tachycardia, PCIs within the previous 6 months, or prior coronary artery bypass grafting (CABG) in addition to the previously mentioned high-risk features.¹² However, there is no consensus on the definition of "early."

ANTIPLATELET AGENTS

Platelets are at the core of coronary artery thrombosis. Platelet activation and adhesion to subendothelial matrix elements occur as a result of plaque rupture. Platelet aggregation may be initiated by shearing forces, fibrinolytics, thrombin, thromboxane A₂, adenosine diphosphate, epinephrine, serotonin, or plasmin. These trigger the arachidonic acid pathway, the protein kinase C pathway, or other pathways that result in platelet aggregation. The final common pathway of

platelet activation is exposure of GP IIb/IIIa receptors on the surface of the platelet. Bivalent fibrinogen molecules cross-link activated platelets together by using these receptors.

The GP IIb/IIIa antagonists are considerably stronger antiplatelet agents than aspirin, because they interrupt platelet activation regardless of agonist. In contrast, aspirin only inhibits platelet aggregation stimulated through thromboxane A₂ and mediated through the arachidonic acid pathway.

Glycoprotein IIb/IIIa Inhibitors

Several different GP IIb/IIIa antagonists are available. *Abciximab* is a chimeric antibody that binds irreversibly to the GP IIb/IIIa antagonists. The duration of action is longer than that of the smaller peptide molecules. As a result, benefits may be realized with a shorter duration of infusion. *Eptifibatide* is a synthetic heptapeptide that binds reversibly to the GP IIb/IIIa receptor. *Tirofiban* is a synthetic small molecule with reversible binding to the GP IIb/IIIa receptor. All require an intravenous infusion to demonstrate sustained benefits. Reversal of platelet inhibition after cessation of infusion is more rapid with the polypeptide or small molecules, offering an advantage when bleeding complications occur.

The GP IIb/IIIa inhibitors have been evaluated for use in three clinical areas: with PCI; for medical stabilization of patients with ACS; and in combination with low-dose fibrinolysis.

With PCI, GP IIb/IIIa inhibitors are recommended for use in high-risk patients undergoing PCI in the cardiac catheterization laboratory. Six large trials together enrolled more than 10,000 PCI patients and found that patients treated with GP IIb/IIIa inhibitors (in addition to aspirin and heparin) have an approximately 40 percent reduced risk of death or AMI in 30 days. Some of this benefit was sustained for up to 3 years (13 percent reduction).

Medical Stabilization of ACS

Glycoprotein IIb/IIIa antagonists also have been shown to be efficacious for medical stabilization and treatment of patients with ACSs, although the results are less impressive than with PCI patients. Four large trials evaluated GP IIb/IIIa antagonists for the medical stabilization of patients with UA or non-Q-wave AMI.¹³⁻¹⁶ The trials evaluated tirofiban and eptifibatide and demonstrated improved outcomes with the use of these agents when a triple composite end point of death, AMI, and recurrent ischemia was used as the main outcome.¹³⁻¹⁵ However, abciximab was not found to be of benefit in patients who did not undergo coronary angiography within 48 h.¹⁶ In a meta-analysis of six randomized placebo-controlled trials, a small reduction in the composite end point of death or AMI was noted in patients receiving GP IIb/IIIa inhibitors (11.8 vs. 10.8 percent).¹⁷ There was no difference between placebo and GP IIb/IIIa when the end points of death and AMI were considered individually. Glycoprotein IIa/IIIb inhibitors showed the greatest reduction in patients undergoing PCI. There were not sufficient data in the meta-analysis to determine whether the GP IIb/IIIa inhibitors are effective in patients who do not undergo PCI. **At this time, the greatest benefit from GP IIb/IIIa inhibitors is for patients undergoing PCI.** The AHA/ACC guidelines for the management of UA/NSTEMI patients makes administration of GP IIb/IIIa inhibitors to patients in whom a PCI is planned a class I recommendation.¹² The GP IIb/IIIa inhibitors, eptifibatide and tirofiban, are considered class IIa for ACS patients in whom PCI is not planned. Abciximab is not recommended for patients who will be receiving medical management without PCI.

Combination Therapy: Fibrinolytic Therapy GP IIb/IIIa Inhibitors

Although much of coronary thrombosis is red clot (fibrin and erythrocytes), central platelet thrombus (white clot) is fully resistant to

fibrinolytic therapy. These platelets secrete plasminogen activator inhibitor 1, which is a potent inhibitor of fibrinolysis. In theory, combination therapy with antiplatelet agents and fibrinolytics will attack both components of coronary thrombosis. This is one explanation why even a weak antiplatelet agent reduces mortality rate as much as treatment with streptokinase alone.

Preclinical studies and dose-ranging trials of GP IIb/IIIa antagonists combined with a 50 percent reduced fibrinolytic dose found that fibrinolysis occurred more rapidly and was more stable.¹⁸ Two large RCTs of combination therapy found divergent results. GUSTO-V found no advantage (as measured by death at 30 days) over strategies using rPA.¹⁹ ASSENT-3 found improvement in survival, AMI, and recurrent ischemia with abciximab added to TNK and unfractionated heparin (UFH) without an increase in intracranial hemorrhage and a nonsignificant increase in major bleeding with enoxaparin.²⁰ **At this time, the use of combination therapy with GP IIb/IIIa inhibitors is unproven as a superior treatment to standard fibrinolytics alone or in combination with low-molecular-weight heparin (LMWH).**

Aspirin

Aspirin should be given as soon as possible to all patients with ACSs. In platelets, aspirin prevents formation of thromboxane A₂, an agonist of platelet aggregation. This inhibition persists for the 9- to 10-day life of the platelet, because platelets are unable to generate new cyclooxygenase. Aspirin alone has been shown to be as efficacious as streptokinase alone. Aspirin alone reduces mortality rate by 23 percent. In conjunction with streptokinase, mortality rate is reduced by 43 percent. Aspirin used in conjunction with fibrinolytic therapy further reduces ischemic events and coronary artery reocclusion. Doses larger than 160 mg cause immediate, nearly complete inhibition of thromboxane A₂. Smaller doses may be effective for long-term prophylaxis but may not be effective for acute use. Aspirin reduces vascular events in patients with AMI and patients with UA.¹ In patients with prior MI or stroke, it reduces vascular events by about 4 percent.²¹

The side effects of aspirin are mainly gastrointestinal and dose related. They can be reduced by using diluted or buffered aspirin solutions, lowest possible doses, or concurrent antacid or H₂ antagonist administration. In the setting of acute ischemia, the delay in absorption of enteric-coated aspirin is best avoided. Due to the substantial benefits of aspirin therapy during ACS, it should not be withheld from patients with minor contraindications (vague allergy, history of remote peptic ulcer, or gastrointestinal bleeding).¹ Other antiplatelet agents, such as clopidogrel, can be substituted if true aspirin allergy or active peptic ulcer disease exists.¹² The aspirin dose should be at least 160 mg.

Adenosine Diphosphate Receptor Antagonists

Ticlopidine and *clopidogrel* are antiplatelet agents that inhibit platelet aggregation induced by a wide range of agonists. Clopidogrel is preferred to ticlopidine in the ACS setting, because it has more rapid inhibition of platelets and limited side effects. The CURE trial randomized 12,562 patients with UA/NSTEMI to clopidogrel (300-mg loading dose and 75-mg daily dose) or placebo.²² All patients received aspirin. The clopidogrel group had a 20 percent reduction in death, AMI, or stroke between 3 and 12 months. There was an excess of bleeding in the clopidogrel group compared with controls.

Current AHA/ACC guidelines recommend clopidogrel in patients who have aspirin allergy, and early administration in patients in whom noninvasive management or PCI is planned.¹⁸ Because of an increased bleeding risk, it is recommended that this agent be withheld 5 days before CABG, if possible.

The inhibitory effect of ticlopidine is delayed 24 to 48 h after its administration.¹ It is effective in reducing 6-month vascular death and AMI rate in patients with UA. Side effects include neutropenia, which is more common in patients treated for longer than 2 weeks. The dose is 250 mg twice per day. Because clopidogrel has fewer serious side

effects and acts more rapidly than ticlopidine, there is little reason to use ticlopidine in the ED.

ANTITHROMBINS

Heparin

Heparin is a specific antithrombin agent. Thrombin generation plays an intricate role in the pathogenesis of coronary artery thrombosis. Thrombin converts soluble fibrinogen to insoluble fibrin; activates coagulation factors V and VIII, which exert positive feedback on coagulation through the prothrombinase complex; and activates factor XIII, which stabilizes thrombus formation by promoting fibrin cross-linking. In addition, thrombin serves as a platelet agonist.

Unfractionated heparin consists of a mixture of molecules with molecular weights varying between 2000 and 20,000. The different-size molecules have different effects on the coagulation system. Heparin complexes with antithrombin III, and this complex inactivates thrombin and activated factor X. The heparin-antithrombin III complex is not effective against clot-bound thrombin.

Heparin reduces the risk of AMI and death during the acute phase of UA. The combination therapy of aspirin and heparin reduces the short-term risk of death or AMI by 56 percent compared with aspirin alone. When heparin is used in combination with aspirin, recurrence of ischemia is diminished after cessation of the heparin infusion.²³ Thus, **combination therapy with aspirin and heparin is indicated for patients with ACSs.**

Unfractionated heparin has some limitations. It has an unpredictable anticoagulant response, because the bioavailability of heparin is variable. It requires careful laboratory monitoring and dose adjustment. The weight-adjusted regimen is recommended, with an initial bolus of 60 to 70 units/kg (maximum, 5000 units) and an infusion of 12 to 15 units/kg per hour (maximum, 1000 units/h).¹²

Low-Molecular-Weight Heparins

The LMWHs have greater bioavailability, lower protein binding, a longer half-life, and achieve a more reliable anticoagulant effect. As a result, they can be administered in a fixed dose subcutaneously once or twice a day and achieve a stable therapeutic response without the need for monitoring anticoagulation.

Several clinical trials have compared LMWH with standard heparin regimens for treatment of ACS. The largest RCT showed that, at 14 and 30 days, the risk of death, AMI, or recurrent angina was at least 15 percent lower in patients with angina/NSTEMI who received (aspirin and) enoxaparin compared with those who received (aspirin and) UFH, without an increase in major bleeding complications among patients with UA or non-Q-wave infarction.²⁴ The benefit of enoxaparin was related to the TIMI risk score, with a significant decrease in the composite end point of death, AMI, and recurrent ischemia requiring PCI at 14 days in patients with a TIMI risk score above 3.¹¹ Because the level of anticoagulant activity is not rapidly measured, there is some concern about the use of these agents in patients requiring emergent PCI. However, recent trials have suggested that it is safe in this setting, in patients in whom CABG is planned, it is recommended that LMWH be held and UFH be used in the 12 to 24 h before surgery. The ACC/AHA guidelines consider enoxaparin preferable to UFH for patients with UA/NSTEMI, unless CABG is planned in the next 24 h.¹² Other LMWHs have not had the same efficacy as enoxaparin in clinical trials of UA/NSTEMI patients.

Direct Thrombin Inhibitors

These agents bind to the catalytic site of thrombin, bind to thrombin in clot, and are resistant to agents that degrade heparin. Hirudin, a 65-amino acid peptide, is derived from the medicinal leech and is one

of the most potent, naturally occurring anticoagulants. One large clinical trial was terminated because hirudin increased the incidence of intracranial bleeding compared with heparin. *Bivalirudin* (Hirulog) may reduce the short-term risk of postischemic complications relative to high-dose UFH in patients PCI for unstable or postinfarction angina, but benefits do appear to persist long term. Similarly, inogatran does not appear to offer benefits over UFH for the treatment of patients with ACS.²⁵ Thus, at this time, there is no clearly defined role for direct thrombin inhibitors in the medical management of ACS patients in the ED.

LIMITING INFARCT SIZE

Nitrates

Nitrates relax vascular smooth muscle in arteries, arterioles, and veins through the metabolic conversion of organic nitrates to nitric oxide. The pulmonary capillary wedge pressure, systemic arterial pressure, and left ventricular end-systolic and end-diastolic volumes decrease. Reduction in right and left ventricular filling pressures that result from peripheral dilatation combined with afterload reduction that results from arterial dilatation decrease cardiac work and myocardial oxygen requirements. Nitroglycerin has direct vasodilator effects on the coronary vascular bed and increases global and regional myocardial blood flows. When obstructing atherosclerotic lesions contain intact vascular smooth muscle, nitrates may dilate these vessels, thereby improving blood flow. Platelet aggregation is also inhibited by nitroglycerin.

When nitroglycerin is used in AMI patients not treated with thrombolytics, several clinical trials have demonstrated a reduction in infarct size, improved regional function, and decreased rate of cardiovascular complications. The mortality rate appears to be reduced by 35 percent with the use of nitrates. It is important to note that, in most studies, intravenous nitroglycerin was titrated to 10 percent reduction in mean arterial pressure for normotensive patients and to 30 percent reduction in mean arterial pressure for hypertensive patients. It was not titrated to symptom resolution. Thus, when used for patients with AMI, **intravenous nitroglycerin should be titrated to blood pressure reduction rather than to symptom (chest pain) resolution.** Studies in patients who have received fibrinolytic agents have not found a benefit to the addition of nitroglycerin. Unfortunately, large numbers of the control (non-nitroglycerin) patients were prescribed nitroglycerin by their physicians, thus precluding optimal data interpretation.

The ACC/AHA guidelines recommend the use of intravenous nitroglycerin for the first 24 to 48 h for patients with AMI and recurrent ischemia, congestive heart failure, or hypertension.¹ Benefits are likely to be greatest in patients not receiving concurrent fibrinolytic therapy. The UA/NSTEMI guidelines recommend that intravenous nitroglycerin be used in patients with UA who are not responsive to sublingual nitroglycerin tablets.¹²

The most serious side effect of nitroglycerin is hypotension, which may result in reflex tachycardia and worsening ischemia. Nitrates should not be used for patients with right ventricular infarction.²⁶ **Nitroglycerin should be used very cautiously for patients with inferior wall ischemia,** because one third of such patients might have right ventricular involvement. Patients with right ventricular infarction are volume dependent. Administration of nitrates reduces preload and commonly results in hypotension in these patients. The development of hypotension is associated with an increased infarct size. When nitroglycerin results in hypotension and bradycardia, the drug should be discontinued, legs should be elevated, and fluid should be administered. Atropine may be necessary in some cases.

β -Blockers

β -Adrenergic antagonists have antiarrhythmic, anti-ischemic, and anti-hypertensive properties. During AMI, they diminish myocardial oxygen demand by decreasing heart rate, systemic arterial pressure, and myocar-

dial contractility. Prolongation of diastole may augment perfusion to ischemic myocardium. Studies in the mid-1980s set immediate β -antagonist administration in AMI as a standard by reduced chest pain, wall stress, infarct size, incidence of cardiovascular complications, and mortality rate for patients not treated with fibrinolytics. For patients treated with fibrinolytics, β -antagonists decrease the risk of nonfatal reinfarction and recurrent ischemia if given within several hours of symptom onset.

The ACC/AHA guidelines recommend that all patients with STEMI who do not have a contraindication to (3-antagonists be treated with these agents within 12 h of onset of infarction, regardless of whether they have received fibrinolytic therapy.¹ Patients with recurrent ischemia and tachyarrhythmias should receive (3-antagonist therapy. The AHA/ACC guidelines recommend that patients with UA or NSTEMI receive early treatment with (3-antagonists, when not contraindicated.¹²

Relative contraindications to β -adrenergic antagonists are heart rate slower than 60 beats/min, systolic blood pressure below 100 mm Hg, moderate to severe left ventricular failure, signs of peripheral hypoperfusion, PR interval longer than 0.24 s, second-degree or third-degree atrioventricular block, severe chronic obstructive pulmonary disease, history of asthma, severe peripheral vascular disease, and insulin-dependent diabetes mellitus.¹ Use of β -antagonists should be individualized for patients with these conditions.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme inhibitors reduce left ventricular dysfunction and left ventricular dilatation and slow the development of congestive heart failure during AMI. Studies have consistently shown a reduction in mortality rate for patients treated with oral ACE inhibitors during and soon after AMI. A meta-analysis of 15 trials including more than 100,000 patients supported a 6.5 percent reduction in short-term mortality rate, with an absolute benefit of 4.6 fewer deaths per 1000 patients treated with early ACE inhibitor therapy.²⁷ Oral administration is recommended; intravenous enalaprilat is associated with increased hypotension.

The ACC/AHA guidelines recommend that patients with STEMI or heart failure receive treatment with ACE inhibitors within the first 24 h (not necessarily in the ED).¹ The UA/NSTEMI guidelines recommend ACE inhibitors when hypertension persists after treatment with nitroglycerin and β -blockers in patients with depressed left ventricular function or CHF.

Contraindications to ACE inhibitors include hypotension, bilateral renal artery stenosis, renal failure, or history of cough or angioedema due to prior ACE inhibitor use. The efficacy of ACE inhibitors in UA has not been well evaluated.

Magnesium

Magnesium produces systemic and coronary vasodilatation, possesses antiplatelet activity, suppresses automaticity, and protects myocytes from calcium influx during reperfusion. Studies, however, are conflicting: some have found mortality rate reduced by about 75 percent, whereas others have showed no benefit at all. The disparity in findings may be related to the interval between symptom onset and magnesium administration and various concurrent therapies (including fibrinolysis). In light of these conflicting data, the ACC/AHA guidelines support correction of documented hypomagnesemia during AMI and treatment of torsades-type ventricular tachycardia with a prolonged QT interval.¹ Magnesium bolus and infusion in high-risk patients, such as the elderly and those in whom reperfusion therapy is not suitable, is considered possibly beneficial.¹

Calcium Channel Antagonists

Calcium channel blockers have antianginal, vasodilatory, and antihypertensive properties. Calcium antagonists have not been shown to re-

duce mortality rate after AMI. In fact, they may be harmful to some patients with cardiovascular disease.¹ Nifedipine is the most studied of the calcium channel blockers for the treatment of AMI. This short-acting dihydropyridine has been associated with a nonsignificant increase in mortality rate when given during or shortly after AMI in several clinical trials.²⁸ Immediate-release nifedipine may be harmful as a result of a coronary "steal" syndrome, in which coronary perfusion pressure is reduced through disproportionate dilatation of the coronary arteries adjacent to the ischemic zone and/or reflex activation of the sympathetic nervous system, with a resultant increase in myocardial oxygen demand.

Diltiazem also has been associated with increased mortality rate, particularly for patients with CHF.²⁹ Similarly, studies evaluating verapamil have not found mortality-rate benefits. Verapamil is detrimental for patients with CHF or bradydysrhythmia. There are no data supporting the use of second-generation dihydropyridines (amlodipine and felodipine) for treatment of AMI.

The ACC/AHA guidelines state that "these agents are still used too frequently in patients with AMI and that β -adrenoreceptor blocking agents are a more appropriate choice."¹ Verapamil and diltiazem are considered potentially beneficial for use in patients with ongoing ischemia or atrial fibrillation with rapid ventricular response who do not have CHF, left ventricular dysfunction, or atrioventricular block, and when (3-adrenergic antagonists are contraindicated.^{3,30}

SPECIAL ISSUES IN TREATMENT OF AMI COMPLICATIONS

Recurrent or Refractory Ischemia

Patients unresponsive to medical management with continued ischemia require an individualized approach to treatment. Depending on the infarct distribution and coronary anatomy, decisions could be made regarding continued medical management, rescue angioplasty, or CABG. Emergency cardiology referral should be considered. Refractory ischemia should be investigated with coronary catheterization. Patients with ACS after stent placement should be treated aggressively with anticoagulation and may require urgent coronary catheterization.

Intraaortic balloon counterpulsation delivers phased pulsations synchronized to the electrocardiograph, so that balloon inflation will occur at the time of aortic valve closure and deflation occurs just before onset of systole. The augmented coronary perfusion pressure during diastole enhances coronary blood flow. Balloon deflation during systole allows the left ventricle to eject blood against a lower resistance. The net effect of intraaortic balloon counterpulsation is an increase in cardiac output, reduction in systolic arterial pressure, increase in diastolic arterial pressure, little change in mean arterial pressure, and reduction in heart rate. The reduction in left ventricular afterload leads to reduced myocardial oxygen consumption, thereby decreasing the amount of myocardial ischemia. Intraaortic balloon counterpulsation is recommended for patients with ACS who are refractory to aggressive medical management or are hemodynamically unstable, as a means to bridge a patient's stability en route to definitive treatment.

Cardiogenic Shock

This is discussed in Chap. 33.

Right Ventricular Infarction

One third of patients with inferior wall myocardial infarction have right ventricular involvement. The most serious complication of right ventricular infarction is shock. Right ventricular infarction results in a reduction in right ventricular end-systolic pressure, left ventricular

end-diastolic size, cardiac output, and aortic pressure as the right ventricle becomes more of a passive conduit to blood flow. Left ventricular contraction causes bulging of the interventricular septum into the right ventricle, with resultant ejection of blood into the pulmonary circulation. As a result, right ventricular infarction in the setting of a large left ventricular infarction has a particularly devastating effect on hemodynamic function. Factors that reduce preload (volume depletion, diuretics, and nitrates) or decrease right atrial contraction (atrial infarction and loss of atrioventricular synchrony) and factors that increase right ventricular afterload (left ventricular failure) can lead to significant hemodynamic derangements.

Treatment of right ventricular infarction includes maintenance of preload, reduction of right ventricular afterload, and inotropic support of the ischemic right ventricle, in addition to early reperfusion. Patients with right ventricular infarction should not be treated with drugs, such as nitrates, that reduce preload. In the setting of right ventricular infarction, nitrates often will reduce cardiac output and produce hypotension. Instead, patients with marginal preload or hypotension should be treated with volume loading (normal saline). The increased preload will improve right ventricular cardiac output. If cardiac output is not improved after 1 to 2 L of normal saline, inotropic support with dobutamine should be initiated.

High-degree heart block is very common in patients with right ventricular infarction. The loss of right atrial contraction can greatly compromise right ventricular cardiac output. Restitution of atrioventricular synchrony is important. For patients who require pacing in the setting of right ventricular infarction, it may be necessary to establish atrioventricular sequential pacing leads. Patients who do not attain hemodynamic improvement after placement of a ventricular pacer may still improve with atrioventricular sequential pacing.

When right ventricular infarction is accompanied by left ventricular dysfunction, the use of nitroprusside to reduce afterload or intra-aortic balloon counterpulsation may be of benefit. Reduction in left ventricular afterload may help passive movement of blood through the right ventricle.

Selected Dysrhythmias in AMI

ATRIAL FIBRILLATION Atrial fibrillation associated with AMI most typically occurs in the first 24 h and is usually transient. It more often occurs in patients with excess catecholamine release, hypokalemia, hypomagnesemia, hypoxia, chronic lung disease, and sinus node or left circumflex ischemia. Patients with supraventricular tachycardia, atrial fibrillation, and atrial flutter who have hemodynamic compromise should receive cardioversion with 100 J, 200 to 300 J, and then 360 J, if lower energies fail. Patients without hemodynamic compromise, clinical left ventricular dysfunction, reactive airway disease, or heart block can be treated with β -adrenergic antagonists, such as atenolol (2.5 to 5 mg over 2 min to a total of 10 mg) or metoprolol (2.5 to 5 mg every 2 to 5 min to a total of 15 mg). Patients with contraindications to β -adrenergic antagonists can be treated with digoxin (0.3- to 0.5-mg initial bolus with a repeat in 4 h) or a calcium antagonist such as verapamil or diltiazem. Digoxin will take longer to work but is still preferred by the ACC/AHA guidelines, because of the potential negative inotropic effects of calcium antagonists, their lack of efficacy in reducing mortality during AMI, and potentially harmful effects in some subsets of AMI patients.³⁰ The AHA/ACC recommend sotalol as the initial antiarrhythmic agent in the setting of ACS based on its (3-blocking activity. This medication is contraindicated in patients with CHF. The alternative anti-arrhythmic agent is amiodarone.³⁰ The etiology of the tachydysrhythmia should also be addressed. Heparin should be given, because atrial fibrillation during AMI is associated with a threefold risk in systemic embolization.

BRADYDYSRHYTHMIAS The increased mortality in patients with heart block during AMI is related to more extensive myocardial dam-

age and not to the heart block itself. As a result, pacing has not been shown to reduce mortality in patients with atrioventricular (AV) block or intraventricular conduction delay. Nonetheless, pacing is recommended to protect against sudden hypotension, acute ischemia, and precipitation of ventricular dysrhythmias in certain patients.

The risk of developing third-degree heart block during AMI is increased in the setting of first-degree AV block, both types of second-degree AV block (more likely with Mobitz II), left anterior hemiblock, left posterior hemiblock, right bundle-branch block, and left bundle-branch block. The prognosis is related to the site of infarction, the site of the block (intranodal vs. infranodal), the type of escape rhythm, and the hemodynamic response to the rhythm.

Atropine is recommended for sinus bradycardia when it results in hypotension, ischemia, or ventricular escape rhythms and for treatment of symptomatic AV block occurring at the AV nodal level (second-degree type 1 or third-degree AV block). Atropine will reverse decreases in heart rate, systemic vascular resistance, and blood pressure that are mediated by parasympathetic activity. It should be used cautiously in the setting of AMI, because the parasympathetic tone is protective against infarct extension and ventricular fibrillation and may result in increased myocardial oxygen demand.

Temporary *transcutaneous* pacers are recommended for patients at moderate to high risk of progression to AV block (Table 51-3). *Transvenous* pacing should be considered in patients who require permanent pacing and in patients with a very high likelihood (>30 percent) of requiring permanent pacing (see Table 51-3). Patients with right ventricular infarction who are very dependent on atrial systole may require AV sequential pacing to maintain cardiac output.

SYNCOPE Barbara
K. Blok Tina M.
Newman

Syncope is a sudden, transient loss of consciousness associated with inability to maintain postural tone. Syncope accounts for approximately 3 percent of ED visits each year. The elderly population has the highest incidence and is at increased risk for morbidity from syncopal episodes.¹ Near-syncope, a premonition of syncope without loss of consciousness, shares the same basic pathophysiologic processes as syncope. Vertigo and dizziness, which lack a premonition of syncope, are not considered near-syncope (see Chap. 231).

PATHOPHYSIOLOGY

The final common pathway of syncope is a lack of vital nutrient delivery to the brainstem reticular activating system, leading to loss of consciousness and postural tone. Most commonly, an inciting event causes a drop in cardiac output, which, unless corrected rapidly, decreases oxygen and substrate delivery to the brain. Less commonly, vasospasm or other alterations in flow singularly reduce central nervous system blood flow. The reclined posture of syncope and the response of autonomic autoregulatory centers reestablish cerebral perfusion, leading to a spontaneous return of consciousness.

ETIOLOGY

The differential diagnosis of syncope is vast and includes everything from common benign disorders to life-threatening processes (Table 52-1). The most common causes of syncope are cardiac dysrhythmia, vasovagal reflex-mediated, and orthostatic hypotension.^{2,3} In the Framingham Heart Study, 7814 patients were followed for 17 years, and 822 reported syncope. The causes were: vasovagal (21%), cardiac (10%), orthostatic (9%), unknown (37%)⁴

Reflex-Mediated Syncope

Under normal circumstances a physical or emotional stress leads to increased sympathetic outflow and a subsequent increase in heart rate, blood pressure, and cardiac output. In patients with reflex-mediated

TABLE 52-1 Causes of Syncope

Reflex-mediated	Cardiac*
Vasovagal	Structural cardiopulmonary disease Valvular heart disease
Situational	Aortic stenosis
Cough	Tricuspid stenosis
Micturition	Mitral stenosis Cardiomyopathy
Defecation	Pulmonary hypertension Congenital heart disease Myxoma
Swallow	Pericardial disease Aortic dissection Pulmonary embolism
Neuralgia	Myocardial ischemia Myocardial infarction Dysrhythmias
Carotid sinus syndrome	Bradydysrhythmias
Orthostatic hypotension* (See text)	Stokes-Adams attack
Psychiatric	Sinus node disease
Neurologic	2nd- or 3rd-degree heart block
Transient ischemic attacks*	Pacemaker malfunction
Subclavian steal*	Tachydysrhythmias
Migraine	Ventricular tachycardia
	Torsade de pointes
Medications (Table 52-2)*	Supraventricular tachycardia
Breath Holding (pediatric)	Atrial fibrillation or flutter

*Etiology that must be considered in the ED. If these etiologies cannot be excluded or the underlying cause readily addressed, the patient should be admitted.

syncope (also termed neurocardiogenic or neurally mediated syncope), the stimulus produces an abnormal autonomic nervous system reflex. Most commonly, an initial increase in sympathetic outflow is inappropriately withdrawn and replaced by increased vagal tone. Hypotension with or without bradycardia follows, leading to decreased cerebral perfusion and syncope. Less commonly, the stimulus leads directly to vagal hyperactivity and symptoms. Prodromal symptoms are varied, but include blurring of vision, dizziness, pallor, nausea, and diaphoresis.

The classic example of reflex-mediated syncope is the vasovagal faint incited by a noxious stimulus (pain, fear) or a characteristic setting. Vasovagal syncope is typically preceded by warning symptoms, which may last several minutes. This diagnosis should not be made without the typical prodromal symptoms. The individual is usually in the vertical position at the time of the event. Attacks are aborted or resolved after reclining, which increases central circulation and cerebral perfusion. Upright tilt table testing can be used to diagnose vasovagal syncope.⁵

Carotid sinus hypersensitivity is another type of reflex-mediated syncope. The carotid body, located at the carotid bifurcation, is a pressure-sensitive organ. The stimulation of an abnormally sensitive carotid body by external pressure may lead to two autonomic responses. Most commonly, there is an abnormal vagal response leading to bradycardia and asystole of greater than 3 s. Less commonly, there is a vasodepressor response leading to a decrease in blood pressure of more than 50 mmHg without a significant change in heart rate. Both responses may occur simultaneously. Carotid sinus hypersensitivity is more common in men, the elderly, and among those with ischemic heart disease, hypertension, and certain head and neck malignancies. Although a number of patients may have a hypersensitive carotid sinus response on testing, unless this response culminates in syncope or recurrence of prodromal symptoms and can be associated with an inciting event, such as shaving or turning of the head, it cannot be definitely diagnosed as the cause of syncope. Approximately 25 percent of patients with carotid sinus hypersensitivity have true carotid sinus syndrome with spontaneous symptoms.² Carotid sinus hypersensitivity should be considered in all older patients with recurrent syncope and negative cardiac evaluations.

In situational syncope, there is an abnormal or hypersensitive autonomic reflex response to a specific physical stimulus (see Table 52-1).

Additionally, there may be a component of raised intracranial pressure or increased intrathoracic pressure leading to decreased cerebral perfusion. The physical stimulus may be associated with another underlying disease process: esophageal stricture in swallow syncope, prostatic hypertrophy or bladder neck obstruction with micturition syncope, and constipation with defecation syncope.

Orthostatic Syncope

When a person assumes an upright posture, blood is shifted to the lower part of the body and cardiac output drops. When a drop in cardiac output or blood pressure occurs in a healthy individual, the autonomic nervous system responds with an increase in sympathetic output and a decrease in parasympathetic output. This autonomic nervous system reflex produces an increase in heart rate and peripheral vascular resistance, leading to an increase in both cardiac output and blood pressure, thereby allowing the individual to maintain an upright posture. If the autonomic response is insufficient to counter the drop in cardiac output, decreased cerebral perfusion and syncope may follow if the person remains upright. Symptom onset is usually within the first 3 min after assuming the upright posture, but may be more delayed in some patients. Symptoms are characteristic of decreased cerebral perfusion, with blurred vision, dizziness, and tunnel vision. Orthostatic hypotension is defined as a fall in systolic blood pressure of greater than 20 mm Hg upon assuming the upright posture. Caution should be taken in diagnosing a patient with orthostatic syncope based on orthostatic blood pressure measurements alone, because 5 to 55 percent of patients with other causes of syncope have orthostatic hypotension on physical examination.⁶ To establish orthostasis as the cause of syncope, the patient should have recurrence of syncope symptoms on orthostatic testing.

Autonomic dysfunction may cause severe symptoms, with failure of vasoconstriction during orthostatic stress. Autonomic dysfunction may be a primary disease process or secondary to peripheral neuropathy, certain medications such as ganglionic blockers, spinal cord injury, and a variety of other neurologic diseases. Commonly, orthostatic symptoms are due to other conditions that lead to volume depletion, including gastrointestinal losses, bleeding, and diuresis. Medications commonly contribute to orthostatic syncope by blunting the chronotropic response of the heart to orthostatic stress or by leading to relative or absolute volume depletion. The elderly are more susceptible to orthostatic hypotension for many reasons, including use of diuretics and α -blocking agents, varying degrees of autonomic dysfunction, and other changes related to aging.

Cardiac Syncope

The causes of cardiac syncope are divided into two categories: dysrhythmias and structural cardiopulmonary lesions. In both settings, the heart is unable to provide adequate cardiac output to maintain cerebral perfusion. Although both brady- and tachydysrhythmias may lead to transient cerebral hypoperfusion, there is no absolute high or low heart rate that will produce syncope. Symptoms depend on both the autonomic nervous system's ability to compensate for a decrease in cardiac output and the degree of cerebrovascular atherosclerotic disease. A variety of dysrhythmias may lead to syncope (see Table 52-1). A bradydysrhythmia is more likely to be an incidental finding on electrocardiogram (ECG) rather than the actual cause of syncope.⁷ Dysrhythmias are most likely to occur in the setting of underlying structural heart disease, be it congenital disease or an acquired defect such as ischemic heart disease or Lyme disease. They may also occur because of a primary electrolyte imbalance as in hypomagnesemia (torsade de pointes). Dysrhythmias rarely occur in structurally normal hearts, but are seen in the familial disorders of Brugada's syndrome, long QT syndrome and catecholamine polymorphic ventricular tachycardia. Syncope from dysrhythmias is typically sudden, with prodromal symptoms, if any, lasting less than 3 s. Many patients report lack of any warning or premonition when questioned.

A wide variety of cardiopulmonary disorders may lead to syncope. Syncope caused by underlying structural cardiopulmonary disease often occurs in the setting of physical exertion, but also may be seen in response to vasodilation from medication or heat stress. A decrease in systemic vascular resistance is normally compensated by an increase in cardiac output to maintain arterial perfusion. In the presence of obstruction to flow, the upper limit of cardiac output is relatively fixed, limiting the compensation for decreased systemic vascular resistance and leading to a decrease in arterial perfusion. Aortic stenosis should be excluded as a cause of syncope in the elderly. The classic presentation is chest pain, dyspnea on exertion and syncope. Hypertrophic cardiomyopathy is characterized by asymmetric left ventricular hypertrophy and occurs most commonly in the young, although this entity is frequently present in persons older than the age of 60 years. Pulmonary outflow obstruction may also lead to syncope. Up to 13 percent of patients with acute pulmonary embolism develop syncope secondary to the acute obstruction to blood flow by a large embolus.⁸

Medications

Medications may contribute to syncope by a variety of means (Table 52-2).⁹ Antihypertensive medications such as (3-blockers or calcium channel blockers commonly lead to a blunted heart rate response after orthostatic stress. Diuretics may produce volume depletion and subsequent orthostatic hypotension. Some medications have proarrhythmic properties, increasing the concern for dysrhythmia as the cause of syncope.

Psychiatric Illness

Psychiatric disorders are found in a modest percentage of patients with syncope. In one study, the most frequent psychiatric diagnoses were generalized anxiety disorder and major depressive disorder.¹⁰ Hyperventilation has been used as a provocative maneuver in diagnosing panic disorder and generalized anxiety disorders, and can lead to hypocarbia, cerebral vasoconstriction, and subsequent syncope.^{11,12} Hyperventilation may not be obvious to the observer but can be documented by end-tidal CO₂ monitoring.¹¹ In general, a patient with syncope and a psychiatric disorder is likely to be young, with repeated episodes of syncope, multiple prodromal symptoms, and a generally positive review of symptoms. A psychiatric cause for syncope should be one of exclusion, assigned only after organic causes have been excluded.

Neurovascular Syncope

Cerebrovascular disorders are rarely the primary cause of syncope, but must be considered in any patient with syncope and signs or symptoms indicating central nervous system pathology.

Brainstem ischemia may cause a decrease in blood flow to the reticular activating system, leading to sudden brief episodes of loss of consciousness. These episodes of loss of consciousness are typically associated with other signs and symptoms of posterior circulation ischemia,

including diplopia, vertigo, and nausea, and possibly vertebrobasilar bruits. Subclavian steal is a rare cause of brainstem ischemia. It is characterized by an abnormal narrowing of the subclavian artery proximal to the origin of the vertebral artery such that with exercise of the ipsilateral arm, blood is shunted, or "stolen," from the vertebrobasilar system to the subclavian artery supplying the arm muscles. Because of anatomy, it is more common on the left. Physical examination may reveal decreased pulse volume and diminished blood pressure in the affected arm. Other causes of brainstem ischemia include vertebrobasilar atherosclerotic disease and basilar artery migraines.

Subarachnoid hemorrhage is a devastating disease process that may present with syncope. Accurate data regarding frequency of syncope presentation of subarachnoid hemorrhage is not readily available, but it does not seem to be particularly common. As intracranial pressure increases there is a decrease in cerebral perfusion pressure, which may cause syncope. The patient typically complains of sudden severe headache and may have focal neurologic findings.

Syncope in Special Populations

THE ELDERLY Because of both normal physiologic changes with aging and age-related disease processes, the elderly are at increased risk for syncope. They also are susceptible to increased morbidity from either the trauma of the syncopal episode or from iatrogenic events during subsequent hospital admission.

As a person ages, the blood vessels become calcified and less compliant, leading to diminished flow rates. The left ventricle also becomes less compliant, resulting in increased diastolic filling pressures and an increased dependence on the "atrial kick." There is a general decrease in adrenergic receptor responsiveness of both the heart and the peripheral blood vessels. Decreased adrenergic responsiveness contributes to the diminished chronotropic response seen after orthostatic stresses in the elderly. Incidence of vasovagal syncope actually decreases with age, in part as a consequence of this decreased responsiveness of the autonomic nervous. The elderly also have a less-sensitive thirst mechanism and a decreased endocrine response to volume depletion. Pathophysiologic processes that may contribute to diminished cerebral perfusion include disorders such as hypertension, atherosclerosis, and valvular disease. Chronic hypertension shifts the cerebral autoregulation mechanism to higher pressures. Orthostatic hypotension and postprandial hypotension are more common among the hypertensive elderly. Atherosclerotic disease leads to ischemia and myocardial infarction and subsequent congestive heart failure and dysrhythmias. Aortic stenosis is the most common obstructive cardiac lesion in the elderly, producing a fixed cardiac output. Risk for syncope increases when increased demand for cardiac output cannot be met.¹³ Diabetes may lead to autonomic dysfunction and peripheral neuropathy. Finally, medication usage is much more common in the elderly population, again increasing the risk of orthostasis and decreasing autonomic responsiveness to orthostatic stress. It is important to note that syncope in the elderly population is most often multifactorial and the etiology may, therefore, be difficult to establish, particularly in the ED.

PREGNANCY Pregnancy is associated with numerous physiologic changes including increased heart rate, decreased peripheral resistance, and increased stroke volume. In late pregnancy, the enlarged uterus may compress the inferior vena cava, decreasing venous return. The incidence of cardiac dysrhythmias, especially premature ventricular contractions, increases during normal pregnancy in young healthy women. However, a positive correlation has not been shown between symptoms of presyncope or syncope and cardiac dysrhythmia.¹⁴ Vasovagal syncope is a diagnosis of exclusion.

PEDIATRICS Syncope in the pediatric population is discussed elsewhere in this text (Chap. 131).

EMERGENCY DEPARTMENT EVALUATION

The goal of the emergency department evaluation of the patient with syncope is to identify those at increased risk for both immediate decompensation as a result of an underlying disease process and for future risk of serious morbidity or sudden death. The core components of the ED evaluation of syncope are a careful history, a thorough physical examination, and the electrocardiogram. The history and physical examination alone will identify the cause of syncope in most patients in whom a diagnosis can be established.²

History

Clinical history should be obtained from the patient and any witness of the event. Emphasis should be placed on the events leading up to the loss of consciousness, the characteristics of the loss of consciousness, and symptoms occurring after regaining consciousness. The history should begin with a detailed description of the events preceding the loss of consciousness, including position, environmental stimuli, and the involvement of strenuous activity or arm exercise. All premonitory symptoms should be recorded, looking for neurologic symptoms, such as vertigo or focal weakness, and cardiac symptoms, such as palpitations. Duration of loss of consciousness and symptoms occurring after regaining consciousness should also be documented. Symptoms associated with syncope that should raise concern of an immediately life-threatening diagnosis include chest pain (acute myocardial infarction, aortic dissection, pulmonary embolism, aortic stenosis), headache (subarachnoid hemorrhage), and abdominal or back pain (leaking abdominal aortic aneurysm, ruptured ectopic pregnancy). A sudden event without warning and events associated with exertion should increase suspicion of a cardiac dysrhythmia or structural cardiopulmonary lesion.¹⁶ Antecedent illness or substance use should be documented. The past medical history should include questions regarding underlying structural heart disease including congenital heart disease, valvular heart disease, coronary artery disease, and cardiomyopathy. The past medical history should also include details about prior cardiopulmonary events, including prior myocardial infarction, pulmonary embolism, ventricular dysrhythmias, and congestive heart failure. Any prior history of syncope should also be documented, as patients who have recurrent syncope with more than five episodes in 1 year are more likely to have vasovagal syncope or a psychiatric diagnosis than dysrhythmia as the cause.² All medications should be recorded, including over-the-counter medications such as laxatives. Patients aggressively dieting to lose weight may have electrolyte disturbances or be taking amphetamine-like medications. The family history is important in regards to history of prolonged QT syndrome, dysrhythmias, sudden cardiac death, or other cardiac risks.

Special attention should be paid to patients presenting with single-car motor vehicle crashes (especially driving off the road), particularly if the patients are elderly. Clinicians may become preoccupied by the trauma evaluation and miss the possibility of syncopal event.

Seizure is the most common event mistaken as syncope. The two conditions do not share the same pathophysiologic mechanisms. Occasionally, the underlying mechanism that causes syncope may result in an associated seizure (e.g., cerebral hypoperfusion). History is very important in differentiating syncope from seizure.¹⁵ Pre- and postmonitory symptoms may assist in differentiation. A classic aura or postictal confusion and muscle pain indicate seizure while characteristic prodromal symptoms of nausea and diaphoresis suggest reflex-mediated syncope. Witness information of the event may also be useful. Witnessed head turning or unusual posture during the event is consistent with seizure. Extremity movement is less reliable, as the brief asynchronous movements that may follow the loss of consciousness with syncope are often confused with the tonic-clonic movements of seizures. Urinary incontinence is not useful in the distinction. A wide transitory, anion gap acidosis follows a generalized seizure but is not present in simple syncope.

Physical Examination

Evidence of trauma without defensive injuries to the hands or knees should raise suspicion of a sudden event without warning, such as a dysrhythmia. The physical examination should focus on both the cardiovascular and neurologic systems. Blood pressure measurements should be taken in both arms. Unequal blood pressures should increase suspicion of aortic dissection or subclavian steal. The presence of orthostatic hypotension and symptoms should be sought. To appropriately evaluate orthostasis, the patient should be supine for a period of 5 min and then should arise to the standing position. After standing, blood pressure measurements should be taken two to three times over the next few minutes. A decrease in systolic blood pressure greater than 20 mm Hg is considered positive. Cardiac examination may reveal the murmur of hypertrophic cardiomyopathy or aortic stenosis. The neurologic examination may uncover findings of focal neurologic disease or evidence of autonomous instability such as the presence of peripheral neuropathy. Rectal examination should be performed to evaluate for gastrointestinal bleeding.

Electrocardiogram

A 12-lead ECG should be obtained, even though the electrocardiogram and rhythm strip lead to a diagnosis in only a small number of patients.³ The ECG should be evaluated for evidence of prior cardiopulmonary disease, acute ischemia, dysrhythmia, and heart block, prolonged QT interval. Patients should be monitored for abnormal cardiac activity until a cardiac origin has been reasonably excluded.

Laboratory Testing

Laboratory testing is directed by results of the history and physical examination. For example, a patient with orthostatic symptoms and heme-positive stool test warrants at least a complete blood count (CBC). A reproductive-age female should have a urine pregnancy test. Although electrolyte abnormalities may be implicated as a cause of seizures, they are rarely the cause of syncope.³ Evidence of an irritable myocardium, profound weakness, dehydration, or diuretic use merits serum electrolyte determination, particularly potassium.

Carotid Massage

Carotid massage is used to diagnose carotid sinus hypersensitivity in the patient with a history suggestive of carotid sinus syndrome. Although not general emergency practice at this time, it can be done at the bedside in the ED with continuous electrocardiographic and blood pressure monitoring after informed consent has been obtained. Each carotid body is separately massaged for 5 to 10 s. The test is considered positive if symptoms are reproduced in the presence of asystole greater than 3 s or fall in systolic blood pressure of >50 mm Hg. Carotid massage should not be done if the patient has known carotid stenosis, if bruits are present, if there is history of recent (<3 months) stroke or myocardial infarction, or if there is a history of ventricular tachycardia or fibrillation. Neurologic deficits resulting from cardiac massage are rare, with deficits lasting more than 24 h in approximately 0.1 percent of patients.^{17,18} Only a small number of patients with carotid hypersensitivity will have the true carotid sinus syndrome.

Hyperventilation Maneuver

A hyperventilation maneuver (open-mouthed, slow, deep breaths at a rate of 20 to 30 breaths per minute for 2 to 3 min) can be very useful in the young patient with undiagnosed syncope and suspected psychiatric illness. This can easily be performed in the ED. A recurrence of prodromal symptoms or syncope significantly correlates with psychiatric (anxiety-provoking) causes of syncope.¹¹

Neurologic Testing

Studies fail to show any benefit of routine computed tomography (CT) scanning, electroencephalogram (EEG), or lumbar puncture for patients who lack a history or physical examination that supports a neurologic cause of syncope.³

DISPOSITION

Figure 52-1 provides a general management strategy.

Diagnosis Established

If a cause of syncope can be determined by the initial history, physical examination and ECG, identification of high-risk patients is simple. Those patients with acute neurologic deficits or life-threatening disorders are at immediate risk of morbidity. Additionally, patients with cardiac causes of syncope represent a high-risk group for major morbidity or death and need further inpatient monitoring and evaluation. In the Framingham Study, the hazard ratios for cardiac syncope were 2, 2.66, and 2 for death from any cause, myocardial infarction or death from coronary heart disease, and fatal or nonfatal stroke, respectively. Patients with reflex-mediated syncope (including vasovagal, orthostatic, and medication-related syncope) had no increased risk of cardiovascular morbidity or mortality.⁴ Unfortunately, on evaluation in the ED, a cause of syncope is not identifiable in up to half of patients.³

Unexplained Syncope

Patients with an unknown etiology of syncope after the initial ED evaluation need a further inpatient or outpatient medical evaluation that focuses on the identification of risk factors for morbidity and mortality (see Figure 52-1).

The evaluation of the patient with unexplained syncope should focus on identifying those at high risk for a cardiac etiology. Heart disease should be suspected in patients presenting with exertional syncope or an abnormal cardiac history, examination or electrocardiogram. Patients with underlying heart disease, irrespective of cause, are at greatest risk of cardiac arrhythmia and death.¹⁸ This is further supported by a prospective study that focused on risk stratification of patients with syncope based on clinical and electrocardiographic characteristics.¹⁹ **The study found four significant predictors of sudden cardiac death or signifi-**

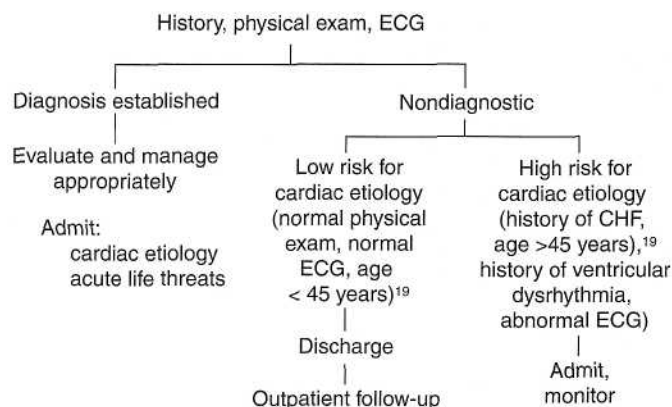

FIG. 52-1. ED management of syncope.

cant dysrhythmia within one year of a syncopal event: abnormal electrocardiogram (anything other than nonspecific ST-T changes), age older than 45 years, history of ventricular dysrhythmia, and history of congestive heart failure. Numbers of predictors are correlated with degree of risk. This is also consistent with prior studies that show that the prognosis of syncope in patients without heart disease is very good.^{20,21} The young patient with syncope, a normal physical examination, and a normal electrocardiogram has a very low risk of morbidity.

Indications for hospital admission, therefore, include patients with acute neurologic or life-threatening disorders and patients at risk for a cardiac etiology of syncope (see Figure 52-1). Patients without a clear diagnosis of vasovagal episode who are discharged from the ED should be accompanied by a responsible adult and be advised not to drive, work at heights, or operate machinery until further outpatient evaluation.

POST-ED EVALUATION

Inpatient Evaluation

With the exception of those patients with acute life-threatening diagnoses (stroke, aortic dissection, etc.), the core of the inpatient evaluation is focused on identification of underlying heart disease and detection of dysrhythmias (Table 52-3). All admitted patients require

TABLE 52-3 Post-ED Testing for Syncope

Test	Indication	Utility
Cardiac syncope		
Electrocardiographic monitoring	Admission Outpatient event monitor if no significant cardiac disease suspected History, examination or ECG suggestive of structural heart disease Documented	Cardiac syncope confirmed if recurrent symptoms occur during monitored dysrhythmia; excluded if recurrent symptoms reported during sinus rhythm
Echocardiography		Confirm and quantify suspected structural heart disease
Electrophysiology testing	dysrhythmia or serious underlying heart disease	Identifies inducible tachydysrhythmias and some bradydysrhythmias Identifies exercise-induced dysrhythmias and postexercise syncope
Stress testing	Exercise-related syncope	
Neurologic syncope		
CT/MRA/Carotid Doppler	Neurologic signs or symptoms	Identify cerebrovascular abnormality or subclavian stenosis
Electroencephalography	Suspected seizure	Document underlying seizure disorder
Reflex-mediated syncope		
Tilt table testing	Recurrent syncope, cardiac etiology excluded	Positive test establishes diagnosis of neurocardiogenic syncope
Psychogenic		
Psychiatric testing	Young patient, no underlying heart disease	Identifies underlying psychiatric disorder predisposing to syncope

continuous electrocardiographic monitoring. Dysrhythmia as the cause of syncope is confirmed in the patient with recurrent symptoms during a monitored dysrhythmia and excluded in the patient with recurrent symptoms and sinus rhythm. An echocardiogram should be performed on patients with known or suspected heart disease to evaluate for abnormalities, such as valvular disorders, congenital anomalies and cardiomyopathies, and to determine overall cardiac function. Abnormalities are usually clinically apparent and will seldom be found in patients with a normal cardiac examination and ECG. Stress testing is used to identify exercise-induced dysrhythmias or ischemia, or to reproduce postexertional syncope. It should be performed in patients with exercise-related syncope, once hypertrophic cardiomyopathy has been excluded by echocardiography. Electrophysiology (EP) testing is typically reserved for patients with documented dysrhythmia, preexcitation or underlying heart disease. EP testing involves invasive electrical stimulation and monitoring of the heart to uncover possible conduction abnormalities that predispose patients to tachydysrhythmias (both ventricular and supraventricular). EP studies may also detect bradydysrhythmias, but the yield is lower.

Outpatient Evaluation

Patients undergoing outpatient syncope evaluation are deemed to be at low risk for serious cardiac dysrhythmias. Long-term monitoring, which includes external or implanted loop-event monitors, is useful to further evaluate potential dysrhythmias (see Table 52-3). Tilt table testing is also suggested for patients with recurrent, unexplained syncope. This test is designed to identify reflex-mediated syncope by rapidly moving the patient from a supine position on the tilt table to an upright position of 60 degrees for 45 min. A positive end point is reached if syncope, hypotension, or the patient's typical symptoms are reproduced. Repeat testing with isoproterenol or sublingual nitroglycerin is performed if the initial evaluation is negative. Recurrent reflex-mediated syncope resistant to conservative therapies has been successfully treated with a cardiac pacemaker. Psychiatric referral is recommended for young patients without underlying heart disease who have frequent syncopal events. Generalized anxiety and depressive disorders are the most commonly assigned diagnoses.

CONGESTIVE HEART FAILURE AND ACUTE PULMONARY EDEMA W. Franklin Peacock IV

With 4.7 million cases and approximately 550,000 new patients each year,¹ the United States is currently experiencing a heart failure (HF) epidemic. Heart failure disproportionately affects the aged. Fewer than 1 percent of Americans younger than 50 years are stricken, but prevalence doubles each decade until, by age 80 years, nearly 10 percent carry the diagnosis. It is the leading cause of hospitalization among those older than 65 years,¹ accounts for nearly 1,000,000 hospitalizations annually, and up to 60 percent of discharged HF patients are rehospitalized within 6 months due to recurrent decompensation.² With predictions that the cohort older than 65 years will double in the next 30 years, the impact of HF is expected to increase. The costs of HF are roughly double that of any cancer diagnoses in the United States. In 2002 the estimated direct costs will exceed 15 billion dollars.²

PROGNOSIS

Heart failure has a poor prognosis. Once symptomatic, 2-year mortality is about 35 percent and over the next 6 years increases to 80 percent for men and 65 percent for women.¹ Symptom severity predicts outcome. Annual mortality rates are 5 to 10 percent in mild-moderate HF and 30 to 40 percent in severe HF. After the development of pulmonary edema, only 50 percent survive 1 year. After cardiogenic shock, up to 85 percent die within 1 week.

The New York Heart Association (NYHA) HF classification is used as a prognostic scale in most existing studies (Table 53-1). This scale is limited by excluding asymptomatic HF, has poor sensitivity and high interobserver variability, but does predict mortality. One-year mortality exceeds 50 percent in class IV. The American Heart Association scale uses risk factors to determine interventions. This system recognizes that earlier intervention has the greatest potential for morbidity and mortality reductions (see Table 53-1).³

PATHOPHYSIOLOGY

Heart failure may present acutely as a result of acute pump dysfunction from acute myocardial infarction. Mechanistically, loss of a critical mass of myocardium results in immediate symptoms. If there is symptomatic hypotension with inadequate perfusion, cardiogenic shock is present (see Chap. 33).

TABLE 53-1 Heart Failure Classifications and Stages

NYHA Class	ACC/AHA Class	Stage	Patient Description	Median BNP (pg/mL)
	A	High risk for developing LVD	Hypertension, coronary artery disease, diabetes mellitus, family history of cardiomyopathy	<100
I	B	Asymptomatic LVD	Previous MI or LV systolic dysfunction, asymptomatic valvular disease, no limitations of physical activity	100
II and III	Symptomatic LVD Known structural heart disease, reduced exercise tolerance, shortness of breath and fatigue with ADL			220 to 450
IV		Refractory end-stage heart failure	Marked symptoms at rest despite maximal medical therapy	1000

Abbreviations: ACC/AHA = American College of Cardiology/American Heart Association; ADL = activity of daily living; BNP = B-type natriuretic peptide; LV = left ventricular; LVD = left ventricle dysfunction; MI = myocardial infarction; NYHA = New York Heart Association.

Heart failure can present precipitously as acute pulmonary edema (APE). Acute pulmonary edema is the clinical manifestation of a downward spiral of rapidly decreasing cardiac output (CO) and rising systolic vascular resistance (SVR) on the face of underlying cardiac dysfunction. Even relatively small elevations of blood pressure (BP) can result in decreased CO. Decreasing CO triggers increased SVR, which further worsens CO. Acute pulmonary edema can present acutely with severe symptoms, and, if the extremely elevated SVR is not promptly reversed, it will be the terminal event. Heart failure can also present insidiously as the final consequence of a cascade of pathologic neurohormonal and hemodynamic reflexes initiated by myocardial injury or stress. Threats to CO trigger a neurohormonally mediated cascade that includes activation of the renin-angiotensin-aldosterone system and the sympathetic nervous systems. Levels of norepinephrine, vasopressin, endothelin (a potent vasoconstrictor), and tissue necrosis factor- α are increased. Although not available clinically, levels of these hormones directly correlate with mortality in HF patients.

The combined clinical effects of neurohormonal activation are sodium and water retention and increased SVR. These compensatory mechanisms may maintain BP and perfusion, but at the cost of increased myocardial workload, wall tension, and, hence, myocardial oxygen demand. Although some patients are initially asymptomatic, the mechanism of cardiac remodeling, a secondary pathologic process, begins to occur. The type of remodeling determines future hemodynamics and therapies.

Natriuretic peptides (NPs) are the endogenous counterregulatory arm to the pathologic neurohormonal activation of HF. Three types are recognized: atrial NP, primarily secreted from the atria; B-type NP (BNP), secreted mainly from the cardiac ventricle; and CNP, localized in the endothelium. Natriuretic peptides result in vasodilation, natriuresis, decreased levels of endothelin, and inhibition of the renin-angiotensin-aldosterone system and the sympathetic nervous systems. BNP is the only NP for which an assay is currently available. BNP is synthesized as N-terminal pre-pro-BNP, which itself is cleared to two substances, inactive N-terminal pro-BNP, with a half-life of approximately 2 h, and physiologically active BNP, with a half-life of about 20 min.⁴

Because elevated levels of neurohormones portend a worse prognosis in HF, their attenuation provides the theoretical basis for most therapies proven to delay HF morbidity and mortality. These include treatment with angiotensin-converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), spironolactone, β -blockers, and nesiritide.

SYSTOLIC VERSUS DIASTOLIC HF

The law of LaPlace describes wall tension as a product of pressure (afterload) and ventricular radius. Increased wall tension is the stimulus

for cardiac remodeling. Initially, myocytes hypertrophy or die (apoptosis) to form scar tissue. The dominant response determines HF type. Many different pathologies can lead to the clinical presentation of HF (Table 53-2).

Heart failure is classified as systolic or diastolic by ejection fraction (EF) measurement, which is normally 60 percent. *Systolic dysfunction*, defined as an EF under 40 percent, is most commonly from ischemic heart disease, but other causes may be considered. Mechanistically, the ventricle has difficulty ejecting blood. Impaired contractility leads to increased intracardiac volumes and pressure and *afterload sensitivity*. With circulatory stress (e.g., walking), failure to

†Includes idiopathic (see Chap. 55).

improve contractility, despite increasing venous return, results in increased cardiac pressures, pulmonary congestion, and edema.

In *diastolic HF*, contractile function is preserved, and the EF is normal or higher. The main pathology is impaired ventricular relaxation, causing an abnormal relation between diastolic pressure and volume. This results in a left ventricle (LV) that has difficulty receiving blood. Decreased LV compliance necessitates higher atrial pressures to ensure adequate diastolic LV filling and results in *preload sensitivity*. The frequency of diastolic dysfunction increases with age. Chronic hypertension and LV hypertrophy are often responsible for this condition (see Table 53-2). Coronary artery disease also contributes, as diastolic dysfunction is an early event in the ischemic cascade.

As many as 30 to 50 percent of elderly HF patients have circulatory congestion on the basis of diastolic dysfunction.⁵ Treatment for volume overload, the most common ED presentation, is the same irrespective of EF. Because patients with diastolic dysfunction are preload dependent, excessive diuresis or venodilation may exacerbate the underlying deficit in ventricular filling and cause hypotension. After hemodynamics are stabilized and congestion resolved, treatment of diastolic dysfunction requires consideration of the underlying etiology. Determining HF type is difficult from the history and physical examination. Consequently, an echocardiogram is usually necessary. Determining the etiology for diastolic dysfunction is rarely an ED task, but the workup may be initiated from an observation or acute care unit.

Some differentiate left- from right-side HF. Isolated left-side HF is associated with dyspnea, fatigue, weakness, cough, paroxysmal nocturnal dyspnea, and orthopnea in the absence of peripheral edema, jugular venous distention (JVD), or hepatojugular reflux. Right-side HF has peripheral edema, JVD, right upper quadrant pain, and hepatojugular reflex, without pulmonary symptoms. Abnormal pressure and chamber volumes are eventually reflected to the contralateral side. Untreated or poorly controlled left-side HF eventually may be reflected on the right. With isolated right-side HF (e.g., right ventricular infarct), left-side HF is less likely but can eventually occur. This traditional distinction (right vs. left HF), although often mentioned, does not have great bearing on the ED approach. For example, volume overload is approached in a uniform manner for the most part. This distinction has greatest applicability when there is suspicion of valvular heart disease or right ventricular infarction (see Chaps. 50 and 54).

High output HF can occur when the normally intact myocardium is unable to meet excess functional demands. These instances are relatively few but include anemia, thyrotoxicosis, large atrioventricular shunts, beriberi, and Paget disease of the bone. The appropriate treatment for these conditions is symptomatic and addresses the causative pathology.

DIAGNOSIS

History and Physical Examination

Acute pulmonary edema is characterized by severe respiratory distress, relative hypertension, and cool diaphoretic skin. Rales may be heard over most of the lung fields, JVD is marked, but peripheral edema may or may not be present. In comparison with pulmonary edema, decompensated HF is a difficult diagnosis. It occurs in a population of patients at risk for many comorbidities, and errors in diagnosis are further compounded by a lack of accurate testing available in real time. The ED diagnostic error rate is reported as 12 percent, equally divided between over- and underdiagnosis.⁶ Errors occur because neither history nor physical examination are accurate for HF. Dyspnea has a sensitivity and specificity of about 50 percent; orthopnea has a specificity of 88 percent, but with no better sensitivity; and rales have a predictive accuracy of only 70 percent. Edema is even worse as a HF indicator. The best physical finding suggestive of an el-

evated pulmonary capillary wedge pressure (PCWP) is the S3, with a specificity of 99 percent. However, it is difficult to detect in the ED, and its sensitivity is 20 percent.⁶ Similarly, JVD, with a specificity of 94 percent, has a sensitivity of 39 percent. In other studies, reported confounders impeding a correct HF diagnosis include obesity, deconditioning, and female sex.

Chest Radiography

Until recently, ancillary tests available in the ED offered little accuracy improvement over history and physical examination. Even though the HF diagnostic gold standard is echocardiography, because of limitations on technology or performance expertise, it is not used for this purpose in most EDs. Therefore, other measures are used. Chest radiographs (CXR) are easily obtained but are a blunt tool for evaluating cardiopulmonary status. Although a normal CXR cannot exclude abnormal LV function, it helps eliminate other diagnoses (e.g., pneumonia). The radiographic findings of left-side HF are, in descending order of frequency, dilated upper lobe vessels, cardiomegaly, interstitial edema, enlarged pulmonary artery, pleural effusion, alveolar edema, prominent superior vena cava, and Kerley lines.⁸ **Because acute abnormalities lag the clinical appearance by up to 6 h, therapy is not withheld pending an CXR.**

In chronic HF, congestive signs have unreliable sensitivity, specificity, and predictive value for identifying patients with high PCWP. Radiographic pulmonary congestion is absent in 53 percent of patients with mild to moderately elevated PCWP (16 to 29 mm Hg) and in 39 percent of those with markedly elevated PCWP (>30 mm Hg).⁹

Cardiomegaly can be helpful for diagnosing HF. However, although a cardiothoracic ratio larger than 60 percent correlates with increased 5-year mortality, CXR sensitivity for cardiomegaly can be poor. This observation is explained by intrathoracic cardiac rotation. In one study of echocardiographically proven cardiomegaly, 22 percent had a normal cardiothoracic ratio.¹⁰

Pleural effusion can be missed by the CXR, especially if the patient is intubated and supine. In patients with pleural effusions, the sensitivity, specificity, and accuracy of the supine CXR for HF were reported to be 67, 70, and 67 percent, respectively.¹¹

The sensitivity for HF with a portable CXR is poor. In mild HF, only the finding of dilated upper lobe vessels was reported in more than 60 percent of patients. Nevertheless, in the ED setting, the CXR is helpful. The frequency that CXR HF parameters are present increases with HF severity. With severe HF, some CXR findings occurred in at least two thirds of patients, except for Kerley lines (11 percent) and prominent vena cava (44 percent).⁸ Absence of any associated findings in CXR without significant vital sign or pulse oxymetric abnormalities is reassuring.

Natriuretic Peptide Assay

Natriuretic peptide measurement offers improved diagnostic accuracy for HF. These proteins are released by ventricular pressure or volume stimulus and, consequently, correlate with elevated PCWP. As a point-of-care assay, BNP, predicts the presence of HF. In non-HF, BNP levels averaged 38 pg/mL, compared with HF patients whose mean level was 1076 pg/mL.⁶ When HF is graded by NYHA class, BNP levels vary directly with severity. BNP is helpful in patients most difficult to diagnose, i.e., those with combined COPD and HF. In dyspnea due to COPD, BNP levels were less than 100 pg/mL, compared with HF patients whose levels exceeded 1000 pg/mL. An analysis of edematous patients found similar results.⁶ When signs and symptoms raise suspicion of HF, a BNP level may contribute to an accurate diagnosis.

In ED patients, BNP levels also correlate with subsequent clinical events. Emergency department BNP levels greater than 480 pg/mL were associated with a 40 percent rate of death or HF re-hospitaliza-

tion within 6 months, compared with 3 percent when levels were lower than 230 pg/mL.¹² Mortality is also predicted by BNP. With BNP levels above 73 pg/mL, mortality is markedly increased in the next 12 months versus those with BNP levels below 73 pg/mL.¹³

The diagnosis of HF is suggested by the proper clinical scenario and a BNP greater than 100 pg/mL. This test has a coefficient of variation of about 10 percent; but in the ranges that BNP occurs clinically, this number is not statistically significant. At the 100 pg/mL level, BNP demonstrates a sensitivity of 90 to 94 percent and a specificity of 76 to 94 percent. The positive and negative predictive values are 79 to 92 percent and 89 to 96 percent, respectively, and the overall accuracy is 83 to 94 percent.^{14,15} There are confounders to BNP as an HF test. BNP is increased in the elderly, women, those with cirrhosis or renal failure, possibly those on hormone replacement therapy, and probably those with pulmonary embolus and primary pulmonary hypertension. Consequently, the clinical application of the BNP assay is that a level below 100 pg/mL effectively excludes HF with good reliability, and a markedly elevated BNP is strong evidence of HF. However, lesser elevations (100 to 250 pg/mL) should prompt consideration of other confounding diagnoses and confirmatory testing.

Differential Diagnosis

The differential diagnosis should be considered from two perspectives: (1) conditions that mimic or may be confused with HF, and (2) conditions that precipitate or worsen HF (Table 53-3). Many of the conditions that mimic HF can actually precipitate it. Until excluded, acute myocardial infarction must always be considered as the etiology of the HF exacerbation. Further, breathlessness is a common symptom, so other dyspneic conditions should be considered. A common confounder is coexisting obstructive pulmonary disease. Severe hypertension and peripheral vasoconstriction suggest acute HF, even with audible wheezing. Pneumonia or pulmonary embolus can mimic or exacerbate HF. Differentiating HF from other causes can be challenging. History and physical examination may help, but the CXR is misleading when chronic HF findings are unrelated to the presentation. Comparison views may be helpful here. Edema is seen in HF but is nonspecific, because it is found in hypoproteinemic states, hepatic or renal failure, and vascular diseases.

Acute valvular insufficiency
Drug overdose/effect
Dysrhythmias
Pericardial tamponade
Tension hydro- or pneumothorax
High output state
Sepsis
Anemia
Thyroid dysfunction

TREATMENT

General Measures

The initial approach is driven by the acuity of presentation, volume status, and systemic perfusion. In critical patients, airway management supersedes all else. This is in contrast to the mildly symptomatic patient whose evaluation may precede emergent stabilization procedures.

Initial stabilization is aimed at maintaining airway control and adequate ventilation. Supplemental oxygen use may be guided by pulse oximetry. Because hypoxia is a greater risk than hypercarbia, O₂ is not withheld due to CO₂ retention concerns. Arterial blood gas measurements may be helpful in the critically ill or if CO₂ retention is likely. Endotracheal intubation with mechanical ventilation or support is indicated if stability is unclear.

Noninvasive positive pressure ventilation (NIPPV) is controversial in the HF patient (see Chap. 18). Some investigators report that it temporizes the properly selected patient while awaiting hemodynamic interventions to become effective. Biphasic positive airway pressure (BiPAP) involves delivery of separately controlled inspiratory and expiratory pressures by face mask. Continuous positive airway pressure (CPAP) delivers constant pressure throughout the respiratory cycle. For a trial of NIPPV close monitoring, hemodynamic stability, and patient cooperation are required. NIPPV may offer a mortality benefit over invasive mechanical ventilation in COPD, but data are controversial in acute pulmonary edema. The use of NIPPV may decrease need for endotracheal intubations; however, mortality appears to be unchanged, and some report that patients on CPAP have higher rates of myocardial infarction than do patients treated with BiPAP,¹⁶ although even this finding is unclear.

Standard initial ED measures include cardiac monitoring, pulse oximetry, 12-lead electrocardiogram, intravenous access, and frequent vital sign assessments. Coronary artery disease is one of the most common underlying conditions associated with HF. As many as 14% of ED patients presenting with acute decompensated HF will have positive serum cardiac markers.^{17a} If acute myocardial infarction is suspected, emergent reperfusion therapy is considered. Chest radiography, complete blood cell count, electrolytes, BNP level, and cardiac markers are generally measured.

Other considerations include liver enzymes in the face of hepatomegaly, which may exclude etiologies other than passive congestion. In the presence of widened anion gap acidosis, an elevated lactate level may confirm cardiogenic shock. Testing for drug levels, e.g., digoxin, is guided by the presentation. Ethanol and drug screening may be needed, and assay for Mg²⁺ is considered with arrhythmia or severe hypokalemia. A urinary drainage catheter is placed as needed to monitor fluid status in the severely ill, or if urine output is sufficient to interfere with the patient's ability to rest.

Precipitants of decompensation should be measured (Table 53-4).

Acute Pulmonary Edema

The failing heart is very sensitive to increases in afterload. In some, systolic BP as low as 150 mm Hg can precipitate pulmonary edema. Prompt recognition and afterload reduction can avoid the need for intubation. An initial approach is repeated sublingual administration of nitroglycerin (NTG), 0.4 mg, at rate of up to one per minute, until intravenous NTG (0.2 to 0.4 µg/kg per min) is initiated, or BP declines and symptoms improve. Intravenous NTG is titrated rapidly upward (200 µg/min or higher) until BP is controlled. If pressures remain elevated, and clinical improvement is not achieved, conversion to intravenous nitroprusside may be required. Nesiritide may be an appropriate alternative to NTG in selected patients who do not require immediate endotracheal intubation. The critical end point is rapidly lowering the filling pressure to prevent the need for endotracheal intubation.

*Very common.

These agents should be administered as soon as vascular access is established. Volume reduction with diuretics is also critical to lower BP and cardiac filling pressures. Intravenous furosemide or bumetanide are the preferred diuretics in the setting of acute pulmonary edema (Table 53-5). Ethacrynic acid is used if there is a serious sulfa allergy. These diuretics share the parameters of rapid onset; diuresis can begin 10 to 15 min after intravenous furosemide. If urine output is inadequate in 20 to 30 min, the diuretic dose is increased and repeated. Diuretics also have an early effect as weak venodilators.

Morphine (2 to 5 mg IV) is also used as a venodilator. Successful management of BP and cardiac filling pressure is reflected by a marked improvement in respiratory status long before any significant diuresis.

Contraindications to Vasodilation

Several pathologic conditions increase the risk of hypotension as a consequence of overly aggressive vasodilation. Physiologically, these

are the preload-dependent states and include right ventricular infarction, aortic stenosis, or volume depletion. Hypertrophic cardiomyopathy (HCM) is also a contraindication to vasodilation. Combined with acute pulmonary edema, the latter is a very difficult management problem. Increases in cardiac contractility or heart rate can increase the dynamic outflow obstruction of HCM, and conditions of decreased preload or afterload also worsen the obstructive gradient. Therapy is aimed at decreasing the outflow gradient by slowing heart rate and cardiac contractility. Although this can be accomplished with intravenous (3-blockers, it is best done in the intensive care unit (ICU) with hemodynamic guidance. If there is coexistent shock, phenylephrine (40 to 100 μ g/min IV) is the preferred pressor, because it results in peripheral vasoconstriction without increasing cardiac contractility.

Decompensated HF

These patients may have stable vital signs, adequate oxygenation, and ventilation. However, patients will have some signs and symptoms (e.g., shortness of breath, orthopnea, JVD, rales, and possibly an S_3). Most require only diuresis, oxygen, and BP control. Selecting optimal treatment requires determining perfusion status and estimating the degree of pulmonary congestion. The worse the decompensation, the closer the management models reflect that required for pulmonary edema, described above. Vasoconstricted patients will benefit from vasodilators; those with congestion require diuretics. The most common presentation of ED HF is the vasoconstricted congested patient; for these patients, treatment with vasodilators and diuretics will generate the best outcomes. In addition, this strategy, by decreasing PCWP, is likely to produce the best clinical results in chronic HF, because mortality rates are linked directly to the PCWP.

Stable HF

Very large trials provide evidence-based data for managing stable outpatient, systolic HF. The principal drugs are β -blockers, ACEIs, ARBs, hydralazine or nitrates, diuretics, digoxin, and spironolactone. In

TABLE 53-5 Treatment Options for Congestive Heart Failure

Diuretics for Heart Failure			
Diuretic	Dose	Effect	Complications
Furosemide	No prior use: 40 mg IVP If prior use: Double last 24-h usage (range, 80-180 mg) If no effect by 20-30 mins: re-double dose	Diuresis starts within 15-20 min Duration of action is 4-6 h	4- K^+ , Mg^{2+} , hyperuricemia, hypovolemia Ototoxicity, pre-renal azotemia, sulfa allergy
Bumetanide	1-3 mg	Diuresis starts within 10 min Peak action at 60 min	Same as above
Ethacrynic acid	50 mg	Similar to furosemide	Same as above, T ototoxicity
Vasodilators for Acute Heart Failure			
Vasodilator	Dose	Titration End Point	Complications
SLNTG IV NTG	0.4 mg, q1-5 min 0.2-0.4 (μ g/kg per min (starting dose)	Blood pressure Symptoms	Hypotension Headache
Nitroprusside	0.3 μ g/kg per min (starting dose), 10 μ g/kg per min (maximum)	Blood pressure Symptoms	Hypotension, cyanide toxicity, ?coronary steal Thiocyanate toxicity
Nesiritide	2 μ g/kg bolus, then infusion of 0.01 μ g/kg per min	Titration usually unnecessary	Hypotension
Morphine	2-5 mg IV, q3-5 min	Blood pressure Respiratory rate Symptoms	Respiratory depression Hypotension Altered mental status

Abbreviations: IVP = intravenous push; NTG = nitroglycerin; SL = sublingual.

general, the strategy focuses on maintaining the lowest possible BP for mentation, ambulation, and urination. All HF patients without contraindications should be chronically treated with ACEI and (3-blockers (Table 53-6), even in the setting of stable disease and minimal symptoms. The neurohormonal antagonism requirements of HF therapy differ from those of most diseases for which therapy is driven by continuing symptoms. The emphasis on neurohormonal antagonism for HF represents a major management shift. Historically, diuretic relief of congestion was the main thrust of ED therapy. Although diuretics are important for acute symptomatic congestion relief, they do not improve mortality. Neurohormonal antagonism is required for the greatest mortality improvement. If there are no contraindications, ACEI therapy can be initiated for outpatient use from the ED or observation unit. Alternatively, patients already taking medications can have the dosage increased. Consultation with the patient's physician is advisable.

Details of Pharmacotherapy

DIURETICS Diuretics are indicated for pulmonary edema and decompensated HF. Loop diuretics provide rapid symptomatic relief of congestive symptoms and improve the effects of ACEIs by decreasing intravascular volume. Most ED patients require intravenous dosing because bowel wall edema can prevent proper gastrointestinal absorption. Dosing is guided by symptoms and prior usage. Suggested dosing is listed in Table 53-5. Once congestion is resolved, a fixed maintenance dose is continued to prevent recurrence, but, because there is no mortality benefit, they are not used as monotherapy in HF.¹⁷

Loop diuretics promote water and sodium excretion and are effective except in severe renal dysfunction. Furosemide is inexpensive and efficacious. If bumetanide is used, 1 mg equals 40 mg of furosemide. Some patients require adding a thiazide diuretic, such as metolazone, for efficacy. Metolazone (5 to 20 mg PO, daily) can be given 20 to 30 min before furosemide in decompensated HF. The effectiveness of combination therapy results from acting on different sites of the nephron. Ethacrynic acid is the only loop diuretic that can be used in patients with a significant sulfa allergy.

Potassium-sparing diuretics, such as spironolactone, are generally reserved for class III and IV HF but not for mild decompensated HF. Aggressive diuresis can result in severe hypokalemia and must be monitored carefully. An increasing QT interval may suggest hypocal-

cemia, hypokalemia, or hypomagnesemia. Ototoxicity is rare but may occur if used in conjunction with aminoglycoside antibiotics.

Urinary diuretic response requires monitoring. With more symptoms or less response to initial intravenous diuretics, dosing may be doubled and repeated in 20 to 60 min or as needed based on urine output. If output remains inadequate and the patient is in an observation unit, hospitalization should be considered. Adequate output should exceed 500 mL by 2 h, unless the creatinine exceeds 2.5 mg/dL when output goals are halved.¹⁸ Diuretic response correlates with prognosis. Poor diuresis in the setting of acute pulmonary edema has a fourfold increase in acute mortality.¹⁹

As an outpatient, diuretic use is guided by daily measured body weight. Patients taking diuretics should limit their salt intake to less than 3 g daily. In addition, agents that antagonize diuretic action are discouraged. These agents include nonsteroidal anti-inflammatory drugs and cyclooxygenase-2 inhibitors, especially rofecoxib.

VASODILATORS Vasodilators are also indicated for pulmonary edema and decompensated HF. The commonly used vasodilators are NTG, nitroprusside, and nesiritide (see Table 53-5). Because all may exert significant hypotensive effects, they are not recommended if there are signs of cardiogenic shock (hypoperfusion or symptomatic hypotension). Before their use, the physician should auscultate for murmurs and inquire about HCM or aortic stenosis, because if these disorders are treated with vasodilators, hypotension may result. In any patient who becomes acutely hypotensive after the administration of vasodilators, the physician should consider the differential diagnoses listed in Table 53-7.

Nitroglycerin Nitroglycerin can be beneficial in HF provided there is adequate BP, in particular if there is hypertension. A short-acting, rapid-onset, systemic arterial and venous dilator, it decreases mean arterial pressure by reducing afterload and preload. Its coronary vasodilatory effects also may decrease myocardial ischemia and thereby improve cardiac function.

Nitroglycerin is administered intravenously, sublingually, or transdermally. Sublingual NTG can be given as often as needed to reach a desired clinical end point, provided there is adequate BP. Intravenous NTG is initiated at 0.2 to 0.4 (xg/kg per min (10 to 30 (xg/min), rapidly increased by 5 to 10 |xg/min increments, and titrated to BP and symptomatic improvement. High doses may be required in the acute setting.

The most important complication, hypotension, may be seen transiently. If persistent, hypotension is more likely due to volume depletion or right ventricular infarct. It usually resolves after cessation of NTG. If this fails to improve BP, a small fluid bolus (e.g., NS 250 mL) may be required. Headache is frequent, but acetaminophen usually is adequate therapy. Methemoglobinemia has been reported with use of high doses of NTG.

NITROPRUSSIDE If further afterload reduction is required (i.e., continued high systemic vascular resistance usually manifested by persisting elevated BP despite NTG doses >200 (xg), intravenous nitroprusside may be used. A more potent arterial vasodilator than NTG, its hemodynamic effects include decreased BP and LV filling pressure and increased CO. The initial dose is usually 0.3 |xg/kg per min and titrated up every 5 to 10 min based on BP and clinical response. The

TABLE 53-6 ACEI and p-Blocker Contraindications

ACEI contraindications
Angioedema
Progressive azotemia (creatinine >3 mg/dL, or increasing)
Bilateral renal artery stenosis
Systemic hypotension (SBP <80 mm Hg, especially in ambulatory patients)
Hyperkalemia
Pregnancy
Hemodynamic instability
Intolerance secondary to severe cough [3-blocker contraindications
Unstable hemodynamics, or congested and requiring IV diuresis
(most ED patients)
Severe bronchospastic airway disease
Symptomatic bradycardia
Advanced heart block
Acute vascular insufficiency or worsening claudication/rest pain
Class IV stable HF (therapy should be provided by HF specialist)
Inotropic therapy or cardiogenic shock
Severe conduction system disease (unless protected by a pacemaker)

Anaphylaxis

major complication is hypotension. Long-term use (many days at high dose) is associated with thiocyanate toxicity, especially in renal failure.

Nesiritide Identical to endogenous BNP, nesiritide has acutely beneficial hemodynamic effects. It has diuretic and natriuretic properties that result in increased urinary sodium and volume, but without increased urinary potassium or creatinine clearance. Physiologically, it is the counterbalance to pathologic neurohormonal elevations of HF; nesiritide antagonizes the renin-angiotensin-aldosterone system and sympathetic nervous systems and decreases pathologic elevations of neurohormones in HF.

The hemodynamic effects include vasodilation of veins, arteries, and coronaries, which causes a rapid decrease in right atrial pressure, pulmonary artery pressure, PCWP, SVR, mean arterial pressure, and increases stroke volume and CO.²⁰ Although more expensive, nesiritide results in better PCWP decrease, superior clinical improvement, and less dyspnea by 24 h than does NTG. Complications are similar to those with NTG, but with less headache. In the first 3 h of use, the rate of symptomatic hypotension with nesiritide is about 0.5 percent.²¹

Because the hemodynamic profile of nesiritide, i.e., decreasing myocardial oxygen consumption (MVO₂) and causing coronary vasodilation, suggests safety in suspected acute coronary syndromes, it is not necessary to delay treatment while awaiting cardiac marker results. Small pilot studies suggest superior outcome with nesiritide as compared with NTG for HF patients with a concurrent acute coronary syndrome.

Nesiritide is used in acute decompensated HF without cardiogenic shock. It should be used concurrently with ACEI, p-blockers, and diuretics. Recommended dosing is an initial bolus of 2 [xg/kg, followed by a fixed intravenous dose of 0.01 (xg/kg per min. The most common complication is dose-dependent hypotension, with an overall rate of 4 percent.

OTHER HF DRUGS

Angiotensin-Converting Enzyme Inhibitors Because they decrease mortality and hospitalizations,¹⁷ in the absence of contraindications (see Table 53-6), all HF patients should be on an ACEI before hospital discharge. Enalapril decreases 1-year mortality in class IV HF by 31 percent and in class II and III HF by 16 percent. For mortality reduction, ACEIs are better than ARBs or the combination of hydralazine and isosorbide.

The ACEI-induced angioedema results from increased bradykinin. Emergent anaphylaxis treatment is outlined in Chap. 34 but should obviously include permanent ACEI cessation. Cough can complicate ACEI therapy but should prompt a search for other causes (e.g., worse HF or infection) before it is considered a side effect. If ACEI related, the cough disappears within 1 to 2 weeks of stopping the drug. If cough is not severe, education of the benefits and encouragement to continue the ACEI are appropriate. Hydralazine/isosorbide is considered if the patient is unable to take ACEIs or ARBs.

Angiotensin-converting enzyme inhibitors can induce hypotension, so therapy may be delayed during aggressive diuresis. Hyponatremia suggests renin-angiotensin-aldosterone system activation and may predict ACEI-induced hypotension. If symptomatic on the first dose of ACEI, diuretics can be decreased and the ACEI continued. Mild azotemia during ACEI use is tolerated as long as the patient does not have bilateral renal artery stenosis, oliguria, or creatinine levels above 3 mg/dL. Potassium and renal function require close follow-up when ACEIs are started.

In general, low doses are started and titrated upward, but even lower than target doses of ACEIs reduce mortality. In addition, because they inhibit neurohormonal pathways, ACEIs may take weeks to months to exert symptomatic benefit. Even in the absence of symptomatic improvement, ACEI therapy should be continued for the long-term effects on LV remodeling and mortality.

ACEI Alternative: Angiotensin Receptor Blockers Angiotensin II promotes aldosterone release, LV remodeling (including apoptosis), arterial vasoconstriction, and renal damage. The angiotensin receptor blockers (ARBs) block angiotensin II receptors by preventing its adverse effects and may cause fewer side effects than ACEIs. Cough and angioedema are reported less frequently with ARBs, but it is unclear whether ARBs should replace ACEIs as first-line HF treatment.

ACEI Alternative: Hydralazine/isosorbide Dinitrate The combination of hydralazine and isosorbide dinitrate decreases preload and afterload and achieves protective effects against ventricular remodeling. It reduces mortality when compared with placebo, but enalapril-treated patients have better long-term outcomes. Hydralazine/isosorbide dinitrate should be considered second-line therapy and only in patients who have proven ACEI intolerant. Complications include drug-induced lupus, hypotension, gastrointestinal complaints, and headache.

p-Blockers Norepinephrine levels are elevated in HF, contribute to myocardial hypertrophy, increase afterload and coronary vasoconstriction, and are associated with mortality. Beta blockers reduce sympathetic nervous system activity and are used in HF for mortality reduction and symptom relief, with effects comparable to some ACEIs. Metoprolol decreases 1-year mortality as much 34 percent in class II and III chronic HF²³ and decreases sudden death by 41 percent. Other studies have shown benefit in NYHA class II, III, and IV HF.

P-blockers are unlikely to be initiated in the acute setting, except perhaps to control rate-related HF. They are generally reserved for stable patients. All HF patients are considered for p-blockers, except as listed in Table 53-6.

Patients on maintenance p-blockers presenting in an acutely decompensated state represent a difficult management problem. Terminating the P-blockers may cause deterioration from p-blocker withdrawal. However, higher doses may compromise tenuous hemodynamics. The optimal compromise may be a short course of an intravenous inotrope (e.g., milrinone) to support hemodynamics while stabilizing with intravenous diuretics and vasodilators. If there is hypoperfusion or pulmonary edema, the p-blockers may be stopped.

Digoxin This alkaloid inhibits myocardial cellular membrane Na⁺K⁺ATPase. It is used to control ventricular response in atrial fibrillation. However, in HF with atrial fibrillation, p-blockers may be more effective. Digoxin can improve clinical symptoms when ACEIs and p-blockers are initiated and during the time it takes for their clinical effects to manifest, and digoxin is considered if therapy with ACEIs, P-blockers, and diuretics fail to control HF symptoms.

Digoxin is not used unless the patient is receiving other HF therapies. Levels need close monitoring in the elderly, patients with renal insufficiency, and those with electrolyte abnormalities (hypokalemia increases toxicity risk). Digoxin is started at 0.125 mg per d. Using the highest tolerable dose is no longer recommended.

Spirolactone The aldosterone antagonist spironolactone decreases mortality by about 30 percent in class III and IV HF,²⁴ but is not recommended in patients with NYHA class I or II HF. Adverse effects include hyperkalemia and gynecomastia. Recommended usage of spironolactone is for symptomatic patients, despite ACEI, p-blockers, digoxin, and diuretics. Contraindications are creatinine levels above 2.5 mg/dL or a potassium levels above 5 mEq/L. In general, spironolactone is not initiated from the ED.

Morphine Sulfate Morphine can be used in acute pulmonary edema, provided there is adequate BP. It reduces anxiety, is a venodilator, and treats the chest pain of acute myocardial infarction. Initial dosing is 2 to 5 mg IV and titrated to clinical effect. Despite its

long historic use in this setting, there are no studies demonstrating efficacy. Because it is a respiratory and central nervous system depressant, it should be avoided in patients with diminished respiratory effort or altered sensorium. Naloxone should be available, if needed. Complications include hypotension, hypoventilation, sedation, nausea, and vomiting.

Anticoagulation

CHRONIC THERAPY The risk of thromboembolism in the clinically stable HF outpatient is low, estimated at 1 to 3 percent per year, and is greatest with the lowest EF. Warfarin is used in HF, but there are insufficient data to guide a precise approach. Most investigators recommend warfarin for significant LV dysfunction and atrial fibrillation, LV thrombus, or prior embolic event. Warfarin therapy is unlikely to be initiated solely by the emergency practitioner.

INPATIENT THERAPY Hospitalized HF patients are at greater risk for sustaining a deep venous thrombosis (DVT) and its complications. In a study of admitted HF patients, subcutaneous enoxaparin decreased venographically documented DVT, from 14.9 to 5.5 percent with 40 mg of enoxaparin daily.²⁵ This therapy can be initiated in the ED. Empiric DVT prevention in hospitalized, bedridden HF patients must be balanced against the relatively low risk of complications associated with anticoagulant prophylaxis.

Drugs to be Avoided in HF

CALCIUM CHANNEL BLOCKERS Calcium channel blockers are not routinely recommended in HF. Short-term use may result in pulmonary edema and cardiogenic shock, and long-term use may increase the risk of worsening HF and death.²⁶ These adverse effects have been attributed to the negative inotropic effects of calcium channel blockers. If necessary, amlodipine, with no clear adverse mortality effect, may be used for compelling clinical reasons (e.g., as an antianginal agent despite maximal therapy with nitrates and β -blockers).

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS Nonsteroidal anti-inflammatory drugs should be avoided in HF. They inhibit the effects of diuretics and ACEIs and can worsen cardiac and renal function.¹⁷ The routine use of aspirin for coronary artery disease prophylaxis, with concurrent ACEI treatment, is controversial.

ANTIARRHYTHMICS HF patients are sensitive to the pro-arrhythmic and cardiodepressant effects of antiarrhythmics. Because their use does not prevent sudden cardiac death, suppression of asymptomatic ventricular arrhythmias usually is unnecessary.

Except for immediate treatment of life-threatening ventricular arrhythmias, class I antiarrhythmics (e.g., quinidine, procainamide, and flecainide) should not be used in HF. Some class III agents (e.g., amiodarone) do not increase the risk of sudden death, so these agents are preferred for atrial arrhythmias.¹⁷ However, due to toxicity, amiodarone is not recommended for chronic use to prevent sudden death in patients already treated with mortality reducing drugs (ACEIs or β -blockers).¹⁷

COMPLICATIONS OF HEART FAILURE

Sudden Death or Ventricular Arrhythmias

HF is an important sudden death risk factor. Ventricular arrhythmias are common, and premature ventricular contractions occur in 95 percent of dilated cardiomyopathy patients. Nonsustained ventricular tachycardia is seen in 30 to 40 percent. Sudden death risk increases

in proportion to the decrease in EF and HF severity, occurring in 10 to 40 percent of HF patients. Progressive pump failure is the fatal event in about 50 percent.

Because arrhythmias are common in HF and neither Holter monitoring nor electrophysiologic studies predict sudden death risk, symptoms guide therapy. Syncope, resuscitation after cardiac arrest, and sustained and symptomatic nonsustained ventricular tachycardia suggest aggressive management. In these patients, electrophysiologic testing and consideration for an implantable cardioverter-defibrillator are warranted.¹⁷ **Prophylactic administration of antiarrhythmics is not effective, and may increase mortality.**

DISPOSITION

Acute Pulmonary Edema

Most patients with acute pulmonary edema are likely to require ICU admission. A subset of initially severely hypertensive patients will improve greatly while still in the ED. For these patients, if the hypertension is controlled and dyspnea resolved, admission to a non-ICU monitored bed may be feasible. In more stable patients, the choice of medication may determine disposition. Patients receiving nitroglycerin requiring frequent titration adjustment due to tachyphylaxis should be admitted to an ICU environment. Patients receiving nesiritide can be managed in a telemetry unit. This decision also depends on the underlying etiology. Because even transient hypertension can result in a recurrence of hemodynamic decompensation, close monitoring is needed.

Decompensated HF

These patients usually require hospital admission, intravenous diuresis, vasodilator therapy, oral medication dose titration to target levels, and correction of any of the reversible causes of HF decompensation. If the clinical scenario suggests acute coronary syndrome, ICU admission is warranted.

All patients with new-onset HF, poor social support, hypoxemia, hypercarbia, concurrent infection, respiratory distress, syncope, or symptomatic hypotension should be admitted to the hospital. Stable fluid-overloaded patients with a prior HF diagnosis and without a malignant cause for their exacerbation may be admitted to a non-monitored setting or an ED observation unit.

Those with mild symptoms secondary to a clearly correctable precipitant (e.g., medication noncompliance), whose symptoms resolve with therapy; have normal laboratory, chest radiograph, and electrocardiographic evaluations; have a strong social situation; and are likely to comply with outpatient follow-up are candidates for ED discharge. More significant symptoms or inadequate response to therapy likely warrant hospital admission.

Admission requirements may correlate with BNP levels. In one study, HF patients requiring hospitalization had BNP levels above 700 pg/mL, whereas those able to be treated as outpatients had BNP levels below 254 pg/mL.⁶ In another study, patients with BNP levels above 480 pg/mL had 6-month rates of death and re-hospitalization greater than those with BNP levels below 230 pg/mL.¹² These findings need to be confirmed in larger studies.

Observation, Acute Care, and Short-Stay Unit

Intensive HF management with vasodilators and diuretics has beneficial effects in preventing inpatient hospitalizations and decreasing repeat admissions.^{18,27} Protocol-driven therapy improves outcomes, as compared with nonprotocol management, and ensures that the many

multidisciplinary interactions required for successful HF management occur in a timely fashion.¹⁸ It is important that patients entered into an intensive regimen of diuretics are properly selected. Heart failure management entry and exclusion guidelines are listed in Tables 53-8 and 53-9, respectively.²⁷ Suggested guidelines for disposition from the observation/acute care unit are listed in Table 53-10. Posttherapy BNP levels may assist in predicting posthospitalization course. Patients whose BNP levels decline with therapy have lower subsequent rehospitalization and death rates than do those whose BNP levels are unchanged or increase despite therapy.

Discharge Home

Discharged patients require outpatient follow-up by a physician knowledgeable in the management of HF. Further, social service evaluation may be helpful to ensure medication compliance, dietary education, and re-enforcing smoking cessation instructions. Smoking cessation has the same mortality effect as the best medication therapies.²⁸

TABLE 53-9 Heart Failure Vasodilation and Diuresis Protocol Exclusion Criteria*

Hemodynamic instability
Unstable vital signs (BP >220/120 mm Hg, RR >25, HR >130 beats/min)
Unstable airway or needing >4 L/min nasal cannula O ₂ for Sao ₂ <90%
Requiring continuous vasoactive medication (e.g., nitroglycerin, nitroprusside, dobutamine, or milrinone) except nesiritide Evidence of cardiogenic shock (systolic BP <90 mm Hg, altered mental status, peripheral vasoconstriction) Clinically significant arrhythmia (e.g., nonsustained VT not due to electrolyte imbalance) Signs of acute coronary syndrome (ECG change or cardiac marker elevation)
Chronic renal failure requiring dialysis Complex decompensation (underlying precipitant is not clearly cardiac or volume related) Multiple comorbidities Acute mental status abnormality

*Any one positive result excludes the patient from the heart failure protocol and suggests inpatient management.

Abbreviations: ECG = electrocardiogram; HR = heart rate; RR = respiratory rate; Sao₂ = arterial oxygen saturation; VT = tidal volume.

TABLE 53-10 Discharge Guidelines from Observation/Acute Care/Short-Stay Units

Patients not meeting all of the following criteria should be considered for inpatient treatment*

- Patient reports subjective improvement
- Ambulatory, without long-suffering orthostasis
- Resting HR <100 beats/min
- Systolic BP >80 mm Hg
- Net urine output > 1000 mL and no new decrease in urine output <30 mL/h (or <0.5 mL/kg per h)
- Room air Sao₂ >90% (unless on home O₂)
- All CK-MB <8.8 ng/mL, and troponin T <0.1 n-g/L
- No ischemic-type chest pain
- No new clinically significant arrhythmia
- Stable electrolyte profile

*Except as appropriate in the end-stage palliative-care cohort. Abbreviation: CK-MB = muscle and brain types of creatine kinase; HR = heart rate; Sao₂ = arterial oxygen saturation.

normal cardiac anatomy may have murmurs associated with anemia, thyrotoxicosis, sepsis, fever, renal failure with volume overload, pregnancy, and other conditions associated with increased cardiac output. A diastolic murmur or a new murmur associated with symptoms at rest always should be considered abnormal and warrants referral for cardiology evaluation and echocardiographic study. Figure 54-1 presents an algorithm for the clinical assessment of a newly discovered systolic murmur.² The studies referred to by Etchells and colleagues used cardiologists as examiners, and these issues have not been tested in the emergency department setting. However, the algorithm can be expected to prompt the clinician to perform the appropriate examinations and maneuvers to help uncover an abnormal murmur. Whenever the clinician is uncertain of the diagnosis of a newly discovered murmur, referral should be made to a cardiologist or back to the primary care physician. In general, the urgency for an accurate diagnosis and appropriate referral or admission depends on the severity of symptoms, not the presence of the murmur. The exception is a patient with suspected aortic stenosis and syncope who may appear well at rest yet is at risk for another cardiovascular event. See Chap. 145 for admission recommendations in the setting of endocarditis. See Chap. 55 for admission indications in the setting of hypertrophic cardiomyopathy.

New cardiac murmurs, especially those of valvular insufficiency, can also be a sign of endocarditis. Endocarditis is discussed in detail in Chap. 145 and **Table 145-6 lists regimens for antibiotic prophylaxis before procedures, in patients with valvular disease or prosthetic valves.**

A truly innocent (physiologic) murmur is associated with no abnormal symptoms or signs. The soft systolic ejection murmur begins after S₁ and ends before S₂, and the heart sounds are completely normal. The review of systems elicits no symptoms compatible with cardiovascular disease, and other findings on complete physical examination are normal.

54

VALVULAR EMERGENCIES

David M. Cline

Ninety percent of valvular disease is chronic, with decades between the onset of the structural abnormality and symptoms. Through chronic adaptation by dilatation or hypertrophy, cardiac function can be preserved for years, which may delay the diagnosis for one to two decades. In contrast to the more common chronic presentations, acute rupture of a cardiac valve presents with dramatic symptoms. The emergency physician most commonly encounters patients with valvular disease after the diagnosis has been made but is occasionally the first to suspect valvular dysfunction based on the patient's symptoms and examination. Compared with the general population, patients with hemodynamically significant valvular heart disease have a 2.5-fold increased rate of death and a 3.2-fold increased rate of stroke.¹

The four heart valves prevent retrograde flow of blood during the cardiac cycle, allowing efficient ejection of blood with each contraction of the ventricles. The mitral valve has two cusps, whereas the other three heart valves normally have three cusps. The right and left papillary muscles promote effective closure of the tricuspid and mitral valves, respectively. The papillary muscles are attached to the cusps of the atrioventricular (AV) valves by tendinous cords, the chordae tendineae. Abnormalities of the valvular cusps, the papillary muscles, the chordae tendineae, or the cardiac chambers themselves can cause valvular dysfunction.

DIAGNOSING A NEWLY DISCOVERED MURMUR

The first step in diagnosing a newly discovered murmur is to consider it in the context of the patient's medical condition. Patients with

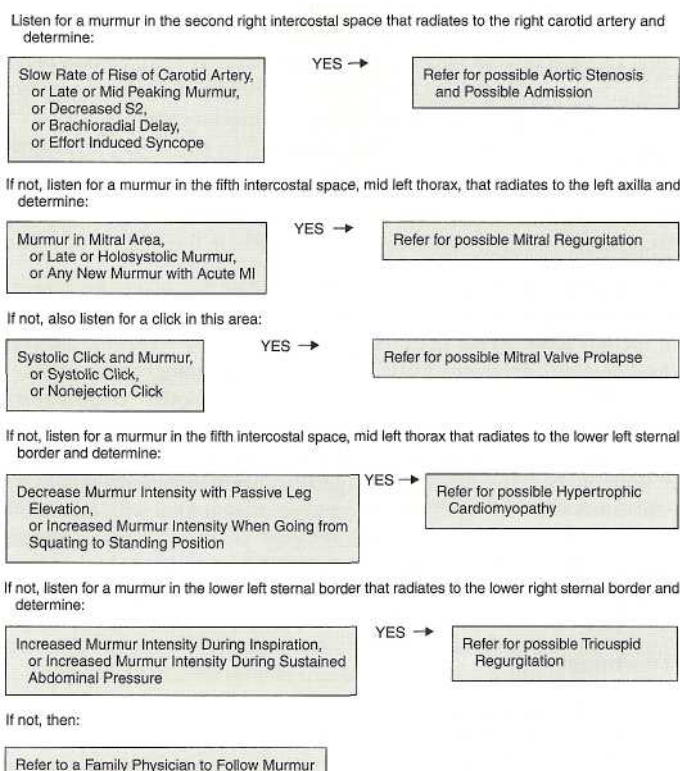

FIG. 54-1. Algorithm for evaluation of newly discovered systolic murmur.

MITRAL STENOSIS

Pathophysiology

Despite its declining frequency, rheumatic heart disease is still the most common cause of mitral valve stenosis. Scarring from rheumatic endocarditis causes fusion of the commissures and matting of the chordae tendineae, which interferes with valve closure. Calcification over time makes the valve less mobile. Progressive stenosis may lead to pulmonary hypertension, which may signal the need for surgery. Most patients eventually develop atrial fibrillation because of progressive dilatation of the atria. Pulmonary hypertension may lead to pulmonary and tricuspid valve incompetence. Although the valvular obstruction is slowly progressive, acute symptoms are produced when the obstruction prevents an increase in cardiac output to meet an increased need, such as during exercise.

Clinical Features

Conditions that prompt symptoms in mitral stenosis include exertion, tachycardia, anemia, pregnancy, infection, emotional upset, and atrial fibrillation. As with all valvular diseases, exertional dyspnea is the most common presenting symptom. Paroxysmal nocturnal dyspnea and acute pulmonary edema may occur with more severe disease. In the past, hemoptysis was the second most common presenting symptom but is less common now with earlier recognition and treatment. Hemoptysis may be massive if a bronchial vein ruptures. Other common symptoms and signs include orthopnea and premature atrial contractions. Systemic emboli may occur and result in myocardial, kidney, central nervous system, or peripheral infarction. Embolic stroke is more frequent in the presence of atrial fibrillation. As the disease progresses, symptoms of right-sided heart failure may develop.

Signs of mitral stenosis include a mid-diastolic rumbling murmur, with crescendo toward the S₂. With the onset of atrial fibrillation, the presystolic accentuation of the murmur disappears. Typically the S₁ is loud and is followed by a loud opening snap that is high-pitched and heard best at the right of the apex. The apical impulse is small and tapping, representing an underfilled left ventricle. Systemic blood pressure is typically normal or low. If pulmonary hypertension is present, signs may include a thin body habitus, peripheral cyanosis, and cool extremities because of low cardiac output. With pulmonary hypertension, the auscultatory findings are less evident.

Diagnosis

The electrocardiogram (ECG) may demonstrate notched or biphasic P waves and right-axis deviation. On the chest radiograph, straightening of the left heart border (i.e., loss of the pulmonary window), indicating left atrial enlargement, is a typical early radiographic finding. Eventually, findings of pulmonary congestion are noted: redistribution of flow to the upper lung fields, Kerley B lines, and an increase in vascular markings. The chest radiograph is useful in assessing the degree of pulmonary congestion. The diagnosis of mitral stenosis should be confirmed with echocardiography and/or consultation with a cardiologist. Transesophageal echocardiography yields a more complete analysis of valvular dysfunction, especially of the mitral valve. However, transthoracic echocardiography generally is performed first.³

Treatment

The sequelae or complications of mitral stenosis may require emergency department intervention. The medical management of mitral stenosis includes intermittent diuretics to alleviate pulmonary congestion, the treatment of atrial fibrillation (see Chap. 28), and anticoagulation for patients at risk for arterial embolic events. Patients with mitral stenosis and paroxysmal or chronic atrial fibrillation or a history

of an embolic event should be on long-term warfarin therapy with an international normalized ratio (INR) goal of 2 to 3.⁴ Patients with severe mitral stenosis should be counseled to avoid strenuous physical activity. Hemoptysis may occur in the setting of mitral stenosis and pulmonary hypertension. Bleeding may be severe enough to require blood transfusion, consultation with a thoracic surgeon, and emergency surgery.

MITRAL INCOMPETENCE

Pathophysiology

Infective endocarditis or myocardial infarction can cause acute rupture of the chordae tendineae or papillary muscles or cause perforation of the valve leaflets. Common causes of chronic mitral incompetence include myocardial infarction, mitral valve prolapse syndrome, rheumatic heart disease, coronary artery disease, and collagen-vascular disease. Inferior myocardial infarction due to right coronary occlusion is the most common cause of ischemic mitral valve incompetence. Rarely, trauma may cause acute mitral incompetence. Patients with acute mitral valve rupture deteriorate rapidly. Intermittent mitral incompetence can be due to ischemia, which causes papillary muscle dysfunction. Although an association between appetite-suppressant drugs (fenfluramine and phentermine, or dexfenfluramine alone) and aortic regurgitation generally has been accepted,^{5,6} the suspected association of mitral incompetence with the appetite-suppressant drugs remains unclear.⁷

Acute regurgitation into a noncompliant left atrium quickly elevates pressures and causes pulmonary edema. In contrast, in the chronic state, the left atrium dilates so that left atrial pressure rises little, even with a large regurgitant flow. As an adaptation, the total stroke volume of the left ventricle increases so that effective forward flow into the aorta is maintained despite the large regurgitant volume across the mitral valve.

Clinical Features

Acute mitral incompetence presents with dyspnea, tachycardia, and pulmonary edema. Usually an S₃ and S₄ will be heard. Acutely, the harsh apical systolic murmur starts with S₁ and may end before S₂. These patients may deteriorate quickly to cardiogenic shock or cardiac arrest. Intermittent mitral incompetence usually presents with acute episodes of respiratory distress due to pulmonary edema and can be asymptomatic between attacks. The pronounced dyspnea may mask angina that accompanies the ischemia. Patients may have an active apical impulse, systolic thrust, and thrill at the apex.

Chronic mitral incompetence may be tolerated for years or even decades. The first symptom is usually exertional dyspnea, sometimes prompted by atrial fibrillation. If patients are not anticoagulated, systemic emboli occur in 20 percent and are often asymptomatic. Endocarditis is still a feared complication. Signs of chronic mitral incompetence include a late systolic left parasternal lift. There is a high-pitched holosystolic murmur that is best heard in the fifth intercostal space, mid-left thorax, and radiates to the axilla. The first heart sound is soft and often obscured by the murmur. An S₃ is usually heard and is followed by a short diastolic rumble, indicating increased flow into the left ventricle.

Diagnosis

In acute disease, the ECG may show evidence of acute inferior wall infarction (more common than anterior wall infarction in this setting). On the chest radiograph, acute mitral incompetence from papillary muscle rupture may result in a minimally enlarged left atrium and pulmonary edema. Auscultation of acute mitral regurgitation may be dif-

difficult in a tachycardic and dyspneic patient. The diagnosis of acute mitral incompetence should be suspected in patients with new-onset pulmonary edema, especially when the heart is smaller than expected on the chest radiograph or when the patient does not respond to conventional therapy. Echocardiography is essential to make the diagnosis with certainty, and emergency bedside echocardiography should be considered for the acutely ill patient. However, transthoracic echocardiography may underestimate lesion severity, and the transesophageal technique should be undertaken as soon as the patient is adequately stable.

In chronic disease, the ECG may demonstrate findings of left atrial enlargement and left ventricular hypertrophy (LVH). On the chest radiograph, chronic mitral incompetence produces left ventricular and atrial enlargement that is proportional to the severity of the regurgitant volume. For patients with chronic but undiagnosed disease, the diagnosis should be confirmed with transthoracic or transesophageal echocardiography as the clinical picture demands, usually on an outpatient basis.

Treatment

In acute severe mitral incompetence, the goal of medical therapy is to diminish the amount of regurgitation, thereby increasing forward flow and reducing pulmonary congestion. Pulmonary edema should be treated initially with oxygen, intubation for failing respiratory effort, diuretics, and nitrates as the patient tolerates (see Chap. 53 for general principles). Nitroprusside increases forward output by increasing aortic flow and partially restoring mitral valve competence as left ventricular size diminishes. Start nitroprusside at 0.3 μ g/kg per min IV unless the patient is hypotensive. There may be a subset of patients whose mitral regurgitation is worsened by nitroprusside (those patients who respond with a dilatation of the regurgitant orifice).⁸ Thus careful monitoring is essential. Hypotensive patients should receive inotropic agents such as dobutamine titrated from 2.5 to 20 μ g/kg per min in addition to nitroprusside.

Aortic balloon counter pulsation increases forward flow and mean arterial pressure while diminishing regurgitant volume and left ventricular filling pressure and can be used to stabilize a patient while awaiting surgery. Emergency surgery should be considered in cases of acute mitral valve rupture. The urgency of the situation may leave little time for intubation, intravenous afterload reducers, echocardiography, and assembling the surgical team for emergency valve replacement. When acute cases of ischemic mitral valve incompetence are suspected, the patient may be treated with nitrates, provided that the patient is not hypotensive. If endocarditis is a potential underlying etiology, the patient will need specific evaluation and treatment. (See Chap. 145 for management of endocarditis).

There is no accepted therapy for asymptomatic mitral regurgitation. Atrial fibrillation should be treated with anticoagulation using heparin and ventricular rate control with β -blockers or calcium channel blockers. Although the risk of embolization is less than in patients with mitral stenosis, patients with mitral incompetence and atrial fibrillation generally are maintained on warfarin therapy with an INR goal of 2 to 3.⁹ Patients with acute mitral incompetence or sustained atrial fibrillation in the setting of chronic mitral incompetence generally are hospitalized.

MITRAL VALVE PROLAPSE

Pathophysiology

The etiology of mitral valve prolapse (MVP), or the click-murmur syndrome, is not known but may be congenital. MVP is the most common valvular heart disease in industrialized countries, affecting approximately 2.4 percent of the population.¹⁰ One or both of the mitral

valve leaflets prolapse into the atrium during systole, and this may or may not be accompanied by regurgitant flow. Population studies have found no increased risk of atrial fibrillation, syncope, stroke, or sudden death.^{10,11} Male sex, age over 45, and the presence of regurgitation, recognized clinically by a short systolic murmur, place the patient in a higher-risk group for complications.¹² Click-murmur syndrome has unique symptoms that differentiate it from other forms of mitral regurgitation.

Clinical Features

Most patients are asymptomatic. Symptoms include atypical chest pain, palpitations, fatigue, and dyspnea unrelated to exertion. Symptoms are more common in those who know they have the syndrome. In patients with MVP without mitral regurgitation at rest, exercise provokes mitral regurgitation in 32 percent of patients and predicts a higher risk for morbid events.¹³ The classic cardiac finding is a midsystolic click. The second heart sound may be diminished by the late systolic murmur, with crescendos into S₂ (not present in all patients). Some patients may have pectus excavatum, a straight thoracic spine, or scoliosis.

Diagnosis

The diagnosis is unlikely to be made in the emergency department, nor is it important to do so. The ECG is usually normal, as is the chest radiograph, unless the thoracic cage abnormalities described earlier are seen. Referral to a cardiologist and outpatient echocardiography is recommended to confirm the clinical diagnosis of MVP and to identify any associated mitral regurgitation.³

Treatment

Initiating treatment for MVP is rarely required for patients seen in the emergency department. The treatment of asymptomatic MVP is reassurance. Patients with palpitations, chest pain, or anxiety frequently respond to β -blockers. Avoiding alcohol, tobacco, and caffeine also may relieve symptoms. Aspirin 80 to 325 mg orally daily is recommended for MVP patients with focal neurologic events who do not have indications for warfarin therapy. Patients with MVP associated with atrial fibrillation and additional risk factors for embolization such as age greater than 65, mitral regurgitation, hypertension, or heart failure should be on warfarin (INR goal of 2-3).⁹ Patients with MVP and atrial fibrillation without the listed additional risk factors can be managed with aspirin 160 mg PO daily.

AORTIC STENOSIS

Pathophysiology

Degenerative heart disease or calcific aortic stenosis is the most common cause of aortic stenosis in adults residing in the United States. Congenital heart disease is the most common cause of aortic stenosis in young adults, with the presence of a bicuspid valve accounting for 50 percent of cases. Rheumatic heart disease is the third most common cause in the United States but remains the most common cause worldwide. The prevalence of critical aortic stenosis is about 3 percent in patients over age 74. Calcification is a common feature of aortic stenosis in older adults regardless of the cause.¹⁴ Blood flow into the aorta is obstructed, producing progressive LVH and low cardiac output. This produces a marked reduction in coronary blood flow.

Clinical Features

The classic triad of aortic stenosis is dyspnea, chest pain, and syncope. Exercise may induce acute symptoms. Symptoms appear late in

the course of the disease. In active persons, the symptoms appear more rapidly. Dyspnea is usually the first symptom, followed by paroxysmal nocturnal dyspnea, exertional syncope, angina, and myocardial infarction. Atrial fibrillation is less common than in mitral disease, but 10 percent of patients have atrial fibrillation at the time of surgery. With isolated aortic stenosis, endocarditis occurs in only 2 percent of patients.

The most common signs include a pulse of small amplitude. The carotid pulse can be assessed most accurately and is found to have a slow rate of increase. Blood pressure is normal or low, with a narrow pulse pressure. LVH is common. There is paradoxical splitting of S₂. S₃ and S₄ are commonly present. Classically, there is a harsh systolic ejection murmur that is best heard in the second right intercostal space and that radiates to the right carotid artery. Brachioradial delay is an important finding in aortic stenosis.¹⁵ The examiner palpates simultaneously the right brachial artery of the patient with the thumb and the right radial artery of the patient with the middle or index finger. Any palpable delay between the brachial and radial arteries is considered abnormal.¹⁵ Sudden death, usually from dysrhythmia, occurs in 25 percent of patients. Without surgery, 75 percent of patients with aortic stenosis will be dead within 3 years of the time of diagnosis.¹⁶

Diagnosis

Syncope in the setting of a new systolic murmur always should raise the possibility of aortic stenosis as the etiology (see Figure 54-1). Other ancillary findings available in the emergency department are nonspecific. The ECG usually demonstrates criteria for LVH and, in 10 percent of patients, left or right bundle branch block. The chest radiograph is normal early, but eventually LVH and findings of congestive heart failure are evident if the patient does not have valve replacement. The patient should be admitted and echocardiography undertaken.

Treatment

Patients presenting with pulmonary edema can be treated with oxygen and diuretics, but nitrates should be used with caution because reducing preload may cause significant hypotension. Nitroprusside is not well tolerated in patients with aortic stenosis. Atrial fibrillation may severely compromise cardiac output. New-onset atrial fibrillation may require anticoagulation with heparin, as well as cardioversion. Negative inotropic drugs may be poorly tolerated. Patients with profound symptoms secondary to aortic stenosis, such as syncope, usually are admitted to the hospital. Patients with aortic stenosis should limit vigorous physical activity.

AORTIC INCOMPETENCE

Pathophysiology

In 20 percent of patients, the cause of aortic incompetence is acute in nature. Infective endocarditis accounts of the majority of acute cases; aortic dissection at the aortic root is the second most common cause. Trauma to the aortic valve may cause acute regurgitation. In acute cases, a sudden increase in backflow of blood into the ventricle raises left ventricular end-diastolic pressure, which may cause acute heart failure. Increased ventricular pressure elevates pressure in the left atrium, and pulmonary congestion results. Calcific degeneration, congenital disease (most notably bicuspid valves), systemic hypertension, myxomatous proliferation, and rheumatic heart disease cause most chronic cases. Marfan syndrome, syphilis, ankylosing spondylitis, Ehlers-Danlos syndrome, and Reiter syndrome are less frequent causes. An association between the appetite-suppressant drugs (fenfluramine and phentermine or dexfenfluramine alone) has been found

for aortic incompetence.⁵⁻⁷ Chronic disease is more common in males than in females, with a ratio of 3:2. In chronic disease, the ventricle progressively dilates to accommodate the regurgitant blood volume. Wide pulse pressures result from the fall in diastolic pressure, and marked peripheral vasodilation is seen. During exercise and tachycardia, the diastolic filling period shortens, thus decreasing the length of time per minute that regurgitation can occur. Cardiac function is therefore close to normal with exercise early in the course of the disease. In contrast, isometric exercise or stress may precipitate symptoms earlier in the disease process.

Clinical Features

In acute disease, dyspnea is the most common presenting symptom, seen in 50 percent of patients. Many patients have acute pulmonary edema with pink frothy sputum. Patients may complain of fever and chills if endocarditis is the cause. Patients may present with systemic emboli or a persistent sinus tachycardia. Dissection of the ascending aorta typically produces a "tearing" chest pain that may radiate between the shoulder blades. Sudden death is common in patients with both acute and chronic aortic incompetence.

Elevated temperature is common with acute endocarditis. Patients commonly have tachycardia, tachypnea, and rales. Classically, there is a high-pitched blowing diastolic murmur heard immediately after S₂, best heard in the right second or third intercostal parasternal area. In the face of failure, there may be an S₃ with a long diastolic murmur, and there may be associated systolic flow murmur.

In the chronic state, about one-third of patients have palpitations associated with a large stroke volume and/or premature ventricular contractions. Frequently these sensations are noticed in bed. Patients may complain of stabbing chest pain, fatigue, or dyspnea. Two-thirds of patients have no symptoms for up to 20 years despite a hemodynamically significant lesion, defined as a diastolic blood pressure of less than 70 mm Hg. Symptoms of left ventricular failure may occur late in the course of the disease and include dyspnea, pulmonary edema, ischemic chest pain, and sweating.

In the chronic state, signs include a wide pulse pressure with a prominent ventricular impulse, which may be manifested as head bobbing. A "water hammer pulse" may be noted; this is a peripheral pulse that has a quick rise in upstroke followed by a peripheral collapse. Other classic findings include accentuated precordial apical thrust, pulsus biferiens, Duroziez sign (a to-and-fro femoral murmur), and Quincke pulse (capillary pulsations visible/palpable at the proximal nailbed while pressure is applied at the tip).

Diagnosis

In patients with acute regurgitation, the chest radiograph demonstrates acute pulmonary edema with less cardiac enlargement than expected. In chronic aortic incompetence, the ECG demonstrates LVH, and the chest radiograph shows cardiomegaly, aortic dilatation, and possibly evidence of congestive heart failure. Echocardiography is essential for confirming the presence of and evaluating the severity of valvular regurgitation. Bedside transthoracic echocardiography should be undertaken in the unstable patient, who is potentially in need of emergency surgery. Transesophageal echocardiography is needed when aortic dissection is suspected. ECG changes may be seen with aortic dissection, including ischemia or findings of acute inferior myocardial, suggesting involvement of the right coronary artery.

Treatment

In cases of acute aortic regurgitation, death from pulmonary edema, ventricular dysrhythmias, or circulatory collapse is common even with intensive medical management. Pulmonary edema should be treated initially with oxygen and intubation for failing respiratory effort. Di-

uretics and nitrates can be used but cannot be expected to be effective. Nitroprusside (start at 0.3 [xg/kg per min] along with inotropic agents such as dobutamine (start at 2.5 [xg/kg per min] or dopamine (start at 2.5 [JLg/kg per min] can be used to augment forward flow and reduce left ventricular end-diastolic pressure in an attempt to stabilize a patient prior to emergency surgery. Intra-aortic balloon counterpulsation is contraindicated. Although β -blockers are used often in treating aortic dissection, these drugs should be used with great caution, if at all, in the setting of acute aortic valve rupture because they will block the compensatory tachycardia. Emergency surgery may be lifesaving. Chronic aortic regurgitation typically is treated with vasodilators such as angiotensin-converting enzyme (ACE) inhibitors or nifedipine (initiated by a patient's private physician). In a randomized trial of severe by asymptomatic aortic regurgitation, nifedipine was shown to reduce or delay the need for aortic valve replacement compared with digoxin.¹⁷

RIGHT-SIDED VALVULAR HEART DISEASE

Pathophysiology

Symptomatic right-sided valvular heart disease is much less common than symptomatic left-sided valvular disease. However, the prevalence of tricuspid regurgitation is 14.8 percent in men and 18.4 percent in woman, the majority of whom are asymptomatic.¹⁸ Drug users with endocarditis due to aggressive organisms, such as *Staphylococcus aureus*, are the largest group of patients with isolated symptomatic tricuspid disease. Chronic obstructive pulmonary disease (COPD) associated with pulmonary hypertension may cause tricuspid regurgitation. Right ventricular failure with dilatation may lead to tricuspid valve incompetence. Rheumatic heart disease may affect more than one valve, and tricuspid valve disease is seen frequently in conjunction with left-sided valvular disease. Rarely, blunt trauma can lead to tricuspid valve incompetence. Pulmonary valvular incompetence is most commonly due to pulmonary hypertension, and symptoms of pulmonary hypertension dominate the clinical picture. The most common cause of pulmonary stenosis is congenital tetralogy of Fallot, which is usually corrected surgically in infancy.

Clinical Features

The most common presenting symptoms of right-sided valvular disease are dyspnea and orthopnea. As the disease progresses, signs of right-sided heart failure are evident: jugular venous distention with a prominent *a* wave, peripheral edema, hepatomegaly, splenomegaly, and ascites.

In tricuspid valve incompetence, the murmur is soft, blowing, and holosystolic and best heard along the lower left sternal border. In tricuspid valve stenosis, the rumbling crescendo-decrescendo diastolic murmur occurs just prior to S₁. This murmur is best heard along the lower left sternal border. Because of the organisms involved, patients presenting with tricuspid valve incompetence in association with endocarditis are acutely ill with sepsis.

Diagnosis

The diagnosis of right-sided valvular heart disease requires echocardiography. Transesophageal is more accurate than transthoracic.

Treatment

The treatment of right-sided valvular heart disease should first address the underlying cause, such as the treatment for COPD associated with pulmonary hypertension. Diuretics, often in very high doses, are used to manage the effects of elevated venous pressure, such as leg edema

and hepatic congestion. Patients may present to the emergency department with complications of diuretic therapy, such as volume depletion or electrolyte abnormalities.

PROSTHETIC VALVE DISEASE

Prosthetic valves are implanted in 40,000 patients per year in the United States. There are approximately 80 types of artificial valves, each with advantages and disadvantages. Patients who receive prosthetic valves are instructed to carry a descriptive card in their wallet. The prosthetic valves can be divided into two basic groups: mechanical, nontissue models and bioprostheses using porcine, bovine, or human valves. Complications of prosthetic valves are more common in patients who have advanced heart disease, including cardiac dilatation, LVH, congestive heart failure, or dysrhythmias, at the time of their original operation. Survival is higher and primary valve failure is lower in patients with mechanical valve replacement, but bleeding is more common than with bioprosthetic valves.¹⁹

Pathophysiology

Prosthetic valves tend to be slightly stenotic, and a very small amount of regurgitation is common because of incomplete closure. Patients with mechanical valves require continuous anticoagulation. Some bioprostheses do not require long-term anticoagulation, unless atrial fibrillation coexists. Several complications can lead to dysfunction of artificial valves. Thrombi can form on a prosthetic valve and become large enough to obstruct flow or prevent closure. The dysfunction due to thrombi can be acute or slowly progressive. Bioprostheses may degenerate gradually, undergoing gradual thinning, stiffening, and possible tearing, which result in valvular incompetence. The sutures that secure the prosthetic valve may become disrupted, leading to paravalvular regurgitation as a fistula forms at the periphery of the valve. Mechanical models suddenly may fracture or fail. These failures usually bring sudden symptoms and often are fatal before corrective surgery can be accomplished.

Bleeding and systemic embolism originating from a thrombus on the prosthetic valve are the most important complications of mechanical heart valves, occurring at a rate of 1.4 and 1 percent per year, respectively, for patients on warfarin.²⁰ Lifelong anticoagulation is required to reduce the risk of thromboembolism and valve thrombosis. The optimal anticoagulation regimen is controversial, with disagreement concerning the intensity of warfarin therapy as well as the need for an antiplatelet agent. Embolism is more common after mitral valve replacement. Embolism occurs less frequently with bioprostheses, and bleeding complications depend on the therapy given.

Patients with artificial valves develop endocarditis at a rate of 0.5 percent per year. Infections occur more frequently during the first 2 months after operation. The most common organisms during this period are *Staphylococcus epidermidis* and *S. aureus*. Gram-negative organisms and fungi are also frequent causes of endocarditis during this early period. Late cases of endocarditis are similar to those affecting native valves. The most frequent organism is *Streptococcus viridans*, but *Serratia* and *Pseudomonas* also occur. Patients with prosthetic valves and endocarditis may develop a ring abscess around the valve, which requires valve replacement. Patients with mechanical prostheses have an increased rate of intravascular destruction of red blood cells. Usually the red blood cell loss is easily corrected by the bone marrow. Finally, patients with prosthetic valves may be particularly susceptible to hemodynamic compromise from a new arrhythmia, such as atrial fibrillation.

Clinical Features

Many patients have persistent dyspnea and reduced effort tolerance after successful valve replacement. This is more common in the presence

of preexisting heart dysfunction or atrial fibrillation. Many symptoms of valvular dysfunction described in the preceding sections on specific valvular disease may occur in the setting of prosthetic valves. However, in addition to those symptoms, patients with prosthetic valves experience symptoms specific to the presence of the artificial valve.

Large paravalvular leaks usually present with congestive heart failure. Patients with new neurologic symptoms may have thromboembolism associated with the valve thrombi or endocarditis. Minor embolic episodes, such as transient neurologic symptoms, amaurosis fugax, or self-limited ischemic episodes in the extremities or organs in the absence of endocarditis, are common. Patients may present with major embolic events, including stroke, mesenteric infarction, or sudden death. Major bleeding due to anticoagulant therapy also can occur, with hemorrhagic stroke the most common lethal bleeding complication.

Patients with prosthetic valves usually have abnormal cardiac sounds. Mechanical valves have loud, metallic closing sounds. Systolic murmurs are present commonly with mechanical models. Loud diastolic murmurs generally are not present with mechanical valves. Patients with bioprostheses usually have normal S₁ and S₂, with no abnormal opening sounds. The aortic bioprosthesis usually is associated with short midsystolic murmur. Only the mitral bioprosthesis normally is associated with diastolic rumble.

Diagnosis of Prosthetic Valve Dysfunction or Complications

New or progressive symptoms referable to the heart suggest a prosthetic valve disorder. Therefore, new or progressive dyspnea of any form, new onset or worsening of congestive heart failure, decreased exercise tolerance, or a change in chest pain compatible with ischemia all suggest valvular dysfunction. Persistent fever in patients with prosthetic valves should be evaluated for possible endocarditis. Changes in valve position may be noted on chest radiographs if comparison views are available. Blood studies that may be helpful include a complete blood count with red blood cell indices and coagulation studies if the patient is on warfarin. Emergency echocardiographic studies should be requested if there is any question about valve dysfunction. Ultimately, echocardiography and/or cardiac catheterization may be required for diagnosis.

Emergency Department Management and Admission Indications

Patients suspected of having acute prosthetic valvular dysfunction need immediate referral to a cardiac surgeon for possible emergency surgery. Medical management of patients with acute mitral or aortic valvular incompetence should be guided by the preceding section. The need for the intensity of anticoagulation therapy varies with each type of mechanical valve but ranges from an INR goal of 2 to 3.5.⁴ Patients with bioprosthetic valves without additional risk factors for embolism should receive aspirin therapy (160 mg/d).⁹ Acute prosthetic valvular dysfunction due to thrombotic obstruction has been treated successfully with thrombolytic therapy,⁹ but requires consultation with a cardiologist. Lesser degrees of obstruction should be treated with optimization of anticoagulation. Disposition of patients with worsening of symptoms can be problematic, and consultation with the cardiologist may be needed prior to consideration for discharge.

55 THE CARDIOMYOPATHIES, MYOCARDITIS, AND PERICARDIAL DISEASE

James T. Niemann

THE CARDIOMYOPATHIES

The term *cardiomyopathy* is used to describe a group of diseases that directly alter cardiac structure and impair myocardial function. Four types of cardiomyopathy are currently recognized: (1) dilated cardiomyopathy (DCM), (2) hypertrophic cardiomyopathy (HCM), (3) restrictive cardiomyopathy, and (4) arrhythmogenic right ventricular cardiomyopathy.¹ It is acknowledged that there are some primary heart

muscle disorders that do not fit readily into one of these four groups, and these conditions have been termed unclassified cardiomyopathies. Finally, the term *specific cardiomyopathies* is now used to describe heart muscle diseases that are associated with specific cardiac or systemic disorders. They often present with hemodynamic findings similar to those of the idiopathic dilated or restrictive form of cardiomyopathy. Some specific cardiomyopathies are listed in Table 55-1. As a group, the cardiomyopathies are the third most common form of cardiac disease encountered in the United States, following coronary (ischemic) heart disease and hypertensive heart disease. HCM is the second most common cause of sudden cardiac death in the adolescent population and the leading cause of sudden death in competitive athletes.²

Dilated Cardiomyopathy

Hemodynamically, DCM is characterized by depressed myocardial systolic function and systolic pump failure. Left ventricular (LV), and often right ventricular (RV), contractile force is diminished, resulting in a low cardiac output and increased end-systolic and end-diastolic ventricular volumes and intracavitary pressures. LV, and often RV, dilatation accompanied by compensatory hypertrophy are the hallmarks of DCM. Histologic findings are nonspecific.

Approximately 80 percent of cases of DCM are of unknown etiology; that is, they are not associated with specific cardiac or systemic disorders (see Table 55-1) and are considered idiopathic.³ The idiopathic form of DCM is the cause in approximately 25 percent of all cases of congestive heart failure (CHF) and the primary indication for cardiac transplantation in the United States. The prevalence of idiopathic DCM is estimated to be approximately 36 cases per 100,000 population. Blacks and males have a 2.5-fold increase in risk compared to whites and females. Most patients are diagnosed between the ages of 20 and 50 years, and the majority have advanced symptoms of CHF at the time of initial presentation.³

CLINICAL FEATURES AND DIAGNOSIS As a result of systolic pump failure, the patient presents with symptoms of CHF: dyspnea on exertion, orthopnea, and paroxysmal nocturnal dyspnea. Depressed ventricular contractile function and dilatation may result in the formation of mural thrombi, and the patient may present with manifestations

of peripheral embolization (e.g., an acute neurologic deficit, flank pain, and hematuria or a pulseless, cyanotic extremity). Chest pain with features of typical angina pectoris occurs in approximately one-third of patients. Chest pain in these patients is felt to be due to limited coronary vascular reserve rather than atherosclerotic coronary artery disease.

Murmurs are frequently heard during cardiac auscultation and are not necessarily indicative of primary valvular disease. Ventricular dilatation and the resultant annular dilatation and displacement of the papillary muscles of the atrioventricular valves inhibit leaflet coaptation and complete valve closure. Holosystolic regurgitant murmurs of mitral and tricuspid valve origin are frequently heard at the apex or lower left sternal border in the patient with biventricular failure. On occasion an apical diastolic rumble may be heard and is due either to accentuated, early-diastolic atrial-to-ventricular flow (the result of mitral regurgitation and left atrial overload) or to a loud summation gallop. An enlarged, pulsatile liver may be found if tricuspid insufficiency is significant. Bibasilar rales and dependent edema are common additional findings.

The chest radiograph invariably shows an enlarged cardiac silhouette and increased cardiothoracic ratio; biventricular enlargement is common. Evidence of pulmonary venous hypertension ("cephalization" of flow and enlarged hila) is also frequent and may serve to differentiate cardiac enlargement due to myocardial failure from that due to a large pericardial effusion.

The electrocardiogram (ECG) is almost always abnormal. Left ventricular hypertrophy and left atrial enlargement are the most common findings. Q or QS waves and poor R-wave progression across the anterior precordium may produce a pseudoinfarction pattern. Atrial fibrillation and ventricular ectopy are common rhythm disturbances.

Echocardiographic studies in a symptomatic patient demonstrate a decreased ejection fraction, increased systolic and diastolic volumes, and ventricular and atrial enlargement.

TREATMENT AND DISPOSITION A timely assessment is indicated in patients who present with newly diagnosed symptomatic CHF, and evaluation typically requires hospitalization. Echocardiography is indicated to exclude known causes of heart failure that may be correctable (e.g., pericardial effusion or valvular disease), to estimate ejection fraction, and to rule out other potential complications (e.g., mural thrombi) that may be amenable to therapy. Symptom-directed therapy is best initiated in the inpatient setting in order to minimize adverse drug effects, although protocols for short stay/observation units are being investigated. Almost all patients will benefit symptomatically from digitalis glycoside therapy and diuretics, but these drugs have not been shown to improve survival rates and may require different doses in men and women. Detailed reviews suggest the use of angiotensin-converting enzyme inhibitors and β -blockers, specifically carvedilol and metoprolol, have been shown to improve survival in patients with DCM and CHF.^{4,5} Patients with complex ventricular ectopy who are determined to be at risk for sudden cardiac death may benefit from amiodarone therapy or an implanted cardioverter-defibrillator (ICD).⁶

Patients with a known DCM and chronic CHF may present to the ED with a mild-to-moderate worsening of symptoms. In most instances, the cause is noncompliance with medical therapy or dietary indiscretion.⁷ Such patients can often be managed in the ED with intravenous diuretics, reinstitution of prescribed medications, counseling of the patient, and timely referral to the primary care physician. However, other causes of an acute exacerbation of symptoms in a disease characterized by a slow and progressive history must be considered (see Chap. 53) and, if present or suspected, require hospitalization for definitive management.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy is characterized by LV and/or RV hypertrophy that is usually asymmetrical and involves primarily the

TABLE 55-1 Common Causes of Specific Cardiomyopathies

Neuromuscular disorders (muscular dystrophy, Friedreich ataxia)
Familial cardiomyopathy

interventricular septum. The diagnostic hallmarks of the disease remain echocardiographic asymmetrical septal hypertrophy and histologic hypertrophy associated with myocardial fiber disarray surrounding areas of increased loose connective tissue.^{8,9} In approximately 50 percent of cases, it is a familial disease with autosomal dominant inheritance. In the rest, it is sporadic. There is no apparent sex or ethnic predilection. Molecular genetics has demonstrated that HCM is a heterogeneous disease of the sarcomere with many mutations. The most common mutation involves the p-myosin heavy chain. There is evidence that particular genotypes have more rapidly progressive courses. The prevalence in the general population is approximately 1 in 500. The annual mortality rate in the overall HCM population is about 1 percent per annum, but up to 4 to 6 percent in childhood and adolescence.

Hemodynamically, HCM is characterized by abnormal LV diastolic function due to reduced compliance of the hypertrophied left ventricle. This decreased compliance is reflected by an increase in LV filling pressure. Cardiac output, ejection fraction, and end-systolic and end-diastolic volumes are usually normal. During cardiac catheterization and hemodynamic monitoring, a systolic pressure gradient between the body of the left ventricle and the subvalvular outflow tract can be recorded in some patients at rest or after provocation (e.g., exercise or isoproterenol infusion). The majority of clinical symptoms in this heart muscle disease are the result of impaired diastolic relaxation and restricted LV filling.

CLINICAL FEATURES AND DIAGNOSIS Severity of symptoms in most instances is related to the patient's age; the older the patient, the more severe the symptoms. Dyspnea on exertion is the most frequent initial complaint and is due to exercise-induced sinus tachycardia, which results in an abrupt elevated LV diastolic pressure and pulmonary venous hypertension. Additional symptoms include chest pain, palpitations, and syncope. A family history of death due to cardiac disease, frequently described as "massive heart attack" or "heart failure," is not uncommon. Complaints of paroxysmal nocturnal dyspnea and pedal edema are infrequent.

Chest pain in HCM patients is due to an imbalance between the oxygen demand of the hypertrophied left ventricle and the available myocardial blood flow. In older patients, associated atherosclerotic coronary artery disease may further limit myocardial perfusion. Precordial or retrosternal chest discomfort in HCM may mimic angina pectoris or may be "atypical." Response to nitroglycerin administration is poor and highly variable.

The HCM patient may be aware of forceful ventricular contraction and complain of an abnormal heartbeat or "palpitations." Atrial and ventricular dysrhythmias are not uncommon in these patients; rapid atrial dysrhythmias, especially atrial fibrillation, are particularly poorly tolerated because of the increased importance of the atrial contribution to LV filling in the poorly compliant heart and require aggressive management in hemodynamically unstable patients.

Jugular venous pressure is usually not elevated; however, a prominent *a* wave may be noted on close inspection of the neck veins. The upstroke of the carotid arterial pulse is rapid and frequently biphasic or bifid (*pulsus bisferiens*). The apical impulse is sustained and hyperdynamic, and a presystolic lift is common.

The first and second heart sounds are usually normal, and a fourth sound (*S₄*) will be heard in most patients. The characteristic systolic ejection-type murmur of HCM is heard best at the lower left sternal border or at the apex and rarely radiates to the carotid arteries. Easily performed bedside maneuvers can be used to increase the intensity and duration of the murmur (Table 55-2). Interventions that decrease LV filling and the distending pressure in the LV outflow tract or that increase the force of myocardial contraction accentuate the murmur of HCM. Such interventions include standing and during the strain phase of the Valsalva maneuver. The murmur is also louder with the first sinus beat following a premature ventricular contraction. Maneuvers that increase LV filling (squatting, passive leg elevation, and hand

grip) have an opposite effect on murmur characteristics. The murmurs of HCM and mitral valve prolapse are similar and are compared in Table 55-2.

ECG findings of LV hypertrophy and left atrial enlargement are found in 30 percent and 25 to 50 percent, respectively, of HCM patients. Evidence of chamber enlargement is most common in patients with large gradients across the LV outflow tract. Q waves of considerable amplitude (more than 0.3 mV), termed septal Q waves, are seen in about 25 percent of patients and may be encountered in the anterior, lateral, or inferior leads. These Q waves may mimic those seen following myocardial infarction (pseudoinfarction pattern). The polarity of the T wave may serve as a diagnostic clue in the differentiation between HCM septal Q waves from Q waves due to myocardial infarction. Upright T waves in those leads with QS or QR complexes are usually found in HCM; T-wave inversion in such leads is highly suggestive of ischemic heart disease.

The chest radiograph is frequently normal, and identifiable abnormalities are largely nonspecific. Many patients do not show radiographic evidence of LV or left atrial enlargement. Evidence of pulmonary venous congestion is unusual.

Echocardiography has played a substantial role in the diagnosis of HCM, in the correlation of the auscultatory and hemodynamic events with LV anatomic changes, and in defining inheritance patterns. The characteristic echocardiographic finding is disproportionate septal hypertrophy. Additional described echocardiographic abnormalities include normal or reduced LV end-diastolic dimensions, systolic anterior motion of the mitral valve, and midsystolic closure of the aortic valve.

TREATMENT AND DISPOSITION A systematic review reveals that the majority of patients with HCM who seek medical care typically do so because of declining exercise tolerance, chest pain, or syncope.⁹ Symptoms may mimic those of ischemic heart disease, or in the young patient, symptoms may be ascribed to a noncardiac cause. The patient who presents complaining of exercise intolerance or chest pain in whom the typical murmur of HCM is heard should be referred for echocardiographic evaluation. Syncope in patients with HCM typically occurs during or immediately after exercise. If HCM is suspected in a patient with syncope, hospitalization is indicated. The work-up in such cases is extensive and includes echocardiographic studies as well as extended ambulatory (Holter) monitoring, exercise stress testing to assess blood pressure response, and tilt testing. Syncope in patients with HCM may be due to one or more factors and may presage sudden cardiac death.⁹ Vigorous exercise is discouraged for such patients, and preparticipation screening guidelines have been developed for competitive athletes to minimize the risk of sudden death due to HCM.¹⁰ (J-Blockers are the mainstay of therapy for patients with chest pain.

TABLE 55-2 Effect of Bedside Interventions on the Murmur of Hypertrophic Cardiomyopathy Compared to Mitral Valve Prolapse

	Hypertrophic Cardiomyopathy	Mitral Valve Prolapse
Valsalva maneuver (strain phase)	Murmur increased	Click closer to <i>S₁</i> ; murmur increased
Standing after squatting	Murmur increased	Click closer to <i>S₂</i> ; murmur increased
Passive leg elevation in supine patient	Murmur decreased	Click closer to <i>S₂</i> ; murmur decreased
Hand grip	Murmur decreased	Click closer to <i>S₁</i> ; murmur increased
Squatting	Murmur decreased	Click closer to <i>S₂</i> ; murmur decreased

Restrictive Cardiomyopathy

The restrictive forms are among the least common of the described cardiomyopathies. *Restrictive cardiomyopathy* is defined as heart muscle disease that results in "restricted" ventricular filling, with normal or decreased diastolic volume of either or both ventricles. Systolic function is usually normal, and ventricular wall thickness may be normal or increased, depending on the underlying cause. The hemodynamic hallmarks include (1) elevated LV and RV end-diastolic pressure, (2) normal LV systolic function (ejection fraction greater than 50 percent), and (3) a marked decrease followed by a rapid rise and plateau in early-diastolic ventricular pressure. The rapid rise and abrupt plateau in the early-diastolic ventricular pressure trace produce a characteristic "square-root sign" or "dip-and-plateau" filling pattern due to increased myocardial stiffness. This pattern is not diagnostic, however, and may be seen in constrictive pericarditis, with which restrictive cardiomyopathy is commonly confused. Differentiation between the two is critical because constrictive pericarditis can be cured surgically. The diagnosis of restrictive cardiomyopathy should be considered in a patient presenting with CHF but no evidence of cardiomegaly or systolic dysfunction.¹¹

Restrictive cardiomyopathy may result from systemic disorders (amyloidosis, sarcoidosis, hemochromatosis, progressive systemic sclerosis [scleroderma], carcinoid heart disease, endomyocardial fibrosis, hypereosinophilic syndrome), but most cases are idiopathic. The idiopathic form is sometimes familial, with autosomal dominant transmission. There has been no clearly demonstrated predilection for gender or ethnicity.

CLINICAL FEATURES AND DIAGNOSIS Symptoms are typical of CHF and include dyspnea, orthopnea, and pedal edema. Right-sided manifestations may predominate and result in hepatomegaly, right upper quadrant pain, and ascites. Chest pain is uncommon, except in amyloidosis.

Findings on physical examination depend on the stage or severity of myocardial involvement. An S_3 is almost always present, and an S_4 is often heard if the patient is in sinus rhythm. Pulmonary rales, jugular venous distention, Kussmaul sign (jugular venous pulse rises during inspiration rather than falling), hepatomegaly, pedal edema, and ascites are also typical findings.

The chest radiograph may reveal signs of CHF in the absence of cardiomegaly. Chamber enlargement due to wall thickening, but not dilatation, and nonspecific ST-T-wave changes are usually noted on the ECG. Cardiac conduction disturbances are common in amyloidosis and sarcoidosis. Atrial fibrillation may occur in the setting of atrial enlargement. Low-voltage QRS complexes (QRS amplitude less than 0.7 mV) have been frequently described in patients with restrictive cardiomyopathy secondary to amyloidosis and hemochromatosis.

TREATMENT AND DISPOSITION Symptoms and signs of CHF, particularly right-sided failure, with a normal-size cardiac silhouette on chest radiograph should prompt a suspicion of underlying restrictive cardiomyopathy. The differential diagnosis includes constrictive pericarditis, or diastolic LV dysfunction (most commonly due to ischemic heart disease, hypertension, or age-related changes in ventricular diastolic compliance). Doppler echocardiographic studies and cardiac catheterization with hemodynamic assessment are often required to differentiate between the above-mentioned entities. Computed tomography and magnetic resonance imaging of the heart are felt to be of value in differentiating constrictive pericarditis and restrictive cardiomyopathy.¹¹ Timely diagnosis is important because constrictive pericarditis can be surgically corrected and diastolic LV dysfunction not due to restrictive cardiomyopathy usually responds well to drug therapy (β -blockers or calcium-channel blockers). The medical management of restrictive cardiomyopathy is less effective and symptom directed (diuretics and angiotensin-converting enzyme inhibitors) unless due to sarcoidosis (corticosteroid therapy) or he-

mochromatosis (chelation therapy). The need for admission is usually determined by the severity of symptoms and the availability of a timely and usually invasive work-up.

Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic cardiomyopathy, or dysplasia, is the rarest of the cardiomyopathies. Familial disease is common with an autosomal dominant inheritance pattern with incomplete penetrance. This cardiomyopathy is characterized by progressive replacement of the RV myocardium with fibrofatty tissue in an eventual global distribution. The left ventricle and septum are usually spared.¹²

CLINICAL FEATURES AND DIAGNOSIS The typical presentation is that of sudden death or ventricular dysrhythmia in a young or middle-aged patient. The findings upon physical examination are normal. The chest radiograph shows no specific findings, and the heart size is not enlarged. The ECG may show a right bundle branch pattern and precordial T-wave inversion. Echocardiographic studies, radionuclide angiography, and cardiac catheterization are routinely required to confirm the diagnosis. The echocardiogram has the highest sensitivity and positive predictive value for the diagnosis of RV abnormalities and typically shows RV contraction abnormalities and RV enlargement.¹² Magnetic resonance imaging has been shown to detect fatty infiltration of the myocardium and may become the preferred diagnostic test.

TREATMENT AND DISPOSITION The majority of patients present after aborted sudden cardiac death, with syncope, or with complex ventricular ectopy. Following such presentations, hospitalization is invariable. Ventricular tachycardia can be suppressed with antiarrhythmic drugs, but ablative procedures or implantation of an antiarrhythmic device may be necessary.

MYOCARDITIS

Definition

Myocarditis is broadly but nonspecifically defined as inflammation of the heart muscle and is most frequently characterized pathologically by focal infiltration of the myocardium by lymphocytes, plasma cells, and histiocytes. Varying amounts of myocytolysis and destruction of the interstitial reticulin network are also seen.¹³ Because many episodes are mild, they do not always come to medical attention; thus their incidence is unknown. The pathologic changes have been ascribed to a number of infectious agents (Table 55-3), some of which involve the myocardium secondarily as part of a systemic disease process. Myocarditis is frequently accompanied by pericarditis.

Clinical Features and Diagnosis

Fever is common, as is sinus tachycardia, which is usually out of proportion with respect to the extent of temperature elevation. Signs and symptoms depend on the extent of myocardial involvement and resultant depression of myocardial systolic function. In severe cases, progressive heart failure, with its associated symptoms, may be seen. With less extensive myocardial involvement, pericarditis and the clinical manifestations of systemic illness (fever, myalgias, headache, and rigors) may overshadow clinical signs of myocardial dysfunction, and myocarditis may not be suspected. Retrosternal or precordial chest pain is a frequent presenting complaint and is most commonly secondary to associated pericardial inflammation (myopericarditis). This chest pain may mimic angina in its character. A pericardial friction rub is commonly heard in patients with myopericarditis.

The chest roentgenogram is usually normal, and reported abnormalities (cardiomegaly and pulmonary venous hypertension and/or

pulmonary edema) vary with disease severity and are nondiagnostic. Reported ECG changes include nonspecific ST-T-wave changes, ST-segment elevation (due to associated pericarditis), atrioventricular block, and prolonged QRS duration. Levels of cardiac enzymes (creatinine kinase and CK-MB) and troponin may be elevated.¹³ Echocardiographic studies may reveal depressed systolic function in severe cases. Children are not expected to have a different presentation.

TREATMENT AND DISPOSITION Current therapy in cases of idiopathic or viral myocarditis is largely supportive and symptom-directed. Myocarditis in rheumatic fever and complicating diphtheria or meningococcemia necessitates directed antibiotic therapy. Immunosuppressive therapy may be of value in selected patients.¹⁴ Admission is usually indicated if the patient presents with symptoms of rapidly progressive CHF.

UNEXPLAINED HEART FAILURE AND CARDIOMEGALY: DIFFERENTIAL DIAGNOSIS AND EVALUATION

Symptoms of CHF and associated cardiomegaly or evidence of cardiomegaly in an asymptomatic patient necessitates a directed evaluation. In the vast majority of instances, one of the following five disease entities will eventually be diagnosed. Where appropriate, recognized diagnostic clues are noted.

1. **Hypertensive heart disease.** Systemic arterial hypertension affects 10 to 20 percent of the adult population. This is a disease with a high prevalence that may be diagnosed at a number of stages. Patients with a dilated cardiomyopathy and untreated cardiac failure frequently present with an elevated blood pressure due to autonomically mediated compensatory reflexes. Isolated involvement of the myocardium as the major manifestation of systemic arterial hypertension is rare. A careful search for evidence of other end-organ damage due to arterial hypertension should be undertaken (examination of fundi, assessment of renal function, evaluation for focal neurologic changes, or history of such entities).
2. **Ischemic heart disease (ischemia cardiomyopathy).** Most patients with clinical signs of biventricular heart failure and cardiomegaly due to obstructive coronary arterial disease relate a history of typical anginal pain or documented myocardial infarction. A few do not, and clinical presentation and physical findings in these cases mimic those of an idiopathic dilated cardiomyopathy.
3. **Valvular heart disease.** Although the incidence of rheumatic heart disease in the United States is low, it remains prevalent in underdeveloped countries and is frequently first diagnosed in recent immigrants. The growing geriatric population is prone to calcific aortic stenosis and mitral annular calcification. In addition, bicuspid or unicuspid aortic valve abnormalities remain the most common congenital heart disease. All valvular diseases may present with CHF or incidental cardiac enlargement, and systolic and diastolic murmurs may be noted. Echocardiographic studies are the diagnostic tests of

choice in patients with suspected valvular heart disease. Hemodynamic and angiographic studies may be confirmatory.

4. **Myocarditis.** Patients with severe myocarditis may present with signs and symptoms of progressive cardiac insufficiency. Such patients are usually young, have no significant past cardiac history, have few risk factors for atherosclerotic coronary arterial disease, and present with a recent, abrupt onset of symptoms during or immediately following a systemic or viral illness.
5. **Idiopathic cardiomyopathy.** This diagnosis should be considered only if the first four entities have been excluded. A careful search for potential causes should then be undertaken.

PERICARDIAL DISEASE

The pericardium consists of a serous or loose fibrous membrane (visceral pericardium) overlying the epicardium and a dense collagenous sac (parietal pericardium) surrounding the heart. The space between the visceral and parietal pericardium may contain up to 50 mL of fluid under normal conditions, and intrapericardial pressure is normally subatmospheric. Because its layers are serosal surfaces and because of its proximity and attachments to other structures, the pericardium may be involved in a number of systemic or localized disease processes (Table 55-4). A recent review affirmed the clinical presentation of pericardial heart disease is variable and dependent on the pericardium's response to injury and how this response affects cardiac function.¹³ In this section the clinical manifestations and evaluation of acute and constrictive pericarditis and nontraumatic cardiac tamponade are discussed.

Acute Pericarditis

CLINICAL FEATURES The most common symptom is precordial or retrosternal chest pain, which is most frequently described as sharp or stabbing. It may be of sudden or gradual onset and radiate to the back, neck, left shoulder, or arm; referral to the left trapezial ridge (due to inflammation of the joining diaphragmatic pleura) is a particular distinguishing feature. Chest pain due to acute pericarditis may be aggravated by inspiration or movement. *Typically, chest pain is most severe when the patient is supine and is often relieved when the patient sits up and leans forward.* In most instances, these characteristics allow the pain of acute pericarditis to be distinguished from the ischemic pain of angina or acute myocardial infarction.

Associated symptoms include (1) low-grade, intermittent fever, particularly if pericarditis is infectious in origin or of the idiopathic type; (2) dyspnea, due to accentuated pain with inspiration; and (3) dysphagia, ascribed to irritation of the esophagus by the posterior pericardium.

TABLE 55-4 Common Causes of Acute Pericarditis

Idiopathic
Infectious
Viral (coxsackie virus, echovirus, HIV)
Bacterial [especially <i>Staphylococcus</i> , <i>Streptococcus pneumoniae</i> , /3-hemolytic streptococci (acute rheumatic fever), <i>Mycobacterium tuberculosis</i>]
Fungal (especially <i>Histoplasma capsulatum</i>)
Malignancy (leukemia, lymphoma, metastatic breast and lung carcinoma, melanoma)
Drug-induced (procainamide, hydralazine)
Systemic rheumatic diseases (systemic lupus erythematosus, rheumatoid arthritis, scleroderma, polyarteritis nodosa, dermatomyositis)
Radiation-induced
Postmyocardial infarction (Dressler syndrome)
Uremia
Myxedema

A pericardial friction rub is the most common and important physical finding in pericarditis, but may be difficult to appreciate in a noisy ED. It is best heard with the diaphragm of the stethoscope at the lower left sternal border or apex when the patient is sitting and leaning forward or in the hands-and-knees position. It may be audible only during a certain phase of respiration and characteristically is transient (e.g., heard one hour and not the next). No inference as to the amount of pericardial fluid should be drawn from the presence or absence of a pericardial friction rub.

A pericardial rub is most often triphasic in character, consisting of a systolic component due to ventricular contraction, an early diastolic component occurring during the early phase of ventricular filling, and a presystolic component synchronous with atrial systole. It is less commonly biphasic, with a systolic component with either an early diastolic or presystolic component. A monophasic rub is unusual (18 percent of cases) but is most often systolic.

DIAGNOSIS

Electrocardiogram Serial ECGs recorded over a number of days may be diagnostic in acute pericarditis. The evolutionary ECG changes during acute pericarditis and convalescence have been divided into four stages. During stage 1, or the acute phase, ST-segment elevation (reflecting associated subepicardial inflammation and/or injury) is prominent in the precordial leads, especially V₅ and V₆, and in standard lead I. PR-segment depression may be noted in leads II, aVF, and V₄ to V₆ (Figure 55-1). In stage 2, the ST segment begins returning to the isoelectric line, and T-wave amplitude decreases. T-wave inversion is rarely seen until stage 3. Stage 3 is characterized by an isoelectric ST segment and T-wave inversion in those leads previously showing ST-segment elevation. Resolution of repolarization abnormalities is the hallmark of stage 4.

If a large pericardial effusion develops during the course of acute pericarditis, additional ECG abnormalities may be noted, including low-voltage QRS complexes and electrical alternans. These phenomena are due to the insulating effect of pericardial fluid, which attenuates electrical signals of myocardial origin, and the pendular motion of the heart within the fluid-filled pericardial space.

Although serial ECG tracings are of diagnostic value in acute pericarditis, sequential ECG assessment is not a diagnostic luxury afforded the emergency physician. Differentiating pericarditis from the normal variant with "early repolarization" is a common problem and can be difficult when only a single 12-lead ECG is available. The ST-T-wave changes present in the early repolarization or normal variant ECG mimic those of pericarditis and have been reported in 2 percent of healthy young adults. Investigations attempting to distinguish these two conditions have yielded conflicting results. However, a simple criterion offers considerable diagnostic utility, namely, the ST-segment/T-wave amplitude ratio in leads V₅, V₆, or I.¹⁵ Using the end of the PR segment as baseline, or 0 mV the amplitude or height of the ST segment at its onset is measured in one of the aforementioned leads and recorded in millivolts. The height of the T-wave in the same lead is measured from the baseline to the T-wave peak. *If the ratio of ST amplitude (in millivolts) to T-wave amplitude (in millivolts) is above 0.25, acute pericarditis is likely* and if the ratio is less than 0.25, acute pericarditis is unlikely. Sensitivity at an ST/T ratio >0.25 for acute pericarditis is greater than 0.85 and the specificity more than 0.8 [LR (+) about 4 and LR (—) about 0.2]. This criterion may allow differentiation of acute pericarditis (stage 1) from early repolarization during ED evaluation (see Figure 55-1). Pericarditis alone does not cause significant cardiac rhythm disturbances.

Radiographic Assessment Conventional posteroanterior and lateral chest radiographs are of limited value. The cardiac silhouette may be of normal size and contour in acute pericarditis and in some instances, the setting of cardiac tamponade. If previous chest radiographs are available for comparison, a recent increase in the size of the cardiac

silhouette or an increase in the cardiothoracic ratio without radiographic evidence of pulmonary venous hypertension aids in distinguishing an expanding pericardial effusion from left heart failure. The epicardial "fat-pad sign" is rarely seen on the lateral chest radiograph and has been reported in only 15 percent of cases of acute pericarditis during fluoroscopy with image intensification. If acute pericarditis is suspected on the basis of history, physical examination, or ECG, posteroanterior and lateral chest radiographs, which may demonstrate a pleuropulmonary or mediastinal abnormality, may assist in establishing the underlying cause (e.g., neoplastic or infectious).

Echocardiographic Studies Echocardiography has become the procedure of choice for the detection, confirmation, and serial follow-up of patients with acute pericarditis and a pericardial effusion.

Normally, the pericardial sac is only a "potential" space, and the myocardium is echocardiographically in direct contact with surrounding thoracic structures. The anterior RV wall is in contact with the chest wall, and the posterior LV wall is in contact with the posterior pericardium and adjacent pleura. When a pericardial effusion is present, the pericardial space fills with echo-free fluid. Echocardiographically, a separation is seen between the right ventricle and the chest wall and between the left ventricle and the posterior pericardium. Quantitation of the size of the effusion is arbitrary and is determined by where the echo-free space is seen (anterior or posterior) and when in the cardiac cycle it occurs. For example, when an echo-free space is seen only posteriorly and only during systole, a small effusion is said to be present.

Ancillary Laboratory Evaluation The laboratory studies listed in Table 55-5 may be of value in establishing an etiologic diagnosis.¹⁶ Serum CK-MB and troponins may be elevated in acute pericarditis due to associated myocarditis.¹⁷

TREATMENT AND DISPOSITION Most patients with idiopathic or presumed viral pericarditis will respond to nonsteroidal anti-inflammatory agents administered for 7 days to 3 weeks. If a specific cause is identified, therapy should be directed toward the underlying disease. Patients with an enlarged cardiac silhouette on chest radiograph should be admitted for early Doppler echocardiography to assess the extent of the effusion and degree of hemodynamic compromise.

Nontraumatic Cardiac Tamponade

PATHOPHYSIOLOGY An increase in the amount of fluid within the pericardial sac results in an increase in intrapericardial pressure. The normal fibrocollagenous parietal pericardium has elastic properties and stretches to accommodate increases in intrapericardial fluid. The initial portion of the pericardial volume-pressure curve is flat; relatively large increases in volume result in comparatively small changes in intrapericardial pressure. The curve becomes steeper as the parietal pericardium reaches the limits of its distensibility. If fluid continues to accumulate, intrapericardial pressure rises to a level greater than that of the normal filling pressures of the right heart chambers. When this occurs, ventricular filling is restricted and results in cardiac tamponade. The point at which this occurs is determined by the slope of the pericardial volume-pressure curve, which is dependent on the rate of fluid accumulation, pericardial compliance (a thickened parietal pericardium is less distensible), and intravascular volume (hypovolemia lowers ventricular filling pressure). Common causes of cardiac tamponade in nontrauma patients are listed in Table 55-6.

CLINICAL FEATURES AND DIAGNOSIS Symptoms are nonspecific, and patients most commonly complain of dyspnea and profound exertional intolerance. Additional complaints may be present due to the underlying disease (e.g., uremia) or if the pericardial effusion has

Stage I

Stage II

Stage III

FIG. 55-1. This series of ECGs was recorded in a 28-year-old male who presented complaining of pleuritic retrosternal pain, cough, and fever. The initial ECG (dated 10-20) demonstrates diffuse ST-segment elevation (stage I). The ST-segment to T-wave amplitude ratio measured in V_6 is 5 mm/10 mm, or 0.50, thus meeting criteria for pericarditis rather than early repolarization (see the text). The ECG dated 10-29 demonstrates a return of the ST segment to the isoelectric point in most leads in which they had been elevated (stage II). The third tracing (dated 11-3) demonstrates resolution of ST changes and the appearance of T-wave inversion in the anterior precordial leads (stage III). These evolutionary changes are typical of and diagnostic for pericarditis and usually occur over several weeks.

developed gradually (e.g., tuberculous pericarditis). Such symptoms may include weight loss, pedal edema, ascites, and so on.

Physical examination most commonly reveals tachycardia and low systolic arterial blood pressure with a narrow pulse pressure. Pulsus paradoxus may also be present. A paradoxical arterial pulse is said to be present when the cardiac rhythm is regular and there are apparent dropped beats in the peripheral pulse during inspiration. There is usually a greater than 10 mm Hg decrease in systolic blood pressure during inspiration in the supine position. A value greater than 25 mm Hg usually separates true tamponade from lesser degrees of restricted car-

diac filling.¹⁸ Pulsus paradoxus is not diagnostic of cardiac tamponade and may be noted in other cardiopulmonary processes. In cardiac tamponade, the neck veins are usually distended with an absent y descent. The apical impulse is indistinct or tapping in quality. Cardiac auscultation may reveal "distant" or soft heart sounds. Pulmonary rales are usually absent, and there may be right upper quadrant tenderness due to hepatic venous congestion.

The chest radiograph may or may not reveal an enlarged cardiac silhouette, and this finding is dependent on the amount of intrapericardial fluid accumulation. The pulmonary vasculature typically ap-

TABLE 55-5 Ancillary Diagnostic Studies in Acute Pericarditis

Complete blood count and differential white blood cell count	May suggest infection or leukemia
Blood urea nitrogen/creatinine	May suggest a diagnosis of uremic pericarditis Particularly in patients with a history of rheumatic heart disease or pharyngitis
Streptococcal serologic testing (antistreptolysin O, anti-DNAse, antihyaluronidase)	If bacterial infection suspected
Blood cultures	Antinuclear antibodies, anti-DNA titers, or rheumatoid factor in patients with systemic symptoms
Serologic studies	Will not facilitate an etiologic diagnosis but can be followed serially to assess response to therapy
Erythrocyte sedimentation rate	
Acute and convalescent viral antibody titers	
Thyroid function studies	

pears normal. An epicardial fat-pad line, or sign, may occasionally be seen within the cardiac silhouette.

The ECG usually shows low-voltage QRS complexes (less than 0.7 mV) and ST-segment elevation (due to the inflammation of the epicardium) with PR-segment depression, as in pericarditis. Electrical alternans (beat-to-beat variation in the amplitude of the P and R waves unrelated to the respiratory cycles) is a classic but uncommon finding (about 20 percent of cases). Electrical alternans is demonstrated in Figure 55-2.

The diagnosis should be suspected based on the clinical examination and chest radiograph findings. Echocardiographic assessment is the diagnostic test of choice. In addition to a large pericardial fluid volume, typical echocardiographic findings described in cardiac tamponade are right atrial compression, right ventricular diastolic collapse, abnormal respiratory variation in tricuspid and mitral flow velocities (Doppler), and dilated inferior vena cava with lack of inspiratory collapse.

TREATMENT AND DISPOSITION Volume expansion with a bolus of NS solution (500 to 1000 mL) will increase intravascular volume, facilitate right heart filling, and increase cardiac output and arterial pressure. However, it is a temporary measure, and patients will require pericardiocentesis as initial definitive therapy and for diagnostic evaluation.

Pericardiocentesis is optimally performed in the cardiac catheterization laboratory using echocardiographic guidance. The major potential complications, namely cardiac perforation and coronary artery laceration, can be minimized. In addition, a pigtail catheter can be inserted to allow continuous fluid drainage and prevention of fluid accumulation.

TABLE 55-6 Cardiac Tamponade in Medical (Nontrauma) Patients

Cause	Approximate Frequency, %
Metastatic malignancy	40
Acute idiopathic pericarditis	15
Uremia	10
Bacterial or tubercular pericarditis	10
Chronic idiopathic pericarditis	10
Hemorrhage (anticoagulant)	5
Other (systemic lupus erythematosus, postradiation, myxedema, etc.)	10

Emergency pericardiocentesis might be necessary within the emergency department if dictated by hemodynamic instability. The technique is described in Chap. 259.

If the equipment is available, echocardiographically guided emergency pericardiocentesis can be performed in the emergency department. Definitive management (insertion of an intrapericardial pigtail catheter through a pericardial window) is best undertaken following admission. After pericardiocentesis, patients require admission in a monitored setting.

Constrictive Pericarditis

PATHOPHYSIOLOGY Constrictive pericarditis is pathologically distinct from acute pericarditis.¹⁹ Following pericardial injury and the resultant inflammatory and reparative process, fibrous thickening of the layers of the pericardium may occur. This fibrous reparative process is most commonly encountered after cardiac trauma with intrapericardial hemorrhage, after pericardiectomy (open-heart surgery, including coronary revascularization), in fungal or tuberculous pericarditis, and in chronic renal failure (uremic pericarditis). When the fibrous and/or collagenous response prevents passive diastolic filling of the normally distensible cardiac chambers, constriction is said to be present. Intrapericardial fluid is not required to produce such a hemodynamic effect. By its nature, constrictive pericarditis is most commonly a slowly progressive process without initial symptoms. However, clinical manifestations may occur early if fluid also accumulates within the thickened, noncompliant pericardial sac (so-called effusive constrictive pericarditis). In the vast majority of cases of constrictive pericarditis that are proved by hemodynamic assessment (see below), a specific cause is never determined.

CLINICAL FEATURES The symptoms of constrictive pericarditis usually develop gradually and may mimic those of CHF and restrictive cardiomyopathy.¹⁹ If symptoms develop within months of a pericardial injury, a combination of pericardial effusion and constriction should be suspected. Exertional dyspnea and decreased exercise tolerance are common complaints; however, orthopnea, paroxysmal nocturnal dyspnea, and chest pain are unusual. Lower-extremity swelling (pedal edema) and increasing abdominal girth (ascites) are also common complaints and are the result of decreased RV diastolic compliance and the resultant increase in systemic venous pressure.

In most instances, physical findings and their correct interpretation will lead the clinician to suspect constrictive pericarditis. Examination of the neck veins with the torso of the patient at a 45° angle from horizontal will reveal jugular venous distention and a rapid y descent of the cervical venous pulse. Elevated venous pressure is also seen in CHF, but a rapid y descent is infrequently encountered. The Kussmaul sign (inspiratory neck vein distention) is frequently but not invariably noted in constrictive pericarditis but rarely noted in uncompensated CHF. A paradoxical pulse is found in a minority of patients, and thus its absence does not exclude a diagnosis of constrictive pericarditis. On cardiac auscultation, an early diastolic sound, a pericardial "knock," may be heard at the apex 60 to 120 milliseconds after the second heart sound. The pericardial knock sounds like a ventricular gallop but occurs earlier than the S₃ of CHF, which it may mimic. The knock is due to accelerated RV inflow in early diastole and early myocardial distention, followed by an abrupt slowing of further ventricular expansion. There is usually no pericardial friction rub. Hepatomegaly, ascites, and dependent edema of varying severity are usually found.

DIAGNOSIS

Electrocardiogram Diagnostic ECG changes have not been described in constrictive pericarditis. However, low-voltage QRS complexes and inverted T waves are common.

FIG. 55-2. This rhythm strip (lead II, top tracing) and plethysmograph (bottom tracing) were recorded in a patient who presented with dyspnea, hypotension, and clinical and echocardiographic evidence of cardiac tamponade. A paradoxical pulse was noted on palpation of the radial artery. The amplitude of the R waves varies from beat to beat (electrical alternans). Similar changes are seen in P-wave amplitude. These ECG changes are not related to the respiratory cycle.

Radiographic Assessment Conventional posteroanterior and lateral chest radiographs most commonly demonstrate a normal or slightly enlarged cardiac silhouette, clear lung fields, and little or no evidence of pulmonary venous congestion. Pericardial calcification, which may be evident in up to 50 percent of patients with constrictive pericarditis, is seen best on the lateral chest radiograph but is not diagnostic of constrictive pericarditis. Thoracic computed tomography (CT) and magnetic resonance imaging (MRI) may also demonstrate a thickened pericardium.²⁰

Echocardiographic Studies On occasion, two-dimensional echocardiography may demonstrate pericardial thickening and abnormal ventricular septal motion in a patient with suspected constrictive pericarditis. However, its diagnostic utility is much less than in a patient with acute pericarditis. Doppler echocardiography is preferred, and cardiac CT and MRI may also be useful.

TREATMENT AND DISPOSITION In cases of significant constriction and impaired ventricular filling, pericardiectomy is the treatment of choice.

PULMONARY EMBOLISM

Jeffrey A. Kline

Despite recent widening educational efforts toward increasing vigilance for pulmonary embolism (PE) among emergency physicians, the diagnosis is difficult. This chapter discusses pulmonary embolism. Thrombophlebitis is discussed in Chap. 59.

INITIAL APPROACH TO THE PATIENT

Even in the current era of unprecedented recognition of the need for prophylaxis and diagnosis of thrombosis, fatal PE often is not diagnosed, even when the patient has recently seen a physician.¹ Patients with PE usually present with symptoms and findings that mimic many other diseases. Moreover, PE may present with almost no symptoms and may even occur in the complete absence of apparent symptoms. Thus, many clinicians are unsure when to consider this diagnosis within their workup. Although details are discussed below, an appropriate approach is shown in Figure 56-1.

Pathophysiology of Pulmonary Embolism

Appropriate consideration of PE within the differential diagnosis begins with recognition of risk factors that predispose to thrombosis, the precursor to PE. Risk factors are embodied by the triad of factors associated with thrombosis described by Rudolph Virchow: hypercoagulability, stasis, and venous injury (Table 56-1). Hypercoagulability, also referred to as *thrombophilia*, can be broadly classified as malignancy (the most common cause) and nonmalignancy. Malignancies of primary adenocarcinoma or brain origin are the most likely to cause

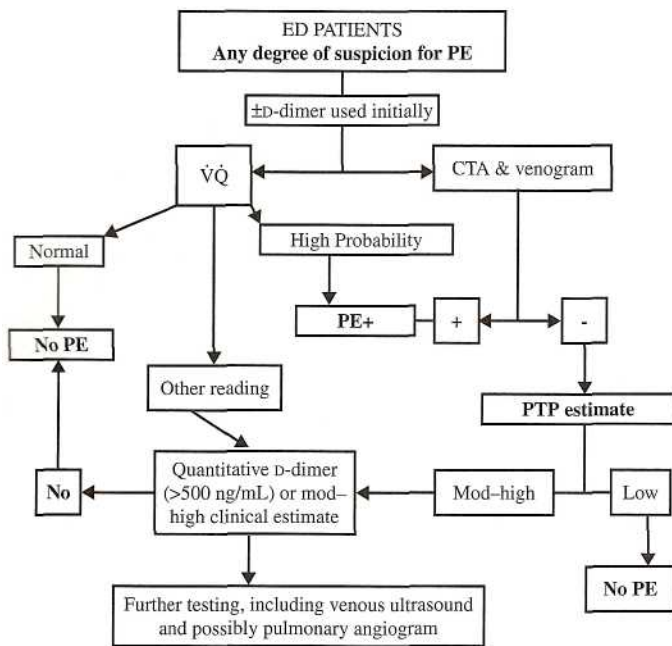

FIG. 56-1. Algorithm for evaluation of suspected PE. *Abbreviation:* CTA = computed tomographic angiogram.

thrombosis. The causes of nonmalignant thrombophilia, listed in descending order of frequency in the ED, include estrogen use, pregnancy, antiphospholipid antibody syndromes, and genomic mutations. The genomic mutations that cause inherited thrombophilia (including the factor V Leiden mutation, the prothrombin mutation, methylenetetrahydrofolate reductase gene mutation, factor VIII mutations, functional or antigenic protein C deficiency, or functional or antigenic protein S deficiency) have been the subject of recent reviews.²³ Emergency department patients can be subjected to immobility resulting in stasis for many reasons, including paralysis, debilitating diseases, or recent trauma. Emergency physicians should recognize that ED patients who are recently discharged after surgery maintain a high risk of PE; the thrombotic mechanisms of stasis and venous injury do not vanish when the postoperative patient leaves the hospital.

Although a remote prior history of PE may seem like a potent predictor of present PE, the importance of this factor is not as strong as

might be expected. If the patient had a clearly reversible factor (e.g., postoperative or postpartum status) at the time of diagnosis and has no thrombophilia, then he or she is at no greater statistical risk for PE than an age-matched patient who never had a PE.

Clinical Features

The clinical manifestations of PE result from cardiopulmonary stress caused by the clot in the lung. This stress produces the symptoms perceived by the patient and the signs observed by the physician. Shortness of breath is the most common symptom of PE, occurring in approximately 90 percent of patients with established diagnoses. The presence of unexplained dyspnea is sufficient to initiate a diagnostic evaluation. No one is certain of the exact mechanism of dyspnea from PE, but ventilation-perfusion mismatch is an important pathophysiologic cause. At the bedside, ventilation-perfusion mismatch is manifested as hypoxemia and tachypnea. The definitions of hypoxemia and tachypnea vary with age and comorbidity, but, as a rule of thumb, a pulse oximetry reading measuring less than 95 percent or an arterial partial pressure of oxygen less than 80 mm Hg should be considered preliminary evidence of relative hypoxemia (the arbitrary definition of hypoxemia is generally accepted as <60 mm Hg; see Chap. 62). A respiratory rate faster than 20 breaths/min should be considered tachypnea. Unfortunately, the degree of ventilation-perfusion mismatch with PE can be capricious, sometimes being severe with small PE and sometimes being mild with large PE. Also, because of changes in the location of the embolic material within the heart and pulmonary vasculature and reflexive adaptations of the pulmonary vasculature and bronchi, the degree of dyspnea and associated findings can change with time. In other words, **patients with PE can have intermittent shortness of breath.** Also, patients with PE often describe their shortness of breath as exertional, distracting the focus of some clinicians toward a search for cardiogenic dyspnea.

Chest pain represents the second most common symptom of cardiopulmonary stress in patients with PE. However, it must be cautioned that up to one third of patients have PE diagnosed on the basis of isolated dyspnea without any history of chest pain. Upon detailed questioning, others will relate only a vague sensation of chest discomfort. Still other patients with smaller clots, lodged in segmental or smaller pulmonary arteries, will point specifically to one extremely painful, localized area of the chest, usually at the periphery and pleuritic in nature. These patients often go on to develop radiographic evidence of lung parenchymal consolidation in the embolized segment of lung, suggesting the presence of hemorrhagic transformation of the ischemic tissue. With time, some patients with peripheral PE develop hemoptysis and, as such, are declared to have pulmonary infarction. Among all patients with PE, patients with infarction are the most likely with PE to develop fever. Patients with massive PE may complain of substernal or epigastric pain that appears to be associated with subendocardial ischemia in the right ventricle (RV). These patients often present in severe distress, with a systolic blood pressure less than 100 mm Hg or a heart rate that exceeds the systolic blood pressure measurement (i.e., a shock index measurement: heart rate/systolic blood pressure >1.0).

Cardiac arrest might be considered the most extreme form of cardiopulmonary stress and occurs in approximately 2 percent of patients with PE. Some clinicians assume that PE always causes pulseless electrical activity upon arrest secondary to complete pulmonary vascular obstruction. This hypothesis has been examined in some detail by using autopsy registries.⁴ These studies suggested that approximately 60 percent of patients who die from PE have pulseless electrical activity (rate >20 beats/min) as the initial arrest rhythm, but about one third have immediate asystole as the proximate cause of arrest. The mechanism of asystole with PE has been postulated as an end effect of inhibited cardiac automaticity from vagal impulses, coupled with infranodal conduction blockade that can occur with very high RV pressures.

TABLE 56-1 Classic Risk Factors for Thrombosis

Hypercoagulability
Malignancy
Nonmalignant thrombophilia
Pregnancy
Postpartum status (<4 wk)
Estrogen
Antiphospholipid antibodies
Genetic mutations
Factor V
Leiden mutation
Prothrombin mutation
Methylenetetrahydrofolate reductase gene mutation
Factor VIII mutations
Functional or antigenic protein C deficiency
Functional or antigenic protein S deficiency
Venous stasis
Bedrest >48 h
Cast or external fixator
Recent hospitalization
Long-distance automobile or air travel
Venous injury
Recent surgery requiring endotracheal intubation
Recent trauma requiring hospitalization (especially lower extremity, pelvis)

Fewer than 10 percent of patients with fatal PE experience ventricular tachycardia or ventricular fibrillation.

Some experts have referred to a spectrum of cardiopulmonary stress from PE, ranging from the peripheral clot causing focal pleuritic chest pain, to the relatively painless syndrome of the dyspneic embolism, to the more rare but devastating massive PE with acute cor pulmonale, to the fatal syndrome of pulseless electrical activity arrest.

Tachycardia represents a cardinal sign of cardiopulmonary stress from PE. As with many other aspects of PE, the etiology of the tachycardia remains obscure and probably results from a combination of factors, including baroreceptor unloading, release of chronotropic agents from the thrombus, and the secondary effects of ventilation-perfusion mismatch, including hypoxemia and perception of dyspnea that leads to anxiety. In most published studies, a heart rate faster than 100 beats/min is used to represent tachycardia. The absence of tachycardia alone does not exclude the presence of PE. About one half of all patients with diagnosed PE have a heart rate slower than 100 beats/min.⁵

Timing of symptom onset carries little prognostic significance in determining who requires an ED evaluation for PE. Similarly, the acuity of onset or lack thereof has no statistical predictive value for the diagnosis. When ED patients are systematically questioned as to their perception of the onset of the first symptom of PE, up to one fourth relate the onset of symptoms over 2 weeks before the date of diagnosis. It is corroborated by the finding that over one half of ED patients with PE have radiographic evidence of more than four clots in their lungs at the time of diagnosis.⁶ Autopsy results show that about one half of patients with fatal PE have multiple clots that exhibit pathologic features suggesting a wide range of ages.

More useful than timing and acuity of onset of symptoms to predict PE is the history of dyspnea, pleuritic chest pain, or findings of tachycardia, tachypnea, or hypoxemia with insufficient explanation.⁷ As one very specific example, the diagnosis of bronchitis does not adequately explain the combination of cough, chest pain, a respiratory rate of 22 breaths/min, a pulse rate of 102 beats/min, and pulse oximetry of 94 percent in a young patient with a clear chest radiograph. If an ED population appropriate for PE evaluation by competent emergency physicians is statistically analyzed, the factors that predict a final di-

agnosis of PE can be somewhat surprising (Table 56-2). For example, the presence of existing lung disease (smoking, asthma, or chronic obstructive pulmonary disease) clearly does not protect a patient from PE, but the presence of these diseases effectively lowers the probability of PE in ED patients selected for evaluation, apparently because patients who smoke or have asthma or chronic obstructive pulmonary disease are more likely to have some other pathologic process that shares the clinical features of PE.

Chest pain, tachypnea, and tachycardia are each frequently associated with PE. However, the presence of all three is not all that frequent but, when noted, is highly suggestive of PE, especially in the face of risks. The absence of all three, particularly without other supporting features, such as altered mental status, syncope, or seizure, are strong indicators that the diagnosis rests with another condition.

Pretest Probability Assessment for PE

Multiple factors must be considered simultaneously to arrive at a pretest probability for PE, i.e., the likely prevalence of PE that could be expected in a group of patients who are very similar to the patient at hand. The importance of the pretest probability for PE cannot be underestimated, inasmuch as its influence has a greater impact on the final decision of whether or not a PE is present than the choice of the laboratory or imaging test used to exclude it (Figure 56-2). The pretest probability guides the choice of diagnostic testing and helps determine when to terminate ancillary investigation. In practice, many clinical factors are used to arrive at a rough (empiric) assessment of pretest probability. The problems with empiric assessment include the fact that it requires *gestalt*. Clinicians often disagree about the empiric pretest probability of PE, and accuracy requires clinical experience.⁸ Unfortunately, empiric assessment of low-risk patients may not produce a low probability of PE. In a multicenter study in Europe, Sanson and colleagues found that clinicians using empiric pretest methods categorize only 14 percent of patients as low risk for PE, but the post-test occurrence of PE in this low-risk group was 19 percent.⁹ To help deal with the shortcomings of empiric assessment, researchers have resorted to the use of decision rules or score systems that incorporate symptoms, signs, and risk factors for PE into scores or algorithms to

TABLE 56-2 Factors That Help Distinguish the Presence or Absence of an Outcome Diagnosis of PE in Outpatients Selected for Evaluation for PE*

	Factors Associated with PE	Factors Associated with Absence of PE	Factors Contributing to the Decision to Evaluate for PE but Do Not Distinguish Presence or Absence of PE
Symptoms	Unexplained dyspnea, hemoptysis	Substernal chest pain, nonspecific dizziness	Pleuritic chest pain, syncope, nonproductive cough, anxiety
Signs	Unilateral leg swelling, heart rate >100 beats/min, hypoxemia (room air pulse oximetry <95% with no history of lung disease)	Wheezing, temperature >102°F, bilateral leg edema, pulse oximetry measured on room air consistently at 100%	Rales, temperature <102°F, respiratory distress, room air pulse oximetry reading of 95-99%
Risk factors	Age >50 y, recent surgery (requiring general anesthesia within past 4 wk), thrombophilia, adenocarcinoma (ovarian, pancreatic, prostate, and gastrointestinal) or brain cancer (especially glioblastoma multiforma), new-onset limb or body immobility >48 h	Age <30 y, COPD, asthma, smoking	Prior PE or DVT with a therapeutic INR and no thrombophilia, pregnancy, estrogen usage, lung or breast cancer, postpartum status, congestive heart failure, or recent travel

*No individual criterion should be used as evidence to not test for PE.

Abbreviations: COPD = chronic obstructive pulmonary disease; DVT = deep vein thrombosis; INR = international normalized ratio; PE = pulmonary embolism. **Source:** Kline JA, Nelson RD, Jackson RE, Courtney DM; Criteria for the safe use of D-dimer testing in emergency department patients with suspected pulmonary embolism: A multicenter United States study. *Ann Emerg Med* 39:144, 2002; Wells PS, Anderson DR, Rodger M, et al: Derivation of a simple clinical model to categorize patients' probability of pulmonary embolism: Increasing the model's utility with the SimpliRED D-dimer. *Thromb Haemost*, 83:416, 2000; and Wicki J, Perneger TV, Junod AE, et al: Assessing clinical probability of pulmonary embolism in the emergency ward: A simple score. *Arch Intern Med* 161:92, 2001.

FIG. 56-2. Plot of posttest probability as a function of pretest probability for three diagnostic tests for pulmonary embolism (PE), magnifying the area of the pretest and posttest probability ranges most relevant to screening for PE in the emergency department. The figure shows that the pretest probability can affect the posttest probability to an even greater extent than the diagnostic performance of the test used to exclude the disease. Points A, B, and C show that doubling the pretest probability has greater impact on posttest probability than does halving the likelihood ratio (LR) of a test that is negative for disease. The negative LR $[(1 - \text{sensitivity})/\text{specificity}]$ represents a composite measure of diagnostic test performance, and the numbers shown for D-dimer, computed tomography, and a low probability ventilation-perfusion lung scan are approximate. Point A shows that a patient with a pretest probability of 20 percent has a posttest probability of about 1 percent after a negative quantitative D-dimer assay. If a test with a negative LR that is twice as high is used on the same patient (point B), the posttest probability increases to only about 2 percent. However, if the pretest probability is doubled from B to C and the same diagnostic test is used, the posttest probability increases to 6 percent.

categorize individual patients into broad groups. Most systems group patients into these cohorts: low-risk (e.g., <10 percent probability), moderate-risk (11 to 60 percent probability), or high-risk (>60 percent probability).⁷⁻¹⁰ Others classify patients into high-risk and non-high-risk categories.⁵ The benefits and drawbacks to these rules have been reviewed elsewhere, and it is not the objective of this chapter to state which rule or system to use; rather, it is to inform the reader of their existence.

No evidence has been published to define the threshold at which the pretest probability reaches a level when a workup for PE should be initiated. Certainly, most experts would agree that all patients who have an empiric or decision rule-derived probability of PE of greater than 10 percent or more than low risk should undergo objective testing. However, it must be recognized that over one half of patients evaluated for PE in the ED are deemed low risk.^{7,10} The optimal choice of diagnostic testing remains in a state of flux. Several of the more common options are discussed, and each is considered in the context of the pretest probability.

ANCILLARY TESTING

Figure 56-2 illustrates the effect of pretest probability on the final outcome as to whether or not PE is present (posttest probability). The figure compares the effect of three tests with three levels of diagnostic performance and shows how pretest probability can cause a greater impact on posttest probability than even the performance of the diagnostic test, as assessed by its negative likelihood ratio.

The Criterion Standard

Studies of new tests for PE are usually compared against a "gold" reference or criterion standard that represents the best available method to diagnose or exclude the disease. For the past four decades, the gold standard has been selective pulmonary angiography with cineangiography to evaluate for the presence of a filling defect or arterial cutoff in the pulmonary vascular tree. When performed by an experienced specialist, pulmonary angiography is a safe procedure that can produce brilliant images with resolution of vessels as small as 3 to 4 mm in diameter. Pulmonary angiography also provides pulmonary arterial pressure data and can serve as the prelude to the use of catheter fragmentation to reduce the clot burden. However, pulmonary angiography itself is not perfect. Approximately 1 percent of patients at high risk are diagnosed with PE within a few months after a normal pulmonary arteriogram, although it is unclear whether the PE developed subsequent to the initial visit. Pulmonary angiography may not accurately diagnose very small (subsegmental) PEs owing to a high degree of variability across radiologists interpreting the examinations.¹¹

Autopsy is another excellent criterion standard, although it should be noted that most pathologists and medical examiners do not perform meticulous microdissection of the lung vasculature to look for small, diffuse PE that may be the cause of death. In recent years, the criterion standard used in published studies of PE has shifted away from requiring absolute proof of the presence or absence of PE and toward the use of outcomes. Researchers have argued that, if the patient feels well several months after having PE excluded, it makes no difference whether the patient had PE, because the patient did not need treatment. This concept evokes debate and remains unresolved.

Electrocardiography

The electrocardiogram is not a particularly discriminating tool in the clinical evaluation of patients with suspected PE. Sinus tachycardia is frequent but presents in many of the considerations in the differential diagnosis. A "normal" electrocardiogram does not have sufficient sensitivity to effectively exclude PE. Its greatest value may be in consideration of the presence of acute coronary syndromes and in determining whether pulmonary hypertension is present.

Arterial Blood Gases and Pulse Oximetry

Most patients with PE have an arterial partial pressure of oxygen (P_{aO_2}) less than 80 mm Hg when breathing room air, but up to 25 percent of patients with PE have a P_{aO_2} >80 mm Hg; a few will have P_{aO_2} greater than 95 mm Hg. Unless there is a concomitant respiratory acidosis (i.e., CO_2 retention), the A-a gradient will usually be widened. The overall sensitivity of an abnormal P_{aO_2} or A-a gradient is approximately 90 percent.¹² However, many diseases in the differential diagnosis on PE are also associated with hypoxemia, and so the specificity of the widened A-a gradient is approximately 15 percent, thus limiting its diagnostic utility. Arterial blood gases, however, may help in risk stratification of patients with PE, because P_{aO_2} appears to correlate with degree of pulmonary vascular occlusion from PE, and severe hypoxemia has been shown to predict poor outcome.¹³ Pulse oximetry of 100 percent tends to favor the absence of PE, although it does not exclude it.

D-Dimer Testing

It is important to understand the type of D-dimer assay that is used in the hospital laboratory (see Chap. 59). For example, the diagnostic sensitivity of qualitative D-dimers is approximately 80 to 85 percent (including the erythrocyte agglutination assays and latex agglutination assays), whereas the sensitivity of quantitative D-dimers (including enzyme-linked immunosorbent assays and turbidimetric assays) is

approximately 95 percent. Some facilities may not use the more rapidly available tests, thus reducing their value. Most published research has restricted the use of the D-dimer to patients with low pretest probability, although one recent study demonstrated excellent sensitivity (96 percent) and specificity, regardless of pretest probability.¹⁴

At least three factors contribute to the presence of PE in a low-risk patient with a normal D-dimer concentration. One is the formation of thrombus in the lung more than 72 h before the blood is assayed for the D-dimer and no new clot forming in that interval. The circulating half-life of the D-dimer is less than 8 h, and patients with symptoms from PE of at least 3 days are more likely to have normal D-dimer concentration.¹⁵ Another reason for the diagnosis of PE in a low-risk patient with a normal D-dimer is the presence of subsegmental PE.¹⁶ Moreover, some diagnoses of PE in the presence of normal D-dimer concentrations result from false-positive confirmatory testing. Extensive work by Wells and colleagues has documented the safety of using the combination of a low pretest probability plus a normal qualitative D-dimer (simpliRED) to exclude PE.⁷ Other investigators have suggested that the combination of a qualitative D-dimer plus a normal index of gas exchange, including a normal alveolar dead-space measurement or a normal calculated difference between arterial and alveolar partial pressures of oxygen, can exclude PE.¹⁷ It is my opinion that, in the presence of a low pretest probability (using published systems or empiric assessment from an experienced clinician), a patient with a quantitative D-dimer concentration below 500 (xg/L does not need to be anticoagulated.

Regardless of the test format or combination of factors used, the clinician must concede that any patient with a positive D-dimer must undergo further testing for PE. The D-dimer will be abnormally high in 75 percent of patients with normal pregnancy and more than 50 percent of patients with active malignancy, postpartum status within 1 week, surgery within the past week, or age older than 80 years. In general, any disease or process that causes increased fibrin deposition or decreased D-dimer clearance can elevate circulatory D-dimer concentration. These conditions include sepsis, hemorrhage, myocardial infarction, stroke, collagen vascular diseases, and liver impairment. Some clinicians argue that D-dimer determination is a waste of time in these patients.

Chest Radiographs

The literature is quite conflicting with regard to the value and findings of plain chest radiographs in ED patients with proven PE and suspected PE, because of patient selection bias. Many of the studies are restricted to inpatients with proven PE. **A normal chest x-ray may be present in fewer than 25 percent.** In the largest sample, cardiomegaly was the most frequent abnormality (27 percent) among those with PE, but most of the patients were inpatients. In the outpatient setting, basilar atelectasis carries the most discriminative value. Because of conflicting findings, the greatest value in plain film chest radiographs is in consideration of the differential diagnosis.

Ventilation-Perfusion Lung Scanning

At present, the ventilation-perfusion (V/Q) scan is a common modality used to image the lungs for PE. The reason it is still used stems primarily from the data afforded by the multicenter study sponsored by the National Institutes of Health, known as PLOPED.¹⁸ The PLOPED study performed V/Q scanning and pulmonary angiography in 755 patients, 30 percent of whom were enrolled from the ED or a clinic. The PLOPED study plus a massive body of published literature and widespread clinical use over the past three decades have established the normal V/Q scan as a strong technique to exclude the presence of PE. A *normal V/Q scan reading* refers to the homogeneous appearance of scintillation activity in the lungs after injection of a radiolabeled material into a peripheral vein, and is also referred to as a *normal perfusion lung scan* (although the scan does not measure lung blood flow or tissue perfusion). A V/Q scan can be read as normal in the absence of

a ventilation phase. A patient with a normal V/Q scan has such a low risk of PE that the disease can be effectively excluded, even in the presence of a high pretest probability. As a caveat, up to 4 percent of patients with normal V/Q scans and suspected PE have confirmed deep vein thrombosis (DVT).¹⁹ Conversely, a high probability reading (Figure 56-2), for all practical purposes, confirms the diagnosis of PE, although, in the presence of a low pretest probability, about one half of patients with a high probability V/Q scan have a pulmonary angiogram that is negative for PE.

In the ED, about one third of patients who undergo V/Q scanning have a normal reading and another 10 percent have a high-probability reading, leaving the majority of scans in a gray area, sometimes referred to as the *nondiagnostic category*. At many centers in the United States, this category is further broken down into low, moderate, and indeterminate categories (Table 56-3). There is no consensus regarding the lower limit of probability after which further pursuit of the diagnosis is no longer indicated. Each of these V/Q scan readings must be considered in the context of the patient's pretest probability.

Patients with a low (<10 percent) pretest probability and a low probability V/Q scan have an approximately 2 percent probability of PE, so many clinicians do not perform further testing with this combination. Patients with a greater than 10 percent pretest probability and a low probability V/Q scan or any patient with a moderate probability or indeterminate probability V/Q scan should undergo further testing. One published method is to order a quantitative D-dimer (if the test has not already been done) and use a level below 500 jJig/L as evidence to exclude PE.²⁰ Another option is to exclude the presence of a DVT in the legs by ordering a lower extremity ultrasound. However, if the leg ultrasound is negative for DVT, this finding only confers a marginal reduction in the probability of PE.²¹ Most authorities recommend that patients in this category receive a follow-up ultrasound in 3 to 7 days. If the follow-up ultrasound is negative, the added value of performing a third ultrasound is minimal. In the presence of a high pretest probability of PE (>60 percent) and any nondiagnostic V/Q scan, the patient should undergo another lung imaging test. At some centers, the next step is a formal pulmonary angiography. Other centers use contrast-enhanced helical computed tomography (CT) of the chest as the follow-up to a nondiagnostic V/Q scan. Ventilation-perfusion scanning is not possible in patients without peripheral venous access and among those who are unable to breathe in aerosolized labeled particles or hold still for imaging.

Computed Tomography

In the past decade, contrast-enhanced helical CT angiogram of the chest has become accepted in some centers as the diagnostic modality of choice for PE. As with many aspects of PE, the diagnostic value of CT angiogram remains controversial and varies from hospital to hospital. The emergency physician should be aware of several technical aspects of the CT angiogram. The CT angiogram requires an intra-

TABLE 56-3 Definition of V/Q Scan Probabilities

V/Q Scan Category	Definition
High probability (>80%)	Two or more large mismatched segments or the equivalent
Intermediate probability (20-79%)	One moderate to two large mismatched segments
Low probability (<20%)	Nonsegmental perfusion defects, matched defects
Normal	No perfusion defects

venous catheter, preferably 20 gauge or larger, into which approximately 150 mL of radio-opaque contrast is injected. Some radiologists are reluctant to administer contrast via a central line. This may be a concern for a 16-gauge Peripherally Inserted Central Catheter (PICC) line but not for a triple-lumen or 7.5-French or larger central line catheter. A timing run with a test dose of 10 mL of contrast would allow determination for the time frame of image acquisition and central line usage. Patients with massive obesity or congestive heart failure can be difficult to image, because the contrast may not opacify the pulmonary arterial tree well. The CT angiogram requires the patient to lie supine with the arms over the head and to breath-hold for about 5 to 10 s. The images are obtained in approximately 3-mm slices from the diaphragm to the apex of the lung. Some centers employ the so-called indirect venography phase by then obtaining 3-cm cuts from the popliteal fossae through the pelvis to image the leg and pelvic veins for DVT. The equipment used to collect and reconstruct the images remains a key issue in the diagnostic accuracy of the CT angiogram.

Although published studies indicate that radiologists' experience has little bearing on their ability to interpret CT angiography, my experience suggests otherwise. Many radiologists believe that the images should be interpreted on the computer screen rather than on the cut films. With the latest generation 16-head multichannel helical (or spiral) ultrafast CT machines (e.g., GE Light Speed QX/I), images can be reconstructed to produce resolution of approximately 2 mm, which is smaller than the purported level of resolution of the pulmonary angiogram. Publications report that radiologists interpret the CT angiogram as positive or negative for PE, although in practice at least 10 percent of scans are read as indeterminate owing to motion artifact or poor vascular opacification. In earlier studies, when the CT angiogram was compared with pulmonary angiography, the aggregated sensitivity of the CT angiogram was approximately 80 percent and the specificity was 85 percent.¹² The major source of false-negative interpretation was the presence of small PEs in subsegmental pulmonary arteries, which could not be imaged with earlier generation CT scans. To my knowledge, the results of CT angiogram have not been compared with autopsy findings. However, several studies demonstrate a 2 percent or lower rate of PE discovered on follow-up after negative CT angiography, although it is unclear if these occurred subsequent to the index study. However, Perrier and associates demonstrated that the rate of PE discovered on follow-up after a negative CT angiogram in ED patients with a positive D-dimer is less than 5 percent.²²

The sensitivity of the CT angiogram may be significantly improved with the addition of the indirect venography phase. In two U.S. EDs, Richman and colleagues demonstrated that the addition of the indirect venography phase to the imaging protocol detects DVT in the absence of a visible PE in 2 percent of all ED patients imaged.²³ Thus, if the presence of DVT in a patient with symptoms or signs of PE is considered tantamount to the diagnosis of PE (at least in terms of initiating treatment), the indirect venography phase confers an additional 17 percent sensitivity to CT angiography. At present, the authors of the original PIOPED study are completing the PIOPED II study to examine the diagnostic sensitivity and specificity of CT angiography (with indirect venography) for PE.

One of the great advantages of the CT angiogram for ED evaluation is its ability to provide information about the presence of other life-threatening thoracic processes. In one series of more than 1000 ED patients, 7 percent of scans had a non-PE finding that warranted immediate attention and another 10 percent required specific action of follow-up. In many cases, the alternative finding can explain the patient's symptoms.²⁴

Several issues influence the diagnostic accuracy of the CT angiogram (Table 56-4). I recommend using the CT angiogram as the procedure of choice if the systems issues and patient issues are favorable. The CT angiogram may also be the test of choice in patients with a chest radiograph that shows a parenchymal infiltrate, for the patient with known emphysema, or a prior nondiagnostic V/Q scan.

TABLE 56-4 Factors That Affect the Diagnostic Accuracy of Computed Tomography for PE

Systems issues that improve test accuracy

- The radiologist has adequate training and comfort in interpreting the images
- The hospital has a multichannel helical CT scanner
- The radiology technicians have a protocol in place to perform the contrast injection
- The indirect venography phase is employed

Individual patient issues that improve test accuracy

- The patient has adequate IV access and can tolerate 150 mL of contrast
- The patient can hold his or her breath and lie supine with the arms over the head
- The patient does not have massive obesity, congestive heart failure, or shock

Factors responsible for false-negative

interpretations

- Inadequate contrast opacification of the pulmonary vasculature
- Inadequate CT scanning equipment to image small vessels
- Failure to use reconstructed images
- Failure to use the indirect venography phase

Factors responsible for false-positive interpretations

- Motion artifact
- Interpretation of a filling defect observed in one image as positive for PE
- Interpreting a vein or bronchus as an artery with a filling defect
- Extrinsic vascular compression from neoplasm or adenopathy

Abbreviations: CT = computed tomography; PE = pulmonary embolism.

TREATMENT

The objectives in treating PE are to eliminate the clot burden and prevent recurrent thrombosis. In most cases, this can be safely accomplished with the combination of heparin (which by itself has little effect on clot burden already present) anticoagulation plus warfarin anticoagulation. Heparin offers several salutary effects. The most important immediate effect of heparin is the initiation of immediate thrombin inhibition, thus preventing thrombus extension. Although heparin has no intrinsic fibrinolytic capacity, by allowing unopposed action of plasmin, it does accelerate clot removal over 48 to 72 h. Heparin also affords a prominent antiplatelet effect, which helps prevent thrombus recurrence and reduces the elaboration of vasoconstrictive chemicals from platelets. Heparin also may inhibit inflammatory processes that contribute to vascular remodeling after PE. Heparin also helps to counteract the transient hypercoagulable state caused by a relative deficiency in protein C in the first days of warfarin therapy. Unfractionated or fractionated heparin will yield good results with a low incidence of serious hemorrhage. Table 56-5 shows the doses of heparin regimens approved by the U.S. Food and Drug Administration.

TABLE 56-5 Regimens Approved by the Food and Drug Administration for the Acute Treatment of Pulmonary Embolism

Drug	Dosage
Unfractionated heparin	80 units/kg bolus IV, then 18 units/kg per h to maintain partial thromboplastin time, INR = 2.5-3.0
Fractionated heparin	
Enoxaparin	1 mg/kg SC BID
Fibrinolytic therapy	
Streptokinase	250,000 units IV over 30 min followed by 100,000 units/h for 24 h
Urokinase	4400 units/kg IV over 10 min followed by 4000 units/kg per h for 12 h
Alteplase	15-mg IV bolus followed by 2-h infusion of 85 mg; discontinue heparin during infusion

Abbreviation: INR = international normalized ratio.

There are very few "absolute contraindications" to anticoagulation in a patient with diagnosed PE. Examples include a recent intraparenchymal brain hemorrhage and active gastrointestinal hemorrhage. Recent abdominal, orthopedic, or gynecologic surgery or even neurosurgery should not be considered absolute contraindications to heparin anticoagulation. Metastatic disease per se, including brain metastases, is also not a contraindication unless the lesions are hemorrhagic.

Emergency physicians have the ability to assess the risks of a patient with PE to decide when to treat with therapy more aggressive than heparin anticoagulation. Low arterial blood pressure offers a specific but nonsensitive indicator of the presence of severe PE. Even the authorities who are skeptical of the importance of fibrinolytic therapy believe that a patient with confirmed PE, a sustained systolic blood pressure less than 100 mm Hg, and no contraindications should be administered fibrinolytic therapy.²⁵ The contraindications to fibrinolysis are the same as those for acute myocardial infarction (see Chap. 51). The Food and Drug Administration has approved three fibrinolytic agents for treatment of PE: streptokinase, urokinase, and alteplase. The approved infusion protocol for alteplase is the same as for the treatment of myocardial infarction, and **heparin should be discontinued only while the fibrinolytic drug is being infused.** In the setting of PE with severe hypotension (systolic blood pressure <80 mm Hg), a bolus injection of alteplase may afford more rapid fibrinolysis with no increased risk of hemorrhage. Systemic infusion is adequate, as intrapulmonary infusion of fibrinolytic therapy does not appear to afford more rapid reduction in clot burden or improve outcome.

In patients with PE, sustained hypotension, and a contraindication to fibrinolytic therapy, the use of catheter fragmentation remains the best option to reduce clot burden at hospitals that have this capacity. In the hands of an experienced thoracic surgeon, surgical thrombectomy can be a lifesaving procedure for patients with large PE and hypotension (with or without a contraindication to thrombolytic therapy). One advantage of surgical thrombectomy is that the patient is placed on right atrial and left atrial or veno-arterial bypass, which effectively bypasses the obstructed pulmonary vasculature to ensure adequate perfusion of vital organs while the clot is removed from the pulmonary vasculature.

The decision-making process becomes more subtle in patients with PE and normal or nearly normal blood pressure. The major question remains as how to accurately and quickly recognize the patient with submassive, "nonhypotensive" PE that is going to cause trouble in the short term. Data are available from a convenience sample of 207 normotensive ED patients diagnosed with PE and treated with heparin at seven urban academic EDs in the United States from 1995 to 1999. An unexpected 4 percent of these initially "stable" patients with PE died within 24 h after diagnosis.

Of all risk-stratification modalities, the largest body of evidence has been published for the use of transthoracic echocardiography to visualize the presence of a dilated, hypokinetic RV as a marker of occult hemodynamic instability. Prospective studies²⁶ and large registries²⁷ have demonstrated that fewer than 10 percent of patients with PE and normal RV size and function die or develop respiratory failure or circulatory shock during hospitalization. However, the specificity of RV dilation or hypokinesis is about 40 percent, because many patients with RV dilation with PE have no in-hospital complications with heparin treatment. Clearly, the presence of RV dilation or hypokinesis indicates risk of a bad outcome, but whether this risk rises to a level that warrants the increased risk of serious bleeding that is associated with fibrinolytic therapy remains a source of research. I believe that RV dilation or hypokinesis should not be used in isolation as the sole reason to administer fibrinolytics. Moreover, a normal echocardiogram, an inadequate acoustic window, or unavailability of echocardiography should not be used to challenge the decision to administer fibrinolytic therapy to a patient with an otherwise overwhelming clinical picture of severe PE. Table 56-6 outlines other clinical factors that can be used to

TABLE 56-6 Factors That Can Help Prognose the Short-Term Outcome of Normotensive Patients with Pulmonary Embolism

Good Outcome Likely	Adverse Outcome More Likely
No syncope or seizure at presentation	Syncope or seizure with respiratory distress at presentation
Age <50 y	Age >70 y
Absence of COPD, CHF, or prior PE	Presence of COPD, CHF, or prior PE
<50% pulmonary vascular occlusion	>50% pulmonary vascular occlusion; floating thrombus in the RV or right atrium observed on echocardiography or CT angiography
Normal ECG	ECG with T-wave inversion in V ₁ –V ₄ and a new incomplete right bundle branch block
Heart rate/systolic blood pressure <0.8	Heart rate/systolic blood pressure >1.0
Pulse oximetry reading >94% breathing room air	Pulse oximetry reading <94% breathing room air
Troponin I concentration <0.4 µg/L	Troponin I concentration >1.0 µg/L
Normal RV function and size	RV dilation or hypokinesis, or an estimated RV systolic pressure >40 mm Hg

Abbreviations: CHF = congestive heart failure; COPD = chronic obstructive pulmonary disease; CT = computed tomography; ECG = electrocardiogram; PE = pulmonary embolism; RV = right ventricle.

prognose the severity of PE. Many of these factors are readily ascertained at the bedside. These factors can be used in conjunction with or instead of echocardiography (when the procedure is not available) to help decide when heparin treatment is not enough.

Recent work indicated that normotensive patients who were randomized to receive alteplase plus heparin were less likely to have a worsening clinical course than were patients who received heparin only.²⁸ The major drawback to this non-blinded study was that most patients treated with heparin only who were then crossed over to receive alteplase experienced clinical deterioration defined as worsening dyspnea or respiratory distress that did not require intubation. Whether this represents a clinically important or patient-oriented outcome remains uncertain. **To date, no study has shown a survival benefit with thrombolytic therapy for the treatment of PE.**

SPECIAL CIRCUMSTANCES

Recurrent Visits

Many patients who are diagnosed with PE return to the ED with complaints that are perceived as similar to those of the first episode. The first objective is to determine whether the patient exhibits signs of cardiopulmonary stress. If the electrocardiogram, heart rate, and pulse oximetry readings are of no concern and a plain film chest radiograph

is normal, the patient does not need to be treated empirically with heparin. The second objective is to determine whether the patient has a therapeutic prothrombin time.

Not every patient with an established diagnosis of PE who is therapeutic on warfarin necessarily needs to be imaged again. However, if the patient does not have a therapeutic prothrombin time (or admitted non-compliance) or has new symptoms or findings (tachycardia, new-onset hypoxemia, unilateral leg swelling, severe unexplained dyspnea, or hemoptysis), then pulmonary vascular imaging should be undertaken, even if the prothrombin time is therapeutic. An effort should be made to determine what imaging modality was used to diagnose the PE the first time and to order that same modality again. For patients with remote history of PE who are not currently being treated, the decision to embark on a diagnostic evaluation hinges on several points. History of PE without an underlying risk or a resolved risk is not associated with recurrence. The clinician is advised to look for other features, shown in Table 56-2, that suggest the presence of PE before testing. This can be an important point, because many patients with prior PE demonstrate abnormal V/Q scans and difficult-to-interpret CT angiograms.

Massive Obesity

Patients who weigh more than 190 kg (400 lb) may be too large to fit into some CT scanners or to image with V/Q scanning. Pulmonary angiography or magnetic resonance angiography are also usually not feasible. In most cases, venous ultrasonography can at best demonstrate poor images of the leg veins. One option is to look for alternative causes of disease and, when none is found and if the patient has no contraindications, to initiate empiric anticoagulation. A quantitative D-dimer assay may help in the decision to administer empiric anticoagulation. A D-dimer concentration less than 500 $\mu\text{g/L}$ can be used as evidence to withhold anticoagulation, whereas a D-dimer concentration greater than 2000 $\mu\text{g/L}$ can be used as evidence of thrombosis when PE is suspected and imaging is impossible. No evidence has been published to support this recommendation, and no study has determined the correct dose of enoxaparin to administer to massively obese patients, but some authorities recommend a ceiling dose of 250 mg per d.

Pregnancy

The ED physician who orders an imaging test on a pregnant patient should be certain to involve the patient, the obstetrician, and the radiologist in the decision-making process. Many centers employ half-dose injection of radioactive material to perform a perfusion lung scan. Filling the bladder with fluid using a urinary drainage catheter and intravenous hydration may help reduce fetal exposure to ionizing radiation. If the perfusion scan is homogeneous, no further testing is necessary. Alternatively, a CT angiogram without indirect venography can be performed and the uterus shielded during image acquisition, which may induce less fetal radiation than V/Q scanning. A D-dimer concentration can be ordered to help select which pregnant patient needs imaging, but the D-dimer is almost always elevated with normal pregnancy. Published studies have indicated that the upper limit of a normal D-dimer increases with each trimester of pregnancy but should not exceed 1000 $\mu\text{g/L}$ at any time.²⁹

Another approach is to order Doppler ultrasound of the lower extremities, because this is noninvasive and carries no ionizing radiation risk. If DVT is present, then treatment decisions are the same as those for PE. The risk of this approach is the potential to terminate the further pursuit of the diagnosis simply because the ultrasound was negative.

When to Start Heparin Before Imaging

This question frequently arises. Studies that have measured perfusion defect and pulmonary vascular resistance have indicated that heparin confers little reduction in clot burden during the first 6 h. Whether any

observed reduction would occur with time alone remains unknown. However, imaging can take 3 to 4 h to complete, and in vitro studies have shown that clot volume can grow up to 50 percent in this interval. Thus, in the absence of a contraindication and **with a pretest probability that exceeds 50 percent, empiric heparin should be administered.** I believe that all hypotensive patients and all normotensive patients with hypoxemia (pulse oximetry reading <95 percent breathing room air) or tachycardia out of proportion to the systolic blood pressure (i.e., a shock index of heart rate/systolic blood pressure >1.0) should receive heparin before imaging.

When to Draw Blood for Hypercoagulability Workup

Measurement of protein C, antithrombin III, or protein S before heparin therapy can be helpful for the diagnosis of a hypercoagulable state. Extra tubes can be drawn for these analyses. The most important factors to measure are the common genomic mutations factor V Leiden and the prothrombin mutation G20210A (assayed by polymerase chain reaction, which is unaffected by heparin or the presence of thrombosis); the antiphospholipid antibodies, including anticardiolipin antibodies (immunoglobulins M, G, and A); and lupus anticoagulant levels. The latter two protein classes can be spuriously elevated in the presence of thrombosis. Similarly, the antigenic and functional levels of proteins C and S and antithrombin can be spuriously decreased with thrombosis. Accordingly, any declaration of excess or deficiency of these proteins should be based on measurements made during follow-up, when radiographic evidence has confirmed the dissolution of clot in the lungs and legs.

Septic Emboli

The approach to septic emboli is somewhat different (see Chap. 145). The mainstay of treatment is early administration of antibiotics. If based on ultrasound, valvular vegetation is huge, or there is significant valvular damage, immediate anticoagulation seems warranted.

Witnessed Cardiac Arrest

Occasionally, the patient with known PE or who is in transit to or from an imaging procedure for PE sustains cardiac arrest that is managed by the ED. The primary treatment for cardiac arrest for PE is cardiopulmonary resuscitation and standard advanced cardiac life support (ACLS) procedures. If no pulse returns within a few minutes, the next step is to bolus inject 100 mg of alteplase or an equivalent dose of fibrinolytic therapy while cardiopulmonary resuscitation is continued for at least 20 min. If the pulse returns in a young patient who has had an imaging procedure to identify the location of the thrombus in the pulmonary vasculature, the next step is to contact a thoracic surgeon to arrange for surgical thrombectomy. Prior administration of fibrinolytic therapy should not be considered a contraindication to surgery after cardiac arrest.

HYPERTENSION

Melissa M. Wu Arjun
Chanmugam

Hypertension is considered one of the most important modifiable risk factors for cardiovascular disease and is the fourth most prevalent chronic medical condition in the United States.¹ Up to 24 percent of the United States general adult population and 32 percent of African Americans may be affected.²

Overall morbidity and mortality rates, and in particular the risk of developing serious cardiovascular, renal, or cerebrovascular disease, increase with poorly controlled blood pressure. Although the public has become more knowledgeable, only two-thirds of Americans with high blood pressure are aware of their diagnosis. Of greater concern is that nearly 75 percent of adult Americans with hypertension are not controlling their blood pressure to below 140/90 mm Hg, and only half are taking their prescription medications as directed.^{1,2} In addition, there are a significant number of patients who are under the care of a physician, but either have undiagnosed hypertension or hypertension that is uncontrolled.

Poorly controlled hypertension may become an increasingly common problem in the United States as the demographic makeup of the country changes. The pattern of elevation in systolic blood pressure (SBP) with diastolic blood pressure (DBP) <90 mm Hg predominates not only in the elderly, but also in the middle aged. The lack of control is not confined to the poor, uninsured, or minorities.

The primary responsibilities of emergency physicians in the approach to hypertensive patients are to recognize and treat true emergencies, to manage the complications of chronic disease, and to arrange the most appropriate follow-up for nonemergent cases.

CLASSIFICATION

The Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure developed a consensus definition of hypertension, which includes a graded classification dependent on risk factors and clinical condition (Table 57-1).¹ In general, either a SBP greater than 140 mm Hg or a DBP greater than 90 mm Hg constitutes hypertension. However, management of hypertension depends more on the individual's clinical condition rather than the absolute systolic or diastolic values. The ED approach is based on four general categories.

Hypertensive Emergency

Hypertensive emergencies, the most serious of these, occur in about 1 percent of all hypertensive patients. *Malignant hypertension* or *hypertensive crisis* have also been used to refer to this category. Target-

TABLE 57-1 Classification of Blood Pressure for Adults Aged 18 Years and Older

Category	Systolic Blood Pressure (mm Hg)	Diastolic Blood Pressure (mm Hg)
Optimal	<120	<80
Normal	<130	<85
High-normal	130-139	85-89
Hypertension		
Stage 1	140-159	90-99
Stage 2	160-179	100-109
Stage 3	≥180	≥110

Note: When systolic and diastolic pressures fall into different categories, the higher category should be used to classify the individual's blood pressure status.
Source: From JNC,¹ with permission.

organ damage is evident when conditions such as hypertensive encephalopathy (see below), intracranial hemorrhage, acute left ventricular failure with pulmonary edema, unstable angina pectoris, acute myocardial infarction, dissecting aortic aneurysm, (worsening) renal failure, and eclampsia exist.¹ A hypertensive emergency is not defined by any absolute pressure measurements. Instead, it is contingent on the presence of relative blood pressure increases combined with evidence of injury to any of the so-called target organs. In fact, a patient with a low baseline pressure can present with "normal" or mildly elevated pressure and be considered to have a true hypertensive emergency, if there is evidence of concurrent related central nervous system (CNS), cardiovascular, or renal dysfunction.

Hypertensive Urgency

Hypertensive urgency is less clearly defined. Most sources concur that hypertensive urgency represents a risk for imminent target-organ damage, although acute organ injury has not yet occurred. In many cases of hypertensive urgency, the presence of preexisting conditions (e.g., renal insufficiency, congestive heart failure, coronary artery disease, CNS disorders, or retinal changes) increases the likelihood of target-organ damage. Again, relative increases in blood pressure are more important than absolute values.

The main challenge for the clinician is differentiating asymptomatic hypertension from a hypertensive urgency. If target-organ dysfunction is not evident, the clinician must judge whether significant risk of such damage is impending without timely intervention. Unfortunately, no evidence-based data exist to guide the practitioner in this regard. If target-organ dysfunction is shown, it must be determined whether this represents chronic disease or an acute deterioration or process. If the latter is the case, then a hypertensive emergency exists. This may be difficult without knowledge of the patient's past medical history, including prior laboratory values and clinical findings. In many cases, the clinician may be obligated to initiate antihypertensive treatment without being certain of the diagnostic classification.

Acute Hypertensive Episode

Acute hypertensive (nonemergency/nonurgency) episode occurs when a patient is found to have stage 3 hypertension (see Table 57-1; systolic pressure of 180 mm Hg or more, and diastolic pressure of 110 mm Hg or more) with no signs or symptoms of evolving or impending target-organ damage.¹ Although many of these patients receive treatment in an effort to prevent target-organ damage, there is some controversy regarding the need for immediate treatment (see below).

Transient Hypertension

Transient hypertension occurs in association with other conditions such as anxiety, alcohol-withdrawal syndromes, sudden cessation of medications, and some toxicologic substances. Treatment is aimed at the underlying cause. One specific type of transient hypertension is "white-coat hypertension,"² a phenomenon that occurs when a patient has an elevated blood pressure in a clinical setting but has a normal pressure at other times. Such patients are normotensive when followed over a 24-h period with ambulatory blood pressure monitoring. A number of studies have shown that at least 20 percent of newly diagnosed hypertensive individuals are actually normotensive in their regular environment.⁴ The cardiovascular morbidity and mortality rates of individuals with white-coat hypertension correlate with their ambulatory blood pressure. Therefore, a single encounter in the ED setting should not be the basis for diagnosis of new-onset hypertension, nor does it constitute an indication to initiate antihypertensive therapy. However, patients do require prompt and close follow-up care for repeat blood pressure testing.

PATHOPHYSIOLOGY

Systemic blood pressure is related to vascular smooth muscle tone. At the cellular level, postsynaptic α_1 and α_2 receptors are stimulated by norepinephrine released from the presynaptic sympathetic nerve ending, ultimately leading to the release of intracellular calcium stores. Calcium release results in smooth muscle contraction via activation of actin and myosin. The increase in smooth muscle tone results in increased peripheral vascular resistance, thereby causing increased blood pressure. When stimulated by norepinephrine, the presynaptic α_2 receptors help to limit this response by preventing further release of norepinephrine through a negative-feedback loop.

There are two major theories to explain how hypertension develops: (1) as a result of alterations in the contractile properties of smooth muscle in arterial walls, and (2) as a response to failure of normal autoregulatory mechanisms. Most individuals with hypertension have elevated peripheral vascular resistance with normal cardiac output. However, some patients may also have elevated cardiac output as a result of increased α -adrenergic and (3)-adrenergic tone.

The concept of autoregulation is important in the vascular beds of the vital organs, including the heart, kidneys, and brain, but has been most extensively studied in the latter.⁵ In the brain, as blood pressure falls, cerebral vasodilation occurs. When blood pressure rises, the autoregulatory response is vasoconstriction, ensuring a stable cerebral blood flow rate across a range of blood pressures. However, autoregulation is effective only within a specific range of blood pressures. Most authorities specify a range of 50 to 150 mm Hg for MAP, within which there is effective autoregulation in the uninjured brain. At pressures beyond this narrow range, the limits of autoregulation are breached, and hypoperfusion or hyperperfusion results. In patients with chronically elevated blood pressure, the narrow range at which autoregulation functions is shifted higher. Thus chronically hypertensive patients can develop symptoms of brain hypoperfusion if their blood pressure is lowered to "normal" levels, because normal levels may be below the limits of the individual's adjusted autoregulation. The lower limit of cerebral autoregulation is generally about 25 percent below a patient's baseline MAP.⁵

When poorly controlled blood pressure is allowed to persist over time, it can cause damage to specific organs and vascular beds. The pathologic change responsible for target-organ damage is fibrinoid necrosis of small arterioles. This process begins when vessels in capillary beds dilate in response to an elevated blood pressure that overwhelms the autoregulatory mechanism. The persistently elevated pressures cause injury to the endothelium, leading to increased vascular permeability and vascular wall injury. Eventually, endothelial damage leads to deposition of fibrin within the vessel walls and causes activation of mediators of coagulation and cell proliferation. A recurrent cycle of vascular reactivity develops, with an increased release of vasoconstrictors, endothelial damage, platelet aggregation, myointimal proliferation, and progressive narrowing of arterioles.

A directly observable example of the vascular changes is *hypertensive retinopathy*. Hypertensive retinopathy is traditionally graded into four categories. In grade I, there is minimal diffuse or focal narrowing of arterioles. In grade II, "copper" and "silver" wiring (increased light reflex) is seen. These are considered relatively mild target-organ effects. In grade III and IV retinopathy, cotton-wool spots (focal ischemia), hard exudates and hemorrhages (vessel leakage), and extensive microvascular changes are seen. Grade IV retinopathy is distinguished by disk edema and in the past has been used to define malignant hypertension or hypertensive crisis. (The term *papilledema* is frequently used, but the disk edema is due to infarction and hypoxia of the optic disk. Thus the term *papilledema* is best reserved for disk edema associated with elevated cerebrospinal fluid pressure.) Grade I and grade II retinopathy are evidence of chronic hypertension. Grades III and IV are evidence of accelerated retinopathy, particularly in the young. Also grade III and IV changes might not be seen in the

elderly. The mechanism of underlying pathology—arteriolar spasm—ultimately leads to degeneration of the muscle of the blood vessel, with subsequent degeneration of the endothelial cells of the vessel lumen. The elderly, who are likely to have arteriosclerotic vessels, are paradoxically protected by the presence of this other underlying pathology.

In the brain, an abrupt, sustained rise in blood pressure exceeding the limits of cerebral autoregulation may be associated with stroke, intracerebral hemorrhage, or hypertensive encephalopathy.⁵ Vascular injury caused by an abrupt or persistent elevation in blood pressure may result in ischemia or infarction in vulnerable regions of the brain. Intracerebral bleeding from dilated vessels may result in cerebral or subarachnoid hemorrhage. Hypertensive encephalopathy is characterized by marked vasospasm with ischemia, punctate hemorrhages, and increased vascular permeability, all leading to cerebral edema (a mechanism similar to retinopathy). This mechanism is different from localized cerebral edema in the area of ischemic stroke caused by emboli or thrombi. An increase in blood pressure may be a physiologic response to maintain adequate cerebral perfusion to areas distal to the occlusion and may not justify classification as a hypertensive emergency. Some researchers are even examining the benefit of induced hypertension as a potential treatment of acute stroke.

In the heart, increased afterload occurring after an acute rise in blood pressure results in increased left ventricular wall tension, that in turn increases myocardial oxygen demand. Angina or myocardial infarction occurs when hypertension causes a decrease in coronary blood flow relative to an increased demand. Pulmonary edema occurs when the sudden increase in MAP precipitates acute left ventricular failure, resulting in elevated end-diastolic pressure and filling volume.

In the kidneys, impaired autoregulation due to elevated blood pressure results in decreased renal perfusion. Decreased renal perfusion stimulates the renin-angiotensin (I and II) cascade, ultimately leading to increased vasoconstriction. If this cycle continues, arteriolar necrosis occurs, ultimately leading to renal impairment. Angiotensin II can exacerbate hypertension not only by causing vasoconstriction, but also by promoting sodium retention via direct stimulation of the proximal tubule and by secretion of aldosterone. Sodium retention induces hypertension in susceptible individuals by a variety of mechanisms, including (1) increased sympathetic nervous system activity; (2) decreased response to dopamine; (3) change in calcium and potassium metabolism; (4) resistance to insulin; and (5) inappropriate response of renal vasculature and adrenals to angiotensin II.⁶

Hypertension is associated with major cardiovascular risk factors such as smoking, hyperlipidemia, diabetes mellitus, age older than 60 years, gender (men and postmenopausal women), obesity, and a family history of cardiovascular disease.¹ In addition, dietary sodium excess in salt-sensitive individuals (50 percent of hypertensive patients) can induce hypertension. Although no single cause of hypertension has been identified, a combination of factors such as these are believed to contribute to elevated blood pressure.

Although most cases of hypertension are considered to be essential (i.e., hypertension with no known cause), several specific causes do exist. Of the known causes, renal disease is the most prevalent and includes renal arteriostenosis, fibromuscular disease of the renal arteries, chronic pyelonephritis, and nonspecific glomerulonephritis. Coarctation of the aorta, although uncommon, is also an important cause of secondary hypertension and should be suspected in any patient with the triad of upper extremity hypertension, a systolic murmur best heard over the back, and delayed femoral pulses. Another cause of hypertension is excessive glucocorticoids, seen in Cushing syndrome, but usually due to exogenous steroid therapy. Endogenous overproduction is less common but results from excessive adrenocorticotrophic hormone (ACTH) production by a pituitary tumor, ectopic ACTH production by a nonpituitary tumor, or glucocorticoid production by tumors of the adrenal cortex.

Pheochromocytomas are tumors that produce catecholamines, as they arise from cells of the sympathetic nervous system (most commonly from the adrenal medulla) and account for fewer than 1 percent of cases of hypertension. The characteristic features of pheochromocytomas are paroxysms of hypertension associated with palpitation, tachycardia, malaise, apprehension, and sweating. Finally, ingestion of foods containing large amounts of tyramine can raise blood pressure by causing release of norepinephrine stored in nerve endings. This normally transient response may become prolonged in patients taking monoamine oxidase (MAO) inhibitors, since these agents block the enzyme that destroys tyramine.

CLINICAL EVALUATION

Overview

The clinical evaluation of hypertensive patients is aimed at determining the underlying reason for the hypertensive episode and ascertaining the effects on end organs. Management is directed by this assessment. Although patients with hypertension present to the ED relatively frequently, the number of individuals who actually require emergent intervention is small.⁷ ED management should begin with an accurate blood pressure measurement, confirmed by **repeat assessment in both arms if the initial value is elevated**. The challenge is to determine whether the presenting blood pressure reading is only a transient circumstantial elevation or is representative of the patient's baseline. The approach to hypertensive patients in the ED is summarized in the algorithm shown in Figure 57-1. Traditional teaching has been that pressure differences between arms >10 mm Hg is abnormal. Recent data indicates that almost 20 percent of hypertensive ED patients may have differences >10 mm Hg between the two arms, without evident pathology.⁸

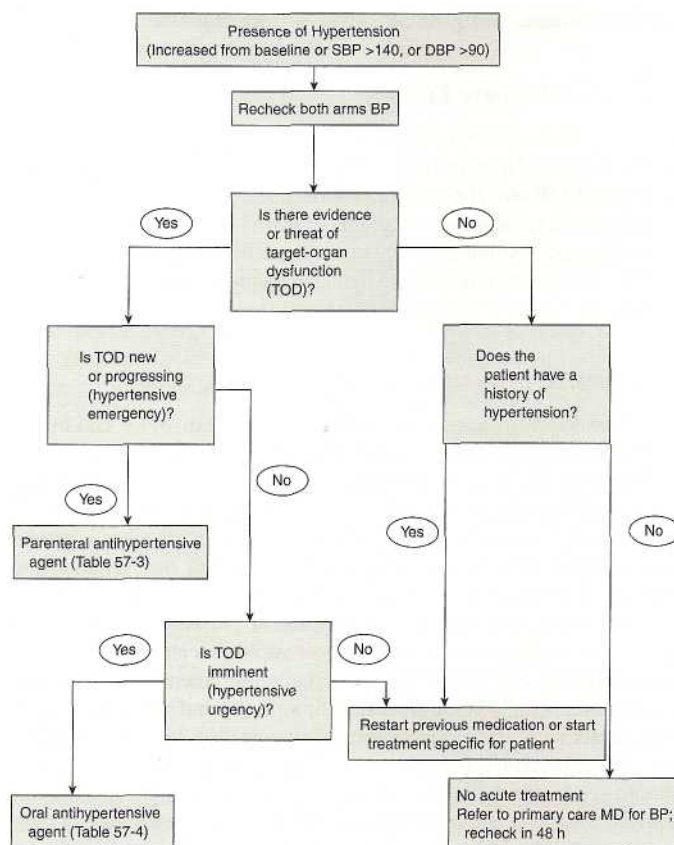

FIG. 57-1. Algorithm for approach to hypertensive patients.

Medical History

Any prior diagnosis of hypertension, including treatment regimens, compliance patterns, and baseline recordings of past blood pressures, are important to ascertain. Elevated blood pressure in the context of several months of noncompliance with antihypertensive medications likely represents a patient's baseline, whereas hypertension after several days of noncompliance could be a more serious abrupt cessation syndrome. A history of all medication use, including over-the-counter and illicit drugs, should be obtained, since many commonly used agents—including cocaine, amphetamines, decongestants, stimulants, oral contraceptives, and nonsteroidal anti-inflammatory drugs (NSAIDs)—may elevate blood pressure. MAO inhibitors in combination with tyramine-containing foods (e.g., beer and aged cheese) or certain drugs (e.g., amphetamines and tricyclic antidepressants) can also precipitate acute blood pressure elevation. Any past medical history of cardiovascular, cerebrovascular, or renal disease; diabetes; hyperlipidemia; chronic obstructive pulmonary disease (COPD); asthma; or gout; or a family history of hypertension or premature heart disease should also be elicited.¹ Patients with elevated pressures should be asked specifically about CNS symptoms (e.g., headache, diplopia, blurred vision, confusion, hemiparesis, and seizures), cardiac symptoms (e.g., chest pain, dyspnea, and palpitations), and renal symptoms (e.g., hematuria and anuria) that may be indicative of progressive end-organ damage.¹

Physical Examination

The blood pressure should be measured with a cuff of the appropriate size for the patient. The width of the inflatable portion of the cuff should be about 40 percent of the circumference of the limb and the length of the inflatable portion should equal 80 percent of the limb's circumference. Using a cuff that is too short, too narrow, or too loose may cause falsely high readings. The blood pressure should be measured at least twice if the first value is elevated (SBP of more than 140 mm Hg or DBP of more than 90 mm Hg). For severe elevation, measure pressure in both arms and legs, and palpate pulses in all extremities. In adults, a differential in brachial systolic pressures of more than 20 mm Hg may suggest the presence of aortic coarctation, aneurysm, or dissection.

Focus the physical examination on the detection of target-organ damage and determine the acuity. Neurologic examinations that reveal focal findings or mental status changes may indicate hypertensive encephalopathy, subarachnoid hemorrhage, or stroke. A careful funduscopic examination may reveal acute changes such as hemorrhages, cotton-wool exudates, or disk or retinal edema (grade III or IV retinopathy). Alternatively, grade II retinopathy suggests chronic uncontrolled hypertension. Hyperreflexia with peripheral edema in a pregnant woman is suggestive of preeclampsia. This physical finding may also be found in elderly patients with multiple small ischemic strokes (cerebral lacunae).

On cardiovascular examination, auscultate for carotid bruits, right or left sided murmurs, third and fourth heart sounds (S₃ and S₄), and a pericardial rub. An S₃ occurs in association with ventricular failure, whereas an S₄ occurs when there is left ventricular hypertrophy and a noncompliant left ventricle. Left-sided congestive heart failure is associated with unexplained tachycardia as an early finding and pulmonary rales as a late finding. Diminished extremity pulses may be found in patients with coarctation of the aorta or aortic dissection. Signs of aortic insufficiency should be sought (see Chap. 58). The abdomen should be examined for a bruit and a palpable pulsatile mass that may indicate the presence of an abdominal aortic aneurysm.¹

Diagnostic Studies

Blood urea nitrogen (BUN), creatinine, electrolyte, and glucose levels should be determined, and complete blood count (CBC), an electro-

cardiogram (ECG), urinalysis, and chest radiograph should be obtained in cases of suspected hypertensive emergencies to look for evidence of target-organ damage.¹ Renal impairment may present as hematuria, proteinuria, or elevations in BUN, creatinine, and potassium levels. Red cell casts suggest glomerulonephritis. The blood glucose level is important because hypoglycemia may simulate hypertensive encephalopathy or stroke. The CBC may reveal microangiopathic hemolytic anemia that may occur as a result of vascular damage after an acute, severe rise in blood pressure. The ECG should be compared with previous tracings. ST-T wave changes may be evidence of ischemia, electrolyte abnormalities, or left ventricular hypertrophy. The chest radiograph may be helpful in showing evidence of left-sided congestive heart failure or aortic dissection. In patients with neurologic symptoms, computed tomography (CT) of the head should be performed to look for evidence of stroke or hemorrhage.

TYPES OF HYPERTENSIVE EMERGENCIES

Hypertensive Encephalopathy

Although no specific blood pressure is pathognomonic, the elevated pressure exceeds the limits of cerebral autoregulation of the low-resistance arteries, resulting in cerebral hyperperfusion with loss of integrity of the blood-brain barrier. In most cases, autoregulation usually cannot accommodate a constant cerebral blood flow above a MAP of 150 to 160 mmHg.

Hypertensive encephalopathy is usually acute in onset and reversible. It is characterized by severe headaches and nausea and vomiting, and may also include altered mental status. Neurologic symptoms can range from confusion and drowsiness to seizures, decreased visual acuity, focal deficits, or even coma. Since the pathologic mechanisms are the same, accelerated hypertensive retinopathy is often seen. The differential diagnosis is diverse and includes intracranial hemorrhage, stroke, meningoencephalitis, brain tumors, toxidromes, and metabolic coma. If hypertensive encephalopathy is suspected, antihypertensive therapy should be initiated while awaiting the results of certain key studies such as serum chemistry tests and CT scan.

Hypertensive encephalopathy is a true medical emergency, and if left untreated, can progress over hours and lead to coma and death. Treatment involves close cardiac monitoring, supplemental oxygen, intravenous access, and arterial monitoring. Immediate reduction of blood pressure by 20 to 25 percent will help reverse the vasospasm that occurs at these pressures; however, excessive reduction in blood pressure must be avoided in order to prevent hypoperfusion and further cerebral ischemia.⁸ The medication of choice is sodium nitroprusside infused at an initial dose of 0.3 (Jig/kg per min and titrated up to a maximum of 10 (ig/kg per min. Intravenous nitroglycerin and labetalol have been successfully used, but they have not replaced nitroprusside as first-line therapy for hypertensive encephalopathy.

Stroke Syndromes (see Chap. 228)

Elevated blood pressure is commonly associated with stroke syndromes and is often the result of a physiologic response to the stroke itself (to maintain adequate cerebral perfusion to the viable but edematous tissue surrounding the ischemic area) and not its immediate cause. In the area of the stroke, cerebral autoregulation is lost, causing tissue blood flow to become directly pressure-dependent. Most patients suffering from embolic or thrombotic strokes without associated hemorrhage do not have substantial elevations in blood pressure and do not need aggressive antihypertensive treatment. Furthermore, if the patient has a longstanding history of hypertension, any rapid reduction in blood pressure may further reduce cerebral blood flow to watershed areas and cause increased ischemia.⁹ In the rare case of a stroke

patient with extreme blood pressure elevation or sustained diastolic pressure greater than 140 mm Hg, the blood pressure may be reduced in a controlled manner by no more than 20 percent with intravenous labetalol in small doses beginning with 5-mg increments.

In contrast to the relatively minor blood pressure elevations seen with most strokes, intracranial hemorrhage commonly results in profound reactive rise in blood pressure. Causes of intracranial hemorrhage include hypertensive vascular disease, arteriovenous anomalies, arterial aneurysms, bleeding associated with tumors, and trauma. Hypertension associated with hemorrhagic stroke is usually transitory and the result of increased intracranial pressure and irritation of the autonomic nervous system. The acute management of blood pressure associated with intracranial hemorrhage is controversial. In the case of subarachnoid hemorrhage, oral nimodipine (60 mg every 4 h) has been used to reverse the vasospasm associated with subarachnoid blood. Intravenous nicardipine (2-mg boluses followed by a 4- to 15-mg per h infusion) is also now used by some for the management of hypertension during this type of hemorrhage.

Acute Pulmonary Edema

The hypertension associated with acute pulmonary edema is usually a result of increased peripheral vascular resistance caused by elevated catecholamines. In some cases, pulmonary edema occurs because an abrupt rise in blood pressure precipitates acute left ventricular failure. The blood pressure must be lowered to reverse this process, and nitroprusside and intravenous nitroglycerin are the agents of choice, although the latter does not reduce blood pressure as much as nitroprusside. Additional standard therapy for pulmonary edema includes nitrates (to reduce preload and afterload), oxygen, diuretics, and morphine sulfate (see Chap. 53).

Acute Coronary Syndromes

Increased left ventricular end-diastolic pressure increases the workload of the heart. Wall tension is one of the greatest determinants of myocardial oxygen demand. Increases in oxygen requirements secondary to hypertension may result in angina. Myocardial infarction may also develop, particularly among those with fixed lesions in coronary arteries, preventing appropriate delivery of required oxygen. The use of agents that increase myocardial oxygen demand, such as diazoxide, hydralazine, and minoxidil, should be avoided.

In cases of hypertension and angina, immediate blood pressure reduction is indicated to prevent myocardial damage, and therapy should be initiated with nitroglycerin, either sublingually or parenterally. For a greater degree of pressure reduction, sodium nitroprusside may be started.

Aortic Dissection (see Chap. 58)

Because aortic dissection is associated with hypertension in about 90 percent of cases, medical therapy aimed at reducing blood pressure can limit the extent of the dissection. Pathophysiology of aortic dissection is discussed in Chap. 58.

The initial medical therapy for a suspected dissection is aimed at reduction of the ventricular ejection force (rate of change in pressure with time, dp/dt) of the heart. The treatment of choice includes either a combination of a (3-adrenergic antagonist (such as esmolol) and sodium nitroprusside, or labetalol alone. Emergency surgical consultation should be obtained for all suspected aortic dissections, although dissections involving the descending aorta are often medically managed. Surgical intervention is indicated in dissections involving the ascending aorta or aortic arch and in cases in which pain and blood pressure cannot be adequately controlled.

Renal Failure

Blood pressure and renal function are intrinsically related. Hypertension may cause acute renal failure or exacerbate chronic renal failure whereas renal disease may result in hypertension. In patients with renal disease, the control of hypertension can delay the progression of further injury. Worsening renal function in the setting of elevated pressure, with elevation of BUN and creatinine levels, proteinuria, or the presence of red cells and red cell casts in the urine, is considered a hypertensive emergency that requires immediate reduction of blood pressure. Nitroprusside is the preferred agent in these cases. Patients who have known renal failure, are dialysis-dependent, and have volume overload may require emergent dialysis if they present with uncontrolled hypertension with other evidence of end-organ dysfunction.

Preeclampsia and Eclampsia

These are discussed in Chap. 106.

Epistaxis

The association between hypertension and epistaxis remains controversial.¹⁰ A definite conclusion of epistaxis as a manifestation of end organ dysfunction due to arterial hypertension has not been made. However, studies have confirmed that those patients with active epistaxis presenting to an ED have a greater chance of having increased blood pressure.¹¹ Some authors have suggested that the presence of active epistaxis should prompt the emergency physician to investigate hypertension as an additional possible diagnosis.¹¹

Although the implications for management decisions regarding epistaxis and hypertension remain unclear at this time, hypertension is a possible diagnosis should be considered in the patient that presents to the ED with high blood pressure and an active nosebleed.

Childhood Hypertensive Emergencies

Hypertension is an uncommon problem in children, occurring in less than 5 percent,¹² and is defined as SBP or DBP equal to or greater than the 95th percentile for age and sex. Blood pressure should be measured with a cuff of the appropriate size as noted earlier. In the majority of confirmed cases of hypertension, renal/renovascular disease and pheochromocytoma are the most common etiologies.

Children often will have nonspecific complaints such as throbbing frontal headache or blurred vision. Physical findings associated with hypertension are similar to those found in adults.

The decision to treat is based on the combination of blood pressure and symptoms, but a guideline for urgent treatment is blood pressure that exceeds previous measurements by 30 percent. The goal of treatment, as in adults, is to reduce pressure within 1 h by 25 percent. Nitroprusside (0.3 μ g/kg per min) and labetalol (1 to 2 mg/kg per h) are the agents of choice to treat hypertensive emergencies of childhood. Pediatric hypertension that may require intervention in the ED probably mandates consultation and likely admission.

TREATMENT OF HYPERTENSIVE EMERGENCIES

Treatment Goals

The treatment goal in hypertensive emergency is the immediate reduction of mean arterial pressure ($MAP = [1/3(SBP - DBP) + DBP]$) in a controlled, graded manner, using improvement in the patient's condition as a guide. **Blood pressure reduction should not exceed 20 to 25 percent reduction within the first 30 to 60 min.**

Agents used in hypertensive emergencies are shown in Table 57-

TABLE 57-2 Parenteral Agents for Hypertensive Emergencies

Drug	Mechanism of Action	Initial Dose	Onset of Action	Duration	Contra-Indications	Adverse Effects
Nitroprusside	Vascular smooth muscle dilator	0.3 µg/kg per min IV	Seconds	3–5 min	Hepatic dysfunction	Cyanide toxicity (prolonged use)
Labetalol	α ₁ ,β-Adrenergic blocker	20 mg IV over 10 min	5 min	4–8 h	Asthma, COPD, bradycardia	Bronchoconstriction, bradycardia
Esmolol	β ₁ -Adrenergic blocker	500 µg/kg IV over 1 min, then 50 µg/kg per min IV	5–30 min	30 min	Asthma, COPD	Bronchoconstriction
Nitroglycerin	Vascular smooth muscle dilator	5–10 µg/min IV	2–5 min	5–10 min		Headache
Hydralazine	Arteriolar dilator	10–20 mg IV or 10–50 mg IM	10 min 20 min	4–6 h	Aortic dissection, CAD	Tachycardia, increases catecholamines
Trimethaphan	Ganglionic blocker	0.3 mg per min IV	1–5 min	10 min		Autonomic effects, tachycardia
Enalaprilat	ACE inhibitor	0.625–1.25 mg IV	15 min	6 h	Renal artery stenosis	Acute renal failure, angioedema
Fenoldopam	Dopaminergic receptor agonist	0.05–0.1 mg/kg per min IV	4 min	8–10 min		Headache, flushing
Nicardipine	Calcium-channel blocker	2 mg IV, then 4 mg/h IV	15–30 min	40 min	Aortic stenosis	Headache, tachycardia
Urapidil	α ₁ -Receptor blocker, 5-HT _{1A} -receptor agonist	12.5–25 mg IV	10–20 min	4–6 h		Headache, vertigo

Abbreviations: ACE = angiotensin-converting enzyme; CAD = coronary artery disease; COPD = chronic obstructive pulmonary disease.

Specific Agents

SODIUM NITROPRUSSIDE (NIPRIDE)

Actions and Pharmacology This rapidly acting arteriolar dilator and venodilator is the drug of choice for hypertensive emergencies and is the standard against which all other agents are compared. It acts by reacting with cysteine to form nitrosocysteine, a potent activator of guanylate cyclase, which in turn stimulates the formation of cyclic guanosine monophosphate (GMP) to relax smooth muscle in both arteries and veins. This decreases preload and afterload, resulting in decreased myocardial oxygen demand. The heart rate may increase slightly secondary to a baroreceptor-mediated reflex, but there is no change in cardiac output or myocardial blood flow unless there is pre-existing coronary artery disease, that can result in a significant reduction in regional blood flow ("coronary steal"; see below). Cerebral blood flow may be affected, decreasing in a dose-dependent manner. Renal blood flow remains unchanged, but plasma renin activity is increased. Pulmonary shunting may occur with nitroprusside use.

The rate of onset is extremely rapid, with a duration of action of 1 to 2 min and a plasma half-life of 3 to 4 min. Nitroprusside is metabolized to thiocyanate in the liver and is excreted slowly by the kidneys. Cyanide is an intermediate metabolite, but cyanide toxicity is

Indications Sodium nitroprusside is an excellent agent for all hypertensive emergencies except eclampsia prior to delivery (because it crosses the placenta). It is only indicated for postpartum eclampsia or in eclampsia resistant to other interventions.

Use The MAP should not be reduced by more than 20 to 25 percent within 30 to 60 min. The solution is made by mixing 50 mg of sodium nitroprusside in 500 mL of D5W (0.1 mg/mL). The infusion is usually started at 0.3 µg/kg per min, titrating up to a maximum of 10 µg/kg per min until the desired blood pressure has been achieved. An arterial

line will allow blood pressure to be closely monitored. Because of rapid degradation and sensitivity to light, sodium nitroprusside solution should be used within 24 h of mixing and be protected from light by wrapping the solution and tubing in aluminum foil.

Adverse Effects and Contraindications The most common complication is hypotension. Prolonged infusions may lead to the rare complications of cyanide toxicity, which may occur in patients with hepatic dysfunction, and thiocyanate toxicity, which is associated with renal failure. This rarely occurs in the ED. Because nitroprusside inhibits hypoxia-induced vasoconstriction in the pulmonary vasculature, there may be increased perfusion to nonventilated areas of the lung. Myocardial ischemia may be worsened by a coronary steal syndrome because of dilation of coronary arteries or by the combination of nitroprusside and clonidine. Another consequence of the vasodilatory effect of nitroprusside is increased intracranial pressure.

LABETALOL

Actions and Pharmacology This antihypertensive agent is a competitive, selective α₁-blocker and a competitive, nonselective β-blocker, with the β-blocking action being 4 to 8 times the α-blocking action. It can be given either PO or IV. It lowers blood pressure by blocking α₁ adrenoreceptors in vascular smooth muscle but, because of the simultaneous β-blockade, causes no reflex tachycardia.

When given intravenously, the distribution to peripheral tissues is rapid, with a large volume of distribution (15.7 L/kg). Onset of action is 5 to 10 min, and the duration of action is 8 h. The elimination half-life is 5.5 h. When taken PO, it is rapidly absorbed, with an absorption half-life of about 12 min and peak plasma concentrations at about 50 min. Labetalol is safe for use in patients with renal insufficiency, because it is predominantly (95 percent) hepatically metabolized. Oral dosing may need to be reduced in patients with hepatic disease. Oral bioavailability is only 25 percent, but increases in the elderly or when taken with food or cimetidine. The elimination half-life after an oral dose is 8 h.

Labetalol reduces systolic arterial pressure and total peripheral vascular resistance. Cardiac output may be slightly decreased or unchanged, pulmonary artery and wedge pressures decrease, and angiotensin II activity decreases, while cerebral blood flow, renal blood flow, and glomerular filtration rates are unchanged. With prolonged use, fluid retention may occur. Labetalol should be used with caution in patients with asthma and COPD, because of its nonselective (3-blocking activity, which decreases the forced expiratory volume in 1 s (FEV₁) by causing bronchospasm. The use of labetalol should also be avoided in patients with bradycardia and second- or third-degree heart block.

Indications Labetalol can be used intravenously for hypertensive emergencies and be easily converted to the oral formulation as the first-line agent for hypertensive urgencies. It offers the advantages of providing a steady, consistent drop in blood pressure without decreasing cerebral blood flow or producing reflex tachycardia. It can be safely used in patients with cerebral vascular disease and coronary artery disease. Labetalol is ideal for use in syndromes associated with excessive catecholamine stimulation, such as from pheochromocytoma, MAO inhibitor-induced emergencies, and abrupt clonidine withdrawal. It has also been used in pregnancy-induced hypertension. It is a class C drug in pregnancy.

Use Labetalol can be given for hypertensive emergencies with repeated, incremental boluses starting with 20 mg IV, until the target blood pressure is achieved or a total dose of 300 mg is reached. After an intravenous bolus, the blood pressure falls in 5 min, with a maximum response in 10 min, and antihypertensive effect lasting for up to 6 h. After a 20-mg loading dose, labetalol may also be given as a continuous infusion by mixing 200 mg in 200 mL of D5W and running this at 2 mg per min (2 mL per min). The infusion should be stopped when the target pressure has been achieved.

The initial oral dose in hypertensive urgencies is 200 mg. Patients experience the onset of effects within 1 to 3 h.

Adverse Effects and Contraindications Labetalol has a prolonged action because of its large volume of distribution and long elimination half-life. In 5 percent of patients, orthostatic hypotension is a complication of therapy. The nonselective p-blocking action can exacerbate heart failure and induce bronchospasm. A paradoxical hypertensive effect may occur when the drug is used in low doses in catecholamine-induced crisis, because of the predominant p-blockade, leaving relatively unblocked a-receptors for the circulating catecholamines. In addition, patients with ischemic heart disease may experience exacerbation of angina, and in some cases, myocardial infarction after abrupt discontinuation of oral therapy.

ESMOLOL

Actions and Pharmacology This is an ultra-short-acting P-selective adrenergic blocker, which has rapid distribution and elimination half-lives of 2 and 9 min, respectively. When given as an intravenous bolus, followed by an infusion, 90 percent of (3-blockade is achieved within 5 min; however, when given as an infusion without a bolus, steady-state blood levels are reached within 30 min. Within 2 min of discontinuing an infusion, there is a significant decrease in the p-antagonist activity, and generally all blockade will resolve within 30 min. Because of its rapid onset of action, short duration of action, and easy reversibility—properties not found in other 3-blockers—esmolol is very useful in acute settings. When compared with sodium nitroprusside, esmolol provides similar rapid control of hypertension without producing the excessive reduction in DBP and reflex tachycardia that are seen with sodium nitroprusside.

Indications Esmolol has been used in the treatment of supraventricular tachycardias; to lower pulse and blood pressure in perioperative

patients and in patients with myocardial infarction, unstable angina, and thyrotoxicosis; and to blunt rises in blood pressure associated with intubation. It has also been used for severe hypertension but is not particularly efficacious as monotherapy.

Use A loading dose of 500 μ g/kg per min given over 1 min prior to the initiation of an infusion of 50 to 300 μ g/kg per min. Esmolol may also be given without a loading dose, but then takes longer to reach a steady state. It is usually used in combination with other agents such as nitroprusside or phentolamine for hypertensive emergencies.

Adverse Effects and Contraindications Because of its P-antagonist activity, the use of esmolol should be avoided in patients with asthma or COPD. It also should not be used to treat patients with cocaine-induced cardiovascular complications, because of the predominant p-blockade, leaving relatively unblocked a-receptors.

INTRAVENOUS NITROGLYCERIN

Actions and Pharmacology This agent acts by causing both arteriolar dilation and venodilation, with a greater effect on the venous system (preload) than on the arterial vasculature (afterload). Onset of action is almost immediate when nitroglycerin is given intravenously, and the half-life is 4 min. The mechanism of action is thought to involve the reduction of sulfhydryl groups at a smooth muscle nitrate receptor, resulting in an increase in cyclic GMP. Nitroglycerin is hepatically metabolized. Cardiac output usually remains unchanged but may decrease slightly.

Indications The main indication for nitroglycerin is in the setting of myocardial ischemia, because it is a better vasodilator of the coronary vessels than is nitroprusside; therefore, it is the agent of choice for moderate hypertension complicating unstable angina, myocardial infarction, or pulmonary edema. It also has a less harmful effect on pulmonary gas exchange than does nitroprusside.

Use The initial infusion rate should be 5 to 10 μ g/min with increases every 5 min in 5 μ g/min increments until symptoms are improved or adverse effects necessitate stopping the infusion.

Adverse Effects and Contraindications The most common side effects include headache, tachycardia, nausea, vomiting, hypoxia, and hypotension.

HYDRALAZINE

Actions and Pharmacology This agent acts as a direct arteriolar dilator, with onset of action within 10 min when given intravenously and a duration of action of 4 to 6 h. The onset of action increases to 20 min when hydralazine is given intramuscularly and to 30 min after an oral dose. The plasma half-life is 2 to 4 h, but the antihypertensive effect may outlast this time interval. Its mechanisms of action are not well understood, but it is known to directly relax vascular smooth muscle, resulting in vasodilation. Hydralazine is metabolized by acetylation in the liver and gut walls by ring hydroxylation and conjugation. In patients who are "slow acetylators" (50 percent of the United States population), there is a higher incidence of hypotension and toxic complications. Within 24 h, 80 percent of hydralazine and its metabolite are excreted in the urine. Doses need to be decreased in patients with renal insufficiency.

Indications The main indication for use of intravenous hydralazine is pregnancy-induced hypertension.¹⁴ The drug can be used orally in combination with other drugs.

Use In cases of eclampsia, hydralazine can be given as either a 10- to 20-mg intravenous dose or a 10- to 50-mg IM dose. This dose can be repeated in 30 min.

Adverse Effects and Contraindications Hydralazine should not be used in patients with aortic dissection or a history of coronary artery disease, because it causes reflex tachycardia and increases plasma renin and catecholamines. It also causes sodium and water retention and can cause headaches, nausea, tachycardia, lethargy, and postural hypotension. A lupus-like syndrome can result from chronic oral use.

TRIMETHAPHAN

Actions and Pharmacology This is a ganglionic blocking agent that inhibits both sympathetic and parasympathetic discharge by occupying receptor sites. This acetylcholine blockade results in vasodilation, improved blood flow to some vascular beds, and a decrease in blood pressure. The heart rate may rise in response to the decrease in peripheral vascular resistance. Cardiac output, stroke volume, and left ventricular work decrease. It has a rapid onset of action, and its effects are of short duration.

Indications Historically, trimethaphan had been the drug of choice for acute aortic dissection, especially of the descending type. However, because it causes a number of serious side effects, it has been replaced by the combination of nitroprusside and (3-blockade as the therapy of choice. It continues as a second-line agent in this setting.

Use Trimethaphan is given by intravenous infusion at a rate of 0.3 to 3.0 mg per min. It is sometimes used in combination with propranolol (1 to 3 mg IV or 10 to 40 mg PO qid) to reduce the velocity and force of left ventricular ejection.

Adverse Effects and Contraindications A number of serious side effects can occur, including bladder atony with urinary retention, ileus, gastric atony, cycloplegia, severe postural hypotension from blockade of circulatory reflex pathways, and even respiratory arrest. Tolerance develops with continued use; therefore, it is mainly useful for short-term administration such as in patients awaiting surgery or in inoperable patients until oral therapy with another agent can be started.

ENALAPRILAT

Actions and Pharmacology This agent, which is the first intravenous ACE inhibitor approved for clinical use, is the biologically active form of the oral ACE inhibitor enalapril that forms after deesterification in the liver. It is effective in patients with chronic heart failure with left ventricular ejection fractions of 20 to 44 percent, because it causes coronary vasodilation and significant reduction in mean arterial blood pressure and pulmonary capillary wedge pressure. It also improves cardiac index and stroke volume without affecting the heart rate or stroke work index.

The onset of antihypertensive effect is within minutes of an intravenous bolus injection, with the maximal decrease in DBP in 30 min and duration of action up to 6 h. The degree of blood pressure reduction seems to be associated with the degree of pretreatment plasma renin activity, thus suggesting that the mechanism of antihypertensive effect may be renin-angiotensin inhibition. Enalaprilat is excreted primarily by the kidney; therefore its dosage should be decreased in patients with severe renal insufficiency.

Indications Enalaprilat is an effective intravenous antihypertensive agent in hypertensive emergencies that can be easily continued as an oral preparation for long-term maintenance therapy.

Use An initial dose of 0.625 to 1.25 mg by intravenous bolus has been found to be effective in reducing blood pressure and heart rate. Doses of

2.5, 5, and 10 mg, up to a maximum of 40 mg, have been tried in different studies but have not been found to show any appreciable difference in the magnitude of blood pressure reduction with increasing dose.¹⁵ A bolus can be given every 6 h. The onset of hypotensive effects is variable.

Adverse Effects and Contraindications This agent produces complications and effects that are similar to those of other ACE inhibitors, most notably angioneurotic edema and deterioration of renal function.

FENOLDOPAM

Actions and Pharmacology This antihypertensive agent is a selective postsynaptic dopaminergic receptor (DA₁) agonist that has potent vasodilatory and natriuretic properties. Recent clinical trials have shown this intravenous agent to be as effective as nitroprusside in the treatment of severe hypertension without causing a change in heart rate.¹⁶ The onset of action is 4 min, with duration of antihypertensive effect of 8 to 10 min.

Indications Fenoldopam has recently been FDA approved for use in treating hypertensive emergencies.

Use The initial dose is 0.05 to 0.1 mg/kg per min and can be increased at increments of 0.1 mg/kg per min to a maximum infusion rate of 1.6 mg/kg per min or to a diastolic pressure of less than 110 mm Hg.

Adverse Effects and Contraindications Mild side effects of headache and flushing occur in about 25 percent of patients. In addition, fenoldopam can cause an increase in intraocular pressure.

NICARDIPINE

Actions and Pharmacology This is a dihydropyridine calcium channel blocker that decreases afterload by reducing total peripheral resistance without reducing cardiac output and without apparent negative inotropic effect on the heart. It improves left ventricular pumping activity in patients with mild to moderate heart failure. Nicardipine also displays a greater vasodilatory effect on coronary than on systemic vessels, and produces a clinically significant decrease in cerebral vasospasm after subarachnoid hemorrhage.¹⁷ The onset of action is 15 to 30 min, with a duration of action of 40 min.

Indications It has been used for the treatment of postoperative hypertension, stable angina, and congestive heart failure, and shows promise for use in patients with subarachnoid hemorrhage.

Use Nicardipine can be given initially as a 2-mg intravenous bolus, followed by a 4- to 15-mg per h infusion.

Adverse Effects and Contraindications Nicardipine does not produce the negative inotropic effects seen with other calcium channel blockers such as nifedipine. Headache occurs as a side effect in 20 to 50 percent of patients. Other less common effects include hypotension, tachycardia, nausea, and vomiting. The use of nicardipine is contraindicated in patients with severe aortic stenosis.

URAPIDIL

Actions and Pharmacology Urapidil is a promising antihypertensive agent that been studied extensively in Europe, but is not yet in use in the United States. It is a peripheral α_1 -receptor blocker and central 5-HT_{1A}-receptor agonist that has been found to be equally effective in the treatment of hypertensive emergencies as nitroprusside when given intravenously.¹⁹ Its mechanism of action is via peripheral arterial vasodilation. In addition, it induces very little reflex tachycardia because of a nonadrenergic, centrally mediated reduction of peripheral sympathetic

tone. In addition, urapidil has no effect on cardiac output or intracranial pressure; therefore it is suitable for patients with preexisting cerebrovascular or cardiovascular disease because of the low risk of hypoperfusion. The onset of action when given intravenously is 10 to 20 min, with a duration of antihypertensive effect of 4 to 6 h. There is also an oral form that can be used for long-term treatment.

Indications Urapidil shows promise for use in treating hypertensive emergencies. It appears to be particularly effective in the treatment of pulmonary edema.

Use The initial dose is 12.5 to 25 mg by intravenous bolus to achieve blood pressure reduction without high risk of severe hypotension. Higher doses can be given, with a maximum of 75 mg.

Adverse Effects and Contraindications Minor side effects of headache, vertigo, and orthostatic dysregulation occur in a small percentage of patients.

TREATMENT OF HYPERTENSIVE URGENCIES

Treatment Goals

The treatment goal in hypertensive urgencies is the gradual reduction of blood pressure within 24 h by using oral antihypertensive agents (Table 57-3). The recommended duration to achieve blood pressure reduction varies from a few hours to 48 h in the literature. Since a common cause of hypertensive urgency is noncompliance with medications, restarting a patient on a previously established regimen is an acceptable strategy. Follow-up in 24 h should be arranged. Admission decisions depend on the patient's comorbid conditions, and the clinician's impression of the patient's anticipated response to therapy.

Specific Agents

SUBLINGUAL NITROGLYCERIN

Indications It is the agent of choice for unstable angina, for immediate treatment of pain in acute myocardial infarction, and for the treatment of left ventricular insufficiency and pulmonary edema.

Use Nitroglycerin is absorbed very quickly through the oral mucosa. It is given as a 0.3- to 0.6-mg tablet or spray under the tongue. The onset of hypotensive effect is in 5 min and can last several hours.

Adverse Effects and Contraindications The most common side effects include headache, tachycardia, nausea, vomiting, hypoxia, and hypotension. It should be used with caution in patients with aortic stenosis.

CLONIDINE

Actions and Pharmacology This agent is a centrally acting α_2 adrenergic agonist that decreases central sympathetic activity, lowering plasma catecholamine levels. Clonidine causes little postural hypotension because vasomotor reflexes are unchanged. It also does not increase heart rate or cardiac output and does not change renal blood flow or glomerular filtration rates. Overall, the effect of clonidine is lower blood pressure, slow the heart rate, and cause sedation.

The onset of action is 30 to 60 min after an oral dose, with peak effects in 2 to 4 h. The duration of action is 6 to 8 h. Clonidine crosses the blood-brain barrier. Because approximately 50 percent is excreted unchanged in the urine in the first 24 h, it can accumulate in patients with renal insufficiency and is not dialyzable; however, in cases of renal failure, it is excreted in the feces.

Indications This is considered to be a second-line agent for the treatment of hypertensive urgencies. It can be used safely in the elderly and in renal failure. It is a good choice for hypertensive urgency associated with cocaine withdrawal. However, because it sometimes requires up to 6 h for an adequate response, it is not ideal for ED use.

Use The initial dose is 0.1 to 0.2 mg, with additional doses of 0.1 mg every hour until the diastolic pressure is below 115 mm Hg or a maximum dose of 0.7 mg has been given. A patient who is given clonidine in the ED setting does not need to be discharged on this specific agent long term.

Adverse Effects and Contraindications The most common side effects include dry mouth, drowsiness, and constipation. Rarely, bradycardia can occur in patients with sick sinus syndrome. Clonidine may interact with other drugs, causing adverse effects such as orthostatic hypotension in patients taking diuretics, decreased and

TABLE 57-3 Oral Agents for Hypertensive Urgencies

Drug	Mechanism of Action	Dose	Onset of Action	Duration	Contraindications	Adverse Effects
Nitroglycerin	Vascular smooth muscle dilator	0.3–0.6 mg SL	5 min	5–10 min	Aortic stenosis	Headache
Labetalol	α_1, β -Adrenergic blocker	200–400 mg PO, repeat every 2–3 h	30–120 min	6–12 h	Asthma, COPD, bradycardia	Bronchoconstriction, bradycardia
Clonidine	Central α_2 agonist	0.1–0.2 mg PO, repeat 0.1 mg every hour	30–60 min	6–8 h	CHF, 2nd- or 3rd-degree heart block	Drowsiness, sedation, tachycardia, dry mouth
Captopril	ACE inhibitor	25 mg PO	15–30 min	4–6 h	Renal artery stenosis	Acute renal failure, angioedema
Nifedipine (extended release)	Calcium channel blocker	10 mg PO, may repeat q30–60 min	5–15 min	3–6 h	Angina, acute hypertension	MI, CVA, syncope, heart block, CHF
Losartan	Angiotensin II receptor antagonist	50 mg PO	60 min	12–24 h	2nd and 3rd trimesters of pregnancy	Allergic (rare)

Abbreviations: ACE = angiotensin-converting enzyme; CHF = congestive heart failure; COPD = chronic obstructive pulmonary disease; CVA = cerebrovascular accident; MI = myocardial infarction; SL = sublingual.

hypertensive effects with cyclic antidepressants, increased sedation with alcohol, and bradyarrhythmias or other dysrhythmias with negative inotropic agents. When high doses of clonidine are abruptly stopped, the well-documented phenomenon of clonidine withdrawal with severe rebound hypertension, tachycardia, flushing, and abdominal symptoms may be seen. If this syndrome occurs, the patient should be given clonidine therapy promptly. The use of β -blockers should be avoided because they may worsen the withdrawal symptoms.

CAPTOPRIL

Actions and Pharmacology This is an ACE inhibitor that is rapidly absorbed PO, with an onset of action within 15 to 30 min, peak effects of blood pressure reduction between 50 and 90 min, and duration of antihypertensive effect of 4 to 6 h. It causes no change in cardiac output, heart rate, or cerebral blood flow. Since captopril is metabolized by the kidneys, its dosing must be decreased in patients with renal insufficiency. Postural hypotension is a rare problem, because it has no effect on baroreceptor reflexes.

Indications Captopril is effective in cases of refractory acute congestive heart failure and is also useful in treating hypertensive urgencies with known renovascular hypertension.

Use The usual oral dose is 25 mg. The dose-response curve for captopril is flat; therefore increasing doses generally do not cause greater reductions in blood pressure.

Adverse Effects and Contraindications Several common side effects include skin rash, cough, and loss of taste. Laboratory abnormalities that can occur include leukopenia, proteinuria, and hyperkalemia. Captopril should not be used in combination with potassium-sparing diuretics. It also should not be given to patients with bilateral renal artery stenosis or unilateral stenosis with one kidney, because of the risk of acute renal failure. In patients with chronic renal failure or collagen vascular disease, there is an increased risk of side effects. A potentially life-threatening complication of this therapeutic agent is angioneurotic edema, which can result in airway compromise.

NIFEDIPINE This dihydropyridine calcium-channel antagonist has been one of the most extensively studied agents for rapid control of blood pressure. Until the last few years, when awareness of serious side effects became more widespread, it had been the most frequently used agent for acute blood pressure lowering in hospitalized patients.

The US Food and Drug Administration (FDA) has never specifically approved the use of short-acting nifedipine for the treatment of hypertension of any kind. Because of the risks of serious adverse reactions, such as acute coronary events or an ischemic stroke, the US National Heart, Lung, and Blood Institute issued a warning in 1995 stating that **this agent should not be used in the treatment of hypertension, angina, and myocardial infarction.**¹⁸

LOSARTAN

Actions and Pharmacology Losartan is a promising new agent that is a highly selective angiotensin II-receptor antagonist. It blocks the vasoconstrictor and aldosterone-secreting effects of angiotensin II. It selectively blocks the binding of angiotensin II to specific receptors found in vascular smooth muscle and the adrenal gland. It undergoes substantial first-pass metabolism by cytochrome P-450 enzymes and is converted to an active metabolite. The half-life of losartan is about 2 h

and of the metabolite about 6 to 9 h. Peak concentrations of losartan and its active metabolite are reached in 1 h and in 3 to 4 h, respectively.

Indications Losartan has been used in clinical trials in the treatment of hypertensive urgency.

Use It is available as 10-, 25-, or 50-mg tablets. The 50-mg dose has been found in studies to produce better results than the lower doses, but higher doses do not produce a more significant blood pressure reduction.

Adverse Effects and Contraindications Because of potential fetal injury, the use of losartan should be avoided in the second and third trimesters of pregnancy. Dosing should be decreased in patients with hepatic insufficiency.

TREATMENT OF ACUTE HYPERTENSIVE EPISODE

As noted, there is a paucity of evidence that acute intervention in blood pressure in the ED is warranted. Rather, there is evidence that in some cases acute interventions may actually be harmful.³ In chronically hypertensive individuals, complications of acute blood pressure reduction can include altered sensorium, seizures, transient ischemic attacks, and amaurosis as well as other visual changes. In addition, there is no evidence of a beneficial effect of acute blood pressure reduction on long-term control or on the chronic effects of hypertension. In general, these patients require no acute ED intervention but should be referred to a primary care physician for follow-up and initiation of therapy. If these patients have previously been diagnosed as hypertensive but have been noncompliant with medications, a reasonable strategy would be to restart the patients on their previous treatment regimen and then refer for appropriate follow-up care within 24 to 48 h.

SELECTION OF CLASS OF ANTIHYPERTENSIVE AGENT

Table 57-4 summarizes guidelines for the selection of an antihypertensive agent for patients in an ambulatory setting with various coexisting conditions.¹³ Diuretics should be the agents of first choice in patients with renal disease and congestive heart failure who are judged to be volume overloaded. Because of their greater prevalence of stage 3 hypertension (SBP of 180 mm Hg or more, and DBP of 110 mm Hg or more), African-American patients may require mult-drug therapy. For treatment of patients with angina pectoris or post-myocardial infarction, β -blockers are indicated. They are also indicated for those patients with a history of migraines, atrial fibrillation with rapid ventricular response, paroxysmal supraventricular tachycardia and senile tremor. The use of β -blockers is safe in the latter part of pregnancy, but their use should be avoided in early pregnancy because of an association with fetal growth restriction. Angiotensin-converting enzyme (ACE) inhibitors should be used in patients with congestive heart failure (see Chap. 53) and can also be used in patients with a history of diabetes mellitus, especially those with diabetic nephropathy. The use of ACE inhibitors should be avoided in pregnant women.

In the elderly, diuretics are the first choice for antihypertensive therapy because the pathophysiology of their hypertension is usually related to total peripheral resistance rather than cardiac output. β -blockers are also recommended as alternative therapy. Use of agents that cause significant orthostatic changes (e.g., calcium channel blockers, peripheral α_1 -adrenergic blockers), as well as drugs that cause cognitive dysfunction (e.g., central α_2 agonists) should be avoided in the elderly.

TABLE 57-4 Antihypertensive Treatment Regimens for Specific Populations

Coexisting Condition	Diuretic	β -Blocker	Angiotensin-Converting Enzyme Inhibitor	α_1 -locker	Calcium Channel Blocker
Older age	++	+/-	+	+	+
Black race	++	+/-	+/-	+	++
Angina pectoris	+	++	+	+	++
Postmyocardial infarction	+	++	+	+	-
Congestive heart failure with systolic dysfunction	++	-	++	+	-
Cerebrovascular disease	+	+	+	+/-	+
Renal disease (Cr >2.3 mg/dL)	++	+/-		+	+
Diabetes mellitus with nephropathy	+	+/-	+	+	+
Migraine	+	++	+	+	+
Atrial fibrillation (with rapid ventricular response)	+	++	+	+	+
Paroxysmal supraventricular tachycardia	+	++	+	+	+
Senile tremor	+	++	+	+	+

Symbols: ++, preferred; +, suitable; +/-, usually not preferred; —, usually contraindicated.

Abbreviation: Cr = serum creatinine.

AORTIC DISSECTION AND ANEURYSMS

Louise A. Prince Gary A. Johnson

Thoracic and abdominal aneurysmal disease comprises a significant subset of emergencies. A ruptured aneurysm or dissecting aneurysm is a prominent cause of sudden death as well as severe abdominal, chest or back pain. These diseases disproportionately affect the elderly. As our patient population becomes older, the incidence of presentation for aneurysms will continue to increase.¹

Abdominal aortic aneurysms (AAA) have a clear familial trend. Eighteen percent of patients with AAA have a family history of aneurysm (a first-degree relative) compared with less than 3 percent of controls. Patients with Marfan syndrome have been found to have mutations in the *FBN1* gene on chromosome 15.¹ Other genetic abnormalities have been investigated as well.¹

The incidence of AAA increases with age, and the disease rarely presents before age 50. Most patients are older than age 60, and male have an increased risk of disease. Patients with other aneurysms and peripheral arterial disease are at increased risk as well.

PATHOGENESIS

Risk factors for aneurysms include connective tissue disorders, family history of aneurysm, and atherosclerotic risk factors (i.e., aging, smoking, hypertension, hyperlipidemia, and diabetes). These risk factors combine to increase the expansive force on the aortic wall or to impair the patient's ability to withstand these forces. The Laplace law [wall tension = (pressure X radius)] dictates that as the aorta dilates the force on the aortic wall increases, therefore causing further aortic dilatation.

Destruction of the media of the aorta is a prominent feature of aneurysm pathogenesis. Elastin and collagen are markedly reduced in the aneurysmal aorta, and fibroblastic units are dramatically decreased. In addition, the normal abdominal aorta has a decreasing number of elastic lamellae as the aorta becomes more distal. This may help account for the prominent infrarenal location of aneurysms in many patients.

Histologic examination of an aneurysmal wall will show an intima that is infiltrated by atherosclerosis and a thinned media. There may be

intraluminal thrombus, and the adventitia often has been infiltrated by inflammatory cells. Patients with saccular outpouchings (blisters) may have an increased risk of rupture. Such blisters have been shown to increase the incidence of rupture of small (<5 cm) aneurysms.²

Rate of aneurysmal dilatation is variable. As a consequence of the LaPlace law, larger aneurysms will expand more quickly than smaller ones. An average rate may be 0.25 to 0.5 cm per year.² Patients with known aneurysms must be followed closely for unpredictably fast expansion.

Dissecting Aneurysms

Aortic dissections occur from a violation of the intima that allows blood to enter the media and dissect between the intimal and the adventitial layers. Common sites for tear include the ascending aorta and the region of the ligamentum arteriosum. The dissecting column of blood ruptures the intima and thus maintains a true and false lumen. The dissection may extend proximally, distally, or both. The patient's symptoms may cease abruptly when the dissection reenters the intima; this may suggest a spontaneous cure clinically. Alternatively, blood may dissect through the adventitia and nearly always will be fatal.

Aortic dissection presents in a bimodal fashion. One group consists of younger patients with specific predisposing conditions. The predominant group consists of patients above age 50 (mean age 63) with hypertension. Two-thirds of patients are male, and 72 percent have hypertension.³ Atherosclerosis is only a minor contributor to the pathogenesis of dissection.

Predisposing conditions for dissection include multiple forms of congenital heart disease, connective tissue disease, and pregnancy. Approximately 25 to 30 percent of patients with Marfan syndrome develop a dissection. Dissection also may be induced iatrogenically from aortic catheterization or cardiac surgery.

Aortic dissections have been classified by two separate systems. The Stanford classification considers any involvement of the ascending aorta a type A dissection and dissections restricted to the descending aorta type B. DeBakey classified type I dissections as those which simultaneously involve the ascending aorta, the arch, and the descending aorta. Type II involves only the ascending aorta and type III only the descending aorta.

Pseudoaneurysms

Pseudoaneurysms (or false aneurysms) may occur when there is a violation of the intima that creates an ulcer into the aortic media. This type of lesion may dilate slowly or cause a deepening of the ulcer and form a pseudoaneurysm; it occurs most commonly in the descending thoracic aorta. Pseudoaneurysms do not evolve commonly into dissections and rupture rarely.⁴

Other Aneurysms

Patients may have aneurysms at anastomoses from prior vascular reconstruction. The aneurysm occurs at the site where the graft is sewn to the artery. Anastomotic aneurysms may occur in the aortic, iliac, or femoral arteries. These aneurysms commonly rupture and cause catastrophic bleeding; however, they also may present with smaller sentinel hemorrhages. Anastomotic aneurysms may erode into the adjacent intestine and form an aortoenteric fistula.

CLINICAL FEATURES

Abdominal Aortic Aneurysms

Symptomatic abdominal aortic aneurysms may present as syncope, back or abdominal pain, shock, or sudden death. Sudden death most

commonly occurs from intraperitoneal rupture of the aneurysm. These ruptures lead to massive, rapid blood loss, and it will not be possible to resuscitate the patient. History that is often cited as classic for acute rupture of the abdominal aneurysm is syncope with no warning symptoms followed by severe abdominal or back pain. Syncope is caused by rapid blood loss and a lack of cerebral perfusion. Patients often regain consciousness after their own compensatory mechanisms have been invoked, but they most often will slip again into shock without prompt medical intervention.

In general, pain is the most common presenting symptom. The pain is described more often as severe and abrupt in onset, and it may be located in the back or abdomen.

Approximately 50 percent of patients describe a ripping or tearing pain.³ Syncope may be present in 10 to 12 percent of patients. Many patients present with atypical sites of pain: flank, groin, isolated quadrants of the abdomen, and hip. Other symptoms such as bladder pain, tenesmus, nausea, and vomiting may complicate the presentation. Constitutional symptoms such as nausea and vomiting are present commonly.

Physical examination of a patient with acute rupture of an aortic aneurysm may detect the aneurysm. Tenderness to palpation of an aneurysm is commonly interpreted as a sign of rupture. However, a lack of tenderness cannot imply an intact aorta. Patients with an obese abdomen are difficult to examine for the presence of an aortic aneurysm. Very thin patients may have an aorta that is easily palpable, and the diameter of the aorta should be measurable.

Evidence of retroperitoneal hematoma may be seen as periumbilical ecchymosis (Cullen sign) or flank ecchymosis (Grey-Turner sign). Retroperitoneal blood also may dissect into the perineum or groin. Scrotal hematomas or inguinal masses may be seen on examination. Retroperitoneal blood also may irritate the psoas muscle and produce an iliopsoas sign. Blood may compress the femoral nerve and present as a neuropathy. The presence or rupture of an AAA typically does not alter femoral arterial pulsations.⁵

Aortoenteric fistulas should be considered in all patients with unexplained gastrointestinal bleeding. A history of aortic graft placement should increase the clinical suspicion of fistula.⁶ The duodenum is involved most frequently, and therefore, bleeding may manifest as hematemesis, melena, or (if there is rapid transport) hematochezia. These fistulas commonly present as massive, life-threatening bleeding. However, mild "sentinel" bleeding may precede a full-blown rupture. Aortic aneurysms also may erode into the venous vasculature and form aortovenous fistulas, which may present as high-output cardiac failure, decreased arterial blood flow distal to the fistula, and increased central venous volume.

AAAs uncommonly may present as chronic contained ruptures. A retroperitoneal rupture may cause enough fibrosis to limit blood loss. The inflammatory response commonly causes pain, which may continue for a significant length of time. Despite the seriousness of this pathology, the patient may appear remarkably well.

An asymptomatic aneurysm may be found on physical examination or radiologic evaluation. Any aneurysm that is found should be referred for follow-up. **Aneurysms greater than 5 cm in diameter at an increased risk of rupture (size is measured outer wall to outer wall). Aneurysms of less than 5 cm are less likely to rupture.** However, patients with such asymptomatic aneurysms must be followed closely by their primary care physicians or surgeons. The management of patients with small, asymptomatic aneurysms (including the timing of surgery) is a controversial topic.¹⁷ Symptomatic aneurysms of any size should be considered emergent.

Thoracic Aortic Aneurysm

Thoracic aortic aneurysms may become symptomatic by compressing, or eroding into adjacent structures. Presenting symptoms can include esophageal, tracheal, bronchial, or even neurologic disorders. A thoracic

aneurysm that erodes to an adjacent structure is generally immediately fatal. Rare patients may survive with the assistance of hemodynamic resuscitation.

Dissecting Aortic Aneurysms

Aortic dissections commonly present (>85 percent) with abrupt and severe pain in the chest or between the scapulae. Recent literature suggests that back pain is a less common presentation than previously thought.³ One half of all patients often describe the pain as tearing or ripping. Pain in the anterior chest often is associated with involvement of the ascending aorta (70 percent). Back pain may indicate involvement of the descending aorta (63 percent). Dissection often presents with dynamic pathology; therefore, pain patterns often change as the anatomic injury migrates.³

The aortic dissection will cause a spectrum of symptoms based on the anatomic course of the lesion. Dissection into a carotid artery may lead to a classic stroke presentation. Forty percent of patients with dissection will have some neurologic sequelae.³ Paraplegia may occur if the arterial blood supply to the spinal cord is interrupted. Abdominal or flank pain may be caused by dissection into the abdominal aorta, renal arteries, or iliac arteries. Dissection of the aortic root may lead to pericardial tamponade.

Systemic constitutional symptoms may occur with the dissection. Nausea, vomiting, and diaphoresis are common. Patients frequently are apprehensive and express feelings of impending doom.

Physical examination may help to eliminate some differential diagnoses but most likely will reveal a normal heart and lung examination. The diastolic murmur of aortic insufficiency may be heard. Decreased pulsation in the radial, femoral, and/or carotid arteries should significantly raise the suspicion of an aortic lesion but is present in less than 20 percent of patients.³ Specific threshold values of blood pressure changes between extremities have not been defined. Hypertension and tachycardia are commonly present, but the dissection also may cause hypotension. Hypotension may accompany pericardial tamponade or coronary artery interruption. Tamponade may result in muffled heart tones, elevated jugular venous pressure, and pulsus paradoxus. Compression of the recurrent laryngeal nerve or the superior cervical sympathetic ganglion may cause either hoarseness of the voice or Horner syndrome, respectively.

DIAGNOSIS

Abdominal Aortic Aneurysms

The differential diagnoses for AAAs include the causes of syncope, abdominal pain, chest pain, back pain, and shock. The presentation of syncope with back pain or shock should strongly suggest aortic disease. However, the diagnosis will be difficult to make in shock or syncope without a significant complaint of pain. Other cardiac, abdominal, and retroperitoneal diseases need to be considered, including renal disorders, hepatobiliary disorders, and pancreatic disease. Unfortunately, some patients may appear well enough to receive benign diagnoses such as musculoskeletal back pain or enteritis and be discharged from the ED.

The diagnosis may be further confused by coexisting pathology. Coronary artery disease and chronic lung disease are often present, and these features may distract the physician from the diagnosis of aneurysmal disease. This is especially true in patients without significant pain.

Aneurysms of large arteries other than the aorta may expand or rupture. Iliac artery aneurysms are notoriously difficult to diagnose because they may be confused with urologic, bowel, or groin disorders. Splenic artery aneurysms may present as undifferentiated shock or intra-abdominal catastrophe. A rupture of the splenic artery has a poor prognosis owing to its intraperitoneal location.

Radiologic studies may be very helpful in confirming a ruptured AAA, but since radiographs often unnecessarily delay operative repairs, the decision to obtain confirmatory studies must be made carefully.

Radiologic evaluation may include plain radiography (Figure 58-1 B), ultrasound (Figure 58-2), computed tomographic (CT) scanning (Figure 58-3), or magnetic resonance imaging. Plain abdominal film may show a calcified and bulging aortic contour, implying the presence of an aneurysm. Approximately 65 percent of patients with symptomatic aortic aneurysmal disease will have a calcified aorta. Some propose that a cross-table lateral film of the abdominal aorta will have a higher yield for calcifications. The lateral view will allow the aorta to be visualized without overlying the vertebral column., anteroposterior projection may show an arch of calcification, most commonly on the patient's left. Rarely, a chronic aneurysm may erode into a vertebral body. Plain film cannot exclude the presence of AAA.

Rapid bedside ultrasonography (see Figure 58-2) is ideal for unstable patients who cannot undergo CT scanning. A technically adequate ultrasound study has virtually 100 percent sensitivity for demonstrating the presence of an aneurysm and measuring its diameter. Obesity or bowel gas may make the study difficult to perform. Rupture cannot be seen reliably on ultrasound.

CT scanning with intravenous contrast material (see Figure 58-3) is useful to demonstrate the anatomic details of the aneurysm and associated retroperitoneal hemorrhage. CT scanning should be obtained on stable patients. Should unusual circumstances occur (such as presence of other prominent acute abdominal conditions) and a CT scan becomes necessary, the patient should be accompanied by a surgeon, who could expedite an emergent operation if necessary.

Dissecting Aneurysms

The ischemic end-organ manifestations associated with many dissections may confuse the differential diagnosis, which includes myocardial infarction, pericardial disease, pulmonary disorders, stroke, musculoskeletal disease of the extremities, spinal cord injuries, intra-abdominal disorders. Ischemic manifestations may change with time (as the dissection progresses), distracting the physician from making the correct diagnosis. Rupture of the dissection into the true lumen may cause a cessation of symptoms, and the correct diagnosis may then be dismissed inappropriately.

Thoracic dissecting aneurysms most commonly (90 percent) will have an abnormality on chest radiography.³ Widening of the mediastinum, an abnormal aortic contour, pleural effusions, or deviation of the trachea, mainstem bronchi, or esophagus may be seen (Figure 58-4). Intimal calcium may be visible and distant from the edge of the aortic contour (calcium sign).

CT scanning may reliably make the diagnosis of aortic dissection (Figure 58-5). Sensitivity for dissection ranges from 83 to 100 percent and specificity ranges from 87 to 100 percent.⁸ Spiral CT scanning with rapid intravenous boluses of radioopaque contrast material may be more sensitive. However, CT scanning cannot reliably give anatomic details of other arterial branches emanating from the aorta and cannot address aortic valve competence.

Angiography is still considered the "gold standard" for diagnosis by many and will provide more anatomic detail than a CT scan.⁸ Angiography also will reliably show complications of dissection, including involvement of branch vessels, aortic valve incompetence, and coronary artery involvement. However, the angiogram is not a perfect study. Erbel⁹ found aortography to have a specificity of 94 percent; a sensitivity of 88 percent. Risks of the procedure include the use of intravenous contrast agents and the delay in assembling an angiography team.

Magnetic resonance angiography (MRA) is comparable to angiography and CT angiography, but is not readily available or practical for most ED patients. CT remains the modality of choice in unstable patients.

FIG. 58-1. A. Lateral view of a calcified infrarenal aortic aneurysm. B. Posteroanterior view of a calcified infrarenal aortic aneurysm.

In experienced hands, a transesophageal echocardiogram (TEE) may be as sensitive and specific as angiography.^{10,12} Sensitivity for dissection ranges from 97 to 100 percent, and specificity ranges from 97 to 99 percent. Some 3 percent of patients cannot tolerate the procedure, which should be performed under sedation or general anesthesia. Known esophageal disease is a relative contraindication. Disrup-

tion of sound transmission by air in the trachea or left bronchi may cause difficulty in evaluating the ascending aorta. Among the imaging techniques mentioned earlier, TEE has the highest diagnostic variability between operators or observers. Therefore, the imaging procedure of choice may vary between institutions. In contrast with AAAs, suspected dissections must be confirmed radiologically prior to operative repair.

Thoracic aortic saccular aneurysms generally are identified on chest radiography. Rarely, the presence of thoracic, pleural, or parenchymal densities may make the diagnosis more difficult. CT scanning will delineate these aneurysms reliably.

EMERGENCY DEPARTMENT TREATMENT

Ruptured Abdominal Aortic Aneurysm

All symptomatic aneurysms require urgent surgical consultation. The emergency physician's role in the care of a patient with an acute rupture of an AAA lies largely in making the diagnosis and assisting with rapid transfer to the operating room.

Any suspected ruptured aneurysm requires immediate operative repair. One-half of patients with a ruptured aneurysm who reach the operating room die.⁷ **Imaging modalities should be restricted to patients who are considered unlikely to have a ruptured AAA.** Standard resuscitative maneuvers (two large-bore intravenous catheters, a cardiac monitor, and supplemental oxygen) are required. The patient suspected of having an AAA may require resuscitation for blood loss.

FIG. 58-2. Bedside ultrasound image of an AAA. This aneurysm measures 6.5 cm.

FIG. 58-3. CT scan of a patient with a 12-cm abdominal aortic aneurysm. Calcification of the wall is seen. Evidence of hemorrhage and surrounding inflammation is seen in the left side of the abdomen.

However, overly vigorous fluid resuscitation may be harmful, and the appropriate amount of intravenous fluids to be given is controversial.

Aortic Dissection

Patients with suspected aortic dissection commonly will require antihypertensive treatment, which must be provided without increasing the shear force on the intimal flap of the aorta. Therefore, medications with negative inotropic effects must be given initially. (β -blockers (e.g., esmolol, metoprolol, or propranolol) are used commonly for this purpose. The optimal blood pressure is undefined and must be tailored to each patient. However, a systolic pressure of 120 to 130 mm Hg may be a convenient starting point.

Esmolol may be given as an initial bolus of 500 μ g/kg over 1 min, followed by an infusion of 50 to 150 μ g/kg per min. Metoprolol may be given IV in three 5-mg doses every 2 min, followed by 2 to 5 mg/h

IV infusion. Labetalol is given as an initial dose of 20 mg IV, with repeat doses of 40 to 80 mg every 10 min to desired effect or a total dose of 300 mg. Calcium channel blockers may be used if a contraindication to (β -blockers) is present.

Vasodilators (such as nitroprusside) may be added for further antihypertensive treatment after successful administration of a negative inotrope. Nitroprusside may be infused at an initial dose of 0.3 μ g/kg per min IV. Patients should have clear evidence of adequate (β -receptor or calcium channel blockade prior to starting a vasodilator. Close monitoring of the pulse rate is required because this is a convenient indicator of blockade in most patients. Aortic dissections may cause hypotension, which requires fluid or blood product resuscitation.

Rapid referral to a surgeon is mandatory. Dissections with involvement of the ascending aorta require prompt surgical repair. Patients with dissecting aneurysms of only the descending aorta are worse surgical risks, and indications for repair are controversial.

FIG. 58-4. Chest x-ray of a dissecting thoracic aneurysm.

FIG. 58-5. CT scan of patient in Figure 58-3 revealing false (*double arrows*) and true aortic lumens in both ascending and descending aorta.

Asymptomatic abdominal and thoracic aortic aneurysms require prompt outpatient referral. Other interventions generally are not needed.

THROMBOPHLEBITIS AND OCCLUSIVE ARTERIAL DISEASE Anil Chopra

THROMBOPHLEBITIS

Deep venous thrombosis (DVT) is a common condition, with potentially life-threatening sequelae. The true incidence, however, is not known because much of DVT is occult. The admission rate for DVT has declined greatly owing to the widespread use of newer outpatient treatments. The most common life-threatening consequence of DVT is pulmonary embolism (PE), with more than 200,000 cases diagnosed every year in the United States, and PE is associated with a 7-day mortality of 25 percent.¹ The recognition and early treatment of a presumed or known DVT is paramount to reducing the morbidity and mortality from its local and thromboembolic sequelae. Pulmonary embolism is discussed in Chap. 56.

Pathophysiology

The formation of venous clots is related to the presence of at least one of Virchow's triad of factors: venous stasis, injury to the vessel wall, and hypercoagulable state. Table 59-1 outlines the clinical risk factors predisposing to DVT, which can be remembered by the mnemonic *thrombosis*; Table 59-2 provides a detailed list of associated condi-

tions. The highest risk of venous thrombosis occurs with major surgery or trauma, prolonged immobilization, malignancy or other hypercoagulable state, and prior thromboembolic disease. Trauma may be caused by major head injury, spinal injury, pelvic fractures, lower extremity fractures, and burns. Recent literature has suggested a fourfold increase in the incidence of DVT with travel longer than 4 h by air and land.² This travel risk may be related not only to immobility but also to posture, decreased fluid intake and urine output with hemoconcentration, and decreased fibrinolysis with lower ambient oxygen with air travel. Compression leg stockings, salicylic acid, and low molecular-weight heparin (LMWH) before travel in high-risk individuals substantially reduces this risk.

The most common cause of hereditary thrombophilia is factor V Leiden due to a gene mutation on factor V. Other hypercoagulable states are listed in Table 59-2. Obstetric risk occurs not only during pregnancy but also in the postpartum period. Medications that predispose to thrombosis include second- and third-generation oral contraceptives and replacement hormones. Surgery risk is diminished with prophylactic subcutaneous unfractionated heparin (UFH), LMWH, or fondaparinux postoperatively. Illnesses with an increased risk include myocardial infarction, congestive heart failure, cerebrovascular accident, nephrotic syndrome, inflammatory bowel disease, and vasculitis (lupus, Behcet syndrome). Presence of liver disease may decrease the risk of DVT by 90 percent.¹

Thrombi most commonly form at the venous cusps of deep veins in the lower extremities, where altered or static blood flow initiates clot formation. Alternatively, an intimal defect anywhere along a vein resulting from injury or central catheters can be the nidus of a clot. Blood clots are composed primarily of red cells, fibrin, and platelets. An immature thrombus may propagate, dissolve, or embolize, depending on various local and systemic factors related to thrombogenesis (in particular venous stasis and activation of the coagulation pathway) and the body's defenses responsible for clot lysis (antithrombin III, protein C, plasmin, and other factors). The signs and symptoms of DVT are typically due to a partly or totally occluded vein, leading to venous outflow obstruction and/or the variable inflammatory response to a clot adhering to endothelium. Pulmonary embolism sometimes may be the first and only clinical indication of an existing DVT.

A postphlebotic syndrome (PPS) may develop after the resolution of a DVT and is related to valvular incompetence, persistent venous outflow obstruction, and abnormal microcirculation. The true incidence of PPS is unknown and depends on the criteria used for diagnosis, but studies have reported incidences of 23 percent 2 years and 28 percent 5 years after a first episode of proximal DVT.³ There is a relation between the extent of the initial thrombosis and subsequent development of PPS.

Superficial Thrombophlebitis

Thrombosis can occur in any superficial vein. There is predilection for varicosities at the saphenous vein or its tributaries. It is a common, benign, self-limiting process but can cause significant incapacitation. Local pain, redness, and tenderness of a cord along the course of the

involved vein are typical findings. Bruising or bleeding may also be noted at the involved site. Doppler ultrasound may be used to confirm the diagnosis if there is any ambiguity or if an alternative diagnosis such as a DVT, cellulitis, or lymphangitis is possible. Demonstration of flow within the involved vein reliably excludes superficial venous thrombosis.

Mild cases can be treated with warm compresses, analgesia, and elastic supports for the involved extremity, with the patient continuing daily activities as tolerated. Severe thrombophlebitis, where the patient is functionally debilitated by symptoms, should be managed with periods of bedrest, elevation of the extremity, support stockings, and

analgesia. Anti-inflammatory medications are commonly used to treat superficial thrombophlebitis. Antibiotics and anticoagulants are of no proven benefit unless septic thrombophlebitis is suspected, such as may occur among intravenous drug users. The incidence of DVT from extension of a superficial thrombus is about 3 percent, but the incidence of embolization is extremely low.⁴ Most thromboses in the proximal greater saphenous vein that extend into the deep system will do so in 1 week. Thus, a follow-up ultrasound examination to exclude extension should occur at that time. Improvement with aggressive therapy can be painfully slow, and symptoms may persist for weeks. Definitive treatment for refractory or recurrent disease is ligation and excision of the involved vein. Patients with recurrent or migratory thrombophlebitis should be investigated to exclude a malignancy or other hypercoagulable state.

Deep Venous Thrombosis

CLINICAL FEATURES The clinical examination is unreliable for the detection or exclusion of DVT. Suspicion of DVT by symptoms alone is sufficient to initiate objective investigations, even with a negative physical examination. The constellation of pain, redness, swelling, warmth, and tenderness is present in less than half of patients with confirmed DVT. Sensitivities are relatively poor for the presence of calf pain (66 to 91 percent), leg swelling (35 to 97 percent), and calf tenderness (56 to 82 percent).⁵ The specificities of any of these findings are even poorer. Although some patients with DVT may have ; low-grade fever, one should be careful to exclude an infectious process, such as cellulitis. Pain in the calf with forced dorsiflexion of the ankle and the leg straight (Homans sign) is not reliable for DVT. The physical findings with DVT depend on its location and the degree of venous obstruction, inflammation, and collateral blood flow. For example, significant iliofemoral vein occlusion can present with minimal to absent clinical findings but can result in a catastrophic PE.

Despite the problem with individual clinical findings or lack thereof, several investigators have developed instruments to risk stratify patients suspected of having a venous thrombosis. One such clinical model developed and validated by Wells and colleagues has been shown to be reliable in predicting the probability of DVT, which was ultimately confirmed by venogram in that study group.⁶ This model incorporates nine predictors (Table 59-3) to categorize patients as having a low, moderate, or high probability of DVT. With this instrument, the likelihoods of DVT are 5, 33, and 85 percent in the low (0 point), moderate (1 or 2 points), and high (>3 points) pretest probability groups, respectively.

Symptomatic DVT will be in the popliteal or more proximal veins in more than 80 percent of cases. An isolated calf DVT will extend proxi

mally only 20 percent of the time, usually within 1 week of presentation.⁷ Unlike proximal DVT, nonextending calf DVT will rarely cause a PE.

Uncommon presentations of DVT include *phlegmasia cerulea dolens* (painful blue inflammation) and *phlegmasia alba dolens* ("milk leg"). In the former, the patient presents with an extensively swollen, cyanotic leg from venous engorgement due to massive iliofemoral thrombosis. This high-grade obstruction can compromise perfusion to the foot from high compartment pressures and lead to venous gangrene.⁸ Petechiae and bullae may be present on the skin. *Phlegmasia alba dolens*, usually seen in association with pregnancy, is also due to massive iliofemoral thrombosis, but the patient's leg is pale or white secondary to associated arterial spasm. Dorsalis pedis and posterior tibial pulses may be diminished or absent, which can lead to a false diagnosis of arterial occlusion. The arterial spasm with milk leg is transient and often followed by venous engorgement, suggesting the correct diagnosis. Patients with large iliofemoral thromboses are at significant risk of shock, gangrene, and major PE.

The PPS is manifest by signs and symptoms that can be difficult to differentiate from recurrent DVT. Pain, swelling, and occasionally ulceration of the skin can occur months to years after the resolution of DVT. Patients with postphlebotic venous insufficiency can have an acute exacerbation of pain and swelling likely secondary to venous dilatation and hypertension. Long-term follow-up of patients reveals that the PPS can occur in up to a third of patients who have had a previous proximal or calf DVT.³

Diagnosis

Owing to the poor accuracy of clinical methods in identifying DVT, **all patients with any signs or symptoms suggesting DVT should undergo an objective diagnostic evaluation.** Less than one third of patients with clinically suspected DVT are found to have the disease after objective investigation.⁷ Several investigative techniques are available to search for a deep thrombus, including plasma D-dimer level, impedance plethysmography (IPG), Doppler ultrasound (duplex), contrast venography, computed tomographic venography, radionuclide scintigraphy, and magnetic resonance imaging (MRI; Table 59-4).

Venography has represented the historical "gold standard" for the detection of DVT but is rarely required owing to the accuracy of noninvasive testing. It can be useful for patients with a high clinical prob-

ability of DVT when noninvasive tests are inconclusive, negative, or impossible to perform. Because it is the reference standard, venography, by definition, has a 100 percent sensitivity and specificity for detection of limb DVT. However, it is an invasive, often painful, and expensive test that is difficult to perform and may cause contrast-related reactions or iatrogenic phlebitis and DVT in about 1 to 3 percent of patients. When contrast is seen throughout the deep venous system (not possible in 5 to 10 percent of tests), a venogram reliably excludes DVT. Inadequate visualization of the deep venous system can occur due to difficulties with venous access (e.g., obesity, severe edema, and cellulitis), dilution of contrast in the proximal lower limb, or a previous thrombus. Computed tomographic venography is a more expensive but less sensitive test for DVT than plain venography or ultrasound and is not recommended.⁹

The choice test used to identify a DVT in North America is ultrasonography. Compression ultrasound (real-time B-mode imaging) produces two-dimensional images of a vein and its surrounding structures and can directly visualize a clot, whereas Doppler flow capacity, when combined with color images, provides a visual and audible evaluation of blood flow for venous obstruction. B-mode ultrasonography combined with Doppler flow is termed a *duplex*. A duplex scan with or without color flow has high sensitivity and specificity for a symptomatic, proximal DVT (clot proximal to the popliteal veins) of 97 percent and 94 percent, respectively, when compared with venography.⁷ Ultrasound is less accurate for detecting pelvic DVT (see below), and its sensitivity for a calf DVT is only 73 percent. It is also often difficult to distinguish an acute from chronic DVT by ultrasound.

Compared with IPG, ultrasound has higher sensitivity and positive predictive value for DVT. Both of these tests are portable, noninvasive, operator-dependent, safe, quick, readily accessible, and provide immediate information. Ultrasound requires more expertise (due to subjective interpretation) and is more expensive, but it remains the test of choice for DVT owing to its higher accuracy. Both tests are insensitive for calf DVTs, and serial testing is required to exclude the extension of clot to proximal veins (see below). Some centers will not routinely scan the leg for a calf DVT, choosing instead to do a more time-limited study looking only for the more significant proximal clots. An additional advantage of ultrasound is its ability to detect alternative pathologies, such as a Baker cyst, hematoma, lymphadenopathy, arterial aneurysm, abscess, and superficial thrombophlebitis.

TABLE 59-4 Diagnostic Tests for DVT

	Indication	Sensitivity (Proximal DVT)	Advantage	Disadvantage
Duplex	Extremity DVT	97%	Noninvasive, portable, detects alternative etiology	Poor sensitivity for calf DVT, serial testing needed
IPG	Duplex not available	>80%	Portable, inexpensive	Poor sensitivity, false-positives, serial testing needed
Venography	Duplex inconclusive or unavailable	100%	Readily available, highly accurate, visualizes calf DVT	Invasive, painful, contrast needed, may cause phlebitis
Radionuclide studies	Inpatients with inconclusive tests and contraindication to contrast	Variable	None	Delayed results, expensive
MRI	Duplex inconclusive, suspected pelvic DVT, PE also suspected	>95%	Noninvasive, highly accurate, safe during pregnancy, detects alternative etiology, distinguishes acute from chronic DVT	Expensive, not readily available, contraindicated with ferromagnetic prosthesis
D-Dimers ELISA Latex agglutination SimpliRED	Ancillary test	Variable 97% <80% 84-94%	Readily available Highly sensitive Inexpensive Bedside test	Poor specificity Expensive, time-consuming Poor sensitivity Interobserver variability

Abbreviations: duplex = Doppler ultrasound; DVT = deep vein thrombosis; ELISA = enzyme-linked immunosorbent assay; IPG = impedance plethysmography; MRI = magnetic resonance imaging; PE = pulmonary embolism.

Impedance plethysmography has been rapidly supplanted by ultrasound for evaluation of patients suspected of having DVT. IPG measures changes in electrical resistance in response to changes in calf volume secondary to venous obstruction. Meta-analysis of studies has shown that IPG has a sensitivity of 73 to 96 percent, specificity of 83 to 95 percent for proximal DVT, but a high negative predictive value of about 97 percent.^{5,7} False-positives can occur with PPS, abdominal or pelvic neoplasms, congestive heart failure, and pregnancy.

Radioisotopes have been used to detect DVT but are not particularly useful in the ED. Several radioisotopes are available, including ^{111m}In- or ^{99m}Tc-labeled antifibrin monoclonal antibodies, ¹²⁵I-labeled fibrinogen, and ^{99m}Tc-labeled red blood cells or macroaggregated albumin. These radioisotopes are incorporated into actively forming thrombi and can be detected by scanning the extremity hours or days after injection. The sensitivity of this technique is poor for proximal DVT, in particular pelvic veins, but about 90 percent for calf DVT, although with a high false-positive rate. Radioisotope evaluation for DVT is reserved primarily for inpatient assessment of diagnostically difficult patients with indeterminate results from other noninvasive tests and positive D-dimers. Radionuclide venography is expensive; time-consuming, results are not available for 24 to 72 h; and is not as accurate as IPG or a duplex for proximal DVT.

Magnetic resonance imaging is being recommended with increasing frequency as the alternative gold standard to venography for imaging the venous system. It is at least as accurate as any other investigational modality and can detect a filling defect in the entire extremity (including calf veins) and pelvic veins, which are not well visualized by ultrasonography or even venography. It is noninvasive, relatively fast, uses no ionizing radiation or contrast material, can distinguish acute from chronic DVT, and can be used to detect thromboembolic disease in pregnancy. An MRI visualizes both extremities simultaneously and can identify alternative causes of extremity swelling, such as cysts, aneurysms, hematomas, tumors, superficial phlebitis, joint effusions, and other masses. Some of the limitations of MRI include its cost, lack of ready availability, lack of portability, and inability to be used in patients harboring ferromagnetic objects (e.g., prostheses and pacemakers).

Recent literature has reported the usefulness of magnetic resonance direct thrombus imaging. This modality allows for direct visualization of the clot rather than of a filling defect. Magnetic resonance direct thrombus imaging detects methemoglobin in the thrombus and distinguishes it from blood and fat without the use of intravenous contrast. With an overall sensitivity of 95 percent for DVT compared with venography (91 percent for calf DVT), it can detect iliofemoral DVT with nearly 100 percent accuracy (compared with venography).¹⁰ As MRI scanning becomes more available and accessible, and scanning speed increases, its associated costs are likely to decline, making it a more attractive tool for DVT detection.

D-Dimer fragments, which are degradation products of fibrin, can be measured as an indicator of the presence or absence of DVT or PE. The reference standard against which all other assays are compared is the quantitative enzyme-linked immunosorbent assay (ELISA). Based on numerous studies, this test has a *mean* sensitivity of 97 percent and specificity of 35 percent for proximal DVT.¹¹ In low-risk patients, the sensitivity is 99 percent. At a discriminate level of less than 500 ng/mL (xg/L) by ELISA, the likelihood of DVT is less than 1 percent, so it is helpful to exclude a venous thrombosis, but the test is expensive and takes several hours to perform. This limits the usefulness of the standard ELISA as a practical ED tool. To overcome this shortcoming, newer rapid quantitative and qualitative ELISA are now available that have similar sensitivities as the standard ELISA, but with a turnaround time of less than 1 h. A second type of D-dimer assay, latex agglutination, is rapid and inexpensive, but not clinically useful due to a sensitivity of less than 80 percent for detecting DVT.⁶ All D-dimer assays are fairly nonspecific tests, as many other conditions, such as sepsis, surgery, trauma, hemorrhage, pregnancy, cardiovascular disease (myo-

cardial infarction, stroke), collagen vascular disease, liver disease, and cancer, are associated with an elevated level. Therefore, it follows that **a D-dimer level is useful only when it is low.**

The most common D-dimer assays recently studied are the third type based on whole blood agglutination. A particularly popular bedside assay, SimpliRED, uses monoclonal antibodies directed against D-dimer and red blood cell surface. This test requires only a drop of blood and provides a result in less than 5 min. The sensitivity of this assay in clinical trials has varied between 84 and 94 percent.⁶ A notable concern with qualitative bedside tests such as the SimpliRED is the potential for interobserver variability due to ambiguity in interpretation of a visual marking. The Joint Commission on the Accreditation of Healthcare Organizations also requires strict quality control for bedside testing.

Clinical Approach to Establishing the Diagnosis

Assessing the pretest clinical probability with a validated instrument such as the Wells model (see Table 59-3) allows for accurate risk stratification of patients and helps guide an appropriate diagnostic strategy. Serial testing and the combination of tests have become the norm in many institutions and are supported by numerous proposed algorithms in the literature. However, the approach at any given institution is dependent on availability of resources, physicians' preferences, and local expertise.

Figure 59-1 outlines a practical, cost-effective approach to diagnosing DVT. Some basic assumptions and facts were used in the formulation of this algorithm. Because the diagnosis of DVT is difficult to establish based solely on history or physical examination, some type of objective testing is necessary. Unless a rapid ELISA D-dimer assay is readily available, a duplex scan will be required as the initial imaging of choice. In low- to moderate-risk patients, a negative ELISA accurately excludes DVT, with a negative predictive value above 99 percent.¹² Use of the SimpliRED test alone to exclude DVT in low-risk patients is controversial and not universally accepted due to variable sensitivities reported in the literature. A recent study did indicate a 100 percent negative predictive value of the SimpliRED assay in low-risk emergency patients, but the prevalence of DVT was only 13 percent in the study population.¹² Patients with a negative duplex scan can be managed in a variety of ways: (1) no further testing in low-risk patients, (2) D-dimer assay (whole blood agglutination or ELISA), or (3) repeat duplex in 1 week. An initial negative duplex scan in low-risk patients or two negative duplex scans 1 week apart carry a less than 1 percent risk of symptomatic proximal DVT or PE at 3 months

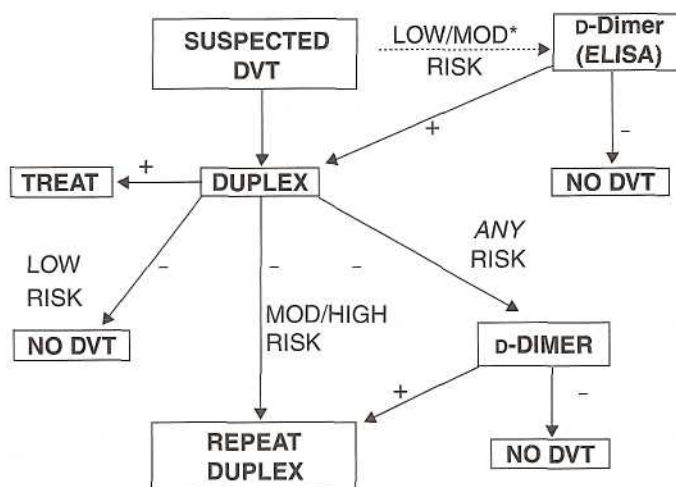

FIG. 59-1. Diagnosis of deep vein thrombosis (DVT). *If available and rapid. Duplex = Doppler ultrasound; ELISA = enzyme-linked immunosorbent assay.

follow-up.^{6,12} Serial duplex scanning, however, is costly and inconvenient for patients with a positive yield of only 1 percent for proximal DVT if all patients with an initial negative ultrasound are rescanned. The negative predictive value of a low D-dimer assay and negative initial duplex scan or IPG is 99 percent or greater for proximal DVT and only slightly lower for calf DVT.^{6,7,13}

In patients with risk factors and in whom duplex or IPG is positive, anticoagulation therapy may be initiated, if there are no contraindications. If the diagnosis is equivocal or there is potential for false-positive or false-negative results, contrast venography or MRI can be performed.

Treatment

Traditional therapeutic measures, including bed rest, continuous leg elevation, and elastic stockings, are of unproven benefit when used in addition to anticoagulation in the management of a DVT. Aggressive anticoagulation will prevent extension of clot and allow for its lysis by the intrinsic fibrinolytic pathways. Early ambulation with appropriate analgesia, as needed, after adequate anticoagulation with heparin is a practical and safe approach. The PPS can be treated with periodic leg elevation, compression stockings, and pain medications, as required.

Prevention of PE is the primary objective in treating DVT. Several studies have documented the accuracy of serial duplex examinations and the safety of withholding anticoagulation in patients clinically sus-

6,7,13

A suspected of having DVT but with a normal initial ultrasound, repeat duplex should be done in these patients 7 days after initial examination. If the second duplex scan is negative, the patient need not be imaged again unless symptoms or signs progress. The risk of a PE within 7 days of a normal duplex scan in patients with symptoms of DVT of the lower extremity is nearly zero. The probability of detecting a proximal DVT on a second ultrasound when there is a normal duplex scan from the week before is approximately 1 percent.¹¹ Subsequent thromboembolism (typically nonfatal) within 3 months of two normal serial duplex studies occurs in about 0.6 percent of patients, which is comparable to the outcome in patients with normal venograms.¹³ Thus, withholding anticoagulation in patients with negative serial ultrasounds is safe, accurate, and cost-effective. However, anticoagulation is recommended for nonextending calf DVT in high-risk groups such as patients with a history of a previous proximal DVT or PE, significant cardiovascular comorbidity (higher risk of fatal PE), a persistent hypercoagulable state, or continued immobilization.

Proven proximal DVT requires immediate anticoagulation to reduce local morbidity and prevent thromboembolism. The preferred treatment is LMWH, such as ardeparin, dalteparin, enoxaparin, nadroparin, reviparin, or tinzaparin. These are *weight adjusted* and given once or twice daily subcutaneously until oral anticoagulation reaches the therapeutic range. The three most commonly used LMWHs for treatment of DVT in North America are dalteparin (200 units/kg every 24 h; maximum, 18,000 units), enoxaparin (1.5 mg/kg every 24 h; maximum, 180 mg), and tinzaparin (175 units/kg every 24 h; maximum, 18,000 units), with dosage based on actual rather than on ideal body weight. The available LMWH agents are *not* simply interchangeable due to differing pharmacokinetic and pharmacodynamic profiles. Despite the recommended maximum daily doses by the manufacturers of these drugs, it is not uncommon for physicians to use higher doses for overweight patients. These drugs have several advantages over UFH, including a more predictable anticoagulant effect, ease of administration, longer half-life, lack of a need to monitor the anticoagulation effect, and a lower incidence of major bleeding and heparin-induced thrombocytopenia (HIT).¹⁴ Low-molecular-weight heparin has a preferential inhibitory effect on factor Xa rather than on factor IIa (thrombin), and the partial thromboplastin time (PTT) cannot be used to monitor its effect. Measurement of anti-Xa levels is expensive, not readily available,

and unnecessary given the very predictable effect of these heparins. However, because all LMWHs are cleared by the kidneys, there is a prolonged effect, with a higher risk of bleeding in renal failure patients unless anti-Xa levels are closely monitored. For this reason, LMWH generally should be avoided in outpatients with a creatinine level higher than 180 μ mol/L (2.03 mg/dL). These patients will require UFH or dose adjustments of LMWH based on anti-Xa levels. Reviparin need not be adjusted in renal patients if given in standard prophylactic doses. **One need not wait for the creatinine result before initiating LMWH therapy**, but subsequent doses should be adjusted with evidence of renal insufficiency.

The once-daily use of LMWH in outpatient treatment has revolutionized the management of DVT and is at least as effective and safe as UFH in the treatment of DVT or PE.¹⁴ Several meta-analyses comparing intravenous UFH with subcutaneous LMWH for treatment of DVT have noted a lower mortality, less major bleeding, reduction in clot extension, and fewer recurrent thromboembolic events in favor of LMWH.¹⁵ The ability to discharge most patients home from the ED after an initial dose of LMWH with next-day follow-up is clearly a safe, practical, and cost-effective strategy that is acceptable to the vast majority of physicians and patients. The treatment plan must be discussed with the continuing care physician, including follow-up in 24 h and institution of warfarin at the same time as LMWH. The patient or the caregiver also will require education regarding administration of LMWH. This can be done during the follow-up visit.

Indications for admission include instability to ambulate, poor social support, unreliable follow-up, difficulty with education for drug administration, need for lytic or invasive therapy, and an alternative serious diagnosis under investigation or that requires treatment (e.g., arterial ischemia, cellulitis, or pelvic mass).

If LMWH is not available or contraindicated, a continuous infusion of UFH can be started until LMWH is initiated or oral anticoagulation reaches therapeutic levels. Weight-adjusted dosing of 80 units/kg bolus followed by an infusion of 18 units/kg per h will rapidly achieve a therapeutic activated PTT (aPTT). (Traditional dosing of a 5000-units bolus followed by an infusion of 1000 units per h will result in subtherapeutic aPTT at 6 h in two thirds of treated patients.) The infusion is adjusted to keep the aPTT between 55 and 80 s (1.5 to 2.5 times normal).

Close monitoring of patients is required to detect bleeding, HIT, and thrombosis. Serious bleeding due to LMWH is very unusual, but, if it occurs, the anti-Xa effect cannot be completely reversed. Protamine can counteract the minor antithrombin effect of LMWH and has been useful to reverse bleeding complications, although its use has been associated with hypotension and anaphylactoid reactions. In the uncommon scenario when heparin is contraindicated in the acute management of DVT, as in patients with HIT, a thrombin inhibitor, such as lepirudin, is an effective alternative. Lepirudin is administered as a 0.4-mg/kg slow bolus over 15 to 20 s (maximum, 44 mg), reduced in half for renal patients. Subsequent infusion is 0.1 to 0.15 mg/kg per h (maximum, 11 mg per h) to keep PPT at 1.5 to 2.5 times normal. In pregnant patients, danaparoid is the preferred agent when heparin cannot be used (1500 to 2250 units SC every 12 h). **Monitoring is not required except in the presence of renal disease.**

It is a common and accepted practice to start heparin (including LMWH¹⁶) and warfarin simultaneously, because early warfarin administration has been shown to be safe and effective. The procoagulant effect before reduction of prothrombin concentrations, particularly in patients with protein C or S deficiency, is controlled by the simultaneous administration of heparin. A loading dose of warfarin is unnecessary. An initial daily dose of 5 mg of warfarin is adjusted to maintain the INR between 2 and 3. A lower initial dose of warfarin may be used in the elderly (4 mg) and in patients with liver disease or at higher risk of bleeding. Heparin is typically continued until the INR is in the therapeutic range for 2 consecutive days (usually 5 to 7 days).

Warfarin is associated with some serious potential adverse effects and should not be used in certain circumstances. The most common adverse effect is bleeding, usually related to the degree of anticoagulation, and typically responds to dose reduction. Skin necrosis secondary to warfarin occurs primarily in patients with a deficiency of protein C or S. The necrosis is due to thrombotic occlusion of small vessels, usually 3 to 8 days after initiation of this drug. Warfarin is contraindicated in patients who are pregnant, have a serious or active bleeding diathesis, or have had very recent major surgery (thoracoabdominal, nervous system, spine, or eye). It causes fetal bleeding and is teratogenic. (Neither UFH nor LMWH crosses the placenta, and both are safe for the fetus.) Low-molecular-weight heparin is the preferred drug for the treatment of a DVT in pregnancy and is continued until delivery. Warfarin can be safely started in the postpartum period, even in breast-feeding women, and is usually continued for 4 to 8 weeks.¹⁷

The duration of warfarin treatment has to be individualized and depends on a history of previous DVT or PE, reversibility of previous thromboembolic risk factors, the effectiveness of warfarin to resolve thrombosis, and the risk of bleeding. Oral anticoagulation should be continued for 3 months for patients with proximal DVT when reversible risk factors are identified. There is no evidence that a longer course of warfarin is needed for patients with PE. For patients with idiopathic DVT or recurrent thromboembolic disease, prolonged anticoagulation for at least 6 months is recommended.¹⁸ Life-long anticoagulation may be necessary in patients with ongoing risk factors, such as hypercoagulable states and malignancy. The recurrence of thromboembolic disease is related to patient-specific risk factors but is estimated to be 6 percent at 1 year and 13 percent at 5 years, despite adequate anticoagulation therapy for the initial DVT. Patients who present with a new or progressive clot despite adequate anticoagulation with warfarin should have LMWH initiated and be investigated for a hypercoagulable state on an urgent outpatient basis. Warfarin resistance is commonly seen in patients with metastatic disease.

The issue of initiating anticoagulation and interference with evaluation for possible hypercoagulability occasionally arises. Because **LMWH does not alter the ability to investigate hypercoagulable states**, there is no need to procure additional blood samples beyond routine coagulation studies in patients with a straightforward DVT. Further, acute-phase reactants can alter blood results with an acute DVT or PE. Initiation of UFH therapy is likely to interfere with the evaluation of hypercoagulability. However, such investigations for the underlying etiology of a DVT typically do not alter management. Thus, patients may be investigated at a later date, when anticoagulation is completed. When a patient is seen in follow-up, hematologic testing includes factor V Leiden, prothrombin molecular tests, screening for antiphospholipid anticoagulants, and a fasting homocysteine level. Upon completion of anticoagulation, further evaluation includes antithrombin III, protein C, protein S, and factor VIII levels, plus other patient-specific tests, as required. When a patient presents with a refractory or progressive clot despite warfarin treatment, LMWH should be initiated, and an urgent referral to a hematologist is necessary. If, for some reason, UFH is used to treat a patient with warfarin-refractory DVT, then at least two extra blood tubes should be obtained before initiation of treatment, and those samples should be held for further testing by the hematologist.

Thrombolytic and Mechanical Therapy

Currently, no controlled clinical trials have shown a survival benefit of thrombolytics over heparin and warfarin. Despite the fact that thrombolysis results in better early vein patency and venous valve integrity, a reduction in the risk of PPS is unproven.¹⁹ In practice, thrombolytic drugs are rarely used to treat DVT. Thrombolytics have a significantly greater bleeding risk, including fatal intracerebral hemorrhage, than does heparin or warfarin. There is a greater risk of bleeding with

thrombolytic use in DVT than in myocardial infarction, likely related to the longer duration of therapy for DVT. The appropriate role of catheter-directed therapy in DVT is unknown, because adequate studies have not been done, but appears reasonable for patients *with phlegmasia cerulea dolens*.

Thrombolysis for DVT, in general, can be considered for extensive iliofemoral thrombosis and upper extremity DVT in patients with a low risk of bleeding. A standard systemic regimen of streptokinase is a loading dose of 250,000 units over 30 min, followed by an infusion of 100,000 units per h for 72 h. For alteplase (tPA), infusions of 0.05 to 0.5 mg/kg per h have been used for variable lengths of time, from hours to days.¹⁹ Catheter-directed thrombolysis with a catheter placed in the popliteal or femoral vein can be done with a tPA bolus of 2 to 10 mg followed by an infusion of 1 to 4 mg per h for 4 to 12 h. Unfractionated heparin should not be given with streptokinase but is optional concurrently with tPA infusions.

An inferior vena cava filter can be placed to prevent a PE when oral anticoagulation is contraindicated, a major complication of anticoagulation occurs (e.g. bleeding, HIT), a DVT persists or propagates despite adequate medical treatment, or embolization occurs after 1 to 2 weeks of therapeutic anticoagulation. Given the ease of insertion, low complication rate, and greater than 95 percent patency rate of a Greenfield filter at 1 year after placement, its indications may be expanded. A free-floating, nonadherent iliofemoral thrombus larger than 5 cm has an up to 60 percent chance of forming a PE; in such cases, filter placement should be considered. These devices reduce the rate of PE but have not been shown to improve early or late survival. After filter placement, there is risk of recurrent DVT unless anticoagulation is initiated.

Surgical thrombectomy was enthusiastically received in previous decades, but owing to high rates of rethrombosis and failure to prevent postphlebotic sequelae, it is rarely considered today. When conventional therapy for DVT is contraindicated or ineffective, thrombectomy followed by heparin and warfarin can achieve long-term patency. Surgical treatment of a DVT is typically reserved for patients when limb viability is jeopardized by a massive venous clot, such as a persistently ischemic leg secondary to *phlegmasia cerulea dolens*.

The ED management of patients who are adequately anticoagulated but present with propagation or a new clot is fairly straightforward. These patients should be started on LMWH with urgent follow-up (or, if otherwise indicated, admission). If they fail LMWH or have large free-floating thrombi, a Greenfield filter should be emergently placed by an interventional radiologist or vascular surgeon. The investigation of these patients for a hypercoagulable state or malignancy need not be initiated in the ED. There is no evidence in the literature that increasing anticoagulation beyond an INR of 3 is effective in treating refractory DVT.

Pelvic Vein Thrombosis

Thrombosis of the pelvic veins typically occurs as an extension from the femoral vein. An isolated pelvic vein clot is extremely uncommon but can occur as a complication in the postpartum period, with pelvic inflammatory disease, and after pelvic surgery or trauma. Clinical presentation of an isolated pelvic vein thrombosis can be difficult to recognize, because the patient may present with nonspecific abdominal symptoms of pain and vomiting without any significant leg findings. Septic pelvic vein thrombophlebitis is a rare but life-threatening condition that may occur with postpartum endometritis and can lead to septic pulmonary emboli. Diagnosis can be difficult because ultrasound and even contrast venography are less accurate than MR venography and computed tomography (CT) with contrast. Treatment of pelvic vein thrombosis is similar to therapy for lower extremity DVT, and surgical clot evacuation is usually unnecessary except in cases of associated pelvic infection.

Axillary and Subclavian Vein Thromboses

Although up to 90 percent of all DVTs occur in the lower extremities, 2 to 4 percent develop in the axillary or subclavian vein. The risk factors for developing a venous thrombus in the upper extremity are outlined in Table 59-2, with a higher incidence being associated with current or recent central venous catheters or transvenous pacemakers, intravenous drug use, excessive or unusual exercise (effort thrombosis), malignancy, and other hypercoagulable states. A predisposing venous stricture or chronic compression (cervical rib, hypertrophied scalene muscle, congenital web, etc.) is commonly detected as a causal factor. Presentation can be an abrupt or gradual onset of swelling in the arm, associated with dilated veins in the hand and forearm. The arm may feel heavy, with pain on physical activity that is relieved with rest. Sudden onset of severe pain and swelling with a change in the color of the arm is a rare presentation. The initial imaging study for investigating a suspected venous thrombosis of an upper limb is by duplex scanning, which has a sensitivity of 56 to 100 percent.²⁰ Venography or MRI may be required when there is high clinical suspicion of DVT, despite a negative duplex.

It is estimated that a PE occurs in 5 to 10 percent of cases involving axillary or subclavian DVTs, although a rate as high as 36 percent has been reported with catheter-associated upper extremity DVT.⁵ Current treatment options include anticoagulation alone or preceded by catheter-directed thrombolysis. The choice of therapy should be discussed with the consulting vascular surgeon and invasive radiologist but should be individualized. The underlying cause, duration of symptoms, comorbidity, and contraindications to thrombolytic agents or anticoagulants can help guide the choice of the most appropriate therapy. Resolution of symptoms and signs depends not only on therapy but also on the development of collateral flow. After initial therapy, an underlying compressive abnormality or venous stenosis, if present, must be corrected (e.g., rib resection and balloon angioplasty).

OCCLUSIVE ARTERIAL DISEASE

Acute limb ischemia secondary to thrombosis or embolism is a true emergency requiring immediate therapy to salvage the limb. Despite improvements in management, mortality is in excess of 25 percent, and amputation is required in 20 percent of survivors. The emergency physician must urgently initiate treatment and investigation of a threatened limb in collaboration with the radiologist and vascular surgeon. An understanding of the pathophysiology, etiology, and clinical presentation of peripheral vascular disease will help guide management in the effort to restore blood flow to the affected limb.

Epidemiology

Intermittent claudication has a prevalence of between 2 and 6 percent for men older than 55 years. With objective noninvasive testing, however, peripheral arterial disease is noted in 11 to 27 percent of elderly men and women equally.²¹ Symptoms of this disease increase with age and are two to four times more common in men than in women. Most of these patients have a long history of smoking, although diabetes, hyperlipidemia, hypertension, and hyperhomocysteinemia are significant risk factors. There has been an increase in the incidence of chronic limb ischemia and arterial embolic disease in the past two decades. At least half of these patients have coronary or cerebrovascular disease. The severity of peripheral vascular disease is closely linked to the risk of myocardial infarction, ischemic stroke, and death from vascular disease.²¹ The most frequently diseased arteries leading to limb ischemia include, in order of occurrence, femoropopliteal and tibial, aortoiliac, and brachiocephalic vessels. Embolic occlusion of an artery also occurs primarily in elderly men and postmenopausal women, given the higher prevalence in this group of heart disease, which is the major source of thromboemboli.

Pathophysiology

Acute limb ischemia results from a blood supply that is inadequate to meet tissue oxygen and nutrient requirements. Ultimately, it will lead to cell death and irreversible tissue damage. Even after perfusion is partly or completely restored, reperfusion injury can occur as oxygen radicals form and cause further cell injury. Reperfusion may not be fully attainable with prolonged arterial obstruction due to distal edema and thrombi forming in the microcirculation. The extent of injury depends on the duration and location of the arterial blockage, the amount of collateral flow, and the previous health of the involved limb. Also, some tissues are more susceptible than others to anoxia, presumably on the basis of differences in cellular respiration and oxygen requirements. Peripheral nerves and skeletal muscle are very sensitive to ischemia, and irreversible changes occur in these tissues within 6 h of anoxia at room temperature.

Nonembolic limb ischemia is secondary to atherosclerosis in the vast majority of patients. Plaque formation within the intima of an artery results from lipid accumulation, proliferation of smooth muscle cells, and fibrogenesis. Further narrowing of the vascular lumen occurs with progression of the atheromatous plaque. Complete or high-grade obstruction can occur at this site of stenosis secondary to plaque rupture or endothelial erosion, which triggers a thrombus formation. Progression of ischemic injury can occur through several mechanisms: (1) propagation of clot to occlude collateral vessels, (2) ischemia-related distal edema leading to high compartment pressures (compartment syndrome), (3) fragmentation of clot into the microcirculation, and (4) edema of the microvasculature cells. Obstruction of the microvasculature can result in distal perfusion impairment despite successful large vessel reperfusion. Uncommonly, arterial thrombosis is noted in an apparently normal vessel with absence of a preexisting atherosclerotic plaque prompting a hypercoagulable workup, but subclinical injury or early atherosclerosis may still underline these events.

An atherosclerotic vessel can give rise to an aneurysm because of its weakened walls. A true aneurysm, involving dilatation of its entire wall, can present clinically with thrombosis, rupture, and hemorrhaging or by its mass effect on adjacent structures.

Etiology

Contrary to previous thought, the recent literature indicates that thrombotic occlusion is a significantly more common cause of acute limb ischemia than is embolism. In the lower limbs, embolic occlusion accounts for fewer than 20 percent of all cases.²² In the upper limbs, most cases of acute limb ischemia are thrombotic and about one third are due to embolism and nearly one fourth secondary to arteritis.²³ Nevertheless, the distinction between a thrombotic and embolic etiology in any given patient is fraught with inaccuracy. Bypass graft thrombosis is occurring with increasing frequency as the rate of revascularization procedures increase for chronic lower limb ischemia.

Emboli originate from the heart in 80 to 90 percent of cases. Atrial fibrillation is associated with at least two thirds of all peripheral emboli, and clot is found most commonly in the left atrial appendage. Mural thrombus in the ventricle after recent myocardial infarction is the second most frequent source, accounting for about 20 percent of all limb emboli. With adequate anticoagulation, the incidence of an embolus originating from a mechanical valve has greatly diminished. Rare cardiac sources of emboli include tumor emboli from atrial myxomas, vegetations from valve leaflets, and parts of prosthetic devices, such as mechanical valves.

Noncardiac sources of arterial emboli include thrombi from aneurysms and atheromatous plaques. Mural thrombus in aneurysms of aortoiliac, femoral, popliteal, and subclavian arteries are the most notable sources. Atheroemboli result from plaque fragmentation and cause obstruction of the microcirculation, thereby producing symptoms in the feet ("blue toe syndrome"), hands, or cerebral circulation

(transient ischemic attack). Iatrogenic embolization during angiographic procedures of the aorta and larger vessels is another likely source of atheroemboli and can be showered to multiple parts of the body. In addition, paradoxical embolization can occur when a venous clot passes from the right to the left side of the heart through an intracardiac shunt, most commonly a patent foramen ovale.

The natural history of an embolus is to fragment and embolize distally or to propagate locally into a larger clot, although associated venous thrombosis can occur, possibly secondary to local ischemia, decreased venous flow, and inflammation. Two thirds of all noncerebral emboli enter vessels of the lower limbs and locate where vessels branch or taper. The most common location for an embolus in the leg is the bifurcation of the common femoral artery followed by the popliteal artery. In the upper limb, the brachial artery is the most common location for an embolism to lodge.

Thrombosis unrelated to atherosclerotic disease can occur at an area of vessel injury, as with invasive catheters, balloons, sites of bypass grafting, or intraarterial drug injection, and with hypercoagulable states. All are potential sources of embolization. Femoral artery catheterization for coronary angiography or angioplasty and vascular access can result in ischemia of an extremity secondary to thrombosis or expanding hematoma; symptoms may be altered by preexisting aortoiliac or femoropopliteal plaques. Radial artery injury during blood gas analysis or the placement of arterial lines rarely leads to tissue ischemia, given the excellent collateral supply from the ulnar artery. Intentional or accidental intraarterial drug injections by medical personnel or for illicit drugs can result in local vasospasm, infectious arteritis, thrombosis, pseudoaneurysms, and mycotic aneurysms. Inert particles or drug crystals can embolize to obstruct end arteries, leading to gangrene of digits, especially as drug users tend to delay seeking medical attention.

Peripheral arterial supply also can be obstructed by vasospastic or inflammatory conditions. *Raynaud disease* involves vasospasm in small arteries and arterioles in response to a stressor, such as cold temperature or emotional stress. Symptoms of local pain, pallor followed by cyanosis, numbness, and paresthesias usually involve the fingers and hands and generally resolve within 30 to 60 min, especially with rewarming. Inflammation of arteries in the limb can occur with collagen vascular diseases, such as rheumatoid arthritis, lupus, and polyarteritis nodosa. When clinically active, these vasculitides are often associated with systemic symptoms and multiorgan involvement. Necrosis of blood vessels and loss of limb tissue is always a possibility. *Thromboangiitis obliterans* (Buerger disease) is an idiopathic occlusive disease resulting from segmental inflammation of arteries in all extremities. It occurs almost exclusively in young smokers (age 20 to 40 years), predominantly males, and is characterized by painful, tender nodules in the limbs with decreased distal flow.

Limb ischemia may occur with nonembolic central causes. A thoracic aortic dissection can propagate into the carotid, subclavian, and iliofemoral systems and present with neurologic and extremity findings. The false lumen created by the dissection occludes flow in the involved artery. *Takayasu arteritis*, which primarily occurs in Asian females, involves the aortic arch and its branches and has a "pulseless phase" when peripheral ischemia and necrosis can develop.

More commonly, low cardiac output states with cardiogenic or hypovolemic shock may present with extremity ischemia in the presence of previous existing arterial disease. Severe left ventricular dysfunction, which can occur with ischemic cardiomyopathy, valvular heart disease, and cardiac tamponade, acutely threatens limb blood flow, particularly in elderly patients with preexisting atherosclerosis. Acute hemorrhage similarly reduces perfusion to the limbs but, with acute intervention, may be reversible.

Clinical Features

Patients with acute limb ischemia will exhibit one or more of the "six Ps": pain, pallor, polar (for cold), pulselessness, paresthesias, and

paralysis. However, a lack of one or more of these findings does not exclude ischemia. Further, total occlusion of a severely diseased artery in patients with peripheral vascular disease with well-developed collateral blood supply may not be a dramatic event and is occasionally silent. Pain alone may be the earliest symptom of ischemia, localized in the limb distal to the site of obstruction. High clinical suspicion is paramount to early intervention to save a limb. Complete arterial obstruction results in visible skin changes, with initial pallor that may be followed by blotchy, mottled areas of cyanosis and associated petechiae and blisters. Livedo reticulosis may be evident. Severe, steady pain in the involved extremity associated with decreased skin temperature is expected. Hypoesthesia or hyperesthesia due to ischemic neuropathy is typically an early finding, as is muscle weakness. An absent palpable pulse distal to the arterial obstruction is not very helpful. It may be an abrupt new sign of an occlusive clot or a longstanding finding of chronic vascular disease. However, an abrupt loss of a previously strong pulse strongly suggests an embolus. As ischemic injury progresses, anesthesia and paralysis become evident and foreshadow impending gangrene. Preservation of light touch on skin testing is a good guide to tissue viability. Necrosis of skin and fat is a late finding.

Despite the generally held belief that limb salvage is possible with reperfusion within 4 to 6 h, tissue loss can occur with significantly shorter occlusion times. As important, mild to severe limb dysfunction is possible even with an injury involving only brief anoxia, with potential for lasting disability. The poor predictability of functional outcome after ischemic injury underscores the need to attain rapid reperfusion and not rely on a probable safe interval until resolution of occlusion. Disability and tissue loss are inevitable after 6 h of occlusive anoxic injury.

Microemboli present clinically with pain and cyanosis in the involved digit, petechiae, and local muscle pain and tenderness at the site of infarction. Several different small areas can be affected with a shower of microemboli originating from a large or unstable source. Although mottling and decreased function may occur, pulses are preserved.

Chronic peripheral arterial insufficiency is characterized by intermittent claudication, which may progress to intermittent ischemic pain at rest. Femoral and popliteal disease often causes reproducible calf pain with activity that is relieved with rest. Pain at rest typically localizes to the foot and is aggravated by leg elevation, improves with standing, and is poorly controlled with analgesics. Shiny, hyperpigmented skin with hair loss and ulceration, thickened nails, muscle atrophy, vascular bruits, and poor pulses are the hallmark of chronic vascular disease. Complete arterial occlusion from thrombosis of a limb in these patients may present subacutely owing to a well-developed collateral circulation.

Diagnosis

Clinical evaluation is the most useful diagnostic tool for the assessment of occlusive arterial disease. A history of an abruptly ischemic limb in a patient with atrial fibrillation or recent myocardial infarction is strongly suggestive of an embolus. Acute ischemia in the limb of a patient known to have advanced peripheral vascular disease is more likely due to thrombosis or a low cardiac output state. In a patient with embolic obstruction, it is unusual to have a history of claudication, and an examination of the uninvolved limb often reveals no evidence of occlusive disease.

At the bedside, blanching the involved extremity with finger pressure and noting a delay in the return of blood as compared with the uninvolved extremity indicates decreased perfusion. However, several factors can influence capillary refill; thus, one cannot rely on the presence or absence of this finding alone.

A hand-held Doppler can document the amplitude of flow or its absence when held over the dorsalis pedis, posterior tibial, popliteal, or

femoral arteries in the lower limb and over the radial, ulnar, brachial, or axillary arteries in the arm. If Doppler flow is detected in the affected limb, an ankle-brachial index (ABI) and segmental leg pressures should be checked. The ABI is the ratio of the systolic blood pressure with the cuff just above the malleoli (with the Doppler probe over the posterior tibial or dorsalis pedis artery) to the brachial pressure in the arm. Patients with chronic peripheral vascular disease have an ABI less than 1.0. With acute arterial obstruction, there is a significant difference in the ABI of the involved (usually <0.5) and uninvolved lower extremities. Segmental blood pressures with Doppler on the posterior tibial or dorsalis pedis and the cuff placed below the knee, above the knee, and high thigh are also useful. A difference of 30 mm Hg or more between any adjacent levels accurately localizes the site of obstruction. With successful reperfusion, the ABI and segmental pressures begin to return to baseline or normalize if no residual obstruction remains after clot dissolution.

If time permits or the diagnosis of arterial occlusion is in question, duplex ultrasonography can be undertaken to detect an obstruction to flow. It is very accurate for detecting obstruction in the common femoral, superficial femoral, and popliteal vessels and at previous bypass grafts. Sensitivity declines for localization of thromboembolic occlusion at calf level and below. In patients with severe peripheral vascular disease (PVD), duplex ultrasonography can detect even incomplete obstruction with a sensitivity greater than 85 percent. Similarly, duplex ultrasonography has high sensitivity for detecting obstruction in the axillary, subclavian, and brachial arteries. (Nevertheless, the diagnostic modality of choice is usually arteriography.) Cardiac monitoring and an electrocardiogram will detect a dysrhythmia, and an echocardiogram can be done to look for an intracardiac thrombus, if such is clinically suspected.

In consultation with a vascular surgeon and during the period of preoperative and/or medical management, an arteriogram can be done to confirm the diagnosis, define the vascular anatomy and perfusion, and guide aggressive management. A particular advantage of arteriography is the ability to perform this test on the operating room table before and during surgery. Use of magnetic resonance arteriography for a limb, although accurate and noninvasive, usually is not practical, given the time constraints, in the face of an acutely ischemic limb. However, when an aortic dissection or sources of microemboli, such as aortoiliac or femoral aneurysms, are suspected, an aortogram, CT, or MRI can be useful. Computed tomography, which is the most readily available among these in most EDs, has a sensitivity similar to that of aortography. Magnetic resonance imaging has higher sensitivity and specificity but is not readily available. Transesophageal echocardiography is also an accurate modality for detecting cardiac or aortic root pathology.

Treatment

The goals of therapy for acute arterial obstruction include restoration of blood flow, preservation of limb and life, and prevention of recurrent thrombosis or embolism. Although no studies to date have established an unequivocal beneficial role of any generally administered antithrombotic agent for acute arterial occlusion, when the diagnosis of acute limb ischemia is known or suspected, current practice is the immediate administration of intravenous UFH, if no contraindications exist. Several authorities suggest that a larger initial bolus be given. Dosing is the same as for DVT. This may help prevent clot extension, recurrent emboli, venous thrombosis, the appearance of microthrombi distal to the obstruction, and reocclusion after reperfusion.²⁴ It is still unclear whether heparin improves outcome in the clinical circumstances of thrombosis in a plaque-laden artery.

Fluid resuscitation and treatment of heart failure and dysrhythmias are sometimes necessary to improve limb perfusion.

Definitive treatment of an obstructing clot should be done in conjunction with a vascular surgeon. Choices for treatment include throm-

bolysis, percutaneous mechanical thrombectomy, and standard surgery. Prompt surgical embolectomy is the optimal therapy for an acute arterial embolism causing limb-threatening ischemia. Catheter embolectomy has been the preferred technique for removal of clot ever since the development of the Fogarty balloon catheter in 1963. It has reduced mortality from arterial emboli by 50 percent and need for amputation by 35 percent.²⁴ Overall mortality from an arterial embolus is about 15 percent and is usually due to the underlying cardiovascular disease. The limb salvage rate ranges from 62 to 96 percent. Similarly, balloon catheters are usually effective in thrombotic occlusions. For bypass graft occlusions, replacement of the graft is preferred to thrombectomy by most vascular surgeons.

Use of thrombolytics as the sole or part of combination therapy for acute limb ischemia is still quite controversial. Catheter-directed, intraarterial thrombolysis is associated with better reperfusion rates than is systemic thrombolysis for arterial clots.²⁴ Ample literature documents the use of streptokinase and tPA infused for hours to days as an alternative to surgery, with a rate of successful reperfusion of 50 to 85 percent.²⁴ Drawbacks to the use of thrombolytics include delay of reperfusion, which may be hours after initiation of drug, and the significant risk of local and systemic bleeding, including fatal intracerebral hemorrhage.

Randomized, multicenter trials have compared thrombolysis with surgery in the management of acute arterial obstruction, and the results do not show decreased mortality, better limb salvage, improved safety, or lowered costs of treatment. Thus, thrombolysis cannot be considered a standard for routine use. However, it is an attractive option for selected patients who may be poor surgical candidates or for distal thromboembolic occlusion in small arteries (such as in the hands, legs, and feet) that are surgically inaccessible and for acute thrombosis in a limb with chronic arterial insufficiency and adequate collateral flow.²⁴

Thrombotic occlusion in arteries with advanced atherosclerosis and a well-developed collateral blood supply often will present subacutely. Management of this condition therefore is more conservative, with heparin alone. An angiogram is helpful to direct therapy and exclude embolic occlusion (radiologically seen as an abrupt cutoff of blood flow in a disease-free or minimally diseased vessel) when limb viability is acutely threatened.

Upper Extremity Ischemia

Acute arterial occlusion in the upper extremities is significantly less common than in the lower limbs. With a well-developed collateral circulation around the shoulder and elbow, arterial occlusion is much better tolerated. Ischemic rest pain and gangrene are rare in the upper limb in the absence of distal embolization. Etiology of upper limb ischemia includes vasospasm, arteritis, trauma, atherosclerotic plaque rupture, embolism, iatrogenic injury (e.g., brachial artery access for cardiac catheterization), thoracic outlet syndromes, aneurysms, and hypercoagulable states. After clinical examination, further investigation of suspected ischemia is done with segmental blood pressure measurements above and below the elbow, Doppler evaluation, duplex ultrasonography, and arteriography. Treatment of acute limb-threatening ischemia of the hand and forearm includes heparinization and emergent surgical thromboembolectomy.

Aneurysms of the Extremity

The incidence of aneurysms in the leg appears to be increasing, likely related to the aging population and better detection methods. Femoral and popliteal aneurysms account for the vast majority of peripheral arterial aneurysms and are due predominantly to atherosclerosis. More than 95 percent of patients with these aneurysms are elderly males. Aneurysms can give rise to local pain, limb edema, and ischemic complications. Acute symptoms can develop with thrombosis or distal

embolization, and rupture is rare. False aneurysms of the femoral artery, consisting of encapsulated hematomas adjoining the vessel lumen, arise from iatrogenic injury and occur more frequently than do true femoral aneurysms. Duplex ultrasonography, CT, or MRI can confirm the clinical diagnosis and detect mural thrombus. Arteriography is of limited value in the diagnosis of an occluded aneurysm due to poor contrast filling.

The risk of ischemic complications from an asymptomatic popliteal aneurysm ranges from 8 to 100 percent (mean, 36 percent).²⁵ Thus, elective surgery after arteriography is recommended for all cases.²⁵ Because 37 percent of patients with a single popliteal aneurysm have an aortic aneurysm and half have a contralateral popliteal aneurysm, a thorough search is indicated after detection of a single aneurysm. Non-operative management is acceptable for asymptomatic femoral aneurysms given their low incidence of complications.

Subclavian artery aneurysms occur from atherosclerosis, trauma, or thoracic outlet obstruction and much less commonly from syphilis or cystic medial necrosis. Thromboembolism gives rise to signs and symptoms typical of distal ischemia, but it also may produce central neurologic deficits from retrograde propagation of clot into the vertebral and carotid circulation. Because of their severe potential morbidity, these aneurysms should be surgically removed promptly after diagnosis.

CARDIAC TRANSPLANTATION

Michael R. Mill Michelle S. Mill

The first clinically successful cardiac transplant was performed in December 1967. Since then, advances in the immunosuppression and postoperative care of these patients have resulted in dramatically improved patient survival. This has been accompanied by a tremendous growth in the number of procedures performed. Data from the registry of the International Society of Heart and Lung Transplantation (ISHLT) and the United Network for Organ Sharing (UNOS) reveal that 61,533 heart transplants were performed at 328 centers throughout the world between January 1, 1983, and December 31, 2001.^{1,2} This total includes more than 2000 heart transplants per year in the United States since 1990. The actuarial survival after transplantation reported by UNOS is 85 percent at 1 year, with 3- and 5-year actuarial survivals of 77 and 69 percent, respectively.³ Given the increased number of patients undergoing transplantation and their excellent long-term survival, these patients will come to the attention of physicians in the ED with increasing frequency.

TRANSPLANT RECIPIENTS

Cardiac transplantation has been applied successfully to patients of all ages, from newborns through persons in their late sixties. Heart transplantation is indicated for patients with end-stage heart failure not remediable by standard medical or surgical therapy. The etiology of heart failure in transplant recipients as reported by the ISHLT/UNOS registry is listed in Tables 60-1 and 60-2.^{1,2} The majority of adult patients have either idiopathic dilated cardiomyopathies or end-stage coronary artery disease (see Table 60-1). Many in the latter group will

Retransplantation	1%	5%	4%
Other	4%	8%	10%

Source: From Boucek MM, et al.²

have undergone previous coronary artery bypass surgery. The predominant diagnoses in children undergoing transplantation are dilated cardiomyopathies and congenital heart disease (see Table 60-2). Many of the children with congenital heart disease will have undergone previous palliative or corrective operations. Patients are evaluated carefully for other irreversible end-organ dysfunction and other systemic illnesses that would separately limit survival.

CARDIAC PHYSIOLOGY AFTER TRANSPLANTATION

The physiologic basis on which cardiac transplantation is grounded is the ability of the denervated heart to support normal circulation. The lack of sympathetic and parasympathetic innervation does, however, induce an altered physiologic state. The denervated heart has a normal sinus rhythm with a heart rate between 90 and 100 beats/min. Denervation results in the absence of the initial centrally mediated tachycardia in response to stress or exercise. The heart remains responsive to circulating catecholamines of either endogenous or exogenous origin. The cardiac response to stress or exertion therefore is blunted. With the onset of exercise, the heart rate initially remains unchanged and then increases gradually to a level of approximately 80 percent of predicted over 10 to 15 min. After termination of exercise, this exercise-induced tachycardia will persist for approximately 20 to 30 min before

slowly returning to the patient's baseline rate. Patients may complain of fatigue or shortness of breath with the onset of exercise that resolves with continued exertion as an appropriate tachycardia develops.

Cardiac hemodynamics after transplantation as measured by cardiac catheterization reveal a normal to mildly depressed cardiac output at rest. With exercise, cardiac output increases in response to increased venous return (preload) and circulating catecholamines. Maximal cardiac outputs of 80 to 100 percent of normal have been measured. Patients are able to resume normal activity levels, including vigorous exercise, following transplantation. A number of posttransplant patients have completed marathons and participated in other rigorous physical activities, and at least one such individual has competed as a professional athlete.

Cardiac denervation results in an altered response to some medications used in emergency resuscitation.⁴ In patients with supraventricular tachycardias, the lack of sympathetic innervation obviates the utility of carotid sinus massage. Atropine, which acts by abolishing reflex vagal slowing, will have no effect on heart rate in patients with symptomatic bradyarrhythmias. Conversely, denervated hearts are quite sensitive to the chronotropic effects of β -adrenergic agents such as isoproterenol, dopamine, and dobutamine. Because these are normal hearts, they are resistant to the proarrhythmic effects of these drugs. Isoproterenol (1-4 μ g/min administered by continuous intravenous infusion) is used preferentially to increase donor heart rates because it has the greatest chronotropic effects and can be titrated easily to achieve the desired heart rate.

CARDIAC EVALUATION OF THE POSTTRANSPLANT PATIENT

Electrocardiograms (ECGs) obtained on transplant recipients should demonstrate normal sinus rhythm. The donor heart is implanted with its own sinus node intact to preserve normal atrioventricular conduction. The technique of cardiac transplantation also results in preservation of the recipient's sinus node at the superior cavoatrial junction. The atrial suture line renders the two sinus nodes electrically isolated from each other. Thus ECGs frequently will have two distinct P waves (Figure 60-1). The sinus node of the donor heart is easily identified by its constant 1:1 relationship to the QRS complex,

FIG. 60-1. Electrocardiogram demonstrating donor and recipient P waves (▼ = donor P wave; T = recipient P wave).

whereas the native P wave marches through the donor heart rhythm independently. The presence of the two separate P waves may lead to confusion about the patient's rhythm. The ECGs may be interpreted erroneously as showing atrial fibrillation, atrial flutter, or frequent premature atrial complexes. The use of calipers aids in definition of the two distinct P waves. Sinus node dysfunction in the posttransplant heart occurs in approximately 4 to 5 percent of patients and is manifest by either sinus brachycardia with heart rates of equal to or less than 50 beats/min or sinus standstill with a junctional escape rhythm with heart rates of 60 to 70 beats/min. This dysfunction occurs in the early postoperative period and resolves spontaneously in most patients. For patients in whom sinus node dysfunction persists, treatment consists of either theophylline, which accelerates the sinus bradycardia in some patients, or implantation of a permanent transvenous pacemaker. The type of pacemaker implanted varies depending on institutional preference but generally is either an atrial pacemaker programmed in the AAIR mode or a ventricular pacemaker programmed in the WIR mode. Use of an atrial rate-responsive pacemaker preserves atrioventricular conduction in addition to providing physiologic rate responsiveness.

Posttransplant chest radiographs show evidence of a prior sternotomy but otherwise generally are normal. Some patients may have evidence of "cardiomegaly" related to the transplantation of a heart from a donor who was larger than the recipient (Figure 60-2).

Echocardiography is a useful tool for evaluating cardiac function after transplantation. Interpretation of the echocardiogram is routine, with the exception of evaluation of atrial size. Because the atrial anastomoses incorporate the posterior walls of the recipient's native atria, echocardiography will show atrial enlargement, but this has no significant effect on cardiac function. Early rejection results in diastolic dysfunction, although the echocardiographic indices may be subtle and difficult to detect. Severe rejection will be accompanied by signs of biventricular enlargement with global hypocontractility and significant atrioventricular valve regurgitation.

IMMUNOSUPPRESSION FOR CARDIAC TRANSPLANTATION

As with all types of solid-organ transplantation, lifelong immunosuppression is required to prevent acute graft rejection. One of the most

significant challenges of clinical transplantation is to maintain an adequate level of immunosuppression to prevent rejection while preserving adequate immunocompetence to avoid serious infectious complications. Since the mid-1980s, standard immunosuppression has employed a triple-drug regimen consisting of cyclosporine (Sandimmune, Neoral), prednisone, and azathioprine (Imuran). Recently, generic formulations of cyclosporine have become available. Care should be taken to maintain patients on the same preparation to prevent alterations in drug levels. The combination of these agents has resulted in superior graft and patient survival rates, has decreased the mortality from infectious complications, and has minimized the side effects of the individual agents. Recently, the newer immunosuppressive agents tacrolimus (Prograf) and mycophenolate mofetil (Cellcept) have been used in place of cyclosporine and azathioprine, respectively. In addition, some programs use induction therapy in the early postoperative period, employing cytotoxic antibody preparations targeted against the T lymphocytes. The most commonly used agents include OKT3, a murine monoclonal antibody, and polyclonal preparations such as antilymphocyte serum (ALS) and antilymphocyte globulin (ALG). Newer induction agents include daclizumab (Zenapax) and basiliximab (Simulect). These therapies are monospecific humanized mouse antibodies targeted against the interleukin 2 (IL-2) receptor of the T cell. With fewer side effects than other induction therapies, they are being used by many transplant programs, especially in patients with perioperative renal insufficiency.⁵

Cyclosporine remains one of the mainstays of immunosuppressive regimens. This fungal metabolite is a potent inhibitor of T-lymphocyte activity and interferes with the generation of IL-2. It is a lipophilic substance that is metabolized in the liver by the cytochrome P450 system. Cyclosporine is usually taken twice daily, and doses are adjusted based on serial blood levels. Target trough levels vary depending on the specific laboratory assay used. Levels are maintained in the range of 300 to 400 ng/dL early after transplantation and then lowered to approximately 150 ng/dL long term. The list of drugs that interact with cyclosporine (Table 60-3) continues to grow yearly, and careful consideration is required before adding or withdrawing medications for an individual patient. Such changes always should be made with the knowledge and input of the patient's transplant physician. Acute increases in cyclosporine levels may be associated with severe renal dys-

function, and acute decreases may result in the development of acute rejection.

Commonly encountered side effects of cyclosporine are listed in Table 60-4. Hypertension occurs in the majority of patients and frequently requires combination therapy to achieve adequate control. Renal insufficiency is also quite common and is mediated at least in part by the vasoconstrictive effects of cyclosporine on the proximal renal tubule. Management of cyclosporine-induced renal insufficiency requires careful monitoring because worsening renal insufficiency results in elevated cyclosporine levels, thus creating a vicious cycle. Although early renal insufficiency is frequently reversible, some patients have developed end-stage renal disease requiring dialysis or renal transplantation.

Formally known as FK-506, tacrolimus is a macrolide antibiotic with an immunosuppressive mechanism similar to that of cyclosporine. Tacrolimus prevents rejection of the transplanted organ by inhibiting the expression of IL-2 in T cells and inhibiting T-cell growth and proliferation. Studies show that replacing cyclosporine with tacrolimus as a primary or rescue immunosuppressant may result in fewer episodes of rejection, less clinically relevant hypertension, and lower doses of maintenance corticosteroids.⁶ Initial studies with tacrolimus after cardiac transplantation suggest that tacrolimus is a safe and effective immunosuppressant alternative to cyclosporine. Oral doses of tacrolimus are typically 0.1 to 0.15 mg/kg divided every 12 h. Doses are adjusted to achieve a goal trough blood level of 10 to 15 ng/dL for the first several months after transplantation and then 5 to 10 ng/dL long term. The most common side effects of tacrolimus are similar to those of cyclosporine, as shown in Table 60-4, with the exception of hirsutism and gingival hyperplasia, which have not been reported. Based on the mechanism by which tacrolimus is metabolized, drugs known to interact with cyclosporine and erythromycin should be considered potential interactants for tacrolimus until proven otherwise.

Azathioprine is a 6-mercaptopurine derivative that acts as a false metabolite in the proliferation of bone marrow stem cells. The typical dose is 1 to 2 mg/kg per d, adjusted to maintain a white blood cell count greater than 5000/fjL. The most common side effect is bone marrow suppression, manifested as neutropenia. In some patients, anemia and thrombocytopenia may be present. The most common drug interaction is with allopurinol, which may be prescribed to treat acute gouty arthritis, itself a side effect of cyclosporine therapy. If allopurinol is to be prescribed, the dose of azathioprine should be decreased to half, and frequent follow-up white blood cell counts should be obtained to avoid profound bone marrow suppression.

Mycophenolate mofetil (MMF), another new immunosuppressant, is a potent inhibitor of de novo purine synthesis inhibiting T- and B-lymphocyte proliferation.⁵ MMF has been approved by the Food and Drug Administration (FDA) for the prophylaxis of organ rejection in renal transplantation when used concomitantly with cyclosporine

and prednisone. MMF is being promoted as an improvement over azathioprine, replacing it in the standard triple-drug immunosuppressive regimen. Clinical studies of MMF after cardiac transplantation suggest that it is a safe and effective alternative to azathioprine in maintenance immunotherapy and possibly more effective in the treatment of refractory and persistent rejection.⁷ Dosing of MMF is typically 1.0 to 1.5 g twice daily. The most common side effects include nausea, vomiting, diarrhea, leukopenia, and an increase in opportunistic infections, especially involving cytomegalovirus (CMV), both tissue-invasive disease and viremia.⁸ Should neutropenia develop, the MMF dosage should be adjusted or the therapy discontinued. Drugs that interact with MMF include antacids and cholestyramine, which decrease absorption of MMF and therefore should not be taken at the same time. Steroids remain an integral part of posttransplant immunosuppression. Prednisone is begun initially at high doses (1.0-1.5 mg/kg per d) after transplantation and weaned over 4 to 6 weeks to a maintenance dose of 0.2 mg/kg per d (about 15 mg/d in the average adult recipient). Many programs now attempt to wean steroids in an effort to avoid the well-known deleterious effects of chronic therapy. Steroid withdrawal is successful in approximately 50 percent of cases.

REJECTION

Rejection after cardiac transplantation is a lifelong risk, although the incidence of rejection decreases with time. Rejection can be divided into three types, based on mechanism of rejection and time after transplantation. *Hyperacute rejection* is mediated by preformed anti-HLA antibodies directed against the donor tissue. Hyperacute rejection results in immediate and irreversible donor heart failure and is a fatal complication unless the patient can be maintained with a mechanical assist device until a new donor heart is located. With the use of ABO blood group-compatible donors and screening of transplant candidates for elevated levels of preformed anti-HLA antibodies, hyperacute rejection is very rare in cardiac transplantation.

Acute rejection, the most common type of rejection encountered, occurs in approximately 75 percent of all patients at some time after transplantation. The incidence of acute rejection is greatest within the first 6 weeks after transplantation as immunosuppressive medications are weaned to chronic maintenance levels. Acute rejection can occur at any time after transplantation. Late episodes usually can be correlated with some change in the patient's immunosuppressive status, such as an acute illness or noncompliance with medications. Acute rejection is a cellular phenomenon resulting in the infiltration of lymphocytes into the myocardium, with subsequent destruction of individual myocytes. Because most episodes of rejection do not cause clinically detectable graft dysfunction, surveillance endomyocardial biopsies are performed on a routine basis after transplantation. Biopsy specimens are examined histologically and graded according to a grading system (Table 60-5) developed by a working group of the ISHLT.⁹ Mild to

TABLE 60-5 Standardized Cardiac Biopsy Grading System

Grade	Histologic Description
0	No rejection
1	A = focal (perivascular or interstitial) infiltrate without necrosis B = diffuse but sparse infiltrate without necrosis
2	One focus only with aggressive infiltration and/or focal myocyte damage
3	A = multifocal aggressive infiltrates and/or myocyte damage B = diffuse inflammatory process with necrosis
4	Diffuse aggressive polymorphous infiltrate ± edema, ± hemorrhage, ± vasculitis, with necrosis

moderate episodes of rejection (grades 0-2) generally are not accompanied by clinical symptoms or hemodynamic changes. Severe rejection (grade 4) can result in profound myocardial dysfunction and death. Patients with grade 2 or higher rejection are treated with augmented steroids or cytotoxic therapy, as outlined below.

Although most episodes of acute rejection are asymptomatic, symptoms can occur. The most common presenting symptoms are dysrhythmias and generalized fatigue. **The development of either atrial or ventricular dysrhythmias in a cardiac transplant recipient must be assumed to be due to acute rejection until proven otherwise.** Arrangements should be made for prompt performance of an endomyocardial biopsy. If patients are hemodynamically compromised by their dysrhythmias, empirical therapy for rejection with methylprednisolone, 1 g IV, may be given. If the diagnosis of rejection is confirmed, standard antirejection therapy should be completed. Atrial dysrhythmias may respond to treatment with digoxin or calcium channel blockers. Ventricular dysrhythmias may respond to lidocaine or other class Ic agents. Frequently, the dysrhythmias will be controlled only with antirejection therapy.

Untreated acute cardiac rejection results in progressive myocardial dysfunction. Diastolic dysfunction occurs first, followed by systolic dysfunction as the degree of myocardial damage increases. Diastolic dysfunction causes symptoms of congestive heart failure with shortness of breath, fatigue, and malaise. Progressive myocardial dysfunction results in low-output syndrome, with symptoms including nausea, vomiting, and/or diarrhea. Severe rejection leads to hypotension and circulatory collapse. Symptoms of rejection may be mistakenly attributed to a viral syndrome or gastroenteritis. Physical examination reveals signs of heart failure, including distended neck veins, an S₃ gallop on cardiac auscultation, rales on pulmonary auscultation, and occasionally, the presence of ascites or peripheral edema. Chest radiographs show enlargement of the cardiac silhouette and pulmonary vascular congestion. ECGs may demonstrate—in addition to dysrhythmias—a decrease in amplitude and widening of the QRS complex.

Patients with signs or symptoms suggestive of acute rejection should be admitted to the hospital with continuous ECG monitoring. Arrangements should be made for performance of an endomyocardial biopsy at the earliest possible time. If facilities for obtaining and interpreting biopsy specimens are not available, transfer to the nearest transplant center should be arranged. Low-output syndrome and/or hypotension should be treated with inotropic agents such as dopamine or dobutamine while specific treatment for rejection is instituted. *Treatment for rejection without biopsy confirmation is contraindicated except when the patient is hemodynamically unstable.* This is especially true in patients whose symptoms are due to an occult infection because of the potential adverse consequences of high-dose steroid therapy. Empirical treatment for rejection should be employed only after consultation with the patient's transplant center.

Standard therapy for acute rejection includes intravenous methylprednisolone 1 g/d for 3 days. In patients with refractory rejection, treatment with specific T-cell cytotoxic agents such as OKT3, ALS, or ALG is required. Occasionally, patients have been supported successfully with mechanical assist devices for profound circulatory collapse while undergoing therapy for rejection, with resulting complete recovery of normal ventricular function.

Chronic rejection is believed to be manifested in the heart by the development of graft atherosclerosis. This antibody-mediated phenomenon is thought to result in injury to the endothelial lining of the coronary arteries, with the subsequent development of intimal hyperplasia. The lesions may be focal but more often are diffuse and concentric, involving the entire length of the epicardial and intramyocardial vessels. Because the heart is denervated, *myocardial ischemia does not present with angina*. Instead, recipients present with heart failure secondary to silent myocardial infarctions or with sudden death. Transplant recipients who present with new-onset shortness of breath, chest fullness, or symptoms of congestive heart failure should

be evaluated for the presence of myocardial ischemia or infarction. This is done in routine fashion with ECG and serial cardiac enzyme determinations. Echocardiography can be used to look for segmental wall motion abnormalities. If evidence for myocardial ischemia or infarction is found, cardiac catheterization with ventriculography and coronary angiography is indicated. The rate of development of graft coronary disease is quite variable, occurring months to years after transplantation; consequently, cardiac transplant programs employ annual follow-up coronary angiograms to detect its presence. The diffuse nature of graft coronary artery disease generally precludes standard methods of myocardial revascularization such as percutaneous transluminal coronary angioplasty, stent implantation, or coronary artery bypass surgery. Retransplantation is the most effective treatment.

INFECTIOUS COMPLICATIONS AFTER CARDIAC TRANSPLANTATION

Infectious complications are fairly common after transplantation, particularly in the early posttransplant period, when the highest doses of immunosuppressive medications are employed. The infectious complications after cardiac transplantation are similar to those following all types of solid-organ transplantation and those in other immunocompromised hosts.¹⁰ The infections encountered most commonly are listed in Table 60-6. Prophylactic regimens are employed by most transplant centers. Pretransplantation, patients are vaccinated with pneumococcal, *Haemophilus influenzae*, and hepatitis B vaccines. Perioperatively, routine antistaphylococcal antibiotics are used. Postoperatively, antifungal mouthwash is used to prevent oral and esophageal candidiasis while the patients are on high-dose steroids and is reinstituted when augmented steroid therapy is required to treat rejection. *Toxoplasma gondii* can infect the transplanted heart; it may result from reactivation of a latent recipient infection or be transmitted with the donor organ. *Toxoplasma* titers are measured in all recipients and donors, and pyrimethamine is administered prophylactically for 6 weeks after transplantation if titers are elevated. Beginning approximately 2 months after transplantation, trimethoprim-sulfamethoxazole is used as prophylaxis against *Pneumocystis carinii* pneumonia (PCP). Antibiotic prophylaxis for any invasive procedure (e.g., dental work, endoscopy, or surgical procedures) is recommended for the lifetime of the patient. Annual flu shots are recommended. *Measles, mumps, rubella, and other live attenuated virus vaccines are contraindicated in transplant recipients.*

Any patient with a history of solid-organ transplantation who presents with symptoms of an infection must be evaluated in an aggressive and thorough manner. Appropriate stains and cultures should be obtained to allow identification of bacterial, fungal, and viral

TABLE 60-6 Common Infections after Cardiac Transplantation

Early posttransplant infections (first month)
Pneumonia: gram-negative bacilli
Mediastinitis: <i>Staphylococcus epidermidis</i> , <i>Staphylococcus aureus</i> , gram-negative bacilli
Intravenous lines: <i>Staphylococcus epidermidis</i> , <i>S. aureus</i> , gram-negative bacilli, <i>Candida albicans</i>
Urinary tract infections: Gram-negative bacilli, enterococcus, <i>C. albicans</i>
Skin: herpes simplex virus
Late posttransplant infections (after first month) and for duration of immunosuppression
Viral: cytomegalovirus (CMV), herpes simplex, varicella-zoster, non-A, non-B hepatitis
Bacteria: <i>Listeria</i> , <i>Nocardia</i> , <i>Legionella</i> , <i>Mycobacterium</i>
Fungi: <i>Aspergillus</i> , <i>Cryptococcus</i> , <i>Candida</i> , <i>Mucor</i> (<i>Phycomyces</i>)
Protozoa: <i>Pneumocystis carinii</i> , <i>Toxoplasma gondii</i>

Source: Horn JE, Barlett JG: Infectious complications following heart transplantation, in Baumgartner WA, Reitz BA, Achuff SC, (eds): *Heart and Heart-Lung Transplantation*. Philadelphia, WB Saunders, 1990, p 223.

pathogens. There should be a low threshold for instituting antimicrobial therapy while awaiting culture results and for admitting patients to the hospital for further evaluation and intravenous antibiotics. Patients with evidence of pulmonary infiltrates but without productive sputum require bronchoscopy with bronchoalveolar lavage and transbronchial biopsy for definitive diagnosis. Pulmonary infections that are encountered frequently include *P. carinii*, *Nocardia*, *Legionella pneumophila*, and *Aspergillus*; these require special stains and studies for accurate diagnosis. Patients with gastroenteritis and nausea, vomiting, and/or diarrhea require special attention. Inability to ingest or adequately absorb immunosuppressive medications may result in the development of an episode of acute rejection. If there is any question about a recipient's ability to maintain adequate oral intake, the patient should be hospitalized and immunosuppressive medications administered intravenously.

Antibiotic therapy for documented infections should be guided by appropriate culture and sensitivities and must take into account underlying renal insufficiency and potential interactions with cyclosporine or tacrolimus.

Of special note is the risk of CMV infection after cardiac transplantation. CMV is a common virus to which the majority of adults have been exposed, as demonstrated by the presence of anti-CMV IgG antibodies in the serum. After transplantation, CMV infections can occur due either to the reactivation of latent virus in a previously infected recipient or the development of a new infection with a different viral strain transmitted with the donor organ. The latter situation is much more serious and potentially life-threatening, particularly in recipients who were CMV-negative prior to transplantation. Routine post-transplant surveillance for CMV infection is performed using serial IgG and IgM antibody testing, and now CMV antigenemia testing is available for early detection of CMV infection. Ganciclovir, available in both intravenous and oral preparations, is used for CMV prophylaxis in high-risk recipients (CMV-negative prior to transplant) as well as moderate-risk recipients (CMV-positive prior to transplant).⁵

CMV disease can occur in either a mild or severe form. Mild disease is manifested by a flulike illness with low-grade fever, fatigue, malaise, and nausea. Severe disease may include profound leukopenia; pneumonitis; gastroenteritis including epigastric pain, vomiting, and diarrhea; and hepatitis with elevated transaminases. CMV pneumonitis carries a mortality of greater than 50 percent. CMV infection typically occurs 4 to 12 weeks after transplantation. The diagnosis is made by the demonstration of cytoplasmic inclusion bodies in biopsy specimens of affected organs. Treatment includes the use of intravenous ganciclovir and, in severe cases, intravenous immunoglobulin infusions. Of particular concern is the documented increased incidence of acute rejection complicating acute CMV infections. Therefore, patients with active CMV disease must be monitored carefully for signs and symptoms of rejection. An endomyocardial biopsy should be performed if there is any suspicion of rejection.

NONINFECTIOUS COMPLICATIONS OF CARDIAC TRANSPLANTATION

In addition to common forms of cancer, those malignancies associated with chronic immunosuppression also occur in cardiac transplant recipients. These include posttransplant lymphoproliferative disorders (PTLDs), which are usually B-cell lymphomas and have been related to the Epstein-Barr virus. PTLDs may occur as early as 1 month after transplantation and may present with a variety of nonspecific symptoms. If diagnosed in their early stages, they may respond to decreased levels of immunosuppression, chemotherapy, and/or radiation therapy, with long-term survival reported.

Aseptic necrosis of the femoral heads and thoracic and lumbar spine compression fractures are not uncommon manifestations of long-term steroid therapy. The development of hip pain referred to the

medial thigh or knee is often indicative of early aseptic necrosis. Magnetic resonance imaging (MRI) is the most sensitive means of detection, and patients should be referred for orthopedic evaluation if this diagnosis is suspected.

PEDIATRIC CARDIAC TRANSPLANTATION

The care and evaluation of pediatric heart transplant recipients is similar to that of adults, with a few special considerations. Rejection surveillance in infants and small children is done primarily with serial echocardiograms. Difficulties with vascular access and the need for anesthesia make serial endomyocardial biopsy procedures impractical. Acute rejection is heralded more frequently by symptoms in children than in adults. Children will present with a low-grade fever, fussiness, and poor feeding. Echocardiography will demonstrate decreased ventricular contractility, thickening of the posterior wall of the left ventricle, cardiac enlargement, and mitral and tricuspid valve insufficiency. Because the signs of rejection may be subtle and difficult to quantify, serial echocardiographic studies are required throughout the postoperative period to establish each patient's baseline echocardiographic characteristics.

Immunosuppression for children is based on standard triple therapy. Because of the more rapid metabolism of cyclosporine and tacrolimus, higher doses and more frequent (thrice daily) dosing often are needed in children. Steroids are withdrawn whenever possible to avoid their deleterious effects on somatic growth.

Childhood infections are encountered frequently and should be treated according to routine practice. Vaccinations with live attenuated virus are avoided. Exposure to chickenpox (varicella) is avoided if possible. If exposure does occur in a recipient without a history of previous infection, treatment with varicella-zoster immune globulin (VZIG) is indicated. Recipients who develop chickenpox are treated with intravenous acyclovir.

EMERGENCY DEPARTMENT EVALUATION AND TREATMENT OF THE POSTTRANSPLANT PATIENT

Cardiac transplant recipients are susceptible to all the acute illnesses that affect the general population. These patients should be treated in the same way as any other acutely ill or traumatized patient. In the assessment of such patients, however, the possibility that symptoms may be due to rejection, infection, or side effects of their immunosuppressive medications always must be considered. Patients taking steroids long term will have adrenal suppression and may need stress coverage if they are severely ill or in need of surgical intervention. Uninterrupted administration of immunosuppressive medications must be ensured to avoid the development of acute rejection. **Nonsteroidal anti-inflammatory drugs (NSAIDs) should be used with extreme caution** because of the potential exacerbation of underlying renal insufficiency secondary to cyclosporine or tacrolimus use.

The evaluation of patients presenting with signs and symptoms of congestive heart failure should include the consideration of rejection, myocardial ischemia, and fluid overload due to renal insufficiency. Echocardiography provides important information regarding cardiac performance and may demonstrate findings suggestive of rejection (global dysfunction) or ischemic dysfunction (segmental wall motion abnormality). Results of routine annual cardiac evaluations are useful in assessing whether echocardiographic abnormalities represent acute changes or chronic conditions. Similarly, the availability of old laboratory test results will aid in assessing the importance and acuity of renal impairment.

Any transplant patient presenting with an acute febrile illness warrants aggressive and complete evaluation. If a specific diagnosis cannot be established by history, physical examination, and readily available laboratory and radiographic tests in the ED, consultation with the infectious disease or transplant service is indicated. The patient

should be admitted to the hospital for further invasive tests and broad-spectrum intravenous antibiotics until culture results are available and a specific diagnosis is made.

In the event that a transplant recipient presents to the ED in extremis, standard cardiopulmonary resuscitation should be performed. Etiologies for hemodynamic collapse related to the posttransplant state include severe acute rejection and myocardial ischemia due to advanced graft coronary disease. Sudden death due to a dysrhythmia also may result from rejection or ischemia. Because of sympathetic denervation, vagally induced bradycardias do not occur; therefore, **atropine has no role in the resuscitation of these patients.** The empirical administration of high-dose steroids (methylprednisolone 1 g IV) maybe beneficial if rejection is present. Finally, hyperkalemia due to chronic renal insufficiency may result in acute dysrhythmias and should be corrected with standard pharmacologic intervention.

NONINVASIVE MYOCARDIAL IMAGING

David A. Bluemke Bennett
Chin Joao A. C. Lima Malek
Tebache

Imaging for myocardial disease has advanced substantially in sophistication. Recent developments include new scintigraphic diagnostic contrast agents in nuclear medicine, Doppler methods in echocardiography, and rapid magnetic resonance imaging (MRI) of the heart. Because the cost of these diagnostic tests is relatively high, it is essential that the "correct" test be selected to arrive at the most accurate diagnosis in a short period, with few false positives or negatives.

CHEST X-RAY

Chest x-ray is often the first imaging test obtained for patients with suspected cardiovascular disease. Ideally, lateral and posteroanterior (PA) views of the chest are obtained, with film exposure at a distance of 6 ft

(1.8 m). Patients should be upright and have a moderately deep inspiration. For patients who are too ill to stand, semi-erect x-rays are obtained with an anteroposterior (AP) film exposure. The AP film has two disadvantages: the heart demonstrates magnification, and the pulmonary vessels, which show information regarding the extent of congestive failure, are somewhat blurred because of longer exposure times.

Cardiac size can be measured from the chest x-ray with an error of ± 10 percent. Factors such as depth of inspiration, conformation of the chest wall, and pulmonary diseases may affect the appearance of heart size on chest x-ray. The cardiothoracic ratio is the ratio between the transverse diameter of the heart on a PA chest x-ray and the greatest internal diameter of the thorax. Although there are other formulas for measuring cardiac size, this method is the quickest and easiest. The normal adult heart measures 50 percent or less of the **transverse** diameter of the chest. In adults, a cardiothoracic ratio greater than 50 percent is considered diagnostic for cardiomegaly. In children, the normal cardiothoracic ratio is 65 percent in the first year and decreases to 50 percent by age 5 years.

The heart and major vessels are visualized in the middle mediastinum and are readily recognized on chest x-ray. The heart and the great vessels appear to have the same density relative to the radiolucent lungs. On the left side, there is usually air around the cardiac border; on the right side, the heart blends in with the density of the liver. In normal individuals, two thirds of the heart lies to the left of the midline.

Chest X-Ray Interpretation

On the PA view of the chest, there are three visible cardiac segments (Figure 61-1A). The lowermost segment, adjacent to the diaphragm, consists of the lateral and apical walls of the left ventricle. A small rounded density may be lateral to the cardiac apex: this represents the epicardial fat pad. Superior to the left ventricle is a rounded short segment that varies considerably in size. This is the pulmonary artery and its left main branch. Prominence of the pulmonary artery is normal in young women. Just below this level, the left atrial appendage forms short portion of the lateral portion of the left heart border. Conditions that result in left atrial enlargement will cause a convex bulge in this portion of the cardiac silhouette. The third and most superior portion of the left edge of the cardiac silhouette is formed by the transverse aortic arch. On a properly exposed chest film, the descending aorta can be seen descending behind the heart shadow. On the right side of the cardiovascular silhouette, the lower rounded portion is due to the lateral border of the right atrium. The upper segment is formed by the superior vena cava. In older adults in whom the ascending aorta becomes more rounded and dilated, the upper segment of the right heart border may become convex, representing the lateral border of the ascending aorta.

On the lateral view of the chest, the anterior and superior-most shadow of the cardiac silhouette is formed first by the ascending aorta, then the pulmonary artery and the pulmonary artery outflow tract, and then the anterior border of the right ventricle (Figure 61-1B). Posteriorly, the superior shadow is due to the left atrium, with the left ventricle forming the cardiac silhouette inferiorly.

Early left ventricular failure is reflected on the chest x-ray by a "redistribution" pattern of blood flow. Normally, the most prominent pulmonary veins are at the lung bases. With the redistribution phase, the vascularity in the upper lung fields is increased relative to that in the lower lung fields.

As pulmonary capillary wedge pressure elevates to 20 to 25 mm Hg (Figure 61-2), fluid moves from the vascular bed into the interstitial spaces of the lung. The chest x-ray appears hazy at this stage, with short lines appearing perpendicular to the pleura (Kerley B lines). As pulmonary capillary wedge pressure increases to 30 to 35 mm Hg, frank alveolar edema ensues due to massive fluid movement from the vasculature to the alveolar spaces.

FIG. 61-2. Pulmonary vascular congestion. Bilateral increased lung**FIG. 61-1.** Normal cardiac size and lung fields. A. Frontal view. The lateral wall of the left ventricle (*long black arrow*), the pulmonary artery (*short black arrow*), and the aortic arch (*black arrowhead*) form three visible cardiac segments on the left side. On the right side, the right atrium (*white arrow*) and superior vena cava (*white arrowhead*) form lower and upper borders, respectively. B. Lateral view. The left ventricle (*arrow*) forms the lower posterior cardiac border, and the left atrium is superior to it (*arrowhead*).

markings are present, particularly in the lower lung fields, with prominent interstitial lung markings. The pulmonary hila are also enlarged.

Cardiac Chamber Enlargement

LEFT VENTRICLE Increased workload by the left ventricle initially results in dilatation of the ventricle, but, if it is sustained, hypertrophy of the left ventricular wall occurs. Hypertrophy is a normal response to increased workload. Chest x-ray findings at this time are usually normal. As the ventricle begins to fail, dilatation results, and the cardiothoracic ratio increases. The apex of the heart also becomes more rounded in appearance. The most marked increases in size of the left ventricle result from hypertension, aortic insufficiency, and cardiomyopathy. Pericardial effusion results in generalized cardiac enlargement (Figure 61-3).

RIGHT VENTRICLE The right ventricle enlarges from processes that increase the work of this chamber, such as pulmonary diseases or pulmonary artery hypertension. Mitral valve disease will also eventually result in right ventricle enlargement. The outflow tract of the right ventricle enlarges first; chest x-ray findings are subtle but include straightening or convexity of the pulmonary artery segment below the aortic knob in the frontal view. Multichamber enlargement is frequent, so that the relative involvement of each cardiac chamber is not easily distinguished on chest x-ray.

LEFT ATRIUM Common cases of left atrial enlargement include mitral valve disease from rheumatic fever and congenital defects resulting in left-to-right shunts. The normal left atrium is posterior and does not form any portion of the cardiac silhouette in a normal patient. Moderate enlargement causes the left atrial appendage to become larger and causes a bulge or straightening of the left cardiac border below the pulmonary artery segment. Further enlargement may cause the right-side border of the left atrium to extend beyond the normal upper aspect of the right atrium and superior vena cava. A double cardiac border is seen on the frontal view on the right side. If the left atrial enlargement is less extreme, a double border may still be seen, because of the increased radiopacity of the left atrium. On the lateral view, the upper posterior border of the cardiac silhouette projects more posteriorly than normal.

FIG. 61-3. Pericardial effusion. Generalized dilatation of the heart is present, with the cardiothoracic ratio measuring greater than 50 percent. Although a similar cardiac silhouette would be present in patients with dilated cardiomyopathy, this patient had documented pericardial effusion.

RIGHT ATRIUM Enlargement of the right atrium causes enlargement of the lower right cardiac contour with increased convexity. Diseases resulting in right atrial enlargement include atrial septal defect, tricuspid stenosis and insufficiency, and right ventricular failure. In multi-chamber disease, right atrial enlargement is not identified separately.

COMPUTED TOMOGRAPHY

In evaluation of the heart, the primary role of conventional computed tomography (CT) has been to exclude other abnormalities, such as aortic dissection, that may secondarily affect cardiac function. Because of excellent anatomic resolution, CT is also useful in depicting paracardiac disease processes that involve the myocardium.

Advantages of CT examination of myocardial structures include good resolution at 0.1 to 0.5 mm² and rapid imaging times of 5 min or shorter for the chest. The low-density epicardial fat usually provides excellent contrast to the higher density of the cardiac structures. Calcifications, present at the site of ventricular aneurysms, of the coronary arteries, or of atherosclerotic change, are easily depicted. With the advent of helical CT scanners, a full three-dimensional (3D) set of images is obtained, allowing multiplanar reconstruction and 3D viewing. Although conventional CT scanners provide one image slice every 2 to 5 s, helical CT is increasingly available to EDs. *Helical CT* and *spiral CT* are synonymous.

Helical Computed Tomography

In conventional (nonhelical) CT scanning, the image acquisition is as follows: scan a slice, move the patient, scan a slice, etc. Thus, there are two distinct parts to the process: turn on the x-ray beam, usually for about 1 to 2 s, and then move the patient to the next table position.

Patient motion to the next position may take an additional 2 to 4 s. Therefore, each slice can take approximately 5 s (1 s of scanning and 4 s of motion), only 20 percent (1 s/5 s) of which is actually imaging time.

In its most basic form, helical CT consists of scanning a patient *continuously* while tracing a helix along the patient's body while the patient is being moved continuously through the CT gantry. In this mode, the x-ray beam is on for perhaps 20 s or longer, and the patient is moved for this same duration. The efficiency of scanning is 100 percent. Most recent technical developments have made available multidetector-row CT (MDCT). Multidetector-row CT has a four-slice detector array and a rotation time of 500 ms. This innovative technology allows the entire heart to be scanned with thin slices (1.25 mm), in a breath-hold of 35 s, and with a temporal resolution of 250 ms. Retrospective or prospective electrocardiogram (ECG) gating is available.

Helical CT data sets are truly 3D. Instead of scanning a series of slices, a volume data set is acquired, with the following results.

Vastly improved multiplanar and 3D reconstructions. Because data sets are acquired in one breath-hold, respiratory misregistration is eliminated. Data appear "smoother," with fewer "stair-step" artifacts in sagittal and coronal reconstructions.

Reconstruction of slices at arbitrary intervals. Because of the 3D nature of helical scanning, images can be reconstructed at small intervals, e.g., 2 to 3 mm. This reduces stair-step artifacts in 3D reconstructions.

Rapid acquisition. Complete helical data sets of a patient's examination are typically acquired within 20 to 30 s, and the patient is then done with the examination.

Electron-Beam Computed Tomography

Electron-beam CT technology (Imatron, South San Francisco, CA) operates by a technology different from helical and conventional CT. With those methods, a large detector array and x-ray unit rotate around the patient. The sheer mass of the x-ray apparatus limits the rate of rotation to about once every 0.5 to 1.0 s. With electron-beam CT, electrons are generated and deflected electromagnetically onto tungsten target rings located in the gantry below the patient. X-rays are generated by the electron bombardment of the target rings. The x-rays are then tightly collimated and directed to pass through the patient onto a double ring of detectors in the gantry above the patient. Because mechanical motion is not involved, imaging times are very rapid: images can be acquired every 58 ms (17 images/s). Similar to helical CT, image resolution is excellent: 0.1 to 0.5 mm². At this rate of image formation, very little blurring of cardiac structures takes place. Calcifications involving the coronary arteries are easily detected, and cine images of the myocardium are available.

Electron-beam CT and helical CT require injection of an iodinated contrast medium to enhance blood in the vessels and myocardial cavities relative to the myocardium itself. With helical CT, approximately 120 mL of iodinated contrast is delivered intravenously at a rate of 3 mL/s. With electron-beam CT, 40 to 80 mL of contrast is given at 2 to 10 mL/s. In both cases, a power injector is used, necessitating large-bore intravenous access.

Radiation exposure is a consideration with all CT scanning methods. With conventional or helical CT, radiation levels are 2 to 4 cGy (2 to 4 rad) per CT slice. If multiple slices are taken at the same level of the heart, then the radiation increases directly in proportion to the number of slices. Electron-beam CT requires less exposure to radiation for the patient: each slice has an exposure of 0.54 cGy (540 mrad). However, more imaging slices are acquired with electron-beam CT in obtaining a cine sequence of the heart, so that 10 cine frames would result in an exposure of 5.4 rad. For comparison purposes, one x-ray of the lumbar spine is approximately equivalent to 1 cGy (1 rad), whereas radiation exposure from a chest x-ray is 0.06 cGy (60 mrad).

Applications

Electron-beam CT is available in only a very few centers across the United States. A major nonemergent application is the detection of coronary artery calcification. The degree of coronary artery calcification bears a strong relation to the presence of significant coronary artery stenosis. Cardiac anatomy, the relation between the chambers of the heart and great vessels, is readily determined with this modality. Because electron-beam CT can obtain cine images of the heart, cardiac function and focal wall motion abnormalities can be determined. Due to the limited availability of this modality, however, the remaining discussion focuses on non-electron-beam methods.

Although helical CT offers very rapid scanning, it is not well suited to assess cardiac function, given its need for contrast medium and radiation, when compared with echo imaging and MRI. Cardiac anatomy, however, is well assessed. Focal abnormalities of the myocardial wall are indicative of cardiac tumor or thrombus (Figure 61-4). Differentiation of these possibilities usually requires cine imaging, so that patients with such masses are referred for echocardiography or MRI.

Computed tomography offers a good depiction of pericardial disease (Figure 61-5). Simple pericardial effusions appear as low density relative to the myocardium, and the extent of effusion can be readily quantified, if necessary. The presence of calcifications of the pericardium is an important factor in the diagnosis of constrictive pericarditis and, with the correct symptoms, improves the specificity of this diagnosis. High-density pericardial fluid collections are likely to represent localized hematomas from trauma or surgery.

Helical CT after intravenous administration of contrast is an excellent modality for assessing diseases of the pulmonary arteries. Pulmonary artery emboli appear as low-attenuation defects in the opacified pulmonary arteries. Helical CT can demonstrate emboli not only in the main pulmonary arteries but also in the third- and fourth-order branches, because of high spatial resolution and cross-sectional imaging of these vessels.

Plain MDCT scans detect and quantify coronary calcifications. This capacity may have a role in ruling out coronary artery disease in patients with atypical chest pain or asymptomatic patients with high cardiovascular risk factors. Enhanced MDCT scans produce high-resolution studies of the cardiac chambers and the valve planes. It may be competitive with transesophageal echocardiography in searching for cardiac thrombi or quantifying valve stenosis. Multidetector-row

CT angioscan may demonstrate the coronary anatomy (origin and proximal course), thus allowing one to look for anomalous coronary anatomy and to assess and follow the patency of venous bypass grafts, coronary stents, or percutaneous coronary angioplasty.¹

NUCLEAR MEDICINE

Nuclear medicine examinations of the heart represent the study of cardiac function and physiology rather than of anatomy. Because of higher spatial resolution, MRI and CT are better suited to anatomic evaluation of the heart. Nevertheless, nuclear medicine examinations of the heart remain a primary means for assessing cardiovascular function; in particular, gated radionuclide angiography of the heart is a mainstay of cardiovascular imaging.

Radiopharmaceuticals and Imaging Techniques

ASSESSMENT OF CARDIAC PERFUSION

Thallium-201 Thallium is a potassium analogue that is transported by the $\text{Na}^+\text{K}^+\text{ATPase}$ system in cells in direct proportion to regional blood flow. Approximately 85 percent of each "pass" of the contrast agent is extracted from the blood across the capillary bed. Thallium is initially extracted by myocardial cells but is then redistributed to maintain equilibrium with the blood at a rate that is proportional to that of regional blood flow. Thus, the early images from a thallium scan reflect blood flow, and the later images (redistribution phase) reflect the intracellular K^+ blood pool. The intracellular K^+ blood pool in turn reflects cellular viability. The redistribution phase is usually imaged 4 to 24 h after the initial injection of thallium.

In combination with exercise or pharmacologically induced coronary hyperemia (from dipyridamole or adenosine), thallium imaging is able to distinguish normal blood flow, ischemia, infarction, and hibernating myocardium. Myocardial tissues distal to a physiologic coronary artery stenosis are unable to increase their blood supply during stress conditions or hyperemia and thus have low radiotracer activity. On 4-h delayed images, however, the thallium redistributes to these areas, and the

radiotracer activity of the myocardium becomes more uniform. With infarction, delayed images show no evidence of radiotracer redistribution, reflecting the lack of intracellular K^+ blood in the area of infarction. With hibernating myocardium, redistribution occurs by 24 h.

Technetium Technetium radionuclides offer greater ease of use and availability for nuclear medicine departments. Whereas thallium requires a cyclotron to produce, technetium agents are widely available and produced by a generator in each nuclear medicine laboratory. The most commonly used technetium agent is technetium-99m sestamibi (^{99m}Tc -sestamibi). This agent is taken up by the myocardium in direct proportion to myocardial blood flow. At this point, the sestamibi molecule becomes trapped within the myocardium and does not redistribute (contrary to the behavior of thallium). Thus, the initial uptake by the myocardium reflects blood flow at the time of injection. Typically, ^{99m}Tc -sestamibi is initially injected at peak exercise or during the period of maximum coronary vasodilatation (induced by dipyridamole or adenosine).

^{99m}Tc -sestamibi does not redistribute on delayed images. Myocardial infarction and decreased flow from physiologically significant coronary stenosis appear as myocardial defects on images. To differentiate these two possibilities, a second dose of ^{99m}Tc -sestamibi is given while the patient is at rest. If the rest images show uniform radiotracer distribution, then the defect seen on stress images is due to ischemia. Persistent areas of absent radiotracer on rest images indicate areas of myocardial infarction.

Gated Radionuclide Angiography

Gated radionuclide angiography (RNA) has remained a clinical gold standard for overall assessment of left ventricular function. This test has the advantage of being applicable to nearly all patients, regardless of body habitus or underlying illness. In addition, unlike echocardiography, RNA is relatively operator independent. Radiation exposure is present but insufficient to prevent serial examination of cardiac function in the same patient.

In RNA, a blood sample is labeled with a technetium-based radionuclide, and a series of images of the heart is acquired. These images are gated to the R wave of the ECG. Function and measurement of ejection fraction involve measuring radioactivity counts at multiple time points throughout the cardiac cycle. The number of radioactive counts is directly proportional to the blood volume in the cardiac chamber. Thus, the method is insensitive to the precise geometry of the left ventricle, because only the overall count rates, and thus volumes, are measured. Other than segmentation of the left ventricle from other cardiac cavities, no geometric assumptions regarding left ventricular anatomy are necessary with the technique. By using gated techniques, with display of images as a cine loop, it is possible to assess segmental function of the heart. However, the resolution of the images is limited, and the strength of the examination relies primarily on accurate quantitation of the global left ventricular function.

Ventricular function is assessed by qualitative evaluation of cardiac wall motion, and quantitative assessment of radionuclide counts as a function of time. Computer-generated curves are verified by an experienced observer's interpretation of regional wall motion determined by gated RNA studies. Radionuclide angiography allows particularly good views of the lateral wall of the left ventricle, where there is no overlap from other cardiac segments. Although systolic function is easily assessed, diastolic function of the left ventricle is more commonly performed by echocardiography.

First-Pass Cardiac Studies

If the radionuclide is rapidly injected, and the acquisition speed of the nuclear images is rapid, the "first pass" of the radionuclide can be tracked as it passes through the heart. This method relies on tracking of the radionuclide bolus as it passes through the ventricular cavities

immediately after contrast injection. In this technique, the acquisition time is very rapid (30 s), although very few heartbeats are evaluated, thus limiting spatial resolution.

Left ventricular ejection fraction measurement is determined by following the passage of the radiotracer between the left and right ventricles. The injection of the radiotracer must be rapid, or poor separation of radiotracer between the two sides of the heart occurs. Patients with dysrhythmias, atrial septal defect, or significant regurgitation across the mitral or tricuspid valves will have poor ejection fraction estimates when using this method. First-pass studies using ^{99m}Tc -sestamibi enable cardiac function and perfusion to be assessed in the same study.

Gated Perfusion Imaging

After injection of ^{99m}Tc -sestamibi, images can be collected such that multiple time points, or cine frames, during the cardiac cycle can be independently collected by gating data acquisition to the cardiac cycle. In this manner, a cine loop, or movie of the cardiac cycle, can be generated. The function of the heart can be qualitatively reviewed to assess for wall thickening or segmental dysfunction. Thus, the perfusion of the heart can be assessed in the same setting as cardiac function. Functional imaging aids in discriminating between true mild perfusion defects and imaging artifacts, such as those due to attenuation from overlying breast tissue or the diaphragm. When severe perfusion defects are present, due to infarct or significant coronary artery narrowing, accurate estimation of ejection fraction is difficult to measure.

Applications

Myocardial perfusion scintigraphy is a noninvasive modality with high sensitivity for the diagnosis and evaluation of coronary artery disease. Physiologically significant coronary stenoses may be evaluated in populations with known or suspected coronary disease, after therapeutic interventions, preoperatively for risk assessment, and for prognostication after acute ischemia or infarction.

A more recent application of this technique has been made to the patients presenting to the ED with chest pain. In a subset of patients with an intermediate or low probability of coronary artery disease and chest pain (unstable angina), the missed diagnosis of acute coronary syndrome (ACS) has been reported to be as high as 5 to 8 percent. Several centers around the country have used myocardial perfusion scintigraphy to further classify this subset into high-risk and low-risk categories to reduce the incidence of missed ACS and the number of unnecessary hospital admissions for noncardiac chest pain. In a large study at the Medical College of Virginia involving 1187 patients, ^{99m}Tc -sestamibi perfusion imaging was used in defining the critical pathways in this population.² Used with established clinical criteria, the cardiac event rate at 1-year follow-up for patients with abnormal scan findings was 42 percent versus 3 percent (revascularization) for those with normal scan findings. In those with abnormal scan findings, 11 percent experienced myocardial infarction and 8 percent suffered cardiac death; in those with normal scan findings, none had myocardial infarction or death. Other centers around the country have reported similarly favorable results.^{3,4}

The nuclear perfusion imaging protocol performed in the ED is very similar to conventional myocardial perfusion stress protocols, with the exception that the injections are performed at rest during chest pain. Preliminary reports indicate that timing of injection during chest pain may improve diagnostic sensitivity; however, other centers have reported good results with injections performed up to within 12 h of the chest pain.⁵ ^{99m}Tc -sestamibi and tetrofosmin are used because of their favorable imaging properties of minimal redistribution and lower radiation dosimetry compared with ^{201}Tl chloride. After intravenous injection, these ^{99m}Tc tracers are highly extracted and retained for several hours within the myocardium in a distribution proportional to coronary blood flow. This permits imaging several hours

later after additional ED evaluation or intervention. Because of the more favorable dosimetry of ^{99m}Tc tracers, a higher dosage approaching 7 to 10 times the injected dose of ^{201}Tl is typically used. This permits high-quality tomographic imaging (single-photon emission CT) and ECG gating, which provides additional information, including assessment of wall motion, wall thickening, and left ventricular ejection fraction. In patients with normal findings on resting perfusion study, further evaluation with a stress myocardial perfusion study may be performed on an outpatient basis. Preliminary studies have shown the cost effectiveness of this risk stratification, and further studies are currently in progress. Figures 61-6, 61-7, and 61-8 illustrate the utility of myocardial perfusion scintigraphy in a patient with acute chest pain.

ECHOCARDIOGRAPHY

Echocardiography is the use of ultrasound to image the heart and great vessels. This general term includes the techniques of M-mode, two-dimensional (2D) imaging, pulsed wave, and color Doppler studies. Frequently, an examination of the heart will apply a combination of these ultrasound methods to the clinical problem at hand.

Echocardiography, after the chest x-ray, represents one of the most commonly applied methods for cardiac diagnosis. In the ED it is particularly useful in trauma to identify hemopericardium as part of the FAST examination (see Chap. 251) and to evaluate pulseless electrical activity. Other standard applications include assessment of cardiac chamber size and function, patterns of flow within the ventricles, pericardial assessment, and identification of cardiac masses, including tumors, valve vegetations or calcification, and thrombi (Figure 61-9). Advantages for this technique include its relatively low cost, portability of the ultrasound equipment, good patient comfort, and safety.

Although the use of echocardiography is extremely widespread, there are limitations to the technique. The method is highly operator dependent. Patient positioning relative to the ultrasound probe is crucial, and specific machine adjustments must be made to optimize the examination to a particular patient. These adjustments may substantially alter the diagnostic ability of the examination. Certain patients have poor "acoustic windows," through which the ultrasound beam "looks" to see the cardiac structures. This limits examination quality in patients with chronic obstructive lung disease, obesity, and some musculoskeletal deformities. The use of transesophageal echocardiography, in part, alleviates the limitations of the technique for these patient populations.

Acoustic Impedance

The physics of sonography are discussed in detail in Chap. 303. At tissue interfaces, sound waves are reflected back to the transducer (specular interface) or scattered into many different directions. The endocardial border represents a specular interface; sound waves are maximally reflected back from this interface when they are incident upon the interface at a 90-degree angle. As the sound waves become more parallel to the endocardium, the reflected waves weaken.

Incident ultrasound waves that are scattered as they reflect from red blood cells may be used to assess the Doppler phenomenon and thus measure the velocity of the red blood cells. The *Doppler phenomenon* refers to increased frequency of the ultrasound wave, when the motion of the red blood cells is toward the transducer, and decreased frequency, when the motion is away from the transducer (the Doppler shift). In Doppler display mode, blood flowing toward the transducer is coded red; blood flow away from the transducer is shown as blue. The intensity of the red or blue is displayed as proportional to the

FIG. 61-6. A 59-year-old white hypertensive man who arrived at the emergency department with 6 h of intermittent chest pain. Findings on physical examination and electrocardiography were unremarkable. Initial cardiac enzyme levels (CK-MB, myoglobin, and troponin T) were normal. ^{99m}Tc -sestamibi single-photon emission computed tomographic perfusion images show a moderate area (arrow) of hypoperfusion in the middle and proximal inferolateral wall. The patient went directly to catheterization, which showed a 95 percent circumflex marginal stenosis that was successfully treated by angioplasty. (Courtesy of Ethan Spiegler, MD.)

FIG. 61-7. Three-dimensional representation of gated single-photon emission computed tomography data at end diastole.

velocity. Velocities are most accurate when the angle between the ultrasound beam and blood flow is close to zero. Pulsed wave ultrasound techniques may be used to assess blood velocity: a series of rapid pulses is sent into the tissue, followed by a short segment of time for receiving the reflected waves.

M-Mode Display

M-mode display is unique in medical imaging to echocardiography. The primary advantage of this display mode is that high time resolution, to approximately one thousandth of a second, can be displayed on the time axis. Compared with this, traditional 2D displays are updated only approximately 30 times per second. Thus, M-mode display has excellent time resolution and can be used to display the periodic motion of, for example, cardiac valves or vegetations. In this display mode, a 2D display is typically first selected. A single line, or slice, of the 2D display is then selected, often across a valve plane. M-mode

displays then show the reflected ultrasound signal along this single line, with continual updating every millisecond.

Applications

MYOCARDIAL INFARCTION Use of echocardiography for evaluation of ACS is limited in the ED. However, applications previously outside of the realm of the ED are now more common with the proliferation of ED-based "chest pain" or "cardiac evaluation" units. Echocardiography is more sensitive and specific than history and ECG findings in diagnosing myocardial infarction in patients presenting with chest pain, in several clinical series, left ventricular wall motion abnormalities were observed in 89 to 100 percent of patients with transmural infarction.⁶ The sensitivity of echocardiography in detecting a nontransmural infarction is somewhat less and depends on the transmural thickness of the infarcted myocardial segment, in addition, patients who had no echocardiographically detected wall motion abnormalities had smaller infarctions and fewer complications.⁶

FIG. 61-8. Bull's-eye representation of gated single-photon emission computed tomographic data. Hypoperfusion of the proximal inferolateral wall, mild hypokinesis, and diminished wall thickening are visible. There is preserved global left ventricular function.

FIG. 61-9. Echocardiography of inferior wall pseudoaneurysm due to prior rupture of the left ventricular wall. [Reprinted with permission from Burton AA, Lima JAC: Echocardiography in patients with acute myocardial infarction, in Lima JAC (ed): *Diagnostic Imaging in Clinical Cardiology*. London, Martin Dunitz, 1998, p. 53.]

Echocardiography is also useful in the diagnosis and management of chest pain due to causes other than myocardial infarction. Patients with chest pain due to myocardial ischemia usually have echocardiographically detectable wall motion abnormalities with pain, even in the absence of infarction. Other causes of chest pain, including aortic dissection, hypertrophic cardiomyopathy, valvular heart disease, pericarditis, and pulmonary embolism, can frequently be identified or suspected based on transthoracic echocardiography.

In addition to facilitating diagnosis, echocardiography early in the course of acute myocardial infarction provides information important in guiding early management and determining short-term prognosis. The location and size of wall motion abnormalities correlate well with the coronary artery involved in an infarction. Obstruction of the left anterior descending coronary artery usually causes abnormal function in the anterior, septal, and apical segments of the left ventricle. Akinesis of the basal anterior segment predicts occlusion of the left anterior descending coronary artery, proximal to the first septal perforator, a finding of prognostic significance. There is overlap in the areas of abnormal wall motion in myocardial infarcts involving the left circumflex and right coronary arteries. Occlusion of either vessel can cause abnormal motion in the middle and basilar segments of the posterior and inferior walls. Wall motion abnormalities confined to the posterior and lateral walls are usually caused by obstruction of the circumflex, whereas abnormalities confined to the inferior basal segment are characteristic of obstruction of the right coronary artery.

A number of factors, including the presence of ischemia, stunning, or overload, confound the relation between the size of regional wall motion abnormalities and the amount of infarcted myocardium. When compared with pathologic examination, echocardiography tends to overestimate the amount of necrosed myocardium early in the course of myocardial infarction. Despite this limitation, echocardiographic estimation of the extent of myocardial infarction correlates well with infarct size as determined by peak creatine kinase, radionuclide imaging, and contrast ventriculography. Echocardiographic evaluation of left ventricular function early in the course of myocardial infarction has been found to be a better predictor of in-hospital mortality than the prognostically strongest clinical parameters. An echocardiographically determined ejection fraction of greater than 40 percent has correlated with a low short-term mortality and might be used to select low-risk patients for early discharge.⁷ In contrast, a tall peaked E wave on

Doppler evaluation of left ventricular filling has been correlated with elevated left ventricular end-diastolic pressure and worse prognosis.

Echocardiography has been used to assess the efficacy of thrombolytic therapy. The time required for improvement of left ventricular function after reperfusion is related to the duration of ischemia and size of the ischemic zone. In patients with successful reperfusion induced by thrombolytic agents or direct angioplasty, echocardiographically detectable improvement in contractility can occur in the first 24 h. The delay in recovery of function, even after successful reperfusion, limits the utility of echocardiography in acutely assessing the success of thrombolytic therapy.

The widespread use of echocardiography early in the course of myocardial infarction reflects the clinical utility, availability, and safety of this technique. Echocardiography does have a number of potential shortcomings in the early diagnosis and management of acute myocardial infarction. The quality of echocardiographic images depends on the skill of the operator and the habitus of the patient. Images adequate for evaluation of wall motion cannot be obtained in 5 to 15 percent of patients in clinical studies of myocardial infarction.⁶ Abnormal wall motion can be present in patients with Wolff-Parkinson-White syndrome, bundle branch block, right ventricular overload, and after cardiac surgery. However, in contrast to patients with myocardial infarction, in these patients, wall thickening is usually preserved. Conversely, myocarditis may cause regional loss of wall thickening and be indistinguishable from infarction by echocardiography. In addition, it is sometimes difficult to differentiate new wall motion abnormalities from preexisting ones by echocardiography. The value of screening cardiac ultrasonography as part of ED evaluation has been too slow to be superior to clinical evaluation and prognostic for hospital stay.

ACUTE MITRAL REGURGITATION This disorder often requires emergent surgery and has a higher mortality rate than that of chronic mitral valve disease. Etiologies include endocarditis, acute ischemia or myocardial infarction, prosthetic valve failure, and chordal rupture due to myxomatous mitral disease or trauma.

Echocardiographic signs in acute mitral regurgitation include the "snake" sign, corresponding to high-frequency fluttering of a ruptured chord in the left atrium. Rupture of the papillary muscle may cause disconnection of the involved tip from the body of the muscle. The direction of the mitral regurgitant distinguishes anterior from posterior flail leaflet: anterior leaflet failure is associated with posteriorly directed jet, and posterior leaflet failure shows anteriorly directed jet. Transesophageal echocardiography appears to be superior to transthoracic imaging for determining the size and etiology of the valvular disorder.

ACUTE AORTIC REGURGITATION Acute aortic regurgitation results from trauma, endocarditis, or aortic dissection. This condition is rapidly fatal and requires immediate surgical repair. Transesophageal echocardiography may be necessary to delineate disruption of valvular or annular architecture in this condition.

For chronic aortic regurgitation, color Doppler demonstrates a regurgitant jet in the left ventricle. In the acute case, however, rapid equilibration of pressures in the aorta and the normal-size left ventricle causes a small, or no, Doppler jet. The spectral pattern of the continuous wave Doppler will have a low peak velocity and an extremely rapid deceleration slope. These findings correspond to the inaudibility of the murmur of acute regurgitation. In the most severe case, there is little diastolic flow into the ventricle, because the aorta and left ventricle become a continuous chamber. Early closure of the mitral valve or diastolic mitral regurgitation on M-mode or 2D echocardiography is an ominous prognostic sign. Early mitral valve closure indicates severe and acute decompensated aortic insufficiency.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging is rapidly becoming the gold standard for noninvasive assessment of cardiac structure and function. The high

contrast between moving blood and the myocardium by MRI, the high spatial resolution (Figure 61-10), and lack of ionizing radiation result in a superb technique for myocardial assessment. Dedicated cardiovascular MR scanners are now widely available at major medical centers, and experience with critically ill patients is becoming widespread. Lack of immediate access to an MR scanner may be limiting in an emergency situation but likely will become increasingly available in cardiac evaluation centers. More commonly patients will be triaged to receive MR studies based on indeterminate echocardiography or CT examinations. Nevertheless, the ED physician should un-

derstand the increasingly important role of MRI for patients that have unresolved questions based on initial imaging results. Magnetic resonance imaging is the most definitive study for problems involving the right side of the heart, the paracardiac structures, and morphologic abnormalities of the myocardium itself. An emerging area of use of MRI is the detection of myocardial infarction in the setting of chest pain with indeterminate ECG or serum enzymes.

This section reviews principles and specific applications of MRI to provide a basis for emergency medicine professionals in requesting and evaluating MR studies.

FIG. 61-10. Magnetic resonance imaging of normal short-axis cardiac anatomy from the base of the heart (A) through the cardiac apex (B). Successive images are displayed left to right, top to bottom. LAD = left anterior descending coronary artery; LV = left ventricle; PM = papillary muscles; RV = right ventricle; RVOT = right ventricular outflow tract; S = septum; T = trabeculations in the right ventricle. [Reprinted with permission from Bluemke DA, Boxerman JL: MRI of acquired cardiac disease, in Stark DD, Bradley WGJ (eds): *Magnetic Resonance Imaging*, 3rd ed. Philadelphia, CV Mosby, 1998, pp. 409-438.]

Principles of Magnetic Resonance Imaging

T1-weighted images (see Chap. 305) are generally those that help define the *anatomy* that is being viewed (Figure 61-11). *T2 images* are those that better define the *pathology* of the tissue. *Proton-density images* may also be generated, in which the image intensity is proportional to the number of protons present. Images can be generated that are sensitive to flowing blood (*bright blood images* or MR angiograms). It is the unique property and strength of MRI that four different physical factors (T1, T2, proton density, and blood flow) can be used to derive a variety of imaging results. In contrast, for CT scanning or echocardiography, only one factor (x-ray attenuation or acoustic attenuation, respectively) is used to generate contrast in images. Magnetic resonance enhances the power of the technique for detecting subtle changes in pathologic tissues relative to normal tissues. Two parameters are particularly helpful in determining MRI contrast: time to repetition (TR) describes the time between radiofrequency pulses, and time to echo (TE) describes the time after each

FIG. 61-11. Paracardiac mass demonstrated by magnetic resonance imaging. Axial images of the chest demonstrating a mass posterior to

the left ventricle. A. T1-weighted image, showing thickening of the posterior wall of the left ventricle. B. T2-weighted image, showing bright increased signal in the mass. Biopsy revealed hemangiopericytoma. [Reprinted with permission from Bluemke DA, Boxerman JL: MRI of acquired cardiac disease, in Stark DD, Bradley WGJ (eds): *Magnetic Resonance Imaging*, 3rd ed. Philadelphia, CV Mosby, 1998, pp. 409-438.]

radiofrequency pulse when the MR scanner "listens" for a signal from the patient. By changing the TR and TE values, different types of image contrast are obtained (see Table 305-1). For more detailed information regarding MR physics, the reader is referred to standard textbooks on the subject, such as that by Berning and Steensgaard-Hansen.⁹

Magnetic Resonance Pulse Sequences

CONVENTIONAL SPIN ECHO IMAGING The most common pulse sequence traditionally used for cardiac imaging is a conventional spin echo sequence gated to the cardiac cycle. In this technique, the TR is equal to the duration of the RR interval. Because the T1 time of the myocardium is on the order of 800 ms, only moderate T1 weighting is achieved (Figure 61-12). Image quality is only moderate and is highly dependent on consistent ECG gating and lack of patient motion during the relatively long acquisition times. However, the contrast difference between the heart, the epicardial fat, and the ventricular cavities is relatively good.

T2 weighting for spin echo images is achieved by gating at several multiples of the RR interval. Imaging times are quite long if conventional spin echo techniques are used. The image quality of T2-weighted images is lower than that of T1 images, because of lower signal-to-noise ratios typically associated with T2 images. Also, artifacts due to respiratory and cardiac motion may be pronounced because of long imaging times. T2-weighted images usually are not necessary for *anatomic* evaluation of the heart but are more helpful for characterization of cardiac or paracardiac masses (see Figure 61-1 IB). In these cases, the mass frequently has somewhat restricted motion relative to the myocardium, so that image quality is often adequate. *Fast spin echo* or *turbo spin echo* T2-weighted pulse sequences are available on most new MR sequences. These methods reduce imaging time for T2-weighted images. Because of the high signal intensity of fat on fast spin echo images, an additional radiofrequency pulse is often added to cause fat to be very dark. This in turn helps to highlight nonfatty structures.

CINE IMAGING Cine imaging for cardiac MRI consists of a motion picture loop of various phases of the cardiac cycle (Figure 61-13). To generate cine images, images must be gated to the cardiac cycle. In cine acquisitions, the imaging pulse is triggered, or gated, to begin based on

FIG. 61-12. Magnetic resonance imaging of aortic dissection. Axial T1-weighted image shows the site of prior repair of the ascending aorta after dissection. There is residual soft tissue thickening around the ascending aorta (arrow). A residual dissection remains in the descending aorta. The patient had a history of Marfan disease.

FIG. 61-13. Magnetic resonance imaging of mitral valve dysfunction. Images during systole and diastole show a dark regurgitant jet extending from the valve plane to the left atrium during systole, compatible with mitral valve regurgitation. Philadelphia, CV Mosby, 1998, pp. 409-38.]

the R wave of the ECG. A complete cine sequence of the heart is acquired within a breath-hold of 12 to 18 heartbeats. The physics of this technique result in saturation of background stationary tissues, whereas flowing blood has a higher and brighter signal. Breath-hold cine imaging of the heart can be performed in any anatomic plane, e.g., parallel to the long axis and short axis of the heart.

Specific Applications of Magnetic Resonance Imaging

CARDIAC AND PARACARDIAC MASSES Patients with cardiac and paracardiac masses may be assessed in the ED or referred for outpatient MRI under variable circumstances. The suspicion may arise from incidental findings from chest plain film or echocardiography. Magnetic resonance imaging, with its high spatial and temporal resolutions, is well suited to image the cardiac anatomy. It benefits from a large field of view and defines the relations of the lesion to the cardiac chambers walls, the valves, the pericardium, the outflow tracts, and the vessels. White-blood (gradient echo) and black-blood (spin echo) ECG-gated sequences can be obtained in any desired plane. Even if a specific diagnosis is difficult to obtain, MRI may characterize certain components of the mass (fat, blood, and fluid), identify their location and extent, and show the degree of vascularization.

LEFT VENTRICULAR ANEURYSM Left ventricular aneurysm is a potential complication of acute transmural myocardial infarction. Usually it is located in the anteroapical or apical region. Patients may suffer from arrhythmias, thromboembolic episodes, and congestive heart failure.

Left ventricular pseudoaneurysm consists of a cardiac rupture contained by adherent pericardium or scar tissue. This condition may be induced by myocardial infarction, cardiac surgery, trauma, and infection. Unlike true aneurysm, it arises from inferior myocardial infarction and thus takes place on the lateral, apical, or inferior surface. Electrocardiogram and chest plain films are nonspecific tests for the diagnosis of these conditions.

Transesophageal echocardiography and MRI are the reasonable next steps when a high index of suspicion is present. Transesophageal echocardiography is more uncomfortable for the patient and does not provide a large field of view as compared with MRI. Also, MRI provides preoperative morphology and functional information to the cardiac surgeon.

ANOMALOUS CORONARY ARTERY The diagnosis of anomalous coronary artery origin should be considered in unexplained syncope (and myocardial infarct and sudden death) among young adults. The pathophysiologic mechanism seems to be the impingement of the anomalous vessel in its path between the aorta and the pulmonary trunk.

Conventional angiography generates 2D projections of the coronary anatomy, whereas MRI identifies the relations of coronary arteries, origins, and proximal courses with the great vessels, thereby allowing a more accurate diagnosis and identifying the risk of cardiac morbidity or mortality in function by the type of anomalous coronary course.

CARDIOMYOPATHY Patients with cardiomyopathy and presenting to the ED may suffer from syncope, atrial or ventricular arrhythmias, and episodes of cardiac failure or sudden death. Cardiomyopathy may result from ischemia, infection, arterial hypertension, valvular disease, genetic affection, or may be idiopathic. Magnetic resonance imaging can evaluate morphology and function in these conditions. It accurately defines the location and the extent of the thickened myocardium, quantifies ventricular mass, and demonstrates the effect of the hypertrophic muscle on chamber volume and ventricular function. Magnetic resonance imaging is well suited to assess treatment effects, such as radiofrequency ablation of a subaortic septal hypertrophic cardiomyopathy. Restrictive cardiomyopathy and constrictive pericarditis are frequently well evaluated by MRI. Both conditions share the same clinical features. The underlying pathologic process is diastolic dysfunction due to myocardial stiffness for restrictive disease and pericardial thickening for the constriction. The differential diagnosis is crucial, because constrictive pericarditis is treated surgically, whereas restrictive disease is treated medically or with transplantation.

CORONARY HEART DISEASE

Myocardial Ischemia and Noninvasive Coronary Artery Disease

Identification Stress-perfusion MRI combines administration of a pharmacologic vasodilator with intravenous injection of a gadolinium MRI contrast agent. First-pass MRI myocardial perfusion evaluates coronary flow reserve. Coronary flow reserve is defined as the ratio of blood flow at maximal vasodilatation, divided by flow at rest. The ratio typically ranges from 3 to 5 in normal individuals. In the presence of fixed coronary stenoses, coronary flow reserve is markedly reduced, and this induces perfusion heterogeneity. In fact, the myocardium perfused by a stenotic coronary vessel will receive less blood flow than the neighboring normal myocardium in maximal vasodilatation.

This indicates that patients with microvascular dysfunction from epicardial vascular disease or diseases altering the microvasculature, such as hypertension or diabetes, may be assessed with these methods.¹¹

An alternative to perfusion MRI, in screening for coronary artery disease, is to evaluate the function of the myocardium during inotropic

stimulation.¹² Dobutamine stress MRI is highly analogous to dobutamine stress echocardiography. In this method, MR cine images of the myocardium are imaged during constant infusion of increasing doses of dobutamine. Dobutamine is an inotropic and chronotropic agent inducing an increase in oxygen demand. High-dose dobutamine stress tests may cause wall motion abnormalities in territories perfused by a coronary vessel with a hemodynamically significant stenosis. These wall motion abnormalities are identified in the MR images.

Myocardial Infarction and Viability The ischemic myocardium may appear dysfunctional. This state may be due to myocardial infarction, stunning, or hibernation. Infarct is a nonviable area, whereas stunned or hibernating myocardium is a viable region with depressed function. It is crucial to differentiate between these conditions, for assessing the prognosis after myocardial infarction and for identifying patients who would benefit from surgical revascularization. Indeed, performing coronary bypass to treat a nonviable myocardial segment is pointless and brings unnecessary risks to the patient.

Nuclear imaging and echocardiography are routinely used to look for viability of any dysfunctional myocardial region during stress tests, mainly with low- or medium-dose dobutamine infusion. Recovery of normal function during stress demonstrates the viability. The same approach is done with MRI,¹³ which is well suited to assess the pattern of myocardial contraction.

The temporal resolution of an up-to-date MR unit (40 ms) is sufficient to obtain perfusion images encompassing the entire left ventricle every one to two heartbeats. Rapid injection of a small volume of contrast is performed by a power injector to achieve first-pass images showing myocardial blood flow. Magnetic resonance images show contrast passage through the right ventricle, the pulmonary arteries, the left ventricle chamber, and then through the left and right ventricular myocardia. The washin and washout of the contrast agent distinguishes pathologic tissue, such as infarct, from normal myocardium.

In acute myocardial infarction, MR images show a subendocardial perfusion abnormality (Figure 61-14). This "core" of the infarct is af-

FIG. 61-14. Midventricular (left ventricle) short axis view obtained with the delayed enhanced technique. The enhanced (arrows) area in-

fects a transmural circumflex artery territory infarct. The ischemic insult appears as a subendocardial hypointense region consisting of microvascular obstruction (no-reflow zone).

ected by microvascular obstruction, despite patency of the major epicardial coronary artery. The presence of microvascular obstruction is associated with long-term cardiovascular complications,¹⁴ such as recurrent myocardial infarction, congestive heart failure, and stroke. In addition to perfusion imaging, late enhancement is analyzed. About 20 min after the intravenous injection of gadolinium-DTPA, myocardial infarction is depicted by a delayed area of tissue enhancement relative to normal, unaffected myocardium.¹⁵ This method readily defines the size of the infarct and its transmural extent (Figure 61-15).

left ventricle in a patient with huge septal, anterior, apical, and inferior infarct. Images were obtained with the delayed enhanced technique. The hyperenhanced circular area defines the infarct extent (arrows), which is transmural in its septal and inferior components.

SECTION 7 • CARDIOVASCULAR DISEASE

In doing so, this method of imaging clarifies the prognosis of the myocardial ischemic insult and may help the clinician and patient with atypical chest pain.

Observation of patients at low risk for ACS has become routine in the case of indeterminate ECG or serum enzyme results. Magnetic resonance methods for myocardial infarction detection have been used recently for evaluating ED patients with indeterminate ECG or serum enzyme results. These methods currently remain confined to major medical centers. Nevertheless, the potential of MR infarct imaging to reduce hospital costs related to patient triage is actively being evaluated.

Section Eight

PULMONARY EMERGENCIES

RESPIRATORY DISTRESS

J. Stephan Staczynski

Common respiratory symptoms that bring patients to the ED include dyspnea (with the associated findings of hypoxia and hypercapnia), wheezing, and cough. Hiccups are an infrequent presenting symptom, but when persistent, they are very distressing to the patient. Cyanosis can be associated with pulmonary and vascular, as well as hematologic conditions. Pleural effusion can be caused by a variety of pulmonary and cardiac diseases. This chapter discusses these symptoms, signs, and disorders as they relate to evaluation of emergency patients. It is worth noting that, despite the increasing availability of and reliance on ancillary tests, the assessment of patients still begins with an accurate history and a careful physical examination in order to make the wisest use of ancillary tests.¹

DYSPNEA

Dyspnea is a subjective feeling of difficult, labored, or uncomfortable breathing. This common emergency department complaint is often described as "shortness of breath," "breathlessness," "not getting enough air," and a variety of other phrases. Dyspnea does not result from a single pathophysiologic mechanism and may result from many disorders. Approximately two-thirds of patients presenting to the ED with dyspnea have either a cardiac or a pulmonary disorder. An emergency physician can usually distinguish these on the basis of history, physical examination, and, occasionally, ancillary tests.

Dyspnea is distinguished from other respiratory symptoms. Tachypnea is rapid breathing; it may or may not be associated with dyspnea, and dyspnea is not always accompanied by tachypnea. Orthopnea is dyspnea in the recumbent position. It is most often the result of left ventricular failure and may be associated with diaphragmatic paralysis or chronic obstructive pulmonary disease (COPD). Paroxysmal nocturnal dyspnea is orthopnea that awakens the patient from sleep. Trepopnea is dyspnea associated with only one of several recumbent positions. Trepopnea can occur with unilateral diaphragmatic paralysis, with ball-valve airway obstruction, or after surgical pneumonectomy. Platypnea is the opposite of orthopnea: dyspnea in the upright position. Platypnea results from the loss of abdominal wall muscular tone and, in rare cases, from right-to-left intracardiac shunting, as occurs from a patent foramen ovale. Hyperpnea is essentially hyperventilation and is defined as minute ventilation in excess of metabolic demand. Hyperpnea may not be associated with dyspnea, and dyspnea is not always associated with increased minute ventilation.

Pathophysiology

Dyspnea is a complex sensation that involves both objective and subjective elements. Unlike other noxious sensations, dyspnea does not have a defined neural pathway, and the perceived difficulty probably arises from the interaction of several pathophysiologic mechanisms.² The following processes are involved in the sensation of dyspnea:

1. A conscious sense of the voluntary peripheral skeletal and respiratory muscular effort that occurs with increased work of breathing.
2. Stimulation of upper airway mechanical and thermal receptors.
3. Decreased stimulation of chest wall afferents.
4. Stimulation of central hypercapnic chemoreceptors in the central medulla.

5. Stimulation of peripheral hypoxic chemoreceptors, primarily in the carotid body in concert with those in the aortic arch.
6. Stimulation of a variety of lung receptors, including intraparenchymal pulmonary stretch receptors, airway irritant receptors, and unmyelinated receptors that respond to interstitial edema or a change in compliance.
7. Stimulation of peripheral vascular receptors, including the right atrial and left atrial mechanoreceptor and the pulmonary artery baroreceptor.

Input from any or all of these receptors is integrated in a complex manner in the central nervous system (CNS) at both the subcortical and cortical level. Many authors believe that dyspnea results from afferent mismatch, when feedback from these peripheral receptors indicates that the work of breathing is greater than would be expected by the patient's level of activity.³

Clinical Features

Dyspnea has many causes but can be divided into general categories (Table 62-1). Because of its mainly subjective component, the presence or degree of dyspnea is difficult to measure, although categorical scales (e.g., the Borg or Fletcher scales) and visual analogue scales can be used in individual patients to gauge changes in the degree of distress in response to therapy.⁴ The initial assessment of any patient with dyspnea should be directed toward identifying imminent respiratory failure. The physician should specifically evaluate for tachypnea, tachycardia, stridor, and use of the accessory respiratory muscles, including the sternocleidomastoid, sternoclavicular, and intercostals. Other signs and symptoms of imminent respiratory failure are inability to speak as a consequence of the breathlessness, agitation or lethargy as a consequence of hypoxia, and paradoxical abdominal wall movement (abdominal wall retracts inward) with inspiration, indicating diaphragmatic fatigue. In patients with any of these signs or symptoms, oxygen should be administered and the need for airway control and mechanical ventilation anticipated. Lesser degrees of dyspnea allow for a more detailed medical history, physical examination, and indicated ancillary tests.

Diagnosis

A detailed medical history often identifies the primary process resulting in dyspnea. Patients often have underlying chronic disorders and can frequently specifically and accurately self-diagnose their exacerbations. The medical history should include recent infectious and environmental exposures that may impair respiratory function. Patients who require daily medications for symptom control should be questioned carefully about compliance and possible drug interactions.

A number of ancillary tests aid in determining the severity and specific cause of dyspnea. Pulse oximetry is a rapid but insensitive screening test for disorders of gas exchange, and results may be normal in acute dyspnea. Arterial blood gas (ABG) analysis is more sensitive for detecting impaired gas exchange, but results may also be normal in acute dyspnea, and ABG analysis cannot evaluate the work of breathing. Rarely, patients who appear dyspneic or tachypneic but who exhibit no evidence of hypoxia or pulmonary disease are shown to be hyperventilating from metabolic acidosis on ABG testing. A chest radiograph may indicate the general category of primary disease; infiltrate, effusion, and pneumothorax. Bedside spirometric analysis (peak expiratory flow, or PEF) before and after bronchodilator therapy

TABLE 62-1 Causes of Dyspnea

Most Common Causes	Most Immediately Life-Threatening
Obstructive airway disease: asthma, COPD	Upper airway obstruction: foreign body, angioedema, hemorrhage
Congestive heart failure/ cardiogenic pulmonary edema	Tension pneumothorax
Ischemic heart disease: unstable angina and myocardial infarction	Pulmonary embolism
Pneumonia	Neuromuscular weakness: myasthenia gravis, Guillain-Barre syndrome, botulism
Psychogenic	

can be used to diagnose and treat dyspnea resulting from asthma or COPD, although it requires voluntary effort that might be difficult for dyspneic patients. B-type natriuretic peptide (BNP) serum levels >100 pg/mL can be used to diagnose congestive heart failure in patients with acute dyspnea in the ED.⁵ Other potentially useful tests include an electrocardiogram and determination of hemoglobin level. Uncommonly, the cause of dyspnea cannot be identified by the history, the physical examination, and these ancillary tests, and specialized testing, including cardiac stress testing, echocardiography, formal pulmonary function testing, computed tomography scanning of the chest, or combined cardiopulmonary exercise testing, is indicated.

Treatment

Just as there is no single cause of dyspnea, there is no single treatment. In severe dyspnea, the primary treatment goal is maintenance of the airway and oxygenation with a P_{aO_2} (partial pressure of arterial oxygen) >60 mm Hg and/or arterial oxygen saturation (S_{aO_2}) ≥90 percent. After this is ensured, or for patients with lesser degrees of dyspnea, disorder-specific treatment can be provided. Patients with unrelieved dyspnea at rest, particularly those with terminal malignancies, may benefit from opioids or benzodiazepines.⁶

HYPOXEMIA

Hypoxia is insufficient delivery of oxygen to the tissues. The amount of oxygen available to the tissues is a function of the arterial oxygen content (CaO_2) and blood flow.

$$CaO_2 = 0.0031 \times P_{aO_2} + 1.38 \times Hb \times S_{aO_2}$$

Tissue hypoxia occurs in states of low cardiac output, low hemoglobin (Hb) concentration, or low S_{aO_2} . The percent oxygen saturation of arterial hemoglobin is, in turn, dependent on the P_{aO_2} , as described by the oxygen-hemoglobin dissociation curve. Hypoxemia is an abnormally low arterial oxygen tension. Under most situations, cardiac output is within a normal range, and hypoxemia is the most common cause of hypoxia. Although the terms *hypoxia* and *hypoxemia* are generally used interchangeably, one can occur without the other. For example, in states of low P_{aO_2} (hypoxemia) with concomitant polycythemia, the patient may have no tissue hypoxia. Alternatively, very anemic patients may suffer tissue hypoxia despite a normal P_{aO_2} . Hypoxemia is arbitrarily defined as a P_{aO_2} <60 mm Hg. As noted above, patients with hypoxemia may not necessarily have dyspnea, and patients with dyspnea may not have hypoxemia.

Relative hypoxemia is the term used when the arterial oxygen tension is lower than expected for a given level of inhaled oxygen. The degree of relative hypoxemia can be assessed by calculating the alveolar-arterial (A-a) oxygen partial pressure gradient. This A-a O_2 gradient measures how well alveolar oxygen is transferred from the lungs to the

circulation. Alveolar oxygen partial pressure is determined by the inhaled oxygen concentration (21 percent for room air), atmospheric pressure (760 mm Hg at sea level), and displacement by water vapor (47 mm Hg for full saturation) and carbon dioxide. Gas in the alveolus is fully saturated with water vapor, and the amount of alveolar oxygen is further reduced by carbon dioxide that freely diffuses from the pulmonary capillaries in an amount determined by the ratio between oxygen consumption and carbon dioxide production, termed the respiratory quotient (R). On a typical diet, the respiratory quotient is 0.8. Thus, alveolar oxygen from breathing room air at sea level has a $PAO_2 = 0.21 \times (760 - 47) - P_{aCO_2}/0.8$. The A-a gradient at sea level for room air is $P(A-a)O_2 = 149 - P_{aCO_2}/0.8 - P_{aO_2}$. **A simplified formula is often used is $P(A-a)O_2 = 145 - P_{aCO_2} - P_{aO_2}$. A normal $P(A-a)O_2$ is under 10 mm Hg in young, healthy patients, and increases with age, predicted by the formula $P(A-a)O_2 = 2.5 + 0.21$ (age in years) (± 11).** This value for the normal A-a gradient is for healthy, asymptomatic individuals measured in an upright or sitting position. The supine position alone, as well as many chronic cardiac or pulmonary diseases, may raise the A-a gradient. Thus, many patients seen in the emergency department already have an elevated A-a gradient due to position or underlying chronic diseases, making it difficult to evaluate increases in the gradient that may be due to an acute pathologic condition.

Pathophysiology

Hypoxemia results from any combination of five distinct mechanisms.

1. **Hypoventilation.** Hypoventilation from a variety of disorders may result in hypoxemia. Regardless of its specific etiology, hypoxemia resulting from hypoventilation alone is always associated with an increased P_{aCO_2} , and a normal A-a O_2 gradient. In the case of pure hypoventilation, the additional CO_2 displaces the inhaled oxygen and lowers the amount in the alveolus. This lowered oxygen content, however, diffuses and mixes normally into the arterial blood.
2. **Right-to-left shunt.** Right-to-left shunting occurs when blood enters the systemic arteries without traversing ventilated lung. There is always a small degree of right-to-left shunting because of the direct left ventricular return of deoxygenated blood from both the coronary veins and the bronchial arteries. Increased right-to-left shunting occurs in a variety of conditions, including pulmonary consolidation, pulmonary atelectasis, and vascular malformations. Regardless of the specific cause of the right-to-left shunt, there is always an increase in the A-a O_2 gradient. Right-to-left shunting does not increase P_{aCO_2} , and patients with a right-to-left shunt may have an abnormally low P_{aCO_2} because of hyperventilation. A hall mark of significant right-to-left shunting is the failure of arterial oxygen levels to increase in response to supplemental oxygen. Although a small improvement is observed with supplemental oxygen, hypoxemia is never fully eliminated because of the continuing mixture of deoxygenated blood into the systemic circulation.
3. **Ventilation-perfusion mismatch.** Ideal pulmonary gas exchange depends on a balance of ventilation and perfusion. Any abnormality resulting in a regional alteration of either ventilation or perfusion can adversely affect pulmonary gas exchange, resulting in hypoxemia. A wide variety of etiologies may result in these regional impairments, including pulmonary emboli, pneumonia, asthma, COPD, and even extrinsic vascular compression. Regardless of its specific etiology, hypoxemia from ventilation-perfusion mismatch is associated with an increased A-a O_2 gradient and hypoxemia improves with supplemental oxygen.
4. **Diffusion impairment.** Pulmonary gas exchange also depends on diffusion across the alveolar-blood barrier. Any condition that influences this diffusion may result in hypoxemia. Regardless of the specific cause of the diffusion impairment, the A-a O_2 gradient is increased and hypoxemia improves with supplemental oxygen. From

a practical standpoint, diffusion impairment alone does not produce clinically significant hypoxemia in humans.

5. *Low inspired oxygen.* Decreased ambient oxygen pressure results in hypoxemia. This is most commonly seen at high altitude or in nonobstructive asphyxia. The A-a O₂ gradient is normal and hypoxemia improves with supplemental oxygen. For example, Denver, at 5400 ft above sea level, has an atmospheric pressure of 620 mm Hg and an inhaled oxygen partial pressure of only $0.21 \times 620 = 130$ mm Hg, as opposed to 160 mm Hg at sea level.

There are three distinct acute compensatory mechanisms for hypoxemia. Initially, minute ventilation increases. Next, pulmonary arterial vasoconstriction decreases perfusion to hypoxic alveoli. While vasoconstriction balances ventilation and perfusion in order to restore arterial oxygenation, it may also cause acute right heart failure and is ineffective with diffuse lung disease. Finally, sympathetic tone increases and improves oxygen delivery by increasing cardiac output, usually with an increased heart rate. Chronic compensatory mechanisms include an increased red blood cell mass and decreased tissue oxygen demands. These compensatory mechanisms appear to be activated at different levels of hypoxemia for different individuals. However, the acute compensatory mechanisms are always activated when Pao₂ reaches 60 mm Hg, and compensatory mechanisms fail when Pao₂ falls below 20 mm Hg.

Clinical Features

The signs and symptoms of hypoxemia are nonspecific. CNS manifestations include agitation, headache, somnolence, coma, and seizures. While tachypnea and hyperventilation are often present, at a Pao₂ <20 mm Hg, there is a central depression of respiratory drive. Cyanosis is not a sensitive or specific indicator of hypoxemia. Patients with chronic compensatory mechanisms may display polycythemia or alterations in body habitus (e.g., pulmonary cachexia). Using a combination of clinical signs, it is possible to predict hypoxemia in children with acute respiratory tract infections with a reasonable accuracy.⁷

Diagnosis

The diagnosis of arterial hypoxemia requires objective measurement. Because hypoxemia is defined as a Pao₂ <60 mm Hg, formal diagnosis requires ABG analysis. Although pulse oximetry is useful for screening purposes and decreased Sao₂ readings accurately predict significant hypoxemia, normal oxygen saturation readings do not exclude hypoxemia.

Treatment

Regardless of the specific cause of hypoxemia, the initial approach remains the same: ensuring a patent airway and providing supplemental oxygenation with a goal of maintaining a Pao₂ >60 mm Hg. Except in patients with right-to-left shunts, arterial oxygenation responds to supplemental oxygen.

HYPERCAPNIA

Hypercapnia is exclusively caused by alveolar hypoventilation and is arbitrarily defined as a Paco₂ >45 mm Hg. Alveolar hypoventilation can be a result of a variety of disorders, including rapid shallow breathing, small tidal volumes, underventilation of the lung, or reduced respiratory drive; it is never a result of increased CO₂ production (Table 62-2).

Pathophysiology

A portion of each tidal volume remains in the non-gas-exchange portion of the respiratory system—termed the "dead space"—and is usu-

TABLE 62-2 Causes of Hypercapnia

Depressed central respiratory drive
Structural CNS disease: brainstem lesions
Drug depression of respiratory center: opioids, sedatives, anesthetics
Endogenous toxins: tetanus
Thoracic cage disorders
Kyphoscoliosis
Morbid obesity
Neuromuscular impairment
Neuromuscular disease: myasthenia gravis, Guillain-Barre syndrome
Neuromuscular toxin: organophosphate poisoning, botulism
Intrinsic lung disease associated with increased dead space
COPD Upper airway obstruction

ally determined by the anatomic size of the conducting airways (trachea and bronchi). The portion of the tidal volume that reaches the alveoli is that which remains after the dead space volume is subtracted: Ta (alveolar volume) = TV (tidal volume) —Td (dead space). Alveolar ventilation per minute is the volume multiplied by the rate: A = Ta X R (respiratory rate) = (TV -Td) X R. Alveolar hypoventilation can result from a decrease in respiratory rate, a decrease in tidal volume, or an increase in dead space. Under some conditions, dead space volume can increase above that caused by the anatomic size of the conducting airways. This increase is a result of ventilation of lung portions with deficient or absent perfusion; these ventilated portions do not participate fully in gas exchange because of inadequate blood flow.

Because the medullary chemoreceptors stimulate both respiratory rate and tidal volume in response to increased CO₂, alveolar ventilation is finely controlled to maintain Paco₂ within a narrow range under most circumstances. In essence, alveolar ventilation is balanced relative to the production of CO₂ to maintain the Paco₂ within a narrow range. Decreased respiratory drive is associated with CNS lesions and toxic depression (see Table 62-2). Thoracic cage and neuromuscular disorders produce hypoventilation by slowing respiratory rate and/or decreasing tidal volume relative to the production of CO₂. Intrinsic lung diseases, such as COPD, produce alveolar hypoventilation because of an increase in dead space.

Clinical Features

The signs and symptoms of hypercapnia depend on the absolute value of Paco₂ and its rate of change. Acute elevations result in increased intracranial pressure, and patients may complain of headache, confusion, or lethargy. With severe hypercapnia, seizures and coma can result. Extreme hypercapnia can result in cardiovascular collapse, but this is usually seen only with acute elevations of Paco₂ > 100 mm Hg. As opposed to acute hypercapnia, chronic hypercapnia, even >80 mm Hg, may be well tolerated.

Diagnosis

Diagnosis of hypercapnia requires ABG analysis. Depending on other factors, pulse oximetry analysis can be normal. With acute hypercapnia, the serum bicarbonate level increases slightly as a result of mass action through the CO₂-bicarbonate equilibrium: bicarbonate increases about 1 mEq/L for each increase of 10 mm Hg in the Paco₂. Patients with chronic hypercapnia have an elevated serum bicarbonate concentration due to the renal response to increased Paco₂: the serum bicarbonate concentration increases about 3.5 mEq/L for each increase of 10 mm Hg in the Paco₂.

Treatment

Treatment of hypercapnia requires maneuvers to increase minute ventilation, both the rate and the tidal volume as appropriate. This involves ensuring a patent airway and may require mechanical ventilation or a

respiratory stimulant such as doxapram.⁸ The disposition of hypercapnic patients depends primarily on the underlying cause and severity. In general, patients with hypercapnia that causes CNS symptoms should be hospitalized. Also, patients with neuromuscular disease—either congenital or acquired—who present with acute hypercapnia should be hospitalized. Some COPD patients have chronic hypercapnia and do not require admission provided they are stable. Conversely, patients with COPD who display worsening hypercapnia despite maximal therapy require hospital admission.

WHEEZING

Wheezes are adventitious lung sounds that can be best described as "musical," produced by airflow through the central and distal airways.⁹ Wheezes have sinusoidal acoustics, over a wide frequency range, typically 100 to 1000 Hz. The duration is prolonged, typically longer than 80 ms. Wheezes differ from the other two main adventitious lung sounds: rhonchi and crackles (rales). Rhonchi are a series of damped sinusoidal sounds of lower frequency (<300 Hz) and prolonged duration (>100 ms). Crackles are a series of intermittent individual sounds, typically of less than 20 ms duration.

Pathophysiology

The current theory is that wheezes are produced by airway flutter and vortex shedding from the central and distal airways, although movement of airway secretions may play a small role. While flutter and vortex shedding are possible in normal airways, these processes are more pronounced in obstructed airways. Airway obstruction is associated with the processes of bronchial smooth muscle contraction (bronchospasm), smooth muscle hypertrophy, increased mucus secretion, and peribronchial inflammation.

Clinical Features

Wheezing is not synonymous with airflow obstruction as evidenced by the observation that wheezing can occur during quiet inspiration in some normal children and adults, and with forced expiration in many more. Conversely, patients with airflow obstruction may not have wheezing; the sensitivity of wheezing in detecting bronchial hyperactivity with airflow limitation of greater than 20 percent is at best 75 percent, and patients with profound obstruction (<20 percent of normal) may have not enough gas movement to generate a sound. These facts notwithstanding, wheezing is usually associated with asthma and other obstructive pulmonary diseases characterized by bronchial obstruction caused by muscular spasm and inflammation (Table 62-3). The duration of wheezing, or, more precisely, that portion of the expiratory phase occupied by wheezing, has been used to quantify the

severity of airflow obstruction in moderate-to-severe acute asthma. As noted above, patients with the most profound obstruction may not wheeze, but their condition can be detected by noting markedly decreased lung sounds.

Most patients with bronchospastic disease (either asthma or COPD) relate a history of previous attacks and response to bronchodilators. The finding of wheezing in a symptomatic patient without such a history is a clue that another process may be present.

Diagnosis

Airflow obstruction can be assessed by bedside spirometric analysis using portable machines; either PEF or forced expiratory volume in 1 s (FEV₁) is measured. Accurate measurement requires a cooperative patient and several (usually three) maximal-effort expirations. Severely dyspneic patients are often not able to perform the maneuver. Likewise, children may not understand the directions well enough to give a maximal effort. Because this test is effort dependent, only the maximal value should be reported. The obtained value should be compared to predicted normal values, dependent primarily on age, gender, and height, with only a small and clinically inconsequential adjustment for weight and ethnic background. For practical purposes, PEF or FEV₁ values >80 percent of the predicted value are within the normal range. Values between 50 and 80 percent of the predicted value constitute mild airflow obstruction, values between 25 and 50 percent constitute moderate airflow obstruction, and values <25 percent constitute severe airflow obstruction. However, the severity of clinical symptoms is dependent as much on the rapidity of the development of obstruction as on its absolute value. Conversely, relief of symptoms is correlated more closely with the relative degree of airflow improvement than with the absolute value.

Spirometric analysis can also be used to monitor response to treatment. Because of variations in effort and measurement, a change in spirometric value of up to 6 percent can be within the error range of the test. Thus, a significant change in PEF or FEV₁ is more than 8 to 10 percent from one measurement to another.

A chest radiograph may be useful in assessing wheezing, particularly for patients without a history of asthma. As noted elsewhere, patients with uncomplicated acute asthma do not require routine chest radiographs during their ED assessment and treatment. Conversely, patients with COPD and congestive heart failure who present with dyspnea and wheezing should have chest radiographs to evaluate for severity and complications.

ABG analysis is useful if clinical examination suggests hypoxemia, hypercapnia, or metabolic acidosis. The ABG analysis may also provide baseline values for further testing and treatment. However, most patients with mild-to-moderate asthma and wheezing can be assessed by spirometric analysis and do not require routine ABG analysis.

TABLE 62-3 Causes of Wheezing

Upper airway (more likely to be stridor, may have element of wheezing)
Angioedema: allergic, ACE inhibitor, idiopathic
Foreign body
Infection: croup, epiglottitis, tracheitis
Lower airway
Asthma
Transient airway hyperreactivity (usually caused by infection or irritation)
Bronchiolitis
COPD
Foreign body
Cardiovascular
Cardiogenic pulmonary edema ("cardiac asthma")
Noncardiogenic pulmonary edema (ARDS)
Pulmonary embolus (rare)
Psychogenic

Abbreviations: ACE = angiotensin-converting enzyme; ARDS = acute respiratory distress syndrome.

Treatment

Treatment of wheezing is directed by the underlying disorder and often involves aerosols of β_2 -agonists (e.g., albuterol) and/or anticholinergics (e.g., ipratropium bromide). Patients with peribronchial inflammation are often treated with systemic (oral or intravenous) or inhaled steroids.

COUGH

Cough is a common and nonspecific symptom that may bring patients to the ED, particularly if the cough interferes with activity or sleep.

Pathophysiology

Cough is a protective reflex that acts to clear secretions and foreign debris from the tracheobronchial tree.¹⁰ Coughing is initiated by stimu-

lation of irritant receptors located largely in the larynx, trachea, and major bronchi. These receptors are stimulated by inhaled irritants (e.g., dust), allergens (e.g., ragweed pollen), toxic substances (e.g., gastric acid), hypo- or hyperosmotic liquids, inflammation (e.g., asthma), cold air, instrumentation, and excess pulmonary secretions. Minor cough receptors located in the upper respiratory tract (sinuses and pharynx) and chest (pleura, pericardium, and diaphragm) may stimulate coughing. Signals from these receptors travel via the vagus, phrenic, and other nerves to the cough center in the medulla.

Once stimulated, the cough center initiates the stereotypical cough pattern: a deep inspiration followed by attempted expiration against a closed glottis that suddenly opens, providing for a forceful exhalation of gas, secretions, and foreign debris from the tracheobronchial tree. Extremely high peak airway velocities have been measured with coughing. The coughing sound is generated at the larynx and resonates in the nasal cavity and the lungs.¹⁰

Coughing patterns vary widely according to the underlying pathologic condition of the lung, the presence or absence of secretions, and whether the cough is voluntary or involuntary. Thus, it is not surprising that the frequency, duration, and quality of coughing vary among patients.

Clinical Features

For the purposes of differential diagnosis, cough has been subdivided into acute and chronic, primarily used to separate the self-limited syndromes of acute bronchitis and upper respiratory infection (URI) from other causes (Table 62-4). Chronic cough is defined as a cough that is present for more than 3 weeks without any periods of resolution. Cough has also been divided into nonproductive and productive with excess sputum production. That distinction may be artificial because, at least for cases of chronic cough, the same disorders produce both nonproductive and productive coughing; the distinction is without diagnostic utility.

Excluding environmental exposures, acute cough is most often caused by URI, lower respiratory tract infection, and allergic reactions. Common URIs are associated with a combination of rhinorrhea, sinusitis, pharyngitis, and laryngitis, with the cough a result of drainage from the nasopharynx onto cough receptors in the pharynx and larynx. A productive cough is the hallmark of acute bronchitis. While pneumonia generally produces a cough, pulmonary secretions may be scant and the cough nonproductive. Mycobacterial and fungal pulmonary infections may produce cough, but the presentation is usually more

subacute or chronic. Acute asthma is often associated with cough, but symptoms of wheezing and dyspnea usually dominate. Occasionally, a patient with asthma may present with coughing, as opposed to wheezing, as the principle manifestation of airflow obstruction.

Chronic cough is caused by a wide variety of disorders, but studies have found that most patients have chronic cough because of (1) smoking, often with chronic bronchitis, (2) postnasal discharge, (3) asthma, (4) gastroesophageal (GE) reflux, and (5) angiotensin-converting enzyme (ACE) inhibitor or angiotensin II receptor blocker therapy (see Table 62-4).^{11,13} The association of smoking, chronic bronchitis, and persistent cough is so obvious as to merit little discussion, other than to firmly point it out to patients. Smoking-induced coughing is usually worse in the morning and, with chronic bronchitis, usually productive. Rhinitis with postnasal discharge is associated with mucus drainage from the nose, a history of "allergies or sinus problems," and frequent clearing of the throat or swallowing of mucus. Chronic cough associated with asthma is usually worse at night, exacerbated by irritants, and associated with episodic wheezing and dyspnea. Asthma can be exacerbated by β -blocker therapy and presents with nocturnal coughing. Cough associated with GE reflux often has a history of heartburn, is worse when lying down, and improves with antacid therapy (antacids, H_2 blockers, or proton-pump blockers). The incidence of ACE inhibitor cough is approximately 10 to 12 percent, although higher values have been published.¹⁴ All ACE inhibitors and angiotensin II receptor blockers have been reported to induce cough and it is not clear whether certain agents have a higher likelihood of inducing cough than others. ACE inhibitor cough is thought to result when the blockade of ACE leads to accumulation of bradykinin and substance P, which stimulate the pulmonary cough receptors and enhance the formation of irritating prostaglandin metabolites. Extreme variability characterizes ACE inhibitor cough: early (1 week) or later (1 year) onset after starting treatment, only slightly bothersome to debilitating symptoms, and variation during the day. The association of pertussis in adults with persistent cough (>2 weeks) was documented from a convenience sample from one emergency department and in isolated outbreaks.¹⁵

Diagnosis

Most causes of acute cough do not warrant routine ancillary tests. A chest radiograph may be used in patients with purulent sputum and/or fever, and spirometric analysis may be used to document the presence of airflow obstruction in patients with asthma.

Patients with chronic cough are usually treated based on clinical assessment first, and ancillary tests are performed only if symptoms persist. Nasolaryngoscopy can be used to document the presence of mucosal inflammation and excessive mucus drainage. Sinus radiographs or computed tomography scanning can document the presence of sinusitis. A chest radiograph can detect focal or diffuse lung disease. Spirometric analysis can identify airflow obstruction, although, in cases of asthma-associated cough, the spirometric values are normal between attacks. GE reflux can be documented by a number of methods; esophageal pH monitoring is probably the most useful.

Treatment

In addition to disease-specific therapy, patients with acute cough may occasionally benefit from antitussives, which block the cough reflex at various locations.¹⁶ The effectiveness of medicinal and herbal antitussives is controversial, and the majority of benefit may be a placebo effect or demulcent effect. The most effective cough suppressants are the opioids, such as dextromethorphan, codeine, and oxycodone. While cough suppressants are usually restricted to patients with a dry cough and avoided in patients with significant sputum production, there is only tradition to support this practice. Demulcents, part of most proprietary cough preparations, soothe the pharynx and somewhat suppress the cough reflex. Of the herbal agents, menthol and the pungent

TABLE 62-4 Causes of Cough

Acute	Chronic: Common	Chronic: Less Common
Upper respiratory infection: rhinitis, sinusitis	Smoking and/or chronic bronchitis	Congestive heart failure
Lower respiratory tract infection: bronchitis, pneumonia	Postnasal discharge	Bronchiectasis
Allergic reaction	Asthma: reactive airways disease	Lung cancer or other intrathoracic mass
Asthma	Gastroesophageal reflux	Emphysema
Environmental irritants	Angiotensin-converting enzyme inhibitor	Occupational and environmental irritants
Transient airway hyperresponsiveness	Angiotensin II receptor blocker	Recurrent aspiration or chronic foreign body
Foreign body		Miscellaneous: cystic fibrosis, interstitial lung disease

spices (e.g., pepper, mustard, garlic, radish, and onions) have an anti-tussive effect.¹⁶

Because chronic cough is most often the result of a few common disorders, an algorithmic approach to treatment using sequential steps appears to be effective.^{13,17}

1. Reduce exposure to lung irritants (e.g., smoking) and discontinue ACE inhibitors, angiotensin II receptor blockers, and (3)-blockers.
2. Treat for postnasal discharge with an oral antihistamine-decongestant and/or an inhaled nasal steroid. If the cough improves, continue treatment and evaluate for sinus disease with imaging studies.
3. Evaluate and treat for asthma.
4. Obtain chest and sinus radiographs if not already done.
5. Evaluate and treat for GE reflux.
6. Refer the patient for bronchoscopy.

By using a sequential approach, tailoring treatment to the clinical symptoms and the patient's responses, more than 95 percent of patients achieve resolution of their cough.¹⁷

HICCUPS

Hiccup, or singultus, is an involuntary respiratory reflex with spastic contraction of the inspiratory muscles against a closed glottis, producing the characteristic sound. As opposed to coughing, where the reflex serves the useful purpose of expelling secretions and debris from the pulmonary tree, a specific protective purpose has not been elucidated for hiccups.¹⁸

Pathophysiology

The afferent arm of the hiccup reflex consists of the phrenic and vagus nerves as well as the thoracic sympathetic chain. There is no well-defined central hiccup center; instead, there is an intensive interconnection among the hypothalamus, medullary reticular formation, respiratory center, and cranial nerve nuclei. The efferent limb of the reflex uses the phrenic nerve, the recurrent laryngeal branch of the vagus nerve, and the motor nerves to the anterior scalene and intercostal muscles.

As noted above, hiccups are produced by spasmodic contraction of the inspiratory muscles (diaphragm and intercostals) against a closed glottis, a breakdown in the normal relationship between inspiration and glottic closure. Inspiration normally inhibits glottic closure and maintains an open airway. During swallowing, the stimulation of glottic closure inhibits inspiration, preventing aspiration. In some manner, the hiccup reflex disrupts the connection between these two processes so that 30 to 40 ms after the onset of inspiration, glottic closure is stimulated. In most cases where a specific cause can be assigned, hiccups appear to result from stimulation, inflammation, or injury to one of the nerves of the reflex arc.

Clinical Features

For diagnostic classification, hiccups are divided into benign self-limited and persistent, or intractable (Table 62-5).¹⁸

Benign hiccups are generally initiated by gastric distention from food, drinking (especially carbonated beverages), or air. Alcohol ingestion appears to precipitate hiccups by relaxing the relationship between inspiration and glottic closure, making it easier for other stimuli to trigger the reflex. Excessive smoking, a sudden change in environmental temperature, and psychogenic events (excitement or stress) are sometimes associated with hiccups.

Persistent hiccups are usually a result of damage or irritation to a branch of the vagus or phrenic nerve. A wide variety of events have been implicated in producing persistent hiccups. One rare but readily treatable stimulus is a foreign body (often a hair) in the external auditory canal that is pressing against the tympanic membrane and stimu-

TABLE 62-5 Causes of Hiccups

Acute: Benign, Self-limited	Chronic: Persistent, Intractable
Gastric distention	Central nervous system structural lesions
Alcohol intoxication	Vagal or phrenic nerve irritation
Excessive smoking	Metabolic: uremia, hyperglycemia
Abrupt change in environmental temperature	General anesthesia
Psychogenic	Surgical procedures: thoracic, abdominal, prostate and urinary tract, craniotomy

lating the auricular branch of the vagus nerve. Several drugs—usually steroids and benzodiazepines—are implicated in inducing hiccups, but the evidence is weak.¹⁹

Diagnosis

Most patients with benign hiccups resolve spontaneously or with simple maneuvers, do not seek medical attention, and do not require specific diagnosis. Patients with persistent hiccups often seek medical attention, occasionally in the ED.

The evaluation of persistent hiccups should start with a history to determine whether a specific event was associated with the onset. Are the hiccups persistent during sleep? Persistence during sleep suggests an organic cause, and resolution during sleep suggests a psychogenic cause, although this distinction is not absolute. Inquiries should be made concerning general anesthesia, surgical procedures, and several metabolic diseases that are associated with persistent hiccups. As noted above, the external auditory canal should be carefully examined. A chest radiograph should be done to evaluate for possible intrathoracic pathology. Fluoroscopy can be useful to evaluate for unilateral versus bilateral diaphragmatic movement during hiccups.

Treatment

A wide variety of physical maneuvers have been used to terminate an acute episode of hiccups. Many of these measures are based on the concept that stimulating the pharynx will block the vagal portion of the reflex arc and abolish the hiccups.²⁰ No one method appears to be more effective than another. Swallowing a teaspoon of granulated sugar dry is about as effective as others and does not involve the infliction of noxious or painful stimulation.

Drug treatment also works by inhibiting the reflex arc.²⁰ A large number of agents have been described as effective, but mostly only as case reports. Of the recommended drugs, only chlorpromazine has been tried enough to have achieved U.S. Food and Drug Administration approval for treatment of intractable hiccups. The recommended dose is 25 to 50 mg IV, with a repeated dose in 2 to 4 h if needed. If improvement is noted, oral therapy with 25 to 50 mg tid or qid should be given. Metoclopramide 10 mg IV or IM and, if effective, followed by 10 to 20 mg qid for 10 days, appears to be effective. Unlike with other agents, the effectiveness of both these drugs is usually evident within 30 min. The major disadvantages are extrapyramidal symptoms with both drugs and hypotension with chlorpromazine.

For more gradual control and with perhaps less risk of adverse reactions, oral treatment can be initiated with nifedipine 10 to 20 mg tid or qid, valproic acid 15 mg/kg per d taken tid, or baclofen 10 mg tid. Initiation and maintenance of these agents is best done in concert with a primary care physician who will follow up with the patient.

CYANOSIS

Cyanosis is a bluish color of the skin and mucous membranes that results from an increased amount of reduced hemoglobin (deoxyhemoglobin) or hemoglobin derivatives. The detection of cyanosis can be highly subjective and is not considered a sensitive indicator of the state of arterial oxygenation. In fact, cyanosis is determined by the absolute amount of deoxygenated hemoglobin in the blood; the amount of oxygenated hemoglobin is of little influence.

Pathophysiology

Traditional teaching has been that cyanosis is usually present when deoxygenated hemoglobin exceeds 5 g/dL. However, this figure is questionable because central cyanosis can be detected with deoxyhemoglobin concentration as low as 1.5 g/dL. In some instances, cyanosis can be detected when SaO_2 has fallen to 85 percent; in others, it may not be detected until SaO_2 is 75 percent.

Various physiologic, anatomic, and physical factors other than the amount of reduced hemoglobin may influence the appearance of cyanosis, making an accurate clinical detection of the degree or even the presence of cyanosis difficult. Physiologic factors include the oxygen content of the blood, level of tissue oxygenation, degree of oxygen extraction, and oxyhemoglobin dissociation curve. Anatomic factors include the status of the cutaneous microcirculation, pigmentation, and thickness of the skin. Physical factors include the lighting under which the patient is examined and the skill of the physician. The tongue is considered one of the most sensitive sites for observing central cyanosis, and the earlobes, conjunctivae, and nail beds are considered to be much less reliable.

Clinical Features

Clinically, the presence of cyanosis suggests the possibility of tissue hypoxia, and possible causes for hypoxia should be considered. Unexplained cyanosis, particularly in association with normal arterial oxygen tension (Pao_2), suggests the possibility of abnormal hemoglobin, such as methemoglobin.

Cyanosis is traditionally divided into two categories: central and peripheral. The central type is seen under conditions with unsaturated arterial blood or abnormal hemoglobin. The mucous membranes and skin are both affected. In contrast, peripheral cyanosis is caused by the slowing of blood flow to an area and an abnormally great extraction of oxygen from normally saturated arterial blood. Congestive heart failure, peripheral vascular disease, shock states, and cold exposure all create states of vasoconstriction and decreased peripheral blood flow. The differentiation between central and peripheral cyanosis may not be possible in conditions where both mechanisms are present (Table 62-6).

Diagnosis

The presence of cyanosis suggests the possibility of hypoxemia, and pulse oximetry analysis is readily available to assist the physician in the early diagnosis of hypoxemia and provide continuous oxygen saturation measurements. However, an exception occurs when the hemoglobin is in a state in which it is unable to bind to oxygen (i.e., methemoglobin or carboxyhemoglobin). In such situations, pulse oximetry analysis not only overestimates the oxygen saturation but also reflects a diminished response to any supplemental oxygen. ABG analysis with co-oximetry is still the gold standard in the assessment of any patient with suspected cyanosis. In central cyanosis, the oxygen saturation measured from the ABG is decreased because of the underlying hypoxemia. In peripheral cyanosis, assuming normal cardiopulmonary and hemoglobin status, the oxygen saturation should be normal. If methemoglobinemia or carboxyhemoglobinemia is suspected, the

TABLE 62-6 Causes of Cyanosis

Central Cyanosis	Peripheral Cyanosis
Hypoxemia	Reduced cardiac output
Decreased F_{IO_2} : high altitude	Cold extremities
Hypoventilation	Maldistribution of blood flow:
Ventilation-perfusion mismatch	distributive forms of shock
Right-to-left shunt: congenital	Arterial or venous obstruction
heart disease, pulmonary	
arteriovenous fistulas, multiple	
intrapulmonary shunts	
Hemoglobin abnormalities	
Methemoglobinemia: hereditary,	
acquired	
Sulfhemoglobinemia: acquired	
Carboxyhemoglobinemia	
(not true cyanosis)	

Abbreviation: F_{IO_2} = fraction of inspired oxygen.

ABG analysis will show a normal Pao_2 (reflecting a normal amount of dissolved oxygen in the plasma), a normal calculated oxygen saturation (from the normal Pao_2), and a decrease in measured oxygen saturation (because of a decreased number of oxygen binding sites).

Few tests are as vulnerable to errors introduced by improper sampling, handling, and storage as are ABG analyses. The technical difficulties with obtaining an arterial sample via percutaneous puncture accounts for much of the high preanalytic error rate for isolated ABG samples obtained in the emergency department, compared to a low error rate for samples obtained from an indwelling arterial catheter.

Special attention should be given to the following sources of preanalytic error with ABG samples. Heparin is the anticoagulant of choice, and one should make sure that the syringe is flushed with heparin and then emptied thoroughly. This will allow adequate anticoagulation of a 2- to 4-mL blood sample with assurance that the results will not be altered by the anticoagulant. Excessive heparin affects the pH, Pco_2 , and PO_2 as well as the hemoglobin determination. Air bubbles that mix with the blood sample will result in gas equilibration, significantly lowering the Pco_2 values with an increase in pH and PO_2 . Any sample obtained with more than minor air bubbles should be discarded. Reducing the temperature of the blood by placing the sample immediately in ice slush will significantly deter changes in the Pco_2 and pH for a period of several hours. As a general rule, arterial blood samples should be analyzed within 10 min or cooled immediately. Failure to properly cool the sample is a common source of preanalytic error.

Hypoxemia, anemia, and polycythemia can be diagnosed by means of hemoglobin and ABG determination. The red cyanosis of polycythemia vera occurs because the increase in the number of red blood cells and the hemoglobin concentration results in sludging of blood flow in cutaneous capillaries and venules. Similarly, cyanosis is enhanced in chronic hypoxemia accompanied by polycythemia.

If the measured Pao_2 and the hemoglobin concentration are normal, the cyanosis may be a result of abnormal skin pigmentation or abnormal hemoglobin. The term pseudocyanosis is used to describe a blue, gray, or purple cutaneous discoloration that may mimic cyanosis. Pseudocyanosis can be caused by heavy metals [e.g., iron (hemochromatosis), gold, silver, lead, and arsenic] or drugs (e.g., phenothiazine, minocycline, amiodarone, and chloroquine). Chrysis is a specific type of pseudocyanosis that is characterized by a gray, blue, or purple pigmentation of areas exposed to light. It is a rare dose-dependent complication of gold treatment that tends to cause permanent discoloration of the skin. Another example of pseudocyanosis is argyria, which is a slate blue-to-gray coloration of the skin resulting from either chronic ingestion or chronic local application of silver salts or colloidal silver. In pseudocyanosis the skin does not blanch with pressure, in contrast to true cyanotic skin, which does

blanch. Carboxyhemoglobinemia does not cause cyanosis. Occasionally, however, carboxyhemoglobinemia does produce a cherry-red flush of the skin, retina, or mucous membranes.

Cyanosis can be caused by methemoglobinemia and sulfhemoglobinemia. Most cases are caused by chemicals or medications. Although a wide range of drugs can produce methemoglobinemia, benzocaine, nitrates, and nitrites are the most common agents implicated in drug-induced methemoglobinemia. Sulfhemoglobinemia most commonly results from either phenacetin or acetanilid. Industrial aniline compounds may produce either sulfhemoglobinemia or methemoglobinemia.

The incidence of acquired methemoglobinemia secondary to industrial exposure to aniline dyes and aromatic amino and nitro compounds has decreased with improvement in occupational health standards. Hereditary methemoglobinemia is a rare genetic disorder affecting the enzyme NADH [nicotinamide adenine dinucleotide (reduced form)]-methemoglobin reductase, resulting in structural alterations of the hemoglobin molecule. This enzyme is the major pathway responsible for converting methemoglobin to its reduced state. This pathway plays a clinically significant role in the treatment of methemoglobinemia because it is the pathway by which the antidote, methylene blue, is able to enhance the reduction of methemoglobin. Patients with NADH-methemoglobin reductase deficiency appear cyanotic but are usually compensated and asymptomatic.

Methemoglobinemia produces visible cyanosis with as little as 1.5 g/dL. Because methemoglobin is incapable of binding with oxygen, the symptoms of methemoglobinemia are secondary to hypoxia, and the severity is related to the quantity of methemoglobin present, the rapidity of onset, and the patient's cardiopulmonary system. Cyanotic patients without cardiovascular or pulmonary disease should be suspected of having methemoglobinemia, especially if cyanosis is not relieved by oxygen administration. An additional clue is that venous blood will appear chocolate brown. Spectrophotometric analysis is required for identification of the pigment and its quantity.

Sulfhemoglobin is inert as an oxygen carrier and can produce deep cyanosis at a level of less than 0.5 g/dL. Unlike methemoglobinemia, sulfhemoglobinemia is irreversible. Treatment is directed toward symptomatic and supportive care as well as the identification and removal of suspected causes.

Treatment

Patients with central cyanosis should be started on supplemental oxygen. Failure to improve suggests impaired circulation (shock), abnormal hemoglobin, or pseudocyanosis. In acquired methemoglobinemia, no treatment is necessary unless signs of hypoxia (i.e., angina, arrhythmias, hypotension, stupor, or coma) are present. Methylene blue 1 to 2 mg/kg of body weight given intravenously over 5 min is the antidote for acquired methemoglobinemia (see Chap. 189). Caution should be taken whenever methylene blue is used; by itself, at high doses, it can cause hemolysis or even precipitate methemoglobinemia and possibly worsen the patient's condition.

PLEURAL EFFUSION

Pleural effusions result from fluid accumulating in the potential space between the visceral and parietal pleurae. While pleural effusions can result from many causes, in developed countries, the most common causes are congestive heart failure, pneumonia, and cancer (Table 62-7).

Pathophysiology

Normally, a small amount of fluid is secreted from the parietal pleural into the pleural space where it is absorbed by the visceral pleural microcirculation. This small amount of pleural fluid reduces friction between the pleural layers and allows for smooth lung expansion and contraction with respiration. Any process that increases fluid production or

TABLE 62-7 Causes of Pleural Effusion

Common		Less Common

		EXUDATES
Cancer: primary or metastatic		Viral, fungal, mycobacterial, or parasitic infection Systemic rheumatologic disorders:
Bacterial pneumonia with parapneumonic effusion		systemic lupus erythematosus, rheumatoid arthritis Uremia, pancreatitis Postcardiac surgery or radiotherapy Drug-related: amiodarone
Pulmonary embolism		
		EITHER TRANSUDATES OR EXUDATES
Transudates after diuretic therapy		Pulmonary embolism

interferes with fluid absorption will result in accumulation in the pleural space. Pleural effusions are traditionally divided into exudates or transudates based on mechanism.²¹ Exudative effusions result from pleural disease, usually inflammation or neoplasia, that results in active fluid secretion or leakage with high protein content. Transudative effusions result from an imbalance in hydrostatic (e.g., congestive heart failure) or oncotic (e.g., nephrotic syndrome) pressure and produce an ultrafiltrate across the pleural membrane with low protein content.

Clinical Features

A pleural effusion may be clinically silent, or come to detection from either symptoms of an underlying disease, an increase in volume of the effusion with the production of dyspnea, or the development of inflammation and associated pain with respiration. Physical findings of a pleural effusion include percussion dullness and decreased breath sounds. Because pleural fluid typically pools in the dependent portions of the hemithorax, small or moderate size effusions have percussion dullness and decreased breath sounds at the lung base with relatively normal lung findings above the level of fluid. With large or massive effusions, it may be impossible to distinguish a fluid level on clinical examination.

Diagnosis

In an adult, 150 to 200 mL of pleural fluid in the hemithorax is required to produce signs on upright chest radiography. When taken in the supine position, chest radiographs may demonstrate only a hazy appearance of pleural fluid in the posterior pleural space. Small free-flowing pleural effusions can be visualized on decubitus radiographic views. Ultrasonography can be used to image pleural effusions, although accuracy depends on operator technique and the quality of interpretation. A significant pleural effusion is large enough to produce a pleural fluid strip more than 10 mm wide on lateral decubitus radiographic views or by ultrasonography.²¹

Diagnostic thoracentesis is done to obtain pleural fluid for analysis in cases without a clearly evident cause, to confirm a suspected diagnosis, or to detect pleural space infection. For example, because the largest single cause of pleural effusion is congestive heart failure, if a patient presents with a typical appearance (cardiomegaly, roughly equal in size bilateral effusions), then a period of treatment with monitoring for pleural fluid resolution is indicated, and routine thoracentesis is reserved for those patients who do not resolve in 3 to 4 days. Otherwise, diagnostic thoracentesis and pleural fluid analysis is indicated.

Light and colleagues developed the most widely used criteria to differentiate transudate from exudates using serum and pleural fluid

TABLE 62-8 Pleural Fluid Diagnostic Tests

DETECTION OF EXUDATIVE PLEURAL EFFUSION L
<p>ihf anc - "leagues criteria for pleural exudate: one or more of the following present (modified) Pleural fluid serum protein ratio >0.5,</p> <p>or</p> <p>Pleural fluid/serum LDH ratio >0.6,</p> <p>or</p> <p>Pleural fluid LDH greater than two-thirds of the upper limit for serum LDH</p>
ADDITIONAL TESTS ON EXUDATIVE EFFUSIONS
<p>Gram stain and culture to detect bacterial infection Cell count</p> <p>Neutrophil predominance: parapneumonic, pulmonary embolism, pancreatitis</p> <p>Lymphocytic predominance: cancer, tuberculosis, postcardiac surgery</p> <p>Glucose: low glucose seen in parapneumonic, malignant, tuberculosis, and rheumatoid arthritis causes of pleural effusions C/tology for malignancy: highest yield is with adenocarcinoma, much</p> <p>lower with squamous cell, lymphoma, or mesothelioma Pleural fluid pH: normal pleural fluid pH around 7.64. In parapneumonic effusions, a pleural fluid pH <7.10 predicts development of empyema or persistence and indicates need for thoracostomy tube drainage Pleural fluid amylase: elevated in pleural effusions due to pancreatitis or esophageal rupture</p> <p>Mycobacterial and fungal stains and cultures: as suggested clinically</p> <p>Tuberculosis pleural fluid markers: polymerase chain reaction for mycobacterial DNA, pleural fluid adenosine deaminase, or pleural fluid interferon-γ</p>

Abbreviation: LDH = lactate dehydrogenase.

protein and lactate dehydrogenase (LDH) levels (Table 62-8).²¹ Several modifications to the original criteria have been proposed.²² Regardless, the sensitivity of these criteria for the detection of an exudative pleural effusion is 98 to 99 percent with specificity from 65 to 86 percent. If the clinical circumstances suggest that the effusion is likely to be transudative, the only tests indicated are pleural fluid and serum protein content and LDH levels. If the pleural effusion is exudative, additional tests are indicated (see Table 62-8).

The distinction between exudates and transudates may be obscured by the effect of diuretic therapy in patients with transudative pleural effusions; during diuresis, the resorption of water is faster than that of protein, so that protein concentration rises into the range consistent with an exudative etiology. A serum to pleural albumin difference of greater than 1.2 g/dL has been proposed to help in this scenario, but this approach will reduce the sensitivity of exudative pleural effusion detection by more than 10 percent.^{21,22}

Treatment

If the patient has dyspnea at rest, therapeutic thoracentesis with drainage of 1 to 1.5 L of fluid is indicated. Patients with pleural empyema (gross pus or organisms on Gram stain) require drainage with large bore thoracostomy tubes. Treatment of parapneumonic effusions is controversial (see Chap. 63). Consensus guidelines recommend thoracostomy tube drainage of parapneumonic effusions with positive cultures, positive Gram stain, or pleural fluid pH below 7.10. Diuretic therapy typically resolves more than 75 percent of effusions due to congestive heart failure within 2 to 3 days.

63 BRONCHITIS, PNEUMONIA, AND PLEURAL EMPYEMA

Donald A. Moffa, Jr. Charles L. Emerman

ACUTE BRONCHITIS

Epidemiology

Uncomplicated acute bronchitis (UAB) refers to an acute respiratory tract infection in which cough, occasionally with phlegm, is the predominant feature, and which is not caused by pneumonia or chronic bronchitis.¹ UAB usually lasts 1 to 3 weeks typically, but may last longer. Approximately 5 percent of adults in the United States report an episode of UAB each year, typically between October and March.

Pathophysiology

Microbiologic studies of UAB have successfully identified pathogens in 16 to 55 percent of cases; more than one pathogen may be identified in up to 10 percent.² Respiratory viruses cause the vast majority of cases of UAB: influenza B, influenza A, parainfluenza, and respiratory syncytial virus are most often implicated, but viruses that commonly produce upper respiratory tract infection (coronavirus, adenovirus, rhinoviruses, and coxsackievirus) have also been identified.

Bordetella pertussis, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Legionella* species are reported in 5 to 25 percent of cases of UAB.^{1,3} Acute bronchitis in adults from *Bordetella pertussis* and parapertussis does not produce the characteristic whooping cough as these infections do in children.³ *Bordetella pertussis*, *Mycoplasma pneumoniae*, and *Chlamydia pneumoniae* are recovered in 10 to 20 percent of adults with chronic or persistent cough lasting more than 2 to 3 weeks.¹ *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis* have been found in sputum of 7 to 44 percent of patients with UAB, but because they are part of the normal oropharyngeal flora, their significance in causing UAB is unknown.³

Clinical Features

The cough of UAB is commonly productive, and in as many as 20 percent of patients may last as long as 2 months.¹ The presence of purulent sputum is unimportant in diagnosing or treating UAB unless other symptoms and clinical findings suggest pneumonia. Fever >38°C (100.4°F), heart rate >100 beats/min, respiratory rate >24 breaths/min, focal chest pain or lung findings, and the absence of rhinorrhea or sore throat suggest pneumonia. Less than 10 percent of patients with UAB are febrile. UAB overlaps with symptoms of other common upper respiratory tract infections. The strongest positive independent predictors for UAB are cough and wheezing, and nausea is the strongest negative independent predictor that the diagnosis is not UAB.⁴ Transient bronchial hyperresponsiveness appears to be the predominant mechanism for the cough of UAB, and differentiating it from asthma may be a challenge since abnormal spirometry will be present in both.¹ In fact, approximately one-third of patients presenting with symptoms of UAB may have asthma.⁵

Diagnosis

Clinical diagnosis of UAB is appropriately made with the following: (1) acute cough (less than 1 to 2 weeks), (2) no prior lung disease, and (3) no auscultatory abnormalities that suggest pneumonia. Pulse oximetry is indicated if the patient describes dyspnea or appears to be short of breath. Bedside spirometry (peak expiratory flow or forced expiratory volume in 1 s) is indicated if the patient describes wheezing or wheezing is heard on examination.

Since most cases of UAB are viral in etiology and because sputum Gram stain and culture do not reliably detect the most common nonviral pathogens, (*Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Bordetella pertussis*), sputum Gram stain and culture are not recommended in evaluation of patients with UAB.¹ In previously healthy, nonelderly adults, chest radiography is not indicated unless the cough has been present 3 weeks or longer or if evidence of pneumonia is found.

Treatment

Many patients receive antibiotics for UAB, although studies have failed to show significant improvement unless treating pertussis is a consideration.¹ Some studies have found pertussis in up to 20 percent of patients with a cough lasting longer than 2 to 3 weeks, but no clinical features allow clinicians to distinguish adults with a cough due to pertussis from other pathogens.¹ At best, antibiotic therapy may decrease duration of cough, decrease purulent sputum production, and return patients to work by less than 1 day each.^{1,3} Even when atypical pathogens are identified in causing the UAB, treatment with the antibiotics amoxicillin, erythromycin, or a fluoroquinolone does not affect outcome, and treatment with antibiotics is significantly more likely to cause side effects including nausea, vomiting, headache, skin rash, or vaginitis.²

Patients with airflow obstruction suggested by wheezing during UAB are more likely to benefit from inhaled bronchodilators than patients who simply have a cough without wheezing.⁶ There is no evi-

dence to support using (3₂-agonists in children with acute cough and without evidence of airflow obstruction.⁶ Inhaled bronchodilator treatment is not without side effects; up to two-thirds of adults receiving them report tremor, shaking, or nervousness.⁶

Acute Exacerbation of Chronic Bronchitis (AECB)

Approximately two-thirds of AECB cases are bacterial in origin, with nontypeable *H. influenzae*, *Streptococcus pneumoniae*, and *Moraxella catarrhalis* the most common organisms identified.⁷ High-risk patients are the elderly and those with poor lung function or structural lung disease, poor performance status, other comorbid illnesses, and those having frequent exacerbations requiring corticosteroids. AECB is characterized by increased dyspnea, increased cough and sputum production, and increasing sputum purulence in a patient with underlying chronic obstructive pulmonary disease (COPD). During AECB, an increased number of bacteria, neutrophils, and inflammatory mediators may be seen in the patient's sputum, and an acute antibody response in serum may be present.

In AECB patients with at least two of the following (1) increased dyspnea, (2) increased sputum volume, or (3) increased sputum purulence, treatment with a broad-spectrum antibiotic such as doxycycline, extended-spectrum oral cephalosporin, an advanced-generation macrolide, amoxicillin-clavulanate, or a fluoroquinolone leads to a modest improvement in clinical outcome, fewer therapeutic failures, and a more rapid recovery of lung function compared to treatment with placebo.⁷ The greatest benefit is seen in patients with more severe disease, including those who are older, who have poorer lung function, more comorbid diseases, and more frequent exacerbations.

PNEUMONIA

Epidemiology

Community-acquired pneumonia (CAP) is a common medical problem, accounting for about 4 million cases and 1 million hospitalizations per year in the United States.⁸ It is the sixth leading cause of death, particularly among older adults, in whom the disease is more common. Whereas older studies of pneumonia pointed to pneumococci as the most common cause of pneumonia, there is an increasing frequency of atypical or opportunistic infections. The classic presentation of pneumococcal pneumonia is generally apparent, but atypical infections, infections in compromised hosts, and infections in patients at the extremes of age may present with more subtle findings. Older patients may present with a change in mental status or a decline in function without the typical respiratory symptoms.

Pathophysiology

Pneumonia may occur through a variety of routes of infection. Pathogenic organisms may be inhaled or aspirated directly into the lungs. Alternatively, some bacteria, such as *Staphylococcus aureus* or *Pneumococcus*, may produce pneumonia as a result of hematogenous seeding. With this in mind, patients most at risk for pneumonia are those with a predisposition to aspiration, impaired mucociliary clearance, or risk of bacteremia (Table 63-1).

Pneumonia is an infection of the alveolar or gas-exchanging portions of the lung. Some forms of pneumonia produce an intense inflammatory response within the alveoli that leads to filling of the air space with organisms, exudate, and white blood cells. Pneumonia can spread throughout the lung via the bronchial tree or through the pores of Kohn. Bacterial pneumonia, with an intense inflammatory response, tends to cause a productive cough, whereas other atypical organisms do not lead to such an intense inflammatory response and may only be associated with mild nonproductive cough.

TABLE 63-1 Risk Factors for Pneumonia

Aspiration risk
Swallowing and esophageal motility disorders
Stroke
Nasogastric tube
Intubation
Seizure and syncope

Chronic diseases
Diabetes
Renal failure
Liver failure
Valvular heart disease
Congestive heart failure
Pulmonary disorders
Chronic obstructive pulmonary disease
Chest wall disorders
Skeletal muscle disorders
Bronchial obstruction
Bronchoscopy
Viral lung infections

Prospective studies of both inpatients and outpatients with CAP fail to identify a specific pathogen in 40 to 60 percent of patients. When an etiology is found, pneumococcus is still the most common single agent, followed by viruses and the atypical agents such as *Mycoplasma*, *Chlamydia*, and *Legionella*. In up to 5 percent, multiple agents are identified. Special populations, including nursing-home residents, chronic alcoholics, and HIV-infected patients, have a somewhat different etiologic spectrum.

Clinical Features

Patients with pneumonia usually present with cough, dyspnea, sputum production, fever and pleuritic chest pain.⁸ However, there is variability in the individual symptoms and physical findings that may make clinical diagnosis difficult.⁹ The typical presentation of pneumococcal pneumonia is a sudden onset of illness with fever, rigors, dyspnea, bloody sputum production, chest pain, tachycardia, tachypnea, and abnormal findings on lung examination. Most other types of pneumonia do not have such a sudden and characteristic presentation. Pneumonia may be preceded by symptoms of a viral upper respiratory infection with coryza, low-grade fever, rhinorrhea, or nonproductive cough. Weight loss, malaise, dizziness, and weakness may be associated with pneumonia. Some of the atypical agents are associated with dramatic presentations of headache or gastrointestinal (GI) illness. Occasionally, pneumonia is associated with extrapulmonary symptoms, including joint pain, hematuria, or skin rashes.

The physical examination may show evidence of alveolar fluid (inspiratory rales), consolidation (bronchial breath sounds), pleural effusion (dullness and decreased breath sounds), or bronchial congestion (rhonchi and wheezing).⁹ Tachypnea, tachycardia, fever, and hypotension are associated with severe illness.

NEUMOCOCCAL PNEUMONIA *Streptococcus pneumoniae* is particularly prevalent at the extremes of age and in the chronically ill; persons at highest risk for infection are the elderly, children under 2 years old, minorities, children who attend group day-care centers, and persons with underlying medical conditions including HIV infection and sickle-cell disease. Classically, patients with pneumococcal pneu-

monia present with sudden onset of disease with rigors, bloody sputum, high fever, and chest pain. In this setting, patients will frequently have lobar pneumonia, with parapneumonic pleural effusions occurring in about 25 percent of patients. Patients with functional or anatomic asplenia or patients being treated with immunosuppressive drugs, such as transplant patients, may have a very rapid progression of disease, with acute prostration and septic shock progressing to multisystem organ failure. Patients with chronic lung disease, nursing-home patients, or otherwise healthy elderly patients tend to have a slower progression of the disease. They may present with malaise associated with minimal cough or sputum production. Along with the frequent finding of leukocytosis, elevation of the serum bilirubin or other liver enzymes may be seen. In addition, hyponatremia may be a finding in many causes of pneumonia, including pneumococcal pneumonia.

Pneumococcal pneumonia will respond to a variety of antibiotics, although there is an increased incidence of penicillin-resistant pneumococci. The risk factors for penicillin resistance include patients at the extremes of age, day-care attendance, immunosuppression from alcoholism or cancer, and recent use of broad-spectrum antibiotics or travel to areas where penicillin resistance is common, especially the Mediterranean region. In addition to penicillin resistance, there is increasing resistance to other common antibiotics, including tetracycline and trimethoprim-sulfamethoxazole (TMP-SMX). Patients with intermediate penicillin-resistant pneumococci may still be effectively treated with routine antibiotics so long as an adequate dose is administered.¹⁰ Patients with highly penicillin-resistant pneumococci may require treatment with either vancomycin, imipenem, or a newer fluoroquinolone.

OTHER BACTERIAL PNEUMONIA *Staphylococcus aureus* is a consideration in patients with chronic lung disease, patients with laryngeal cancer, immunosuppressed patients, nursing-home patients, or others at risk for aspiration pneumonia. *S. aureus* pneumonia may occur in otherwise healthy patients following viral illness, such as during an influenza epidemic, although pneumococcus is still more common. Patients with staphylococcal pneumonia typically have an insidious onset of disease with low-grade fever, sputum production, and dyspnea. The chest radiograph usually demonstrates extensive disease with empyema, pleural effusions, and multiple areas of infiltrate.

Klebsiella pneumonia usually occurs in compromised patients: patients at risk of aspiration, alcoholics, the elderly, and other patients with chronic lung disease. In contrast to *S. aureus*, patients with *Klebsiella* have acute onset of severe disease with fever, rigors, and chest pain. Herpes labialis is occasionally associated with *Klebsiella* pneumonia. Patients with *Klebsiella* may develop abscesses, although more commonly they have a lobar infiltrate.

Pseudomonas causes a severe pneumonia with cyanosis, confusion, and other signs of systemic illness. The chest radiograph usually shows bilateral lower lobe infiltrates, occasionally associated with empyema. *Pseudomonas* is not a typical cause of CAP, but may be seen in patients who have had a prolonged hospitalization, have been on broad-spectrum antibiotics, have been on high-dose steroid therapy, have structural lung disease, or are nursing-home residents.

Haemophilus influenzae pneumonia may be seen in the elderly and should be considered in patients with chronic lung disease, sickle cell disease, or immunocompromised disorders and in alcoholics and diabetics. Routine vaccination of children has markedly reduced the incidence of *H. influenzae* pneumonia in the pediatric population. Patients may either have a gradual progression of disease with low-grade fever and sputum production or occasionally have the sudden onset of chest pain, dyspnea, and sputum production. Bacteremia may be seen in older adults. Pleural effusions and multilobar infiltrates are common findings in *H. influenzae* pneumonia.

Moraxella catarrhalis pneumonia has clinical features similar in spectrum to those of *H. influenzae*. Typically, patients with *M. catarrhalis*

present with an indolent course of cough and sputum production. Fever and pleuritic chest pain are common clinical symptoms. The chest radiograph usually shows diffuse infiltrates.

ATYPICAL PNEUMONIA Atypical agents are being recognized more frequently as a cause of pneumonia in older children, in young adults, and in the elderly. Because these agents lack a cell wall, they do not respond to beta-lactam antibiotics, and current recommendations for empiric antibiotic treatment of CAP take this into account, using either a macrolide or a newer-generation fluoroquinolone.

Legionella can cause a range of illness from benign self-limited disease to multisystem organ failure with acute respiratory distress syndrome. Patients at particular risk include cigarette smokers, patients with chronic lung disease, transplant patients, and immunosuppressed patients. There is no seasonality to *Legionella* pneumonia, making it a more common cause of pneumonia in the summer. *Legionella* pneumonia is commonly complicated by GI symptoms, including abdominal pain, vomiting, and diarrhea. In addition, *Legionella* can affect other organ systems, causing sinusitis, pancreatitis, myocarditis, and pyelonephritis. The chest radiograph frequently shows a patchy infiltrate, with the occasional appearance of hilar adenopathy and pleural effusions.

Chlamydia pneumonia is a common cause of respiratory infection, with about half of the population demonstrating antibodies by the age of 15. Infection with *Chlamydia* usually causes a mild subacute illness

with sore throat, mild fever, and nonproductive cough, although occasionally patients have a more severe course. Patients with *Chlamydia* pneumonia frequently have abnormal physical examination findings, with rales or rhonchi. The chest radiograph usually shows a patchy subsegmental infiltrate. Chlamydial infection has been associated with the development of adult-onset asthma.

Mycoplasma pneumonia also occurs year round, although it tends to cluster in epidemics every 4 to 8 years. As is the case with *Chlamydia*, it may cause a subacute respiratory illness with cough, sore throat, and headache. *Mycoplasma* pneumonia is frequently associated with retrosternal chest pain. Unlike *Legionella*, *Mycoplasma* usually is not associated with GI symptoms. The chest radiograph shows patchy infiltrates, with the common occurrence of hilar adenopathy and pleural effusions. *Mycoplasma* occasionally causes extrapulmonary symptoms, including bullous myringitis, rash, neurologic symptoms, arthritis and arthralgia, hematologic abnormalities, and rarely, renal failure.

Diagnosis

Pneumonia is suspected based on a constellation of symptoms and signs, but individual symptoms and clinical findings lack accuracy for precise diagnosis.⁹ Attempts have been made to combine some of the symptoms and signs into a scoring system that predicts the probability of pneumonia for the purposes of determining the need for chest radiography in adult outpatients (Table 63-2). The results of these attempts have produced scoring criteria with modest likelihood ratios. These

TABLE 63-2 Prediction Rules for Pneumonia in Adult Patients with Cough

Author and Rule	Threshold Score	Sensitivity %	Specificity %	Positive Likelihood Ratio LR(+)	Negative Likelihood Ratio LR(-)
Diehr et al Points: -2 for rhinorrhea -1 for sore throat 1 for night sweats 1 for myalgia 1 for sputum all day 2 for respiratory rate >25 2 for temperature >38°C (100°F) Total score, -3 to 7	0	67	67	2.0	0.50
Singal et al Probability = $(1 + e^{-y})$ Where $y = 3.095 + 1.214 (\text{cough}) + 1.007 (\text{fever}) + 0.823 (\text{rales})$ Each variable = 1 if present and 0 if absent	All three, cough and fever, or cough and rales	76	55	1.7	0.44

Sources: Diehr P, Wood RW, Bushyhead J, et al: Prediction of pneumonia in outpatients with acute cough—A statistical approach. *J Chronic Dis* 37:215, 1984; Singal BM, Hedges JR, Radack KL: Decision rules and clinical prediction of pneumonia: Evaluation of low-yield criteria. *Ann Emerg Med* 18:13, 1989; Gennis P, Gallagher J, Falvo C, et al: Clinical criteria for the detection of pneumonia in adults: Guidelines for ordering chest roentgenograms in the emergency department. *J Emerg Med* 7:263, 1989; and Heckerling PS, Tape TG, Wigton RS, et al: Clinical prediction rule for pulmonary infiltrates. *Ann Intern Med* 113:664, 1990.

clinical criteria are most useful for excluding pneumonia when the prevalence is very low, <5 to 7 percent; that is, if a patient has none of the positive predictors, the probability of pneumonia is very low, from 1 to 4 percent. However, clinical criteria are inadequate for including pneumonia; even if a patient has all of the positive clinical predictors, these scoring systems predict pneumonia with a maximal accuracy of 40 to 50 percent.⁹ Thus for accurate diagnosis, a chest radiograph is required, although in practice high-risk patients are sometimes treated empirically.

Patients with complaints of dyspnea or physical signs of respiratory distress should have oxygen saturation measured by pulse oximetry. In otherwise healthy, mildly ill, ambulatory patients, no further ancillary testing may be necessary. If a patient requires admission, additional tests may be necessary, including complete blood count and determination of serum electrolytes, blood urea nitrogen, creatinine, and glucose levels. Evaluation of arterial blood gas is indicated if patients are markedly desaturated or have severe respiratory distress. No single set of recommendations for diagnostic testing can encompass all patients, and additional ancillary studies should be obtained according to appropriate indications.

In patients with fever, cough, and radiographic abnormalities, the etiology of the infection can be confirmed, at times, by identification of a pathogenic organism from the blood, sputum, or pleural fluid. Atypical agents may be demonstrated by a variety of sophisticated laboratory techniques, including evaluation of titers from acute and convalescence sera or by direct fluorescent antibody testing. Most patients do not require identification of a specific organism.

In hospitalized patients with CAP, the incidence of positive blood cultures increases with increasing disease severity.¹¹ The incidence of positive blood cultures in nonhospitalized patients with CAP is lower, pathogen identification does not alter treatment, and the overwhelming majority of patients respond to empiric antibiotic treatment. Thus blood cultures are recommended only for patients who require hospitalization.

The value of sputum examination in CAP has been debated. Many patients are unable to produce adequate sputum, the Gram stain is frequently negative, and the results rarely change therapy.¹²

The differential diagnosis of patients with cough and radiographic abnormality includes disorders such as lung cancer, tuberculosis, pulmonary embolism, chemical or hypersensitivity pneumonitis, connective tissue disorders, granulomatous disease, and fungal infections. While the radiographic appearance may suggest the underlying microbial etiology, the overlapping variations in radiographic signs between different organisms may lead to misclassification. Pneumococcal pneumonia typically presents with lobar segmental pneumonia. Occasionally, patients may present with the so-called round infiltrate of pneumococcal pneumonia. In general, patients with bacterial pneumonia are more likely to have unilobar or focal infiltrates than patients with viral or atypical pneumonia. Hilar adenopathy is more common in patients with atypical pneumonia. Pleural effusions occur more commonly in patients with bacterial pneumonia, although occasionally patients with viral pneumonia or atypical agents may have small effusions. Cavitory lesions occur in patients with bacterial or tuberculous lesions. Lung abscesses are rare complications of pneumonia in the antibiotic era, but they sometimes occur due to *S. aureus* or *Klebsiella*. Pneumonia may mimic the appearance of lung masses, particularly when the cause is pneumococcal or staphylococcal. Other atypical pneumonia such as Q fever and tularemia may present as discrete masses.

Pneumonia in Special Populations

PNEUMONIA IN ALCOHOLICS Alcoholics have a significantly higher incidence of many lung diseases including pneumonia, tuberculosis, pleurisy, bronchitis, empyema, and COPD, compared to non-

alcoholics. Alcoholics are more likely than the general population to have poor nutrition, to develop aspiration pneumonitis, to be heavy smokers, and to have sequelae of alcoholic cirrhosis and portal hypertension. Compared to the nonalcoholic, the alcoholic has greater oropharyngeal colonization with gram-negative bacteria and is more likely to have pulmonary function abnormalities, including reduced lung volumes, increased airway resistance, and decreased diffusion capacity. In addition, alcoholism depresses granulocyte and lymphocyte counts and impairs delivery of neutrophils to sites of infection.

Streptococcus pneumoniae is still the most common pathogen causing pneumonia in alcoholics, but *Klebsiella* species and *Haemophilus* species are also important agents of infection. In general, rates of pneumonia and death from pneumonia are higher in alcoholics compared to nonalcoholic patients.

PNEUMONIA IN DIABETICS Diabetes mellitus is an independent risk factor for pneumonia. Diabetic patients between the ages of 25 and 64 are four times more likely to have pneumonia and influenza, and diabetics are two to three times more likely than nondiabetics to die with pneumonia and influenza as an underlying cause of death. Pathogens that occur with increased frequency in diabetic patients include *Staphylococcus aureus*, gram-negative bacteria, *Mucor*, and *Mycobacterium tuberculosis*. Infections due to *Streptococcus pneumoniae*, *Legionella pneumophila*, and influenza are associated with increased morbidity and mortality in diabetic patients.

PNEUMONIA IN PREGNANCY Community-acquired pneumonia in pregnancy is one of the most serious nonobstetric infections complicating pregnancy. Maternal anemia and asthma are risk factors for pneumonia, and pregnant women with pneumonia are more likely to experience preterm labor, have a preterm delivery, and deliver a low birthweight infant compared to the expectant mother without pneumonia.¹³ Maternal mortality from antepartum pneumonia is approximately 3 percent. Pregnancy does not seem to alter the course of bacterial pneumonia, but viral pneumonia during pregnancy carries a worse prognosis than in the nonpregnant patient.

Varicella pneumonia may be a particular problem in pregnancy. Pregnant women who develop varicella pneumonia are five times more likely to be smokers, and approximately 16 times more likely to have skin lesions suggestive of the disease. Chest radiography is recommended for patients with symptoms of respiratory tract infection and varicella exposure. An arterial blood gas may be helpful in identifying patients with early respiratory compromise. Intravenous acyclovir may be started in the ED, although there is little evidence that the timing of administration affects outcome.

Pneumocystis carinii pneumonia (PCP) is the most common cause of AIDS-related death in pregnant women in the United States, with a mortality rate around 50 percent. Respiratory failure requiring mechanical ventilation may be experienced by over half of these patients. Combination treatment with pentamidine, steroids, and eflornithine improves survival compared to those patients treated with TMP-SMX alone.

PNEUMONIA IN THE ELDERLY Pneumonia is the most common infection and represents the fifth leading cause of death among the elderly.¹⁴ The incidence of lower respiratory tract infection in the elderly ranges from 25 to 44 cases per 1000 in the general population, with a mortality rate approaching 40 percent. COPD, congestive heart failure (CHF), cardiovascular and cerebrovascular disease, lung cancer, dementia, diminished gag reflex, and other disorders that predispose the elderly to aspiration make them more susceptible to infection. The elderly are three times more likely to have pneumococcal bacteremia than younger patients. The mortality from pneumococcal pneumonia is three to five times greater in the elderly (up to 40 percent) than in those younger than age 65. Although becoming recognized more frequently in the elderly, atypical pathogens such as *Mycoplasma* are still

more common in younger populations. *Legionella* is the most common atypical agent in the elderly and is responsible for up to 10 percent of cases of CAP. Influenza is the most common serious viral infection in the elderly. Postinfluenza bacterial pneumonia is most commonly caused by *S. pneumoniae*, *S. aureus*, and *H. influenzae*.

Elderly patients with pneumonia may complain about falling, weakness, tremulousness, functional decline, or GI symptoms, and may exhibit delirium or confusion. Elderly patients are more likely to be afebrile on presentation, but are more likely than younger adults to have a serious bacterial infection when the temperature is higher than 38.3°C (100.9°F).

Up to one-third of elderly patients with CAP will not manifest leukocytosis. Poor prognostic indicators for pneumonia in the elderly include hypothermia or a temperature greater than 38.3°C (100.9°F), a low white blood cell count, immunosuppression, gram-negative or staphylococcal infection, cardiac disease, bilateral infiltrates, and extrapulmonary disease. Elderly patients with pneumonia frequently require hospitalization and about 10 percent may require intensive care.

PNEUMONIA IN NURSING-HOME PATIENTS Pneumonia is a major cause of morbidity, mortality, and hospitalization among nursing home residents.^{14,15} Nursing home-acquired pneumonia (NHAP) affects patients who are significantly older, have more cerebrovascular disease, and have higher mortality risk scores at hospital presentation.

These patients are less likely to have a productive cough or pleuritic chest pain, but more likely to be confused and have poorer functional status and more severe disease.¹⁵ Eight variables are significant independent predictors of pneumonia in nursing home patients: increased pulse rate, respiratory rate greater than or equal to 30/min, temperature greater than or equal to 38°C (100.4°F), somnolence or decreased alertness, presence of acute confusion, lung crackles on auscultation, the absence of wheezes, and an increased leukocyte count. A patient with one of these variables has a 33 percent chance of having pneumonia, while three or more variables suggest a 50 percent likelihood of pneumonia.¹⁶ Fewer than 10 percent of nursing home patients with pneumonia will have no respiratory symptoms.¹⁶ Fever, although nonspecific, is present in approximately 40 percent of cases of NHAP.¹⁶

The most frequently reported pathogens among patients with NHAP are *Streptococcus pneumoniae*, gram-negative bacilli, and *Haemophilus influenzae*. Because nursing home patients live in close proximity, residents are subject to outbreaks of influenza. Unfortunately, vaccination against influenza is only approximately 33 to 55 percent effective in preventing postinfluenza pneumonia in nursing home patients. *Mycoplasma pneumoniae* and *Legionella* are uncommon causes of pneumonia in nursing home patients.

NHAP is often treated in the hospital, although some studies have suggested that patients can be treated in nursing homes with either intramuscular or oral antibiotics.¹⁷

PNEUMONIA IN HIV PATIENTS Among HIV seropositive individuals, the incidence of bacterial pneumonia is 5.5 per 100 person-years, an incidence higher than that of *Pneumocystis carinii* pneumonia in this population.¹⁸ Among hospitalized patients with HIV, the incidence of bacterial pneumonia is as high as 12.5 per 100 person-years.¹⁸ CAP accounts for roughly three-quarters of bacterial pneumonia diagnosed in patients hospitalized with HIV infection. Compared to HIV seropositive patients hospitalized without pneumonia, those admitted with pneumonia generally have a lower CD4⁺ T-cell count, a higher APACHE II score, a longer length of hospital stay, a greater chance of ICU admission, and higher case-fatality rate.¹⁸

Streptococcus pneumoniae is the most common cause of bacterial pneumonia in patients with HIV and may be recovered on blood culture in 60 percent of patients with HIV compared to 15 to 30 percent of patients without HIV infection who have pneumococcal pneumonia.¹⁸ *Pseudomonas aeruginosa* infection has traditionally been asso-

ciated with neutropenia, hospitalization, central venous catheters, burn wounds, bronchiectasis, and cystic fibrosis, but *Pseudomonas aeruginosa* is a common cause of bacterial pneumonia in HIV-positive patients.¹⁸ HIV-positive patients with *Pseudomonas aeruginosa* pneumonia are more likely to have a lower leukocyte and CD4⁺ T-cell count, longer hospital stay, but similar case fatality rate.¹⁸

Opportunistic infections are more likely to occur with lower CD4⁺ count. Bacterial infections are more likely to cause pneumonia when the CD4⁺ count is above 800 cells/jxL. Between 250 and 500 cells/jxL, infection from *Mycobacterium tuberculosis*, *Cryptococcus neoformans*, or *Histoplasma capsulatum* poses a greater risk. The risk of *Pneumocystis carinii* pneumonia is more likely when the CD4⁺ count is below 200 cells/jxL.

Bacterial pneumonia produces a pleural effusion in up to about 60 percent of patients with AIDS, most commonly due to *Streptococcus pneumoniae* and *Staphylococcus aureus*. Non-Hodgkin lymphoma, Kaposi sarcoma, and adenocarcinoma of lung are the three leading noninfectious causes of pleural effusion in HIV patients. Patients with Kaposi sarcoma, cytomegalovirus (CMV) pneumonia, and hydrostatic pulmonary edema may present with alveolar hemorrhage as seen by bloody fluid on bronchoalveolar lavage or frank hemoptysis. Pulmonary nodules in the HIV patient are most commonly caused by opportunistic infection, bacterial pneumonia, and tuberculosis. Fever, cough, and a nodule size of less than 1 cm are independent predictors of an opportunistic infection. Miliary pneumonia on CT scan or chest radiograph may represent varicella pneumonia.

PNEUMONIA IN TRANSPLANT PATIENTS Bacterial pneumonia is less common after renal transplantation, but more common in patients receiving liver, heart, or lung transplants during the first 3 months after surgery, compared to other surgical patients. Gram-negative bacilli (especially *Pseudomonas aeruginosa* associated with mechanical ventilation), *Staphylococcus aureus*, and *Legionella* predominate in the first 3 months posttransplantation. *Klebsiella pneumoniae*, *Escherichia coli*, and fungi may also cause pneumonia in this time period. These early onset nosocomial bacterial pneumonias carry a substantial mortality rate, approximately 33 percent. CMV, *Pneumocystis carinii*, and fungal infections, especially *Aspergillus* species, are opportunistic infections, which may be seen in the first 6 months post-surgery. After 6 months posttransplant, bacteria more typical of CAP (*Streptococcus pneumoniae*, *Haemophilus influenzae*) are the most likely pathogens and portend considerably less mortality.

Treatment of Community-Acquired Pneumonia

Emergency physicians will most often initiate empiric treatment for outpatients who have CAP. Many different specialty societies and task forces have developed guidelines for the treatment of adults with CAP, including the American Thoracic Society (ATS), The British Thoracic Society, the CDC Working Group, the Canadian Infectious Disease Society, and the Infectious Disease Society of America.^{8,19} Some differences exist between the guidelines, particularly regarding etiologic diagnosis and antimicrobial therapy. All guidelines recognize that although pneumococcal pneumonia is still the single most common cause of CAP, atypical agents are increasingly recognized in adults and adolescents such that empiric therapy should include antibiotics that are active against organisms that lack a cell wall (Table 63-3).

Recommended agents for outpatient therapy include doxycycline, a newer macrolide, or one of the newer fluoroquinolones orally for a varying duration depending on the agent. Other agents or regimens may be effective in individual cases, but these recommendations are thought to provide the broadest coverage for empiric therapy of outpatients. Doxycycline is useful because of its tolerance, bioavailability, and low cost. Erythromycin is a very cost-effective agent for CAP, but is associated with GI side effects in about 25 percent of adult patients.

TABLE 63-3 Antibiotics Commonly Used in Adults with Community-Acquired Pneumonia

Drug	Class	Oral	Intravenous
Doxycycline	Tetracycline	100 mg bid	100 mg q12h
Clarithromycin XL	Macrolide	500 mg qd	
Azithromycin	Macrolide	500 mg on day 1 and 250 mg on days 2–5	500 mg qd
Ampicillin-clavulanate	Penicillin + β -lactamase inhibitor	875/125 mg bid	
Ampicillin-sulbactam	Penicillin + β -lactamase inhibitor		1.5–3.0 g q6h
Piperacillin/tazobactam	Penicillin + β -lactamase inhibitor		3.375 g q6h
Moxifloxacin	Fluoroquinolone	400 mg qd	400 mg qd
Levofloxacin	Fluoroquinolone	500 mg qd	500 mg qd
Gatifloxacin	Fluoroquinolone	400 mg qd	400 mg qd
Cefuroxime	Second-generation cephalosporin		750 mg q8h
Cefpodoxime	Third-generation cephalosporin	200 mg bid	
Cefoperazone	Third-generation cephalosporin		1–2 g q12h
Cefotaxime	Third-generation cephalosporin		1–2 g q8h
Ceftazidime	Third-generation cephalosporin		500–1000 mg q8h
Ceftriaxone	Third-generation cephalosporin		1–2 g qd
Cefepime	Fourth-generation cephalosporin		1–2 g q12h
Imipenem/cilastatin	Carbapenem		500 mg q6h
Meropenem	Carbapenem		1.0 g q8h
Vancomycin	Miscellaneous		1.0 g q12h
Clindamycin	Miscellaneous		600–900 mg q8h

Clarithromycin has fewer GI side effects, although some patients may complain about the taste. Azithromycin has the advantage of once-a-day dosing. The newer fluoroquinolone agents, including moxifloxacin, levofloxacin, and gatifloxacin, have extended coverage that includes both common bacterial agents and atypical agents, along with the advantage of once-a-day dosing. The Centers for Disease Control's Working Group has expressed concern about the development of fluoroquinolone resistance and has recommended that these agents be reserved for patients who cannot tolerate other agents, have documented pneumococcal resistance, or have failed other therapies. Outpatients with CAP are typically treated until afebrile for 3 to 5 days; usually a total treatment of 7 to 14 days.

Emergency physicians play a prominent role in the initiation of treatment for patients being hospitalized with CAP. Recent evidence indicates that early administration of antibiotics, within the first 8 h of presentation, leads to a lower mortality rate and a shorter hospital stay. Although the yield is low, admitting physicians may benefit from the results of the sputum Gram stain, sputum culture, or blood culture obtained in the ED. For patients hospitalized with CAP, therapy should

be initiated with a second- or third-generation cephalosporin or penicillin plus a beta-lactamase inhibitor, with a macrolide to provide coverage against *Legionella* or other atypical agents. Ceftriaxone and cefotaxime provide adequate coverage against most strains of *S. pneumoniae*. Coverage can also be provided by a fluoroquinolone such as levofloxacin, moxifloxacin, or gatifloxacin. The efficacy of monotherapy with fluoroquinolones alone has not been clearly established in patients with severe pneumonia who require ICU admission, and those patients should receive dual therapy. Patients at risk for *Pseudomonas* include those with structural lung disease and those recently treated with high-dose steroids or broad-spectrum antibiotics. In addition to the therapy discussed above, these patients should receive antipseudomonal coverage with antipseudomonal cephalosporins such as cefepime, a carbapenem such as meropenem, a fluoroquinolone with adequate coverage such as ciprofloxacin, an aminoglycoside such as gentamycin, or other antibiotics with antipseudomonal activity.

Disposition

An estimated 75 percent of patients with CAP do not require hospitalization.^{8,19} Many factors influence the prognosis and outcome of CAP. In general, physicians tend to overestimate the risk of pneumonia mortality. Fine and coworkers have developed a decision rule that can be used to estimate the risk of death and ICU placement from pneumonia (Tables 63-4, 63-5, and 63-6). Others have used this rule to guide the need for hospitalization. With this decision rule, patients are assigned to one of five risk categories, with the lowest category having a mortality rate of around 0.1 percent. Although not a prominent part of this decision rule, patients who are immunocompromised as a result of AIDS or chronic alcohol use may require hospitalization. Other factors such as social situation or unusual medical conditions may also play a role in the admission decision. In addition, a chest radiograph that demonstrates bilateral effusions, bilateral infiltrates, moderately large pleural effusions, or extensive pulmonary involvement is associated with a higher risk of mortality. Patients should be considered for admission to an intensive care unit if they are markedly tachypneic or have high oxygen requirements, evidence of shock, or very extensive pulmonary involvement (more than 50 percent of the lung). For patients in risk category III, the admission decision may be made based on the presence of relative hypoxemia, social factors, and the inability to complete a course of oral antibiotics. A brief hospitalization or observation may be considered in these patients.

Emergency physicians play a role in educating patients about their disease. Most patients will achieve some measure of resolution within 3 to 5 days after the initiation of antibiotics. Many hospitalized patients can be switched to oral antibiotics at around 3 days and then subsequently discharged to complete a course of therapy. Large population studies have demonstrated, however, that many patients are still symptomatic at 30 days, with a significant minority of patients experiencing chest pain, malaise, or mild dyspnea even 2 to 3 months after treatment. Patients should be educated about the importance of smoking cessation and moderation of alcohol use. Patients may benefit from instructions about rest, nutrition, hydration, and follow-up. Patients at risk should be educated about the importance of vaccination against pneumococcus and influenza.

PLEURAL EMPYEMA

Epidemiology

Pleural empyema has been defined as pus in the pleural space.²⁰ Many authors expand that definition to include pleural space infections as evidenced by positive Gram stain or culture results or effusions associated with pneumonia (parapneumonic) without pleural fluid sampling.

TABLE 63-4 Assignment to Risk Class I

Age ≤ 50 years

Pleural effusions are present on the chest x-ray of 20 to 60 percent of patients with bacterial pneumonia and often resolve with antibiotic therapy.²¹ Other causes of pleural empyema include complications of penetrating chest trauma, blunt abdominal and chest trauma, perforated esophagus, complication of lung abscess, direct extension from a sub-diaphragmatic infection, vertebral osteomyelitis, other near-pleural infections, and infected hemothorax, hydrothorax, or chylothorax.²⁰

Risk factors for pleural empyema include aspiration pneumonia and its attendant risk factors, immunocompromised patients with gram-negative bacillary infections, fungal infections, tuberculosis, or malignancy. Chronic alcoholics, because of their predisposition to aspiration and *Klebsiella* infections, are at risk to develop pleural empyema. *S. aureus* or mixed anaerobic bacteria are also commonly cultured from pleural empyema.²⁰

Pathophysiology

Pleural empyema has three stages of development.²⁰ The *exudative stage* is characterized by free-flowing pleural fluid. This stage is very amenable to treatment with closed tube drainage since the infected

fluid is free flowing. The exudative stage may be short lived, often with less than a 48-h duration. The *fibrinopurulent stage* is characterized by the formation of fibrin strands through the pleural fluid. This results in loculations throughout the pleural space, making adequate drainage with a single chest tube unlikely. This deposition of fibrin along the parietal pleura will inhibit the resorption of pleural fluid, and restrict access to lymphatics, which also hampers fluid resorption and can ultimately interfere with chest wall mechanics. In the *organizational stage*, which takes several weeks to develop, fibrosis is much more extensive, forming a pleural peel that restricts lung expansion even if the fluid can be evacuated.

Empyema can be a slow indolent process and many patients may have symptoms for several weeks before seeking medical attention. By that time, they have already reached the fibrinopurulent or organizational stage and will require more extensive treatment. Patients who are treated earlier in the course of this illness will tend to require less invasive, less painful, and less expensive therapeutic interventions.

Clinical Features

Patients with empyema will usually have a preceding pulmonary infection. Many will have symptoms of pneumonia that have not resolved; fever, shortness of breath, pleuritic chest pain, cough, and general malaise are common symptoms. Weight loss may occur and anemia from chronic infection may develop. Often these patients appear chronically ill with risk factors as previously discussed: alcoholism, cancer, and other immunocompromising states.

Physical examination will reveal decreased breath sounds and dullness to percussion on the involved side. Patients may be splinting with respirations secondary to pain because of the inflammatory nature of the empyema. Rales and rhonchi are often heard because of an underlying pulmonary infection, but these incidental findings are not diagnostic of pleural empyema.

Diagnosis

A standard chest radiograph will indicate the presence of pleural fluid, but will not make the diagnosis of pleural empyema. Decubitus films will be helpful in determining if the fluid is free flowing or loculated. Aspiration and evaluation of pleural fluid will confirm the diagnosis. The more difficult loculated effusions may require thoracentesis performed with CT or ultrasound guidance. A major advantage of ultrasound over plain radiography is its ability to rapidly differentiate solid (tumor, fibrous peel) from liquid components in the pleural process. Laboratory and microbiologic evaluation of the fluid will allow confirmation of the diagnosis of pleural empyema. Pleural fluid that is gross pus or fluid with positive cultures or Gram stain is considered pleural empyema. Other pleural findings indicative of infection include pleural fluid pH <7.1 , glucose <40 mg/dL, and lactate dehydrogenase >1000 IU/L.²¹

Treatment

The basic principles of pleural empyema treatment are drainage of pus, reexpansion of the lung, and eradication of the infection.²² However, parapneumonic effusions do not always require drainage, particularly if no bacteria are found in the pleural fluid.²² The decision concerning pleural drainage is made through consideration of the patient's general condition, presence of comorbidities, virulence of the infecting pathogen, extent of the pneumonia, and pleural fluid characteristics.²²

Pleural empyema in the exudative stage can be treated with chest tube thoracostomy and antibiotics.²⁰ Treatment in the fibrinopurulent stage may require intrapleural fibrinolytic agents and should be done in consultation with a thoracic surgeon or pulmonary specialist. Urokinase is slightly more efficacious and has fewer side effects than streptokinase in the treatment of pleural empyema.²³ To adequately treat loculated effusions, surgical therapy is often required. Video assisted thorascopic surgery (VATS) appears to be superior to chest tube drainage and streptokinase to drain the pleural cavity and break up loculations.²⁴ Treatment of the organizational stage requires surgical intervention with removal of the fibrous peel. Other surgical options include decortication and rib resection to facilitate chronic drainage to prevent recurrent sepsis.

Initial antibiotic treatment should provide coverage for expected pathogens. A typical regimen for an acute, usually parapneumonic, empyema would include a third-generation cephalosporin (cefotaxime or ceftriaxone) and vancomycin. Antibiotic therapy can be adjusted according to culture results. Initial antibiotic treatment for subacute or chronic empyema should include anaerobic coverage, and a typical regimen would be clindamycin and a third-generation cephalosporin (cefotaxime or ceftriaxone).

Disposition

Patients with a diagnosis of pleural empyema should be admitted to the hospital for drainage of the empyema, intravenous antibiotics, and further evaluation of the extent of their disease. Modification of risk factors (i.e., alcoholism, drug abuse, immunocompromising states) and evaluation for cancer can be addressed during the admission.

ASPIRATION PNEUMONIA AND LUNG ABSCESS Eric Anderson

ASPIRATION PNEUMONITIS AND PNEUMONIA

Epidemiology

Aspiration pneumonia is an alveolar space infection resulting from the inhalation of pathogenic material from the oropharynx. Conversely, aspiration pneumonitis is an inflammatory chemical injury of the tracheobronchial tree and pulmonary parenchyma produced from the inhalation of regurgitated sterile gastric contents.¹ Aspiration pneumonitis can lead to aspiration pneumonia due to the breakdown of the pulmonary defense mechanisms caused by the chemical irritation. The exact incidence of aspiration pneumonia has been difficult to quantitate. It is estimated that 5 to 15 percent of community-acquired pneumonia (CAP), up to 20 percent of CAP in the elderly, and the majority of nursing home-acquired pneumonia is due to aspiration.^{1,3} The true incidence of aspiration pneumonia may even be higher, because of the observation that approximately 50 percent of normal adults and 70 percent of the elderly with CAP aspirate during sleep.^{2,4}

Another population at high risk for aspiration and aspiration pneumonia is the critically ill patient in an intensive care unit.¹ Gastroesophageal reflux and pulmonary aspiration is very common in this population due to a prolonged supine position, gastroparesis from the

underlying illness, endotracheal intubation for ventilatory support, and nasogastric or orogastric tubes for gastric decompression and nutrition.

Aspiration pneumonitis is usually associated with depressed level of consciousness that allows for the regurgitation of gastric contents and inhibits the protective upper airway reflexes from preventing aspiration. The classic patient is young, has a depressed mental status due to recreational or therapeutic drugs, and regurgitates a significant volume of gastric contents.

Risk factors for aspiration pneumonia include conditions that promote oropharyngeal colonization with pathogenic bacteria or conditions that impair the swallowing or gag mechanisms (Table 64-1). The incidence of aspiration is highest in patients with dementia or stroke, and the risk of infection is compounded by poor oral care, leading to oropharyngeal colonization, the placement of nasogastric or gastric feeding tubes, and the use of sedative and neuroleptic drugs.^{5,9} Although many of these patients have evidence of aspiration with dysphagia or emesis or coughing while eating, up to one third of those who aspirate have silent aspiration without evidence of cough or gag. Aspiration has a significant impact on morbidity and mortality in patients in long-term care facilities.

PATHOPHYSIOLOGY

The development of aspiration pneumonitis depends on the volume and pH of the aspirate. General consensus is that aspiration of gastric contents with pH less than 2.5 and an aspirated volume of 0.3 to 0.4 mL/kg (20 to 30 mL in adults) are required to develop aspiration pneumonitis.¹ The injury produced by acid aspiration is initially a direct, caustic effect followed by an inflammatory response that peaks in 4 to 6 h. Many of the symptoms of aspiration are elicited by the inflammatory response to the infectious or irritative material. Proinflammatory cytokines increase capillary permeability and cause fluid and inflammatory cells to enter the area of irritation. These reactions may manifest clinically as cough, pleuritic chest pain, fever, and radiographic findings. Aspiration of solid or very viscous material blocking the airway may result in precipitous asphyxiation.

The potential to aspirate pathogenic bacteria is increased in patients with periodontal disease, with chronic colonization of the upper airways, and when conditions such as small bowel obstruction, tube

feeding, H₂-receptor blockers, or proton pump inhibitors make gastric colonization with pathogenic bacteria possible.¹ The tracheobronchial tree is normally able to handle small amounts of aspirated oropharyngeal contents, because the mucociliary escalator transports the aspirated material back up to the oropharynx, where it is expectorated or swallowed. Alveolar macrophages, polymorphonuclear leukocytes, or lymphocytes destroy infectious particles that are small enough to reach the alveoli. Aspiration of food, various liquids or chemicals, dirt, sand, or other objects result in mechanical or chemical injury to these defense mechanisms and predispose the lungs to infection.

Typical bacterial species involved in aspiration pneumonia include *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Haemophilus influenzae*, and *Enterobacteriaceae* in community-acquired aspiration pneumonia and *Pseudomonas aeruginosa* and gram-negative organisms in hospital-acquired aspiration pneumonia.¹ Anaerobic bacteria were thought to play a significant role in aspiration pneumonia, but studies conducted in the 1990s using special collection techniques demonstrated that anaerobes are not found in the cultures of the lower respiratory tract in patients with aspiration pneumonia.^{10,11}

Characteristic radiographic locations have been described for aspiration pneumonitis and pneumonia.¹² In recumbent patients, the common lung segments involved are those most dependent when supine: the posterior segments of the upper lobes and the superior segments of the lower lobes. In upright patients, the most dependent portions of the lungs are the basal segments of the lower lobes. The inflammatory injury may include, bilateral, patchy, interstitial, or alveolar infiltrates, particularly in aspiration of large volumes, as in near drowning.¹²

CLINICAL PRESENTATION

Witnessed or suspected aspiration is a key feature in the diagnosis of aspiration pneumonitis or pneumonia. A witnessed aspiration of solid or liquid material while eating, during a therapeutic procedure, or after being submerged while swimming or working in water is an obvious clue.^{13,14} Patients with known swallowing or esophageal motility disorders, esophageal obstruction, or enteral tube feedings should be considered risks for aspiration.⁶ Silent aspirators are more difficult to detect. Historical features that suggest silent aspiration include general debility, recurrent cough, hoarseness, or dysphagia. History may be difficult to obtain in chronically debilitated or otherwise noncommunicative patients.

The patient with aspiration pneumonitis may have only minor symptoms, such as nonproductive cough and tachypnea. Aspiration of larger or more acidic gastric contents may produce tracheobronchitis with bronchospasm, bloody or frothy sputum, and respiratory distress. Aspiration of large volumes or very caustic material may result in respiratory failure.

The clinical symptoms of aspiration pneumonia include fever, dyspnea, and productive cough. Other symptoms of systemic infection in the elderly and debilitated patients may be present, including a change in mental status or function, lethargy, or nausea and vomiting.^{2,3} The physical examination may reveal signs classic for pneumonia: tachycardia, tachypnea, fever, rales, or decreased breath sounds in an ill-appearing patient. Patients with underlying pulmonary disease may decompensate rapidly and have more symptoms and signs of respiratory distress.

Chest radiographs in aspiration pneumonia usually show unilateral focal or patchy consolidations in the dependent lung segments, as noted above.¹² Occasionally, bilateral or interstitial patterns can be seen. The right lower lobe is the most common area of consolidation when the aspiration occurs when the patient is upright (Figure 64-1).

Laboratory values will be of little diagnostic value. Early in the course, the white blood cell count may or may not be elevated. Arterial blood gases may reflect hypoxia or hypoventilation, but this may be secondary to the patient's underlying lung disease, and comparison with previous blood gas results would be helpful. Expectorated spu-

TABLE 64-1 Risk Factors for Aspiration Pneumonia and Lung Abscess

Intoxicants	Alcohol and illicit drugs Therapeutic drug overdose Sedative drug use Procedural sedation General anesthesia
Neurologic	Stroke, especially brain-stem involvement with dysphagia Seizure Head trauma Chronic debilitating neurologic condition, especially dementia
Oropharyngeal	Impaired glottic functions Emergent intubation Periodontal disease and poor oral hygiene
Gastrointestinal	High gastric pressures: prior meal, bag-mask ventilation Gastroesophageal reflux Esophageal dysmotility or obstruction Nasogastric, orogastric, and percutaneous gastric tube Tracheobronchial fistula
Other	Supine position Rapid sequence intubation Advanced age Chronic debility Extension neck contractures

FIG. 64-1. Aspiration pneumonia of the right lower lobe.

turn cultures are of low yield, because of the increased rate of contamination from oropharyngeal colonization in most patients with aspiration pneumonia.

Treatment

Patients who have a witnessed aspiration from regurgitation of a large volume of gastric contents should have prompt suctioning of the upper airway. Endotracheal tube placement should be considered, as should placement of an orogastric or nasogastric tube for gastric decompression. Patients who aspirate large volumes of solid material or tenacious material may require suctioning of the tracheobronchial tree or bronchoalveolar lavage to clear the airway. Bronchodilators may be required for aspiration-induced bronchospasm. Prophylactic antibiotics are not recommended, and there is no evidence that corticosteroids prevent lung injury.¹

Healthy persons who aspirate small volumes of nontoxic material may be observed for short time, approximately 1 h, and, if stable and reliable, discharged with instructions to return for worsening symptoms. Antibiotic treatment is not necessary. However, previously healthy patients whose symptoms of aspiration pneumonitis fail to resolve in 24 to 48 h should be treated with broad-spectrum antibiotics¹ (Table 64-2).

Chronically ill or nursing home patients who have a witnessed episode of aspiration followed by respiratory symptoms (cough, dyspnea, tachypnea, or wheezing) are more problematic. These patients are often sent to the ED for evaluation, by which time their symptoms have improved or resolved. These patients are at greater risk for aspiration pneumonia due to their oropharyngeal colonization from pathogenic bacteria. It is not possible to differentiate which patients will be able to spontaneously resolve their symptoms, from those who will progress to aspiration pneumonitis, or aspiration pneumonia. A reasonable, although not validated, approach would be to observe a stable patient (no respiratory distress, no fever, normal or baseline oxygen saturation, no new radiographic infiltrate). A stable patient can be discharged back to the monitored chronic care or nursing home facility. Patients who remain symptomatic or have a new radiographic infiltrate should be considered for admission or continued observation. There is no firm evidence regarding the benefits of antibiotic treatment in this population, and some discourage it because of the potential of selecting resistant organisms in a patient with an otherwise uncomplicated chemical pneumonitis.¹ Nursing home patients with worsening symptoms, fever, cough or sputum production, hypoxemia, or radiographic infiltrate should be considered as developing aspiration pneumonia and receive antibiotic treatment in the hospital or nursing home.¹³

Empiric broad-spectrum antibiotic therapy is indicated in patients with aspiration pneumonia. The specific agents are chosen according to the potential pathogens as determined by the patient's general health and location¹ (see Table 64-2). Agents that treat predominately anaerobes (penicillin or clindamycin) are not sufficient to cover the spectrum of bacteria involved in most aspiration pneumonias and should not be used alone.^{1,10,11}

Disposition

Reliable patients who have a witnessed episode of aspiration and who are otherwise healthy and exhibit no signs of infection or respiratory compromise may be discharged home with instructions to follow up

TABLE 64-2 Empiric Antibiotics Recommended for Common Aspiration Syndromes

Syndrome and Clinical Situation	Antibiotic (Usual Dose)*
Aspiration pneumonitis Signs or symptoms lasting >48 h	Levofloxacin 500 mg per d ¹¹ or Ceftriaxone 1–2 g per d
Small bowel obstruction or use of antacids or antisecretory agents	Levofloxacin 500 mg per d ¹¹ or Ceftriaxone 1–2 g per d, or Ciprofloxacin 400 mg every 12 h or Piperacillin–tazobactam 3.375 g every 6 h or Ceftazidime 2 g every 8 h
Aspiration pneumonia Community-acquired	Levofloxacin 500 mg per d ^f or Ceftriaxone 1–2 g per d
Residence in a long-term care facility	Levofloxacin 500 mg per d ¹ or Piperacillin–tazobactam 3.375 g every 6 h or Ceftazidime 2 g every 8 h
Severe periodontal disease, putrid sputum, or alcoholism	Piperacillin–tazobactam 3.375 g every 6 h or Imipenem 0.5–1.0 g every 6–8 h or Levofloxacin 500 mg per d ^f plus clindamycin 600 mg every 8 h or metronidazole 500 mg every 8 h or Ciprofloxacin 400 mg every 12 h plus clindamycin 600 mg every 8 h or metronidazole 500 mg every 8 h or Ceftriaxone 1–2 g per d plus clindamycin 600 mg every 8 h or metronidazole 500 mg every 8 h

*The doses listed are those for patients with normal renal function.
¹¹Levofloxacin is given by slow infusion over 60 min. Levofloxacin 500 mg per d, may be replaced by gatifloxacin 400 mg per d.

with their primary care physician in the next few days. They should be instructed to watch for shortness of breath, fever, chest pain, unusual fatigue, or the development of a persistent cough and to return promptly to the ED or their primary care physician if any of these symptoms develop.

Patients who appear stable but have risk factors for worsening or very aggressive disease (e.g., diabetes, advanced age, renal dialysis, recent stroke, chronic pulmonary disease, active cancer, and human immunodeficiency virus) should be admitted to a hospital or an observation unit. Oxygen and possibly antibiotics should be started, and the patient should be observed carefully for 12 to 24 h. If stable after 12 to 24 h of treatment and observation, such patients can be sent home and instructed to follow up, as described above, and to return if any signs of deterioration develop. Patients with definite evidence of infection should have antibiotic treatment initiated and then admitted, or selected patients can be treated in the nursing home provided that the nursing home has the ability to monitor and treat these patients.^{1,15} Patients who exhibit hemodynamic or respiratory instability require admission to an intensive care unit.

LUNG ABSCESS

Epidemiology

Lung abscess is defined as a localized suppurative necrotizing process occurring within the pulmonary parenchyma.¹⁶ Lung abscess typically is caused by a suppurative pulmonary bacterial infection secondary to aspiration pneumonia. Lung abscess also can be caused by bacterial infection in an area of lung infarct or as a result of an infected pulmonary pneumocyst. Other causes of cavitary lung lesions include fungal infections, parasitic infections, inflammatory conditions, and primary and metastatic neoplasias (Table 64-3). The incidence of lung abscess has declined tenfold over the past four decades, presumably secondary to improved treatment regimes for pneumonia. The mortality from lung abscesses also has decreased but remains between 2 and

10 percent for community-acquired lung abscess but up to 60 percent for hospital-acquired lung abscess.

Pathophysiology

Lung abscess typically is caused by a breakdown of the usual pulmonary defense mechanisms that allows a parenchymal infection to evolve into an abscess. A lung abscess that evolves from aspiration pneumonia takes approximately 8 to 14 days to form after the aspiratory event. Anaerobic bacteria are the most common isolates from lung abscesses in immunocompetent patients.¹⁷ Aerobic bacteria are found more commonly from lung abscesses in immunocompromised patients and include *S. aureus*, *Escherichia coli*, *Klebsiella pneumoniae*, *P. aeruginosa*, *Streptococcus pyogenes*, *P. pseudomallei*, *H. influenzae*, *Legionella pneumophillia*, *Nocardia asteroides*, *Actinomyces* species, and, rarely, pneumococci.^{16,17}

Medical conditions that predispose for the development of pulmonary abscess include those conditions that predispose to aspiration pneumonia, including poor dentition, gingival disease, chronic alcoholism, chronic debility with extension neck contractures, and chronically depressed mental status (see Table 64-1).

Infectious lung abscesses typically occur in the basal segments of the lower lobes or the posterior segments of the upper lobes. When abscesses occur in the anterior portion of the lungs, a neoplastic etiology should be considered more likely. Cancer causes 8 to 18 percent of lung abscesses at all ages, but the percentage is closer to 30 percent in those older than 45 years.

Clinical Features

Patients with lung abscess classically present with an indolent course of cough, fever, pleuritic chest pain, weight loss, and night sweats. The typical patient will present after having the symptoms for approximately 14 days. There may be cough productive of putrid sputum that layers out when allowed to stand. Hemoptysis can be seen in up to 25 percent of cases. Because the infection is more indolent, vital sign abnormalities typical of an acute infection (tachycardia or tachypnea) are often absent. Laboratory findings usually are nonspecific but commonly include an elevated white blood cell count and erythrocyte sedimentation rate.

Diagnosis

The diagnosis is usually made by a chest radiograph showing an area of dense consolidation with an air-fluid level inside of a cavitary lesion (Figure 64-2), indicating that the abscess cavity communicates with a bronchiole, as occurs in about three fourths of patients with lung abscesses. In the other fourth, the abscess will appear as an area of very dense consolidation on chest radiograph and require a chest computed tomography to disclose the presence of a cavitary lesion. Multiple abscesses are unusual.

The differential diagnosis of cavitary lesions with air-fluid levels seen on chest radiographs includes (1) an infected bullae in a patient with bullous emphysema (infected bullae will have thin walls), (2) a pleural fluid collection with a bronchopleural fistula resulting in a pleural air-fluid level (the pleural air-fluid level will extend to the chest wall and taper at the apex), and (3) a loop of bowel extending through a diaphragmatic hernia (there may nausea or vomiting due to incarceration or audible bowel sounds on the chest wall at the site of the hernia).

Treatment

Medical management will successfully treat 85 to 90 percent of lung abscesses.^{16,18-19} Historically, penicillin was the treatment of choice, but studies have demonstrated that clindamycin is superior in efficacy,

FIG. 64-2. Lung abscess of the left lower lobe demonstrating an air-fluid level.

time to symptom resolution, and side effect profile. Appropriate treatment consists of (1) clindamycin in a dosage of 600 mg IV every 6 to 8 h for adults or (2) an aminopenicillin/p-lactamase inhibitor such as ampicillin/sulbactam 1.5 to 3.0 g IV every 6 h for those who cannot take clindamycin.^{16,18} Concern that clindamycin has only gram-positive coverage has led to the consideration that combination treatment with the addition of a second-generation cephalosporin.¹⁸ Typically, parenteral treatment is initiated until the patient is afebrile and clinically improved, usually in 4 to 8 days. Therapy may be continued with oral clindamycin or amoxicillin/clavulanate.

Drainage usually occurs spontaneously from communication of the abscess cavity with the tracheobronchial tree. This is signaled by the development of an air-fluid level on chest radiographs. Attempts at postural drainage or bronchoscopic drainage of the abscess cavity should be discouraged, because these actions may result in seeding other parts of the lungs with infectious material. Some patients fail medical treatment (Table 64-4). Another reason for failure of medical

treatment is a nonbacterial cause of the abscess, i.e., neoplastic, fungal, inflammatory, or parasitic. Surgical treatments for nondraining lung abscess include image-guided percutaneous drainage or thoracotomy and pulmonary resection.^{20,21}

Disposition

Patients with lung abscess typically will respond to parenteral antibiotics and management of the other medical conditions that predisposed to the development of the abscess. After resolution of symptoms, these patients can be discharged on oral antibiotics for 4 to 8 weeks. Chest radiographic findings will lag behind clinical progress and on average take more than 2 months to resolve.¹⁶

Complications of lung abscess include empyema, massive hemoptysis, contamination of uninvolved lung, and failure of the abscess cavity to resolve. Approximately 10 percent of lung abscesses will require surgical intervention.^{19,21}

TUBERCULOSIS

Janet M. Poponick

EPIDEMIOLOGY

Tuberculosis remains an important infectious disease in the world today; more than one third of the world's population has tuberculosis. It causes 8 million new cases per year, with 2 million deaths per year.¹ In the United States, new cases of tuberculosis steadily declined from the late 1800s until 1984, followed by increases at alarming rates until 1992. Factors believed to be responsible for this resurgence of tuberculosis include an increase in the number of homeless persons, the human immunodeficiency virus (HIV) epidemic, drug abuse, increased immigration, the inability of local and state governments to maintain tuberculosis control programs, and the increase of multidrug-resistant tuberculosis.²

From 1993 to 2000, tuberculosis was once again on the decline in the U.S., primarily due to stronger tuberculosis control programs, which targeted high-risk individuals. In 2000 there were 16,377 cases of tuberculosis reported (5.8 cases per 100,000 population), which represents a 45 percent decrease from 1992, when tuberculosis cases peaked (10.5 cases per 100,000 population).³ Tuberculosis remains more common in urban areas. The case rate for foreign-born persons has increased, whereas the case rate for U.S.-born persons has decreased; in 2000, 46 percent of the cases were in foreign-born persons.^{3,4}

Continued improvement in tuberculosis control and prevention requires recognition and treatment of high-risk populations (Table 65-1), continued funding of programs for surveillance and treatment of non-compliant patients, aggressive screening of foreign-born persons, continued basic research into the pathogenesis and immunologic response, and continued development of new pharmacologic agents.³

PATHOPHYSIOLOGY

Mycobacterium tuberculosis is a slow-growing aerobic rod that has a unique, multilayered cell wall that contains a variety of lipids that account for its acid-fast property. Transmission occurs through inhalation of droplet nuclei into the lungs. Persons with active tuberculosis who excrete stainable mycobacteria in saliva or sputum are the most infectious.⁵

Once the organisms reach the lungs, host defenses are activated.^{1,5} In immunocompetent persons, such defenses may kill off the inhaled mycobacteria and prevent infection. Some organisms may survive, however, and be transported to the regional lymph nodes, where the host's cell-mediated immunity is further activated to contain the infection. Granulomas, known as *tubercles*, may form as a result of this process, which involves activated macrophages. Tubercles are a sign of primary infection and may progress to caseation necrosis and calcification leading to the Ghon complex.⁵ In most cases, the bacteria are contained in the tubercles, but some organisms enter the thoracic duct and spread throughout the body, where they may remain dormant for many years. This is referred to as *latent infection* and is manifested by a positive tuberculin skin test.¹ In most cases of dissemination in immunocompetent hosts, the organisms do not find a suitable area to proliferate. Survival is favored in areas of high oxygen content or blood flow, such as the apical and posterior segments of the upper lobe and the superior segment of the lower lobe of the lung, the renal cortex, the

meninges, the epiphyses of long bones, and the vertebrae.⁵ In immunocompromised hosts, hematogenous spread occurs early, because normal host defenses are unable to contain the organisms, and disseminated disease occurs.⁵

The latent infection may reactivate when a host's immune system is no longer capable of containing the foci of previous hematogenous spread.¹ The young, the elderly, or patients with other chronic debilitating diseases are at higher risk for such reactivation disease. In 5 percent of persons, latent infection may progress to active disease within 2 years after initial exposure, with another 5 percent developing disease over a lifetime.¹ The population at risk for HIV infection is also at risk for tuberculosis. As the host defense system weakens, latent infection may progress to active tuberculosis. The incidence of progression to active disease in HIV patients is reported at 7 to 10 percent per year.¹ Other groups at risk for developing active tuberculosis include those immunocompromised from carcinoma of solid organs, leukemias, transplantation and those with diabetes, chronic renal failure requiring hemodialysis, and silicosis.⁶

Current research emphasizes the basic science involved in the host response to mycobacteria. The key cells are the alveolar macrophages and T lymphocytes, especially the T-helper cells, and the various cytokines and interleukins that are released. With successful treatment, local tumor necrosis factor- α secretion decreases whereas interferon- γ secretion increases.⁷

CLINICAL FEATURES

Primary Tuberculosis

The initial infection is usually asymptomatic and only identified by a positive reaction to purified protein derivative (PPD).¹ Infrequently, a pneumonitis may result that is similar to a viral or bacterial infection. Hilar adenopathy is present but rarely massive. In some cases, especially in immunocompromised patients, the primary infection may be rapidly progressive and fatal.

Reactivation Tuberculosis

When latent infection progresses to active tuberculosis, symptoms can be divided into systemic and pulmonary. The most common symptom is fever, followed by night sweats, malaise, fatigue, and weight loss. Productive cough, hemoptysis, and pleuritic chest pain develop as the infection spreads within the lungs. When the infection is extensive, shortness of breath may develop. The results of a physical examination are generally unremarkable, but rales may be noted over areas of pulmonary infection. Although most cases of tuberculosis are pulmonary, up to 15 percent of cases will have extrapulmonary manifestations.¹ Common sites include the adrenal glands, bones and joints, gastrointestinal tract, genitourinary tract, lymph nodes, meninges, pericardium, peritoneum, and pleura.

Miliary tuberculosis is the result of wide hematogenous spread during the primary infection or secondary seeding of the other organs in an immunocompromised host. Fever, cough, weight loss, hepatomegaly, splenomegaly, lymphadenopathy, and signs of multisystem illness should cause one to suspect miliary disease. Laboratory abnormalities include hyponatremia, anemia, thrombocytopenia, and leukopenia. The chest radiograph shows numerous small nodular lesions.

The most common extrapulmonary site of tuberculosis is the lymphatic system and may involve any of the lymph nodes. Fever is usually absent, and the lymphadenopathy is painless. The nodes may develop draining sinuses.

A tuberculous pleural effusion usually occurs after primary infection, when a subpleural node ruptures into the pleura.⁵ Some cases occur during hematogenous spread. Symptoms are usually fever, short-

TABLE 65-1 Patients with a High Prevalence of Tuberculosis

Patients with the human immunodeficiency virus
Alcoholics and illicit drug users
Residents and staff of prisons or shelters for the homeless

ness of breath, and pleuritic chest pain. The fluid is exudative in nature, and the organisms may not be visible on acid-fast staining. A pleural biopsy is often necessary to confirm diagnosis.

Pericarditis and peritonitis as a result of tuberculosis are difficult to diagnose and often require biopsy. Complications of tuberculous pericarditis include tamponade and constrictive pericarditis.⁵

The central nervous system may become seeded during primary infection, leading to tuberculous (Rich) foci in the meninges, spinal cord, or the brain parenchyma. Rupture of a Rich focus into the subarachnoid space may result in meningitis. In children, the disease is acute, whereas a more indolent course is noted in adults. Fever, signs of meningeal irritation, and cranial nerve deficits are seen. Typical cerebrospinal fluid analysis reveals mononuclear cells and a low glucose level, but early samples may show a predominance of neutrophils.⁵

Pediatric Tuberculosis

Tuberculosis in the pediatric population occurs in the same risk groups as in the adult population (see Table 65-1). Primary tuberculosis is usually an asymptomatic disease and generally found during school screening or household screening programs.⁵ The classic symptoms of fever, night sweats, and weight loss may be seen in older children, but, in those younger than age 5, presentation may be that of miliary tuberculosis, meningitis, or a pneumonia that does not respond to therapy.^{5,8} The most common radiographic findings include hilar adenopathy, mediastinal lymphadenopathy, or consolidated pneumonia. The most common extrapulmonary presentation is cervical lymphadenitis, but meningitis, bone, and joint involvement also may occur.⁸

Tuberculosis and HIV

Tuberculosis (pulmonary and extrapulmonary) often can be the initial clinical manifestation of immunodeficiency and is considered an illness that defines acquired immunodeficiency syndrome (AIDS). Infection with HIV increases the risk of latent disease and the likelihood that initial infection will result in active disease.¹⁹ The incidence of tuberculosis in HIV-positive patients varies according to community prevalence but is much higher than in the general population. Physicians considering a diagnosis of tuberculosis should offer patients HIV testing, which may provide early diagnosis and therapy.

Pulmonary involvement may be difficult to distinguish from other HTV-associated lung disorders. Tuberculosis must be in the differential of any HTV-associated respiratory disorder and can present atypically on chest radiographs. The incidence of extrapulmonary tuberculosis is **higher** in patients diagnosed with HIV infection with the potential to involve any organ system. The most commonly reported extrapulmonary sites are the lymph nodes, pleura, and bones or joints.

Treatment of tuberculosis in HIV-positive individuals is generally effective, but some reports have indicated higher mortality rates in coinfecting patients, especially in those severely immunocompromised.⁹ The incidence of adverse drug reactions to antituberculosis chemotherapy is higher in HIV-positive than in HIV-negative patients. Due to the number of medications taken by patients with HIV potential drug interactions also must be of concern.

Multidrug-Resistant Tuberculosis

The incidence of multidrug-resistant tuberculosis (MDR-TB) peaked during the resurgence of tuberculosis. During that period, most cases involved those coinfecting with HTV and were associated with a high mortality rate. With the increased surveillance of high-risk groups, the overall incidence of drug resistance has decreased.³ However, MDR-TB remains a problem in foreign-born persons, accounting for 72 percent of the MDR-TB cases reported in 2000.³ *Mycobacterium tuberculosis* becomes resistant by spontaneous genetic mutation, often as a

result of inadequate drug therapy or noncompliance with initial treatment.^{2,10} The most powerful predictors of drug resistance remain a history of previous tuberculosis, cavitary lung disease, and positive sputum smears.^{10,12}

In the HIV-positive population, the most common pattern is resistance to both isoniazid and rifampin.⁵ Available data suggest no difference in isoniazid monoresistance among those patients with or without HIV. Rifampin monoresistant tuberculosis has become a problem, especially in those with AIDS.¹³ Cases with rifampin monoresistance were more commonly seen in patients who previously had tuberculosis, a history of diarrhea, rifabutin use, or antifungal therapy.¹³

For those HIV-negative patients treated for MDR-TB strains, a long-term response rate ranging from 56 to 96 percent has been reported. When MDR-TB is diagnosed early and appropriately treated, the cure rate is higher. Recent reports stress the importance of aggressive contact investigation and treatment in specialized centers to appropriately control the spread of MDR-TB.^{11,12} One study from Turkey reported an overall success rate of 77 percent when using aggressive surveillance and treatment protocols.¹⁴ In that study, a mean number of 5.5 drugs were used, some of which are considered second-line treatment.

Treatment of MDR-TB remains challenging and depends on the sensitivity patterns from culture. Most regimens include four to six drugs, with treatment as long as 18 to 24 months after sputum conversion. The fluoroquinolones have been used successfully in treatment of MDR-TB.^{10,14} Side effects of multiple-drug regimens are a common problem. When drug therapy fails, resectional surgery may be necessary to eradicate the disease.

DIAGNOSIS

The diagnosis of tuberculosis can present a challenge to emergency physicians. In the past, physicians mainly considered the diagnosis when presented with a patient with reactivation infection. With the increased incidence of tuberculosis and the appearance of multidrug-resistant strains, one must consider the diagnosis in a wider range of patients. The variable clinical presentation and the time required to culture the organism make emergent diagnosis difficult. A heightened awareness of the disease and the potential of new rapid diagnostic tests can ensure that these patients are not returned to the community without proper therapy.

All prehospital and ED personnel should be trained to suspect tuberculosis, institute appropriate precautions, and notify health care providers of their suspicions. Triage workers should ask appropriate questions to detect potential cases. Patients with suspected tuberculosis should be placed in separate waiting areas, wear surgical masks, and be instructed to cover the mouth and nose when coughing. Any immunocompromised patient with respiratory symptoms should be isolated until tuberculosis can be excluded. Prompt evaluation will ensure a minimal amount of time spent in the ambulatory care setting and a minimal risk of exposure to health care providers and other patients.¹⁵

Skin Test

The most common method to detect exposure to *M. tuberculosis* is a skin test. The Mantoux test, which involves the intracutaneous injection of 0.1 mL of PPD into the forearm, relies on a delayed-type hypersensitivity reaction that is triggered if past infection with tuberculosis has occurred. The test is read between 48 and 72 h after administration by measuring the extent of skin induration at the test site; erythema or other skin changes are not assessed (Table 65-2).⁶ All persons with a positive PPD reaction or recent conversion should be referred for possible treatment of latent tuberculosis.

In a few situations, however, the PPD test may be nondiagnostic. Individuals who have received Bacille Calmette-Guérin immunization

TABLE 65-2 Interpretation of Purified Protein Derivative Skin Test*

1. >5 mm induration is positive in
 - a. Patients with the human immunodeficiency virus
 - b. Patients with close contact with a tuberculosis-infected individual
 - c. Patients with abnormal chest radiograph suggestive of healed tuberculosis
 - d. Patients with organ transplants and other immunosuppressed patients receiving the equivalent of prednisone >15 mg per d for greater than 1 month
2. >10 mm induration is positive in patients not meeting the above criteria but who have other risks
 - a. Injection drug users
 - b. High-prevalence groups (immigrants, long-term—care facility residents, persons in local high-risk areas)
 - c. Patients with conditions that increase the risk of progression to active disease (silicosis, diabetes, carcinoma of the head, neck, or lung)
 - d. Children <4 y of age
3. a 15 mm induration is positive in all others
4. Detection of newly infected persons in a screening program
 - a. a 10 mm induration increase within any 2 y period is positive if younger than 35 y
 - b. a 15 mm induration increase within any 2 y period is positive if 35 y or older
5. If the patient is anergic, other epidemiologic factors must be considered

*A positive reaction does not necessarily indicate disease.

for tuberculosis prevention would be expected to have a positive response. Exposure to nontuberculous mycobacteria also can result in a false-positive PPD reaction.⁶

A competent immune system is required to yield a positive response to the PPD if there has been infection with *M. tuberculosis*. Therefore, individuals with abnormal immune systems, such as in AIDS, may lose their ability to mount a delayed-type hypersensitivity reaction required to produce a positive PPD reaction. Although the Centers for Disease Control and Prevention (CDC) no longer recommend routine anergy testing among HIV-positive individuals, some clinicians use control agents, such as mumps or *Candida*, to assess at-risk patients for anergy. However, reacting to controls does not exclude the diagnosis of tuberculosis, and a negative skin test in a patient suspected of disease requires further evaluation.¹⁶ False negatives have been demonstrated with improper PPD administration. Nonreactivity to a PPD has been occasionally reported in patients with active culture-positive tuberculosis; therefore, a PPD test occasionally may be unreliable in acute stages of the disease.

Chest Radiograph

The chest radiograph is used to screen for disease in individuals with positive PPD skin test and for those with signs and symptoms of active infection. In the past, the classic findings of tuberculosis were those associated with reactivation infection: cavitary or noncavitary lesions in the upper lobe or superior segment of the lower lobe of the lungs.¹⁷ Cavitation can be associated with increased infectivity.⁵ Calcification of the lesions may be a later finding.

With the resurgence of tuberculosis, radiographic findings of primary disease are becoming more common. In primary infection, parenchymal infiltrates in any area of the lung may be found. Isolated ipsilateral hilar or mediastinal adenopathy is sometimes the only finding. Miliary tuberculosis as primary or reactivation disease frequently shows small (1 to 3 mm) nodules throughout the lung fields. Pleural effusions, which are usually unilateral, can occur alone or in association with parenchymal disease. Atelectasis, fibrotic scarring, tracheal deviation, and signs of prior thoracic surgery are other findings. Because tuberculosis has a wide variety of appearances on chest radi-

ographs, comparison with previous films is extremely helpful in determining the significance of an abnormal or unusual finding.

Immunocompromised patients, such as those with advanced HIV, are more likely to have radiographs typical of primary infection or with atypical findings as opposed to classic cavitary lesions. Normal radiographs in the presence of active disease are seen more frequently in HIV-positive patients.^{9,17}

Microbiology

Culture for tuberculosis is the "gold standard" for diagnosis.⁵ Sputum is commonly collected to detect the presence of *M. tuberculosis* by culture and smear. In the absence of a satisfactory sputum sample, gastric aspirates, pleural and other body fluids, and tissue samples may be used for culture and other diagnostic tests. Staining of the specimen for acid fastness (i.e., Ziehl-Neelsen stain) or a fluorochrome procedure is the quickest and least expensive method to provide a presumptive diagnosis of tuberculosis. Approximately 60 percent of culture-positive cases of tuberculosis will have smears in which acid-fast bacilli are detected, although this may be lower in individuals with HIV.⁹

Newer methods are under development to aid in the speed and sensitivity of diagnosing tuberculosis. Although not widely available, techniques that use radiometric technology, DNA probes, polymerase chain reaction, reverse transcription, or other technologies may someday provide definitive results in a matter of hours.⁵ At this time, the technology is used for a DNA fingerprint to understand transmission of disease for epidemiologic purposes.¹⁸

TREATMENT

Because of the possibility of resistance, the treatment of active tuberculosis involves the use of a combination of antimycobacterial medications.^{1,19} Initial therapy usually consists of three or four-drugs [isoniazid (INH), rifampin (RIF), pyrazinamide (PZA), ethambutol (EMB)] for 8 weeks, followed by two-drug continuation treatment for 18 to 31 weeks. The recommended CDC regimens are:¹⁹

1. Daily four-drug (INH, RIF, PZA, EMB) therapy for 8 weeks, followed by either INH/RIF or INH/rifapentine for 18 weeks.
2. Daily four-drug therapy for 2 weeks, followed by two times per week for 6 weeks, with subsequent INH/RIF or INH/RPT for 18 weeks.
3. Three times weekly four-drug therapy for 8 weeks, followed by INH/RIF three times weekly for 18 weeks.
4. Daily three-drug (INH, RIF, EMB) for 8 weeks followed by INH/RIF for 31 weeks.

More prolonged therapy is recommended for immunocompromised patients, such as those with HIV or extrapulmonary disease. Initial therapy may be modified once drug susceptibilities are available. The importance of directly observed therapy (DOT), where patients are observed taking their antituberculosis medications to ensure compliance, cannot be overstated. The CDC recommends that all regimens of two or three times per week should be given by DOT.^{1,6,11,12,19}

Although the standard medications used to treat tuberculosis are generally efficacious and safe, occasionally side effects or drug interactions may be significant (Table 65-3). Isoniazid, the most frequently used antituberculosis agent, has hepatitis as its major toxicity. Advancing age is thought to be a significant risk factor for the development of hepatitis.⁵ Pre-existing liver disease, pregnancy, ethanol use, HIV, and hepatitis C infection have been associated with an increased risk for hepatotoxicity from INH.⁶ In addition, those with pre-existing medical conditions requiring multiple medications may be at higher risk for drug interactions with antimycobacterial agents.¹⁹

TABLE 65-3 and Common Side Effects of Some Drugs Used in Tuberculosis (Adults)
Dosages

Drug	Daily (Maximum)	3 Times Weekly DOT (Maximum)	2 Times Weekly DOT (Maximum)	Potential Side Effects and Comments
Isoniazid (INH)	5 mg/kg PO (300 mg)	15 mg/kg PO (900 mg)	15 mg/kg PO (900 mg)	Hepatitis, peripheral neuropathy, drug interactions
Rifampin (RIF)	10 mg/kg PO (600 mg)	10 mg/kg PO (600 mg)	10 mg/kg PO (600 mg)	Hepatitis, thrombocytopenia, GI disturbances, drug interactions
Rifabutin	5 mg/kg PO (300 mg)	5 mg/kg PO (300 mg)	5 mg/kg PO (300 mg)	Similar to RIF, used for patients who cannot tolerate RIF
Rifapentine (RPT)	ND	ND	10 mg/kg PO (600 mg) once per week	Similar to RIF, used with INH for once weekly continuation phase treatment
Ethambutol (EMB)	15-20 mg/kg PO (1.6 g)	25-30 mg/kg PO (2.4 g)	50 mg/kg PO (4 g)	Retrolbulbar neuritis, peripheral neuropathy
Pyrazinamide (PZA)	15-30 mg/kg PO (2 g)	50-70 mg/kg PO (3 g)	50-70 mg/kg PO (4 g)	Hepatitis, arthralgia, hyperuricemia
Cycloserine	10-15 mg/kg per dPO divided bid	ND	ND	CNS disturbances, seizures, peripheral neuropathy
Ethionamide	10-15 mg/kg per d PO divided bid	ND	ND	Nausea, vomiting diarrhea, abdominal cramps, anorexia
Streptomycin	15 mg/kg IM(1 g)	15 mg/kg IM(1 g)	15 mg/kg IM (1 g)	Ototoxicity, nephrotoxicity
Capreomycin	15 mg/kg IM(1 g)	15 mg/kg IM(1 g)	15 mg/kg IM(lg)	Nephrotoxicity, ototoxicity
Para-aminosalicylic acid	8-12 g per d, divided into two or three doses	ND	ND	GI disturbances, hypothyroidism, hepatitis
Levofloxacin	500-1000 mg per dPO	ND	ND	GI disturbances, dizziness, rash

Abbreviations: CNS = central nervous system; DOT = directly observed therapy; GI = gastrointestinal; ND = no data to support this dosing regimen.

Source: MMWR 52 (RR-11):4, July 20, 2003.

With the emergence of multidrug resistance, other treatment modalities have been used to treat infection that does not respond to antimycobacterial chemotherapy. Among them, surgical resection for MDR-TB is a treatment modality that has been shown to have good results, with cure rates of up to 90 percent.¹⁰⁻¹⁴

Treatment of latent infection with INH should be considered for patients with recent conversion to PPD-positive status, for persons who have been in close contact with an individual with active tuberculosis, and for anergic individuals with known tuberculosis contact.⁶ The decision to institute therapy should be based on the likelihood that the positive PPD reaction represents true exposure to *M. tuberculosis*, the risk of progression to active disease, and the likelihood of INH-induced hepatitis. Therapy should continue for a minimum of 9 months for adults, children, and HIV-infected persons.⁶ Those at risk for INH hepatotoxicity should be monitored closely for its development, if treatment is elected. For those exposed to INH-resistant strains or those who are intolerant to its use, rifampin and pyrazinamide for 2 months have been used with success.⁶ However, careful monitoring for signs of liver failure are mandatory. Rifampin for 4 months is an alternative treatment.⁶

DISPOSITION

Admission

All hospitalized patients with suspected tuberculosis must be placed in respiratory isolation until the diagnosis is certain. Admission is important in cases in which the social situation makes it difficult to obtain a proper diagnosis and for therapy to be instituted. When a patient is proven to have active MDR-TB, hospital admission is also indicated to institute therapy and observe for drug toxicity. Other indications for admission include uncertain diagnosis or patient noncompliance. Physicians should be aware of local laws regarding involuntary hospitalization and treatment. However, less restrictive means, such as court-mandated DOT, are very effective and should be attempted before confinement.²⁰

Outpatient Treatment

The vast majority of patients with tuberculosis can be treated initially as outpatients.¹⁹ Emergency physicians should contact physicians or public health services providing long-term care before discharge. Discharge instructions include home isolation procedures and sites of medication (if DOT is used) and ongoing care. Antituberculosis medications should be instituted by health care professionals who will coordinate the treatment and monitor adverse effects of the medication. Such medications should not be routinely instituted in the emergency department without these measures.

PREVENTION

Prevention of tuberculosis transmission in health care facilities is extremely important. Guidelines for prevention of transmission have been published and are available through the CDC (www.cdc.gov). These recommendations include early detection and treatment of active cases, education and screening of health care workers, and engineering controls (Table 65-4).¹⁵ Ambulatory care facilities that frequently see tuberculosis patients will need isolation rooms available. Personnel who work in emergency or ambulatory settings where patients with tuberculosis are treated should have routine PPD testing to detect occupational exposure and be offered appropriate treatment.^{6,15}

TABLE 65-4 Engineering Controls to Reduce the Transmission of Tuberculosis

High airflow (at least six room air changes per hour) with external exhaust
High-efficiency particulate filters on ventilation system
Ultraviolet germicidal irradiation
Negative-pressure isolation rooms
Personal respiratory protection: high-efficiency particulate filter masks or respirators

SPONTANEOUS AND IATROGENIC PNEUMOTHORAX

William Franklin Young, Jr. Roger L. Humphries

Pneumothorax occurs when air enters the potential space between the visceral and parietal pleura as a consequence of blunt trauma, penetrating trauma, or spontaneous occurrence. Iatrogenic pneumothorax occurs secondary to a diagnostic or therapeutic procedure and is really a subset of penetrating traumatic pneumothorax. Primary spontaneous pneumothorax occurs in individuals without known lung disease and accounts for two-thirds of spontaneous pneumothoraces. Secondary spontaneous pneumothorax occurs in patients with underlying lung disease, especially chronic obstructive pulmonary disease. Emergency department evaluation and management of pneumothorax centers on immediate management of complications such as tension pneumothorax or ventilatory failure, and then on eliminating the intrapleural air and optimizing pleural healing.

SPONTANEOUS PNEUMOTHORAX

Epidemiology

An estimated 20,000 new spontaneous pneumothoraces occur each year in the United States, and there is evidence that the rate is increasing.^{1,2} However, the true incidence of spontaneous pneumothorax is unknown, with estimates that up to 20 percent of such patients do not seek medical help.³ Spontaneous pneumothorax is primarily a disease of male smokers who have greater height-to-weight ratios. Male sex carries a 6:1 relative risk as compared with the risk for females, although more recent studies show a trend to increased cases among women, perhaps because of smoking trends.² Smoking is an important risk factor, with an overall greater than 20:1 relative risk as compared with nonsmokers.⁴ Spontaneous pneumothorax has three age-related occurrence peaks: among neonates (because of hyaline membrane disease or aspiration), among 20- to 40-year-olds (such cases tend to be primary), and among those older than age 40 years (typically secondary cases).⁴ A genetic component is evidenced in the 11 percent of patients who have family members with spontaneous pneumothorax. Contrary to common belief, only 10 to 20 percent of cases occur with exertion. Spontaneous pneumothorax may rarely be associated with menses (catamenial).

Pathophysiology

The pleurae are serous membranes that surround each lung: the parietal pleura lines the thoracic wall and abuts the visceral pleura closely applied to the lung surface. At the hilum of each lung, the parietal and visceral pleurae meet in a continuous reflection around the hilar vessels and bronchus. The intrapleural space has subatmospheric pressure caused by the inherent tendency of the chest wall to expand and the lung to collapse from elastic recoil.

Primary spontaneous pneumothorax seems to result from rupture of a subpleural bleb, usually in an upper lobe.⁵ These blebs are usually multiple and have increased wall tension, allowing distention and eventual rupture. The mechanism of bleb formation remains unknown, but higher upper lobe transpulmonary pressure, local ischemia from decreased upper lobe blood flow, and subclinical emphysema-like changes have been postulated.^{3,5}

Chronic obstructive pulmonary disease (COPD) accounts for most cases of secondary spontaneous pneumothorax. Other causes include cystic fibrosis, pulmonary infections, interstitial lung disease, AIDS, neoplasms, and drug use. Pneumothorax occurs in 5 percent of AIDS patients, is associated with subpleural necrosis from *Pneumocystis* infection, and carries a high mortality.⁶ Because of necrosis of lung tissue and continued air leak, simple aspiration and nondrainage techniques fail in this group of patients.

Regardless of the inciting event, once there is a break in the pleura, air travels down a pressure gradient into the intrapleural space until pressure equilibrium occurs with partial or total lung collapse. Altered ventilation perfusion relationships and decreased vital capacity then contribute to dyspnea and hypoxemia.

Clinical Features

Symptoms are related to the size of the pneumothorax, rate of development, and underlying clinical status of the patient. Patients with mild symptoms may not come for evaluation, whereas those with underlying lung disease may arrive in extremis. Patients with secondary spontaneous pneumothoraces present more dramatically than those with primary pneumothoraces. Tension pneumothorax is rare in either primary or secondary spontaneous pneumothorax. Pneumothorax is an important differential diagnosis in patients with chest pain, because it can mimic ischemia causing ST changes and T-wave inversion on the electrocardiogram (ECG).³

Acute pleuritic chest pain occurs in 95 percent of patients and localizes to the side of the pneumothorax in >90 percent of cases. Dyspnea occurs in 80 percent of patients, and predicts a larger pneumothorax. Patients with COPD who develop a spontaneous pneumothorax may acutely decompensate, with 1 to 17 percent mortality. Decreased breath sounds occur over the affected lung 85 percent of the time, but only 5 percent have tachypnea of more than 24 breaths/min or tachycardia of more than 120 beats/min. Hyperresonance occurs in fewer than one-third. Tracheal deviation and hemodynamic compromise are the hallmarks of tension pneumothorax that demand immediate treatment.

Diagnosis

Tension pneumothorax diagnosed on clinical grounds requires immediate treatment by needle decompression and expeditious chest tube thoracostomy before radiographic evaluation. The traditional "gold standard" for diagnosis of pneumothorax continues to be the 6-foot upright posteroanterior chest radiograph, although the sensitivity of this examination is 83 percent.⁷ The radiographic hallmark of a pneumothorax is visualization of the visceral pleural line with an overlying radiolucent area without vascular or lung markings between the visceral pleural line and chest wall. Pseudo-pneumothorax caused by a skin fold, scapular border, or tubing, is differentiated from true pneumothorax by looking for vascular markings inside the confines of the radiolucent area and the blending of these lines into the chest wall, rather than following the borders of a collapsed lung. Large bullae have been mistaken for pneumothoraces, but bullae and cysts have concave inner margins and rounded edges. Pneumothorax is much more difficult to detect on a supine anteroposterior radiograph. On the anteroposterior view, a deep sulcus sign, representing a deep lateral costophrenic angle, sometimes is a clue to a pneumothorax.⁷

Expiratory radiographs by themselves are no more sensitive than inspiratory films and provide inferior evaluation of lung parenchyma.⁷ In approximately 5 percent of patients, a pneumothorax is better visualized on the expiratory view than on the inspiratory view.⁷ Comparison of paired inspiratory and expiratory films may be more sensitive than either view alone.⁸

Chest computed tomography (CT) may be more sensitive than plain radiographs in detection of pneumothorax and may be helpful in equivocal cases, but most studies comparing supine chest x-ray (CXR) film with chest CT have been in the setting of trauma.

Ultrasonography, although portable and easy to perform, has traditionally been considered an imaging modality incapable of adequately visualizing the lung parenchyma and therefore of little use in the detection of pneumothorax. Ultrasound waves do not transmit well through air and this is a common cause of sonographic artifact and poor quality ultrasonographic imaging in any application. However, European experience with ultrasonography has found this technique capable of detecting pneumothorax after ultrasound-guided pleural or lung biopsy and pneumothorax associated with ventilatory-induced barotrauma with a sensitivity approaching 100 percent.⁹ Ultrasonography has been used to detect traumatic pneumothorax, also with a sensitivity approaching 100 percent.¹⁰ Sonographic signs of a pneumothorax include (1) absence of lung sliding as assessed on the time-motion view (the normal granular pattern is replaced by multiple horizontal artifact lines termed "A-lines"); (2) the demonstration of a "lung point" on the time-motion view, in which, during inspiration, at one transducer position, the normal granular pattern of the lung in contact with the chest wall, is replaced by the multiple horizontal artifact lines as the lung collapses away from the chest wall; and (3) absence of vertical comet-tail artifacts arising from the pleural line on a B-mode two-dimensional view.⁹ As with any ultrasonographic application, the technical ability of the operator and the quality of the interpretation determines the clinical utility of this imaging modality.

Spontaneous pneumothorax should be included in the differential diagnosis of acute chest pain or acute deterioration in a patient with COPD. ST-segment and T-wave changes may be mistaken for ischemia. Occasionally, severe bullous COPD may mimic pneumothorax, and careful review of the CXR is needed with confirmatory CT, if the patient is stable. A thoracostomy with the chest tube inserted into a bulla mistaken for a pneumothorax results in a large pneumothorax, associated bronchopulmonary fistula, and its complications.³

The size of the pneumothorax may be calculated, and some physicians use size as a guide to therapy. Radiologist "best guess" estimates show substantial interobserver disagreement and lack of reproducibility. Most published formulae show only a modest correlation to actual pneumothorax size ($R = 0.7$).^{11,12} Chest CT volume measurements represent the current "gold standard," but the patient's clinical status more than the pneumothorax size, should determine treatment options. A more pragmatic approach is to classify pneumothorax size as small (<3 cm apex to cupola) or large (≥3 cm apex to cupola).¹³

Treatment

Treatment goals are the elimination of intrapleural air, optimization of pleural healing, and prevention of recurrences. There is marked practice variation, but attempts at consensus have been made with varying degrees of application.^{13,15} Observation, oxygen, catheter aspiration (either single or sequential), tube thoracostomy (either minicatheter or standard chest tube), pleurodesis, video-assisted thoracoscopy (VAT), and thoracotomy are all options, but only the latter three procedures reduce the risk of future pneumothorax recurrence.

Because 1.25 percent of intrapleural air is reabsorbed each day, stable patients with a small primary spontaneous pneumothorax may be observed for 3 to 6 h. Concomitant oxygen administration at 3 to 4 L/min increases pleural air resorption three- to fourfold and should be used.⁴ If a repeat chest radiograph shows no increase in pneumothorax size, the patient can be discharged with instructions to return if symptoms develop or worsen. A repeat chest radiograph in 12 to 48 h is recommended. Extended outpatient observation is sometimes needed because a 25 percent pneumothorax would take approximately 20 days to resolve. Critics of this treatment plan point to the 23 to 40 percent of patients treated by observation who eventually require tube thoracostomy.¹ Observation may also be a reasonable approach for those patients with a contraindication to invasive therapy, such as coagulopathy.

Catheter aspiration is underused for treatment of spontaneous pneumothorax and may be as effective as chest tube thoracostomy in primary spontaneous pneumothorax.¹⁶ Multiple techniques, equipment, and protocols are described, making a consensus statement difficult. Success rates from 37 to 75 percent are described with the greater success seen in primary spontaneous pneumothoraces.¹ Techniques include simple one-time aspiration with small plastic 16- to 18-gauge intravenous catheters, repeated aspirations through the same catheter, and small-caliber chest tube with aspiration. Minicatheter tube placement uses a specially designed catheter with multiple side ports, eliminating the problem of single-lumen obstruction seen with intravenous catheters. The technique involves placing a small catheter either into the second anterior intercostal space in the midclavicular line or laterally at the fourth or fifth intercostal space in the anterior axillary line after local anesthesia and sterile preparation. A three-way stopcock is applied, and a 60-mL syringe is used to aspirate the pleural space until resistance is met and the patient coughs. The stopcock is closed, the tube is secured, and a chest radiograph is obtained to assure reexpansion. Aspiration of more than 4 L suggests continued air leak and failure of simple aspiration. Failure to fully expand warrants another aspiration attempt, addition of a Heimlich valve, or formal tube thoracostomy. If the procedure is successful, patients should be

observed for 6 h and, if no recurrence is seen, the catheter is removed and the patient discharged with close follow-up within 24 h.

Standard chest tube thoracostomy with underwater seal drainage is the most commonly used therapy and remains the standard in many hospitals. Proponents point to a low complication rate and a high success rate of 95 percent.¹⁷ If there is a low risk of air leak, a small < 14 Fr tube suffices, otherwise use a 24 to 28 Fr tube with water seal (no suction).¹⁸ Patients with secondary spontaneous pneumothorax, those with recurrent pneumothorax, and those with abnormal vital signs should have chest tube thoracostomy.

Short-term complications of spontaneous pneumothorax include tension pneumothorax, failure to reexpand, persistent air leak, and complications related to the removal of intrapleural air, such as infection, technical errors, and reexpansion pulmonary edema. Reexpansion pulmonary edema is multifactorial, poorly studied, and more often seen in younger patients aged 20 to 39 years, with larger pneumothoraces present for >72 h, rapidly expanded with suction.¹⁸ Pulmonary edema generally occurs on the side of the reexpanded lung. Treatment is supportive and mirrors that for noncardiogenic pulmonary edema.

Disposition

After successful treatment of a spontaneous pneumothorax, referral and consultation regarding potential definitive management with pleurodesis with or without VAT or thoracotomy should be done. Some authors recommend thorascopic surgery for the first spontaneous pneumothorax because of the relatively high rate of pneumothorax recurrence, lower overall cost, success rate of the procedure, and better long-term quality of life.¹⁹ However, the procedure is not risk free, is invasive, and recurrence after VAT requires open thoracotomy with pleurectomy or pleural scarification. Most guidelines recommend definitive treatment only after second recurrence.

Recurrence of pneumothorax is the major long-term complication and the reason that all patients with spontaneous pneumothorax require referral for potential definitive therapy. Primary spontaneous pneumothorax recurs in approximately 20 to 30 percent of patients and is independent of the method chosen to remove the intrapleural air.²⁰ Almost all recurrences occur within 2 years.²⁰ Smoking cessation reduces this risk by half.² Secondary spontaneous pneumothorax recurs in 40 to 50 percent of patients.

IATROGENIC PNEUMOTHORAX

Iatrogenic pneumothorax occurs more often than spontaneous pneumothorax and is a subset of traumatic penetrating pneumothorax. Transthoracic needle procedures (transthoracic needle biopsy and thoracentesis) account for approximately half and subclavian vein catheterization accounts for a fourth of iatrogenic pneumothoraces. Given that one central venous line is placed every minute in the United States, and that pneumothorax occurs after 2 to 6 percent of subclavian line attempts, iatrogenic pneumothorax must be common.²¹ Some of the factors increasing the frequency of iatrogenic pneumothorax include the patient population, underlying disease, body habitus, and experience of the operator. Ultrasound guidance for thoracentesis significantly reduces the pneumothorax complication rate and appears promising for reducing the incidence of pneumothorax with central venous line placement.

Chest radiograph is standard after central line placement or transthoracic needle procedures, but may miss an iatrogenic pneumothorax because of the use of a supine technique or inadequate time for the pneumothorax to develop. Delayed pneumothoraces are common after subclavian line placement; up to a third are not seen on the initial postprocedural chest radiograph.²¹

Treatment for iatrogenic pneumothorax parallels that for spontaneous pneumothorax, with some important caveats. Patients with res-

piratory distress or on mechanical ventilation require large-bore tube thoracostomy. Conversely, patients sustaining a small pneumothorax after a needle puncture and not receiving positive pressure ventilation can be initially treated with simple catheter aspiration with or without a Heimlich valve, which will be adequate in 60 to 80 percent of patients.²¹ Stable patients with a small pneumothorax can be observed and selected patients can be followed as outpatients.²¹ Because prolonged air leak may occur in some patients, usually after pleural or lung biopsy-induced pneumothorax or difficult subclavian vein catheterization attempt, hospitalization is recommended in these patients. Long-term recurrence is not an issue with iatrogenic pneumothorax.

HEMOPTYSIS

William Franklin Young, Jr.
Michael Stava

Hemoptysis is expectoration of blood from the respiratory tract below the level of the larynx. The causes of hemoptysis vary from simple bronchitis to life-threatening pulmonary embolism.¹ Most causes are not life-threatening, but the symptoms are quite frightening to patients and cause them to seek emergent evaluation. Even with careful evaluation, a cause is not identified in up to 25 percent. Priorities in the evaluation of hemoptysis are: (1) ensuring adequate oxygenation and ventilation, (2) confirming a pulmonary source of bleeding, (3) attempting to identify the cause of hemoptysis through appropriate diagnostic evaluation, and (4) appropriate disposition.

EPIDEMIOLOGY

The true incidence of hemoptysis is unknown because many cases are unreported. Before the 1960s, most cases of hemoptysis were caused by tuberculosis, followed by bronchiectasis and lung neoplasia. With the introduction of antibiotics and the increases in cigarette smoking, bronchitis and lung neoplasia have become more common. A retrospective meta-analysis of six prior studies of hemoptysis found an infectious nontubercular cause in approximately 25 percent of hemoptysis cases, tuberculosis caused approximately 5 percent, neoplasia accounted for 28 percent, and miscellaneous and multiple causes accounted for 13 percent.² Of note, 28 percent of hemoptysis cases had an undetermined cause, often referred to as *cryptogenic hemoptysis*. These percentages vary according to patient demographics and location.³⁻⁶ Cardiovascular causes account for 3 percent of total hemoptysis cases, of which three of four are congestive heart failure. Trauma accounts for fewer than 3 percent of hemoptysis cases. In summary, for industrialized countries, of every four cases of hemoptysis, expect about one neoplasm, one nontubercular infectious case, one miscellaneous case, and one idiopathic case.

Hemoptysis has a 60:40 male predominance, and occurs in all age groups. Lifestyle activities such as smoking predispose patients to lung disease and an increased risk of hemoptysis. Male gender, age older than 40 years, and history of smoking are risk factors for a neoplastic cause of hemoptysis.² Hemoptysis in children is rare and most often due to cystic fibrosis, congenital heart disease, infection (pneumonia, tracheobronchitis), and tracheostomy complications.⁷

PATHOPHYSIOLOGY

The causes of hemoptysis are numerous (Table 67-1). The lung has a dual blood supply consisting of the bronchial and the pulmonary vessels, and bleeding may occur from either or both. The bronchial vessels are under systemic circulatory pressure and supply the supporting structures of the lung, and the pulmonary vessels are under low pressure and supply the alveoli. Bleeding from either source may occur by three mechanisms: pulmonary hypertension, erosion into a pulmonary or bronchial blood vessel, and as a complication of a bleeding diathesis. Hemoptysis arising from increases in pulmonary vascular pressure most often results from primary cardiac abnormalities, such left-sided congestive heart failure (comprising 75 percent of cardiac cases) or mitral stenosis.

Infectious causes include bronchitis, pneumonia, lung abscesses, and fungal infections. Inflammatory causes include bronchiectasis and cystic fibrosis. Malignant lesions producing hemoptysis can be primary lung neoplasms or metastatic tumors. Although classically associated with pulmonary embolism, hemoptysis is seen in only 3 to 20 percent of cases. Hemoptysis from vasculitis is usually alveolar in location and part of a larger systemic vasculopathy, such as systemic lupus erythematosus, Wegener granulomatosis, polyarteritis, or Goodpasture syndrome.

TABLE 67-1 Common Causes of Hemoptysis

Infectious: bronchitis, pneumonia, lung abscess, tuberculosis
Neoplastic: lung cancer, bronchial adenoma
Cardiovascular: pulmonary embolism, mitral stenosis, congestive heart failure, pulmonary hypertension, pulmonary angiodysplasia
Alveolar hemorrhage syndromes: Bechet syndrome, Goodpasture syndrome, Wegener granulomatosis
Hematologic: uremia, platelet dysfunction, anticoagulant therapy
Traumatic: foreign body aspiration, ruptured bronchus, arterio-tracheobronchial fistula (aortic aneurysm)
Iatrogenic: bronchoscopy, lung biopsy
Inflammatory: bronchiectasis, cystic fibrosis

Hemophilia, thrombocytopenia, inherited coagulopathy, and iatrogenic use of anticoagulants and thrombolytics may cause hemoptysis. Thrombolytic-induced hemoptysis occurs in fewer than 1 percent of patients receiving thrombolysis and is usually self-limited.⁸

The erosion of bronchial vessels under systemic circulatory pressures from tuberculosis or bronchiectasis can produce severe hemoptysis⁸ (Table 67-2). Severe hemorrhage from the pulmonary circulation can occur from mycetomas, lung abscess, and cavitary lung cancer.

CLINICAL FEATURES

Hemoptysis may be defined as mild, moderate, or severe. Mild hemoptysis is usually defined as less than 20 mL of blood in 24 h, moderate hemoptysis is defined as 20 to 600 mL in 24 h, and severe or massive hemoptysis is defined as more than 600 mL in 24 h.¹ Often patients are unable to accurately estimate the degree of bleeding. The exact amount of hemoptysis required for each categorization is arbitrary, not evidence based, does not predict mortality (except in the severe category), and involves longer time frames than seen in the emergency department. A reasonable categorization for the ED might include scant or blood-streaked sputum, frank hemoptysis, and massive hemoptysis interfering with respiration.

A careful history and physical examination have only moderate roles in identifying a specific etiology.⁹ An abrupt onset of cough with bloody purulent sputum, with or without fever, may indicate acute pneumonia or bronchitis. Hemoptysis is an insensitive marker for pulmonary embolism, and pulmonary infarction secondary to pulmonary embolism causing hemoptysis is often overshadowed by anxiety, dyspnea, and chest pain. A chronic productive cough may reflect chronic bronchitis or bronchiectasis. Fevers, night sweats, and weight loss suggest tubercular infection. Chronic weight loss and change in cough may reflect bronchogenic carcinoma. About 80 percent of neoplasm-caused hemoptysis lasts longer than 1 week. Alveolar hemorrhage syndromes from vasculitis present with dyspnea and mild hemoptysis associated with renal disease and hematuria.

Physical examination is useful in determining the severity of hemoptysis but is unreliable in localizing the site of bleeding.⁹ Fever usually indicates infection. Tachypnea may reflect respiratory compromise with hypoxemia from intrapulmonary blood interfering with gas exchange or from underlying lung disease with altered ventilation and perfusion. Blood pressure usually is not changed, except in massive hemoptysis. The nasal cavity and oropharynx should be carefully examined for extra-pulmonary causes of expectorated blood (pseudohemoptysis) and signs

TABLE 67-2 Common Causes of Massive Hemoptysis

Bronchiectasis

Lung cancer (typically cavitary)
Lung abscess
Arteriotracheobronchial fistula (e.g., aortic aneurysm)
Pulmonary angiodysplasia

of extrapulmonary vasculitis.¹⁰ The cardiac examination may show valvular heart disease (e.g., the diastolic murmur of mitral stenosis). The pulmonary examination may show fine inspiratory crackles associated with alveolar blood or inspiratory and expiratory crackles associated with airway secretions and blood. There may be wheezing from bronchial narrowing. Digital clubbing should be assessed as a sign of chronic lung disease. Muscle wasting or adenopathy may indicate neoplasia.

DIAGNOSTIC EVALUATION

Diagnostic evaluation should first center on the patient's respiratory stability with the assurance of adequate oxygenation and ventilation. Massive hemoptysis requires immediate intervention with supplemental oxygen, intravenous access, typed and cross-matched blood, and urgent consultation with a pulmonologist or thoracic surgeon.⁸ Airway control might necessitate intubation. Patients who are stable should have their sputum evaluated for the degree of hemoptysis and to differentiate true hemoptysis from pseudohemoptysis due to a nasopharyngeal or gastrointestinal source. True hemoptysis often displays a bright red color, frothy appearance, alkaline pH, and the presence of macrophages. Gastrointestinal blood typically is acidic and dark red, although swallowed epistaxis may have similar characteristics. Approximately 10 percent of patients with apparent hemoptysis are identified as having bleeding due to lesions of the upper aerodigestive tract.¹⁰

It is generally agreed that all patients with true hemoptysis require radiographic imaging, starting with a chest radiograph.^{1,2,9} Approximately 80 to 90 percent of individuals with neoplasm as a cause of hemoptysis have an abnormal chest radiograph. Overall, 15 to 30 percent of patients presenting with hemoptysis have a normal chest radiograph, most of whom have hemoptysis from nonspecific bronchitis.¹¹ After chest radiography, further diagnostic options include computed tomography (CT) and bronchoscopy.

Bronchoscopy allows for direct visualization of the more central airways, is better at identifying luminal lesions such as tumors or areas of inflammation, allows for any required biopsy specimens to be obtained, and facilitates placement of selective lung ventilation devices.^{1,12} Patients unstable due to airway obstruction from massive hemoptysis have traditionally undergone rigid bronchoscopy to evacuate clots and determine the source of bleeding. In stable patients with less bleeding, fiberoptic bronchoscopy is generally done.¹³ Although early fiberoptic bronchoscopy has not been shown to appreciably affect the clinical outcome, many researchers recommend this study for individuals with hemoptysis and a normal or nonlocalizing chest x-ray. Because bronchoscopy is an invasive procedure, it carries a higher rate of complications as compared with CT.

Chest CT is noninvasive, more readily available on an urgent basis, more effectively delineates abnormalities in the peripheral airways, and has greater sensitivity in detecting bronchiectasis and nodular lesions such as carcinomas.^{2,14} Limited data suggest that CT is more efficient than bronchoscopy at identifying the cause of bleeding in patients with large or massive hemoptysis.¹⁵ Often, CT and bronchoscopy are performed in the evaluation of hemoptysis, especially in the high-risk patient presenting with hemoptysis, i.e., one who is male, older than 40 years, and has a history of tobacco use.² Close consultation with the follow-up physician is important to determine individual physician preference and to coordinate the timing of these evaluations. In general, patients with hemoptysis and an abnormal chest radiograph require an emergency department chest CT (Figure 67-1).

The laboratory evaluation should be guided by clinical suspicion and might include complete blood cell count, coagulation studies, blood gas analysis, sputum stains and cultures, and evaluation of renal function.

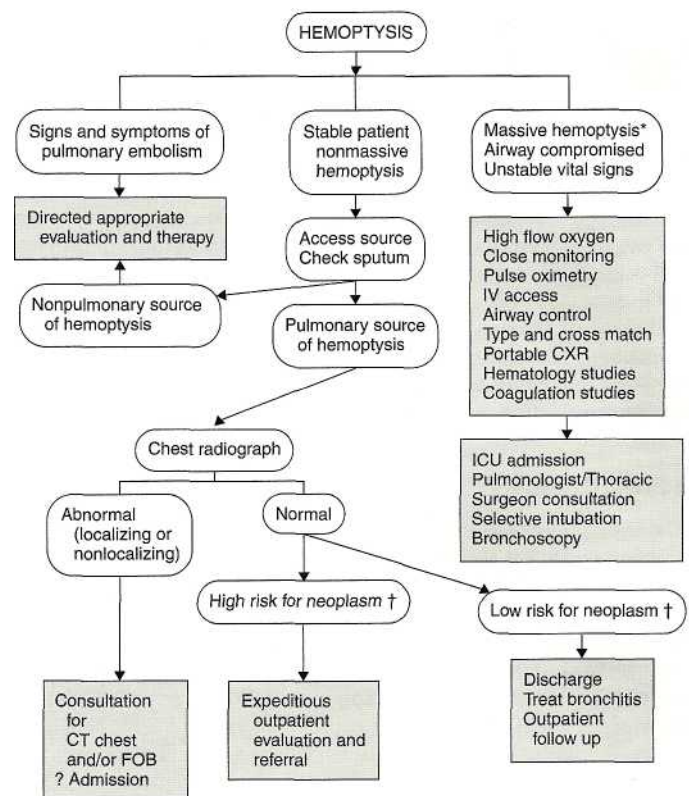

FIG. 67-1. Evaluation of hemoptysis.

†High risk for neoplasm: male, age >40 y, smoking history.

TREATMENT

Treatment in the ED depends on the severity of the hemoptysis. All patients with moderate or severe hemoptysis will require admission and should have intravenous access established, supplemental oxygen provided, laboratory testing initiated and type and cross for potential blood transfusion done.^{1,8}

Patients with ongoing massive hemoptysis are commonly positioned with the bleeding lung down, to minimize soiling of the contralateral normal lung. This belief is theoretical, not based on clinical studies, and a prone head-down position has been advocated as promoting better ventilation and perfusion matching in such patients.^{8,16} Tracheal intubation with a large-diameter endotracheal tube (8 mm or larger to allow for bronchoscopy) is indicated if there is respiratory failure or if the patient is unable to clear blood from the airways. If bleeding persists despite initial measures, an endotracheal tube may be advanced to the mainstem bronchus of the nonbleeding lung to minimize further aspiration of blood and provide ventilation.⁸ The right mainstem bronchus is easily entered by advancing a standard orotracheal tube. Inserting the tube will occlude the right upper lobe tertiary bronchus and ventilate the right middle and right lower lobes only. The left mainstem bronchus is more sharply angled from the trachea, and selective intubation usually requires special equipment and technique. Double-lumen endotracheal tubes usually require fiberoptic bronchoscopy for placement, and their small lumen diameters limit suctioning and airway clearance. Recently, a technique for blind insertion of a 37-French double-lumen endotracheal tube has been described in patients undergoing elective thoracic surgery, with the implication that this technique may be useful in emergency situations.¹⁷ However, there is no published experience with the use of this technique in patients with massive hemoptysis. After intubation, mechanical ventilation should be instituted, as necessary, to support ventilation.

Fresh-frozen plasma and/or platelet concentrates should be administered to correct identified coagulopathies. Tranexamic acid has been recommended based on anecdotal reports, but a recent randomized double-blinded, placebo-controlled trial found no benefit in reducing days of bleeding.¹⁸ Cough suppression with codeine or opioids might be helpful to prevent dislodging of hemostatic clots.

Emergency consultation is needed with a pulmonologist and thoracic surgeon for patients with massive hemoptysis to facilitate bronchoscopy or bronchial artery angiography to localize the specific bleeding site.^{8,13} Approximately 90 percent of massive hemoptysis cases originate from the bronchial circulation, and catheter-directed bronchial artery embolization has proven very effective in controlling the hemorrhage.¹⁹ For patients with massive hemoptysis from localized lesions who continue to bleed despite medical treatment, surgical resection should be considered.²⁰ Massive hemoptysis is less common in children, but similar evaluation and management are appropriate.

PATIENT DISPOSITION

Patients with continuing moderate or severe hemoptysis require admission, often to an intensive care unit.¹³ Patients with massive hemoptysis that has subsided are at high risk for recurrence and require similar intensive management and hospital admission, usually to an intensive care unit. Overall, the in-hospital mortality for patients with massive hemoptysis is about 20 to 25 percent.²⁰ Patients with certain disease processes also will require admission (congestive heart failure, pulmonary embolus), even if hemoptysis is mild. If appropriate specialists are not available, medical stabilization is essential before considering transfer to a hospital that provides such services.

Patients with minor hemoptysis due to bronchitis should be treated for the underlying disease, as appropriate. In those patients with mild hemoptysis, an abnormal chest radiograph, and a benign CT scan, disposition should be decided in close consultation with a pulmonary care specialist. Further evaluation of patients with a normal chest radiograph is important, because of the 5 to 20 percent risk for occult neoplasms of the lungs, trachea, or pharynx, and these patients should be directed to close follow-up with their primary care physician or a pulmonary specialist.^{11,21}

ACUTE ASTHMA IN ADULTS

Rita K. Cydulka

Asthma is a chronic inflammatory disorder characterized by increased responsiveness of the airways to multiple stimuli. Many cells and cellular elements, such as mast cells, eosinophils, T lymphocytes, macrophages, neutrophils, and epithelial cells, play a role in the development of the inflammatory response. In susceptible individuals, the inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and coughing, particularly at night or in the early morning. These episodes usually are associated with widespread, but variable, airflow obstruction that is often reversible spontaneously or with treatment.

Most acute attacks are reversible and improve spontaneously or within minutes to hours with treatment. Although patients appear to recover completely clinically, evidence suggests that asthmatic patients develop chronic airflow limitation. The recognition that asthma is a chronic inflammatory disorder of the airways has significant implications for the diagnosis, management, and potential prevention of its acute exacerbation.

EPIDEMIOLOGY

Asthma affects approximately 4 to 5 percent of the population in the United States.¹ It is the most common chronic disease of childhood, with a prevalence of 5 to 10 percent. On the other end of the spectrum, asthma affects 7 to 10 percent of the elderly, accounting for 68,000 admissions to hospitals in 1991.² About one-half of cases of asthma develop before the age of 10 years and another one-third before the age of 40 years. The 2:1 male-to-female preponderance of asthma in childhood equalizes by age 30 years. Self-reported prevalence rates for asthma in the United States increased by 74 percent from 1980 to 1996.¹ Similar prevalence rates are reported in developed nations throughout the world. From 1980 to 1999, the estimated annual number of office visits for asthma in the United States increased by 83 percent, from 5.9 million to 10.4 million. Whereas the number of ED visits increased by 36 percent

SECTION 8 . PULMONARY EMERGENCIES

(from 1.5 million to 2 million) between 1992 and 1999, the number of hospitalizations and deaths seems to have declined since 1995.¹ In the United States alone, the estimated direct and indirect costs of asthma in all age groups was 6.2 billion dollars in 1990.³

PATHOPHYSIOLOGY

Asthma is characterized by inflammation of the airways, with an abnormal accumulation of eosinophils, lymphocytes, mast cells, macrophages, dendritic cells, and myofibroblasts. The pathophysiologic hallmark of asthma is a reduction in airway diameter caused by smooth muscle contraction, vascular congestion, bronchial wall edema, and thick secretions. These changes are reflected in pulmonary function changes, increased work of breathing, and abnormal distribution of pulmonary blood flow (Table 68-1). Large and small airways often contain plugs composed of mucus, serum proteins, inflammatory cells, and cellular debris. On a microscopic level, airways are infiltrated with eosinophils and mononuclear cells. Evidence of microvascular leakage, epithelial disruption, and vasodilation is frequently noted. The airway smooth muscle is hypertrophied and characterized by new vessel formation, an increased number of epithelial goblet cells, and deposition of interstitial collagen beneath the epithelium. Subepithelial fibrosis, an increase in the thickness of the reticular layer of the basement membrane, is characteristically increased in the large and small airways. Data collected from transbronchial biopsy, alveolar lavage, and specialized airway imaging techniques suggest that inflammation affects all bronchial pulmonary structures.

Current hypothesis states that airway inflammation may be acute, subacute, or chronic. The acute response is determined by early recruitment of cells to the airway. Antigens come in contact with mast cells in the submucosa and cause elaboration of mediators, such as histamine, leukotrienes (including leukotriene B₄), chemokines, tryptase, interleukin 5, interleukin 8, proinflammatory cytokines, and interleukin 4, that produce an intense inflammatory reaction, with bronchoconstriction, vascular congestion, edema formation, increased mucus production, and impaired mucociliary transport. Eosinophils, platelets, and polymorphonuclear leukocytes are recruited to the site, activated, and contribute further to the inflammatory cycle that has already been initiated. The IgE response is controlled by T and B lymphocytes and activated by the interaction of antigen with the mast cell-bound IgE molecules. In the subacute or late phase, recruited and resident cells are activated, causing a more persistent pattern of inflammation.

Chronic inflammation is characterized by persistent cell damage and an ongoing repair process, contributing to some of the microscopic changes seen in the airway. Mediators target ciliated airway epithelium to cause injury or disruption. As a consequence, epithelial cells and myofibroblasts, present beneath the epithelial layer, proliferate and begin to deposit interstitial collagen in the lamina reticularis of the basement membrane. Fibroblasts contribute to the process by releasing cytokines and chemokines, which may be important in initiating

and maintaining the level of airway inflammation and may explain the apparent basement membrane thickening and irreversible airway changes seen in some asthmatics. Clearly, the inflammatory process is multicellular, redundant, and self-amplifying.

Allergic asthma is frequently associated with a personal or family history of allergic diseases, such as rhinitis, urticaria, and eczema. Idiosyncratic, or nonallergic, asthma is associated with no family or personal history of allergy and normal serum levels of IgE. Many stimuli have been noted to provoke an increase in airway responsiveness. Viral respiratory infections are among the most common of the stimuli that invoke acute asthma exacerbation.⁴ Increased airway responsiveness secondary to infection may last anywhere from 2 to 8 weeks.⁴ Exercise is another common precipitant of acute asthma. Unlike other precipitants of acute exacerbation, long-term sequelae is not noted as a result of exercise. Environmental conditions, such as atmospheric pollutants and antigens noted in heavy industrial or densely populated urban areas, are associated with higher incidence and severity of asthma. In addition, indoor antigens, such as mold, house dust mites, cockroaches, and animal dander, are associated with acute asthma. Occupational exposures, such as metal salt, wood and vegetable dust, pharmaceutical, industrial chemical and plastic, biological enzyme, vapors, gases, and aerosols, also may stimulate an asthma attack. Multiple pharmaceutical agents, such as aspirin, (3-blockers (including topical β -blockers), nonsteroidal anti-inflammatory agents, sulfating agents, tartrazine dyes, and food additives and preservatives, have been implicated in acute asthma. As in exercise-induced asthma, exposure to cold air alone can induce acute bronchospasm. Recent evidence indicates that endocrine factors, such as changing levels of estradiols and progesterone during the normal menstrual cycle and pregnancy, may contribute to the level of airway reactivity.⁵ Emotional stress also can produce an asthma attack.

CLINICAL FEATURES

The symptoms of asthma consist of a triad of dyspnea, wheezing, and cough. Many patients will relay the history of asthma upon presentation, but some will not. Early in the attack, patients will complain of a sensation of chest constriction and cough. As the exacerbation progresses, wheezing becomes apparent, expiration becomes prolonged, and accessory muscle use may become evident. Key historical points should be obtained on asthmatics presenting with exacerbation to EDs (Table 68-2). Acute asthma exacerbation can be categorized based on clinical features (Table 68-3).

Physical examination findings are variable. Patients presenting with a severe asthma attack may be in obvious respiratory distress, with rapid breathing and loud wheezing, whereas patients with mild exacerbation may present with only cough and end-expiratory wheezing. At times, wheezing may be audible without a stethoscope. Other conditions may present with wheezing and mimic asthma (Table 68-4). The use of accessory muscles of inspiration indicates diaphragmatic fatigue, whereas the appearance of paradoxical respirations reflects impending ventilatory failure. Alteration in the mental status (e.g., lethargy, exhaustion, agitation, or confusion) also heralds respiratory arrest.

Directed physical examination reveals hyperresonance to percussion, decreased intensity of breath sounds, and prolongation of the expiratory phase, usually with wheezing. Although wheezing results from the movement of air through narrowed airways, the intensity of the wheeze may not correlate with the severity of airflow obstruction. The "silent chest" reflects very severe airflow obstruction, with air movement insufficient to promote a wheeze. A pulsus paradoxus above 20 mm Hg is also indicative of severe asthma. Although tachycardia and tachypnea are usually seen with acute asthma, vital signs normalize very quickly as airflow obstruction improves. Therefore, a normal heart rate, respiratory rate, and the absence of a pulsus paradoxus do not indicate complete relief of airway obstruction.

TABLE 68-1 Physiologic Consequences of Airflow Obstruction

Increased airway resistance
Decreased maximum expiratory flow rates
Air trapping
Increased airway pressure
Barotrauma
Adverse hemodynamic effects
Ventilation-perfusion imbalance
Hypoxemia
Hypercarbia
Increased work of breathing
Pulsus paradoxus
Respiratory muscle fatigue with ventilatory failure

TABLE 68-2 Key Historical Elements When Obtaining a History from Patients with Acute Asthma Exacerbation

Symptoms
Cough
Wheezing
Shortness of breath
Chest tightness
Sputum production
Fever
Pattern of symptoms
Perennial and/or seasonal
Continual or episodic
Onset
Duration
Frequency
Aggravating factors
History of disease
Age of onset and method of diagnosis
Course of disease
Present management and medications
History of oral corticosteroid use
Intensive care unit admissions
History of intubation for asthma exacerbation
Other medical diseases
Family history
Social history
Condition of home
Exposure to allergens
Smoking
Identification of participating causes
Exacerbation profile
Usual pattern of exacerbation and outcome
Best spirometry measures
Risk factors for death from asthma
Past history of sudden severe exacerbations
Prior intubation for asthma
Prior admission for asthma to an intensive care unit
Two or more hospitalizations for asthma in the past year
Three or more emergency care visits for asthma in the past year
Hospitalization or emergency care visit for asthma within the past month
Use of more than two canisters per month of inhaled short-acting (β_2 -agonist)
Current use of systemic corticosteroids or recent withdrawal from systemic corticosteroids
Difficulty perceiving airflow obstruction or its severity
Comorbidity, as from cardiovascular diseases or chronic obstructive pulmonary disease
Serious psychiatric illness or psychosocial problems
Low socioeconomic status in urban residents
Illicit drug use

DIAGNOSIS

Bedside spirometry provides a rapid, objective assessment of patients and serves as a guide to the effectiveness of therapy. The forced expiratory volume in 1 s (FEV₁) and the peak expiratory flow rate (PEFR) directly measure the degree of large airway obstruction. Patient cooperation is essential for these tests to be reliable. Sequential measurements help emergency physicians assess severity and determine response to therapy. Signs on physical examination and a patient's report of symptoms of asthma do not necessarily correlate well with the severity of airflow obstruction. When possible, management decisions should be based on a patient's personal best PEFR or FEV₁ or, if unknown, the percentage of predicted spirometric values in addition to other physiologic and historical factors.

Pulse oximetry is a useful and convenient method for assessing oxygenation and monitoring oxygen saturation during treatment. Determination of arterial blood gas is not indicated in most patients with mild to moderate asthma exacerbation. The main reason to determine arterial blood gas during an asthma attack is to assess for hypoventilation with carbon dioxide retention and respiratory acidosis. Such patients almost always have clinical evidence of severe attacks or spirometry demonstrating a PEFR or FEV₁ of less than 25 percent predicted.⁶ With acute attacks, ventilation is stimulated, resulting in a decrease in partial pressure of carbon dioxide (Paco₂). Therefore, a normal or slightly elevated Paco₂ (e.g., >42 mm Hg) indicates extreme airway obstruction and fatigue and may herald the onset of acute ventilatory failure.

Routine radiography is unnecessary but is indicated in patients with asthma exacerbation if there is clinical indication of a complication such as pneumothorax, pneumomediastinum, pneumonia, or other medical concern. For patients with asthma exacerbations requiring admission, up to one-third of patients will demonstrate an abnormality on chest radiograph.

A routine complete blood cell count is not indicated and likely will show modest leukocytosis secondary to administration of β -agonist therapy or corticosteroid treatment. In patients taking theophylline before ED presentation, a serum theophylline level should be determined. Routine electrocardiogram is also unnecessary but may reveal right ventricular strain, abnormal P waves, or nonspecific ST- and T-wave abnormalities, which resolve with treatment. Older patients, especially those with coexisting heart disease, should have cardiac monitoring during treatment. Asthma index scores have failed to predict outcome better than clinical judgment.

TREATMENT

The goal of treatment of acute asthma in the ED is to reverse airflow obstruction rapidly by repetitive or continuous administration of inhaled β_2 -agonists, ensure adequate oxygenation, and relieve inflammation. The National Asthma Education and Prevention Program (NAEPP) Expert Panel has developed guidelines for emergency treatment of asthma (Figure 68-1),⁷ as have other organizations around the world. The following categories of medications are used in the treatment of acute asthma: β -adrenergic agonists, anticholinergics, and glucocorticoids. Magnesium, heliox (mixture of helium and oxygen), and ketamine may be considered when the aforementioned medications fail to relieve bronchospasm. Mast cell-stabilizing agents, methylxanthines, and leukotriene modifiers are currently reserved for maintenance therapy only.

Adrenergic Agents

β -Adrenergic agonists are the preferred initial rescue medication for acute bronchospasm. β_3 -Adrenergic receptors are divided into two types, β_1 and β_2 . Stimulation of β_1 -receptors increases rate and force of cardiac contraction and decreases small intestine motility and tone, whereas β_2 -adrenergic stimulation promotes bronchodilation, vasodilation, uterine relaxation, and skeletal muscle tremor.

The mechanism of bronchodilator action of β -adrenergic drugs involves stimulation of the enzyme adenyl cyclase, which converts intracellular adenosine triphosphate into cyclic adenosine monophosphate. This action enhances the binding of intracellular calcium to cell membranes, reducing the myoplasmic calcium concentration, and results in relaxation of bronchial smooth muscle. In addition to bronchodilation, β -adrenergic drugs inhibit mediator release and promote mucociliary clearance.

The most common side effect of β -adrenergic drugs is skeletal muscle tremor. Patients also may experience nervousness, anxiety, insomnia, headache, hyperglycemia, palpitations, tachycardia, and hypertension. Despite earlier concerns over potential cardiotoxicity, especially when these drugs were used in combination with theophylline, clinical experience has not shown significant problems.

SECTION 8 . PULMONARY EMERGENCIES

TABLE 68-3 ; Severity of Asthma Exacerbations*
Classifying

	Mild	Moderate	Severe	Respiratory Arrest Imminent
Symptoms				
Breathlessness	While walking	While talking	While at rest	
Position	Can lie down	Prefers sitting	Sits upright	
Talks in	Sentences	Phrases	Words	
Alertness	May be agitated	Usually agitated	Usually agitated	Drowsy or confused
Signs				
Respiratory rate	Increased	Increased	Often >30/min	
Use of accessory muscles; suprasternal retractions	Usually not	Commonly	Usually	Paradoxical thoracoabdominal movement
Wheeze	Moderate, often only end expiratory	Loud; throughout exhalation	Usually loud; throughout inhalation and exhalation	Absent
Pulse per min	<100	100-120	>120	Bradycardia
Pulsus paradoxus	Absent < 10 mm Hg	May be present 10-25 mm Hg	Often present >25 mm Hg (adult) 20-40 mm Hg (child)	Absence suggests respiratory muscle fatigue
Functional assessment				
Peak expiratory flow % predicted or % personal best	80%	-50-80%	<50% or response lasts <2 h	
Pao ₂ (on air)	Normal (test not usually necessary)	>60 mm Hg (test not usually necessary)	<60 mm Hg: possible cyanosis	
Paco ₂	<42 mm Hg (test not usually necessary)	<42 mm Hg (test not usually necessary)	2-42 mm Hg: possible respiratory failure (see text)	
Sao ₂ % (on air) at sea level	>95%	91-95%	<91%	

*The presence of several parameters, but not necessarily all, indicates the general classification of the exacerbation. Many of these parameters have not been systematically studied, so they serve only as general guides. Hypercapnia (hypoventilation) develops more readily in young children than in adults and adolescents.

Abbreviations: Paco₂ = partial pressure of carbon dioxide, arterial; Pao₂ = partial pressure of oxygen, arterial; Sao₂ = arterial oxygen saturation. Source:

Publication No. 97-4051. Bethesda, MD, National Institutes of Health, 1997.

Arrhythmias and evidence of myocardial ischemia are rare, especially in patients without prior histories of coronary artery disease.

The (3-adrenergic agonists used today are analogues of naturally occurring sympathomimetics (Table 68-5). The ideal bronchodilator in this class of drugs would possess pure (3₂-receptor activity bronchodilation without cardiac effects. The older catecholamine bronchodilators, isoproterenol and epinephrine, are not (3₂ specific and have a short duration of action. Isoetharine is more (3₂ selective but still has a short duration of action. Newer agents produced by chemical modification of the parent compound have nearly replaced these drugs. The resorcinol bronchodilators (metaproterenol, terbutaline, and fenoterol) and saligenin bronchodilators (albuterol and carbutoleol) share greater (3₂ specificity and longer duration of action and effectiveness through the oral route due to resistance to intestinal sulfatases.

Aerosol therapy with (3₂-adrenergic drugs produces excellent bronchodilation and is favored over the oral and parenteral routes. The aerosol route achieves topical administration of a relatively small dose of drug, thereby producing local effects with minimum systemic absorption and fewer side effects. Aerosol delivery may be achieved with a metered dose inhaler (MDI) with a spacing device or a compressor-driven nebulizer. A spacing device attached to the inhaler can improve drug deposition when patient technique is inadequate. Even with opti-

mum technique, however, a maximum of 15 percent of the drug dose is retained in the lungs, regardless of the aerosol method used. Dry-powder delivery devices and MDIs using hydrofluoroalkane as the propellant have recently replaced devices run by chlorinated fluorocarbon.

Aerosol treatments may be administered every 15 to 20 min or on a continuous basis. Epinephrine or terbutaline may be administered SC to patients unable to coordinate aerosolized or MDI treatments. Intravenous (3-agonist infusions offer no advantage over aerosolized or MDI-delivered agents and carry potential risk.⁸

Salmeterol xinafoate is a p₂-adrenoreceptor agonist that binds with greater affinity to the (3₂-receptor site than does albuterol. *It is indicated for twice-daily maintenance therapy, should never be used more frequently, and is to be avoided for treatment of acute exacerbation.* Its bronchodilator effect lasts at least 12 h, and tachyphylaxis has not been reported with long-term use. It is an effective treatment for long-term control of asthma, especially nocturnal asthma. Short-acting (3₂-adrenoreceptor agonists are generally added for symptoms that occur despite the use of salmeterol.

Corticosteroids

Corticosteroids are highly effective drugs in asthma exacerbation and form one of the cornerstones of treatment. Although the mechanism of action is unknown, many believe that steroids produce beneficial effects by restoring (3-adrenergic responsiveness and reducing inflammation. The onset of anti-inflammatory effect is delayed at least 4 to 8 h after intravenous or oral administration.

Evidence suggests that corticosteroids administered within 1 h of arrival in the ED reduces the need for hospitalization.⁹ Although there is considerable disagreement over what constitutes the optimal dose in acute asthma, an initial dose of oral prednisone 40 to 60 mg, or an intravenous bolus of methylprednisolone 60 to 125 mg IV in patients unable to tolerate oral medications, is sufficient. High-dose corticosteroid

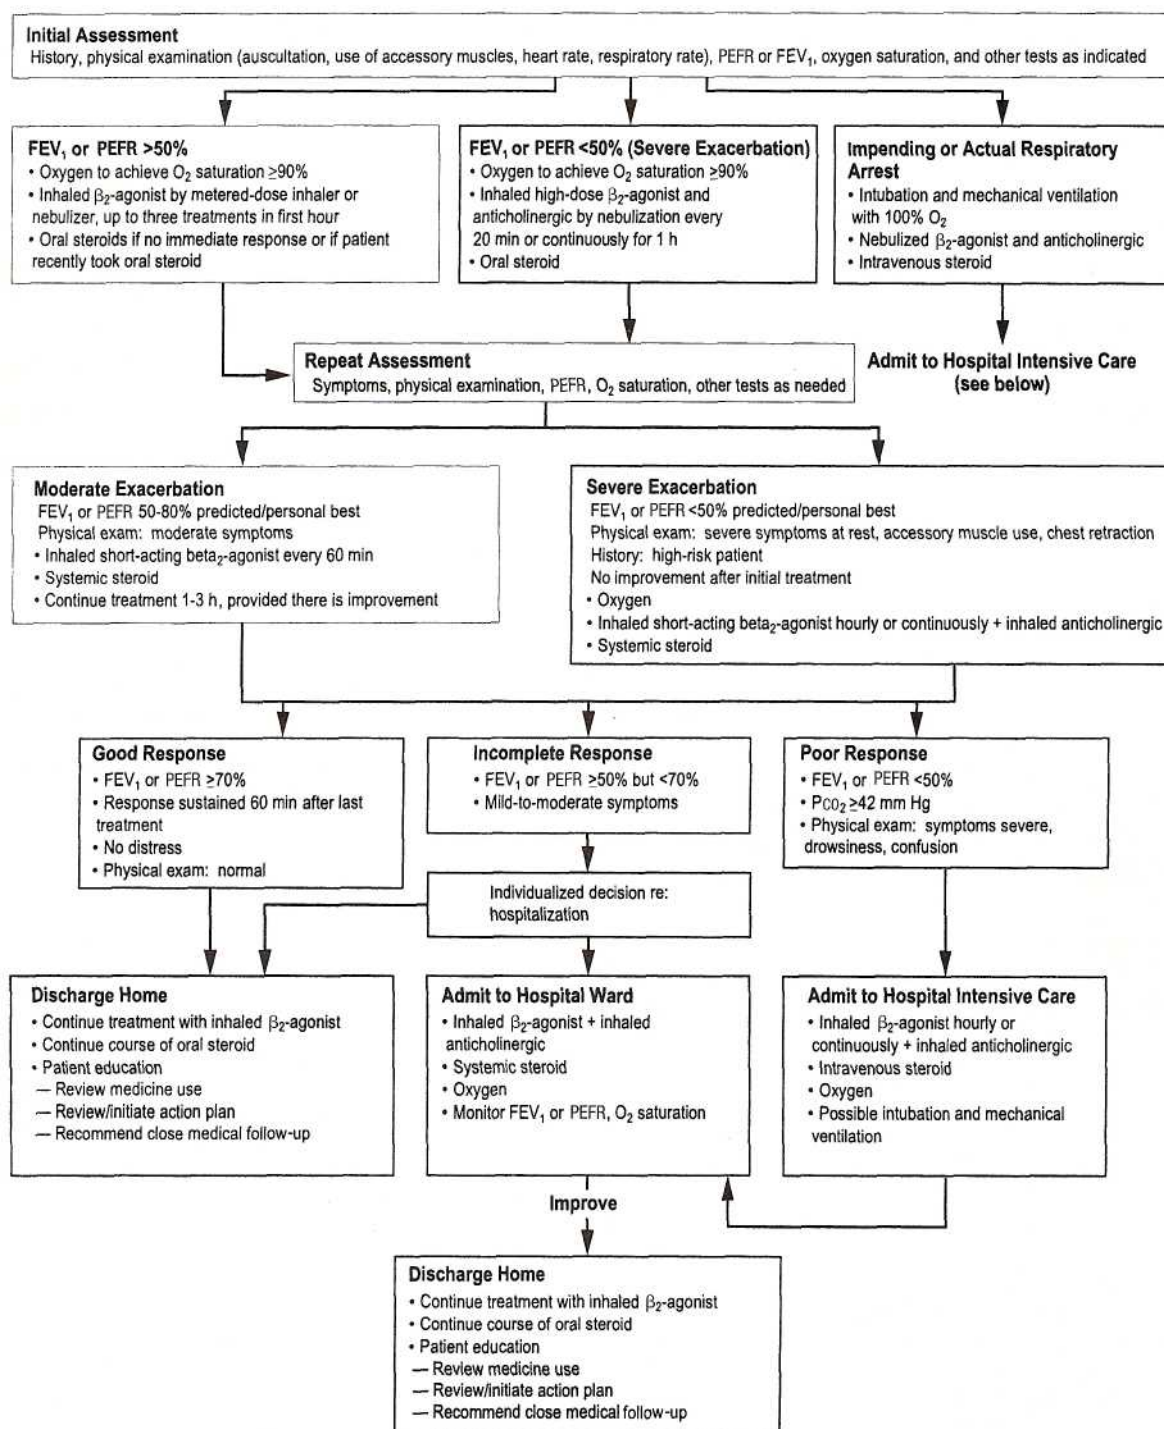

FIG. 68-1. Management of asthma exacerbations: emergency department and hospital-based care. (Adapted with permission from the National Asthma Education and Prevention Program, Expert Panel Report II: *Practical Guide for the Diagnosis and Management of Asthma*. Publication 97-4053. Bethesda, MD, National Institutes of Health, 1997.)

therapy offers no advantage.¹⁰ Additional doses should be given every 4 to 6 h until significant subjective and objective improvements are achieved. Patients who are being discharged home with an FEV_j or PEFR of less than 70 percent predicted after aggressive ED treatment should be prescribed a 3- to 10-day non-tapering burst of oral steroids, prednisone 40 to 60 mg per d, or its equivalent.¹¹

Current recommendations favor maintaining all patients with mild persistent asthma or more severe asthma with inhaled corticosteroids.¹² Therefore, consideration should be given to discharging all

patients with mild persistent or more severe asthma on maintenance inhaled corticosteroids in addition to a burst of oral corticosteroids.¹

Anticholinergics

Plants containing anticholinergic alkaloids have been smoked for hundreds, if not thousands, of years to treat respiratory disorders. In recent years, anticholinergics have been rediscovered as potent bronchodilators in patients with asthma and other forms of obstructive lung

TABLE 68-5 Dosages of Drugs for Asthma Exacerbations in Emergency Medical Care or Hospital

Medications	Adult Dosages	Comments
Inhaled short-acting β_2 agonists		
Albuterol		
Nebulizer solution (5 mg/mL)	2.5–5.0 mg every 20 min for 3 doses, then 2.5–10 mg every 1–4 h as needed or 10–15 mg per h continuously	Only selective β_2 agonists are recommended; for optimal delivery, dilute aerosols to minimum of 4 mL at gas flow of 6–8 L per min
MDI (90 μ g/puff)	4–8 puffs every 20 min up to 4 h, then every 1–4 h as needed	As effective as nebulized therapy if patient is able to coordinate inhalation maneuver; use spacer/holding chamber
Bitolterol		
Nebulizer solution (2 mg/mL)	See albuterol dose	Has not been studied in severe asthma exacerbations; do not mix with other drugs
MDI (370 μ g/puff)	See albuterol dose	Has not been studied in severe asthma exacerbations
Pirbuterol		
MDI (200 μ g/puff)	See albuterol dose	Has not been studied in severe asthma exacerbations
Systemic (injected), β_2 agonists		
Epinephrine (1:1000 or 1 mg/mL)	0.3–0.5 mg SC every 20 min for 3 doses	No proven advantage of systemic therapy over aerosol
Terbutaline (1 mg/mL)	0.25 mg SC every 20 min for 3 doses	No proven advantage of systemic therapy over aerosol
Anticholinergics		
Ipratropium bromide		
Nebulizer solution (0.2 mg/mL)	0.5 mg every 30 min for 3 doses, then every 2–4 h as needed	Should not be used as first-line therapy; should be added to β_2 agonist therapy; may mix in same nebulizer with albuterol
MDI (18 μ g/puff)	4–8 puffs every 6–8 h	Dose delivered from MDI is low and has not been studied in asthma exacerbations
Corticosteroids		
Prednisone	120–180 mg per d in 3 or 4 divided doses for 48 h, then 60–80 mg per d until FEV ₁ , or PEFR reaches 70% of predicted or personal best*	For outpatient “burst,” use 40–60 mg per d, for 3–10 d in adults
Methylprednisolone		
Prednisolone		

*Dosage for admitted patients.

Abbreviations: FEV₁ = forced expiratory volume in 1 sec; MDI = metered dose inhaler; PEFR = peak expiratory flow rate; SC = subcutaneous.

Source: Adapted from the National Asthma Education and Prevention Program, Expert Panel Report II: *Guidelines for the Diagnosis and Management of Asthma*. Publication 97-4051. Bethesda, MD, National Institutes of Health, 1997.

disease. Although comparisons of bronchodilator response between anticholinergics and p-adrenergic agonists have produced conflicting results, the effects of the drugs used in combination is additive. This effect is plausible, because anticholinergics affect large, central airways, whereas p-adrenergic drugs dilate smaller airways.

Anticholinergic drugs competitively antagonize acetylcholine at the postganglionic junction between the parasympathetic nerve terminal and effector cell. This process blocks the bronchoconstriction induced by vagal cholinergic-mediated innervation to the larger central airways. In addition, concentrations of cyclic guanosine monophosphate in airway smooth muscle are reduced, further promoting bronchodilation.

Because of significant systemic side effects, atropine sulfate, once the major nebulized anticholinergic used in the United States, has been virtually replaced by the synthetic quaternary derivative: ipratropium bromide. This drug causes far fewer systemic side effects and is very well tolerated. Ipratropium is currently available as a nebulized solution and an MDI (see Table 68-5).

Aerosolized ipratropium bromide 0.5 mg, should be administered to patients with severe exacerbation.⁷ Potential side effects with nebulized anticholinergics include dry mouth, thirst, and difficulty swallowing. Less commonly, tachycardia, restlessness, irritability, confusion, difficulty in micturition, ileus, blurring of vision, or an increase in intraocular pressure is noted.

Theophylline

Theophylline is no longer considered a first-line treatment for acute asthma.⁷ Studies have shown that theophylline, in combination with inhaled (β_2 -adrenergic drugs, appears to increase the toxicity, but not

the efficacy, of treatment.¹³ Theoretically, theophylline may be a useful adjunct by providing a more sustained bronchodilator effect, contributing to small airway bronchodilation, improving respiratory muscle endurance, and improving resistance to fatigue. Recent data suggest an anti-inflammatory mechanism of action.

The mechanism of action of theophylline remains unknown; 90 percent of theophylline metabolism is hepatic, and the remainder is excreted unchanged through the kidneys. A serum theophylline level should be determined for patients who regularly use theophylline. The most common side effects of theophylline are nervousness, nausea, vomiting, anorexia, and headache. At plasma levels greater than 30 (xg/mL, there is a risk of seizures and cardiac arrhythmias.

Magnesium

Intravenous magnesium sulfate is indicated in the management of acute, very severe asthma (i.e., FEV₁ <25 percent predicted), but its usefulness in mild and moderate exacerbation has not been established.¹⁴ Although the bronchodilating properties of magnesium sulfate can be helpful, it should not be substituted for standard therapy regimens. The dose is 1 to 2 g IV over 30 min.

Heliox, Ketamine, and Halothane

Although several studies have demonstrated that a mixture of 80 percent helium and 20 percent oxygen (heliox) can lower airway resistance and act as an adjunct in the treatment of very severe asthma exacerbation, other studies have failed to demonstrate these effects.^{15,16} Therefore, heliox currently is not indicated for use in mild or moderate bronchospasm.

Several investigators have reported success with ketamine and halothane in cases in which all other treatment modalities have failed. Controlled trials substantiating these claims are lacking.

Mast Cell Modifiers

Cromolyn and nedocromil exert their anti-inflammatory action by blockage of chlorine channels, thus modulating mast cell mediator release and eosinophil recruitment. These agents also inhibit early and late responses to allergen challenge and exercise. Neither is indicated for treatment of acute bronchospasm.

Leukotriene Modifiers

Leukotrienes are potent proinflammatory mediators that contract airway smooth muscle, increase microvascular permeability, stimulate mucus secretion, decrease mucociliary clearance, and recruit eosinophils into the airway. Several leukotriene modifiers, namely montelukast, zafirlukast, and zileuton, are currently available as oral tablets for the treatment of asthma. Leukotriene modifiers improve lung function, diminish symptoms, and diminish the need for short-acting (β_2 -agonists). They may be used as an alternative to low-dose inhaled corticosteroid therapy in mild persistent asthmatics and as steroid-sparing agents with inhaled corticosteroids in moderate persistent asthmatics.¹² Although one trial found that intravenous montelukast can cause rapid bronchodilation when used as adjuvant therapy for acute asthma,¹⁷ it would be premature to recommend its use in the treatment of acute bronchospasm. Currently, there is no indication for the use of any of the leukotriene modifiers in the ED.

Mechanical Ventilation

When, despite the emergency physician's best effort to treat an acute asthma exacerbation, the patient begins to exhibit signs of acute ventilatory failure, noninvasive positive-pressure ventilation may be attempted. However, if the patient manifests progressive hypercarbia and acidosis or becomes exhausted or confused, intubation and mechanical ventilation are necessary to prevent respiratory arrest. Mechanical ventilation does not relieve the airflow obstruction; it merely eliminates the work of breathing and enables the patient to rest while the airflow obstruction is resolved. Fortunately, fewer than 1 percent of asthmatics ever require mechanical ventilation. Direct oral intubation is preferred over the nasotracheal route.

The potential complications of mechanical ventilation in asthmatic patients are numerous. Increased airway resistance may lead to extremely high peak airway pressures, barotrauma, and hemodynamic impairment. Mucous plugging is frequent, often leading to increased airway resistance, atelectasis, and pulmonary infection. Due to the severity of airflow obstruction during the early phases of treatment, the tidal volume may be larger than the returned volume, leading to air trapping and increased residual volume (intrinsic positive end-expiratory pressure). These effects may be avoided in part by using rapid inspiratory flow rates at a reduced respiratory frequency (12 to 14 breaths/min) and allowing adequate time for the expiratory phase. One can achieve the goal of ventilatory support, that is, maintenance of adequate arterial oxygen saturation (>90 percent), without concern for "normalizing" the hypercarbic acidosis. This approach is called *controlled mechanical hypoventilation* or *permissive hypoventilation*. All patients requiring mechanical ventilation must be admitted to an intensive care unit.

SPECIFIC ISSUES THAT AFFECT DIAGNOSIS, EVALUATION, AND TREATMENT

Age

Although newly diagnosed asthma in older populations is not uncommon, differentiation of the etiology of wheezing in older asthmatics

may present a challenge. Historical data may help differentiate between congestive heart failure, pulmonary malignancy, and obstructive airway disease, but distinguishing between chronic obstructive pulmonary disease and acute asthma is often difficult.² Treatment of older asthmatics should proceed in the same manner as treatment of younger asthmatics. Age-related changes in pulmonary function must be considered when determining response to treatment in older asthmatics, and care should be taken to avoid medication interactions.

Gender

Men and women interpret changes in pulmonary function differently. Women express a sensation of dyspnea at higher percentage-predicted PEFR than do men.¹⁸ In addition, cyclic hormonal changes may influence pulmonary function in women.⁵

Pregnancy

Asthma complicates approximately 4 percent of pregnancies. Studies indicate that as many as 42 percent of pregnant asthmatics require hospitalization and that an additional 11 to 18 percent have one or more visits to the ED for exacerbation.⁵

In 1993, the NAEPP Expert Panel developed guidelines for the treatment of asthma exacerbation during pregnancy. The principles of managing acute asthma exacerbation are similar to those of managing exacerbation in a nonpregnant state. They consist of repetitive lung function measurements, maintenance of oxygen saturation at greater than 95 percent, administration of repetitive inhaled β_2 -agonist, and early administration of systemic corticosteroids, in addition to fetal monitoring. Early intervention during acute exacerbation is key to the prevention of impaired maternal and fetal oxygenation. Uncontrolled asthma is associated with a variety of maternal and fetal complications, including hyperemesis, hypertension, toxemia, vaginal hemorrhage, complicated labor, intrauterine growth restriction, preterm birth, increased perinatal mortality, and neonatal hypoxemia. Although no asthma medication labeled to date qualifies for Food and Drug Administration use-in-pregnancy category A rating (for which adequate well-controlled studies in pregnant women have failed to demonstrate risk to the fetus), problems as a result of routine treatment of asthma in the ED have not been reported.

Hyperventilation of pregnancy leads to a higher P_{aO_2} and a diminished P_{aCO_2} . Thus, a P_{aO_2} of less than 70 mm Hg in pregnant women with acute asthma represents fairly severe hypoxemia, and a P_{aCO_2} of greater than 35 mm Hg represents respiratory failure. During asthma exacerbation, the normal alkalosis of pregnancy is aggravated, leading to a decrease in placental blood flow. Hypoxemia is usually more severe in the fetus than in the mother.

β_2 -Agonists and inhaled corticosteroids are considered safe during pregnancy and are recommended as a routine part of asthma management. As in nonpregnant patients, a short burst of oral steroid (prednisone 40 to 60 mg per d) or its equivalent, and inhaled corticosteroids in patients with mild persistent or more severe asthma should be considered for pregnant asthmatics discharged from the ED after treatment for an exacerbation.

DISPOSITION

Disposition decisions should take into account a combination of subjective parameters, such as resolution of wheezing and improvement in air exchange, as assessed by auscultation and patient opinion, objective measures, such as normalization of FEV₁ or PEFR, and historical factors, such as compliance, history of ED use, and hospitalization. The ideal combination of elements needed for successful discharge without risk of early relapse has not yet been determined.¹⁹ Some degree of residual airflow obstruction, airway lability, and inflammation persists after treatment and discharge from the ED.

No single treatment program can be recommended for all patients discharged home from the ED after treatment of exacerbation.

TABLE 68-6 Hospital Discharge Checklist for Patients with Asthma Exacerbations

Intervention	Dose/Timing	Education/Advise	MD/RN Initials
Inhaled medications (metered dose inhaler + spacer/holding chamber) / β_2 -agonist Corticosteroids	Select agent, dose, and frequency (e.g., albuterol) 2-6 puffs q4h 2 puffs qid	Teach purpose Teach technique Emphasize need for spacer/holding chamber Check patient technique	
Oral medications	Select agent, dose, and frequency (e.g., prednisone 20 mg bid for 3-10 d)	Teach purpose Teach side effects	
Peak flow meter	Measure A.M. and P.M. PEFR and record best of three tries each time ^	Teach purpose Teach technique Distribute peak flow diary	
Follow-up visit	Make appointment for follow-up with primary clinician or asthma specialist	Advise patient (or caregiver) of date, time, and location of appointment within 7 d of hospital discharge	
Action plan	Before or at discharge	Instruct patient (or caregiver) on simple plan for actions to be taken when symptoms, signs, and peak expiratory flow values suggest recurrent airflow obstruction	

Abbreviation: PEFR = peak expiratory flow rate.

Source: Adapted from the National Asthma Education and Prevention Program, Expert Panel Report II: *Guidelines for the Diagnosis and Management of Asthma*. Publication 97-4051. Bethesda, MD, National Institutes of Health, 1997.

Although several studies have demonstrated that a short course of oral steroids and (β_2 -agonist bronchodilators reduce relapse rates among discharged patients, other studies have reported high relapse rates regardless of ED management and use of steroids.¹⁹ Patients with histories of previous ED visits and hospitalization are at highest risk of relapse, regardless of management.¹⁹

Current guidelines help to determine hospitalization and discharge criteria based on response to aggressive treatment. A good response to treatment is demonstrated by complete resolution of symptoms and a PEFR or FEV₁ of greater than 70 percent predicted. Such individuals can be safely discharged home. Patients with a poor response to treatment are defined as those with persistent symptoms and FEV₁ or PEFR of less than 50 percent predicted. Such patients are likely to have persistent wheezing and dyspnea at rest despite intensive treatment in the ED and should be admitted. An incomplete response to treatment, the middle ground, is defined as some persistence of symptoms and a PEFR or FEV₁ between 50 and 70 percent predicted. Most asthmatics treated in the ED fall into this category. They may be discharged home safely, provided they have no risk factors for death from asthma (see Table 68-2).⁷ Patients who fail to improve adequately over a period of several hours, because they are in the late phase of their exacerbation, and those with significant risk factors for death from asthma should be admitted to an observation unit or the hospital.⁷

The role of observation units in the care of acute asthma exacerbation is currently being determined. Although early studies indicated no reduction in hospitalization rates after treatment in ED observation units, more recent studies indicated that 59 percent of asthmatics admitted to observation units, where strict care protocols are followed, are successfully treated and discharged.²⁰

Follow-up care must be arranged after an acute exacerbation to ensure resolution and to review the long-term medication plan for the chronic management of asthma. High relapse rates, despite the routine use of steroids, strongly suggest the need for follow-up within days of the ED visit. Patients with asthma should have an appropriate written plan of action that addresses routine care and care of worsening symptoms.

Education of patients should become an integral part of ED care. The ED personnel should provide basic education on asthma and help link patients with primary care providers or asthma specialists while providing discharge instructions. Review of the patient's discharge medication, use of inhaler technique, and the use of peak flow moni-

toring are just some of the issues ED physicians can teach and emphasize (Table 68-6).

CHRONIC OBSTRUCTIVE PULMONARY DISEASE Rita K. Cydulka Mohak Dave

Management of patients with chronic obstructive pulmonary disease (COPD) can be challenging and frustrating. Although many advances in the treatment of other disease entities have emerged over the past several decades, research and progress in the treatment of COPD remain limited. Recent efforts to improve public awareness and research in COPD worldwide have resulted in the recent release of at least five sets of guidelines directed at the evaluation and treatment of COPD.¹⁻⁶ According to the U.S. National Heart, Lung, and Blood Institute and the World Health Organization's Global Initiative for Chronic Obstructive Lung Disease (GOLD), COPD is characterized by airflow limitation that is not fully reversible. The airflow obstruction is generally progressive and associated with an abnormal inflammatory response to noxious particles or gases.⁵ A diagnosis of COPD should be considered in any patient who complains of chronic cough, sputum production or dyspnea, and/or exposure to risk factors for the disease. The diagnosis may be confirmed with spirometric evaluation: a post-bronchodilator forced expiratory volume in 1 s (FEV₁) of less than 80 percent predicted in combination with a ratio of FEV₁ to forced vital capacity of less than 70 percent.⁵ About 85 percent of patients with COPD suffer from chronic bronchitis, and 15 percent suffer primarily from emphysema.⁶ Chronic bronchitis is defined as the presence of chronic productive cough for 3 months in each of 2 successive years in a patient in whom other causes of chronic cough have been excluded. Emphysema is defined as abnormal, permanent enlargement of the airspaces distal to the terminal bronchioles, accompanied by destruction of their walls and without obvious fibrosis. Chronic bronchitis is defined in clinical terms, and emphysema is defined in terms of anatomic pathology. In contrast, the GOLD definition does not distinguish between chronic bronchitis and emphysema.⁵

EPIDEMIOLOGY

Chronic obstructive pulmonary disease is a major worldwide respiratory health problem. It is the sixth leading cause of death in the world, the fourth most common cause of death in the United States, the third most common cause of hospitalization, and the only leading cause of death that is increasing in prevalence.

In North America, COPD is rare in persons younger than 40 years but very common among older individuals, with a prevalence of approximately 10 percent in those 55 to 85 years of age. The disease is more common in men than in women, but the prevalence of COPD in

women has doubled in the past few decades, a reflection of increased smoking behavior of women and increased recognition of COPD in women as a diagnostic possibility by physicians. The prevalence of COPD is highest in those countries that have the greatest cigarette use.

The mortality of patients while hospitalized for a COPD exacerbation is approximately 5 to 14 percent.⁷ Mortality of COPD patients admitted to an intensive care unit for exacerbation is 24 percent. For patients 65 years or older and discharged from the intensive care unit after treatment of a COPD exacerbation, the 1-year mortality is 59 percent, nearly double the expected 30 percent.

Chronic obstructive pulmonary disease is an expensive public health problem in terms of direct economic costs (such as hospital admissions and outpatient treatments), indirect economic costs (such as lost years of life, disability, and loss of working capacity), and reduction in quality of life. Estimations on the annual cost of COPD in the United States reached more than 30 billion dollars in 1995. The use of health care resources by elderly patients with COPD is immense during hospitalization and after discharge.⁸

PATHOPHYSIOLOGY

Cigarette smoking accounts for an estimated 80 to 90 percent of the risk of developing COPD. Age of starting, total pack-years, and current smoking status are predictive of COPD mortality.³ Of note, only 15 percent of smokers develop clinically significant COPD. A variety of other environmental risk factors, such as respiratory infections, occupational exposures, ambient air pollution, passive smoke exposure, and diet, have been suggested as other risk factors. The only proven genetic risk factor is α_1 -antitrypsin deficiency, although this accounts for fewer than 1 percent of COPD patients.

The earliest objective changes in the evolution of COPD are clinically imperceptible and are measured as small increases in peripheral airway resistance or lung compliance. The slow, insidious appearance of dyspnea and hypersecretion often requires several decades of disease. The recently released GOLD guideline stages COPD by severity. The use of this staging system may prove helpful in diagnosing and treating COPD earlier (Table 69-1).

The sedentary habits of many cigarette smokers result in failure to unmask exertional dyspnea, and denial results in suppression of symptoms or attribution of such symptoms to aging, poor conditioning, obesity, or allergies. Further, the respiratory consequences of cigarette smoking are a continuum of slowly evolving and latent effects, unique to each individual, in a complex dose-response relationship. Early in disease evolution, abstinence from smoking may eliminate symptoms and result in physiologic improvement. Once well established, however, abnormalities persist and may progress despite abstinence.

Pathologic specimens from patients with early disease demonstrate minor metaplasia of bronchial epithelium and an increase in bronchial gland number and size. As disease evolves, such findings are exaggerated, acute and chronic inflammatory changes in the epithelium are more notable, and acinar expansion, destruction, and coalescence are seen. Elements of emphysematous disease are invariably present in concert with those of bronchitic disease, although one often predominates.

Despite recognition of causative factors, what determines the clinical onset and rate of progression of chronic airflow obstruction and the direction toward emphysematous or bronchitic patterns are uncertain. Clearly, there is a great deal of variability in disease pattern and severity among individuals with a seemingly similar predisposition to disease.

The central element in the pathophysiology of chronic airflow obstruction is impedance to airflow, especially expiratory airflow, due to increased resistance or decreased caliber throughout the small bronchi and bronchioles. The majority of airway inflammation and obstruction occurs in bronchioles and lung parenchyma. Airflow obstruction results from a combination of airway secretions, mucosal edema, bronchospasm, and bronchoconstriction from impaired elasticity. Impedance to airflow alone accounts substantially for the abnormal physiology of the disease.

TABLE 69-1 Classification of Chronic Obstructive Pulmonary Disease by Severity

Stage	Characteristics
0. At risk	Normal spirometry Chronic symptoms (cough, sputum production)
I. Mild COPD	FEV ₁ /FVC <70% FEV ₁ ≥80% predicted With or without chronic symptoms (cough, sputum production)
II. Moderate COPD	FEV ₁ /FVC <70% 30% ≥FEV ₁ <80% predicted
IIA	50% ≤FEV ₁ <80% predicted
IIB	30% ≤FEV ₁ <50% predicted With or without chronic symptoms (cough, sputum production)
III. Severe COPD	FEV ₁ /FVC <70% FEV ₁ <30% predicted or <50% predicted plus respiratory failure or clinical signs of right heart failure

Abbreviations: COPD = chronic obstructive pulmonary disease; FEV₁ = forced expiratory volume in 1 s; FVC = forced vital capacity; respiratory failure = arterial partial pressure of oxygen <60 mm Hg (8.0 kPa) with or without arterial partial pressure of carbon dioxide >50 mm Hg (6.7 kPa) while breathing air at sea level.

Source: Adapted from Pauwels RA, Buist AS, Calverley PM, et al: Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease. NHLBI/WHO Global Initiative for Chronic Obstructive Lung Disease (GOLD) Workshop summary. *Am J Respir Crit Care Med* 163:1256,2001.

Exaggerated airway resistance reduces total minute ventilation or increases respiratory work. To the degree that alveolar hypoventilation occurs, hypoxemia and hypercarbia result. Even without hypoventilation, hypoxemia occurs due to ventilation-perfusion mismatching.

In addition to obstruction of peripheral airways, all forms of advanced chronic airflow obstruction involve other pathophysiologic elements to complete the overall picture. For example, in dominantly emphysematous disease, destruction and coalescence of alveolar architecture reduce the total "matched" alveolar and capillary surface areas for diffusion of gas, and vascular destruction results in "unmatched" regions where ventilation is wasted. In addition, neurochemical and proprioceptive ventilatory responses in chronic airflow obstruction may be aberrant. For example, ventilatory response to hypercarbia may be blunted during sleep, and ventilatory drive and dyspnea may be exaggerated despite normal pulmonary inflation. The composition of muscle fiber types, breathing patterns, and resistance to fatigue of respiratory muscles are also altered in advanced disease. Moreover, pulmonary arterial hypertension supervenes as chronic airflow obstruction progresses. The right ventricle transiently hypertrophies and then dilates with the evolution of overt cor pulmonale. A low-output state in the pulmonary circulation translates into low left ventricular output. Arterial hypoxemia increases as the effects of right-to-left shunt on poorly oxygenated mixed venous blood are exaggerated. Right ventricular pressure overload is associated with atrial and ventricular arrhythmias.

Although COPD is increasingly becoming recognized as a chronic inflammatory disease, there is no mention in the current guidelines of lower airway inflammation in the definition of COPD.¹¹⁶

CLINICAL FEATURES

Chronic, Compensated COPD

Despite the pathophysiologic segregation of chronic airflow obstruction into categories of pulmonary emphysema, chronic bronchitis, and bronchiectasis, none of these exist as a pure entity in clinical medicine.

Most patients demonstrate a mixture of symptoms and signs. The hallmark symptoms are exertional dyspnea and cough. Chronic, productive cough is common, and minor hemoptysis is frequent, especially in chronic bronchitis and bronchiectasis.

Physical findings include tachypnea, accessory respiratory muscle use, and pursed-lip exhalation. Airflow obstruction causes wheezing during exhalation, especially during maximum forced exhalation, and prolongation of the expiratory time. In dominantly bronchitic disease, coarse crackles are heard as uncleared secretions move about the central airways. In dominantly emphysematous disease, there is expansion of the thorax, impeded diaphragmatic motion, and global diminution of breath sounds. Weight loss is frequent due to poor dietary intake and excessive caloric expenditure for the work of breathing. Plethora due to secondary polycythemia and cyanosis and tremor, somnolence, and confusion due to hypercarbia may be seen in advanced disease. Findings of secondary pulmonary hypertension with or without cor pulmonale may be present. The physical signs of ventricular dysfunction are often disguised or underestimated by the seemingly more overwhelming signs of respiratory disease, or because pulmonary hyperinflation prohibits adequate auscultation.

Acute Exacerbations of COPD

Decompensation is usually due to worsening of airflow obstruction resulting from superimposed respiratory infection, increased bronchospasm, or other respiratory pathology, such as pulmonary embolism, interference with respiratory drive, cardiovascular deterioration, smoking, noncompliance with medications, noxious environmental exposures, use of medications that prevent bronchorrhea, and adverse responses to medication. Disordered ventilatory drive may arise from misuse of oxygen therapy, hypnotics, or tranquilizers. Metabolic disturbances and inadequate oxygen delivery independent of respiratory function may cause decompensated COPD.

Exacerbations of COPD frequently result in progressive hypoxemia. Signs of hypoxemia include tachypnea, tachycardia, systemic hypertension, cyanosis, and a change in mental status. The most life-threatening feature of decompensation is hypoxemia, where arterial saturation falls below 90 percent. With increased work of breathing, muscle production of carbon dioxide increases, and alveolar ventilation is often unable to increase to prevent carbon dioxide retention and respiratory acidosis. Signs of hypercapnia include mental status changes and hypopnea.

Upon presentation to the ED, patients usually complain of dyspnea and orthopnea. The intensified effort to ventilate is further dramatized by the sitting-up-and-forward position, pursed-lip exhalation, accessory muscle use, and diaphoresis. Pulsus paradoxus may be noted during blood pressure recording. Complications such as pneumonia, pneumothorax, pulmonary embolism, or an acute abdomen may be neglected or minimized by the patient's generalized respiratory distress, tachypnea, or global diminution of breath sounds. The physician should maintain a broad differential diagnosis for other disease entities that may be present with similar symptoms of dyspnea, such as asthma, congestive heart failure, pneumonia, pulmonary embolism, tuberculosis, and metabolic disturbances.

DIAGNOSIS

Chronic, Compensated COPD

The most valuable tool in characterizing disease severity is pulmonary function testing. In addition, examination of lung mechanics, analysis of arterial blood gases, description of ventilatory response patterns, tests of respiratory muscle performance, metabolic assessment, and noninvasive survey of hemodynamic reserve can be performed. The ratio of FEV₁ to forced vital capacity should be used to diagnose mild COPD. However, once the disease progresses, the percentage of predicted FEV₁ is a better measure of disease severity.¹¹⁶ Various guide-

lines characterize COPD severity as mild, moderate, or severe, although agreement on precise FEV_i standards remains arbitrary.¹⁻⁶

In the early stages of COPD, arterial blood gas measurements reveal mild-to-moderate hypoxemia without evidence of hypercapnia. As the disease progresses in severity (especially when the FEV_i falls below 1 L), hypoxemia becomes more severe and the development of hypercapnia becomes more evident. Arterial blood gas measurements worsen during acute exacerbations and may worsen during exercise and sleep.

Radiographic examination is often misleading; mild chronic airflow obstruction is not likely to be radiographically apparent. Dominantly bronchitic disease may be associated with subtle or absent x-ray findings. In contrast, dominantly emphysematous disease may be associated with remarkable signs of hyperaeration, such as increased anteroposterior diameter, flattened diaphragms, increased parenchymal lucency, and attenuation of pulmonary arterial vascular shadows, despite only mild-to-moderate physiologic alterations. Right or left ventricular enlargement may not produce relative enlargement of the cardiac silhouette. Certainly, radiography is of unquestionable value in diagnosing complications such as pneumothorax, pneumonia, pleural effusion, and pulmonary neoplasia.

Diagnosing heart failure and assessing ventricular function in patients with COPD is difficult, although the use of B-natriuretic peptide may aid in this differentiation.⁹ Echocardiography or gated nuclear scans to estimate ejection fractions may also be helpful. Electrocardiograms are useful to identify arrhythmias or ischemic injury but do not accurately assess the severity of pulmonary hypertension or right ventricular dysfunction.

Acute Exacerbations of COPD

Assessment of the patient with COPD exacerbation includes a thorough medical history and a thorough history of the patient's recent COPD history, assessment of oxygenation, physical examination, bedside pulmonary function tests (if possible), assessment of sputum, and chest radiography.

Assessing oxygenation is essential. Although pulse oximetry may identify hypoxemia, it cannot identify hypercapnia or acid-base disturbances. Further, unlike asthma, a correlation between FEV_i and oxygenation does not exist. Therefore, the spirometric criteria that have been used to eliminate the need for arterial blood gases in asthmatic patients cannot be safely applied to patients with COPD.¹⁰ A partial pressure of oxygen, arterial (Pao₂) of less than 60 mm Hg or an arterial oxygen saturation (Sao₂) of less than 90 percent in room air indicates respiratory failure. In addition, a patient who is hypercapnic or who has a pH of less than 7.30 likely is experiencing a life-threatening episode of ventilatory failure and needs intensive management in the emergency department and in the intensive care unit.

Beside pulmonary function tests can provide a rapid, objective assessment of patients and serve as a guide to the effectiveness of therapy; however, patient cooperation is essential for these tests to be reliable. Frequently, patients with COPD exacerbation are too dyspneic to cooperate with these tests. As a result, some guidelines do not recommend using these measurements during acute exacerbation.^{3,6} If the patient is able to cooperate, a peak expiratory flow rate (PEFR) of less than 100 L per min or an FEV_i of less than 1.00 L in a patient without chronic severe obstruction indicates a severe exacerbation. Sequential measurements can be very helpful in determining response to therapy. Signs on physical examination and physician estimates of pulmonary function are highly inaccurate.¹¹ Measurement of FEV_i is preferred to PEFR, because FEV_i allows comparison with baseline studies and published guidelines.

Assessment of sputum includes questions about changes in volume and color, especially an increase in purulence. An increase in sputum volume and color changes suggest a bacterial etiology for the exacerbation and indicate a need for antibiotic therapy.¹² Recommendations for obtaining sputum cultures vary among various guidelines.¹⁻⁶

Radiographic abnormalities are common in COPD exacerbation and may elucidate the underlying etiology of the exacerbation, such as pneumonia, or may identify an alternative diagnosis, such as congestive heart failure. Therefore, radiographs should be strongly considered when evaluating a patient with COPD exacerbation.¹³

Electrocardiograms may reveal concurrent disease processes, such as ischemia or acute myocardial infarction, signs of cor pulmonale, and arrhythmias, such as multifocal atrial tachycardia. Theophylline levels should be measured in patients who take theophylline. Other tests, such as complete blood cell counts, electrolytes, B-natriuretic peptide, spiral computed tomography, and D-dimers should be obtained based on the clinical picture.

TREATMENT

Chronic, Compensated COPD

The appropriate and optimal management of decompensated chronic airflow obstruction in an emergency department setting requires an appreciation of chronic day-to-day therapy. Specific management limits further insults to the respiratory system, treats reversible bronchospasm, and prevents or treats complications.

HEALTHY LIFESTYLE Elements include regular exercise, weight control, and smoking cessation. Smoking cessation is the only therapeutic intervention that can reduce the accelerated decline in lung function.¹⁴ Smoking cessation (and long-term oxygen therapy) has been shown to reduce COPD mortality.^{15,16} Pulmonary rehabilitation can improve exercise capacity and quality of life and is recommended in those patients with moderate to severe COPD. Although **there** is some controversy regarding the pneumococcal vaccine in COPD patients, it is currently recommended by the American Thoracic Society.²

OXYGEN The primary goal of long-term oxygen therapy (LTOT) is to increase baseline Pao₂ to at least 60 mm Hg or an Sao₂ of at least 90 percent at rest. The use of long-term oxygen therapy in patients with chronic respiratory failure has been demonstrated to reduce COPD mortality. Long-term oxygen therapy should be started in patients in whom arterial blood gases demonstrate a Pao₂ of 55 mm Hg or less, an Sao₂ below 88 percent, or a Pao₂ between 56 and 59 mm Hg when signs of pulmonary hypertension, cor pulmonale, or polycythemia are present.⁵ Home oxygen therapy accounts for approximately 30 percent of all COPD-related costs in the United States.

PHARMACOTHERAPY Although there is no evidence that pharmacotherapy alters the progression of COPD, it is used to provide symptomatic relief, control exacerbations, improve quality of life, and improve exercise performance. Inhaled bronchodilators are used on an as-needed basis for mild to moderately obstructed patients with intermittent symptoms or on a regular basis to prevent or decrease symptoms, although they probably only chronically improve FEV_i by 10 percent in COPD.

(β_2 -Agonists relax smooth muscle by stimulating β_2 -adrenergic receptors. The use of long-acting inhaled (β_2 -agonists, such as salmeterol and formoterol, may improve overall symptoms and health status. The use of short-acting [β_2 -agonists also improve exercise capacity but may be less convenient to use.

Anticholinergic agents facilitate bronchodilation by blocking the effect of acetylcholine on muscarinic-3 receptors. In those patients with persistent symptoms, who are refractory to (β_2 -adrenergic agents, or who are bothered by side effects, ipratropium bromide is the drug of choice. The regular use of inhaled ipratropium also has been shown to improve health status.

Consideration should be given to combining [β_2 -agonists with ipratropium, because the combination may improve bronchodilation more than

either drug alone.¹⁴ With increasing symptoms, even after optimization of the above two classes of bronchodilators, theophylline may be helpful.

Evidence is currently lacking to recommend the use of long-term systemic corticosteroid therapy for all patients with COPD.¹⁴ Only about 20 to 30 percent of patients with COPD improve when given chronic oral steroids. Initiating corticosteroid therapy requires careful analysis so as not to subject a nonresponder to the side effects unnecessarily.

Data from large trials studying the effects of inhaled corticosteroids in COPD showed that regular treatment with inhaled corticosteroids is indicated only for patients with a documented spirometric response to inhaled corticosteroids, those with an FEV₁ of less than 50 percent, or those with predicted and recurrent exacerbations requiring antibiotic treatment or systemic corticosteroids.⁵

Although some studies support the use of theophylline in stable COPD patients, most current COPD guidelines consider it an adjunct therapy.¹⁶

MOBILIZATION OF SECRETIONS Assurance of generous oral fluid intake and atmospheric humidification, avoidance of antihistamine and decongestant agents, and limitation of antitussive use help mobilize respiratory secretions. The efficacy of specific expectorant products is dubious.

Acute Exacerbations of COPD

The goals of emergency therapy in exacerbation of COPD are to correct tissue oxygenation, alleviate reversible bronchospasm, and treat the underlying etiology of the exacerbation (Table 69-2). Factors that influence therapy in the ED include (1) the patient's mental status; (2) degree of reversible bronchospasm; (3) recent medication usage and evidence of potential toxicity; (4) prior history of exacerbation courses, hospitalization, and intubation; (5) the presence of contraindications to any drug or class of drugs; and (6) specific causes or complications related to the exacerbation.

OXYGEN The first goal in the treatment of COPD is to correct or prevent life-threatening hypoxemia, aiming for a Pao₂ greater than 60 mm Hg or an Sao₂ greater than 90 percent. This can be accomplished in the ED with any of the following devices: standard dual-prong nasal cannula, simple face mask, Venturi mask, and non-rebreathing mask with reservoir and one-way valve. The need to increase Pao₂ must be balanced against the possibility of producing hypercapnia, so monitoring of oxygenation and CO₂ levels with arterial blood gases is imperative. Improvement after administration of supplemental oxygen may take 20 to 30 min to achieve a steady state. If adequate oxygenation is not achieved or respiratory acidosis ensues, assisted ventilation may be required.

(3₂-ADRENERGIC AGONISTS (VAgonists and anticholinergic agents are first-line therapies in the management of acute, severe COPD recommended by most guidelines.¹⁶ Aerosolized forms, via nebulizer or metered dose inhalers, are preferred because they minimize systemic toxicity, although limited data exist regarding the optimal dose and frequency of administration. According to American Thoracic Society guidelines, (3₂-agonist agents may be administered every 30 to 60 min, if tolerated.² Nebulized aerosols administered every 20 min may result in more rapid improvement of FEV₁, but the incidence of side effects is greater.¹⁶ Side effects of (3₂-agonists include tremor, anxiety, and palpitations. p₂-Agonists should be accompanied by heart monitoring in patients known to have or are suspected of having coexisting heart disease.

ANTICHOLINERGICS Anticholinergic agents, such as ipratropium and glycopyrrolate, produce similar short-term improvements in airflow obstruction measured by FEV₁ and PEFR, as do (3₂-agonists.³⁻⁶ Whereas some guidelines favor (3₂-agonists as a first-line therapy, oth-

TABLE 69-2 Summary for Emergency Department Management of Exacerbations in Chronic Obstructive Pulmonary Disease

Assess severity of symptom
Administer controlled oxygen therapy
Perform arterial blood gas measurement after 20-30 min if Sao ₂ remains <90% or if concerned about symptomatic hypercapnia
Administer bronchodilators
p ₂ -agonists and/or anticholinergic agents by nebulization or MDI with spacer
Consider adding intravenous methylxanthine, if needed
Add corticosteroids
Oral or intravenous
Consider antibiotics
If increased sputum volume, change in sputum color, fever, or suspicion of infectious etiology of exacerbation
Consider noninvasive mechanical ventilation
Laboratory evaluation
Chest x-ray
CBC with differential
Electrolytes
Arterial blood gases
ECG as needed At all times
Monitor fluid balance
Consider subcutaneous heparin (venous thrombosis prophylaxis)
Identify and treat associated conditions (e.g., heart failure, arrhythmias)
Closely monitor condition of the patient

Abbreviations: CBC = complete blood cell count; ECG = electrocardiogram; MDI = metered dose inhaler; Sao₂ = arterial oxygen saturation. *Source:* Adapted from Pauwels RA, Buist AS, Calverley PM, et al: Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease. NHLBI/WHO Global Initiative for Chronic Obstructive Lung Disease (GOLD) Workshop summary. *Am J Respir Crit Care Med* 163:1256, 2001.

ers favor anticholinergic agents. Ipratropium bromide given by metered dose inhaler with a spacer or as an inhalant solution by nebulization (0.5 mg or 2.5 mL of the 0.02% inhalant solution) is the usual agent of choice, although aerosolized glycopyrrolate 2 mg in 10 mL of saline, has been shown to be effective. The timing of repeat doses of anticholinergic agents has not been well studied. Side effects are minimal and appear to be limited to dry mouth and an occasional metallic taste.

Evidence regarding the efficacy of the combination of a 3₂-adrenergic agent and an anticholinergic agent compared with a single agent alone is conflicting, although many physicians favor using this combination initially and some favor using it if the response to maximal doses of a single bronchodilator is poor.

CORTICOSTEROIDS The use of a short course (7 to 14 days) of systemic steroids appears more effective than placebo in improving FEV₁ iⁿ acute severe exacerbations of COPD, although their role in mild-to-moderate exacerbations needs to be delineated further.^{17,18} If used, the optimal effective dose ranges from one to three times the maximal physiologic adrenal secretion rate (i.e., the equivalent of prednisone, 60 to 180 mg per d). Hyperglycemia is the most common adverse effect.

ANTIBIOTICS All current guidelines recommend antibiotics for the treatment of COPD exacerbation if there is evidence of infection, such as change in volume of sputum and increased purulence of sputum. Saint's meta-analysis demonstrated a small, but statistically significant, benefit for antibiotics in terms of resolution of obstruction and symptoms.¹² The benefits are more apparent in more severe exacerbations.⁶ Antibiotic choices should be directed at the most common pathogens known to be associated with COPD exacerbation, namely

Streptococcus pneumoniae, *Haemophilus influenzae*, and *Moraxella catarrhalis*. There is little evidence regarding the duration of treatment; 3 to 14 days is typical in these studies.

METHYLYXANTHINES The role of methylxanthines, such as theophylline and aminophylline, in the treatment of COPD exacerbation remains controversial. Current evidence does not support the routine use of methylxanthines for COPD exacerbations, although most guidelines suggest their use in certain situations, such as severe exacerbation when other therapy has failed or in patients already using methylxanthines who have subtherapeutic drug levels.³ⁿ⁵ The bronchodilation effect of aminophylline is limited, and its therapeutic range is narrow.

The intravenous loading dose usually required to obtain an initial serum concentration of 8 to 12 (xg/mL is 5 to 6 mg/kg ideal body weight in patients not currently receiving the drug. In patients who regularly use theophylline, a mini-loading dose should be administered: (target concentration—currently assayed concentration) X volume of distribution (i.e., 0.5 times ideal body weight in liters). With the mini-load method, the target concentration should be between 10 and 15 |xg/mL. The intravenous maintenance infusion rate is 0.2 to 0.8 mg/kg ideal body weight per h. It is important to lower maintenance rates when treating patients with lower clearance rates due to congestive heart failure or hepatic insufficiency and raise maintenance rates in patients with higher clearance rates, such as smokers.

Maintenance theophylline infusion in patients on chronic oral therapy is complicated, because it is difficult to account for enteric drug yet to be absorbed. Loading and maintenance doses may need to be reduced to minimize the risk of "summation toxicity" due to continued enteric absorption. Standard-release preparations may continue to be absorbed for up to 6 h, and sustained-release preparations may require up to 12 h. Therefore, maintenance infusion rates should be reduced for 6 h after ingestion of a standard-release formulation and 12 h after ingestion of a sustained-release preparation (including 24-h release forms). Theophylline and aminophylline should not be given orally in an emergency setting unless decompensation is not severe, alimentary motility is assured, and forthcoming ambulatory care is imminent.

ASSISTED VENTILATION Mechanical ventilation is indicated in patients with COPD exacerbation if there is evidence of respiratory muscle fatigue, worsening respiratory acidosis, deteriorating mental status, and in those with clinically significant hypoxemia refractory to supplemental oxygen by usual techniques (Table 69-3). The main goals of assisted ventilation are to rest ventilatory muscles and to restore gas exchange to a stable baseline.

TABLE 69-3 Indications for Invasive Mechanical Ventilation

Severe dyspnea with use of accessory muscles and paradoxical abdominal motion
Respiratory frequency >35 breaths per min Life-threatening hypoxemia: $Pao_2 < 50$ mm Hg (<5.3 kPa) or $Pao_2/Fio_2 < 200$ mm Hg Severe acidosis (pH <7.25) and hypercapnia ($Paco_2 > 60$ mm Hg or >8.0 kPa) Respiratory arrest
Somnolence, impaired mental status
Cardiovascular complications (hypotension, shock, heart failure)
NIPPV failure

Abbreviations: Fio_2 = fraction of inspired oxygen; NIPPV = noninvasive positive pressure ventilation; $Paco_2$ = partial pressure of carbon dioxide, arterial; Pao_2 = partial pressure of oxygen, arterial.

Source: Adapted from Pauwels RA, Buist AS, Calverley PM, et al: Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease. NHLBI/WHO Global Initiative for Chronic Obstructive Lung Disease (GOLD) Workshop summary. *Am J Respir Crit Care Med* 163:1256,2001.

Noninvasive positive pressure ventilation (NIPPV) can be delivered via a nasal mask, full face mask, or mouthpiece. No particular mode of ventilation or ventilatory device has been shown to be clearly superior. Studies have demonstrated better outcomes in terms of intubation rates, short-term mortality rates, symptomatic improvement, and length of hospitalization in patients with respiratory failure who receive NIPPV.¹⁹ Disadvantages of NIPPV include slower correction of gas-exchange abnormalities, risk of aspiration, inability to control airway secretions directly, and possible complications of gastric distention and skin necrosis. Contraindications to the use of NIPPV include an uncooperative or obtunded patient, inability of the patient to clear airway secretions, hemodynamic instability, respiratory arrest, recent facial or gastroesophageal surgery, burns, poor mask fit, or extreme obesity.

Invasive ventilation should be considered in patients with ventilatory or respiratory failure who do not qualify for NIPPV The methods most commonly used are assisted control ventilation, pressure support ventilation, or pressure support ventilation in combination with intermittent mandatory ventilation. Adverse events associated with invasive ventilation include pneumonia, barotrauma, and failure to wean.

OTHER OPTIONS There is currently little evidence to support the use of a mixture of helium and oxygen or magnesium in the treatment of acute COPD exacerbation. Factors underlying the exacerbation, comorbidities, and other etiologies of dyspnea should be identified and treated.

Future Considerations and New Therapies

Bronchodilators play an important role in the long-term management of patients with COPD, but they do not alter the progression of COPD. Major advances include the development of long-acting anticholinergic agents, such as tiotropium bromide. Tiotropium bromide has the benefit of once-daily dosing. Inflammation is being investigated more closely in the pathogenesis of COPD, especially the role of neutrophils. Corticosteroids, chemokine (interleukin 8) inhibitors, leukotriene B₄ inhibitors, adhesion molecule inhibitors, and phosphodiesterase inhibitors are being studied with the goal of inhibiting neutrophil activity. Surfactant replacement and lung reduction therapies are also under investigation. Evidence suggests that the imbalance between proteases in COPD patients may be restored by inhibiting proteolytic enzymes, such as neutrophil elastase inhibitors, cathepsin inhibitors, matrix metalloproteinase inhibitors, and secretory leuko-protease inhibitors, or by increasing antiproteases, such as α_1 antitrypsin. Evidence also exists that oxidative stress is increased in patients with COPD, and that reactive oxygen species are involved in the pathogenesis of COPD. Therefore, antioxidants such as iV-acetyl

TABLE 69-4 Indications for Hospital Admission for Acute Exacerbations of Chronic Obstructive Pulmonary Disease

Marked increase in intensity of symptoms, such as sudden development of resting dyspnea
Severe background of chronic obstructive pulmonary disease Onset of new physical signs (e.g., cyanosis, peripheral edema) Failure of exacerbation to respond to initial medical management Significant comorbidities Newly occurring arrhythmias Diagnostic uncertainty
Older age Insufficient home support

NHLBI/WHO Global Initiative for Chronic Obstructive Lung Disease (GOLD) Workshop summary. *Am J Respir Crit Care Med* 163:1256, 2001.

cysteine and spin-trap antioxidants such as α -phenyl- β -tertbutyl nitron may be useful. Pulmonary vasodilators, such as prostacyclin analogues, nitric oxide donors, endothelial antagonists, and angiotensin antagonists, are being studied in the hope of preventing the progression of pulmonary hypertension and cor pulmonale. Mucus regulators, such as tachykinin antagonists, sensory neuropeptide-release inhibitors, mediator and enzyme inhibitors, MUC gene suppressors, and mucolytic agents, may inhibit the hypersecretion of mucus, without affecting normal mucus secretion and normal mucociliary clearance.

DISPOSITION

Admission Criteria

Patients who fail to improve adequately or deteriorate despite medical therapy, have significant comorbid illnesses, or are without an intact social support system at home should be hospitalized. Unfortunately, objective criteria regarding hospital admission, observation unit stay, and ED discharge are lacking. The GOLD guidelines offer criteria that may help guide the emergency physician's disposition decision-making process (Tables 69-4 and 69-5). Although Emerman and colleagues found that patients with an FEV₁ > 40 percent predicted and no clinical evidence of respiratory distress after treatment have a low rate of relapse and may be safely discharged home,²⁰ current data indicate that 43 percent of patients with COPD exacerbation discharged home from the ED have ongoing symptoms at 2 weeks and 43 percent have a relapse of symptoms.²¹ The primary goals of hospitalization are to manage the acute exacerbation, prevent further deterioration, and educate patients about disease management.

Discharge

If the patient is deemed stable enough for discharge to home, the following should be arranged: (1) adequate supply of home oxygen, if needed; (2) adequate and appropriate bronchodilator treatment; (3) consideration of a short course of oral corticosteroids;¹⁸ and (4) a follow-up appointment with their physician.

THE LUNG TRANSPLANT PATIENT

Thomas P. Noeller

Since the first successful single-lung transplant in 1983 and the first successful double-lung transplant in 1986, lung transplantation has become a viable therapeutic modality for end-stage pulmonary disease. Currently, about 75 centers in the United States perform lung transplants, and in 2002 a total of 1042 patients underwent lung transplant nationally.¹ On April 29, 2003, the United Network for Organ Sharing listed 3843 patients on a waiting list for lung transplantation and noted that 481 patients had been removed from a waiting list owing to death during 2002.¹ In 2001, 21 percent of lung transplant recipients were

transplanted within 6 months of listing on the waiting list and 38 percent were on the waiting list longer than 2 y before transplant.² Overall survival rates are 77 and 42 percent at 1 and 5 years, respectively.² The long-term survival rates were slightly higher at centers performing more than 30 lung transplants per year. Single- and double-lung transplants and heart-and-lung transplants are most commonly performed for cystic fibrosis, idiopathic pulmonary fibrosis, and emphysema, including α_1 -antitrypsin deficiency.³ Primary pulmonary hypertension, congenital heart disease, and Eisenmenger's complex also may be indications for heart-and-lung transplantation. Living donor lobar transplantation, performed for 290 patients from 1991 through 2001, primarily for cystic fibrosis, is now an option for some patients.

MANAGEMENT OF PRETRANSPLANT PATIENTS

Pretransplant patients are likely to present with exacerbations of their underlying disease; assessment and management should be targeted to these processes. The transplant coordinator should always be contacted early in the course of evaluation and treatment to aid in timely disposition (Table 70-1).

Important features to note are the respiratory rate, pulse oximetry measurement, and physical findings of cyanosis, diaphoresis, use of accessory muscles, signs of congestive heart failure, and adequacy of peripheral perfusion. Supplemental oxygen should be applied, intravenous access obtained, and the patient placed on a cardiac monitor. A chest radiograph should be obtained to identify infiltrates or pneumothorax, and an arterial blood gas analysis should be performed when adequacy of ventilation is in question. β_2 -Agonists, anticholinergics, and antibiotics should be given as indicated.

Although the perioperative use of corticosteroids was formerly considered a contraindication to transplantation, this notion has changed somewhat. A maintenance dose of prednisone, 0.2 to 0.3 mg/kg per d, is acceptable to most centers. If the patient requires a corticosteroid burst or an increase in the maintenance dose to treat an acute exacerbation, the transplant coordinator should be contacted. A dose of prednisone larger than 20 mg per d may result in the patient being suspended from the transplant list until such time that the dose can safely be tapered down to 20 mg per d or less. In primary pulmonary hypertension and Eisenmenger complex, consideration should be given to therapies that may help to decrease pulmonary vascular resistance, such as morphine sulfate, nitrates, and furosemide. For patients with respiratory failure, noninvasive ventilation or endotracheal intubation with mechanical ventilation may be required, thereby increasing the risk of barotrauma. Ventilator dependence has generally been regarded as a relative contraindication to lung transplantation. Successes have been reported, but ventilator-dependent patients have a much higher mortality after transplantation.⁴

Idiopathic pulmonary fibrosis is a common indication for lung transplantation and has a worse 1- and 5-y posttransplant survival

compared to other lung diseases. Treatment with high-dose steroids is rarely successful at achieving a remission, and supportive therapy is the mainstay of acute management. The transplant team may recommend cytotoxic drugs, such as cyclophosphamide and azathioprine, for their steroid-sparing effect.

Chronic infection, especially common in patients with cystic fibrosis, is a major issue with regard to eligibility for transplantation. Patients with cystic fibrosis tend to be infected with multiple organisms by the time transplantation is considered. The most common organisms include *Pseudomonas* spp., *Burkholderia cepacia*, *Aspergillus*, and nontuberculous mycobacteria. *Aspergillus* and mycobacterial infections have not been associated with worse outcomes in posttransplant patients. However, infection with *B. cepacia* and pan-resistant *Pseudomonas* spp. has been associated with poor outcomes and is considered a contraindication to transplantation in some centers. Therefore, emergency physicians need to pay particular attention to infection-control measures and antibiotic selection in pretransplant patients with cystic fibrosis. In general, those patients requiring antibiotics for acute infections require admission for broad spectrum, multiple-drug regimens to prevent the development of pan-resistant strains.

In patients with primary pulmonary hypertension, survival correlates with the New York Heart Association (NYHA) classification. Prostacyclin has been approved for treatment of NYHA class III or IV patients, in whom it has been shown to improve hemodynamics and exercise tolerance and survival. Calcium channel blockers are the main treatment for NYHA class I and II patients. In acute decompensation, morphine, nitrates, and furosemide may reduce pulmonary vascular resistance and improve dyspnea.

MANAGEMENT OF POTENTIAL DONORS

Identification and early management of potential donors have become part of the practice of emergency medicine. The establishment of brain death is generally not done in the ED; however several steps need to be taken to maximize organ retrieval in appropriate patients. Most organ procurement organizations work closely with their local EDs by providing education in the various facets of organ procurement. Early communication with the organ procurement organization is encouraged, because it can help to identify factors that may qualify or disqualify a potential donor, provide assistance in speaking with families about organ donation, and guide the clinicians through the complicated process.

Initial management is focused on maintaining the integrity of potential donor lungs by optimizing hemodynamics and preventing aspiration. Accepting centers generally require a clear chest radiograph, partial pressure of arterial oxygen greater than 450 mm Hg on 100 percent fraction of inspired oxygen, and no obvious infection on bronchoscopic evaluation. Mechanical ventilation should maintain arterial P_{aO_2} at greater than 80 mm Hg, P_{aCO_2} between 35 and 45 mm Hg, and a pH between 7.30 and 7.45. Hemodynamics should be monitored, with a desirable central venous pressure greater than 10 mm Hg. If systemic blood pressure cannot be maintained with fluid resuscitation alone without causing pulmonary edema, then dopamine may be used. Transfusions may be used to maintain a hematocrit above 30 percent to optimize tissue oxygenation. However, it is crucial to specify the use of blood that is cytomegalovirus (CMV) negative so as not to infect a CMV-negative recipient. Although these criteria are used to determine acceptability for donation, it has been observed that aggressive management of lung donors generally considered unacceptable produces identical 30-day and 1-year mortality rates among recipients when compared with recipients who received transplants from traditionally acceptable donors.⁵

MANAGEMENT OF POSTTRANSPLANT PATIENTS

Transplant patients are managed by a multidisciplinary team composed of transplant surgeons, pulmonologists, nurse coordinators, pharmacists,

physical therapists, dietitians, psychologists, and social workers. At each transplant center, a nurse coordinator is on call to address concerns regarding the care of posttransplant patients in the ED. Patients tend to be well educated and well informed about their disease, but the nurse coordinator may be able to provide additional information regarding recent infection history, medication doses, rejection history, and potential complications in a specific patient. Coordinators should always be called early in the course of patient assessment and management.

Posttransplant patients are at risk for several complications related to their underlying disease, medication side effects, and immunocompromised state. Most centers use cyclosporine or tacrolimus, azathioprine or mycophenolate mofetil, and prednisone for maintenance immunosuppression. In addition, prophylaxis against *Pneumocystis carinii* pneumonia is undertaken with trimethoprim-sulfamethoxazole (TMP-SMX).⁶ Prophylaxis against herpes simplex virus (HSV) and CMV is indicated based on the specific immunologic status of the donor and the recipient. Inhaled cyclosporine and corticosteroids are used to help prevent the development of bronchiolitis obliterans.

Patients learn to measure their pulmonary function (FEV₁: forced expiratory volume in 1 s; and forced vital capacity), systemic blood pressure, and temperature daily. They carry a diary with vital signs, present medications and doses, names of hospital contacts, and guidelines for contacting the nurse coordinator. Because most patients return to their home communities 2 to 3 months after surgery, they may be initially treated and stabilized in their hometown ED before transfer back to the transplant center. Common warning signs of a fever, cough, sputum, or FEV₁ decline by more than 10 percent for over 48 h should prompt a call or visit to the transplant center.

The most frequent complications prompting ED presentation are infection and rejection, which can be difficult to differentiate clinically. When these diagnoses are suspected, the patient should be placed in respiratory isolation. Initial assessment is similar to that in the pretransplant patient with regard to stabilization and supportive care. In addition to the standard evaluation of airway, respiratory, and circulatory status, initial assessment should include a chest radiograph, arterial blood gases, FEV₁ measurement, complete blood cell count with differential, serum electrolytes, magnesium, creatinine, and appropriate drug levels. Bronchoscopy is necessary to diagnose subclinical rejection and infection. Each transplant center has a protocol concerning bronchoscopy indications.

Early Complications

REJECTION Acute rejection is common and may occur three to six times in the first postoperative year. After the first year, the frequency of acute rejection decreases, but it can occur for several years after transplant. Signs of rejection include cough, chest tightness, fever ($>0.5^{\circ}\text{C}$ above baseline), hypoxemia, decline in FEV₁ (>10 percent), and the development of infiltrates on the chest radiograph. Radiographic abnormalities are less common more than 6 weeks post-transplant, and an acute rejection episode actually may be "radiographically silent" after this period. Clinically, acute rejection may be difficult to distinguish from infection. Therefore, bronchoscopy with transbronchial biopsy is frequently necessary to make the definitive diagnosis. During episodes of acute rejection in patients with single-lung transplants, there is a proportional decrease in blood flow to the transplanted lung, which can be monitored with radionuclide perfusion scans.

Acute rejection is treated with large doses of intravenous methylprednisolone 500 to 1000 mg on day 1, followed by 500 mg IV every day on days 2 and 3. Clinical response is gauged by improvements in oxygenation, spirometry, and radiographic appearance and typically occurs within 24 to 48 h after treatment is initiated. Failure to do so should suggest infection as an alternative diagnosis. After clinical improvement, the maintenance dose of prednisone is increased, with a slow taper back to baseline.

INFECTION Infectious complications are the most common cause of morbidity and mortality in lung transplant patients.^{7,9} Infections may be due to bacteria, fungi, or viruses and most commonly affect the allograft. Bacterial pneumonia is the most common complication in the first 3 months after transplant due to decreased mucociliary clearance, diminished cough reflex, disrupted lymphatics, reperfusion injury, and immunosuppression. Late or recurrent infections are associated with an increased risk of bronchiolitis obliterans. Infectious agents may be present in the donor lung, generating infection in the posttransplant immunosuppressed host. The vast majority of washings from a donor before retrieval will grow at least one organism. Perioperative antibiotics based on culture and sensitivity results have decreased the rate of invasive infection significantly. Infection with pan-resistant *Pseudomonas* spp. or *B. cepacia* is associated with increased morbidity and mortality and is generally associated with a higher risk of bronchiolitis obliterans. *Pneumocystis carinii* pneumonia is now rare due to common prophylaxis with TMP-SMX.⁶ Other commonly encountered infectious agents include gram-negative and gram-positive bacteria, *Mycobacterium* spp., *Aspergillus*, CMV, HSV, and Epstein-Barr virus (EBV).

Cytomegalovirus is the most commonly encountered viral agent implicated in posttransplant pulmonary infection. Its clinical spectrum is broad, ranging from asymptomatic shedding to CMV pneumonitis. The risk of infection is directly related to the donor's and recipient's pretransplant immune status. Donor-positive, recipient-negative status is universally associated with the development of CMV infection in the recipient unless aggressive prophylaxis is undertaken with ganciclovir, acyclovir, and intravenous immunoglobulin. If the recipient is CMV positive, a regimen of ganciclovir followed by acyclovir is used. If the donor and recipient are CMV negative and either the donor or recipient is HSV positive, only acyclovir is used. Cytomegalovirus matching has not altered long-term outcome in lung transplant patients, so most centers will transplant regardless of CMV status.

Cytomegalovirus infections occur most commonly between 14 and 100 days posttransplant and can manifest as either a flulike syndrome or severe multisystem disease, including pneumonitis, hepatitis, bone marrow suppression, gastritis, and colitis. Key laboratory features include neutropenia with or without thrombocytopenia, conversion of anti-CMV IgM to positive, and positive CMV cultures from urine, buffy coat, or bronchoalveolar lavage. Definitive diagnosis of CMV pneumonitis requires histopathologic confirmation of tissue obtained by transbronchial biopsy. After confirmation of diagnosis, treatment with ganciclovir or foscarnet is indicated. Cytomegalovirus pneumonitis may be complicated by acute rejection or by bacterial or fungal pneumonia.

Other viral agents, in particular HSV and EBV, have been implicated in posttransplant infections. Herpes simplex virus has a presentation similar to that of CMV, with diagnosis based on viral culture and differential staining of biopsy specimens. Treatment is with acyclovir. Epstein-Barr virus may present as a mononucleosis-type syndrome but is also associated with the development of posttransplant lymphomas.

Fungal infections are less common but carry a relatively high risk of associated morbidity and mortality. *Candida albicans* is a common airway colonizer but a much less common pathogen. Systemic candidiasis is usually associated with prolonged courses of broad-spectrum antibiotics. The treatment for *C. albicans* is fluconazole, but other *Candida* species may require treatment with amphotericin B. *Aspergillus* spp. also may colonize the airways; this does not require treatment unless associated with invasive disease, as demonstrated by ulcerations, or histologic evidence of invasion. Itraconazole with amphotericin B is frequently successful in treating early infections, but disseminated disease is usually fatal.

Lung transplant patients are subject to bacterial endocarditis because, during the transplant operation, the donor pulmonary veins are attached to the atrium by the establishment of a cuff. Therefore, antimicrobial prophylaxis is necessary before dental and other invasive procedures associated with risk for bacteremia.

OTHER PULMONARY COMPLICATIONS Airway dehiscence and stenosis are now uncommon postoperative complications.¹⁰ Airway dehiscence typically occurs within 3 weeks of transplantation, while the patient is still in the hospital. Bronchial stenosis limits clearance of secretions and leads to pneumonia. Treatment is with stenting or laser therapy. Spontaneous pneumothorax necessitates the placement of a thoracostomy tube and evaluation of the airways by bronchoscopy.

MEDICATION EFFECTS Various induction agents are used in the perioperative and immediate postoperative periods. These agents include high-dose corticosteroids and T-cell lytic therapy with equine-derived antithymocyte globulin, a polyclonal thymocyte preparation, or OKT-3, a murine monoclonal antibody. The most common post-transplant immunosuppressive agents include cyclosporine, azathioprine, and prednisone. Recently, two new drugs have come into common use: tacrolimus and mycophenolate mofetil (MMF). These medications have significant toxicity (see Table 99-2).

Tacrolimus and cyclosporine work in a similar fashion, by inhibiting transcription of genes leading to T-cell activation. Each drug has a narrow therapeutic window, making it necessary to monitor drug levels frequently. Recent studies have suggested that tacrolimus may be more effective than cyclosporine at preventing acute rejection, leading to wider use of this agent in immunosuppressive regimens.¹¹

Mycophenolate mofetil inhibits lymphocyte proliferation by interfering with purine synthesis. It has been compared with azathioprine, the immunosuppressive mechanism of which is not entirely known. Recent trials have suggested superiority of MMF over azathioprine in preventing acute rejection episodes and possibly decreasing the incidence and severity of bronchiolitis obliterans.¹¹

Glucocorticoids and cyclosporine can exacerbate glucose intolerance, worsen osteoporosis, and cause myopathy and systemic hypertension. Cyclosporine and tacrolimus have similar side-effect profiles. Commonly, chronic cyclosporine or tacrolimus use at the levels employed in lung transplant immunosuppression results in renal insufficiency by decreasing renal blood flow and by a direct effect on the renal tubules, thereby causing hyperkalemia and hypomagnesemia. Nonsteroidal anti-inflammatory drugs should be avoided, because these will act synergistically with cyclosporine to further reduce glomerular filtration. Neutropenia often may result from azathioprine or CMV infection. The primary side effects of MMF are gastrointestinal.

Drugs that are metabolized by the P-450 system will interact with cyclosporine and tacrolimus metabolism (see Table 99-3). Drugs that induce these enzymes (e.g., phenytoin, rifampin, and phenobarbital) may lower cyclosporine and tacrolimus levels acutely, possibly precipitating rejection. Drugs that inhibit cyclosporine and tacrolimus metabolism (e.g., erythromycin, ketoconazole, cimetidine, and the calcium channel blockers) may elevate levels into the toxic range and should be avoided unless appropriate changes in dosing are made to compensate. Azathioprine-induced bone marrow suppression can be enhanced with concomitant use of allopurinol. Mycophenolate mofetil absorption may be affected by antacids and cholestyramine, and renal excretion may be affected by competing drugs, such as acyclovir and ganciclovir, in the setting of renal insufficiency.

cause the large airways become bronchiectatic as the small airways are obliterated, episodes of bacterial bronchitis are common. Typically the chest radiograph is clear of infiltrates. Current treatment for bronchiolitis obliterans is augmentation of immunosuppression, including high-dose steroids. The prevalence of bronchiolitis obliterans in long-term survivors is 20 to 50 percent. The course of the disease is highly variable, with some patients stabilizing at a lower level of pulmonary function and others progressing to respiratory failure and death.

POSTTRANSPLANT LYMPHOPROLIFERATIVE DISEASE Posttransplant lymphoproliferative disease (PTLD) can be a consequence of T-cell suppression with long-term cyclosporine use. The overall incidence in lung transplant patients is approximately 8 percent. The disease tends to occur with primary EBV infection after lung transplant. Because younger patients are more likely to be EBV negative at the time of transplantation, they tend to develop EBV infection and PTLD at a higher rate, especially among Caucasian males.¹³ Presenting features include isolated lymphadenopathy, painful otitis media (secondary to tonsillar involvement), or a viral-like syndrome. The occurrence of PTLD within 1 year of transplantation is usually localized and can be successfully treated with reduced immunosuppression and high-dose acyclovir, with a relatively good prognosis. In contrast, PTLD after 1 year tends to be disseminated, unresponsive to treatment, and usually fatal.

Late Complications

BRONCHIOLITIS OBLITERANS The most frequent cause of death after the second posttransplant year is bronchiolitis obliterans, which is characterized by chronic allograft dysfunction and airflow limitation.¹² Current evidence suggests that chronic rejection plays the most important role in the development of bronchiolitis obliterans, but other factors, such as CMV infection, toxic fume inhalation, and chronic foreign body exposure caused by abnormal mucociliary clearance, may contribute. Diagnostically, the yield from bronchoscopy and biopsy is low. Therefore, diagnosis rests on clinical criteria (i.e., ≥ 20 percent fall in FEV₁ without any other identifiable cause). Be-

PULMONARY IMAGING

Janet M. Poponick

Imaging of the chest is common practice in the evaluation of patients with dyspnea, chest pain, or trauma. This chapter reviews the use of plain chest radiography, ventilation-perfusion scans, computed tomography, and thoracic ultrasonography in the ED. The value of an imaging study depends on the technical quality of the procedure and the ability of the physician to interpret the image. Although many studies

and findings may have excellent interobserver reliability, others do not. Thus, clinical decisions should be based on knowledge of the value and limitations of image interpretation.

PLAIN RADIOGRAPHY

Chest radiography, which is the most commonly ordered radiologic examination, evaluates the lung parenchyma, cardiac and mediastinal size, and the bony structures of the chest wall. The examination is preferably done in the radiology department with the patient in the standing position with the x-ray beam passing posterior to anterior [posterior-anterior (PA) view]. The patient must be able to take a deep breath and hold while the picture is taken. A "good inspiration" is defined as visualizing the ninth rib above the diaphragm. Adding the lateral film visualizes the posterior lung bases and the retrosternal area, and also helps to localize infiltrates and masses anatomically.

For unstable patients, portable chest radiography is performed at the bedside, with patients sitting upright. Portable chest radiography is limited by the low power of the equipment and variations in radiographic technique. The bedside study is obtained as an anterior-posterior (AP) view, with the x-ray beam passing anterior to posterior, which magnifies the mediastinal structures. For a trauma victim on a backboard, the portable film may be more difficult to interpret. Skin folds and clothing under a patient may mimic a pneumothorax. In the supine position, air rises anteriorly, making the diagnosis of a small pneumothorax very difficult.¹ Fluid collections layer posteriorly in supine patients, causing a diffuse haziness in the lung fields, which can be confused with infiltrate or contusion. The magnification of the mediastinal structures produced by AP imaging may mimic a mediastinal hematoma suggesting aortic injury. Therefore, chest radiographs are limited by a patient's overall condition, the patient's ability to cooperate with directions, and the technique chosen. The PA and lateral chest radiographs remain the best views.

Occasionally, other techniques and views may be useful. While inspiratory and expiratory chest radiographs are equally sensitive for pneumothorax detection, an expiratory film may accentuate a free air-lung interface, enabling the diagnosis of a small pneumothorax not seen on the inspiratory view.² In suspected foreign-body aspiration, the expiratory film may show hyperinflation on the affected side as air is trapped behind the foreign body. Lateral decubitus views can be used to demonstrate a freely flowing pleural effusion with the affected side down and can visualize a small pneumothorax with the affected side up. Apical lordotic views can be used to better visualize the lung apices in cases with possible infiltrate or tumor in that region.

The chest radiograph should be systematically analyzed so as not to miss key information. Specific abnormalities to note on the chest radiograph are pulmonary edema, infiltrates, lung nodules and masses, hilar size and contour, cardiac size and configuration, pleural effusions, and pneumothorax. Identify the study by patient name to ensure that the radiograph is of the correct patient. Assess the technique and the quality of the study. In a good-quality study, the trachea is visible in the midline, the medial borders of the clavicle are centrally located over the superior mediastinum, and the thoracic spine is visible through the mediastinal structures. Identify and note the positioning of all lines, the endotracheal tube, and the nasogastric tube. The trachea should be followed to the left and right main-stem bronchi and to the mediastinal structures. Look at the mediastinum for evidence of free air, for density behind the heart, and for cardiac size (which should be less than 55 percent of the thoracic size on the erect view and less than 58 percent on the supine view). Assess position of the diaphragms, looking at position, contour, and subdiaphragmatic free air: the right hemidiaphragm should be slightly elevated when compared with the left (0.5 to 2.5 cm is normal). Assess the lung fields and pleura, looking for masses, infiltrates, free air, or effusions. Finally, assess the soft tissue and bones, looking for subcutaneous air or fractures.

Aortic injuries are often suspected in the trauma patient with a deceleration mechanism of injury. Radiographic findings of a mediasti-

nal hematoma have traditionally been used as a screening study for aortic injury: mediastinal widening, deviation of the nasogastric tube or endotracheal tube to the right, loss of aortic knob contour, and apical capping. While mediastinal widening is often subjectively estimated, a mediastinal width of greater than 8 cm at the carina, or a mediastinal width at the carina of greater than 25% of the thoracic diameter have been commonly used to identify a wide mediastinum. Because of patient position and technique, supine portable AP chest radiographs often have a wide mediastinum that is normal when the chest radiograph is obtained by upright PA technique. A reverse Trendelenburg radiograph is helpful in this situation because tilting the bed to 45 degrees approximates the anatomy of an upright radiograph.³ This technique can be used in the trauma resuscitation room while the patient is fully immobilized by elevating the head of the stretcher 45 degrees. This technique reduces the need for further aortic studies by about 25 percent.

Pneumothorax may be difficult to visualize in the supine position due to air layering anteriorly. A pneumothorax is usually visualized and its size reasonably well estimated on the upright PA chest radiograph.⁴ If visible on the supine view, the size of a pneumothorax can also be estimated on a supine film by using the average intrapleural distance and a nomogram.⁵

VENTILATION-PERFUSION SCANS

The ventilation-perfusion (V/Q) scan is often the initial screening test for patients with suspected pulmonary embolism (PE).⁶⁻⁸ The study has a low incidence of adverse reactions, is noninvasive, and requires little advance patient preparation.⁶

The V/Q scan is a two-step process. First, the perfusion study is performed in which technetium-99m (^{99m}Tc)-macroaggregated albumin is injected intravenously and becomes trapped within the pulmonary circulation. Images are obtained with the patient in multiple positions. If the perfusion study is normal, the ventilation portion of the test may be avoided.^{6,9} The ventilation portion of the examination is performed with the patient breathing an aerosolized solution of ^{99m}Tc diethylenetriaminepentaacetic acid (DTPA). The aerosol is deposited deep into the lungs in proportion to alveolar ventilation. Images are obtained from different projections. Procedural problems arise when a patient is unable to lie still. The ventilation study may be limited if a patient cannot take a deep breath, follow instructions, or is on a ventilator. A problem with central deposition of the aerosol may occur in patients with chronic obstructive pulmonary disease. Newer agents, such as Tc99m Technegas, which distribute more diffusely to all areas of lung ventilation, have been developed.⁶

Diagnosis of PE on V/Q scan is based on documenting perfusion defects in an area of normal ventilation, a mismatched defect. Perfusion defects in areas of associated ventilation abnormalities, or matched defects, may be seen with parenchymal lung disease, making interpretation difficult. The V/Q scan is correlated with the chest radiograph and assigned one of three readings: normal or near-normal, high probability, and nondiagnostic.⁶ The high probability scan is one with large segmental mismatches (intact ventilation but absent perfusion). The nondiagnostic category has both perfusion and ventilation abnormalities, which are neither normal nor high probability. This new system of V/Q reporting is less cumbersome than previous systems, which used high, intermediate, and low probability categories developed from the Prospective Investigation of Pulmonary Embolus Diagnosis (PIOPED) study.¹⁰

The test characteristics (sensitivity and specificity) of the V/Q scan vary according to the interpretation and the utility of this test depends on the pretest clinical suspicion of PE.^{8,9} A V/Q scan result other than normal or near-normal has a sensitivity of 98 percent [95% CI, 95 to 99%] for PE. Thus a normal or near-normal V/Q scan excludes PE and is sufficient to withhold further diagnostic study or treatment. The PIOPED study found that a normal V/Q scan had a 4 percent overall

prevalence of PE found on angiography.¹⁰ But perhaps more importantly, patients in this category were followed and had no demonstrable morbidity or mortality. Conversely, a high-probability V/Q scan has a specificity of 98 percent (95% CI; 96 to 99%); this result is sufficient to diagnose and treat PE. The PIOPED study found that a high-probability V/Q scan had an 87 percent overall prevalence of PE found on angiography.¹⁰ Unfortunately, 50 to 70 percent of V/Q scans fall into the nondiagnostic category. For this group, the next diagnostic test would be pulmonary angiography, which would identify PE in approximately 25 percent of cases.¹⁰

PULMONARY ANGIOGRAPHY

Pulmonary angiography remains the gold standard for accurately diagnosing PE.⁶⁻⁸ A pulmonary angiogram is performed by a flexible catheter advanced from a peripheral large vein, typically the femoral vein, through the right atrium and ventricle, and into the pulmonary artery. Selective injections of contrast media are made into the lobar pulmonary arteries by using the results of the V/Q scan to guide which lobar arteries should be inspected first. A PE is definitely identified by an intraluminal filling defect in two views or an abrupt cutoff of dye. Narrowing or luminal irregularities can be caused by other processes and are not considered diagnostic for PE.

In the PIOPED study, pulmonary angiography had good interobserver reliability: review of study angiograms by another radiologist reached the same diagnosis in 92 percent of cases. Interobserver agreement was best for lobar (98 percent) and segmental (90 percent) PE. However, at the subsegmental level, interobserver agreement was only 66 percent.¹¹ Despite this variation, pulmonary angiography remains the gold standard to which newer technologies in CT and magnetic resonance imaging (MRI) are compared.

Complications of pulmonary angiography include (1) fatalities in 0.5 percent; (2) major nonfatal complications such as renal failure, significant hematoma, or respiratory distress in 17 percent; and (3) minor complications such as angina, urticaria, or bronchospasm in 5 percent. Those with a known left bundle-branch block require a temporary pacemaker during the procedure to avoid complete heart block. Those with known renal insufficiency should be adequately hydrated before and after the procedure. Disadvantages of the procedure include patient discomfort, high cost, and the need for an experienced invasive radiologist. Newer noninvasive techniques are replacing pulmonary angiography in many centers.

COMPUTED TOMOGRAPHY

CT provides sharp cross-sectional anatomic displays, which enable identification of fluid collections and distinction between soft tissue structures. The chest CT eliminates overlap of tissues and delineates mediastinal structures very well. Chest CT is usually obtained with intravenous radiocontrast agents. Improved computer technology has enhanced the ability to obtain good quality scans in a short period of time. The current programs have made it possible to evaluate pulmonary nodules and interstitial lung disease more accurately.^{12,13} Computer programs using helical CT scans allow accurate airway visualization, similar to a bronchoscopy.⁷ In the ED, helical CT scans are useful in assessing the mediastinum of a patient with blunt trauma for aortic injury, in assessing the patient with a possible aortic dissection, or evaluating the patient with pulmonary embolism. The disadvantages of chest CT include cost, radiation exposure, and adverse reactions to intravascular radiocontrast media. Transporting the unstable patient should be done with cardiac monitoring and appropriate personnel.

Blunt trauma to the chest and abdomen often requires further evaluation by CT.¹⁴ In many cases, pneumothorax is diagnosed by looking at the upper cuts of the abdominal CT scan, often identifying a small pneumothorax not seen on supine chest radiograph.^{11,15} The risk of

progression is small and most small (minuscule) and moderate (anterior) radiographically occult pneumothoraces can be managed without initial placement of a thoracostomy tube if the patient is not to undergo positive pressure ventilation.¹⁶

Helical CT scanning with intravenous radiocontrast can be useful to evaluate trauma patients for possible aortic injury. Some investigators recommend helical CT for all patients with high-speed deceleration injury even if the initial chest radiograph is normal because approximately 50 percent of such patients with a normal chest radiograph have been found to have multiple injuries on CT scan.¹⁷

Helical CT scan of the chest is helpful in patients with signs and symptoms of aortic dissection: an accurate diagnosis of dissection will be obtained in more than 96 percent of such patients.¹⁴ Helical CT scan can accurately identify dissection by visualizing an intimal flap with opacification of the true and false lumens. In patients with type B (descending aorta) dissection, no other study is necessary. A disadvantage of helical CT scan in type A (ascending aorta) dissection is that aortography is still required to assess the aortic valve and major arterial vessels prior to surgery.

In many centers, the helical CT scan has become the initial noninvasive test for the evaluation of possible PE.^{7,8,18} The helical CT scan can be performed in minutes, provides imaging of other pulmonary disorders that may produce dyspnea, has overall good test characteristics (86 percent sensitivity and 93 percent specificity), and has a very low frequency of nondiagnostic or uninterpretable studies (less than 8 percent).^{8,18} The disadvantages of helical CT include the use of radiocontrast media, radiation exposure, and the special expertise needed to interpret the test. In patients with abnormal chest radiographs and underlying pulmonary disease, the V/Q scan is usually nondiagnostic and the helical CT scan is a cost-effective means of evaluating such patients.

After intravenous injection of approximately 120 mL of radiocontrast dye, the scan is performed from the aortic arch to the diaphragms. Patients must be able to hold their breath, typically for 20 to 24 s, although faster CT scanners may require only 10 s of breath-holding to image. Breath holding may be difficult for dyspneic patients and motion artifact leads to a nondiagnostic study in 2 to 4 percent. While intravenous radiocontrast dye may be a disadvantage, it can also be used to scan for deep venous thrombosis (DVT) by obtaining CT cuts from the knees to the mid-abdomen. The combined helical CT scan of the chest and contrast venography of the lower extremities is convenient and easy to do while the patient is in the radiology suite.¹⁸

An acute embolus is diagnosed when thrombus is seen central within the vessel with distention of the involved vessel. Chronic emboli are eccentric and contiguous with the vessel wall.¹⁸ Interpretations of scans are extremely accurate for central embolus (sensitivity approaching 100 percent), but significantly less at the subsegmental level (sensitivity 53 to 91 percent).⁸ The prevalence and clinical consequence of these small subsegmental PE among outpatients is unknown.

There is still debate over the use of helical CT scan or V/Q scan as the initial noninvasive test for evaluation of PE. Both a normal or near-normal V/Q lung scan or normal helical CT scan have excellent sensitivities and clinically exclude PE. Because of the large number of nondiagnostic V/Q lung scans seen in patients with underlying lung disease or radiographic infiltrates, the CT scan may be the appropriate first test in such patients.

THORACIC ULTRASONOGRAPHY

Thoracic ultrasonography can be used to image pleural diseases (effusion, pneumothorax), parenchymal lung diseases (pneumonia, tumors), and chest wall problems (tumor, rib fracture), and to assess diaphragmatic movement.¹⁹ Ultrasonography is less expensive and more conveniently brought to the patient than CT. Ultrasonography provides real-time immediate images as opposed to other imaging modalities.

SECTION 8 • PULMONARY EMERGENCIES

Ultrasonography can be used to guide placement of drains, aspirations, and biopsies. As with other ultrasonographic applications, operator technique and the quality of the interpretation is key to overall accuracy.

In the ED, one application of bedside thoracic ultrasonography is to detect traumatic pneumothorax and hemothorax in the supine patient. The ultrasonographic viewing areas for a pneumothorax are the anterior second to fourth intercostal spaces and the sixth to eighth intercostal spaces in the midaxillary line on both the right and left sides for a total of four imaging areas. Pneumothorax is identified by disappearance of lung sliding with respiration and loss of the comet-tail artifact at the pleural interface. The ultrasonographic viewing areas for a hemothorax (pleural fluid) are the right and left intercostal oblique views. Fluid in the pleural space was identified as an anechoic space distal to the hyperechoic line representing the diaphragm. Bedside ultrasonography has a sensitivity approaching 100 percent in detecting traumatic pneumothorax and a sensitivity of approximately 96 percent in detecting traumatic hemothorax.^{20,21}

MAGNETIC RESONANCE ANGIOGRAPHY

Recent improvements in technology make magnetic resonance angiography (MRA) a possibility in the evaluation of patients with PE.⁷ The focus has been on the development of a fast, three-dimensional gadolinium-enhanced scan, which has been reliable in small studies to the segmental vessels (negative predictive value 100 percent). DVT may also be assessed at the same time, similar to the protocol described using CT angiography. For those with CT contrast allergy or renal insufficiency, MRA is a promising alternative for evaluation of PE.

GASTROINTESTINAL EMERGENCIES

ACUTE ABDOMINAL PAIN

E. John Gallagher

SCOPE AND DEFINITIONS

Acute abdominal pain is commonly defined as pain of less than 1 week's duration.¹ This chapter discusses nontraumatic acute abdominal pain in postpubescent males and females. Abdominal pain in women in the third trimester of pregnancy or the first month postpartum is discussed in Chaps. 102, 105.

EPIDEMIOLOGY

Data from the U.S. National Center for Health Statistics indicate that stomach and abdominal pain was the principal reason offered by patients for visiting EDs in 2000 (annual incidence approximately 63/1000 ED visits).² Admission rates for abdominal pain vary markedly, ranging from 18 to 42 percent, with rates as high as 63 percent reported in patients over 65 years of age.

PATHOPHYSIOLOGY

Abdominal pain is traditionally divided into three categories: visceral, parietal, and referred. In general, visceral (autonomic) and parietal (somatic) are considered the two basic causes of abdominal pain. Referred pain can be considered separately as a cortical misperception of either visceral or parietal afferent stimuli. Although each type of pain is thought to have a different neuropathophysiology, the categories are not entirely discrete. For example, visceral pain often blends with parietal pain as a pathologic process evolves. Still, these distinctions are clinically useful ways of thinking about abdominal pain.

Visceral Pain

Visceral abdominal pain is usually caused by stretching of fibers innervating the walls or capsules of hollow or solid organs, respectively. Less commonly, it is caused by early ischemia or inflammation. Severity ranges from a steady ache or vague discomfort to excruciating or colicky pain. Because the visceral afferents follow a segmental distribution, visceral pain can be localized by the sensory cortex to an approximate spinal cord level determined by the embryologic origin of the organ involved. For example, foregut organs (stomach, duodenum, biliary tract) produce pain in the epigastric region; midgut organs (most small bowel, appendix, cecum) cause periumbilical pain; and hindgut organs (most of colon, including sigmoid) as well as the intraperitoneal portions of the genitourinary tract cause pain initially in the suprapubic or hypogastric area.

Because intraperitoneal organs are bilaterally innervated, stimuli are sent to both sides of the spinal cord, causing intraperitoneal visceral pain to be felt in the midline, independent of its right- or left-sided anatomic origin. For example, stimuli from visceral fibers in the wall of the appendix enter the spinal cord at about T10. When obstruction causes appendiceal distention in early appendicitis, pain is initially perceived as midline periumbilical area, corresponding roughly to the location of the T10 cutaneous dermatome.

Parietal or somatic abdominal pain is caused by irritation of fibers that innervate the parietal peritoneum, usually the portion covering the an-

terior abdominal wall. Because parietal afferent signals are sent from a specific area of peritoneum, parietal pain—in contrast to visceral pain—can be localized to the dermatome superficial to the site of the painful stimulus. As the underlying disease process evolves, the symptoms of visceral pain give way to the signs of parietal pain, causing tenderness and guarding. As localized peritonitis develops further, rigidity and rebound appear.

Referred Pain

Referred pain is felt at a location distant from the diseased organ. Similar to visceral pain, and in contrast to parietal pain, referred pain produces symptoms, not signs. Unlike visceral pain, referred pain is usually ipsilateral to the involved organ and is felt in the midline only if the pathologic process is also located in the midline. This is because referred pain, in contrast to visceral pain, is not mediated by fibers providing bilateral innervation to the cord. Similar to visceral pain, referred pain patterns are based upon developmental embryology. For example, the ureter and the testes were once anatomically contiguous, and therefore share the same segmental innervation, supplying afferent fibers to the lower thoracic and upper lumbar segments of the spinal cord. Thus acute ureteral obstruction is often associated with ipsilateral testicular pain. Other sites of referred pain reflect similar dermatomal sharing, providing explanations for otherwise puzzling associations, e.g., supra- or subdiaphragmatic irritation and ipsilateral supraclavicular or shoulder pain; gynecologic pathology and back or proximal lower extremity pain; biliary tract disease and right infra-scapular pain; and myocardial ischemia and midepigastria, neck, jaw, or upper extremity pain.

CLINICAL FEATURES

Conceptual Framework

CLASSIFICATION The classification scheme divides abdominal pain into two main categories: Intraabdominal (i.e., arising from within the abdominal cavity or retroperitoneum) and extraabdominal. Intraabdominal causes are divided by organ system into the "3-G's": GI (gastrointestinal), GU (genitourinary), and GYN (gynecologic), plus a fourth, less common but often catastrophic group of VASCULAR emergencies. Each of these four is further subdivided into specific diagnoses within that organ system. Pain of extraabdominal origin, which is substantially less common, is similarly divided into four broad etiologic categories of cardiopulmonary, abdominal wall, toxic-metabolic, and neurogenic. A systematic evaluation is necessary in the assessment of acute abdominal pain.

Finally, nonspecific abdominal pain (NSAP), which is the most common cause of abdominal pain among ED patients, is listed as a third category. Nonspecific abdominal pain stands alone since it is not known to what extent it may represent an underlying intra- vs. extraabdominal problem.

ABDOMINAL TOPOGRAPHY By combining the four-quadrant approach traditionally used by U.S. physicians with selected aspects of a strategy widely employed throughout Europe and Asia, a simple model of abdominal topography can be developed. In addition to the four standard quadrants (RUQ, RLQ, LUQ, LLQ), this model includes four areas of the abdomen that are not discrete, but rather constitute combinations of all or part of two or more quadrants: (1) upper half of

abdomen (UHA), which includes an area of pain as small as the midepigastrum, or as large as the RUQ + LUQ combined; (2) lower half of abdomen (LHA), which similarly includes an area of pain as small as the midhypogastrum or as large as the RLQ + LLQ combined; (3) central (CTL), which includes an area of pain composed of the centermost "quarters" of all four discrete quadrants, such that carving out these areas from each quadrant defines a periumbilical or central quadrant; and (4) generalized (GEN), which includes poorly localized pain encompassing much, perhaps most, of the abdomen, including at least some portion of all four discrete quadrants.

This topographic configuration incorporates both the early (visceral, poorly localized) and late (parietal, better localized) pain of an evolving intraabdominal pathological process, as well as the more generalized pain associated with toxic-metabolic derangements.

However, the association between the location of overlying pain or tenderness and underlying disease is so variable that about one case of abdominal pain in every three that comes to operation presents in a fashion that clinicians retrospectively regard as atypical. Failure to appreciate this may represent the largest single reason that error in the clinical diagnosis of abdominal pain is so common.

Historical Features

Historical data can be conveniently divided into attributes of pain, associated symptoms, and past history.

PAIN ATTRIBUTES The principal characteristics of abdominal pain include location, quality, severity, onset, duration, aggravating and alleviating factors, and change in any of these features over time.

ASSOCIATED SYMPTOMS These can be subdivided into one of the four main organ systems associated with intraabdominal pain.

Gastrointestinal Symptoms Anorexia, nausea, and vomiting (unless bloody) are among the least helpful symptoms in altering the conditional probability that a patient does or does not have a GI cause of abdominal pain. For example, vomiting has been reported in over 40 percent of patients with salpingitis, and in over 60 percent of patients with renal colic. Lower GI symptoms such as nonbloody diarrhea or constipation are similarly too insensitive and nonspecific to significantly alter the probability of a GI cause of abdominal pain.

Genitourinary Symptoms The hallmark of abdominal pain of GU origin is the concomitant development of some, often subtle, alteration in micturition, e.g., dysuria, frequency, urgency, hematuria, incomplete emptying, or incontinence (usually overflow). Non-GU pathology may develop in organs contiguous to the GU system, giving the appearance of an intrinsic GU problem. For example, an inflamed appendix lying across the bladder may cause urinary frequency.

Gynecologic Symptoms Distinguishing GI from GYN causes of acute abdominal pain is one of the most challenging clinical dilemmas in emergency practice. A thorough gynecologic history is indicated, including menses, mode of contraception, fertility, sexual activity, sexually transmitted diseases, vaginal discharge, recent dyspareunia, and a past gynecologic history, to include pregnancies, deliveries, abortions, ectopics, cysts, fibroids, pelvic inflammatory disease, and laparoscopy.

Vascular Symptoms History of MI, other ischemic heart disease or cardiomyopathy, atrial fibrillation, anticoagulation, congestive failure, peripheral vascular disease, or a family history of aortic aneurysm are all pertinent historical features in older patients.

PAST MEDICAL HISTORY This includes a history of recent and current medications (including nonsteroidal antiinflammatory drugs and

antibiotics), past hospitalizations, in- or outpatient surgeries, diabetes, other chronic diseases (including HIV status and risk factors), and any history of recent trauma. A social history that includes habits (tobacco, alcohol, and other drug use), occupation, possible toxic exposures, and living circumstances (homeless, dwelling heated, running water, living alone, other family members ill with similar symptoms) provides important background and context in which to place the presenting complaint of acute abdominal pain.

Physical Examination

GENERAL The patient's general appearance, including facial expression, diaphoresis, pallor, and degree of agitation provides information about the severity of pain. Although this is critically important in determining the need for analgesia, intensity of abdominal pain may bear no relationship to the severity of illness. For example, the pain of early mesenteric ischemia may be a vague discomfort, in contrast to the excruciating pain of ureteral colic. Nevertheless, uncomplicated kidney stones have no short-term mortality, while the majority of patients with ischemic small bowel go on to die.

Patients with colicky pain, which is characteristically visceral due to distention of a hollow organ, are often unable to lie still, while those with peritonitis prefer to remain immobile.

VITAL SIGNS A reliable means of obtaining a core temperature is important, although absence of fever, especially in the elderly, has no predictive value. Careful counting of rate and observation of depth of respirations for 15 s is often overlooked. However, it can provide crucial information about tachypnea or hyperpnea, which may be subtle. Pulse and blood pressure should include orthostatic changes if, after obtaining the history, there is any reason to suspect intravascular volume contraction. A pulse increase of thirty points lying to standing at 1 minute (or the development of symptoms of presyncope) has been shown to be highly specific for the loss of a liter of blood or its equivalent (roughly 3 L of NS). Changes in blood pressure have not been shown to be discriminatory, probably because they are late findings representing failure of a reflex tachycardia to maintain cardiac output. The tilt-test threshold of thirty points of pulse change may not be applicable to patients on medications such as beta-blockers, diabetics (who may have an autonomic neuropathy), and among the elderly, due to the effects of aging on the cardiac conducting system.

ABDOMEN

Inspection The abdomen should be inspected for distention (with air or fluid), scars, and masses.

Auscultation Contrary to conventional teaching, absent or diminished bowel sounds provide little clinically useful information. Patients with operative confirmation of peritonitis due to perforation of peptic ulcer have been noted to have normal or increased bowel sounds preoperatively. Hyperactive or obstructive bowel sounds, although of limited value, are somewhat more helpful for the diagnosis of small bowel obstruction (SBO). However, many with SBO can also have absent or diminished bowel sounds. It appears, therefore, that only hyperactive or obstructive bowel sounds have clinical utility, increasing the likelihood of SBO by about fivefold; however, normal or absent bowel sounds appear very nearly valueless, as evidenced by their occurrence with roughly the same frequency in both SBO and perforated peptic ulcer.

Palpation The vast majority of clinical information obtained from examination of the abdomen is acquired through gentle palpation, using the middle three fingers, and beginning at a distance from the area of maximum pain. Voluntary guarding (contraction of the abdominal

musculature in anticipation of or in response to palpation) can be diminished by asking patients to flex their knees. Those who remain guarded following this maneuver will often relax if the clinician's hand is placed over the patient's, and the patient is then asked to use their own hand to palpate their abdomen. In contrast to the symptom of pain, tenderness is a *sign* in which pain is produced by palpation. Optimally, the patient's tenderness will be confined to one of the four discrete quadrants. However, this is often not the case, and one finds more diffuse tenderness encompassing one or more of the four combined areas noted above. Peritoneal irritation is suggested by rigidity (involuntary guarding or reflex spasm of abdominal muscles), as is pain referred to the point of maximum tenderness when palpating an adjacent quadrant.

Rebound tenderness, often regarded as the clinical criterion standard for peritonitis, has several important limitations. In patients with peritonitis, the combination of rigidity, referred tenderness, and especially pain with coughing usually provides sufficient diagnostic confirmation that little additional information is gained by eliciting the unnecessary pain of rebound. False positives occur in about one patient in four without peritonitis, perhaps due to a nonspecific startle response. Based on this, one might reasonably question whether rebound has sufficient predictive value to justify the discomfort it causes patients.

Enlargement of the liver or spleen, and other masses, including a distended bladder, should be sought. One should also examine for hernias in both men and women, particularly those that are tender, suggesting incarceration or strangulation.

In women, the pelvic examination—like the pregnancy test—may provide the clinician with relevant information that would not have been expected on the basis of the history. For this reason, it is wise to perform a pelvic examination in the evaluation of abdominal pain, particularly in women of reproductive age.

Although the rectal examination is widely regarded as an essential component in the assessment of abdominal pain, particularly in suspected appendicitis, there is little evidence that rectal tenderness in patients with RLQ pain provides useful incremental information beyond what has already been obtained by other components of the physical examination. Grossly melanotic, maroon, or bloody stool indicates GI bleeding. The test for occult blood, although routinely done, loses sensitivity if not performed serially over several days. Conversely, repeated rectal examinations performed over several hours by multiple examiners tends to reduce the specificity of the test for occult blood, presumably due to local trauma. Among patients with a final diagnosis on follow-up of NSAP, 10 percent had a positive stool test for occult blood.

Basic Laboratory and Radiographic Tests

The complete blood count and plain abdominal film are among the most overutilized tests in emergency practice. Neither test offers sufficiently powerful likelihood ratios (see below) to revise disease probability. One approach to the use of both these tests is to take note only of high threshold abnormalities, e.g., a very elevated WBC ($>20,000/\text{mm}^3$), but to resist the temptation to draw *any* reassurance from a "normal" WBC or a "nonspecific bowel gas pattern."

THE BLOOD COUNT The limited clinical utility of the CBC can be demonstrated most readily by examining its performance characteristics in the three most common causes of abdominal pain: **Appendicitis**, biliary tract disease (principally cholecystitis), and NSAP. Based upon a metaanalysis of three studies containing a total of over 1800 patients, a WBC exceeding the threshold value of $10,000/\text{xL}$ only doubled the odds of appendicitis, while a WBC below this cutoff point reduced the odds by only about half. As noted below in the discussion of likelihood ratios (LRs), an LR (+) = 2 and an LR (—) = 0.4 are of marginal clinical value.

For acute cholecystitis, the LRs of the WBC count are virtually identical to those seen in appendicitis, and of equally limited clinical utility.

In one large, well-conducted series of patients with NSAP, 28 percent (95% CI; 22 to 34%) of patients were reported to have WBC counts $>10,500/\text{xL}$. In the development of a decision rule for identification of NSAP, investigators did not find the CBC to be of value in distinguishing patients with NSAP from other, more serious diagnoses. Because of the design of studies on NSAP, it is not possible to calculate a specificity or likelihood ratios for the performance of the WBC count in this setting. However, using 28 percent as the approximate sensitivity of the test, it is possible to estimate that, in order for leukocytosis to be of any value in NSAP (defined as producing LR that deviate significantly from 1), the WBC count would have to demonstrate substantially better specificity than was seen in either appendicitis or cholecystitis.

All of the above refers only to individual WBC counts. There is some evidence that serial counts may assist in the identification of appendicitis. However, in this setting, it would seem wiser to obtain a CT rather than risk a perforation or other complication while obtaining serial WBCs and waiting for development of leukocytosis.

PLAIN ABDOMINAL RADIOGRAPH The plain abdominal radiograph (PAR) is often ordered as an "abdominal series," the meaning of which is variously defined. In some institutions, this includes an upright abdomen, in others an upright chest; in still others, only a single supine film is obtained. The utility of the erect abdominal film, when added to the combination of the supine abdominal and erect chest film, is generally low and does not impact management. Abdominal films in suspected appendicitis, NSAP, or urinary tract infection are also unlikely to be helpful, and can be misleading.

An additional limitation of the plain abdominal radiograph is poor interrater reliability for commonly used radiographic signs.

Restriction of PARs to patients with suspected obstruction or perforation would reduce utilization by over 80 percent with no adverse impact on management. Ultrasound may be a more sensitive test for detection of free air than the combination of upright chest and left lateral decubitus plain films (93 vs. 79 percent), which is one of the principal uses for plain radiography in abdominal pain.³ Ultrasound can be extremely helpful, particularly as a rapid bedside screening test, but it is highly operator-dependent and limited by overlying gas and obesity. Computed tomography (CT) is markedly superior for identifying virtually any abnormality that could be seen on plain films, particularly SBO and renal colic (Tables 72-1 and 72-2). Bedside sonography, combined with computed tomography would seem to be the key to obviating the need for continued use of the PAR in the future.

DIAGNOSIS AND TESTING

Diagnosis is now more closely linked to appropriate disposition and treatment than was the case when the only interventions in abdominal pain were laparotomy or observation with medical management.

Accurate diagnosis is extremely difficult using only clinical information and basic laboratory tests. When initial and final diagnoses are compared, diagnostic accuracy falls somewhere between 50 and 65 percent overall. Diagnostic error in adults with abdominal pain increases in proportion to age, ranging from a low of 20 percent if only young adults are considered, to a high of 70 percent in the very elderly.

Although some improvement in clinical diagnostic accuracy occurs with experience, most is due to diagnostic imaging.

Performance Characteristics of Diagnostic Tests

Tables 72-1, 72-2, 72-4-72-11 provide a summary of the performance of diagnostic tests used in the ED work-up of acute abdominal pain. These test properties are displayed as sensitivity, specificity, and likelihood ratios. When derived from a metaanalysis of several studies,

TABLE 72-1 Diagnostic Tests for Small Bowel Obstruction

Target Diagnosis	Test	Sensitivity (Range)	Specificity (Range)	LR(+)	LRH
Small bowel obstruction (SBO)	Plain abdominal films	63% (44-71%)	54% (38-65%)	1	0.7
SBO high-grade	CT with IV +/- PO contrast	90% (81-97%)	96% (85-98%)	22	0.1
SBO low- & high-grade	CT with IV +/- PO contrast	64% (55-85%)	79% (68-88%)	3	0.5
SBO with ischemia	CT with IV +/- PO contrast	83% (32-100%)	88% (61-100%)	7	0.2

sensitivity and specificity, bounded by 95 percent confidence intervals (CIs), are calculated using the Summary Receiver Operating Characteristics (SROC) methodology, which adjusts for interstudy variation in diagnostic threshold.⁴ Under conditions where merged studies are too clinically or statistically heterogeneous for valid metaanalysis, aggregate sensitivity and specificity are calculated as weighted means, bounded by ranges.

DEFINITION OF LIKELIHOOD RATIOS (LR'S)⁵ In the far right-hand columns of Tables 72-1, 72-2, 72-4-72-11, test performance is expressed using positive and negative likelihood ratios (LRs).

LRs are often divided into positive and negative LRs, expressed as follows: LR of a positive test = (TPR/FPR) = [(true positive rate)/(false positive rate)] = [sensitivity/(1 — specificity)]. LR of a negative test = (FNR/TNR) = [(false negative rate)/(true negative rate)] = [(1 — sensitivity)/specificity]. LR calculations derived from sensitivities or specificities of 100 percent are calculated conservatively by using the midpoint of the 95% CI surrounding the estimate of sensitivity or specificity in order to avoid obtaining a clinically meaningless LR (+) of ∞ or an LR (—) of 0.

The formal definition of an LR (+) is simply a special case of the general definition of LRs: An LR (+) is the likelihood that a *positive* test result would be found in a patient *with* the target disorder, compared to the likelihood of a *positive* test result occurring in a patient *without* the target disorder. The definition of an LR (—) is the likelihood that a *negative* test result would be found in a patient *with* the target disorder, compared to the likelihood of a *negative* test result occurring in a patient *without* the target disorder.

INTERPRETATION OF LR'S In general, an LR (+) of 1 to 2, or an LR (—) of 0.5 to 1, alters disease probability by a small and clinically insignificant degree. In contrast, LR (+)s >10, or LR (—)s <0.1 may have a very substantial impact on clinical decision-making through meaningful revision of disease probability. LR (+)s of 2 to 10, or

LR (—)s of 0.5 to 0.1 may still make some small contribution to management, depending on their magnitude and the clinical context in which they are applied. Because LRs are odds, a diagnostic test with an LR (—) = 0.1 is as powerful as a diagnostic test with an LR (+) = 10.

CLINICAL APPLICATION OF LR'S Likelihood ratios (LRs) combine the stability of sensitivity and specificity with the utility of predictive values, resulting in an index of test performance that can be applied directly to a particular patient at the bedside. This is done by multiplying an LR (+) or LR (—) times the pretest odds of disease, resulting, respectively, in an increase or decrease in post-test odds of disease. The larger the LR (+) or the smaller the LR (—), the more powerful the test is to revise the posttest probability of a given target disorder.

Although odds (O) and probabilities (p) are mathematically different, they are conceptually similar and easily interconverted according to the following formulas: $O = p/(1 - p)$, and $p = O/(O + 1)$. Thus, if $O = 1$, $p = 1/(1 + 1) = 1/2 = .5$ or 50 percent probability; conversely, if $p = 0.5$ or 50 percent, $O = .5/(1 - .5) = .5/.5 = 1$.

Once determined, an LR can be incorporated directly into the calculation of posttest probability by employing Bayes' theorem: (LR) X (clinically estimated pretest odds of disease) = (posttest odds of disease). This simple equation illustrates a convergence between the central strategy underlying diagnostic testing, i.e., the revision of disease probability, and the fundamental nature of likelihood ratios.

The performance characteristics of the various tests shown in Tables 72-1, 72-2, 72-4-72-11 are incorporated into the discussion of specific diagnoses below.

SPECIFIC DIAGNOSES

The data in Table 72-3 were drawn from a combined series of over 8500 cases of acute abdominal pain (<1 week duration) presenting to over 200 EDs in 17 countries during a 10-year period. The data were collected on a highly standardized instrument.

TABLE 72-2 Diagnostic Tests for Renal Colic

Test	Sensitivity [95% CI] (Range)	Specificity [95% CI] (Range)	LR(+)	LR(-)
Microscopic Urinalysis	84% [81-87%]*	48% [43-53%]	2	0.3
Plain abdominal film	58% (39-68%)	74% [47-88%]	2	0.6
Nonenhanced helical CT (criterion standard)				
Intravenous pyelogram (IVP)	78% [67-88%]	95% [91-99%]	16	0.2
Ultrasound (without Doppler)	74% (19-100%)	95% (90-100%)	15	0.3
Doppler ultrasound (resistive index)	90% [79-97%]	100% [94-100%]	30	0.1

* Brackets indicate 95% CI; parentheses indicate range.

TABLE 72-3 Causes of Acute Abdominal Pain Stratified by Age

Final Diagnosis	>50 Years (N = 2406)	<50 Years (N = 6317)
Biliary tract disease	21%	6%
Nonspecific abdominal pain (NSAP)	16%	40%
Appendicitis	15%	32%
Bowel obstruction	12%	2%
Pancreatitis	7%	2%
Diverticular disease	6%	<.1%
Cancer	4%	<.1%
Hernia	3%	<.1%
Vascular	2%	<.1%
Gynecologic	<1%	4%
Other	13%	13%

In virtually all large series of acute abdominal pain in adults, the substantial majority of final diagnoses include nonspecific abdominal pain (NSAP), appendicitis, and biliary tract disease (usually cholecystitis), in that order, accounting for nearly 75 percent of all acute abdominal pain. However, as shown in Table 72-3, as patients age, the triad remains, but the order changes to: biliary tract disease (again, usually cholecystitis), followed by NSAP and appendicitis.

Intraabdominal Diagnoses by Organ System

GASTROINTESTINAL

Appendicitis In spite of a large number of algorithms and decision rules incorporating many different clinical and laboratory features, an accurate preoperative diagnosis of appendicitis has remained elusive for more than a century. In at least 20 percent of patients with appendicitis, the diagnosis is missed; conversely, normal appendices are found in 15 to 40 percent of all operations performed for suspected appendicitis. Thus the diagnosis of appendicitis turns out to be either a false positive or false negative just about as often as it turns out to be correct.⁶

Among patients presenting to an ED with acute abdominal pain, the pretest probability, or prevalence, of appendicitis is roughly 10 to 25 percent. Converting this to odds to facilitate multiplication by LR_s, the pretest odds of appendicitis in patients with undifferentiated acute abdominal pain is roughly between 0.1 and 0.3. Five clinical features appear to have sufficiently powerful LR (+)_s that the presence of *any one* should drive up the clinical odds to the point that an imaging procedure is indicated. Those clinical features with some predictive value include: Pain located in the RLQ [LR (+) = 8]; pain migration from the periumbilical area to the RLQ [LR (+) = 3]; rigidity [LR (+) = 4]; pain before vomiting [LR (+) = 2 to 3]; and a positive psoas sign [LR (+) = 2]. Anorexia is not a useful symptom. In fact, about one patient in three with surgically documented appendicitis is *not* anorectic preoperatively.

In excluding the diagnosis of appendicitis, the absence of RLQ pain [LR (—) = 0.2], presence of similar previous pain [LR (—) = 0.3], and absence of typical pain migration to the RLQ [LR (—) = 0.5] are only somewhat helpful. This is because no single historical or physical finding is sufficiently powerful to exclude the diagnosis. Therefore, to clinically rule out appendicitis, one relies upon the absence of several key features, or the presence of a strong competing alternative diagnosis. Lacking either of these conditions, an imaging procedure, usually a CT, should be obtained.

Although sonography is an option in suspected appendicitis, the **CT is generally preferred in adults and nonpregnant women** with a working diagnosis of appendicitis because ultrasound of the appendix is technically challenging, highly operator-dependent, and often unavailable after hours. Additionally, although ultrasound has a sufficiently powerful LR (+) that a positive finding usually results in surgery, its poor LR (—) precludes its use as a screening (rule-out) test. Color-flow Doppler added to the standard graded compression grayscale sonography improves test performance by detecting appendiceal and periappendiceal inflammation. However, the increment in LR_s is insufficient to change the clinical implications of the test results, i.e., a positive finding still favors surgical intervention, and a negative result fails to exclude the diagnosis.

As shown in Table 72-4, CT of suspected appendicitis can be targeted at the RLQ or include the entire abdomen and pelvis. It can be performed as an unenhanced (noncontrast) study, or may be done with various combinations of PO, IV, or colonic contrast. Although the focused appendiceal CT obtained with colonic contrast appears to have excellent test properties and has been shown to alter management in the majority (59 percent) of cases,⁷ these targeted examinations are not commonly performed because they are so narrowly focused on the RLQ that a negative result often requires a repeat abdominopelvic CT. Evidence of appendicitis on any type of abdominal CT has such a high

LR (+) that it almost invariably drives surgical intervention. Although the LR (—) is sufficiently strong to reduce the odds of appendicitis by about tenfold, it is not as strong as the LR (+). Absence of evidence of appendicitis on CT, or even visualization of an apparently normal appendix therefore does not exclude the diagnosis with the same degree of certainty that a positive CT confirms it.

For example, if the clinician is working with a 50 percent pretest probability of appendicitis (not an unreasonable estimate, given the prevalence of the disease in the population), a negative CT reduces that posttest probability to just under 10 percent. While this finding, depending upon the clinical picture, might be sufficient to stay the surgeon's hand, logical application of Bayes' theorem does not support use of a negative CT as grounds for discharging the patient from the ED. In order to make such a disposition, the prior probability of appendicitis would have to be substantially lower than 50 percent. This example also assumes the optimal conditions under which the studies used to generate the contents of Table 72-4 were conducted, i.e., complete filling of the entire appendiceal lumen in order to exclude distal appendicitis, a helical machine with narrowly collimated beams (optimally 5-mm cuts), and an experienced radiologist trained in body CT available to read the images. The relative rarity of such conditions may help to explain the observation that, in spite of several well-conducted clinical trials demonstrating the salutary impact of advances in abdominal imaging on diagnostic accuracy in appendicitis, the population-based incidence of misdiagnosis and perforation have not changed over the past decade.⁸

Biliary Tract Disease This is the most common diagnosis in ED patients ≥ 50 years old. Among those found to have pathologically confirmed acute cholecystitis, the majority lack fever and about 40 percent lack a leukocytosis. Recognition that the diagnoses of cholecystitis, "biliary colic," and symptomatic common duct obstruction may represent pathologically distinct entities that cannot be reliably distinguished from one another on clinical grounds, has led some authors to redefine the *clinical* target disorder as simply "biliary tract disease." Although there is an association between symptomatic biliary tract disease and steady postprandial upper abdominal pain that radiates to the upper back, the likelihood ratios of individual signs, symptoms, and combinations of signs and symptoms are relatively weak discriminators. Just over one-third of patients have pain isolated to the RUQ, although about two-thirds have tenderness in that location. Most of the remainder complain of diffuse pain in the upper half of the abdomen, and among those with pain in the lower abdomen, it is almost invariably in the RLQ. Among the one-third who do not have RUQ tenderness, the distribution is about equally divided among the upper half, the right side, and generalized tenderness throughout the belly.

As shown in Table 72-5, sonography is the initial test of choice for patients with suspected biliary tract disease. In many institutions, this can be performed rapidly at the bedside by the ED physician as an extension of the clinical assessment. Ultrasound is better in the identification of cholecystitis than in the detection of common duct obstruction. Cholescintigraphy (radionuclide scanning) of the biliary tree is a more sensitive test than sonography for the diagnosis of both these conditions.⁹ At present, CT does not have a major role in the initial work-up of biliary tract disease, although it will often identify unexpected abnormalities of the gallbladder on an abdominopelvic double contrast CT obtained for other reasons, particularly if thinly collimated cuts are obtained. MR cholangiography has shown extremely good sensitivity and specificity in identifying stones and other obstructions of the common duct.¹⁰

Small Bowel Obstruction The central issues in small bowel obstruction (SBO) are diagnosis of the primary disorder and early detection of secondary strangulation or ischemia, when present. Only two historical features (previous abdominal surgery and intermittent/colicky pain) and two physical findings (abdominal distention and abnormal bowel sounds) appear to have predictive value. Although about

TABLE 72-4 Diagnostic Tests for Appendicitis

Test	Sensitivity [95% CI] (Range)	Specificity [95% CI] (Range)	LR(+)	LR(-)
Plain abdominal radiograph	48% [41-54%]	58% [54-62%]	1	0.9
Abdominopelvic ultrasound (real-time, graded compression, gray-scale)	55% [48-62%]	95% [93-97%]	11	0.5
Abdominopelvic ultrasound (color Doppler added to gray-scale)	84% [77-91%]	96% [88-100%]	21	0.2
Abdominopelvic unenhanced helical CT (no PO, IV, or colonic contrast)	88% [82-94%]	97% [94-99%]	29	0.1
Abdominopelvic helical CT (double [PO + IV] contrast; no colonic contrast)	91% [81-98%]	95% [90-98%]	18	0.1
Focused appendiceal (RLQ) unenhanced helical CT (no PO, IV, or colonic contrast)	87% [78-93%]	97% [92-99%]	29	0.1
Focused appendiceal (RLQ) helical CT (PO contrast only; no IV or colonic contrast)	76% [62-87%]	95% [90-98%]	15	0.3
Focused appendiceal (RLQ) helical CT (PO + colonic contrast; no IV contrast)	100% [94-100%]	95% [84-99%]	21	0.03
Focused appendiceal (RLQ) helical CT (colonic contrast only; no PO or IV contrast)	98% [90-100%]	98% [89-100%]	49	0.02
MRI (gadolinium-enhanced)	97% [85-100%]	92% [75-99%]	12	0.03

two-thirds of SBO presents with generalized or central abdominal pain, and about half have generalized tenderness, the LRs of these findings alone or in combination are such that SBO is another diagnosis that requires imaging confirmation. The general limitations of bowel sounds have been noted previously. As shown in Table 72-1, and also discussed above, the plain abdominal film is hampered by a large number of indeterminate readings, leaving it with LRs that are of marginal utility. The CT is far superior to the plain film in detection of high-grade SBO, but is limited in its ability to identify low-grade obstruction, which may require small-bowel follow-through.¹¹

Those patients with ischemic bowel secondary to strangulation are extremely difficult to detect clinically or with plain radiography. Here the CT is useful in altering the likelihood of ischemia, and has been shown to have a substantial impact on treatment.

Acute Pancreatitis About 80 percent of acute pancreatitis in the United States is caused by alcohol or gallstones, with one etiology predominating over the other depending on the population studied. The pain and tenderness of acute pancreatitis are limited to the anatomic area of the pancreas in the upper half of the abdomen in only a minority of instances. Most patients' pain and tenderness include this area, but in about half the pain extends well beyond the upper abdomen to cause generalized tenderness. This may be related to the absence of a capsule that might otherwise contain the inflammation, and to the difficulty of localizing pathology that—much like that of an abdominal aortic aneurysm—resides deep in the belly and extends into the retroperitoneum. Other features of the history and physical exam, such as quality of pain—which is steady and severe in the majority of patients—or vomiting, have not been shown to have sufficient discriminatory power

TABLE 72-5 Diagnostic Tests for Biliary Tract Disease

Target Diagnosis	Test	Sensitivity [95% CI] (Range)	Specificity [95% CI] (Range)	LR(+)	LR(-)
Cholelithiasis	Plain abdominal radiograph	64% [59-68%]	68% [52-83%]	2	0.5
Cholelithiasis	Ultrasound (US)	91% [84-97%]	97% [95-99%]	30	0.1
Cholelithiasis	CT	85% (77-96%)	97% (86-99%)	28	0.2
Acute cholecystitis	US	86% (65-97%)	97% (87-100%)	29	0.1
Acute cholecystitis	Color velocity imaging & power Doppler US	93% (77-100%)	97% (88-100%)	31	0.1
Acute cholecystitis	Radionuclide scanning	95% [91-98%]	90% [86-94%]	10	.05
Common duct obstruction	US	90% (38-95%)	92% (48-97%)	11	0.1
Common duct obstruction	CT	83% (51-90%)	87% (44-94%)	6	0.2
Common duct obstruction	Radionuclide scanning	93% (81-99%)	92% (84-100%)	12	0.1
Common duct obstruction	MR cholangiography	95% (85-96%)	97% (85-99%)	32	0.05
Common duct stone	US	85% (19-76%)	89% (52-98%)	8	0.2
Common duct stone	CT	71% (29-82%)	86% (55-92%)	5	0.3
Common duct stone	MR cholangiography	95% (86-100%)	96% (87-100%)	24	0.05

to make them clinically useful. Thus most patients with upper, central, or generalized abdominal pain and tenderness, who lack an alternative explanation for their presentation will require further testing.

As lipase assays have improved in accuracy and speed over the last several years, serum lipase has begun to replace amylase as the preferred ED screening test for suspected acute pancreatitis. By setting the threshold for a positive test at twice the upper limit of normal serum lipase, the likelihood ratios for lipase are better than twice as powerful as those of serum amylase in confirming or excluding the diagnosis of acute pancreatitis (Table 72-6).¹² Preliminary reports that ratios of urine to serum amylase or of lipase to amylase improve diagnostic accuracy have not been validated. Like amylase, the accuracy of serum lipase in the diagnosis of acute pancreatitis is inversely related to the time elapsed between symptom onset and presentation.

Depending upon institutional custom, a diagnosis of acute pancreatitis may be sufficient to determine the appropriate admitting service. However, in settings where not all pancreatitis is admitted to a single service, or where it is expected that the ED will make a monitored vs. unmonitored bed admitting decision, it may be necessary for the ED to assess the patient for biliary pancreatitis and for the likelihood of peripancreatic complications, such as necrosis, hemorrhage, or drainable fluid collections. Although the height of pancreatic enzyme elevations do not have prognostic value, a double contrast helical CT stages severity and predicts mortality earlier than the Ranson criteria.

Because timely identification of biliary pancreatitis is important, early assessment for common bile duct obstruction is necessary, particularly among patients over 50 years old. All patients with an ALT >150 U/L (about 3X normal), including alcoholics, are at increased risk of biliary pancreatitis (see Table 72-6). Because elevations in transaminase due to alcoholic hepatitis may mask an increased ALT secondary to obstruction, this subset of alcoholic patients warrants evaluation for common duct obstruction. Unfortunately, there are no blood tests or imaging modalities short of MR cholangiography that possess a sufficiently powerful LR (—) to exclude common duct obstruction in all patients (see Table 72-6). Depending on availability, a double contrast helical CT is usually performed first to examine the pancreas and identify peripancreatic complications. Contingent upon the CT protocol used—principally the thinness of the collimated beam—the common bile duct may be adequately visualized. Usually, however, it is necessary to follow the CT with a sonogram of the biliary tree because the LR (—) of ultrasound is superior to CT in this setting (see Table 72-6).¹³ If sonography is unavailable, a radionuclide scan is a reasonable alternative test for the detection of *complete* ob-

struction. In the future, the problem of distinguishing primary inflammatory (usually alcoholic) pancreatitis from secondary obstructive (usually biliary) pancreatitis may be resolved through wider availability of MR cholangiopancreatography (MRCP). This test simultaneously and noninvasively images the pancreas and common bile duct, and may ultimately obviate the need for purely diagnostic ERCP.

Diverticulitis Clinical diagnostic accuracy in one large study of colonic diverticulitis was only 34 percent [95% CI; 26 to 42%]. When the "possible/equivocal" clinical diagnoses were removed from analysis, and only those patients with a pretest diagnosis of either "highly suspected" or "very unlikely" were included as clinical positives and negatives respectively, the LR (+) was 2 to 3, and the LR (—) was 0.4, neither of which offers much help in the revision of disease probability. Of those patients with diverticular abscesses, diagnostic performance was somewhat better, with 70 percent categorized as "highly suspected" and the remainder as "possible/equivocal." No documented abscesses were categorized clinically as "very unlikely."

Pain in diverticulitis was confined to the LLQ in less than one-fourth of documented cases, and to the lower half of the abdomen in only an additional one-third of patients. With respect to tenderness, it was as likely to be generalized as it was to be limited to the lower half of the abdomen or to the LLQ. About 10 percent of patients with operatively confirmed diverticulitis lacked abdominal pain and 20 percent had no abdominal tenderness whatsoever, most of whom were elderly. Older patients are also at risk for a severe and often fatal complication of diverticulitis only rarely seen in younger age groups: free perforation of the colon.

As shown in Table 72-7, CT with colonic contrast is the test of choice for diverticulitis, demonstrating excellent performance characteristics that are superior to ultrasound. Sonography relies on identification of an inflamed diverticulum to make the diagnosis, which is often obscured in patients with complicated diverticulitis.¹⁴ In contrast, CT accurately identifies abscesses and other complications, informing surgical management strategies.¹⁵

GENITOURINARY

Renal Colic As in appendicitis, a number of clinical decision rules have been developed to identify patients with the preimaging diagnosis of ureterolithiasis. Most algorithms include features of the pain, e.g., location (unilateral flank), onset (abrupt), quality (colicky), and radiation (groin/testicle/labia). Although hematuria and plain abdomi-

TABLE 72-6 Diagnostic for Acute Pancreatitis

Target Diagnosis	Test	Sensitivity (Range)	Specificity (Range)	LR(+)	LR(-)
Inflammation	Serum amylase	82% (72-93%)	85% (78-94%)	5	0.2
Inflammation	Serum lipase >2X normal	90% (79-99%)	92% (85-98%)	11	0.1
Pancreatic necrosis	CT with PO & bolus IV contrast	92% (75-100%)	95% (92-100%)	18	0.1
Drainable collections	Transabdominal ultrasound (US)	54% (23-83%)	88% (47-100%)	4	0.5
Drainable collections	CT with PO & bolus IV contrast	90% (72-100%)	48% (32-85%)	2	0.2
Drainable collections	MRI (unenhanced)	92% (66-100%)	88% (79-100%)	8	0.1
Acute hemorrhagic pancreatitis	Unenhanced CT (criterion standard)	—	—	—	—
Biliary pancreatitis	Serum alanine aminotransferase (ALT) >3X normal	54% (38-73%)	92% (77-96%)	7	0.5
Common bile duct obstruction	US	90% (38-95%)	92% (48-97%)	11	0.1
Common bile duct obstruction	CT	83% (51-90%)	87% (44-94%)	6	0.2
Common bile duct obstruction	Radionuclide scanning	93% (81-99%)	92% (84-100%)	12	0.1
Common bile duct obstruction	MR cholangiography	95% (85-96%)	97% (85-99%)	32	0.05

TABLE 72-7 Diagnostic Tests for Acute Diverticulitis

Target Diagnosis	Test	Sensitivity (Range)	Specificity (Range)	LR (+)	LR (—)
Inflammation or abscess	Ultrasonography (high resolution, graded compression)	83% (77-91%)	95% (86-99%)	17	0.2
Inflammation or abscess	Helical CT with colonic contrast only (no IV or PO contrast)	98% (88-99%)	99% (96-100%)	98	0.02

nal films still appear in many clinical algorithms, the weak LR of both tests, as shown in Table 72-2, do not provide strong support for their continued inclusion in the diagnostic evaluation of suspected renal colic.¹⁶

Although the IVP has a specificity comparable to unenhanced helical CT, because of the IVP's poor sensitivity, demonstrated in head-to-head comparison, noncontrast helical CT has become the criterion standard for the diagnosis of renal colic. Traditional sonography has performance characteristics that are similar to those of the IVP (see Table 72-2). However, with the addition of Doppler ultrasound, elevation of the "renal resistive index" in one kidney relative to the other may identify the presence of a stone in the ipsilateral ureter. Based on preliminary data, this test appears to have a strong LR (+), but its LR (—), though good, is not as powerful as that of unenhanced helical CT (see Table 72-2). Because this test requires specialized equipment and a skilled operator, its availability to the ED is not comparable to CT.

In older patients, any presentation that resembles renal colic, with or without hematuria, mandates the exclusion of an abdominal aortic aneurysm (AAA). This is yet another reason to obtain a noncontrast helical CT, since it performs extremely well in the detection of both ureteral stones and AAAs.

Because the GU tract is mostly retroperitoneal, it only uncommonly causes significant anterior abdominal tenderness. A notable exception to this is an impacted stone at the ureterovesical (U-V) junction where the ureter enters the bladder, producing ipsilateral lower quadrant pain and tenderness. Because stones at the U-V junction (like those at the uretero-pelvic [U-P] junction) are less likely to produce colicky pain than are stones located between the top and bottom of the ureter, impaction of a stone at the U-V junction on the right may easily mimic appendicitis, and will require a noncontrast CT to identify stone disease. If this shows neither a stone nor evidence of other intraabdominal pathology, a double contrast abdominopelvic CT should be obtained, searching for evidence of appendicitis.

Acute Urinary Retention Another common GU cause of abdominal pain is acute urethral obstruction, producing a distended bladder. When the obstruction is truly acute, the tense bladder often feels like a solid mass rather than a fluid-filled hollow viscus. However, if one always considers this common entity when confronted with a midline mass of variable tenderness arising from the lower half of the abdomen, insertion of a urethral catheter easily makes the diagnosis and treats the immediate problem.

GYNECOLOGIC PAIN

Acute Pelvic Inflammatory Disease Absence of a criterion standard has further confounded the already clinically difficult diagnosis of acute pelvic inflammatory disease (PID). Laparoscopic and histopathologic findings, both of which have been proposed as diagnostic standards, are discordant. Because gross laparoscopic findings have historically been used as the standard in most well-designed studies, the LR of clinical features, laboratory results, and sonographic findings that follow have been measured against direct macroscopic inspection of the adnexa, unless otherwise noted.

Symptoms such as lower abdominal pain, which would be expected to have a high LR (—) for PID, have not been studied because they typically represent inclusion criteria for study enrollment. To date, there have been no historical features associated with laparoscopic PID that demonstrate clinically useful LR in more than one study population. Similar to lower abdominal pain, signs such as adnexal and cervical motion tenderness have not been well-studied because they have also been used as inclusion criteria in most investigations. The only physical finding associated with laparoscopic PID across more than one study population is an abnormal vaginal discharge. In spite of this statistical association, the LR of vaginal discharge range from 0.5 to 2.5, representing very limited power to alter disease probability. Elevated temperature and a palpable mass have been inconsistently associated with PID. The white blood cell count has not been found to be helpful in any of the studies that examined it. For the performance characteristics of other laboratory tests that have been associated with PID (e.g., the erythrocyte sedimentation rate [ESR] and C-reactive protein [CRP]), see Table 72-8. An examination of this table suggests that the best noninvasive test presently available for suspected PID is transvaginal sonography, in which a positive test result, such as a thickened tubal wall, increases the likelihood of PID about 18 times. If this is supplemented by transvaginal power Doppler, a negative test result, such as absence of the hyperemia associated with tubal inflammation, will decrease the likelihood of PID by about tenfold.¹⁷

As in the evaluation of ectopic pregnancy (see below), the role of culdocentesis in the diagnosis of PID is *not* well-supported by evidence.

Ectopic Pregnancy In ruptured ectopic pregnancy, abdominal pain is almost universally present. However, as emphasis in ectopic pregnancy has shifted to identification of patients prior to rupture—with the goal of preserving fertility—pain may be absent at this earlier stage, with a sentinel complaint of only vaginal bleeding. Therefore, any woman of childbearing age who presents to the ED with abdominal pain *or* abnormal vaginal bleeding should receive a qualitative pregnancy test (either urine or serum) as a screening measure.

The poor predictive performance of historical features, such as "risk factors," and of the physical examination (sensitivity 19 percent, LR [—] = 0.8 for ectopic pregnancy among women with high hCG levels), argue persuasively that this diagnosis cannot be excluded on clinical grounds.

For this reason, the results of a urine or serum pregnancy test, independent of other data, will determine if further testing is indicated to exclude an ectopic. All commercial pregnancy tests are highly accurate, with excellent LR (Table 72-9). If the qualitative hCG is positive, the preferred test is bedside transvaginal sonography (TVS), targeted solely at answering the question: Is this pregnancy in the uterus? In patients not undergoing treatment for infertility, clear visualization of an intrauterine pregnancy (IUP) in two perpendicular views essentially excludes an ectopic pregnancy. If an IUP is not seen, this must be interpreted in the context of the discriminatory zone (DZ) of the quantitative hCG. The DZ is the threshold level of serum HCG, above which a *normal* IUP should be seen on sonography. The accuracy of TVS permits reduction of the DZ to an operator-dependent level of 1500 mIU/mL. The performance of the TVS in the identification or exclusion of intrauterine and ectopic pregnancy is shown as a func-

TABLE 72-8 Diagnostic Tests for Acute Pelvic Inflammatory Disease

Target Diagnosis	Test	Sensitivity [95% CI] (Range)	Specificity [95% CI] (Range)	LRI+I	LR(-)
Salpingitis (macroscopic laparoscopy)	Erythrocyte sedimentation rate >15 mm per h	78% (45-81%)	44% (25-57%)	1	0.5
Salpingitis (macroscopic laparoscopy)	C-reactive protein	70% (54-93%)	59% (48-90%)	2	0.5
Salpingitis (macroscopic laparoscopy)	Endometrial biopsy	80% (70-89%)	76% (67-89%)	3	0.3
Salpingitis (macroscopic laparoscopy)	<i>Gonococcus</i> or <i>Chlamydia</i> cultured from upper genital tract	65% [41-85%]	100% [75-100%]	5	0.4
Salpingitis (macroscopic laparoscopy)	Transvaginal power Doppler	100% [83-100%]	80% (56-94%)	5	0.1
Endometritis (endometrial biopsy)	Conventional transvaginal sonography	85% [54-98%]	100% [91-100%]	18	0.2
Salpingitis (fimbrial minibiopsy)	Laparoscopy (macroscopic)	50% [29-71%]	80% [66-90%]	2	0.6
Endometritis (endometrial biopsy)	Laparoscopy (macroscopic)	93% [68-100%]	67% [41-87%]		0.1
	Laparoscopy (macroscopic)	48% [30-67%]	79% [66-88%]		0.7
Salpingitis/endorrhetitis (fimbrial minibiopsy or endometrial biopsy)					
<i>Chlamydia</i> cultured from upper genital tract	Laparoscopy (macroscopic)	53% [28-77%]	67% [22-96%]		0.7

tion of hCG levels in Table 72-9.¹⁸ Although there is a broad range of normal variation in hCG kinetics, failure of levels to increase by about 66 percent within 48 h in first-trimester pregnancy suggests an abnormal gestation. This will not distinguish a threatened miscarriage or blighted pregnancy from an ectopic. However, it does signal a potential problem that requires tracking of serial hCGs over time and subsequent investigation with TVS. If a diagnosis cannot be firmly established, laparoscopy is indicated.

Progesterone levels may be helpful if >22 ng/mL, since this markedly reduces the likelihood of an ectopic. A serum progesterone below this threshold, however, is not helpful (LR [+]=1), since most pregnant women with levels <22 ng/mL will not be harboring an ectopic.¹⁹

As shown in Table 72-9, culdocentesis compares poorly to TVS performed by an experienced sonographer above the DZ, both in the

identification of ectopic pregnancy and in distinguishing ruptured from unruptured ectopics. Indeed, LR associated with culdocentesis, analyzed under conditions that optimize test performance by excluding nondiagnostic (dry) taps, range between 0.4 and 3, indicating poor discrimination. These data suggest that, with the widespread availability of quantitative hCG measurement and experienced TVS, there is little justification for performing this invasive and painful procedure.

VASCULAR

Abdominal Aortic Aneurysm Although abdominal aortic aneurysms (AAAs) have little in common with aortic dissections, these two major forms of catastrophic disease of the aorta are often lumped together. Dissections are uncommon causes of abdominal pain and, because they almost invariably originate in the thoracic aorta,

TABLE 72-9 Diagnostic Tests for Ectopic Pregnancy

Target Diagnosis	Test	Sensitivity [95% CI] (Range)	Specificity [95% CI] (Range)	LR(+)	LR(-)
Pregnancy	Serum hCG [a 10 mIU/mL = (+)]	99% [92-100%]	98% [94-100%]	50	.01
Pregnancy	Serum hCG [≥25 mIU/mL = (+)]	98% [91-100%]	99% [94-100%]	98	.02
Pregnancy	Urine hCG [>20 mIU/mL = (+)]	98% [96-100%]	98% [96-99%]	49	.02
Pregnancy	Urine hCG [>50 mIU/mL = (+)]	95% [90-98%]	99% [97-99%]	95	.05
IUP	TVS on all patients w/ (+) hCG	94% [90-97%]	93% [88-97%]	13	.06
IUP	TVS on patients w/ hCG <1500 mIU/mL	33% [10-65%]	98% [90-100%]	16	0.7
IUP	TVS on patients w/ hCG >1500 mIU/mL	98% [95-99%]	90% [81-96%]	10	0.2
Ectopic	TVS on all patients w/ (+) hCG	56% [35-76%]	99% [97-100%]	56	0.4
Ectopic	TVS on patients w/ hCG <1500 mIU/mL	25% [5-57%]	96% [87-99%]	6	0.8
Ectopic	TVS on patients w/ hCG >1500 mIU/mL	80% [52-96%]	99% [97-100%]	80	0.2
Ectopic	Progesterone <22 ng/mL	98% [96-100%]	29% [27-31%]	1	.07
Ectopic	Culdocentesis	56% (38-81%)	70% (20-86%)	2	0.6
Ruptured ectopic	Culdocentesis	68% (52-84%)	76% (39-93%)	3	0.4

usually produce chest or upper back pain before migrating into the abdomen as the dissection moves distally.

AAAs on the other hand tend to enlarge, become aneurysmal over years, and rather than dissect, leak and rupture. Fewer than half of AAAs present with the triad of hypotension, abdominal or back pain, and a pulsatile abdominal mass; over three-quarters are normotensive. Spontaneous containment of bleeding is the principal determinant of prehospital survival and degree of hypotension, if any, on arrival. Absence of abdominal pain or tenderness is entirely compatible with a contained leak extending into the retroperitoneum. Neither the presence or absence of femoral pulses or an abdominal bruit have LRs that deviate very far from 1, and therefore are not helpful clinically. In fact, palpation is the only feature of the physical exam that has been shown to have some clinical utility. As might be expected, the LR (—) for palpation is poor, ranging from 0.5 to 0.7 in a recent pooled analysis. The LR (+), however, ranges from 12 to 16 as the size of the aneurysm increases from >3 cm to >4 cm.²⁰ Thus, inability to palpate an enlarged aorta in a patient with suspected AAA should not deter one from obtaining an imaging procedure in a stable patient or moving directly to the OR if the patient is unstable. Conversely, palpation of an enlarged aorta in the same patient should only serve to increase the urgency with which imaging or surgical intervention occurs as the next step, again contingent upon hemodynamic instability.

In emergency practice, this means that any stable patient, particularly one over 50 years old, presenting with recent onset of abdominal/flank/low back pain is likely to require either a normal aortic sonogram (performed by an experienced operator) or a noncontrast helical CT (criterion standard) before an AAA can be excluded from the differential diagnosis. Although sonography has the advantage of ready availability at the bedside in many EDs, in contrast to the CT it can only identify an AAA, and cannot provide additional information about leakage or rupture (Table 72-10). In unstable patients, if a bedside sonogram can be obtained during resuscitation, visualization of an enlarged aorta in the setting of a suggestive clinical picture is taken as de facto evidence of leakage or rupture, requiring immediate surgery.

Because MRI is limited in its ability to identify fresh bleeding, MR technology, including MR angiography, is not an appropriate emergency procedure.

As noted earlier, the appearance of "renal colic" in older patients should be regarded as representing an AAA until the CT proves otherwise. Fortunately, the important distinction between a kidney stone and an AAA can be readily made by obtaining a helical unenhanced abdominopelvic CT.

Mesenteric Ischemia Mesenteric ischemia can be divided into arterial and venous disease (mesenteric venous thrombosis [MVT]). Arterial disease can be subdivided into occlusive and nonocclusive (NOMI or low-flow state). Finally, occlusive arterial disease (generally understood to mean superior mesenteric artery occlusion) may be further

categorized into thrombotic or embolic. Several features combine to produce a very high mortality associated with mesenteric ischemia: (1) Unless young patients have an arrhythmia (usually atrial fibrillation causing embolization) or a hypercoagulable state (causing MVT), individuals with mesenteric ischemia tend to be older with substantial age-related comorbidity; (2) the small bowel, which is supplied by the superior mesenteric artery, has a warm ischemia time of only 2 to 3 h; (3) the clinical picture is characterized initially by poorly localized visceral-type abdominal pain, without tenderness; (4) patients may become transiently better after a few hours of ischemia at the time of onset of mucosal infarction, only to develop peritoneal findings as full-thickness necrosis of the bowel wall becomes clinically apparent over several more hours; and (5) timely diagnosis requires that conventional angiography, an invasive procedure, be obtained early in older, often fragile patients who may not appear initially to be as ill as they are.

There are some distinctions that can be made among the four major forms of mesenteric ischemia: (1) embolic disease is the most abrupt in onset, and MVT the most indolent, with the temporal profile of arterial thrombosis somewhere in between; (2) NOMI is usually accompanied by clinical evidence of a low-flow state, typically due to cardiac disease, which responds to improvement in cardiac output; (3) MVT may be more amenable to noninvasive diagnosis with CT, occurs in younger patients, has a lower mortality, and can be treated with immediate anticoagulation; (4) following diagnosis, arteriography with papaverine infusion may be an important component of treatment in patients with splanchnic vasoconstriction.

Elevation of serum phosphate was initially thought to be a sensitive marker for mesenteric ischemia, but this has not been supported by subsequent work. As shown in Table 72-11, serial serum lactates that remain *persistently* normal reduce the likelihood of mesenteric ischemia by more than tenfold. Unfortunately the test has a weak LR (+) because lactate is elevated in many other conditions, and therefore lacks adequate power to increase the probability of mesenteric ischemia in any clinically important way. Conventional invasive angiography is the diagnostic and initial therapeutic procedure of choice at the present time (see Table 72-11).²¹

Ischemic Colitis As is characteristic of all vascular diseases, ischemic colitis is predominantly a disease of older patients. About 80 percent of individuals have diffuse or lower abdominal visceral pain, accompanied by diarrhea in about 60 percent, often mixed with blood. In contrast to mesenteric ischemia, ischemic colitis is not generally due to large-vessel occlusive disease, angiography is not usually indicated, and if performed is often normal. The diagnosis is typically made by colonoscopy, which is preferred to sigmoidoscopy. Color Doppler sonography can also be used for diagnosis. Rectal sparing, in contrast to ulcerative colitis, is a typical finding in ischemic colitis. Not surprisingly, the severity of the presentation is related to the extent

TABLE 72-10 Diagnostic Tests for Abdominal Aortic Aneurysm

Target Diagnosis	Test	Sensitivity (Range)	Specificity (Range)	LR[+]	LR[-]
Uncomplicated abdominal aortic aneurysm (AAA)	Sonography	92% (81-100%)	89% (85-100%)	9	0.1
Leaking/ ruptured AAA (intra- or retro-peritoneal)	Sonography	12% (4-52%)	84% (34-100%)	1	1
Uncomplicated or leaking/ruptured AAA (intra- or retro-peritoneal)	CT	97% (82-100%)	95% (86-100%)	19	.03
Detailed preoperative anatomy	Conventional angiography	No longer a preferred emergency procedure			
Detailed preoperative anatomy	MRI/MRA	Not a preferred emergency procedure at this time			

TABLE 72-11 Diagnostic Tests for Ischemia of the Small and Large Bowel

Target Diagnosis	Test	Sensitivity [95% CI] (Range)	Specificity [95% CI] (Range)	LR(+)	LR(-)
Small bowel ischemia	Conventional angiography	88% (62-98%)	95% (93-100%)	18	0.1
Small bowel ischemia	CT & CT angiography (including multi-detector row image acquisition with 3D reformatting)	77% (57-92%)	85% (71-100%)	5	0.3
Small bowel ischemia	Gadolinium-enhanced MRA (including 3D reformatting)	83% (78-100%)	89% (71-99%)	8	0.2
Small bowel ischemia/infarction	Serum lactate (persistent elevation without alternative explanation)	90% (66-100%)	62% (42-77%)	2	0.2
Ischemic colitis	Colonoscopy	93% (82-100%)	90% (85-100%)	9	0.1
Large bowel infarction	Color Doppler sonography	82% [48-98%]	92% [64-100%]	10	0.2

of occlusion and ischemia. In the majority of cases, only segmental portions of the mucosa and submucosa slough. These then go on to heal uneventfully with conservative management. At the opposite end of the spectrum is full-thickness infarction of the colon, occurring in about 20 percent of cases. Bowel necrosis, whether segmental or pancolitic, causes peritonitis, requiring partial or complete colectomy.

In between mucosal/submucosal ischemia and full-thickness infarction of the large bowel is an intermediate form of ischemic colitis involving portions of the muscular layer of the large bowel. These areas of deep but incomplete ischemia may later heal with stricture formation, placing the patient at risk for subsequent large bowel obstruction or chronic segmental colitis. In many instances, the attack of ischemic colitis that led to stricture formation may have been so mild that medical care was not sought at the time, and the episode forgotten entirely by the patient.

Extraabdominal Diagnoses

CARDIOPULMONARY If the patient is complaining of pain in the upper half of the abdomen (with or without tenderness), the chest should be examined for basilar involvement of lung parenchyma or pleura. Because the stethoscope exam is neither sensitive nor specific for the diagnosis of pneumonia, pulmonary infarction, small pleural effusions, or small pneumothoraces, a chest film should be obtained. Whether a decubitus or expiratory film is requested depends on clinical suspicion of effusion or pneumothorax, respectively. A negative film, especially if the pain is pleuritic in quality, introduces pulmonary embolism into the differential diagnosis.

If the pain is epigastric, and the patient is in an age/gender group in whom coronary artery disease is prevalent, a further cardiac history and ECG should be obtained. Ischemic cardiac pain referred to the epigastrium is not associated with significant tenderness, although cutaneous dysesthesia may be present, similar to that found in the upper extremity in other ischemic cardiac pain patterns.

ABDOMINAL WALL Pain originating from the abdominal wall may be confused with visceral pain because superficial innervation from the lower thoracic roots enter the spinal cord via the same dorsal horn as the deeper visceral afferents. A useful and underutilized test is the sit-up test, also known as Carnett's sign. Following identification of the site of maximum abdominal tenderness, patients are asked to fold their arms across their chest and sit up halfway. The examiner maintains a finger on the tender area, and if palpation in the semi-sit-up position produces the same or increased tenderness, the test is said to be positive for an abdominal wall syndrome. The logic of this is that tensing of the abdominal muscles would be likely to protect the underlying peritoneum and intraabdominal organs, thus reducing tenderness if the cause of pain were deep. In patients unable to perform a sit-up,

simply asking them to raise their head and shoulders off the bed is usually sufficient to tense the abdominal muscles.

Abdominal wall syndromes overlap with hernias, neuropathic causes of abdominal pain, and NS AP.

HERNIAS Hernias represent a special type of abdominal wall syndrome, characterized by a defect through which intraabdominal contents protrude, often intermittently, during transient increases in intraabdominal pressure. Uncomplicated hernias are ordinarily asymptomatic or at worst, aching and uncomfortable, but do not generally cause significant pain unless they have become incarcerated or strangulated. Although the vast majority of hernias are inguinal, there are many other types that must be considered, including incisional, periumbilical, and particularly in women, femoral hernias. Sonography of the abdominal wall is helpful in identifying hernias and other causes of abdominal wall pain.

OTHER ABDOMINAL WALL SYNDROMES Other causes of abdominal wall pain include rectus sheath hematomas and trauma to other portions of the abdominal wall. In older patients or in those on anticoagulants, the trauma may be minor and forgotten. In circumstances in which the injury is due to stretching, causing tearing of muscle fibers, the overlying skin will not show any evidence of bruising that might otherwise provide a clue to the presence of bleeding into the abdominal wall.

TOXIC-METABOLIC

Toxic A large number of infectious agents irritate the GI tract, producing pain that is usually crampy. Concomitant vomiting or diarrhea suggests a gastroenteritis or enterocolitis. Although many agents cause both upper and lower GI tract symptoms, in adults usually one symptom complex predominates over the other. Because most of these infections are confined to the mucosa of the GI tract, there is an absence of significant tenderness. This is because the parietal peritoneum is not irritated by mucosal disease. If infarction, penetration, or perforation of the bowel wall occurs, as may happen with some of the invasive dysenteries (e.g., *Salmonella*), peritoneal tenderness follows. This is the reason that abdominal tenderness of any significance should never be attributed to uncomplicated "gastroenteritis." Furthermore, because the overall incidence of symptomatic mucosal GI infections declines markedly with age (with the exception of antibiotic-associated diarrhea), the probability of "gastroenteritis" as the basis for abdominal complaints, particularly pain, in the elderly is very low indeed.

Other infections are associated with abdominal pain, although their pathophysiology is less clear. These include group A beta-hemolytic streptococcal pharyngitis, with or without associated scarlet fever, Rocky Mountain spotted fever, and early toxic shock syndrome.

The other major category of toxic causes of abdominal pain are those secondary to poisoning and overdose. These are numerous and tend to be nonspecific/nondiagnostic in most instances. An exception to this is envenomation by the female black widow spider, which is said to mimic peritonitis. This might represent a diagnostic dilemma if no history was taken and only the abdomen was examined. However, because the rigid abdomen following envenomation is due to muscular spasm, which begins at the site of the bite and gradually spreads to involve other large muscle groups of the back and proximal extremities, the prominence of extraabdominal signs and symptoms, as well as their historical evolution, should point the clinician away from a primary intraabdominal process. Isopropanol-induced hemorrhagic gastritis may be associated with cramping pain. Cocaine-induced intestinal ischemia progressing to infarction and perforation has been reported. Iron poisoning produces abdominal pain, and may cause hematemesis due to its direct corrosive effects on the GI tract. Large amounts of iron left in the stomach may also cause perforation. Mercury salts cause severe corrosion of the GI tract, associated with shock. Acute inorganic lead toxicity is typically associated with severe, crampy, abdominal pain. This is in contrast to *chronic* lead toxicity in which abdominal pain, if present, is usually less severe and often associated with constipation. The development of abdominal pain following electrical injury suggests a potentially serious complication and the need for admission. Opioid withdrawal produces abdominal pain, usually crampy in character, associated with diaphoresis and piloerection. In some individuals, the abdominal skin is dysesthetic, but significant tenderness should not be present. Mushroom toxicity, though rarely fatal, is commonly accompanied by a chemical gastroenteritis and severe abdominal pain out of proportion to tenderness.

Metabolic Anion-gap metabolic acidoses, particularly those seen in diabetic (DKA) and alcoholic (AKA) ketoacidosis, are common causes of abdominal pain. Although the discomfort associated with DKA and AKA has been attributed to gastric distention and paralytic ileus, this has not been clearly substantiated. In DKA or AKA, it is critical to consider the possibility that an underlying abdominal problem may have triggered the ketoacidosis, rather than the reverse. This is a particularly challenging clinical problem when amylase or lipase levels are elevated, since both AKA and DKA can be a consequence or a cause of acute pancreatitis. If the acidosis is resistant to standard treatment, or the pain persists after normalization of the pH, intraabdominal disease should be suspected.

Of the endocrinopathies associated with abdominal pain, adrenal crisis is the most striking. Patients are often shocky and diffusely peritoneal. The syndrome appears to be related to hypocortisolism rather than hypoaldosteronism. Without a history of similar prior episodes following reduced intake or absorption of adrenal steroids, these patients may be indistinguishable from those with an intraabdominal catastrophe. Other endocrinopathies and electrolyte abnormalities associated with abdominal pain include thyroid storm and hypo- and hypercalcemia. This pain is generally crampy, and tenderness is absent unless the hyperthyroid state has caused acute hepatomegaly and distention of the liver capsule. Hypoglycemia has been reportedly associated with abdominal pain, but the evidence supporting this is unconvincing.

A painful sickle cell crisis is a common cause of abdominal pain, second only to musculoskeletal pain as the most common manifestation of a vasoocclusive crisis in homozygous (SS) disease. Occasionally, patients with SC disease and other symptomatic heterozygous forms may present with abdominal pain due to splenomegaly or splenic infarct. Those with heterozygous sickle trait (SA) are almost invariably asymptomatic. The most reliable means of determining whether the abdominal pain is part of a crisis or secondary to an underlying intraabdominal problem is to ask the patient whether or not this is the pain of a typical crisis or whether it represents a pattern break. If the latter, the problem is usually localized to the RUQ, either

secondary to biliary tract disease (about 75 percent of those with SS have bilirubin stones due to chronic hemolysis) or hepatomegaly due to sinusoidal sludging of sickled cells. Additional considerations for SS patients include pancreatitis, *Salmonella* infection, and mesenteric venous thrombosis.

Less common "metabolic" entities associated with abdominal pain include virtually all forms of vasculitis, especially systemic lupus and Henoch-Schlein purpura, porphyria, and familial Mediterranean fever. Each of these may produce peritonitis.

NEUROGENIC The hallmark of neurogenic abdominal pain is a dysesthetic sensation, particularly in response to light touch in the area of discomfort. This has been characterized by one author as the "hover" sign, in which the patient shows signs of discomfort when the examining hand is hovering just above or is passed very lightly over the area of dysesthesia. A positive hover sign may be mistakenly interpreted as indicating a generally hyperreactive patient, rather than a normal physiologic response to a dysesthetic or anticipated dysesthetic stimulus.

Because deep and superficial nerve fibers from the same area of the abdomen may enter the cord together, dysesthesias have also been reported with other, more serious, intraabdominal disease, such as appendicitis. In the latter, however, the problem is usually more acute, and either upon presentation or subsequently, is accompanied by tenderness (in contrast to dysesthesia alone). This category includes neural entrapment syndromes such as rectus nerve entrapment and iliohypogastric entrapment following a Pfannenstiel incision. A number of other incisional entrapment syndromes have been described. Many of these patients will have a positive Carnett's test, but the hover sign is probably more indicative of neurogenic abdominal pain.

Radicular problems causing abdominal pain include diabetic or zosteriform radiculopathy, the latter characterized by dysesthesias outlining a dermatome, usually with some "spillover" into contiguous dermatomes on either side of the involved root. The dysesthesias may present as lancinating, ticlike bouts of shooting pain or continuous burning. Accompanying vesicles confirm the diagnosis, although the pain may precede the cutaneous eruption by several days. Diabetic neuropathic involvement of a root, plexus, or nerve can be confirmed by electromyography.

There is evidence that greater attention to the examination of the abdominal wall reduces the frequency with which the diagnosis of NSAP is made. In one report, about 25 percent of patients with the diagnosis of NSAP were found to have abdominal wall syndromes.

Nonspecific Abdominal Pain (NSAP)

Despite a thorough work-up, the largest single group of patients seen in the ED will have no definite diagnosis, and will receive the designation of nonspecific abdominal pain (NSAP). It is essential that diagnostic terms with specific meanings, such as gastroenteritis or gastritis, not be used as catch-all phrases to describe patients with NSAP. Although NSAP is a diagnosis of exclusion, there are some clinical features characteristically associated with it. Nausea, present in nearly half the patients, is the most common symptom after abdominal pain. Pain location is usually mid-epigastric or in the lower half of the abdomen. Tenderness is not usually severe, is absent in about one-third of the patients, and localized to the RLQ or mid-epigastrium in another one-third. Laboratory tests are usually normal, although a mild leukocytosis is entirely compatible with NSAP. Abdominal radiographs are virtually always normal or nonspecific. The key to confirming NSAP is reexamination over time (see below).

Special Considerations

Diagnostic accuracy of acute abdominal pain in those <50 years old is less than 50 percent, reaching a low of about 30 percent in octoge-

narians. For a detailed discussion of diagnosing abdominal pain in the elderly, see Chap. 73.

The causes of abdominal pain in elderly patients differ substantially from those seen in younger patients. For example, as shown in Table 72-12, the most common cause of abdominal pain in virtually all consecutive series of adults presenting to the ED is NSAP. However, when ED patients are dichotomized by age at 50 years old, NSAP remains at the top of the list of diagnoses in the younger cohort, but among older patients is markedly diminished in prevalence to <20 percent (see Table 72-3).

There are a number of serious vascular causes of abdominal pain seen almost exclusively among patients >50 years old, such as mesenteric ischemia, ischemic colitis, and AAA.

Among common causes of abdominal pain in both young and old, the nature of the presentation and evolution of the same illness is often very different. Using appendicitis as the most common example, those >50 years old are much more likely to have generalized pain and tenderness (about 14 percent) than are younger patients (about 2 percent). The absence of localization to an area of maximum pain or tenderness may help to account for the nearly tenfold difference in perforation rate (4 percent vs. 37 percent) in those >60 years old when compared to their younger counterparts. Later presentation in the course of their illness may also contribute to the increased perforation rate (75 percent of the elderly with appendicitis have >24 h of symptoms before seeking care), as may the higher frequency of distention in older patients, making the physical examination more difficult.

An additional contributor to the high incidence of perforation in appendicitis in the elderly is an understandable but unfortunate reluctance to operate on frail elderly patients without clear-cut signs of peritoneal irritation. This is reflected in the well-established inverse association between negative laparotomies and perforated appendices. At about the age of 45 years, the negative laparotomy rate begins to decrease in parallel with the increase in perforations until each plateaus at about 80 years of age. Thus, the negative laparotomy rate for appendicitis is lowest in the oldest, who are the group most likely to perforate, and therefore most in need of early, expedient surgery.

Therefore, one must assume that the elderly patient with abdominal pain has surgical disease. In support of this is the observation that about 40 percent of all patients >65 years old presenting to the ED with abdominal pain ultimately require surgery.

HIV/AIDS There are several features of HIV/AIDS patients presenting to the ED with abdominal pain that merit special attention. Ab-

dominal pain is rarely the index event that identifies a patient with HIV. Rather, most patients presenting with HIV-associated acute abdominal pain will have previously met criteria for AIDS and be aware of their diagnosis.

Distinguishing acuity of pain from an extensive background of severe, chronic illness represents the principal challenge in the evaluation of abdominal pain in HIV-positive patients. Identifying a precise infectious etiology for the pain at the time of presentation is well beyond the purview of emergency medicine.

Enterocolitis is the most common cause of abdominal pain in AIDS patients. It is typically accompanied by profuse diarrhea and dehydration. If associated with fecal leukocytes, it is more often accompanied by bacteremia than in immunocompetent patients. Perforation, when it occurs, tends to be large bowel perforation, often caused by cytomegalovirus (CMV). Obstruction presents in a typical fashion, but may be due to an unusual cause such as Kaposi sarcoma, lymphoma, or atypical mycobacteria.

Biliary tract disease is very common in AIDS patients, presenting in one of two unique forms: (1) AIDS-related cholangiopathy, caused principally by CMV or *Cryptosporidium* spp. (this can be treated with sphincterotomy), and (2) AIDS-associated cholecystitis, which is usually acalculous and has a propensity for early perforation.

TREATMENT

General Strategies

HYPOTENSION Clinically important decreases in cardiac output are commonly underdiagnosed in the elderly. This is because many older patients have chronic systolic hypertension, making the traditional threshold value of 100 mm Hg systolic an insensitive marker for shock in the elderly. Conversely, healthy young women with abdominal pain, particularly if pregnant, may run systolic BPs that rarely reach 100 mm Hg. Thus in abdominal pain, as in all other clinical circumstances, hypotension is relative; the BP must be interpreted in context if it is to provide meaningful information.

In abdominal pain with relative hypotension, management depends on the presumed etiology. In the absence of heavy GI bleeding, which is not usually accompanied by abdominal pain, younger patients are most likely to be volume-contracted from vomiting, diarrhea, decreased oral intake, or third-spacing into the GI tract or peritoneum. Treatment is isotonic crystalloid.

In a smaller number of young patients, hypotension may be the result of abdominal sepsis. In this setting, in addition to appropriate antibiotics (see below) and isotonic crystalloid, pressors may be necessary to sustain BP until more definitive intervention can be undertaken. Vasoconstrictors are indicated in septic (vasodilatory) shock, with norepinephrine bitartrate (Levophed) or high-dose dopamine as the usual choice of agents.

In older patients, in addition to volume contraction and a higher incidence of abdominal sepsis, associated cardiovascular disease represents a third possible cause of decreased cardiac output. Indeed, in nonocclusive mesenteric ischemia, diminished cardiac output is the cause, rather than the consequence, of the presenting abdominal pain. In this circumstance, if the problem is acute myocardial ischemia, an aortic balloon pump may be necessary to buy time until the underlying problem can be corrected with angioplasty or bypass. If the decreased cardiac output is secondary to congestive failure, appropriate treatment for CHF is indicated with the caveat that digoxin is thought to be contraindicated in mesenteric ischemia because of a theoretical concern about worsening vasoconstriction. If pump failure appears to be the problem, dobutamine may be used while slowly administering isotonic crystalloid. Arterial or venous pH and lactate levels are a more accurate means of monitoring end-organ perfusion and shock than is the BP.

TABLE 72-12 Most Common Causes of Acute Abdominal Pain

Final Diagnosis	Proportion of > 10,000 Patients	
Nonspecific abdominal pain (NSAP)	34%	
Appendicitis	28%	
Biliary tract disease	10%	
Small bowel obstruction	4%	
Acute gynecologic disease	4% Salpingitis	68%
	Ovarian cyst Ectopic	21%
	Incomplete abortion	6% 5%
Pancreatitis	3%	
Renal colic	3%	
Perforated peptic ulcer	3%	
Cancer	2%	
Diverticular disease	2%	
Other (<1% each)	6%	

ANALGESICS In the U.S., analgesia is usually withheld from patients with acute abdominal pain until a firm treatment plan is formulated. There is no evidence to support this longstanding practice, which has been attributed to Sir Zachary Cope. More than 75 years ago, Dr. Cope wrote that provision of analgesia to patients with abdominal pain might obscure the diagnosis, with dire consequences. There are many reasons why this may have been sage advice in 1921, not the least of them being the likely outcome of perforation and sepsis in the preantibiotic era. However, much has changed since that time in both the diagnosis and treatment of abdominal pain: (1) There have been major advances in diagnostic technology, the accuracy of which—in contrast to the serial clinical examination—is largely independent of the patient's degree of evolving pain and tenderness; (2) There have been parallel advances in therapeutic technology, including the universal availability of antibiotics and sophisticated intra- and perioperative monitoring.

There are at least five published randomized clinical trials, too heterogeneous for metaanalysis, but each consistent with the hypothesis that administration of opioids to patients with abdominal pain is at least safe. Although none of these trials answers the question definitively, at least one of them suggests that diagnosis and management of abdominal pain may, if anything, be facilitated by opioids. The plausibility of this is supported by an improved ability to obtain a history from a patient relieved of severe pain, and the enhanced localization of tenderness through reduction of guarding. In spite of these data, about 75 percent of emergency physicians recently surveyed indicated that they did not administer opioids until after a surgeon had seen the patient.²²

The information on the safety of opioids cannot be extrapolated to nonsteroidal antiinflammatories (NSAIDs) such as parenteral ketorolac, because NSAIDs are not pure analgesics and have the potential to mask evidence of early peritoneal inflammation. At the present time all available evidence, and the recent recommendation of the Agency for Healthcare Research and Quality (AHRQ),²³ favors judicious use of opioid analgesia in the ED management of acute abdominal pain.

ANTIEMETICS Metoclopramide (Reglan) appears to be a more effective antiemetic than prochlorperazine (Compazine). Most patients will respond within 10 min to 10 to 20 mg of intravenous metoclopramide given slowly to minimize extrapyramidal side effects. In many institutions, 25 to 50 mg of intravenous diphenhydramine (Benadryl) is administered as prophylaxis against dystonias. Liberal use of antiemetics may obviate the need for insertion of a nasogastric tube, whose therapeutic value in abdominal pain has never been convincingly demonstrated.

ANTIBIOTICS Antibiotics are indicated in suspected abdominal sepsis and in most patients with localized, and all patients with diffuse, peritonitis. Endogenous gut flora cause abdominal infections in the GI or GU tract. Primary gynecologic infections, of which PID is the prototype, behave differently and will be discussed separately under the treatment of suspected PID, below. In all intraabdominal nongynecologic infections, minimal coverage should be targeted at anaerobes and facultative aerobic gram-negatives. An exception to this generalization is the need to provide additional coverage for gram-positive aerobes (e.g., *Pneumococcus*) in spontaneous bacterial peritonitis (SBP). SBP, also known as primary peritonitis, occurs in patients with cirrhosis and ascites, probably due to spontaneous bacteremic seeding of ascitic fluid. The modifier "primary" is used to distinguish SBP from the more common peritonitis secondary to intraabdominal organ inflammation, ischemia, leakage, or perforation.

Historically, a two-drug regimen, attacking gram-negative aerobes with an aminoglycoside (gentamicin or tobramycin, 1.5 mg/kg IV q8h, or amikacin 5 mg/kg IV q8h) and anaerobes with metronidazole (1 g intravenous loading dose, followed by 500 mg IV q6h, given slowly) or clindamycin (900 mg IV q8h) has been used to obtain the requisite coverage for intraabdominal infections. While dual therapy may still be necessary for sicker, older, immunocompromised, or hypotensive pa-

tients, monotherapy with a second-generation cephalosporin, such as cefoxitin (2 g IV q6h) or cefotetan (2 g IV q6h) is often adequate for those who are less ill. Alternative "combined" monotherapy includes ampicillin-sulbactam (3 g IV q6h) or ticarcillin-clavulanate (3.1 g IV q6h). For patients requiring a more potent regimen, but in whom one is reluctant to use an aminoglycoside, the combination of piperacillin-tazobactam (3.3 g IV q6h) appears to be at least as effective as imipenem-cilastatin (1 g IV q6h, maximum dose), particularly in treatment of suspected biliary sepsis, and is less likely to cause seizures.

For patients with a history of severe allergy to penicillins or cephalosporins, aztreonam (2 g IV q6h, maximum dose) and clindamycin or metronidazole is a safe alternative. In SBP, monotherapy with a third-generation cephalosporin such as ceftriaxone (2 g IV q12h, maximum dose) or cefotaxime (2 g IV q4h, maximum dose) broadens the spectrum sufficiently to cover for *Pneumococcus* in addition to the gram-negative enteric bacteria, such as *E. coli*.

Gynecologic infections differ from those of the GI and GU tract in several important respects: (1) They do not generally cause a septic syndrome; (2) elderly patients, who are most likely to suffer mortality from delay in the treatment of abdominal infections or sepsis, do not generally present with primary gynecologic infections as the cause of their abdominal pain; and (3) treatment of PID requires different antibiotic combinations than do GI and GU infections.

For outpatient treatment of PID, the combination of a single dose of ceftriaxone 250 mg IM plus azithromycin 1 g PO given under direct observation, has become standard in many EDs. However, the CDC still recommends ceftriaxone 250 mg IM plus doxycycline 100 mg PO bid for 14 days rather than azithromycin for outpatient PID. For inpatient treatment, the recommendation remains cefoxitin 2 g IV q6h plus doxycycline 100 mg q12h IV until improvement, then 100 mg PO bid to complete 14 days. However, many inpatient physicians are also using azithromycin in preference to doxycycline. If there is evidence of a tubo-ovarian abscess, the cure rate may be increased with use of triple antibiotic coverage: clindamycin 900 mg IV q8h plus gentamicin 1.5 mg/kg IV q8h plus ampicillin 1 g IV q6h. Doses of all aminoglycosides recommended assume normal renal function, and must be adjusted for decreased glomerular filtration rate.

DISPOSITION

General Indications for Admission

In addition to those with a specific diagnosis requiring admission, the following patients should be seriously considered as candidates for hospitalization: those who appear ill; any elderly or immunocompromised (including HIV-positive) patient (with or without comorbidity) in whom the diagnosis is unclear; young, apparently healthy patients in whom the diagnosis is unclear and all potentially serious causes of abdominal pain have not been reasonably excluded; intractable pain or vomiting; acute or chronically altered mental status; inability to follow discharge or follow-up instructions; undomiciled, living in a shelter, or otherwise lacking social supports; and alcohol or other drug use.

Nonspecific Abdominal Pain

A substantial number of patients who are discharged with the diagnosis of NSAP are initially admitted as suspected appendicitis. This may be the reason that there appears to be an unexplained predominance of RLQ pain among patients discharged with the diagnosis of NSAP.

Although this entity is poorly understood pathophysiologically, follow-up among patients discharged from the ED with this diagnosis has found that nearly 90 percent are better or asymptomatic at 2 to 3 weeks. Similarly, follow-up of patients discharged from inpatient services with the diagnosis of NSAP has shown that about 80 percent have no further problems and are asymptomatic at 5 years. Of the re-

mainder, about one-third are rehospitalized, of whom one-third of these have appendicitis. Some of these individuals probably had early appendicitis on their prior admission, with spontaneous resolution due to disimpaction of the appendiceal lumen. Of this group, it is plausible that some later developed recurrent appendicitis and required appendectomy. The remaining two-thirds of patients who were neither rehospitalized nor asymptomatic, turned out to have benign gynecologic and colonic problems, most commonly irritable bowel.

The key to confirming NSAP as a working diagnosis is reexamination in 24 h, repeated as necessary over time if patients remain symptomatic. Whether this occurs on the inpatient service, in an ED observation unit, or follow-up in the ED depends on the culture of the institution, the clinician's degree of uncertainty about the diagnosis, and the presence of facilities for reliable outpatient follow-up.

ABDOMINAL PAIN IN THE ELDERLY

Robert McNamara

EPIDEMIOLOGY

A recent study of 10 northern New Jersey EDs reported that 4.2 percent of the visits for those age 65 and greater were for abdominal pain.¹ In the United States, the elderly (age 65 and up) accounted for 15.1 percent of the 108 million ED encounters in 2000.² Regardless of the current frequency of ED visits for abdominal pain in the elderly, one can count on a steadily rising volume of such cases. Current projections predict that the number of those aged 65 and older will rise from 13 percent of the population in the year 2000 to approximately 20 percent by the year 2030.³ Practicing emergency physicians rate abdominal pain as the most challenging clinical situation in this population.³ Over half of the patients aged 65 or greater who present to the ED with abdominal pain require admission, and one-quarter to one-third will require surgical intervention at some point during their hospital stay.^{4,5} The mortality rate across all causes of abdominal pain in the elderly is 11 to 14 percent, justifying its anxiety-provoking reputation.^{5,6} The mortality rate can double if the diagnosis rendered in the ED is incorrect.^{6,7}

PATHOPHYSIOLOGY

The approach to acute abdominal pain in all age groups requires an understanding of the visceral and somatic pathways of pain perception. Neural pathways are not rerouted as we age; however, it is an accepted axiom that the perception of abdominal pain or at least the reporting of it is altered in the elderly.⁷ There is limited proof of this axiom for abdominal pain; however, it is fairly clear that ischemic heart disease is associated with altered pain perception or reporting in the elderly. Other factors such as fear, stoicism, and communication problems may affect the reporting of abdominal pain in older persons.^{7,8}

Aging is associated with several factors that influence the prevalence and spectrum of abdominal conditions encountered in this population (Table 73-1). For example, older patients have a statistically increased frequency of abdominal aortic aneurysms. The presence of

TABLE 73-1 Influence of Aging on Abdominal Pain

Increased Risk in the Elderly	Resultant Disease
ASCVD	AAA, mesenteric ischemic, ischemic colitis
Cholelithiasis	Cholecystitis, pancreatitis
Carcinoma	Large bowel obstruction, intussusception
Immobility	Colonic volvulus, Ogilvie's syndrome
Medications	Peptic ulcer disease, pancreatitis
Prior surgery	Small bowel obstruction

Abbreviations: AAA = abdominal aortic aneurysm; ASCUD = atherosclerotic cardiovascular disease.

comorbid diseases and their associated therapy contributes to the complexity of care. Other important pathophysiologic features include decreased cardiopulmonary reserve, lowered tolerance for hypovolemic shock, and the treatment issues of altered pharmacodynamics and pharmacokinetics.

CLINICAL FEATURES

The History

History taking in older patients with abdominal pain should follow the same general sequence and rules as in younger patients. Unfortunately, an accurate history may be difficult to obtain in this age group. Serious abdominal disease may cause an acute mental status change or distract the patient's attention. Memory deficits or underlying dementia can obscure important aspects, such as the time and nature of the onset of pain.⁸ The noise and pace of the ED are often inconsistent with the needs of the older patient who is attempting to relay historical information about his or her abdominal pain. The following historical aspects should be covered:

1. *Time of onset:* Pain awakening the patient from sleep should always be considered significant.
2. *Mode of onset:* Sudden, severe pain suggests serious disease, including a ruptured abdominal aortic aneurysm, aortic dissection, superior mesenteric artery embolus, perforation of a peptic ulcer, or volvulus. However, these disorders may present without a sudden onset. For example, in one prospective series of patients over the age of 70 with perforated ulcers, only 47 percent reported a sudden onset of pain.⁶
3. *Progression since onset:* Steady improvement is reassuring; worsening is not.
4. *Location of the pain:* In general, this seems to be reliable in the elderly. For example, appendicitis in this age group, although diagnostically difficult, generally presents with right-lower-quadrant pain.⁹
5. *Character of the pain:* Severe pain should be taken as an indicator of serious disease. Think of mesenteric ischemia, perforation of a gastric ulcer, vascular accidents, and volvulus.
6. *Referral or radiation of the pain:* As with location, this aspect of abdominal pain should not change with aging. For example, the referral pattern is helpful in diagnosing older patients with biliary tract disease.⁸
7. *Precipitating and relieving factors:* Pain with movement suggests irritation of the peritoneum. The results of any self-treatment should be determined.
8. *Prior episodes:* This generally suggests a medical cause with the notable exceptions of mesenteric ischemia (intestinal angina) and cholecystitis.
9. *Associated symptoms:* Anorexia, vomiting, bowel habits, and urinary symptoms are key areas to cover. In general, pain almost always precedes vomiting in surgical causes of abdominal pain, while the converse is true in 75 percent of patients with gastroenteritis or a nonspecific cause of abdominal pain.⁴
10. *Further history:* A detailed review of systems is desirable to seek other causes of abdominal pain, especially those of a cardiopulmonary nature. Do not neglect a careful review of medications, including over-the-counter nonsteroidal antiinflammatory agents. Underlying alcohol abuse must also be a consideration in this age group.

The Physical Examination

As with the history, the abdominal examination in the older patient proceeds in the same manner as for younger patients. Complicating factors may include the patient's stoicism or inability to report pain

and the less pronounced muscular response to inflammation.^{7,8} The following should be addressed:

1. *General appearance:* An ill-appearing older patient with abdominal pain should cause immediate concern, given the high mortality rate in general case series of elderly patients with abdominal pain.^{4,6} On the other hand, the clinician can be misled by a deceptively "well" appearance in the face of serious underlying disease.⁸
2. *Vital signs:* Reflexively think of a ruptured abdominal aortic aneurysm in the hypotensive older patient with abdominal pain.¹⁰ Determination of a core temperature is advisable; however, lack of fever commonly occurs with serious infectious causes of abdominal pain. Tachypnea and tachycardia are nonspecific findings but should raise the possibility of a cardiopulmonary disorder or sepsis.
3. *Inspection and auscultation:* Distention is common in large bowel obstruction, including sigmoid and cecal volvulus.¹¹ High-pitched "rushes" suggest small bowel obstruction.
4. *Abdominal palpation:* In general, the location of tenderness is generally reliable in the older patient. Appendicitis usually manifests right-lower-quadrant tenderness,^{6,9,12} while cholecystitis and pancreatitis generally cause tenderness in the expected location.⁸ Unfortunately, abdominal guarding or muscular rigidity may be lacking despite the presence of chemical or infectious peritoneal irritation. This is partially attributed to the relatively thin abdominal musculature of older patients.^{7,8} Disturbingly, of patients over the age of 70 with a perforated ulcer, only 21 percent had epigastric rigidity.⁶
5. *Rectal examination:* This should be performed routinely, and the detection of occult blood should receive follow-up evaluation. In one series of patients over the age of 50, about 10 percent of those discharged from the ED with a diagnosis of nonspecific abdominal pain were diagnosed with cancer, principally of the large bowel, within a year.¹³
6. *Further examination:* There should be careful inspection for hernias, particularly of the femoral canal in the older female patient. Aortic dissection may manifest with unequal femoral pulses. The back should be inspected for herpes zoster. Genital and pelvic examinations may reveal the cause of pain. Assessment of the heart and lungs may yield clues to a nonabdominal cause of the pain.

SPECIFIC DIAGNOSES AND ISSUES

This section reviews the major diagnostic causes of abdominal pain in the older patient and points out specific diagnostic issues to consider in this population. The frequency of each particular disease varies in the reported case series of elderly patients presenting to the ED with abdominal pain. Cholecystitis (12 to 41 percent) is generally the most frequently encountered disease of a surgical nature, followed by bowel obstruction (7 to 14 percent). Nonspecific abdominal pain is also a frequent diagnosis (10 to 23 percent). Perforated viscus, appendicitis, diverticulitis, and pancreatitis each generally represent around 4 to 7 percent, depending on the case series. Aortic aneurysms and mesenteric ischemia are less common.^{4,6,8} General coverage of the following conditions can also be found in other chapters.

Appendicitis

Diagnostic problems surrounding appendicitis in the elderly are well known in emergency medicine. In one series, only 51 percent of patients over the age of 60 with proven appendicitis had that diagnosis made during the ED phase of their care.¹³ Delayed presentation is common and contributes to the higher perforation and complication rate. One must be careful not to exclude appendicitis because of prolonged symptoms, as a small but significant percentage of the elderly will wait more than a week to seek care for this condition (see Chap. 78).

The abdominal pain is generally reported to be in the right lower quadrant; however, the description may be vague or the pain poorly localized.^{9,13} Migration has been reported from a low of 5 percent to as high as 64 percent of elderly patients with appendicitis.⁹ Anorexia, an expected finding in younger patients, may be lacking (reported in 19 to 44 percent), while nausea and vomiting are reported in roughly half of elderly patients with appendicitis.^{8,9,13} Diarrhea and urinary tract symptoms do not exclude the disease.

Fever may be absent in one-third or more. Tenderness in the right lower quadrant is a frequent finding occurring in 80 to 90 percent. The presence of rigidity and rebound tenderness ranges from 20 percent to more than 80 percent.^{8,9} Laboratory assessment is potentially misleading, as most studies indicate that 20 percent or more will have a white blood cell count below 10,000.^{9,13} Up to 17 percent of the elderly with appendicitis have hyperbilirubinemia.¹² Abdominal radiographs rarely add to the diagnostic process and can lead one astray by suggesting small bowel obstruction.⁸

It is prudent to include appendicitis in the differential diagnosis of any elderly patient with abdominal pain who has not undergone an appendectomy. The clinician must not expect a neat diagnostic package. In one series, only 20 percent of older patients with appendicitis had all of fever, nausea or vomiting, tenderness in the right lower quadrant, and an elevated white blood cell count.¹³

Acute Cholecystitis

Acute cholecystitis (see Chap. 85) is the most common surgical emergency in older patients with abdominal pain. Fortunately, physicians have a record of high diagnostic accuracy for this condition in the elderly.⁶ The presenting features of acute cholecystitis in the older population are similar to those in younger patients. Right-upper-quadrant or epigastric pain is present in most, while radiation to the back or shoulder area occurs in about one-third. Roughly half will report nausea or vomiting, and jaundice will occur in 10 to 30 percent. Fever may be absent in over half of these patients. Laboratory testing may be misleading, as 30 to 40 percent can have a normal white blood cell count. Plain radiographs are of little value; the diagnostic study of choice is ultrasonography. Computed tomography is generally of limited usefulness.⁸⁻¹⁴

Conservative management is generally unsuccessful and operative delay increases the complication rate. The older patient can appear deceptively well with acute cholecystitis; however, the overall mortality rate is approximately 10 percent.¹⁵ Additionally, a clinical picture of fever, jaundice, and altered mental status without significant abdominal findings has been described in a subset of elderly patients with acute cholecystitis.

Small Bowel Obstruction

The diagnosis of small bowel obstruction is usually straightforward in the older patient (see Chap. 79). Colicky pain, distention, and vomiting that progresses from gastric contents to bile-stained or feculent are the cardinal features. Prior surgery is still the principal risk factor in this age group, and the physician should conduct a careful search for hernias. The mortality rate for small bowel obstruction in the elderly ranges from 14 to 45 percent. Errors in management most frequently relate to misinterpretation of radiographic studies and excessive delays in operative management.⁷

Perforated Peptic Ulcer

Although peptic ulcer disease most frequently presents as gastrointestinal bleeding, perforation is an important cause of abdominal pain in the older patient (see Chap. 77). The expected description of a sudden acute onset of epigastric pain is reported in only one-half of patients over age 70 with a perforated ulcer.⁶ The pain has usually been

present only for a matter of hours and is generally severe, constant, and present to some degree in the epigastrium. Free intraperitoneal perforation can cause generalized pain or lower-quadrant symptoms.⁸ Vomiting is infrequent. The physical examination is expected to reveal epigastric tenderness, although muscular guarding is variable. In one study, only 21 percent of the elderly with a perforated ulcer had epigastric rigidity.⁶ Fever is generally not present early on.

The key diagnostic mistake is excluding this diagnosis because of a lack of free air on plain radiographs. Roughly 40 percent of patients with perforated ulcers will not have this finding on their initial chest radiograph. The left lateral decubitus view or the lateral view of the upright chest radiograph may help to detect the presence of free air. Repeat radiographs after instillation of 500 mL of air via a nasogastric tube can increase the diagnostic yield of plain radiographs, although its use is somewhat controversial. Computed tomography is capable of detecting small amounts of air in the peritoneal cavity. In one series, missed perforated ulcer was the leading cause of death in elderly patients with abdominal pain, and in each case the plain radiographs did not reveal free air.⁷

Large Bowel Obstruction

A carcinoma is the leading cause of large bowel obstruction, while volvulus and diverticulitis account for most of the remaining cases. All of these precipitating conditions are more common in the elderly. The overall mortality rate approximates 40 percent. Distention is common, and vomiting and constipation are reported in about half of the patients. Importantly, a significant percentage (up to 20 percent) will report diarrhea. A history of rectal bleeding, altered bowel habits, or weight loss may be present with underlying carcinoma.¹¹ The pain is usually gradual in onset; however, cecal volvulus can present with the acute onset of severe, colicky pain.¹⁶ Sigmoid volvulus is two to three times more frequent than cecal volvulus and more commonly presents with a gradual onset of pain. Fever or the presence of peritoneal irritation suggests a perforation or gangrenous bowel.

The principal diagnostic study is plain abdominal radiography; however, cecal volvulus may appear as small bowel obstruction and require a barium enema to make the diagnosis.¹⁶ In one large series, a cecal diameter of 10 cm was not useful in predicting perforation. In fact, cecal diameters of up to 20 cm responded to routine decompression methods.¹¹ Colonic pseudo-obstruction, also known as Ogilvie syndrome, can present in a manner similar to that of large bowel obstruction. This is massive gaseous distention of the colon, generally occurring in chronically ill, immobilized older patients. It is thought to be a result of an imbalance in the regulation of the colonic motor function by the autonomic nervous system.¹⁷ The abdomen is distended and tympanic but usually nontender. A cavernous rectal vault is an important clue on physical examination. Old medical records frequently reveal several such presentations. It is important to avoid surgery in these patients as there is no underlying mechanical blockage. Neostigmine (2.0 mg IV) has a high success rate in the treatment of this condition.¹⁷

Diverticulitis

The presence of diverticula increases with age, and acute inflammation, diverticulitis, is a common cause of abdominal pain in the older patient (see Chap. 81). Computed tomography is the diagnostic study of choice, as a barium enema or colonoscopy can precipitate perforation. Also, diverticulitis can be mistaken for a pelvic mass of gynecologic origin in the older female.

Acute Mesenteric Infarction

The management of mesenteric ischemia is complicated by diagnostic delays that are often associated with a fatal outcome. Early diagnosis

markedly improves the chances of survival,¹⁸ and in a recent series it was the leading diagnosis in only 25 percent of those admitted with mesenteric infarction.¹⁹ The key to making the correct diagnosis is to consider this possibility in the elderly patient with abdominal pain and risk factors for the disease. Classically, superior mesenteric artery occlusion by an embolus or thrombus accounted for the majority of cases, but infarction resulting from low flow states is becoming more common.¹⁹ Inferior mesenteric artery occlusion, venous thrombosis, arteritis, and dissection are other causes of this condition.

The specific risk factors are listed in Table 73-2. The principal manifestation of mesenteric infarction is severe abdominal pain, often refractory to narcotic analgesics. Severe pain, with gradually increasing intensity, combined with a relatively normal abdominal examination, is considered the sine qua non of early mesenteric infarction. If an embolus is the cause, sudden, severe pain may be reported.¹⁸ There may be a history of prior episodes of spontaneously resolving pain, particularly with mesenteric arterial thrombosis. Associated gastrointestinal symptoms are very common. Nausea, anorexia, and vomiting are common, and up to half will report diarrhea. Objective findings on physical examination represent intestinal necrosis and possible perforation. Theoretically, the stool should be guaiac-negative early on. Patients will inevitably develop guaiac-positive stools. Laboratory abnormalities such as metabolic acidosis and extreme leukocytosis are likewise indicators of advanced, perhaps irreversible disease.

The critical aspect of care is to pursue mesenteric angiography based on the history and physical examination without waiting for hard evidence from the exam or diagnostic studies. One series reported a 90 percent survival rate when angiography was performed prior to the onset of peritonitis.¹⁸ The usual survival rate is 30 percent or less.

Abdominal Aortic Aneurysm

Rupture of an abdominal aortic aneurysm is a lethal condition that will be more frequently encountered as the population ages (see Chap. 58). The incidence of abdominal aortic aneurysm in men increases rapidly after age 55 and peaks at the age of 80 at 5.9 percent. In women, the incidence rises quickly after age 70, peaking at 4.5 percent at age 90.²⁰ With rupture, the mortality rate among those who reach the hospital is generally on the order of 50 percent or higher. A favorable outcome depends on a rapid diagnosis and early operative intervention. Unfortunately, initial misdiagnosis is common, occurring in 30 percent of patients in one series.¹⁰

The most common symptom is abdominal pain, occurring in 70 to 80 percent, and not back pain, which is noted by just over half. The typical pain is sudden and significant. Atypical locations include the hips, inguinal area, and external genitalia. Syncope may be part of the presenting picture with or without significant blood loss from the aneurysm. Because of the lethal nature of this condition, the diagnosis should be considered in any older patient, especially male, with back, flank, or abdominal pain. Hypotension occurs at some point in the majority of these patients. Palpation of a tender, enlarged (>5 cm) aorta is the key physical finding. Unfortunately, the size of the aorta is often difficult to determine on examination.

TABLE 73-2 Risk for Mesenteric Ischemia

Mesenteric Condition	Risk Factors
SMA embolus	Atrial fibrillation, recent MI
SMA thrombosis	Atherosclerosis, low CO states
Nonocclusive infarction	Low CO states (esp. CHF), digoxin therapy
Venous thrombosis	Hypercoagulability, prior DVT, liver disease

Abbreviations: CHF = congestive heart failure; CO = cardiac output; DVT = deep venous thrombosis; MI = myocardial infarction; SMA = superior mesenteric artery.

Management of the unstable patient with a clinically suspected ruptured abdominal aortic aneurysm involves immediate operative intervention without confirmatory testing. A supine plain radiograph of the abdomen will often reveal a clue to the diagnosis, such as a calcified aortic outline or loss of the renal or psoas outline. In the stable patient, ultrasonography can delineate the size of the aorta, while computed tomography gives more information regarding actual rupture.²⁰ Any such testing must include careful monitoring of the patient's condition, with appropriate alerting of the operating theater and surgical team.

The most common diagnostic mistake is to diagnose renal colic in these patients. This is understandable given the severe pain and the location of the pain. Furthermore, abdominal aortic aneurysm may present with hematuria. It should be axiomatic that aortic aneurysm be strongly considered in any patient over the age of 50 suspected of having renal colic. An episode of hypotension is often wrongly ascribed to developing sepsis or a "vagal" reaction in the patient initially misdiagnosed as having renal colic.¹⁰

Other Conditions and Causes

The list presented above is certainly not comprehensive for abdominal pain in the elderly. Aortic dissection is common in this age group and may cause abdominal pain directly or by causing ischemia of intraabdominal organs, including the bowel. The diagnosis of pancreatitis in this age group is generally straightforward. Tumors can serve as lead points for intussusception in elderly patients. Acute gastric volvulus should be considered in the older patient with sudden epigastric pain, repetitive nonproductive retching, and inability to pass a nasogastric tube. Older patients with underlying vascular disease may develop ischemic colitis, which can be difficult to distinguish from other forms of colitis.

The list of other conditions that can cause abdominal pain in the older patient is extensive, highlighting the need for the comprehensive evaluation of such patients. The most important disease to suspect is acute myocardial ischemia. Virtually all other "chest" diseases can cause abdominal pain, including pneumonia, pulmonary embolism, empyema, tuberculosis, congestive heart failure, esophageal rupture, and endocarditis. Genitourinary disease including renal colic, pyelonephritis, epididymitis, and testicular torsion is a possible cause of abdominal pain in the elderly. Diabetic ketoacidosis, herpes zoster, hypercalcemia, addisonian crisis, hemochromatosis, and retroperitoneal or rectus sheath hematomas secondary to anticoagulant therapy are examples of "medical" causes of abdominal pain in the elderly.

DISPOSITION

A period of observation with serial examinations should be considered in the elderly patient with undifferentiated abdominal pain. Depending on the circumstances, this could occur in the ED, an observation unit, or in an inpatient unit. Patients with severe pain or worsening pain while in the ED should generally not be sent home. Resolved pain is generally reassuring, and such patients who are discharged should receive routine follow-up with their primary care providers. Biliary tract disease and underlying cancer are possibilities in this circumstance.¹³ If an older patient is to be discharged with abdominal pain, the patient should be instructed to return if the symptoms worsen or do not resolve in a brief period of time (6 to 8 h). Vomiting after discharge should prompt reevaluation.

PEPTIC ULCER DISEASE Peptic ulcer disease, including gastric, duodenal, and stomal ulcers, remains the most common etiology for upper GI hemorrhage, encompassing approximately 60 percent of all cases.² Duodenal ulcers, which comprise approximately 29 percent of all ulcers, will rebleed in approximately 10 percent of cases, usually within 24 to 48 h. Gastric ulcers, which comprise approximately 16 percent of all cases, are more likely to rebleed. Stomal ulcers are uncommon (fewer than 5 percent of all upper GI bleeds) and are present in only one-third of bleeding patients with a history of peptic ulcer surgery.

EROSIVE GASTRITIS AND ESOPHAGITIS Erosive gastritis, esophagitis, and duodenitis together are responsible for approximately 15 percent of all cases of upper GI hemorrhage. Irritative factors, such as alcohol, salicylates, and nonsteroidal anti-inflammatory agents, are predisposing factors.

ESOPHAGEAL AND GASTRIC VARICES Esophageal and gastric varices result from portal hypertension and, in the United States, are most often a result of alcoholic liver disease. Although varices account for only about 6 percent of all cases of upper GI hemorrhage, they are highly likely to rebleed and carry a high mortality rate. Nevertheless, many patients with end-stage cirrhosis never develop varices, many patients with documented varices never bleed, and many patients with a documented history of varices presenting with upper GI bleeding will bleed from nonvariceal sites.

MALLORY-WEISS SYNDROME Mallory-Weiss syndrome is upper GI bleeding secondary to a longitudinal mucosal tear in the cardioesophageal region. The classic history is repeated retching followed by bright red hematemesis, but coughing and seizures also have been reported as etiologic factors.

OTHER ETIOLOGIES Stress ulcer, arteriovenous malformation, and malignancy are other etiologies of upper GI hemorrhage. Ear, nose, and throat sources of bleeding can also masquerade as GI hemorrhage. An aortoenteric fistula secondary to an aortic graft is an unusual but important cause of bleeding to keep in mind. Classically, this will present as a self-limited "herald" bleed preceding a subsequent massive hemorrhage.

Causes of Lower Gastrointestinal Bleeding

The most common cause of what initially appears to be lower GI bleeding is actually upper GI bleeding. Thus, proximal etiologies should be sought.

Among patients with an established lower GI source of their bleeding, the most common etiology is hemorrhoids. Among those with nonhemorrhoidal bleeding, angiodysplasia and diverticular disease are most common, followed by adenomatous polyps and malignancies.⁴

DIVERTICULOSIS Diverticular bleeding is usually painless and is thought to result from erosion into the penetrating artery of the diverticulum. Diverticular bleeding may be massive. Patients are often elderly with underlying medical illnesses that contribute to morbidity and mortality rates.

ANGIODYSPLASIA Arteriovenous malformations (angiodysplasia), usually of the right colon, are a common etiology of obscure lower GI bleeding, particularly in the elderly population. They are thought to be more common in patients with hypertension and aortic stenosis.

OTHER ETIOLOGIES Numerous other lesions may result in lower GI hemorrhage. Whereas carcinoma and hemorrhoids are relatively common causes of bleeding, massive hemorrhage is unusual. Similarly, inflammatory bowel disease, polyps, and infectious gastroenteritis rarely

GASTROINTESTINAL BLEEDING David T. Overton

Gastrointestinal (GI) bleeding is a common problem in emergency medical practice and should be considered potentially life threatening until proven otherwise.

Acute upper GI bleeding in adults has an overall annual incidence of approximately 100 per 100,000. It is more common among males and markedly more common among the elderly. Its associated mortality rises with age.^{1,2} Lower GI bleeding is somewhat less common, with an annual incidence of approximately 20 per 100,000. It, too, is more common among males and among the elderly.³

As with all true emergencies, the traditional triad of medical history, physical examination, and diagnosis often must be accomplished simultaneously with resuscitation and stabilization. **Factors associated with a high morbidity rate are hemodynamic instability, repeated hematemesis or hematochezia, failure to clear with gastric lavage, age older than 60 years, and coexistent organ system disease.**

PATHOPHYSIOLOGY

Causes of Upper Gastrointestinal Bleeding

Upper GI bleeding is defined as that originating proximal to the ligament of Treitz, whereas lower GI bleeding originates more distally.

cause severe bleeding. In addition, Meckel diverticulum is an unusual but important etiology to keep in mind.

DIAGNOSIS

Medical History

Although the medical history may suggest the source of bleeding, it is often misleading. Thus, clinicians should strive to maintain a broad differential and clinical approach. Although most patients will volunteer complaints of hematemesis, hematochezia, or melena, GI bleeding may have more subtle presentations. Patients who present with hypotension, tachycardia, angina, syncope, weakness, confusion, or even cardiac arrest may harbor occult, underlying GI hemorrhage.

Historical features such as hematemesis, coffee-ground emesis, melena, or hematochezia should be sought. Classically, hematemesis or coffee-ground emesis suggests a source proximal to the right colon, and hematochezia indicates a more distal colorectal lesion. However, exceptions to these rules occur. Weight loss and changes in bowel habits are classic symptoms of malignancy. Vomiting and retching, followed by hematemesis, is suggestive of a Mallory-Weiss tear. A history of an aortic graft should suggest the possibility of an aortoenteric fistula. A history of medication use should be determined, in particular salicylates, glucocorticoids, nonsteroidal anti-inflammatory agents, and anticoagulants. Alcohol abuse is strongly associated with a number of causes of GI bleeding, including peptic ulcer disease, erosive gastritis, and esophageal varices. Ingestion of iron or bismuth can simulate melena, and certain foods, such as beets, can simulate hematochezia. In such instances, stool guaiac testing will be negative. A history of GI bleeding should be sought, although recurrent bleeding episodes often originate from different sources.

Physical Examination

The vital signs may reveal obvious hypotension and tachycardia or more subtle manifestations such as a decreased pulse pressure or tachypnea. Clinicians should remember that some patients can tolerate substantial volume losses with minimal or no changes in vital signs. Similarly, paradoxical bradycardia can occur in the face of profound hypovolemia.

Skin findings should be noted. Cool, clammy skin is an obvious sign of shock. Spider angiomas, palmar erythema, jaundice, and gynecomastia suggest underlying liver disease. Petechiae and purpura suggest an underlying coagulopathy. Skin findings may be suggestive of Peutz-Jeghers, Rendu-Osler-Weber, or Gardner syndrome. A careful ear, nose, and throat examination occasionally may reveal an occult bleeding source that has resulted in swallowed blood and subsequent coffee-ground emesis or melena. The abdominal examination may disclose tenderness, masses, ascites, or organomegaly. A rectal examination is indicated to detect the presence of blood, its appearance (bright red, maroon, or melanotic), and the presence of masses.

Laboratory Data

In patients with significant GI bleeding, the most important laboratory test is to type and cross-match blood. Another important laboratory test is the complete blood count. In addition, blood urea nitrogen (BUN), creatinine, electrolyte, glucose, coagulation studies and liver function studies should be considered. The initial hematocrit level often will not reflect the actual amount of blood loss. Upper tract hemorrhage may elevate BUN levels through digestion and absorption of hemoglobin. Coagulation studies, including prothrombin time, partial thromboplastin time, and platelet count, are of obvious benefit in patients taking anticoagulants or those with underlying hepatic disease. An electrocardiogram should be considered in patients statistically likely to have coronary artery disease. Silent ischemia can occur sec-

ondary to the decreased oxygen delivery accompanying significant GI bleeding; thus, supplemental oxygen is advised for such patients.

Diagnostic Studies

Routine abdominal radiographs are often obtained in patients with GI bleeding. In the absence of specific indications, they are of limited value. Similarly, routine admission chest x-rays for patients with acute GI hemorrhage, even those admitted to the intensive care unit, have been shown to be of limited utility in the absence of known pulmonary disease or abnormal findings on lung examination.⁵ Barium contrast studies similarly are of limited diagnostic value in an emergency setting. Further, barium limits the use of subsequent endoscopy or angiography.

Angiography sometimes can detect the site of bleeding, particularly in cases of obscure lower tract hemorrhage. Moreover, angiography permits therapeutic options such as transcatheter arterial embolization or the infusion of vasoconstrictive agents. However, to be diagnostic, **angiography requires a relatively brisk bleeding rate (0.5 to 2.0 mL per min).**

Technetium-labeled red cell scans also have been used to localize the site of bleeding in obscure hemorrhage. Such localization can be used to map the therapeutic approach, whether via angiography or operatively. **Scintigraphy appears more sensitive than angiography and can localize the site of bleeding at a rate of 0.1 mL per min.**

Another approach is colonoscopy, which may be not only diagnostic but, through the use of endoscopic hemostasis, also therapeutic. In most circumstances, endoscopy is more accurate than arteriography or scintigraphy.

Controversy in the literature remains as to whether scintigraphy, angiography, or colonoscopy, and in which order, should be the initial diagnostic procedure of choice in the evaluation of lower GI bleeding.⁶⁻⁹ Thus, these decisions are often based on local availability and consultant preference.

TREATMENT

Primary

Immediate resuscitative measures take priority. Patients with profuse upper GI hemorrhage may require definitive airway management to prevent aspiration of blood. Oxygen should be administered, and cardiac monitoring is indicated. Volume replacement should be initiated with crystalloids via large-bore intravenous lines. The decision to administer blood should be based on the clinical findings of volume depletion or continued bleeding rather than on initial hematocrit values. General guidelines for initiation of blood transfusion are continued active bleeding and failure to improve perfusion and vital signs after the infusion of 2 L of crystalloid. The threshold for blood transfusion should be lower in the elderly. Coagulation factors should be replaced as needed. A urinary catheter is indicated in patients with hypotension. A nasogastric (NG) tube should be placed in all patients with significant GI bleeding, regardless of the presumed source. **Concerns that NG tube passage may provoke bleeding in patients with varices are unwarranted.** Bright red or maroon blood per rectum unexpectedly originates from upper GI sources approximately 14 percent of the time.¹⁰ A negative gastric aspirate does not conclusively exclude an upper GI etiology and may result from intermittent bleeding, pyloric spasm, or edema preventing reflux of duodenal blood. If bright red blood or clots are found on NG aspiration, gentle gastric lavage should be performed. To be effective, a large-bore tube, usually oral, must be used. Room temperature water is the preferred irrigant, because iced solutions have no proven benefit and have theoretical disadvantages. The addition of levaterenol to the lavage solution is similarly of unproven benefit. Overvigorous suction should be avoided, because it may produce gastric erosions that can confuse findings on subsequent endoscopy.

Secondary

ENDOSCOPY Upper GI endoscopy is the most accurate technique for the identification of upper tract bleeding sites. It predicts morbidity and, with the advent of therapeutic endoscopy, is associated with improved outcomes. Early therapeutic endoscopy, where available, should be considered the treatment of choice for significant upper GI bleeding. Thus, early consultation for potential endoscopy should be considered in patients with significant hemorrhage.

Esophageal varices can be endoscopically treated by band ligation or injection sclerotherapy. Sclerotherapy, which controls acute hemorrhage in up to 90 percent of patients, may decrease the duration of hospitalization and the amount of blood transfused when compared with portal-caval shunting. However, complications of sclerotherapy include perforation, sepsis, stricture formation, and portal and mesenteric venous thrombosis. Endoscopic band ligation appears to be as effective as sclerotherapy, but with a decreased incidence of complications, in particular rebleeding and esophageal stricture formation.¹¹ In addition, band ligation appears superior to sclerotherapy in the long-term management of varices.¹²

Endoscopic hemostasis (with injection sclerotherapy, electrocoagulation, heater probes, and lasers) also has been used successfully in a variety of nonvariceal etiologies of upper GI bleeding.

In lower GI bleeding, proctoscopy is often diagnostic in patients with anorectal sources of bleeding, such as hemorrhoids. If an anorectal source is suspected, the patient should be evaluated carefully for significant volume loss or more dangerous proximal sources of bleeding mimicking anorectal bleeding. Colonoscopy can be diagnostic in other forms of lower tract hemorrhage, such as diverticulosis or angiodysplasia, and may allow ablation of bleeding sites by using the aforementioned technologies.

DRUG THERAPY Infusions of somatostatin and its synthetic, longer-acting derivative, octreotide, have been shown to be effective in reducing bleeding from varices and peptic ulcer disease. Octreotide has been shown to be as effective as sclerotherapy in acute variceal bleeding.¹³ Both agents, when used in addition to sclerotherapy, are more effective than sclerotherapy alone.^{14,15} These agents possess the advantages of vasopressin, with considerably fewer side effects. They should be considered useful adjuncts before endoscopy or when endoscopy is unsuccessful, contraindicated, or unavailable.¹⁶ The dose of octreotide is 50 μ g IV bolus, followed by 50 μ g 8-24h; the dose of somatostatin is 250-500 μ g IV bolus followed by 250-500 μ g per h. See Chap. 86 for detailed discussion of somatostatin and octreotide.

Vasopressin has been used to control GI bleeding, most commonly from varices. However, adverse reactions are common, including hypertension, dysrhythmias, myocardial and splanchnic ischemia, decreased cardiac output, and gangrene from local infiltration. Although the concomitant use of nitroglycerin has been shown to reduce the incidence of these side effects, the use of vasopressin has been largely supplanted by the use of somatostatin, octreotide, and therapeutic endoscopy.

Studies have also suggested that the proton-pump inhibitor omeprazole may be useful to reduce rebleeding, transfusion requirements, and the need for surgery in the treatment of bleeding peptic ulcers.^{17,18}

Other drugs may be of benefit in patients with GI hemorrhage, but are of less concern in the initial emergency department management. For instance, beta-blocker therapy has been shown to be beneficial in patients with varices in preventing initial variceal bleeds and rebleeding.^{19,20} In addition, the treatment of *Helicobacter pylori* infection with antibiotics reduces the recurrence of peptic ulcer and rebleeding.²¹ However, the use of H₂ antagonists in acute upper GI hemorrhage remains of unproven benefit, with no conclusive evidence for reduction in the rates of rebleeding, surgery, or death.

— OON TAMPONADE Balloon tamponade with the Sengstaken-Blakemore tube or its variants can provide therapeutic benefit and presumptive diagnostic information. It can control documented variceal

hemorrhage in 40 to 80 percent of patients. The device consists of gastric and esophageal balloons and, depending on the variation, may include gastric and/or esophageal aspiration ports. The gastric balloon should be inflated first. If bleeding does not cease, the esophageal balloon should then be inflated by using a manometer to ensure that the pressure does not exceed 40 to 50 mm Hg. Radiologic confirmation of proper balloon placement is suggested. The device should be kept in place 24 h after bleeding has ceased. Some authors recommend deflating the esophageal balloon for 30 to 60 min every 8 h to prevent mucosal ulceration.

Like vasopressin therapy, balloon tamponade is frequently associated with adverse reactions, often severe. Mucosal ulceration, esophageal or gastric rupture, asphyxiation from dislodged balloons, tracheal compression secondary to balloon inflation, and aspiration pneumonia have been reported. Many authors recommend routine prophylactic endotracheal intubation to prevent pulmonary complications. Because of the incidence of adverse reactions, the use of balloon tamponade has decreased considerably and should be considered an adjunctive or temporizing measure supplementing the more definitive modalities of band ligation or sclerotherapy.

SURGERY With patients who do not respond to medical therapy and in whom endoscopic hemostasis, if available, fails, emergency surgical intervention is indicated. Surgical consultation on any patient admitted to the hospital for GI bleeding is prudent in case uncontrollable rebleeding occurs.

DISPOSITION

Patients with significant GI hemorrhage will require hospital admission, and early referral to an endoscopist is advisable. Corley and colleagues found five variables to be independent predictors of adverse outcomes in upper GI bleeding: initial hematocrit less than 30 percent, initial systolic blood pressure lower than 100 mm Hg, red blood in the NG lavage, history of cirrhosis or ascites on examination, and a history of vomiting red blood.²² Such patients are more likely to require a greater intensity of inpatient care.

In contrast, certain subsets of patients with upper GI bleeding are low risk and potentially eligible for early discharge. Patients are risk stratified by clinical and endoscopic criteria, so endoscopy must still be performed before discharge. Rockall and coworkers developed a risk score for variceal upper GI bleeding based on age, presence of shock, comorbidity, diagnosis, and endoscopic findings.²³ Longstreth and associates developed similar guidelines.²⁴ A randomized controlled trial found no difference in outcome between admitted and discharged low-risk patients. Adoption of such guidelines requires close coordination between the emergency physician and gastroenterologist.

ESOPHAGEAL EMERGENCIES

Moss H. Mendelson

Patients develop a wide variety of problems related to the esophagus. The complaints of dysphagia, odynophagia, or ingested foreign body immediately implicate the esophagus. The esophagus also is often the site of pathology in patients presenting with chest pain, upper gastrointestinal bleeding, malignancy, and mediastinitis. Many diseases of the esophagus can be evaluated over time in an outpatient setting, but several, such as variceal bleeding and esophageal perforation, can be

fulminant and rapidly fatal, requiring a unique knowledge base for effective, emergent intervention.

ANATOMY AND PHYSIOLOGY

The esophagus is a muscular tube approximately 20 to 25 cm long. The majority of the esophagus is located in the mediastinum, posterior and slightly lateral to the trachea, with smaller cervical and abdominal components as well, as shown in Figure 75-1. There is an outer longitudinal muscle layer and an inner circular muscle layer. The upper third of the esophagus is made up of striated muscle. From the lower half down, the esophagus is all smooth muscle [including the lower esophageal sphincter (LES)]. The esophagus is lined with stratified squamous epithelial cells that have no secretory function.

Two sphincters regulate the passage of material into and out of the esophagus. The upper esophageal sphincter (UES) prevents air from entering the esophagus and food from refluxing out of the esophagus into the pharynx. The LES regulates the passage of food into the stomach and prevents stomach contents from refluxing into the esophagus. The UES is composed primarily of the cricopharyngeus muscle. Additional tone is variably provided by the inferior pharyngeal constrictor and the cervical esophagus.¹ The UES has a resting pressure of around 100 mm Hg. The LES is not discretely identifiable on an anatomic basis. The smooth muscle of the lower 1 to 2 cm of the esophagus, in combination with the skeletal muscle of the diaphragmatic hiatus, functions as the sphincter, with a resting pressure of

FIG. 75-1. Anatomic relations of the esophagus (seen from the left side). The esophagus is about 25 cm (10 in.) long. The distance from the upper incisor teeth to the beginning of the esophagus (cricoid cartilage) is about 15 cm (6 in.); from the upper incisors to the level of the trachea, 22 to 23 cm (9 in.); to the cardia, 40 cm (16 in.). Structures contiguous to the esophagus that affect esophageal function are demonstrated.

25 mm Hg. The pressure within the resting body of the esophagus closely approximates intrathoracic pressure. Dysfunction of the LES is a major source of esophageal symptoms and is discussed below.

Three major anatomic constrictions exist within the esophagus and are important when faced with an esophageal foreign body or food bolus impaction, discussed below. The constrictions occur at the cricopharyngeus muscle, the level of the aortic arch/left main stem bronchus, and the gastroesophageal junction. An empty, collapsed esophagus has no apparent constrictions; the narrow areas are only apparent with esophageal filling.

The innervation of the heart mirrors that of the esophagus, and a convergence of visceral and somatic stimuli occurs within the sympathetic system. This is the anatomic basis that makes esophageal and cardiac chest pain notoriously similar, as discussed below.²

The esophageal blood supply is derived from several arterial sources. The inferior thyroid artery, small branches of the thoracic aorta, and ascending branches from the left gastric and inferior phrenic arteries supply the esophagus throughout its length. The esophageal venous circulation includes a submucosal plexus of veins that drains into another plexus of veins surrounding the outside of the esophagus. Blood flows from this outer plexus into the inferior thyroid, azygos, coronary, and gastric venous systems, the latter an important link between portal and systemic circulation. Variceal dilatation of the submucosal system can lead to massive upper gastrointestinal (GI) bleeding, reviewed below.³

DYSPHAGIA

Dysphagia is defined as difficulty with swallowing. The vast majority of patients with dysphagia will have an identifiable, organic process causing their symptoms.

Patients with dysphagia can be classified into two broad pathophysiologic groups; those with transfer dysphagia and those with transport dysphagia.⁴ Transfer dysphagia occurs very early in the swallowing process (as the food bolus moves from the oropharynx through the UES) and is often reported as difficulty in initiating a swallow. In transport dysphagia, there is impaired movement of the bolus down the esophagus and through the LES. Transport dysphagia is perceived later in the swallowing process, usually 2 to 4 s or more after swallowing is initiated, and most commonly results in the feeling of food "getting stuck." This initial differentiation between transfer and transport dysphagia provides valuable information regarding the likely underlying esophageal pathology, as noted in Table 75-1. Another useful classification scheme divides dysphagia into obstructive

disease versus motor dysfunction. Functional or motility disorders usually cause dysphagia that is intermittent and variable. Mechanical or obstructive disease is usually progressive (solids, then liquids).

Clinical Features

Historical information is key to the diagnosis of dysphagia. Though often occurring as an independent symptom, dysphagia can be associated with odynophagia, which is painful swallowing (suggesting an inflammatory process), or with chest pain that is esophageal in nature and suggests gastroesophageal reflux disease (GERD) or a motility disorder. Additional pertinent historical features to elicit in a patient complaining of dysphagia include the following: Has this been an acute, subacute, or chronic course? Is the dysphagia present for solids, liquids, or both? Is it intermittent or progressive? Is there a sensation of the food being stuck in the esophagus, and where? Is there any past history of esophageal disease? Transport dysphagia that is present for solids only generally suggests a mechanical or obstructive process. Motility disorders typically cause transport dysphagia for solids and liquids.

A poorly chewed meat bolus that impacts in the esophagus is a well-recognized complication of esophageal disease. A preceding history of dysphagia may or may not be present. An impacted food bolus can be the presenting complaint for a variety of underlying esophageal pathologies. The bolus may be well localized by the patient; in general, patients able to identify a level of dysphagia below the neck are usually anatomically accurate, whereas those complaining of dysphagia in the neck may be reporting sensations referred from elsewhere in the esophagus.⁵ Esophageal filling proximal to the impacted bolus can cause inability to swallow secretions and can present an airway/aspiration risk.

Physical examination of patients with dysphagia should focus on the head and neck and the neurologic exam. Signs of previous cerebrovascular accident, muscle disease, or Parkinson's disease can be present. Cachexia and cervical or supraclavicular nodes can be observed in patients with cancer of the esophagus. Watching the patient take a small sip of water can also provide very valuable information. Unfortunately, the physical examination is often normal in patients with dysphagia, despite the high-yield nature of this complaint.

Diagnosis

The diagnosis of the underlying pathology of dysphagia is most often made outside of the ED. The work-up is dependent on whether transfer or transport dysphagia is thought to be present, as noted above.

TABLE 75-1 Dysphagia

Transfer Dysphagia (Oropharyngeal)	Transport Dysphagia (Esophageal)
Discoordination in transferring bolus from pharynx to esophagus	Improper transfer of the bolus from the upper esophagus into the stomach
Swallowing symptoms—gagging, coughing, nasal regurgitation, inability to initiate swallow, need for repeated swallows	Swallowing symptoms—food "sticking," retrosternal fullness with solids (and eventually liquids), possibly odynophagia
Risk of aspiration present	Risk of aspiration present, generally less pronounced than in transfer dysphagia
Long term—weight loss, malnutrition, chronic bronchitis, asthma, multiple episodes of pneumonia	Long term—malnutrition, dehydration, weight loss, systemic effects of cancer
Neuromuscular disease (80%)—cerebrovascular accident; polymyositis and dermatomyositis, scleroderma, myasthenia gravis, tetanus; Parkinson's disease, botulism, lead poisoning, thyroid disease	Obstructive disease (85%)—foreign body; carcinoma, webs, strictures, thyroid enlargement, diverticulum, congenital or acquired large vessel abnormalities
Localized disease—pharyngitis; aphthous ulcers; candidal infection; peritonsillar and retropharyngeal abscesses; carcinoma of tongue, pharynx, larynx; Zenker diverticulum; cricopharyngeal bar; cervical osteophytes	Motor disorder—achalasia, peristaltic dysfunction (nutcracker esophagus), diffuse esophageal spasm, scleroderma
Inadequate lubrication—scleroderma	Inflammatory disease

Initial evaluation of dysphagia in the ED can include anteroposterior (AP) and lateral neck radiographs, which can be helpful in transfer dysphagia and cases in which the transport dysfunction seems proximal. Chest radiography should be obtained in patients thought to have transport dysphagia. Direct laryngoscopy can be used to identify structural lesions.

Ultimately, oropharyngeal dysphagia is best worked up with video-esophagography, a specialized form of a barium swallow study in which videotaped images are reviewed at low-speed playback to allow detailed analysis. Traditional barium swallow is usually the first test for patients with transport dysphagia. Manometry and esophagoscopy are also employed, depending on the clinical picture. If a foreign body is suspected, the diagnostic evaluation takes yet another path (see Chap. 76).

Selected Structural or Obstructive Causes

Neoplasms are a common cause of transfer and transport dysphagia. The esophagus or surrounding structures can be the primary site. Esophageal cancer is diagnosed in about 10,000 people a year in the United States. Ninety-five percent of esophageal neoplasms are squamous cell; the remaining 5 percent are adenocarcinomas. Men are affected three times as often as women. Risk factors for squamous cell disease include alcohol, smoking, achalasia, and previous caustic ingestion with lye. Barrett's esophagus predisposes to adenocarcinoma, which has shown an increase in incidence in recent years.⁶ There is usually a fairly rapid progression of dysphagia from solids to liquids (6 months). In addition to dysphagia, patients with neoplasm may present with bleeding. Early diagnosis impacts outcome, and for this reason the emergency physician should assume a neoplastic cause in patients over age 40 who present with new-onset dysphagia. These patients need an expedient work-up to rule out malignancy. Definitive diagnosis is made by endoscopy with biopsy. Survival is dismal; the median is less than 1 year.

Esophageal stricture occurs as a result of scarring from GERD or other chronic inflammation. Generally strictures occur in the distal esophagus, proximal to the gastroesophageal (GE) junction and may interfere with LES function. Symptoms may build over years and are often noted solely with solids. Stricture can serve as a barrier to reflux, so heartburn may decrease as dysphagia increases. Evaluation involves ruling out malignancy and treatment is dilatation.⁷

Schatzki ring is the most common cause of intermittent dysphagia with solids. This fibrous, diaphragm-like stricture near the GE junction is present in up to 15 percent of the population, the majority of whom are asymptomatic. The etiology is debated; a ring may form over time in response to GERD.⁸ Steakhouse syndrome (food impaction in the esophagus due to poorly chewed meat) is a frequent presentation for patients with this obstructive phenomenon. Treatment of Schatzki ring is dilatation.

Esophageal webs are thin structures of mucosa and submucosa found most often in the mid or proximal esophagus. They can be congenital or acquired. Esophageal webs also occur as a component of Plummer-Vinson syndrome (along with iron-deficiency anemia), and can be seen in patients with pemphigoid and epidermolysis bullosa. Treatment, again, is dilatation.

Diverticula may be found throughout the esophagus. Pharyngo-esophageal, or Zenker diverticulum is a progressive outpouching of pharyngeal mucosa, just above the UES, caused by increased pressures during the hypopharyngeal phase of swallowing.⁵ Presentation is usually after age 50, as this is an acquired disease. Patients complain of typical transfer dysfunction; additionally, they may have halitosis and the feeling of a neck mass. Diverticula can also be seen in the body of the esophagus, usually in association with a motility disorder.

Selected Motor Lesions Causing Dysphagia

Neuromuscular disorders typically result in misdirection of the food bolus, with repeated swallowing attempts. Liquids, especially at the ex-

tremes of temperature, are generally more difficult to handle than solids. Symptoms are often intermittent in nature. Cerebrovascular accident (CVA) is the most common cause in this category. Oropharyngeal muscle weakness is often the mechanism, though there can be poor function of the UES as well. Polymyositis and dermatomyositis are the second most common causes of transfer dysphagia in this category.

Achalasia is a dysmotility disorder of unknown cause and the most common motility disorder producing dysphagia. Impaired swallowing-induced relaxation of the LES is noted, along with the absence of esophageal peristalsis. Most patients present between 20 and 40 years of age. Achalasia may be associated with esophageal spasm and chest pain and with odynophagia. Associated symptoms can include regurgitation and weight loss. Dilatation of the esophagus can be massive enough to impinge on the trachea and cause airway symptoms.⁹ Therapy involves decreasing the LES pressure by oral medications, the endoscopic injection of botulinum toxin into the muscle of the sphincter dilations, or surgical myotomy.

Diffuse esophageal spasm refers to normal peristalsis that is periodically interrupted by simultaneous (nonperistaltic) contraction. Dysphagia is intermittent and does not progress over time. These patients! also commonly complain of chest pain, discussed below. Therapy involves controlling any reflux that might be present and consideration of smooth muscle relaxants and/or antidepressants, though no data convincingly show that medications are efficacious.¹⁰

CHEST PAIN OF ESOPHAGEAL ORIGIN

Most esophageal causes of chest pain are not immediate threats to life however, differentiating esophageal pain from ischemic chest pain can be impossible in the ED. Patients with esophageal pain can report spontaneous onset of pain or pain at night, regurgitation, odynophagia dysphagia, or meal-induced heartburn; however, these symptoms are also found in patients with coronary artery disease (CAD), and then is no historical feature that is sensitive or specific enough to routinely make a differentiation between the two.

To minimize missing patients with acute coronary syndrome* (ACS), the emergency physician's default assumption is that the pain is cardiac in nature and not esophageal. The high rate of admission for chest pain of noncardiac etiology is well publicized and appropriate. Ultimately, esophageal disease is often found to be the underlying pathology; the incidence of esophageal disease in patients with chest pain and normal coronary arteries has been reported as ranging from 20 to 60 percent.⁵ The use of ED observation units can help sort these patients out by providing time for a protocol-driven, rapid rule-out of acute myocardial infarction, followed by risk stratification for underlying ACS with stress or radionuclide testing, all done on an outpatient basis (see Chap. 49 for further discussion). At a minimum, an electrocardiogram (ECG) and chest radiographs should be obtained in all patients with ambiguous presentations.

If chest pain is determined to be noncardiac in nature, treatment aimed at esophageal disease is often initiated empirically. There are 1 reliable data on which to base a therapeutic plan for these patients.¹ Outpatient options beyond 6 to 8 weeks of empiric treatment for GERD include an acid infusion test, esophagoscopy, and/or manometry to help clarify pain of esophageal origin.

Gastroesophageal Reflux Disease (GERD)

Reflux of gastric contents into the esophagus causes a wide array of symptoms and long-term effects. It affects up to 25 percent of the adult population, possibly with even higher rates in elderly populations.¹ Classically, a weak LES has been the mechanism held responsible for reflux, and this is seen in some patients. However, transient relaxation of the LES complex (with normal tone in between periods of relaxation) is the primary mechanism causing reflux. Patients with moderate to severe reflux also often have concomitant hiatal hernia.¹³ Pre-

longed gastric emptying, agents that decrease LES pressure, and impaired esophageal motility predispose to reflux. Table 75-2 highlights some common contributors.

As noted, differentiating esophageal symptoms from acute ischemic coronary symptoms is often not possible in the ED. Heartburn is the classic symptom of GERD, and chest discomfort may be the sole manifestation of the disease. The burning nature of the discomfort is probably due to localized lower esophageal mucosal inflammation. Many GERD patients will report other associated gastrointestinal symptoms, such as odynophagia, dysphagia, acid regurgitation, and hypersalivation. The association of pain with meals can be helpful in identifying pain that is due to GERD. Postural changes in pain can also be useful: increasing intraabdominal pressure or negating the advantage of gravity can exacerbate reflux symptoms dramatically. Antacid-induced relief of symptoms is often noted in reflux disease, though the pain can return after the transient antacid effect wears off, and a certain number of patients with ischemic disease also report improvement with the same therapy. Unfortunately, like cardiac pain, GERD pain may be squeezing, pressure-like, and include a history of onset with exertion and offset with rest. Both types of pain may be accompanied by diaphoresis, pallor, and nausea and vomiting. Radiation of esophageal pain can occur in one or both arms, the neck, the shoulders, or the back. Given the serious outcome of unrecognized ischemic disease compared with the relatively benign nature of esophageal pain, a cautious approach to these patients is warranted.

Over time, GERD can cause complications: strictures can develop, with associated dysphagia as discussed above, and inflammatory esophagitis can develop, also discussed below. A severe consequence of GERD, Barrett esophagus, is present in up to 10 percent of patients with GERD.¹⁴ This condition is identified by biopsy; simple columnar epithelium replaces the normal stratified squamous epithelium in the distal esophagus. Metaplasia and ulceration can be present. Barrett esophagus is considered a premalignant condition, with a well-reported association between the development of metaplasia and the onset of adenocarcinoma.¹⁵

Less obvious presentations of GERD also occur. Pulmonary symptoms, especially asthma exacerbations, and multiple ear/nose/throat symptoms are well described. GERD is present in many asthmatics, and can contribute to their disease by aspiration of minute amounts of gastric contents, with subsequent inflammation and bronchospasm, and by esophageal activation of reflex vagal tone with consequent bronchospasm. Unfortunately, identifying asthmatic patients with GERD who will benefit with antireflux therapy remains difficult.^{15,16} GERD has been implicated in the etiology of dental erosion, vocal cord ulcers and granulomas, laryngitis with hoarseness, chronic sinusitis, and chronic cough.^{17,18}

Comprehensive treatment of reflux disease involves decreasing acid production in the stomach, enhancing upper tract motility, and

eliminating risk factors for the disease. As noted above, mild disease is often treated empirically. H₂ blockers or proton-pump inhibitors are mainstays of therapy. Dosage is titrated for each patient. A prokinetic drug may also greatly decrease symptoms. Simple ED discharge instructions should be given to all patients thought to be experiencing reflux-related symptoms: Avoid agents that exacerbate GERD (ethanol, caffeine, nicotine, chocolate, fatty foods), sleep with the head of the bed elevated (30°), and avoid eating within 3 h of going to bed at night. Management of Barrett's esophagus includes intensive treatment of the underlying GERD with proton-pump inhibition. Often, laser or photodynamic ablation therapy and surgical treatment are employed as well. Close monitoring for dysplastic change is essential.

Esophagitis

Esophagitis can cause prolonged periods of chest pain and almost always causes odynophagia as well. Diagnosis of advanced esophagitis is by endoscopy. Low-grade disease can be seen by histopathologic examination.

INFLAMMATORY ESOPHAGITIS GERD may induce an inflammatory response in the lower esophageal mucosa. Over time, this can progress to esophageal ulcerations, scarring, and stricture formation. The presence of reflux-induced esophagitis warrants aggressive pharmacologic therapy with acid-suppressive medications. If this treatment regimen is not sufficient, surgical options are considered.¹⁵ Ingested medications can also be a source for inflammatory esophagitis, usually from prolonged contact of the medication with the esophageal mucosa. Ulceration can be associated with this process. Multiple medications have been implicated. Common offenders include nonsteroidal and other antiinflammatory drugs, potassium chloride, and especially antibiotics (e.g., doxycycline, tetracycline, and clindamycin).¹⁹ Risk factors for pill-induced esophageal injury include swallowing position, fluid intake, capsule size, and age. Withdrawal of the offending agent is generally curative.

INFECTIOUS ESOPHAGITIS Patients with immunosuppression [acquired immunodeficiency syndrome (AIDS), iatrogenic causes, cancer] can develop an infectious esophagitis. AIDS has made esophageal infection more routine in the ED. The diagnosis of infectious esophagitis in an otherwise seemingly healthy host should prompt a search for underlying immunocompromise. Candidal species are the most common pathogens, often associated with dysphagia as a primary symptom. Herpes simplex, cytomegalovirus, and aphthous ulceration are also seen and may be more frequently associated with odynophagia. Other agents are rare and include other fungal infections, mycobacteria, and other viral pathogens such as varicella zoster and Epstein-Barr virus. Endoscopy with biopsy and culture is used to establish this diagnosis.²⁰

TABLE 75-2 Causes of Gastroesophageal Reflux Disease

Decreased Pressure of Lower Esophageal Sphincter	Decreased Esophageal Motility	Prolonged Gastric Emptying
High-fat food	Achalsia	Medicines (anticholinergics)
Nicotine	Scleroderma	Outlet obstruction
Ethanol	Presbyesophagus	Diabetic gastroparesis
Caffeine	Diabetes mellitus	High-fat food
Medicines (nitrates, calcium channel blockers, anticholinergics, progesterone, estrogen)		
Pregnancy		

Esophageal Motility Disorders

Esophageal dysmotility is the excessive, uncoordinated contraction of esophageal smooth muscle. Debate continues over the correlation between symptoms (pain) and observed motor events during manometry, a primary diagnostic modality for these disorders.¹⁰ Achalasia and diffuse esophageal spasm were discussed above. The other motility disorders commonly recognized include ineffective esophageal motility, hypertensive LES, and nutcracker esophagus.

Clinically, chest pain is the presenting symptom in the majority of patients with these disorders. The onset is usually in the fifth decade. The pain often occurs at rest and is dull or colicky in nature. Stress or ingestion of liquids at the extremes of temperature may serve as a trigger. An acute episode of pain may be followed by hours of dull, aching, residual discomfort. Many patients will also experience dysphagia, which is usually intermittent. Pain from spasm may respond to

nitroglycerin. Calcium channel blockers and anticholinergic agents can also be employed.

"*Nutcracker esophagus*" is a motility disorder in which there are high-amplitude, long-duration peristaltic contractions in the distal body of the esophagus or the LES. Manometric criteria require readings of > 180 mm Hg. The cause of nutcracker esophagus is unknown. The disease is the most common motility disorder found in patients with noncardiac chest pain.¹⁰ Patients with this disorder frequently have associated psychiatric disorders and about one-third have GERD.

ESOPHAGEAL PERFORATION

Perforation of the esophagus can occur secondary to a number of disparate processes²¹ as noted in Table 75-3. Iatrogenic injury is the most frequent cause of esophageal injury, accounting for up to 75 percent of all perforations. Endoscopy, a prime offender, has a lower rate of perforation when performed on an esophagus free of disease than on a diseased esophagus. Dilation of strictures increases the risk of perforation greatly. Other intraluminal procedures, such as variceal therapy and palliative laser treatment for cancer, are also associated with perforation. A well-recognized clinical scenario of postemetic perforation, Boerhaave syndrome, is responsible for roughly 10 to 15 percent of esophageal perforations and is discussed below.

Perforation causes a dramatic presentation if esophageal contents leak into the mediastinum. A fulminant, necrotizing mediastinitis with polymicrobial infection that rapidly leads to shock and death can ensue. Perforation into the pleural or peritoneal spaces can occur as well, and contamination of these large potential spaces also tends to result in rapidly progressive infection and shock. If the perforation is small and leakage is contained by contiguous structures, the course may be significantly more indolent. Most spontaneous perforations occur through the left posterolateral wall of the distal esophagus.²² Proximal perforation, seen mostly with instrumentation, tends to be less severe than distal perforation and can be contained locally as a periesophageal abscess with minimal systemic toxicity.

Pain is classically described as acute, severe, unrelenting and diffuse, and is reported in the chest, neck, and abdomen. Pain can radiate to the back and shoulders, or back pain may be the predominant symptom. Pain is often exacerbated by swallowing. Dysphagia, dyspnea, hematemesis, and cyanosis can be present as well. Less acute and atypical presentations are also described. Esophageal perforation is of-

ten ascribed to acute myocardial infarction (MI), pulmonary embolus, peptic ulcer disease, aortic catastrophe, or acute abdomen, resulting in critical delays in diagnosis, the most important factor in determining morbidity and mortality outcome.

Physical examination varies with the severity of the rupture and the elapsed time between the rupture and presentation. Abdominal rigidity with hypotension and fever often occur early. Tachycardia and tachypnea are common. Cervical subcutaneous emphysema is common in cervical esophageal perforations. Mediastinal emphysema takes time to develop. It is less commonly detected by examination or radiography in lower esophageal perforation, and its absence does not rule out perforation.²³ Hammon crunch, caused by air in the mediastinum being moved by the beating heart, can sometimes be auscultated. Pleural effusion develops in half of patients with intrathoracic perforations and is uncommon in those with cervical perforations. Pleural fluid can be due to either direct contamination of the pleura space or a sympathetic serous effusion from mediastinitis.

Making the correct diagnosis in a timely manner in an ill patient with esophageal perforation requires suspicion on the clinician's part. Chest x-ray can suggest the diagnosis. If a pleural effusion is aspirated, elevated amylase in the pleural fluid suggests esophageal perforation. Computed tomography (CT) of the chest or emergency endoscopy are most often used to confirm the diagnosis. Selection of the procedure depends upon the clinical setting and the local resources available.

Perforation of the esophagus is associated with a high mortality rate regardless of the underlying cause. The elapsed time between perforation and the initiation of therapy, the location of the perforation and the etiology all affect outcome. Rapid, aggressive management is key to minimizing the morbidity and mortality associated with esophageal perforation. In the ED, resuscitation of shock, broad spectrum parenteral antibiotics, and emergent surgical consultation should be obtained as soon as the diagnosis is seriously entertained. Patients with systemic symptoms and signs after perforation need operative management. Criteria are developing for the nonoperative management of perforation in select patients.²¹

Instrumentation, especially endoscopic dilatation, has a relatively high rate of perforation; therefore it is patients with strictures who sustain these injuries, usually perforating distally around the level of the obstruction. A patient with a relatively healthy esophagus undergoing instrumentation will more commonly perforate proximally. Perforation from other instrumentation, including nasogastric tube placement, has been reported.²⁴

Boerhaave syndrome refers to full-thickness perforation of the esophagus following a sudden rise in intraesophageal pressure. The mechanism is sudden, forceful emesis in about three-fourths of the cases; coughing, straining, seizures, and childbirth have been reported as causing perforations as well. Alcohol is frequently an antecedent to this syndrome, which is seen more commonly in males. The perforation is usually in the distal esophagus on the left side.

Trauma to the esophagus accounts for roughly 10 percent of all esophageal perforations. Rupture from blunt injury is rare. Penetrating wounds to the esophagus from neck trauma occur but are often masked by more rapidly fatal injuries to the surrounding critical structures, such as the airway and major vessels. A combination of esophagography and esophagoscopy is used to assess patients for potential esophageal injury.

Foreign-body ingestion may result in perforation of the esophagus as well. The perforation is almost always at one of the sites of anatomical narrowing, where foreign bodies become wedged. The injury can be due to pressure necrosis from the object (coin), penetration from the object (pin, bones), or chemical irritation from the object (battery, pill).

TABLE 75-3 Causes of Esophageal Perforation

Causes of Perforation	Comments
Iatrogenic	Intraluminal procedures Endoscopy Dilatation Variceal therapy Gastric intubation Intraoperative injury
Boerhaave syndrome	"Spontaneous" usually associated with transient increase in intraesophageal pressure
Trauma	Penetrating Blunt (rare) Caustic ingestion
Foreign body	Includes pill-related injury
Infection	Rare
Tumor	May be intrinsic or extrinsic cancer
Aortic pathology	Aneurysm Aberrant right subclavian artery
Miscellaneous	Barrett esophagus Zollinger-Ellison syndrome

ESOPHAGEAL BLEEDING

The general approach to upper gastrointestinal bleeding (UGIB) from an esophageal source does not differ from the approach for bleeding from other sources and is addressed in more depth in Chaps. 74 and

86. Resuscitation proceeds concurrently with the diagnostic effort of history, physical examination, and laboratory evaluation. Gastric lavage through a nasogastric tube or larger-bore gastric tube is generally accepted, and early airway management should be considered. Prompt mobilization of resources—including blood products, gastroenterology consult for endoscopy, and an appropriate inpatient level of care—is important.

About 60 percent of variceal bleeding will resolve with supportive care alone. The rate of spontaneous cessation is higher for nonvariceal sources of UGIB (up to 80 percent). Patients who continue to bleed need specific intervention. Early endoscopy is generally accepted in patients with UGIB for its diagnostic and therapeutic applications. Multiple pharmacotherapeutic agents (somatostatin analogues) have a role in controlling variceal bleeding, but efficacy in nonvariceal bleeding is less certain. Balloon tamponade is generally considered a last-resort therapy when pharmacologic management has failed and endoscopy is either not feasible secondary to massive bleeding or is ineffective. Surgical treatment can also be considered for patients who fail endoscopic and medical intervention.

Varices develop in patients with chronic liver disease in response to portal hypertension. Around 60 percent of patients with chronic liver disease will develop varices. Of patients who develop varices, 25 to 30 percent experience hemorrhage.²⁵ Patients who develop varices from alcohol abuse have a higher risk of bleeding, especially if there is ongoing alcohol consumption. About two-thirds of patients who have an index bleed experience recurrent hemorrhage, 50 percent occurring within 6 weeks of the initial episode.

With variceal bleeding, endoscopic therapy is often first-line in attempts to control the hemorrhage. Sclerotherapy and ligation are the main alternatives, though the use of injected Histoacryl (a tissue adhesive) to obstruct the variceal lumen has gained popularity. Some authors consider the combination of a vasoactive drug (e.g., octreotide or terlipressin) with endoscopic therapy to be superior to endoscopy alone. More recent review seems to support a trial of medical therapy alone for variceal bleeding in cirrhotics, with results comparable to primary sclerotherapy.^{26,27} Shunting procedures performed transvenously or by surgical approach can also be considered.²⁸ Despite progress in treating variceal bleeding, mortality remains high. Concurrent hepatic failure is a risk factor for poor outcome.

Mallory-Weiss syndrome is arterial bleeding from longitudinal mucosal lacerations of the distal esophagus/proximal stomach. The majority of these lacerations are located at the GE junction, with only 10 percent found in the lower esophagus proper. Mallory-Weiss tears are responsible for between 5 and 15 percent of upper GI hemorrhages. They can occur at any age but are most common in the fourth through sixth decades. The pathophysiology of Mallory-Weiss syndrome is thought to be a transient, large pressure gradient between thorax and stomach, experienced maximally at the GE junction.

Acute onset of upper GI bleeding is the usual presentation, though some patients can present with melena or hematochezia. Rarely the presentation will be one of isolated abdominal pain or syncope. Less than half of patients with Mallory-Weiss tears will report a history of vomiting prior to hematemesis. The spectrum of severity of bleeding is broad, but overall a low relative incidence of surgical intervention or adverse outcome is seen. Initial treatment is supportive as the vast majority of Mallory-Weiss tears stop bleeding spontaneously. Ongoing hemorrhage can require treatment with electrocoagulation, sclerotherapy, and laser photocoagulation. Angiographic embolization or surgical intervention remain options as well.

Esophageal cancer often results in heme-positive stools but is an uncommon cause of significant upper or lower GI bleeding.

SWALLOWED FOREIGN BODIES

Wade R. Gaasch Robert A. Barish

Swallowed foreign bodies, a common presentation in emergency departments, can be innocuous or life threatening. In the United States, approximately 1500 people die yearly as a result of ingesting foreign bodies.¹ Often thought to be confined to the pediatric population.

foreign body ingestion occurs in all age groups. The pediatric age group accounts for approximately 80 percent of all cases, followed by edentulous adults, prisoners, and psychiatric patients. The presence of dentures eliminates the tactile sensitivity of the palatal surface vital to the identification of small items. A correlation exists between age groups and specific types of ingested material. Children most often ingest coins, toys, crayons, and ballpoint pen caps; adults tend to have problems with meat and bones.² In addition, psychiatric patients and prison inmates may ingest such unlikely objects as spoons and razor blades.

PATHOPHYSIOLOGY

Most objects pass spontaneously, but 10 to 20 percent require some intervention, and only 1 percent demand surgical treatment.³ Ingested foreign bodies may be found anywhere throughout the digestive tract, but the majority of articles tend to lodge in several physiologic "narrow spaces." The pediatric esophagus has five areas of constriction where coins and other objects may become trapped: cricopharyngeal narrowing (C6), the most common site; the thoracic inlet (T1); the aortic arch (T4); the tracheal bifurcation (T6); and the hiatal narrowing (T10-11). Most pediatric obstructions occur in the proximal esophagus; the vast majority of adult impactions arise from esophageal disease in the distal esophagus. Because 97 percent of adults presenting with meat impaction harbor pathologic esophageal conditions, barium swallow must be performed to confirm foreign body clearance and evaluate possible underlying disease.

Once an object has traversed the pylorus, it usually continues to the rectum and is passed in the stool. If, however, the object has irregular or sharp edges, it may become lodged anywhere in the gastrointestinal tract. Objects that lodge in the esophagus (not necessarily limited to those with sharp or irregular contour) can result in airway obstruction, stricture, or perforation with resulting mediastinitis, cardiac tamponade, paraesophageal abscess, or aortotracheoesophageal fistula. Perforation may be the result of direct mechanical erosion, as with bones, or chemical corrosion, as with button batteries.

CLINICAL PRESENTATION

Objects lodged in the esophagus generally produce anxiety and discomfort. Adult patients often complain of retrosternal pain. Patients are likely to retch or vomit and experience dysphagia, resulting in choking, coughing, or aspiration if they attempt to wash down the object. Eventually, patients may be unable to swallow their own secretions. In the adult, the history often provides all the pertinent information necessary for diagnosis and treatment. However, this is often not true for children. In those 16 years and younger, symptoms include refusal to eat, vomiting (with or without hematemesis), gagging, choking, stridor ("pseudoasthma"), neck or throat pain, inability to swallow, increased salivation, and foreign body sensation in the chest.

The differential diagnosis for patients suspected of having swallowed a foreign body (Table 76-1) includes dysphagia, esophageal carcinoma, and gastroesophageal reflux disease.⁴

Physical examination must include careful evaluation of the nasopharynx, oropharynx, neck, and subcutaneous tissues for air resulting from perforation of a hollow viscus. Laryngoscopy, direct or indi-

rect, should be done, especially when the patient complains of a stinging sensation or has ingested a bone. Although physical signs are not always present, findings consistent with foreign body ingestion 16 years and younger consist of red throat, dysphagia, palatal abrasion, temperature elevation, anxiety and distress, and peritoneal signs.

EMERGENCY DEPARTMENT MANAGEMENT

General Care

Because the great majority of ingested foreign bodies traverse the entire gastrointestinal tract without any problems, treatment can be expected once the object has passed through the pylorus.⁵ If, however, foreign body obstructs the esophagus, prevention of aspiration is paramount. This can be accomplished by inserting a tube above the obstructing body to remove unswallowed fluids above the impaction. Conditions warranting consultation with an endoscopist and possible hospital admission are listed in Table 76-2. In almost all cases, endoscopy allows removal of a foreign body without complications.⁶

The offending object can be located in several ways. A radiopaque object will be demonstrated on standard x-ray films of the neck or abdomen. The procedure of choice for finding and then extracting a foreign body in the esophagus is endoscopy.⁷ This procedure has a high success rate and thus avoids progression to surgery.⁸ It is also time efficient.⁹ Although many other diagnostic methods are available, they are not as reliable and thorough as endoscopy, so the time spent in waiting for and conducting such tests may not be time well spent for a frightened, uncomfortable patient.

If endoscopic equipment and expertise are not available, an esophagogram can be performed. Consultation with an endoscopist is strongly recommended before initiation of any contrast study, because direct visualization of the foreign body after contrast administration may not be possible because of interference from swallowed contrast medium.

The type of contrast agent must be chosen based on the anticipated clinical findings and course.¹⁰ If perforation is suspected, a water-soluble contrast agent (Gastrografin) should be used. However, because water-soluble agents are pulmonary irritants, barium should be used if aspiration is possible. The least amount of barium possible should be instilled, because barium will block the endoscopic field. If perforation and aspiration are possible, a nonionic contrast agent is indicated.

Progress of the object through the gastrointestinal tract must be monitored with repeat abdominal x-ray films, usually 2 to 4 hours apart. The use of metal detectors, if available, has been advocated as a means of localizing and tracking the progression of metal objects, thereby avoiding repeated radiation exposure. Abdominal examinations should be done frequently to detect early signs of developing peritonitis should perforation occur. Virtually all symptomatic patients will require observation and esophagoscopy. If a nonfood object becomes lodged in the esophagus or is unable to pass through the pylorus, it must be removed as soon as possible with the use of esophagogastroscopy. Fatal lead encephalopathy has been reported in a child who ingested a lead curtain weight, which supposedly had been in the stomach for an extended period.¹¹

Food Impaction

Meat impaction may be treated expectantly, provided the patient can manage the secretions. Time and sedation often will allow the meat to pass into the stomach, but the bolus should not be allowed to remain impacted longer than 12 h. Endoscopy is the preferred method for removal. Alternatives have been suggested if endoscopy is not available.

The use of proteolytic enzymes, such as an aqueous solution of papain (e.g., Adolph's Meat Tenderizer), to dissolve a meat bolus is *not* recommended, because of the number of reported complications and because of increasing availability of and expertise in endoscopy. Several reports in the literature have described esophageal perforation secondary to the enzymatic action of the solution. Mucosal ischemia resulting from distention of the esophageal wall renders the esophagus more susceptible to enzymatic degradation. Hemorrhagic pulmonary edema also has been reported after aspiration of Adolph's Meat Tenderizer.

Intravenous administration of glucagon to relax esophageal smooth muscle also has been suggested as a method of treating food impaction. A test dose should be given to ensure that hypersensitivity does not exist; then the recommended dose is 1 mg. If the food bolus is not passed in 20 min, an additional 2 mg is given IV. An esophagogram must be performed after treatment to ensure passage. This strategy was questioned by Tibbling and associates who found no statistical difference in disimpaction rates between patients given spasmolytic drugs and those given placebo.¹² For patients with esophageal obstruction caused by food, more efficient approaches to treatment are endoscopy and esophagoscopy.

Bell and Eibling reported the successful use of nifedipine, which reduces lower esophageal sphincter pressure and the amplitude of the sphincter contractions without changing the amplitude of contractions in the body of the esophagus.¹² By this mechanism, a bolus of food lodged in the vicinity of the gastroesophageal junction may pass. The recommended dose is 10 mg administered sublingually. Sublingual nitroglycerin also has been used successfully, but it can cause hypotension.

Coin Ingestion

Because as many as 35 percent of children with a coin lodged in their esophagus will be asymptomatic, some authors recommend that radiographs be performed in *all* children suspected of swallowing coins to determine the presence and location of the object. However, Caravati and colleagues noted no difference in 5-day morbidity rates between children who underwent radiographic evaluation and those who did

not after coin ingestion.¹⁴ Coins in the esophagus lie in the frontal plane with the flat side visible on an anteroposterior radiograph; coins in the trachea lie in the sagittal plane (Figure 76-1).

The use of a Foley catheter, initially reported in the late 1960s, has been promoted as a safe and effective technique for removal when the coin has been impacted for fewer than 24 h. Before attempting extraction, the airway must be secured with endotracheal intubation. The catheter is passed down the esophagus beyond the object and the balloon is inflated. As the catheter is slowly withdrawn, the object is withdrawn along with it. Retrieval of a coin by this technique is less effective after 24 h. Most clinicians prefer using the Foley catheter under fluoroscopic guidance. Foley catheter retrieval of foreign bodies may be complicated by aspiration, and personnel and equipment for airway control must be immediately available. If endoscopic expertise is readily available, Foley catheterization retrieval should be a secondary option.

Button Battery Ingestion

A button battery lodged in the esophagus is a true emergency, because of the extremely rapid action of the alkaline substance on the mucosa. Burns to the esophagus have been reported to occur in as few as 4 h, with perforation as soon as 6 h after ingestion. Button batteries in the esophagus require emergency removal if significant morbidity is to be averted. Outcome does not appear to be affected by battery discharge state but is affected by chemical composition.¹⁵ Lithium cells are associated disproportionately with adverse outcome. Mercuric oxide cells tend to fragment more frequently than other cells; however, the threat of heavy metal poisoning has not been supported by the literature or clinical experience. This fact notwithstanding, blood and urine mercury levels should be measured whenever a mercury-containing cell is observed to have split while in the gastrointestinal tract.

Button ingestion can be managed along two main pathways (Figure 76-2). If the button battery is lodged in the esophagus, its location should be documented by radiograph; then emergent endoscopic removal is mandatory. Given the widespread expertise with endoscopy, we cannot recommend alternative techniques, many of which are associated with significant complications. Ipecac has no place in the management of button battery ingestion.¹⁵ Button batteries that have passed the esophagus need not be retrieved in the asymptomatic patient unless the cell is not passing through the pylorus after 48 h of observation. This is rarely the case unless the battery is of large diameter and the patient is younger than 6 years. In this case, endoscopic

Columbus, Ohio Chapter of the American College of Emergency Physicians, 1997, case 27.]

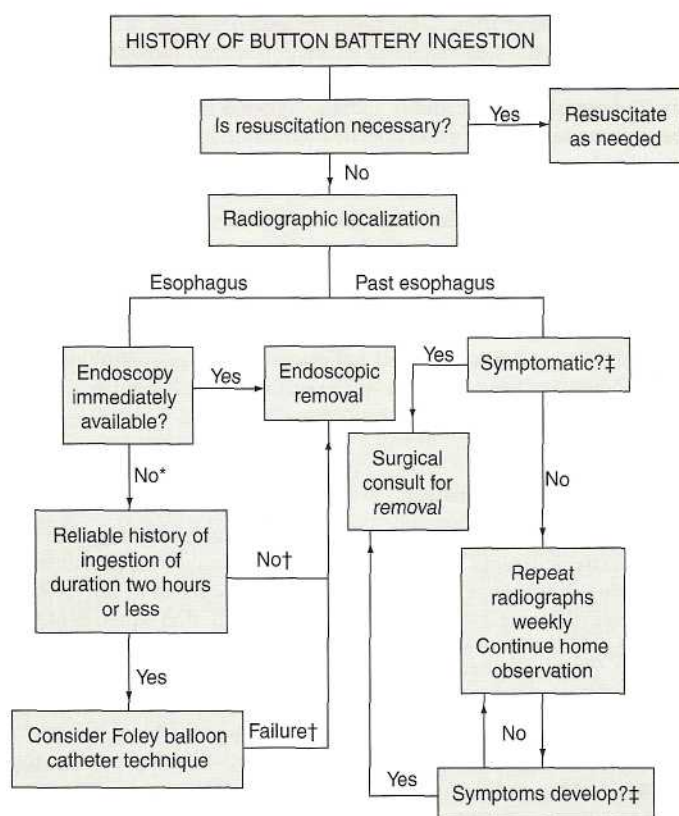

FIG. 76-2. Algorithm for management of button battery ingestion. *Button batteries in the esophagus must be removed. Endoscopy should be used, if available. The balloon catheter technique can be used if the ingestion occurred no more than 2 h previously, but it should not be used after this period, because it may increase the amount of damage to the weakened esophagus. †When the Foley technique fails or is contraindicated because more than 2 h have elapsed, the button battery should be removed endoscopically. This may require transfer of the patient. ‡Acute abdomen, tarry or bloody stools, fever, persistent vomiting. (Adapted from Kuhns DW, Dire DJ: Button battery ingestions. *Ann Emerg Med* 18:293, 1989.)

retrieval is the preferred option. Most batteries pass completely through the body within 48 to 72 h, although passage has been reported to take as long as 14 days. All patients with signs and symptoms of gastrointestinal tract injury require immediate surgical consultation. Assistance with cell identification may be obtained by calling the National Button Battery Ingestion Hotline (National Capital Poison Center, Washington, DC) at 1-202-625-3333.

Ingestion of Sharp Objects

Management of ingested sharp and pointed foreign bodies is controversial. Objects longer than 5 cm and wider than 2 cm rarely will pass the stomach. Objects of that size and those with extremely pointed edges, such as open safety pins or razor blades, must be removed before they pass from the stomach because 15 to 35 percent will cause intestinal perforation, usually in the ileocecal valve.

Paul and Jaffe recommended the following management for children who have swallowed sharp objects.¹⁶ All patients should have an initial radiograph and physical examination. If the patient is symptomatic or has ingested a sewing needle, surgical consultation for possible endoscopy and laparotomy is indicated. Children who have swallowed a sharp object (other than sewing needles) but are asymptomatic can be managed on an expectant basis. Progression of the sharp object should be documented with serial radiographs. If progression past the stomach

is not seen, a water-soluble contrast film may document gastrointestinal perforation. At the first sign of perforation, the object should be removed even if the patient remains asymptomatic. If the object does not progress through the gastrointestinal tract, surgical retrieval is indicated.

Cocaine Ingestion

Cocaine ingestion is an increasingly widespread problem. Carriers will ingest multiple small packets of cocaine in attempts to conceal the drug. A favored packet is the condom, which may hold up to 5 g of cocaine. Rupture of even one such packet may be fatal. Webb recommended surgery as the safest method of recovery to avoid the likelihood of packet rupture during endoscopic retrieval.² If the packet appears to be passing intact through the intestinal tract, the clinician may choose to observe the patient and wait for the packet to be delivered spontaneously through the rectum.

PEPTIC ULCER DISEASE AND GASTRITIS

Matthew C. Gratton
Howard A. Werman

Peptic ulcer disease is a chronic illness manifested by recurrent ulcerations in the stomach and proximal duodenum. Acid and pepsin are thought to be crucial to ulcer development, but it is now recognized that the great majority of peptic ulcers are directly related to infection with *Helicobacter pylori* or nonsteroidal anti-inflammatory drug

(NSAID) use.^{1,2} Gastritis is acute or chronic inflammation of the gastric mucosa and has various etiologies. Dyspepsia is continuous or recurrent upper abdominal pain or discomfort with or without associated symptoms (nausea, bloating, regurgitation, etc.).³ Dyspepsia may be caused by a number of diseases or may be functional.

EPIDEMIOLOGY

Approximately 10 percent of the U.S. population older than 17 years have peptic ulcer disease at some time. One third of them report an active ulcer within the past year.⁴ Peptic ulcer disease has a high rate of morbidity, with 8 million physicians' visits and 275,000 hospitalizations per year and a high cost to society of \$5.65 billion per year in lost wages and medical care.⁴ The prevalence of *H. pylori* infection in white Americans younger than 35 years is about 10 percent, rising to almost 80 percent by age 75. Forty-five percent of black Americans younger than 25 years are infected.⁵ Presumably because of improvements in the standard of living, the prevalence of *H. pylori* is decreasing in most developed countries.⁶ The prevalence of dyspepsia is 25 to 30 percent in the United States.^{3,7}

PATHOPHYSIOLOGY

Hydrochloric acid and pepsin destroy gastric and duodenal mucosa. Mucous and bicarbonate ion secretions protect mucosa. Prostaglandins protect mucosa by enhancing mucous and bicarbonate production and by enhancing mucosal blood flow, thereby supporting metabolism. The balance between these protective and destructive forces determines whether peptic ulcer disease will occur. *Helicobacter pylori* infection or NSAIDs are thought to be the causal agents of peptic ulcer disease in almost all cases.¹² *Helicobacter pylori* infection is present in 95 percent of duodenal ulcers and 80 percent of gastric ulcers.⁸ Although traditional treatment of peptic ulcers by various modalities heals most ulcers, eradication of *H. pylori* reduces recurrence rates from 80 to 15 percent for duodenal ulcers and from 50 to 10 percent for gastric ulcers.⁸ *Helicobacter pylori* is a spiral, urease-producing, flagellated bacterium that is found living between the mucous gel and the mucosa primarily in the gastric antrum.⁵ The production of urease, cytotoxins, proteases, and other compounds is thought to disturb the mucous gel and cause tissue injury.^{2,5} In the presence of acid and pepsin, ulceration may occur. Chronic active (usually asymptomatic) gastritis is an almost universal finding with *H. pylori* infection, but only 10 to 20 percent of infected people develop peptic ulcer disease.^{5,9} It is unclear why most infected persons do not develop symptomatic peptic ulcer disease, but it most likely reflects an interaction of factors, including host and pathogen (different virulence of strains of bacteria).⁹

Helicobacter pylori has been linked to mucosa-associated lymphoid tissue lymphoma, and regression has been documented with eradication of infection. In addition, *H. pylori* infection is considered a definite risk factor for adenocarcinoma of the stomach. However, because the prevalence of gastric cancer in the United States is very low and the *H. pylori* infection rate is very high, other factors undoubtedly are involved.⁵

Nonsteroidal anti-inflammatory drugs inhibit prostaglandin synthesis, thereby decreasing mucous and bicarbonate production and mucosal blood flow, allowing ulcer formation.² Gastrin-secreting tumors produce ulceration due to high levels of acid and pepsin production, but acid alone rarely causes ulceration. However, inhibition of acid secretion may allow ulcers to heal and is the basis for traditional ulcer treatments.

Hereditary factors cause a predisposition to peptic ulcer disease. There is an association between chronic renal failure, renal transplantation, cirrhosis, chronic obstructive pulmonary disease, and peptic ulceration, but the precise mechanism is unclear. Cigarette smoking is a predisposing factor for peptic ulcer disease, perhaps due to an inhibi-

tion of bicarbonate ion production or to increased gastric emptying (but not to increased acid production). Emotional stress may predispose to peptic ulcer disease, but diet and alcohol use do not.

Acute gastritis may be related to ischemia from severe illness (shock, trauma, severe burns, organ failure, etc.) or the direct toxic effects of agents (NSAIDs, alcohol, bile acids, etc.). *Helicobacter pylori* infection causes acute and chronic gastritis (both usually asymptomatic). Chronic gastritis may also be caused by autoimmune factors that destroy gastric parietal cells, resulting in the loss of acid production and the loss of intrinsic factor production, which in turn cause malabsorption of vitamin B₁₂ and, hence, pernicious anemia.

CLINICAL FEATURES

Burning epigastric pain is the most classic symptom of peptic ulcer disease. The pain also may be described as sharp, dull, an ache, or an "empty" or "hungry" feeling. Pain may be relieved by milk, food, or antacids, presumably due to buffering and/or dilution of acid. Pain recurs as the gastric contents empty, and the recurrent pain may classically awaken the patient at night. Pain tends to occur daily for weeks, resolve, and then reoccur in weeks to months. Although no symptoms allow complete discrimination, Talley and colleagues found that peptic ulceration is more likely than nonulcer dyspepsia or cholelithiasis in the presence of night pain; pain relieved by food, milk, or antacids; and a shorter duration of pain.⁷ Postprandial pain, food intolerance, nausea, retrosternal pain, and belching are not related to peptic ulcer disease.¹⁰ Atypical presentations are common in those older than 65 years, including no pain, epigastric pain not relieved by eating, nausea, vomiting, anorexia, weight loss, and bleeding.¹¹

A change in the character of the patient's typical pain may herald a complication. Abrupt onset of severe or generalized pain may indicate perforation with spillage of gastric or duodenal contents and resulting peritonitis. Rapid onset of mid-back pain may be due to posterior penetration into the pancreas, with the development of pancreatitis. Nausea and vomiting may indicate gastric outlet obstruction from scarring or edema. Vomiting bright red blood or coffee-ground emesis or passing tarry or melanotic stool or hematochezia indicates ulcer bleeding.

On physical examination, the only positive finding in patients with uncomplicated peptic ulcer disease may be epigastric tenderness. This finding is neither sensitive nor specific for the diagnosis.⁷ Other physical findings may be indicative of complications: a rigid abdomen consistent with peritonitis in perforation; abdominal distention or a succussion splash due to obstruction; occult or gross blood per rectum or nasogastric tube with ulcer bleeding.

Epigastric pain, nausea, and vomiting may be present with acute gastritis, but the most common presentation is gastrointestinal bleeding, ranging from occult blood loss in the stool to massive upper gastrointestinal hemorrhage. Physical findings may be normal, may reflect only the gastrointestinal bleeding, or may reflect a severe underlying associated illness (as listed above).

DIAGNOSIS

A definitive diagnosis of peptic ulcer disease cannot be made on clinical grounds alone.¹⁰ Uncomplicated peptic ulcer disease can be strongly suspected in the presence of a "classic" history, including epigastric burning pain; relief of pain with milk, food, or antacids; and night pain accompanied by "benign" physical examination findings, including normal vital signs with or without mild epigastric tenderness. The differential diagnosis of epigastric pain is extensive and, in addition to peptic ulcer disease, includes gastritis, gastroesophageal reflux disease, cholelithiasis, pancreatitis, hepatitis, abdominal aortic aneurysm (AAA), gastroparesis, and "functional" dyspepsia. A careful history may elicit features that point away from peptic ulcer disease: burning pain radiating into the chest, water brash, and belching may suggest gastroesophageal reflux disease; more severe pain radiating to

the right upper quadrant and around the right or left side suggests cholelithiasis; radiation through to the back indicates pancreatitis or AAA; chronic pain, anorexia, or weight loss may indicate gastric cancer. Myocardial ischemic pain may also present as epigastric pain and should be strongly considered in the appropriate clinical setting.

Physical examination findings may suggest other diagnoses: right upper quadrant tenderness points to cholelithiasis or hepatitis, an epigastric mass to pancreatitis (pseudocyst), a pulsatile mass to AAA, jaundice to hepatitis, and peritoneal findings to an acute abdomen.

In a patient presenting with epigastric pain, a number of ancillary tests may be helpful to exclude peptic ulcer disease complications and to narrow the differential diagnosis. A normal complete blood count will rule out anemia from chronic gastrointestinal bleeding due to peptic ulcer disease, gastritis, or cancer (but does not rule out acute blood loss). Elevated liver function test results may indicate hepatitis, and elevated lipase levels may indicate pancreatitis. An acute abdominal series may show free air associated with perforation. A "limited" emergency department ultrasound examination may show gallstones or an AAA. An electrocardiogram and cardiac enzyme determination are indicated if there is a suspicion of myocardial ischemic pain.

The definitive diagnosis of peptic ulcer disease is made by visualization of the ulcer via upper gastrointestinal barium contrast radiography or via upper gastrointestinal endoscopy. Endoscopy has a higher yield rate for ulcer and other mucosal pathologic conditions, which may affect clinical care¹ (Table 77-1). However, endoscopy also has a higher cost and complication rate.¹

Because most peptic ulcers are caused by *H. pylori* infection and eradication of *H. pylori* dramatically decreases ulcer recurrence rate, it is important to note how to diagnose infection. *Helicobacter pylori* can be diagnosed by endoscopic tests, including the rapid urease test, histologic study, or culture, and noninvasive tests, including serologic tests, urea breath tests, and stool antigen tests.^{1,6,9,12,13} The rapid urease test (also known as the *Campylobacter*-*Wke*, organism test) detects the presence of urease in a biopsy specimen (presumptive evidence of *H. pylori* infection) with 90 to 95 percent sensitivity and 90 to 100 percent specificity and a cost of \$6 to \$20. Histologic study using special stains has a sensitivity and specificity above 90 percent and costs \$60 to \$250. Culture is difficult and has a sensitivity no better than that of histologic studies (although it has 100 percent specificity if results are positive). *The aforementioned costs do not include the cost of endoscopy.* Serologic studies detect immunoglobulin G antibodies to *H. pylori* via latex agglutination or enzyme-linked immunosorbent assay tests with high sensitivity and specificity at a cost of \$10 to \$100 (higher sensitivity, specificity, and cost with enzyme-linked immunosorbent assay). Serologic studies are not useful as a test of cure, because antibodies remain for several years after eradication of infection. The urea breath test also relies on the presence of urease produced by *H. pylori*. Urea, labeled with ¹³C or ¹⁴C instead of ¹²C, is ingested and, in the presence of bacterial urease, is broken down into labeled carbon dioxide and ammonia. The labeled carbon dioxide is detected in the breath 30 min later. Sensitivity and specificity are greater than 90 percent, and the cost is \$250 to \$350 for ¹³C and \$20 to \$65 for ¹⁴C (¹⁴C is radioactive and, hence, is contraindicated in children and women of childbearing potential). This test is ideal for con-

firmed cure of infection. *Helicobacter pylori* antigens can be detected in the stool with 80 to 100 percent sensitivity. Testing performed 4 weeks or more after completion of *H. pylori* eradication therapy may prove useful as a test of cure.

TREATMENT

After peptic ulcer disease is diagnosed, the goal of treatment is to heal the ulcer while relieving pain and preventing complications and recurrence. Traditional ulcer therapy heals, relieves pain, and prevents complications, but does not prevent recurrence. Treatment of *H. pylori* infection, when present, dramatically decreases the recurrence rate.⁸ If NSAID-associated ulcers are present, the offending agent must be stopped to reduce the recurrence rate.

Traditional therapy includes proton pump inhibitors (PPIs), histamine (H₂) receptor antagonists (H₂RAs), sucralfate, and antacids^{1,14} (Table 77-2). Proton pump inhibitors decrease acid production by irreversibly (covalent bond) binding with a sulfhydryl group of a H⁺K⁺ATPase molecule (proton pump) located on the gastric parietal cell, thus blocking hydrogen ion secretion. Proton pump inhibitors generally heal ulcers faster than do H₂RAs and also have some in vitro inhibitory effect against *H. pylori*.^{1,14} They are metabolized in the liver by the cytochrome P450 system and therefore may decrease the metabolism of many other drugs. In addition, PPIs may inhibit the absorption of drugs that rely on gastric acidity. Serious side effects are rare. Histamine receptor antagonists competitively inhibit the actions

TABLE 77-2 Traditional Drugs for Peptic Ulcers

Drug (PO)	Dosage	
H ₂ receptor antagonists		Serious adverse reactions rare with all in class; dosages should be decreased in renal failure
Cimetidine	400 mg bid	More likely to have drug interactions due to more inhibition of cytochrome system
Famotidine	20 mg bid	
Nizatidine	150 mg bid	
Ranitidine	150 mg bid	
Proton pump inhibitors		Serious adverse reactions rare with all in class
Lansoprazole	15 mg qd	
Omeprazole	20 mg qd	
Rabeprazole	20 mg qd

of histamine on the H_2 receptors of the gastric parietal cells. All four drugs heal ulcers approximately equally and are available in over-the-counter preparations.^{1,14} Because of renal excretion, dosage adjustments must be made in patients with renal failure. Side effects are uncommon, but cimetidine has more significant drug interactions than do the other three due to inhibition of cytochrome P450 activity.¹⁴ Sucralfate appears to protect the ulcer from acid exposure (by forming a sticky gel that adheres to the ulcer crater) and allows healing to occur about as well as H_2 RA. Sucralfate has few side effects but does inhibit absorption of a number of medications.¹⁴ Antacids heal ulcers by buffering gastric acid and are as effective as H_2 RA. Magnesium- and aluminum-containing antacids can inhibit absorption of drugs. In renal failure, aluminum can accumulate and cause osteoporosis and encephalopathy, so aluminum-containing antacids should be avoided. Due to the simplicity of H_2 RA, PPI, and sucralfate dosing requirements, antacids currently are used mainly on an as-needed basis for ulcer pain until healing occurs.

Although NSAIDs should be stopped in patients with peptic ulcer disease whenever possible, misoprostol may prevent ulcer formation in those on concurrent NSAID therapy. Misoprostol is a prostaglandin analogue that may act by increasing mucous and bicarbonate production and by increasing mucosal blood flow.

If *H. pylori* infection is diagnosed in the presence of peptic ulcer disease, eradication is clearly indicated.¹⁴ Multiple regimens have been proposed and studied, mainly by using combinations of a PPI (or ranitidine bismuth citrate) and two antibiotics, most commonly clarithromycin and amoxicillin or metronidazole.^{12,15,16} Cure rates of 80 to 90 percent are typical.¹² Although some European studies demonstrate that 7-day regimens are sufficient for cure, authorities in the United States recommend 10- to 14-day regimens for the best cure rates.^{12,15} A typical 14-day regimen of lansoprazole, clarithromycin, and amoxicillin would cost approximately \$228.¹⁵

Patients generally do not present to the emergency department with a definitive diagnosis of peptic ulcer disease but rather with a symptom, such as epigastric pain. If appropriate history, physical examination, and laboratory evaluation result in a physician's impression of "possible peptic ulcer disease" or "dyspepsia," the physician is left with three main options: empiric treatment with conventional antiulcer medication, immediate referral for definite diagnosis (endoscopic or radiologic study), or noninvasive testing for *H. pylori* followed by antibiotic therapy for patients with positive test results.^{1,9}

Traditional emergency department treatment would entail initiating a trial of antacids and/or H_2 RA and early referral to a primary care provider to direct evaluation and subsequent treatment. This remains a reasonable option. Immediate referral for definite diagnosis is mandated if certain "alarm" features are present: age older than 45 to 50 years, weight loss, long history of symptoms, anemia, persistent anorexia, early satiety, persistent vomiting, or gastrointestinal bleeding.^{1,9,12,15} Cost-effectiveness analysis and consensus statements support treatment of *H. pylori*-positive dyspeptic patients with antimicrobial and antisecretory therapy followed by endoscopic study only in those with persistent symptoms.^{1,12,15,17} It also would be reasonable for the emergency department physician to begin symptomatic therapy, order serologic testing for *H. pylori*, and refer for early follow-up with a primary care provider for initiation of antibacterial therapy if the test results are positive.

COMPLICATIONS

Hemorrhage

In the United States, about 150,000 patients per year are admitted to the hospital with gastrointestinal bleeding due to peptic ulcer disease.¹⁸ Factors predicting death include large initial bleed, continued or recurrent bleeding, older age, and comorbid illness.¹⁸ The mortality

rate is 2 to 3 percent for the 80 to 85 percent of patients who do not rebleed, compared with 20 percent or greater for those who do bleed while hospitalized.¹⁸ Shock, low initial hematocrit, red blood in the emesis or stool, and failure of blood to clear with lavage predict further bleeding.¹⁸

Treatment for ulcer bleeding should focus on restoring hemodynamic stability by intravenous administration of isotonic saline solution and packed red blood cells. Appropriate blood work should be performed, including a complete blood count and type and cross-matching for several units of packed red cells. Two large-bore intravenous lines should be started, and the patient should be placed on oxygen and a cardiac monitor. A nasogastric tube should be inserted and lavaged with water until clear. This does not slow bleeding but does allow monitoring of ongoing bleeding and clears the stomach for endoscopy. An H_2 RA or PPI can be started, but there is no proof that either reduces rebleeding rates.

Most patients should undergo upper gastrointestinal endoscopy for diagnostic, prognostic, and treatment purposes. An actively bleeding vessel seen on endoscopy heralds a 35 percent chance of emergency surgery and an 11 percent mortality rate. Morbidity and mortality decrease with findings of a nonbleeding visible vessel, an adherent clot and a flat, pigmented spot. A low of 0.5 percent emergency surgery and a 2 percent mortality rate is realized if a clear base is found.¹⁸ Treatment through endoscopy includes injection therapy with epinephrine, alcohol, or combinations; heat probe or bipolar electrical coagulation; or laser therapy. All of these treatments stop bleeding, prevent recurrences, and decrease transfusion rates and length of hospital stay. The technique chosen depends on the equipment available and the experience of the endoscopist.¹⁸

The rebleeding rate after endoscopic therapy is about 20 percent and can be treated by repeat endoscopy or emergency surgery. Surgery is also indicated if bleeding cannot be controlled by initial endoscopy. Angiography with arterial vasopressin or embolization can be considered if endoscopy has failed and surgery is thought to be very high risk.¹⁸

Hospitalization in an intensive care setting is indicated for all patients with significant upper gastrointestinal bleeding due to peptic ulcers. If clinical and endoscopic features suggest a low risk of rebleeding, a ward bed may be acceptable.

Perforation

Perforation is heralded by the abrupt onset of severe epigastric pain as gastric or duodenal contents spill into the peritoneal cavity, followed by the development of chemical and then bacterial peritonitis. Patients may not have a prior history of peptic ulcer disease and may in fact have no antecedent history of ulcer-like symptoms. Elderly patients may not have dramatic pain or impressive peritoneal findings.

When the diagnosis is suspected, appropriate laboratory tests, including a complete blood count, type, and cross-match, and a lipase level determination, should be performed; two large-bore intravenous lines started; oxygen and a monitor placed; a nasogastric tube inserted and placed on suction; and an acute abdominal series obtained. Free air is not always present. Some authorities suggest instillation of air into the stomach through the nasogastric tube to detect perforation. This procedure may open a sealed perforation, causing more spillage, and nonvisualization of free air does not rule out a perforation; thus, it is not recommended. Broad-spectrum antibiotics should be given and a surgical consult promptly obtained. In some cases, nonsurgical therapy has been successful, but operative intervention is the standard in the United States.

Obstruction

Obstruction occurs because of scarring of the gastric outlet due to chronic peptic ulcer disease, edema due to an active ulcer, or some

combination of both. Resulting symptoms include abdominal fullness, nausea, and vomiting, and signs may include abdominal distention and a succussion splash. Dehydration and electrolyte imbalances may occur. Treatment includes rehydration with intravenous fluids, correction of electrolyte abnormalities, and relief of distention with nasogastric suction. Hospitalization is almost always indicated. The outlet may open as edema subsides, but surgical correction is often necessary.

DISPOSITION

Patients with complications always require consultation, and most require admission to an appropriate inpatient unit based on the diagnosis and hemodynamic stability. Most patients with epigastric pain or dyspepsia do not leave the emergency department with a definitive diagnosis, but, if critical diagnoses (e.g., AAA or myocardial ischemia) are still in the differential, consultation for admission and appropriate workup is indicated. When uncomplicated peptic ulcer disease, gastritis, or dyspepsia is strongly suspected, the great majority of patients can be discharged with antacids and an H₂RA, with or without a serologic test for *H. pylori*, and close follow-up with their primary care provider. If "alarm" features (indicating possible cancer or bleeding) are present, consultation for early endoscopy is indicated.

Discharge instructions should include an explanation of the diagnosis and home treatment, specific follow-up instructions, and warning symptoms that should prompt immediate reevaluation. The explanation of the diagnosis should specify that peptic ulcer disease is a presumptive diagnosis and that more definitive diagnostic testing may be necessary. Home treatment should include a reminder to take medications as directed; a warning against use of alcohol, tobacco products, and aspirin or other NSAIDs; and a recommendation to avoid foods that appear to upset the individual's "stomach." Specific follow-up should include a name and phone number of the appropriate provider whenever possible and a time frame for reevaluation, generally 24 to 48 h, if not improving, or 1 to 2 weeks, if improving. Warning symptoms that merit immediate reevaluation include those that may be attributed to ulcer complications or confounding illness: worsening pain, increased vomiting, hematemesis or melena, weakness or syncope, fever, chest pain, radiation of pain to the neck or back, and shortness of breath.

ACUTE APPENDICITIS Denis

J. FitzGerald Arthur M.
Pancioli

EPIDEMIOLOGY

While reports on the stability of the incidence of acute appendicitis vary, the incidence of appendectomy appears to be declining due to more accurate preoperative diagnosis.^{1,2} Still, despite the introduction of newer imaging techniques, acute appendicitis can be extremely difficult to diagnose.

PATHOPHYSIOLOGY

Acute appendicitis is thought to begin with an obstruction of the lumen. The obstruction can result from food matter, adhesions, or lymphoid hyperplasia. Despite the obstruction, mucosal secretion continues, leading to an increase in intraluminal pressure. This pressure eventually will exceed capillary perfusion pressure and will obstruct venous and lymphatic drainage. With such vascular compromise, the epithelial mucosa begins to break down, allowing bacterial invasion by bowel flora. The subsequent inflammatory response and edema further exacerbate the increased intraluminal pressure. Eventually, this increased pressure leads to arterial stasis and tissue infarction. The end result is perforation and spillage of the infected appendiceal contents into the peritoneum.

In order to understand the clinical presentation and the clinical progression of acute appendicitis, it is important to consider the innervation and anatomic variability of the appendix. Presumably, the initial luminal distention triggers the visceral afferent pain fibers from the appendix, which enter the spinal cord at the tenth thoracic vertebra. As is characteristic of visceral afferent innervation, this pain is generally vague and poorly localized. Based on the anatomic level of these afferent fibers at the tenth thoracic level, the pain generally is perceived by the patient at the periumbilical or epigastric region. Eventually, as the inflammatory process continues, the appendiceal serosa and adjacent structures become inflamed. This inflammation triggers the somatic pain fibers, which innervate the peritoneal structures, typically localizing the pain in the right lower quadrant. This explains the migration of pain from the periumbilical area to the right lower quadrant, classically associated with acute appendicitis.

However, there are many exceptions to the classic presentation. These exceptions are often due to the variability of the anatomic location of the appendix. In a study of 71,000 human appendix specimens removed over a 40-year period, 26 percent were retrocecal, and 4 percent were located in the right upper quadrant.⁴ **With the retrocecal appendix, the pain of acute appendicitis may localize to the flank rather than the right lower quadrant.** Similarly, in pregnant patients, the gravid uterus may displace the appendix, leading to a presentation of right upper quadrant or flank pain. In male patients, a retroileal appendicitis may irritate the ureter, causing pain in the testi-

cle. A pelvic appendix may irritate the bladder or rectum and cause suprapubic pain, pain with urination, or the feeling of a need to defecate. These anatomically based variations in presentation help to explain the difficulty in making the diagnosis of acute appendicitis.

CLINICAL FEATURES

History

The primary symptom in acute appendicitis is abdominal pain. In approximately one-half to two-thirds of patients with appendicitis, the pain evolves in a classic pattern. Beginning in the epigastrium or periumbilical region early in the illness, the pain is vague initially and difficult to localize. Patients may describe their discomfort as indigestion or as a feeling of the need to defecate or pass flatus. In the classic presentation, periumbilical pain is followed by anorexia, nausea, and vomiting. As the illness progresses, the pain becomes more localized, typically in the right lower quadrant. In one meta-analysis, right lower quadrant pain was 81 percent sensitive and 53 percent specific for the diagnosis of acute appendicitis. Similarly, migration of the pain from initial periumbilical pain to the right lower quadrant was 64 percent sensitive and 82 percent specific for the diagnosis of acute appendicitis.⁵

In addition to abdominal pain, the classic symptoms in appendicitis include anorexia, nausea, and vomiting. In acute appendicitis, these symptoms typically appear after the onset of vague abdominal pain. Anorexia is the most common of these symptoms, with 68 percent sensitivity and 36 percent specificity.⁵ Vomiting is more variable in acute appendicitis, occurring in about half of patients with acute appendicitis.⁵ The significance of the temporal relationship between abdominal pain and onset of vomiting as a predictor of acute appendicitis has not yet been established. Table 78-1 provides a summary of the sensitivity and specificity of many symptoms associated with appendicitis.

Physical Examination

Like the history, the findings on physical examination of a patient with acute appendicitis depend on the duration of the illness prior to the examination. Early in the course of acute appendicitis, the patient may not have localized tenderness. As the illness progresses, the patient typically develops tenderness, especially to deep palpation, over

McBurney's point. This is a point just below the middle of a line connecting the umbilicus and the anterosuperior iliac spine. Pain in the right lower quadrant with palpation of the left lower quadrant (Rovsing sign) also may be elicited. As with the subjective pain, the localization of tenderness varies with the anatomic position of the appendix. If the patient has a pelvic appendix, the patient's tenderness may be most pronounced on rectal examination. With a retrocecal appendix, tenderness to palpation may be attenuated by the overlying cecum or may be most pronounced in the right flank.

Additional components of the physical examination that may help in the diagnosis include rebound tenderness, voluntary guarding, local muscular rigidity over the inflamed area (involuntary guarding), and tenderness on rectal examination. The sensitivity and specificity of these findings are seen in Table 78-1.

Special maneuvers that can aid in the diagnosis of acute appendicitis include the psoas sign and the obturator sign. The examiner checks for a *psoas sign* by placing the patient in the left lateral decubitus position and extending the right leg at the hip. If an inflamed appendix is overlying the psoas muscle, this maneuver will cause an increase in the patient's pain, thereby eliciting a positive psoas sign. The *obturator sign* is evaluated by passively flexing the right hip and knee and internally rotating the hip. This action will stretch the obturator muscle. An inflamed appendix may irritate the obturator muscle, and this maneuver will increase pain, indicating a positive obturator sign.

Fever is another relatively late physical finding in acute appendicitis. At the onset of pain, the patient's temperature probably will be normal. If the temperature is taken frequently during the progression of the illness, it will usually rise 1 to 2°C. Temperatures above 39°C (102.2°F) are uncommon in the first 24 h of the illness but not uncommon after rupture of an appendix.

DIAGNOSIS

The diagnosis of acute appendicitis should be suspected in any individual with epigastric, periumbilical, right flank, or right-sided abdominal pain who has not had an appendectomy. Women of childbearing age should have a pelvic examination and pregnancy test to exclude gynecologic causes of pain. The evaluation of abdominal pain in women is difficult and is discussed in detail in Chap. 102. Additional studies including a complete blood count (CBC), urinalysis

TABLE 78-1 Summary of Clinical Examination Operating Characteristics for Appendicitis*

Procedure	Sensitivity	Specificity	LR(+) [95% CI]	LR(-) [95% CI]
Right lower quadrant pain	0.81	0.53	7.31-8.46 ^T	0-0.28 ^f
Rigidity	0.27	0.83	3.76 (2.96-4.78)	0.82 (0.79-0.85)
Migration	0.64	0.82	3.18(2.41-4.21)	0.50 (0.42-0.59)
Pain before vomiting ^j	1.00	0.64	2.76 (1.94-3.94)	NA
Psoas sign	0.16	0.95	2.38(1.21-4.67)	0.90 (0.83-0.98)
Fever	0.67	0.79	1.94(1.63-2.32)	0.58 (0.51-0.67)
Rebound tenderness test	0.63	0.69	1.10-6.30 ^t	0-0.86 ^f
Guarding	0.74	0.57	1.65-1.78 ^t	0-0.54 ^f
No similar pain previously	0.81	0.41	1.50(1.36-1.66)	0.323 (0.246-0.424)
Rectal tenderness	0.41	0.77	0.83-5.34 ^f	0.36-1.15 ^f
Anorexia	0.68	0.36	1.27(1.16-1.38)	0.64 (0.54-0.75)
Nausea	0.58	0.37	0.69-1.20 ^t	0.70-0.84 ^f
Vomiting	0.51	0.45	0.92(0.82-1.04)	1.12 (0.95-1.33)

*LR(+) indicates the positive likelihood ratio with its 95% CI; LR(-), the negative likelihood ratio with its 95% CI. In heterogeneous studies, the LRs are reported as ranges.

^jOnly one study on this is included in the meta-analysis.

(UA), and imaging studies are often needed to help make the diagnosis. Clinical observation is another common diagnostic modality.

Complete Blood Count

The WBC is of limited value.^{6,7} The sensitivity of an elevated WBC above 10,000/ μ L in acute appendicitis is 70 to 90 percent, but the specificity is very low.⁷ More important, the positive and negative predictive values of an elevated WBC in acute appendicitis are 92 and 50 percent, respectively.⁸ The diagnostic value of C-reactive protein and erythrocyte sedimentation rate have been studied in acute appendicitis with mixed results.⁹

Urinalysis

Abnormal urinalysis results, excluding proteinuria, are found in 19 to 40 percent of patients with acute appendicitis.^{10,11} Abnormalities include pyuria, hematuria, and bacteriuria, possibly related to the extension of appendiceal inflammation to the ureter. The presence of greater than 20 white blood cells per high-powered field (without epithelial cells) in the urine should elevate consideration of urinary tract pathology in the differential diagnosis.¹⁰

Imaging Studies

Imaging studies performed in the evaluation of possible acute appendicitis include plain radiographs, ultrasound studies, and computed tomographic (CT) scans. Plain radiographs of the abdomen are abnormal in 24 to 95 percent of patients with acute appendicitis.⁷ Radiographic indicators of possible acute appendicitis include appendiceal fecalith, appendiceal gas, localized paralytic ileus, blurred right psoas muscle, and free air. Since many of these signs are seen in multiple other processes, abdominal radiographs have limited diagnostic value in acute appendicitis.

Graded compression ultrasonography is reported to have a sensitivity of 94.7 percent with a specificity of 88.9 percent.¹² The principle of this technique is the fact that normal bowel loops and a normal appendix can be compressed with the application of moderate pressure, whereas an inflamed appendix cannot be compressed. The diagnostic criteria for acute appendicitis include the visualization of a non-compressible appendix that has a diameter of 6 mm or greater, demonstration of an appendicolith, or demonstration of a periappendiceal abscess. This technique has limitations with a retrocecal appendix, in that the overlying bowel may limit visualization and compression testing. In addition, an early perforation may be missed because the diameter of the appendix may be normal after perforation.¹³ Finally, color Doppler ultrasound studies may be helpful when the appendix is well visualized but equivocal in size. With this technique, hyperemia in the wall of the appendix has been found to be a sensitive indicator of inflammation.¹⁴

Given its wide availability and usefulness in establishing alternative diagnoses, a CT scan is probably the best choice as initial imaging study, although its radiation exposure limits its application in pregnant women and children. In one study that directly compared CT scan with ultrasound in 100 patients, the CT scan had greater sensitivity (96 vs. 76 percent), greater accuracy (94 vs. 83 percent), and a greater negative predictive value (95 vs. 76 percent). In this study, there was no significant difference when CT scan was compared with ultrasound with regard to specificity or positive predictive value.¹⁵ CT scan findings suggesting acute appendicitis include pericecal inflammation, abscess, periappendiceal phlegmon, and fluid collections. Even if the appendix is not directly visible, localized fat stranding in the right lower quadrant can still reliably point to the diagnosis. A recent trend in CT technology involves the use of a focused appendiceal approach to evaluate patients for appendicitis.¹⁶ The purported advantages of this approach include less scanning time, less radiation, and often no intravenous contrast material. However, there remains debate

over whether focused appendiceal CT scan or traditional nonfocused abdominal CT scan is the better choice.^{16,17} **CT scanning does appear to change management decisions and decreases unnecessary appendectomies in women. It is not as useful for changing management decisions in men.**¹⁸

Clinical Observation

For patients presenting atypically with suspicion for appendicitis, clinical observation in the emergency department with serial abdominal examinations is another method for identifying evolving cases of appendicitis.¹⁹

SPECIFIC ISSUES THAT AFFECT DIAGNOSIS, EVALUATION, AND TREATMENT

Special Populations

Certain groups of patients (e.g., very young, very old, pregnant, AIDS patients) present atypically and more often have delayed diagnoses as a result, with a concomitant increase in complications, such as appendiceal perforation. Very young patients present insiduously. The rate of misdiagnosis is high, with a consequent increase in the perforation rate, particularly in children under 5 years of age.²⁰ Diagnosis in children can be confounded by difficulty with communication and atypical symptoms, including concurrent respiratory symptoms or suspected gastroenteritis.²⁰ Peritonitis in children can present with varied signs such as lethargy, inactivity, and hypothermia. A high index of suspicion and early surgical consultation are recommended for children. Ultrasound and CT scan also can be used to assist in diagnosis.^{21,22}

Misdiagnosis rates in the elderly can exceed 50 percent, with a high incidence of perforation ranging from 40 to 70 percent.²³ Mortality rates for patients over age 70 with acute appendicitis approach 30 percent.²⁴ In addition to late presentation with an advanced course, anatomic changes in the appendix involving the vascular bed and reduced mural thickness are thought to contribute to the fulminant course of appendicitis seen in the elderly. One study found that the most significant predictors of acute appendicitis in the aged were tenderness, rigidity, pain at diagnosis, fever, and previous abdominal surgery.²⁵ Since extensive laboratory studies may obscure the diagnosis in patients with other concurrent medical problems, a high index of clinical suspicion is needed in management of the elderly.

Appendicitis remains the most common extrauterine surgical emergency in pregnancy, and fetal mortality rates can be four times higher if the appendicitis is complicated by perforation and peritonitis.²⁶ Consequently, the diagnosis of appendicitis must be entertained in any gravid patient presenting with abdominal pain and gastrointestinal symptoms. Ultrasound can be used to aid in diagnosis, particularly in differentiating obstetric causes of pain from appendicitis.

Patients with AIDS are particularly susceptible to complications from appendicitis. Although symptoms are no different for appendicitis in this population,²⁷ diagnosis can be delayed because of the baseline frequency of gastrointestinal symptoms unrelated to appendicitis and the occurrence of nonsurgical opportunistic pathologic conditions with similar presentations. One study noted a higher incidence of perforation in this population, possibly related to the delay in presentation or to the immunocompromised state.²⁷ One clear difference in management relates to the WBC, which is generally not elevated even in acute appendicitis.

TREATMENT

Appendectomy is the standard of care for acute appendicitis. Patients who are being prepared for appendectomy should be given nothing by mouth, have intravenous (IV) fluid resuscitation, and be given preoperative antibiotics. Antibiotics are most effective when given prior to surgery. In patients with uncomplicated appendicitis, antibiotics decrease the incidence of postoperative wound infections.²⁸ In patients

with perforation, early antibiotics have been shown to decrease post-operative abscess formation.²⁸ There are multiple acceptable approaches to antimicrobial therapy as long as the regimen covers anaerobic flora, enterococci, and gram-negative intestinal flora.²⁸ One such sample regimen is monotherapy with either tazobactam-piperacillin 3.375 g IV or ampicillin-sulbactam 3.00 g IV.

Analgesia should be given to treat acute abdominal pain.²⁹ A short-acting parenteral narcotic such as fentanyl administered IV is a good choice for pain management.

DISPOSITION

In general, patients with abdominal pain can be stratified into four groups with respect to their potential for appendicitis. The first group is composed of patients who demonstrate the classic presentation for acute appendicitis. The management of these patients is straightforward, involving prompt surgical consultation and subsequent appendectomy. The emergency department course is focused on preoperative preparation, as outlined previously.

The second group includes patients with signs and symptoms that are suspicious but not diagnostic for appendicitis. This group of patients most likely would benefit from imaging studies, either CT scan or ultrasound, to elucidate the diagnosis. Observation for a 4- to 6-h period with serial examinations may clarify the diagnosis. Surgical consultation is clearly indicated in patients in whom the examination becomes progressively more characteristic of appendicitis or if a surgical finding is identified on an imaging study.

The third group involves patients with abdominal pain in whom appendicitis is considered to be a remote diagnostic possibility. These patients should be observed in the ED for a period with serial examinations. If the course remains benign and no other contraindications to discharge exist, the discharge diagnosis should be *nonspecific abdominal pain*. Patients should be told that no clear cause for their symptoms was found but that over time their symptoms will either abate or coalesce into a recognizable pattern. Follow-up instructions should include a description of worrisome symptoms that suggest progressive disease and warrant return to the emergency department. Patients should be reevaluated in 12 to 24 h by their primary physician or by the emergency department to ensure resolution of symptoms. Patients should be cautioned to avoid strong analgesics that might mask evolving pathologic processes; instead, they should be instructed to return if their pain increases. In this fashion, the emergency physician establishes a clear continuity of care for the patient with guidelines that minimize the likelihood of an adverse outcome.

The fourth group is composed of all high-risk special populations presenting with abdominal pain. This group includes elderly, pediatric, pregnant, and immunocompromised patients. As emphasized earlier, these patients require a high index of clinical suspicion and a low threshold for imaging studies and surgical consultation to avoid morbidity and mortality from undetected appendicitis.

INTESTINAL OBSTRUCTION

Salvator J. Vicario
Timothy G. Price

Intestinal obstruction is the inability of the intestinal tract to allow for regular passage of food and bowel contents secondary to mechanical obstruction or adynamic ileus. Adynamic ileus (paralytic ileus) is the more common entity but is usually self-limiting and does not require surgical intervention. Mechanical obstruction can be caused by either intrinsic or extrinsic factors and generally requires definitive intervention in a relatively short period of time to determine the cause and minimize subsequent morbidity and mortality.

Both large and small intestines may be obstructed by various pathologic processes (Table 79-1). Extrinsic, intrinsic, or intraluminal processes precipitate mechanical obstruction. Differentiating small bowel obstruction (SBO) from large bowel obstruction (LBO) is

TABLE 79-1 Common Causes of Intestinal Obstruction

Duodenum	Small Bowel	Colon
Stenosis	Adhesions	Carcinoma
Foreign body (Bezoars)	Hernia	Fecal impaction
Stricture	Intussusception	Ulcerative colitis
Superior mesenteric artery syndrome	Lymphoma	Volvulus
	Stricture	Diverticulitis (stricture, abscess)
		Intussusception
		Pseudo-obstruction

important because the incidence, clinical presentation, and modes of therapy vary depending on the anatomic site of the obstruction. The small intestine is characterized by transverse linear densities that extend completely across the bowel lumen (plicae circulares). The colon is situated peripherally in the abdomen, is larger in diameter, and contains short, blunt, and thick projections (haustra) that arise from the bowel wall and extend only partially into the lumen. Haustra are less numerous and situated farther apart than plicae circulares.

SMALL BOWEL OBSTRUCTION

The most common cause of SBO is adhesions following abdominal surgery.¹ Although in most cases several months to years have passed from the time of the previous surgery, SBO may occur within the first few weeks following surgery.² The second most common cause of SBO is incarceration of a groin hernia¹ (see Chap. 80). This can occur in infants as well as adults and should be suspected anytime there is a complaint of a "knot" or growth in the inguinal region that fails to reduce with manipulation. Other sites that occasionally are responsible for SBO secondary to hernia include the umbilicus, femoral canal, and rarely, the obturator foramen. Umbilical hernias are more readily apparent and occur in any age group. Obturator or femoral hernias are much less common. Elderly females are particularly susceptible to these hernias, which may present with femoral or medial thigh pain. Finally, a defect in the mesentery itself may cause intestinal obstruction.

Other causes of SBO are much less common and generally are the result of intraluminal or intramural processes. Primary small bowel lesions include polyps, lymphoma, or adenocarcinoma. An unusual cause of intraluminal obstruction is gallstone ileus. In this situation, a gallstone has eroded from the gallbladder through the bowel wall and can cause obstruction at the ileocecal valve. Besides the findings of bowel obstruction, one may note air in the biliary tree on abdominal radiographs. Lymphomas may be the leading point of intussusception and present as SBO. Bezoars are most commonly composed of vegetable matter or pulp from persimmons. Patients who have undergone gastrointestinal pyloroplasty or pyloric resection are most susceptible to intraluminal obstruction by bezoars.

Inflammatory bowel disease also may affect the small bowel at various sites. Likewise, infectious processes including abscesses may obstruct the bowel. Radiation enteritis is also a possible cause of SBO in patients who have undergone radiation therapy.

LARGE BOWEL OBSTRUCTION

Colonic obstruction is almost never caused by hernia or surgical adhesions. Neoplasms are by far the most common cause of LBO.^{3,4} Therefore, anyone who has symptoms of colonic obstruction should be evaluated for a neoplasm. Diverticulitis may create significant secondary obstruction and mesenteric edema. Stricture formation may occur with chronic inflammation and scarring. Fecal impaction is a common problem in elderly, debilitated patients and may present with symptoms of colonic obstruction.

The next most frequent cause of LBO after cancer and diverticulitis is sigmoid volvulus. Elderly, bedridden, or psychiatric patients who are taking anticholinergic medication are most often subject to this mechanical problem. A history of constipation may precede the volvulus and presenting symptoms. Radiographic appearance is usually classic (Figure 79-1). Finally, although much less common, cecal volvulus also may cause LBO. There is a higher incidence of cecal volvulus in gravid patients.⁵

PATHOPHYSIOLOGY

Normal bowel contains gas as well as gastric secretions and food. Intraluminal accumulation of gastric, biliary, and pancreatic secretions continues even if there is no oral intake. As obstruction develops, the bowel becomes congested, and there is failure of intestinal contents to be absorbed. Vomiting and decreased oral intake follow. The combination of decreased absorption, vomiting, and reduced intake leads to volume depletion with hemoconcentration and electrolyte imbalance and ultimately can cause renal failure or shock.⁴

Bowel distention often accompanies mechanical obstruction. Distention is due to the accumulation of fluids in the bowel lumen, an increase in intraluminal pressure with enhanced peristaltic contractions, and air swallowing. When intraluminal pressure exceeds capillary and venous pressure in the bowel wall, absorption and lymphatic drainage decrease. At this stage, bacteria may enter the bloodstream, the bowel becomes ischemic, and septicemia and bowel necrosis can develop. Shock ensues rapidly. Mortality approaches 70 percent if bowel obstruction has been allowed to progress this far. With a *closed-loop ob-*

FIG. 79-1. Sigmoid volvulus. Note distention of large bowel and central stripe, giving a "coffee bean" appearance.

struction, this sequence of events may occur more rapidly. In this instance, there is no proximal escape for bowel contents. Examples of closed-loop obstruction include an incarcerated hernia and complete colon obstruction in the presence of a closed ileocecal valve.

CLINICAL FEATURES

The site and nature of the obstruction and the preexisting condition of the patient will determine the clinical presentation. Almost all patients will have abdominal pain.³ The pain generally is described as crampy and intermittent. Pain of mechanical SBO is often episodic, usually lasting for a few minutes at a time, and it may be periumbilical or more diffuse. In adynamic ileus, the pain tends to be less intense and more constant. If the obstruction is proximal, vomiting is usually present. The vomitus in proximal obstruction is usually bilious but is feculent in distal ileal obstruction. The pain of LBO is usually hypogastric. LBOs may be associated with feculent vomitus.

Other features that are consistently present with obstruction of small bowel or colon include the inability to have a bowel movement or pass flatus. Care should be taken to avoid the diagnosis of constipation because this symptom is secondary to partial or complete obstruction. Partial bowel obstruction, however, is often associated with regular passage of stool and flatus.

Physical findings vary depending on the site, duration, and etiology of the pathologic process. Early symptoms usually are associated with some abdominal distention, often impressive with colonic obstruction yet not readily apparent in cases of incarcerated hernia. Abdominal tenderness may be minimal and diffuse or localized and severe.^{2,3} Patients who have developed peritonitis will have severe tenderness. The abdomen may be tympanitic to percussion. Mechanical obstruction will produce active, high-pitched bowel sounds with occasional "rushes." If obstruction has been present for several hours, peristaltic waves and bowel sounds may be diminished. Patients with an adynamic ileus may have some abdominal distention associated with diminished or absent bowel sounds. Careful search for localized or rebound tenderness is essential to rule out the possibility of gangrenous or perforated bowel, which requires immediate surgical intervention.

Elderly patients have signs and symptoms that are similar to younger patients with intestinal obstruction. Adhesions and hernias are common causes for SBO in this age group, whereas carcinomas are the most likely etiology of LBO because of the increased likelihood of cancer as people age.⁶ Elderly patients who are debilitated or confused or who are on multiple medications may be unable to give a detailed history. Patients over 60 years old are more likely to succumb secondary to complications of bowel obstruction.² Careful examination for characteristic bowel sounds and masses or blood in stool and radiographic investigation often will distinguish bowel obstruction from ileus. Emptiness of the left iliac fossa has been reported to be a reliable sign of sigmoid volvulus.⁷

AH patients with abdominal pain or distention should be examined for signs of organomegaly or masses that may suggest a cause of the obstruction. A rectal examination may identify fecal impaction, rectal carcinoma, occult blood, or stricture. The absence of stool or air in the vault may aid in the diagnosis of bowel obstruction, but its presence does not eliminate a more proximal obstruction because patients may not be able to evacuate preexisting rectal contents. A pelvic examination should be performed to identify any gynecologic pathology causing obstruction. A vaginal pessary can cause colonic obstruction due to extrinsic compression of the colon.⁸

LABORATORY AND RADIOGRAPHIC FINDINGS

All patients with suspected obstruction should have flat and upright abdominal radiographs and upright chest x-ray or a lateral decubitus view if the patient cannot be upright. An abdominal radiograph can confirm the diagnosis, identify free air or masses, and localize the site to large or small bowel (Figure 79-2A,B). Laboratory studies usually

B

FIG. 79-2. A. Flat-plate abdominal film illustrates distended loops of small bowel. B. Upright film demonstrates multiple air-fluid levels and "stepladder" appearance. (From Harris JH, Harris WH: *The Radiology of Emergency Medicine*, 3d ed. Baltimore, Williams and Wilkins, 1993, p. 843, with permission.)

include a complete blood count and electrolyte levels. Depending on the duration of symptoms and site of obstruction or whether there is bowel necrosis, one may find a wide range in white blood cell (WBC) counts and hemoglobin, hematocrit, and electrolyte values. A white count greater than 20,000/L or left shift should make one suspect bowel gangrene, intra-abdominal abscess, or peritonitis.⁴ Extreme WBC elevation ($>40,000/L$) suggests mesenteric vascular occlusion. The serum amylase and lipase levels may be mildly elevated. Levels of serum electrolytes usually are normal or mildly reduced,³ depending on whether the obstruction is of short or long duration or whether there is associated emesis. Increases in hematocrit, blood urea nitrogen (BUN), and creatinine are consistent with volume depletion and dehydration. Other indications of the severity of obstruction or secondary complications include increased urine specific gravity, ketonuria, elevated lactate levels, and metabolic acidosis.

Further investigations to determine the site or etiology of obstruction include sigmoidoscopy or barium enema. Upper gastrointestinal studies are rarely indicated. Barium enema can determine the cause and site of LBO (Figure 79-3). Sigmoidoscopy can identify friable mucosa, intraluminal lesions, or the dark-blue gangrenous mucosa associated with dead bowel. If the diagnosis is unclear, repeated examination, preferably by the same examiner, will be necessary. The use of contrast-enhanced computed tomography (CT) has been advocated to delineate partial from complete bowel obstruction.^{9,10}

FIG. 79-3. Barium enema examination demonstrating incomplete filling of the sigmoid secondary to volvulus. Note the "parrot beak" appearance of the point of the volvulus. (From Schwartz GR: *Principles and Practice of Emergency Medicine*, 3d ed. Malvern, PA, Lea & Febiger, 1992, p. 1720, with permission.)

TREATMENT

If a true mechanical obstruction is diagnosed, then surgical intervention is often required. Prior to surgical intervention, a nasogastric tube should be inserted to remove excess bowel contents and air. Intravenous fluid replacement is needed because of loss of absorptive capacity, decreased oral intake, and vomiting. Patients can be monitored prior to surgical intervention by the response of blood pressure and heart rate and measurement of urine output. Surgery should not be delayed unnecessarily by attempting to use long intestinal tubes (Baker, Cantor, or Miller-Abbott) or excessive testing. A volvulus of the sigmoid colon usually will decompress via sigmoidoscopy and insertion of a rectal tube. Should a closed-loop obstruction, bowel necrosis, or cecal volvulus be suspected, then surgical intervention should be performed without delay.³ All patients with mechanical obstruction require broad-spectrum antibiotic coverage preoperatively because the risk of infection and septicemia is significant in most conditions.⁹ There are many possible regimens. Monotherapy could be tazobactam-piperacillin 3.375 g IV q6h or ampicillin-sulbactam 3.00 g IV q6h.

If adynamic ileus is the primary problem or the diagnosis is uncertain, conservative measures, including intravenous fluids, nasogastric decompression, and observation, generally are effective in allowing the bowel to resume normal activity and function. Any medication that inhibits bowel mobility should be discontinued. Abdominal CT contrast radiography is used commonly to distinguish partial SBO from ileus or for the differentiation of strangulated from simple SBO.^{6,13}

PSEUDO-OBSTRUCTION

Intestinal pseudo-obstruction (Ogilvie syndrome) also may mimic bowel obstruction. Although any segment of bowel may be affected, low colonic obstruction is the most common clinical presentation. Large amounts of gas will be present in the large intestine. Radiographs reveal a dilated colon with well-defined septa and haustral markings and very little fluid, making air-fluid levels uncommon.¹⁴ Patients may be using anticholinergic or tricyclic antidepressants, which depress motility. One must avoid the use of barium studies because the patient may be unable to evacuate the barium. Preference should be given to colonoscopy after digital rectal examination as an early intervention to rule out true obstruction or significant lesions. Colonoscopy also will treat the pseudo-obstruction by decompression. Surgery usually is not helpful and may be harmful.¹⁴ Neostigmine infusion is reported to be effective at relieving pseudo-obstruction in patients who had not responded to conservative means.¹⁵

HERNIA IN ADULTS AND CHILDREN Frank W. Lavoie Marv Harkins Becker

A *hernia* is defined as the protrusion of any body part from its natural cavity. The protrusion may be internal or external and in a wide range of locations. However, the usual use of the term *hernia* refers to external herniation through the abdominal wall. Hernias also may be interparietal, within the layers of the abdominal wall. Abdominal wall hernias occur in adults and children and may be subdivided further into groin (inguinal or femoral), umbilical, anterior abdominal, pelvic, or lumbar locations.

PATHOPHYSIOLOGY

General Characteristics

Essential to the understanding of hernias are the anatomic characteristics of the abdominal cavity and, in particular, its fascial and aponeurotic layers. Embryologic development produces localized areas of inherent weakness in the abdominal wall. These include areas where extraperitoneal structures penetrate (as in the inguinal, femoral, and obturator canals, the sciatic foramen, and the umbilical region) and areas devoid of strong multilayer structural support (as in the anterior abdominal wall's linea alba and semilunar line). In addition, surgical incision and trauma may produce areas of abdominal wall weakness.

A hernia may contain preperitoneal fat, intraperitoneal structures such as omentum and bowel, and occasionally retroperitoneal organs. A hernia sac is composed of peritoneum and any intraperitoneal structures that accompany it.

If the contents of a hernia can be returned to their natural cavity by external manipulation, the hernia is termed *reducible*; if they cannot, it is termed *irreducible* or *incarcerated*. Incarcerated hernias are subject to inflammatory and edematous changes and are at risk for strangulation. *Strangulation* of a hernia refers to vascular compromise of the incarcerated contents. When strangulation is not rapidly relieved, necrosis and gangrene develop.

The presence of a hernia in and of itself is not an emergency condition. It is when the hernial sac becomes incarcerated or stuck that a surgical emergency is present.

Risk Factors

Lack of developmental maturity of anatomic structures is known to predispose to the formation of hernias, as in indirect inguinal and umbilical hernias in premature infants. Family history, undescended testis, and genitourinary abnormalities are additional risks for inguinal hernia. Conditions that increase intra-abdominal pressure such as ascites, peritoneal dialysis, ventriculoperitoneal shunt, cystic fibrosis,

chronic obstructive pulmonary disease, and pregnancy are thought to be associated with abdominal wall hernia.

Specific Hernia Types

INDIRECT INGUINAL HERNIA The inguinal canal is a tract through muscle and fascial layers in the abdominal wall that forms during fetal development to allow for the passage of the gubernaculum, the testis, and the spermatic cord in males and the round ligament in females. The canal is defined by an internal ring defect in the transversalis fascia and transverses the abdominal aponeurosis lateral to the inferior epigastric vessels and a more medial ring defect in the external oblique aponeurosis (Figures 80-1 and 80-2).

The reproductive organs develop in the peritoneal cavity and then pass through the inguinal canal via an evagination of the peritoneum. This outpouching of peritoneum is called the *processus vaginalis*. After passage of these organs, the processus vaginalis is normally reabsorbed, thus preventing future travel of intraperitoneal contents through the inguinal canal. A congenitally persistent processus vaginalis is the etiology for all indirect inguinal hernias. Latent passage of contents through a persistent patent processus vaginalis along the inguinal canal is called an *indirect inguinal hernia*. Acquired myoaponeurotic defects also may contribute to indirect inguinal hernia in adults.

Passage of the testis is thought to enlarge the canal and increase the likelihood of inguinal hernia in males. It is more common on the right side due to later passage of the right testis. Indirect inguinal hernias frequently incarcerate and strangulate, particularly in the first year of life and in females.¹

DIRECT INGUINAL HERNIA These hernias are protrusions directly through the transversalis fascia and the external inguinal ring, medial to the inferior epigastric vessels (see Figures 80-1 and 80-3). Direct inguinal hernias are acquired defects that do not involve passage through the inguinal canal. They occur predominantly in adults and rarely incarcerate and strangulate. Recurrence after repair is more frequent than for an indirect inguinal hernia.

FEMORAL HERNIA A femoral hernia is a protrusion below the inguinal ligament and adjacent to the femoral vessels in the femoral canal (see Figure 80-1). Femoral hernias are more common in women due to the different anatomic structure of the pelvis. Femoral hernias are far less common than inguinal hernias, but they more frequently incarcerate and strangulate.²

UMBILICAL HERNIA Congenital umbilical hernias occur commonly, especially in children of African descent (Figure 80-4). In utero contraction of the umbilical cord insertion forms a fibromuscular umbilical

FIG. 80-1. Groin hernias.

FIG. 80-2. Indirect inguinal hernia.

ring. Incomplete development or weakness of this ring allows herniation of abdominal contents. These hernias rarely incarcerate and usually spontaneously seal over time.¹³

Umbilical hernias also may develop in adults. This acquired defect is more common in women and is associated with obesity, pregnancy, and ascites. Unlike congenital umbilical hernias, acquired umbilical hernias frequently incarcerate.

EPIGASTRIC HERNIA An epigastric hernia involves herniation through the linea alba of the rectus sheath, above the umbilicus (see Figure 80-4).

SPIGELIAN HERNIA Herniation at the site of the semilunar or arcuate line, just lateral to the rectus muscle, through the combined aponeurosis of the transversus abdominis and internal oblique muscles is known as a *spigelian* or *lateral ventral hernia*. This hernia is frequently interparietal, making diagnosis difficult (see Figure 80-4).

PELVIC HERNIA Pelvic hernias are rare. They occur internally and cannot be palpated on examination. There are *sciatic hernias*, passing through sciatic foramen; *perineal hernias*, passing between perineal muscles; and *obturator hernias*, passing through the obturator canal with the obturator vessels. Obturator hernias frequently incarcerate.⁴

LUMBAR HERNIA Herniation rarely may occur through the inferior or superior lumbar triangles.

INCISIONAL HERNIA Herniation through a surgical incision is a frequent complication of abdominal surgery occurring in 10 to 20 percent of patients who have undergone laparotomy. Obesity and postoperative wound infections are known risk factors. Incarceration of the bowel can occur. Elective repair is recommended, but recurrence rates after repair are high.⁵

EPIDEMIOLOGY

The incidence of abdominal hernia is estimated to be from 10 to 20 per 1000 births and is greater among premature infants.⁶ In the screening

FIG. 80-3. Direct inguinal hernia.

FIG. 80-4. Anterior abdominal wall hernias.

of otherwise healthy young adult military recruits, approximately 3 percent are determined to have groin hernias.⁷ Approximately 750,000 herniorrhaphies are performed annually in the United States on inguinal hernias alone, most on an outpatient basis.⁸

All inguinal hernias occur more commonly in males than in females. Femoral hernias are more common in females and hernias of the anterior abdominal wall are of similar incidence. Indirect inguinal hernia is the most common hernia in both sexes. The distribution of hernia types by sex is shown in Figures 80-5 and 80-6.

Indirect inguinal hernias have a bimodal distribution, with peaks in the first year of life and after the age of 40 years.⁹ Direct inguinal hernias are characteristically seen in adults, with a large male preponderance after 40 years of age. The incidence and distribution of other uncommon hernias are less clear.

CLINICAL FEATURES

Most hernias are detected on routine physical examination or as an asymptomatic lump by the patient. Some patients note soreness in the area, but significant pain is not common unless incarceration has occurred.

Patients with incarceration frequently present a history of hernia that on presentation will no longer reduce. If incarceration occurs, pain may develop suddenly. With infants, irritability may be the only presenting complaint. Incarceration may be accompanied by nausea and vomiting if bowel obstruction has occurred. Incarcerated hernias are a leading cause of bowel obstruction, second only to postoperative adhesions.

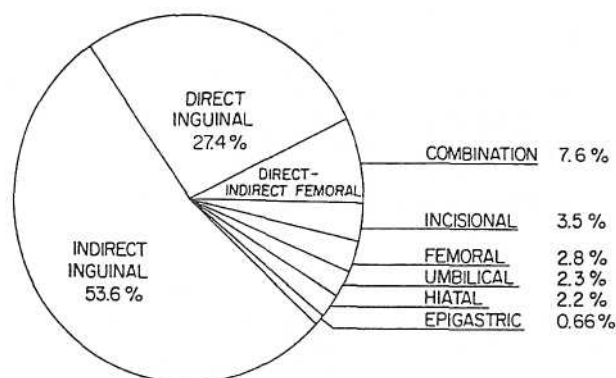

FIG. 80-5. The relative distribution of common hernias seen in 1655 men in 1965 and 1967. The high proportion of indirect and direct inguinal hernias is striking. (Reproduced with permission from Ponka JL: *Hernias of the Abdominal Wall*. Philadelphia, Saunders, 1980, p. 85.)

FIG. 80-6. The distribution of common hernias in 325 women in 1965 and 1967. Note the relatively greater frequency of incisional, umbilical, hiatal, and femoral hernias in the female. (Reproduced with permission from Ponka XL: *Hernias of the Abdominal Wall*. Philadelphia, Saunders, 1980, p. 85.)

If strangulation occurs, the patient may be toxic. Unrelieved strangulation may result in perforation, abscess formation, peritonitis, or septic shock.¹⁰

Physical examination of the patient with a hernia may reveal an abnormal soft tissue mass. In inguinal hernias in males, swelling may extend into the scrotum. The consistency of the mass varies depending on the content of the hernial sac. If incarceration is present, the mass is usually tender due to inflammation of the bowel wall or omentum and surrounding tissues. Tachycardia and mild temperature elevation also may be present.

Pain and hypesthesia along the medial aspect of the thigh to the knee are associated with obturator hernias. These patients also may have intermittent bouts of small bowel obstruction of several years' duration.

DIAGNOSIS OF INGUINAL HERNIAS

Patients frequently present to the emergency department with a complaint of groin pain. In males, palpation of the inguinal canal is easily performed by inversion of scrotal skin and passage of a finger through the external ring. The patient is then asked to cough or perform Valsalva. If an inguinal hernia is present, the examiner should feel a tapping sensation at the tip of the finger.

In females, the external ring is generally narrower and the skin of the labium majora is not easily inverted, making passage of a finger difficult. Therefore, failure to palpate a hernial sac in women is not foolproof.

Groin hernias have a large number of differential diagnostic possibilities (Table 80-1). They most commonly are confused with tender lymph nodes and hydroceles. Lymph nodes are generally movable, firm, and multiple. Hydroceles may transilluminate and are not tender. Incarcerated hernias will not transilluminate and are tender. If bowel is contained in the hernia sac, bowel sounds may be heard and peristalsis may be seen. Testicular torsion or tumor may be confused with in-

TABLE 80-1 Differential Considerations in Groin Hernia

Direct inguinal hernia	Indirect inguinal hernia	Testicular torsion
Femoral hernia	Lymph nodes	Retractile or undescended testis
Hydrocele		Epididymitis
Spermatic cord tumor	Testicular tumor	Groin cellulitis
		Femoral thrombophlebitis
		Femoral artery aneurysm

carcerated inguinal hernias. In children, retractile or undescended testes may be mistaken for hernias.

Laboratory studies may be helpful if incarceration has occurred. The white blood cell count may be elevated, with a shift to the left. Electrolyte abnormalities and elevation of the serum urea nitrogen level may occur as a reflection of the patient's state of hydration and toxicity. In the elderly and immunocompromised, laboratory studies may not be reliable indicators of the patient's condition. Occasionally, as part of a diagnostic evaluation for abdominal pain, a hernia is detected on barium enema.

Abdominal x-rays are recommended if bowel obstruction or perforation is suspected. Free air may be seen under the diaphragm on an upright chest film. Flat and upright films of the abdomen, including the groin, should be obtained to assess for air-fluid levels and other signs of obstruction. Loops of bowel may be seen entering a hernial sac.

Suspicion of spigelian or pelvic hernias often necessitates use of sonography or computed tomography for diagnosis,^{11,13} because detection of herniation is frequently difficult and confusion with other masses is possible.

TREATMENT

Incarcerated hernias require immediate attention. If there is a reliable history that the incarceration is of recent onset, an attempt may be made to reduce the hernia. **If there is any question of the duration of the incarceration, no attempt at reduction should be made so that dead bowel is not introduced into the abdominal cavity.**

Before an attempt is made to reduce the hernia, the patient should be placed in the Trendelenburg position. Pain medication or anxiolytics should be considered and administered as needed to allow the patient's abdominal musculature to relax. A warm compress over the area also may be useful. Only gentle compression of the hernia should be used, and nothing should be forced.

The treatment for an incarcerated hernia that cannot be manually reduced is surgical fixation. If strangulation is suspected or shock is present, broad-spectrum antibiotics and fluid resuscitation are also necessary. Mortality is high in the elderly when emergency surgery is necessary.

Most asymptomatic or reducible hernias are repaired electively. Elective treatment has changed significantly over the past 20 years. Historically, hernias were repaired by using an open technique and primary closure with sutures. Currently, there are many accepted techniques, including mesh closures and laparoscopic approaches. Outpatient surgery is the norm, and local anesthesia is an adequate option for many patients. Complication and recurrence rates vary greatly and are operator dependent. The need for repair of all groin hernias has recently come into question.¹⁴

DISPOSITION

Any acutely incarcerated hernia that cannot be reduced, regardless of type or the patient's age, requires immediate surgical evaluation and repair.

Adult patients with reducible hernias may be discharged and referred for discussion of elective surgical repair. They should be advised to avoid conditions that increase intra-abdominal pressure, such as heavy lifting. Return to the emergency department is necessary if the patient has recurrence and is unable to reduce the hernia promptly. After surgical evaluation, patients who are not candidates for operative repair may be fitted with trusses.

In children, inguinal hernias have a high risk of incarceration, particularly in the first year of life. These hernias should be electively repaired shortly after diagnosis and therefore require emergency surgical consultation. Infants with inguinal hernias reduced in the emergency department should generally have repair within a few days.¹⁵

Umbilical hernias in children very rarely incarcerate. Spontaneous closure of the umbilical ring occurs in 80 percent of these children by

age 3 or 4 years. Discharge and primary care observation are the standard of care for young children with hernias smaller than 2.0 cm in diameter. Children older than 4 years or with larger hernias should be referred for surgical evaluation.

cosal cells as the result of cross-reactivity with antigens from enteric bacteria; and nonspecific immunologic injury to the gut mucosa as the result of a chronic inflammatory process for both ulcerative colitis and Crohn disease. Cytokines, including interleukins and tumor necrosis factor, have been invoked in the perpetuation of the inflammatory response. The efficacy of anti-tumor necrosis factor such as infliximab (Remicade) in active Crohn disease and fistulizing Crohn disease supports the role of immunologic factors. Whether immune factors play a primary or secondary role in the pathogenesis of these diseases is not known. Extraintestinal manifestations suggest a role for immune complexes or an autoantibody response at various involved sites.

Epidemiology

The peak incidence of Crohn disease occurs between 15 and 22 years of age, with a secondary peak from 55 to 60 years. There is a 20 to 30 percent increased risk of Crohn disease among women as compared with men. The disease has a worldwide distribution but is more common in people of European extraction. It is four times more common among Jews than non-Jews and is more common in whites than blacks, Asians, or Native Americans. A family history of inflammatory bowel disease is present in 10 to 15 percent of patients, particularly with early onset of disease. Ulcerative colitis as well as Crohn disease may be present in other family members, and siblings of patients with Crohn disease have a higher incidence of the disease.

Pathology

The most important pathologic feature of Crohn disease is the involvement of all the layers of the bowel and extension into mesenteric lymph nodes. In addition, the disease is discontinuous, with normal areas of bowel ("skip areas") located between one or more involved areas. The appearance of the mucosa varies with the extent and severity of the disease. Longitudinal, deep ulcerations are characteristic. These often penetrate the bowel wall, resulting in fissures, fistulas, and abscesses. Late in the disease, a cobblestone appearance of the mucosa results from the criss-crossing of these ulcers with intervening normal mucosa.

Clinical Features

The clinical course of Crohn disease varies and in the individual patient is unpredictable. Abdominal pain, anorexia, diarrhea, and weight loss are present in most cases. Chronic abdominal pain, fever, and diarrhea may be present for several years before the definitive diagnosis is established. Approximately one-third of patients develop perianal fissures or fistulas, abscesses, or rectal prolapse, particularly when there is colonic involvement. Finally, patients may also present with complications of the disease, such as obstruction with vomiting, crampy abdominal pain, and obstipation, or an intraabdominal abscess with fever, abdominal pain, and a palpable mass. In 10 to 20 percent of patients, the extraintestinal manifestations of arthritis, uveitis, or liver disease may be presenting symptoms. Crohn disease should also be considered in the differential diagnosis of patients with fever of unknown etiology.

The clinical course and manifestations of the disease appear to be related, partly because of its anatomic distribution; in 30 percent the disease involves only the small bowel; in 20 percent only the colon is involved; and in 50 percent both the small bowel and colon are involved. A small percentage of patients present with disease involving the mouth, esophagus, and stomach. Patients with Crohn's disease of the stomach may demonstrate symptoms similar to those associated with peptic ulcer disease (see Chap. 77).

The recurrence rate for patients with Crohn disease is 25 to 50 percent within 1 year for patients whose disease has responded to medical management; the recurrence rate is higher for patients who require surgery. Patients with ileocolitis have the highest recurrence rate following surgery. The incidence of hematochezia and perianal disease

CROHN DISEASE

Crohn disease is a chronic granulomatous inflammatory disease of the gastrointestinal (GI) tract; the exact cause is still unknown. **Crohn disease can involve any part of the GI tract from the mouth to the anus.** The ileum is involved in the majority of cases. In 20 percent, the disease is confined to the colon, making differentiation from ulcerative colitis difficult. The terms *regional enteritis*, *terminal ileitis*, *granulomatous ileocolitis*, and *Crohn disease* are all used to describe the same disease process.

Etiology and Pathogenesis

Environmental, genetic, infectious, and host factors have all been implicated as a cause of both Crohn disease and ulcerative colitis. Immunologic factors undoubtedly play a major role. Several mechanisms have been proposed, including autoimmune destruction of the gut mu-

is higher when the colon is involved, as in ileocolitis or Crohn colitis. A slight increase in the incidence of arthritis may be associated with Crohn colitis. Except for the additional concern of growth retardation, childhood-onset Crohn disease seems to have a course similar to that of adult-onset disease.

Extraintestinal manifestations are seen in 25 to 30 percent of patients with Crohn disease (Table 81-1), and the incidence of these complications does not differ between patients with Crohn disease and those with ulcerative colitis. Extraintestinal manifestations are divided among arthritic (19 percent), dermatologic (4 percent), hepatobiliary (4 percent), and vascular (1.3 percent) complications. Peripheral arthropathies are commonly seen in both ulcerative colitis and Crohn disease and tend to manifest during exacerbations of the underlying disease process. Ankylosing spondylitis can be detected in up to 20 percent of patients with inflammatory bowel disease. Symptoms may occur before, during, and after bouts of Crohn disease or ulcerative colitis.

Dermatologic complications include erythema nodosum and pyoderma gangrenosum. Ocular manifestations include episcleritis and uveitis.

Hepatobiliary disease is common in patients with inflammatory bowel disease and includes pericholangitis, chronic active hepatitis, primary sclerosing cholangitis, and cholangiocarcinoma. Gallstones are detected in up to 33 percent of patients with Crohn disease. The incidence of acute and chronic pancreatitis is increased in patients with Crohn disease and ulcerative colitis.

Vascular manifestations include thromboembolic disease, vasculitis, and arteritis. Patients with thromboembolic complications have a mortality rate of approximately 25 percent. Thromboembolic disease is the result of a hypercoagulable state induced in patients with both

Crohn disease and ulcerative colitis and ranks as the third leading cause of death in patients afflicted with these conditions, behind peritonitis and malignancy. Malnutrition and chronic anemia are seen in many patients with longstanding Crohn disease. Growth retardation can be seen in children.

Hyperoxaluria is a common and potentially treatable occurrence in patients with ileal disease and steatorrhea. This results from increased colonic absorption of dietary oxalate and accounts for the occurrence of nephrolithiasis in 20 to 25 percent of patients with ileal disease. Finally, myelodysplastic disease, osteomyelitis, and osteonecrosis have been reported as rare complications of ulcerative colitis, and in particular, Crohn disease.

Complications

More than three out of four patients with Crohn disease will require surgery within the first 20 years of the onset of initial symptoms. Abscess and fissure formation is seen in approximately 30 percent of patients. Abscesses can be characterized as intraperitoneal, retroperitoneal, interloop, or intramesenteric. These patients present with abdominal pain and tenderness typical of their underlying disease, but may also have fever spikes and a palpable mass. Patients with retroperitoneal abscesses may present with hip or back pain and difficulty ambulating. Liver abscesses have also been reported in patients with Crohn disease.

Fistulas are the result of extension of the intestinal fissures seen in Crohn disease into adjacent structures. The most common sites are between the ileum and the sigmoid colon, the cecum, another ileal segment, or the skin. Internal fistulas should be suspected when there are

TABLE 81-1 Extraintestinal Manifestations of Inflammatory Bowel Disease

Manifestation	Description
ARTHRITIC	
Peripheral arthritis	Migratory monoarticular or polyarticular pain in peripheral joints (hip, knee, ankle, wrist) with effusion
Ankylosing spondylitis	Pain and stiffness of spine, hips, neck, and rib cage with limitation in truncal motion, loss of lumbar lordosis; decreased chest expansion and forward cervical flexion in advanced disease
Sacroiliitis	Low back pain with morning stiffness, relieved by exercise; progressive joint sclerosis
OCULAR	
Episcleritis	Eye burning or itching without visual changes or pain; scleral and conjunctival hyperemia
Uveitis	Acute blurring of vision, photophobia and pain; perilimbic scleral injection
DERMATOLOGIC	
Erythema nodosum	Painful, red, raised nodules on extensor surfaces of arms or legs
Pyoderma gangrenosum	Ulcerative lesions with a necrotic center and violaceous skin typically found in pretibial region or trunk
HEPATOBIILIARY	
Cholelithiasis	Varies from asymptomatic stones to right upper quadrant pain, fever, vomiting
Fatty liver	Mild right upper quadrant pain; hepatomegaly
Pericholangitis	Mild elevation in serum alkaline phosphatase, asymptomatic
Chronic active hepatitis	Autoimmune elevation of liver aminotransferase enzymes, may progress to cirrhosis
Primary sclerosing cholangitis	Pruritus progressing to jaundice, fatigue, and lethargy; laboratory findings vary from mild elevations of alkaline phosphatase to cirrhosis, portal hypertension, and liver failure; male predominance
Cholangiocarcinoma	Extrahepatic biliary mass, evidence of biliary obstruction, jaundice, right upper quadrant pain, fever, malaise
Pancreatitis	Varies from painless elevation of serum amylase to clinically apparent central abdominal pain radiating to back; may be associated with drugs such as azathioprine, 6-mercaptopurine, sulfasalazine, mesalamine, olsalazine, metronidazole
VASCULAR	
Thromboembolic disease	Symptoms of deep venous thrombosis and pulmonary emboli; portal vein, mesenteric vein, and hepatic venous thrombosis reported
OTHER	
Malnutrition	Fatigue, malaise, muscular wasting, cachexia
Chronic anemia	Fatigue, malaise, pallor, dyspnea; may be microcytic (blood loss), macrocytic (B ₁₂ deficiency) or autoimmune hemolytic
Nephrolithiasis	Flank pain, nausea, vomiting, hematuria; stones result from increased dietary oxalate absorption (calcium oxalate stones) and dehydration (urate stones)

changes in the patient's symptom complex, including bowel movement frequency, amount of pain, or weight loss. Enterovesical fistulas are rare complications of Crohn disease.

Obstruction is the result of both stricture formation due to the inflammatory process and of edema of the bowel wall. The distal small bowel is the most common site of obstruction. Symptoms include crampy abdominal pain, distention, nausea, and bloating.

Perianal complications are seen in one-third of patients with Crohn disease and include perianal or ischiorectal abscesses, fissures, fistulas, rectovaginal fistulas, and rectal prolapse. These are more commonly seen in patients with colonic involvement.

While gastrointestinal bleeding is common in patients with Crohn disease, only about 1 percent of patients develop life-threatening hemorrhage.¹ In patients with Crohn disease, bleeding is the result of erosion into a vessel in the bowel wall. Toxic megacolon occurs in 6 percent of all cases of Crohn disease and is associated with massive gastrointestinal bleeding in over half the cases. Fifty percent of all cases of toxic megacolon occur in patients with Crohn disease. Free perforation, however, rarely occurs.

When bowel symptoms are present, malnutrition, malabsorption, hypocalcemia, and vitamin deficiency can be severe. In addition to the complications of the disease itself are complications associated with the treatment of the disease with sulfasalazine, steroids, immunosuppressive agents, and antibiotics. These include leukopenia, thrombocytopenia, fever, infection, profuse diarrhea, pancreatitis, renal insufficiency and liver failure.

The incidence of malignant neoplasm of the GI tract is three times higher in patients with Crohn disease than for the general population.

Diagnosis

In the majority of patients, the definitive diagnosis of Crohn disease is established months or years after the onset of symptoms. Occasionally, the initial presenting complaint is not related to the GI tract but is an extraintestinal manifestation such as arthritis or uveitis. A provisional diagnosis of appendicitis or pelvic inflammatory disease may change to Crohn disease at the time of surgery. A careful and detailed history for previous bowel symptoms that preceded the onset of acute right lower quadrant pain and the absence of true guarding or rebound in patients with Crohn disease may provide clues to the correct diagnosis before surgery.

A definitive diagnosis of Crohn disease is confirmed by an upper GI series, an air-contrast barium enema, and colonoscopy. Oral barium studies with fluoroscopy are fairly sensitive and specific for detecting ileal involvement. The characteristic radiographic findings in the small intestine include segmental narrowing, destruction of the normal mucosal pattern, and fistulas. Segmental involvement of the colon (right-sided colitis) with rectal sparing is the usual feature.

Colonoscopy is the most sensitive technique for examining patients with Crohn colitis. This technique is useful in detecting early mucosal lesions, in defining the extent of colonic involvement, and in surveillance for the occurrence of colon cancer. As mentioned earlier, rectal sparing with involvement of the proximal colon helps to differentiate Crohn colitis from ulcerative colitis. Abdominal CT scanning is the most useful diagnostic test in patients with acute symptoms who have known or suspected Crohn disease. Findings such as bowel wall thickening, mesenteric edema, and local abscess formation suggest the diagnosis of Crohn disease. Extraintestinal complications such as gallstones, renal calculi, hydronephrosis, sacroileitis, and osteomyelitis can also be seen on CT scan. Intraabdominal abscesses, mesenteric inflammation, and fistulas are also diagnosed using computed tomography.

Differential Diagnosis

Diseases that should be considered in the differential diagnosis of Crohn disease (Table 81-2) include lymphoma, ileocecal amebiasis, sarcoidosis, deep chronic mycotic infections involving the GI tract,

gastrointestinal tuberculosis, Kaposi's sarcoma, *Campylobacter* enteritis, and *Yersinia* ileocolitis. Fortunately, most of these are uncommon conditions and can be differentiated by appropriate laboratory tests. *Yersinia* ileocolitis and *Campylobacter* enteritis may cause chronic abdominal pain and diarrhea similar to Crohn disease, but can be diagnosed by appropriate stool cultures. Acute ileitis should not be confused with Crohn disease. Young patients with acute ileitis usually recover without sequelae and should not undergo surgery. When Crohn disease is confined to the colon, ischemic bowel disease (particularly in the elderly) and pseudomembranous enterocolitis as well as ulcerative colitis must be included in the differential diagnosis.

Treatment

The aim of therapy includes relief of symptoms, induction of remission, maintenance of remission, prevention of complications, optimizing timing of surgery, and maintenance of nutrition. In a disease that is virtually incurable, the emphasis should be on relief of symptoms and prevention of complications. The pharmacologic agents available for the management of Crohn disease include symptomatic agents, antiinflammatory agents, antibiotics, and immunomodulators. Treatment guidelines have been developed for adult patients with Crohn disease.^{2,3} Initial evaluation in the ED should focus on determining the severity of the attack; identifying significant complications such as obstruction, intraabdominal abscess, life-threatening hemorrhage, or toxic megacolon; and eliminating other possible causes of the patient's complaints. Laboratory evaluation should include a CBC, serum electrolytes, BUN, creatinine, and a type and cross-match where appropriate. Plain radiographs of the abdomen may reveal evidence of obstruction, perforation, or toxic megacolon. Initial treatment

I Table 81-3) consists of adequate fluid resuscitation and restoration of electrolyte balance. Nasogastric decompression should be initiated in any patient with evidence of obstruction, peritonitis, or toxic megacolon. Broad-spectrum antibiotics (ampicillin or a cephalosporin, an aminoglycoside, and metronidazole) should be used in patients with fulminant colitis or peritonitis. Patients with severe disease should receive intravenous steroids such as hydrocortisone 300 mg per d or an equivalent dose of methylprednisolone (48 mg per d) or prednisolone (60 mg per d).

Sulfasalazine (Azulfidine), 3 to 4 g per d, has been shown to be effective in treating patients with mild to moderate active Crohn disease. The mechanism of action is not known but is presumed to be through the topical action of 5-aminosalicylic acid, which is released by the action of colonic bacteria on sulfasalazine. Sulfapyridine is also a by-product of this breakdown. Many of the toxic side effects of sulfasalazine are attributable to sulfapyridine. These include nausea, vomiting, anorexia, epigastric distress, arthralgias, headache, diarrhea, male infertility, and hypersensitivity reactions (pericarditis, pleuritis, pancreatitis, arthritis, and rash). Because of the toxicity profile associated with sulfasalazine 5-aminosalicylic acid derivative agents are now available for either oral or topical use. A slow, timed-release mesalamine (Pentasa) 4 g per d or a pH-dependent release mesalamine (Asacol, Claversal, Salofalk) 2 to 4 g per d have the primary advantage of delivery into the colon. Olsalazine (Dipentum) 1 g per d is a derivative of the sodium salt of 5-aminosalicylic acid, which is converted to two 5-aminosalicylic molecules in the colon and has identical antiinflammatory properties. Balsalazide (Colazide) 1.5 to 6 g per d has the 5-aminosalicylic acid moiety bound to an inert molecule. The mesalamine formulations are most effective in colonic disease. The topical preparations have limited usefulness and are effective only in the management of Crohn disease limited to the rectum or the distal 40 cm of rectosigmoid.

Oral glucocorticoids such as prednisone (40 to 60 mg per d) are reserved for more severely affected patients and are effective primarily in small intestinal disease as well as in ileocolitis. Alternatively, an ileal-released form of budesonide (9 mg per d) may be beneficial in these patients. Immunosuppressive drugs such as 6-mercaptopurine (6-MP) (1 to 1.5 mg/kg per d) or azathioprine (2 to 2.5 mg/kg per d) are useful as steroid-sparing agents, in healing fistulas, and in patients

in whom there are serious contraindications to surgery. Recent evidence suggests that they are also effective as maintenance agents. Both agents have been associated with leukopenia, fever, hepatitis, and pancreatitis, necessitating the need for close follow-up, particularly during the initial phase of therapy. Thioguanine (6-TG), the active metabolite of azathioprine and 6-MP may offer a safer alternative.⁴ The response to immunosuppressives should not be expected before 3 to 6 months following the initiation of therapy. Cyclosporine (4 mg/kg per d for 7 to 10 d) and methotrexate (15 to 25 mg per week) have been used in refractory cases.

Metronidazole (10 to 20 mg/kg per d) has been shown to be effective in controlled clinical trials and is particularly useful in treatment of patients with perianal complications and fistulous disease. Ciprofloxacin (1.0 to 1.5 mg/kg per d) has also been used in this setting as well as in active Crohn's ileitis and ileocolitis.

Patients with medically-resistant moderate to severe Crohn's disease may benefit from the anti-tumor necrosis factor antibody infliximab (Remicade) 5 mg/kg intravenously.⁵ Active tuberculosis can develop after initiation of treatment with infliximab. Before initiation of treatment, patients should be screened for tuberculosis.⁶ In addition, patients with perianal disease have been shown to respond to repeated infusions of 5 mg/kg at 0, 2, and 6 weeks.⁷ Newer agents such as CDP571 (Cellcept), etanercept, thalidomide, and interleukin therapy may also be beneficial in these settings.

Maintenance therapy and the effectiveness of various therapeutic agents in Crohn disease is variable. Glucocorticoids should not be used for maintaining a remission because of the lack of sufficient evidence of their efficacy and the potential for long-term complications. When a patient is responsive to immunosuppressive therapy, it would seem advisable to continue this in a reduced dose for the maintenance of remission. Similarly, a reduced dose of 5-aminosalicylic acid derivatives is appropriate for the maintenance of remission of colonic disease. The addition of sulfasalazine, azathioprine, and 6-mercaptopurine to prednisone does not improve the response rate and increases the risk of side effects.

Diarrhea can be controlled by the use of loperamide (Imodium) 4 to 16 mg per d, diphenoxylate (Lomotil) 5 to 20 mg per d, and in some cases, cholestyramine (Questran) 4 g 1 to 6 times a day. The latter is particularly useful as an exchange resin in patients who have limited ileal disease or resection, no bowel obstruction, and mild steatorrhea. The mechanism of action is binding bile acids and eliminating their known cathartic action. The primary aim of dietary therapy is the maintenance of nutrition and the alleviation of diarrhea. Elimination of lactose from the diet is of benefit in patients with lactose intolerance. Reduction in dietary oxalate should be considered in every patient. In addition, supplementation of trace metals, fat-soluble vitamins, and medium-chain triglycerides should be considered in selected patients.

Disposition

Patients who demonstrate signs of fulminant colitis, peritonitis, or complications such as obstruction, significant gastrointestinal hemorrhage, severe dehydration, or fluid/electrolyte imbalance should be hospitalized under the care of a gastroenterologist or surgeon. Hospital admission should be considered in less severe cases that fail outpatient management. Surgical intervention is indicated in those patients with complications of the disease, including intestinal obstruction or hemorrhage, perforation, abscess or fistula formation, toxic megacolon, and perianal disease. In addition, surgery may be indicated in those patients who fail medical therapy. The recurrence rate after surgery approaches 100 percent.

When patients with Crohn disease are discharged from the ED, alterations in their therapeutic regimen should be discussed with a consulting gastroenterologist. Close follow-up of these patients must be assured prior to discharge.

ULCERATIVE COLITIS

Ulcerative colitis is a chronic inflammatory disease of the colon. The inflammation tends to be progressively more severe from proximal to the distal colon. The rectum is involved nearly 100 percent of the time. Clinically, the characteristic symptom is bloody diarrhea. The etiology, like that of Crohn disease, remains unknown.

Epidemiology

Epidemiologic considerations are similar to those of Crohn disease; the disease is more prevalent in the United States and northern Europe, and peak incidence occurs in the second and the third decades of life. There is a slight predominance of men among patients with the disease. First-degree relatives of patients with ulcerative colitis have a 15-fold risk of developing ulcerative colitis and a 3.5-fold risk of developing Crohn disease.

Pathology

Ulcerative colitis involves primarily the mucosa and submucosa. Microscopically, the disease is characterized by mucosal inflammation with the formation of crypt abscesses, epithelial necrosis, and mucosal ulceration. The submucosa, muscular layer, and serosa are usually spared. In the usual case, the disease increases in severity more distally, the rectosigmoid being involved in 95 percent of cases. In the early stages of the disease, the mucous membranes appear finely granular and friable. In more severe cases, the mucosa appears as a red, spongy surface dotted with small ulcerations oozing blood and purulent exudate. In very advanced disease, one sees large, oozing ulcerations and pseudopolyps (areas of hyperplastic overgrowth surrounded by inflamed mucosa).

Clinical Features

The clinical features and course of ulcerative colitis vary but are somewhat dependent on the anatomical distribution of the disease in the colon. The disease is classified as mild, moderate, or severe depending on the clinical manifestations. Patients with mild disease have fewer than four bowel movements per day, no systemic symptoms, and few extraintestinal manifestations. Of all patients with ulcerative colitis, 60 percent have mild disease; in 80 percent of cases, the disease is limited to the rectum. Occasionally, constipation and rectal bleeding are the presenting complaints. Progression to pancolitis occurs in 10 to 15 percent of patients with mild disease.

Patients with severe disease constitute 15 percent of those with ulcerative colitis. Severe disease is associated with frequent bowel movements, anemia, fever, weight loss, tachycardia, low serum albumin, and more frequent extraintestinal manifestations. Patients with severe disease account for 90 percent of the mortality from ulcerative colitis. Virtually all severely affected patients have pancolitis.

Moderate disease is seen in 25 percent of patients. The clinical manifestations are less severe and patients demonstrate a good response to therapy. These patients usually have colitis extending to the splenic flexure (left-sided colitis), but may develop pancolitis.

Most commonly, ulcerative colitis is characterized by intermittent attacks of acute disease with complete remission between attacks. Such a pattern occurs in the majority of patients. In other patients, the first attack is followed by a prolonged period of inactivity. Infrequently, patients run a chronically active course. The factors associated with an unfavorable prognosis and increased mortality include higher severity and extent of disease, a short interval between attacks, and onset of the disease after 60 years of age.

Extraintestinal complications of ulcerative colitis include peripheral arthritis, ankylosing spondylitis, episcleritis, uveitis, pyoderma gangrenosum, and erythema nodosum (see Table 81-1). Clinically ap-

parent liver disease may occur in 5 to 10 percent of patients. The manifestations of liver disease may include any of the following: peri-cholangitis, chronic active hepatitis, fatty liver or cirrhosis, cholelithiasis, sclerosing cholangitis, and bile duct carcinoma.

Complications

Although blood loss from sustained hemorrhage may be the most common complication of the illness, toxic megacolon is an associated clinical entity that must not be missed.

Toxic megacolon develops in advanced cases of colitis when the disease process begins to extend through all layers of the colon. The result is a loss of muscular tone within the colon, with dilatation and localized peritonitis. If the colon continues to dilate without treatment, signs of toxicity will develop. Plain radiography of the abdomen demonstrates a long, continuous segment of air-filled colon greater than 6 cm in diameter. Loss of colonic haustra and "thumbprinting," representing bowel wall edema, may also be seen. The distended portion of the atonic colon can perforate, causing peritonitis and septicemia. Mortality from this complication is approximately 50 percent if perforation occurs, but less than 10 percent if surgery is undertaken prior to perforation.

A patient with toxic megacolon appears severely ill; the abdomen is distended, tender, and tympanitic. Severe diarrhea (more than 10 bowel movements per day) is often seen but may have ceased prior to onset. Fever, tachycardia, and signs of hypovolemia are typically part of the clinical picture. Leukocytosis, anemia, electrolyte disturbances, and hypoalbuminemia are the supporting laboratory results.

Some of the more prominent features of toxic megacolon, such as leukocytosis and peritonitis, can be masked in the patient taking corti-costeroids. When such therapy is being administered, greater suspicion is required to make the diagnosis. Antidiarrheal agents, hypokalemia, narcotics, cathartics, pregnancy, enemas, and recent colonoscopy have been implicated as precipitating factors in toxic megacolon. Medical therapy with nasogastric suction, intravenous prednisolone 60 mg per d, or hydrocortisone 300 mg per d, parenteral broad-spectrum antibiotics active against coliforms and anaerobes, and intravenous fluids should be attempted as initial therapy and in preparing the patient for possible surgery. However, prolonged medical treatment of these patients increases mortality; therefore early surgical consultation must be sought with the aim of performing a colectomy if clinical improvement is not noted in 24 to 48 h with medical treatment.

Perirectal fistulas and abscesses may occur in up to 20 percent of patients with ulcerative colitis. Massive gastrointestinal hemorrhage, obstruction secondary to stricture formation, and acute perforation are other complications of the disease.

There is a 10- to 30-fold increase in the development of carcinoma of the colon in patients with ulcerative colitis. The major risk factors for the development of carcinoma of the colon are extensive involvement and prolonged duration of the disease. The cumulative risk of cancer after 20 and 30 years is 5 to 10 percent and 12 to 20 percent, respectively. Additional factors that constitute increased risk of cancer in patients with ulcerative colitis include early onset of the disease and a family history of colon cancer. The availability of fiberoptic colonoscopy allows surveillance of ulcerative colitis patients with periodic colonoscopies and biopsies to detect the high-grade dysplasia thought to predict the development or association of colon cancer. In patients with pancolitis, such surveillance should start 8 to 10 years after the onset of the disease.⁸

Diagnosis

Laboratory findings in patients with ulcerative colitis are nonspecific; they may include leukocytosis, anemia, thrombocytosis, decreased serum albumin, and abnormal liver function studies. Therefore, the diagnosis of ulcerative colitis rests on the following: a history of abdominal cramps and diarrhea, mucoid stools, stool examination nega-81 • ILEITIS, COLITIS, AND DIVERTICULITIS

tive for ova and parasites, stool cultures negative for enteric pathogens, and confirmation by sigmoidoscopic or colonoscopic examination. The results of the latter examination are abnormal in 95 percent of the patients with ulcerative colitis. The observed pathologic changes vary depending on the severity and duration of the disease. Granularity, friability, ulceration of the mucosa, and, in more advanced cases, pseudopolyps are quite characteristic.

Sigmoidoscopy may be done in the office or the ED to confirm the clinical suspicion, but the appearance is not specific. Biopsy may help differentiate acute from chronic colitis (crypt distortion) and diseases caused by specific etiology, such as amebiasis (see "Pathology," above). Barium enema examination may be useful in differentiating ulcerative colitis from Crohn disease and defining the extent of involvement of the colon. Colonoscopy, however, is the most sensitive method for making the diagnosis and defining the extent and severity of the disease. In addition, colonoscopy is extremely useful in the evaluation of the patient for the development of dysplasia or colon cancer. Barium enema examination should be done with caution or postponed in moderately ill patients. Rigid or fiberoptic proctosigmoidoscopy can be used, however, even in the severely ill patient, provided that it is done gently and without the administration of any enemas or laxatives.

Differential Diagnosis

The major diseases that should be considered in the differential diagnosis of ulcerative colitis include infectious colitis, Crohn colitis, ischemic colitis, radiation colitis, toxic colitis from antineoplastic agents, and pseudomembranous colitis (see Table 81-2). When the disease is limited to the rectum, particular attention should be paid to sexually acquired diseases, which are frequently seen in the male homosexual population (gay bowel disease). Some of the more common diseases in this category include rectal syphilis, gonococcal proctitis, lymphogranuloma venereum, and inflammations caused by herpes simplex virus, *Entamoeba histolytica*, *Shigella*, and *Campylobacter*.

Treatment

Patients with severe ulcerative colitis should be treated with intravenous steroids, replacement of fluids, correction of electrolyte abnormalities, and broad-spectrum antibiotics active against coliforms and anaerobes (ampicillin and clindamycin or metronidazole); hyperalimentation may be considered for the individual patient (see Table 81-3). Steroid options include hydrocortisone 300 mg per d IV or an equivalent dose of methylprednisolone (48 mg per d IV or PO) or prednisolone (60 mg per d PO). Recently, cyclosporine (4 mg/kg per d) has been advocated for cases of fulminant colitis that have failed treatment with intravenous corticosteroids.⁹ The use of complete bowel rest and routine administration of parenteral nutrition remains controversial in patients with fulminant disease.¹⁰ When toxic megacolon is suspected, nasogastric suction should be initiated, a surgical consultation obtained, and the patient observed by frequent examinations and flat films of the abdomen. When the diagnosis of toxic megacolon is established and the patient fails to show dramatic clinical improvement within 24 to 48 h, emergency surgery should be considered.

The majority of those with mild and moderate disease can be treated as outpatients. Glucocorticoids are effective in inducing a remission in the majority of cases and constitute the mainstay of therapy in an acute attack. Daily doses of 40 to 60 mg of prednisone are usually sufficient and can be adjusted depending on the severity of the disease. In the treatment of patients with active proctitis, proctosigmoiditis, and left-sided colitis (less than 60 cm of active disease), 5-aminosalicylic acid enemas have been used with great success. Topical steroid preparations (beclomethasone, hydrocortisone, tixocortol, and budesonide) have also been successful and offer the benefit of fewer systemic side effects. This therapy has also been used to maintain remission in these patients. Once clinical remission is achieved, steroids should be slowly tapered and dis-

continued. There is no evidence that maintenance dosages of steroids reduce the incidence of relapses.

Sulfasalazine has been used in the treatment of acute attacks but is probably inferior to steroids, especially in the more severe cases. Its primary usefulness is in the form of adjunctive therapy and in the maintenance of a remission. Maintenance doses of 1.5 to 2 g per d significantly reduce the recurrence rate of the disease.

In addition to sulfasalazine, the newer 5-aminosalicylic derivatives are quite effective in inducing remission of ulcerative colitis as well as maintaining it. The main advantage of the newer agents is reduced side effects from the sulfapyridine moiety of sulfasalazine. The choice of agents available for the treatment of ulcerative colitis is very similar to that in Crohn disease [mesalamine (Pentasa, Asacol), olsalazine (Dipentum), and balsalazide]. Topical glucocorticoid enemas or 5-aminosalicylic enemas (Rowasa, 2 to 4 g/60 mL per d for 3 weeks) or suppositories (500 mg bid) are quite effective in distal proctosigmoiditis and have lower systemic side-effect profiles. In refractory cases, a combination of glucocorticoids and immunomodulators such as 6-mercaptopurine (1 to 1.5 mg/kg per d) or azathioprine (2 mg/kg per d) should be considered. The beneficial effects of this combination therapy will not be seen before 3 to 6 months, somewhat limiting its usefulness in very sick patients. For these reasons, surgical intervention with elective proctocolectomy may be necessary. Newer agents under investigation for the treatment of ulcerative colitis include nicotine, heparin, biological therapies, and immunomodulating drugs including infliximab (Remicade).

Supportive measures in the treatment of mild to moderately sick patients include the replenishment of iron stores, a nutritious diet with the elimination of lactose, and adequate physical and psychological rest. Hydrophilic bulk agents such as psyllium (Metamucil) can be used in some patients to improve stool consistency. Antidiarrheal agents should be used with caution in ill patients because they may precipitate toxic megacolon and because they are generally ineffective.

Disposition

Patients with fulminant attacks of ulcerative colitis should be hospitalized for aggressive fluid and electrolyte resuscitation and careful observation for the development of complications. Patients with complications such as gastrointestinal hemorrhage, toxic megacolon, and bowel perforation should also be admitted with consultation to both a gastroenterologist and a surgeon. In addition to toxic megacolon, the indications for surgery include colonic perforation, massive lower gastrointestinal bleeding, suspicion of colon cancer, and disease that is refractory to medical therapy (large doses of steroids required to control the disease). Age and patient acceptance often influence the choice of surgical procedure, with the increased performance of continent procedures.

Patients with mild to moderate disease can be discharged from the ED. Close follow-up should be arranged with the patient's physician or gastroenterologist, and any adjustment in medical therapy discussed. In addition, the patient should be instructed to eat a low-residue diet. Patients should be instructed to return if symptoms do not improve or worsen. Particular attention should focus on the quantity of diarrhea, toleration of oral intake, and associated symptoms such as fever, rectal bleeding, or abdominal pain.

PSEUDOMEMBRANOUS ENTEROCOLITIS

Pseudomembranous enterocolitis is an inflammatory bowel disorder in which membrane-like yellowish plaques of exudate overlie and replace necrotic intestinal mucosa.

Epidemiology

Clostridium difficile is a spore-forming obligate anaerobic bacillus that causes pseudomembranous colitis. Three different syndromes

have been described: neonatal pseudomembranous enterocolitis, post-operative pseudomembranous enterocolitis, and antibiotic-associated pseudomembranous colitis. Recent antibiotic use, gastrointestinal surgery or manipulation, severe underlying medical illness, and advancing age have all been identified as risk factors for developing pseudomembranous colitis. Transmission of the organism has been implicated from direct human contact as well as contact with inanimate objects (commodes, telephones, rectal thermometers).

Pathophysiology

Hospitalized patients are colonized with *C. difficile* in 10 to 25 percent of cases, so the development of diarrhea in recently discharged patients should suggest consideration of *C. difficile*. There is a linear relationship between the length of hospital stay, colonization with *C. difficile* and the development of *C. difficile* diarrhea.¹¹ Broad-spectrum antibiotics—most notably clindamycin, cephalosporins, and ampicillin/amoxicillin—alter the gut flora in such a way that toxin-producing *C. difficile* can flourish within the colon, producing clinical manifestations of pseudomembranous colitis. However, almost any antibiotic (including metronidazole and vancomycin) can lead to pseudomembranous colitis, and chemotherapeutic agents and antiviral agents have also been implicated. Bowel ischemia, recent bowel surgery, uremia, malnutrition, shock, and Hirschsprung disease also contribute to the development of pseudomembranous colitis. Most disease-producing strains of *C. difficile* produce two toxins: toxin A, an enterotoxin, and toxin B, a cytotoxin, that interact in a complex and not completely understood manner to produce pseudomembranous colitis and its associated symptoms.

Clinical Features

Pseudomembranous colitis results in a spectrum of clinical manifestations that vary from frequent, mucoid, watery stools to a toxic picture that includes profuse diarrhea (20 to 30 stools per day), crampy abdominal pain, fever, leukocytosis, dehydration, and hypovolemia. Examination of the stool may reveal the presence of fecal leukocytes. These are not generally found in more benign forms of antibiotic-induced diarrhea.¹² Complications of the disease include severe electrolyte imbalance, hypotension, and anasarca from decreased serum albumin. In 1 to 3 percent of patients, toxic megacolon or colonic perforation may occur in patients with pseudomembranous colitis.¹³ The disease typically begins 7 to 10 days after the institution of antibiotic therapy, although symptoms may develop within a few days or up to several weeks after the antibiotic is discontinued. Extraintestinal complications are rare and include arthritis, visceral abscesses, cellulitis, necrotizing fasciitis, osteomyelitis, and prosthetic device infection.¹⁴

Diagnosis

The diagnosis is suggested by a history of diarrhea that develops during administration of antibiotics or within 2 weeks of their discontinuation. The diagnosis may be confirmed by stool examination for the *C. difficile* toxin and colonoscopy.

The diagnosis is confirmed by the demonstration of *C. difficile* in the stool and by the detection of the toxin in stool filtrates. The organism is best identified by stool culture using a selective growth medium. This technique has a sensitivity approaching 100 percent, but lacks specificity because the presence of *C. difficile* does not necessarily mean it causes disease. In addition, culture results take between 28 and 72 h, thus limiting their utilization in establishing the diagnosis in patients with suspected pseudomembranous colitis.

Instead, *C. difficile* toxins are detected directly using a number of techniques including tissue-culture assay, enzyme-linked immunosorbent assays (ELISA), latex agglutination, dot-immunobinding assays, and polymerase chain reaction (PCR). Tests vary in their sensitivity,

specificity, and time to completion. While tissue-culture assays are considered the gold standard, most laboratories utilize the ELISA technique to detect the clostridial toxins; it has a sensitivity of 63 to 94 percent and a specificity of 75 to 100 percent.¹⁵ Five to twenty percent of patients require more than one stool specimen to detect toxin. Colonoscopy reveals characteristic yellowish plaques within the intestinal lumen. Lesions may be seen throughout the entire alimentary tract, although they are typically limited to the right colon. Colonoscopy is not routinely needed to establish a diagnosis of pseudomembranous colitis. It may be used in patients who require a rapid diagnosis and those who cannot produce a stool specimen due to ileus.

Treatment

The treatment of pseudomembranous colitis includes discontinuing antibiotic therapy and instituting supportive measures such as the administration of fluids and the correction of electrolyte abnormalities. Twenty-five percent of patients will respond to these measures alone. For those patients with mild to moderate disease who do not respond to supportive measures, metronidazole 250 mg qid is the therapy of choice.¹² Vancomycin 125 to 250 mg qid is an alternative regimen, although it is considerably more expensive than metronidazole, and metronidazole is just as effective. Vancomycin should be reserved for cases in which the patient has not responded to or is intolerant of metronidazole, the organism is resistant to metronidazole, or in children or pregnant patients.

Severely ill persons must be hospitalized. Oral vancomycin, 125 to 250 mg qid for 10 days, is effective in the majority of severely ill patients. The symptoms usually resolve within a few days. Rarely, emergency colectomy may be required for patients with toxic dilatation of the colon or colonic perforation.

Relapses occur in 10 to 20 percent of patients. The use of antidiarrheal agents may prolong or worsen symptoms in patients with pseudomembranous colitis and should be avoided. Steroids and surgical intervention are rarely needed.

Disposition

Patients with severe diarrhea, symptoms that persist despite appropriate outpatient management, or those with a systemic response (fever, leukocytosis, severe abdominal pain) should be hospitalized. Patients with pseudomembranous colitis who are suspected of having a toxic megacolon, intestinal perforation, or those who fail to respond to appropriate medical therapy should have an immediate surgical consultation. For those patients who are discharged, discontinuation of any antibiotics and good oral intake must be encouraged. Metronidazole or vancomycin are equally effective in the treatment of antibiotic-induced colitis.

DIVERTICULITIS

Diverticulitis is an acute inflammation of the wall of a diverticulum and surrounding tissue caused by either a micro- or macroperforation.

Epidemiology

Acquired diverticular disease of the colon has become an increasingly common disorder of industrialized nations. Radiologic studies have suggested that one-third of the population will have acquired the disease by age 50 and two-thirds by age 85. Diverticula are rare in individuals under age 20.

Diverticulitis is estimated to occur in 10 to 25 percent of patients with known diverticulosis. The incidence of diverticulitis increases with age. Only 2 to 4 percent of patients with diverticulitis are under the age of 40. Diverticulitis in the younger age group tends to be a

more virulent form of the disease, with frequent complications requiring earlier surgical intervention. Although the frequency of the disease is higher in men, there is an increasing incidence of diverticulitis in women.

Pathophysiology

Colonic diverticula are false diverticula because they do not include all layers of the bowel wall. They consist of mucosa and submucosa with a peritoneal covering that has herniated through a defect in the circular muscle layer of the wall. The sites of herniation are located between the mesenteric and antimesenteric taenia, where intramural blood vessels penetrate the muscularis. Cecal diverticuli, on the other hand, are true diverticula.

The cause of diverticular disease is not known. It is still unresolved whether diverticular disease is a disorder of colonic motility, a colonic muscle abnormality, a connective tissue disorder, or a normal concomitant of aging. Low-residue diets have been implicated as a major factor in the pathogenesis of diverticular disease. The most common hypothesis is that acquired diverticula arise because of high intraluminal pressures in areas of relative weakness of the colonic wall. This is based on observations that the majority of patients have diverticula located within the sigmoid colon. Laplace's law states that the tension on the wall of a hollow cylinder is inversely proportional to the radius of the cylinder multiplied by the pressure within the cylinder. This suggests that the intraluminal pressure in the colon is greatest where the lumen is narrowest. The diameter of the colon is smallest in the sigmoid region, and thus this region of the colon is the most likely location for the development of diverticula.

The acute complications of diverticular disease can be divided into two broad categories: (1) inflammation and its associated complications, and (2) bleeding (see Chap. 74).

Inflammation, or diverticulitis, is the most common complication of diverticular disease. It was thought to occur when fecal material became inspissated in the neck of an acquired diverticulum, resulting in obstruction of the neck of the diverticulum and subsequent proliferation of colonic bacteria, mucous secretion, and distention of the diverticulum. The latter mechanism probably contributes to a small percentage of cases of diverticulitis. More commonly, clinical diverticulitis results from high pressure in the colon, erosion of the wall of the diverticulum, and microperforation and inflammation of pericolic tissue. Fortunately, fecal contamination of the peritoneum is usually limited because perforation of a diverticulum occurs into the leaves of the mesentery or because the contamination is walled off by the mobile loops of the sigmoid colon or small bowel and adjacent pelvic structures. Free perforation may occur with generalized peritonitis, but it is uncommon. Other complications include intestinal obstruction and fistula formation between the diverticula and the bladder in a male or vagina in a female.

Clinical Features

The most common symptom of diverticulitis is pain. This is commonly described as a steady, deep discomfort in the left lower quadrant. Patients will frequently complain of a change in bowel habits, either in the form of diarrhea or increasing constipation. Tenesmus is another common symptom. The involved diverticulum may irritate the bladder or ureter, causing the patient to have urinary frequency, dysuria, or pyuria. If a fistula develops between the colon and the bladder, the patient may present with recurrent urinary tract infections or pneumaturia. **Paralytic** ileus with abdominal distention, nausea, and vomiting may develop secondary to intraabdominal irritation and peritonitis. Small bowel obstruction may also occur as an adjacent loop of small bowel becomes kinked or narrowed in the inflammatory mass.

The clinical presentation may be indistinguishable from acute appendicitis. This may occur when the patient has a redundant sig-

moid colon lying on the right side of the abdomen or a cecal diverticulum that becomes inflamed. The possibility of diverticulitis or appendicitis should always be considered in the patient 50 years of age or older with right lower abdominal pain. Cases of diverticulitis in the cecum or ascending colon have also been reported.

Perforation is characterized by sudden lower abdominal pain progressing to generalized abdominal involvement. Prior steroid use predisposes the patient to perforation and may mask some of the typical signs and symptoms.

Physical examination frequently demonstrates a low-grade fever, around 38°C (100.4°F). However, the temperature may be more elevated in patients with generalized peritonitis or in those who have formed an abscess. The abdominal examination reveals localized tenderness, often with voluntary guarding and rebound tenderness. With careful palpation, one may be able to appreciate a fullness or mass over the involved segment of the colon. Rectal examination will often reveal tenderness on the left side. Occult blood may be present in the stool. When free perforation does occur, diffuse abdominal tenderness, rigidity, guarding, and rebound tenderness may be noted. In the female patient, a pelvic examination should always be carried out to eliminate a gynecologic source of symptoms.

Diagnosis

The diagnosis is usually suspected by the clinical history and the findings on physical examination. The presence of peritoneal signs or generalized peritonitis should suggest free perforation or rupture of a peridiverticular abscess. The presence of an abdominal mass associated with occult blood in the stool could indicate colon cancer. Colonic or small bowel obstruction, though uncommon, may necessitate surgical intervention.

The acute abdominal series may be normal or may demonstrate associated ileus, partial small bowel obstruction, free air indicating bowel perforation, or extraluminal collections of air that might indicate a walled-off abscess. Abdominal ultrasonography is an inexpensive non-invasive method but is operator-dependent and lacks specificity.

Abdominal CT is the diagnostic procedure of choice.¹⁶ It can demonstrate inflammation of pericolic fat, presence of diverticula, thickening of the bowel wall, or peridiverticular abscess. Colon cancer is best ruled out by sigmoidoscopy or colonoscopy.

Barium contrast studies can easily demonstrate diverticula but are insensitive in detecting the presence of diverticulitis. In addition, barium introduced under high pressure carries the risk of precipitating a colonic perforation. Water soluble contrast enemas have also been used in some centers to establish the diagnosis.

Laboratory studies should include routine screening blood tests, urinalysis, and an acute abdominal series. However, these all lack sensitivity and specificity for the diagnosis. Leukocytosis was seen in only 36 percent of patients with acute diverticulitis.¹⁷ Sigmoidoscopy or colonoscopy are generally performed only after the acute inflammatory process has subsided.

Differential Diagnosis

In patients over the age of 40 presenting with complaints of abdominal pain, a change in bowel habits, and urinary symptoms, a diagnosis of colonic diverticulitis should be entertained. These symptoms, however, are nonspecific, and a number of pathologic entities may present with similar signs and symptoms (see Table 81-2). Some of the most important are discussed below.

Symptoms of irritable bowel syndrome include diffuse crampy or colicky abdominal pain, brought on by meals or emotional upset. The patients may also describe a bloated or distended sensation in the abdomen. The symptoms are usually intermittent and chronic. The passage of flatus or a bowel movement may bring relief. The disease is characterized by alternating bouts of constipation and diarrhea. On

physical examination, the patient is afebrile and a cordlike mass may be appreciated in the left lower quadrant corresponding to the sigmoid colon. Signs of localized or generalized peritonitis are not seen. Laboratory studies are normal.

Patients who have colon carcinoma may present with a change in bowel habits, either diarrhea or constipation, and/or abdominal pain that can mimic symptoms of diverticular disease. There may be blood mixed with the patient's stools and weight loss. Physical examination may reveal a palpable mass, usually nontender. Fever and chills are less common, and laboratory studies may demonstrate anemia without evidence of leukocytosis. An acute abdominal series may demonstrate findings of colonic obstruction. This can be produced by an inflamed diverticulum or a carcinoma in an area of the bowel with underlying diverticulosis. Fiberoptic colonoscopy can be useful in differentiating diverticular disease from carcinoma. A perforated colonic carcinoma may mimic acute diverticulitis.

Pelvic inflammatory disease may present with abdominal pain, fever, and leukocytosis. The disease is usually found in young women. A careful pelvic examination should be carried out in all female patients with lower abdominal pain. A history of irregular menses and the finding of vaginal discharge should aid in the diagnosis.

Ischemic colitis can present with a broad range of clinical manifestations. Mild transient ischemia may result in mucosal sloughing and painless rectal bleeding. If the disease progresses to gangrene, the patient develops severe abdominal pain and peritonitis. Pain may be out of proportion to physical findings. A plain film of the abdomen may reveal thumbprinting in the region of the involved colonic segment. In more advanced cases, there may be gas within the bowel wall, or, if perforation has occurred, free air in the abdomen. Cautious endoscopic evaluation and contrast x-ray studies are helpful in distinguishing ischemic colitis from diverticulitis.

Treatment

Initial resuscitation of patients with acute diverticulitis should focus on determining the severity of the illness, eliminating other causes of symptoms, and appropriate fluid and electrolyte resuscitation (Table 81-4). In patients who demonstrate signs of toxicity such as fever, tachycardia, leukocytosis, and severe abdominal pain, intravenous antibiotics are administered. These should include an aminoglycoside (gentamicin or tobramycin 1.5 mg/kg IV) and either clindamycin 300 to 600 mg IV or metronidazole 500 mg IV or ticarcillin-clavulanic acid or imipenem. The patient is placed on bowel rest, but in this case, nothing by mouth is given and intravenous fluids are administered.

TABLE 81-4 Treatment of Acute Diverticulitis

Restore fluid and electrolyte balance
Nothing by mouth Nasogastric suction
for
Obstruction
Adynamic ileus Broad-
spectrum antibiotics
Aminoglycoside (gentamicin or tobramycin)
Metronidazole or clindamycin
Ticarcillin-clavulanic acid or imipenem (alternative therapy)
Observe for complications
Obstruction
Perforation
Intraabdominal abscess Outpatient
Management (nontoxic patients)
Liquids only for first 48 h
Oral Antibiotics:
Ampicillin, TMP/SMX, Ciprofloxacin, or Cefalexin
and
Metronidazole or Clindamycin

Nasogastric suction is necessary only if the patient manifests signs of bowel obstruction or an adynamic ileus.

Outpatient treatment consists of bowel rest and broad-spectrum oral antibiotic therapy. Patients are instructed to limit activity and to maintain a liquid diet for 48 h. If symptoms improve, low-residue foods are added to the diet. Broad-spectrum antibiotics covering both aerobic and anaerobic bacteria are given. Predominant colonic aerobes include *Escherichia coli*, *Klebsiella*, and *Enterobacter*, while *Bacteroides fragilis*, *Peptostreptococcus*, and *Clostridium* are the predominant colonic anaerobes. Common oral antibiotic agents effective against aerobic organisms include ampicillin (500 mg q6h), trimethoprim-sulfamethoxazole (2 tablets q12h), ciprofloxacin (500 mg q12h), or a cephalosporin such as cefalexin (500 mg q6h). One of these agents is taken in combination with metronidazole (Flagyl 500 mg q8h), or clindamycin (Cleocin 300 mg q6h), which are utilized to treat the anaerobic organisms. Practice guidelines have been developed for the care of patients with sigmoid diverticulitis.¹⁸

Disposition

Patients who have localized pain without signs and symptoms of local peritonitis and without evidence of systemic infection may be treated on an outpatient basis. Careful follow-up should be arranged with the patient's primary physician. Patients should be instructed to return if fever develops, if they are unable to tolerate oral intake, or if there is worsening abdominal pain.

If a patient has systemic signs and symptoms of infection, has failed outpatient management, or demonstrates signs of localized peritonitis, hospitalization is necessary. Surgical consultation should be obtained at the time of hospitalization. Urgent surgical consultation is indicated if free perforation, intestinal obstruction, abscess, or fistulas are found. In addition, early surgical involvement is indicated in immunocompromised patients and patients under the age of 45 years with diverticulitis.

ANORECTAL DISORDERS **Brian E. Burgess James K. Bouzoukis**

Anorectal disorders range from simple to complex, may be varied and multiple, and at times can manifest signs and symptoms of underlying serious local or systemic disorders that may be life-threatening.

ANATOMY

The rectum is an anatomic structure that begins at the S3 vertebral body and descends for about 13 to 15 cm. This entodermal intestine unites with and opens into an orifice of ectodermal origin, the anal canal, which is about 4 cm long. The junction of these two embryonic structures is the dentate line, which marks the anatomic beginning of the anal canal and is in continuity more distally with the perianal skin at the anal verge. The mucosa of the anal canal consists of stratified squamous epithelium but contains no hair follicles or sweat glands. At the anal verge, the anoderm thickens and includes in its structure hair follicles and other cutaneous appendages. Proximal to the dentate line, the rectal ampulla narrows to conform to the opening of the anal canal; in doing so its mucosa takes on a pleated appearance, forming 8 to 14 convoluted longitudinal folds: the columns of Morgagni. Each adjacent column is connected at the dentate line by a flap of mucosa that forms a small anal crypt, normally 1 to 3 mm in longitudinal depth. Connected to the crypts are a number of glands that lubricate the stool for passage. Inflammation, obstruction, and infection of these crypts

and glands become the source of anal sepsis, as characterized by the development of cryptitis, perianal abscesses, and fistulas. The anal wall, from its mucosal lining to the intersphincteric space, which separates the internal from the external sphincters, is a continuation of the usual layers of the wall of the colon and rectum. The innermost lining, the mucosa, continues to the anal verge, undergoing a transition just proximal to the dentate line from rectal columnar to cuboidal to squamous epithelium. The submucosa, which normally contains the bulk of the bowel's blood vessels (and autonomic nerves), thickens considerably proximal to the dentate line. The hemorrhoidal arteries supply the anorectum, while the venous network in this area is referred to as the internal hemorrhoidal plexus. The superior (internal) hemorrhoidal veins drain into the portal system, whereas the inferior (external) hemorrhoidal veins drain into the inferior vena cava. The inner circular muscle layer of the rectum thickens considerably as it terminates distally in the anorectum to form the internal sphincter muscles. The more attenuated longitudinal muscles of the rectum extend caudally, blending with fibers of voluntary skeletal muscles from the levator ani and external sphincter groups, to form the intersphincteric space (Figure 82-1).

Additional sphincteric support is provided by an outer layer of voluntary skeletal muscles which make up the external sphincters, and are divided into three parts: deep, superficial, and subcutaneous. The external sphincters are actually a caudal extension of the puborectalis muscle, which interacts with the levator ani muscle, forming the pelvic floor. The puborectalis, the proximal external sphincters, and the internal sphincters form the ring of muscles that one palpates when performing a digital examination of the anorectum.

Lateral to the external sphincters is the ischioanal space, and superior to the levator ani is the supralelevator (pelvirectal) space, where deep, life-threatening infections can occur.

Inferior mesenteric nodes drain the proximal two-thirds of the rectum, whereas the lower one-third of the rectum and proximal anal canal are drained by both the inferior mesenteric nodes and the internal iliac nodes. The inguinal nodes usually drain lymphatics distal to the dentate line.

Parasympathetic nervous stimulation (S2-S4) supports elimination via rectal wall contraction with concomitant internal anal sphincter relaxation, while sympathetic stimulation (L1-L3) maintains continence through rectal wall inhibition and contraction of the internal anal sphincter.

FIG. 82-1. Coronal section of the anorectum.

EXAMINATION OF THE PATIENT

No matter how much historical information is obtained, no definitive diagnosis can be made without a careful examination of the anus and rectum, including anoscopy and, if necessary, proctoscopy. Patient education before and during the examination will be helpful in obtaining maximal cooperation.

The lateral or Sims position, performed with the appropriately draped patient lying on his or her left side, with the left leg extended and the right knee and hip flexed, is probably the most commonly used approach for performing a routine digital rectal examination and is the preferred position for elderly or pregnant patients. From the Sims position, one should elevate the upper buttock to provide better exposure of the perianal area; if needed, endoscopic examination of the anus and distal rectum can be performed with the patient in this position. In debilitated patients, one may have to perform the examination with the patient in a supine, lithotomy position.

Examining a patient placed in the knee-chest position requires a cooperative patient who is not too ill or in too much distress. This provides for a thorough inspection of the perianal area and is convenient for anoscopy and proctoscopy. Thighs should be at right angles to the table with the feet extended over the end of the table.

A digital examination should always be performed before doing any endoscopic procedure. After performing a digital examination and determining that the patient will tolerate passage of an anoscope, introduce a well-lubricated, lighted anoscope, remove the obturator, and gently rotate as needed to view the anorectum circumferentially. No bowel preparation is needed to perform an anoscopic examination. It is usually difficult to perform a proper sigmoidoscopic examination in an ED setting. Ordinarily, the lower bowel must be prepped; a natural bowel movement, spontaneous or induced 1 to 2 h before examination, is usually sufficient preparation. In some acute situations, such as trying to determine the source of lower GI bleeding or obtaining cultures in a case of suppurative proctitis, emergency proctoscopy may be performed. A rigid sigmoidoscope should be utilized with the patient placed in a Sims position. An inexperienced endoscopist should not attempt to pass the sigmoidoscope beyond the rectosigmoid junction, where the lumen is greatly angulated, because of the risk of perforation.

HEMORRHOIDS

The anorectal area is drained by the internal and external hemorrhoidal venous systems. The internal hemorrhoidal veins, which in essence are submucosal vascular cushions that may contribute to anal continence, are located proximal to the dentate line and drain into the portal system through the superior rectal veins and the inferior mesenteric vein. They also communicate freely with the external hemorrhoidal veins, which are subcutaneous to the anoderm and drain primarily through the pudendal and iliac venous systems. When these hemorrhoidal plexuses become excessively engorged, prolapsed, or thrombosed, they are referred to as hemorrhoids—one of the most common problems afflicting human beings. Internal hemorrhoids course along the terminal branches of the superior rectal artery and are constant in their location, coursing longitudinally at the right postero-lateral, right anterolateral, and left lateral positions (at the 2-, 5-, and 9-o'clock positions when the patient is viewed prone) (Figure 82-2). Internal hemorrhoids are not readily palpable and can best be visualized through an anoscope. Their appearance is consistent with the columnar epithelial surface of the surrounding anal canal. External hemorrhoids, which are located distal to the dentate line, form as a result of dilatation of veins at the anal verge and can be seen at external inspection. Their appearance is consistent with the stratified squamous epithelium of the surrounding anoderm with exquisite sensory innervation.

Although the cause of enlarged hemorrhoids is not always known, there is an association with constipation and straining at stool. Hem-

FIG. 82-2. Common sites of hemorrhoids. A. Internal hemorrhoids at 2, 5, and 9 o'clock. B. Protrusion of anal cushions.

orrhoidal veins are devoid of valves and with age they lose supportive connective tissue surrounding the vasculature which may contribute to the formation of hemorrhoids. They are prevalent during pregnancy and may be the result of sustained increased pressure on the venous drainage of the rectum. One of the physiologic shunts of the portal system involves the hemorrhoidal veins. Consequently, increased portal pressure, occurring as a result of chronic liver disease, may produce marked dilatation and varix formation of the hemorrhoids. The bleeding that can result is extremely difficult to control.

Tumors of the rectum and sigmoid colon, often associated with constipation, tenesmus, and incomplete evacuation, may cause hemorrhoids and must be ruled out in all cases of rectal bleeding in patients over the age of 40. Ascites, ovarian tumors, distended bladders, and excessive fibrosis from radiation therapy may contribute to the formation of external hemorrhoids.

Clinical Features

Hemorrhoids may become more prominent as one strains, whereby a few localized curvilinear swellings may appear. Uncomplicated internal hemorrhoids are painless due to lack of sensory innervation, and

the chief complaint is painless, bright-red rectal bleeding with defecation. Bleeding is usually limited, with the blood being found on the surface of the stool, on the toilet tissue, or dripping into the toilet bowl. Internal hemorrhoids may be palpable on digital examination when thrombosed or prolapsed.¹ Nonreducible, prolapsed internal hemorrhoids may become thrombosed and gangrenous, exhibiting exquisite pain. Painless bleeding may also occur with external hemorrhoidal bleeding; however, pain is usually present when the external hemorrhoids become thrombosed. External thrombosed hemorrhoids usually exhibit a bluish-purple discoloration. Pain, when present, may be noted with palpation, can be quite severe at the time of defecation, and usually subsides with time. Although the most common cause of rectal bleeding is hemorrhoids, other, more serious causes should be sought in all patients who present with bleeding as the chief complaint. Clinical signs cannot reliably differentiate colonic lesions from hemorrhoids.² Chronic, slow blood loss may go unnoticed, but can result in significant anemia. As they increase in size, hemorrhoids may prolapse, requiring periodic reduction by the patient. Internal hemorrhoids may be classified as first degree, which do not prolapse; second degree, which prolapse and spontaneously reduce; third degree, which prolapse and require manual reduction; and fourth degree, which prolapse and are not reducible. When prolapse occurs, the patient may develop a mucous discharge and pruritus ani.

If the prolapse cannot be reduced, strangulation can result. Other complications include severe bleeding, thrombosis, infarction, gangrene, sepsis, and hepatic abscess formation. Both strangulation and thrombosis are extremely painful and are accompanied by significant edema that must be treated before surgical intervention. Ulceration of the overlying mucosa may also occur. External skin tags from old thrombosed external hemorrhoids may occasionally be noted on examination.¹

Treatment

Most treatment is local and nonsurgical unless a complication such as acute thrombosis and gangrene is present. This conservative therapy is suggested for mild to moderate symptomatic patients with first- to third-degree hemorrhoids. Manual reduction of an uncomplicated, prolapsed internal hemorrhoid in a patient with minimal symptoms, along with warm sitz baths (decreasing sphincter pressures) for at least 15 min three times a day and after each bowel movement are the most effective way to relieve pain. Following the bath, the anus must be dried gently but thoroughly to avoid maceration of the perianal skin. Topical analgesics and steroid-containing ointments may provide relief. The patient should not sit on the commode for a prolonged period. Bulk laxatives, such as psyllium seed compounds, or other stool softeners should be used after the acute phase is treated. Laxatives causing liquid stool must be avoided; this can result in cryptitis and anal sepsis. The addition of bran or other forms of roughage to the patient's diet should help to prevent future problems.

As a rule, internal hemorrhoids will bleed and treatment most often involves conservative observation with the addition of stool softeners and a high-fiber diet. Surgical consultation in the emergency department should be obtained for fourth-degree incarcerated internal hemorrhoids.

External hemorrhoidal hematoma formation is usually self-limiting with resolution in 1 week. External hemorrhoids may thrombose and selection of therapy for thrombosed external hemorrhoids depends on the severity of symptoms. If the thrombosis has been present for more than 48 h, the swelling is not tense, and the pain is tolerable, the patient may be treated with sitz baths and bulk laxatives. Suppositories, which are placed proximal to the anorectal ring, are of no help. If, on the other hand, thrombosis is acute, has lasted less than 48 h, and

is extremely painful, significant relief can be provided by excising the clots. With the patient in side-lying or prone position, the area of the overlying skin to be incised is infiltrated with a local anesthetic such

as bupivacaine (Marcaine) 0.5 percent with epinephrine (1:200,000) and bicarbonate using a 30-gauge needle.¹ While applying gentle traction to the skin adjacent to the thrombosed hemorrhoid, an elliptical incision distal to the anal verge is made in the overlying skin, exposing the thrombosis, which is then locally excised through the opening (Figure 82-3). Because of the multiloculated clots that are invariably present, the technique of unroofing a thrombosed hemorrhoid with an elliptical incision and removing the overlying skin gives far better results than the simple incision and evacuation of a clot. Bleeding is controlled by tucking the corner of a small piece of gauze into the wound and leaving it in place for a few hours. A small pressure dressing may be applied external to the gauze and removed when the patient takes the first sitz bath 6 to 12 h after the drainage procedure. Narcotics may be prescribed, but only judiciously, since they cause constipation and may produce more problems. Complications such as continued bleeding, recurrence, infection, fistula, and abscess formation may occur and close follow-up care is therefore suggested. Referral for definitive hemorrhoidectomy is also prudent. Emergent surgical consultation and intervention for hemorrhoids is indicated for: continued and severe bleeding, incarceration and/or strangulation (fourth-degree hemorrhoids), and intractable pain. Incarcerated hemorrhoids are quite painful, may become infected, develop necrosis, and may be associated with urinary retention.¹ In general, for less urgent hemorrhoids surgical treatment, usually as a referral, can consist of sclerosing injections, the use of rubber-band ligation,³ photocoagulation, cryotherapy, electrocautery, or excision. Up to 5 percent of patients undergoing rubber-band ligation may develop acute thrombosis of external hemorrhoids, and immunocompromised patients so treated may develop pelvic sepsis. Excision should not be performed in the ED on immunocompromised patients, pediatric patients, pregnant patients, patients with portal hypertension, and those who are anticoagulated.

CRYPTITIS

Anal crypts are the superficial mucosal pockets that lie between the columns of Morgagni (Figure 82-4). They are formed by the puckering action of the sphincter muscles and normally flatten out during the passage of a stool. Sphincter spasm and superficial trauma caused by repeated bouts of diarrhea, or trauma produced by evacuation of large, hard stools associated with constipation cause breakdown in the mucosal lining of the crypts. This permits infecting organisms to enter pockets and inflammation to extend into the lymphoid tissue of both the crypts and anal glands. Cryptitis could well be the common denominator for the development of fissure in ano, fistula in ano, and perirectal abscesses.

FIG. 82-3. Elliptical excision of thrombosed external hemorrhoid.

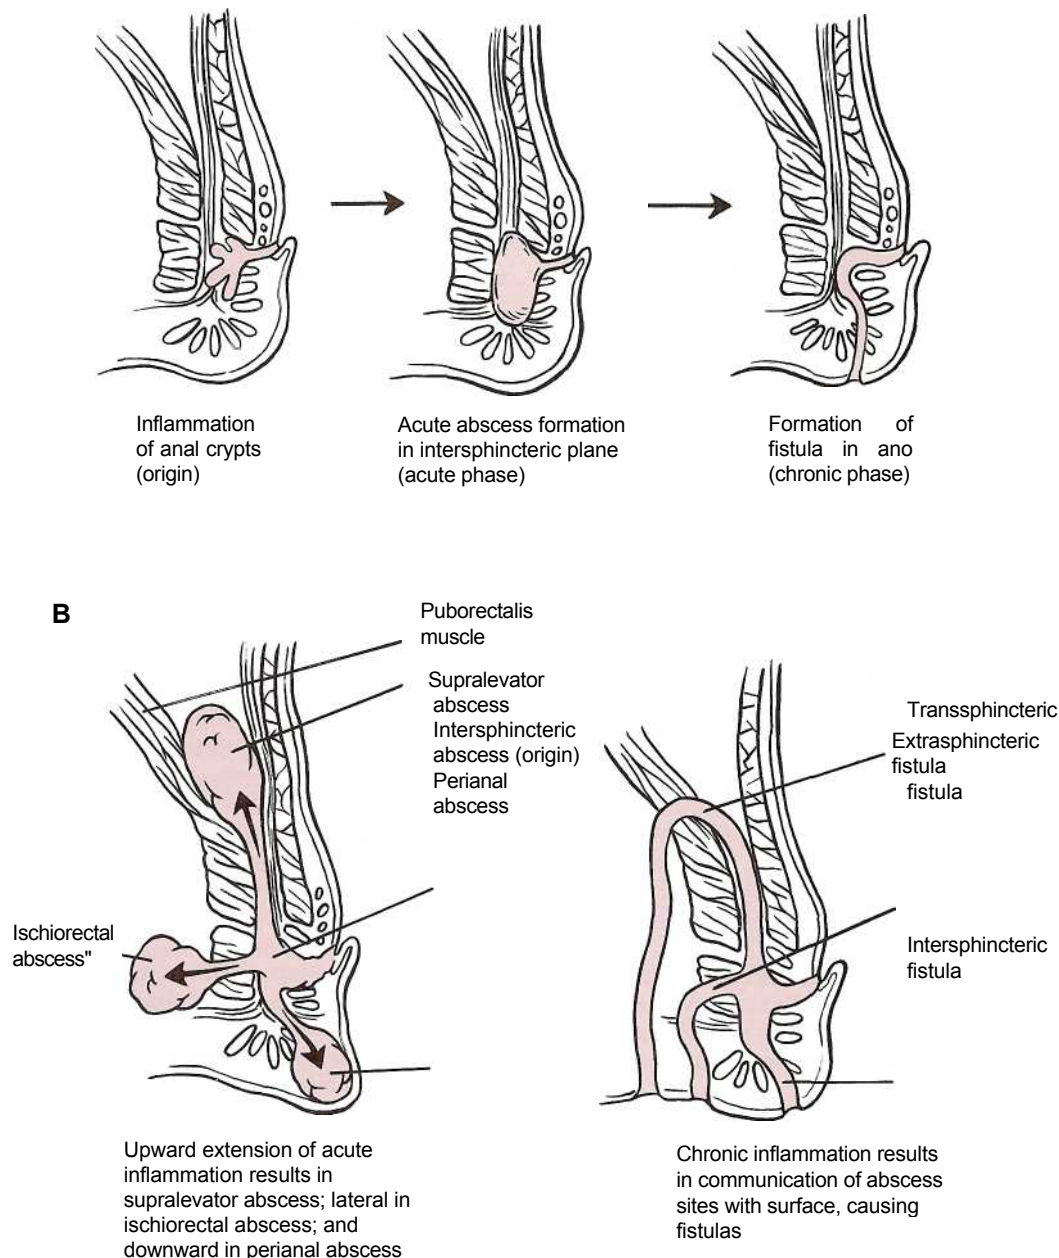

FIG. 82-4. Illustration of mechanism for anorectal abscess and fistula formation.

Associated with cryptitis is the development of hypertrophied anal papillae, which lie between adjacent crypts. When hypertrophy occurs, the papillae may be palpated as small, hard nodules along the wall of the anal canal. Rarely, papillae may hypertrophy and present as a prolapsing polypoid tumor. The crypts most commonly involved are in the posterior half of the anal ring, and in most cases, in the posterior midline, the same location where anal fissures occur.

Clinical Features

Initially, the locally inflamed crypts produce no symptoms, but as the trauma from recurrent diarrhea or passage of large, hard stools continues, the inflammation of the crypts extends to the adjacent papillae, producing an edematous swelling of the sensitive anoderm that lines this part of the canal. At this stage the patient **will** experience pain with bowel movements, and if there is an associated papillitis or fissure in ano, there will also be a small amount of bleeding. Anal pain, spasm, and itching with or without bleeding are the cardinal signs and symptoms of cryptitis.

Treatment

Treatment of anal cryptitis, which should be conservative, is based on establishing a definitive diagnosis and ruling out the possibility of more serious anorectal problems. The diagnosis can be suspected clinically from the history and the palpation of the tender, swollen crypt and its associated hypertrophied papillae. Definitive diagnosis of cryptitis is made by anoscopic examination.

The goal of treatment is to control the trauma of abnormal bowel movements and thus enable the inflammation to subside. Bulk laxatives and additional roughage added to the diet to produce formed, soft stools and hot sitz baths both enhance healing by keeping the anus clean and the crypts empty.

Surgical referral is indicated when the infection has progressed and there is a deep, redundant crypt that will not drain adequately on its own. Gentle insertion of a hooked probe into the crypts brought into view through the anoscope will reveal the involved crypt(s) to be deeper than normal and definitely more tender. In these cases, the roof

(mucosal surface), as outlined by the passage of a hooked probe, should be infiltrated with local anesthetic and excised. Thus what had been a deep pocket is converted into an open wound that should heal with proper control of bowel movements and frequent sitz baths.

FISSURE IN ANO (ANAL FISSURE)

This disorder is the result of a superficial linear tear of the anal canal beginning at or just below the dentate line and extending distally along the anal canal, to the anal verge (see Figure 82-4). The epithelium in this area consists of anoderm, which has a rich supply of somatic sensory nerve fibers. Consequently, anal fissures are the most common cause of painful rectal bleeding. Anal fissures are common among children and young adults and are the most frequent cause of rectal bleeding in infants.⁴

Anal fissures, as they become more chronic, are often associated with swelling of the surrounding tissues and raised edges, producing hypertrophic papillae proximally and the characteristic sentinel pile distally. The latter is frequently misdiagnosed as an external hemorrhoid when in actuality it is the result of edema and fibrosis secondary to the ulcerating fissure. In more than 90 percent of cases, anal fissures occur in the midline posteriorly. In 10 percent to 40 percent of women but in only 1 percent of men it may be in the midline anteriorly. This almost constant location of anal fissures may be because of the posterior angulation of the rectum on the anus where the posterior midline of the anorectal canal becomes the "lesser curvature" for the passage of stool. Women may develop anterior fissures postpartum. A fissure not located in the midline should arouse suspicion that another, potentially life-threatening cause may be involved. Such diagnostic possibilities include Crohn disease, chronic ulcerative colitis, squamous cell carcinoma of the anus, adenocarcinoma of the rectum invading the anal canal, localized anal cancers such as Bowen disease and extramammary Paget disease, leukemia, lymphoma, syphilitic fissures, chlamydia, gonorrhea, and a tuberculous ulcer. Such patients must be referred for a diagnostic biopsy of the ulcer edge, culture of the anal canal, and a systemic evaluation. Interestingly, fissures due to Crohn disease and tuberculosis are often painless whereas fissures associated with AIDS are painful and may be associated with incontinence. Painless fissures associated with Crohn disease are often associated with external skin tags.⁴

Most often, the traditional midline anal fissure is caused by the trauma produced by the passage of a particularly hard and large fecal mass, but it is also seen after frequent acute episodes of diarrhea. Children with constipation will commonly complain of painful defecation only to find an anal fissure upon closer inspection. Fissures persist because of the severe, chronic internal sphincter spasm that occurs along with the secondary infection of its base.

Clinical Features

Pain of the sharp, cutting variety is the most common symptom. Typically, the pain is most severe during and immediately after a bowel movement. The pain may persist as a dull ache for a few hours after each bowel movement, but invariably it subsides between movements, which is a feature that distinguishes fissures from other forms of painful anorectal disease. The bleeding is bright red and small in quantity, usually being noticed only on the toilet paper. In infants, the presence of small amounts of bright blood on the stool or toilet paper is usually the presenting complaint for an anal fissure. Sphincter spasm and pain may be severe enough to make the patient retain stool and avoid defecation.

The diagnosis of anal fissure is usually suggested by the history; however, the anal area must be examined in all cases. With proper exposure, the sentinel pile, if present, and frequently the distal end of the fissure itself, may be seen. The mere retraction of the buttocks and the anal skin may cause considerable discomfort; sphincter spasm may be

so severe that the patient will not permit digital examination. Application of a topical anesthetic may provide some relief. If the fissure can be visualized and is present in the posterior midline, rectal examination can be deferred until the patient is having less spasm and pain.

Treatment

Treatment is aimed at providing symptomatic relief, relieving the anal sphincter spasm, and preventing stricture formation. Hot sitz baths for at least 15 min three to four times a day and after each bowel movement will relax the sphincter and provide symptomatic relief. The addition of bran to the diet will serve to prevent stricture formation by providing a bulky stool. Local analgesic ointments provide symptomatic relief. The use of hydrocortisone-containing ointments does provide relief and helps with healing. In a study that compared the effectiveness of these three modalities, most rapid healing of fissures occurred with sitz baths and a diet rich in bran, though healing was aided by both, an analgesic ointment or a hydrocortisone-containing ointment. Meticulous anal hygiene is imperative; following defecation, the anus must be cleaned thoroughly. Healing is by the development of granulation tissue and the reepithelialization of the ulcerated area. Relapse rate after medical treatment for chronic anal fissures has been noted as high as 50 percent. If healing does not occur in a reasonable amount of time or relapses are frequent, anal dilatation or operative treatment consisting of partial sphincterotomy and excision of the fissure may be required.

ANORECTAL ABSCESSSES

Abscesses are frequently encountered in the perianal and perirectal region. Almost all begin with involvement of an anal crypt and its gland. The mechanism involves obstruction of an anal gland that opens in the base of an anal crypt which normally drains into the anal canal. When obstruction occurs, the gland orifice is blocked, resulting in infection and abscess formation. The abscesses are typically polymicrobial with both aerobic and anaerobic bacteria. As they persist fistula formation may develop as a common chronic sequela. From there, the infection can progress to involve any of the potential spaces that are normally filled with fatty areolar tissue and have little inherent resistance to the progression of infection. These spaces, which can become infected alone or in combination with each other, are as follows: the perianal space, the intersphincteric space, the ischiorectal space, the deep postanal space (connecting the ischiorectal space on each side posteriorly), and the supralelevator or pelvirectal space (Figures 82-4 and 82-5). An element of cryptitis can frequently be identified by anoscopic examination.

The perianal abscess is most common and the supralelevator abscess occurs least often. It presents close to the anal verge, posterior midline, as a superficial tender mass, which may or may not be fluctuant. In contradistinction, ischiorectal abscesses, which are second most common, tend to be larger, indurated, well circumscribed, and are present more laterally, on the medial aspect of the buttocks. Usually the patient will exhibit swelling, fever, and anorexia. Deeper perirectal abscesses may not manifest cutaneous signs, but rectal pain and tenderness are invariably present. The isolated perianal abscess not associated with deeper, perirectal abscesses is the only type of anorectal abscess that can be adequately treated in an ED setting. Although clinical evaluation of abscesses is usually sufficient, if pain is out of proportion to physical findings or if the extent of the abscess is uncertain, ultrasonography can be helpful.⁵

Ischiorectal and other deep abscesses pose a different problem. The ischiorectal fossa forms a large potential space on either side of the rectum, communicating behind it through the deep postanal space, and in males has extensions anteriorly above the perineal membrane to the prostate. Intersphincteric, submucous, and supralelevator abscesses may not present with swelling, though they usually exhibit constitutional

symptoms. Infections in this area are insidious and extensive and can spread to an area some distance from the anal verge. These abscesses can be large, and yet only a diffuse, nonfluctuant, tender "mass" may be palpable either through the rectal wall or the overlying skin. If only induration is present, endorectal ultrasonography,⁵ needle localization, exam under anesthesia, CT scanning, or magnetic resonance imaging (MRI) may be needed to confirm the diagnosis. Ultrasound may be more useful to diagnose intersphincteric and submucosal abscesses, whereas CT or MRI are capable of detecting those as well as deeper abscess formations such as supralelevator and ischiorectal rectal abscesses. A variety of diseases and other conditions are associated with the development of fistulous abscesses, including Crohn's disease; carcinoma of adjacent organs; radiation fibrosis; trauma; Hodgkin's disease; tuberculosis; gonococcal proctitis; lymphogranuloma venereum; immunocompromised states; and infections by *Chlamydia*, *Actinomyces*, Herpes, *Staphylococcus aureus*, *Streptococcus* spp., *E. coli*, *Proteus*, and *Bacteroides*.

Clinical Features

Anorectal abscesses are more common in young middle-aged males. Initially, the patient notices a dull, aching, or throbbing pain that becomes worse immediately before defecation, is lessened after defecation, but persists between bowel movements. The pain, significantly increased by the increased pressure in the rectum, occurs just before defecation. Acute prostatitis is in the differential diagnosis. Perianal abscesses, easily palpable, are usually not accompanied by fever, leukocytosis, and sepsis in the immunocompetent patient.

As the abscess spreads, increases in size, and comes nearer to the surface, the associated pain becomes more intense. Pain will be aggravated by straining, coughing, or sneezing. As the abscess progresses, pain and tenderness interfere with walking or sitting. Ischiorectal abscesses are painful and may express fewer outward signs upon examination; however, as they become larger, they may become indurated and erythematous more lateral to the anal verge compared to the perianal abscess. The patient appears markedly uncomfortable and may be febrile. A tender mass may be present upon rectal examination or there may be a tender, erythematous area with or without fluctuance. Leukocytosis may be present. Intersphincteric abscesses exhibit pain with defecation, may be associated with rectal discharge and fever, and a tender mass may be palpable on digital examination. Supralelevator abscesses in contrast often present with few outward

signs as the patient complains of buttock or perirectal pain. Fever, leukocytosis, and at times urinary retention are not uncommon.¹

Treatment

Treatment is surgical and should be performed as soon as the diagnosis is made, before the abscesses become fluctuant. Drainage should be both early and extensive. All perirectal abscesses (supralelevator, intersphincteric, and complicated ischiorectal) should be drained in the operating room. Despite apparently adequate incision and drainage under local anesthesia, there is a relatively high incidence of recurrent abscess formation requiring a second procedure.

Isolated, simple, fluctuant perianal abscesses that are not associated with the presence of any deeper abscesses may be drained using local anesthetics and often, procedural sedation, in an ED setting. The local anesthetic should be administered with the finest-gauge needle available (30-gauge) and should be accompanied by the administration of systemic analgesia or conscious sedation. Needle aspiration over the painful region may be done to localize the pus if needed. If a simple, linear drainage incision is made, the abscess is more likely to recur because of premature closure of skin edges. Whenever this technique is used the abscess cavity must be packed initially with strips of gauze for at least 24 h. These patients will require closer follow-up care and definitive surgical repair should be considered. To ensure adequate drainage, a cruciate incision can be made over the fluctuant part of the abscess (Figures 82-6A and B). No packing is required, but if it is used it should be removed in 24 h. The wound should be covered with a bulk dressing; sitz baths should be started the next day.

As a rule, antibiotics are not necessary after an abscess has been adequately drained. On the other hand, patients with fever, leukocytosis, valvular heart disease, or those with cellulitis should be given broad-spectrum antibiotics. Patients whose immune system may be compromised by diabetes mellitus, inflammatory bowel disease, AIDS, malignancies, and chemotherapy should be given broad-spectrum antibiotics. Surgical consultation and strong consideration for admission would be prudent. Current tetanus immunization should be noted. Delay in appropriate treatment may lead to sphincter dysfunction.

FISTULA IN ANO

An anal fistula is an abnormal tract that connects the anal canal with the skin and is lined with epithelium and granulation tissue. A fistula

FIG. 82-6. Technique of drainage of perianal abscess.

in ano most commonly results from a perianal or ischiorectal abscess (see Figure 82-4). These abscesses usually originate in the glands, which are located in the intersphincteric space and have drainage ducts that empty at the level of the dentate line. These fistulae may be associated with ulcerative colitis, Crohn disease, colonic malignancies, sexually transmitted disease, actinomycosis, anal fissures, foreign bodies, or tuberculosis. Although anterior-opening fistulas tend to follow a simple, direct course to the anal canal (Goodsall's rule), posterior-opening fistulas may follow a devious, curving path, including some that are horseshoe-shaped, opening in the posterior midline (Figure 82-7). Crohn disease should be considered in patients with anorectal disorders when rectal strictures, painless fissures, skin tags, cavitating ulcers, and complex fistulae are present.

Clinical Features

As long as the tract remains open, there is a persistent, blood-stained, malodorous discharge. More commonly, the tract becomes blocked periodically, producing bouts of inflammation and even local, recurrent abscess formation that is relieved by spontaneous rupture. An abscess may be the only sign of fistula in ano. This underscores the importance of an accurate diagnosis for successful treatment. Ultrasound has been used to identify intersphincteric fistula development, though inadequate focal length precludes sufficient examination of deeper fistulae. Ultrasound utilizing a 7-MHz endoprobe and enhanced with a 3 percent hydrogen peroxide solution has been used to identify fistula in ano, and appears to be superior, increasing accuracy from 62 to 95 percent compared to traditional perianal ultrasound.⁶ (Figures 82-8A and

B). High-resolution MRI and possibly endoluminal MRI are often the tests of choice for detecting simple fistulae as well as more complex interconnecting and deeper fistulae.

Treatment

The only definitive treatment is surgical excision. Improperly excised fistulas may result in permanent fecal incontinence.

VENEREAL PROCTITIS

Sexually transmitted diseases (STDs) of the anorectum are not uncommon among patients who practice anal sex. The infecting organisms that cause AIDS, gonorrhea, and syphilis are essentially the same ones that are transmitted via vaginal coitus; infection is transmitted and perpetuated almost entirely by men who fail to use condoms (Table 82-1). Exceptions to this are seen in women whose lymphogranuloma venereum (LGV) due to chlamydial infection extends directly to the rectum from the vagina, and on occasions when there is contamination of the anus by gonococcal-laden discharge emanating from the urethra or cervix.

As a rule, if the patient has an anorectal infection caused by one of the STD organisms, the assumption must be made that another STD may be present; appropriate blood tests must be obtained, and patients should be anoscoped or proctoscoped in order to obtain specimens for Gram stain as well as for viral and bacterial cultures.

Clinical Features

Most venereal diseases involving the anorectal area manifest themselves initially with itching, seepage, and mild pain or irritation. Some infections may persist with mild to minimal symptoms, rendering the patient a carrier of the disease. Most venereal infections, however, will produce significant symptoms of pain, bleeding, and discharge in addition to bothersome pruritus.

CONDYLOMATA ACUMINATA Condylomata acuminata, commonly known as anal warts, are caused by a papillomavirus and are probably sexually transmitted in more than 90 percent of cases. They begin as discrete, soft, fleshy growths on the skin of the perianal area as well as on the squamous epithelium of the anal canal. Occasionally, the mucosa of the lower rectum becomes involved. Patients usually first notice the presence of a growth in the perianal area as well as

FIG. 82-7. Goodsall's rule.

B

associated pruritus and varying degrees of anal pain. With time, bleeding and anal discharge become part of the symptom complex. Evaluation of a patient with condyloma acuminata should include screening for HIV, *Chlamydia*, syphilis, gonorrhea, herpes, hepatitis, cytomegalovirus, and *Giardia*. Topical podophyllum and chemotherapy have been used in the past but the recurrence rate is significant. These patients should be referred to an appropriate specialist for definitive treatment involving laser ablation, cryotherapy, electrocautery, immunotherapy, and surgical excision. Overall recurrence remains at about 40 percent. Because cases of squamous cell carcinoma arising in association with condyloma acuminata have been reported, multiple biopsies must be taken.

Treponema pallidum

Viruses

Herpes simplex type 2
 Human immunodeficiency virus
 Papillomaviruses

GONORRHEA Symptoms of gonococcal proctitis vary, ranging from none to the more common symptoms of severe rectal pain with profuse yellow, bloody discharge. The symptoms usually start about 1 week after exposure. Patients in the acute phase generally have mild burning and/or pruritus with some purulent seepage. Anoscopic examination during this phase of the disease reveals marked hyperemia and edema of the rectal mucosa and diffuse inflammation with purulent discharge from the anal crypts. Unlike nonvenereal cryptitis, infection is not confined to the posterior crypt. Diagnosis is made by Gram stain and cultures. Dissemination involving the heart, liver, CNS, and joints should be considered.

CHLAMYDIAL INFECTIONS *Chlamydia trachomatis* is an obligate human intracellular parasite that causes, among other conditions, both urogenital and anorectal infections. The lymphogranulomatous (LGV) variety occurs mainly in tropical and subtropical climates. Infection can involve the rectum by perirectal lymphatic invasion from vaginal seeding or from direct anorectal mucosal infections. The non-LGV chlamydial organisms may infect the rectal mucosa, although they do not cause the extensive rectal scarring and stricturing that its lymph gland-invading cousin from the tropics does. A patient with chlamydial proctitis may be asymptomatic or may present with nonspecific symptoms, including anal pruritus, pain, and purulent discharge. Tenesmus and bleeding may also be present.

The more severe form of proctitis occurring with this infection is usually due to the LGV type of chlamydia. Acutely painful anal ulcerations associated with prominent unilateral lymph node enlargement can be noted. Fever and constitutional flulike symptoms may be seen. In addition to rectal scarring which is a late sequela, infection of the perirectal tissue results in perirectal abscesses and chronic fistulas.

Red, friable mucosa may be seen on anoscopy. *Chlamydia* may be identified by culture. The LGV forms may be distinguished from the non-LGV variety by the Frei intradermal test or the LGV complement fixation test. Immunofluorescent antibody testing is the diagnostic test of choice. Treatments for the non-LGV chlamydial proctitis include the standard treatments for *Chlamydia*. Treatment for LGV chlamydial infections should be maintained for at least 21 days.

SYPHILIS The causative agent is the spirochete *Treponema pallidum*. Chancres that form a few weeks after infection are the characteristic lesion of primary syphilis and usually manifest themselves at the anal verge or in the anal canal. Rarely will a chancre involve the rectal mucosa, although proctitis due to syphilis can occur in the absence of a chancre. Syphilitic chancres are typically painless, although anal chancres are often very painful. If they are not identified and treated, they will resolve and the patient will proceed to develop secondary and tertiary syphilis. Condylomata lata, which are flatter and firmer than condylomata acuminata, appear in the perianal region as a manifestation of the secondary stage of syphilis. The fluorescent treponemal antibody (FTA) test becomes positive in about 1 month, and the rapid plasma regain (RPR) and the Venereal Disease Research Laboratory (VDRL) tests are also commonly used to diagnose syphilis. AIDS patients may remain nonreactive and CNS infections are not uncommon.

HERPES Anorectal herpes is almost always caused by the type 2 herpes simplex virus (HSV-2). Symptoms occur within a few weeks after

exposure and consist of itching and soreness in the perianal area, progressing to severe anorectal pain. Initially, the virus manifests itself as small, discrete groups of vesicles superimposed on an erythematous base. These vesicles enlarge, coalesce, and rupture, forming exquisitely tender aphthous ulcers that appear on the perianal skin, the anoderm, and even the rectal mucosa. The pain and tenesmus from these lesions may be so intense that the patient is reluctant to have a bowel movement, resulting in constipation and possibly fecal impaction. The patient may develop a flulike illness with inguinal adenopathy noted on examination during the initial course of the illness. Symptoms persist for 1 to 2 weeks and are frequently recurrent, though less pronounced, during the ensuing year. Topical analgesia may be needed for adequate examination. Viral cultures and immunofluorescent testing are helpful for diagnosis. Treatment consisting of adequate pain medication, stool softeners, and acyclovir is in order.

AIDS-RELATED INFECTIONS Ironically, infection of the rectum by the human immunodeficiency virus (HIV) per se does not cause any local reaction or symptoms, but its effect on the patient inoculated with this virus can be devastating. Patients who have been rendered immunodeficient by HIV are subject to a variety of opportunistic infections that affect the intestinal, anorectal, and other body systems. Infections with herpes simplex type 1 as well as type 2 are commonly seen in AIDS patients. Protozoal infections involving *Entamoeba histolytica* and *Giardia lamblia* may affect the homosexual population following oral-anal sex. Crampy, abdominal pain with diarrhea, occasionally bloody and malodorous, is frequently present with both. Testing stool for ova and parasites confirms the diagnosis. Table 82-2 lists other common enteric organisms that infect AIDS patients. Severe rectal pain, diarrhea, and hematochezia are common presenting symptoms.

Treatment

Success in the management of patients with acute venereal proctitis depends on suspecting the diagnosis, obtaining specimens to confirm the diagnosis, and initiating therapy as expeditiously as possible. Patients presenting with symptoms of anorectal pain, rectal discharge, and/or tenesmus should be considered to have proctitis until proven otherwise. Anoscopy or proctoscopy and a Gram stain should be performed to document the presence of acute proctitis. In addition to the appropriate culture specimens, blood should be drawn to check for syphilis.

Antibiotic therapy should not be delayed pending the results of cultures. Empirical therapy aimed at eradicating gonorrhea, non-LGV chlamydia, and incubating syphilis should be initiated for any patient presenting with symptoms and physical signs suggestive of acute proctitis. This therapy should be administered to all patients with acute proctitis even if there are concomitant lesions suggestive of herpetic or papillomavirus infections. As is the case for STDs in general, these patients must be referred for appropriate follow-up to ensure completion of therapy and eradication of disease.

RECTAL PROLAPSE

Rectal prolapse, known as procidentia, is the circumferential protrusion of part or all layers of the rectum through the anal canal. There

are three classes of rectal prolapse: (1) prolapse involving the rectal mucosa only, (2) prolapse involving all layers of the rectum, and (3) intussusception of the upper rectum into and through the lower rectum so that the apex of the intussusception protrudes through the anus. In the first group, seen primarily in children under the age of 2, the prolapse occurs because of the loose attachment of the mucosa to the submucosal layers, and there is an associated weakness of the anal sphincter. In the second and third groups, prolapse occurs because of the laxity of the pelvic fascia and muscles in addition to a generalized weakening of the anal sphincters. In all cases, the rectum does not conform with, but lies anterior to the sacral concavity, thus obliterating the angulation that normally occurs between rectum and anus. The prolapsing mucosa of a partial prolapse rarely protrudes more than 4 cm beyond the anal verge; the mucosal folds emanate in a radial fashion from the central lumen of the prolapsed mucosa. Mucosal prolapse is frequently associated with third- and fourth-degree hemorrhoids. Complete rectal prolapse (procidentia) occurs at the extremes of life, most commonly in elderly women.

Clinical Features

Most patients are able to detect the presence of a mass, especially following defecation or strenuous activity. In more advanced cases, this may be present when they stand or walk. Irritation to the rectal mucosa caused by recurrent prolapse results in a mucous discharge with some associated bleeding. Some patients may present because of blood-stained mucus on their undergarments; others because of fecal incontinence caused by associated anal sphincter weakness. Patients may complain of a dull, aching pain with the inability to completely evacuate during defecation. In pediatric patients, parents often mistakenly believe that the prolapsed mucosa is hemorrhoids.

Treatment

In young children, after appropriate analgesia and sedation, prolapse can be reduced manually by replacing the protruding mucosa proximal to the anorectal ring of sphincter muscles. Every effort should be made to prevent the child from becoming constipated, and the child should be referred for further evaluation.

Surgical intervention is generally indicated in all other age groups unless the prolapse is minimal. A variety of effective surgical procedures are available and may be used depending on the degree of prolapse and the general health of the patient. All patients should be referred to have a least a proctosigmoidoscopic examination or a colonoscopy to rule out tumor, polyps, or diagnose inflammatory bowel disease. In addition, one should check for the possibility of an anterior rectal wall ulcer that may occur in patients with recurrent prolapse.

If vascular compromise appears to have occurred, reduction may be necessary on an emergency basis. Because of the risk of having reduced ischemic bowel that could perforate, these patients must be hospitalized.

ANORECTAL TUMORS

Carcinoma of the anal area represents less than 5 percent of all large bowel malignancies. At the level of the dentate line and extending approximately 1 cm proximal is a transitional zone of epithelium connecting the squamous cell epithelium of the anoderm with the columnar epithelium of the rectum. This transition zone includes columnar, cuboidal, transitional, and squamous epithelial cells that represent the source for a variety of malignancies that arise in the anal canal. For the purpose of grading malignancies, the United Nations World Health Organization has divided the anal canal into two regions: (1) malignancies of the portion proximal to the dentate line and including the transitional zone are referred to as anal canal neoplasms, and (2) tumors arising in the anoderm distal to the dentate line are referred to as anal margin neoplasms.

TABLE 82-2 Anorectal AIDS-Related Infections

Herpes simplex type 1
<i>Mycobacterium avium-intracellulare</i>
Cytomegalovirus
<i>Salmonella enterocolitis</i>
<i>Shigella</i>
<i>Campylobacter</i>
<i>Entamoeba</i>
<i>Giardia</i>

Anal margin neoplasms, including Bowen disease, squamous cell carcinoma, basal cell carcinoma, and Paget disease, have a low-grade malignant potential and are slow to metastasize. Anal canal neoplasms, including adenocarcinoma of glands and ducts, transitional carcinoma, melanoma, Kaposi sarcoma, and villous adenoma on the other hand are far more virulent, metastasize early, and have a poor prognosis. Squamous cell carcinoma of the anal canal has a much poorer prognosis than its anal margin counterpart. Anal canal malignancies metastasize not only to mesenteric lymph nodes and the portal circulation, but also to the regional inguinal nodes and via the systemic circulation.

Included among the anal canal neoplasms is Kaposi sarcoma, the most common AIDS-related malignancy. The anal canal is the third most common site for malignant melanoma (after the skin and the eye) which when it occurs there, may not be pigmented and is frequently overlooked.

Clinical Features

Early anal canal malignancies usually cause nonspecific symptoms such as pruritus, pain, and bleeding admixed with stool. The sensation and presence of a lump in the anal canal may be erroneously diagnosed as a hemorrhoid. As the neoplasm progresses, the patient experiences anorexia, weight loss, diarrhea, constipation, narrowing of the caliber of the stool, and eventually tenesmus with or without bowel movement. They may be ulcerative and involve part of the canal; however, complete obstruction may also occur.

Anal canal tumors may produce partial rectal prolapse; hemorrhoidal dilatation and prolapse may also occur. More advanced malignancies may present as perirectal abscesses or fistulas.

Villous adenomas, which arise from the rectal columnar epithelium, frequently produce diarrhea and a profuse rectal discharge, with secondary excoriation of skin and pruritus. Patients may suffer a significant loss of electrolytes, resulting in a clinically significant hypokalemia and/or hyponatremia.

Treatment

The anal margin neoplasms tend to be circumferential and may present as persistent ulcers or as chronic dermatologic conditions such as eczema or mycotic infections. Any ulcer that fails to heal within 30 days or any discrete skin lesion that fails to improve with appropriate therapy must be biopsied to rule out the presence of malignancy.

Virtually all anorectal tumors can be detected by careful visual examination of the perianal area, digital palpation of the distal rectum and anal canal, and procto- or sigmoidoscopic examination. The emergency physician should suspect these lesions when the clinical history is suspicious, and complete a thorough physical examination, including digital and anoscopic examination. Appropriate surgical consultation and referral is imperative. Failure to look, feel, and think would be the only reason not to suspect the presence of these curable but life-threatening lesions.

RECTAL FOREIGN BODIES

The medical literature is replete with the variety of foreign bodies that have been reported to have been inserted into the rectum. Most foreign bodies are in the rectal ampulla and are therefore palpable through digital examination and detectable on proctoscopic examination. More proximal foreign bodies are usually not palpable. Any patient presenting with an intrarectal foreign body must have x-rays of the abdomen taken to demonstrate not only the position, shapes, and number of foreign bodies, but also the possible presence of free air. Perforation of the rectum or colon is the most frequent and most serious complication. Perforation of the rectum below the peritoneal reflection often causes retroperitoneal injuries and may yield extraperitoneal air along

the psoas muscles on a flat plate radiograph. Perforation above the peritoneal reflection usually reveals intraperitoneal free air under the diaphragm noted on an upright CXR. Fever, leukocytosis, abdominal pain, peritoneal signs, and rectal bleeding are clinical manifestations suggestive of perforation. Both can result in life-threatening sepsis, although perforation below the peritoneal reflection may be managed with more conservative therapy.

Treatment

Although some foreign bodies can be removed in the ED, many require surgical intervention, particularly if they are made of glass or have sharp edges. If the foreign body is removed in the emergency department and is of a size or shape that could cause perforation, a follow-up proctoscopic examination and x-ray studies must be performed. In questionable cases, observations for at least 12 h should be done to ensure that perforation has not occurred. Rectal and anal lacerations may be present and require repair.

Sphincter relaxation is mandatory for removal of large foreign bodies. If the patient's sphincters are taut or otherwise not sufficiently relaxed, local infiltrative anesthesia must be administered to achieve proper relaxation. Intravenous sedation should be considered. After the patient has been sedated and placed in the lithotomy position, local anesthetic is injected through a fine, 30-gauge needle to raise an intradermal wheal at the 6 and 12 o'clock positions. The index finger of the physician's nondominant hand is then inserted into the anal canal to act as a guide for a ly-in. larger-gauge needle through which anesthetic is injected circumferentially along the internal sphincter muscles as they course along the anal canal. Five milliliters of anesthetic should suffice for each quadrant of infiltration. Large bulbar objects create a vacuum-like effect in the rectal ampulla, making it difficult to retrieve the object by simple traction. The vacuum can be overcome by passing a catheter beyond the object and injecting air. A modification of this technique is to insert Foley catheters around the foreign body and, after the vacuum is relieved by injecting air, to inflate the balloon of the Foley catheter and use the catheters as traction devices to deliver the foreign body or manipulate it into a more accessible position.

If there is a risk of perforation or if excess manipulation (potential for bacteremia) will be needed to remove the foreign body, the patient should be prepared for emergency surgery, which includes obtaining appropriate laboratory studies, initiating intravenous therapy with crystalloid solution, and administering a loading dose of a broad-spectrum antibiotic (such as a third-generation cephalosporin) with adequate coverage for anaerobic as well as aerobic bacteria.

PRURITUS ANI

Pruritus ani is a symptom complex that occurs secondary to a variety of anal and systemic problems. It is not in itself a specific disease process. It affects men far more often than women, and it occurs most commonly during the fifth and sixth decades of life.

There is an entity of primary or idiopathic pruritus ani, the etiology of which is unknown. To make such a diagnosis, one has to rule out the many specific, known causes of secondary pruritus ani such as local infections, local irritants, systemic illnesses, and psychogenic causes. Even so, idiopathic pruritus ani may occur in association with or be precipitated by secondary pruritus ani. Table 82-3 lists the major categories of the various likely causes of secondary pruritus ani.

The etiology of pruritus ani includes many of the various categories that have been discussed in this chapter. The pruritus that accompanies such conditions as fissures, fistulas, hemorrhoids, and prolapses occurs as a result of the perianal skin being exposed to and macerated by constant mucous and purulent discharge. It is probably the increased perianal moisture caused by these conditions that results in itching. The itching triggers a vicious cycle of scratching, excoriation, and more itching.

TABLE 82-3 Pruritus Ani

Anorectal disease
Dietary factors
Local infection
Local irritants
Dermatologic conditions
Systemic illness
Psychogenic factors

Numerous dietary factors have been implicated and are associated with secondary pruritus ani, although proof of cause is lacking for most of them. Those dietary factors most commonly listed include excessive consumption of caffeine-containing liquids (such as coffee, tea, or colas) and beer, although there have been conflicting reports demonstrating a correlation between pruritus ani and alcohol consumption. Milk, chocolate, tomatoes, and citrus fruits are other food products that allegedly contribute to pruritus ani. Likewise, certain drugs, such as colchicine and mineral oil, have been associated with pruritus ani. Ingestion of these products can result in increased liquidity and seepage of fecal material, which in itself is a probable cause of pruritus ani.

Infectious agents that have to be considered as causes of pruritus ani include bacteria, viruses, fungi, spirochetes, and parasites. More common bacterial infections, such as staphylococci and streptococci, in addition to all sexually transmitted organisms, will cause pruritus, if not actual pain. Pinworms (*Enterobius vermicularis*) are the most common cause of anal pruritus in children (see Chap. 49). *Candida albicans* is commonly found on the perianal skin but is not usually associated with pruritus; the *Trichophyton* species, on the other hand, are always associated with pruritus.

Local irritants, if not the initial cause, commonly contribute to the incidence of pruritus. Fecal contamination resulting from poor anal hygiene is by far the most common irritant to the perianal skin. Lysozyme from intestinal mucous secretions, acting together with bacterial exotoxins to raise the stool and skin pH, will cause pruritus. Ironically, patients who compulsively clean their anus, particularly if they use perfumed toilet tissue, soaps, detergents, or hygiene sprays can cause pruritic reactions. Also, wearing of synthetic, tight-fitting underwear retains moisture that normally exudes from the perianal area, another leading cause of pruritus.

Dermatologic conditions contributing to this symptom complex include atopic dermatitis, lichen planus, psoriasis, and seborrheic der-

matitis. Any of the anal margin neoplasms, particularly Bowen's disease and extramammary Paget's disease, may initially manifest itself as pruritus.

Finally, systemic conditions, such as diabetes mellitus, lymphoma, and certain vitamin deficiencies (vitamins A and D and niacin), because of their secondary effect on the perianal skin, will cause pruritus.

Clinical Features

Appearance of the perianal skin will depend on the severity and chronicity of the underlying conditions that are causing the pruritus. The skin will appear normal with early, mild cases. With acute, more severe exacerbations, the perianal skin will appear reddened, edematous, and moist; frequently, there are excoriations caused by scratching. In chronic cases, the perianal skin takes on a thickened, almost leathery, depigmented appearance. The normal radiating folds of skin thicken into rugae and may include factitiously induced superficial fissures.

Treatment

Pruritus, like any other symptom, suggests the presence of an underlying cause that should be diagnosed and treated appropriately. Thus excision of malignancies or surgical correction of fistulas, prolapses, or hemorrhoids would be the definitive treatment for patients with those conditions.

In most cases, specific anorectal lesions are not apparent, and the patient must be referred to a proctologist or dermatologist for probable long-term management.

In the meantime, the patient should be advised to make certain dietary changes, if appropriate, and should be instructed about proper anal hygiene. Scratching of the area must be avoided; if necessary, the patient should be advised to wear gloves at bedtime, when most of the scratching is likely to occur. Patients with maceration of perianal skin should use moist cotton rather than toilet paper. Soaps should be avoided, and the patient should take sitz baths for at least 15 min two to three times a day. The skin should then be thoroughly dried by gently blotting with a soft cloth. Zinc oxide ointment can provide a protective covering for the perianal skin and may enhance healing. Fungicidal creams should be prescribed for patients with secondary fungal infections. One percent hydrocortisone cream is effective for the allergic component of the inflammation. Finally, as an adjunct to providing

FIG. 82-9. Sonographic technique for axial imaging. Transducer may be a 5- to 10-MHz linear array, curved linear array, or sector scanner, operating at highest penetrating frequency. Patient in dorsal lithotomy position. A. Drawing shows female positioning; male positioning identical, with scrotum elevated. Transducer is placed directly on the perineal body between vagina (anterior) and rectum (posterior). Transducer is pressed posteriorly and angled cranially to caudally. IS = ischium. B. Sagittal diagram shows transducer position with respect to anterior sphincter apparatus. SYM = symphysis pubis. C. Axial sonogram with patient supine shows well-defined 3-mm hypoechoic internal sphincter (arrows) and 3.5-mm echogenic striated external sphincter (arrowheads).

SECTION 9 • GASTROINTESTINAL EMERGENCIES

symptomatic relief, consider prescribing hydroxyzine hydrochloride (Atarax) as an effective bedtime sedative.

PILONIDAL SINUS

Pilonidal sinus has nothing to do with the anorectum, anatomically or embryologically. Pilonidal sinuses or cysts occur in the midline in the upper part of the natal cleft overlying the lower sacrum and coccyx. Because of their proximity to the anus, infected pilonidal cysts (abscesses) are sometimes mistakenly diagnosed as perirectal abscesses. An abscessed pilonidal sinus is always located in the posterior midline over the sacrum and coccyx (although there may be secondary fistulous openings on either side of the midline) and does not communicate with the anorectum. On the other hand, long, horseshoe-type fistulas emanating from a perirectal abscess may drain close to the location of a pilonidal sinus but not in the midline.

Although once thought to be congenital in nature, pilonidal sinus is now considered an acquired problem. The sinus is formed by the penetration of the skin by ingrowing hair, which causes a foreign body granuloma reaction. The sinus is perpetuated by the presence of the hair and repeated bouts of infection. Although pilonidal sinuses or infected pilonidal cysts occur most commonly in white men before the fourth decade of life, a small portion of patients may develop this problem in their fourth decade. Pilonidal sinus and abscess formation should be considered a chronic and recurring disease.

Carcinoma is a rare complication of chronic, recurring pilonidal sinus disease. It is more frequent in men and is usually a well-differentiated dermal-type squamous cell carcinoma.

Treatment of pilonidal sinus is described in detail in Chap. 152, under Cutaneous Abscesses.

PROCTALGIA FUGAX

This painful condition, which lasts intermittently for a few months, is thought to occur as a result of transient perianal muscle spasm causing exquisite pain in the lower rectum and anus. The pain is often acute, can be quite severe, usually lasts for a few seconds, and may be associated with irritable bowel syndrome. A thorough examination is required to exclude structural causes, although there is usually no significant cause for this condition.⁴

HIDRADENITIS SUPPURATIVA

The perianal surface containing the apocrine sweat glands, in association with the perineal, groin, and axillary regions often become the sites of significant edema, superficial fistulae, and small superficial abscesses. Chronic inflammation, edema, tissue induration, and watery discharge may occur. Postpubescent patients are commonly affected as the apocrine ducts become blocked. Good hygiene, warm soaks, intermittent antibiotics, incision and drainage, and at times extensive surgery with skin grafts are needed for effective treatment.

PERIANAL ULTRASOUND AND MRI

Diagnostic imaging has expanded greatly over the last 10 to 20 years. Older tests utilizing barium contrast and fistulograms have given way to ultrasound, CT scanning, and MRI. Traditionally, distal rectum and anal ultrasonic evaluations were performed utilizing endorectal sonography. Endorectal ultrasound has been used for the diagnosis and management of certain perirectal abscesses, rectal tumor evaluation and staging, and anal sphincter evaluation for incontinence. More recently transperineal sonography is being utilized, providing equivalent information with better patient tolerance.⁷ Views in both the axial and longitudinal planes provide significant information about perirectal anatomic structures (Figures 82-9 and 82-10). Limitations such as decreased ultrasonic penetration above the distal 5 cm of rectum and pos-

FIG. 82-10. Longitudinal sonography. A. Drawing shows transducer in parasagittal plane, adjacent to rectum and parallel to vaginal opening. Transducer can be angled laterally or medially. With medial and caudal angulation, the oblique coronal plane can be achieved. IS = ischium. B. Oblique sagittal sonogram shows hypoechoic internal sphincter (arrows) and mixed-echogenicity external sphincter (asterisk) as imaged from left of rectum. Transducer, 9 MHz.

sible difficulty with skin contact due to structural anatomic variances may hinder adequate views. The technique involves utilization of a 5 to 10 MHz curved linear array transducer in both the axial and longitudinal planes with the patient in the supine position. The probe can be moved in a fanlike fashion to provide a more panoramic view of the perirectal region. Normally, the hypoechoic internal sphincter is about 3 mm thick and surrounds the rectal mucosa, which is more echogenic. More peripherally, the external sphincter is about 5 mm thick, and has mixed echogenicity. This technique may be used to identify some perirectal abscesses, fistula tracts, and local tumors.⁷ The transperineal technique is often better tolerated by the patient compared to the transrectal or endoanal approach. Perianal evaluations using a cone-shaped 10-MHz probe may be utilized. Other techniques may be utilized for evaluation such as a pelvic ultrasound (limited to females) and are slightly more invasive. Endorectal ultrasound with a condom-covered transducer is an uncomfortable, somewhat invasive technique which

may require sedation. Drawbacks to this technique include patient discomfort, ultrasound scatter from air bubbles within the condom and incomplete preparation with stool present. CT scan and MRI may be used and are thought to be complementary, though cost and availability are possible concerns.⁷ Endoluminal MRI has been used to detect anal sphincter invasion with an accuracy of 92 percent compared to endosonography at 50 percent.⁸ Endoanal ultrasound has been used to detect sphincter damage and anal malignancy staging; however, the primary use in the emergency department is to detect abscess and fistula formation in the appropriate presentation. As such, the abscess and fistulous tract will present as a hypochoic shadow. In fact, endoanal ultrasound has been found to be superior to CT and digital examination for the detection of fistulous tracts and abscesses.⁹ Caution must be taken as ultrasound may miss extension of the fistulas into the ischioanal and supraleator regions. Difficulty in distinguishing abscess cavities, granulation tracts, and scar tissue has been described. MRI, used to detect granulation, is quite useful for detecting fistulae. New MRI endoprobes are being developed and may further enhance the ability to detect these fistulae.⁹

stipation but also the nongastrointestinal emergencies manifested as gastrointestinal dysfunction.

An important and often difficult step in the evaluation of patients with vomiting, diarrhea, or constipation is having the patient define the illness. The lay person's definitions of *vomiting*, *diarrhea*, and *constipation* often differ tremendously from the medical definitions. For example, patients often say "vomiting" when they really mean "coughing up sputum." Some patients complain of "constipation" and mean that they are straining to defecate. Defining the complaint allows the physician to treat patients correctly and in turn increases patients' satisfaction. A complete history of the current illness is the first step toward the correct diagnosis.

After defining the illness, the emergency physician's next step is to determine whether the illness represents an emergency. At the end of the emergency department evaluation, the cause of the patient's symptoms may not be clear. Nevertheless, the physician must decide, based on limited information, whether a patient may be discharged safely and what the initial treatment plan will be.

VOMITING

Pathophysiology

Vomiting is a complex, highly coordinated activity involving the gastrointestinal tract, the central nervous system, and the vestibular system. In 1952, Wang and Borison identified a medullary vomiting center.¹ The proximity of the medullary vomiting center to other central nervous system nuclei allows for the coordinated activity of vomiting.¹ Three stages of vomiting have been described: nausea, retching, and emesis.² Nausea is the subjective feeling that immediately precedes vomiting and is accompanied by hypersalivation and tachycardia. Retching occurs when the pylorus contracts and the fundus relaxes, thereby moving food to the gastric cardia. Emesis occurs when the powerful abdominal muscles contract simultaneously and thus eject food or gastric secretions from the stomach.

Clinical Features

HISTORY There are various causes of vomiting (Table 83-1). Fortunately, the patient's history often leads the physician to the correct diagnosis. Asking the right questions will help to uncover the etiology.

First, define the vomitus. Is it bloody, bilious or nonbilious, feculent or posttussive? Hematemesis is seen with gastritis, peptic ulcer disease, gastric and esophageal tumors, and Mallory-Weiss tears. Nonbilious emesis occurs with gastric outlet obstruction, as in patients with pyloric strictures secondary to ulcer disease or infants with pyloric stenosis.

Second, determine what symptoms accompany the vomiting. Is the patient febrile? Fever could point toward an infectious or inflammatory source, or it could represent a toxicologic cause, such as salicylate intoxication. Is there associated abdominal pain, back pain, headache, or chest pain that may point to a specific cause? Pancreatitis, cholecystitis, peptic ulcer disease, appendicitis, and pelvic inflammatory disease typically cause abdominal pain. Back pain usually accompanies aortic dissections, rupturing aortic aneurysm, pyelonephritis, and biliary or renal colic. Vomiting is one of the signs of increased intracranial or intraocular pressure and may be a foreboding sign in patients complaining of headache. The complaint of vomiting associated with chest or epigastric pain might suggest a diagnosis of myocardial ischemia. In female patients, obstetric and gynecologic causes of vomiting should always be considered. In a pregnant woman, epigastric pain and vomiting accompanying hypertension may indicate preeclampsia.

Learning more about the patient is as important as defining the illness. What complicating medical conditions does the patient have? Is

VOMITING, DIARRHEA, AND CONSTIPATION

Annie T. Sadosty Jennifer J. Hess

Vomiting, diarrhea, and constipation are among the most common complaints of patients presenting to emergency departments. Gastrointestinal dysfunction is the final common pathway for a variety of diseases. Therefore, many patients complaining of vomiting, diarrhea, or constipation have a cause for their symptoms remote from the gastrointestinal system. Emergency physicians must consider not only the gastrointestinal emergencies manifested as vomiting, diarrhea, or con-

Rx (prescription)	Medication side effect (naloxone, opioid analgesics, erythromycin, chemotherapy, ipecac)	Medication side effect (antibiotics, chemotherapy, laxatives, antacids, sorbitol, colchicine)
Obstetrics and gynecology	Pregnancy (ectopic, uterine, molar) Preeclampsia Hyperemesis gravidarum	
Endocrine or metabolic	Adrenal insufficiency Thyrotoxicosis Diabetic ketoacidosis Alcoholic ketoacidosis Reye syndrome Uremia	Adrenal insufficiency Thyrotoxicosis Uremia
Neurologic	Autonomic neuropathy (gastroparesis in diabetes) Vestibular disorders (cranial nerve VIII) Migraine headache Hypertensive encephalopathy Hydrocephalus Increased ICP (intracranial neoplasms, subdural or epidural hematoma, subarachnoid hemorrhage, cerebral edema)	Autonomic neuropathy (diabetes)

(continued)

the patient diabetic? If so, could the vomiting be a manifestation of diabetic ketoacidosis? In a patient with a history of peripheral vascular disease, vomiting may be a sign of mesenteric ischemia. Patients with a history of multiple abdominal surgeries are at risk for intestinal obstruction due to adhesions. Knowledge of the medications to which the patient has access is also critical, because intentional and unintentional poisonings often present first with emesis. Physicians should be suspicious of drug-induced toxicity in patients taking medicines known to have gastrointestinal toxicity (e.g., lithium, digoxin, or theophylline). The social history provides clues, too. Vomiting in a person who enjoys mushroom hunting may well represent *Amanita* poisoning.

PHYSICAL EXAMINATION Clinical clues also may assist in making the diagnosis. In addition to evaluating the ABCs, much of the physician's initial attention should be directed toward the assessment of hydration status. Severely volume-depleted patients require immediate intervention, lest circulatory collapse be imminent. The abdominal, genitourinary, and pelvic examinations are often revealing. Physicians should search carefully for tenderness, peritoneal signs, hernias, masses, and evidence of obstruction or torsion. The findings of a careful physical examination may point toward unsuspected causes of vomiting, such as bulimia (scars on the dorsum of hands), pneumonia (consolidative findings on lung examination), or Addison disease (hyperpigmentation). The rectal examination is important. An anal fistula may be the only clue to Crohn disease in an otherwise healthy teenager with vomiting or a hard stool mass in the rectal vault may indicate fecal impaction.

Acquire data selectively and smartly. Order diagnostic tests according to the differential diagnosis. In the vomiting, premenopausal woman, consider pregnancy high on the differential diagnosis, and rule it in or out with a pregnancy test. Other laboratory tests that may be of assistance are determination of blood urea nitrogen, creatinine, and amylase levels; liver function tests; determination of blood alcohol and drug levels; and urinalysis. Addisonian crisis can present with vomiting, and the laboratory results may show hyperkalemia and hyponatremia. An electrocardiogram can help if the physician is considering the diagnosis of myocardial ischemia. Chest and abdominal radiography can assist in the determination of the presence or absence of pneumoperitoneum, pneumonia, or intestinal obstruction.

Treatment

Initial management of the acutely ill, vomiting patient is the same, regardless of cause. The ABCs always take precedence. For patients with circulatory collapse secondary to severe dehydration, aggressive volume repletion must begin immediately upon arrival. Two large-bore intravenous catheters should be placed, and crystalloid should be administered aggressively to restore circulation quickly.

For patients with less acute conditions, treatment hinges on making the correct diagnosis. A vomiting patient with diabetic ketoacidosis will not respond to symptomatic therapy with antiemetics: vomiting continues until the underlying illness is treated. It is important, therefore, to recognize the illnesses that are not self-limited and to treat them appropriately. However, not all patients with the chief complaint of vomiting

TABLE 83-1 Vomiting and Diarrhea: The GASTROENTERITIS Mnemonic (Continued)

are discharged from the emergency department with a clear diagnosis. These patients should be treated symptomatically, and follow-up should be ensured. For patients with mild to moderate dehydration who are actively vomiting, we recommend intravenous rehydration and antiemetic therapy directed toward the mechanism involved in eliciting the emesis (Table 83-2). For instance, vertigo and motion sickness will respond best to pharmacologic treatment with anticholinergics and antihistamines. The treatment of nausea from visceral distention involves blocking vagal afferents with serotonin (5-HT₃) receptor agonists. It is also important to note the form of drug delivery to ensure successful administration of the medication in the ED or upon dismissal.

Disposition

Patients with life-threatening causes of vomiting should be admitted to the hospital, as should severely dehydrated patients with presumably self-limited causes of emesis. The patient in whom the diagnosis is unclear, but who the physician feels confident does not have a life-threatening cause of emesis, may be discharged safely, provided the patient tolerates fluids in the ED and that follow-up the next day, if vomiting continues, is ensured. A dehydrated patient who cannot tolerate oral intake should not be discharged.

DIARRHEA

Epidemiology

At the turn of the twentieth century, diarrhea was one of the leading causes of death in the United States. In the 1990s, however, diarrhea

accounted for fewer than 0.5 percent of all deaths in the United States.³ Most diarrheal deaths occur in the elderly and the young.^{3,4} Worldwide, however, diarrhea remains one of the leading causes of death. In fact, in 1990, diarrhea was listed as the fourth leading cause of death globally and was responsible for a total of 2.9 million deaths.⁵ Despite the low U.S. mortality rate, diarrhea causes significant morbidity. It is the second most common reason for work absenteeism and is estimated to cost \$608 million in lost productivity per year.^{6,7}

Pathophysiology

There are four basic mechanisms of diarrhea: increased intestinal secretion, decreased intestinal absorption, increased osmotic load, and abnormal intestinal motility. Knowledge of normal intestinal function assists in understanding these various mechanisms. Normally, the jejunum receives between 6 and 8 L per d of fluid in the form of oral intake and gastric, pancreatic, and biliary secretions. Dietary intake actually constitutes a small portion of the jejunal load (1.5 L). A healthy small intestine absorbs nearly 75 percent of the fluid to which it is exposed. The 2 L of fluid not absorbed by the small intestine then enters the colon, where fluid is absorbed at an even higher rate. The absorptive power of the colon approaches 90 percent efficiency and far exceeds that of the small intestine. In fact, the colon can make up for a decrease in small intestinal absorption. Under normal conditions, very little fluid (<100 mL) is lost in the stool each day.⁸

In diarrheal states, normal intestinal physiology is disrupted. At a cellular level, intestinal absorption occurs through the villi, and secretion occurs through the crypts. Fluids are absorbed via two mechanisms: passively with the transport of sodium and actively with the

absorption of glucose. Selected enterotoxins block the passive sodium resorption and specifically stimulate sodium excretion, resulting in a net loss of fluid. The glucose-dependent mechanism of water absorption, however, is unaffected by these toxins and can be exploited by including glucose in the rehydration treatments. The composition of oral rehydration therapies recommended by the World Health Organization is based largely on this physiology. In addition, diarrheal states, enterotoxins, inflammation, or ischemia disrupt the structure of the intestinal villi preferentially to the crypts. As a result, diarrhea occurs because of diminished intestinal villi absorption *and* unopposed crypt secretion (the crypts are more resilient after injury).⁹ Diarrhea also accompanies the delivery of an osmotic load to the intestine. For example, administration of a laxative results in the collection of an osmotically active, nondigestible agent within the intestinal lumen. Osmosis occurs, drawing fluid into the intestinal lumen, and results in diarrhea. Increased intestinal motility causes diarrhea, as in patients with irritable bowel syndrome, neuropathies, or a shortened intestine secondary to surgery.

Clinical Features

HISTORY The definition of diarrhea varies within the medical literature, so it is not surprising that patients' definitions vary, too. Many patients come to the emergency department complaining of "diarrhea" when what they really have is soft stools or two stools per day compared with their usual one. Strictly speaking, diarrhea is present when the daily stool weight exceeds 200 g.¹⁰ Practically speaking, however, diarrhea is present when the patient is making more stools of lesser consistency more frequently.

Once a true diarrheal illness is confirmed, the physician's focus should change toward attempting to ascertain the cause of the diarrhea. There are many causes of diarrhea. Fortunately, the history usually leads the physician to the etiology. The first step is to determine whether the diarrhea is acute (<3 weeks) or chronic (>3 weeks). The acute diarrheas are of greatest concern to the emergency physician, for they are more apt to be a manifestation of an immediately life-threatening illness (infection, ischemia, intoxication, or inflammation).¹⁰

The next step is to define the diarrhea. Is it bloody or melanotic? Is it associated with possible food poisoning (see Chap. 150), or the ingestion of certain foods, such as milk or sorbitol? Does it resolve or persist with fasting? This can indicate an osmotic or secretory diarrhea, respectively. Are the stools of smaller volume localizing to the large intestine or of larger volume indicating small intestine pathology? What symptoms accompany the diarrhea? Is there fever or abdominal pain, which may suggest diverticulitis or infectious gastroenteritis? Seizures accompanying diarrhea often point toward shigellosis but could also indicate theophylline toxicity. Does the patient have heat intolerance and anxiety, suggesting thyrotoxicosis, or paresthesias and reverse temperature sensation, suggesting ciguatera?

Define the host. A patient's medical and surgical history often assists in narrowing the differential diagnosis. For example, diarrhea resulting from malabsorption secondary to pancreatic exocrine insufficiency need not be considered in an otherwise healthy host. Conversely, the differential diagnosis for diarrhea is broadened for a patient with acquired immunodeficiency syndrome. Medications commonly have diarrhea as a side effect or sequela. Is the patient taking medication that may have contributed to the diarrhea (e.g., antibiotics, lithium, chemotherapy, colchicine, and laxatives)? Has the patient traveled outside the United States or to the countryside recently? Rural hiking places the patient at risk for *Giardia*, particularly if water-purification procedures were not strictly followed, and travel to Third World countries increases the chances of parasitic infection and traveler's diarrhea. Sexual and occupational histories are also important. A patient's sexual preference or occupation may be the physician's only clue to a diagnosis of "gay" bowel disease or organophosphate poisoning.

PHYSICAL EXAMINATION As with a vomiting patient, the examination begins with the ABCs. Thus, assessment of hydration status occurs shortly after the physician arrives at the bedside. Like the history, a careful physical examination can help narrow the differential diagnosis. Only by doing a thyroid examination can the physician discover a thyroid mass that may be contributing to diarrhea. Several other findings may be helpful in uncovering the underlying cause of the diarrhea, especially if it is more chronic in nature. These examination findings include oral ulcers, erythema nodosum, episcleritis, or an anal fissure, which would point toward inflammatory bowel disease. Reiter's syndrome, the triad of arthritis, conjunctivitis, and urethritis or cervicitis, should raise thoughts of *Salmonella*, *Shigella*, *Campylobacter*, or *Yersinia*. **Abdominal and rectal examinations are critical. Especially in the elderly, fecal impaction may result in diarrhea as liquid stool passes around the impaction.** Special attention should be given to the presence or absence of surgical scars, tenderness, masses, or peritoneal signs. Checking the stool for the presence or absence of blood is also important, because bloody diarrhea can be caused by inflammation, infection, or ischemia. An elderly patient with bloody diarrhea and abdominal pain out of proportion to the physical examination may have mesenteric ischemia—a true emergency.

DIAGNOSTIC STOOL EVALUATION Tests specific to the emergency department evaluation of a patient with diarrhea include Wright stain for fecal leukocytes; stool culture for bacteria, ova, and parasites; and stool analysis for *Clostridium difficile* toxin. Diagnostic testing, although rarely helpful to the emergency physician, occasionally is helpful to the primary care physician. Who should be tested? Stool cultures for bacteria should be obtained in children, toxic patients, patients with a protracted diarrheal illness lasting longer than 3 days, and immunocompromised patients in whom infectious diarrhea is suspected. A request for an ova and parasite evaluation can be made for patients at risk for parasitic disease. In addition, patients at risk for *C. difficile* colitis should have a stool sample sent for *C. difficile* toxin assay.

Wright Stain When applied to a stool sample, Wright stain allows detection of fecal leukocytes. A positive Wright stain has a sensitivity of 82 percent and a specificity of 83 percent for the presence of bacterial pathogen.¹¹ Historically, Wright stain for fecal leukocytes has been used to differentiate invasive from noninvasive infectious diarrheas. In the past, this was an important distinction: physicians were reluctant to prescribe antibiotics for patients with infectious diarrhea, because of the fear of prolonging the *Salmonella* carrier state. They therefore reserved antimicrobial treatment for the toxic patients who they felt *truly* had invasive diarrhea. Recently, this dictum has been questioned, and many physicians now treat patients with diarrheal illness with antibiotics regardless of whether or not the diarrhea is invasive or bacterial in origin.¹² Therefore, ascertaining the presence or absence of fecal leukocytes is superfluous.

Bacterial Stool Culture Bacterial stool culture is an expensive and labor-intensive diagnostic test that plays a minor role in the emergency department evaluation of a patient with diarrhea. Most laboratories culture for only three common bacterial pathogens: *Salmonella*, *Shigella*, and *Campylobacter*. Because of a low sensitivity for detecting pathogens, each positive routine stool culture costs the laboratory approximately \$950 to \$1200, depending on the number of samples tested and the number of tests run on each sample.⁹ To limit cost and increase yield, diagnostic testing should be limited to patients with high pretest probabilities of bacterial disease: severely dehydrated or toxic patients, children, immunocompromised patients, and patients with diarrhea lasting longer than 3 days.⁹ In addition, if other enteric pathogens are suspected, the laboratory should be notified so that appropriate testing may be performed.

Ova and Parasitic Evaluation Patients in whom a parasitic cause of diarrhea is suspected should have stool sent for evaluation for ova and parasites. These tests lack sensitivity, because many parasites are fastidious and shedding of the organisms is intermittent. Multiple samples may need to be collected to be sufficient to yield a positive result. Recently, direct immunofluorescence staining has been shown to improve the sensitivity for detecting *Giardia* and *Cryptosporidium*.¹³

***Clostridium difficile* Toxin Assay** Diarrhea in a patient with an antecedent history of antibiotic use or hospitalization may be caused by pseudomembranous colitis from *C. difficile* infection. This is diagnosed with the *C. difficile* toxin assay. Unfortunately, this assay has a 10 percent false-negative rate and is rarely available to the emergency physician, because the turnaround time on the test approaches 24 h.¹⁴

Other Diagnostic Tests If diarrhea is not felt to be infectious in origin, data acquisition should be dictated by the differential diagnosis. Rarely are serum chemistry results or complete blood count results diagnostic or necessary. Electrolyte measurements are warranted in severely dehydrated patients, regardless of the cause of dehydration. These measurements also can be helpful in patients experiencing an Addisonian crisis. Serum drug levels can assist the physician in making the diagnosis of theophylline, lithium, or heavy metal intoxication. In patients with a history of abdominal surgery, abdominal films may help rule out partial obstruction as a cause of diarrhea. A chest radiograph may help diagnose an occult pneumonia (i.e., *Legionella*) in a patient with diarrhea and a cough. For patients in whom mesenteric ischemia is suspected, mesenteric angiography is the test of choice.

Treatment

Initial treatment of any patient begins with the ABCs. Rehydration of severely dehydrated patients should begin immediately after large-bore intravenous access is achieved. Thereafter, treatment is dictated by the differential diagnosis. The emergency medicine approach to a patient with diarrhea, therefore, hinges on treating or excluding the

life-threatening causes of diarrhea. Because infectious diarrhea is the most common cause of acute diarrhea, after the differential diagnosis is considered, physicians most commonly are left considering that diagnosis.

NONINFECTIOUS DIARRHEA Almost all true diarrheal emergencies (e.g., gastrointestinal bleed, adrenal insufficiency, thyroid storm, toxicologic exposures, acute radiation syndrome, and mesenteric ischemia, all discussed elsewhere in this textbook) are of noninfectious origin. The emergency physician must be ever mindful of them, because patients with those conditions require intensive treatment and hospitalization. The less emergent, noninfectious causes of diarrhea are listed in Table 83-1.

ANTIBIOTIC OR DRUG-ASSOCIATED DIARRHEA Drugs have many direct and indirect effects on gastrointestinal function. For example, erythromycin accelerates the rate of gastric emptying, clavulanate stimulates small bowel motility, and antibiotics may reduce fecal anaerobes. Fecal anaerobes are important for carbohydrate metabolism and bile acid breakdown. Gut carbohydrates can cause osmotic diarrhea, and bile acids are colonic secretory agents. Nonantibiotics that can cause diarrhea include laxatives, antacids, oral contrast agents, lactose, sorbitol, nonsteroidal anti-inflammatory agents, and cholinergics.

Antibiotic-associated diarrhea is usually moderate in severity, without cramps, fever, or fecal leukocytes. Stool assays for pathogens are negative. Symptoms resolve upon withdrawal of the antibiotic or drug. Metronidazole or vancomycin are not indicated.

INFECTIOUS DIARRHEA Viruses cause the vast majority of infectious diarrheas, followed by bacterial and parasitic organisms. Treatment of infectious diarrhea involves antibiotic therapy, antimotility agents, restoration of fluid balance, and avoidance of agents that worsen diarrhea (Table 83-3). See Chap. 81 for a discussion of *C. difficile* colitis.

For the past 30 years, two pervasive myths involving the use of antibiotics and antimotility agents in the treatment of infectious diarrhea have dictated the management of large numbers of patients with diarrhea. These myths are discussed in detail below, and a discussion of the modern medical approach to infectious diarrhea follows.

Antibiotics

MYTH For years, physicians avoided antibiotic use in the treatment of infectious diarrhea because of a fear of prolonging the *Salmonella* carrier state. This fear arose from an article published in 1969 in which the duration of *Salmonella* excretion after a salmonellosis epidemic was studied.¹⁵ The study compared the length of excretion in patients who received antibiotics (ampicillin or chloramphenicol) with that of patients who were not treated and found that *Salmonella* excretion was longer in the cohort that received antibiotics. The authors concluded that, because of a prolonged carrier state, antibiotics should not be given to patients suspected of having a diarrheal illness due to *Salmonella*.

MODERN MEDICINE For adults with domestically acquired diarrhea in whom the origin is felt to be infectious, antibiotics (500 mg of ciprofloxacin by mouth as a single dose for onset of travelers' diarrhea or twice daily for 3 days)^{12,16} shorten the duration of illness by approximately 24 h. Regardless of the causative agent, all patients—even those who had a negative Wright's stain, negative stool culture, and a low diarrheal illness score, suggesting less clinically significant disease and/or a viral cause—improved on ciprofloxacin.¹⁷ Even though most infectious diarrheas are self-limited, because of the inconveniencing and occasionally life-threatening nature of the disease, **we recommend ciprofloxacin treatment for all patients believed to have an infectious diarrhea who do not have a contraindication to antimicrobial treatment** (e.g., pediatric age group, allergy, pregnancy, or drug interaction). Trimethoprim/sulfamethoxazole (Bactrim DS; one tablet by mouth as a single dose or twice daily for 3 days) also shortens the duration of infectious diarrhea in adults but was proven to be inferior to a course of ciprofloxacin secondary to resistant organisms.¹⁷

Antimotility Agents

MYTH Since the early 1960s, the use of antimotility agents in the treatment of diarrhea has been denounced by most of the medical community. This dictum emerged out of a 1963 study published by Formal and colleagues.¹⁸ In this study, guinea pigs were starved and poisoned to make them susceptible to *Shigella* infection (an organism to which

TABLE 83-3 Empiric Treatment of Traveler's Diarrhea in the Adult

Rehydration Fluids: chicken broth with fruit juices, Gatorade, noncaffeinated sodas, packages of salts and glucose to be reconstituted with boiled or treated water,

Ceralyte 90, Pedialyte Foods: complex carbohydrates (bananas, bread, rice, apple juice, and tortillas), potatoes, crackers, *Lactobacillus-contains* yogurt

	Trade Name	Dosage	Comments
Antimotility Agents			
Bismuth subsalicylate	Pepto Bismol	30 mL or 2 tablets every 30 min for 8 doses; repeat on day 2	Salicylate toxicity may occur with excessive dosing; may cause bismuth encephalopathy in HIV patients
Loperamide	Imodium	4 mg initially, then 2 mg after each unformed stool for no more than 2 d; maximum, 16 mg per d	Preferred first-line agent for antimotility, with minimal central opiate effects
Diphenoxylate and atropine	Lomotil	4 mg qid for <2 d	Recommended as a second-line agent with more central opiate effects (narcotic related to meperidine); may potentiate the action of barbiturates, tranquilizers, and alcohol
Antibiotics Ciprofloxacin			
	Cipro	500 mg single dose or 500 mg bid for 3 d	Indicated for moderately severe illness; complete 3-d course if single dose fails; significant drug-drug interactions may occur
Trimethoprim/sulfamethoxazole	Bactrim	160 mg/800 mg for single dose, 160mg/800mg bid for 3 d	Indicated for moderately severe illness; resistance limits reliable effectiveness
Bismuth subsalicylate	Pepto Bismol	30 mL or 2 tablets every 30 min for 8 doses; repeat on day 2 Prophylaxis: 2 tablets chewed with each meal and at bedtime	Indicated for mild illness and prophylaxis; see comments above

Abbreviation: HIV = human immunodeficiency virus.

guinea pigs are not usually susceptible). They were then inoculated with *Shigella*, and a subset of the study was then given opium. The authors discovered an association between opium administration and fatal *Shigella* infection. From these data, the authors concluded that a major defense mechanism of the guinea pig is its peristaltic activity and that antimotility agents (opium) might increase susceptibility to enteric infection.

A study in 1973 on human volunteers perpetuated the myth. In this study, DuPont and Hornick examined, among other things, the effect of diphenoxylate and atropine (Lomotil) on shigellosis.¹⁹ The authors found that Lomotil seemed to diminish the number of unformed stools but in so doing may have increased patients' susceptibility to invasive infection, because fever was prolonged only in the patients receiving Lomotil. However, the sample size in this study was 25, and there were four treatment arms, making the number of patients in each treatment arm approximately six. The authors admitted that the study was inconclusive due to its small sample size and suggested that further investigation occur before conclusions could be made regarding the use of Lomotil in infectious diarrhea. Nevertheless, the two studies led to a nearly universal avoidance of the use of antimotility agents in patients with infectious diarrhea.

MODERN MEDICINE In 1990, Ericsson and colleagues²⁰ published a paper that addressed the use of loperamide (Imodium) in the treatment of traveler's diarrhea. In a study of 227 adults with acute diarrhea, combination treatment with Bactrim and loperamide was proven to be safe and effective in treating traveler's diarrhea. In 1993, a randomized, placebo-controlled, double-blind study was performed in Thailand comparing the use of ciprofloxacin and loperamide with ciprofloxacin and placebo in the treatment of adults with bacillary dysentery.²¹ The study showed that loperamide combined with ciprofloxacin decreased the number of diarrheal stools and shortened the duration of illness in adult patients with dysentery due to *Shigella* or enteroinvasive *Escherichia coli*. No complications were seen in the group treated with loperamide. Although the study size was small ($n = 88$), it was much larger than in the 1973 study by DuPont and Hornick,¹⁹ and it was the first of its kind to suggest the safety of antimotility agents in the treatment of adult invasive diarrheas. We therefore recommend the prescription of loperamide (see Table 83-3 for dosing), because it has clearly been proven to shorten duration of symptoms when combined with an antibiotic regimen. Diphenoxylate and atropine (Lomotil) is a more potent antidiarrheal whose modern-day safety is less well studied. For patients with severely inconveniencing diarrhea refractory to loperamide, diphenoxylate and atropine may be helpful. It should be used with caution, however, in patients with a history of constipation or cardiac disease.

Rehydration For patients presenting to the emergency department with significant dehydration, intravenous fluid therapy is indicated. For a mildly dehydrated patient who is not vomiting, oral rehydration therapy is recommended. Glucose-containing, caffeine-free beverages are the fluids of choice. Recall that it is the glucose transport mechanism that is unaffected by the enterotoxins, allowing for water absorption in the small intestine. For patients who can afford to buy it, Gatorade is a good rehydration choice with mild dehydration. The World Health Organization recommends a solution with a higher sodium concentration well suited to more extensive dehydration. Mildly dehydrated patients should aim to drink 30 to 50 mL/kg over the next 4 h. For moderate dehydration, patients should drink 100 mL/kg over the next 4 h.¹⁰

Dietary Restrictions Patients should be counseled to avoid caffeine, which stimulates gastric motility, and sorbitol-containing chewing gum or raw fruits, which can exacerbate an osmotic diarrhea. Lactose should be avoided initially until the colonic villi are able to recover and produce the necessary digestive enzymes. Patients should be encouraged to attempt early solid food intake with these restrictions, because this has been shown to expedite the recovery from diarrheal illnesses.²²

Disposition

Patients with the noninfectious emergencies outlined above warrant hospitalization. Most other patients can be discharged home safely. When deciding whether to admit a patient with diarrhea, conservatism should be the rule with the young and the elderly. They do have higher morbidity and mortality rates and should be evaluated with a careful eye. Regardless of age, any toxic patient should be admitted, as should any patient who cannot convincingly comply with oral rehydration guidelines. Upon discharge, patients with infectious diarrhea should be counseled on limiting the spread of disease through the use of judicious hand washing. Work excuses should be given liberally to patients employed in the food, day-care, and health care industries. Prevention strategies for infectious diarrhea can be reiterated for those who acquired the diarrhea with foreign travel. A quick, but helpful phrase that can be shared for prevention is, "Peel it, boil it, cook it, or forget it!" For tourists tempted with luscious foods of the native land, this remains a difficult task!

CONSTIPATION

Epidemiology

Constipation is the most common digestive complaint in the United States and accounts for more than 2.5 million physician visits per year.^{23,24} There is an age-related increase in the incidence of constipation, with 30 to 40 percent of adults older than 65 years citing constipation as a problem.^{24,25}

Pathophysiology

The cause of constipation is usually multifactorial. Dietary intake affects bowel motility. Diminishing intake of fiber associated with decreased fluid intake can result in constipation. In addition, exercise, medical conditions, and medications affect gut motility. Sedentary patients often become constipated. Medical conditions such as hypothyroidism, hyperparathyroidism, lead poisoning, and chronic neurologic disorders are well-known causes. Some anal pathologic conditions cause painful defecation and in turn can result in constipation due to consequent fear, particularly in children. Patients confined to a hospital bed after an orthopedic injury, for example, may become constipated due to their inability to use a bedpan successfully. Certain medications, such as calcium-channel blockers, iron, narcotic analgesics, and antipsychotics, are also common causes of constipation. Indeed, constipation is a complicated condition with multiple causes (Table 83-4).

TABLE 83-4 Differential Diagnosis of Constipation

ACUTE OR SUBACUTE	
Gastrointestinal: obstructing cancer, volvulus, stricture, hernia, adhesion, pelvic or abdominal masses, inflammation	Medicinal: addition of new medicine (e.g., antipsychotic, anticholinergic, narcotic analgesic, antacids)
Environmental: change in defecation regimen (e.g., forced to use bedpan)	
Exercise and diet: decrease in level of exercise, fiber intake, fluid intake	
CHRONIC	
Gastrointestinal: slowly growing tumor, colonic dysmotility, anal pathology	
Medicinal: chronic laxative abuse, antipsychotics, anticholinergics, narcotic analgesics	
Neurologic: neuropathy, Parkinson disease, paraplegia, cerebral palsy	
Endocrine: diabetes, hypothyroidism, hyperparathyroidism	
Rheumatologic: scleroderma	Toxicologic: lead poisoning

Clinical Features

HISTORY The easiest, most practical definition of *constipation* is the following: the presence of hard stools that are difficult to pass. Some patients become bowel fixated and feel they are constipated if they do not have a daily bowel movement. They are not.

The differential diagnosis of constipation is broad. Determining the onset of the constipation helps narrow the differential diagnosis. Acute constipation represents intestinal obstruction until proven otherwise. Tumors, strictures, and volvuloses can present as acute constipation. Physicians often mistake subacute for chronic constipation. The important distinction here is to determine exactly when bowel habits changed. In general, acute and subacute conditions have the same differential diagnosis. Chronic constipation, that is, a lifelong or persistent habit, is usually less ominous and, if uncomplicated, can often be managed on an outpatient basis. The presence or absence of associated symptoms may help guide decision-making. Vomiting rarely accompanies benign constipation. Inability to pass flatus also raises concern about obstruction. A history of gradually diminishing stool caliber may suggest colon cancer, especially if accompanied by weight loss. The physician should ask the patient about recent changes in dietary fiber or fluid intake. What other medical problems does the patient have? Is there a history of hypothyroidism or diabetes? An antecedent history of diverticulitis may point toward inflammatory stricture. A history of nephrolithiasis could suggest hyperparathyroidism as a cause for constipation. A quick review of the patient's medication list also may point to the culprit.

PHYSICAL EXAMINATION The physical examination should concentrate on ruling out organic causes of constipation. First and foremost, intestinal obstruction must be ruled out. The patient should be examined carefully for the presence or absence of hernias and abdom-

inal or pelvic masses. Rectal and pelvic examinations are necessary. In addition to detecting the presence or absence of an obstructing rectal mass, rectal examination enables the physician to ascertain whether there is fecal impaction. Anal fissures are also detected during the rectal examination. In addition, rectal examination allows the physician to determine whether the stools are bloody. Guaiac-positive stools can be seen in functional constipation and constipation resulting from colon cancer. With constipation resulting in fecal impaction, one can develop pressure necrosis of the rectal mucosa that forms stercoral ulcers on the rectal walls. These ulcers may yield guaiac-positive stools or be revealed by fecaliths on an abdominal plain film. With constipation caused by tumor, stools are also often guaiac positive. Constipation and new ascites in postmenopausal women should prompt evaluation for ovarian or uterine carcinoma. Signs of hypothyroidism may also be evident during the physical examination.

The evaluation of a constipated patient depends on the clinician's level of concern for organic causes of constipation. Patients with a long-standing history of constipation often require little, if any, data acquisition, provided the history and physical examination do not point toward an organic process. An upright chest film and abdominal flat and erect films should be obtained in patients who are at risk for intestinal obstruction: patients with prior abdominal surgery, associated vomiting, significant abdominal distention, abdominal pain, and an acute or subacute history of constipation. In addition to assessing the presence or absence of intestinal obstruction, abdominal films allow the physician to assess stool burden. In patients in whom an organic cause for constipation is suspected, a complete blood count should be obtained to screen for anemia. In addition, thyroid function tests may be helpful with patients in whom the physician suspects hypothyroidism. Electrolyte abnormalities, specifically hypokalemia and hypercalcemia, can be associated with constipation and are worth checking in patients suspected of having an organic cause.

TABLE 83-5 Medical Adjuncts Used in the Treatment of Constipation (Listed from Least to Most Potent)

Type	Generic Name	Trade Name	Prn Doses	Side Effects	Mechanism
Fiber	Bran	NA	1 cup qd	Bloating, flatulence	Increase stool bulk or transit time,
	Psyllium	Metamucil	1 tsp tid	Bloating, flatulence	increase gut motility
Emollient	Docusate sodium	Colace	100mgqdbid	Cramping	Facilitates mixture of stool fat and water
Stimulants	Bisacodyl	Dulcolax	10mgPRtid	Incontinence, rectal burning	Stimulates the myenteric plexus, thereby increasing intestinal motility
	Anthraquinones	Peri-Colace	1-2 tablets PO qd/bid	Melanos coli, degeneration of myenteric plexus	
	Senna	Senokot, Ex-lax	2 tablets PO qd/bid or 15-30 mL qd/bid	Laxative abuse, nausea, melanos coli, cramping	
Saline laxative	Magnesium	Milk of magnesia	15-30 mL qd/bid	Magnesium toxicity	Colonic transit time is shortened
		Magnesium citrate	100-240 mL qd/bid	Cramping, flatulence, hypermagnesemia	
Suppository	Glycerin suppository	NA	1 PRqd	Rectal irritation	Local rectal stimulation prompts defecation
Hyperosmolar agents	Lactulose	NA	15-30 mL qd/bid	Cramps, flatulence, belching, nausea	Osmotically active nonabsorbable sugars pull fluid into the gut
	Sorbitol	NA	15-30 mL qd/bid	Cramps, flatulence	
	Polyethylene glycol	Golytely	1 gal/4 h	Nausea, cramping, anal irritation	
Enemas	Tap water	NA	500 mL PR	Local trauma	Colonic distention encourages evacuation
	Soap suds	NA	1500 mL PR	Local trauma	
	Monophosphate	Fleets	1 UPR	Local trauma, hyperphosphatemia (especially in patients with renal failure)	

Abbreviation: NA = not applicable.

Treatment

FUNCTIONAL CONSTIPATION The treatment of functional (chronic) constipation involves a multidisciplinary approach. Many patients come to the emergency department looking for medication. Medications often employed in the treatment of constipation are listed in Table 83-5. However, the most important part of treatment is dietary and behavior modification. The most important prescription a patient with constipation receives is for a strict dietary and exercise regimen, because, without adequate fluid (1.5 L per d), fiber (10 g per d), and exercise, medicinal methods usually fail.²⁴ In addition, patients should be urged to take advantage of the gastrocolic reflex by attempting to defecate daily after a certain meal.

In its extreme form, functional constipation can result in a variety of potentially life-threatening complications. Fecal impaction and intestinal pseudo-obstruction are two sequelae of which the emergency physician should be acutely aware.

Fecal Impaction Patients with fecal impaction must be disimpacted manually before leaving the emergency department. Manual disimpaction is not a glamorous procedure, and, as a result, many physicians avoid doing it. This is unfortunate, because enemas, the alternative therapy, rarely work for fecal impaction. It must be remembered that manual disimpaction can be a painful procedure for which patients at times require sedation. After disimpaction, a host of medicines may be used to assist the patient in achieving normal fecal flow. The agents in Table 83-5 are listed in the order most easily tolerated by patients.

Intestinal Pseudo-Obstruction Intestinal pseudo-obstruction is a condition seen in patients with a long-standing history of colonic dysmotility. Patients present in a manner that mimics intestinal obstruction: abdominal distention, crampy abdominal pain, and obstipation. Abdominal x-ray films may reveal a severely dilated colon. Treatment is varied and is best determined in consultation with a surgeon. Sometimes the symptoms resolve with conservative management. Other times, however, patients require operative or colonoscopic decompression of the very dilated intestine.

ORGANIC CONSTIPATION The treatment of organic constipation is dictated by the cause of the constipation. In the emergency department, the precise cause of the constipation is not always known. Emergency physicians often suspect organic causes, such as hypothyroidism and hyperparathyroidism, but seldom actually confirm these diagnoses in the emergency department. Patients in whom an organic cause of constipation is suspected and who are without evidence of obstruction may start a bowel-cleansing regimen. Fecal impaction also occurs with organic constipation (i.e., hypothyroidism or hyperparathyroidism) and must be managed aggressively, as outlined above. Constipation caused by intestinal obstruction is an emergency. Definitive treatment is dictated by the cause of the obstruction. For example, sigmoid volvulus often can be reduced by means of rigid sigmoidoscopy. Large-bowel obstruction resulting from colon cancer requires operative management. Regardless of the cause, intestinal obstruction warrants surgical consultation to assist with management decisions.

Disposition

Many constipated patients can be safely discharged from the emergency department with the caveat that certain key aspects have been adequately addressed (Table 83-6).²⁵ Patients with functional constipation with or without fecal impaction can be managed safely as outpatients provided patients with fecal impaction are disimpacted manually before discharge. Patients with organic constipation of a nonobstructive cause also can be managed safely as outpatients. The primary care provider should be contacted to ensure follow-up and to communicate concern for an organic process. If thyroid function tests

1. Possible obstructing lesion
2. Systemic illness
3. Electrolyte imbalance
4. Potential for intestinal perforation with self-administered enemas

Source: Adapted from Holson et al.²⁶

were performed, the primary care doctor should be informed so that they may be followed up.

Referral to a gastroenterologist is warranted for patients with nonorganic constipation of recent onset; chronic constipation associated with weight loss, anemia, or change in stool caliber; refractory constipation; and constipation requiring chronic laxative use.²¹ Patients with organic constipation of obstructive origin require hospitalization and surgical evaluation.

JAUNDICE

Richard O. Shields, Jr.

Jaundice is a physical finding that emergency physicians see as a presenting complaint and as an abnormal finding during the evaluation of other complaints and symptoms. Except in neonates, jaundice itself causes no adverse effects; it serves as a clinical marker of a defect in the metabolism and excretion of bilirubin. The task is to initiate laboratory evaluation or imaging studies, identify the underlying cause of jaundice, and determine whether admission or outpatient care is needed.

PATHOPHYSIOLOGY

Jaundice or icterus is the yellowish discoloration of the sclera, skin, and mucous membranes caused by the deposition of bile pigments associated with elevated levels of bilirubin in the blood (hyperbilirubinemia). Jaundice usually can be detected clinically when serum bilirubin levels reach 2.0 to 2.5 mg/dL or above, about twice the upper level of normal. It is usually first noticed in the sclera, because scleral tissue contains a large amount of elastin, which has a high affinity for bilirubin. Jaundice is easier to detect in people with light complexions and in the presence of significant anemia. The brownish discoloration of the sclerae in many people with darker complexions may be confused with scleral icterus and makes it more difficult to detect. A greenish tint to the skin indicates longstanding jaundice during which some of the bilirubin deposited in the skin has been metabolized to biliverdin. A yellow-orange discoloration of the skin can be caused by the presence of high levels of carotene in the blood (resulting from the dietary intake of large amounts of P-carotene) or by longstanding hemochromatosis. Neither will discolor the sclera.

Bilirubin, a breakdown product of hemoglobin from injured or senescent red blood cells and other heme-containing proteins, is produced in the reticuloendothelial system and then released into the plasma, where it is bound to albumin. Hepatocytes take up the bilirubin, conjugate it (mostly as mono- and diglucuronides), and excrete it through the bile channels into the small intestine. In the gut, bacterial enzymes release some of the bilirubin and reduce it to urobilinogen and the other pigments that give fecal material its typical color. Some urobilinogen is reabsorbed into the portal circulation, where most is taken up by the liver and re-excreted into the bile. A small amount reaches the kidneys and is excreted unchanged into the urine. Hyperbilirubinemia and jaundice, therefore, can be produced by an overproduction of bilirubin in the reticuloendothelial system, a failure of hepatocyte uptake of bilirubin, a failure of the hepatocyte to conjugate or excrete bilirubin, or an obstruction of biliary excretion into the intestine.

Depending on whether the defect occurs before or after the conjugation phase in the hepatocyte, two types of hyperbilirubinemia can be produced: unconjugated and conjugated. If increased production of bilirubin exceeds the ability of the liver to process it or if there is a defect in bilirubin uptake or conjugation, then levels of the unconjugated form will rise, producing unconjugated hyperbilirubinemia. Causes include hemolysis from hemoglobinopathies, hemolytic anemias or transfusion reactions, and in-born errors of bilirubin metabolism.

If the liver can produce but not normally excrete conjugated bilirubin because of a metabolic defect or intra- or extrahepatic obstruction, conjugated hyperbilirubinemia and cholestasis result. Intrahepatic cholestasis is caused by decreased excretion of conjugated bilirubin, hepatocellular damage, or damage to the biliary endothelium. Obstruction of biliary outflow by a congenital defect, inflammation, a mass lesion, or gallstones produces extrahepatic cholestasis.

It is helpful clinically to categorize conditions that produce jaundice as disorders of bilirubin metabolism (e.g., hemolysis and in-born errors), hepatocellular disorders (e.g., viral hepatitis and drug toxic-

ity), or bile duct obstruction (e.g., gallstones and tumor).¹ More than one type can be present in a given patient (Table 84-1).

CLINICAL FEATURES

A careful history and physical examination and select laboratory studies should enable the diagnosis. Often, however, more extensive diagnostic procedures, such as ultrasonography, computed tomography, or biopsy, are needed.

A family history of jaundice or a history of recurrent mild jaundice that resolves spontaneously is most consistent with a familial disorder of bilirubin metabolism, such as Gilbert, Rotor, Crigler-Najjar, or Dubin-Johnson syndrome. Most patients with sickle cell disease develop chronic jaundice from ongoing hemolysis, but in the presence of abdominal pain, vomiting, and fever, acute cholecystitis or biliary obstruction must be strongly suspected. The patient should also be asked about other hemoglobinopathies or prior episodes of hemolysis.

Hepatic causes of jaundice can be acute or chronic. The sudden appearance of jaundice in a previously healthy young person, especially if preceded by a brief prodrome of fever, malaise, and myalgias, is likely to be caused by a viral hepatitis. Inquire about body fluid exposure over the previous few months, including transfusion of blood products, intimate contact with someone with hepatitis or jaundice,

promiscuous sexual activity, intravenous drug use, accidental needle-stick injuries or mucosal contact with body fluids, travel to countries where hepatitis is prevalent, raw shellfish ingestion, and recent tattoos or body piercing. Many times, however, no history of exposure can be elicited. Right upper quadrant pain and tenderness and hepatomegaly may be present, but pruritus is usually absent. Examine for needle tracks, because patients may not volunteer a history of drug use. Jaundice caused by drugs and hepatotoxins also may appear suddenly. Toxic hepatitis should be suspected if a history of ingestion or exposure to such substances is obtained. Signs of hepatocellular damage may be present with toxicity from agents such as acetaminophen, halothane, methyl dopa, isoniazid, or phenytoin. Cholestatic changes predominate in toxicity from anabolic steroids, oral contraceptives, and chlorpromazine. *Amanita* mushroom poisoning, carbon tetrachloride, and phosphorus can produce massive hepatic necrosis.²

Jaundice that develops gradually may fall into the hepatic or bile duct obstruction categories. Alcoholic liver disease and cirrhosis are likely if jaundice is accompanied by weakness, peripheral muscle wasting, ascites, spider angiomas, pruritus, and symptoms of portal hypertension. A reliable history of sustained, significant alcohol intake should be sought from the patient or from family and friends. A history of any previous episodes of jaundice, pancreatitis, or hematemesis should be obtained. Fever, vomiting, and right upper quadrant tenderness accompany episodes of alcoholic hepatitis. The presence of asterix, fetor hepaticus, or encephalopathy indicates advanced disease.

Jaundice that develops acutely with abdominal pain, vomiting, fever, and right upper quadrant tenderness is strongly suggestive of acute cholangitis, most commonly from choledocholithiasis. A history of fatty food intolerance and typical biliary colic is supportive. Cholecystitis alone does not produce jaundice. Painless jaundice in an older patient, especially if accompanied by an epigastric mass and weight loss, strongly suggests biliary obstruction from a malignancy. A history of known gastrointestinal malignancy accompanied by a hard, nodular liver indicates metastatic disease as the cause of jaundice. A history of prior biliary tract surgery, pancreatitis, cholangitis, acquired immunodeficiency syndrome, or inflammatory bowel disease should be elicited, because these conditions may be associated with the development of biliary obstruction.

Hepatomegaly with pedal edema, jugular venous distention, and a gallop rhythm makes congestive cardiac failure the likely cause of jaundice.

LABORATORY EVALUATION

The initial laboratory evaluation of the jaundiced patient should include determinations of the serum bilirubin level (total and the direct-reacting fraction), the serum liver aminotransferase levels, and the serum alkaline phosphatase level; urinalysis for bilirubin and urobilinogen; a complete blood count; prothrombin time; and any other pertinent tests suggested by the physical examination and history (e.g., determinations of serum amylase or lipase levels). The serum bilirubin level is measured by the van den Bergh reaction with the use of two techniques to measure total bilirubin and conjugated bilirubin (the direct fraction). The indirect fraction can then be calculated by subtracting the direct fraction from the total.

If the patient has unconjugated hyperbilirubinemia, the bilirubin is usually only mildly elevated and consists predominately (>85 percent) of the indirect fraction. Because unconjugated bilirubin is tightly bound to albumin, it does not appear in the urine. Liver aminotransferase levels will be normal, and the blood count and smear may show evidence of anemia or hemolysis. A Coombs test and hemoglobin electrophoresis may be helpful if no history of hemolytic anemia or hemoglobinopathy is known. Gilbert's syndrome is the most common cause of mild unconjugated hyperbilirubinemia. This is an inherited deficiency in bilirubin conjugation that produces no symptoms other than variable elevations of bilirubin and no adverse effects. Factors

that can cause bilirubin to rise include fever, heavy physical exertion, fasting, surgery, and heavy alcohol consumption.

A direct-reacting fraction of at least 30 percent (and usually much higher) is present with conjugated hyperbilirubinemia. Conjugated bilirubin is water soluble and appears in the urine at very low serum concentrations. Urobilinogen will be absent from the urine if significant cholestasis is present. If liver enzyme levels are normal, the jaundice is caused by sepsis or recent systemic infection, in-born errors of bilirubin metabolism (such as Rotor syndrome or Dubin-Johnson syndrome), or pregnancy, rather than by primary hepatic disease. If liver enzyme levels are abnormal, which is much more common, the pattern of abnormality suggests the cause. Predominance of aminotransferase elevation is more suggestive of hepatocellular disease, such as viral or toxic hepatitis or cirrhosis, whereas marked elevations of alkaline phosphatase (two to three times normal) and - γ -glutamyl transpeptidase suggest intra- or extrahepatic obstruction, such as malignancy or gallstones.

Further laboratory testing and imaging studies should be undertaken next, directed by which type of jaundice is present. If the initial laboratory studies suggest hepatocellular disease and the clinical examination suggests viral hepatitis, then serologic studies for viral hepatitis should be done. If the clinical picture points to alcoholic liver disease or other toxins, then platelet count and serum albumin levels should be determined to help estimate the degree of liver injury. If results of the serologic studies are negative, there is no improvement with withdrawal of the suspected toxic agent, or there is no other obvious etiology, liver biopsy should be considered.

If the clinical examination and initial laboratory findings suggest intrahepatic cholestasis or extrahepatic biliary obstruction, ultrasound studies should be performed to look for gallstones, dilated extrahepatic biliary ducts, or masses in the liver, pancreas, or portal area. Computed tomography also can be used but is usually more costly, involves radiation exposure, and is less sensitive than is ultrasound at detecting stones in the gallbladder.

DISPOSITION

Jaundice alone is not an indication for admission. A hemodynamically stable patient with new-onset jaundice without evidence of liver failure or acute biliary obstruction can be discharged from the emergency department, if the appropriate laboratory studies have been ordered and follow-up has been arranged. Surgical consultation should be obtained if extrahepatic biliary obstruction is suspected. For other admission indicators, refer to the appropriate chapters in this text.

CHOLECYSTITIS AND BILIARY COLIC William

J. Brady Thomas P.
Aufderheide Judith E.
Tintinalli

Biliary tract emergencies result primarily from obstruction by biliary calculi in the gallbladder and bile ducts. The four major biliary tract emergencies related to gallstones include biliary colic (symptomatic cholelithiasis), cholecystitis, gallstone pancreatitis, and ascending

cholangitis. While gallstones are common, most are asymptomatic. The incidence of new-onset biliary pain among patients with previously asymptomatic gallstones is about 2 percent per year for the first 5 years and 15 percent at 10 years.¹ Although the classic patient with symptomatic biliary tract disease is an obese female aged 20 to 40 years, the disease occurs in all age groups and must be especially considered in diabetics and the elderly.² Upper abdominal pain is the chief complaint most predictive of biliary colic or cholecystitis.³

Certain patient subpopulations exhibit gallstone-related illness at differing rates and in differing fashion. Cholelithiasis can occur in children, albeit infrequently. Gallstones in this age group may be idiopathic or may develop due to hemolytic disorders, cystic fibrosis, obesity, ileal resection, or long-term use of total parenteral nutrition. Among pregnant patients, recent reports support a strong association between pregnancy and gallstone formation. Valdivieso and colleagues⁴ studied the natural history of gallstones during pregnancy. Using ultrasound, they reported that 12 percent of the recently pregnant women had gallstones versus 1.3 percent of the nonpregnant control group. Maringhini et al⁵ demonstrated not only an increase in the incidence of biliary sludge and gallstones as pregnancy progressed, but the resolution of these same stones postpartum. While pregnancy seems to predispose to cholelithiasis, cholecystitis remains uncommon.⁶ The elderly have a reasonably high incidence of symptomatic gallstones and related complications; the overall frequency of gallstone disease in the elderly has been estimated to be between 14 and 27 percent based on large population studies.⁷ Elderly patients with acute cholecystitis are more likely than younger patients to have biliary sepsis and gangrenous changes in the gallbladder, resulting in increased perioperative morbidity. The increased severity of cholecystitis in the elderly is thought to be secondary to impaired immune defense mechanisms, delays in diagnosis, and comorbidities common to this age group. Mortality rates of 19 percent have been reported.⁸

A number of risk factors (Table 85-1), including familial tendency, are associated with cholecystitis and calculi. Clinical characteristics associated with an increased risk of the development of pigment stones are Asian descent, chronic biliary tract infection, parasitic infection (e.g., *Ascaris lumbricoides*), chronic liver disease (particularly related to alcohol), and chronic intravascular hemolysis (sickle cell anemia and hereditary spherocytosis). Hepatitis A, B, C, and E viruses; HIV; and the herpesviruses are associated with viral cholangitis and hepatitis.⁹

PATHOPHYSIOLOGY

Bile is manufactured in and secreted from hepatocytes and transported to the gallbladder for storage via the canaliculi, ductules, and bile ducts. The bile ducts become progressively larger and eventually coalesce to form the right and left hepatic ducts, which unite to form the common hepatic duct. The common hepatic duct joins with the cystic duct from the gallbladder to form the common bile duct, which empties into the duodenum through the ampulla of Vater. The pancreatic duct often merges with the common bile duct immediately prior to entering the duodenum. The wall of the gallbladder is innervated with sympathetic and parasympathetic nerves from the celiac plexus.¹⁰

Bile is composed primarily of water (80 percent), bile acids (10 percent), lecithin and other phospholipids (4 to 5 percent), cholesterol (1 percent), conjugated bilirubin, electrolytes, mucus, and various proteins. The major stimulus for release of bile is the gastrointestinal hormone cholecystokinin, which is secreted from the small intestinal mucosal cells when fats and amino acids enter the duodenum. Cholecystokinin causes forceful contraction of the gallbladder, relaxation of the sphincter of Oddi, increased hepatic bile production, and ultimately release of bile into the duodenum for digestion of a meal. Approximately 95 percent of bile is conserved via enterohepatic circulation.

Gallstones, crystalline structures formed from both normal and abnormal bile components, are divided into three major types: cholesterol (70 percent), pigment (20 percent), and mixed (10 percent). Cholesterol stones, the most commonly encountered gallstones, contain more than 70 percent cholesterol monohydrate. The formation of such stones is complex, involving cholesterol supersaturation of the bile; the formation of monohydrate crystals, with aggregation into successively larger structures; and delayed gallbladder emptying with bile stasis. Pigment stones are subdivided into black and brown varieties. Black stones are noted in patients with advanced liver disease and hemolytic disorders, while brown stones are found commonly in patients of Asian descent, usually resulting from bacterial or parasitic infection. Both subtypes of pigment stones result from abnormal solubilization of unconjugated bilirubin coupled with the precipitation of calcium salts. The calcium content of cholesterol stones is much lower than that of pigment stones, making cholesterol stones most frequently radiolucent and pigment stones radiopaque. Anatomically, cholesterol gallstones are found in the gallbladder, cystic duct, intrahepatic ducts, and common bile duct. Brown pigment stones have a distribution similar to that of cholesterol gallstones, while black stones occur exclusively in the gallbladder.

The pathogenesis of symptomatic cholelithiasis involves stone migration from the gallbladder into the biliary tract and eventual obstruction. The stone, once lodged in either the cystic or common bile duct, produces increased intraluminal pressure and distention of the hollow viscus, resulting in pain, nausea, and vomiting. Forceful, repetitive contractions of the entire biliary system may relieve the obstruction. If obstruction persists, particularly in either the cystic duct or the infundibulum of the gallbladder, acute cholecystitis may develop. The inflammatory response in acute cholecystitis results from a combination of three factors: mechanical, chemical, and infectious. The mechanical factor produces the rise in intraluminal pressure and distention of the viscus, which culminates in visceral ischemia. Chemical inflammation occurs with the release of various mediators (lysolecithin, phospholipase A, and prostaglandins), resulting in direct mucosal injury. The contribution to the inflammatory response by bacterial agents is variable, occurring in 50 to 80 percent of patients with acute cholecystitis. Bacterial pathogens include Enterobacteriaceae (70 percent, particularly *Escherichia coli* and *Klebsiella* species), enterococci (15 percent), *Bacteroides* (10 percent), *Clostridium* species (10 percent), group D *Streptococcus*, and *Staphylococcus* species. The inflammatory process may progress to gangrene of the gallbladder wall with or without perforation.

Gallstone pancreatitis is similarly multifactorial, since it is experimentally produced by injecting bile, bacteria, and trypsin under pressure.¹¹

CLINICAL FEATURES

Gallbladder diseases is a continuum, ranging from asymptomatic cholelithiasis, to biliary colic, to acute cholecystitis. Location, radiation, and duration of pain are *all* poor discriminators of gallbladder disease. There is overlap of signs and symptoms with peptic ulcer disease, gastritis, esophageal reflux, and nonspecific dyspepsia. In addition, it has been difficult to determine which symptoms are attributable to biliary tract disease.^{12,13} RUQ pain is a common symptom in patients with and without gallstones.^{3,14} Up to 25 percent of post-cholecystectomy patients may experience RUQ pain of unknown cause. Upper abdominal or epigastric pain is the predominant symptom of biliary tract disease^{3,14} thus accounting for the difficulty in using clinical signs and symptoms to make or exclude the diagnosis. Radiation of pain to the left upper back appears to be more commonly associated with biliary tract disease than with other upper gastrointestinal disorders, with a likelihood ratio of 4.0 for gallbladder pathology.¹⁴ In fact, no single clinical finding has a negative LR sufficient to rule out the diagnosis.¹⁵ The duration and character of the pain are also nonspecific, but the pain of biliary colic is reported to persist for 2 to 6 h. Pain quality is generally persistent, not colicky, and pain episodes are infrequent, occurring at intervals of more than a week.⁹ Gallstone pain is not related to meals in at least one-third of patients,^{14,16} and clinical studies have not been able to identify an association with fatty food intolerance that is different from its association with a number of other upper gastrointestinal disorders.^{3,14,16} Investigators have noted a circadian rhythm to biliary colic,¹⁶ with a peak of symptoms occurring around midnight to 1 a.m., and a time distribution from 9 p.m. to 4 a.m. Attacks tend to recur at the same time. This circadian rhythm has obvious diagnostic implications for patients who present with upper abdominal pain during the midnight shift.

Acute cholecystitis usually begins with pain similar to that of biliary colic but that persists beyond the typical 6 h. Associated nausea, vomiting, and anorexia are noted; a history of fever and/or chills is not uncommon. Patients may have either a history of similar attacks or documented gallstones. As the inflammatory process progresses, the patient's pain changes in character and location from visceral (dull and poorly localized mid-upper abdominal) to parietal (sharp and localized RUQ). The examination reveals a patient in moderate-to-severe distress with signs of systemic toxicity, including tachycardia and fever. The abdomen is tender in the RUQ, at times with evidence of localized peritoneal irritation, distention, and hypoactive bowel sounds. Generalized peritonitis with rigidity is rare and, if found, suggests perforation. The Murphy sign—worsened pain or inspiratory arrest resulting from deep, subcostal palpation on inspiration—has been estimated to be 97 percent sensitive for acute cholecystitis.³ However, a recent metaanalysis³ of 17 studies calculated a sensitivity of 65 percent and specificity of 87 percent, an LR (+) of 2.8 (95% CI 0.8-8.6) and an LR (-) of 0.5 (95% CI 0.2-1.0) for Murphy sign. Volume depletion is frequently found. Jaundice, usually not present, may be found in patients with prolonged biliary obstruction with late onset of inflammation or in cases of chronic intravascular hemolysis.

Acalculous cholecystitis, which occurs in 5 to 10 percent of patients with acute cholecystitis, tends to have a more rapid, malignant course. Patients frequently are elderly and have a history of diabetes mellitus. Other risk factors include multiple trauma, extensive burn injury, prolonged labor, major surgery, gallbladder torsion, systemic vasculitic states, and bacterial or parasitic infections of the biliary tract. Patients with acalculous cholecystitis are indistinguishable from those with calculous cholecystitis with two major exceptions: acalculous cholecystitis frequently occurs as a complication of another process

TABLE 85-2 Clinical Manifestations of Gallbladder Disease

Shock

(e.g., multiple trauma or extensive burns), and patients frequently are gravely ill on initial presentation.

Refer to Table 85-2 for a comparison of the clinical manifestations of the continuum of gallbladder disease.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of biliary colic includes other conditions associated with upper abdominal pain, including gastritis, gastroesophageal reflux, pancreatitis, hepatitis, and peptic ulcer disease. Atypical myocardial infarction should be considered in older patients. Acute renal colic can be associated with upper abdominal and upper back pain. Both conditions can also be associated with flank tenderness, nausea, and vomiting. Renal colic does not have a circadian rhythm, and the pain is colicky, not continuous as in biliary colic. Nonetheless, it can be difficult to distinguish biliary from renal colic, and definitive imaging studies may be needed to make the correct diagnosis. Acute pyelonephritis, like cholecystitis, can be associated with flank and upper quadrant pain, but pyuria confirms the former diagnosis. Appendicitis can sometimes be associated with RUQ pain, especially in pregnancy or in patients with a retrocecal or redundant appendix. In women of childbearing age, the differential diagnosis is expanded to include a wide variety of gynecologic disorders, including pelvic inflammatory disease, perihepatitis (Fitzhugh-Curtis syndrome), and ectopic pregnancy. Pregnancy testing, gynecologic history, and pelvic examination should focus on the correct diagnosis. Finally, pneumonia or pleural effusion can be associated with RUQ pain. Diagnosis is confirmed by chest x-ray. However, pancreatitis can also be associated with pleural effusions, usually on the right.

DIAGNOSTIC STUDIES

Because of the poor predictive value of history, physical examination, and laboratory findings for cholecystitis, the most important features for diagnosis are a high clinical suspicion and ultrasound imaging.³ Results of laboratory studies in patients with biliary colic are frequently normal.³ The hemogram may reveal chronic anemia with or without evidence of hemolysis in patients with pigment stones. The white blood cell count, serum bilirubin level, alkaline phosphatase level, and aminotransferase levels are often normal. The serum lipase level should be obtained to rule out pancreatitis. The urine must be examined to exclude other causes of abdominal pain. In females, serum or urine pregnancy testing should be performed to rule out obstetric causes of abdominal pain. A negative pregnancy test result also enables one to proceed safely with radiologic studies, if indicated.

The presence of leukocytosis or abnormal liver function study results or lipase levels are often used as indicators for the diagnosis of acute cholecystitis. However, no single test or combination of laboratory tests has a sufficiently high sensitivity to detect acute cholecystitis.^{3,17} A

retrospective review of ED patients with acute cholecystitis found that 32 percent lacked a white blood cell count greater than 11,000 cells/mL.¹⁸ Typical signs, symptoms, and laboratory findings may not be present in patients over age 60. The sensitivity of Murphy sign was only 48 percent in the elderly.¹⁹ In a cohort of geriatric emergency department patients with abdominal pain who were determined at surgery to have acute cholecystitis, 56 percent were afebrile, 41 percent had no leukocytosis, and 13 percent were both afebrile and had normal values on routine laboratory tests.²⁰

Additional studies in patients with biliary colic may be performed to support the diagnosis and rule out other causes of upper abdominal pain with nausea. Plain film radiographs of the abdomen demonstrate gallstones in only 10 to 20 percent of cases. The majority of stones are cholesterol and therefore radiolucent. Pigment and mixed stones containing at least 4 percent calcium by weight are radiopaque. Abdominal films are more useful in excluding other causes of pain. A chest radiograph should be obtained to identify right lower lobe pneumonia or pleural effusions. A 12-lead electrocardiogram should be considered in older patients to exclude an acute coronary syndrome.

Ultrasonography is now the initial diagnostic modality of choice. It may show the presence of stones as small as 2 mm, gallbladder distention, wall thickening, and pericholecystic fluid, and during the procedure a sonographic Murphy sign may be elicited. Ultrasonography has an unadjusted sensitivity of 94 percent and a specificity of 78 percent for the diagnosis of acute cholecystitis,²¹ and when adjusted for spectrum bias, sensitivity is 88 and 80 percent. These figures can be replicated by emergency-physician-performed ultrasound examinations.^{22,23} The sonographic Murphy's sign was found to be present in emergency physician examinations (sensitivity, 75 percent) more often than in radiological examinations (sensitivity, 45 percent). The decreased accuracy of emergency physicians in determining pericholecystic fluid, wall thickness, air in the gallbladder, and ductal dilatation did not result in any adverse outcomes. The reduction in length of ED stay from 223 min to 180 min was the major advantage of emergency physician ultrasound.²² A recent prospective study²⁴ investigated the use of ultrasound by the emergency physician (EP) in the evaluation of the right upper quadrant pain. In this study, EPs performed ultrasound examinations on 116 such patients. Using formal abdominal ultrasound performed by radiology as the gold standard, EP exhibited reasonably high rates of agreement for detecting cholelithiasis and lesser rates of agreement for the diagnosis of cholecystitis. The authors concluded that ultrasound performed by the EP may be used to exclude cholelithiasis. They cautioned, however, that EPs with limited experience must interpret scans revealing possible cholecystitis with caution and advise that a confirmatory test is warranted before cholecystectomy.²⁴

Computed tomography (CT) scanning can be most useful in the diagnosis of acute cholecystitis when other intraabdominal disorders are considerations in the differential diagnosis. Wall thickening, pericholecystic fluid, and subserosal edema can be identified. However, the sensitivity of CT scanning is insufficient (as low as 50 percent) for it to replace ultrasonography as the diagnostic procedure of choice.²⁵

Radioisotope cholescintigraphy using technetium-iminoacetic acid analogues (HIDA) has a sensitivity and specificity of 97 and 90 percent, respectively.²¹ The study is performed by injecting radioisotopes intravenously. The material is absorbed by the hepatocytes and secreted into the biliary tract. A normal patient will have a clearly outlined gallbladder and cystic duct within 1 h. Failure to demonstrate the gallbladder within this time frame is consistent with cystic duct obstruction. The HIDA scan can only be used in patients with a serum bilirubin level of less than 5 mg/dL. With serum bilirubin above this level, an alternative radioisotope study, the DISIDA scan, is preferred.

COMPLICATIONS

Fluid and electrolyte deficits due to protracted vomiting and anorexia, and upper gastrointestinal hemorrhage from emesis-related Mallory-

Weiss tears can coexist with biliary tract emergencies. Complications associated with cholelithiasis include gallstone pancreatitis, ascending cholangitis, and cholecystitis. Patients with cholecystitis may further develop a number of serious complications, including gallbladder empyema and emphysematous (gangrenous) cholecystitis.

Approximately 70 percent of cases of acute pancreatitis are due to either gallstones or alcohol. Depending on the population studied, gallstones are involved in 30 to 70 percent of patients with acute pancreatitis. Of all patients with gallstones, 15 to 20 percent will develop pancreatitis as a result of biliary calculi. Patients with pancreatitis due to gallstones will present similarly to patients with pancreatic inflammation caused by ethanol, with epigastric or diffuse abdominal pain radiating to the back, associated with nausea and vomiting. Patients may manifest symptoms of both acute cholecystitis and acute pancreatitis. Management includes intravenous fluids, nasogastric decompression, analgesics, and parenteral antibiotics (Table 85-3) with subsequent surgery. In patients who present in extremis or in those who demonstrate clinical deterioration, urgent biliary decompression (surgical or endoscopic) is mandatory.

Ascending cholangitis is a life-threatening emergency with a mortality rate approaching 100 percent in untreated or improperly treated patients. The process results from complete biliary obstruction in the presence of bacteria (gram-negative organisms as well as enterococcal and various anaerobic species). As the obstruction persists, intraluminal pressure increases, resulting in reflux of bacteria into the lymphatic vessels and hepatic veins, with eventual entrance into the systemic circulation. The obstruction most often is due to choledocholithiasis (gallstone obstruction of the common bile duct) and less often to biliary tract strictures, surgical anastomotic strictures, various postprocedural complications, and extrinsic compression from malignancy. Patients present with jaundice, fever, RUQ pain, mental confusion, and shock. The classic Charcot triad of fever, jaundice, and RUQ pain is noted in only 25 percent of patients. Management includes initial volume resuscitation with vasopressor support in cases unresponsive to crystalloid infusion alone, broad-spectrum parenteral antibiotics, and rapid decompression (surgical or endoscopic) of the biliary tree.

Gallbladder empyema, a life-threatening complication of cholecystitis, results from complete obstruction of the cystic duct with bacterial infection of the stagnant bile and abscess formation within the gallbladder wall. Risk factors include age, diabetes mellitus, trauma, burns, vasculitis, and bacterial or parasitic infections of the biliary tract. The presentation is similar to cholangitis, with fever, RUQ pain, altered mentation, and hypotension. Patients frequently develop gram-negative sepsis and require immediate broad-spectrum antibiotic coverage, fluid resuscitation, and urgent surgical consultation for cholecystectomy. The outcome is poor without prompt definitive care.

Gangrene of the gallbladder wall may be focal or diffuse. Focal gangrene results from segmental ischemia of the gallbladder wall caused by severe distention, acute inflammation, empyema, torsion with arterial compromise, or coexisting vasculitis. Patients with diabetes mellitus are at risk for this complication. Perforation of the wall may occur in a contained fashion (into the omentum) or free (into the peritoneal cavity).

TABLE 85-3 Antibiotic Choices for Acute Cholecystitis with Sepsis and Ascending Cholangitis

Ampicillin, gentamicin, and metronidazole
Ciprofloxacin and/or metronidazole
Piperacillin-tazobactam
Ampicillin-sulbactam
Ticarcillin-clavulanate
Imipenem
Third-generation cephalosporin and metronidazole or clindamycin
Aztreonam and clindamycin

Gangrene of the entire gallbladder, also known as emphysematous cholecystitis, is an uncommon complication, occurring in approximately 1 percent of patients with cholecystitis. Emphysematous cholecystitis is acalculous in 30 percent of patients. The gallbladder wall becomes ischemic, with eventual bacterial infection and gangrene. Patients present in extremis with fever, RUQ pain, and septic shock. Plain-film radiographs may demonstrate air in the gallbladder itself, the gallbladder wall, or the biliary tree because of the frequent presence of gas-forming organisms. An abdominal CT scan is the suggested imaging study. The bacteriology of either focal or diffuse gallbladder gangrene includes gram-negative, gram-positive, and anaerobic organisms. Polymicrobial infection is common. Management is similar to that of gallbladder empyema. Mortality rates for gangrenous cholecystitis are very high because of associated sepsis and attendant comorbidity in the typical elderly diabetic patient.

TREATMENT

Patients with accurately diagnosed uncomplicated symptomatic cholelithiasis do not necessarily require immediate surgical intervention. Patients presenting with biliary colic and emesis are best treated with antispasmodic agents (glycopyrrolate), opiate analgesics (meperidine), and antiemetics (promethazine). Meperidine is the analgesic of choice because it produces significantly less spasm of the sphincter of Oddi than do other narcotic agents, such as morphine. Ketorolac tromethamine has been shown effective in relieving the pain of gallbladder distention. This distention causes the release of prostaglandins, which are associated with the production of pain. Ketorolac inhibits the production of prostaglandins, which may explain why it is effective in this situation. It is not as effective in relieving pain in the presence of infection. Gastric decompression with nasogastric suction may be warranted for protracted vomiting. Volume deficits and electrolyte imbalance can be corrected with isotonic intravenous fluids. With an accurate diagnosis, resolution of symptoms, correction of intravascular volume deficits, and a demonstrated ability to maintain hydration orally, the patient may be discharged from the ED. Prior to discharge, the case should be discussed with a surgical consultant or the patient's primary care physician to arrange for timely outpatient follow-up. Patients may be given oral narcotic-acetaminophen pain medication for the common residual abdominal aching. If the symptoms do not resolve within a 4- to 6-h period in the ED, the diagnosis of biliary colic must be questioned. Such prolonged pain may represent early, acute cholecystitis.

Patients with uncomplicated symptomatic cholelithiasis have several options for definitive treatment, including open or laparoscopic cholecystectomy, medical dissolution therapy, and gallstone lithotripsy. Open cholecystectomy with intraoperative cholangiogram provides definitive cure for patients with biliary colic. The laparoscopic technique is rapidly replacing the traditional open cholecystectomy as the procedure of choice. Patients with frequent or severe attacks of biliary colic, a history of associated complications of gallstones, large biliary calculi (>2 cm in diameter), a congenitally abnormal hepatobiliary system, diabetes mellitus, or a desire for rapid cure are best managed with open or laparoscopic cholecystectomy or endoscopic retrograde cholangiopancreatography with possible endoscopic sphincterotomy (ES). Approximately 5 percent of patients have complications from cholecystectomy. The majority of these adverse outcomes are wound infections. Abscess, hemorrhage, bile leakage, and fistula formation are infrequent. Approximately 8 percent of patients develop complications from ES. Pancreatitis and hemorrhage are the most common complications within 30 days of the procedure. Complications occurring months to years later, such as recurrent stones and cholangitis, are seen in about 10 percent of patients. Medical dissolution therapy with oral bile acid treatment is an option for those with small radiolucent stones (about 10 percent of patients).

Treatment of calculous and acalculous acute cholecystitis is surgical. Basic supportive medical therapy occurs in the emergency department prior to hospital admission and/or surgery. As with biliary colic, patients with acute cholecystitis require volume resuscitation with intravenous isotonic fluid, pain control with opiate analgesics, and bowel rest with nasogastric suction and antiemetic agents. Antibiotic treatment is recommended despite the questionable role of acute infection in all cases of early acute cholecystitis. In patients presenting without sepsis, single-agent therapy with a third-generation cephalosporin is adequate. In patients with sepsis, a widened spectrum of antibiotic therapy is recommended (see Table 85-3).

Patients with obvious infection should receive broadened coverage with ampicillin, gentamicin, and clindamycin, or the equivalent (see Table 85-3). A minority of patients (usually those with either acalculous or emphysematous cholecystitis or a complication of cholecystitis) present in septic shock and require aggressive resuscitation. All patients with acute cholecystitis must be admitted to the hospital for continued intravenous fluid therapy and antibiotics. Approximately 75 percent of patients treated medically have a complete remission of symptoms within 2 to 7 d of hospitalization; the remainder of patients experience either a progression of the inflammatory process or a complication of acute cholecystitis within this time frame. Most often, surgery is performed 24 to 72 h after admission, once symptoms have resolved. Surgical options include open or laparoscopic cholecystectomy. Patients with a toxic presentation or clinical deterioration require immediate surgery.

Source: National Center for Infectious Diseases. Viral Hepatitis Surveillance. Disease Burden from Hepatitis A, B, and C in the United States. http://www.cdc.gov/ncidod/diseases/hepatitis/resource/dz_burden02.htm.

Alcoholic liver disease and viral hepatitis comprise the vast majority of cases of acute and chronic liver disease. Other causes include a variety of toxins, idiosyncratic drug reactions, and autoimmune and metabolic hepatobiliary diseases.^{4,10,12}

Pathophysiology

Hepatobiliary diseases are classified according to the main pathologic processes involved and include hepatocellular, cholestatic, immunologic, and infiltrative disorders. Considerable overlap occurs among these different processes, with a common result being progressive hepatic dysfunction.

Hepatic cirrhosis results from fibrous scarring mixed with hepatocyte regeneration in response to sustained inflammatory, toxic, or metabolic insults. Over time, the functional anatomy of the liver is replaced by scar tissue, isolating nodules of regenerating hepatocytes. These isolated foci are less efficient at performing the metabolic functions of the normal, highly structured liver. In addition to causing progressive loss of synthetic and metabolic function, scarring increases resistance to blood flow from the splanchnic circulation, leading to portal hypertension and portal-systemic shunting. Reduced blood flow through the liver deprives the remaining hepatocytes of substrate for synthesis of essential proteins and degradation of toxins, worsening the metabolic deficiencies of chronic liver disease. Portal hypertension results in splenomegaly and the development of gastroesophageal varices. Varices are thin-walled submucosal vessels prone to ulceration and hemorrhage. Splenomegaly contributes to anemia and thrombocytopenia.

Ascites develops secondary to portal hypertension. Abnormalities in renal sodium and water excretion [caused by diminished glomerular filtration rate (GFR) and elevations in both aldosterone and anti-diuretic hormone] also contribute to ascites. Ascites worsens chronic fatigue and compromises respiratory function. It sets the stage for recurrent episodes of spontaneous bacterial peritonitis. Encephalopathy results from the accumulation of a variety of neurotoxic substances. Each of these complications will be further addressed below.¹⁰

Clinical Features

Clinical presentation of acute liver disease is variable. Symptoms of hepatocellular necrosis accompanying viral hepatitis include anorexia, nausea, vomiting, and low-grade fever. Cholestatic disease is accom-

HEPATIC DISORDERS AND HEPATIC FAILURE

Joshua S. Broder
Rawden Evans

This chapter will review the epidemiology, pathophysiology, and clinical presentations of acute and chronic liver failure. It will summarize laboratory testing and evidence-based emergency diagnosis and management of complications of hepatic failure, including gastrointestinal hemorrhage, spontaneous bacterial peritonitis, hepatorenal syndrome, and hepatic encephalopathy. The differential diagnosis of jaundice is discussed in Chap. 84, and cholecystitis and biliary colic are discussed in Chap. 85.

ACUTE AND CHRONIC LIVER DISEASE

Epidemiology

In the year 2000, chronic liver disease was the twelfth leading cause of death in the United States and the tenth leading cause of death among U.S. men, accounting for 17,214 deaths (1.5 percent).^{1m3} Despite the high toll of chronic liver disease, new infections with hepatitis viruses A, B, and C actually declined in the last decade in the United States (Table 86-1).

About one-third of the U.S. population has acquired immunity to hepatitis A virus (HAV). There are approximately 125,000 to 200,000 cases of HAV infection reported yearly, with an estimated 100 related deaths. Fulminant liver failure is a rare complication of HAV infection, and chronic infection does not occur.^{4,5}

Vaccination against hepatitis B virus (HBV) has reduced the incidence of fulminant hepatic failure by as much as three-quarters in some studies.⁶ Chronic infection occurs in only 6 to 10 percent of cases of hepatitis B. In contrast, chronic hepatitis C occurs in 85 percent of those infected, with 70 percent developing resulting chronic liver disease.^{7,8}

The hepatitis D virus (HDV) is uncommon and is described as a defective agent because infection depends on concomitant or preexisting chronic infection by HBV. In individuals with chronic HBV infection, superinfection with HDV often results in a rapidly progressive or fulminant form of liver disease carrying a high short-term mortality rate. This variety of infection is most commonly associated with intravenous drug use.⁹

Acute illness with liver function test abnormalities also occurs with infection by other hepatotropic viruses such as cytomegalovirus (CMV), herpes simplex virus (HSV), Coxsackie virus, and Epstein-Barr virus (EBV), although these agents are unlikely to cause clinically evident hepatitis and jaundice in otherwise healthy individuals.

panied by jaundice, pruritus, clay-colored stools, and dark urine. Cholestasis resulting from intrahepatic processes and infiltrative disease presents more insidiously with the slow development of jaundice and few other constitutional complaints.

Chronic liver disease often presents with complications of advancing cirrhosis and portal hypertension that include abdominal pain, ascites, gastrointestinal bleeding, fever, and altered mental status. However, progressive generalized fatigue may be the only symptom of chronic liver disease in the absence of supervening complications.

Features of history are sometimes useful: sexual behaviors, travel, volume and duration of alcohol use, illicit drug use, consumption of nutritional supplements (vitamin A), history of blood transfusions, needle-stick blood exposures, herbal remedies, mushroom ingestion, or raw oyster consumption.

Family history can identify some hereditary conditions that cause only mild symptoms or laboratory abnormalities (e.g., Gilbert syndrome, Dubin-Johnson, or Rotor syndrome). Other familial disorders can lead to severe, premature, chronic liver failure. Examples include Wilson disease, hemochromatosis, or α_1 -antitrypsin deficiency.

Physical findings of acute hepatitis often are limited to moderate liver enlargement and tenderness, with or without jaundice. Chronic liver disease is accompanied by a host of physical findings, including sallow complexion, extremity muscle atrophy, palmar erythema, cutaneous spider nevi, parotid gland enlargement, and testicular atrophy and gynecomastia. The liver may be uniformly enlarged and firm or, in advanced cirrhosis, shrunken and grossly nodular. Splenomegaly and ascites accompany portal hypertension.

Liver Function Tests

Laboratory tests for hepatobiliary disease can be divided into three general categories: (1) markers of acute hepatocyte injury and death, (2) measures of hepatocyte synthetic function, and (3) indicators of hepatocyte catabolic activity. Traditional liver function tests are actually a mix of markers of hepatocyte injury, including aspartate aminotransferase (AST or SGPT), alanine aminotransferase (ALT or SGOT), and alkaline phosphatase, and indicators of hepatocyte catabolic activity (direct and indirect bilirubin). Tests that reflect hepatocyte synthetic function include prothrombin time and albumin. Ammonia reflects catabolic function of the liver, although levels do not correlate accurately to clinical status.

BILIRUBIN Bilirubin is a metabolite of heme proteins, including hemoglobin, myoglobin, and cytochromes. Laboratory tests for bilirubin are conducted by an assay that differentiates the conjugated form (direct bilirubin) from the unconjugated form (indirect bilirubin). Unconjugated bilirubin has poor water solubility and is carried in serum tightly bound to albumin. This complex is taken up by hepatocytes, which conjugate the bilirubin, increasing its water solubility, before secretion it into the bile. Bilirubin is then excreted in the stool, with a small percentage undergoing enterohepatic recirculation. Normally, the total serum bilirubin level is less than 1.1 mg/dL, with 70 percent being unconjugated.

An increase in the supply of unconjugated bilirubin reaching the liver (e.g., due to erythrocyte hemolysis) may temporarily exceed the capacity of hepatocytes to conjugate bilirubin, increasing both the indirect and total values. As hepatocytes conjugate the excess substrate, the direct bilirubin also will increase.

Similarly, decreased hepatocyte metabolic capacity (e.g., due to chronic or acute hepatocyte injury) can increase indirect and total bilirubin. Bilirubin is also elevated in states of biliary stasis or obstruction (e.g., due to an obstructing gallstone).

TRANSAMINASES Transaminases are intracellular enzymes found in hepatocytes and some other cell types. Hepatocyte injury or necrosis results in release of these enzymes into the circulation, just as cre-

atine phosphokinase and troponin are released in conditions of myocyte injury and death. Elevated levels may result from any hepatocyte injury, whether induced by infection, ischemia, or toxins such as alcohol, acetaminophen, carbon tetrachloride, or hepatotoxic mushrooms. Elevations in the hundreds of units per liter suggest mild injury, whereas levels in the thousands suggest extensive acute hepatic necrosis. This test may be near normal in end-stage liver failure, where no acute hepatocyte injury occurs.

Commonly measured transaminases include AST and ALT. AST is a nonspecific marker because it is found not only in liver but also in heart, smooth muscle, kidney, and brain. Elevated AST also may be due to medications, including acetaminophen, nonsteroidal anti-inflammatory drugs, angiotensin-converting enzyme (ACE) inhibitors, nicotinic acid, isoniazid, sulfonamides, erythromycin, griseofulvin, and fluconazole. ALT is a more specific marker of hepatocyte injury.

Calculation of the AST-ALT ratio may suggest the etiology of hepatic injury. A ratio of greater than 2 is common in alcoholic hepatitis because alcohol stimulates AST production. A ratio of less than 1 is typical of acute or chronic viral hepatitis. In the absence of active alcohol use, mild elevations of AST and ALT and a ratio greater than 1 suggest underlying cirrhosis.

ALKALINE PHOSPHATASE Elevated alkaline phosphatase (AP) is associated with biliary obstruction and cholestasis. Mild to moderate elevations accompany virtually all hepatobiliary disease; however, elevations greater than four times normal strongly suggest cholestasis. AP is a nonspecific marker, also derived from bone, placenta, intestine, kidneys, and leukocytes. The specificity of AP for cholestasis can be improved by comeasurement of the enzyme 7-glutamyl transpeptidase (GGTP), which when elevated supports the diagnosis of cholestasis. However, like AST, GGTP production is stimulated by alcohol consumption and is also elevated by drugs inducing hepatic microsomal enzyme activity such as phenobarbital and warfarin. GGTP may rise in acute and chronic pancreatitis, acute myocardial infarction, uremia, chronic obstructive pulmonary disease, rheumatoid arthritis, and diabetes mellitus.

Isolated significant elevation of AP without marked hyperbilirubinemia (AP-bilirubin ratio of 1000:1) is characteristic of infiltrative and granulomatous liver disease such as lymphoma, fungal infections, sarcoidosis, and tuberculosis. The uncommon conditions primary biliary cirrhosis and primary sclerosing cholangitis elevate AP disproportionately to bilirubin levels.

AP levels in healthy children are often two- to threefold higher than the upper limit of normal for adults. Doubling of AP levels is common and normal in pregnancy. Incidental findings of three- to fivefold elevations in transaminase levels and doubling of AP in otherwise healthy diabetics and the obese suggest the presence of nonalcoholic steatohepatitis (NASH). Other conditions associated with NASH include jejunoileal bypass, total parenteral nutrition, hyper- and hypothyroidism, and the antiarrhythmic drug amiodarone.¹⁴

LACTATE DEHYDROGENASE Lactate dehydrogenase (LDH) is often included in liver test panels, although its lack of specificity is limiting. Moderate elevations are seen in all hepatocellular disorders and cirrhosis but less so in purely cholestatic conditions. LDH may become significantly elevated as a result of hemolysis and accompany a related increase in unconjugated bilirubin. The isoenzyme LDH-5 is specific to the liver, and tests for it are sometimes useful, although not widely available.

AMMONIA Metabolism of nitrogen-containing compounds results in the generation of ammonia, which is further metabolized to urea via the Krebs cycle in the liver. An elevated serum ammonia level may occur in acute and chronic liver disease as a manifestation of hepatic metabolic failure. Very high ammonia levels are seen in fulminant liver failure, contributing to overall toxicity and signifying poor prognosis.

In cirrhosis with worsening portal hypertension and isolation of remaining functional hepatic tissue, ammonia formed by colonic bacteria is carried into the general circulation. This process is worsened by large intestinal protein loads such as occur with gastrointestinal bleeding. However, elevated serum ammonia levels do not reliably correlate with acute worsening of hepatic function in the cirrhotic and serve more as a marker of generalized decline than as a useful diagnostic tool or therapeutic end point.

PROTHROMBIN TIME Prolongation of the prothrombin time (PT) in liver disease reflects the decreased synthesis of the vitamin K-dependent coagulation factors II, VII, IX, and X and as such serves as a real measure of liver function. Prolonged PT is a common complication of advancing cirrhosis, although it also may be seen in acute hepatitis and exacerbations of chronic compensated liver disease. When present in acute viral hepatitis, prolonged PT often indicates severe disease with widespread hepatocellular necrosis. There is some correlation between the extent of PT prolongation and clinical outcome in fulminant liver disease.

Although PT is often used as a marker of hepatic function, abnormal values may occur in the presence of a normal liver. Abnormalities in PT also result from fat malabsorption by the gut because vitamin K is fat-soluble. Cholestatic syndromes interfere with fat absorption and thereby promote vitamin K deficiency. Vitamin K deficiency can be distinguished from liver synthetic dysfunction by administration of parenteral vitamin K (phytonadione 10 mg IM). A 30 percent reduction in PT within 24 h should occur in vitamin-deficiency states.

ALBUMIN Like PT, the albumin level reflects liver synthetic function. It may decrease in advancing cirrhosis or severe acute hepatitis, marking a poor short-term prognosis. Albumin is less useful in evaluating fulminant liver disease because its serum half-life is approximately 3 weeks, whereas PT becomes prolonged in a matter of days. Serum albumin also reflects overall nutritional status, and a low value may be nonspecific in a chronically ill individual.

VIRAL HEPATITIS SEROLOGY Serum testing for viral hepatitis is often offered as screening panels by hospital laboratories. In hepatitis A, IgM anti-HAV is detectable at the onset of clinical illness. Hepatitis B serology is somewhat more complicated. Hepatitis B surface antigen (HBsAg) is measurable *before* clinical illness and elevations in transaminases are seen and remain elevated for 1 to 2 months. Antibodies to the hepatitis B core antigen (anti-HBc) appear 2 weeks after HBsAg, and their presence is useful in defining the so-called "window period" before antibody to the surface antigen (anti-HBsAg) appears. Anti-HBc may be the only reliably positive test in the window period and also provides a rough estimate of the time of exposure for epi-

demologic purposes. Antibody testing for hepatitis C has become standardized in recent years and is now part of all viral hepatitis screening panels. The alphabetized nomenclature is expanding as more infectious agents responsible for acute and chronic liver disease are recognized. However, hepatitis A, B, and C remain the principal varieties of concern to practitioners in North America.^{5,9}

Nonhepatic Causes of Abnormal Liver Tests

Multiple nonhepatic causes may lead to abnormal liver function tests. Abnormal liver test results occur in up to one-third of those screened. Only 1 percent of these indicate clinically significant liver disease.^{15,16} Hypoalbuminemia accompanies protein wasting enteropathies, malnutrition, and nephrotic syndrome. AP elevations occur with a variety of bone diseases, pregnancy, and malignancies. AST elevations accompany acute myocardial infarction and rhabdomyolysis. Bilirubin elevations occur in severe hemolysis, sepsis, and syndromes involving abnormal erythropoiesis. PT elevations occur in vitamin K deficiency, chronic antibiotic use, warfarin therapy, and long-standing steatorrhea.

SPECIFIC CLINICAL SYNDROMES

Cirrhosis and Complications of End-Stage Liver Disease

The evaluation and treatment of patients with acute or chronic liver failure are primarily supportive. The goals are (1) to identify and eliminate any reversible cause of liver injury and (2) to identify and treat complications of hepatic dysfunction (Table 86-2). Treatment and admission criteria for liver failure patients are usually similar to those for patients without liver disease presenting with the complication in question. A few specific therapies are now emerging.

End-stage liver disease has three major consequences: loss of hepatic synthetic function, loss of hepatic degradative capacity, and portal hypertension. Complications of end-stage liver disease result from one or more of these. For example, gastrointestinal hemorrhage results from altered portal blood flow but is complicated by loss of hepatic synthetic function, with resulting coagulopathy. Life-threatening complications of end-stage liver disease include variceal hemorrhage, spontaneous bacterial peritonitis, hepatorenal syndrome, and hepatic encephalopathy, each of which will be discussed below.

Gastroesophageal Varices and Hemorrhage

Gastroesophageal varices form as intrahepatic fibrosis increases resistance to blood flow from the portal vein to the inferior vena cava. Blood flow increases through collateral vessels, including thin-walled gastric and esophageal vessels, which are prone to bleeding due to their superficial location and lack of supporting connective tissue.

TABLE 86-2 Fulminant Liver Failure

Presentation	Causes/Associations	Complications
Acute hepatocellular necrosis with rapid development of encephalopathy and liver failure developing in <8 weeks	Hepatitis B, C, D Hepatitis A (rare) Hepatotoxins Acetaminophen Isoniazid Halothane Valproic acid Mushrooms Carbon tetrachloride (Reye syndrome and acute fatty liver of pregnancy resemble fulminant liver failure, but microvesicular fatty infiltration occurs without hepatocellular necrosis)	Encephalopathy Hypoglycemia Hyponatremia Hypokalemia GI hemorrhage Renal failure Cerebral edema Sepsis Spontaneous bacterial peritonitis

The prevalence of asymptomatic esophageal varices in patients with cirrhosis correlates with the Child-Turcotte-Pugh class, reaching 35 percent in mild (class A) cases and 60 percent in moderate to severe cases (classes B and C). The prevalence of *large* varices, which may be most likely to bleed, is roughly equal among these classes (29, 24, and 24 percent, respectively).¹⁷

Mortality associated with variceal hemorrhage has decreased with the wider availability of endoscopic and pharmacologic therapy but remains high. A Veterans Administration study found that 30-day mortality in patients with variceal hemorrhage decreased from 29.6 to 20.8 percent over an 11-year period from 1981 to 1991, whereas 6-year mortality declined from 74.5 to 69.7 percent. Sclerotherapy decreased mortality in the late group to 17 and 68 percent at 30 days and 6 years, respectively.¹⁸

CLINICAL FEATURES Bleeding symptoms may include hematemesis, "coffee-grounds" emesis, melena, or (with massive hemorrhage) even bright red blood per rectum. Symptoms may be more occult, such as light-headedness, generalized weakness, or fatigue. Vital-sign abnormalities may be masked by coexisting medical conditions and medications. Patients with end-stage liver disease may have baseline hypotension due to decreased intravascular oncotic pressure, and beta blockers may prevent reflex tachycardia.

Variceal bleeding should be suspected in any patient with melena or hematemesis and a history of liver disease. Gastric lavage should be performed to identify ongoing hemorrhage and determine the need for immediate endoscopy. Patients with hemodynamic instability or continued bleeding despite lavage deserve emergent endoscopy. Known or suspected gastroesophageal varices are not a contraindication to naso- or orogastric tube placement. Review of the medical literature **shows no evidence of increased risk of iatrogenic hemorrhage from placement of naso- or orogastric catheters.**

TREATMENT Hemodynamic and airway stabilization take priority over precise diagnosis. Large-bore intravenous access should be obtained immediately, and packed red blood cells and fresh frozen plasma should be ordered in anticipation of coexisting coagulopathy. In the patient with hematemesis, hemodynamic instability, or altered mental status, early intubation should be considered.

Endoscopy Endoscopy provides definitive diagnosis of the source of bleeding and can provide direct hemostasis by banding or sclerother-

apy. Endoscopy has been shown to reduce mortality in some studies.¹⁸ However, a recent Cochrane review found *no advantage* to early endoscopy compared with pharmacologic therapy for treatment of acute variceal bleeding. Patients treated with endoscopy or one of several vasoactive drugs had similar rates of failure to achieve initial hemostasis, rebleeding, blood transfusion, and mortality. Endoscopy was associated with a greater complication rate than was pharmacotherapy.¹⁹

Balloon tamponade with inflated gastroesophageal obturators such as the Sengstaken-Blakemore tube is used infrequently because of the high rate of complications and the increasing effectiveness and availability of pharmacotherapy and endoscopic sclerotherapy. Principal complications of these devices include bronchopulmonary aspiration and esophageal rupture. p-Blockers and portosystemic shunt surgery or transjugular intrahepatic portosystemic shunts (TIPS) are effective prophylactic measures in some patients with gastroesophageal varices but have no proven role in the management of acute gastro-esophageal hemorrhage.

Pharmacotherapy A number of pharmacologic therapies are temporizing measures while awaiting assistance from a gastroenterologist or transfer of the patient to a tertiary care facility.

VASOACTIVE DRUGS As indicated earlier, sclerotherapy and vasoactive medications have similar efficacy in establishing initial hemostasis.¹⁹ However, in patients with variceal bleeding, addition of vasoactive agents to endoscopy improves initial hemostasis.²⁰ The two classes of vasoactive drugs are somatostatin and octreotide and vasopressin and terlipressin. Somatostatin and octreotide are preferred because they do not have serious side effects (Table 86-3).

Somatostatin and its synthetic analogue octreotide cause specific *relaxation* of mesenteric vascular smooth muscle, reducing portal venous pressure without arterial vasospasm. Octreotide should be considered for initial therapy due to its proven efficacy and minimal side effects. Several recent randomized, controlled studies have demonstrated similar efficacy of octreotide and sclerotherapy in the initial management of variceal bleeding.²¹⁻²⁴ Somatostatin and octreotide reduce transfusion requirements by approximately 1 unit per patient treated and slightly improve initial hemostasis.²⁵ Side effects from octreotide appear less common than with vasopressin or terlipressin therapy.²⁶ However, somatostatin and octreotide do not appear to reduce rebleeding, need for balloon tamponade, or overall mortality.²⁵

TABLE 86-3 Pharmacologic Therapy for Acute Variceal Hemorrhage

Agent	Dosing	Mechanism	Advantages	Disadvantages
Octreotide	50 µg IV bolus, then 50 µg per h continuous IV infusion	Synthetic analogue of somatostatin	Reduces transfusion requirement As effective as endoscopy Additive benefit with sclerotherapy	Minimal
Antibiotics piperacillin/tazobactam or quinolone	3.375/g IV (levofloxacin 500 mg IV or ciprofloxacin 400 mg IV or gatifloxacin 400 mg IV)			
Plus clindamycin/flagyl or cephalosporin	(ceftriaxone 2 g IV q24 or cefotaxime 2 g IV q8)			
Plus clindamycin/flagyl or ampicillin Plus clindamycin	2 g IV plus gentamycin 900 mg IV			
Somatostatin (endogenous hormone)	250–500 µg IV bolus, then 250–500 µg per h continuous IV infusion	Decreases portal pressure by specific relaxation of mesenteric vascular smooth muscle	—	Minimal

SECTION 9 • GASTROINTESTINAL EMERGENCIES

Vasopressin and its synthetic analogue terlipressin act by nonspecific *arterial vasoconstriction*, reducing inflow through the mesenteric circulation and thereby reducing portal pressure. Side effects of end-organ ischemia are potentially severe, including stroke, myocardial infarction or arrhythmia, mesenteric infarction, or limb ischemia. Because of its adverse-effect profile, vasopressin generally is not given in the ED; terlipressin generally is not available in the United States.²⁷

ANTIBIOTICS A recent Cochrane review found that antibiotic therapy reduced all-cause mortality from variceal bleeding by 27 percent and infections by 60 percent with minimal side effects. Empirical therapy should cover enteric organisms.²⁸

Ascites and Spontaneous Bacterial Peritonitis

Ascites and anasarca commonly develop in cirrhotic patients due to the combination of portal hypertension, hypoalbuminemia, and poor renal excretion of sodium and water. These factors increase the transportal hydrostatic pressure gradient and decrease the intravascular oncotic pressure, leading to transit of water into the extracellular space and peritoneum. Patients may complain of abdominal pain and dyspnea due to abdominal distention that may limit diaphragmatic movement. Moreover, hydrothorax may occur in the presence of diaphragmatic hernias, and abdominal contents may herniate into the thorax.

Spontaneous bacterial peritonitis occurs as normal bowel flora translocate across the bowel wall, a process facilitated by bowel wall edema and poor production of immunologically active proteins by the liver. Once in the peritoneum, bacteria benefit from a poorly defended site with an ample growth medium, ascites. Antibiotic therapy must target normal bowel flora, including anaerobes and gram-negative rods.

CLINICAL FEATURES The most common life-threatening complication of ascites is spontaneous bacterial peritonitis (SBP), classically presenting with fever and diffuse abdominal pain and tenderness. However, fever may be absent. In patients with known ascites, the 1-year incidence of spontaneous bacterial peritonitis is 29 percent. Recurrence of SBP is as high as 44 percent, and survival in patients with a first episode of SBP is low (68.1 percent at 1 month and 30.8 percent at 6 months), probably a result both of acute infection and coexisting illness.²⁹ Abdominal paracentesis is necessary to obtain ascitic fluid analysis in cases of suspected spontaneous bacterial peritonitis. However, physical examination has poor and variable sensitivity for the detection of ascites (50-90 percent).³⁰ Blind paracentesis of the left lower quadrant has a reported average success rate of 58 percent.³¹

PARACENTESIS: PROCEDURE A scrupulously sterile technique must be used to avoid introducing skin flora into the peritoneum, causing iatrogenic infection. Classically, the patient is positioned supine. Most patients undergoing this procedure in the ED will have moderate to tense ascites on examination (hence the suspicion for SBP). An appropriate position for needle placement can be located by percussion dullness in either lower lateral abdominal quadrant. Regions with prior abdominal surgery should be avoided because postoperative adhesions may result in adherence of bowel to the parietal peritoneum, leading to iatrogenic bowel perforation during paracentesis. The patient's bladder should be emptied either by catheterization or by spontaneous voiding just before the procedure.

Sterile skin preparation with Betadine solution is performed, and sterile drapes are applied. Anesthesia is obtained by local infiltration with 1% lidocaine. Although special paracentesis trays are available commercially, an 18- or 20-gauge angiocatheter and 20-mL syringe are adequate for the procedure. To avoid postprocedure leakage of ascites from the puncture site, aspiration should follow a Z track: First, the initial skin puncture is performed. Second, traction is applied to the skin and needle, displacing the skin puncture to a location over the distal parietal peritoneum. Third, the needle is advanced through the peri-

toneum with continuous aspiration performed. The needle should be advanced only as far as is necessary to initiate flow of ascites. Finally, when the needle is removed and traction is no longer applied, the skin puncture should no longer overlie the peritoneal puncture site, limiting ascites leakage.

ULTRASOUND-GUIDED PARACENTESIS No studies to date have directly compared the safety of ED paracentesis with ultrasound guidance versus blind paracentesis. In patients with malignant ascites, ultrasound-guided paracentesis has a high reported success rate with low complications (hypotension 2.6 percent, mortality 1.6 percent).³² One study demonstrated free fluid volumes in descending order in the following locations: perihepatic space, pericystic space, right para-colic gutter, and left lower quadrant. This same study demonstrated air-filled bowel loops in the projected path of a left lower quadrant paracentesis needle. Based on these findings, investigators have suggested that ultrasound could improve the safety and efficacy of paracentesis.³³

LARGE-VOLUME PARACENTESIS Secondary indications for abdominal paracentesis in patients presenting with tense ascites include symptomatic relief of abdominal pain, anorexia, and dyspnea. Patients who have tense ascites despite high-dose diuretic therapy may require frequent paracentesis for temporary relief. Discussion with the patient's primary care physician or gastroenterologist may help to guide therapy.

Large-volume paracentesis can be safe and effective, and volumes as great as 6 to 9 L have been removed without complication. Some studies suggest that volume expanders such as exogenous albumin or dextran or reinfused concentrated albumin (prepared by dialysis of the patient's ascitic fluid) may reduce the incidence of renal dysfunction. Other studies show that large-volume paracentesis does not worsen existing hyponatremia or renal failure.^{34,36}

LABORATORY TESTING OF ASCITIC FLUID Once ascitic fluid is obtained, it should be sent for a white blood cell count with differential, glucose and protein determinations, Gram stain, and bacterial culture and sensitivity. A total white blood cell count greater than 1000/ μ L or a neutrophil count greater than 250/ μ L is diagnostic of spontaneous bacterial peritonitis. Low glucose or high protein values are suggestive of infection. Gram stains and culture results may be negative (30-10 percent), and empirical therapy should be initiated in the ED based on clinical suspicion. Culture sensitivity may be increased by the addition of 10 mL of ascites to blood culture bottles. Additional studies that may be of value to the inpatient evaluation include cytology, albumin, LDH, and tumor markers.

ANTIBIOTIC AND ADJUNCTIVE THERAPY OF SBP Empirical therapy should cover typical enteric flora. Studies demonstrate the usual organisms in SBP to be Enterobacteriaceae (63 percent), *Streptococcus pneumoniae* (15 percent), enterococci (6-10 percent), and anaerobes (<1 percent). Suggested regimens are shown in Table 86-4. There is no compelling evidence for the superiority of cefotaxime over ampicillin-tobramycin for SBP, and oral quinolones have not been shown effective for clinically mild SBP.²⁸

Patients may have had prior infections with resistant organisms, so microbiologic sensitivities from prior admissions should be reviewed, if available. For resistant *Escherichia coli* or *Klebsiella*, imipenem or meropenem or a fluoroquinolone should be added. Addition of intravenous albumin (1.5 g/kg at diagnosis, 1 g/kg on day 3) to antibiotic therapy may reduce renal failure and hospital mortality in patients with SBP.³⁷

Hepatorenal Syndrome

Hepatorenal syndrome is the development of acute renal failure in a patient with histologically normal kidneys in the presence of preexist-

TABLE 86-4 Diagnosis Bacterial Peritonitis and Treatment of Spontaneous

Clinical Setting	Cirrhosis with Ascites
Presentation	Any of the following: fever, abdominal pain and tenderness, worsening encephalopathy
Diagnosis	Ascitic fluid WBC >1000/mL PMN >250/mL
Treatment	Any of: Cefotaxime 2.0 g IV q8h, q4h if life-threatening Ticarcillin-clavulanic acid 3.1 g IV q6h Pipracillin-tazobactam 3.375 g IV q6h Ampicillin-sulbactam 3.0 g IV q6h Ceftriaxone 2.0 g IV q24h PLUS Albumin 1.5 g/kg IV at diagnosis and 1 g/kg IV on day 3
Disposition	Hospitalize, unless clinically well, compliant, with access to timely follow-up

ing chronic or acute hepatic failure. Renal function may recover after liver transplantation, and kidneys from hepatorenal syndrome patients can perform normally when transplanted into patients with renal failure from other causes.³⁸

The precise cause of renal dysfunction in cirrhotic patients is unknown, although new studies have found links to cytokines, endothelin, and the renin-angiotensin-aldosterone system. Disruption of normal renal blood flow has been demonstrated using Doppler ultrasound techniques.

The presence of new renal failure in a cirrhotic patient should be viewed as a marker of extreme morbidity. Median survival for hepatorenal syndrome is approximately 21 days with intensive medical therapy. One should undertake an urgent search for reversible causes of renal failure, such as intravascular volume depletion (prerenal azotemia), intrinsic renal disease (such as drug-induced interstitial nephritis), postrenal obstruction, or infection.

Recent studies of terlipressin with albumin infusion found improved renal function and survival; future studies are necessary to substantiate these findings.^{39,40}

Hepatic Encephalopathy

Hepatic encephalopathy is a poorly understood syndrome thought to be due to accumulation of nitrogenous waste products normally metabolized by the liver. These products may be chemically similar to normal neuropeptides, resulting in an altered level of consciousness and characteristic motor findings. Hepatic encephalopathy spans a spectrum of illness from chronic fatigue to acute lethargy. Characteristic motor findings include asterixis, a repetitive tonic-clonic wrist flexion elicited after forced wrist hyperextension.

The development of hepatic encephalopathy in a patient with chronic liver disease suggests a shift in the existing balance between the liver's ability to metabolize waste products and the supply of those products to the liver and brain. Sources of nitrogenous wastes include protein metabolism from dietary sources and protein load from occult gastrointestinal bleeding. In addition, the production of nitrogenous wastes depends in part on gastrointestinal flora. Changes in gut flora due to addition or removal of antibiotic therapy may precipitate hepatic encephalopathy.

Changes in the liver's metabolic capacity may result from worsening of the patient's underlying liver condition, hypoperfusion states such as sepsis, or iatrogenic interventions. For example, hepatic en-

cephalopathy is a common complication following TIPS, a procedure in which portal blood is shunted to the inferior vena cava, bypassing the liver. Although this procedure may succeed in reducing portal hypertension and esophageal varix bleeding, it also reduces hepatic metabolism of nitrogenous wastes by reducing hepatic blood flow.

To appreciate the presence or worsening of encephalopathy, determine if there are changes in personality, worsening dementia, alterations in levels of consciousness, or declining neuromuscular function. Table 86-5 lists clinical stages of encephalopathy. Asterixis characterizes stage II and is elicited by having the patient hold the arms straight up and extending the wrists. The hands begin to flap repetitively. Another manifestation of asterixis is back-and-forth tongue movement when the tongue is extended. A patient with known encephalopathy in stage I or II who is otherwise well and has no other acute comorbidities can be managed as an outpatient generally after consultation with the primary care physician or gastroenterologist.

Hepatic encephalopathy is a diagnosis of exclusion. In the cirrhotic patient presenting with altered mental status or lethargy, multiple other causes must first be ruled out, even in the presence of an elevated serum ammonia level. Patients with end-stage liver disease are often coagulopathic and may have spontaneous or traumatic subdural hematoma. Decreased hepatic gluconeogenesis and glycogen stores and poor nutritional status increase the risk of hypoglycemia and nutritional encephalopathies such as Werneck-Korsakoff syndrome. Cirrhotic patients often are treated with diuretics, increasing the risk of symptomatic hyper- or hyponatremia. Patients also may have decreased hepatic clearance of drugs such as benzodiazepines, prolonging their effect and leading to accidental overdose. Renal failure and sepsis from any source (spontaneous bacterial peritonitis, pneumonia, urinary tract infection, bacteremia, meningitis) are other considerations. Gastrointestinal bleeding always should be excluded as a precipitant of hepatic encephalopathy.

TREATMENT After the preceding comorbidities have been excluded, treatment is aimed at reducing the production of nitrogenous wastes by reducing protein intake and the metabolic activity of intestinal bacteria (Table 86-6).

Lactulose is the current mainstay of therapy. Lactulose is a synthetic disaccharide containing one molecule of galactose and one of fructose. It is minimally absorbed into the bloodstream. In the colon it is degraded primarily into lactic acid. By acidifying the gastrointestinal environment, ammonia is trapped and is excreted in the stool. Blood ammonia levels can be reduced up to 50 percent. Lactulose also inhibits glutamine-dependent ammonia production in the gut wall.

Lactulose can be given orally or rectally. The oral dose is 20 g in a glass of water, fruit juice, or carbonated citrus beverage. For rectal administration, 300 mL of lactulose syrup is diluted with 700 mL of water or normal saline. The enema should be retained for 30 min.

Other agents such as antibiotics and benzodiazepine receptor antagonists generally are not administered in the ED. Antibiotics such as neomycin and rifaximin directly inhibit bacterial growth and protein metabolism, so they are not given intravenously for hepatic encephalopathy. Neomycin can cause nephro- and ototoxicity, whereas Rifaximin apparently does not. Flumazenil may have short-term benefit in some patients with hepatic encephalopathy but has no effect on survival or long-term recovery.⁴¹

TABLE 86-5 Staging of Hepatic Encephalopathy

Stages	Features
I	General apathy
II	Lethargy, drowsiness, variable orientation, asterixis
III	Stupor with hyperreflexia, extensor plantar reflexes
IV	Coma

TABLE 86-6 Pharmacologic Therapy of Hepatic Encephalopathy

Medication	Dose	Mechanism
Lactulose	20 g (30 mL) PO or 300-mL retention enema q4–6h	Alters GI pH, trapping NH ₃ and stimulating nitrogen-fixing bacteria

Vascular diseases of the liver are relatively uncommon when compared with the preceding conditions, but they warrant brief inclusion because their consideration is key to timely diagnosis, treatment, and ultimately improved outcome. These conditions include portal vein thrombosis, hepatic vein thrombosis (Budd-Chiari syndrome), and nonthrombotic venoocclusive disease.

Portal vein thrombosis can result as a late complication of abdominal trauma, sepsis, pancreatitis, and hypercoagulable states and in neonates with umbilical vein infection. Portal hypertension and related complications develop in a subacute manner. Splenomegaly may occur in the absence of hepatomegaly, and liver histology is normal. The diagnosis is made by angiography, and therapy is surgical.⁴²

Hepatic vein thrombosis, or Budd-Chiari syndrome, has both acute and chronic presentations that include abdominal pain, hepatomegaly, ascites, and usually mild alterations in liver function studies. Causes and associations include a history of abdominal trauma, oral contraceptive use, polycythemia vera, paroxysmal nocturnal hemoglobinuria, hypercoagulable states, and congenital webs of the vena cava. Diagnosis can be made by Doppler ultrasound of the hepatic veins, and therapy includes anticoagulation.⁴³

Nonthrombotic occlusion of hepatic venules creating a small-vessel variant of Budd-Chiari syndrome is associated with the ingestion of certain medicinal teas containing pyrrolizidine alkaloids. These alkaloids are found in *Senecio* and *Crotalaria* genera of plants.⁴⁴ Veno-occlusive hepatic disease also occurs rarely as a complication of chemotherapy and bone marrow transplantation.

ACUTE AND CHRONIC PANCREATITIS Robert J. Vissers Riyad B. Abu-Laban

ACUTE PANCREATITIS

Pancreatitis is a common cause of abdominal pain, and the lack of a pathognomonic clinical presentation and the absence of a diagnostic "gold standard" make this disease a diagnostic challenge. Its clinical presentation can vary from mild abdominal pain to refractory shock, and many of its signs and symptoms are shared by other intra-abdominal conditions.

Epidemiology

Acute pancreatitis is secondary to cholelithiasis or alcohol abuse in up to 90 percent of cases in the United States, but the etiology varies in different countries.¹ The overall prevalence is estimated to be 0.5 percent, but this also depends on the setting and patient population. Patients with biliary pancreatitis are more commonly female and over 50 years of age and represent the most common form of pancreatitis in a community hospital setting. Alcoholic pancreatitis presents more frequently to urban emergency departments and is seen most commonly in men between the ages of 35 and 45.²

The list of other factors associated with the development of acute pancreatitis is extensive, including drugs, infection, inflammation, trauma, and metabolic disturbances. Drugs account for up to half the remaining cases after alcohol and biliary diseases have been excluded (Table 87-1).

Pathophysiology

Although there are many distinct etiologies for acute pancreatitis, the specific mechanism that leads to the disease state remains unclear. The central pathophysiologic cause is believed to be the activation of digestive zymogens in the pancreatic acinar cells instead of the small intestine and subsequent autodigestion of the pancreas.^{1,3,4} A number of factors (e.g., endotoxins, toxins, ischemia, infections, and anoxia) are believed to trigger the activation of proenzymes. Activated proteolytic enzymes, such as trypsin, then digest cellular membranes within the pancreas and cause edema, interstitial hemorrhage, vascular damage, coagulation, and cellular necrosis.¹ This noninfectious destruction of the pancreatic parenchyma rapidly causes a local inflammatory reaction that further contributes to the vascular dilatation, permeability, and edema.

Adult pancreatitis is distinguished from most other intra-abdominal diseases by its propensity to cause remote systemic effects. It is believed that this represents an extension of the localized process into a generalized systemic inflammatory response.⁴ This may lead to shock, acute respiratory distress syndrome (ARDS), and eventually, multi-system organ failure. Recently, pancreatitis research has focused on the identification of systemic inflammatory mediators. A number of compounds have been implicated, including bradykinin, complement,

TABLE 87-1 Drugs Associated with Acute Pancreatitis*

Antiarrhythmics: Amiodarone, amlodipine
Antiasthmatic: Montelukast
Antibiotics: Erythromycin, azithromycin, clarithromycin, sulfamethoxazole, quinolones, pentamidine, paromomycin, rifampin, dalfopristin-quinupristin
Antiepileptics: Carbamazepine, valproic acid, topiramate
Antifungals: Metronidazole
Antihypertensives: Diazoxide, indapamide, methyldopa
Antilipemic agents: All types
Antineoplastic agents: L-Asparaginase, pegaspargase, cytarabine, tamoxifen, mycophenolate, vinorelbine, anagrelide, interleukin ² (IL-2) analogues, interferons
Antipsychotics: Risperidone
Antiretrovirals: All types
Diphenoxylate (opiate agonist)
Diuretics: Thiazides, furosemide, ethacrynic acid, metolazone
Ergotamines
Estrogens: All types
Etanercept (anti-TNF)
Ethanol
Gastrointestinal agents: Cholestyramine, cimetidine, octreotide, ranitidine, proton pump inhibitors
Glucocorticoids: All types
Hydroxyurea
Nonsteroidal anti-inflammatory agents: All types
Retinoic acid derivatives
Salicylates
Somatropin (growth hormone)

*Clinical Pharmacology, <http://cpip.gsm.com>.

platelet-activating factor, nitrous oxide, and most recently, inflammatory cytokines.⁴ Inflammatory mediators presently hold the most promise for the identification of better prognostic markers and potential therapies for acute pancreatitis; however, their clinical usefulness remains to be seen.⁵

Clinical Features

The major symptom of acute pancreatitis is midepigastria or left upper quadrant pain. It is described most commonly as a constant, boring pain that often radiates to the back as well as the flanks, chest, or lower abdomen. Although usually described as severe, the intensity can be extremely variable and does not correlate with the severity of the disease.¹ The pain is exacerbated in the supine position and can be relieved when sitting with the trunk and knees flexed. Colicky discomfort is atypical and suggests another etiology. Nausea and vomiting are common, and abdominal bloating from gastric and intestinal hypomotility is a frequent complaint.

Physical examination usually reveals a patient in moderate distress. Low-grade fevers and tachycardia are frequently present, and hypotension is not unusual.¹ About 10 percent of patients have respiratory symptoms secondary to atelectasis, pleural effusion (usually left sided), and rarely, ARDS. Abdominal examination is notable for epigastric tenderness. Peritonitis is a late finding, presumably due to the retroperitoneal location of the organ. Bowel sounds may be diminished from an associated ileus. Cullen sign, a bluish discoloration around the umbilicus, and Grey Turner sign, a bluish discoloration of the flanks, are characteristic but rare signs of hemorrhagic pancreatitis.

Patients with pancreatitis may present in hypovolemic shock and multisystem organ failure. Hypotension can result from fluid third-spacing, hemorrhage, increased vascular permeability, vasodilatation, cardiac depression, and vomiting.²

Diagnosis

The absence of a pathognomonic clinical syndrome often precludes a diagnosis based solely on presentation. Unfortunately, the only diagnostic

"gold standard" is pathologic examination of the pancreas. Laboratory and radiographic investigations can be helpful in the diagnosis of acute pancreatitis, but both suffer from limited diagnostic accuracy.

LABORATORY TESTS Serum amylase and lipase are the most widely used laboratory tests in the evaluation of acute pancreatitis (Table 87-2). Both enzyme markers, released during pancreatic inflammation, lack the sensitivity and specificity to be the sole indicators of disease and must be interpreted in the context of the clinical setting.^{6,8}

Amylase This digestive enzyme, used to cleave starch into smaller carbohydrates, is found primarily in the pancreas and salivary glands. Low levels of amylase also can be found in numerous other tissues, including the fallopian tubes, ovaries, testes, adipose tissue, small bowel, lung, thyroid, skeletal muscle, and certain neoplasms. As a result, serum amylase can be elevated in many conditions, making this test relatively nonspecific.

Amylase levels are expressed in either Somogyi units (SU) or international units (IU), with the normal ranges generally reported as 60 to 160 SU/100 mL or 110 to 300 IU/L, respectively.⁸ Amylase has a half-life of about 2 h, and although its elimination is incompletely understood, it is at least partially cleared by the kidneys, leading to elevated levels in renal failure.

Not only are there many extrapancreatic causes of an elevated amylase, but serum amylase levels may be normal in proven cases of acute pancreatitis.⁹ The lack of a diagnostic "gold standard" has made estimates of the sensitivity of this test difficult, but most studies suggest a sensitivity of 80 to 90 percent if blood is sampled within 36 h of symptom onset.⁸ **Amylase rises quickly but, because of its short half-life, returns to normal in 3 to 4 days (even in the presence of ongoing inflammation),** making it less sensitive after the first 36 h.

The main difficulty in using serum amylase for the diagnosis of acute pancreatitis is its poor specificity. Depending on the cutoff used, the specificity of amylase ranges from 40 percent when the normal range is used to greater than 90 percent at a cutoff of five times the upper limit of normal. The best accuracy appears to occur at a cutoff of three times the upper limit of normal, which improves the specificity to 75 percent without greatly compromising the sensitivity.^{7,8}

Lipase This enzyme, which catalyzes the breakdown of triglycerides into free fatty acids, is found predominantly in the pancreas, but lipase activity is present in the gastric and intestinal mucosa and in the liver. An elevated serum lipase level has been noted in a number of nonpancreatic diseases, most of which are intestinal or hepatobiliary disorders.^{7,10} Heparin may cause a release of endothelial membrane-bound lipase into the serum, resulting in a measurable increase in lipase activity within minutes of heparin administration. Lipase is cleared by the kidneys and can be elevated to three times the upper limit of normal in renal failure. The half-life is approximately 7 h, and serum lipase will remain elevated for several days after amylase has returned

to baseline. Lipase activity is expressed in units per liter, and the normal range varies greatly depending on the assay used.

The addition of colipase to these assays has improved the specificity to greater than 90 percent (specificity ranges from 80 to 99 percent depending on the cutoff used). In addition, the sensitivity of lipase is at least as good as amylase (>90 percent). The most appropriate cutoff in the emergency department appears to be two times the upper limit of normal.^{7,8}

Lipase is a more accurate test than amylase in the diagnosis of acute pancreatitis. Although lipase suffers from imperfect sensitivity, a recent study of over 5000 patients in whom both amylase and lipase tests were ordered found that the addition of amylase was not warranted.¹¹ **It is not cost-effective to order amylase or lipase determinations indiscriminately in all cases of undifferentiated abdominal pain.**⁶

Other enzymatic markers have been investigated, including isoenzymes of amylase, but variables such as time, cost, and test accuracy have prevented their use in clinical practice.⁸ Lipase-amylase ratios and amylase-creatinine clearance ratios add little to the diagnosis of acute pancreatitis beyond lipase determination alone.^{2,3}

RADIOLOGY Plain radiographs of the chest and abdomen are most useful in excluding other diseases that may be confused with pancreatitis. Calcification of the gland is suggestive of chronic pancreatitis. A sentinel loop secondary to small bowel ileus or a colon-cutoff sign suggesting local colonic ileus may be present, but neither is diagnostic. Chest radiographs may reveal an elevated hemidiaphragm or a pleural or pericardial effusion.

Ultrasonography is most helpful in the identification of gallstones or dilatation of the biliary tree, which has both diagnostic and therapeutic implications in pancreatic disease. Although pancreatic edema and associated pseudocysts may be visualized on ultrasound, it is generally an insensitive test for the diagnosis of acute pancreatitis, particularly in nonbiliary etiologies. Overlying bowel gas or adipose tissue and the retroperitoneal location of the pancreas frequently impair adequate imaging.²

Because of better anatomic definition, computed tomographic (CT) scanning may facilitate grading the severity of the disease and enable better prognostication and is the primary imaging modality used in acute pancreatitis.¹² CT scan cannot be used to rule out pancreatitis because it is insensitive in early or mild disease.

Endoscopic retrograde cholangiopancreatography (ERCP) is employed rarely in emergency department evaluation but can be very useful for patients in whom the etiology of the pancreatitis remains unclear after initial assessment. Magnetic resonance imaging (MRI), particularly magnetic resonance pancreatography (MRP), is being used for the evaluation of pancreatic carcinoma and chronic pancreatitis. MRP may be used as an alternative to ERCP, but its utility in acute pancreatitis is unclear.¹³

Prognostic Markers

For most patients, acute pancreatitis is a self-limited disease, but 5 to 10 percent suffer from significant associated morbidity and mortality.^{2,14} It can be difficult to identify patients at risk, although signs of a systemic response suggest a more complicated course. Ranson has identified multiple diagnostic criteria to predict patient outcome.¹⁵ The criteria on admission are age >55 years; BS >200 mg/dL; white blood cell count (WBC) >16,000/L; serum glutamic-oxaloacetic transaminase (SGOT) >250 units/L; and lactate dehydrogenase (LDH) >700 IU/L. The number of factors present is then used to predict mortality. Although they serve as a reminder of features that portend a worse prognosis, **the Ranson criteria have poor predictive value in the acute setting** that does not improve on clinical judgment.¹⁵ Other scoring systems have been used to predict severity in pancreatitis, such as the acute physiology and chronic health evaluation (APACHE II) score, but complexity and poor sensitivity on initial

TABLE 87-2 Laboratory Utilization in Suspected Acute Pancreatitis

Test Characteristic	Amylase	Lipase
Sensitivity	80-90%	90%
Specificity	75%	90%
Suggested best cutoff	3X upper limit of normal	2X upper limit of normal
Prognostic value	Poor	Poor
Rate of rise	Rapid	Rapid
Return to baseline	3-4 days	7-14 days
Other	No additional benefit to ordering both amylase and lipase.	

presentation limit their role in the emergency department.¹ In general, the presence of extra-abdominal complications or comorbid conditions indicates an increased mortality risk. Hypotension, tachycardia of more than 130 beats/min, a Po₂ of less than 60 mm Hg, oliguria, increasing blood urea nitrogen (BUN) or creatinine, and hypocalcemia are key **indicators** of a potentially complicated course.^{13,14} **The absolute level of serum amylase or lipase does not correlate with severity.**⁸ A CT scan, particularly if contrast-enhanced, may provide valuable estimates of the severity and prognosis in cases of moderate to severe acute pancreatitis.¹² Complications include phlegmons, abscesses, or pseudocysts,¹⁶ usually in the first 2 to 3 weeks after the onset of pancreatitis. Systemic complications include pulmonary, cardiovascular, renal, hematologic, central nervous system, and metabolic abnormalities¹⁴ (Table 87-3).

Treatment

Of patients with acute pancreatitis, 90 percent recover without complications and require supportive measures only.¹ The general principle is to "rest the pancreas." Although the use of a nasogastric tube has been widely advocated, no studies have demonstrated that nasogastric suction alters the course of the illness, and it should not be used in routine management. It is traditionally recommended to withhold all oral intake, but clear liquids do not appear to be harmful in mild to moderate disease.

The mainstay of treatment for acute pancreatitis is fluid resuscitation. A balanced electrolyte solution, such as normal saline, should be administered for rehydration. Amounts should be given to ensure renal perfusion and good urine output of about 100 mL per h. In unstable patients, hemodynamic monitoring may be required, and pressors are indicated for persistent hypotension despite adequate fluid resuscitation.

Other aspects of supportive care include parenteral narcotics and antiemetics.

In biliary pancreatitis, urgent decompression is indicated if there is persistent biliary obstruction, ideally by endoscopic sphincterotomy of the ampulla of Vater.^{1,12} If the obstruction is transient, most patients can be managed with supportive care, and elective cholecystectomy may be performed once inflammation subsides.

Empiric antibiotics are not indicated in mild to moderate pancreatitis but should be considered in severe disease. Approximately 20 percent of acute pancreatitis cases develop a severe course characterized by pancreatic necrosis and local and systemic complications. Almost half of these cases are complicated by infected pancreatic necrosis within the first 2 weeks of illness. Since needle aspiration is the

only method of distinguishing between infected and sterile necrosis, evidence of a complicated, severe course is an indication for treatment. Infections are thought to occur from direct transmural spread from the colon. Infections are often **polymicrobial** and predominantly gram-negative bacteria such as *E. coli*, *Pseudomonas* spp., *Klebsiella* spp., and gram-positive staphylococci and enterococci accounting for the remainder. Antibiotic choice should be guided by suspected etiologic bacteria and the ability to penetrate pancreatic tissue. The traditionally utilized penicillins, first-generation and second-generation cephalosporins, and aminoglycosides have poor penetration and should not be used in prophylaxis or treatment. Intravenous imipenem or a quinolone (ofloxacin or ciprofloxacin) in combination with metronidazole are recommended and have demonstrated high tissue levels as well as bactericidal activity. Controversy exists over whether antibiotic therapy alone may preclude surgical intervention in infected necrotizing pancreatitis. Although many other drugs have been used as potential therapeutic agents in acute pancreatitis, such as H₂ blockers, steroids, nonsteroidal anti-inflammatory drugs, and glucagon, none has demonstrated benefit in controlled, prospective trials.²

Peritoneal lavage may provide short-term clinical improvement but does not appear to alter clinical outcome. Acute fluid collections are rarely symptomatic and frequently resolve spontaneously. Laparotomy is indicated for hemorrhage control and abscess drainage. Abscesses and pseudocysts also may be drained radiologically or endoscopically, if indicated.

Disposition

Patients with mild pancreatitis, no evidence of systemic complications, and a low likelihood of biliary tract disease may be managed as outpatients if they are able to tolerate oral fluids and their pain is well controlled. A clear-liquid diet is recommended, oral analgesics should be prescribed, and follow-up in 24 to 48 h is needed. All other patients with acute pancreatitis should be admitted to the hospital. Patients with significant systemic complications, shock, or extensive pancreatic necrosis will need an intensive care setting. Evidence of a pancreatic abscess requires surgical consultation.

CHRONIC PANCREATITIS

Chronic pancreatitis is a chronic inflammatory condition that causes irreversible damage to pancreatic structure and function.

Epidemiology

Table 87-4 lists the causes of chronic pancreatitis. Of these, alcohol abuse is the most important, accounting for 70 to 80 percent of cases.¹⁶ Most of the remaining cases are idiopathic. The mean ages of onset and death in chronic pancreatitis are 42 and 52 years, respectively. Because the disease can be undiagnosed, the true prevalence is unknown, with estimates ranging from 0.04 to 5 percent.¹¹ As with alcohol abuse, chronic pancreatitis is most common in men. Gallstones are not a cause of chronic pancreatitis despite their role in the acute form of the disease.¹⁸⁻¹⁹ It is believed that acute pancreatitis does not

progress to chronic disease unless complications such as pseudocysts or ductal strictures are present.

Pathophysiology

The pathophysiology of chronic pancreatitis remains poorly understood.^{1,7} In contrast to acute pancreatitis, the pancreas is pathologically abnormal in chronic pancreatitis, both before and after exacerbation. In alcohol-induced disease, it is thought that alcohol either is directly toxic to acinar cells or induces pathologic changes in secretory function.¹⁸ The risk of alcohol-induced chronic pancreatitis is clearly related to the amount and duration of alcohol consumption.¹⁶ Once established, the disease may progress despite abstinence, although the mortality rate is reduced.¹⁸ Chronic pancreatitis, regardless of the etiology, results in interstitial inflammation with duct obstruction and dilatation leading to parenchymal loss and fibrosis. This causes pain and eventual impairment of both exocrine and endocrine pancreatic functions, with endocrine impairment occurring later in the disease process.¹⁷ Clinically significant malabsorption does not occur until more than 90 percent of glandular function is lost.¹⁶ The etiology of pain is likely multifactorial and may include parenchymal inflammation, pressure on acinar tissue or small ducts, perineural inflammation, and duodenal or common bile duct stenosis.¹⁸ It is controversial whether pain "burns out" as chronic pancreatitis progresses.¹⁷

Clinical Features

The hallmark of chronic pancreatitis is abdominal pain, but in about 10 percent of cases the disease may be painless.¹⁹ As in acute pancreatitis, pain is usually midepigastria and may radiate to the back, although abdominal tenderness is often less prominent.² Nausea and vomiting may be present. In the early stages of chronic pancreatitis, discrete attacks of pain (formerly called *relapsing pancreatitis*) occur, lasting days to weeks.¹⁶ Pain is frequently worse after alcohol ingestion or a fatty meal. As the disease progresses, pain-free periods become less frequent and often disappear completely.² In distinction to acute pancreatitis, patients with chronic pancreatitis appear chronically ill and may have signs and symptoms of pancreatic insufficiency, including weight loss, steatorrhea, clubbing, and polyuria. Stigmata of chronic liver disease may be present if the etiology is alcohol abuse.

Diagnosis

Differentiating acute and chronic pancreatitis may be difficult during an exacerbation because the primary distinction is based on disease reversibility.² Laboratory investigations are nonspecific in chronic pancreatitis. Amylase and lipase levels may be elevated but have no prognostic significance and are usually normal, particularly when fibrosis is advanced. Glucose tolerance is often impaired, occasionally with an elevated fasting blood sugar level. In 5 to 10 percent of patients with chronic pancreatitis, compression of the intrahepatic portion of the bile duct leads to elevations of bilirubin and alkaline phosphatase levels.¹⁷ Pancreatic calcification on abdominal radiographs is considered pathognomonic for chronic pancreatitis and is present in some 30 percent of patients, particularly those with alcohol-induced disease.^{16,20} Lists of diagnostic criteria for chronic pancreatitis have been developed because no single "gold standard" exists.²¹ Either CT scan or ultrasound may be indicated to identify local complications of chronic pancreatitis, such as abscess or pseudocyst. The differentiation between chronic pancreatitis and pancreatic cancer can be challenging and is an essential component of imaging interpretation. Both MRP and endoscopic ultrasonography are being used in the diagnosis and differentiation of chronic pancreatitis. Their role is still being defined, but they appear to be less sensitive than ERCP in mild disease and have limited indications in the emergency setting.^{13,21}

Treatment

The management of chronic pancreatitis in the ED involves ruling out other diagnoses or complications and includes supportive care. Intravenous narcotic analgesics and antiemetics usually are required. Fluid and electrolyte abnormalities should be corrected. The long-term goals of treatment are pain control, relief of mechanical obstruction or complications, correction of malabsorption, and alteration of the disease course. Pancreatic extracts frequently are administered to improve absorption and reduce pain. Cessation of alcohol ingestion is essential because the 5-year mortality rate of chronic pancreatitis in patients who continue to abuse alcohol is 50 percent.¹⁶ If pain is increasing or intractable, imaging should be performed to assess for complications such as pseudocyst or mechanical obstruction. Surgery, either open or endoscopic, can be helpful in such cases. Other complications include mechanical obstruction of the duodenum or common bile duct, fistulas, ascites or pleural effusions, splenic vein thrombosis, and pseudoaneurysm. Celiac plexus nerve block is performed frequently for long-term pain control.

Disposition

Many patients with chronic pancreatitis can be discharged safely from the ED once complications have been ruled out or addressed. Appropriate follow-up is particularly important if pain management is poor or significant weight loss or symptom changes have occurred. Hospital admission may be required during severe pain exacerbation.

COMPLICATIONS OF GENERAL SURGICAL PROCEDURES

Edmond A. Hooker

Outpatient surgical procedures are commonplace, and, with increasing pressure for cost containment, admitted patients are being discharged earlier in their postoperative course. As a result, more patients are presenting to the ED with postoperative fever, respiratory complications, genitourinary complaints, wound infections, vascular problems, and complications of drug therapy (Table 88-1). This chapter reviews the complications common to all surgical procedures and those specific to one procedure.

The operating surgeon should be called when one of his or her patients appears in the ED with a surgical complication. This is not just courtesy but provides continuity of care important for the patient's well-being.

FEVER

Fever is a common presenting complaint (Table 88-2). A mnemonic for the common causes of postoperative fever is the "five Ws": wind (atelectasis or pneumonia), water (urinary tract infection), wound, walking (deep vein thrombosis), and wonder drugs (drug fever or pseudomembranous colitis).¹ Fever during the initial 24 h is usually caused by atelectasis; however, necrotizing streptococcal and clostridial infections also occur in surgical wounds early in the postoperative course. Respiratory complications, such as pneumonia and atelectasis, and intravenous catheter-related problems, such as thrombophlebitis, are the predominant causes of fever in the 24- to 72-h period.

Urinary tract infections become evident 3 to 5 days postoperatively. Seven to 10 days postoperatively, clinical manifestations of wound infections develop. Deep venous thrombosis can result in fever any time but usually not until the fifth postoperative day. Antibiotic-induced pseudomembranous colitis occurs up to 6 weeks postoperatively. An approach for evaluating and managing fever in postoperative patients is presented in Table 88-3. It is important to remember that leukocytosis can be absent in up to one-third of patients with clinically significant infections.²

RESPIRATORY COMPLICATIONS

Respiratory complications occur in many surgical patients and range from atelectasis and pneumonia to pneumothorax or pulmonary embolism.

Atelectasis

Atelectasis, the collapse of pulmonary alveoli, is very common. Contributing factors include inadequate clearance of secretions after general anesthesia, decreased intra-alveolar pressure, and postoperative pain, which results in hypoventilation. Although atelectasis can occur after any procedure, it frequently occurs after upper abdominal and thoracic surgery. The presentation varies from an isolated fever to tachypnea, dyspnea, and tachycardia.

Evaluation includes a chest radiograph, pulse oximetry, and a complete blood count (CBC). Chest radiographs may be normal or show platelike linear densities, triangular densities, or lobar consolidation. Mild hypoxemia from ventilation and perfusion mismatch is common, but hypercarbia is uncommon. Patients with mild atelectasis and no evidence of hypoxemia may be managed as outpatients with pain control

and increased deep breathing. Admission is indicated for aggressive pulmonary toilet and supplemental oxygenation in debilitated patients, patients with underlying lung disease, patients with hypoxemia, or those in whom the diagnosis is in question.

Pneumonia

Pneumonia usually presents between 24 and 96 h postoperatively. Predisposing factors include prolonged ventilatory support and atelectasis.

TABLE 88-1 Complications of General Surgical Procedures

Complication	Important Points
Fever	Wind, water, wound, walking, wonder drugs
Pulmonary complications	
Atelectasis	<24 h, treat with pulmonary toilet, discharge unless ill or hypoxemic
Pneumonia	24–96 h, polymicrobial, most require admission
Pneumothorax	Multiple causes, consider expiratory views, consider needle aspiration
Pulmonary embolism	Dyspnea is main symptom, high index of suspicion
Gastrointestinal complications	
Intestinal obstruction	Obtain radiographs, search for causes
Intraabdominal abscess	CT diagnosis, early broad-spectrum antibiotics
Pancreatitis	Always consider in postoperative patients with abdominal pain
Cholecystitis	Usually in older patients, can be acalculous
Fistulas	Can be high output, admit if concerns over output
Genitourinary complications	
Urinary tract infection	3–5 d, oral antibiotics, most discharged
Urinary retention	Rapid catheter drainage, most discharged
Acute renal failure	Prerenal, renal, and postrenal causes, most admitted
Wound complications	
Hematoma	Caused by poor hemostasis, can drain most, but be careful with neck hematomas and hematomas after vascular surgery
Seroma	Painless swelling, clear fluid, drain and discharge
Infection	Open, drain, and culture; be careful with wounds associated with respiratory, gastrointestinal tract, genitourinary tract, or secondary to trauma
Necrotizing fasciitis	Pain out of proportion to physical findings
Dehiscence	Careful with abdominal incisions (evisceration)
Vascular complications	
Superficial thrombophlebitis	Usually aseptic, local therapy and discharge
Deep venous thrombosis	Upper and lower extremity, Doppler studies
Complications of drug therapy	
Diarrhea	Consider pseudomembranous colitis
Drug fever	Many drugs implicated, requires admission
Tetanus	Can occur after gastrointestinal surgery
Procedure-specific complications	See text

Abbreviation: CT = computed tomography.

TABLE 88-2 Common Causes of Postoperative Fevers in General Surgical Patients

Atelectasis	Pseudomembranous colitis
Pneumonia	Hepatitis
Urinary tract infections	Peritonitis
Skin and soft tissue injury	Pulmonary embolism
Thrombophlebitis (septic and sterile)	Transfusion reaction
Deep vein thrombosis	
Intraabdominal abscesses	
Unrelated bacterial infection	

Presenting symptoms can include dyspnea, chest pain, productive cough, fever, and tachypnea. Postoperative pneumonia is likely to be polymicrobial. After cultures of sputum and blood are obtained, parenteral antimicrobial therapy with an aminoglycoside and an anti-pseudomonal penicillin should be administered. Admission to the hospital is generally indicated.

Pneumothorax

Pneumothorax can occur as a complication of thoracic wall surgery, breast biopsy, laparoscopic abdominal surgery, abdominal paracentesis, nasogastric and feeding tube insertion, thoracic surgery, central venous catheter insertion, endoscopic procedures, shoulder arthroscopy, and tracheostomy. The pathophysiology varies with these different procedures, but clinical features are similar. Patients complain of chest pain, shoulder pain, or dyspnea. Physical findings can include tachypnea, hyperresonance to percussion, and decreased breath sounds on the affected side. Diagnosis is confirmed by chest x-ray with expiratory views.

Chest radiograph
Gram stain and culture of wound exudate
Urinalysis (culture if infected)
Sputum gram stain and culture
Blood cultures
If diarrhea present, consider immunoassay of specimen for <i>Clostridium difficile</i> toxin Further tests as indicated (e.g., computed tomography, radionuclide studies, venography, arteriograms)
TREATMENT
If source identified, start antibiotics; admission based on condition of patient
If no source identified, consider admission, change and culture all catheters,
stop all medication that might cause fever

Pulmonary Embolus

Pulmonary embolism may present any time during the postoperative period. A lower extremity or pelvic thrombus dislodges and migrates to the pulmonary vasculature. The presenting signs and symptoms depend on the size of embolus and the underlying cardiopulmonary status of the patient. Patients have different degrees of dyspnea, chest pain, cough, and anxiety. Hemoptysis is usually seen only late in a patient's course and with massive pulmonary embolism. The patient may have essentially normal vital signs or be tachypneic and tachycardiac. Diagnosis of pulmonary embolism is difficult because of the poor sensitivity of noninvasive tests. Although hypoxemia and a widened alveolar-arterial oxygen gradient are frequently found with larger emboli, patients may have normal oxygen content and a normal alveolar-arterial gradient. Diagnosis requires venous Doppler ultrasonography, ventilation-perfusion scan, pulmonary computed tomography (CT), or pulmonary angiography. Patients with low clinical suspicion, normal vital signs, good oxygenation, and a low probability scan can be discharged, provided other causes of their symptoms have been addressed.

GENITOURINARY COMPLICATIONS

The most common postoperative genitourinary complication is urinary tract infection. However, patients may present with acute urinary retention and acute renal failure (ARF).

Urinary Tract Infection

Urinary tract infections can occur after any surgical procedure. However, there is an increased incidence in patients who have had instrumentation of the genitourinary tract or bladder catheterization. The cause is direct contamination of the urinary bladder, most commonly with *Escherichia coli*. Other organisms isolated include *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Proteus mirabilis*, *Klebsiella*, *Pseudomonas*, and enterococci. Oral antibiotics are appropriate for most infections; however, elderly or debilitated patients and patients with evidence of sepsis require admission for parenteral antibiotics.

Urinary Retention

Acute urinary retention occurs in about 4 percent of all surgical patients.³ It is postulated that urinary retention occurs as the result of catecholamine stimulation of α -adrenergic receptors in the bladder neck and urethral smooth muscle. Increased incidence of urinary retention is likely to occur in elderly males, with excessive fluid administration during surgery, and with the use of spinal or epidural anesthesia.

Patients with urinary retention present with lower abdominal discomfort, urinary urgency, and inability to void. The diagnosis is confirmed by placement of a Foley catheter. The bladder can be safely drained quickly without clamping, because there appears to be no foundation for the fears of hematuria, postobstructive diuresis, and hypotension.⁴ For patients with normal renal function and no anatomic obstruction, continued catheter drainage is not necessary. For patients with retention after genitourinary procedures, the urologist must be consulted before disposition. Prophylactic antibiotics can be given if the genitourinary tract has been instrumented, if retention is prolonged, or if the patient is at risk for infection.

Acute Renal Failure

Acute renal failure is classified according to the primary cause: prerenal, intrinsic, or postrenal. Volume depletion is the most common prerenal cause. Intrinsic causes include acute tubular necrosis and drug nephrotoxicity. Obstructive uropathy is the cause of postrenal ARF. Patients with ARF have oliguria or anuria and, depending on the degree of ARF, may have signs of uremia and electrolyte abnormalities.

Patients should be examined for signs of hypovolemia and have a urinary catheter placed. Indwelling urinary catheters must be irrigated or replaced. If the patient is hypotensive, a fluid bolus is given to determine whether the cause is prerenal. In patients with urinary outlet obstruction, the urinary catheter is diagnostic and therapeutic. If there is doubt about the cause of the renal failure, central venous pressure and pulmonary capillary wedge pressure measurements can be helpful. The presence of postobstructive uropathy above the urinary bladder can be confirmed with abdominal ultrasound. When no prerenal or postrenal cause can be identified, there is likely to be an intrinsic cause of ARE.

WOUND COMPLICATIONS

Wound complications are frequent and include hematomas, seromas, infections, necrotizing fasciitis, and dehiscence. The patient's surgeon should be notified of all wound complications.

Hematomas

Wound hematomas result from unrecognized inadequate hemostasis. Patients have pain, pressure, and swelling within the wound. Patients with wound hematomas may be febrile and have sanguineous or serous wound drainage. Differentiating between hematoma and wound infection can be difficult. A few sutures are removed to allow the hematoma to drain, and cultures are obtained. If there is no evidence of infection and hemostasis can be maintained, the patient can be discharged. In patients with a hematoma of the neck or who have undergone vascular surgery, extreme caution and consultation are appropriate.

Seromas

A seroma, a collection of serous fluid, is usually the result of inadequate control of lymphatics during dissection but can occur under split-thickness skin grafts and areas with large dead spaces (e.g., axilla, groin, neck, or pelvis). Patients have painless swelling below the wound or graft, and needle aspiration yields a serous fluid. Aspiration confirms the diagnosis and alleviates the problem, although aspiration may have to be repeated later.

Infection

Systemic factors (e.g., extremes of age, poor nutrition, or diabetes) contribute to wound infections; however, local factors (e.g., necrotic tissue, poor perfusion, foreign bodies, and hematomas) are of greatest significance. In nontraumatic, uninfected operative wounds in which the respiratory, alimentary, and genitourinary tracts were not entered, infection rates are low. In these cases, the infecting organism is usually from the skin but can originate from remote infected sources (e.g., urinary tract infection). If there is a remote infected source, the organism is probably the same in both infections. Wounds associated with entering the respiratory, alimentary, or genitourinary tract or secondary to trauma have a higher risk of infection.

Presenting signs and symptoms of wound infections include increasing pain, erythema, swelling, drainage, and tenderness at the incision site. Wounds not involving the perineum and not associated with entry into the gastrointestinal or biliary tract are most often infected with *S. aureus* or streptococci. Such wounds can be safely managed with drainage, culture of the wound, irrigation, loose packing with gauze, and outpatient antibiotics. Wounds involving the perineum or associated with the gastrointestinal or biliary tract are often infected with multiple organisms, including gram-negative bacteria and anaerobes. Parenteral broad-spectrum antibiotics are administered, and admission is necessary.

Necrotizing Fasciitis

Necrotizing fasciitis is a feared complication. The usual cause is direct contamination of the wound with group A streptococcus or *S. aureus*;

however, mixed aerobic and anaerobic infections have been reported. Risk factors include diabetes mellitus, alcoholism, immunosuppression, and peripheral vascular disease, but necrotizing fasciitis also occurs in young, otherwise healthy individuals. Early clinical differentiation from cellulitis can be difficult. CT may show asymmetric fascial thickening, gas tracking along fascial planes, or focal fluid collections; however, the actual sensitivity and specificity of CT in the diagnosis of necrotizing fasciitis has not been defined.⁵ Magnetic resonance imaging has been shown to be highly sensitive but not totally specific for necrotizing fasciitis and can be a useful adjunct.⁶ The presence of marked systemic toxicity and pain out of proportion to local findings indicate fasciitis. In more advanced cases, there may be deep pain with patchy areas of surface hypesthesia, crepitation, or bullae. Treatment should include antibiotics and immediate surgical debridement. Antibiotic choice is controversial but probably should include penicillin or cephalosporin, an aminoglycoside, and clindamycin.⁷

Wound Dehiscence

Wound dehiscence can be superficial or can extend into the deeper fascial planes. Dehiscence is caused by inadequate closure or intrinsic host factors, such as malnutrition, glucocorticoid use, or diabetes. The patient may have serosanguineous fluid leaking from the wound. Dehiscence of abdominal incisions has the potential for evisceration. If evisceration is not present, conservative management using abdominal binders is appropriate. However, if there is any uncertainty, operative exploration is indicated.

VASCULAR COMPLICATIONS

Postoperative vascular complications include thrombophlebitis and deep venous thrombosis. Superficial thrombophlebitis usually occurs in the upper extremities, secondary to prolonged cannulation of the vein or infusion of irritating fluids. Deep venous thrombosis is secondary to stasis, endothelial damage, or hypercoagulopathy.

Superficial Thrombophlebitis

Superficial thrombophlebitis of the lower extremities is most frequently secondary to stasis in varicose veins. It is usually aseptic. The patient complains of redness and warmth of the affected vein. If there is no evidence of surrounding cellulitis or lymphangitis, the patient is treated with local heat and elevation. Suppurative superficial thrombophlebitis is characterized by erythema, palpable tender cord, lymphangitis, and pain. Suppurative thrombophlebitis requires excision of the affected vein.

Deep Venous Thrombosis

When lower extremity superficial thrombophlebitis is seen, the possibility of concurrent deep venous thrombosis must be considered. Swelling of the extremity is the most specific physical sign, and its presence requires diagnostic evaluation. Doppler ultrasonography is generally the preferred diagnostic test. Patients with normal color-flow study results should be treated with elevation and bedrest. Repeat color-flow Doppler ultrasound studies should be performed in 3 days if symptoms persist but sooner if symptoms worsen.

COMPLICATIONS OF DRUG THERAPY

Many medicines have been reported to cause drug fever (Table 88-4).⁸ The mechanisms proposed are hypersensitivity reactions, pyogenic effect, and disturbed thermoregulation. In patients in whom no source for the fever can be found, it is appropriate to consider stopping medications known to cause drug fever.

TABLE 88-4 Some Medications Associated with Drug Fever

Allopurinol	Lysergic acid
Aminoglycosides	Mebendazole
Amphetamine	Methyldopa
Amphotericin B	Metoclopramide
Antihistamines	Nifedipine
Asparaginase	Nitrofurantoin sodium
Azathioprine	Nomifensine
Barbiturates	Oxprenolol
Benzotropine	Para-aminosalicylic acid
Bleomycin sulfate	Penicillins
Carbamazepine	Phenytoin sodium
Cephalosporins	Procainamide
Chlorpromazine	Propafenone
Cimetidine	Propylthiouracil
Clofibrate	Prostaglandin E ₂
Cocaine derivatives	Quinidine sulfate
Dobutamine	Rifampin
Folate	Ritodrine
Heparin	Salicylates
Haloperidol	Streptokinase
Hydralazine	Streptomycin sulfate
Hydroxyurea	Sulfonamides
Ibuprofen	Tetracycline
Interferon	Thioridazine
Iodides	Tolmetin
Isoniazid	Triamterene
Levamisole	Trifluoperazine
Lincomycin	Vancomycin

Many antibiotics can cause diarrhea; however, the greatest concern in postoperative patients is pseudomembranous colitis. Pseudomembranous colitis is due to the toxin produced by the bacterium *Clostridium difficile*. Pseudomembranous colitis is related to antibiotic use, which destroys the normal enteric bacterial flora, allowing an overgrowth of the *C. difficile*. Even short courses of antibiotics have been associated with pseudomembranous colitis. Patients have watery and sometimes bloody diarrhea, elevated temperature, and crampy abdominal pain. Although tissue culture for *C. difficile* is the diagnostic gold standard, the diagnosis is usually made by detecting *C. difficile* cytotoxin in the stool.¹ This immunoassay is slightly less sensitive than is the tissue culture, but it is technically easier to do and provides an answer within 2 to 3 h. If results on the first specimen are negative and the diagnosis is still suspected, a second sample should be sent for immunoassay. When severe illness is present, consider empiric therapy with metronidazole while awaiting diagnostic studies.

COMPLICATIONS OF BREAST SURGERY

Breast biopsy is a common procedure. Although complications are infrequent, patients can develop minor wound infections and hematomas. Rarely, pneumothorax has been reported. Wound hematomas frequently require operative control for proper evacuation and hemostasis.

Early complications seen with mastectomies include wound infection, necrosis of skin flaps, and the accumulation of seromas. The most common late complication is lymphedema of the arm. The incidence of postmastectomy lymphedema ranges from a low of 5.5 percent to a high of 80 percent. Most patients can be managed by using a combination of fitted compression garments, nighttime elevation, and minor activity restrictions.⁹

COMPLICATIONS OF GASTROINTESTINAL SURGERY

Patients who have undergone any gastrointestinal surgery may have intestinal obstruction, intra-abdominal abscess, pancreatitis, cholecysti-

tis, fistulas, and tetanus. Certain procedures, such as anastomoses, gastric surgery, placement of gastrostomy tubes, biliary tract surgery, other laparoscopic surgery, stomas, colonoscopy, and rectal surgery have specific complications.

General Considerations

INTESTINAL OBSTRUCTION Ileus, a functional obstruction of the bowel, is postulated to be the result of stimulation of the splanchnic nerves, leading to neuronal inhibition of coordinated intrinsic bowel wall motor activity. It is expected after any operation in which the peritoneal cavity is violated. After gastrointestinal surgery, small bowel tone usually returns to normal within 24 h, and colonic function returns within 3 to 5 days.¹⁰ Ileus can also occur after nongastrointestinal procedures, is usually secondary to anesthetic agents, and function returns to normal after 24 h. Prolonged ileus can be caused by peritonitis, intra-abdominal abscess, hemoperitoneum, pneumonia, electrolyte imbalance, sepsis, and medications.

Presenting symptoms of ileus include nausea, vomiting, obstipation, constipation, abdominal distention, and abdominal pain. When these symptoms are present in the first few days after surgery, they are most often due to adynamic ileus. The symptoms of adynamic ileus are most often mild and respond to nasogastric suction, bowel rest, and intravenous hydration. However, in cases of prolonged ileus, the physician must always look for an underlying cause. Evaluation of patients with suspected ileus includes abdominal radiographs to identify air-fluid levels, chest x-ray, CBC, electrolytes, and urinalysis for secondary causes of ileus.

Mechanical ileus of the bowel is most often secondary to adhesions. Small bowel obstruction above the ligament of Treitz is associated with frequent bouts of bilious emesis. In cases of more distal obstruction, pain and distention become more severe, the frequency and volume of vomiting decrease, and emesis becomes more feculent. Abdominal radiographs demonstrate multiple air-fluid levels and a paucity of gas in the colon; however, with high obstruction, above the ligament of Treitz, there may be no air-fluid levels. In the ED, differentiating between functional ileus and mechanical bowel obstruction can be difficult. Both disorders result in different degrees of abdominal pain, distention, nausea, vomiting, and constipation. Once the diagnosis of mechanical obstruction is confirmed or suspected, surgical consultation is indicated.

INTRA-ABDOMINAL ABSCESS Intra-abdominal abscess is caused most frequently by preoperative contamination, spillage of bowel contents during surgery, contamination of a hematoma, or postoperative anastomotic leaks. Patients may have abdominal pain, nausea, vomiting, ileus, abdominal distention, fever, chills, anorexia, and abdominal tenderness. If the diagnosis is suspected, CT or ultrasound studies of the abdomen are required. The patient should receive broad-spectrum antibiotics. Although some abscesses are amenable to percutaneous drainage, many patients require surgical exploration.

PANCREATITIS Pancreatitis after abdominal surgery is secondary to direct manipulation or retraction of the pancreatic duct. It most commonly occurs after gastric resection, biliary tract surgery, and endoscopic retrograde cholangiopancreatography (ERCP). Clinical presentation varies from mild nausea, vomiting, and abdominal discomfort to intractable vomiting, leukocytosis, and left pleural effusion. Severe hemorrhagic presentation can cause lumbar pain accompanied by blue-gray discoloration of the skin in the flank area (Turner sign) or similar changes around the umbilicus (Cullen sign). Although the serum amylase level rises in acute pancreatitis, it is also elevated in patients with severe cholecystitis, renal insufficiency, intestinal obstruction, perforated ulcer, or ischemic bowel. A serum lipase measurement may help to identify those with true pancreatitis, although it may be

elevated in a patient with a perforated viscus. Abdominal radiographs may show localized ileus in the region of the pancreas (sentinel loop). CT is useful in defining pancreatic fluid collections or abscesses. In general, the treatment of postoperative pancreatitis is similar to the treatment of nonoperative pancreatitis: bowel rest, antiemetics, and nasogastric suction.

CHOLECYSTITIS Patients may present during the postoperative period with biliary colic, acute calculous cholecystitis, or acute acalculous cholecystitis. The etiology of these disorders in the postoperative period is not clear. Ultrasound studies of the gallbladder and pancreas should be performed to aid in the diagnosis.

Acalculous cholecystitis is of particular concern in the postoperative period. Although it may occur in any age group, it seems to be more common in elderly males. Signs and symptoms are similar to those for calculous cholecystitis, but ultrasound studies fail to reveal gallstones. Liver function studies and the neutrophil count may be normal. Important findings on ultrasonography include gallbladder enlargement, wall thickening, and pericholecystic fluid collection. Hepatobiliary scintigraphy may be helpful. Early diagnosis is critical, because early operative intervention can reduce morbidity and mortality rates.

FISTULAS Enterocutaneous fistulas can occur almost anywhere in the gastrointestinal tract and are usually the result of technical complications or direct bowel injury. High-output fistulas can result in electrolyte abnormalities and volume depletion. Fistulas involving the proximal gastrointestinal tract are frequently high output and are of the greatest concern. Sepsis is the other major complication. Most patients require admission, although many fistulas ultimately close spontaneously.

TETANUS Although most cases of tetanus in the United States occur after minor trauma, there have been numerous reports of tetanus after general surgical procedures. *Clostridium tetani* is found in the gastrointestinal tract of 1 percent of the population.¹¹ During gastrointestinal surgery, there is spillage of *C. tetani*. Proliferation of the organism is facilitated by the presence of devitalized tissue, blood clots, and surgical suture. Incubation can take from 0 to 73 days, at which time the toxin leads to clinical tetanus.¹² The classic symptoms of tetanus, trismus, and opisthotonos may not be manifest at initial presentation. Patients may present with nonspecific symptoms of abdominal discomfort, fever, and abdominal wall rigidity. Diagnosis is based on physical examination and a history of inadequate immunization.

Specific Considerations

ANASTOMOSIS Anastomotic leaks occur most frequently after esophageal and colonic surgeries and least frequently after gastric and small intestinal anastomoses. The cause of anastomotic leakage is related mainly to surgical technique.

Intrathoracic esophageal anastomotic leaks usually manifest within 10 days of surgery. The presentation is dramatic, with fever, chest pain, tachypnea, tachycardia, and possibly shock. Chest x-ray may reveal a pneumothorax with pleural effusion. Disruption can be confirmed by contrast esophagography using a water-soluble contrast agent. Even with immediate reoperation, morbidity and mortality rates are high.

The signs and symptoms of gastric anastomotic leaks include abdominal pain, fever, leukocytosis, gastric outlet obstruction, hyperamylasemia, hyperbilirubinemia, peritonitis, and shock. Plain radiographs may reveal pneumoperitoneum or air-fluid levels. The patient should have immediate volume resuscitation, parenteral broad-spectrum antibiotics, and nasogastric tube drainage. Immediate surgery is required.

Small intestinal anastomoses infrequently leak because of the excellent blood supply and rapid healing of the area. However, if a leak occurs, the patient usually presents with local abscess formation or peritonitis. Treatment is immediate reoperation.

Colorectal anastomoses are prone to disruption because of the large number of pathogenic bacteria, propensity for colonic distention, and a single thin layer of circular muscle to support sutures. The patients usually present 7 to 14 days postoperatively with evidence of intra-abdominal or pelvic abscess. CT can be helpful in diagnosis. Patients should receive broad-spectrum parenteral antibiotics, nasogastric tube drainage, and adequate fluid resuscitation in preparation for surgery.

GASTRIC SURGERY Patients who have undergone partial or complete gastrectomy can present with a few distinct syndromes: dumping syndrome, alkaline reflux gastritis, afferent loop syndrome, and post-vagotomy diarrhea. Although these complications are rare, the symptoms can be disabling.

Dumping syndrome can occur early or late after a meal. Although the precise etiology of dumping symptoms is unclear, it occurs when the pylorus is bypassed or removed. The hyperosmolar chyme contents of the stomach are dumped into the jejunum, resulting in rapid influx of extracellular fluid and an autonomic response.

Patients experience nausea, epigastric discomfort, palpitations, abdominal colic, diaphoresis, and, in some cases, dizziness and syncope. Patients with early dumping symptoms experience diarrhea, whereas those with late dumping symptoms, 2 to 4 h postprandially, usually do not. The late dumping syndrome is believed to be due to a reactive hypoglycemia. The mainstay of treatment is dietary modification; eating small, dry meals; and separating solids from liquids. In refractory cases, pyloroplasty can be tried. Most of these patients do not require admission.

Patients with reflux gastritis present with continual burning epigastric pain that is aggravated by meals and unrelieved by vomiting. The syndrome is caused by reflux of bile into the stomach. Diagnosis is made by endoscopic examination.

Patients with afferent loop syndrome also present with severe epigastric pain 1 to 2 h after eating, which is relieved by vomiting. The vomitus will be bilious, without food. The syndrome occurs in patients who have undergone gastroenterostomy (Billroth II) reconstruction after partial gastrectomy. Diagnosis is made by contrast radiography or endoscopy. Operative reconstruction is required.

Whereas most patients undergoing truncal vagotomy have increased bowel movements, some will have diarrhea. The precise etiology is not clear. Patients present with diarrhea that is variable in its occurrence and not associated with food intake. It is often unpredictable and explosive, which can lead to weight loss, malnutrition, and severe social complications. The incidence of the diarrhea decreases with time, and treatment is mostly symptomatic.

GASTROSTOMY TUBES Most gastrostomy tubes are now placed by an endoscopist via percutaneous endoscopy or by a radiologist via percutaneous fluoroscopy. If the patient has undergone a laparotomy, the general surgeon may place a gastrostomy tube at the time of surgery. If the tube was placed by the surgeon and has not been replaced, it will have a bumper holding the tube in place. The tube has to be cut and the bumper allowed to pass, or the bumper has to be removed by endoscopic technique. For further discussion, see Chap. 89, "Complications of Gastrointestinal Devices."

BILIARY TRACT SURGERY More than 50 percent of all cholecystectomies are now performed laparoscopically. There are complications seen after open and laparoscopic cholecystectomies (Table 88-5) and complications related to the laparoscopic technique (Table 88-6).¹³⁻¹⁴ Patients are likely to present to the ED with nonspecific abdominal symptoms.

The evaluation of abdominal pain after cholecystectomy depends on the clinical condition of the patient. If there are signs of peritoneal irritation or fever, an injury to the biliary system is likely. The patient should have an abdominal CT in addition to a CBC, electrolyte measurements,

TABLE 88-5 Complications of Cholecystectomy

Wound infection

liver function tests, and a serum lipase test. Endoscopic retrograde cholangiopancreatography will be required to identify the site of the injury; however, a collection of bile can be seen on CT. Depending on the ERCP results, reoperation may be necessary. Small collections of bile may require only observation or percutaneous drainage.

Patients presenting soon after cholecystectomy with pain, pancreatitis, and/or jaundice may have retained common duct stones. If CT does not reveal an intra-abdominal collection of fluid, an ERCP should be performed. Endoscopic sphincterotomy is usually an effective means of dealing with retained stones. Patients presenting late after cholecystectomy with fever, pain, and jaundice may have bile duct stricture. Diagnosis requires ERCP. Stents are usually tried first, but surgical repair may be necessary. A more recent concern has been the spillage of gallstones into the peritoneal cavity at the time of surgery. Initially, such stones were thought to be innocuous. However, they have been linked to abdominal pain, pelvic pain, dysmenorrhea, intraabdominal abscess, colcutaneous fistula, and implantation into the ovary with subsequent infertility.¹⁵

OTHER LAPAROSCOPIC SURGERIES Laparoscopic techniques are now being used for an increasing number of procedures. In addition to cholecystectomy, they have been used for appendectomy, colon resection, antireflux surgery, herniorrhaphy, fundoplication, and most gynecologic surgical procedures, including hysterectomy. The complications associated with these procedures have not been completely identified; however, they are likely to be similar to those seen with cholecystectomy.

TABLE 88-6 Complications of Laparoscopy

RELATED TO PNEUMOPERITONEUM	
Cardiac arrhythmias during the procedure	
Subcutaneous emphysema

MISCELLANEOUS	
Retained intraabdominal gallstones	
Biliary cutaneous fistula	
Chronic pain	
Infertility	
Cholelithiasis	
Metastases to the trocar site	

STOMAS The two most common stomas placed are the ileostomy and the colostomy. Problems with these stomas can be quite debilitating. Most

(e.g., Crohn disease or cancer). Possible complications include ischemia and stomal necrosis, peristomal skin irritation, peristomal hernia, and stomal prolapse.

Ischemia and stomal necrosis are manifested very early in the postoperative course. The cause is inadequate blood supply to the stoma. Normally, the stoma is pink, without evidence of cyanosis. Any evidence of compromised blood flow requires surgical evaluation.

Peristomal maceration and skin destruction are most likely secondary to a poor seal of the stomal appliance. Consultation with an en-terostomal therapist for a properly fitting appliance is indicated.

Prolapse can occur with ileostomies and colostomies. The cause is usually inadequate fixation of the intra-abdominal portion or too large an abdominal wall opening. Patients present with the stoma protrusion, with or without pain. The stoma must be examined to determine viability. The stoma should be pink and painless. Reduction should be attempted if the tissue is viable, followed by consultation with a surgeon. Definitive therapy requires surgical revision.

Parastomal hernias are secondary to too large an abdominal wall opening. As with any hernia, the physician should determine whether the hernia is incarcerated, attempt reduction, and consult a surgeon. Definitive therapy requires local reconstruction of the orifice.

COLONOSCOPY Potential complications of colonoscopy include hemorrhage, perforation, retroperitoneal abscess, pneumoscrotum, pneumothorax, volvulus, postcolonoscopy distention, bacteremia, and infection.

Hemorrhage is the most common complication and can be secondary to the polypectomy procedures, biopsies, laceration of the mucosa by the instrument, or tearing of the mesentery or spleen.¹⁶ If the bleeding is intraluminal, the patient will present with rectal bleeding. Patients with mesenteric or splenic injury will present with signs of intraabdominal bleeding. Treatment of intraluminal bleeding depends on the magnitude of hemorrhage. Signs of intra-abdominal bleeding require emergency laparotomy.

Perforation of the colon with pneumoperitoneum usually is evident immediately but can take several hours to manifest.¹⁷ Perforation is usually secondary to intrinsic disease of the colon (e.g., diverticulitis) or to vigorous manipulation during the procedure. Most patients will require immediate laparotomy; however, in some patients presenting late (1 to 2 days later) without signs of peritonitis, expectant management may be appropriate.

RECTAL SURGERY Patients who have undergone hemorrhoidectomy frequently have problems with postoperative urinary retention, the management of which has been discussed previously. Three other problems that can occur are constipation, rectal hemorrhage, and rectal prolapse.

The management of constipation in a patient who has undergone rectal surgery is no different from that of any other patient with constipation. Gentle rectal examination is indicated, and enemas can still be used. Posthemorrhoidectomy rectal hemorrhage can occur immediately postoperatively but may be delayed (4 ± 2 days).¹⁸ Proposed causes of delayed bleeding include sepsis of the pedicle, disruption of a clot, and sloughing of tissue.¹⁹ The patient may present with minimal bleeding or massive hemorrhage. Although ligation of the affected vessel is needed, a temporary tamponade with a Foley catheter may be helpful.

Patients may present with mucosal prolapse or complete rectal prolapse. Mucosal prolapse occurs when the surgeon has not removed all redundant mucosa during hemorrhoidectomy and is much more common than rectal prolapse. Local treatment by a surgeon is usually corrective. Rectal prolapse can occur after any anorectal surgical procedure and likely is related to injury of the puborectalis muscle. The patient will present with the sensation of protrusion and may complain of pain. The treatment is reduction and surgical consultation.

complications are related to technical errors as to where the stomas are placed; however, there can be problems of new disease within the stoma

Infection after anorectal surgery is surprisingly uncommon. The patient usually complains of increasing pain and fever. Examination of the area is necessary to detect an abscess or cellulitis. Founder's gangrene may follow anorectal surgery. If this is suspected, broad-spectrum parenteral antibiotics are given immediately. The patient requires immediate surgical debridement.

NASOGASTRIC TUBES

The NG tube is probably the most common device placed in the GI tract. Tubes range in size from 6 to 18 F (1 F = 0.3 mm). These devices are relatively easy to place blindly in an alert, cooperative patient. Obtunded patients or those without an active gag reflex may require endotracheal intubation before NG insertion. It is important to note that the presence of an endotracheal tube with an inflated balloon does not prevent passage of these tubes into the respiratory tract.

Major complications have been reported with the use of NG tubes (Table 89-1). Improper placement is the principal cause of these complications, and different techniques have been proposed to help identify improper placement of NG tubes (Table 89-2). However, according to published research, none of the techniques have proven effective. The technique that is probably most commonly used, insufflation of air into the NG tube while listening over the stomach, has many reported failures. A recently proposed technique used capnography with excellent results.²

Placement of the NG tube into the respiratory tract can result in pneumonia or pneumothorax. If charcoal is instilled, the outcome can be fatal. Although not the standard of care, chest radiographs may aid in the confirmation of NG placement before instilling charcoal or other medications. If the tube is identified in the chest cavity, it must be determined whether it entered through the lungs or through the esophagus. All possible charcoal should be removed by suctioning before removing the NG tube or, in the case of charcoal thorax, by chest tube drainage.

There are numerous reports of intracranial placement of NG tubes. Most cases have been reported in trauma patients; however, there is at least one report of intracranial placement in a nontrauma patient. As with any catheter insertion, force should never be used, and NG tubes should be inserted through the mouth in trauma patients who may have facial or basilar skull fractures. Any time a NG tube is placed and cannot be easily removed, an x-ray should be obtained to determine the location of the tube.

OROGASTRIC LAVAGE TUBES

Large-bore tubes (28 to 40 F) are used for gastric decontamination and charcoal instillation. The use of these tubes has come into relative disfavor in recent years.³ This was not because of complications but rather because of a lack of proven efficacy. Complications have only been rarely reported with the use of the tubes but have included esophageal tears and inability to remove the tube secondary to esophageal spasm. If an orogastric lavage tube cannot easily be removed, the patient should undergo fluoroscopic examination with contrast to determine its exact location and any kinking. If the tube is simply stuck because of esophageal spasm, glucagon can be given to assist in its removal.⁴

COMPLICATIONS OF GASTROINTESTINAL DEVICES

Edmond A. Hooker

The gastrointestinal (GI) device that is most commonly used by emergency physicians is the nasogastric (NG) tube. Other GI devices encountered in the emergency department include large-bore orogastric tubes, small-bore nasointestinal ("feeding") tubes, and transabdominal feeding tubes (gastrostomy, jejunostomy, and gastrojejunostomy tubes). Although complications from the use of these are rare, they must be anticipated and prevented, if possible.

TABLE 89-2 Techniques for Identifying Nasogastric and Nasointestinal Feeding Tube Placement**Indicates gastric placement**

Epigastric auscultation of air insufflated through the tube Aspiration of visually recognizable gastrointestinal secretions pH testing of aspirates (pH ≤ 6 indicates gastric placement) Failure to detect end-tidal carbon dioxide pattern using capnograph **Indicates tracheobronchial placement** Coughing or choking Inability to speak Air bubbles when proximal end of tube is placed in water

NASOINTESTINAL TUBES

The small-bore nasointestinal tubes (more commonly called feeding tubes) are usually placed to support nutrition. Complications of these tubes include all of those described with NG tubes (see Table 89-1), but the former are also more easily dislodged and clogged. With numerous reports of placement of these tubes into the respiratory tract and subsequent intrapulmonary instillation of tube feedings, most institutions require radiographic confirmation of tube placement.^{3*} A novel technique using a magnetic detector has been introduced recently and may help obviate a radiograph.⁷ Because patients can easily dislodge these tubes after initial confirmation of placement, some recommend pH testing before each use.⁸

Replacement of a dislodged tube should be performed according to the manufacturer's instructions and radiographic confirmation should be obtained (Table 89-3). When one of these tubes is clogged from buildup of sediment, the physician can attempt to unclog the tube by instilling saline or cola drink into the tube and leaving it for 30 min; however, replacement frequently will be necessary.⁹

TRANSABDOMINAL FEEDING TUBES

Although the techniques for the initial placement of transabdominal feeding tubes (gastrostomy, jejunostomy, and gastrojejunostomy) are beyond the scope of emergency physicians, complications related to these tubes need to be recognized (Table 89-4). These tubes can be placed by a surgeon via open technique, by a gastroenterologist via endoscopic technique (percutaneous endoscopic gastrostomy), or by a radiologist via percutaneous techniques. The radiographic technique has been associated with fewer complications than has open or endoscopically assisted placement.^{10,11}

Frequent minor complications are associated with the use of these tubes, including purulent drainage and leakage around the stomal site, clogging, dislodgement, and vomiting and diarrhea.

Drainage from the stomal site is a common finding and represents a foreign-body reaction due to the catheter. As long as there is no evidence of cellulitis or necrotizing fasciitis, local skin care with hydro-

TABLE 89-3 Method for Inserting a Nasointestinal Feeding Tube*

- Step 1: Prepare nares with topical anesthetic and lubricant. Restrain uncooperative patients. Lubricate and insert the stylet into the feeding tube (ensure that the stylet does not protrude beyond tip of tube).
- Step 2: Place tube through nares into hypopharynx. If patient starts coughing or choking, tube may be in respiratory tract or coiled up in hypopharynx. The cooperative patient may swallow liquids to assist passage.
- Step 3: After successful passage, remove stylet from tube and obtain a chest x-ray that includes the epigastric area. If tube is in proper position, start feedings.

* **Warnings:** Never reinsert a stylet into a feeding tube while the tube is still in the patient and never use a feeding tube before radiographic confirmation of placement.

TABLE 89-4 Complications Seen with Transabdominal Feeding Tubes

Complication	Initial Considerations
Purulent drainage from stoma	Local care with hydrogen peroxide unless cellulitis is present
Leakage from stoma	Carefully replace with larger tube
Tube occlusion	Attempt irrigation, most often just replace
Dislodged tubes	Gently replace, confirm placement with x-rays
Pneumothorax	High index of suspicion, consider needle aspiration
Bacteremia	Consider as potential source in septic patient
Bleeding from tract	If recently inserted, consider local injection, consult
Bleeding from granuloma buildup	Local therapy with silver nitrate
Infection of surrounding skin	Consultation, pull tube, IV antibiotics
Necrotizing fasciitis	Consider MRI to help confirm, surgical debridement
Peritonitis	Determine if fistula exists, consultation, IV antibiotics
Pulmonary aspiration of feedings	Reduce flow rate, half-strength feeds, consider Jtube
Vomiting or diarrhea	Reduce flow rate, half-strength feeds, stop feeds
Gastroesophageal reflux	Reduce flow rate, half-strength feeds, consider Jtube
Intestinal obstruction	Step feedings, NPO, admit and observe
Gastric outlet obstruction	Reposition tube
Gastric volvulus	Surgical consult
Gastric perforation	Surgical consult
Esophageal perforation	Surgical consult
Colonic perforation	Surgical consult
Colocutaneous fistula	Surgical consult
Electrolyte abnormalities	Change feedings or increase free water
Gastrointestinal bleeding	Endoscopy and therapy directed at cause

Abbreviation: NPO = non per os.

gen peroxide and warm water usually will clear up the problem. If there is granuloma formation with localized bleeding from friable skin, local treatment with silver nitrate usually will help.

Leakage of gastric contents can become a problem. This is managed by careful insertion of a larger tube. Care should be used not to force too large a tube into the stoma, because this can cause separation of the stomach wall from the abdominal wall.

Prevention is the best treatment for clogging of gastrostomy (G) and jejunostomy (J) tubes. Frequent flushing with water and careful crushing of pills usually can prevent this problem. Vomiting and diarrhea can be relieved by decreasing the amount of the feedings and/or diluting the feedings.

If the tube cannot be unclogged or if it has fallen out, replacement will be necessary. If the tube was placed by a surgeon or gastroenterologist and has not been replaced, it probably will have a bolster (also called a mushroom) holding the tube in place (Figure 89-1). This will prevent the tube from being removed. The bolster must be removed endoscopically or the tube may be cut off and the bolster allowed to pass through the GI tract.¹² The latter technique is generally safe in adults; however, its use in children has been associated with

FIG. 89-1. Percutaneous endoscopic gastrostomy tube with a mushroom bolster in place. (Adapted with permission from Gauderer MWL, Ponsky JL: A simplified technique for constructing a tube feeding gastrostomy. *Surg Gynecol Obstet* 152:83, 1981.)

more frequent complications.¹³ Endoscopic removal is advisable when there is suspected or potential obstructive disease of the GI tract, such as pyloric stenosis, intestinal pseudoobstruction, and intestinal stricture (e.g., due to radiation, ischemia, or inflammatory bowel disease). If the tube is cut, an abdominal radiograph should be obtained 1 week later to confirm passage of the internal component. Most reported complications from a retained internal bolster have occurred when the bolster did not pass within 1 to 2 weeks.¹⁴ When the feeding tube has already been replaced or was originally placed via radiographic technique, it should have a balloon holding it in place. The balloon usually can be deflated and the tube easily removed. If there is a problem with removal, the tube can be cut off halfway down; this usually will allow the balloon to deflate. If the catheter still cannot be removed easily, it can be cut off at the skin and the internal component allowed to pass. **It should be replaced as quickly as possible to prevent closure of the tract.** Although there is no published research stating how long it takes for a tract to mature, tracts that are 7 to 10 days old probably will remain open long enough to allow replacement. The physician first must determine, if possible, which type of tube is being used. If the tube is available, replacement with the same size is usually possible. If the tube is not available, it can be difficult to determine whether the tract is for a J or G tube. Location on the abdominal wall is not helpful. A tract for a G tube is usually larger. Old records may be useful and should be obtained, if possible. After determining the type of tract and size of tube used previously, insertion should be performed by the physician with a water-soluble lubricant. If the size of the tube being replaced cannot be ascertained, it is reasonable to start with a 16-F replacement G tube or Foley catheter. The lubricated tube should pass easily into the stoma without additional equipment. If resistance is met, the attempt should be abandoned. A smaller tube can be tried to keep the tract open. After replacing the tube, a 20- to 30-mL bolus of a water-soluble contrast material (e.g., Gastrografin) should be instilled through the tube, and **a supine abdominal x-ray should be obtained within 1 to 2 min.**¹⁵ The x-ray should demonstrate rugae of the stomach for a G tube and flow into a small bowel for a J tube. If there is any question of improper placement, immediate consultation should be obtained.

A special caution regarding J tubes should be noted. Jejunostomy tracts are smaller, and smaller tubes are used (8 to 14 F). These tubes **usually are not sutured in place** and frequently become dislodged. They can be replaced with catheters made specifically for jejunostomies or with Foley catheters. **If a Foley catheter is used to replace**

a lost J catheter, the balloon should never be inflated because it can cause a bowel obstruction or damage the jejunum. The tube is lubricated, inserted into the stoma, and advanced 20 cm. These tubes are easily replaced if the tract is mature; however, if resistance is met, referral to a radiologist for fluoroscopic placement using guidewires is recommended.¹⁶

THE LIVER TRANSPLANT PATIENT

Steven Kronick

DEMOGRAPHICS AND SURVIVAL

More than 70,000 liver transplantations have been performed worldwide. In the United States, 5181 liver transplantations were performed at 123 centers in 2001. At present, the number of transplantations performed is limited only by the availability of organ donors. The use of living donors has expanded the potential for liver transplantation.¹ In October of 2002, more than 17,000 patients in the United States were on the liver transplant waiting list. Improvements in surgical techniques, immunosuppression protocols, and patient selection have increased mean patient survival to 87 percent at 1 year and 80.9 percent at 3 years.²

Transplantation is the treatment of choice for end-stage liver disease (ESLD) refractory to all other interventions and is considered an effective means to improve quality of life as well as survival.³ Indications for liver transplantation are listed in Table 90-1. The incidence of transplant-related problems is high (Table 90-2), and evaluation is made difficult by the fact that many of the complications present with similar signs, symptoms, and laboratory abnormalities. Most transplant-related problems will require, at a minimum, direct communication with the transplant center for consultation and follow-up.⁴

TRANSPLANT PROCEDURE

The harvested liver can tolerate ischemia up to 24 h, but it functions best if ischemia time is less than 8 h. The risk of preservation injury increases after this time. Most patients undergo bilateral subcostal incision with upper midline extension to the xiphoid process. After recipient hepatectomy, the donor liver is placed in the recipient, typically in the same (orthotopic) location as the liver it is replacing. Venovenous bypass, used by some centers, may predispose the patient to thrombosis and pulmonary embolism. Normal color and consistency return to the organ in approximately 15 min. Early bile production after vascular reanastomosis is most indicative of graft function. The preferred method for biliary tract reconstruction is an end-to-end choledochocholedochostomy. The use of a percutaneous biliary drain varies by center, and when it is used, it may stay in place for several weeks to months. In children with biliary atresia and in adults whose anatomy will not allow choledochocholedochostomy, Roux-en-Y choledochojejunostomy is performed.⁵ Newer techniques being used increasingly in pediatric patients include reduced-size liver transplant, split-liver transplant, and living-related transplantation.⁶

POSTOPERATIVE COMPLICATIONS

Immediate postoperative complications are not seen in the emergency department because patients typically remain hospitalized for approximately 1 to 2 weeks. Postoperative problems seen in the emergency department relate most commonly to bleeding, biliary, vascular, and wound complications.⁷

Bleeding Complications

The vast majority of postoperative bleeding complications in patients will occur in the first week and will not be seen in the ED. Gastrointestinal bleeding can develop after discharge. It should be managed in the usual fashion but may signal graft dysfunction and be accompanied by profound hypoglycemia and progressive coagulopathy.⁴ Portal hypertension is reversed by liver transplantation, and gastrointestinal (GI) bleeding from varices postoperatively may be indicative of portal

TABLE 90-1 Indications for Liver Transplantation

Primary biliary cirrhosis
Primary sclerosing cholangitis
Fulminant and subfulminant hepatitis
Cirrhosis due to hepatitis B or C virus
Alcoholic cirrhosis
Children: biliary atresia (accounts for >50%)
selected inborn errors of metabolism
Controversial indications Hepatocellular carcinoma
Contraindications Extrahepatic malignancy Liver metastases
Extrahepatic organ failure Noncompliance Active substance abuse
AIDS

TABLE 90-2 Common Complications Following Liver Transplantation

Complication	Percent with Complication
Infection	>60
Rejection	>50
Neurologic	£47

Renal insufficiency	£25
Hemorrhage	£20
Biliary stenosis, leak	£20
GI	£15
PTLD	4

Abbreviation: PTL = posttransplant lymphoproliferative disorder.

vein thrombosis. Another contributing factor that may predispose patients to GI bleeding is high-dose steroids. Cytomegalovirus (CMV), herpes simplex virus (HSV), and candidal infection also can lead to significant bleeding.

Biliary Complications

Biliary problems account for a significant proportion of complications, and incidence may be as high as 28 percent.⁸ Leaks, strictures (ductal narrowing), and obstruction (ductal blockage) account for 80 percent of these complications. In general, leaks occur early, with 38 percent in the first 30 days and most (80 percent) within the first 6 months.⁹ Early leaks tend to be more severe owing to duct disruption and higher immunosuppression, notoriously difficult to treat, and generally due to hepatic artery thrombosis or other technical causes. Leaks after the first month are invariably associated with either elective or inadvertent removal of an indwelling biliary catheter.¹⁰ In children, stricture and obstruction are responsible for 90 percent of complications.⁹ For patients with Roux-en-Y procedures, the leak tends to occur at the anastomosis, whereas for the majority of patients who have choledochocholedochostomy, the leak is at the anastomosis early or the T-tube site later.⁵ The cause of biliary injury is either immunologic or preservation injury, infection, or ischemia. Biliary leaks present most commonly with peritonitis, fever, abdominal pain, constipation, and abdominal distention, but signs and symptoms may be subtle or masked due to the use of immunosuppressive agents. Laboratory abnormalities are often nonspecific and include leukocytosis, hyperbilirubinemia, and increased alkaline phosphatase. If abdominal drains are still in place, one may see bile in the drain, or if a T-tube is present, bile may appear at the tube site.⁷ Evaluation should include right upper quadrant ultrasound, although sensitivity for biliary abnormality may be only 50 percent. Since there is an association of biliary abnormality with hepatic artery thrombosis (HAT), Doppler ultrasonography should be performed to evaluate vascular flow to the graft. Treatment of the leak includes drainage of abscess, if present, and intravenous antibiotics. Broad-spectrum antibiotic coverage should be directed against gram-positive, gram-negative, and anaerobic organisms.⁸ Bacterial infections tend to be polymicrobial and include *Enterobacter*; *Enterococcus*, *Bacteroides*, *Clostridium*, and *Pseudomonas* species.⁴

After 12 months, stricture and/or obstruction accounts for the vast majority of biliary complications. Development of a biliary complication is heralded by three typical presentations. Most common is intermittent episodes of fever and fluctuating liver function tests. The second presentation is gradual asymptomatic worsening of liver function tests. Finally, biliary complication may present as acute bacterial cholangitis with fever, chills, abdominal pain, jaundice, and bac-

teremia. Stricture or narrowing of the bile duct frequently develops insidiously.¹⁰ The presentation of biliary complications can be difficult to distinguish clinically from rejection, HAT, CMV infection, or a recurrence of a preexisting disease (especially hepatitis).

Liver transplant recipients with suspected biliary complications should be referred to the transplant center. All patients should have a complete blood count (CBC) with platelet count and differential; serum chemistries, including electrolytes, blood urea nitrogen (BUN), creatinine, basic coagulation studies, liver function tests, amylase, and lipase levels; cultures of blood, urine, bile, and ascites, if present; chest x-ray; and abdominal ultrasonography with Doppler flow studies. Ultrasound rules out the presence of fluid collections, screens for the presence of thrombosis of the hepatic artery or portal vein, and identifies any dilatation of the biliary tree, although the absence of biliary dilatation does not rule out obstruction or other posttransplantation pathology. The intrahepatic ductal system rarely appears dilated appreciably by ultrasound, even in the presence of complete obstruction. Patients often require cholangiography for complete evaluation. Patients with choledochocholangiostomy may be best evaluated by endoscopic retrograde cholangiopancreatography (ERCP) because it permits both a radiographic diagnosis and the potential for nonoperative intervention. Patients who have Roux-en-Y hepaticojejunostomy or those who cannot have ERCP must undergo percutaneous cholangiography. Early broad-spectrum prophylactic antibiotics should be administered prior to any biliary tract manipulation.

Vascular Complications

Vascular complications are less common than biliary complications but are associated with high morbidity, mortality, and graft failure. Hepatic artery thrombosis (HAT) is the most common vascular complication and tends to occur within the first 3 weeks after transplantation.¹¹ The incidence reported is between 5 and 40 percent and tends to be higher in children.¹² For this reason, children are frequently treated prophylactically with antiplatelet agents.

The presentation of HAT in the early postoperative period may be signaled by elevated prothrombin (PT) and transaminase levels, little or no bile production, liver abscess, or unexplained sepsis or as a biliary tract problem (leak, obstruction, abscess, or breakdown of the anastomosis). HAT may present with massive hepatic necrosis, sepsis, fever, and bacteremia after early thrombosis, bile leak because the hepatic artery is the sole blood supply, or relapsing fever with bacteremia secondary to focal abscesses or biloma, or it can be asymptomatic if collaterals have formed.⁷ HAT is ominous and frequently requires retransplantation. Occasionally, if diagnosed early, immediate thrombectomy and revision of the anastomosis may preclude the need for retransplantation. Pediatric patients are more susceptible to HAT and have a much more varied presentation, with an incidence as high as 26 percent in children and 31 percent in neonates. Duplex ultrasonography has a sensitivity of 92 percent for the diagnosis of HAT.¹³ If ultrasound is not diagnostic and suspicion remains, one should proceed to angiography. Hepatic artery rupture is uncommon and generally associated with intra-abdominal sepsis and poor prognosis.⁷ Portal vein thrombosis is less common and affects 2 to 3 percent of patients. The diagnosis is suggested by variceal hemorrhage, massive ascites, or other signs of portal hypertension. Initially, effort is directed toward reducing the portosystemic pressure gradient, but retransplantation may be necessary.

Wound Complications

Wound problems are probably underreported and include infection, hematomas, and seromas as the most common complications. Presentation may be subtle. Fever, chills, incisional pain, swelling, erythema, or drainage may not always be present due to immunosuppressive diminution of signs of inflammation. Infection can lead to necrotizing

fasciitis. An increased degree of suspicion is necessary. Adequate drainage and early broad-spectrum antibiotic coverage should be considered.

REJECTION

Acute allograft rejection is seen most commonly at 7 to 14 days. The incidence of acute rejection varies from 40 to 80 percent during the first posttransplant year. After several months, the incidence of acute rejection decreases steadily, but it may be triggered at any time by tapering of immunosuppressive agents. Although frequently subtle in presentation, symptoms of rejection include fever, liver tenderness, lymphocytosis, eosinophilia, liver enzyme elevation, and a change in bile color or production. In the perioperative period, the differential diagnosis must include infection, acute biliary obstruction, and vascular insufficiency. The diagnosis can be made with certainty only by excluding other causes of graft dysfunction and biopsy, which usually requires referral back to the transplant center for management and follow-up. Acute rejection typically is treated by a high-dose glucocorticosteroid bolus followed by a rapid taper over 5 to 7 days. This treatment is effective in 65 to 80 percent of transplant recipients.⁴ Secondary therapy includes the infusion of antilymphocyte globulin (e.g., OKT3), which is accompanied by a variety of potential side effects. Both these therapies are best managed at an experienced transplant center.

Chronic allograft rejection occurs in approximately 5 to 10 percent of recipients and is a major cause of late graft failure. The primary manifestation of chronic rejection is a persistently cholestatic liver injury pattern with elevated serum alkaline phosphatase and bilirubin, which can be associated with pruritus. Significant loss of hepatic synthetic function is often not evident until late in the course of chronic rejection. The diagnosis is made by biopsy.

INFECTION

General Considerations

The vast majority of liver transplant recipients have at least one episode of infection at some time after their transplantation, and many have more than one episode. Infections or their complications are believed to account for a large number of deaths. Vigilance for infection must remain high because immunosuppression-induced blunting of the inflammatory response may mask the classic signs and symptoms of infection.

Timing of infection after transplantation can be organized into three segments: less than 1 month, 1 to 6 months, and greater than 6 months (see Table 99-3).¹⁴

INFECTION IN THE FIRST 30 DAYS Infection in the first 30 postoperative days is primarily from bacteria and fungi. The patient is typically at the greatest level of immunosuppression, and the anastomoses are at their most vulnerable. The vast majority of infectious agents seen in less than 1 month are the same nosocomial agents seen in similar surgical patients. Opportunistic organisms are notably absent in the first month. CMV is discussed below.

During the first postoperative month, intra-abdominal infections—including cholangitis, peritonitis, and liver and other intra-abdominal abscesses—predominate. Presentation is marked by fever, abdominal pain and distension, ascites, and occasionally, jaundice. Workup should include a CBC with differential, liver function tests, urinalysis, chest x-ray, abdominal ultrasound, and blood and fluid cultures. Evaluation may include ultrasound, computed tomographic (CT) scan, T-tube cholangiography, ERCP, liver biopsy, and cultures of blood, urine, or aspirated fluid. The organisms responsible tend to be enterococci, gram-negative aerobes, anaerobes, *Staphylococcus*, and *Candida*

species. Patients also may present with pneumonia or urinary tract infections related to intubation or indwelling bladder catheterization while hospitalized.

INFECTIONS AFTER 30 DAYS From 1 to 6 months, most infection is from viruses [reactivation, donor transmission, Epstein-Barr virus (EBV)] or opportunistic organisms. Special cultures must be obtained if less common organisms such as fungi, viruses, CMV, *Nocardia* species, and *Mycobacterium tuberculosis* are suspected.

After 6 months, the incidence of serious infection declines, with cholangitis predominating. Risk of infection after 6 months approaches that of the general population, although morbidity and mortality may be higher. A high index of suspicion should be maintained whenever immunosuppression is high. Close monitoring is essential because rapid deterioration can take place while the patient is still in the ED.

Bacterial Infection

Bacterial infection is most common in the first month. Although gram-negative organisms predominate (especially *Pseudomonas aeruginosa*), gram-positive and anaerobic organisms are not uncommon. Broad-spectrum antibiotics should be considered early in the patient's course. Bacterial infection is frequently associated with the vascular or biliary anastomosis, especially HAT but also portal vein thrombosis. Ischemia may lead to bile leak and abscess or deep soft tissue infection. After the first month, the incidence of bacterial infections decreases and the incidence of opportunistic infection increases, but vigilance for bacterial illnesses should remain high. Community-acquired pneumonia is most likely due to *Streptococcus pneumoniae* and *Haemophilus influenzae*. Meningitis shows a high preponderance of *Listeria monocytogenes* as well as *S. pneumoniae*, *Staphylococcus aureus*, and gram-negative rods. Empirical antibiotic coverage should be aimed at these flora.

Fungal Infection

Although uncommon, fungal disease is seen most within the first 2 months; it can be disseminated and is accompanied by high mortality. Fungal disease can present with multiple organ involvement, peritonitis, fungemia, pneumonitis, or asymptomatic colonization. The incidence of fungal disease is continuing to decrease, but mortality remains high. Mortality is up to 78 percent if disease is systemic. *Candida* species are responsible for up to 75 percent of fungal illnesses. The diagnosis is by culture or biopsy, and the fungus may be difficult to isolate. Disseminated infection is present when infection is found in two or more sites and is associated with even higher mortality. Fungal infection becomes more likely with retransplantation, the Roux-en-Y procedure, preoperative steroid use, accompanying vascular complications, the use of three or more intravenous antibiotics, and when the transplant is performed emergently. Endemic mycoses (coccidioidomycosis, histoplasmosis, blastomycosis) are always possible in the immunocompromised host but are seen rarely in liver transplant patients.⁴

Viral Infection

Viral illnesses tend to present within the first few months. Viral and bacterial illnesses are often seen concurrently.

CYTOMEGALOVIRUS INFECTION The most common viral agent and the most common cause of infection after transplantation is cytomegalovirus (CMV), a herpesvirus. It is reported to occur in between 23 and 85 percent of all liver transplant patients. Despite its high incidence and morbidity, it is rarely fatal unless disseminated and rarely has a significant effect on graft survival, (t generally occurs

within the first 3 months, with the peak incidence in the third and fourth weeks. Later occurrence generally is related to the need to increase immunosuppression for the treatment of a prolonged episode of rejection. CMV can cause primary infection, or the infection can be a reactivation. Infection has three basic effects. First, it can produce a mononucleosis-like syndrome with spiking fever, arthralgias, malaise, neutropenia, atypical lymphocytes, and thrombocytopenia, with mild or moderate elevation in transaminase levels. Jaundice is rare. Second, CMV is frequently associated with opportunistic infection, which may be due to an additional immunosuppressive effect of its own. Finally, there is an increased propensity for allograft rejection.

CMV pneumonitis is characterized by bilateral interstitial infiltrates that may lead to acute respiratory distress syndrome. Diagnosis may require bronchoalveolar lavage, but the appearance of the chest x-ray and the clinical picture may be suggestive enough for diagnosis. CMV pneumonitis may be seen in conjunction with *Pneumocystis carinii* pneumonia (PCP).

CMV hepatitis may present similarly to rejection, with fever, malaise, anorexia, abdominal pain, hepatomegaly, and liver dysfunction. Liver biopsy is frequently needed for diagnosis but still may not be able to distinguish CMV disease from rejection. Disseminated disease is frequently associated with an increase in immunosuppression, especially with treatment with OKT3.

CMV chorioretinitis may present with decreased visual acuity, photophobia, scotomata, floaters, eye redness, or pain. Its presence signals a poor prognosis and the presence of profound immunosuppression.

There are three patterns of CMV infection. The patient at greatest risk is the seronegative recipient of a seropositive donor. Disease also maybe caused by reactivation of latent virus that replicates after the initiation of immunosuppression—typically in the seropositive recipient of a liver from a seronegative donor. Finally, a seropositive recipient may receive a liver from a seropositive donor, which may produce either reactivation or superinfection, although it is clinically impossible and irrelevant to distinguish between them.

Effective treatment depends on rapid diagnosis. Treatment is with intravenous ganciclovir for 2 to 4 weeks. Diagnosis traditionally has been based on histology and culture. Standard fibroblast tube cell culture, however, can require 10 to 14 days for incubation. Serologic markers are too insensitive in the immunosuppressed patient, and electron microscopy is cumbersome. The shell-vial technique can detect the presence of CMV after 16 h of incubation. It is an indirect immunofluorescence testing method that uses a monoclonal antibody directed at an early antigen of the virus. Early detection and high antigenemia correlate positively with the severity of the infection.

OTHER VIRUSES Other viruses may cause illnesses in the posttransplant patient. Up to 34 percent of all transplant patients develop HSV, and half of these present within the first 3 weeks. Mucocutaneous or genital disease is generally due to reactivation of latent infection. It is usually not severe, and diagnosis can be made with Tzanck smear or culture. EBV can cause primary infection in children or the more common reactivated infection in adults. The disease can be self-limited and cause a mononucleosis-like syndrome, with fever, tonsillitis, and lymphadenopathy, or it may progress to a polymorphous, multiorgan B cell infiltrative process with high mortality. Finally, it may produce a localized solid tumor. EBV plays a role in the development of a post-transplantation lymphoproliferative disorder and has a high incidence (20 to 30 percent) in patients maintained on immunosuppression and higher (80 percent) in patients who have received antithymocyte antibody. Adenovirus and enteroviruses may cause systemic illness but are uncommon.

Parasitic Infection

Parasites are not common. PCP may present concomitantly with CMV or by itself. Diagnosis may require bronchoalveolar or transbronchial

biopsy. Prophylaxis with trimethoprim-sulfamethoxazole (Bactrim) for the first 3 months has greatly reduced the incidence of PCP. *Toxoplasma gondii* is also uncommon but may cause a meningoencephalitis or single or multiple mass lesions. *Toxoplasma* infection may cause fever, mental status changes, focal neurologic signs, seizures, or visual changes.

COMPLICATIONS OF IMMUNOSUPPRESSIVE AGENTS

Therapeutic immunosuppression is accompanied by a number of side effects and complications. Common and most life-threatening are the infections that occur with the suppression of cell-mediated immunity. The agents of immunosuppression also have a number of nonspecific toxicities that complicate their use (see Table 70-2). Combined toxicities can produce or worsen preexisting renal insufficiency, hypertension, and hyperglycemia. Hypertension is perhaps the best example of combined toxicity.

Azathioprine interferes with both B and T cell responses to antigenic stimulation. Generalized myelosuppression is a common side effect resulting in leukopenia and, to varying degrees, thrombocytopenia and anemia (megaloblastic) and generally is seen within the first few weeks. Other observed toxicities include hepatitis, cholestasis, HAT, pancreatitis, dermatitis, and alopecia. Prolonged use also predisposes to malignancies such as squamous cell carcinoma of the skin and lip, cervical carcinoma, and lymphoproliferative disorder. Mycophenolate mofetil is a new antiproliferative agent often used to replace azathioprine. Again, leukopenia is a common toxicity, although GI distress is seen as well.

Glucocorticoids act primarily by inhibiting T cell and macrophage function. In addition to immune suppression, long-term use of glucocorticoids suppresses endogenous adrenal function, which may produce Cushing syndrome and cause hypertension, glucose intolerance, osteoporosis, avascular necrosis of the hip, cataracts, pancreatitis, peptic ulcer disease, delayed wound healing, behavioral disorders, and malignancies.

Cyclosporine and FK506 inhibit T cell proliferation. Nephrotoxicity is a common and usually reversible side effect manifest by elevated serum creatinine levels, hypertension, hyperkalemia, hyperuricemia, and gout. Patients are sensitive to dehydration. Other side effects include headache, hirsutism, gingival hyperplasia, hyperglycemia, hypomagnesemia, hypercholesterolemia, hypertriglyceridemia, hepatotoxicity, and hemolytic uremic syndrome. Unlike those of other immunosuppressive agents, blood levels of cyclosporine and FK506 can be monitored along with serum creatinine to avoid serious toxicity; however, random levels are rarely helpful, and the dose is adjusted based on trough levels.⁴

Nonsteroidal anti-inflammatory agents should be avoided because they may increase nephrotoxicity.

There are numerous drug interactions to consider with a patient taking immunosuppressive agents, and it is suggested that before starting any new drug, interactions with the patient's immunosuppressants should be determined. Some of these interactions and adverse effects are summarized in Tables 99-2 and 99-3.

INCIDENTAL PROBLEMS

Immunization

All live virus vaccines are contraindicated in immunosuppressed patients. Vaccines consisting of denatured protein, carbohydrate, or killed virus are safe, so diphtheria-pertussis-tetanus (DPT), inactivated polio, *H. influenzae* Pittman type, and Heptavax are all safe. Live viral or bacterial vaccines are absolutely contraindicated (oral polio, measles, mumps, rubella, yellow fever, bacille Calmette-Guerin, TY21a typhoid, and varicella). All of these may produce clinical disease.

Surgery

If surgery for problems other than those related to the graft is necessary, complications secondary to chronic steroids and immunosuppression should be anticipated. Also, caution must be taken in the presence of a coagulopathy. It is recommended that immunosuppression not be stopped unless there is sepsis, in which case the doses of immunosuppressive agents might need to be reduced. Two series looking at cardiac and general surgery showed no documented decline in graft function and no need for stress dosing of steroids.^{15,16}

Bone Disease

Skeletal complications are responsible for significant morbidity and, because of increased survival times in transplant recipients, are becoming more prevalent. Osteopenia and osteonecrosis can occur due to immobility, poor nutritional status, decreased muscle mass, steroid use, and immunosuppressive drugs. The first 3 to 6 months after transplantation are accompanied by accelerated bone loss (mostly trabecular). Fractures are common in the first year postoperatively, particularly at sites of trabecular bone (vertebrae and ribs), although long bone and pelvic fractures are also seen. The incidence of vertebral compression fracture may be as high as 38 percent. Patients may develop avascular necrosis of the femoral head from steroid use. Fractures should be treated in the standard fashion.

Neurologic Complications

It is reported that between 9 and 42 percent of all adult liver transplant patients have a neurologic complication at some time during their posttransplant course.¹⁷ Neurologic complications in children, however, are much less common. Common presenting problems include headache, seizures, and mental status changes. The etiology is more likely to be noninfectious than infectious. Common noninfectious etiologies are immunosuppressive toxicity, metabolic derangement, and hemorrhage.

Central nervous system (CNS) infection is most common in the first few months, with viral and fungal etiologies predominating. CNS CMV infection is rare, and CNS herpesvirus infection is seen with the same frequency as in the general population. Bacterial etiologies include *Listeria*, *Klebsiella*, *S. aureus*, *Nocardia*, and *Escherichia coli*. *Aspergillus*, *Candida*, and *Cryptococcus* species are the more common fungal agents involved. Cryptococcal disease is most common between 2 and 7 months. Patients presenting with headache, seizures, or mental status changes need to be evaluated for the presence of metabolic derangement as well as hemorrhage or infection. They often will require CT scan of the head and lumbar puncture to rule out these etiologies. Neuropathic pain may be seen and is poorly responsive to opioids. It may respond to tricyclic antidepressants.

Cardiovascular Disease

Cardiovascular complications are the leading late cause of death in liver transplant patients. Liver transplant patients are at risk for the development of diabetes, hyperlipidemia, and hypertension, so their risk of cardiovascular disease also increases. Their relative risk, however, still surpasses that of age- and sex-matched patients.^{15,18}

Malignancy

The second leading cause of late death in liver transplant patients is de novo malignancy. There is an increased risk of new malignancy including squamous cell carcinoma, lymphomas, AND posttransplant lymphoproliferative disorder (PTLD). There is no increased risk of lung, colon, breast, or prostate cancer.¹⁹ The most common posttransplant malignancy is squamous cell cancer of the skin, but sarcoma,

Kaposi sarcoma, and hepatobiliary cancer occur. PTLTD accounts for 20 to 50 percent of de novo tumors after liver transplant and is more frequent in pediatric liver transplant recipients. Immunosuppression and EBV infection have been implicated.

GASTROINTESTINAL IMAGING

Michael J. Bono

BASIC IMAGING TECHNIQUES

Plain Film Radiography

Plain films remain the workhorse imaging study for the emergency department evaluating a patient with abdominal pain. Plain films can be obtained quickly, cause no discomfort to the patient, and are relatively inexpensive compared with other gastrointestinal (GI) imaging modalities. The emergency physician can interpret plain films. Unlike the chest, where the organs have great differences in water and air content

and, hence, in radiodensity, the abdomen contains structures of similar radiodensities. Only the presence of air and fat in the bowel or other structures allows identification of organ boundaries, and the air is transient. A plain film of the abdomen represents a "snapshot" of a dynamic system and should be examined systematically. A time-honored technique is to first examine the bones (spine, ribs, pelvis, and hips); the upper quadrants, flanks, and mid-abdomen for organ masses and calcifications; and then the lower abdomen. The physician should attempt to look at the area of special interest last.

At most centers, an "acute abdominal series" includes a supine film centered at the iliac crest, an upright film centered at the crest, and an upright posteroanterior chest film. The supine film detects fluid or blood in the peritoneum and gas in the bowel, and the upright film displays any air-fluid levels. If the patient is too ill to stand, a left lateral decubitus (left side down) view is acceptable, but a right lateral decubitus is not. On a left lateral decubitus view, free air can be detected between the liver and the peritoneum; this is not possible in a right lateral decubitus view (right side down) because air in the bowel loops will contact the peritoneum. The standard upright posteroanterior chest view is best for demonstrating free air in the peritoneal cavity and other pathologic conditions of the chest that cause abdominal pain, such as pneumonia, pneumothorax, or atelectasis.

Contrast Radiography

Barium sulfate remains the standard substance for contrast GI imaging. Barium is an insoluble material that is suspended in different carriers by different manufacturers. It has high viscosity and is not absorbed by the GI tract. Gastrograffin is a water-soluble substance, has low viscosity, and, like barium, is not absorbed by the GI tract in most normal adult patients. It is absorbed slightly by the gut in children. Gastrograffin draws substantial amounts of fluid into the bowel lumen, and its low viscosity causes rapid transit through the small bowel into the colon. It therefore has a considerable laxative effect. Gastrograffin is not a recommended oral contrast agent in children, in particular neonates and infants, because the fluid shifts and laxative effect may cause significant fluid and electrolyte disturbances.

Computed Tomography

Computed tomography (CT) provides imaging of solid organs and, very importantly, a view into the retroperitoneum. Unlike plain radiographs, CT is not dependent on the amount of air and gas in the bowel. Oral contrast material is given to identify bowel, and intravenous contrast material enhances the density of blood vessels. The introduction of the helical CT scan (spiral CT) has made a significant impact on abdominal imaging due to the speed of the procedure. Routine CT scanning of the abdomen usually requires the patient to lie motionless for 15 to 30 min, whereas the helical CT scan may be finished in a single breath hold. The radiation dose to the patient is unchanged. Another advantage of helical CT is improved vascular opacification, which allows excellent imaging of the thoracoabdominal aorta and renal arteries. Data obtained from helical CT can be reformatted in several ways, revealing three-dimensional surface anatomy and obviating arteriography.

Radionuclide Scanning

Radionuclide scanning has been virtually replaced by ultrasonography for emergency department patients with right upper quadrant pain. Technetium-99m-labeled iminodiacetic acid (IDA) is injected intravenously, is taken up by hepatocytes, is secreted into the bile canaliculi, and then flows into the small bowel. Normally there is a small amount of reflux into the cystic duct and gallbladder, but in cholecystitis the cystic duct is frequently occluded. The gallbladder, hepatic duct, and common duct should be visualized within 1 h of iminodiacetic acid administration, but total test time may be several hours.

Ultrasonography

Ultrasound is a valuable tool for the diagnosis of select conditions in the ED. It is noninvasive and inexpensive and should be readily available to the ED physician. Improvements in transducer technology have greatly improved ultrasound imaging. Ultrasound is somewhat operator dependent, and the images are difficult to interpret in obese patients or patients with large amounts of intestinal air or gas. Air is a poor conductor of ultrasound, because it scatters, refracts, and reflects the sound waves. Fluid-filled structures transmit sound exceedingly well, and because most soft tissues are composed of different amounts of water, ultrasound is feasible throughout the GI tract and pelvis. A full bladder is an acoustic window into the pelvis, and the liver helps transmit ultrasound in the right upper quadrant.

SPECIFIC GASTROINTESTINAL CONDITIONS

Plain Film Radiography

In the past, tradition dictated the routine use of plain films to screen patients with acute abdominal pain.¹ Routine plain-film screening of patients with acute abdominal pain is not advisable, because the yield of positive findings that would change clinical management is low, in the range of 10 to 40 percent.² However, in the proper clinical setting, plain abdominal radiographs are entirely appropriate and are still considered the first test of choice. In patients with a suspected perforated ulcer or free air in the abdomen, plain films demonstrate free air, if present, in a large percentage of patients.³ Plain films may demonstrate as little as 1 to 2 mL of air.⁴ In patients with suspected small bowel obstruction, plain films are the initial method of imaging. Plain films have a sensitivity of 69 to 82 percent for revealing high-grade small bowel obstruction, but, when combined with barium contrast studies, the sensitivity rate may approach 100 percent.^{5,6} Low-grade small bowel obstruction is difficult to demonstrate on plain films and has much lower diagnostic rates.⁷ Other appropriate conditions for the use of plain film radiographs include moderate or severe abdominal tenderness, suspicion of bowel ischemia, ingestion of radiopaque foreign bodies, and penetrating foreign bodies, such as gunshot wounds.

Abdominal Computed Tomography

Computed tomography is the diagnostic tool of choice for many acute abdominal conditions. It is the first imaging study of choice for patients with suspected diverticulitis, pancreatitis, pancreatic pseudocyst, aortic aneurysm, blunt trauma, and appendicitis. The diagnosis of appendicitis can be made on clinical evaluation, but CT has been proven remarkably sensitive and specific in confirming the diagnosis.⁸ Patients with signs and symptoms consistent with acute appendicitis who are otherwise healthy may undergo CT without oral or intravenous contrast, although the sensitivity and specificity are inferior to those of contrast CT.^{9,11} CT is a useful adjunct to plain films in suspected cases of intestinal ischemia, where specific findings may include pneumatosis intestinalis, portal venous gas, mesenteric vessel occlusion, and enlargement of a thrombosed vein.¹² Although patients with suspected small bowel obstruction should be imaged initially with plain radiographs, CT has similar sensitivity in revealing high- and low-grade obstructions. When CT correctly showed a small bowel obstruction, the cause of the obstruction was demonstrated in 95 percent of cases. CT offers another advantage to the emergency physician evaluating the patient with multiple potential causes for acute abdominal pain. Although never advocated as a "screening tool," CT scanning can pinpoint a diagnosis in 95 percent of cases where clinical judgment and other imaging studies fail to narrow a wide range of potential diagnoses.¹³

Ultrasonography

Ultrasound is the initial imaging study of choice for evaluation of patients with right upper quadrant pain. By using the liver as an acoustic window, ultrasound can detect cholelithiasis, cholecystitis, choledocholithiasis, biliary duct dilation, and pancreatic masses, both solid and cystic. Ultrasound is also the modality of choice for evaluating patients with pelvic pain. Transvaginal scanning has supplemented the transabdominal approach because of better visualization with higher-frequency endovaginal probe transducers (see Chap. 113, "Pelvic Ultrasonography"). Ultrasonography of the genitourinary system is discussed in Chap. 100, "Renal Imaging."

Graded-compression ultrasound imaging for acute appendicitis has been studied extensively. Sensitivities for appendicitis range from 68 to 93 percent and specificities between 73 and 100 percent, with accuracy in the 95 percent range.¹⁴ Graded-compression ultrasonography can reduce negative laparotomy rates.¹⁵ The ultrasonographer is searching for a tubular structure off the cecum that is compressible without pain and is no larger than 6 mm in diameter. An infected, inflamed appendix is tender, larger than 6 mm in diameter, fluid filled, and noncompressible. The appendix is difficult to visualize, and the examination is best left to experienced ultrasonographers, which is the reason CT has replaced ultrasound for evaluation of the appendix in many institutions. Negative ultrasound results in the face of a strong clinical suspicion should never delay surgical intervention. The false-negative rate for graded-compression ultrasonography is from 6 to 14 percent. Other disease processes that can confuse the clinical picture are cecal diverticulitis, inflammatory bowel disease involving the terminal ileum, and periappendiceal phlegmon. Graded-compression ultrasonography is most helpful in the evaluation of patients with atypical right lower quadrant pain and a suspicion of appendicitis.

Air Contrast or Barium Enema

For children with signs and symptoms suggestive of intussusception, air contrast enema is preferred over barium enema to avoid the potential risk of barium spillage into the peritoneal cavity. Plain films may demonstrate signs of intestinal obstruction, such as distended loops, air-fluid levels, and a paucity of bowel gas in the right lower quadrant, the so-called Dance sign. A barium enema may be useful for the diagnosis of bowel obstruction, volvulus, appendicitis, and diverticulitis, usually in consultation with surgical colleagues, although its emergency use has been supplanted by CT scanning.

Angiography

Computed tomography has replaced angiography for imaging patients with suspected abdominal aortic aneurysm. Angiography may be helpful in evaluating patients with lower GI bleeding, particularly when combined with colonoscopy to pinpoint the bleeding lesion.¹⁶

Radionuclide Scanning

Radionuclide scanning can be a useful adjunct to ultrasonography for patients with right upper quadrant abdominal pain. When the ultrasound results are negative or inconclusive in a patient with suspected cholecystitis or cystic duct obstruction, radionuclide scanning may be diagnostic in the absence of stones. It may take several hours for the radioisotope to localize to the affected area.

Magnetic Resonance Imaging

Magnetic resonance imaging currently has no role in imaging the GI tract in the emergency department patient. Magnetic resonance imaging is outstanding for imaging the central nervous system and musculoskeletal system, but cost, time in the scanner, and poor image quality due to move-

SECTION 9 • GASTROINTESTINAL EMERGENCIES

ment of the bowel limit applicability. Magnetic resonance imaging is being evaluated as a tool for imaging relatively stationary GI structures, such as the appendix and biliary tree, and has shown some promise.^{17,18}

RENAL AND GENITOURINARY DISORDERS

ACUTE RENAL FAILURE

Richard Sinert Peter R.
Peacock, Jr.

Acute renal failure (ARF) is the deterioration of renal function over hours or days resulting in the accumulation of toxic wastes and the loss of internal homeostasis. Clinicians have only indirect measures of glomerular filtration rate (GFR) to define ARF, such as a 50 percent decline in creatinine clearance or a 50 percent increase in serum creatinine from baseline. The diagnosis of ARF is complicated by the fact that acute declines in GFR, especially early in their course, are asymptomatic.

With the advent of advanced critical care, treatment of streptococcal infection, and other advances, ARF is increasingly a disease of the critically ill rather than of ambulatory patients. The most clinically significant aspect of ARF is usually the underlying primary multi-organ disease process that has triggered it, rather than any primary renal disease. The emergency physician is in the unique position to identify patients at risk for ARF and ameliorate ongoing renal damage or prevent iatrogenic injury.

EPIDEMIOLOGY

The distinction between community- and hospital-acquired ARF is important for the differential diagnosis, treatment, and eventual outcome of patients with ARF (Table 92-1). The annual incidence of community-acquired ARF is approximately 100 per 1 million population¹ and will be diagnosed in only 1 percent of hospital admissions at presentation, whereas hospital-acquired ARF will occur in as many as 4 percent of hospital admissions and 20 percent of critical care admissions.³ This increased incidence of hospital-acquired ARF is multifactorial, related to an aging population with increased risk of ARF,⁴ the high prevalence of nephrotoxic exposures possible in a hospital setting, and increasing severity of illness.

Because the majority of community-acquired ARF is secondary to volume depletion, it has been estimated that as many as 90 percent of cases presenting to the ED have a potentially reversible cause.² Hospital-acquired ARF often occurs in an intensive care unit and is commonly the end result of multi-organ failure. This dichotomy in the etiology of ARF explains the higher mortality, dialysis requirements, and rates of progression to end-stage renal failure seen in hospital- as opposed to community-acquired ARF.

Mortality rates for ARF are approximately 50 percent and have changed little since the advent of dialysis. This curious statistic simply reflects the changing demographics of ARF from community- to hospital-acquired settings. Currently, the mortality rate for hospital-acquired ARF is reported to be as high as 70 percent and is directly correlated to the severity of the patient's other disease processes. Mortality among patients presenting to the ED with prerenal ARF may be as low as 7 percent.³ With the advent of dialysis, the most common causes of death associated with ARF are sepsis and cardiac and pulmonary failure. Interestingly, patients older than 80 years with ARF have mortality rates similar to those of younger adult patients.⁴ Pediatric patients with ARF represent a different set of etiologies and have mortality rates averaging 25 percent.⁵

PATHOPHYSIOLOGY

The driving force for glomerular filtration is the pressure gradient across the glomerulus to Bowman's space of the proximal tubule.

Glomerular capillary pressure depends on renal blood flow (RBF), which is maintained by cardiac output and autoregulated by the combined resistances of the renal afferent and efferent arterioles.

Regardless of the cause, global or regional decrease in RBF is the final common pathway in ARF. The relation between reductions in RBF and GFR is most straightforward in prerenal failure, in which tubular and glomerular function are normal, and GFR is depressed by compromised renal perfusion. Intrinsic renal failure occurs with diseases of the glomerulus, interstitium, or tubule and is associated with the release of renal vasoconstrictors. Postobstructive renal failure initially results in an increase in tubular pressure decreasing the filtration driving force. This pressure gradient soon equalizes, and the maintenance of depressed GFR depends on vasoconstrictors.

Under normal circumstances, the kidneys receive 25 percent of cardiac output, and even then the partial pressure of oxygen in the outer medulla is typically 5 to 15 mm Hg. After an ischemic insult of any sort, total RBF normalizes, but the outer medulla is affected by a marked regional decrease in perfusion.⁶ Microvascular congestion, resulting from edema, red blood cell trapping, and activation of the coagulation cascade and leukocyte adherence, amplifies the ischemic injury.⁷ Part of the physiologic response to this insult is persistent preglomerular capillary vasoconstriction, resulting in depressed GFR. This response is likely to be adaptive, thereby allowing the body to preserve volume that would be lost due to the decreased reabsorptive capacity of the injured tubules, and has been appropriately referred to as *acute renal success*?

Injured renal tubular cells lose their brush border, polarity, and cell-to-cell and cell-to-matrix connections, including tight junctions. Some tubular cells slough off into the tubule, forming casts. These events further depress GFR in the affected nephrons via back-leak of ultrafiltrate and tubular obstruction.

During the period of depressed RBF, the kidneys are especially vulnerable to further insults. Exposure to known nephrotoxins such as radiocontrast agents, aminoglycosides, and nonsteroidal anti-inflammatory drugs at this time explains the high rate of iatrogenic ARF.

Recovery from ARF is first dependent on restoration of RBF. In prerenal failure, restoration of circulating blood volume is usually sufficient. Rapid relief of urinary obstruction in postrenal failure results in a prompt decrease of vasoconstriction. Clearance of tubular toxins and initiation of therapy for glomerular diseases decrease vasoconstriction and restore RBF in patients with intrinsic renal failure.

Once RBF is restored, the remaining functional nephrons will increase their filtration and eventually hypertrophy. Depending on the size of this remnant nephron pool, GFR will proportionately recover. If the number of remaining nephrons is below some critical number, continued hyperfiltration results in progressive glomerular sclerosis, eventually leading to nephron loss. A vicious cycle then ensues until complete renal failure occurs. This sequence explains the commonly observed scenario in which progressive renal failure occurs after the initial recovery from ARF.⁶

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of ARF is classified according to pathophysiologic terms: prerenal, intrinsic renal, and postrenal etiologies. Prerenal is the most common etiology of ARF presenting to the ED, followed by intrinsic renal and postrenal. These percentages change dramatically when examining in-hospital ARF (see Table 92-1). Acute renal failure has a different spectrum in the pediatric population: a

TABLE 92-1 Etiology of Community-Acquired and Hospital-Acquired ARF

Community-Acquired		Hospital-Acquired	
Prerenal	70%	Prerenal	20%
Intrinsic	20%	Acute Tubular Necrosis	70%
Postrenal	10%	Postrenal	10%

higher incidence of intrinsic renal causes for ARF (45 percent) secondary to diseases such as glomerulonephritis and hemolytic-uremic syndrome. Elderly male patients are more likely to suffer ARF from obstruction and infection.

Prerenal Failure

The differential diagnosis for prerenal azotemia can be broken down into volume loss, fluid sequestration, decreased cardiac output, and diseases of the large and small renal arteries (Table 92-2). Besides being an independent cause of ARF, prerenal failure is a common precursor to ischemic and nephrotoxic causes of intrinsic renal failure.

Postrenal Failure

Postrenal or obstructive ARF accounts for 5 to 17 percent of all community-acquired ARF, and in the elderly population, the rate is as high as 22 percent (Table 92-3). Risk factors include both extremes of age, male sex, malignancy, nephrolithiasis, and retroperitoneal disease. Timely relief of obstruction is essential for the return of normal renal function; significant permanent loss of renal function happens over the course of 10 to 14 days in the setting of complete urinary obstruction. The risk of permanent renal failure is significantly greater if obstruction is complicated by urinary tract infection.

Intrinsic Renal Failure

Intrinsic ARF is less common in community-acquired ARF, but it is the most common cause in hospitalized patients. Intrinsic renal failure

 Megaureter (prune belly) syndrome
 Retrocaval ureter
 Retroperitoneal tumor

Blood clot Adults

Urethra and bladder outlet

Phimosis or urethral stricture (male preponderance)
 Benign prostate hypertrophy
 Cancer of prostate, bladder, cervix, or colon
 Neurogenic bladder: diabetes mellitus, spinal cord disease, multiple sclerosis, Parkinson's disease, anticholinergic drugs and a-adrenergic antagonists
 Miscellaneous: trauma, blood clot, calculi

Ureter

Vesicoureteral reflux (female preponderance)
 Calculi, uric acid crystals
 Papillary necrosis: sickle cell disease, diabetes mellitus, pyelonephritis
 Tumor: carcinoma of ureter, uterus, prostate, bladder, colon, rectum, retroperitoneal lymphoma, uterine leiomyomata
 Retroperitoneal fibrosis: idiopathic, tuberculosis, sarcoidosis, methylsergide, propranolol
 Stricture: tuberculosis, radiation, schistosomiasis, nonsteroidal anti-inflammatory drugs
 Miscellaneous: aortic aneurysm, pregnant uterus, inflammatory bowel disease, blood clot, trauma, accidental surgical ligation

Intrarenal

Crystals: uric acid, sulfonamide, acyclovir, indinavir
 Protein casts: multiple myeloma, amyloidosis

can result from injury to the glomerulus, tubule, interstitium, and vasculature (Table 92-4). In community-acquired intrinsic ARF, drugs and infection are common precipitants, whereas in the hospital, toxic and ischemic insults cause the majority of cases (Table 92-5).^{1,2}

Radioccontrast-induced nephropathy is a common cause of in-hospital ARF, with a typical course of increasing creatinine over 3 to 5 days, followed by complete resolution. The occurrence of radioccontrast-induced nephropathy has been linked to increased in-hospital mortality. Risk factors include chronic renal insufficiency (CRI), diabetes (in particular the insulin-dependent type), age, hypovolemia, hypoalbuminemia, myeloma, and type and dose of contrast.

Crystal-induced nephropathy involves precipitation of crystals within the renal tubules, resulting in mechanical and inflammatory injuries of the tubular epithelium. Chronic renal insufficiency and hypovolemia predispose patients to this form of renal injury, and urinary pH affects the formation of many of these crystals. Uric acid in the setting of tumor lysis syndrome and medications, in particular acyclovir, sulfonamides, indinavir, and triamterene, are the most common causes of this form of ARF.

Angiotensin-converting enzyme inhibitors (ACEIs) may precipitate ARF in rare patients. By dilating postglomerular capillaries, they increase RBF and decrease GFR. These changes naturally result in a modest (10 to 20 percent) increase in serum creatinine, but in rare

Rapidly progressive glomerulonephritis: Goodpasture syndrome, Wegener granulomatosis, Henoch-Schönlein purpura, SLE, membranoproliferative glomerulonephritis
Postinfectious glomerulonephritis
Vascular diseases
Malignant hypertension
Scleroderma
Thrombotic thrombocytopenic purpura
Hemolytic uremic syndrome
Renal vein thrombosis
Polyarteritis nodosa

Abbreviation: SLE = systemic lupus erythematosus.

cases the increase can be more dramatic; in both circumstances the changes are observed shortly after initiation of ACEI therapy.⁹ Acute renal failure occurring in the setting of ACEI initiation should prompt consideration of bilateral renal vascular stenosis, in which case maintenance of GFR is dependent on postglomerular arteriole vasoconstriction. Volume depletion and concomitant vasoconstricting medications are other common precipitants for ACEI-induced ARF. Angiotensin receptor blockers also have the potential to precipitate ARF.¹⁰ Hyperkalemia, usually mild, is a relatively common complication of ACEI administration.

Cyclooxygenase inhibitors (most nonsteroidal anti-inflammatory drugs) comprise another family of medications frequently implicated in ARF. Renal effects of selective cyclooxygenase II inhibitors seem to be very similar to those of nonselective inhibitors.¹¹ Risk factors for adverse reactions to these medications are age, CRF, congestive heart failure, diabetes, volume depletion, and use of diuretics or ACEIs. Edema and ARF are typically observed early in the course of treatment

TABLE 92-5 Drugs Associated with Acute Renal Failure

Reduction in renal perfusion through alteration in intrarenal hemodynamics
NSAIDs, angiotensin-converting enzyme inhibitors, cyclosporine, tacrolimus, radiocontrast agents, amphotericin B, interleukin 2
Direct tubular toxicity
Aminoglycoside antibiotics, radiocontrast agents, cisplatin, cyclosporine, tacrolimus, amphotericin B, methotrexate, foscarnet, pentamidine, organic solvents, heavy metals, intravenous immunoglobulin
Heme-pigment-induced tubular toxicity (rhabdomyolysis)
Cocaine, ethanol, lovastatin
Intratubular obstruction by precipitation of the agent, its metabolites, or byproducts
Acyclovir, sulfonamides, ethylene glycol, chemotherapeutic agents, methotrexate
Allergic interstitial nephritis
Penicillins, cephalosporins, sulfonamides, rifampin, ciprofloxacin, NSAIDs, thiazide diuretics, furosemide, cimetidine, phenytoin, allopurinol
Hemolytic-uremic syndrome
Cyclosporine, tacrolimus, mitomycin, cocaine, quinine, conjugated estrogens

Abbreviation: NSAIDs = nonsteroidal anti-inflammatory drugs.

and are dose dependent. In reported cases, ARF has resolved with discontinuation of the medication.

Aminoglycosides are another important cause of iatrogenic renal injury. The trough concentration seems to be more relevant than the peak concentration in predicting renal injury, and once-daily dosing has been shown to reduce the incidence of nephrotoxicity.

Hemoglobin and myoglobin in the settings of hemolysis or rhabdomyolysis are deposited and concentrated in the renal tubules. Renal injury in these settings occurs through obstruction and direct tubular toxicity, the latter being dependent in part on low urine pH. Myeloma light-chain nephropathy may be similar. In patients with myoglobinuric ARF induced by crush injury, the incidence of hyperkalemia among patients surviving to the hospital was 42 percent, and mortality was 15 percent in the same population.

CLINICAL FEATURES

History

Acute renal failure itself has few symptoms until severe uremia has developed. At that time, nausea, vomiting, drowsiness, fatigue, confusion, and coma are common findings. Patients are more likely to present with symptoms related to the cause of their ARF.

Patients with prerenal ARF commonly present with thirst, orthostatic lightheadedness, and decreasing urine output. Excessive vomiting, diarrhea, urination, hemorrhage, fever, or sweating can reduce circulating volume enough to precipitate ARF. Causes of endothelial leak and third spacing, such as sepsis, pancreatitis, burns, and hepatic failure, can result in prerenal ARF. Progression of heart failure from whatever cause or overdiuresis of the compensated congestive heart failure patient can result in ARF. Decreased fluid intake from physical or cognitive disability can result in hypovolemia sufficient to cause ARF, and ARF is a common finding among elderly patients presenting with vague mental status change.

Intrinsic renal diseases can be anticipated because of symptoms of their precipitant cause. Ischemic acute tubular necrosis (ATN) is uncommon in community-acquired ARF but might be expected in the setting of cardiac arrest or other cause of prolonged hypotension. Crystal-induced nephropathy can present with flank pain and hematuria, as can nephrolithiasis and papillary necrosis. Pigment-induced ARF should be suspected in patients with possible rhabdomyolysis (e.g., muscle tenderness, recent coma, seizures, drug abuse, alcohol, excessive exercise, or limb ischemia) and with hemolysis (e.g., recent blood transfusion). Darkening urine and edema with or without constitutional symptoms, such as fever, malaise, and rash, should raise suspicion of acute glomerulonephritis, which may have been preceded by pharyngitis or cutaneous infection. Fever, arthralgia, and rash are common with acute interstitial nephritis. Cough, dyspnea, and hemoptysis raise the possibility of the pulmonary-renal syndromes (Goodpasture disease or Wegener granulomatosis).

Postrenal failure should be suspected in patients with appropriate risk factors. Symptoms of urethral obstruction often are not communicated to the physician because of their gradual onset. Anuria strongly suggests obstruction, although vascular obstruction and fulminant renal disease are also possible. Alternating oliguria and polyuria are virtually pathognomonic of obstruction.

Physical Examination

The patient's volume status should be assessed. Hypotension and tachycardia are obvious clues to decreased renal perfusion, but blood pressure and pulse are insensitive indicators of hypovolemia. It is important to recognize that a normal blood pressure may be relatively hypotensive for a chronically hypertensive patient. Evaluation of mucosal membrane moisture, tissue turgor, and an orthostatic pulse

increase may suggest hypovolemia. Base deficit, lactate, central venous pressure, and central venous oxygen saturation may be more sensitive and reliable indicators of hypovolemia. There is growing evidence that use of early invasive hemodynamic monitoring may improve resuscitation outcomes.¹³

Fever suggests infectious or autoimmune causes. Examination of the skin (e.g., livedo reticularis, digital ischemia, butterfly rash, palpable purpura, and petechiae) may suggest a systemic vasculitis, atheroembolic disease, or endocarditis. Maculopapular rashes raise the possibility of allergic interstitial nephritis, and stigmata of intravenous drug abuse should suggest endocarditis.

Examination of the eyes may find evidence of autoimmune vasculitis (keratitis, iritis, uveitis, and dry conjunctiva), liver disease (jaundice), multiple myeloma (band keratopathy from hypercalcemia), diabetes mellitus, hypertension, or atheroemboli (retinopathy).

The cardiac examination may find signs suggesting peripheral arterial emboli (atrial fibrillation), endocarditis (murmurs), and heart failure (jugular venous distention, hepatojugular reflux, or S₃ gallop). The pulmonary examination may suggest heart failure, Goodpasture syndrome, or Wegener granulomatosis (rales). The abdominal examination may find evidence of aortic aneurysm, nephrolithiasis, crystal nephropathy or papillary necrosis (flank tenderness), or urinary obstruction (pelvic, rectal masses, prostatic hypertrophy, and bladder distention). Examination of the extremities may suggest rhabdomyolysis (limb cyanosis, pulselessness, and edema), vasculitis (palpable purpura), or atherosclerotic disease (diminished pulses).

DIAGNOSTIC SEQUENCE/CLINICAL APPROACH

In the critically ill patient with ARF, resuscitation is the first priority, and multiple diagnostic and therapeutic processes can proceed simultaneously. Electrocardiography is often the fastest screening test for significant hyperkalemia, although it may not always show abnormalities, even in the setting of critically high potassium levels. Chest radiography helps evaluate for increased volume, effusions, and pneumonia, all of which can result from or precipitate ARE. After obvious intravascular volume deficits are corrected, the remainder of the initial diagnostic sequence focuses on the exclusion of urinary obstruction and interpretation of basic blood and urine tests.

After having the patient void, a urinary catheter should be placed. A properly positioned bladder catheter is diagnostic of and therapeutic for obstruction below the level of the bladder. If no urine is obtained, catheter placement should be tested by irrigation or ultrasound. If irrigation fluid returns freely, the catheter tip is most probably in the bladder, and obstruction above the bladder should be investigated. Large postvoid residuals (more than 125 mL) on catheterization suggest obstruction below the bladder, and catheter drainage will need to be maintained until the obstruction is relieved. Urine will need to be sent for urinalysis with microscopy, electrolytes, osmolality, and culture.

It has traditionally been recommended that the catheter be clamped intermittently to prevent hypotension and hematuria during drainage of a distended bladder, but experimental and clinical evidence provides no support for this practice. Hematuria upon catheter drainage of a distended bladder is related to the degree of bladder wall damage before relief of obstruction and is not correlated with the rate of emptying. Urine should be completely and rapidly drained from an obstructed bladder, because prolonged urine stasis predisposes the patient to urinary tract infection, urosepsis, and renal failure. Urine output has limitations in the estimation of blood volume; in the setting of ARF, its use is particularly problematic.

Concerns about postobstructive diuresis, however, are appropriate. Many investigators recommend admission of patients with persistent diuresis greater than 250 mL per h for more than 2 h in otherwise uncomplicated urethral obstruction. The syndrome of postobstructive diuresis is important to recognize, because it can result in sig-

nificant volume loss and even death. This complication of obstruction typically occurs when the obstruction has been prolonged and has resulted in ARF or significant volume overload.

ANCILLARY TESTS

Imaging

Once obstruction below the bladder level has been investigated, obstruction in the upper urinary tract should be investigated. Imaging studies can reliably identify hydronephrosis, but it is important to realize that, in intermittent or partial obstruction, hydronephrosis may not be present and may be absent in complete obstruction with retroperitoneal fibrosis. Further, functional dilatation can occur in the setting of chronic reflux. Renal ultrasound is considered the test of choice, with approximately 90 percent sensitivity and specificity for detecting hydronephrosis due to mechanical obstruction. The addition of Doppler and other advanced ultrasound techniques will allow evaluation of RBF and may suggest specific etiologies. If the renal ultrasound detects hydronephrosis, a secondary imaging study to define the location of obstruction is required. Intravenous pyelogram had been the gold standard for evaluation of the urinary tract for obstruction, but its dependence on radiopaque contrast and the availability of other modalities limit its value in the setting of ARF. Noncontrast computed tomography and magnetic resonance imaging have significant utility for this indication. Noncontrast computed tomography is widely available, has sensitivity for hydronephrosis that is equivalent to that with ultrasound, and has the added advantage of describing the site and often the cause of obstruction. Magnetic resonance pyelography has performed well in published studies, with 100 percent sensitivity and 98 percent specificity when compared with the combination of ultrasound and contrast pyelography. If functional obstruction is a consideration in the presence of a dilated genitourinary tract, radionuclide scans and magnetic resonance urography before and after diuretics can be obtained.

Chemistry and Urine Analysis

In combination, microscopic urinalysis and serum and urine chemistries have a great utility in determining the etiology of ARF. **However, the diagnosis must first be suspected, and without knowledge of a patient's baseline blood urea nitrogen (BUN) and creatinine (Cr), it is possible to overlook evidence of significant renal injury.** A patient with a very low baseline Cr can lose more than half of functioning nephrons before developing an elevated Cr. Serum urea nitrogen is depressed in patients with malnutrition and hepatic synthetic dysfunction and can be increased in the setting of protein loading, gastrointestinal hemorrhage, or trauma.

Creatinine provides the most accurate and consistent estimation of GFR (Table 92-6). Creatinine is a breakdown product of the skeletal muscle protein creatine, and its level is thus linked to muscle mass. Therefore, patients with lower muscle mass (e.g., older patients and women) have lower GFRs for any given Cr level. Several conditions can interfere with the correlation of serum Cr and GFR. Glomerulonephritis causes increased tubular secretion, whereas trimethoprim, cimetidine, and salicylates cause decreased secretion, thus altering the Cr level independently of the GFR. The rate of increase in serum Cr can be used to estimate GFR. In patients with no renal function (GFR = 0), serum Cr will increase 1 to 3 mg/dL a day. Lesser increases in Cr indicate residual GFR, whereas faster increases suggest muscle breakdown (e.g., rhabdomyolysis).

The ratio of BUN to Cr can suggest hypovolemia, because of differences in the way each is handled in the nephron. Both substances are passively filtered at the glomerulus; however, whereas Cr remains within the tubule, urea is highly permeable to renal tubules and is pas-

TABLE 92-6 of Glomerular Filtration Estimation Rate by

Serum Cr (mg/dL)	GFR (mL/min)
1.0	Normal baseline
2.0	50% reduction
4.0	70-85% reduction
8.0	90-99% reduction

Abbreviations: Cr = creatinine; GFR = glomerular filtration rate.

sively reabsorbed with sodium. Therefore, in the setting of avid sodium retention, urea clearance is as low as 30 percent of GFR, whereas in the setting of adequate volume and sodium, urea clearance can increase to 70 to 100 percent of GFR. Thus, if the patient has normal concentrating ability, in the setting of prerenal failure, the serum ratio of BUN to Cr is typically greater than 20.
